Observational Conditions (Location, Nature, Spatial Configuration, Participants, Environment, Variable), Stair Configuration (Direction of Movement (up/down), Slope, Distance), Sample (Collection method and Size), Results (Density, Incline Speed, Relationship between Speed and Density), and Additional Information. In Table 64.18, the following information is provided: Source, Observational Conditions (Location, Nature, Spatial Configuration, Participants, Environment, Variable), Stair Configuration (Direction of Movement (up/down), Slope, Distance), Sample (Collection method and Size), Results (Density, Specific Flow, Relationship between Flow and Density), and Additional Information.

Travel Phase: Exits and Narrowings

As described in Chap. 59, a key element in assessing the movement of sub-populations around a space is the change of widths of the spaces traversed. These typically occur at exit locations, which act as a connector between adjacent spaces. These changes influence the local population densities experienced, along with the potential for operating exit devices (e.g. the ability to get the door open or open to its full extent given the local population density). As such, exits (which include a device for separating two or more spaces that typically also represents a narrowing) and openings (a breach in space separation that typically represents a change in the width of the space) provide an important constraint to the movement of sub-populations within a structure, and certainly one that should be supported by empirical data within any egress analysis.

The representation of exits and openings can be addressed in a number of ways ranging from imposing a flow rate that limits the achievable flow, to allowing the flow conditions to emerge from the predicted conditions produced by the model [9, 22] (see also Chap. 60). Given the variety of attributes that may be required to produce a genuinely predictive model and the manner in which data-sets are typically presented, the following data, in its current form, is likely to be of most value in capping flow rates and validating predictive approaches, This does not preclude its use to configure predictive models; it may, however, mean that the data needs to be manipulated for the specific methods adopted within the predictive model being employed.

Many of the previously reviewed examples of horizontal movement also include reference to flow through exits and openings as a key constraint upon horizontal movement, i.e. a change in the density and flow conditions present. It is also explicitly represented in the original work by Nelson and MacLennan [107] and in Chap. 60. A wide range of previous empirical work in this area is also described in Daamen's thesis [116] and Daamen and Hoogendoorn [121] have published an array of their own empirical results describing exit flows by exit width, lighting levels, population type and door status (see Fig. 64.11). Daamen [116] also provides estimates for flow capacities associated with a range of different exits in rail rolling stock.

A number of other works provide specific examples of flow performance through exits and openings (be they narrowings or bottlenecks). These include Seyfried et al. [160, 161], who examined the flow rates generated at exits and narrowings based on their width and the densities evident, and reviewed the estimations of Nelson and MacLennan, Predtechenskii and Milinskii, Weidmann, Hoogendoorn, and the measurements of Kretz, Nagai and Muller (see Fig. 64.12).

Rinne et al. [125] performed a number of evacuations and monitored the performance of 32 exits to establish the flow rates produced. The exits were categorized according to the 22 evacuations from which the data came, the nature of this evacuation, the type of door involved, the door width, the flow performance produced, the people involved and the status of the door [125]. The data from these evacuations are shown in Fig. 64.13.

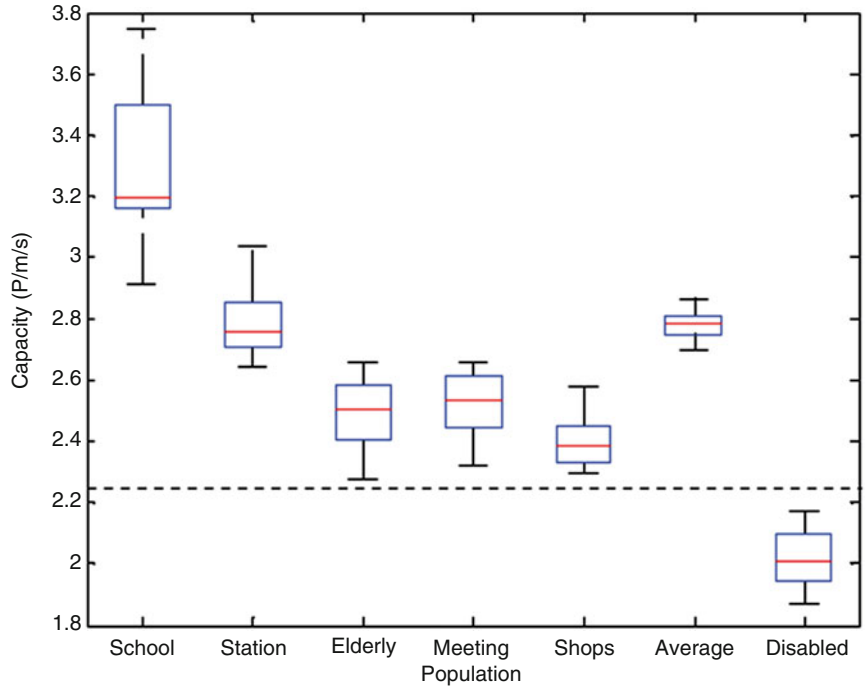

Fig. 64.11 Daamen and Hoogendoorn flow capacity of the exit as a function of population type (Reproduced from original [116, 121])

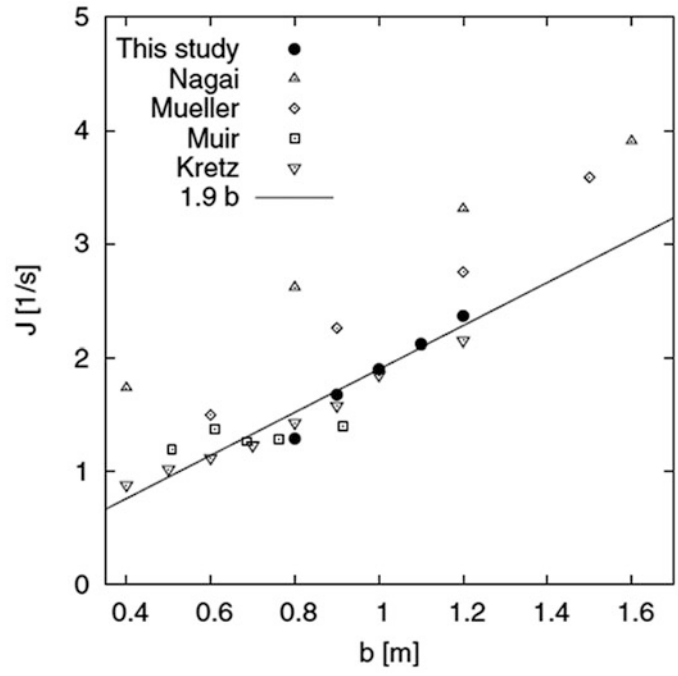

Fig. 64.12 Seyfried et al. comparison of flow performance (/s) through exits with work of others (Reproduced from original [160, 161])

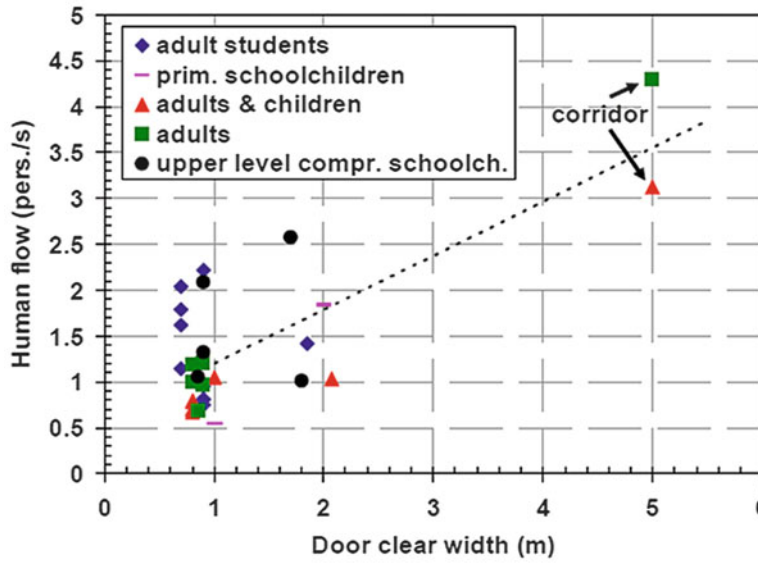

Fig. 64.13 Rinne et al. data relating to exit performance (Reproduced from original [125])

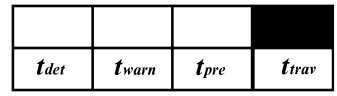
Several researchers have also looked at the travel speeds that can be achieved at and around exit points. This data can be used where flow rates are predicted/simulated by models, as opposed to being imposed by the user. Kholshevnikov et al. [109] presented a vast amount of data collected over 30 years in Russia from a number of data collection activities and combined it with their own efforts to produce the relationships between speed and density at exits, shown in Fig. 64.14. This is categorized according to the population densities recorded (which ranged from 1 to 13.5 persons/m^2) and the occupancies involved (retail, sports structures, train station, and experimental surroundings).

Schadschneider et al. [122] reviewed the experimental work of Kretz, Muir, Muller, Nagai and Seyfried, looking in some detail at the experimental conditions (and the initial distribution of the participants) along with the width of the exit/narrowing and the existence of competition among the participants (see Fig. 64.15).

The above paragraphs give a flavor of the range of studies regarding the performance of exits and narrowings. Others which the reader may wish to refer to include Thompson [113], Kendik [162], Smith [111], Gwynne et al. [47, 163], and Gwynne [164].

A summary of other data on exit flow through openings is given in Table 64.19. Although there is some overlap with the review material discussed, it is presented in a more consistent manner, in context with the scenario conditions and is presented in more detail. In order to achieve this, the following information is provided: Source, Observational Conditions (Location, Nature, Spatial Configuration, Participants, Environment, Variable), Door Configuration (Type—Single/Double/Sliding, Direction of Opening Relative to Movement—Against/ With, Width), Sample (Collection method and Size), Density, Results (Component Flow and Specific Flow), and Additional Information.

Travel Phase: Escalators (Up and Down)



Kinsey [173], in his PhD dissertation, performed a review of data currently available related to movement on escalators, collected and presented more data on escalator usage (speeds and flows) and also considered decision-making in relation to escalator usage.

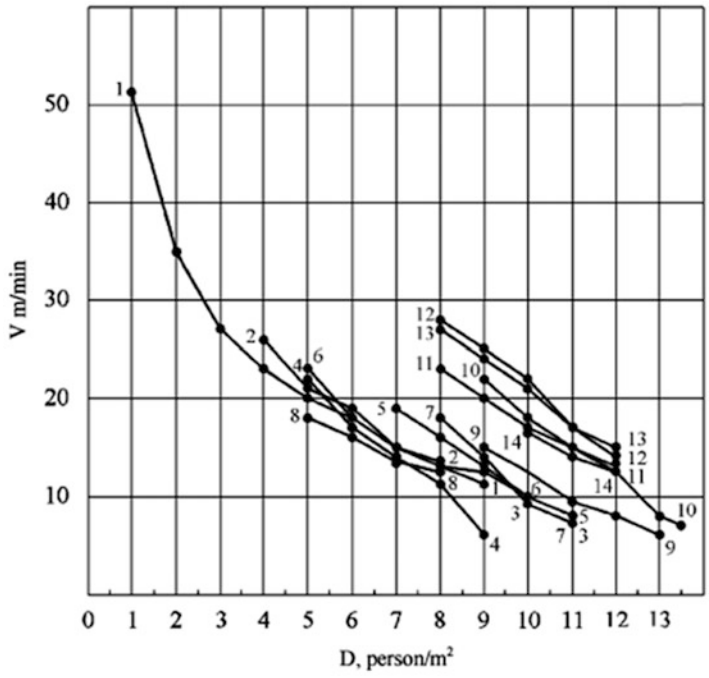


Fig. 64.14 Kholshevnikov et al. relationship between speed and density relating to exit opening (Reproduced from original [109]). Where curve (*1*) represents different buildings, (*2–4*) retail, (*5*) sports structures, (*6–9*) underground stations, (*10–14*) experimental conditions

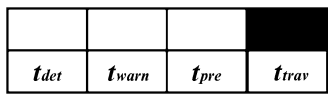
Tables 64.20 and 64.21, provide a summary of published data on speeds and flows on escalators, respectively. This includes the data reviewed by Kinsey and Kinsey's own data. The following information is provided in Table 64.20: Source Observational Conditions (Location, Nature, Spatial Configuration, Participants, and Variable), Escalator Configuration (State (Moving/Static), Direction (up/down), Speed, Height, Horizontal Length), Sample (Collection method and Size), Results (Mean and Range) and Additional Information. It should be noted that horizontal speed is utilized in Table 64.20 rather than incline speed presented previously in Table 64.17 relating to stair movement. Horizontal speed is presented here since this is the speed commonly presented in the literature to describe movement on escalators. It should also be noted that in the case of moving escalators that the speed presented is the speed of movement of the individual over and above that of the speed of the moving escalator.

In Table 64.21, the following information is provided: Source, Observational Conditions (Location, Nature, Spatial Configuration, Participants, and Variable), Escalator Configuration (State, Direction, Horizontal Speed, and Width), Sample (Collection method and Size), Peak Recorded Flow, and Additional Information. It should be noted that, unless otherwise specified, the width of the escalator is the step width.

Vulnerabilities - Situational: Movement in Smoke



The presence of smoke during an emergency has been shown to have a range of different effects upon evacuee performance. These effects may be psychological (see Chap. 58), physiological and physical (see Chaps. 61 and 63). These impacts may affect the performance in a number of ways in terms of the following:

- Recognition and response to fire (t_{pre})—in that the presence of smoke may act as a cue to indicate the existence of an incident and may then influence the time for an individual to respond to the incident,
- Redirection of movement—in that the perception of the presence and severity of the smoke may discourage the use of a particular route,
- Reduction in the efficiency of movement (t_{trav})—where the presence of smoke can lead to reduced walking speeds [31] and
- Posture change—in some cases the presence of smoke may lead occupants to abandon walking and adopt crawling behaviors, which in turn can influence the travel speeds that can be attained [31].

It is specifically the last two effects (i.e. the impact of smoke on walking speed and crawling speed), that are discussed in this section. Some discussion regarding the first two impacts listed above (i.e. impact of smoke on recognition and response and impact of smoke on exit choice behaviors), is presented in Chaps. 58, 61, and 63. Data relating to these aspects have also been reviewed in some detail by Xie Hui [182], Ronchi et al. [183], Gwynne [164], and Nilsson [184].

It is now widely acknowledged that some people are prepared to move through smoke in order to reach a position of safety [31]. In some circumstances (e.g. tunnels), it is accepted that evacuees will be exposed to smoke for a short duration [185]. However, in most engineering applications, the interaction between the evacuating population and smoke is assumed not to take place, i.e. the separation of the evacuating population and the deteriorating environment is assumed to be successful. Although engineering designs are likely to be developed on the basis that evacuees are *not* exposed to deteriorating environmental conditions, the potential for this interaction should still be considered. There may be situations, for example, where the engineer is testing the robustness of his/her design, making extremely conservative assumptions regarding the performance of the evacuating population, or going beyond the standard performance based scenarios considered as part of engineering design. For that reason, information and data regarding movement in smoke is included in this chapter.

It has been estimated that over 60 % of evacuees in small residential buildings move through smoke to evacuate [36]. A study of the behavior of evacuees from the bomb blast in the World Trade Center in 1993 [36] showed that 94 % of occupants of Tower 1 moved through smoke. Given the location of the incident, and the routes available once the evacuation commenced, movement through smoke was unavoidable; however, this did not prevent people commencing or continuing their evacuation. Detailed study of the evacuation of two high-rise residential buildings [36] has also shown that around 96 % of the occupants located above the fire floor moved through smoke.

Studies by Bryan [30] have shown that the proportion of people turning back rather than entering smoke increases with the smoke density. However, the exact proportion of those willing to move through smoke will be scenario-specific. In a space relatively free of smoke where smoke-free options are available, people may turn back rather than attempting to move through dense smoke, while those escaping the enclosure of fire origin or those with no alternative options will continue to move through often dense smoke, particularly if they know it will lead to an exit in a relatively short period of time. The decision to move through smoke may also depend on the person's motivation, e.g. in dwelling fires, parents are prepared to move through smoke to rescue their children or other precious belongings. In tunnel fires, some have been known to walk for several hundred meters in dense smoke [186].

The examples given in the previous paragraphs have demonstrated that people are willing to move through smoke when required to do so. It is clear, however, that the actual percentage of people that will be willing to move through smoke may be highly dependent upon the scenario faced and the options available. In this section, the actual percentage of people that are willing to move through smoke is not the focus of the discussion; instead, it is the impact that the smoke has on movement performance that is considered in some detail.

Given that people may interact with smoke, it is important to consider the impact that smoke has on walking speed. This section considers the available data sets that describe (1) the correlation between the smoke and occupant speed assuming the individual remains upright, and (2) the travel speeds that can be expected should an individual decide/be forced to crawl. The likelihood of an individual initiating crawling behavior is not addressed.

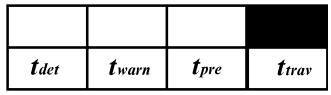
In section "Upright Movement in Smoke" we present several data-sets related to the travel speeds during the upright movement in smoke on a horizontal place. In section "Crawling Movement in Smoke" we present several data-sets on the travels speeds attained when crawling in smoke. In both cases, only a small number of data-sets are available and, therefore, rather than presenting in tabular form, a more detailed discussion of the data-sets is presented.

In the studies which have considered the impact of smoke on movement, smoke conditions are generally represented through an extinction coefficient (m^{-1}) or optical density (m^{-1}) (see Chaps. 61 and 63). The extinction coefficient unit is adopted here. The smoke has a number of influences upon an individual's ability to move: (1) highly irritant smoke can cause intense pain to the eyes, affecting the individual's ability to keep his/her eyes open; (2) the extinction coefficient of the smoke reduces visibility levels. The toxic and irritant agents can also have physiological effects that further reduce the individual's well-being and then indirectly reduce their walking speed (see Chap. 63).

Before examining or employing the data discussed below, it is important to note that the experimental conditions present in these studies vary considerably in terms of the presence and type of irritant gases, the characteristics of the participants, the structural configuration employed in the trials, and measurement techniques adopted. The variation in experimental conditions is a feature of all of the data discussed in this chapter; however, particular care should be taken with regards to movement

in smoke, given the limited data available. This area of investigation is particularly susceptible to ethical constraints which may limit the conditions to which trial participants might be exposed, and which inevitably impacts on the credibility and utility of the results. Again, it is recommended that readers should refer to the original papers before making decisions as to the most relevant data set to use.

The Ph.D. theses of Xie Hui [182], Nilsson [184], Kady and Davis [187], Ronchi [188] include extensive reviews of the data available relating to different aspects of movement in smoke and the reader is referred to these for further information.



Upright Movement in Smoke

Four data-sets which suggest a correlation between extinction coefficient and attainable speed are presented below: Jin [189], Frantzich and Nilsson [190, 191], Wright et al. [192], and Galea et al. [193]. An overview of these data-sets, derived from the work of Xie Hui [182], is provided in Table 64.22.

The first set of experiments in this area was performed by Jin in 1976 [189, 194–196]. The details of his experiments are discussed at length in Chap. 61 of this handbook; therefore only a brief overview is provided here. Jin tested 38 individual subjects (age range 20–51 years) in a 20-m-long corridor filled with two types of smoke analogous to the early stage of a fire: the first was a highly irritant white smoke produced by burning wood cribs and the second, a less irritant black smoke produced by burning kerosene. From the experimental results Jin derived a correlation between the extinction coefficient and the achievable walking speeds for both the irritant and non-irritant smoke (see Fig. 64.16).

In the experiments involving irritant smoke, the visibility fell away sharply as the extinction coefficient approached 0.5 m^{-1}. The occupant speed of movement, which was initially over 1 m/s reduced rapidly to approximately 0.3 m/s as extinction coefficients reached approximately 0.5 m^{-1}. The sharp drop in walking speed is explained by the fact that the subjects could not keep their eyes open in the irritant smoke, causing a zigzag movement or use of the walls for guidance (see Chap. 61).

A more gradual decrease in walking speeds was evident in non-irritant smoke (see Fig. 64.16). Participants once again moved initially at over 1 m/s and slowed down to approximately 0.5 m/s when the extinction coefficient reached 1.0 m^{-1}. In these trials, participants continued to walk at a reduced speed, behaving as if in darkness and feeling their way along the walls, but without the associated discomfort and clenched eyes that were apparent in the irritant smoke. The Jin data-set, although small, provides a direct comparison between the impact of irritant and non-irritant smoke in comparable conditions.

Frantzich and Nilsson's study [190, 191] (see also Chap. 61) involved a series of

Table 64.22 Overview of smoke travel speeds for upright individuals (Derived from the work of Xie Hui [182])

Research	Corridor length (m)	Smoke properties	Extinction coefficient (m–1)	Data points

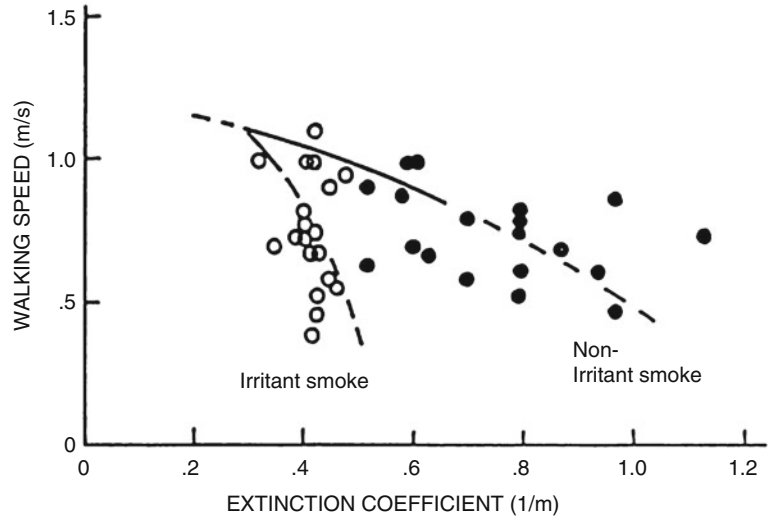

Fig. 64.16 Walking speed in smoke from Jin [189] (Reproduced from original)

experiments conducted in a smoke-filled tunnel. The sample comprised 30 males and 16 females aged 18–29 years (45 valid measurements were made). Participants were asked to walk through a tunnel 37 m long by 5 m wide, with a ceiling height of between 2.5 and 2.7 m in one of two illumination levels (lights on (21 lx) and lights off) and wayguidance systems (flashing lights, rows of flashing lights and floor markings). The route was more complex than that in Jin's experiments in that participants had to negotiate a number of obstacles, namely pillars which supported the ceiling and six cars placed inside the tunnel. The tunnel was filled with artificial smoke, with acetic acid used to provide irritation. The range of extinction coefficients measured was 1.9–7.4 m^{-1}, which was greater than in Jin's experiments. The participants were provided with the scenario that they had entered the tunnel in their car, and they were asked to get out and act as they would in such a situation if it was a real incident. The movement of participants was filmed using thermal imaging infra-red cameras. The calculated walking speeds ranged from 0.2 to 0.8 m/s (speeds included time stopping to rest) and results indicate that the speed decreased across the data-set as the extinction coefficient increased. Subjects also continued walking despite the low visibility and also tended to walk using the tunnel walls for guidance, an observation also noted by Jin (see Chap. 61,).

A comparison of Frantzich and Nilsson [191] and Jin's data [189] is provided in Fig. 64.17.

From Fig. 64.17 it is apparent that there is a wide scattering in the data currently available, which seems to have been due to differences in participants' characteristics, the levels of irritancy produced, the complexity of the spaces (Jin's experiments involved a simple corridor whilst Frantzich and Nilsson's was more complex including obstacles), and potentially the wayguidance systems in place. It should also be noted that the participants were in close proximity to the walls in both the Jin and Frantzich and Nilsson trials; the opportunity for evacuees to use walls as a means of guidance may well be different in an open space which in turn may influence their behavior and performance. It is therefore difficult to determine, with any level of confidence, a representative walking speed for a particular extinction coefficient. Frantzich and Nilsson developed two regression models from their data [191] for situations with no illumination (lights off) and illumination (lights on). The relationship between the smoke extinction coefficient K and walking speed for the illuminated movement ($R^2 = 0.32$) is given below. This is the

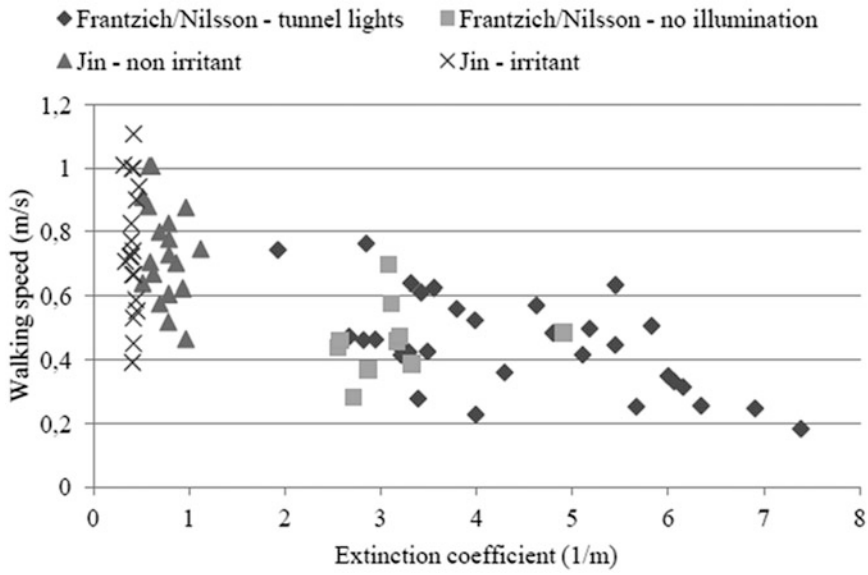

Fig. 64.17 Comparison of Frantzich and Nilsson and Jin's data (Reproduced from Ronchi [188])

relationship that has been adapted by Korhonen and Hostikka [197] for use in the FDSEvac model.

$$Walking\ Speed(m/s) = 0.706 - 0.057K$$

Frantzich and Nilsson [191] also conducted regression analysis to consider the influence of being in proximity to walls and produced the following ($R^2 = 0.454$):

$$Walking\ Speed\ (m/s) = 0.692 - 0.073K + 0.139\ (proportion\ wall\ contact)$$

Wright et al. [192] also conducted experimental trials to examine travel speeds in a smoke-filled environment that employed different lighting and wayguidance systems. The trials were performed in a two-storey test facility that included a 13 m corridor. Non-toxic white smoke was generated from a mineral-based fluid. A single smoke density (extinction coefficient 2.5 m^{-1}, OD 1.1 m^{-1}) was maintained in the corridor during the trials. The trials therefore focused on the performance of different systems at a given extinction coefficient. Eighteen participants (7 men and 11 women, ranging from 23 to 63 years of age, mean 46 years) took part in the trials and experienced the same set of six scenarios; i.e. five way guidance systems separately employed and a separate scenario with normal overhead lighting only. The speeds recorded ranged from 0.61 to 0.71 m/s for normal lighting [192], producing an average speed of 0.5 m/s. A range of other scenario conditions, employing two different LED systems, incandescent lighting, electroluminescent lighting and overhead emergency lighting were also examined. These produced mean speeds of 0.85 m/s (range 0.79–0.91 m/s) for LED1, 0.82 m/s (range 0.76–0.88 m/s) for LED2, 0.84 m/s (range 0.78–0.91 m/s) for Incandescent lighting, 0.75 m/s (range 0.69–0.81 m/s) for electroluminescent lighting and 0.53 m/s (range 0.48–0.58 m/s) for overhead emergency lighting. Other trials were conducted by Wright et al. and are described in detail elsewhere [192].

Galea et al. [193] also conducted a series of experiments to collect data on human movement

and behavior that might occur during a maritime evacuation. The experiments were conducted in a specially designed Ship Evacuation Behaviour Assessment Facility (SHEBA), and involved an assessment of the walking speeds of 360 participants as they traversed an 11 m corridor. Measurements of participant speed were performed in a clear (smoke-free) environment and in a smoke-filled environment with extinction coefficients of 0.0, 0.23, 1.15, and 2.30 m^{-1}. These were conducted at various degrees of heel and trim (i.e. pitching perpendicular to the direction of movement or in the direction of movement), in order to represent various sea states and scenario conditions; however, only the trials conducted on the flat are reported here, given their potential applicability to the built environment.

According to the SHEBA data-set, the participants' average unimpeded walking speed measured in a smoke free environment was approximately 2.2 m/s. This speed is much higher than the unimpeded walking speeds suggested in the Jin [189] and Frantzich [191] data-sets (see Chap. 61 and Frantzich and Nilsson [66, 190, 191]) and has been attributed [193] to a combination of factors, i.e. the participants in the SHEBA data set were highly motivated, familiar with the environment, required to perform relatively straightforward tasks and traverse a shorter route. Notwithstanding, the results indicate a reduction in walking speed with increased smoke density which is consistent with other studies, see Fig. 64.18.

The SHEBA study also defined 'mobility' as the walking speed in smoke as a fraction of the walking speed measured in a smoke free environment (i.e., the speed as a fraction of the speed attained in a clear environment). Figure 64.19, compiled by Hui Xie [182] illustrates how the mobility varied with different smoke densities for the SHEBA data set, and how this compares with the derived 'mobility' from the Jin and Frantzich and Nilsson studies. It is apparent that the relative reduction factor is broadly comparable across the three studies examined.

Xie Hui [182] performed a further analysis on the results from Jin's work (as part of his model development), and reported the relationships between extinction coefficient, K, and the *reduction* in walking speed as being (i.e. relative to performance in smoke-free environment):

$$Reduction\ Factor = -0.16K^2 - 0.488K + 1.105$$

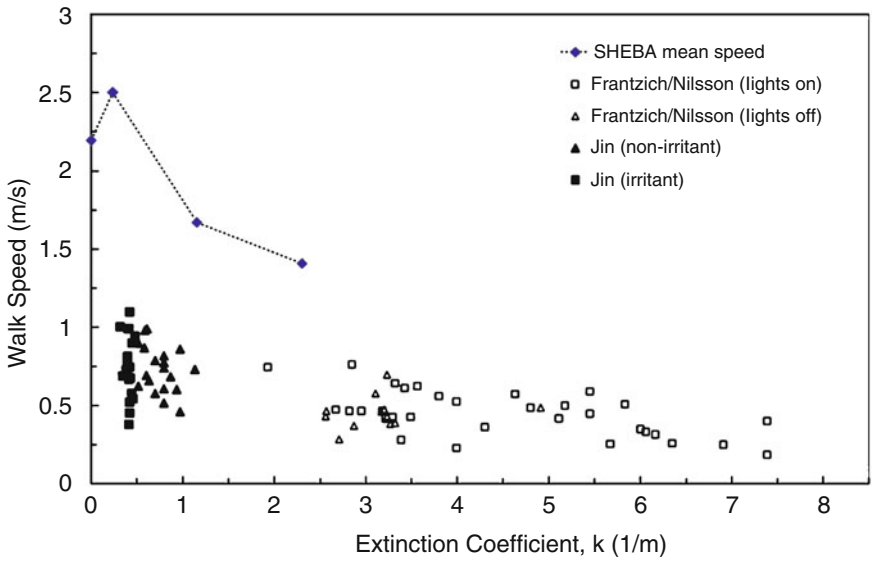

Fig. 64.18 Relationships between walking speed and extinction coefficient from a number of researchers derived by Xie Hiu [182]

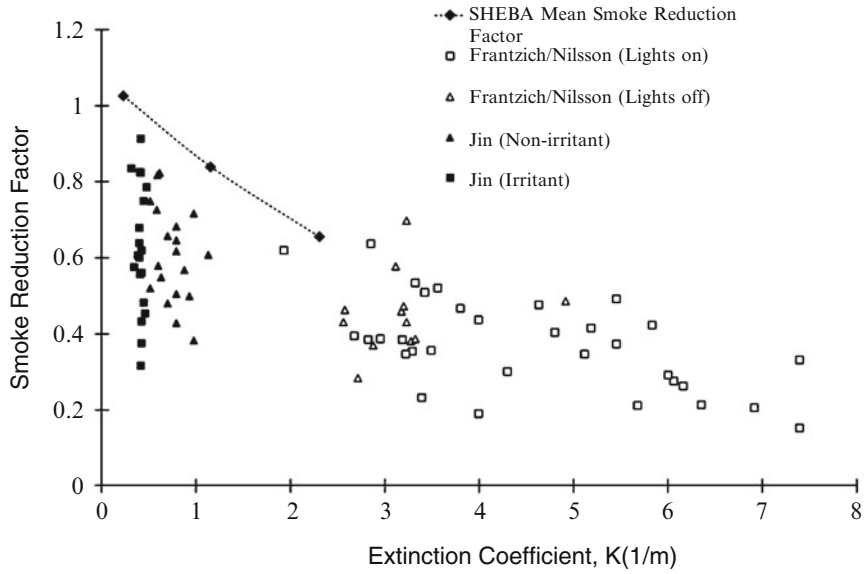

Fig. 64.19 Relationships between speed reduction factor and extinction coefficient derived by Xie Hiu [182]

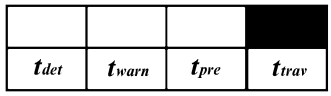
between extinction coefficients of 0.2 and 1.0 m^{-1} for non-irritant smoke and

$$Reduction\ Factor = -2.08K^2 - 0.38K + 1.06$$

between extinction coefficients of 0.1 and 0.5 m^{-1} for irritant smoke.

These equations might then be applied to an individual's initial travel speed to estimate the impact of the smoke conditions upon performance. This assumes that the effect is *relative* to an individual's initial starting performance rather than producing an *absolute* effect upon all individuals in the same manner and then determining a specific walking speed for a given extinction coefficient; i.e., the impact gets progressively more severe in relation to the individual's initial performance rather than being independent of the individual involved. These two assumptions are discussed in detail by [183].

Crawling Movement in Smoke



As discussed in Chaps. 61 and 63, the physiological effects of exposure to fire can influence evacuees' decision making and performance. The descending hot smoke layer can also lead occupants to crawl in an attempt to evacuate the building safely—either forcing them to do so in an attempt to avoid the worsening conditions or instigating a planned response to the presence of smoke through some procedural instruction or training. It may therefore be important, depending on the complexity of the engineering analysis being performed, to refer to data on crawling speeds and to understand the interrelationships between crawling speed and density. This is discussed in the paragraphs below.

Compared to the research on the upright walking speeds, there has been relatively little research conducted in this area until recently. The most significant being the work of Muhdi et al., Nagai et al., and Kady [170, 198], Kady et al. [187, 199].[1] The study by Muhdi et al. [200] was designed to measure and compare individual maximum and normal walking and crawling speeds, and concluded that (assuming a comparable level of effort), crawling results in a significant reduction in speed compared to walking. His

[1] It should be noted that Kady and Muhdi in this paragraph refer to the same person.

later study [187] compared the walking speed and crawling speed of persons of different body composition (normal, overweight and obese) and concluded that gender and body composition were major determinants of occupant normal crawling speed, accounting for 80 % of the variance. He again showed that the mean individual normal crawling speed was significantly less than the mean walking speed, with the mean crawling speeds of 0.79 m/s being comparable to that of 0.71 m/s obtained in his earlier study [200]. The study by Nagai et al. [170] also compared speeds of walkers and crawlers through a corridor and exit, and examined the impact of crowd density on crawling and walking speeds. The average individual normal crawling speeds measured in these experiments was 0.73 m/s which is also comparable to that obtained by Kady and Muhdi [187, 200]. Kady [199] further investigated the relationship between speed and density and concluded that the location of crawlers relative to the exit affects the density of crawlers produced and subsequently the speed of the individual crawlers and the population movement speed. The relationship derived between crowd crawling speed and crawling crowd density is shown in Fig. 64.20 and can be expressed by:

$$Crawling\ Speed = 0.7973 + 0.2909D - 0.1503D^2$$

It appears that this quadratic model provides a good fit to the data ($p = 0.004$), whilst the R^2 value indicates that crowd density accounts for 42.7 % of the variability in crowd crawling speed.

A summary of the current data on crawling speeds is given in Table 64.23. In addition to the crawling speed data (means, standard deviation and ranges), Table 64.23 provides information on the Source Observational Conditions (Location, Nature of the experiment, Spatial Configuration (details of the test route), Participants and Variables). An Additional Information column provides other relevant information related to the instructions to the subjects and precision of measurement. In all of the experiments, crawling was considered to be achieved when a subject rested on their knees and flattened palms with arms and thighs perpendicular to the floor and feet comfortably extended and spaced [201]. *It should be noted that in each of the experiments, subjects utilized adjustable knee pads and gloves which would not be expected to be available under normal emergency conditions.*

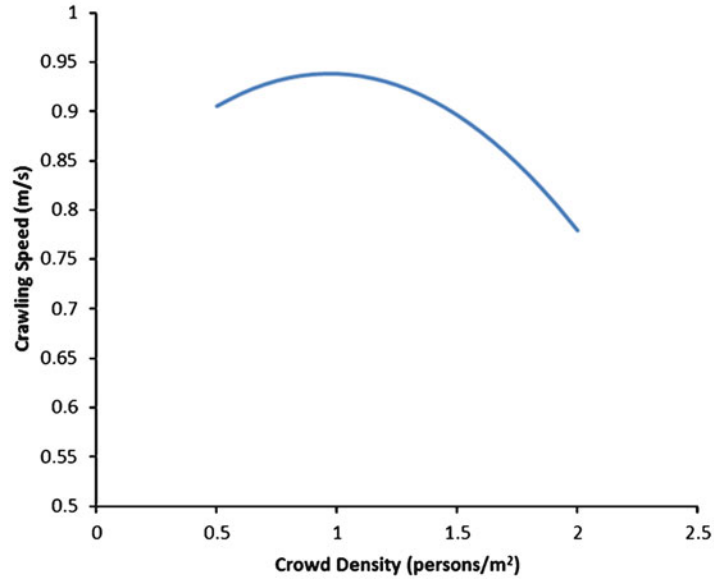


Fig. 64.20 Relation between crawling speed and density on a flat surface (From [199])

Table 64.23 Summary crawling speed data

Source	Observational conditions (L: location, N: nature, S: spatial configuration, P: participants, V: variable)	Type of crawling	Sample		Mean (m/s) [standard deviation, range]	Additional information
			Collection method	Size		
Kady [199]	L: USA	'Normal' pace	Timing by 6 photo sensors at 10 ft. intervals to digital timer	Groups of 2–9	**CW1**: 0.68 [–, 0.63–0.72][a]	[a]Crowd crawling speeds depending on group size— individuals randomly assigned to walking/crawling in different groups (n = 2–9) and track widths (CW1 = 3, CW2 = 4, CW3 = 5 ft) allowing for recovery time

Vulnerabilities: Innate: Impaired Movement

During the last three decades, there has been a growing effort to improve access to buildings for the entire population. It is now reasonably established in the regulation of developed countries that all new or refurbished public buildings should provide access for all and that existing buildings should make 'reasonable' provision. This improved access means that building populations are now more diverse and span a spectrum of movement abilities. The fast-changing anthropometric profile of occupants, as well as the large number of mobility-limiting diseases such as asthma and heart conditions, may have an impact upon issues relating to ingress and egress from a building. Although, the exact nature of this impact is not well understood at the moment, this still needs to be taken into account in fire safety design.

As noted previously, significant percentages of national and international populations have disabilities/impairments that impact on their ability to evacuate buildings [202]. These include those with physical and mental impairments, including the elderly and the obese. Since the prevalence of disability increases with age, and we are an increasingly aging society, it is expected that building populations will become even more diverse in terms of the physical and mental capabilities in the future. One potential impact on the engineering timeline is with respect to the t_{trav} component and it is therefore important to understand the range of capabilities of people with disabilities in terms of movement on both flat and inclined surfaces; i.e. stairs and ramps. It is also important to recognize that the percentage of those with mobility impairments may increase during an incident where injuries may occur leading to immediate limitations that cannot be immediately addressed through the presence of movement aids/devices. Limitations and impairments are certainly not confined to movement; for instance, sensory and cognitive impairments may also influence the performance of an evacuee. Those with visual impairments may experience difficulty in wayfinding, including locating and reading exit signage and indeed also may have reduced movement speeds. Those with hearing impairments may find it difficult to hear alarms, those with mental impairments may experience difficulty in recognizing alarms and understanding the need to evacuate, and those with limited dexterity may experience difficulty using particular types of door furniture to facilitate their escape. Although some [203–207] have researched the latter the body of research is limited and therefore this section focuses upon data specifically related to movement.

Although design and procedural measures are frequently implemented in multi-storey buildings to aid those who are unable or find movement (particularly stair movement) difficult e.g. use of refuges, elevators, assistive evacuation devices, buddy systems, it is clear that many people with disabilities will attempt to use stairs irrespective of their limitations. This was particularly noticeable in the WTC evacuation on 9/11, where the evacuation of mobility impaired occupants within the entire evacuating population was described as "slow and arduous" [145].

It is important to note that those with mobility impairments often use devices such as walking sticks/canes, crutches, rollators, frames or manual or electric wheelchairs to aid their movement and may also be assisted by friends/family. Therefore, in addition to expected lower movement speeds people with such impairments may often require more space (both in a stationary position and in movement) than a person evacuating without such aids. Clearly, if the routes that comprise the means of escape are not of sufficient width to facilitate passing in such cases, this may impact the movement of the entire evacuating population using that particular component. This was evident in the evacuation of WTC where it was reported that 51 % of the occupants of WTC1 and 33 % of the occupants of WTC2 indicated that injured and disabled people in the stairwell were a 'constraint to evacuation' [145], and where the evacuating population often reported having to wait until reaching the landings before being able to overtake slower moving individuals on stairs [208].

Design guidance regarding exit and stair sizing generally makes assumptions of optimum flows derived from data on largely able-bodied

populations. It is therefore essential to understand the capabilities of those with disabilities in the movement component of means of escape, namely their speeds on the horizontal, on ramps and on stairs.

Summaries of the data related to both unassisted and assisted unimpeded speeds on the horizontal, ramps and stairs (ascent and descent) and door traversal speeds are given in Tables 64.24, 64.25, 64.26, 64.27, 64.28, and 64.29. Tables 64.24, 64.25, 64.26, 64.27, 64.28, and 64.29. include, in addition to descriptive statistics (mean, standard deviation and range) for each data set, the Source of the data as well as the conditions under which the measurements were made; i.e., Observational Conditions (Location, Nature of the study, Spatial Configuration of the space in which measurements were made, Participants and the Variables). Separate tables are provided according to whether the subject group was moving with assistance of another person or without assistance, since this may have affected the movement speed. It is important to note, however, that across the studies, the nature and level of assistance varied. In all tables the conditions under which the observations/measurements were made are noted. In most cases the research comprised of an experimental study involving persons moving as individuals within a building or space; however, in some studies the measurements related to individuals moving in a more general evacuation involving others. In the former, the speeds are presented as in the original papers as unimpeded movement speeds, while in the latter, although densities were described as low, there may have been some influence of others on an individual's movement and so additional information is provided. Attention should be paid to the *Additional Information* columns in the tables which describe these conditions.

Where known, the distances over which measurements were made are also noted (under Spatial Configuration); in the case of horizontal movement this is simply a distance covered; in the case of stairs, information is in the form of a distance (if available) or the number of storeys over which the measurements were made. The distance over which movement is measured is particularly important when choosing speed data since individuals with reduced mobility may be expected to experience some reduction in speed as they tire over longer distances, i.e. the development of fatigue. The study by Kuligowski [220] reported in Table 64.27 is the only study to consider the variation in speed achieved over subsequent portions of the escape route and reference should be made to the original source for further information.

It is also important to mention in this respect that the movement speeds presented in the tables do not generally include periods of rest, unless otherwise noted. The exception is the study by Hunt et al. [214] which did include stops in the calculation of movement speed. The study by Boyce et al. [203, 204] noted that 14 % of those with a 'locomotion disability' required at least one rest over the 50 m horizontal route. Analysis of the WTC evacuation on 9/11 [145, 208] also suggested that some individuals with impairments had to stop to rest for short periods of time. The need to rest is likely to be dependent upon the distance travelled and exertion required relative to the severity of one's disability, although no studies have specifically looked at the impact of fatigue on the movement of people with disabilities over longer distances. The behavior of individuals with disabilities evacuating may also be important for evacuation modeling. For example, the Boyce et al. study [203, 204] noted that the majority of persons with disabilities sought support from handrails; this was particularly evident when ascending and descending stairs where 91 % and 94 % respectively of those moving unassisted utilized the hand-rail for support.[2]

The stair incline is also important in relation to stair movement and is described in Table 64.27 if reported in the original source or if it could be

[2] where significant differences are evident in the terminology used in this section, the authors have adopted the terms employed in the source material.

derived. The study by Fujiyama and Tyler [212] is interesting in that it is the only study presented here which compared the movement speeds for the same subject group across different stair geometries. Tables 64.24, 64.25, 64.26, and 64.27 also include a brief description of the floor covering if noted in the original source; different floor coverings may provide different resistances to movement and therefore may have an influence on speeds achieved, particularly for wheelchair users, and this should be taken into account when considering the data relative to the intended application. It should also be noted that different researchers have used different terminology to denote the subject groups, e.g., those who have difficulty walking in some studies are described as 'mobility impaired', in others as having a 'locomotion disability'. The terminology used in the tables is simply that which was adopted in the source material and users should refer to the source for a fuller understanding of the definitions of these terms. Care should also be taken to note the instructions given to participants of the experimental studies as they began their movement. Instructions ranged from moving in a 'prompt manner' to 'normal speed' and 'fast speed'. The nature of the instructions provided is important as it might have influenced the efforts of the participants and subsequently the speeds achieved.

It will be noted that few studies have been designed specifically to consider speeds of movement that can be achieved by those using different assistive techniques/devices (carry chairs, evacuation chairs, stretchers, drag mattress). In this respect the reader is directed to the studies of by Hunt et al. [214], Kuligowski et al. [21], and Lavender et al. [217]; the former study investigated speeds of assistive movement of highly trained personnel in a hospital environment; the latter the speeds which could be achieved by professional fire fighters in assisted escape. Data from these studies is presented in Table 64.18.

It is clear from Tables 64.24, 64.25, 64.26, and 64.27 that the abilities of people with disabilities and the elderly cover a wide spectrum with respect to horizontal and vertical movement. It is important in egress analysis to consider not only the variance in speed but also variation in spatial requirements of different individuals, since this may have a significant impact on flow performance produced. Indeed Boyce et al. [203, 204] has suggested that for analytical purposes, individuals should be categorized according to the mobility aid used and whether or not they require assistance so that potential interactions with the evacuating population can be fully realized.

The ability of individuals with disabilities and those assisting persons with disabilities to negotiate doors has also been studied by a number of researchers. Boyce et al. [203, 204], for example, examined the necessary time for people with disabilities to go through a door by pulling and pushing the door, which was subjected to a range of closing forces. The analysis of this data suggested that the ability of people with disabilities to negotiate doors subjected to a range of closing forces may depend on different factors including: the type of aid used (since it is implies a movement speed and particular technique in maneuvering the technical aid though the door), how old the participant was (since this is inherently related to strength) and the presence and severity of a dexterity or reaching and stretching disability. Hunt et al. [214] also investigated the time for teams of well-trained hospital staff to negotiate doors whilst handling different evacuation devices, i.e., a stretcher, rescue sheet and Evac+chair. They found that female handling teams took longer than male handling teams to maneuver through closed doors and found that generally it was easier to negotiate doors which opened away from the handlers. The data from both studies is presented in Table 64.25.

Identifying Applicable Data-Sets

Egress analysis is frequently presented to a third party for scrutiny as part of the performance-based design process (see Chap. 57). As mentioned previously, egress analysis is used to

provide an estimate of the Required Safe Egress Time (t_{RSET}). This is then compared against the Available Safe Egress Time (t_{ASET}). Egress analysis is typically achieved through the use of engineering calculations or computational tools (see Chaps. 59 and 60), both of which require support from the use of data. In this process, one group of people perform the analysis while another group (e.g. AHJs, code enforcers, etc.) judge the approach adopted, including the relevance and credibility of the data employed. For this judgment to be fair, accurate and credible, a comprehensive and detailed description of the key elements involved is required—including the data employed. Just as this assessment is required in the presentation of any results to a third party, an equivalent description (and understanding) is required on the part of the engineer in initially selecting the data. This is not trivial; indeed, given the immature nature of the field, it can be problematic. Given this, it is important that the engineer poses a series of questions of the data-sets to be used to establish if the background information related to the data is to their satisfaction. The answers to these questions will then determine whether the data is appropriate for the current application and the same answers should also be reflected in the presentation of any results produced. The reader should also examine the material provided in Chap. 57, as the answers to these questions shown below may complement the material presented in that chapter.

Below is a list of questions that the engineer should consider when identifying data sets for use. Although not a definitive list, these questions should assist the engineer in the selection of the most appropriate data-sets. Indeed, these questions formed the basis of the table format used when presenting the various data-sets provided earlier in the chapter. The engineer should consider the answers to these questions whilst choosing, interpreting and using the data and the answers to these questions should also be reflected in the eventual presentation of the results to the third parties, i.e. the background information that places the data (and the egress results) into context.

What is the origin of the data? **For instance**, **is it derived from**:

- Non-emergency movement,
- Evacuation drills or unannounced evacuations
- Experimental work,
- A real incident,
- Survey?

Is this appropriate and valid for the current project?

What is the nature of this data? **For instance**, **is the format**

- Numerical: Raw/Compiled/Composite/Extrapolated,
- Descriptive: reports/anecdotes/journalism,
- Graphical,
- Function/Relationship-based,
- Primary/Secondary, and

Is the sample large/small, **representative/unrepresentative**?

Does the data format support the current application? *If not*, *is the engineer able to derive the necessary data from it*? *Is the data sufficiently representative to be used in the current application*?

Is this source considered appropriate, **valid and reliable**?

- Is it adequately documented?
- Who collected it?
- How was it collected?
- When was it collected?
- What data collection techniques were employed?
- What research methods were employed to collect and analyse the data?
- What was the observed scenario?

Is there enough known about the data and the original event scenario?

Population characteristics/performance issues

- How many people were involved in the event and in the sample?
- Who was involved?
- Were they familiar with the structure?
- Where was the population located?

- What were they doing at the time of the incident?
- Are there sub-populations of particular concern within the space e.g., an impaired population?
- What attributes/issues might influence the results produced?
  - Physical—age/gender/health/fatigue/impairment/weight/encumbrance/children/elderly
  - Psychological/Behavioral—exposure to information/familiarity/cognitive abilities/experience/motivation/status
  - Social—role/hierarchy/relationships (employment/social/familial)/responsibilities/(alone/groups/crowd)/affiliation/culture
  - Situational—activities/engagement/commitment/alertness/location/proximity to incident/intoxication

Procedural (organizational) characteristics

- What was the emergency procedure employed?
- Was the population aware that the incident was going to take place?
- What notification systems were in place?
- How many staff members were actively engaged in the emergency procedure?
- What was the nature of the message/information being provided?
- Were people expected to assemble and, if so, where were the assembly points?
- What non-emergency procedures were in place that might have influenced the effectiveness of the emergency procedure?

Structural characteristics

- What was the structural configuration?
  - Existence of egress routes, doors, etc.,
  - Number of floors,
  - Use of the structure,
  - Dimensions of the space and egress components.

Environmental characteristics

- What was the cause of the incident?
- How did the incident develop?
- Where was the incident located?
- Did it spread beyond the room of origin?
- What cues were present?
- Did this influence the availability of egress routes?
- Did the spaces have environmental pollution/noise (visual/aural) that might have influenced evacuee performance?
- Were the spaces cluttered/confined?
- What were the expected lighting levels?
- What impact did the environmental conditions have on the evacuating population?
  - Physiological,
  - Psychological,
  - Behavioral.
- Were there external conditions (e.g. weather conditions) that influenced the performance of the evacuating population?

It would be impossible in this chapter to provide this level of detailed information for all of the data sets that exist in the public domain. However, the tables are structured such that space is provided for the key elements for each type of data to be included (see section "Structure of Data Presentation"). The tables presented in this chapter should therefore allow the engineer to answer the majority of these questions, or at least establish, with additional reference to the original source material, where insufficient information is provided to answer them; i.e. the omission of information can be established.

Using the Data

It is acknowledged that the presentation and availability of the data is only a small part of the engineering process. Another key step is for the engineer to select an appropriate data-set (or more likely data-sets) for the scenario at hand. Given the nature of this scenario, it may be that the scenario conditions do not exactly match those of the data presented; i.e., that the engineer is required to potentially select and use several data-sets to represent a single real-world scenario. This might occur where the key factors

in the scenario are not adequately addressed by a single data-set, where the data is not considered reliable enough, where the data is not adequately described and/or where the data is considered too old.

In addition, the engineer may also be required to manipulate single/combined data-sets in order to reflect specific aspects of the scenario, even where the original data-set is deemed to be an ideal match. The engineer might therefore be required to combine whole data-sets, splice parts of data-sets together, or manipulate the manner in which a data-set is applied across the area/population/timeline being examined. For this to occur the engineer would need to be able to match the data-sets against the scenario factors being represented and ensure that the manipulation of the data-sets adequately represented the real-world conditions while not undermining the original meaning of the data; i.e., the appropriateness of the original data selection.

As an example, a workflow of such data manipulation is shown in Fig. 64.21. This is intended to outline the process through which an engineer might pass and is but one of many that might occur. Stages (4, 7, 8) outline the initial definition of the quantitative component of the data-sets (i.e., the extent of certain factors), while Stages (5, 6, 9, 10) outline the qualitative aspects that help define the scenario and influence the manipulation of the eventual data-set generated (i.e., the nature of certain factors).

Initially, the engineer describes the scenario, $\boldsymbol{S}$, given the real world situation at hand and the factors and conditions associated with it. For instance, the engineer has to calculate the egress time for a population in a hotel with a fire assumed to start in one of the rooms on an upper floor.

The engineer first outlines the scenario in question in as much detail as possible (Stage (1)). The engineer then (Stage (2)) determines whether specific data and supporting information is available to enable the examination of the scenario described, $\boldsymbol{S}$. For instance, a previous incident may have been documented at that site or a number of evacuation trials may have been recorded from that structure (or similar structures). Given that this data is not available, the engineer consults the available guidance and literature (Stage (3)), to identify data-sets and information, $\boldsymbol{L}$, that may relate to the scenario. For instance, the data presented in Table 64.4. In Stage (4), the quantitative data included in $\boldsymbol{L}$ is collated to produce a number of data-sets, $\boldsymbol{E}$, that are deemed to relate to the scenario. Similarly in Stage (5), given the issues highlighted in $\boldsymbol{L}$, a set of behavioral and procedural issues, $\boldsymbol{I}$, are identified that need to be accounted for in the representation of the scenario—in the 'model' of the scenario.

In Stage (6), these issues, $\boldsymbol{I}$, are coupled together—integrated to establish a schema describing how they might interact to produce effects during the simulated scenario. In other words, how do the issues identified combine to produce the modeled scenario of interest? This schema may take the form of a number of questions that guide the engineer in what might be expected. For instance, how might intoxication affect performance of guests in a hotel given the use of voice alarm? In Stage(7), given the data-sets, $\boldsymbol{E}$, the real-world scenario, $\boldsymbol{S}$ and the schema describing expected performance, $\boldsymbol{F}$, the data-sets are compiled such that the data-sets selected are clearly associated with key elements in the schema in order to represent the scenario, $\boldsymbol{E}^*$. Here, the interaction between key factors is quantified; for instance, the pre-evacuation times of the intoxicated, in a hotel given the use of voice alarm. Whereas $\boldsymbol{E}$ represents data-sets that address factors associated with the scenario, $\boldsymbol{S}$, $\boldsymbol{E}^*$ represents how these may be spliced and combined to specifically address aspects of the behavioral schema produced, $\boldsymbol{F}$.

In Stage (8), the refined data-sets are manipulated such that a final distribution of data is produced for the factors highlighted, $\boldsymbol{Q}$. This reflects the range of values that might represent the key factors and interactions in $\boldsymbol{F}$. For instance, several functions are produced to represent the influence of intoxication and voice alarm in a hotel setting. In Stage (9), the data distribution, $\boldsymbol{Q}$, is compared against the schema, $\boldsymbol{F}$, to identify shortfalls in the quantitative representation of the schema—of the qualitative factors that are expected to influence performance—to

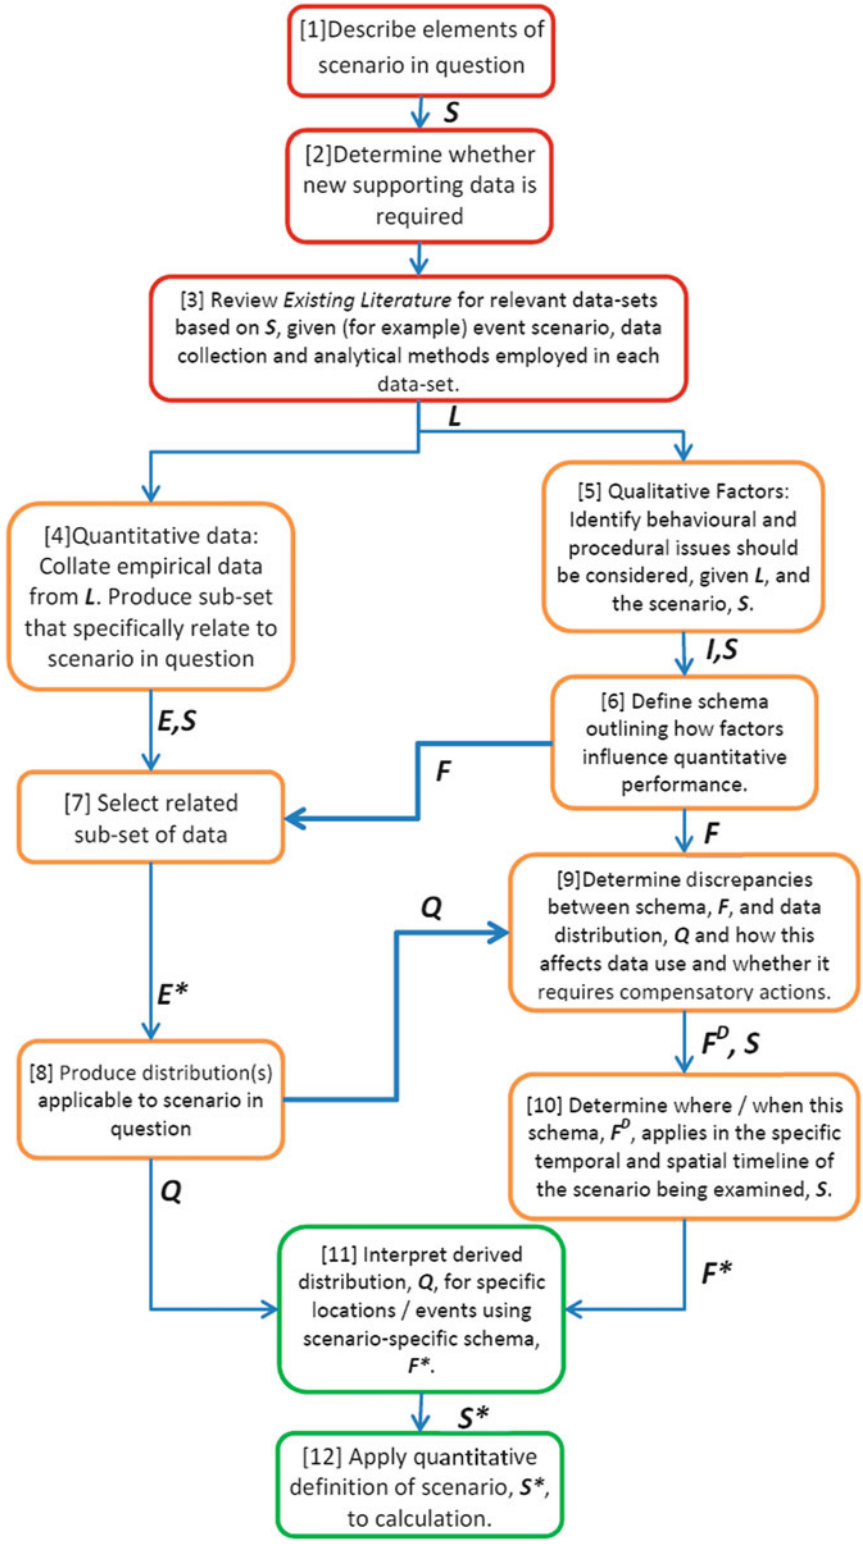

Fig. 64.21 Manipulation of multiple data-sets to fit the scenario

generate a schema that is numerically represented to some degree, $\boldsymbol{F^D}$. This represents the factors that will be depicted in the 'model' scenario. In Stage (10), this schema, $\boldsymbol{F^D}$, is then applied across the space and time being represented in the scenario, $\boldsymbol{S}$, to determine whether modifiers need to be applied, producing $\boldsymbol{F}$*. For instance, whether proximity to the incident, alarm coverage/notification, etc., need to be taken into account when applying the data to different areas/times/populations during the scenario. Will someone in the room of origin respond in the same way as someone with no visual access to the incident given that they are both intoxicated, in a hotel, awake, etc.?

In Stage (11), the refined schema, $\boldsymbol{F}$*, representing both the quantifiable issues and the manner in which is applied across the temporal/spatial environment is then applied to the data distribution, $\boldsymbol{Q}$. This then produces a quantified definition of the scenario, $\boldsymbol{S}$*, that is used to configure the model employed in the egress analysis.

Obviously, the process is over-simplified and presented in a linear manner when in fact it may be a highly iterative process. In reality, the engineer may iterate between these stages, ignore some and/or introduce others. However, the example is presented to demonstrate that the data presented may need significant manipulation both to broadly address the factors present in the scenario being addressed and then to customize the derived data-sets to represent local situations within the scenario. This will require skill and judgment. This process should be documented, not only to identify the data-sets and the steps involved, but also to make the assumptions and actions clear to third party viewers.

Summary

This chapter has presented a range of data-sets relative to the engineering time line commonly used to represent response and evacuation behaviors. Although these may inform a number of research, engineering and regulatory practices, the objective of this chapter has been to facilitate more effective, reliable and informed egress analysis as part of the performance-based design process. This data might be used to therefore to develop, configure, employ and validate computational and engineering egress tools as part of this effort.

Given the range of data types provided, the data have been provided in a number of tables reflecting the different evacuation phases, behavioral elements and influential factors involved. In each case, the data is accompanied by as much relevant background information as possible. Where space was an issue, background information has been abbreviated, and, in all instances by necessity, background information that would ideally have been included has been excluded due to space and time limitations.

The data-sets are not, therefore, provided in sufficient detail for the reader to make a definitive selection. Instead, the data and associated description should provide sufficient information for the reader to narrow down their review and focus on the most relevant data-sets for their particular application. This emphasizes the importance of the user following up on data-sets of interest by reference to the original sources. It is hoped that this approach should save them time and ensure that the most credible data is employed.

Acknowledgements The authors would like to acknowledge the following researchers for their feedback during the development of this chapter: Dr. David Purser, Dr. Brian Hoskins, Dr. Daniel Nilsson. The authors would also like to acknowledge Dave Boswell (Hughes Associates, Inc), for his efforts during the review process, along with Dr. Erica Kuligowski (NIST), section editor. Finally, the authors would like to acknowledge the following researchers for reviewing the data-sets presented to ensure consistency and accuracy: Dr. Michael Kinsey (Arup), Dr. Enrico Ronchi (Lund University), Dr. Anand Veeraswamy, Dr. Xie Hui, Ms. Maria Pretorius and Ms. Aoife Hunt (University of Greenwich).

Liquid Fuel Fires

65

D.T. Gottuk and D.A. White

Introduction

Liquid fuel spill and pool fires represent potential hazards in many applications ranging from accidents at industrial plants using combustible liquids to arson fires with flammable fuels. A pool is characterized as a confined body of fuel that typically has a depth greater than 5 mm. A pool can result due to a liquid fuel release that collects in a low spot, such as a trench, or can exist as a result of normal storage of fuels in tanks and containers. A fuel spill is generally associated with thin fuel layers resulting from an unconfined release of fuel. The nature of a spill fire is highly variable, depending on the source of the release, surface features of the substrate (e.g., concrete, ground, water) on which the fuel is released, and the point and time of ignition. The ability to characterize fuel spills and the resulting fires in a consistent and conservative manner is required for many engineering analyses. This chapter provides an overview of the most relevant factors and methodology for evaluating a liquid fuel spill or pool fire in terms of fire growth and size.

The chapter is organized in three major sections corresponding to the three primary steps of evaluating the development of a liquid fuel spill or pool fire: (1) "Spill or Pool Size," (2) "Fire Growth," and (3) "Fire Size." The first section deals with the process of estimating the physical size of any given fuel release or pool of fuel. Both static (fixed quantity of liquid) and continuously flowing spill fires have been considered. Once a liquid fuel spill or pool has occurred, ignition of the fuel will lead to a transient fire growth period. This transient period of a liquid fuel fire is dictated by the flame spread rate across the surface of the liquid. The second section of the chapter addresses the assessment of fire growth rate by providing an overview of flame spread on liquid fuels. The third section discusses the available data and correlations that can be used to evaluate the size of the fire in terms of heat release rate and flame height.

The heat release rate of a fire is the primary parameter used in determining the impact of a fire on its surroundings. The impact of a fire is dealt with in other chapters of this handbook. The heat transfer from liquid fuel spill or pool fires is addressed by Beyler [1].

Spill or Pool Size

The first step in analyzing a liquid fuel fire is to characterize the physical dimensions of the fuel spill or pool. The area of the initial body of fuel will correlate to the size of the resulting fire. A confined fuel release or existing open container of fuel will result in a pool fire of a known area. A pool fire represents a body of fuel that is confined by physical boundaries. In other words, the walls of a room or obstructions on a floor will limit a fuel release to a smaller area than the potential

unconfined spill area. In almost all cases, a confined fuel release will create a pool that has a greater depth than the depth of an unconfined spill. When fuel is released onto a surface, it will spread laterally based on several factors, including the initial momentum of the fluid, the fluid surface tension, and the features of the substrate onto which it spilled. Some substrate features that need to be considered are porosity of material and surface roughness. Porous materials, such as sand or even some floor coverings like carpet, can result in different spill sizes and different fuel burning rates. Surface structure can have similar effects, either by impeding liquid spread due to roughness, non-uniformity pooling, or by exaggerating liquid spread via slopes.

In general, fuel spills can be characterized as either continuously flowing or instantaneous (static). These characterizations are considered with respect to when the spill is ignited. In the case of a continuously flowing spill, ignition has occurred while the fuel is moving away from the source. For a static spill, the fuel nominally spreads to a maximum area and then is ignited, such that the flame spreads across the fuel surface. For a continuously flowing spill fire, the flame may spread across the fuel surface initially, but the flame front is ultimately controlled by the spread of the fuel over the substrate until steady-state burning conditions occur.

The area of a continuously flowing spill that is not burning will continue to increase until a physical boundary is reached or the source of the release is exhausted. A continuous spill that is burning will have a steady-state spill size based on a balance between the volumetric flow rate and the volumetric burning rate of the fuel. This concept is developed later in the section "Fire Size."

For a confined pool, the area, A, is dictated by the boundaries, and the pool depth, δ, can be simply calculated based on the volume, V, of liquid:

$$\delta = \frac{V}{A} \tag{65.1}$$

For an unconfined spill, the area has typically been determined via Equation 65.1 with an estimate of the fuel depth. In the past, engineers have conservatively estimated spill depths based on the minimum depth required to support flame spread (see "Fire Growth Rate" section). The use of a minimum depth will result in the largest possible spill area that can support a flame, therefore, the largest possible fire.

Literature results provide a basis for estimating spill depths. Table 65.1 summarizes spill depths for both noncombustible liquids and combustible fuel spill fires on unconfined surfaces. Although the table shows a range of fluid depths, the data can be simplified when considering only a range of typical hydrocarbon fuels that are commonly associated with fire scenarios, as discussed below.

The most recent work of Benfer [7] and Mealy et al. [8], systematically evaluated spill depths for a range of liquids and substrates. The average spill depth for all liquid/substrate combinations evaluated by Mealy et al. [8] was 0.72 mm, which is consistent the previously cited data and the general rule proposed in the last edition of this handbook for estimating an unknown spill fire scenario. However, it should be noted that the range of spill depths measured by Mealy et al. and Benfer was from 0.12 up to 2.9 mm depending upon the specific liquid/substrate scenario. This relatively wide range of empirical depths demonstrates the importance of understanding key variables governing fluid spread such that an appropriate spill depth is used when performing an engineering analysis. The primary two factors governing the spread of a liquid and the spill depth are the surface tension of the liquid and the surface characteristics of the substrate.

Fundamental fluid dynamics and empirical data have clearly established that spill depth is a function of the surface tension of the liquid. Figure 65.1 shows this relationship based on the experimental results for a range of liquids. As can be seen in Fig. 65.2, the surface tension of different fuels from 10 °C to 50 °C ranges from 16 to 27 dyn/cm. Water based liquids will bound most fuels of interest, as can be seen in Table 65.1 and Fig. 65.1. The surface tensions of water

Table 65.1 Summary of fixed-quantity, unconfined liquid spill data

Reference	Fuel	Quantity of fuel	Spill depth	Spill area	Surface
Chambers [2]	JP-4	4–189 L (1–50 gal)	1.1–2.9 mm	3–65 m^2	Concrete runway
Gottuk et al. [3]	Water	3.8–30 L (1–8 gal)	1.1–3.4 mm	1–11 m^2	Smooth, unfinished concrete and tile floor
Gottuk et al. [3]	6 % AFFF	3.8–19 L (1–5 gal)	0.6–1.1 mm		Smooth, unfinished concrete
Gottuk et al. [4]	JP-8	2–3 L (0.5–0.8 gal)	0.7–1.1 mm	2.1–3.1 m^2	Smooth concrete with polyuethane coating
Purtorti et al. [5]	Gasoline	0.25–1 L (0.07–0.26 gal)	0.5–0.7 mm	0.4–1.8 m^2	Wood parquet and vinyl tile
Modak [6]	#2 fuel oil	0.005–0.030 L	0.22 mm	0.0075–0.04 m^2	Both epoxy-coated concrete and steel (spill depths were the same for both surfaces and were independent of the volume of liquid spilled.)
	Lubricating oil		0.34 mm		
	Motor oil		0.75 mm		
	Hydraulic oil		0.84 mm		
Benfer [7]	3 % AFFF	0.2–450 mL	0.17–0.65 mm	0.01–1 m^2	Smooth, unfinished concrete
	6 % AFFF		0.22–0.67 mm		
	Water		0.95–2.9 mm		
	Gasoline		0.22–0.64 mm		
	Denatured alcohol		0.12–0.77 mm

[a]Values presented are average spill depths measured during multiple tests with one standard deviation
[b]All fuels noted for Mealy et al. reference, excluding lube oil

is 73 dyn/cm and AFFF has a value of approximately 15–16 dyn/cm at temperatures of 15–32 °C [9]. Figure 65.1 shows results for 3 % aqueous film forming foam (3 % AFFF) concentrate and a 3 % fluoro-protein foam concentrate (3 % FP) with surface tension of 17 and 27 dyn/cm, respectively.

Given that the surface tension of most fuels is relatively similar (i.e., 20–27 dyn/cm); this parameter is generally not as influential when

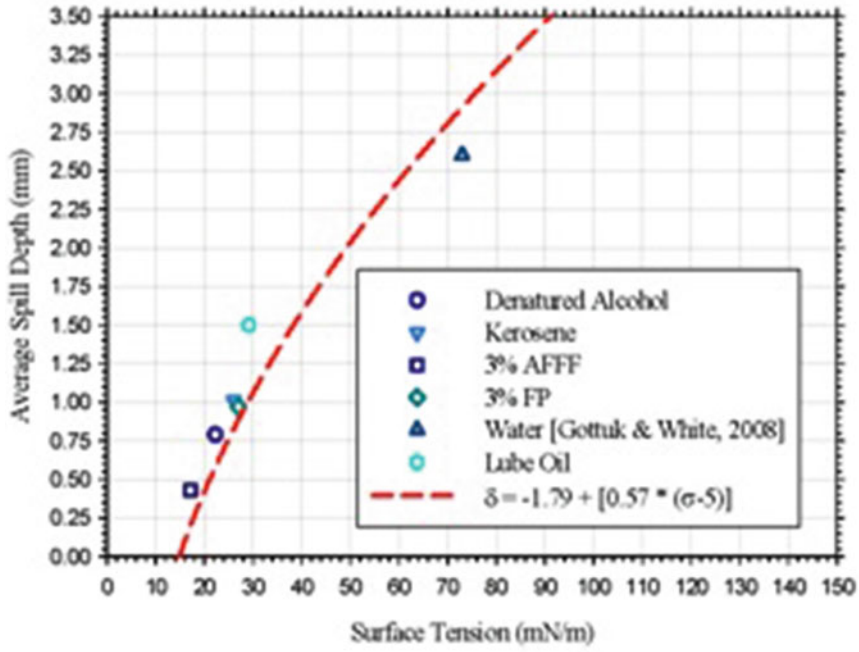

Fig. 65.1 Relationship between average spill depth and liquid surface tension [8]

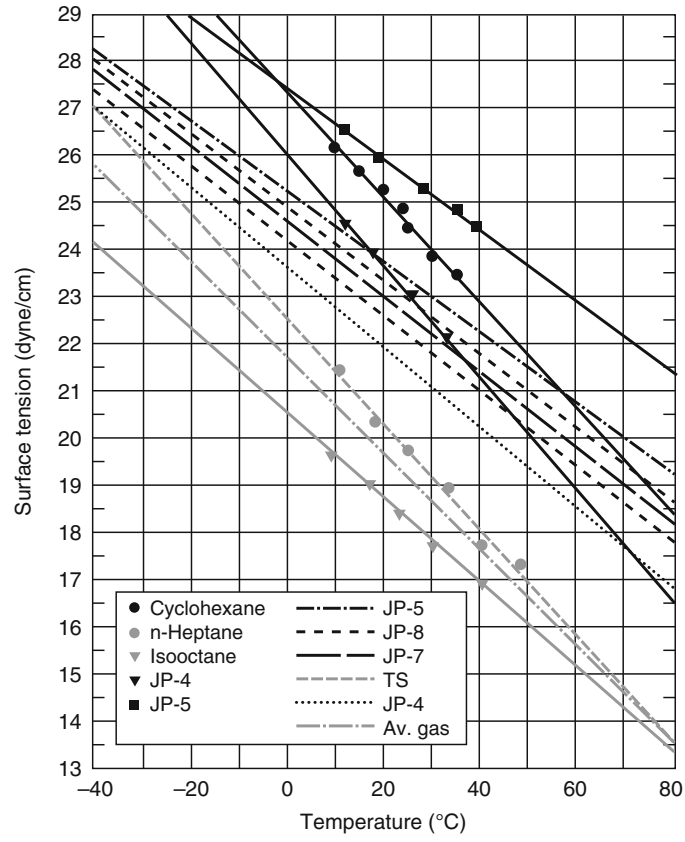

Fig. 65.2 The effect of temperature on surface tension of hydrocarbon liquids (Data taken from Moran et al. [9] and CRC [10])

considering the characteristics of a fuel spill (i.e., average depth variation of 0.71–1.01 for fuels excluding lube oil, which has a surface tension above 27) (see Fig. 65.1). The more dominant variable is the surface topography which can play a larger role in the extent of spread and the spill depth. The impact of substrate on spill depth is shown in Table 65.1. The roughness and uniformity of a substrate will dictate the speed and extent to which a liquid spreads and, thus, the equilibrium spill depth. For rougher, non-uniform surfaces, deeper equilibrium spill depths will be achieved due to the fuel being unable to spread to its full potential. Deeper spill depths result in longer burning durations with higher peak mass burning rates (i.e., larger fires). It is for this reason, from a spill dynamics standpoint, that an understanding of the surface on which a spill occurs is typically more important than understanding the fuel that was spilled.

Although from an ideal fluid dynamics point of view [8], there should be no dependence of spill depth on spill quantity, empirical data as well as transient spill models (Raj et al., 1974 and Grimaz et al., 2007) indicate that some dependence exists. These inconsistencies are an artifact of the variability in the surface characteristics that are not accounted for in the theoretical solution using ideal smooth, flat surfaces. Figure 65.3 shows the spill areas per unit volume and spill depths from spilling 0.5, 5.0, and 20 L of 3 % AFFF and 3 % FP on smooth concrete [8]. The measured area per unit volume for these scenarios consistently decreased with increasing fuel spill quantity, which is indicative of an increasing trend in spill depth. The JP-4 fuel spill data of Chambers [2] (Table 65.1) shows a similar trend for spills on a concrete runway, but with higher depths; the area per volume of fuel spilled decreased from 0.88 to 0.34 m^2/L for spills ranging from 4 to 190 L with a corresponding increase in spill depth from 1.1 to 2.9 mm. Due to limited experimental data, this data by Chambers provides the best estimate of upper limit fuel depths for large quantity spills at a time of 120 s. Spill depths of upwards of 3.4 mm were also noted for spills of water up to 30 L (where water has a surface tension of 73 dyn/cm compared to most fuels, which are below 27).

Total spill area will also be dictated by time until the liquid spread reaches the maximum area. Various spread models can be used for estimating this transient period; however, the use of idealized substrates will impact the results [8]. Based on the results from extended duration spill tests [8] with liquids (3 % AFFF, 3 % FP and gasoline) of 0.25–0.5 L spilled on smooth, impermeable surfaces (i.e., coated concrete and vinyl), the spill area was at least 90 % of the maximum spill area by 300 s. At 30 s, the spill area was approximately 50 % of the maximum steady-state area. This transient development period can have an impact on the resulting fire size

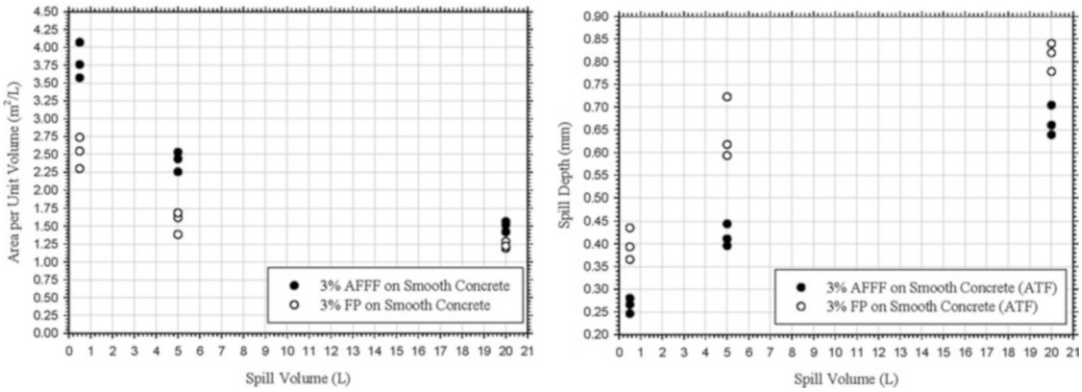

Fig. 65.3 Comparison of area per unit volume (*left*) and spill depth (*right*) to various quantity spills of 3 % AFFF and 3 % FP on smooth concrete (surface tension of 17 and 27 (dynes/cm, respectively))

based the time of ignition compared to the time to reach the maximum spill area [8].

For similar test on coated concrete, vinyl, and smooth concrete, lube oil exhibited a slightly different trend then the other liquids, reaching 75–90 % of the total spill area in the initial 30-s. This larger fraction is attributed to the high viscosity of the liquid relative to all other liquids. The high viscosity of the lube oil inhibits the spread of the liquid beyond the initial spill area.

Spills on rough/absorbent surfaces or spills involving fluids with high viscosities, generally achieve a large fraction of their spill area potential soon after being spilled. The lack of fluid spread after the initial spill can be attributed to several different factors including; the physical characteristics of the substrate impeding the movement of the fluid, the absorbency of the substrate removing liquid from the bulk flow of fluid thus reducing the spill area potential, or the internal forces within the liquid (i.e., viscosity) inhibiting the spread of the spilled volume.

As can be noted in Table 65.1, there is quite a bit of variability in spill depths for smaller quantities of fluid. The larger variability of depths for smaller spill quantities is attributed to the greater dependency on multiple variables, such as the initial spill height, surface features, and fluid properties. An example of the variability in spill depths is shown in Fig. 65.4, which presents the 6 % AFFF solution and water data of Fig. 65.1. For the water, depths varied for releases at different heights and different quantities. However, this effect was not observed for releases of the 6 % AFFF solution. Figure 65.4 also shows that similar water spills on vinyl tile floor produced the same spill depths as released on smooth concrete. Modak [6] reported that for very small spills of various oils (see Table 65.1) on steel and epoxy-coated concrete, the spill areas (and depths) were the same for both substrate materials. However, spill areas were smaller for untreated concrete due to fuel absorption into the substrate surface. This is similar to the trends observed by Mealy et al.

In summary, spill depths for liquids can vary significantly based on a number of factors ranging from the type of liquid and substrate, the volume spilled, the time frame and other spill parameters. However, as a general rule for common fuels, a spill depth of 0.7 mm can be used with reasonable confidence. Based on the work of Mealy et al. [8], the differences in calculated mass burning rates resulting from the use of an average spill depth of 0.7 mm as opposed to a substrate specific mass burning rate value were generally small and highly dependent upon the

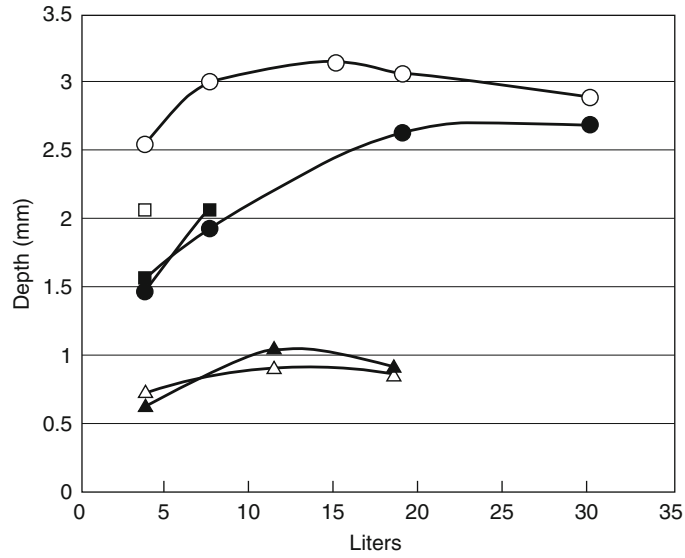

Fig. 65.4 Spill depths for 6 % AFFF solution and water releases on smooth concrete and tile floors for various fuel volumes and release heights: [3] AFFF on concrete from 0.6 m (△), AFFF on concrete from 1.0 m (▲), water on concrete from 0.6 m (○), water on concrete from 1.0 m (●), water on tile floor from 0.15 m (□), and water on tile floor from 0.9 m (■)

quantity of fuel spilled. The use of the 0.7 mm spill depth approximation as opposed to a substrate specific spill depth for spills greater than 1 L (0.26 gal), will provide baseline mass burning data that is accurate to within 10 %.

Based only on the few tests by Chambers [2] for JP-4 fuel spilled on a concrete runway, large quantities of fuel (~38 L (10 gal) and more) may result in deeper spill depths of upwards of 3 mm. This greater depth can be used as a bounding value in a fuel spill fire analysis when a longer lasting but smaller fire is worth evaluating compared to using a depth of 0.7 mm. Equation 65.4 summarize the rule of thumb for fuel depths, $\boldsymbol{\delta}$:

$$\boldsymbol{\delta = 0.7 \text{ mm for most fuels and conditions}} \tag{65.2a}$$

$$\boldsymbol{\delta = 2.9 \text{ mm for quantities of 38 L(10 gal) where analysis warrants longer duration fires}} \tag{65.2b}$$

If a more accurate estimate is needed, then Table 65.1 and reference [4] should be used to provide guidance.

It is also interesting to note that Chambers [2], Gottuk et al. [3], and Putorti et al. [5] observed increases in burning fuel spill areas after the liquid spill was ignited. Fires increased the initial fuel spill area by 22–89 % for fuel releases ranging from 2 to 190 L. The practical implication of this increase in spill area is that the fires may be substantially larger than would be predicted per the initial fuel spill areas. However, the larger area would also result in much shorter burning times before the fuel is consumed. Since the last edition of this chapter, additional work by Mealy et al. [8] showed that there was no measurable increase in burn area compared to initial spill area on non-combustible surfaces for spills up to 20 L.

Fire Growth Rate

The temperature of the spilled liquid relative to its flashpoint is the single most important factor in identifying the flame spread rate over the surface of the liquid. The flame spread rate, in turn, determines the heat release rate history of the growing fire. Other factors also affect the flame spread rate, including the depth of the spilled liquid, size of the spill, type of liquid, and the substrate.

Generally, hazard assessments involving flammable, liquid pool fires require a conservative characterization of the fire growth rate history, peak burning rate, and fire duration. The purpose of the hazard assessment often defines that only a subset of these parameters are required. Peak burning rate and maximum burning duration at the peak burning rate are typically relevant to fire effects such as fire exposure to building elements, ignition of other fuel targets, or general environmental conditions that result from the fire.

The characterization of the spill or pool fire heat release rate history from ignition to peak burning rate (full involvement of pool fuel surface area) is important when dealing with time-related concerns or events. Examples of time-dependent concerns include egress or life safety conditions, activation of detection or suppression systems, spread of fire to other fuel packages, or failure of building elements. Presuming that one is interested in the pool fire heat release rate growth history, this can be defined as the integration of the flame spread rate for the particular geometry in question (e.g., circular for unconfined pools, rectangular for trenches) multiplied by the burning rate per unit surface area for the given liquid. Estimating the flame spread rate over the surface of the flammable/combustible liquid spill becomes critical in characterizing the fire growth history.

Most ignitions of flammable liquid fuels result in flame spread that can be characterized by one of two major flame spread mechanisms for liquid fuels: liquid phase-controlled flame spread or gas phase-controlled flame spread. Flame spread rates for these two regimes can be grossly benchmarked: 1–12 cm/s for liquid phase-controlled flame spread and 130–220 cm/s for gas phase-controlled flame spread. A third regime for flammable liquid spills on porous surfaces can be defined where flame spread rates are measured in terms of cm/min. For some hazard analyses, identifying the appropriate flame spread region may sufficiently characterize the flame spread rate in a conservative fashion. The primary driver of the flame spread regime is the temperature of the spilled liquid relative to its flashpoint.

Basic Theory of Flame Spread on Liquids

Flame spread on liquid fuels has been widely studied in small-scale experiments and theoretical studies [11–29]. The flame spread rates are known to be dependent on fuel temperature and fuel flashpoint. Below the flashpoint temperature, the flame spreads by way of surface tension-induced flow of hot fuel ahead of the advancing flame. Above the flashpoint, the flame spread is by way of gas phase spread, which can be as rapid as 2 m/s. The majority of liquid flame spread studies have been limited to pure fuels, and most of the studies have used alcohol fuels in trays less than 10 cm wide. The majority of liquid flame spread studies have been focused on pure fuels with heavy emphasis on alcohol fuels in trays less than 10 cm wide. This chapter includes empirical data from nonpure hydrocarbon fuels [30] as well as data from large-scale studies [8, 31].

Flame Spread Regimes Several flame spread regimes have been identified in the literature. These flame spread regimes are most notably a function of the liquid temperature. The dependence of flame spread rates on liquid temperature has been studied by a number of investigators [11–27]. The most extensive work has been done with narrow pans of alcohol fuels with fuel depths of 2–5 mm. These investigations indicate that the flame spread velocity is a strong function of fuel temperature, even when the fuel temperature is well below the flashpoint. Figure 65.5 shows the extensive work that Akita [14] conducted using methanol in a 2.6-cm-wide pan. Akita observed a number of different flame spread regimes. Above the flashpoint, spread was via the gas phase. Below the flashpoint, he

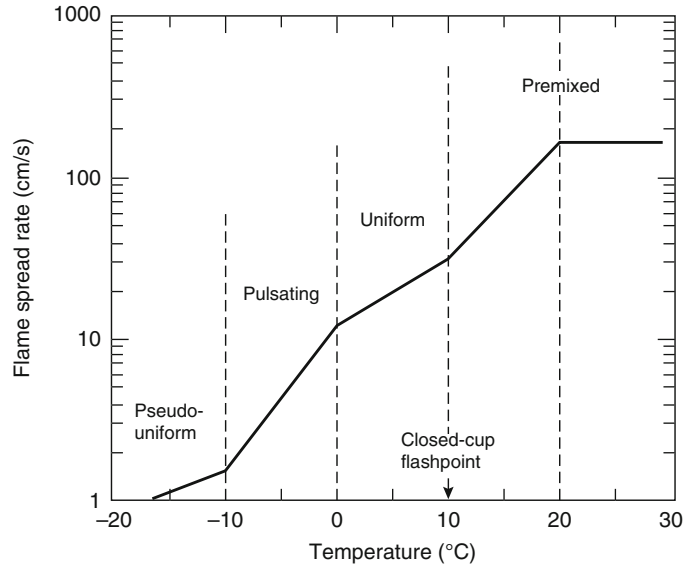

Fig. 65.5 Flame spread rate on 1-cm-deep methanol as a function of fuel temperature in a 2.6-cm-wide pan [14]

observed regions of uniform, pulsating, and pseudo-uniform spread. The mechanistic explanations for these phenomena below the flashpoint are not widely agreed upon. A more detailed discussion of flame spread regimes and their mechanisms can be found in the review article by Ross [32].

Semilog plots of flame spread rate as a function of liquid temperature have a characteristic shape with three regions: the liquid-controlled region, the gas phase–controlled region, and the asymptotic gas phase-controlled region. The slopes of the curve are different in each of these regions, and these differing slopes serve to define the regions. The transition from liquid to gas phase–controlled burning occurs at a temperature T_{go}; the transition from gas phase control to asymptotic gas phase spread occurs at a temperature T_{gm}. Figure 65.6 graphically portrays these temperatures with respect to flame spread rates. Figure 65.6 is intended as a conceptual depiction and the omission of units on the axes is intentional.

Figure 65.6 is conceptually the same as a figure first described by Glassman and Hansel [33]. In their paper, they identified the temperature at which gas phase-controlled flame spread begins as the firepoint of the liquid; they also identified the temperature at which the maximum flame spread rate occurs as the stoichiometric temperature (the liquid temperature at which the vapor concentration at the surface is stoichiometric). While this interpretation is consistent with the interpretation of data for multicomponent fuels, in light of Glassman and Dryer [19], it is not practical to define a firepoint temperature for a multicomponent fuel. The difficulties are due to the need to model evaporation of many high-volatility components in a multicomponent fuel during the open heating that is required in the determination of a firepoint. Determination of the firepoint of a multicomponent fuel would require closed-cup heating of a fuel to a test temperature, exposing the liquid surface, and applying an ignition source. If the fire does not continue, the test temperature is below the firepoint. Additional temperature tests would be required until the firepoint temperature is bracketed to the desired accuracy. This process is not practical. Similarly, for a multicomponent fuel it is not always practical to define the stoichiometric temperature, since determination of the vapor pressure of each component is, at the least, tedious and often impossible. Thus, while Glassman and Hansel's definitions are not easily generalized to multicomponent fuels, their pure fuel concepts can still provide guidance and

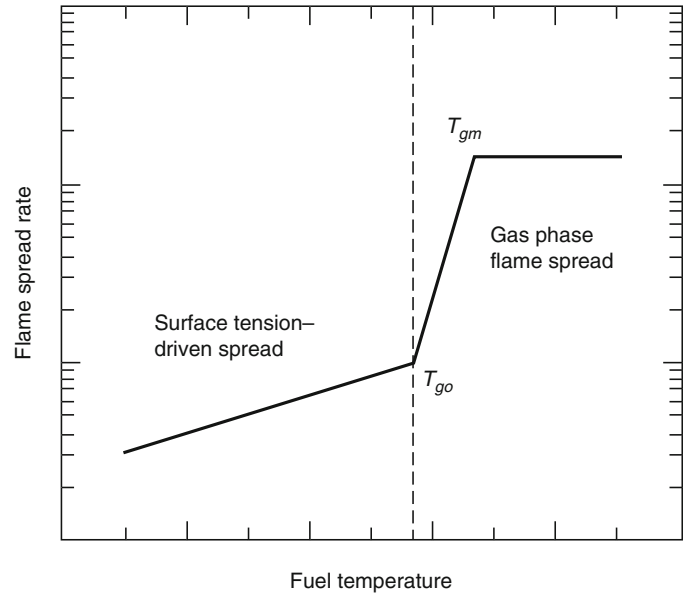

Fig. 65.6 Graphic representation of the definitions of T_{go} and T_{gm}

motivation for the interpretation of multicomponent liquid fuel flame spread results.

Pool Dimensions The physical dimensions of a liquid fuel spill or pool influence the flame spread rate, assuming an ignition source is present. The primary factors of importance are pool depth and characteristic width of the pool, as discussed below.

Pool dimensions, including fuel depth, have no effect on the flame spread rate for situations where the flame spread mechanism is considered gas phase-controlled. However, the depth of a flammable liquid does have a significant impact on the flame spread rate for liquid phase-controlled burning. In general, the average flame spread velocity for liquid phase-controlled spread increases with fuel depth, which is primarily governed by whether the fuel release is confined or unconfined.

Scientific study of liquid flame spread can be traced back as far as the 1930s [11]. Most of the early work was done on relatively small-scale test setups, much using pans only 1–6 cm wide with alcohol fuels at depths of 2–5 mm [12–14]. Work by Mackinven, Hansel, and Glassman [15] at Princeton is especially relevant here because it involved extensive experiments with decane, a pure fuel with similar characteristics to aviation fuels and other low-flashpoint multicomponent hydrocarbon fuels that are common to fire hazard assessments. The Princeton research documented the effects of pan width and fuel thickness on observed flame spread rates [15].

Several investigators have performed experiments to characterize the impact of fuel depth on liquid-controlled flame spread. Mackinven et al. [15] demonstrated the systematic variation of flame spread rates with fuel depth. They investigated decane fuel depths from 1 mm to 2 cm and found the flame spread rate to increase with fuel depth as shown in Fig. 65.7. This increase can be attributed to the retarding effect of small fuel depths on liquid recirculation flows that cause flame spread. Calculations by Torrance [16, 17] are in excellent agreement with Mackinven et al.'s experimental data shown in Fig. 65.7. These calculations indicate that decane flame spread rates increase with pool depth up to 3 cm, with greater fuel depths beyond this no longer increasing the flame spread rate. Of course, fuel depths for unconfined fuel spills will always be far less than 3 cm. Investigations by Mackinven et al. [15] as well as Burgoyne and Roberts

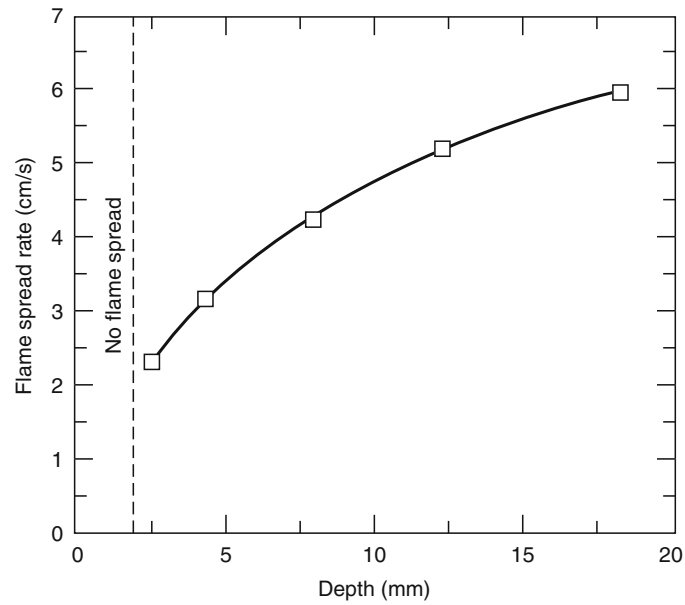

Fig. 65.7 Flame spread rate on decane as a function of fuel depth [15]

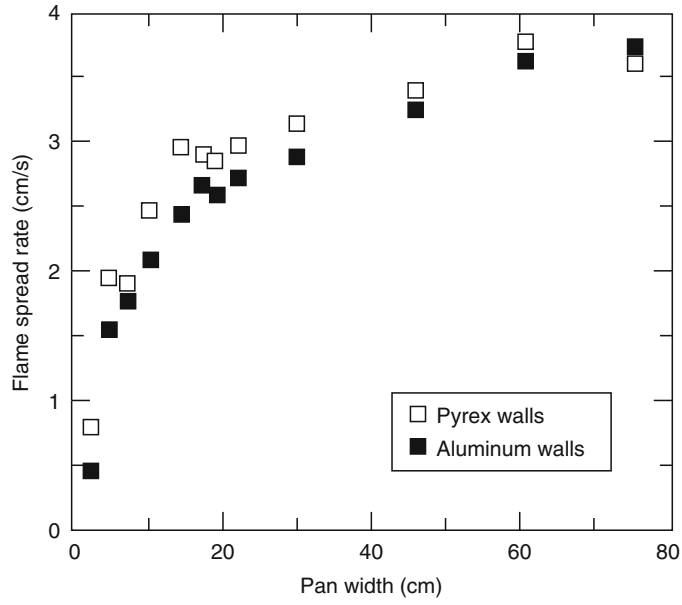

Fig. 65.8 Flame spread rate on decane as a function of pan width [15]

[12, 13] indicate that flames do not spread away from the ignition source in liquid pools at or less than 1.5 mm deep. More recent work by Burelbach, Epstein, and Plys [34] demonstrated that the limiting fuel thickness for flame spread was 2.0 mm for decane and 2.3 mm for dodecane. Minimum fuel depths for flame spread are for the liquid-controlled spread regime. There is no evidence for fuel depth or pan width effects on gas phase flame spread [12, 14, 18, 20, 23, 25].

Mackinven et al. [15] found that for pan widths up to 20 cm the flame spread rates on decane are a strong function of pan width. At pan widths from 20 to 80 cm, the maximum width they studied, they observed only slight increases in flame spread rate. Their results are shown in Fig. 65.8. Both aluminum and glass pan walls were used. The small differences between these two wall materials may be attributed to heat conduction effects; however, the major influence at pan widths less than 20 cm is independent of wall material and has been attributed to a momentum reduction associated with viscous drag on the walls. The relative independence of pan width above 20 cm indicates that flame radiation is not a pivotal mechanism in determining liquid phase-controlled flame spread. The results were confirmed by Mackinven et al. by shielding the liquid ahead of the flame from flame radiation during flame spread experiments (20- to 80-cm-wide pans). They observed modest changes in flame spread rates between the shielded and unshielded experiments.

Temperature Effects The work of Burgoyne and Roberts [12] showed that at small pan widths the temperature dependence of the flame spread rate is a function of the pan width as shown in Fig. 65.9. Unfortunately, their work extends only from 2.5 to 6.3 cm widths. The dependence on pan width disappears above 41 °C, the flashpoint of isopentanol. The work of Mackinven et al. [15] using varying pan widths (see Fig. 65.8) with decane 21 °C below the closed-cup flashpoint (44 °C) as well as work by Burgoyne and Roberts [12] indicates that pan width ceases to have an impact on the temperature dependence of the flame spread rate at pan widths greater than 20 cm.

Flame spread experiments above the flashpoint indicate that flame spread is via the gas phase. The flame spread rate increases rapidly from the flashpoint to the liquid temperature at which a stoichiometric fuel-air mixture exists above the liquid surface. Above this temperature, the flame spread rate is no longer temperature

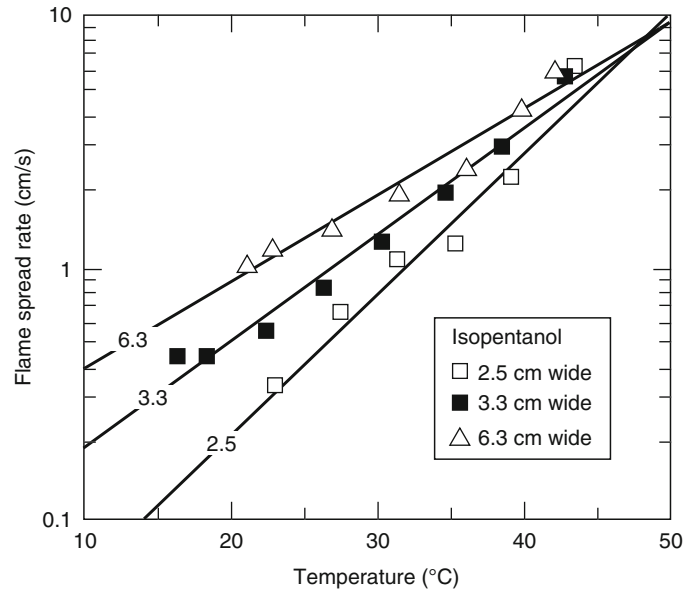

Fig. 65.9 Effect of pan width on the temperature dependence of flame spread rate on isopentanol [12]

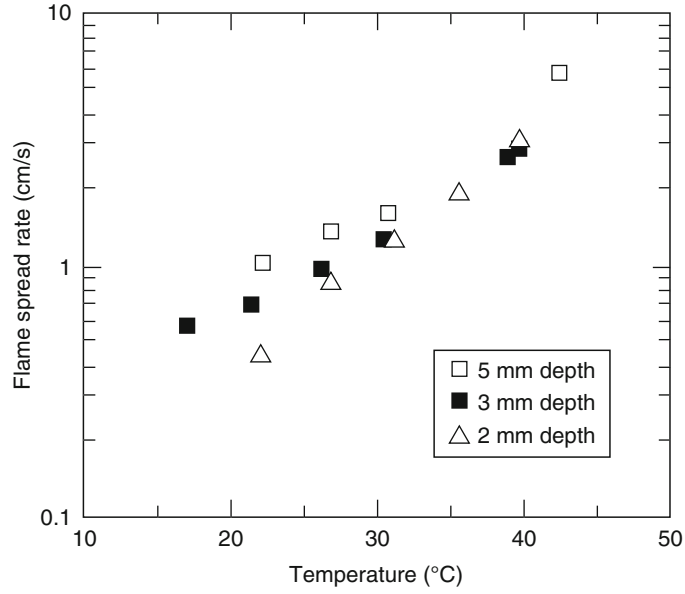

Fig. 65.10 Effect of fuel depth on the temperature dependence of flame spread rate on isopentanol [12]

dependent. The flame spread velocities measured by Burgoyne and Roberts [12], Akita [14], Nakakuki [20], and Hirano et al. [25] in this temperature region are from 1.3 to 2.2 m/s depending on the fuel. These velocities are similar to flame spread rates measured in stratified fuel-air mixtures found near ceilings of mine tunnels [35–37].

The work of Burgoyne and Roberts also indicates that the temperature dependence of the flame spread rate is a function of the fuel depth [12]. They investigated isopentanol at fuel depths of 2–5 mm and their results, shown in Fig. 65.10, indicate that variations in flame spread rate with fuel temperature below the flashpoint (41 °C) are lessened by increasing fuel depth.

Empirical Data

An overview of the experimental results for flame spread velocities follows, including alcohol fuels, multicomponent hydrocarbon fuels, and blends of multicomponent hydrocarbon fuels. Although the bulk of the data is for laboratory-scale pools, there is limited data for large-scale pools of hydrocarbon fuels as well as some data for large-scale spills of jet fuel (hydrocarbon).

White, Beyler, Fulper, and Leonard [30] measured flame spread rates for aviation fuels, mixtures of these multicomponent hydrocarbon fuels, as well as 1-pentanol (alcohol). These measurements were made over a range of fuel temperatures in a pan 20 cm wide by 163 cm long. The results for pure JP-5 and JP-8 are shown in Figs. 65.11 and 65.12. The flame spread rates range from 3 to 140 cm/s over a temperature range of 10–90 °C. The solid symbols indicate liquid-controlled flame spread and the open symbols indicate gas phase flame spread. JP-5 is a high-flashpoint kerosene used by the U.S. Navy that has a specified minimum flashpoint of 60 °C [38]. JP-8 is a newer U.S. Air Force fuel, very similar to commercial Jet A-1, that is a kerosene with a lower specified minimum flashpoint of 38 °C [39]. The flame spread rates in the liquid-controlled regime for JP-8 are 0.5–2 cm/s greater than for JP-5. At temperatures approximately 12–20 °C above the closed-cup flashpoint, flame spread rates increase very rapidly to over 100 cm/s. The major difference in flame spread characteristics of JP-5 and JP-8 is the temperature at which the flame spread rate rapidly increases: 68 °C for JP-5 and 58 °C for JP-8.

Figure 65.12 shows several data points where the application of the ignition source was systematically varied from 3 to 460 s in the most sensitive temperature region (the transition between liquid-controlled and gas phase–controlled flame spread). At higher and lower temperatures such ignition delays have little or no effect on the observed flame spread rate. Assuming that the flame spread rate is a function of the liquid temperature relative to the flashpoint temperature, the results are consistent with an increase in the flashpoint of approximately 10 °C during the 3–460 s between fuel discharge and ignition. No systematic study of flashpoint variations with time for multicomponent fuels appears elsewhere in the literature.

The flame spread results for JP-5 and JP-8 indicate that the single most important determinant of flame spread is the initial temperature of the liquid prior to ignition relative to the fuel's

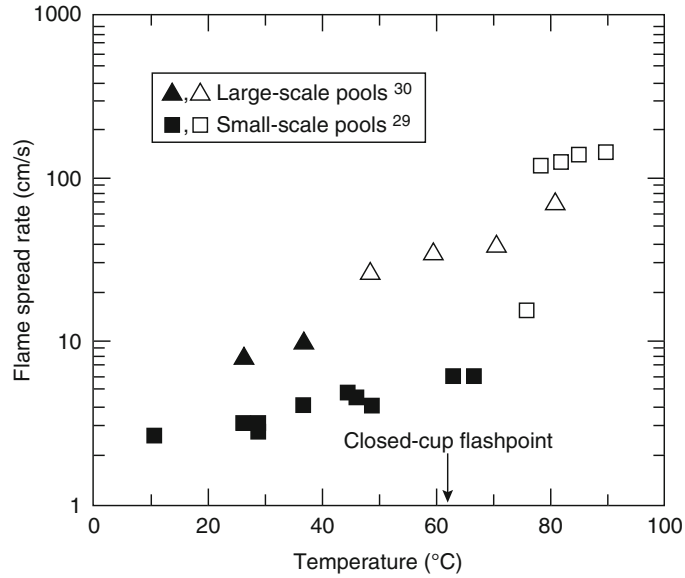

Fig. 65.11 Flame spread rate for JP-5 as a function of temperature. *Solid symbols* denote liquid-controlled flame spread and *open symbols* denote gas phase flame spread for small-scale data only

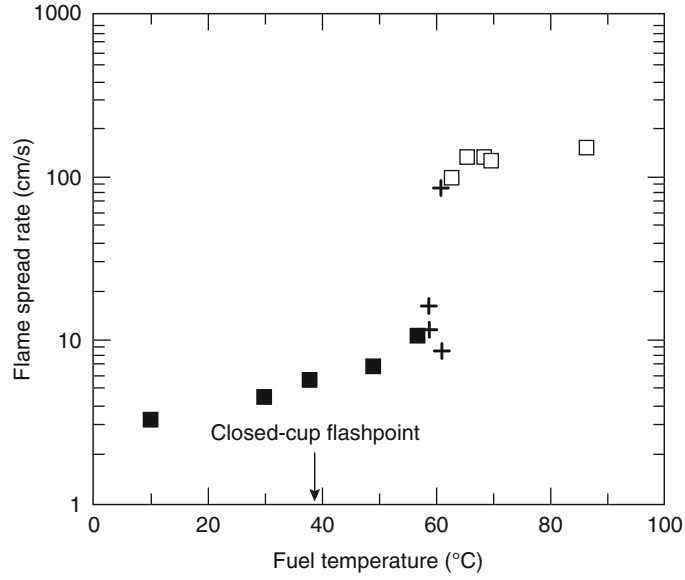

Fig. 65.12 Flame spread rate for JP-8 as a function of temperature. *Solid symbols* denote liquid-controlled flame spread and *open symbols* denote gas phase flame spread; + indicates variable times to ignition of 3, 160, 240, and 460 s. The normal time to ignition is 35 s. Longer ignition times reduce the flame spread rate [30]

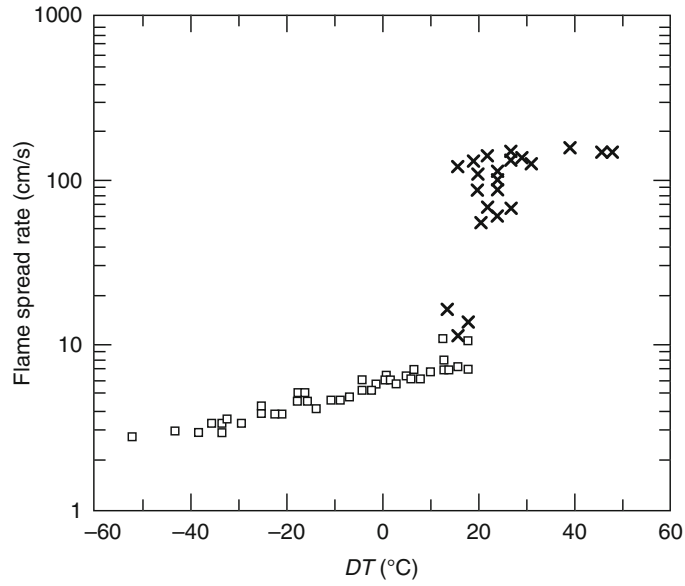

Fig. 65.13 Flame spread rate for all JP fuels as a function of $DT(T_{fl} - T_l)$ [30]

flashpoint. Hillstrom [18] also observed this correlation and found that plotting the flame spread rate as a function of the temperature difference between the closed-cup flashpoint, T_{fl}, and the liquid fuel temperature, T_l, correlated data for a number of hydrocarbon fuels. Figure 65.13 shows flame spread rate data for pure JP-5, pure JP-8, and mixtures of the two fuels plotted as a function of $DT(T_{fl} - T_l)$. In Fig. 65.13 square symbols represent liquid-controlled flame spread and the *X* symbols indicate gas phase flame spread. The treatment of the data effectively correlates all of the jet fuel data over a range of *DT* from −50 °C to +50 °C. This representation of the data clearly shows the importance of *DT* $(T_{fl} - T_l)$ in determining flame spread rate.

Figure 65.13 also shows excellent consistency in the transition from liquid-controlled flame spread to gas phase spread at $DT = 18$ °C.

Leonard et al. [31] performed large-scale flame spread experiments as part of an effort to evaluate the fire hazards of mixed jet fuels on aircraft carrier flight decks. The experiments, which evaluated pure JP-5, pure JP-8, and mixtures of these two jet fuels, were carried out in a large-scale pan 1.52 m in width by 12.2 m in length. The Leonard et al. experiments are the largest pool fire flame spread experiments reported in the literature. The jet fuels were evaluated over a range of temperatures by introducing heated fuel into the large pan, which was also temperature controlled by circulation of water through chambers on the underside of the pan bottom. The results for JP-5 are presented in Fig. 65.11. The results for JP-8 are illustrated in Fig. 65.14.

The large-scale results can easily be compared with small-scale results in both Figs. 65.11 and 65.14. This comparison yields identical qualitative results. The flame spread rates for the large-scale tests are notably higher for both the JP-5 and JP-8 liquid-controlled flame spread tests. Data for the JP-8 tests indicate that the liquid-controlled flame spread rate is 10–11.6 cm/s whereas the JP-5 tests show 8.2–10 cm/s in this regime. As with the small-scale tests, there is approximately 1.5–1.8 cm/s difference between the two jet fuels, with the JP-8 fuel slightly faster. The transition to gas phase flame spread appears to occur at a lower temperature for both fuels. Similar gas phase flame spread velocities are obtained between small- and large-scale tests. The disparity between the small- and large-scale tests for these two fuels cannot be attributed to a single factor. It is speculated that the difference in flame spread behavior of the two experimental data sets may be due, in part, to width effects and flame radiation effects. Further work is necessary to identify the specific mechanisms responsible for this observed difference.

A recent set of experiments evaluating aircraft hangar fire detection technologies [8] included large-scale jet fuel spill fires. The work of Hill, Scheffey, Walker, and Williams [8] evaluating alternative fire protection methods for U.S. Air Force aircraft hangars represents the largest spill fires evaluated in the literature for flame spread. A volume of 114 L (30 gal) of JP-8 was spilled on a concrete pad. The main focus of this research was fire suppression systems, and an important aspect evaluated was the impact of various suppression systems on the flame spread rate after system activation. Experiments measured the flame spread rate over the large

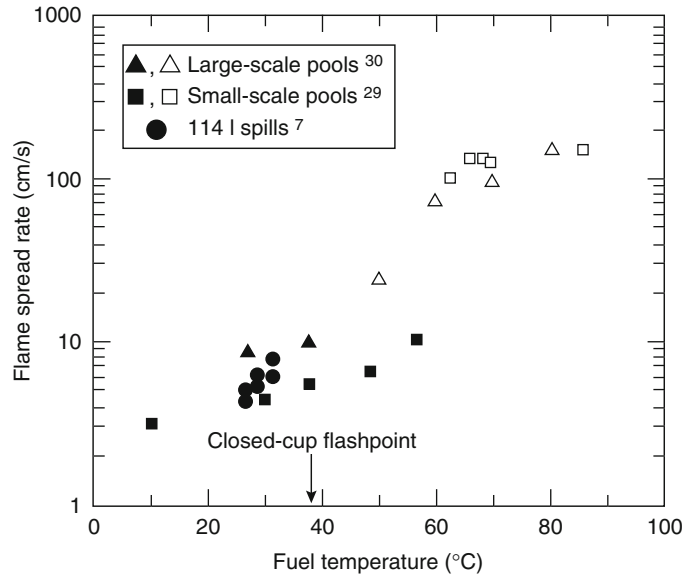

Fig. 65.14 Flame spread rate for JP-8 as a function of temperature. *Solid symbols* denote liquid-controlled flame spread and *open symbols* denote gas phase flame spread

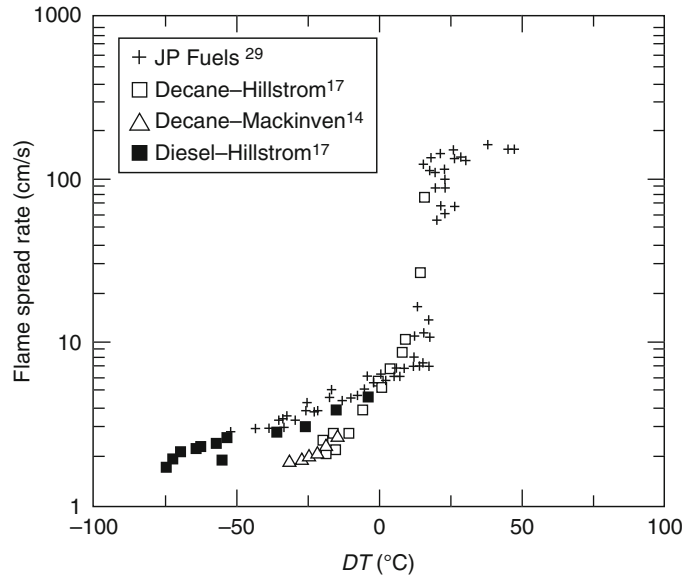

Fig. 65.15 Comparison of JP fuel data with other hydrocarbon flame spread data from the literature

spill area, which covered approximately 30 m^2 at the time of ignition, both before and after operation of the suppression system. The full free-burn spill size was on the order of 37 m^2 with time for complete burnout at roughly 2 min. Measured flame spread rates for the JP-8 spills prior to suppression system activation have been identified in Fig. 65.14. The temperature of the JP-8 fuel was approximately 25 °C ± 2 °C. These flame spread rates fall close to the data points from the small-scale tests. The Hill et al. data points show a 1.5–3.5 cm/s increase over the small-scale data for the liquid-controlled flame spread results. The large-scale spill data show higher flame spread rates in comparison to the small-scale pool experiment data.

Although there are depth issues associated with the comparison of pool experiments to spill experiments, the trend appears to be that larger-scale flame spread experiments yield higher flame spread rates for the liquid-controlled flame spread regime with a transition to gas phase spread occurring at a lower temperature than observed in the small-scale pool experiments. While these differences may not be fully explainable, it is important to note that irrespective of the experiment scale, peak flame spread rates for the liquid-controlled flame spread regime are approximately 10 cm/s for JP-5 and 12 cm/s for JP-8. Furthermore, although the transition to gas phase spread seems to occur at a lower temperature, the maximum gas phase flame spread rates are maintained in the 120–200 cm/s range for both JP-5 and JP-8. Support for using a maximum flame spread velocity of 10 cm/s for liquid-controlled flame spread over hydrocarbon fuels can be drawn from Fig. 65.15, which shows a comparison of the jet fuel data from White et al. [30] and other hydrocarbon data from the literature. The results of the jet fuels were consistent with those of Hillstrom [18] and Mackinven et al., [15], which show a very modest variation in flame spread rate below the flashpoint temperature. Figure 65.15 shows a comparison between the jet fuel data of White et al., [30], the decane data from Hillstrom [18], the diesel fuel data from Hillstrom [18], and the decane data from Mackinven et al. [15]. The decane results show a rise in the flame spread rate at a smaller value of *DT* than for the JP fuels. Also, below the closed-cup flashpoint, the decane shows lower flame spread rates. This variation may be due to the effect of using a water substrate in the decane tests rather than steel as used in the jet fuel work. All the data in Fig. 65.15 were collected in 20-cm-wide pans.

Empirical data for flame spread over alcohol pools consist of small-scale test data. White et al. [30] performed the largest experiments, utilizing a 20-cm-wide pan evaluating 1-pentanol as part of their study. Results from these 1-pentanol flame spread tests, illustrated in Fig. 65.16, were performed to assess the effect of fuel type on flame spread for an alcohol fuel that had a similar flashpoint to the jet fuels primarily under study in this specific piece of work. Pentanol was chosen, in part, due to the previous pentanol flame spread work performed by Burgoyne and Roberts [12].

Liquid-controlled flows were observed at temperatures less than 52 °C. The change from liquid-controlled flame spread to gas phase flame spread occurred at approximately 4 °C above the closed-cup flashpoint. Figure 65.16 illustrates a comparison of the 1-pentanol results from White et al. [30] with the alcohol data from Burgoyne and Roberts [12]. The 1-pentanol results take on the same characteristic dependence on *DT*, with the Burgoyne and Roberts data showing rapid rise in the flame spread rate at somewhat lower values of *DT* than the 1-pentanol data. The slope difference between the Burgoyne and Roberts data and the 1-pentanol data for the liquid-controlled flame spread regime can be attributed to the effect of pan width on the temperature dependence of flame spread rate in this regime. It is very interesting to note that in Fig. 65.16 the data for alcohol flame spread are similar to the hydrocarbon data with respect to the maximum of 10 cm/s liquid-controlled for flame spread rates with the gas phase flame spread rates falling between 150 and 200 cm/s.

Table 65.2, reproduced from White et al. [30] shows the closed-cup flashpoint, T_{fl}, the transition from liquid to gas phase-controlled burning, T_{go}, and the transition from gas phase control to asymptotic gas phase spread, T_{gm}, for the small-scale jet fuel data, the 1-pentanol data, and the decane data from Hillstrom [18]. The difference $T_{go} - T_{fl}$ averages 15 °C for the hydrocarbon fuels. The difference $T_{gm} - T_{go}$ averages 6 °C and the overall difference $T_{gm} - T_{fl}$ averages 21 °C. These results may be expected to represent general properties for small hydrocarbon pools but should not be used for alcohol fuels.

Glassman and Dryer [19] have pointed out some discrepancies in the measurement of flashpoints and firepoints of alcohols versus hydrocarbons and the relevance of flashpoints to the hazards of liquid fuels. Although each of the standard flashpoint/firepoint testing methods has its own difficulties, it is clear from the work

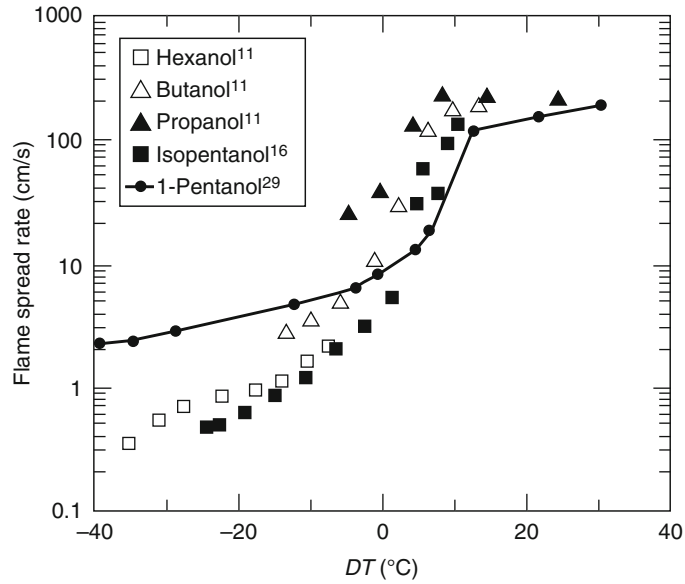

Fig. 65.16 Comparison of the 1-pentanol data with the alcohol (Data of Burgoyne and Roberts [12])

Table 65.2 Critical temperatures (°C) for flame spread [30]

Fuel	T_{fl}	T_{go}	$(T_{go} - T_{fl})$	T_{gm}	$(T_{gm} - T_{go})$	$(T_{gm} - T_{fl})$
JP-8	39	57	18	62	5	23
25/75 JP-8/5	42	60	18	66	6	24
50/50 JP-8/5	48	65	17	72	7	24
75/25 JP-8/5	54	68	14	74	6	20
JP-5	63	76	13	79	3	16
Decane [5]	44	56	12	62	6	18
Average 1–6	—	—	15	—	6	21
1-Pentanol	48	52	4	62	10	14

of Glassman and Dryer that none of the standard flashpoint testing methods correlate with the onset of gas phase flame spread for all fuels. Glassman and Dryer point out major differences between alcohol and hydrocarbon flashpoints and point to the large quenching diameter for these two classes of fuels. Based on Glassman and Dryer's observations, transition to gas phase flame spread would be expected at temperatures near the closed-cup flashpoint for alcohol fuels, as observed for the 1-pentanol test results.

However, there are differences in $T_{go} - T_{fl}$ between jet fuels and decane. The more volatile aviation fuels are characterized by $T_{go} - T_{fl} \sim 18\ ^\circ\text{C}$ while decane and JP-5 are characterized by $T_{go} - T_{fl} \sim 12\ ^\circ\text{C}$. This 6 °C difference may be due to the loss of light ends from the more volatile hydrocarbon mixtures and is consistent with the variations in flame spread rate with ignition time delay represented in Fig. 65.12. White et al. point out that it appears that the actual flashpoint of the JP-8 may have increased by approximately 6 °C during the discharge and ignition delay period. While this deduction seems reasonable, a more systematic study of this issue is warranted. The important consideration for hazard analyses is that multicomponent hydrocarbon fuels can incur a reduction in effective flashpoint depending on the volatility of the fuel and the time period between the fuel release and ignition. The conservative approach would be to assume instantaneous ignition of the released fuel.

Fuel-soaked beds of porous media (e.g., small beads of glass or metal) have been used in flame spread experiments to simulate a fuel spill onto a porous surface. Flame spread over porous media generally occurs at rates on the order of 1–8 cm/min, which is similar to measures of flame spread over the surface of relatively thick solids. Takeno and Hirano [40] have experimentally evaluated several parameters important to characterizing the flame spread rate over porous media soaked with fuel. Figure 65.17 represents the results from their study. Table 65.3 identifies the conditions of each experiment portrayed in Fig. 65.17.

These tests used a steel tray 3.5 cm wide and 60 cm long that was filled with either glass or lead beads. Four observations can be made from these data: (1) the flame spread velocity increases slightly as the diameter of the beads, d, increases and there appears to be little dependence on the liquid viscocity (see Fig. 65.17, conditions A, B, C) for 90 % by volume of decane and 10 % hexane; (2) the flame spread for pure decane is a function of the bead diameter and the viscosity (conditions E, F, G, H) with the flame spread velocity decreasing as d increases for smaller values of d, reaching a minimum flame spread rate at approximately $d = 0.25$ cm, from which point the flame spread velocity increases with d, and fuel viscosity effects are more pronounced with flame spread rate decreasing as the viscosity of the fuel increases; (3) for situations where the liquid level is below the top surface of the bead bed (conditions J, K), flame spread velocities are reduced and depend little on bead diameter or fuel viscosity; (4) when the glass beads are replaced with lead beads (conditions D, I, L), similar variations are observed as with the glass beads; however, the flame spread rates are reduced by approximately 10 %. In general,

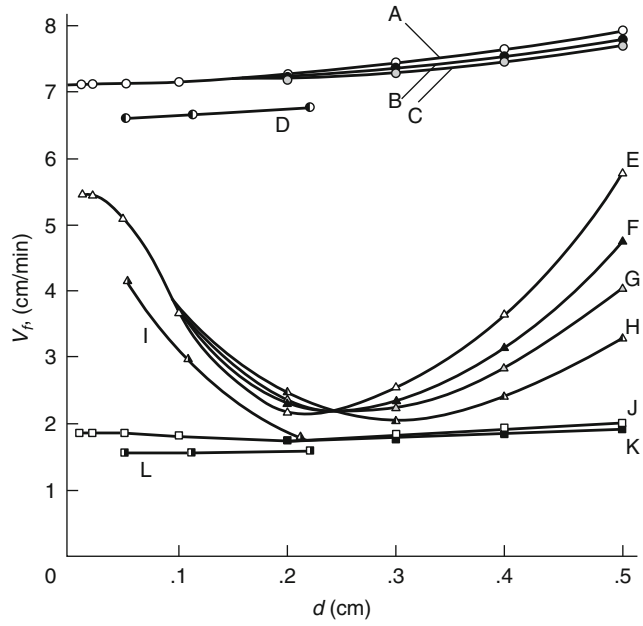

Fig. 65.17 Variations of flame spread rate with bead diameter [40]. Table 65.3 lists conditions

the flame spread rates for pure decane ranged from 2 to 6 cm/min whereas the mixtures of 90 % decane/10 % hexane spanned 7–8 cm/min.

Ishida [41] has also investigated fire growth on fuel-soaked ground with a rectangular pan using central ignition. The shallow square steel tray measured 50 · 50 · 2 cm deep. The tray was filled with glass beads. Radial flame spread rates were measured for decane fuel over varying bead diameters. Figure 65.18, which reproduces Ishida's results, demonstrates that the average flame spread velocity decreases as the bead diameter increases. It is also interesting to note that the flame spread rate accelerates as the fire size increases. The average flame spread rate over the duration from a 2 cm flame diameter to a 30 cm diameter ranges from 6 to 10 cm/min for the bead diameters investigated.

Using Flame Spread Velocities to Characterize the Rate of Involvement of a Pool or Spill

Characterizing the fire growth rate history of a fuel release fire is dependent on describing the time-dependent history of the area involved with fire. The flame spread rate must be placed in the context of the fuel release geometry as well as the location of the ignition point. Thus, the geometry of the released fuel and the relative location of the ignition source define the framework for characterizing the area of involvement.

An example for a circular pool of fuel follows. A circular pool with the ignition source in the center yields the most rapid involvement of the entire fuel release. Assuming that uniform spread occurs, a circular fire will develop and the area of the pool involved will be a function of the fire radius:

$$A_{\text{fire}} = \pi r^2 \tag{65.3}$$

where A_{fire} is the area of the fire in m^2 and r is the radius of the fire in m at any given time, t (s). Assuming a constant flame spread velocity, the radius of the burning area can be defined as

$$r = vt \tag{65.4}$$

where v is the flame spread velocity in m/s. Substituting Equation 65.4 into Equation 65.3:

$$A = \pi v^2 t^2 \tag{65.5}$$

Table 65.3 Experimental conditions of fuel-soaked beds presented in Fig. 65.17

	Combustible liquid	Viscosity μ (cp)	Material of beads	Initial liquid level y_s (cm)	Symbol
A	90 % decane + 10 % hexane	0.846 (normal)	Glass	0.0	○
B	90 % decane + 10 % hexane	2.617	Glass	0.0	●
C	90 % decane + 10 % hexane	4.552	Glass	0.0	○

F	Pure decane	2.617	Glass	0.0	▲
G	Pure decane	4.552	Glass	0.0	△
H	Pure decane	6.872	Glass	0.0	△
I	Pure decane	0.846	Lead	0.0	▲
J	Pure decane	0.846	Glass	–0.5	□
K	Pure decane	4.552	Glass	–0.5	■
L	Pure decane	0.846	Lead	–0.5	◨

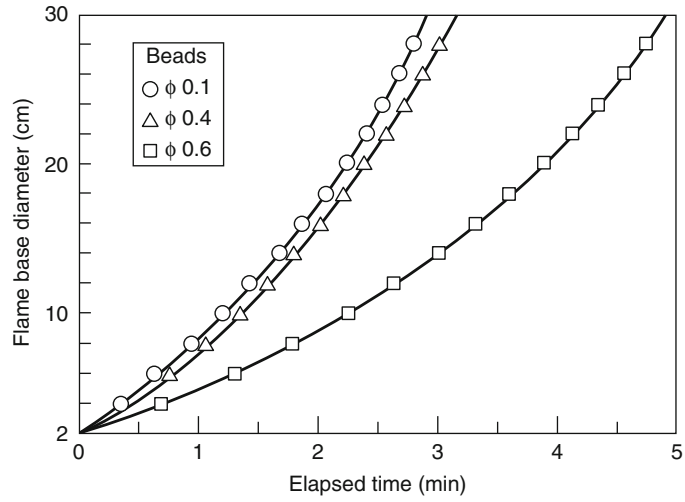

Fig. 65.18 Diameter of flame pillar base as a function of elapsed time [41]

In this manner, Equation 65.5 can be used to identify the area of the spill involved at any time subsequent to the ignition. Assuming that the mass burning rate per unit area is at a constant value $\dot{m}'' = \dot{m}''_{\max}$ and does not change as a function of time, a t^2 fire develops. Of course the time limit is defined when the fire involves the maximum area of the spill and this limit can be defined as follows:

$$t_{A,\max} = \frac{r_{A,\max}}{v} \tag{65.6}$$

where $t_{A,\max}$ is the time the entire pool surface becomes involved with fire, and $r_{A,\max}$ is the maximum radius of the fuel release.

A similar approach can be applied to a rectangular trench. Assuming an ignition source at one end of the trench, an alternative example can be developed. The trench geometry area is defined as

$$A = wl \tag{65.7}$$

where w is the width of the trench in m and l is the length of the trench involved with fire in m. Assuming w is small compared to l and that the ignition source at one end of the trench spans the width of the trench and that the flame spread rate is constant, the length of trench involved is

$$l = vt \tag{65.8}$$

Substituting Equation 65.8 into Equation 65.7 yields the time-dependent area of the trench involved:

$$A = wvt \tag{65.9}$$

In this manner, Equation 65.9 can be used to identify the area of the trench involved at any time subsequent to the ignition at one end. Assuming that the mass burning rate per unit area is at a constant value $\left(\dot{m}'' = \dot{m}''_{\max}\right)$ and does not change as a function of time, a t^1 fire develops. Of course the time limit is defined when the fire involves the maximum area of the trench and this limit can be defined as follows:

$$t_{A,\max} = \frac{l_{\max}}{v} \tag{65.10}$$

where $l_{\max}$ is the maximum length of the trench.

This type of approach can be used for other fuel release configurations and ignition source locations. The heat release rate is then the area of the fuel release involved multiplied by the burning rate per unit area as well as the heat of combustion. This relationship is explained in more detail in the following section.

Fire Size

The fire size is primarily characterized by the heat release rate and the flame height. The heat release rate, $\dot{Q}$, is calculated as

$$\dot{Q} = \dot{m} \cdot \Delta h_c \tag{65.11}$$

where $\dot{m}$ is the mass burning rate of the fuel and Δh_c is the fuel heat of combustion. The fuel mass burning rate can be calculated via Equation 65.12 or 65.13 as follows:

$$\dot{m} = A \cdot \dot{m}'' \tag{65.12}$$

where A is the spill fire area and $\dot{m}$ is the mass burning rate per unit area (kg/m^{2}s),

$$\dot{m} = A \cdot \dot{y} \cdot \rho \tag{65.13}$$

where $\dot{y}$ is the fuel burning regression rate (m/s) and ρ is the density of the fuel. The regression rate is the rate at which the fuel surface descends in a vertical direction as it burns; values are often reported in units of mm/min and therefore must be converted to m/s for the above calculations. Both, $\dot{m}''$ and $\dot{y}$ are empirically based values that are related per Equation 65.14:

$$\dot{m}'' = \dot{y} \cdot \rho \tag{65.14}$$

The literature has presented data for both parameters and both are presented below. The most commonly referenced database was developed by Blinov and Khudiakov [42] for pool fires and presented by Hottel [43] as shown in Fig. 65.19, which shows the regression rate and flame height results for various fuels burning in a broad range of pan sizes, 0.004–23 m in diameter. The data indicate that the fuel regression rate is approximately constant at 4 mm/min for all fuels tested burning as confined pool fires with diameters greater than 1 m. For smaller diameter fires, there is considerable difference in regression rates for the fuels presented. Hottel [43] discusses the trends in the burning rate data based on the balance of heat transfer to the fuel.

For fire sizes greater than about 1 m in diameter, the dominant mode of heat transfer to the liquid is via radiation from the plume. For smaller sizes, heat conduction from the pan (walls) or the substrate and convective heat transfer will constitute a larger fraction of the heat transferred to the liquid, thus having a larger effect on the burning rate of the fuel. Hottel [43], Burgess, Strasser, and Grumer [44], and Burgess, Grumer, and Wolfhard [45] present detailed discussions on these heat-transfer effects. At larger diameters (typically 1–2 m), the burning fuel regression rate tends to level out at a constant maximum value, $\dot{y}_{\max}$. For these pools in the radiation dominant region, Burgess et al. [44] with the U.S. Bureau of Mines correlated the maximum regression rates of various single-component burning fuels (pan fires) based on the thermochemistry of the liquids as follows:

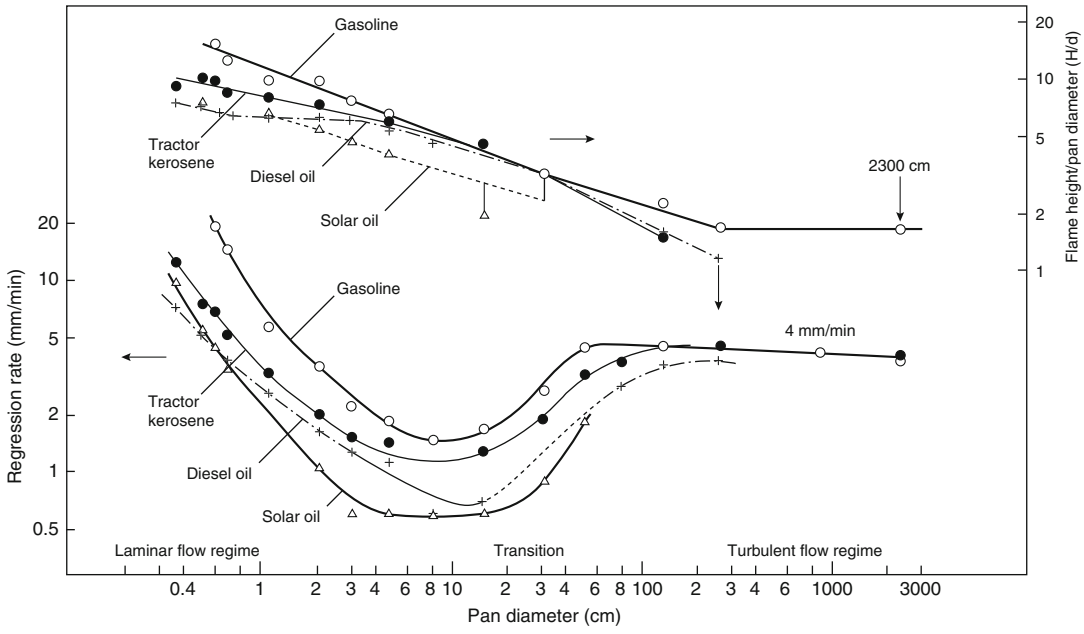

Fig. 65.19 Regression rate and flame height data for liquid pools (From Blinov and Khudiakov [42])

$$\dot{y}_{\max} = 1.27 \times 10^{-6} \frac{\Delta h_c}{\Delta h_{v,\text{sen}}} (\text{m/s}) \qquad (65.15)$$

where Δh_c is the heat of combustion and $\Delta h_{v,\text{sen}}$ is the sensible heat of vaporization, calculated as

$$\Delta h_{v,\text{sen}} = \Delta h_v + \int_{T_0}^{T_b} C_p dt \qquad (65.16)$$

where

Δh_v = Heat of vaporization at the boiling point, T_b

C_p = Specific heat of the liquid fuel

T_o = Initial temperature of the liquid

The use of the sensible heat of vaporization accounts for the temperature dependence of the regression rate, which will vary appreciably (up to tens of percent) from the value calculated using only Δh_v. As the correlation expressed by Equation 65.15 suggests, the fuel regression rate is not constant for all fuels at larger diameters as indicated for the limited fuels in Fig. 65.19. Based on a broad range of hydrocarbon pan fires, Zabetakis and Burgess [46] fit Equation 65.15 to the data shown in Fig. 65.20. The fit is quite good except for the cryogenic fuels, liquefied natural gas and liquefied propane gas. It is noted that the data apply to single-component fuel fires burning in unvitiated air under calm conditions (e.g., no wind).

Further work by the Bureau of Mines researchers, Grumer et al., [48], suggested that the regression rate for blended fuels can be represented by the same correlation (Equation 65.15) when the heats of combustion and vaporization are presented as shown in Equation 65.17 for each component of the fuel.

$$\dot{y}_{\max} = 1.27 \times 10^{-6} \left[\frac{\sum_{i=1}^{N} n_i \Delta h_q}{\sum_{i=1}^{N} n_i \Delta h_{vi} + \sum_{i=1}^{N} m_i \int_{T_0}^{T_b} C_p(T) dt} \right] \qquad (65.17)$$

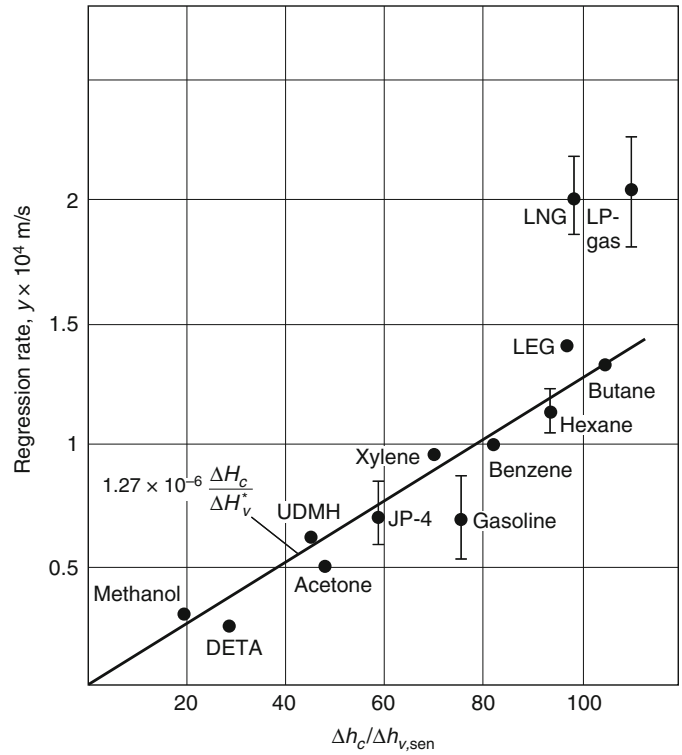

Fig. 65.20 Burning fuel regression rate plotted versus thermochemical properties of fuels burning as pan fires (Taken from Mudan [47])

where n_i and m_i are the mole fraction composition in the vapor and liquid phases, respectively.

A blended fuel with components of widely varying volatility will not burn at a uniform rate. Initially, the high volatile components will burn, and as time proceeds the burning will become more characteristic of the remaining lower volatile components. For blends such as gasoline that have components with similar heats of combustion and heats of vaporization and $n_i \approx m_i$ Equation 65.17 can be represented by

$$\dot{y}_{\max} = n_1 \dot{y}_1 + n_2 \dot{y}_2 + \ldots \qquad (65.18)$$

Equation 65.18 has been reported to yield good estimates of the regression rate for multicomponent fuel blends [48]. Even for blends with widely varying boiling points, Equation 65.18 provides rough estimates except for the initial and final stages of the fire.

Converting the regression rate data of Fig. 65.20 via Equation 65.14 allows the corresponding maximum mass burning rate per unit area, $\dot{m}''_{\max}$, to be plotted against the ratio of the heat of combustion to the heat of vaporization (Fig. 65.21). The fit to the data is represented by

$$\dot{m}''_{\max} = 1 \times 10^{-3} \frac{\Delta h_c}{\Delta h_{v,\,\text{sec}}} = \text{kg/m}^2\text{s} \qquad (65.19)$$

The fit of Equation 65.19 to the burning rate data is not as good as Equation 65.15 to the regression rate data. However, Equation 65.19 does cover a wider range of fuels, including the liquefied gases.

The regression rate is particularly useful for confined pool fires of significant depth. For many spills, particularly continuously flowing fuels, the more useful quantity is the mass burning rate per unit area. As noted in the previous discussion, the burning rate of pool fires with diameters greater than 0.2 m (see Fig. 65.19) increases with increasing diameter. Zabetakis and Burgess [46] developed the following relationship to represent the burning rate per unit area as a function of pool diameter, D:

$$\dot{m}'' = \dot{m}''_{\max}[1 - \exp(-k\beta D)] \qquad (65.20)$$

where the product $k\beta$ is represented as a single value. k is the extinction coefficient (m^{-1}) and ® is the mean-beam-length correction. The maximum steady-state burning rate per unit area, $\dot{m}''_{max}$, is also referred to in the literature by Babrauskas [49] as $\dot{m}''_{\infty}$, the mass burning rate for an infinite-diameter pool. If a confined pool is not circular, D is equal to the effective diameter, expressed as

$$D = \left(\frac{4A}{\pi}\right)^{1/2} \tag{65.21}$$

where A is the area of the pool.

Other than the data presented in Fig. 65.21, the most comprehensive collection of burning rate data has been compiled by Babrauskas [49] and is presented in Table 26.13 in Chap. 26, "Heat Release Rates." The correlation presented by Equation 65.20 agrees extremely well with the experimental data of some fuels, such as gasoline. The greatest disagreement occurs for alcohol fuels for which Babrauskas proposes a set of constant values for different diameter ranges (see Chap. 26) [50]. Due to difficulties in experimentally evaluating the cryogenic fuels, there tends to be more scatter in the data, and thus not as good a correlation with Equation 65.20 as seen for other hydrocarbon fuels.

The use of Equation 65.20 applies to confined pool fires burning in the open, under still-air conditions and in a vessel (e.g., pan or tank) without an excessive lip height [49]. The burning rate correlations presented have been developed from confined pool fire experiments. There generally has been limited data available for burning rates of unconfined fuel spill fires.

Gottuk et al. [4] conducted a series of JP-8 and JP-5 fuel spill fires on a smooth polyurethane-coated concrete slab, as used in Navy aircraft hangars. The spill fires consisted of both continuously flowing fuel releases (~0.4, 0.8, and 1.7 L/min) and 1–3 L of fixed quantities of fuel that were poured onto the concrete, allowed to spread

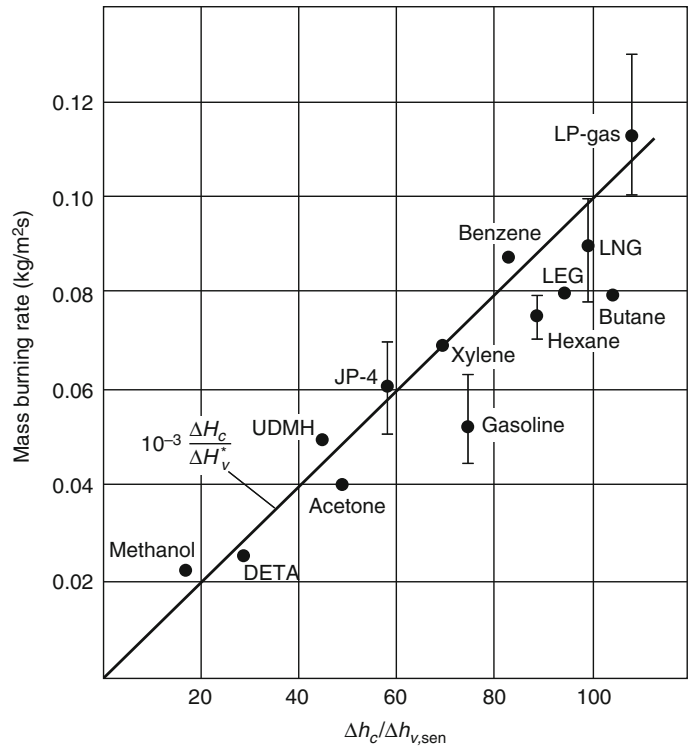

Fig. 65.21 Mass burning rate per unit area versus the thermochemical property of fuels burning as pan fires (Taken from Mudan [47])

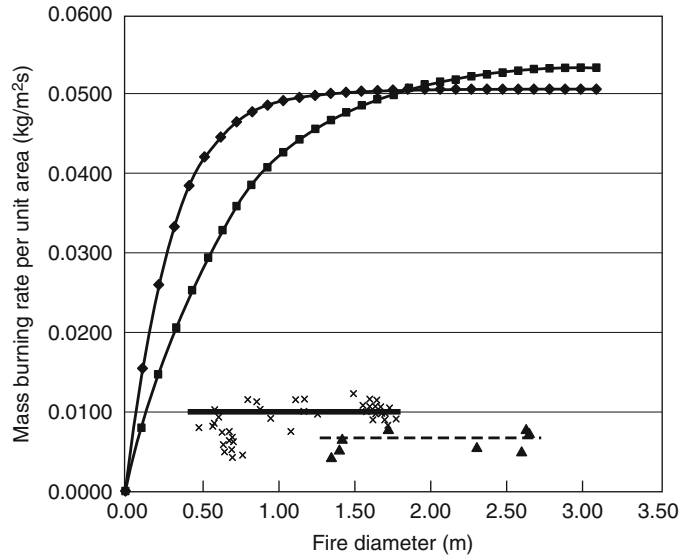

Fig. 65.22 Mass burning rates for unconfined JP-8 spill fires on concrete: [4] (x) denote 0.4–1.7 L/min continuous spill fires with an average value (—) for diameters >1.5 m; (▲) denote 1–3 L fixed-quantity spills with an average value (– – –) for diameters >1.5 m; the calculated pool fire burning rates per Equation 65.20 are shown for JP-4 (—◆—) and JP-5 (—■—)

to nearly a maximum size, and then ignited at the edge of the spill. The burning rate per unit area data for the unconfined spill fires are presented in Figs. 65.22 and 65.23 for both JP-8 and JP-5, respectively. Figures 65.22 and 65.23 show the experimentally measured $\dot{m}''$ for each test versus the measured diameter of the spill fires. Also included for comparison are the curves for burning rate for pool fires as calculated per Equation 65.20, using the data of Table 26.13. A curve for JP-8 does not appear in Fig. 65.22, due to a lack of experimental pool fire data. However, it is expected, based on fuel property data, that the burning rate curve for JP-8 is bounded by the curves for JP-4 and JP-5.

Putorti et al. [5] investigated gasoline spill fires on parquet and vinyl flooring substrates and various carpets. These fires consisted of fixed quantity (0.25–1.0 L) spills that were ignited approximately 60 s after release. Consistent with the results for the JP-8 and JP-5 spill fire data noted above [4], the burning rates for gasoline on the nonabsorbing materials were found to be one-fifth that of the maximum rate for pool fires (i.e., ~80 % reduction). Based on these limited fuel spill fire data, the previous edition of this chapter suggested that burning rates for unconfined liquid fuel spills be estimated as one-fifth of the maximum pool burning rate. At the time, the actual mechanism for this large difference was not known, but had been hypothesized to be primarily due to differences in heat transfer between the fuel and substrate for spills compared to deeper pools. Since the last edition of this chapter, work has shown this hypothesis to be incorrect [8].

A more recent test program conducted by Mealy, Benfer and Gottuk [8] has provided additional insight regarding the burning dynamics of unconfined fuel spills compared to pool fires. A series of tests evaluated the burning dynamics of multiple fuels (gasoline, kerosene, denatured alcohol), at various depths (0.5–20 mm), on multiple substrates (concrete, wood, vinyl, steel, water). Several different fuel supply scenarios were also considered: fixed quantity pool fires, continuously flowing spill fires, and fixed quantity spill fires. Based upon the testing conducted, the burning rate of a liquid fuel spill/pool fire was determined to be primarily dependent upon several factors, including, fuel depth, fuel supply duration and substrate.

Fuel depth was identified as a factor because it is directly related to the fuel supply duration for fixed quantity/fixed area fires (i.e., a pool fire). For these scenarios, a depth of 5 mm represents the minimum depth for which a peak, steady-state mass burning rate comparable to the

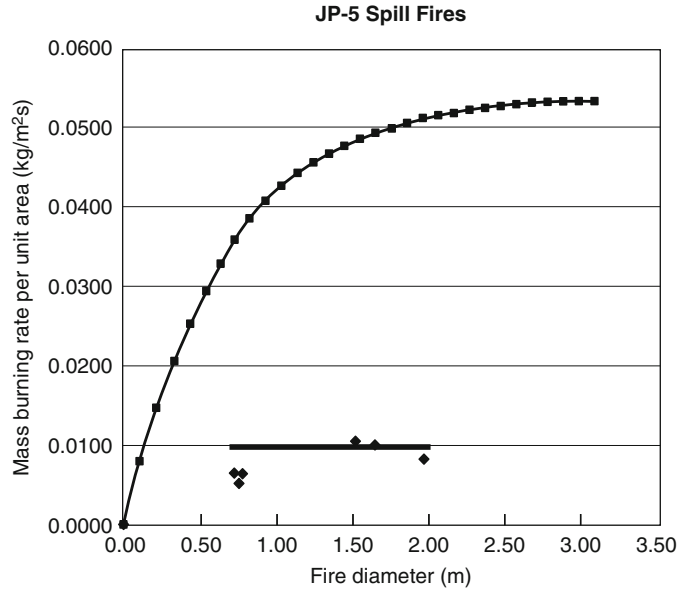

Fig. 65.23 Mass burning rates for 0.4–1.7 L/min unconfined JP-5 spill fires on concrete (◆) [4]. The average value for diameters >1.5 m is shown as (—); the calculated pool fire burning rate per Equation 65.20 is shown as (—■—)

diameter dependent maximum mass burning rate (see Equation 65.20) has sufficient time to be achieved. This was true for steel, water, concrete, and vinyl substrates. At depths less than 5 mm, the peak burning rates were consistently less than the diameter dependent maximum burning rate. This reduction in peak burning rate (also presented as heat release rate per unit area, HRRPUA, of fuel surface) can be seen in Fig. 65.24, which shows burning rates for six pan fires of gasoline with increasing fuel depths from 1 to 18 mm. As can be seen, until the depth reached 5 mm, the fire did not burn long enough to achieve the steady-state peak burning rate as achieved at the 18 mm depth, which burned for over 6 min. At the shallower depths approaching unconfined spill fires (~1 mm), the fires burned for less than a minute, which is typical for a spill fire.

The reduction in mass burning rate associated with a 1 mm fuel depth was on the order of 70–80 %, equivalent to the trends observed by the previous studies [4, 5] noted above. The results of spill fire tests are summarized in Table 65.4. Based upon the data collected, correlations were developed for both gasoline and kerosene that can be used to predict the reduction in peak mass burning rate as a function of fuel depth and fuel area:

$$C_\delta = 0.95^*\left(1 - e^{-0.71\delta}\right) \quad \text{for gasoline} \tag{65.22a}$$

$$C_\delta = 0.91^*\left(1 - e^{-0.58\delta}\right) \quad \text{for kerosene} \tag{65.22b}$$

where C_δ is the depth coefficient and δ is the calculated fuel depth (mm). However, to date, depth coefficient correlations have only been developed for gasoline and kerosene fuels. If depth coefficients for other fuels are required it is recommended that either Eq. 22a or 22b be used based on similar properties or an average coefficient of 0.69 be used for spill depths ≤5 mm and a coefficient of 1.0 be used for spill depths >5 mm.

The product of these depth correlations with the diameter dependent mass burning rate correlation (Equation 65.22) provides a more accurate prediction of mass burning rates for thin fuel layer fire scenarios:

$$\dot{m}''(D,\delta) = C_\delta^*\left(\dot{m}''_\infty\left(1 - e^{-k\beta D}\right)\right) \tag{65.23}$$

Although the 5 mm depth criterion is appropriate for all fixed quantity scenarios, the same is not true for continuously-fed fire scenarios. For continuous-fed spills, Mealy et al. maintained

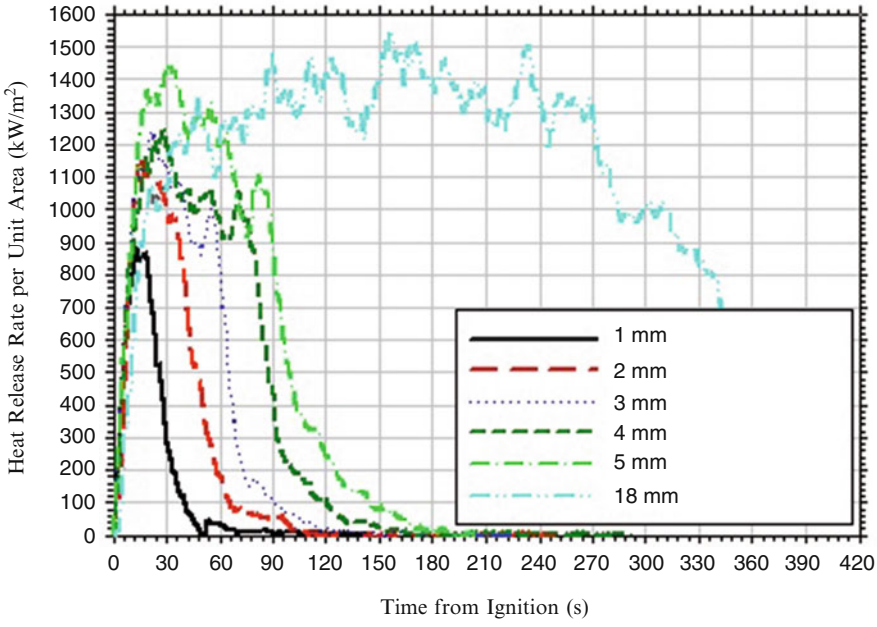

Fig. 65.24 Summary of HRRPUA data measured for gasoline on water in 1.5 m^2 (16 ft^2) pan fire tests with fuel depths of 1, 2, 3, 4, 5 and 18 mm

Table 65.4 Peak burning rates for unconfined fuel spill fires

Description	Peak mass burning rate per area (kg/m^2s)	Standard deviation	Reference
JP-8			
1–3 L spills	0.007[a]	0.0014	Gottuk et al. [4]

[a]Represents average for fires with diameters greater than 1.5 m burning for a maximum of 3 min
[b]Represents average for fires with diameters between 0.75 and 1.45 m
[c]Represents average for fires with diameters less than 0.75 m
[d]Represents average for fires with diameters less than 0.6–3.0 m

fuel depths on the order of 1 mm while still achieving peak mass burning rates that were comparable to the diameter dependent maximum mass burning rates. These results further demonstrate that it is not the depth of fuel that impacts the peak mass burning rate, but that it is the duration of fuel supply. If the fuel supply is sufficient to allow enough time to reach a steady-state, than the maximum mass burning rate is achievable. In addition to the impact of fuel supply duration on the burning rate of combustible fuels, specifically kerosene and diesel, the ignitability and flame spread potential of the fuel at thin depths is very small, making the fuel very challenging to ignite and burn in a thin depth spill scenario without a large external heat exposure.

An additional parameter identified as having an impact on the mass burning rate of a fuel was

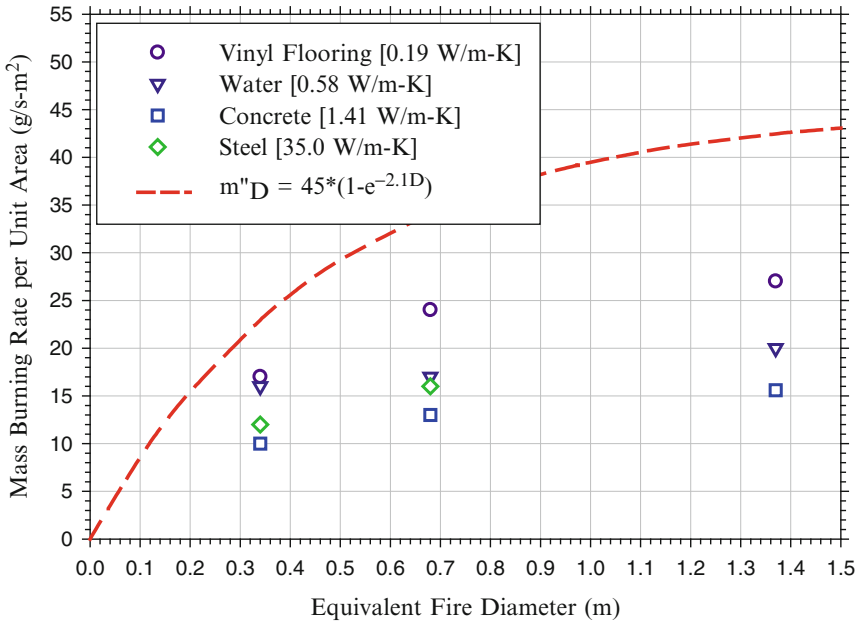

Fig. 65.25 Comparison of peak mass burning rates per unit area for 1 mm (0.04 in.) gasoline fires on substrates with various thermal conductivities (shown in *brackets*) [8]

the substrate on which the fuel is burning. However, the influence of the substrate was only found to be significant for fuel depths less than 5 mm. The data collected by Mealy et al. [8] showed differences in the mass burning rates of 1 mm depth liquid fuels burning on surfaces with differing thermal properties (Fig. 65.25). The rank order of the mass burning rates for each fire size were consistent with the highest burning rates occurring on vinyl flooring and the lowest on concrete. For the scenarios evaluated, no specific thermal property of the substrates (i.e., thermal conductivity, thermal inertia, thermal effusivity, and thermal diffusivity) could be directly correlated to the rank order of burning rates. In general, less thermally conductive materials (i.e., vinyl and water) produced mass burning rates higher than those achieved in tests with more thermally conductive substrates (i.e., steel and concrete). However, the ranking of mass burning rates with respect to the thermal conductivity of the substrates was not appropriate when evaluating the case of the concrete and steel. In this case, the mass burning rates measured on the concrete were consistently lower than those measured on the steel despite the fact that the thermal conductivity of steel is an order of magnitude larger than that of concrete. This discrepancy may be attributed to the reflectivity of the steel and the resulting re-radiation from the steel substrate to the fuel layer. This reflected heat would then be transferred into the fuel layer thus raising the mass burning rate of the fuel.

Empirical data has also shown that a delay in ignition time of a fixed quantity fuel spill can have a significant effect on the peak fire size obtained. Changing the ignition delay (i.e., the time between the spill and the ignition of the fuel) from 30 to 300 s produced an average reduction in fire size (burning rate) of approximately 50 % for 0.5 and 1 L gasoline and denatured alcohol spill fires [8]. The primary impact of longer ignition delay times is the result of shallower fuel depths due to a combination of larger spill areas and prolonged periods of evaporation. Given that most fuel spill fires nominally burn out in less than 1–2 min, longer ignition

delay times can lead to both lower peak heat release rates and shorter duration fire exposures that are quite fast events.

Based on Equations 65.11 and 65.12, the heat release rate of an unconfined spill or confined pool fire can be calculated per Equation 65.24 once the area of the fire is determined and an appropriate mass burning rate per area is identified.

$$\dot{Q} = \dot{m}'' \cdot A \cdot \Delta h_c \tag{65.24}$$

However, in the case of an unconfined, continuously flowing spill fire, the area is neither known a priori nor can it be calculated per any fuel depth correlations as with a fixed quantity spill. As fuel flows from a continuous source, the size of the resulting spill will continue to increase indefinitely until a physical boundary is reached or the fuel is ignited and burns. The transient nature of a continuous spill fire is very dependent on the timing of the fuel ignition and the flame spread rate relative to the fuel flow rate and size of the spill at the time of ignition. For example, if a continuously flowing spill is immediately ignited at the source, the fire size will be equal to the spill size if the flame spread rate is faster than the fuel spill spread rate. However, if the fuel spill spread rate is faster than the flame spread rate, the spill will continue to spread out ahead of the flame front.

As discussed below, a continuously flowing spill fire will reach a steady-state burning size, characterized by the equivalent steady-state diameter, D_{ss}. It is possible for a fuel spill to reach a diameter that is larger than D_{ss} before it is ignited. In this case, the flame will spread across the fuel surface to the larger diameter and then the spill fire will reduce in size until D_{ss} is reached. These examples are only several of multiple scenarios that can occur. Currently, complete and accurate models of burning fuel spills do not exist. In order to estimate the transient nature of a continuous fuel spill fire, the engineer must consider the fuel spill rate, the relative time of ignition, and the steady-state burning spill area.

The steady-state burning spill area, A_{ss}, results due to a balance between the volumetric flow rate of the liquid release, $\dot{V}_L$ (m^3/s), and the volumetric burning rate of the fire as described by

$$\dot{V}_L = A_{ss} \cdot \dot{y} = \frac{\pi {D_{ss}}^2}{4} \dot{y} \tag{65.25a}$$

or, alternatively in terms of the mass burning rate as

$$\dot{V}_L = A_{ss} \frac{\dot{m}''}{\rho} = \frac{\pi {D_{ss}}^2 \dot{m}''}{4\rho} \tag{65.25b}$$

The steady-state size of the spill can be explicitly solved by rearranging Equations 65.25a and 65.25b in terms of D_{ss} (m):

$$D_{ss} = \left(\frac{4\dot{V}_L}{\pi \dot{y}}\right)^{1/2} \tag{65.26a}$$

$$D_{ss} = \left(\frac{4\dot{V}_L \rho}{\pi \cdot \dot{m}''}\right)^{1/2} \tag{65.26b}$$

The calculation of the spill size per Equation 65.26 assumes that all fuel is burned from the spill; that is, there are no other losses of fuel from the spill, such as into a porous substrate. As noted by the examples above, D_{ss} does not necessarily correspond to the maximum fire size but equals the size of the fire once the burning rate becomes constant and equilibrium conditions are reached.

Empirical correlations can also be used to calculate the equivalent diameter of a continuous spill fire. Mansfield and Linley [51] developed a correlation for the burning spill diameter as a function of fuel flow rate for large release rate fires on concrete. The following correlation was developed for 568–2271 L/min (150–600 gpm) continuous spill fires of JP-5 ranging in size from 15 to 24 m in diameter:

$$D_{ss} = 134\left(\dot{V}_L\right)^{1/2} : D_{ss}\,(\mathrm{m}) \text{ and } \dot{V}_L\left(\mathrm{m}^{3/5}\right) \tag{65.27a}$$

$$D_{ss} = 3.5\left(\dot{V}_L\right)^{1/2} : D_{ss}\,(\mathrm{ft}) \text{ and } \dot{V}_L(\mathrm{g\,pm}) \tag{65.27b}$$

where 1 m^3/s = 15,850 gpm.

The tests of Mansfield and Linley [51] were conducted outside with 2.2–12.5 m/s (5–28 mph)

winds and ambient temperatures ranging from 7 °C to 32 °C. Using Equation 65.25b with the diameter and spill rate data of Mansfield and Linley [51], the mass burning rate per unit area of the large JP-5 continuous spill fires is calculated to be in the range of 0.055 kg/m^{2}s, which agrees with the pool fire burning rate data reported by Babrauskas [50] in Table 26.21 of this handbook. As noted above, despite typical spill depths of about 1 mm and less, continuous flowing spill fires will reach the peak (steady-state) mass burning rate if allowed to burn long enough.

In order to assess the thermal threat associated with a fuel spill/pool fire scenario, the peak fire size must be coupled with exposure duration. Estimating exposure duration can be accomplished using one of two techniques. The first technique assumes that the peak fire size is reached instantly and is maintained so long as fuel is present. Using this technique, the burning duration for a given fire scenario can be calculated using Equation 65.28.

$$t_b = \frac{4m}{\pi D^2 \dot{m}''_\infty} \tag{65.28}$$

where t_b is the burning duration for a given scenario (s), m is the mass of fuel available to burn (kg [lbs.]), D is the effective spill diameter (m [ft]), and $\dot{m}''_\infty$ is the peak mass burning rate per unit area for the given fuel (g/s-m^2 [lbs./s-ft^2]). Traditionally, many have assumed that the peak heat release rate of a liquid fuel fire is reached instantaneously and maintained for the duration of the fire as calculated via Equation 65.28. Consequently, the exposure times associated with this assumption are most likely underestimated as shown in Fig. 65.26 as the "predicted" curve. In general, this approach tends to over-predict the peak thermal exposure resulting from a fuel spill/pool scenario.

The second technique that can be used to approximate the transient behavior of a fire resulting from the ignition of a liquid fuel spill/pool is to characterize the development, peak, and decay of the fire. This is accomplished by approximating the spread velocity on the hydrocarbon pool surface from the point of ignition, the time to develop maximum burning conditions, and the time to consume all fuel at a

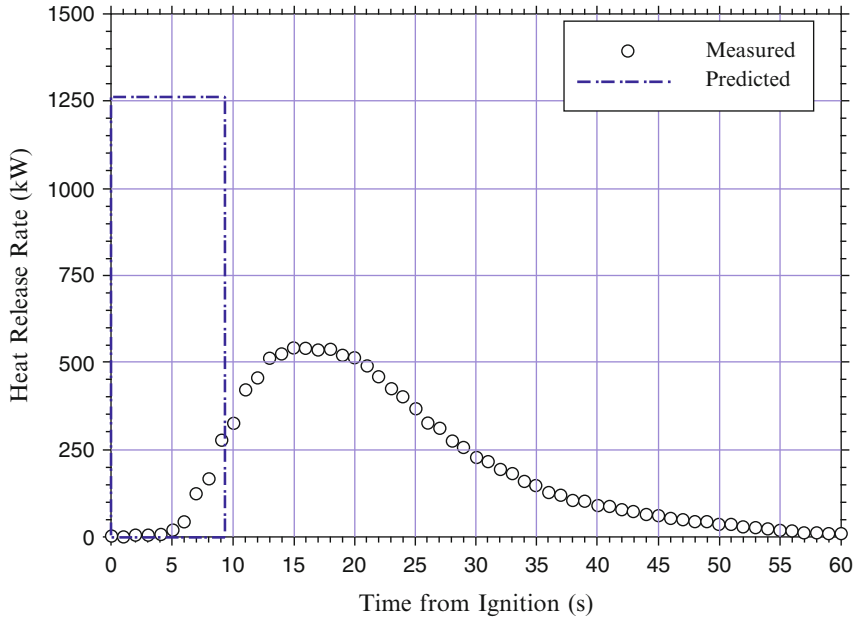

Fig. 65.26 Comparison of measured and predicted spill fire heat release rates using assumption that peak heat release rate is achieved instantly [8]

given location. Mealy et al. provide a methodology for estimating the fire growth and decay [8].

For liquid pool fires (depths ≥0.5 mm), although the entire fuel surface may be fully involved, the burning rate per area (or regression rate) will increase over time until the maximum steady-state value is reached [46]. The transient time period may be tens of seconds to minutes, depending on the type of fuel, the fuel depth, and the bounding materials (e.g., building walls or metal tank). During this transient period, the temperature gradient in the fuel is being established. Once the fuel surface reaches the boiling temperature, the burning rate approaches the steady-state value. If a transient analysis of a fire is required, further consideration must be given to the mass burning rate (or regression rate) that is selected. The use of the maximum value may not be appropriate for the entire burning duration.

Other Factors and Limitations

The spill areas and burning rates of liquid spill or pool fires presented in this chapter have been developed from experimental data of fires on level surfaces. In many applications, fuel spills will occur on inclined and/or cluttered surfaces. Under these conditions, fuel spread will ultimately be dependent on the geometry of the surface, which may lead to pooling of the fuel, channeling, and/or larger wetted areas than would occur on a level surface. Fuel flowing on an inclined surface can result in faster and wider spread of fire. No published studies have evaluated the impact of three-dimensional fuel flow on spill fire burning rates.

This chapter has primarily addressed the burning of liquid fuel fires that occur in the open. Liquid fuel fires in enclosures were studied by Mealy et al. [52] and showed that spill fire scenarios are unaffected by the enclosure (assuming sufficient air supply) since the duration of a spill fire is quite short. However, pool fires in an enclosure have been shown to have enhanced burning (~60 %) relative to open burning when a radiating upper layer is created in the compartment fire [52]. This increase can be moderated by restricted ventilation to the compartment, which can decrease the mass burning rate of a pool fire.

Babrauskas [49] and Zabetakis and Burgess [46] have reported that burning rates of pool and spill fires both increase and decrease under increased wind speeds. Burgess and Hertzberg [53] reported that wind speeds increased the burning rate for small-diameter fires; however, burning rates never exceeded the maximum burning rate in still air corresponding to larger diameter fires. High wind speeds can cause fuel to spill out of contained areas or cause unconfined spill fires to move in the direction of the wind. At higher wind speeds, flames can also be blown off.

For pool fires in pans or tanks, the lip height can impact the burning rate of the fuel. There is limited data on this topic and experimental results show both an increase and decrease in the burning rate with larger lip heights [49]. Much of the experimental data have been for small pan diameters (<1 m) (e.g., Emmons [54]).

Flame Height

The flame height of a liquid spill or pool fire can be calculated based on a number of experimental correlations [55]. The following correlation developed by Heskestad [55] has been shown to be quite robust for different fuels over a wide range of pool fire sizes:

$$L_f = 0.23\dot{Q}^{2/5} - 1.02D \qquad (65.29)$$

where

L_f = The 50 percentile intermittent flame height (m)

$\dot{Q}Z$ = The heat release rate (kW)

D = The diameter of the fire (m)

The use of Equation 65.29 to characterize unconfined spill fire heights was evaluated by Gottuk [4] for JP-8 and JP-5 spill fires on concrete. The results of the comparison are shown in Figs. 65.27 and 65.28, which present measured intermittent flame heights (50 percentile) and

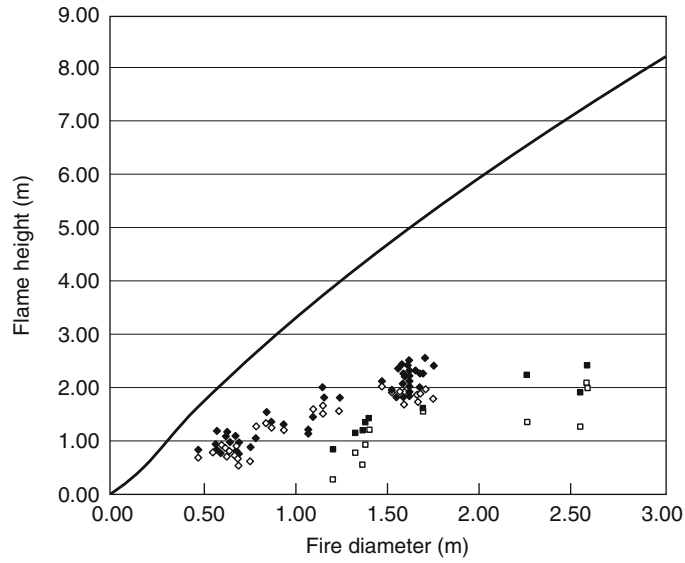

Fig. 65.27 Comparison of measured and predicted flame heights for unconfined JP-8 spill fires: [4] measured (◆) and predicted (◇) 0.4–1.7 L/min continuously flowing spill fires; measured (■) and predicted (□) 1–3 L fixed-quantity spill fires; and predicted pool fires (——)

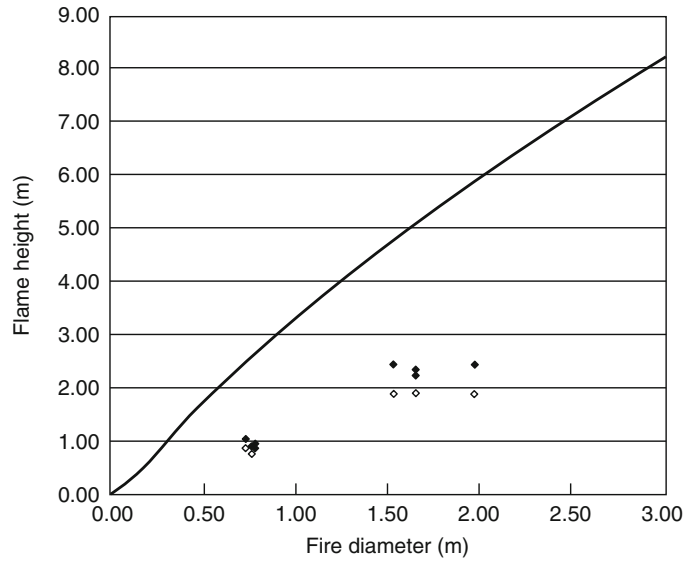

Fig. 65.28 Comparison of measured and predicted flame heights for unconfined JP-5 spill fires: [4] measured (◆) and predicted (◇) 0.4–1.7 L/min continuously flowing spill fires; and predicted pool fires (——)

predicted flame height values plotted versus the spill diameter. For comparison, the predicted flame heights of pool fires are also plotted as a curve in each figure. The predicted pool fire heights are based on Equation 65.29 and pool burning rate data of Table 26.13. Consistent with the difference in the mass burning rates between spill and pool fires, the spill flame heights are considerably shorter than those for pool fires of the same diameter. Using the Heskestad flame height correlation (Equation 65.29) with the spill fire data yields predicted heights that are approximately 17 % lower compared to the measured spill fire flame heights. For most engineering applications, the Heskestad flame height correlation (Equation 65.29) provides satisfactory predictions for both liquid pool and spill fires.

Fire Hazard Analysis Framework

When conducting fire hazard analyses, fuel type and spill/pool configuration parameters are often user selected and/or varied to assess a wide range of fire scenarios. In this case, the user would identify the fuels of interest and obtain the relevant fire property data. Four different scenarios are identified for fire hazard analyses based upon the identification of confined and unconfined spill scenarios and fixed quantity and continuously-fed fuel supplies. These four paths generally encompass the vast majority of potential liquid fuel scenarios and require different analytical approaches to understand the resulting fire threat. The approach presented will lead to the calculation of the largest possible fire size. It is important to note that in some analyses, a smaller fire size that lasts longer may actually be a worst-case of more challenging fire hazard. The discussion above can be used to assess such scenarios (Fig. 65.29).

The first spill/pool scenario considered was a fixed quantity of fuel in a confined area. For the purposes of this discussion, it is assumed that the quantity of fuel is such that it covers the entire area of confinement otherwise it is considered as a fixed quantity, unconfined scenario. Based upon this assumption, an equilibrium spill depth can be calculated using the known volume of

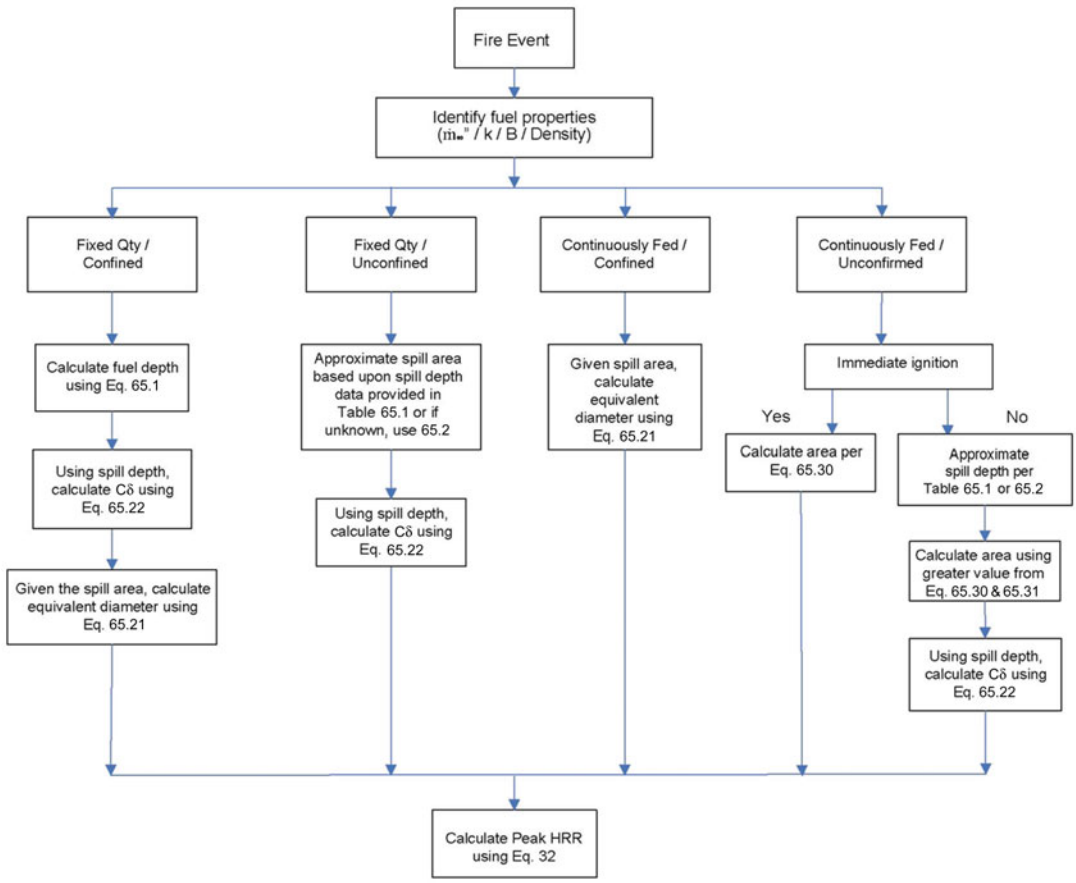

Fig. 65.29 Analytical framework for characterizing fuel spill/pool fire scenarios from a fire hazard viewpoint

liquid spilled and the area of confinement as shown in Equation 65.1.

$$\delta = \frac{V_o}{A_o} \tag{65.1}$$

where δ is the fuel depth (mm [ft]), Vo is the volume of liquid (L [gal.]), and the A_o is the area of confinement (m^2 [ft^2]).

The second scenario considered is a fixed quantity spill that is unconfined. In this scenario, the bulk flow of the liquid as well as the length of time between the spill and the ignition of the liquid dictates the area covered as opposed to bounding obstacles inhibiting the flow. For a specific spill scenario in which the substrate and/or ignition delay times are known, more representative spill depths can be approximated using the data provided in Table 65.1 (and Table 7.1 of Ref. [4]). Otherwise Equation 65.2 recommended for guidance:

$$\delta = 0.7 \text{ mm for most fuels and conditions} \tag{65.2a}$$

$$\delta = 2.9 \text{ mm for quantities of 38 L (10 gal) where analysis warrants longer duration fires} \tag{65.2b}$$

Once an appropriate spill depth has been determined, the area of coverage for a given quantity spill can be calculated using Equation 65.1. Similarly, if the area of coverage is known and a fuel depth is assumed, one can approximate the quantity of liquid spilled using Equation 65.1.

The next scenario considered is a continuously-fed, fixed area (i.e., confined) fuel supply. In this scenario, it is assumed that the fuel supply rate is equal to or greater than the mass burning rate, such that a fixed area of some depth is maintained for an extended period of time. It is also assumed that the fuel does not overflow the confined area. In this scenario, the area is known and the depth of fuel is not important given that fuel is continuously supplied, and thus burn-out does not occur (i.e., steady-state burning is allowed to develop).

The final scenario identified is a continuously-fed, unconfined spill scenario. For this scenario, it necessary to identify the time of ignition given that this time will dictate the initial spill area. To address this parameter, two paths are possible. The first path assumes ignition immediately upon release of the liquid. Once ignited, the burning area of fuel will grow in size until an equilibrium spill area is achieved, which will occur when the fuel burning rate equals the fuel supply rate. Equation 65.32 represents the balance between these rates (based on Equation 65.25).

$$A_{ss} = \frac{\rho \dot{V}_L}{\dot{m}''} \tag{65.30}$$

where A_{ss} is the equilibrium spill fire burning area (m^2 [ft^2]), $\dot{V}_L$ is the volumetric fuel supply rate (m^3/s [ft^3/s]), ρ is the fuel density (kg/m^3 [lbs./ft^3]), and $\dot{m}''$ is the mass burning rate per unit area (kg/s-m^2 [lbs./s-ft^2]). Once this equilibrium solution is obtained, the maximum area of the spill is known, and the depth of fuel is not important given that fuel is continuously supplied and burning will reach a steady-state.

The other path identified for the continuously-fed, unconfined scenario is a delayed ignition (i.e., liquid is permitted to spill and spread for some period of time prior to ignition). As shown in Equation 65.31, in this scenario, the area of coverage of the spilled liquid prior to ignition can be determined based upon the product of the volumetric flow rate, $\dot{V}_L$, the ignition delay time, and an assumed spill depth.

$$A_t = \frac{\dot{V}_L t}{\delta} \tag{65.31}$$

where A_t is the spill area (m^2 [ft^2]) at a given point in time, $\dot{V}_L$ is the volumetric fuel supply rate (kg/s [lbs/s]), t, is the time in seconds after the spill occurs prior to ignition, and δ is the calculated fuel depth (m [ft]). Using a spill depth from Table 65.1 or the average spill depth of 0.72 mm, an initial spill area can be approximated by Equation 65.33. Once ignited,

the initial spill area will grow or regress to the equilibrium spill area, as calculated for the immediate ignition scenario with Equation 65.32. Consequently, the initial area calculated may provide the maximum fire size, but it will only last for a brief period of time as the fire regresses to the equilibrium area.

Once the spill areas and corresponding spill depths have been calculated, it is necessary in some spill scenarios to calculate the depth coefficient, a parameter developed to modify the maximum fuel burning rate based on small depths causing early burn out before steady-state burning can be achieved. The correlations developed for gasoline and kerosene are provided in Equations 65.22a and 65.22b.

$$C_\delta = 0.95^*\left(1 - e^{-0.71\delta}\right) \quad \text{for gasoline} \tag{65.22a}$$

$$C_\delta = 0.91^*\left(1 - e^{-0.58\delta}\right) \quad \text{for kerosene} \tag{65.22b}$$

where C_δ is the depth coefficient and δ is the calculated fuel depth (mm). If depth coefficients for other fuels are required it is recommended that either Eq. 22a or 22b be used based on similar properties or an average coefficient of 0.69 be used for spill depths ≤5 mm and a coefficient of 1.0 be used for spill depths >5 mm.

Once the fuel depth, fuel coverage area, and depth coefficient are determined using the methods described above, the final step in the analysis is the prediction of the heat release rate of the fire. Calculating the peak and/or transient heat release rates requires knowledge of a fuel's maximum mass burning rate per unit area ($\dot{m}''_\infty$, also seen as $\dot{m}''_{max}$), optical properties of the fire plume (kβ), and the heat of combustion of the fuel (ΔH_c). Using this fuel data, combined with the spill parameters described above, a transient heat release rate for the given scenario can be calculated. The general form for this calculation is presented in Equation 65.26 and expanded below as Equation 65.32, which calculates the peak heat release rate for a given fuel:

$$\begin{aligned}\dot{Q}_p &= C_\delta \dot{m}''_\infty \left(1 - e^{-k\beta D}\right) A \Delta H_C \\ &= C_\delta \dot{m}''_\infty \left(1 - e^{-k\beta D}\right) \frac{\pi D^2}{4} \Delta H_C\end{aligned} \tag{65.32}$$

where $\dot{Q}_p$ is the peak fire size (kW [Btu/s]), C_δ is the depth coefficient, $\dot{m}''_\infty$ is the peak mass burning rate per unit area for the given fuel (g/s-m^2 [lbs./s-ft^2]), kβ is an empirical constant specific to the fuel, A is the spill area (m^2 [ft^2]), ΔH_c is the heat of combustion of the fuel (MJ/kg [BTU/lbs.]), and D is the effective spill diameter (m [ft]). The effective diameter of non-circular spills can be calculated using Equation 65.21.

$$D = \sqrt{\frac{4A}{\pi}} \tag{65.21}$$

Equations 65.32 and 65.21 provide a means of calculating a peak heat release that is both fuel depth and fire diameter dependent. This prediction provides the largest potential fire that a given liquid fuel fire can produce.

Example 1 A 208 L (55 gal) drum of gasoline is suddenly ruptured during a warehouse accident. The fuel is released quickly across the floor of the warehouse and is ignited when it comes in contact with a piece of faulty equipment. Determine the maximum size of the resulting fire.

Solution First, the size of the spill is calculate by estimating the spill depth. Since gasoline is spilled on an unknown floor material, a depth value of 0.71 mm is selected from Table 65.1. Using Equation 65.1 and assuming that the release occurs instantaneously (i.e., the spill is nearly at its maximum diameter at the time of ignition) and is allowed to spread freely, the spill area is calculated as

$$A = V/\delta = 208\ \text{L}/0.71\ \text{mm} = 293\ \text{m}^2$$

Per Equation 65.21, the corresponding diameter of the burning spill is 19.3 m. To account for the short duration of the spill fire due to the shallow spill depth, δ, the depth coefficient is

calculated per Equation 65.22a to modify the peak mass burning rate:

$$C_\delta = 0.95^*\left(1 - e^{-0.71\delta}\right) = 0.38$$

The heat release rate for the fire is then calculated per Equation 65.32 as

$$\dot{Q}_p = C_\delta \dot{m}''_\infty \left(1 - e^{-k\beta D}\right) A \Delta H_C = C_\delta \dot{m}''_\infty \left(1 - e^{-k\beta D}\right) \frac{\pi D^2}{4} \Delta H_C$$
$$= 0.38 \cdot 0.055 \cdot (1 - \mathrm{e}\text{^}(-2.1\ \ 19.3))\,\pi\,(19.3\mathrm{m})^2/4 \cdot 43.7 = 267\,\mathrm{MW}$$

From Table 26.21, the heat of combustion of gasoline is 43,700 kJ/kg, the density is 740 kg/m^3, and the maximum mass burning rate per unit area of gasoline, $\dot{m}''_{\max}$, is 0.055 kg/m^{2}s.

The intermittent flame height is calculated per Equation 65.29 as

$$L_f = 0.23\dot{Q}^{2/5} - 1.02D$$
$$= 0.23(26.700\,kW)^{2/5} - 1.02(12.2\,m) = 5.8\,m$$

If it is assumed that the fuel spill burns at the maximum rate for the duration of the fire, the burn time, t_b, for the fuel spill fire will be only 2 min:

$$t_b = \frac{m_f}{\dot{m}''A} = \frac{V \cdot \rho}{\dot{m}''A} = \frac{0.208\,m^3 \cdot 740\mathrm{kg}/m^3}{0.021\mathrm{kg}/m^2 s \cdot 293\,m^2}$$
$$= 25\,s$$

Where the mass burning rate, $\dot{m}''$, is calculated per Equation 65.23 as

$$\dot{m}''(D,\delta) = C_\delta * \left(\dot{m}''_\infty \left(1 - e^{-k\beta D}\right)\right)$$
$$= 0.38\left(0.055\left(1 - \left(1 - e^{-21*193}\right)\right)\right)$$
$$= 0.0209\frac{kg}{m2s}$$

As illustrated in Example *2*, the predicted burn time of 25 s is most likely too short. In reality, the fire will last longer due to the fact that the flame takes time to spread across the spill.

Example 2 Consider the situation in Example *1*. What is the time required for the entire spill to become involved in the fire? The temperature in the warehouse is 20 °C.

Solution The most critical step in determining the time for the entire spill to become involved in the fire is to identify both the temperature of the liquid fuel spill and the flashpoint of the fuel. The flashpoint of gasoline is indicated to be −45 °C as documented in the third edition of the *SFPE Handbook* in Kanury's [56] table, "Selected Ignition, Flammability, and Autoignition Properties of Some Fuels in Air." Assuming that the gasoline is at the same temperature as the warehouse, 20 °C, the spill temperature is well above the closed-cup flashpoint. The elevated temperature indicates that gas phase flame spread will occur if the spill is ignited. A reasonable and generally conservative approximation of the upper gas phase flame spread velocity is 200 cm/s.

The problem statement does not specify the location of the ignition source relative to the spill. The most conservative posture for fastest involvement would be to assume that the ignition source is in the center of a circular spill. Using Equation 65.8 for circular spills will define the time for full involvement:

$$t_{A,\max} = \frac{r_{A,\max}}{v}$$

where $r_{A,\max}$ is 6.1 m and v is 2.0 m/s. The time for full involvement becomes

$$t_{A,max} = \frac{9.65}{2.0\,m/s}$$

$$t_{A,max} = 4.8\,s$$

If the ignition source was located at the perimeter of the gasoline spill, it would take approximately

10 s to travel the full 19.3 m diameter of the pool to involve the spill completely. Irrespective of the ignition location, the time to involve the entire spill is small in the context of most hazard analyses time scales. Therefore, when gas phase flame spread is governing the involvement of a spill or pool of flammable liquid, it is often acceptable to assume instantaneous ignition of the entire fuel surface. This assumption may not be valid for extremely large spills (e.g., tanker spills) or when there are short time-scale concerns.

The difference between gas phase flame spread and liquid-controlled flame spread can be illustrated by assuming that the drum of gasoline in the foregoing example contained diesel fuel. The flashpoint of diesel fuel ranges from 52 °C to 96 °C according to the 1994 edition of NFPA 325 [57]. Since the warehouse is at 20 °C, substantially below the flashpoint of diesel fuel, flame spread would be governed by liquid-controlled mechanisms. A conservative upper bound of the liquid-controlled flame spread in this case would be 10 cm/s. Assuming that the area of the diesel spill was identical to the gasoline spill and that there was a strong enough ignition source present to ignite the spill, a time to full ignition of the spill can be estimated. Assuming that the ignition source was in the center of the spill, Equation 65.8 would be used again, where the maximum radius of the spill is 6.1 m and the flame spread velocity is 0.1 m/s. The time for full involvement becomes

$$t_{A,max} = \frac{9.65}{0.1\,m/s}$$

$$t_{A,max} = 67\,s$$

The conservative estimation of the time for full involvement of the diesel fuel is significantly greater than for the gas phase spread over gasoline.

Nomenclature

A	Area (m^2)
A_s	Area of spill (m^2)
A_{ss}	Steady-state area of continuously flowing burning fuel spill (m^2)
C_p	Specific heat of liquid fuel
D	Diameter (m)
D_{ss}	Steady-state area of diameter of burning fuel spill (m)
DT	$T_{fl} - T_l$
Δh_c	Heat of combustion (kJ/kg)
$\Delta h_{v,sen}$	Sensible heat of vaporization (kJ/kg)
k	Extinction coefficient (m^{-1})
l	Length of a trench involved with fire (m)
l_{max}	Maximum length of trench (m)
L_f	Flame height (m)
$\dot{m}''$	Fuel-mass burning rate per unit area (kg/m^2s)
$\dot{m}''_\infty$	Fuel-mass burning rate per unit area for infinite size pools (kg/m^2s)
$\dot{m}''_{max}$	Maximum fuel-mass burning rate per unit area (kg/m^2s)
m_i	Mole fraction of fuel in liquid phase
n_i	Mole fraction of fuel in vapor phase
$\dot{Q}$	Heat release rate (kW)
r	Radius of the fire
$r_{A,max}$	Maximum radius of the fire for complete involvement of fuel release
t	Time
$t_{A,max}$	Time at which fuel release becomes completely involved
T_b	Boiling point temperature of liquid fuel
T_{fl}	Closed-cup flashpoint temperature of fuel
T_{gm}	Minimum liquid temperature at which asymptotic gas phase spread occurs
T_{go}	Liquid temperature at the transition from liquid to gas phase–controlled burning
T_l	Liquid fuel temperature
T_o	Initial temperature of liquid fuel
v	Flame spread velocity (cm/s)
V	Volume (m^3)
$\dot{V}_L$	Volumetric flow rate of liquid fuel (m^3/s)
w	Width of a trench (m)
$\dot{y}$	Regression rate (m/s)
$\dot{y}_{max}$	Maximum regression rate (m/s)

Greek Letters

β Mean-beam-length correction
ρ Density (kg/m^3)
δ Pool or spill depth (m)

Fire Hazard Calculations for Large, Open Hydrocarbon Fires

66

Craig L. Beyler

Introduction

A major challenge in industrial fire protection is controlling the impact from large, open hydrocarbon fires. The primary mechanism for injury of damage from such fires is thermal radiation. Depending on the circumstances and conditions leading to such an event, a different type of open fire may result. For example, ignited releases can produce pool fires, jet flames, vapor cloud fires, or fireballs, all of which behave differently and exhibit markedly different radiation characteristics. This chapter presents detailed techniques for calculating impacts from large, open hydrocarbon fires. Examples are included throughout this chapter to illustrate the application of these expressions.

The first section of this chapter discusses hydrocarbon pool fires, an area in which considerable work has been done, including various important geometric parameters (e.g., flame height), thermal radiation models, and atmospheric absorption of radiation. The second section deals with turbulent jet flames and flares, first presenting significant geometric effects and thermal radiation models, then discussing aerodynamic effects on radiant energy and flame stability.

Whereas the above cases involve primarily steady-state thermal radiation, the third section considers two very important cases that involve unsteady radiant effects—burning vapor clouds and fireballs. Although developmental work in both of these areas is still ongoing, limited data are available to lend some confidence to the use of these models.

The following part of this introduction presents an event tree for the release of a flammable material to guide the user's selection of appropriate potential impacts and model application. It cannot be overstressed that prudent judgment should be exercised in the application of any of these calculation schemes to yield a safe and fair evaluation of scenarios of interest.

Event Tree for Flammable Material Release

Figure 66.1 depicts a typical event tree for the release of a flammable material, showing the pathways that lead to the various types of open fires. For this purpose, assume the release occurs from a pressurized container because all types of open fires may be realized from a pressurized release. In this example, the pressurized container may be either a large vessel (for storage, reaction, batching, etc.) or a pipeline (for transfer, fittings, instruments, etc.). The pressure may be the result of either normal operations or abnormal external events. For example, a tank may be pressurized because it contains a compressed liquid or because it has been exposed to an external fire; a pipeline may be pressurized because of a pumping operation or because of

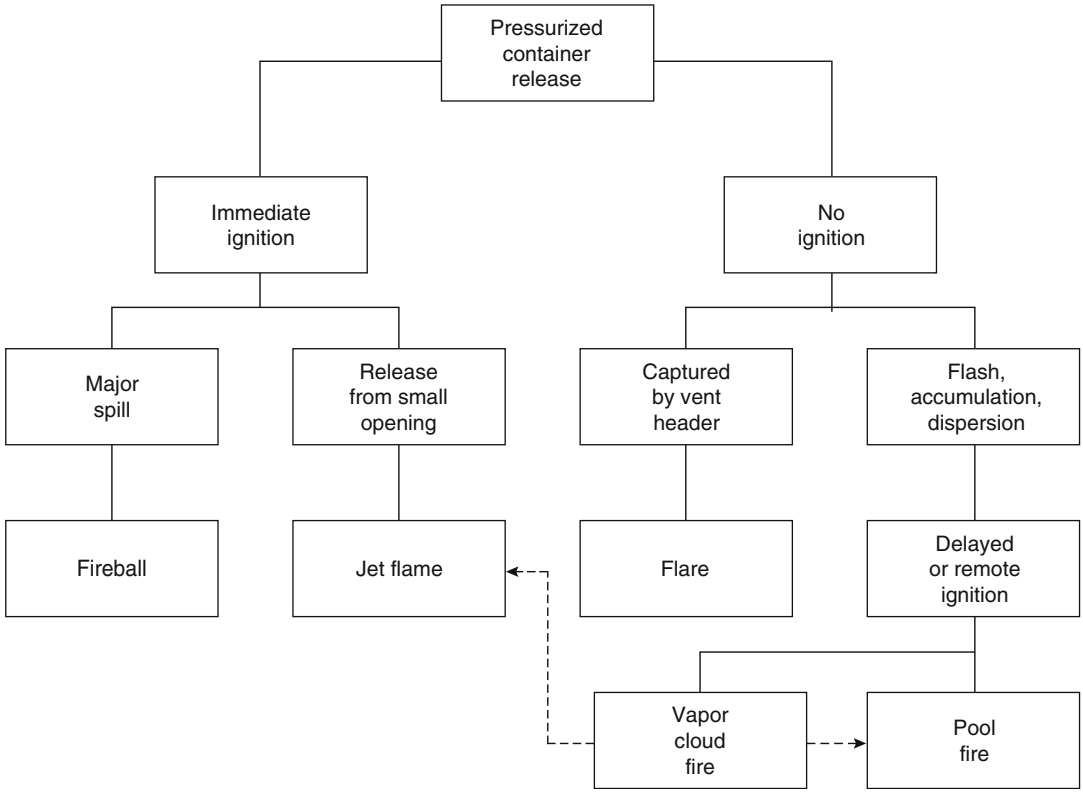

Fig. 66.1 Example event tree for release of flammable material

steam tracing on a blocked-in segment. Finally, the release may be due to a major failure (e.g., spontaneous tank failure) or a minor accident (e.g., breakage of a fitting).

While tracing the pathways in the event tree, note that a release may or may not be accompanied by immediate ignition. With immediate ignition, that is, following the left branch of the tree, a jet flame will result if the release is from a relatively small opening. Such a release could be either vapor or liquid and, if liquid, could also involve flashing of liquid into vapor and/or accumulation of liquid. If the release is the result of a major spill and there is immediate ignition, the result is usually a fireball, the size of which is strongly affected by the amount of flash vaporization and liquid entrainment that occurs on release.

If ignition does not occur immediately upon release, the right branch of the event tree is followed. Releases through relief valves, either accidental or intentional, may be captured by a vent header system and directed to a flare. Flares must accordingly be designed for expected accident or operational flow capacities, and the design should include consideration of resulting hazard zones.

If the unignited release is to the atmosphere, the spill will be accompanied by flash vaporization, liquid entrainment, accumulation, and/or vapor dispersion. A delayed local ignition following accumulation results in a pool fire whose characteristics are strongly influenced by the geometry of containment (or lack thereof).

Absence of a local ignition source, either immediate or delayed, allows a vapor cloud to form as the vapors disperse downwind. A portion of this vapor cloud will be flammable, and, depending on the size of the release, the flammable region could extend significantly downwind. A remote ignition source can ignite the cloud, resulting in a vapor cloud fire that burns from the

point of ignition back toward the source of the cloud, that is, the release point. Note also that the event tree shows dashed pathways from the vapor cloud fire to a pool fire or a jet flame. This is intended to show that the transient burning of the vapor cloud fire back to the release point can initiate a subsequent steady burning jet flame or pool fire, and consideration must be given to potential impacts from both types of fire.

Finally, this event tree represents an example of potential pathways leading to hazardous open fires. Scenarios will be encountered that will be similar to the event tree depicted in Fig. 66.1 or to parts thereof, but it is important to recognize that in all cases, the event tree must be structured to reflect the actual scenario under consideration.

Hydrocarbon Pool Fires

The thermal radiation hazards from hydrocarbon pool fires depend on a number of parameters, including the composition of the hydrocarbon, the size and shape of the pool, the duration of the fire, its proximity to the object at risk, and the thermal characteristics of the object exposed to the fire. The objectives of this section of the chapter are to review available techniques for determining the thermal radiation hazards from liquid hydrocarbon pool fires under various credible spill conditions.

The state of the art of predicting the thermal environment of hydrocarbon pool fires consists essentially of semiempirical methods, some of which are based on experimental data. Needless to say, such semiempirical methods are always subject to uncertainties.

Estimating the thermal radiation field surrounding a fire involves the following three major steps:

1. Geometric characterization of the pool fire; that is, the determination of burning rate and the physical dimensions of the fire. In calculating thermal radiation, the size of the fire implies the time-averaged size of the visible envelope.
2. Characterization of the radiative properties of the fire; that is, the determination of the average emissive power of the flames. The intensity of thermal radiation emitted by pool fires depends on a number of parameters, including fuel type, fire size, flame temperature, and composition. The major sources of emission in large hydrocarbon fires are the water vapor, carbon dioxide, and soot.
3. Calculation of radiant flux at a given location. This can be accomplished once the geometry of the fire, its radiation characteristics, and the location, geometry, and orientation of the receiver are known. For large distances (hundreds of meters), the absorption of thermal radiation in the intervening atmosphere becomes appreciable. This is dependent on the pathlength, flame temperature, and the relative humidity in the atmosphere.

Certain references [1–7] provide general information concerning radiation heat transfer relevant to pool fires, and others [8–37] are specific studies of pool fire radiation heat transfer underpinning the methods of analysis.

Pool Fire Geometry

The flame geometry for the solid flame model is generally determined by assuming that the flame is a solid, gray emitter having a regular well-defined shape such as a circular or a tilted cylinder. The dimension of the flame area is characterized by the flame base diameter, the visible flame height, and the flame tilt. The flame diameter is dependent on the pool size (spill volume and/or spill rate). The flame height appears to depend on the flame diameter and the burning rate. These factors, which influence the flame geometry, are discussed in this chapter.

The pool fire geometry is determined by the manner and location of the fuel release. Chapter 17 provides detailed means for predictions of the extent of the spill or pool, the spread of flame over the fuel surface, and the resulting burning rate. This information will

be required for determination of the flame height and the radiation analyses that follow.

The height or length of a flame is a significant indicator of hazard because it directly relates to flame heat transfer and the propensity to impact surrounding objects. A plume of hot gases rises above a flame; the temperature, velocity, and width of this plume change as it rises due to the mixing of the plume with the surroundings. The height and temperature of the flame are important in estimating the ignition of adjacent combustibles. Above the fuel source, the flaming region is characterized by high temperature and is generally luminous. Flame from the pool fires fluctuate periodically so that the tip of the flame will be significantly different from the length of the continuous combustion (or luminous) region. Consequently, flame height has been defined by various criteria in order to correlate data. Investigators have used the degree of luminous flame intermittency, flame temperature, or visible estimations. Hence, correlations for flame height could have inherent variation with the instantaneous flame length due to factors involving flame fluctuation and flame definition. For additional information, see Chap. 13.

Flame Length Many investigators have developed correlations for turbulent flame lengths in a quiescent air environment. Most are based on the dimensional analysis of experimental data using Froude modeling principles; some are based on approximate theoretical models involving some empirical factors (see Chap. 13 for additional general information on flame heights).

These correlations are generally cast in terms of a nondimensional burning rate and a nondimensional velocity that arise out of Froude modeling as follows:

$$m^* = \frac{\dot{m}''}{\rho_a \sqrt{gD}} \tag{66.1}$$

$$u^* = \frac{u_w}{u_c} = \frac{u_w}{\left(g\dot{m}''D/\rho_a\right)^{1/3}} \tag{66.2}$$

An alternative to m^* is the nondimensional heat release rate, Q^*, which is proportional to m^*:

$$Q^* = \frac{\dot{Q}}{\rho_a c_p T_a D^2 \sqrt{gD}} \tag{66.3}$$

Most flame length correlations take the form of

$$\frac{H}{D} = a\left(m^*\right)^b \left(u^*\right)^c \tag{66.4}$$

Correlations of this form for mean flame length are summarized in Table 66.1. Mean flame length is generally defined as the height where the flame is present above this height 50 % of the time.

Mudan [14] and Munoz et al. [41] have compared correlations with pool fire data. Figure 66.2 shows the comparison of data compiled by Mudan [14] with the various correlations. The correlations based on smaller-scale data tend to overestimate the flame heights. Munoz et al.'s comparisons with their 1- to 6 m-diameter pool fires show the same general trend. Munoz's data are both the most modern data and the smallest flame heights observed overall. Considerable variations are apparent among the correlations and considerable scatter exists in the data.

Figure 66.2 shows the flame height to diameter ratio, H/D, as a function of the nondimensional burning rate, m^*, for a range of pool fire data assembled by Mudan [14] with the correlations shown in Table 66.1 for comparison.

Flame Tilt Angle Flame length under wind conditions has been studied by several investigators. Figure 66.3 illustrates a general schematic for the windblown flame. The pool fire flame follows a curved trajectory, and the angle, θ, approximates the trajectory. The vertical and horizontal components of the flame length measured along the angle are also shown in the figure.

Welker and Sliepcevich [44] and Emori and Saito [45] derived correlations from small-scale experiments. They correlated the angle of inclination as a function of crosswind velocity, $v_{\tilde{a}}$, but the results do not compare well with larger-scale data. Flame tilt angle correlations in the literature take the form of

$$\cos\theta = \begin{matrix} du^{*e} \\ 1 \end{matrix} \quad \text{for} \quad \begin{matrix} u^* \geq 1 \\ u^* < 1 \end{matrix} \qquad (66.5)$$

Table 66.2 summarizes the available correlations.

In Fig. 66.4, a comparison of observed flame tilt angle is shown for hydrocarbons pool fire data

Munoz et al. [41]	0.96	−0.26	HC pools (1–6 m)

Note: For all correlations when u* is less than one, use value calculated for u* = 1

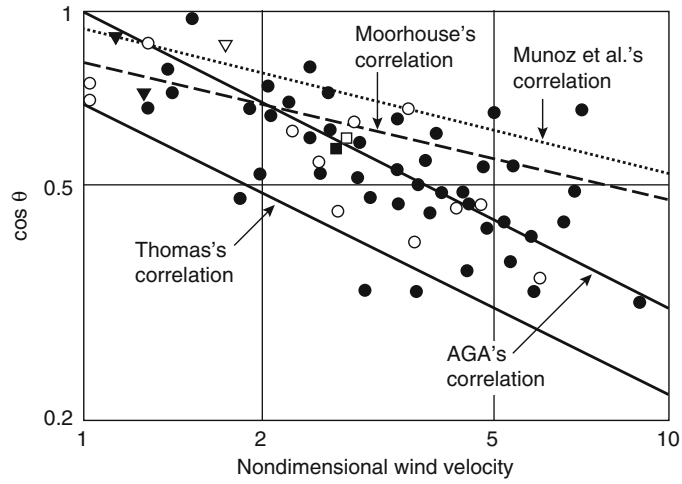

Fig. 66.4 Relationship between nondimensional wind velocity and flame tilt angle (As modified [14])

compiled by Mudan [14] with correlations summarized in Table 66.2. Although there is considerable scatter in the measured flame tilt, the correlation given by AGA represents the flame tilt most accurately. Defaveri et al. [47] have studied the effects of wind on high-momentum flames.

Geometry of Trench or Line Fires Moorhouse [16] conducted limited large-scale LNG trench fires with aspect ratios ranging from 1.5 to 2.5. Mudan and Croce [17] reported on large-scale tests with LNG trenches having aspect ratios of up to 30.0. All the data seem to indicate that flame geometry of trench fires is more sensitive to wind conditions than is flame geometry of conventional pool fires. Flame height is a strong function of trench width and relatively independent of the trench length. Indeed, for large aspect ratios, the trench fires break up into small flamelets having a typical base dimension of the trench width, W.

Based on an extensive analysis of the motion picture data of LNG trench fires, Mudan and Croce [17] suggested that the trench fire geometry can be represented by a Froude number or dimensionless wind velocity, u_t*:

$$u_t^* = \frac{u_w}{2\sqrt{gW}} \tag{66.6}$$

The measured flame length as a function of the modified Froude number is shown in Fig. 66.5. The flame length correlation is

$$\frac{H}{W} = \begin{cases} 2.2 & u_t^* \geq 0.25 \\ 0.88 u_t^{*-0.65} & \text{for} \quad 0.25 < u_t^* \leq 0.1 \\ 4.0 & u_t^* \leq 0.1 \end{cases} \tag{66.7}$$

The flame drag distance along the ground, W', is given by the following expression:

$$\frac{W'}{W} = \begin{cases} 3.5 & u_t^* \geq 0.25 \\ 23.3 u_t^{*1.37} & \text{for} \quad 0.25 < u_t^* \leq 0.1 \\ 1 & u_t^* \leq 0.1 \end{cases} \tag{66.8}$$

The flame tilt, θ, is given by the following expression:

$$\frac{\theta}{\theta} = \begin{cases} 3.5 & u_t^* \geq 0.25 \\ 23.3 u_t^{*1.37} & \text{for} \quad 0.25 \leq u_t^* \leq 0.042 \\ 1 & u_t^* \leq 0.042 \end{cases} \tag{66.9}$$

Caution must be exercised in using the correlations given by Equations 66.7, 66.8, and 66.9 because they are based only on LNG fire data.

Thermal Radiation Hazards from Liquid Hydrocarbon Pool Fires

The structure of hydrocarbon pool fire flames generally follows the description of flames and plumes in Chap. 13. Figures 66.6, 66.7, and 66.8 show velocities and temperatures in heptane pool fires up to 6 m in diameter. Figure 66.6 shows velocities rising as the square root of height and maximizing near the top of the flame before declining. These general trends mirror that of smaller flames. Figure 66.7 shows the centerline temperatures of heptane pool fires. Although most of the results are similar to trends in smaller flames, the centerline temperatures for the 6 m pool are larger than is seen in smaller flames. This has been observed by others in large pool fires [32, 41]. Figure 66.8 shows the thermal structure of the lower portion of a 6 m heptane pool fire, which is remarkably similar to the trends in smaller flames.

Although the general thermal and flow structure of large hydrocarbon pool fires is similar to smaller flames, the radiative behavior of large

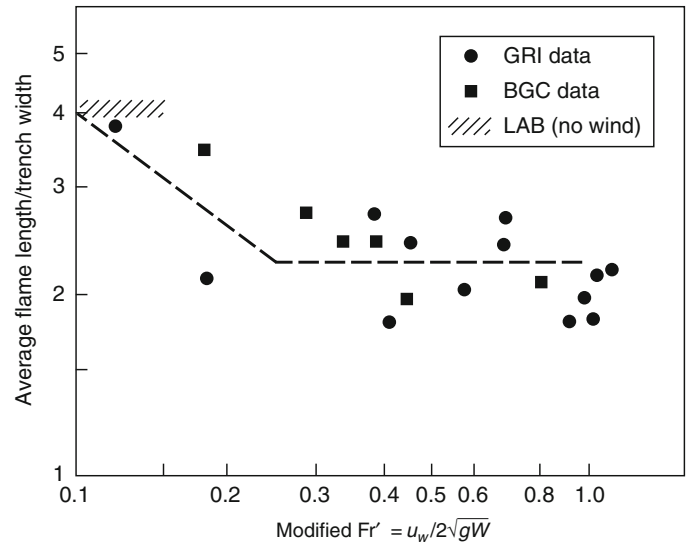

Fig. 66.5 Nondimensional flame height as a function of the Froude number [17]

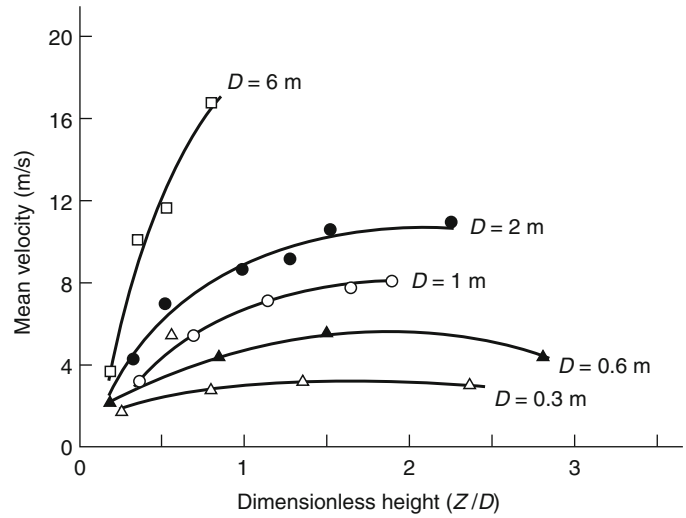

Fig. 66.6 Centerline upward velocities measured in heptane pool fires from 0.3 to 6.0 m diameters. Z is the height above the pool surface and D is the pool diameter [26]

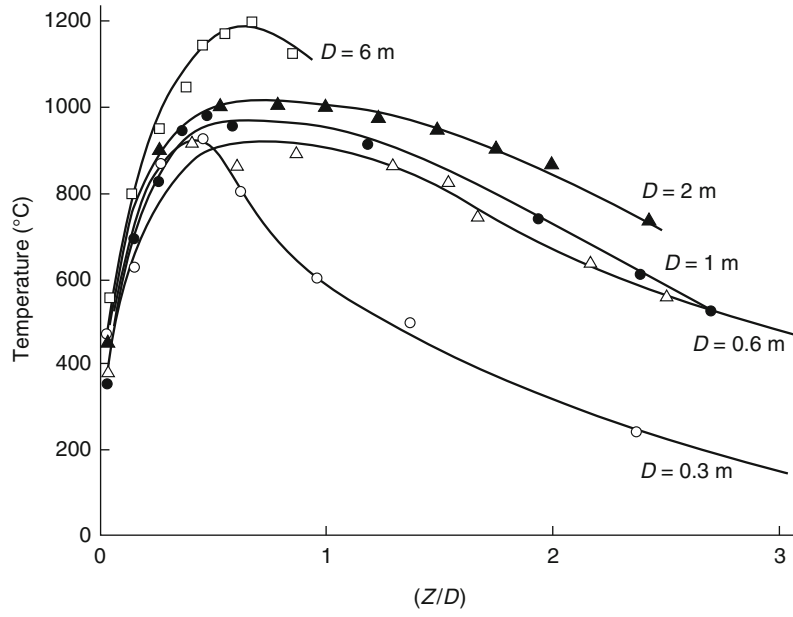

Fig. 66.7 Centerline temperatures measured in heptane pool fires from 0.3 to 6.0 m diameters. Z is the height above the pool surface and D is the pool diameter [26]

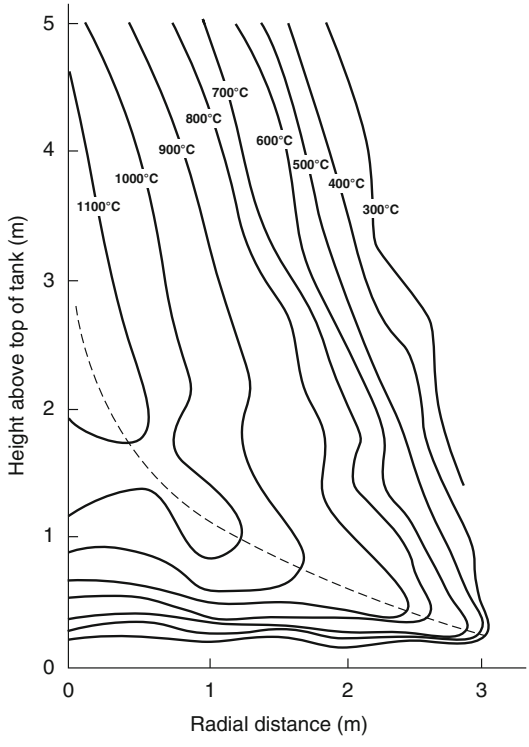

Fig. 66.8 Thermal structure of the near pool region of a 6-m-diameter heptane pool fire. The origin is the center of the pool surface [26]

pool fires is significantly different than smaller flames. Figure 66.9 shows the radiative fraction, the fraction of the heat release rate emitted as radiation, as a function of the pool diameter. The radiative fractions for diameters up to 1 m are in the region of 0.3–0.4, typical of sooty fuels in smaller fires. As the diameter of the pool fire increases beyond 1 m, the radiative fraction begins to decrease as smoke begins to obscure the flame from view and blocks radiation from the luminous flame regions. This effect becomes quite pronounced with radiative fractions as low as 0.05 for a 50-m-diameter kerosene pool fire.

Models and calculation procedures for radiation from hydrocarbon pool fires make use of simplifications and idealizations. Before delving into these methods, it is worthwhile to examine the actual radiative structure of pool fire flames as determined from detailed measurements [41]. In contrast to calculation methods, the radiant output of a pool fire is not uniform over a supposed flame surface area defined by the visible flame height and the pool diameter. Figure 66.10 shows the contours of mean emissive power from a 3-m-diameter gasoline pool fire and a 6-m-diameter diesel fuel pool fire.

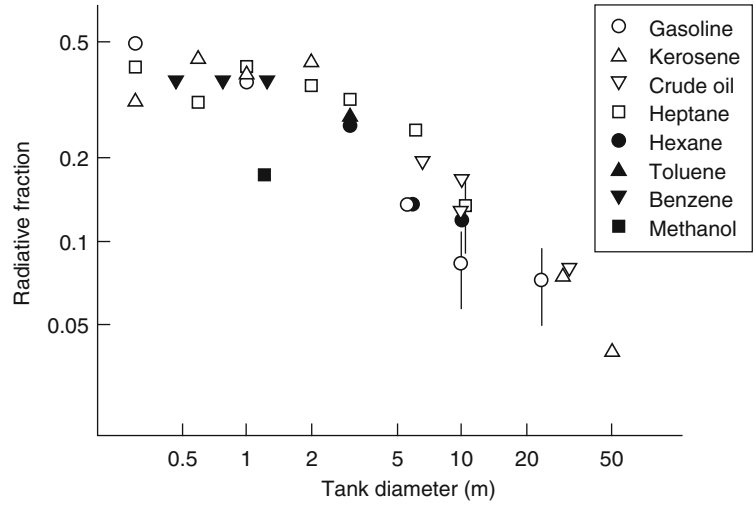

Fig. 66.9 Radiative fractions measured for pool fires from 0.3 to 50.0 m diameters [49]

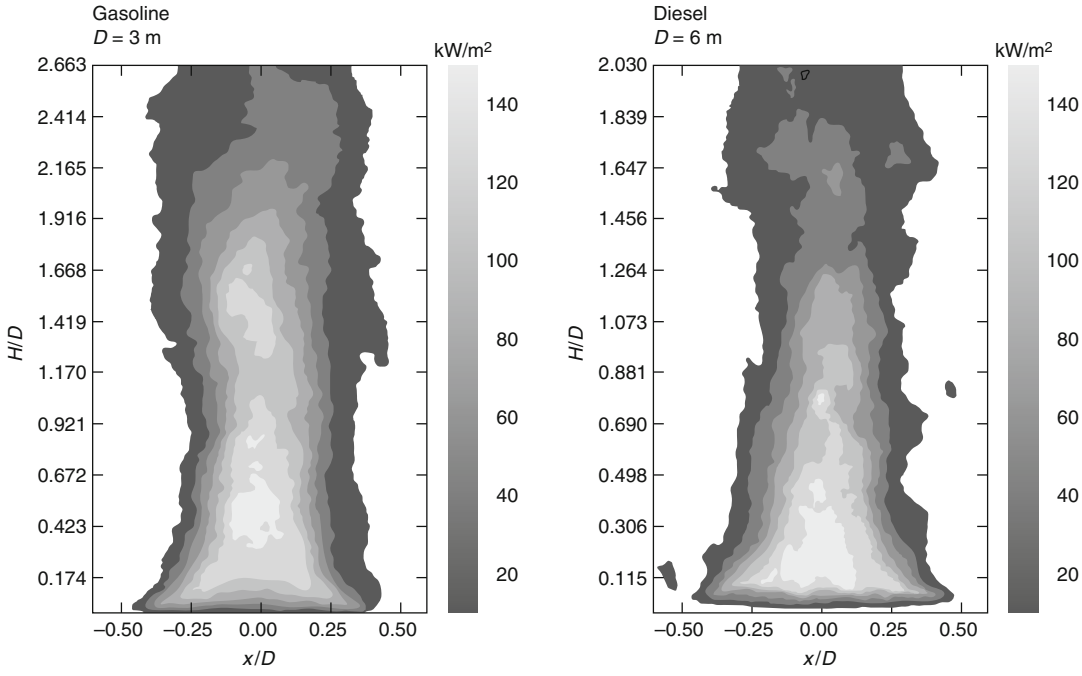

Fig. 66.10 Measured mean emissive power contours for a 3-m-diameter gasoline pool fire (*left*) and a 6-m-diameter diesel fuel pool fire (*right*) [41]

These contours were determined from quantitative infrared camera data. Clearly, the emissive power is a strong function of space, ranging from over 140 kW/m^2 to near zero within the cylindrical space that would normally be regarded as the flame in most pool fire radiation models. Figure 66.11 shows the emissive power averaged over the width of the radiation profile as a function of height above the pool surface normalized by the pool diameter. Note that the averaging occurs over a radial distance less than the pool diameter due to the necking of the flame as seen in Figs. 66.8 and 66.10. This look at actual pool fire emissive power distributions should tend to

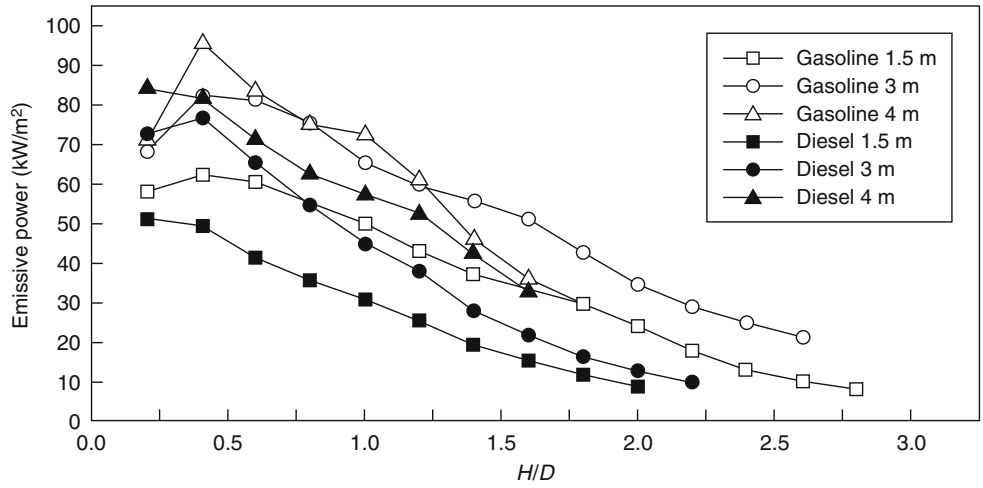

Fig. 66.11 Emissive power averaged over the measured flame width as a function of the nondimensional height above the pool surface [41]

remind us of the approximations made in defining a flame shape, height, and average emissive power over that shape. Although it is a useful formalism, the emissive power found and used in these methods should be regarded as an empirical fitting parameter that results in suitable agreement with radiant flux measurements at a distance. Also, it should tend to reinforce that methods described in the following sections should be used as a complete package without mixing methods or sources of data.

Calculation Procedure: Flame Radiation to External Target

This section provides methods for assessing the impact of radiation from pool fires to potential targets. The goal is to provide methods for calculating safe separation distances between fire sources and potential targets that would be damaged or adversely affected by radiation from the fire. The methods in this section include a range of levels of detail and rigor. Some methods are most appropriate for very crude initial hazard assessments, whereas the more detailed methods are capable of better predictions though requiring more engineering effort. Where separations exist and a simple method demonstrates that the separation is far more than required for safety, it may not be necessary to perform a more rigorous analysis. In other more critical applications, the highest accuracy methods available are required.

The methods presented in this section have been evaluated and included by the Society of Fire Protection Engineers (SFPE) in *Engineering Guide on Pool Fire Radiation* [50]. In that reference, the methods are described fully, the assumptions inherent in the methods are identified, limits of applicability are assessed, and available input data and data sources are identified. The accuracy of the methods are examined through comparisons of the methods with available experimental data.

Calculation Methods

Estimating the thermal radiation incident on an object involves the following three major steps:

1. Determine the geometric characteristics of the pool fire, that is, determine the burning rate and physical dimensions of the fire.
2. Determine thermal radiation characteristics of the fire.
3. Calculate the incident radiant flux at the target location.

It is extremely important that a single methodology be used for all three steps of this process. The available methods include empirical elements that, if indiscriminately used, can lead to unpredictable results. Because of this fact, each method is described fully and independently from other methods, even when some elements of the analysis appear similar.

Four methods for estimating radiation from pool fires were identified and evaluated [50]. Two methods are generally classifiable as simple screening methods and two are more detailed procedures. The screening methods include a very simple correlation developed by Shokri and Beyler [48], and the classical point source model. The more detailed procedures are those developed by Shokri and Beyler [48] and by Mudan [14].

Screening Methods

Shokri and Beyler Correlation Based on experimental data from large-scale pool fire experiments, Shokri and Beyler [48] developed a simple correlation of radiant heat flux at ground level as a function of the radial position of a vertical target. The incident heat-flux correlation (in kW/m^2) is given by

$$\dot{q}'' = 15.4\left(\frac{L}{D}\right)^{-1.59} \tag{66.10}$$

where D is the diameter of the pool fire and L is the distance from the center of the pool fire to the target edge. Note that the edge of the circular pool has a value of L/D of 0.5. Although this correlation was determined from circular pool fires, an equivalent-area circular source can be used for noncircular pools with an aspect ratio of approximately one. The equivalent diameter is given by

$$D = \sqrt{\frac{4A}{\pi}} \tag{66.11}$$

where A is the surface area of the noncircular pool.

This method assumes that the pool is circular or nearly circular. It assumes that the target is vertical and located at ground level. It is known that the radiant heat flux is maximized near the midheight of the radiating source and that a target facing the center of radiation will give the maximum heat flux at a given location. As such, at heights above ground level the radiant flux is expected to exceed that given by Equation 66.10.

Figure 66.12 shows a semilogarithmic plot of the data from Hägglund and Persson [18], Yamaguchi and Wakasa [19], Seeger [20], Yumoto [21], Dayan and Tien [22], and May and McQueen [23] with the correlation given by Equation 66.10. Figure 66.13 shows a comparison of the measured and predicted heat fluxes for the original data included in Fig. 66.12, as well as additional data from the literature that were not used to develop the correlation.

A safety factor of 2 is recommended for use with Equation 66.10 [50]. Figure 66.14 shows a comparison of all the available data to the predictions using Equation 66.10 with a safety factor of 2. Figure 66.14 clearly shows that essentially all the data is overpredicted by Equation 66.10 with a safety factor of 2 applied. The safety factor of 2 is a recommendation for use in design applications. Where a realistic result is required, no safety factor should be applied.

Point Source Model To predict the thermal radiation field of flames, it is customary to model the flame by a point source located at the center of real flame. The point source model is the simplest configurational model of a radiant source. Whereas more realistic radiator shapes give rise to very complex configuration factor equations, the point source model provides a simple relationship that varies with the inverse square of the distance, R. For an actual point source of radiation or a spherical source of radiation, the distance R is just the distance from the point or from the center of the sphere to the target. See Fig. 66.15 for a graphic representation of relevant nomenclature.

The point source model is widely used (see Drysdale [51], for example), though it has really never been developed as a rigorous methodology. The method as presented and evaluated here follows the development as given by Drysdale [51].

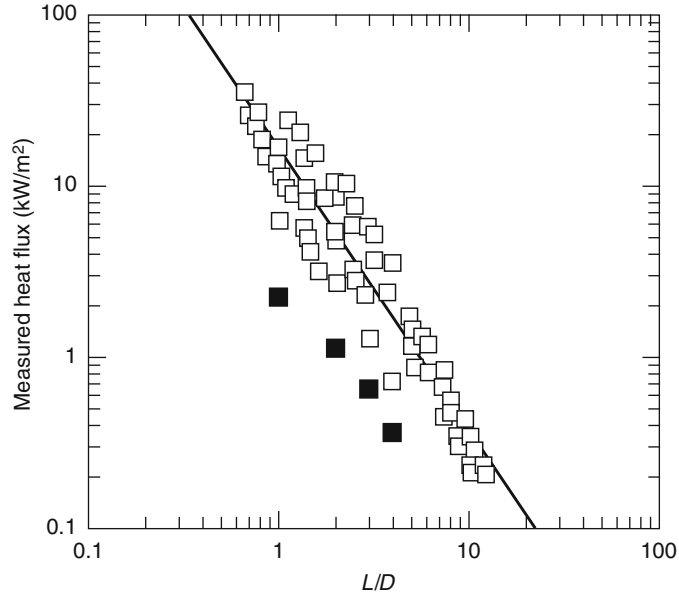

Fig. 66.12 Measured incident radiant heat flux at ground level to a vertical target as a function of the distance from the pool center to the target normalized by the pool diameter. Solid symbols are 50-m-diameter kerosene data. The *solid line* is Equation 66.10 [48]

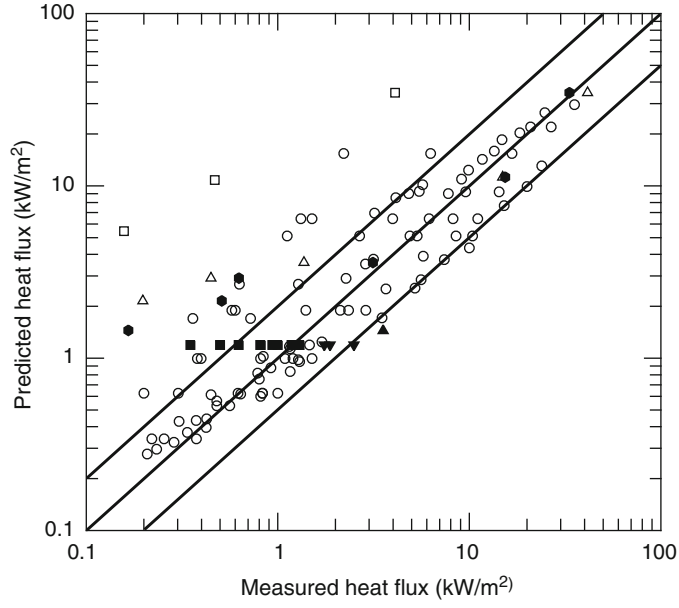

Fig. 66.13 Comparison of measured and calculated radiative heat flux from large pool fires using the Shokri and Beyler correlation (Equation 66.10). *Solid lines* indicate equality of measured and predicted heat fluxes based on the correlation developed by Shokri and Beyler [48]

The incident radiative heat flux is given by

$$\dot{q}'' = \frac{\dot{Q}_r \cos\theta}{4\pi R^2} \tag{66.12}$$

where

$\dot{Q}_r$ = Total radiative energy output of the fire

θ = Angle between the normal to the target and the line of sight from the target to the point source location

R = Distance from the point source to the target

The location of the equivalent point source, P, is at the center of the pool fire and at the midheight of the flame. The flame height in

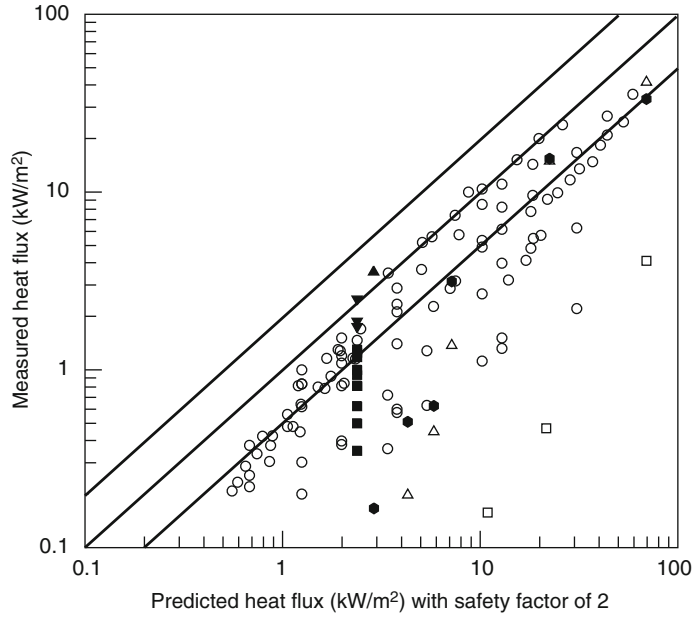

Fig. 66.14 Comparison of measured and calculated radiative heat flux from large pool fires using the Shokri and Beyler correlation (Equation 66.10) and a safety factor of 2. *Solid lines* indicate equality of measure and predicted heat fluxes based on the correlation developed by Shokri and Beyler [48] with a safety factor of 2

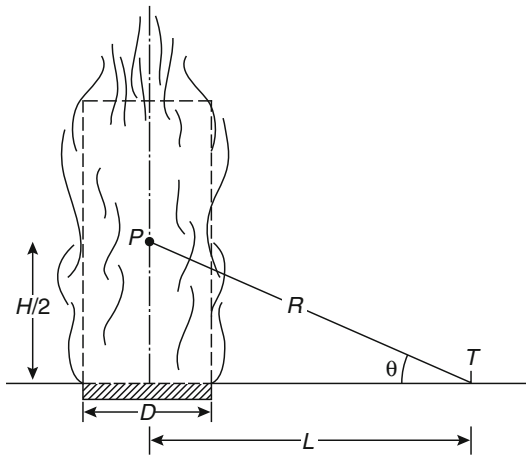

Fig. 66.15 Nomenclature for use with the point source model

meters is given by the Heskestad [42] correlation, Equation 66.13:

$$H = 0.235\dot{Q}^{2/5} - 1.02D \tag{66.13}$$

where $\dot{Q}$ is the heat release of the pool fire in kW and D is the diameter of the pool fire in meters.

If the pool has a length-to-width ratio near one, an equivalent diameter can be used for noncircular pools in the determination of the flame height. The equivalent diameter is given by Equation 66.11:

$$D = \sqrt{\frac{4A}{\pi}} \tag{66.11}$$

where A is the surface area of the noncircular pool.

The distance from the point source location to the target location is given by the Pythagorean theorem:

$$R = \sqrt{L^2 + {H_T}^2} \tag{66.14}$$

where H_T is the height of the target relative to the height of the equivalent point source at $H/2$, and L is the horizontal distance from the center of the pool to the target.

For a target on the ground, $H_T = H/2$. For a target at the midheight of the flame, $H_T = 0$.

The radiative energy output is given by the radiative fraction, χ_r, multiplied by the total heat release rate:

$$\dot{Q}_r = \chi_r \dot{Q} = (0.21 - 0.0034D)\dot{Q} \tag{66.15}$$

where the radiative fraction is a function of both the fuel and the pool area and D is the pool diameter in meters.

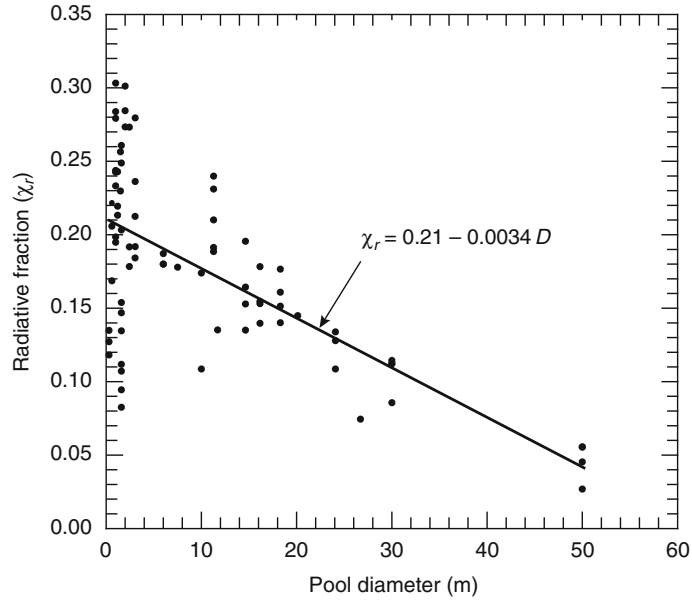

Fig. 66.16 Radiative fraction (χ_r) as a function of pool diameter. The *solid line* is a curve fit to the data [50]

The radiative fraction deduced from the experiments [50] is plotted in Fig. 66.16 as a function of pool diameter, D. The radiative fractions were determined using the point source method for the most remote data point for each experiment. The curve fit used in Equation 66.15 above is also shown in Fig. 66.16. At pool diameters above 50 m, the radiative fraction for 50 m should be used.

Estimating the thermal radiation from a pool fire to a target involves the following steps based on the point source model:

1. Determine the heat release rate, $\dot{Q}_r$.
2. Determine the diameter of the pool fire, or use Equation 66.11 for noncircular pools.
3. Determine the location of the equivalent point source, P. The equivalent point source is on the centerline of the pool at a height equal to one-half the flame height given by Equation 66.13.
4. Calculate the distance, R, from the equivalent point source location to the target location using Equation 66.14.
5. Determine the radiative output of the flame from Equation 66.15.
6. Calculate the radiative heat flux to the target using Equation 66.12.

Figure 66.17 shows a comparison of all the available data with the prediction of the point source model [52]. The lines shown on the plot reflect predictions that are one-half and twice those of the measured data. At heat fluxes above about 5 kW/m^2, there are systematic, non-conservative results.

The point source configuration factor is known to be a very simplistic representation of a pool fire. It is a correct assumption at large distances from the fire. A theoretical analysis of radiation from a small pool fire by Modak [52] indicated that the point source model is within 5 % of the correct incident heat flux when L/D is greater than 2.5. This result is, however, dependent on the specific flame modeled and was not derived from experimental data. The method is known to underpredict incident heat fluxes at closer locations (e.g., see Drysdale [51]). The poor performance at heat fluxes above 5 kW/m^2 indicates that the point source model is not a good choice under conditions where ignition of combustibles is to be considered.

A safety factor of 2 is recommended for use with the point source model at heat fluxes less than 5 kW/m^2. Figure 66.18 is a comparison of predicted and measured heat fluxes with the

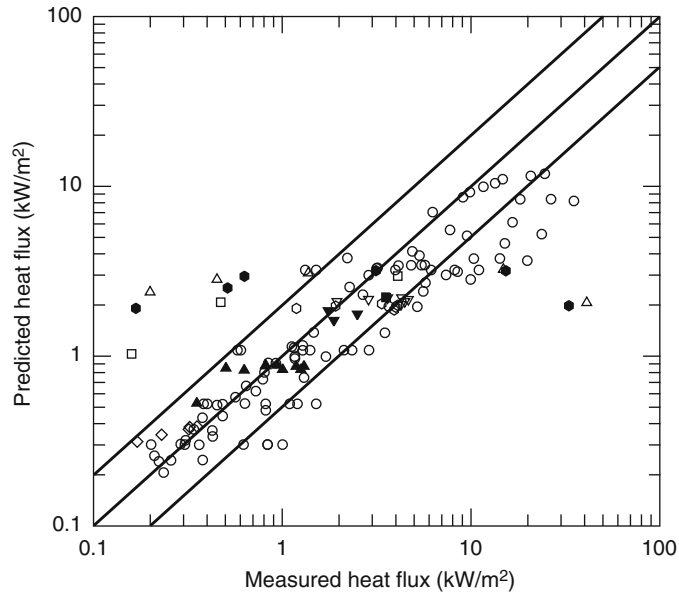

Fig. 66.17 Comparison of measured and calculated radiative heat flux from large pool fires using the point source model. *Solid lines* indicate equality of measured and predicted heat fluxes based on the point source model

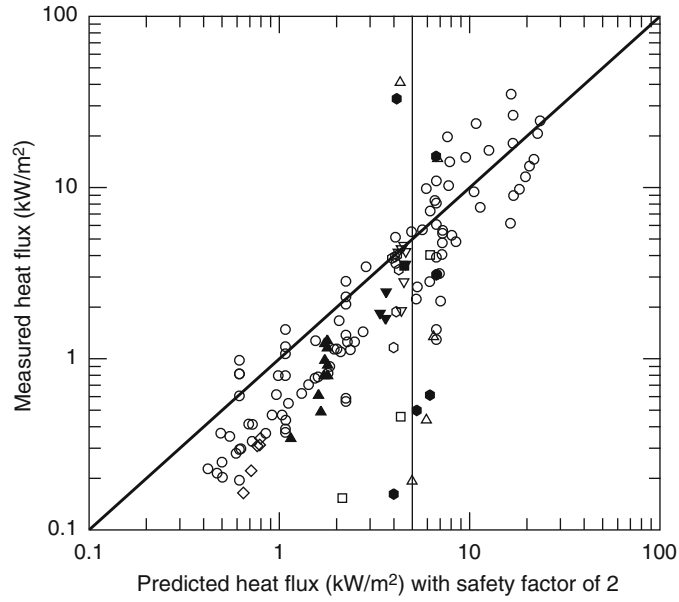

Fig. 66.18 Comparison of measured and calculated radiative heat flux from large pool fires using the point source model and a safety factor of 2. *Solid lines* indicate equality of measured and predicted heat fluxes based on the point source model

inclusion of the recommended factor of safety. The vertical line is located at the maximum heat flux for which the point source model is recommended for use. Figure 66.18 clearly shows that essentially all the data are overpredicted by the point source model with a safety factor of 2 applied for heat fluxes less than 5 kW/m^2. The safety factor of 2 is a recommendation for use in design applications. Where a realistic result is required, no safety factor should be applied.

Detailed Methods

Shokri and Beyler Shokri and Beyler [48] have described a method for prediction of radiation from pool fires based on the pool fire radiation

data available in the open literature. They correlated experimental data of flame radiation to external targets in terms of an average effective emissive power of the flame. The flame is assumed to be a cylindrical, blackbody, homogeneous radiator with an average emissive power. Shokri and Beyler [48] have treated radiant heat transfer from a source to a target based on the concept of the angle factor, also variously known as the shape, geometrical, configuration, or view factors, including those given by many authors [1, 3, 53–60] and the incident radiative flux (in kW/m^2) to a target outside the flame, $\dot{q}''$ is given by

$$\dot{q}'' = EF_{12} \tag{66.16}$$

where E is the emissive power of the pool fire flame, kW/m^2, and F_{12} is the view or configuration factor between the target and the flame.

The configuration factor is a function of the target location, the flame height, and the diameter, and lies between zero and one. When a target is very close to a flame, the configuration factor approaches one because everything viewed by the target is the flame. The flame is idealized as a cylinder with a diameter equal to the pool diameter, D, and a height equal to the flame height, H_f. If the pool has a length-to-width ratio near one, an equivalent-area circular source can be used for noncircular pools in the determination of flame height. For noncircular pools, the effective diameter will be defined as the diameter of a circular pool with an area equal to the actual pool area given by Equation 66.11:

$$D = \sqrt{\frac{4A}{\pi}} \tag{66.11}$$

where A is the surface area of the noncircular pool.

Flame height of the pool fire flame is determined using the Heskestad [42] correlation given by Equation 66.13:

$$H = 0.235\dot{Q}^{2.5} - 1.02D \tag{66.13}$$

where

H = Flame height, m
$\dot{Q}$ = Heat release of the pool fire, kW
D = Diameter of the pool fire, m

Given the diameter and height of the flame, the view factor, F_{12}, is determined using Equation 66.17 applicable to cylindrical radiation sources. For horizontal and vertical target orientations, expressions for estimating the configuration factor are found in Equations 66.17a and 66.17b, respectively.

$$F_{12,H} = \frac{(B - 1/S)}{\pi\sqrt{B^2 - 1}} \tan^{-1}\sqrt{\frac{(B+1)(S-1)}{(B-1)(S+1)}} - \frac{(A - 1/S)}{\pi\sqrt{A^2 - 1}} \tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}} \tag{66.17a}$$

$$F_{12,V} = \frac{1}{\pi S}\tan^{-1}\left(\frac{h}{\sqrt{S^2-1}}\right) - \frac{h}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}} + \frac{Ah}{\pi S\sqrt{A^2-1}}\tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}} \tag{66.17b}$$

where

$$A = \frac{h^2 + S^2 + 1}{2S}, \qquad B = \frac{1 + S^2}{2S}$$
$$S = \frac{2L}{D}, \quad h = \frac{2H}{D}$$

and

L = Distance between the center of the cylinder to the target
H = Height of the cylinder
D = Cylinder diameter

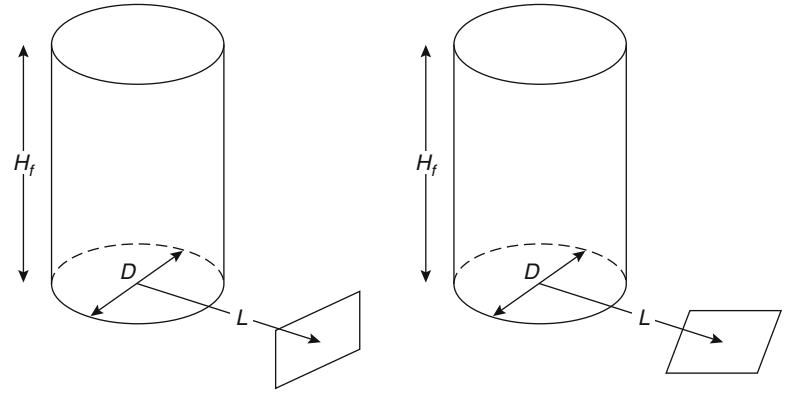
See Figs. 66.19 and 66.20 for an illustration of the nomenclature.

The maximum configuration or shape factor at a point is given by the vectorial sum of the horizontal and vertical view factors:

$$F_{12,\max} = \sqrt{F_{12,H}^2 + F_{12,V}^2} \tag{66.18}$$

Precalculated maximum view factors are shown in Figs. 66.21, 66.22, 66.23, 66.24, and 66.25.

Fig. 66.19 Cylindrical flame-shape configuration factor geometry for vertical and horizontal targets at ground level



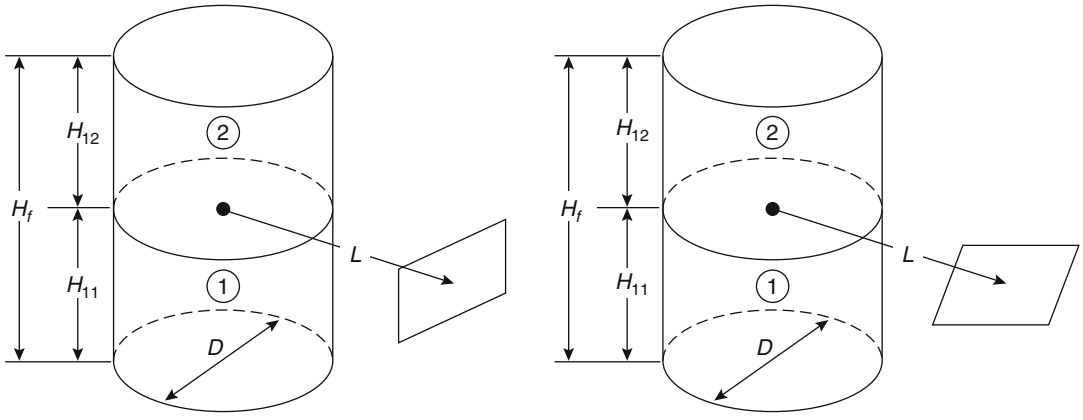


Fig. 66.20 Two-cylinder representations of the configuration factor for target above ground level

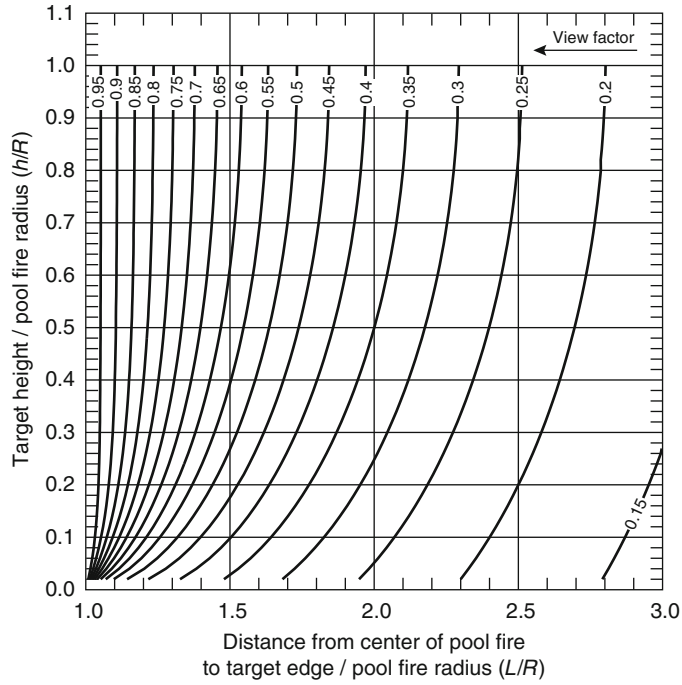
Fig. 66.21 Maximum configuration factor for a flame height to pool fire radius ratio $H/R_p = 2$



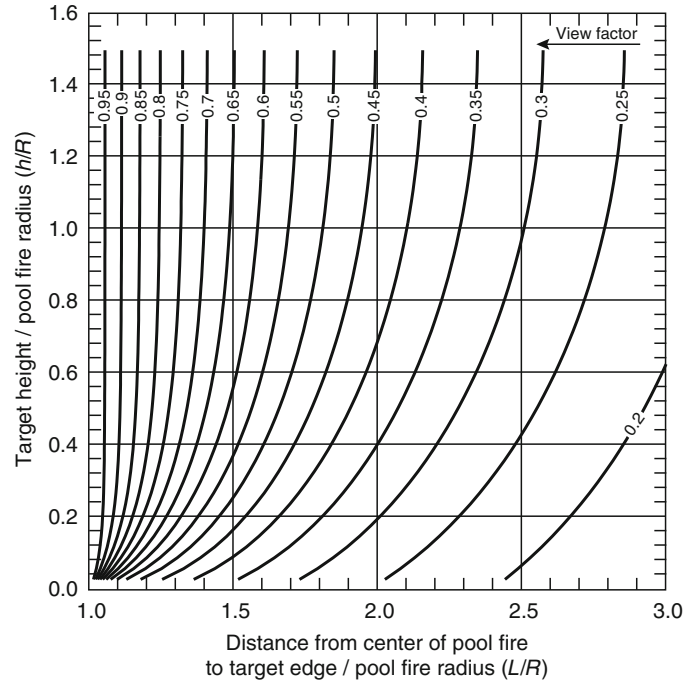


Fig. 66.22 Maximum configuration factor for flame height to pool fire radius of ratio $H/R_p = 3$

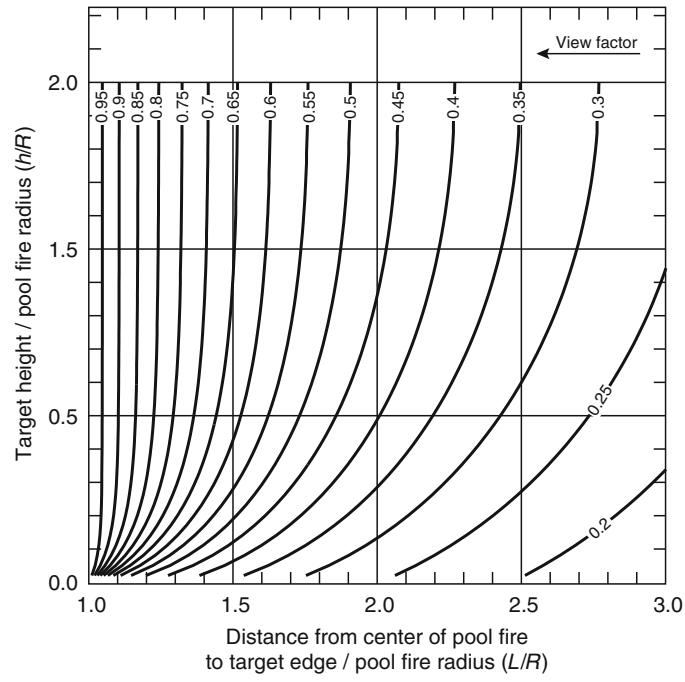

Fig. 66.23 Maximum view factor for a flame height to pool fire radius ratio $H_f/R = 4$

Each figure gives the maximum view factor for a flame of a particular flame height to pool radius ratio (H/R_p): 2, 3, 4, 5, and 6, respectively. The target location is defined in each figure by the ratio of the target height to the pool radius, and the ratio of the distance of the target from the pool center to the pool radius. The view factors are represented as contours. The figures

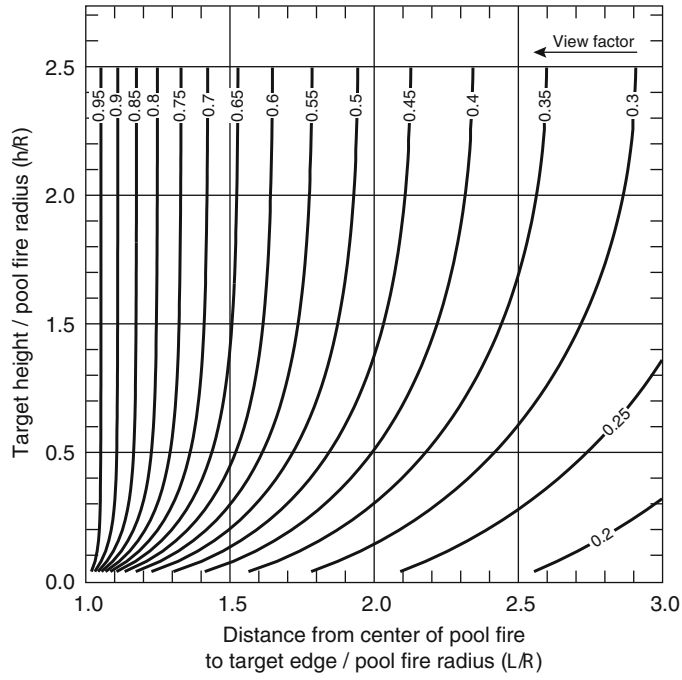

Fig. 66.24 Maximum configuration factor for a flame height to pool fire radius ratio $H/R_p = 5$

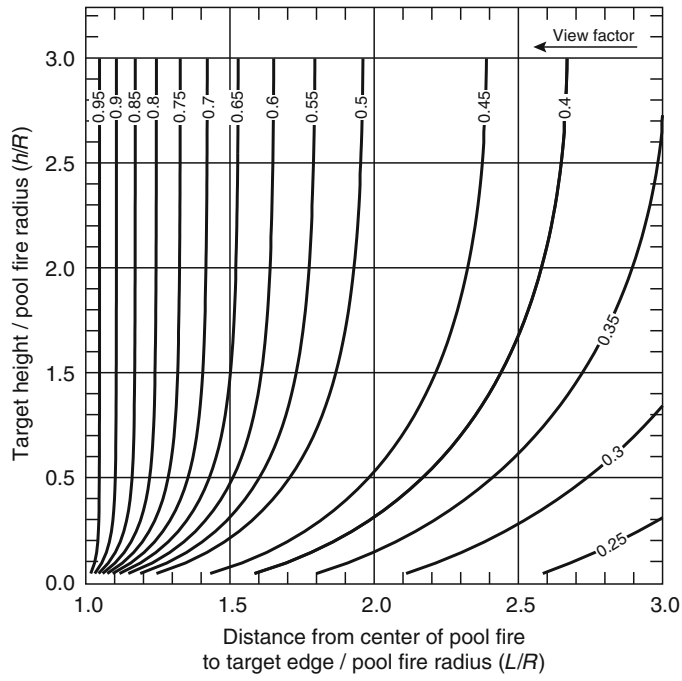

Fig. 66.25 Maximum configuration factor for a flame height to pool fire radius ratio $H/R_p = 6$

include only target locations up to one-half the flame height. The curves for target heights above one-half the flame height are symmetric about the half-height and as such need not be included. For example, the view factor for a target at one-fourth of the flame height and three-fourths of the flame height are identical.

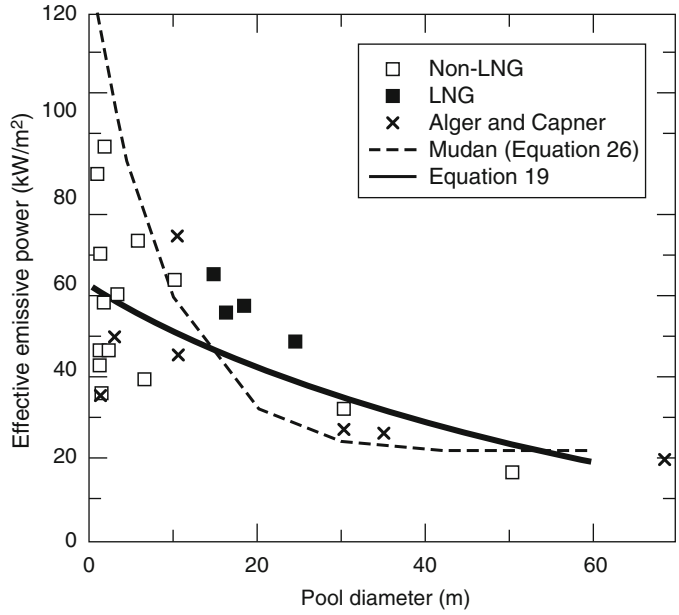

Fig. 66.26 Effective emissive power as a function of the pool diameter determined by Shokri and Beyler [48]. The *solid line* is Equation 66.19 and the *dashed line* is Equation 66.26

Shokri and Beyler [48] determined the effective emissive power of the flame by fitting experimental measurements of radiant heat flux from pool fires to external targets. The effective emissive power of the pool fire in terms of effective pool diameter is given by the following correlation:

$$E = 58\left(10^{-0.00823D}\right) \tag{66.19}$$

This represents the average emissive power over the whole of the flame and is significantly less than the emissive powers that can be attained locally. The emissive power is reduced with increasing pool diameter due to the increasing prominence of black smoke outside the flame that obscures the radiation from the luminous flame. Figure 66.26 is a comparison of Equation 66.19 with the data used by Shokri and Beyler [48] to develop Equation 66.19.

Figure 66.27 shows a comparison of the predicted and measured heat fluxes, using the best fit emissive power for each experiment (the value plotted in Fig. 66.26). Figure 66.27 shows that the cylindrical model is an excellent representation of the view factor over a wide range of conditions. Figures 66.26 and 66.27 together illustrate that the major uncertainty is in the definition of the emissive power and not in the view factor model. Figure 66.28 shows the overall performance of the model.

Summary of the Procedure for the Shokri and Beyler Pool Fire Radiation Method Estimating the thermal radiation field surrounding a fire involves the following steps based on the method developed by Shokri and Beyler [48]:

1. Determine the heat release rate, $\dot{Q}$.
2. Determine the height of the pool fire flame from Equation 66.14.
3. Calculate the view factor from Equation 66.17 (and Equation 66.18, if needed). If the target is above ground level, then a two cylinder representation is required. Alternatively, the precalculated view factors in Figs. 66.21, 66.22, 66.23, 66.24, and 66.25 may be used.
4. Determine the effective emissive power of the flame from Equation 66.19.
5. Calculate the radiative heat flux to the target using Equation 66.16.

Factor of Safety A safety factor of 2 is recommended for use with the Shokri and Beyler method [50]. Since this method is most applicable at heat fluxes greater than 5 kW/m^2, the

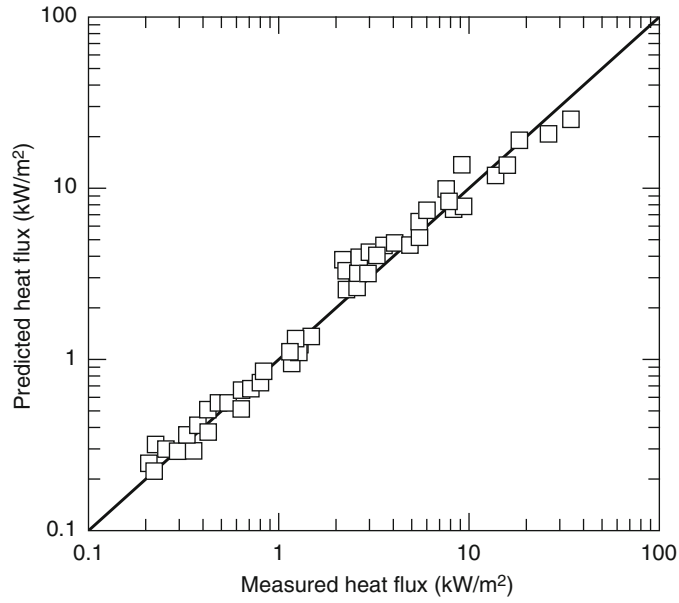

Fig. 66.27 Comparison of measured and calculated incident radiant heat flux using effective emissive powers. The *solid line* indicates equality of the measured and predicted heat fluxes based on the method developed by Shokri and Beyler [48]

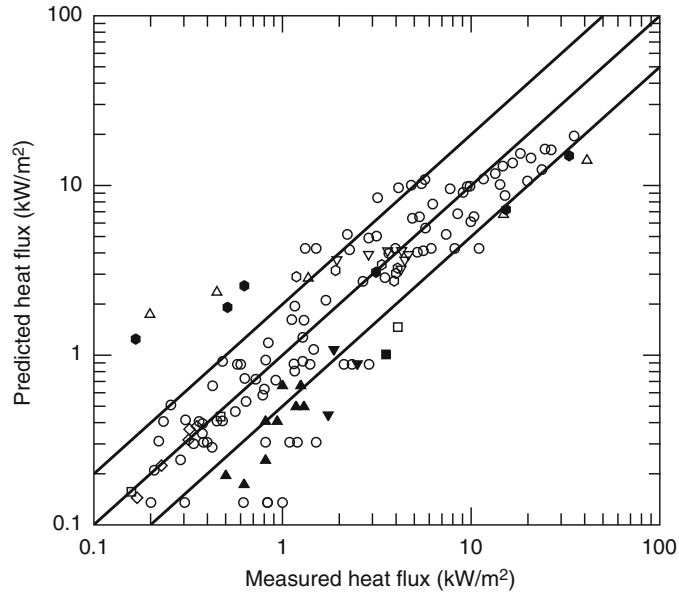

Fig. 66.28 Comparison of measured and calculated radiative heat flux from large pool fires using the detailed method developed by Shokri and Beyler [48]. *Solid lines* indicate equality of measured and predicted heat fluxes based on the method developed by Shokri and Beyler [48]

recommended factor of safety is applicable only for heat fluxes above this level. Figure 66.29 is a comparison of predicted and measured heat fluxes with the inclusion of the recommended factor of safety. The vertical line is located at the minimum heat flux for which the Shokri and Beyler model is recommended for use. Figure 66.24 clearly shows that essentially all of the data are overpredicted by the Shokri and Beyler model with a safety factor of 2 applied for heat fluxes greater than 5 kW/m^2. The safety factor of 2 is a recommendation for use in design applications. Where a realistic result is required, no safety factor should be applied.

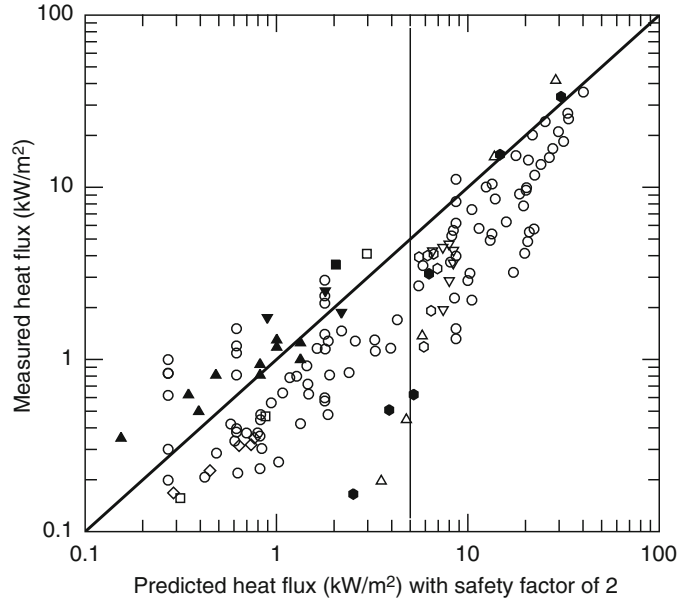

Fig. 66.29 Comparison of measured and calculated radiative heat flux from large pool fires using the detailed method developed by Shokri and Beyler and a safety factor of 2. *Solid lines* indicate equality of measured and predicted heat fluxes based on the detailed method developed by Shokri and Beyler [48] with a safety factor of 2

Mudan Method Mudan [14] has presented a method for estimating thermal radiation from pool fires for no-wind conditions and for wind-blown flames. The thermal radiation intensity to an element outside the flame envelope is given by the following equation:

$$\dot{q}'' = EF_{12}\tau \tag{66.20}$$

where

E = Average emissive power at flame surface, kW/m^2

F_{12} = View factor

τ = Atmospheric transmissivity

Equation 66.20 is used with the assumption that the flame is a vertical or tilted cylinder. This requires the flame diameter and height to be determined. The flame diameter is taken to be the pool diameter, D. See Fig. 66.30 for general nomenclature.

The flame height correlation used in this method is based on the correlation of mean visible height, H_f, of turbulent diffusion flames (in absence of wind) developed by Thomas [38]. The correlation for a circular fire is given by Equation 66.21:

$$\frac{H}{D} = 42\left(\frac{\dot{m}''_\infty}{\rho_a\sqrt{gD}}\right)^{0.61} \tag{66.21}$$

where

D = Pool diameter

$\dot{m}''_\infty$ = Mass burning rate per unit pool area, kg/m^{2}s

ρ_a = Ambient air density, kg/m^3

g = Gravitational acceleration, 9.8 m/s^2

If the pool has a length-to-width ratio near one, an equivalent-area circular source can be used for noncircular pools in the determination of the flame height. For noncircular pools, the effective diameter will be defined as the diameter of a circular pool with an area equal to the actual pool area, given by Equation 66.11 as

$$D = \sqrt{\frac{4A}{\pi}} \tag{66.11}$$

In the presence of wind, the flame length is given by the following correlation developed by Thomas [38] (Equation 66.22):

$$\frac{H}{D} = 55\left(\frac{\dot{m}''_\infty}{\rho_a\sqrt{gD}}\right)^{0.67} \left(u^*\right)^{-0.21} \tag{66.22}$$

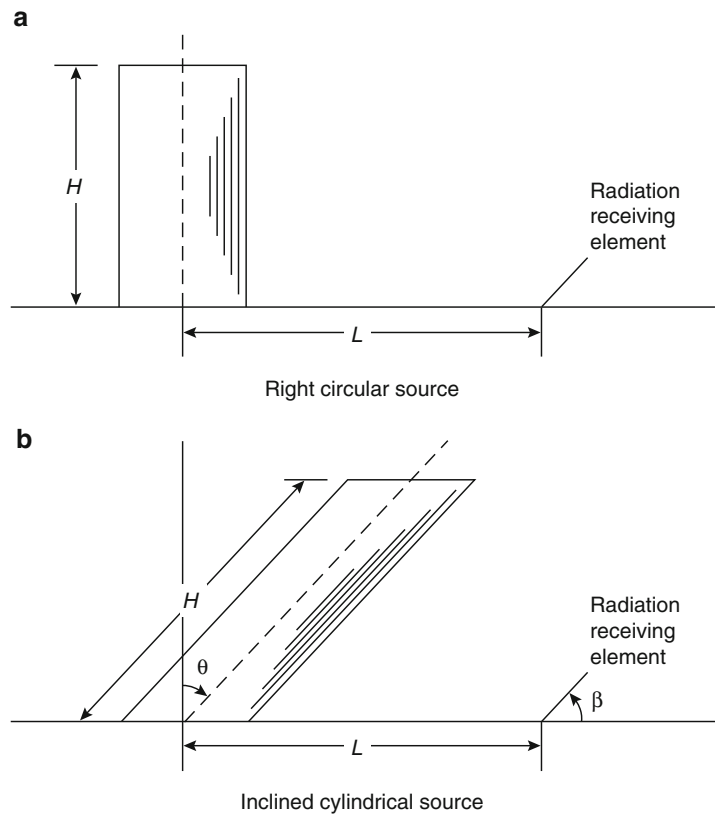

Fig. 66.30 Configuration factor calculation geometries for right and inclined cylinders

where u^* is the nondimensional wind velocity given by Equation 66.22:

$$u^* = \frac{u_w}{\left(g\dot{m}''_\infty D/\rho_a\right)^{1/3}} \tag{66.2}$$

where u_w is the wind speed, m/s, and ρ_a is the ambient density, kg/m^3.

In the presence of a significant wind, the flame may not remain vertical, and a flame tilt angle due to the wind is relevant to the assessment of radiation. The American Gas Association (AGA) [37] proposed the following correlation to determine the flame tilt (Equation 66.23):

$$\cos\theta = \begin{cases} 1 & \text{for } u^* \le 1 \\ 1/\sqrt{u^*} & \text{for } u^* \ge 1 \end{cases} \tag{66.23}$$

where u* is the nondimensional wind velocity given by Equation 66.19 with the wind velocity measured at a height of 1.6 m above the ground.

The turbulent flame is approximated by a cylinder. Under wind-free conditions, the cylinder is vertical (Fig. 66.30a). Under the influence of wind, the cylinder is assumed to be tilted (Fig. 66.30b). View factors for horizontal and vertical targets of a vertical cylinder for no-wind conditions are as follows:

$$F_{12,V} = \frac{1}{\pi S}\tan^{-1}\left(\frac{h}{\sqrt{S^2-1}}\right) - \frac{h}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}} + \frac{Ah}{\pi S\sqrt{A^2-1}}\tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}} \tag{66.24a}$$

$$F_{12,H} = \frac{(B-1/S)}{\pi\sqrt{B^2-1}}\tan^{-1}\sqrt{\frac{(B+1)(S-1)}{(B-1)(S+1)}} - \frac{(A-1/S)}{\pi\sqrt{A^2-1}}\tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}} \tag{66.24b}$$

where

$$S = \frac{2L}{D} \quad h = \frac{2H}{D}$$
$$A = \frac{h^2 + S^2 + 1}{2S} \quad B = \frac{1 + S^2}{2S}$$

and

L = Distance between the center of the pool fire and the target
H = Height of the pool fire
D = Pool fire diameter

If the target is either at ground level or at the flame height, then a single cylinder can represent the flame. If the target is above the ground, then two cylinders must be used to represent the flame. One cylinder represents the flame below the height of the target, and the other represents the flame above the height of the target. See Fig. 66.20 for an illustration of the nomenclature.

The overall view factor is the sum of the two component view factors.

The maximum configuration factor at a point is given by the vectorial sum of the horizontal and vertical target configuration factors given by Equation 66.18:

$$F_{12,\max} = \sqrt{F_{12,H}^2 + F_{12,V}^2} \tag{66.18}$$

The configuration exchange factor for windblown flame has been given by Mudan [57], who employed a contour integral approach developed by Sparrow [58] to determine closed-form equations for view factors from a tilted cylinder.

The view factor for a tilted cylindrical flame with a circular base is as follows:

$$\begin{aligned}\pi F_V = {} & \frac{a\cos\theta}{b - a\sin\theta}\frac{a^2 + (b+1)^2 - 2b(1 + a\sin\theta)}{\sqrt{AB}}\tan^{-1}\sqrt{\frac{A}{B}\left(\frac{b-1}{b+1}\right)}^{1/2} \\ & + \frac{\cos\theta}{\sqrt{C}} \times \left[\tan^{-1}\frac{ab - \left(b^2 - 1\right)\sin\theta}{\sqrt{b^2 - 1}\sqrt{C}} + \tan^{-1}\frac{\left(b^2 - 1\right)\sin\theta}{\sqrt{b^2 - 1}\sqrt{C}}\right] \\ & - \frac{a\cos\theta}{(b - a\sin\theta)}\tan^{-1}\sqrt{\frac{b-1}{b+1}}\end{aligned} \tag{66.25a}$$

$$\begin{aligned}\pi F_H = {} & \tan^{-1}\sqrt{\frac{b+1}{b-1}} \\ & - \frac{a^2 + (b+1)^2 - 2(b + 1 + ab\sin\theta)}{\sqrt{AB}} \times \tan^{-1}\sqrt{\frac{A}{B}\left(\frac{b-1}{b+1}\right)}^{1/2} \\ & + \frac{\sin\theta}{\sqrt{C}} \times \left[\tan^{-1}\frac{ab - \left(b^2 - 1\right)\sin\theta}{\sqrt{b^2 - 1}\sqrt{C}} + \tan^{-1}\frac{\left(b^2 - 1\right)^{1/2}\sin\theta}{\sqrt{C}}\right]\end{aligned} \tag{66.25b}$$

where

$a = H/R$
$b = L/R$
$A = a^2 + (b+1)^2 - 2a(b+1)\sin\ \theta$
$B = a^2 + (b-1)^2 - 2a(b-1)\sin\ \theta$
$C = 1 + \left(\mathrm{b}^2 - 1\right)\cos^2\theta$

When the angle of tilt is zero, Equations 66.25a and 66.25b reduce to Equations 66.24a and 66.24b, respectively. The maximum configuration factors at the target location are determined using Equation 66.18. Figures 66.31 and 66.32 show the calculated configuration factor for no-wind conditions and underwind conditions for a target at ground level. For the no-wind condition, Fig. 66.20 can also be used to determine the view factor for a more general set of target locations.

The emissive power, E, of the flame is given by the following correlation:

$$E = E_{\max}\mathrm{e}^{-sD} + E_s\left[1 - \mathrm{e}^{-sD}\right] \tag{66.26}$$

where

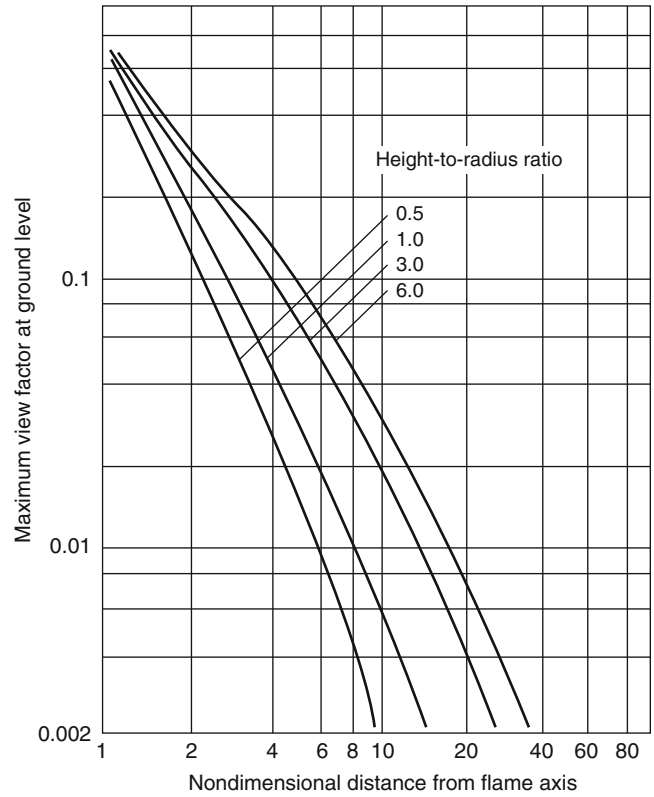

Fig. 66.31 Maximum configuration factors for a ground-level object from a right circular cylinder. The nondimensional distance from the flame is L/R

E = Equivalent blackbody emissive power, 140 kW/m^2
s = Extinction coefficient, 0.12 m^{-1}
D = Equivalent pool diameter, m
E_s = Emissive power of smoke, 20 kW/m^2

Atmospheric Absorption

The radiation from the fire to surrounding objects will be partially attenuated by absorption and scattering along the intervening path. The principal constituents of the atmosphere that absorb thermal radiation are water vapor (H_2O) and carbon dioxide (CO_2). Table 66.3 indicates the composition of various gases in the atmosphere. The CO_2 content in the atmosphere is generally constant at about 330 ppm by volume. The water vapor content varies strongly with temperature and humidity. Figure 66.33 indicates the relationship between atmospheric temperature, relative humidity, and the amount of precipitable water vapor in a given pathlength.

The principal absorption bands for water vapor are at 1.8, 2.7, and 6.27 μm. Minor absorption bands also exist at 0.94, 1.1, 1.38, and 3.2 μm. Strong absorption by CO_2 exists in the 2.7 μm region, the 4.3 μm region, and the region between 11.4 and 20 μm. Weaker absorption bands are present at 1.4, 1.6, 2.0, 4.8, 5.2, 9.4, and 10.4 μm. As the temperature of the emitting or absorbing species increases, the bands tend to broaden.

A useful concept for the quick estimation of atmospheric absorption of continuum radiation is the "equivalent bandwidth of complete absorption." One calculates the integral of absorption over an absorption band and interprets the result as the width of a "rectangular," *complete* absorption band equivalent to the real band profile. For a continuum source, the effect of such opaque bands is then easy to estimate. Three absorption

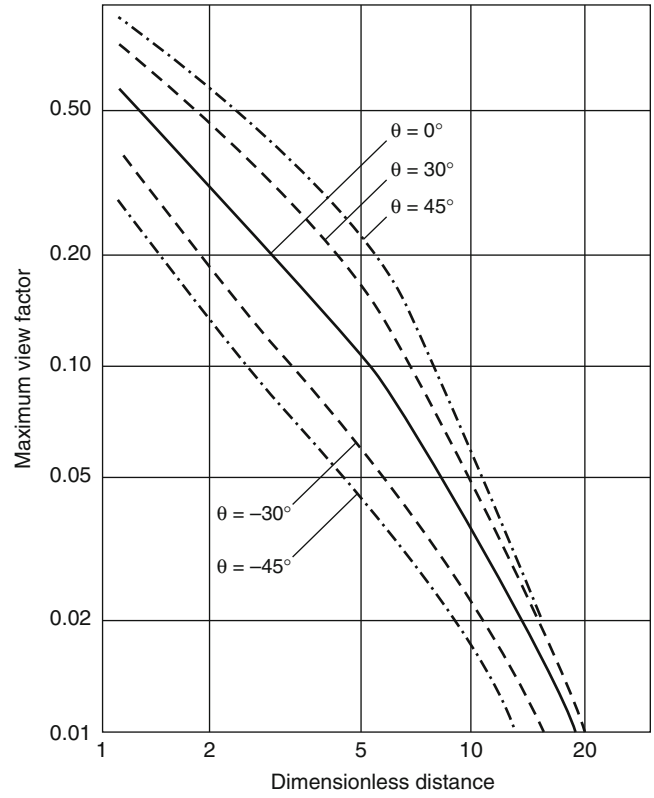

Fig. 66.32 Maximum configuration factors for tilted circular cylinders with targets at ground level. The dimensionless distance is L/R

bands in the range of interest (5.5 m → 5.5 μm) can be described in this way. These are the water vapor bands at 1.87 and 2.7 μm and the 4.3 μm, CO_2 band. The water absorption beyond about 4.7 μm is not as readily dealt with, because the band structure is not narrow compared to the range of interest. However, the fraction of total energy from a 1300 K blackbody that lies beyond 4.7 μm is about 25 % and that beyond 5.5 μm is only 19%. The results of total absorption bandwidth calculations for the above three bands of interest are given in Tables 66.4 and 66.5. These calculations are based on the data available in the *Infrared Handbook* [59]. Also given in the tables are the fractions of a 1300 K blackbody energy that will be absorbed in each of these bands.

The absorption by the water vapor and carbon dioxide in a certain length of the atmosphere of blackbody radiation from a source can also be

Table 66.3 Composition of constituent gases in the atmosphere and their concentrations

Constituent gas	Concentration in atmosphere (% by volume)
Nitrogen	78.088
Oxygen	20.949
Argon	0.93
Carbon dioxide	0.033
Neon	1.8 × 10−3

Pathlength through the atmosphere (m)	Total absorption bandwidth Δλ (μm)	Fraction of 1300 K blackbody energy absorbed
1000	0.28	0.04
100	0.22	0.03
10	0.17	0.02
1	0.065	0.01
0.3	0.033	0.004

calculated using the emissivity charts published by Hottel and Sarofim [60]. The procedure to calculate the absorption in the water vapor band is as follows:

1. Determine the partial pressure of water vapor, in atmospheres, based on

$$p_w' = \frac{RH}{100}\exp\left(14.4114 - \frac{5328}{T_a}\right) \qquad (66.27)$$

where RH is the relative humidity and T_a is the ambient temperature in Kelvin.

2. Define a pathlength, L (in m), from the flame surface to observer. Determine the partial pressure-pathlength parameter:

$$p_w L = p_w' L(T_s/T_s) \qquad (66.28)$$

where
T_s = Source surface temperature (K)
T_a = Ambient temperature (K)

3. For the source temperature, and $p_w L$, determine the water vapor emissivity, ε_w, using emissivity plots given in Fig. 66.34.
4. Calculate the water vapor absorption coefficient.

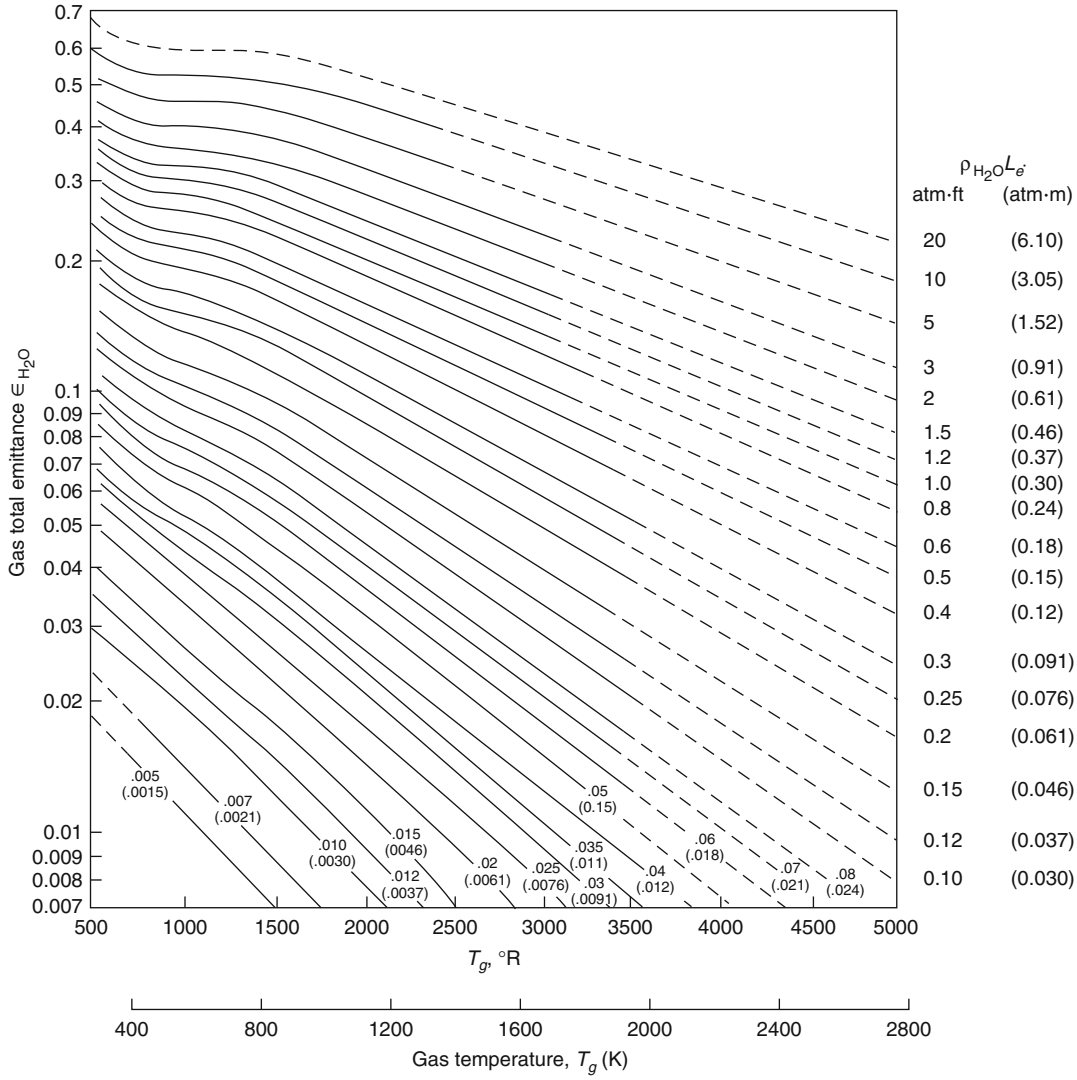

Fig. 66.34 Total emissivity of water vapor in a mixture of total pressure of 1 atm [60]

$$\alpha_w = \varepsilon_w (T_a/T_s)^{0.45} \tag{66.29}$$

The procedure to determine the absorption by carbon dioxide is very similar. The partial pressure of CO_2 remains relatively constant at about 3×10^{-4} atm. The absorption coefficient is given by

$$\alpha_c = \varepsilon_c (T_a/T_s)^{0.65} \tag{66.30}$$

The emissivity of the carbon dioxide band is shown in Fig. 66.35. There is also a correction factor due to spectral overlap for the calculation of emissivity of a CO_2-H_2O mixture. This effect, however, accounts for a change in emissivity of about 5 % at 1200 K and even less at higher temperatures [60].

The transmissivity is given by

$$\tau = 1 - \alpha_w - \alpha_c \tag{66.31}$$

and is used in determining the thermal radiation hazard. The procedure outlined in this section may be simplified further if it is assumed that the flame temperature and the ambient temperature remain constant. For most hydrogen fuels,

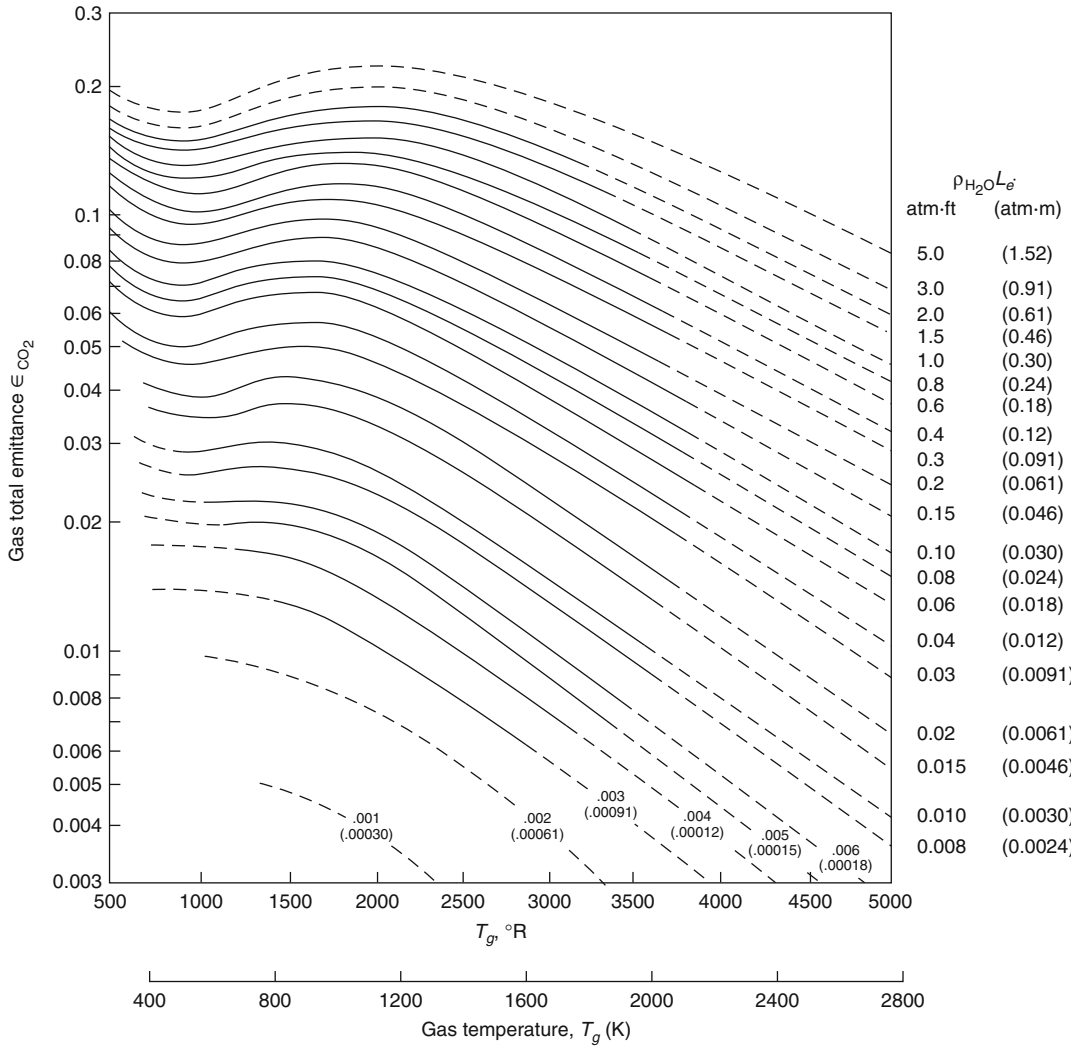

Fig. 66.35 Total emissivity of carbon dioxide in a mixture of total pressure of 1 atm [60] where p_{CO_2} is the partial pressure of carbon dioxide and L_e is the equivalent pathlength

the flame temperature is approximately 1400 K. If it is assumed that the typical ambient temperature is 293 K (20 °C) the transmissivity may be plotted as a function of pathlength. In Fig. 66.36 the transmissivity is shown as a function of pathlength for various relative humidities. Figure 66.36 provides a quick estimate of atmospheric absorption of thermal radiation.

Summary of the Procedure for the Mudan Pool Fire Radiation Method Estimating the thermal radiation field surrounding a fire involves the following steps based on the method developed by Mudan [14]:

1. Determine the height of the pool fire flame and tilt angle from Equations 66.2, 66.21, 66.22, and 66.23.
2. Calculate the configuration factor from Equations 66.18, 66.24, and 66.19. Figures 66.21, 66.22, 66.23, 66.24, and 66.25, 66.31, or 66.32 may be used where appropriate.
3. Determine the effective emissive power of the flame from Equation 66.26.

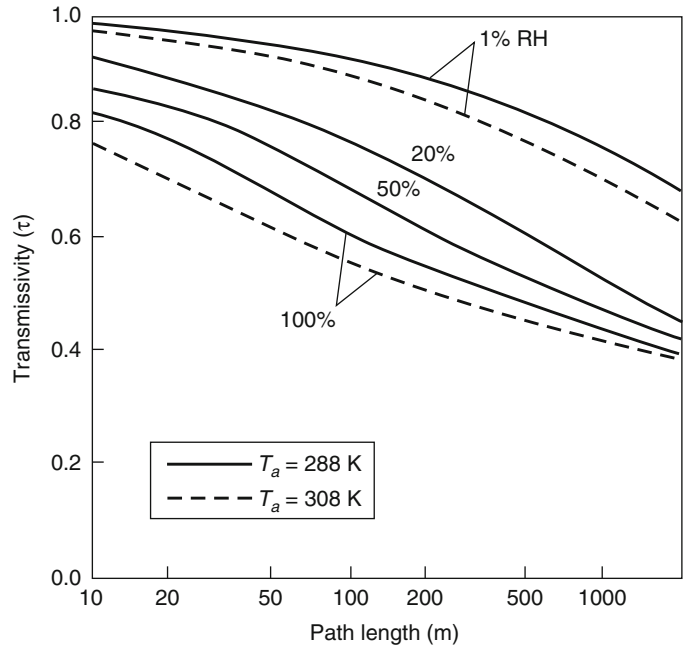

Fig. 66.36 Transmissivity as a function of pathlengths; source temperature 1400 K

4. Calculate the radiative heat flux to target using Equation 66.20.

Figure 66.37 shows a comparison of data with the predictions of this method [50]. The predictions tend to be conservative, and the differences between measured and predicted values are relatively uniform over the full range of heat fluxes. No validation data are available for wind-tilted conditions.

A safety factor of 2 is recommended for use with the Mudan method [50]. Figure 66.38 is a comparison of predicted and measured heat fluxes with the inclusion of the recommended factor of safety. Figure 66.33 clearly shows that essentially all the data are overpredicted by the Mudan model with a safety factor of 2. The safety factor of 2 is a recommendation for use in design applications. Where a realistic result is required, no safety factor should be applied.

Summary and General Recommendations

Table 66.6 summarizes the methods included in this section and their ranges of applicability. All the methods used with the indicated safety factors provide conservative results. However, the variations in the predicted versus measured heat fluxes (i.e., the goodness of fit) vary considerably between methods. Methods that minimize these variations are inherently more reliable in that the method better explains the experimental data. The methods that minimize the variation are the point source model and the Shokri and Beyler method, when used in their applicable ranges. Table 66.7 shows the correlation coefficient of each method over the indicated ranges of application. The methods with the greatest correlation coefficient better explain the variations observed in the database. Although at less than 5 kW/m^2 there is little difference between the performance of the point source model and the Mudan [14] model, the simplicity of the point source model argues for its use.

The point source model and the Shokri and Beyler model are the preferred models based on both the conservative nature of these methods and the minimization of the variations between the data and the experiments.

Because heat fluxes below 5 kW/m^2 cannot lead to ignition of combustibles, any analysis involving a combustible target should be performed using the Shokri and Beyler model.

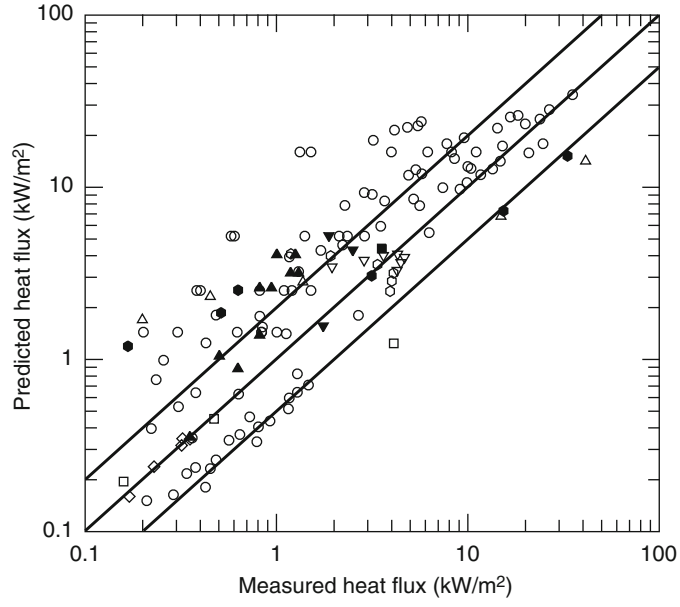

Fig. 66.37 Comparison of measured and calculated radiative heat flux from large pool fires using the detailed method developed by Mudan [14]. *Solid lines* indicate equality of measured and predicted heat fluxes based on the detailed method developed by Mudan [14]

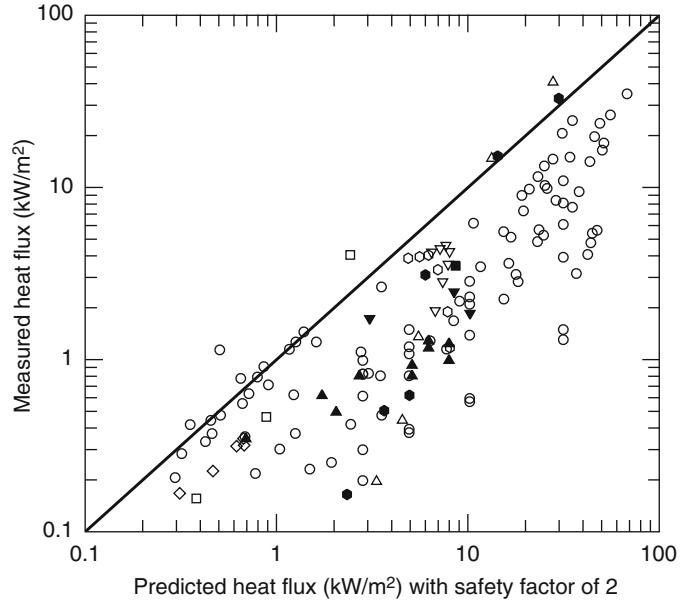

Fig. 66.38 Comparison of measured and calculated radiative heat flux from large pool fires using the detailed method developed by Mudan with a safety factor of 2. *Solid lines* indicate equality of measured and predicted heat fluxes based on the detailed method developed by Mudan with a safety factor of 2 [14]

Table 66.6 Summary of the methods

Method	Range of use (kW/m^2)	Recommended safety factor	Preferred methods
Shokri and Beyler correlation	All heat fluxes, ground level only	2	–
Point source model	0–5 kW/m^2	2	$\leq$5 kW/m^2
Shokri and Beyler model	$\geq$5 kW/m^2	2	$\geq$5 kW/m^2
Mudan model	All heat fluxes	2	–

Table 66.7 Correlation coefficients for the methods

Heat-flux calculation method	Correlation coefficient	Correlation coefficient with safety factor
Point source model (below 5 kW/m^2)	0.51	0.38
Mudan model (below 5 kW/m^2)	0.53	0.34
Shokri and Beyler model (above 5 kW/m^2)	0.52	0.66
Mudan model (above 5 kW/m^2)	0.35	0.57

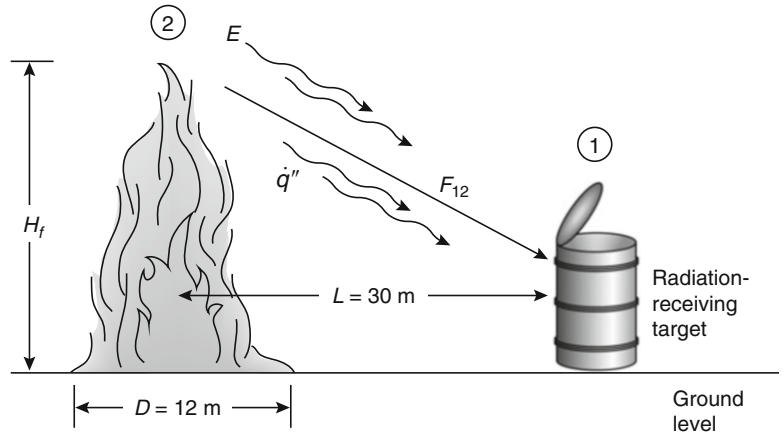

Fig. 66.39 Toluene pool fire with target at ground level

Because pain and second-degree burns can occur at 5 kW/m^2, many analyses involving human exposure can be performed using the simple point source model. If exposure is less than 1 min, it may be necessary to use the more complex Shokri and Beyler model for human exposure.

Illustration of the calculation procedure: In this section two sample calculations are presented to illustrate the calculation procedure for the thermal radiation from pool fires.

Example 1 Toluene from a tank is assumed to spill to form a pool in a diked area of 12 m diameter. The distance from the center of the pool fire to the target edge is assumed to be 30 m.

Calculate flame radiative heat flux to the target at ground level with no wind (Fig. 66.39) using:

(a) Shokri and Beyler correlation
(b) Point source model
(c) Shokri and Beyler detailed method using shape factor algebra
(d) Mudan detailed method using shape factor algebra

CALCULATION PROCEDURE

Properties of toluene (Chap. 26):

Heat of combustion, $\Delta H_c = 40{,}550$ kJ/kg

Mass burning rate, $\dot{m}''_\infty = 0.1126$ °kg/m$^2 \cdot$ s

Properties of air at 20 °C, $\rho_a = 1.2$ kg/m^3

(a) Heat flux from the Shokri and Beyler correlation, Equation 66.10:

$$\dot{q}'' = 15.4\left(\frac{L}{D}\right)^{-1.59}$$

where $L = 30$ m and $D = 12$ m. Therefore, heat flux to the target is

$$\dot{q}'' = 15.4\left(\frac{30}{12}\right)^{-1.59} = 3.6 \text{ kW/m}^2$$

(b) Heat flux from point source model, Equation 66.12:

$$\dot{q}'' = \frac{\dot{Q}_r \cos\theta}{4\pi R^2}$$

The radiative energy output, $\dot{Q}_r$, is given by the

radiative fraction, χ_r, multiplied by the total heat release rate, $\dot{Q}$, from Equation 66.15:

$$\dot{Q}_r = \chi_r \dot{Q}$$

Figure 66.18 can be used to determine χ_r from curve fit to the experimental data as

$$\chi_r = 0.21 - 0.0034D$$

and $\dot{Q}$, total heat release rate, is given by

$$\dot{Q} = \dot{m}''_\infty \Delta H_c A$$

and A, area of the pool, can be expressed from Equation 66.11:

$$A = \frac{\pi}{4} D^2$$

Combining the above equations yields

$$\dot{Q}_r = (0.21 - 0.0034D)\left(\dot{m}''_\infty \Delta H_c \frac{\pi}{d} D^2\right)$$
$$= 87,371 \text{ kW}$$

The distance, R, from the point source location to the target location is given by the Pythagorean theorem, Equation 66.14:

$$R = \sqrt{L^2 + H_T{}^2}$$

where $L = 30$ m and H_T is given by

$$H_T = \frac{H}{2}$$

H is the height of the flame from Equation 66.13:

$$H = 0.23\dot{Q}^{2/5} - 1.02D = 32.11 \text{ m}$$

$$\mathrm{H}_T = \frac{0.23\left(\dot{m}''_\infty \Delta H_c (\pi/4) D^2\right)^{2/5} - 1.02D}{2} = 16 \text{ m}$$

$$R = \sqrt{30^2 + 16^2} = 34 \text{ m}$$

The angle, θ, between the normal to the target and the line of sight from the point source location can be estimated as

$$\theta = \tan^{-1}\left(\frac{1H}{2L}\right) = 0.49 \text{ rad}$$

The heat flux from the point source model is

$$\dot{q}'' = \frac{\dot{Q}_r \cos\theta}{4\pi R^2} = \frac{87,371 \times \cos(0.49)}{4 \times \pi \times 34^2}$$
$$= 5.3 \text{ kW/m}^2$$

(c) Heat flux from the Shokri and Beyler detailed method using shape factor algebra with target at ground level and no wind, Equation 66.16:

$$\dot{q}'' = EF_{12}$$

The emissive power of the flame, E, is given by Equation 66.19:

$$E = 58\left(10^{-0.00823D}\right)$$
$$E = 58\left(10^{-0.00823 \times 12}\right) = 46.2 \text{ kW/m}^2$$

Equation 66.17a can be used to determine the shape factor in the horizontal direction:

$$F_{12,H} = \frac{[B - (1/S)]}{\pi\sqrt{B^2 - 1}} \tan^{-1}\sqrt{\frac{(B+1)(S-1)}{(B-1)(S+1)}}$$
$$- \frac{[A - (1/S)]}{\pi\sqrt{A^2 - 1}} \tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}}$$

Equation 66.17b can be used to determine the shape factor in the vertical direction:

$$F_{12,V} = \frac{1}{\pi S}\tan^{-1}\left(\frac{h}{\sqrt{S^2 - 1}}\right) - \frac{h}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}}$$
$$+ \frac{Ah}{\pi S\sqrt{A^2 - 1}}\tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}}$$

where

$$S = \frac{2L}{D} = \frac{2 \times 30}{12} = 5$$
$$H_f = 0.23\dot{Q}^{2/5} - 1.02D = 32.11 \text{ m}$$
$$h = \frac{2H_f}{D} = \frac{2 \times 32.11}{12} = 5.35$$
$$A = \frac{h^2 + S^2 + 1}{2S} = \frac{5.35^2 + 5^2 + 1}{2 \times 5} = 5.46$$
$$B = \frac{(1 + S^2)}{2S} = 2.6$$

Substituting values of A, B, S, and h in the shape factor equation to determine $F_{12,H}$ and $F_{12,V}$, the $F_{12,H}$ is equal to 0.039, and $F_{12,V}$ is equal to 0.088.

The maximum shape factor at a point is given by the vectorial sum of the horizontal and vertical shape factors:

$$F_{12,\max} = \sqrt{F_{12,H}^2 + F_{12,V}^2}$$

Therefore, the maximum shape factor at a point is equal to 0.097. Therefore, heat flux to the target is

$$\dot{q}'' = EF_{12,\max} = 48 \times 0.097 = 4.5 \text{ kW/m}^2$$

(d) Heat flux from the Mudan detailed method using shape factor algebra with target at ground level and no wind, Equation 66.20:

$$\dot{q}'' = EF_{12}\tau$$

The emissive power of the flame, E, is given by Equation 66.26:

$$E = E_{\max} e^{-sD} + E_s(1 - e^{-sD})$$
$$E = 140e^{-0.12 \times 12} + 20(1 - e^{-0.21 \times 12}) = 48.43 \text{ kW/m}^2$$

Equation 66.24a can be used to determine the shape factor in the horizontal direction:

$$F_{12,H} = \frac{[B - (1/S)]}{\pi\sqrt{B^2 - 1}} \tan^{-1}\sqrt{\frac{(B+1)(S-1)}{(B-1)(S+1)}} - \frac{[A - (1/S)]}{\pi\sqrt{A^2 - 1}} \tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}}$$

and Equation 66.24b can be used to determine the shape factor in the vertical direction:

$$F_{12,V} = \frac{1}{\pi S}\tan^{-1}\left(\frac{h}{\sqrt{S^2-1}}\right) - \frac{h}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}} + \frac{Ah}{\pi S\sqrt{A^2-1}}\tan^{-1}\sqrt{\frac{(A+1)(S-1)}{(A-1)(S+1)}}$$
$$H_f = 42D\left(\frac{\dot{m}''_\infty}{\rho_a\sqrt{gD}}\right)^{0.61} = 27.79 \text{ m}$$
$$h = \frac{2H_f}{D} = \frac{2 \times 27.79}{12} = 4.63$$
$$S = \frac{2L}{D} = \frac{2 \times 30}{12} = 5$$
$$A = \frac{h^2 + S^2 + 1}{2S} = \frac{4.63^2 + 5^2 + 1}{2 \times 5} = 4.74$$
$$B = \frac{(1 + S^2)}{2S} = 2.6$$

Substituting values of A, B, S, and h in the shape factor equation to determine $F_{12,H}$ and $F_{12,V}$, $F_{12,H}$ is equal to 0.035, and $F_{12,V}$ is equal to 0.084.

The maximum shape factor at a point is given by the vectorial sum of the horizontal and vertical shape factors:

$$F_{12,\max} = \sqrt{F_{12,H}^2 + F_{12,V}^2}$$

Therefore, the maximum shape factor at a point is equal to 0.091.

Therefore, heat flux to the target is

$$\dot{q}'' = EF_{12,V}\tau = 48.43 \times 0.091 \times 1 = 4.45 \text{ kW/m}^2$$

Table 66.8 summarizes the results for each of the methods.

EXAMPLE 2 Calculate flame radiative heat flux from a 10-m-diameter toluene pool fire to a vertical target 2 m above the ground at 12 m from the center of the pool (Fig. 66.40) with no wind, using:

(a) Shokri and Beyler method using shape factor algebra
(b) Mudan method using shape factor algebra

CALCULATION PROCEDURE

(a) Heat flux from the Shokri and Beyler detailed method using shape factor algebra with target height 2 m above ground level and no wind

Properties of toluene (Chap. 26)

Heat of combustion, $\Delta H_c = 40{,}550$ kJ/kg

Mass burning rate, $\dot{m}''_{\infty} = 0.1126°\text{kJ/kg}$

Properties of air at 20 °C $\rho_a = 1.2$ kg/m^3

Heat flux is given by Equation 66.16:

$$\dot{q}'' = EF_{12}$$

The emissive power of the flame, E, is given by Equation 66.19:

$$E = 58\left(10^{-0.00823D}\right)$$
$$E = 58\left(10^{-0.00823\times 10}\right) = 48 \text{ kW/m}^2$$

The flame height, H, is given by Equation 66.13:

$$H = 0.23\dot{Q}^{2/5} - 1.02D$$

where

$$\dot{Q} = \dot{m}''_{\infty}\ \Delta H_c A \text{ kW}$$

$$\dot{Q} = 360{,}000 \text{ kW}$$

$$H = 28 \text{ m}$$

Because the target is above the ground, but it is not at the flame height, two cylinders must be used to represent the flame. Because the target is strictly vertical, it is not necessary to calculate the horizontal shape factor.

The shape factor for the target located above ground level can be calculated from Figs. 66.21, 66.22, 66.23, 66.24, and 66.25 or by the following method. For the vertical target, Equation 66.17b can be used to determine the shape factor at location H_{f1}:

Table 66.8 Summary of the heat flux from 12-m-diameter toluene pool fire to 30 m target at ground level with no wind

Heat flux calculation method	Heat flux (kW/m^2)
(a) Shokri and Beyler correlation	3.6
(b) Point source model	5.3
(c) Shokri and Beyler method using shape factor algebra	4.5
(d) Mudan method using shape factor algebra	4.45

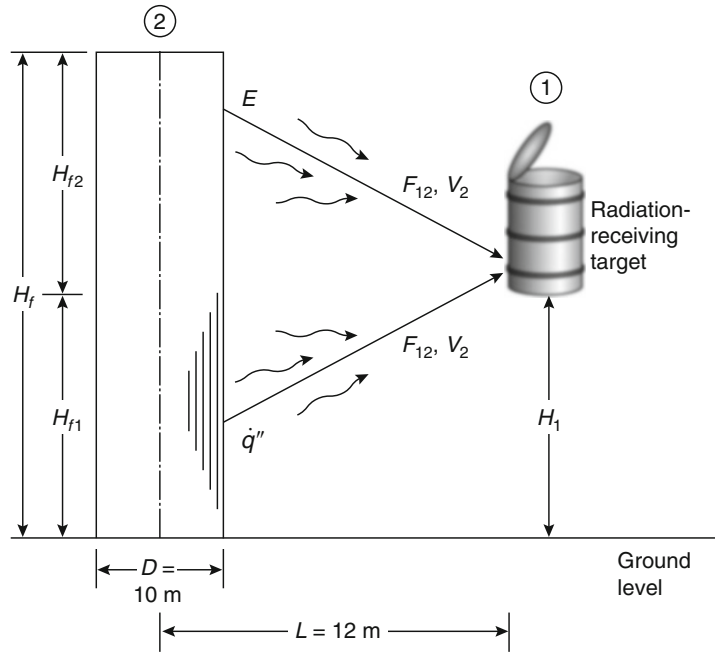

Fig. 66.40 Toluene pool fire with target above ground level

$$F_{12,V1} = \frac{1}{\pi S}\tan^{-1}\left(\frac{h}{\sqrt{S^2-1}}\right) - \frac{h_1}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}} + \frac{A_1 h_1}{\pi S\sqrt{A_1^2-1}}\tan^{-1}\sqrt{\frac{(A_1+1)(S-1)}{(A_1-1)(S+1)}}$$

$$S = \frac{2L}{D} = \frac{2\times 12}{10} = 2.4$$

$$H_{f1} = \frac{2H_{f1}}{D} = \frac{2\times 2}{10} = 0.4$$

$$A_1 = \frac{H_{f1}^2 + S^2 + 1}{2S} = \frac{0.4^2 + 2.4^2 + 1}{2\times 2.4} = 1.44$$

Substituting values of A_1, S, and H_{f1} in the shape factor equation to determine $F_{12,V1}$, the $F_{12,V1}$ is equal to 0.066. Shape factor at location $H_{f\,2}$ is given by

$$F_{12,V2} = \frac{1}{\pi S}\tan^{-1}\left(\frac{H_{f2}}{\sqrt{S^2-1}}\right) - \frac{H_{f2}}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}} + \frac{A_2 H_{f2}}{\pi S\sqrt{A_2^2-1}}\tan^{-1}\sqrt{\frac{(A_2+1)(S-1)}{(A_2-1)(S+1)}}$$

$$S = \frac{2L}{D} = \frac{2\times 12}{10} = 2.4$$

$$H_{f2} = \frac{2H_{f2}}{D} = \frac{2\left(H_f - H_{f1}\right)}{D} = \frac{2(28-2)}{10} = 5.2$$

$$A_2 = \frac{H_{f2}^2 + S^2 + 1}{2S} = \frac{5.2^2 + 2.4^2 + 1}{2\times 2.4} = 7.04$$

Substituting values of A_2, S, and $H_{f\,2}$ in the shape factor equation to determine $F_{12,V2}$, $F_{12,V2}$ is equal to 0.206. Therefore, total shape factor is given by

$$F_{12,V} = F_{12,V1} + F_{12,V2} = 0.066 + 0.206 = 0.27$$

Therefore, heat flux to the target at 2 m above ground is

$$\dot{q}'' = EF_{12,V} = 48\times 0.27 = 13.0\ \text{kW/m}^2$$

(b) Heat flux from Mudan [14] method using shape factor algebra with target height 2 m above ground level and no wind

Heat flux is given by Equation 66.20:

$$\dot{q}'' = EF_{12}\tau$$

The emissive power of the flame, E, is given by Equation 66.20:

$$E = E_{\max}\mathrm{e}^{-sD} + E_s\left(1-\mathrm{e}^{-sD}\right)$$

$$E = 140\mathrm{e}^{-0.12\times 10} + 20\left(1-\mathrm{e}^{-0.21\times 10}\right) = 56.14\ \text{kW/m}^2$$

The flame height, H, is given by Equation 66.21:

$$H_f = 42D\left(\frac{\dot{m}''_\infty}{\rho_a\sqrt{gD}}\right)^{0.61} = 25.4 \text{ m}$$

Because the target is above the ground, but it is not at the flame height, two cylinders must be used to represent the flame. Because the target is strictly vertical, it is not necessary to calculate the horizontal shape factor.

The shape factor for the target located above ground level can be calculated from Figs. 66.21, 66.22, 66.23, 66.24, and 66.25 or by the following method. For the vertical target, Equation 66.24a can be used to determine the shape factor at location H_1:

$$F_{12,V1} = \frac{1}{\pi S}\tan^{-1}\left(\frac{H_1}{\sqrt{S^2-1}}\right) - \frac{H_1}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}} + \frac{A_1H_1}{\pi S\sqrt{A_1^2-1}}\tan^{-1}\sqrt{\frac{(A_1+1)(S-1)}{(A_1-1)(S+1)}}$$

$$S = \frac{2L}{D} = \frac{2\times 12}{10} = 2.4$$

$$H_1 = \frac{2L}{D} = \frac{2\times 2}{10} = 0.4$$

$$A_1 = \frac{H_1^2+S^2+1}{2S} = \frac{0.4^2+2.4^2+1}{2\times 2.4} = 1.44$$

Substituting values of A_1, S, and h_1 in the shape factor equation to determine $F_{12,V1}$, $F_{12,V1}$, is equal to 0.066.

Shape factor at location H_2 is given by

$$F_{12,V2} = \frac{1}{\pi S}\tan^{-1}\left(\frac{H_2}{\sqrt{S^2-1}}\right) - \frac{H_2}{\pi S}\tan^{-1}\sqrt{\frac{(S-1)}{(S+1)}} + \frac{A_2H_2}{\pi S\sqrt{A_2^2-1}}\tan^{-1}\sqrt{\frac{(A_2+1)(S-1)}{(A_2-1)(S+1)}}$$

$$S = \frac{2L}{D} = \frac{2\times 12}{10} = 2.4$$

$$h_2 = \frac{2H_{f2}}{D} = \frac{2\left(H_f - \mathbf{H}_{f1}\right)}{10} = \frac{2(24.5-2)}{10} = 4.5$$

$$A_2 = \frac{H_2^2+S^2+1}{2S} = \frac{4.5^2+2.4^2+1}{2\times 2.4} = 5.62$$

Table 66.9 Summary of the heat flux from 10-m-diameter toluene pool fire to 12 m target at 2 m high above ground level with no wind

Heat flux calculation method	Heat flux (kW/m^2)
(a) Shokri and Beyler method using shape factor algebra	13.0
(b) Mudan method using shape factor algebra	15.2

Substituting values of A_2, S, and h_2 in the shape factor equation to determine $F_{12,V1}$, $F_{12,V2}$ is equal to 0.206. Therefore, total shape factor is given by

$$F_{12,V} = F_{12,V1} + F_{12,V2} = 0.066 + 0.188 = 0.27$$

Therefore, heat flux to the target at 2 m above ground is

$$\dot{q}'' = EF_{12,V} = 56.14 \times 0.25 = 15.2 \text{ kW/m}^2$$

Table 66.9 summarizes the results for each of these methods.

Heat Transfer to Targets Within Pool Fires

Temperatures within pool fires have been widely measured and reported [61]. Over a very wide range of pool sizes (0.1–50 m diameter), the maximum time-averaged flame temperatures are generally observed to be approximately 900–1100 °C. Table 66.10 shows measured maximum average temperatures reported in the literature. This maximum has been found to be remarkably independent of the fuel. The maximum time-averaged temperature is observed on the pool centerline over approximately the lower 40 % of the flame height.

Effective radiation temperatures can be measured with optical pyrometers, narrow angle radiometers, or scanning spectrometers. These measurements tend to yield maximum, average, effective radiation temperatures somewhat larger than the actual maximum temperatures, up to 1200 °C (see Wayne and Kinsella [69], Hägglund and Persson [18]), which is a reflection of the fourth-power dependence of radiation on temperature. The radiation is affected by the maximum temperature excursions rather than simply the average. Effective radiation temperatures measured outside the flame can be significantly lower than this due to obscuration by smoke outside the flame.

Table 66.10 Maximum time-averaged temperatures of pool fires

Investigator	°C
Cox and Chitty [62]	1000
McCaffrey [63]	820
Terai and Nitta [72]	770
Kung and Stavrianidis [65]	920
Hägglund and Persson [18]	1000
Russell and Canfield [66]	1100
Gregory et al. [72]	1000
Johnson et al. [32]	1200
Anderson et al. [68]	1000

Average fluxes to objects immersed in flames have been widely measured. Most of the work that has been reported was performed to assess the energy input to liquid tanks for the purpose of determining venting requirements while the remainder of the work has been performed to assess the heating of weapons and nuclear fuel containers. Most of this work has focused on objects located in the lower portions of the flame where the maximum temperatures and fluxes are expected. Table 66.11 summarizes the results of a number of investigations and assessments of existing data. Based on the available data, a maximum time-averaged heat flux of 120 kW/m^2 is a reasonable, conservative representation of the available data. These investigations include data in which the size of the object was small relative to the size of the flame, but the objects were sized to represent tanks and/or weapons. The object was fully immersed in optically thick flames on all sides.

Measurements made with objects comparable inside to the pool fire are far less common (Taylor et al. [70], McLain [71]). Heat fluxes in this situation are less than those observed when the object is much smaller than the pool fire. This

Table 66.11 Large-scale pool fire maximum average heat-flux measurements

Gregory et al. [72]	160

[a]Object site comparable to pool fire

results from the reduced flame pathlengths observed. The flames are not uniformly optically thick as seen by the object. Measurements of heating rates to objects on the order of 1–3 m in size heated by comparably sized pool fires result in average heat fluxes in the range of 75–85 kW/m^2 (see Table 66.11). These heat fluxes were deduced from measured rates of the temperature of tank contents.

The extinction coefficient, k, of pool fires has been measured by several investigators. Typically, pool fires are found to have average extinction coefficients of about 2 1/m. An extinction coefficient of 2 1/m is consistent with the observation that pool fires reach their asymptotic, radiatively dominated burning rate at pool diameters of 1 m.

The effect of the object size on flame heat fluxes has not been systematically studied. However, it has been observed that larger objects, even if significantly smaller than the flame, do yield smaller heat fluxes than smaller objects. Gregory et al. [72] have observed this effect in 9 × 18 m pool fires with objects up to 1.4 m in diameter. They found fluxes to 1.4-m-diameter calorimeters were 30–40 % less than for 0.1–0.2-m-diameter calorimeters. Similarly, measurements using conventional heat-flux transducers (Gardon or Schmidt/Boelter) tend to yield higher fluxes than observed with calorimeters, which are sized to represent normal tanks or weapons. Table 66.11 summarizes available heat-flux data as measured with small calorimeters. It is thought that these effects result from two phenomena. First, the larger calorimeters effectively average the fluxes over the size of the calorimeter. This spacial averaging process tends to reduce the measured fluxes. Second, the larger calorimeters can significantly perturb the flame in the region surrounding the calorimeter, yielding reduced temperatures surrounding the calorimeter. The size of the region affected scales with the diameter of the calorimeter. With small calorimeters, this length is small compared to 1/k so that the radiant fluxes are not much affected. For large calorimeters, the reduction in local flame temperature may be significant over radiative length scales, and radiant fluxes are reduced.

Most measurements that have been performed have been made in the center of the flame where the highest fluxes are expected. Relatively few measurements have been made within the flame near the flame edge. Temperature profiles have been measured by Russell and Canfield [66] and Johnson et al. [32]. Their temperature results indicate that temperatures are reduced to about half the centerline value at one-half the pool radius. Russell and Canfield [66] made small-scale calorimeter measurements about 0.3 m from the visible flame edge. Measurements made facing the flame edge were less than 20 kW/m^2 while measurements made facing the body of the flame were about 135 kW/m^2. This value should be compared to fluxes measured on the centerline of the fire of 160 kW/m^2 made with Gardon gauges. This indicates that fluxes within the flame are relatively constant until and unless the radiative pathlengths are small enough to reduce the flame emissivity as discussed previously.

Thermal Radiation from Jet Flames

Large turbulent diffusion flames are encountered in a processing environment as a result of an accidental release of hydrocarbon vapors or the intentional disposal of unwanted gases in a flare. Flaring is the combustion process that has been the traditional method for safe disposal of large

quantities of unwanted flammable gases and vapors in the petroleum industry. With the advent of air quality standards, flaring has also taken on an added importance as a method of industrial environmental control, because most gases that could previously be vented to the atmosphere must now be burned in a flare. The flaring of gases in the petroleum industry occurs in three ways:

1. *Production flaring*. In a production oil field where no provision exists for collecting and processing of gas, there is a requirement for safe disposal of flammable gases. There was a time when almost all gas released was flared, but the great value now placed on natural gas has made gas recovery economical for some fields. Nevertheless, if gas occurs in small quantities that are uneconomical to process or if the gas is so sour that processing is expensive, it can still be flared.
2. *Process flaring*. Flaring also takes place in petrochemical plants, oil refineries, and gas processing plants where the flare system is one of the off-site facilities. In process flaring, the gas that leaks past safety valves protecting various process units is brought to the flare and burned. This gas feeds the small flames that burn almost continuously on refinery stacks. Process flaring can occur at much greater rates when process units are evacuated during a shutdown or when off-specification products are produced during start-up.
3. *Emergency flaring*. This occurs when large volumes of volatile liquids or flammable gases have to be disposed of safely in an emergency such as fire, power failure, or overpressure in a process vessel.

The flaring process involves the release of a tremendous amount of energy. Because a portion of this energy release is in the form of thermal radiation, it represents a substantial hazard to personnel, equipment, and the environment. The sizing of flare system, both in diameter and height, is of major importance to ensure personnel safety during flaring operations. The ability to predict the thermal radiation field from flares is essential in the design of a reasonably sized, safe operating flare. Experimental data on thermal radiation from full-scale flares are rare, and when available at all, the flow rate and composition of the flared gases are usually unknown. However, several scale-model studies have been conducted to examine the geometric and radiative characteristics of flares.

The geometric characteristics of hydrocarbon flares are similar to turbulent jet flames. In fact, many of the geometric descriptions of flares are based on small-scale turbulent jet flame experiments. The base diameter of a flare stack, height of the stack, and composition of the burning substance are often known to the user. In modeling accidental releases of hydrocarbon gases, these relevant data may have to be estimated.

The analytical models describing the geometric characteristics of turbulent jet diffusion flames are described in the following section. The models describe parameters such as the flame height, flame width, and flame tilt. Thermal radiation models, the aerodynamic effects on radiation heat transfer, and blowout stability of jet flames, as well as calculation procedures, are also described in this section.

Geometry of Turbulent Jet Flames

Combustion in a flare or jet fire occurring in the form of a strong turbulent flame may be buoyancy or momentum dominated. Such a flame presents a number of challenging phenomena for study, including the effect of crosswind on flame shape and size; radiation and formation; and dispersion of smoke and other gaseous pollutants. While applying these models to industrial flares, it is also important to recognize the effects of steam in suppressing smoke formation and thermal radiation. The fundamentals of combustion in flares have been studied by Brzustowski [77–79], Brzustowski and Sommer [80], and Brzustowski et al. [81, 82]

Turbulent Jet Flame Height in Stagnant Surroundings

A reasonable measure of progress of burning of a diffusion flame is its height or length. At low velocities the flame is generally attached to the

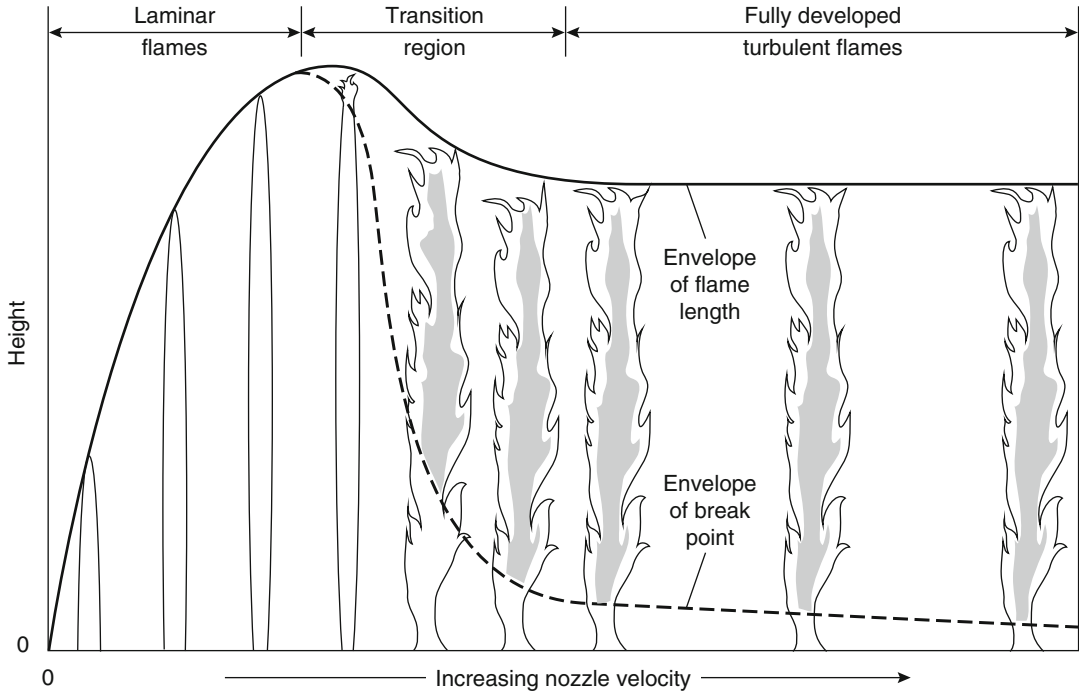

Fig. 66.41 Progressive change in flame type with increasing jet velocity

point of release, but at higher velocities it becomes detached, may become unstable, and extinguish. If, however, the flame impinges on an obstruction, this may serve to stabilize it. Predicting the height or length of the diffusion flame of gas jet burning in still air has long been considered one of the classical solved problems in combustion science. State-of-the-art papers on this subject were published by Hottel and Hawthorne [83], and Hawthorne et al. [84]. Hottel and Hawthorne [83] considered the case of a primary fuel jet of higher velocity issuing into an infinite atmosphere of air with allowance for primary air in the fuel jet. They observed the progressive change in the flame shape and size as the nozzle velocity was increased. This is illustrated in Fig. 66.41, which is based on the work of Hottel and Hawthorne [83] and further interpretation by Gugan [85]. In the laminar regime the flame length is approximately proportional to the velocity, while in the turbulent regime it is independent of velocity. Turbulence spreads from the flame tip downward. As velocity increases there are, successively, a region where the flame may be on the port or lifted, a region where only a lifted flame occurs, and a point beyond which there is blow-off.

Hawthorne et al. [84], in the earliest attempts, have developed a set of experimental data and a theoretical model for flame length for turbulent flame jets. They envisage the flame as an inverted cone with the apex on the orifice. The equation for the length of the flame was shown to be expressible, largely from momentum consideration, in the form

$$L = \frac{5.3 d_j}{C_T} \left\{ \frac{T_F}{\alpha_T T_j} \left[C_T + (1 - C_T) \frac{M_a}{M_f} \right] \right\}^{1/2} \tag{66.32}$$

where

L = Length of visible turbulent flame measured from the break point, m

d_j = jet diameter, m

C_T = Fuel concentration in stoichiometric fuel-air mixture

Table 66.12 Constant for Equation 66.32

Hydrocarbon fuel	CT	αT	T_F/T_j
Methane	0.091	1.0	7.4
Ethane	0.074	1.04	9.0
Propane	0.038	0.96	7.6

α_T = Mole of reactant per mole of product for stoichiometric fuel-air mixture
M_a, M_f = Molecular weight of air and fuel
T_F, T_j = Adiabatic flame temperature and temperature of jet fluid (absolute)

The factor 5.3 appearing in Equation 66.32 is the ratio of visible length to the width of the flame at the point where stoichiometric air has been entrained. This factor was determined from experimental data.

Equation 66.32, for determining the flame length, reduces to a much simpler expression for most hydrocarbon gases. The value of parameters C_T, α_T, and T_F/T_j for various hydrocarbons are given in Table 66.12.

Because C_T is typically much less than unity, α_T is approximately unity, and T_F/T_j varies between 7 and 9. Equation 66.32 may be approximated by the following equation:

$$L = \frac{15 d_j}{C_T}\left(\frac{M_a}{M_f}\right)^{1/2} \tag{66.33}$$

Momentum-controlled flame lengths as discussed above are generally 200–300 times the jet nozzle diameter. Although these are the tallest possible jet flames, over a wide range of conditions, jet flames are buoyancy controlled.

A number of investigators have measured jet flame lengths [77, 80, 86–89]. All their flame height results are in the form of a power law of the Froude number, u^2/gD, where u is the nozzle velocity and d is the nozzle diameter. Flame heights, L, are correlated as

$$\frac{L}{D} \approx (\mathrm{Fr})^{1/5} \sim \left(\frac{u^2}{gD}\right)^{1/5} \sim \frac{\dot{Q}^{2.5}}{D} \tag{66.34}$$

where $\dot{Q}$ is the heat release rate. All the available results can satisfactorily be described by

$$L = 0.2\dot{Q}^{2/5}$$

Figure 66.42 from McCaffrey [89] shows L/D as a function of $u/\sqrt{gD}, \sqrt{\mathrm{Fr}}$. The correlation is seen to hold over a range of about five decades in $\sqrt{\mathrm{Fr}}$. The low end of the correlation corresponds to pool fires and the high end corresponds to momentum-dominated flames.

Kalghatgi [90] and McCaffrey and Evans [91] have studied the stability and liftoff characteristics of momentum jet flames. These phenomena have a profound effect on flame radiation as indicated in Fig. 66.42.

Brzustowski [77] and Brzustowski and Sommer [80] proposed that the end of a turbulent diffusion flame at very high Reynolds number occurs at that point on the axis of maximum fuel concentrations where the fuel concentration equals the lean limit. In theory, this criterion can be applied to any flow configuration for which cold-flow concentration data at sufficiently high Reynolds number are available. Brzustowski [77] has also used some full-scale flare test data to support the lean limit criterion. With this criterion, the flame length for momentum-dominated jets is given by the following equation:

$$\frac{L}{d_j} = \frac{Y_{fj}}{0.32}\left(\frac{\rho_j}{\rho_a}\right)^{1/2}\left[1 + \frac{M_a}{M_f}\left(\frac{1}{0.297\ C_L} - 1\right)\right] \tag{66.35}$$

For a flame where buoyancy is the dominating force, the flame length is given by

$$\frac{L}{d_j} = 2.96\left(\frac{\rho_j}{\rho_a}\right)^{1/2} \mathrm{Fr}^{1/5} Y_{fj}^{3/5} \times \left[1 + \frac{M_a}{M_f}\left(\frac{1}{0.297 C_L} - 1\right)\right]^{3/5} \tag{66.36}$$

where C_L is fuel concentration at the lean flammability limit, by volume, and Fr is the Froude number. Because C_L is about 5 % or less for most hydrocarbons and M_a/M_f is approximately unity, Equations 66.35 and 66.36 may be simplified to the following two equations for momentum- and buoyancy-dominated flames, respectively.

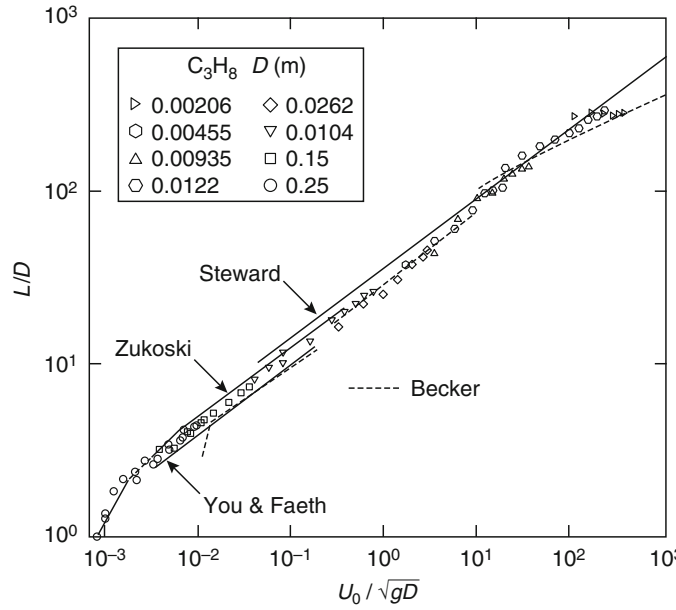

Fig. 66.42 Flame height per nozzle diameter as a function of $u\sqrt{gD}$ [89]

$$\frac{L}{d_j} = \frac{10.5}{C_L}\left(\frac{M_a}{M_f}\right)^{1/2} \tag{66.37}$$

$$\frac{L}{d_j} = 6.1\left(\frac{u_j^2}{d_j g}\right)^{1/5}\left(\frac{1}{C_L}\right)^{3/5}\left(\frac{\widetilde{C}_a T_a}{\Delta\widetilde{H}}\right)^{1/5} \tag{66.38}$$

where $\widetilde{C}_a$ = molar heat capacity of air and $\Delta\widetilde{H}$ = molar heat of combustion.

Equations 66.37 and 66.38 are functionally very similar to the expressions obtained by Hawthorne et al. [84] and Putnam and Speich [87]. These expressions indicate the similarity in three independent experiments.

Turbulent Jet Flame Length in Crosswind Conditions

A series of controlled experiments have been conducted by Brzustowski et al. [81] and Gollahalli et al. [92] in wind tunnels involving hydrogen and propane flames in the presence of wind. The work indicates that in such fires the initial effect of cross flow was to shorten the flame, after which increases in a cross-flow velocity caused increases in the flame length. Shortly before blow-off conditions were reached, flame length was observed to decrease with an increase in crosswind.

The results obtained by Brzustowski et al. [81] and Gollahalli et al. [92] with zero-wind condition are consistent with the model equations given in the previous section. Based on wind tunnel data and limited comparison with full-scale data, Brzustowski [79] has proposed the following procedure to determine the flame shape in the presence of crosswind for a jet flame.

1. Calculate the dimensionless lean limit concentration:

$$\overline{C}_L = C_L\left(\frac{u_j}{u_w}\right)\left(\frac{M_f}{M_a}\right) \tag{66.39}$$

2. If $\overline{C}_L \le 0.5$, then $\overline{S}_L = 2.04\left(\overline{C}_L\right)^{-1.03}$
   If $\overline{C}_L > 0.5$, then $\overline{S}_L = 2.71\left(\overline{C}_L\right)^{-0.625}$
3. If $\overline{S}_L > 2.35$, then $\overline{X}_L = \overline{S}_L - 1.65$.
   If $\overline{S}_L \le 2.35$, then determine $\overline{X}_L$ by following the equation

$$\overline{S}_L = 1.04\overline{X}_L^2 + 2.05\overline{X}_L^{0.28} \tag{66.40}$$

4. Determine the dimensionless rise, $\overline{Z}_L$, of the flame tip above flame tip:

$$\overline{Z}_L = 2.04\overline{X}_L^{0.28} \tag{66.41}$$

5. Calculate dimensional coordinates of the flame tip using the following equation:

$$X = \overline{X}_L d_j \left(\frac{\rho_j}{\rho_a}\right)^{1/2} \left(\frac{u_j}{u_w}\right)$$
$$Z = \overline{Z}_L d_j \left(\frac{\rho_j}{\rho_a}\right)^{1/2} \left(\frac{u_j}{u_w}\right) \tag{66.42}$$

Kalghatki [93] conducted a series of 103 small-scale wind tunnel experiments to determine the size and shape of turbulent hydrocarbon jet diffusion flames in the presence of crosswind. The tests were conducted with methane, propane, ethylene, and commercial butane. The burner diameter ranged from 6 to 22 mm, and the range of velocities was between 13 and 200 m/s. The crosswind velocities were varied from 2.6 to 8.1 m/s. Based on these tests, Kalghatki [93] concluded that the turbulent jet flame can be described by a frustum of a cone and the geometry of a jet flame under influence of wind can be represented by five geometric parameters:

1. Angle α_B, subtended by the burner tip and the tip of the flame with respect to vertical
2. Angle α, subtended by the flame with respect to vertical
3. Vertical length, L_{BV}, of the flame tip from the plane of the burner
4. The flame base width, W_1
5. The flame tip width, W_2

These parameters are expressed in terms of a dimensional variable called *effective source diameter* and a nondimensional velocity, R. The definitions of these two parameters are

$$D_s = D\left(\frac{\rho_j}{\rho_a}\right) \tag{66.43}$$

where
D = Source diameter, m
ρ_j = Density of jet fuel, kg/m^3
ρ_a = Density of ambient air, kg/m^3

$$R = \frac{U}{U_j} \tag{66.44}$$

where
U = Crosswind speed, m/s
U_j = Jet velocity, m/s

In Fig. 66.43 the variation of the vertical flame length parameter is shown as a function of the nondimensional velocity, R. Also shown in Fig. 66.43 are the correlations suggested by Brzustowski for propane, methane, and ethylene. In order to predict the actual flame length, the flame tilt with respect to the burner axis must be known. Figure 66.44 shows the data on flame tilt and the comparison with Brzustowski's calculation procedure. It is seen that the calculation procedure underestimates the flame tilt. Therefore, the measured flame lengths are slightly larger than the ones predicted using Brzustowski's model. Based on these results, Kalghatki [93] suggests the following correlations to determine the flame length and flame tilt parameters.

$$\alpha_B = 94 - \frac{1.6}{R} - 35R \tag{66.45}$$

$$\alpha = 94 - \frac{1.1}{R} - 30R \tag{66.46}$$

$$\frac{L_{BV}}{D_s} = 6 + \frac{2.35}{R} + 20R \tag{66.47}$$

Here the angles α are in degrees. The range of validity of these correlations are for the values of R greater than 0.02 and less than 0.25. The upper limit for R is not a serious limitation to the applicability of the model. For values of R less than 0.02, the wind-free data may be used to determine the flame lengths and the tilt may be assumed to be zero. It should be noted that the flame length given by Equation 66.47 determines only the vertical component. Actual inclined flame height is given by dividing Equation 66.47 by the cosine of the angle of tilt given by Equation 66.45. It is worth noting that the actual inclined flame length ratio is independent of the velocity ratio and is relatively constant at a value of about 120. This indicates that the majority of the tests conducted in this program were momentum-dominated turbulent jets. Sonju and

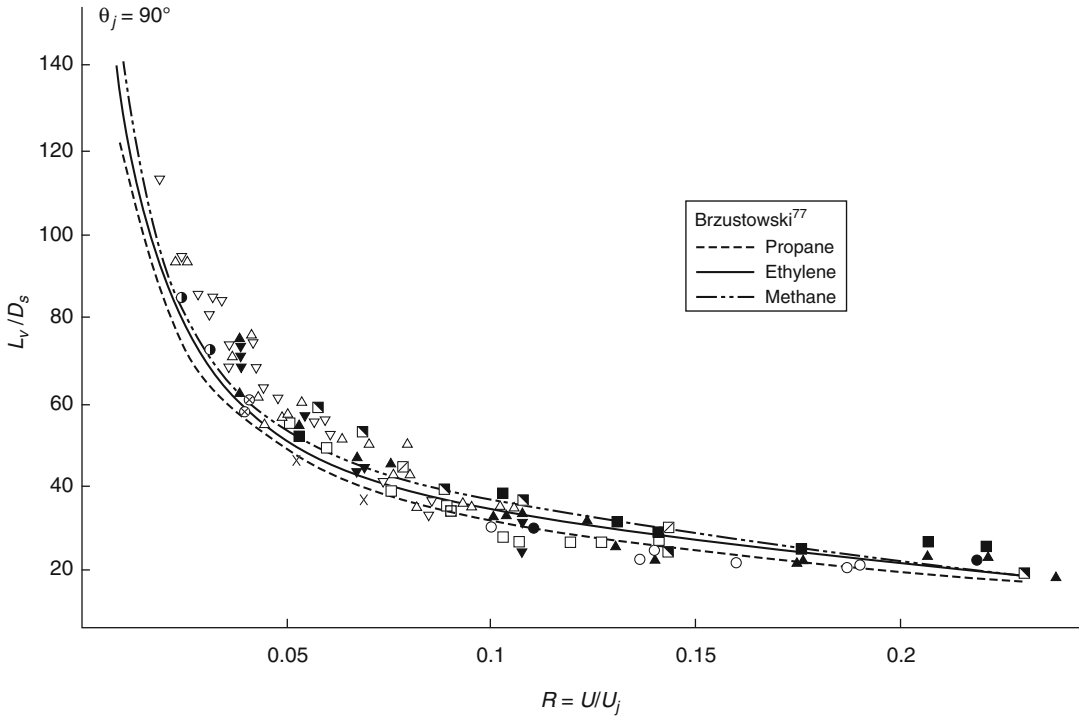

Fig. 66.43 Variation of the flame length above burner tip with velocity ratio, R [93]

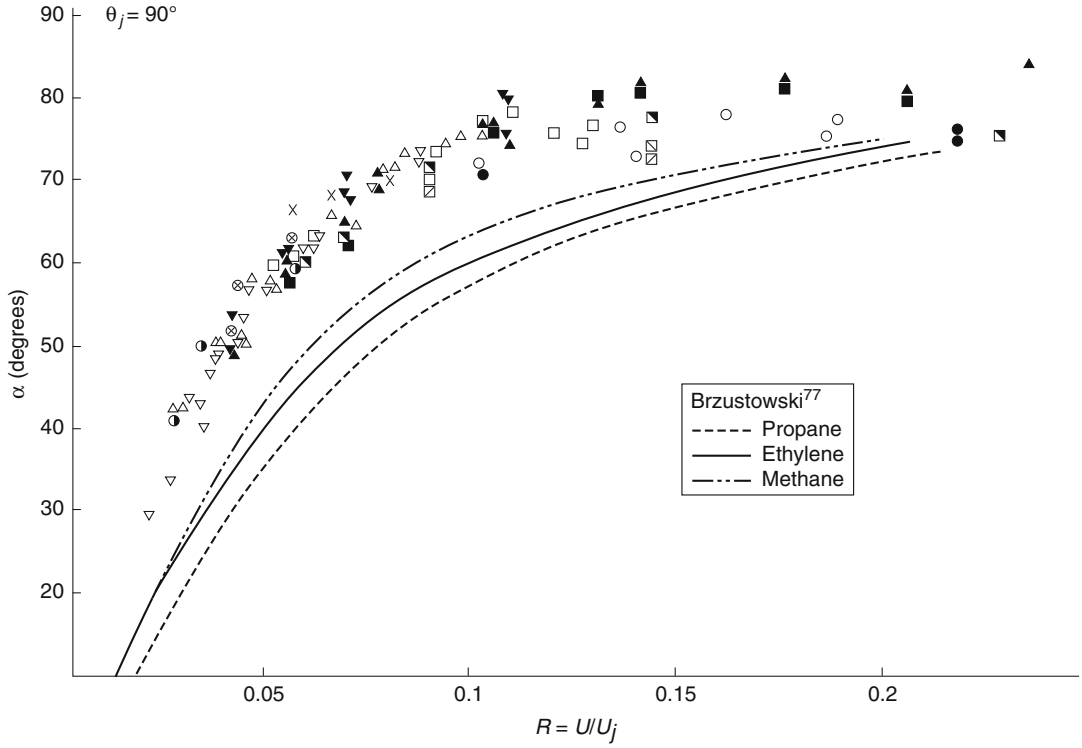

Fig. 66.44 Variation of angle of tilt with velocity ratio, R [93]

Hustad [94] conducted an experimental study on turbulent diffusion flames. The flare diameters ranged from 2.3 to 80 mm and the velocities ranged from 5 to 250 m/s. Their data indicate that the flame length is proportional to the one-fifth power of the Froude number. For Froude numbers greater than 100,000, the flame lengths appear to be independent of the Froude number. These results are consistent with the data of Putnam and Speich [87].

Turbulent Jet Flame Diameter in Crosswind Conditions

The work of Hawthorne et al. [84] described above also includes jet flame diameter calculation. They observed that the jet diameter increases as a function of distance. The measured spreading angles were in the range of 3–8° (one-half angle). The equivalent diameter for thermal radiation calculations can be calculated from the following equation:

$$\frac{D_c}{d_j} = \sec\theta + \frac{L}{d_j}\sin\theta\sec^2\theta \qquad (66.48)$$

The data of Kalghatki [93] for the base and tip widths of the flames indicate the spreading angle is a function of the nondimensional velocity ratio, R. For a jet flame in windblown surroundings, Kalghatki [93] gives the following correlation of jet diameter:

$$\frac{W_2}{D_s} = 80 - \frac{0.57}{R} - 570R + 1470R^2 \qquad (66.49)$$

$$\frac{W_1}{D_s} = 49 - \frac{0.22}{R} - 380R + 950R^2 \qquad (66.50)$$

From these calculations, it can also be deduced that the cone half-angle for the frustum decreases from a value of about 5° at $R = 0.025$ to a value of about 2.8° at $R = 0.2$. Therefore, at large, relative wind speeds, a diffusion flame takes an almost cylindrical shape. The data of Sonju and Hustad [94] indicate that the flame diameter increases as one-fifth power of the flame Froude number. The suggested constants, proportionally, for methane and propane flames are 2.5 and 4.0, respectively.

Kalghatki [93] also conducted some limited tests with nonorthogonal jet flames and concluded that the flame lengths are dependent on wind direction. These tests were conducted with relative wind angles varying from 45 to 135° (with 90° representing orthogonal cross flow). The value of the nondimensional velocity was greater than 0.025. The data indicate that for a given angle of tilt, the flame length remains relatively constant; however, the flame length decreases with increasing angle of tilt. The data of flame length and wind direction over the entire velocity ratios are shown in Fig. 66.45. As can be seen from Fig. 66.45, there appears to be a linear relationship between flame length and wind direction. The correlation suggested by Kalghatki [93] is

$$\frac{L_B}{D_s} = 163 - 0.64\theta_j \qquad (66.51)$$

where θ_j is the angle between wind and jet (degrees).

Aerodynamic Effects on Flame Stability

A jet diffusion flame in still air will lift off the tip of the burner and form a stable lifted flame when the flow velocity through the burner is increased beyond a limiting value known as the liftoff stability limit. If the flow velocity is increased further, the flame is extinguished at some limiting rate known as the *blowout stability* limit.

At the base of a lifted diffusion flame, the local turbulent burning velocity will be equal to the local flow velocity. If the flow rate through the burner is increased, the flow velocity will also increase and the base of the flame will be blown downstream to a new position where the turbulent burning velocity equals local flow velocity. The flame will blow out when the change in the burning velocity cannot keep up with the flow velocity anywhere in the jet as one moves downstream from the base of the jet flame.

The distance along the burner axis where the mean concentration equals the stoichiometric

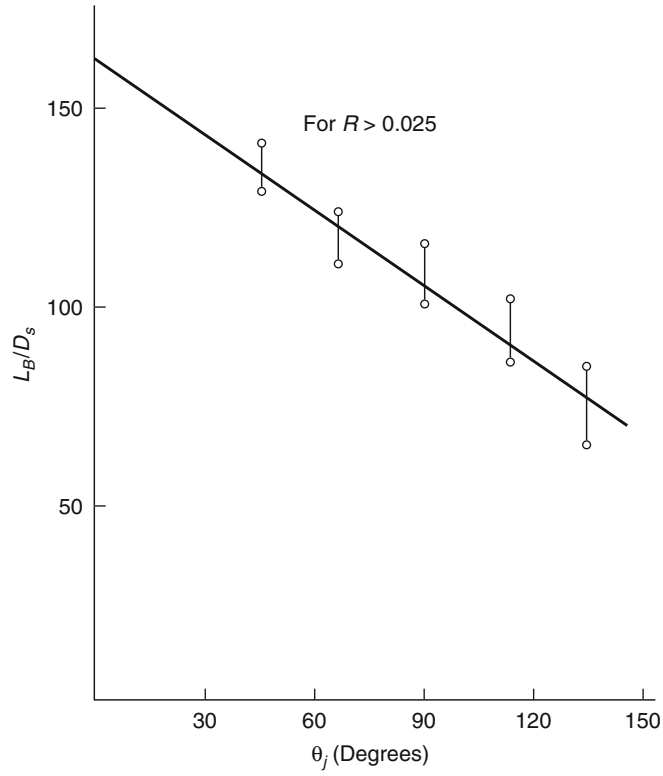

Fig. 66.45 Variation of flame length with jet axis orientation [93]

level is independent of the flow velocity and is given by the following equation:

$$\frac{H}{d_e} = 4\frac{\widetilde{\theta}_e}{\widetilde{\theta}_s}\left(\frac{\rho_e}{\rho_a}\right)^{1/2} + 5.8 \qquad (66.52)$$

where
H = Height along the jet axis, m
d_e = Effective jet diameter, m
$\widetilde{\theta}_e$ = Fuel mass fraction at jet exit
$\widetilde{\theta}_s$ = Stoichiometric fuel mass fraction
ρ_e = Jet mixture density, kg/m^3
ρ_a = Ambient air density, kg/m^3

The effective jet diameter is defined as follows. For subsonic jets:

$$d_e = d_j \text{ for } \mathrm{M} < 1$$

For choked flow:

$$d_e = d_j\left[\frac{2+(\gamma-1)\mathrm{M}^2}{\gamma+1}\right]^{(\gamma+1)(\gamma-1)}\frac{1}{\sqrt{M}} \qquad (66.53)$$

where
d_j = Jet diameter, m
M = Mach number after expansion to ambient pressure
γ = Ratio of specific heats

All things being equal, the larger of the value of H, the more scope there will be for the base of the flame to seek a new stable position as the flow velocity is increased, and therefore it will be more difficult to blow out the flame. Similarly, larger values of burning velocity will lead to larger flow velocities to blow out the flame. The critical velocity at the burner exit for blowout will depend on the burning velocity, the density ratio, and the Reynolds number based on H.

$$\frac{U_e}{S_u} = f\left(R_H, \frac{\rho_e}{\rho_a}\right) \qquad (66.54)$$

where
U_e = Critical velocity at jet exit, m/s
S_u = Maximum burning velocity, m/s
R_H = Reynolds number given by

Table 66.13 Relevant properties of hydrocarbon gases to determine blowout stability

Gas	Molecular weight	Dynamic viscosity at 0 °C (micropoises)	Maximum burning rate S_u (m/s)	Ratio of specific heats	Stoichiometric air-fuel ratio
Methane	16	102.7	0.39	1.31	17.2
Propane	44	74	0.45	1.13	15.7
Ethylene	28	91	0.75	1.255	14.9
Acetylene	26	93.5	1.63	1.25	13.3
Butane	54	80	0.44	1.1	15.7
Hydrogen	2	84	3.06	1.33	34.7

$$R_H = HS_u \frac{\mu_e}{\mu_e} \tag{66.55}$$

where μ_e = dynamic viscosity.

The typical values of the relevant parameters for typical fuels are given in Table 66.13.

Kalghatki [90] conducted a systematic study of the blowout stability of jet diffusion flames in still air. The fuel gases used were methane, propane, ethylene, acetylene, and commercial butane. The burner diameters ranged from 0.2 to 12 mm. The universal stability limit is given by the following equation:

$$\overline{U}_e = 0.017 R_H \left(1 - 3.5 \times 10^{-6} R_H\right) \tag{66.56}$$

where

$$U_e = \frac{U_e}{S_u} \left(\frac{\rho_e}{\rho_a}\right)^{1.5} \tag{66.57}$$

The validity of Equation 66.56 is shown in Fig. 66.46. It should be noted that Equation 66.56 is valid only up to a Reynolds number of 100,000.

Thermal Radiation Hazards from Hydrocarbon Jet Flames

Point Source Model for Jet Flame Radiation

For incident heat flux from a jet flame to a target outside the flame, it is customary to model the flame by a point located at the center of the real flame, as mentioned earlier in the pool fire section. The radiant heat flux per unit area and per unit time received by a target at a distance R from the point source is given by

$$\dot{q}'' = \frac{\dot{Q}_r \cos\theta}{4\pi R^2} \tag{66.58}$$

where $\dot{Q}_r$ is the radiative output given by the radiation fraction, χ_r, multiplied by the total heat release rate:

$$\dot{Q}_r = \chi_r Q$$

The geometrical aspects of the representation of thermal radiation field given by the point source model are surprisingly accurate for flare stacks, even in the case of long windblown flames. Many of the early experimental investigations relevant to jet flames were concerned with flares. The work covers a variety of jet flames, including flames of natural gas and of liquified petroleum gas (LP-gas). Representative accounts of work using natural gas are those by Chamberlain [95], Johnson et al. [96] at Shell, and by Cook et al. [97] at British Gas. Accounts of work on jet flames of LP-gas at Shell and British Gas have been given by Hirst [98] and Tam and Cowley [99]. The work on flames formed part of a study of emission and gas dispersion of jets as well as of combustion.

Hirst [98] describes experiments using liquefied propane. Tests were carried out using orifices ranging from 9 to 52 mm in diameter and pressures from about 6 to 20 bar. Both horizontal and vertical releases were studied. A series of tests were done with vertical releases. The liquid rose in a strongly divergent cone bending with the wind. The cone angle was typically 30° for the plume but up to 90° in the flash region. The

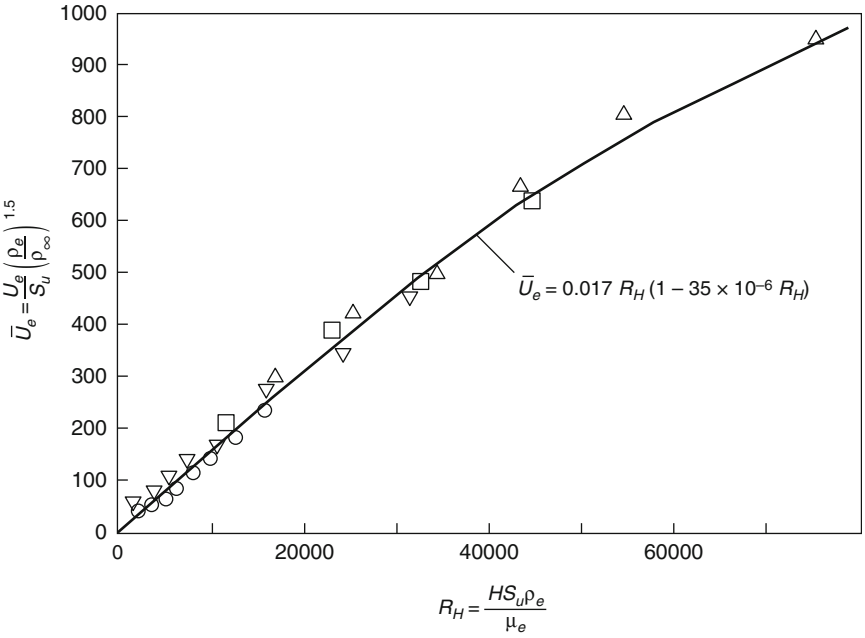

Fig. 66.46 Universal blowout stability curve for diffusion flames [90]

releases usually reached a steady state before ignition. The visible clouds at ignition were large, extending up to 45 m vertically and 70 m downwind. In most cases fireballs formed and in several tests rose to 100 m; the most fully developed fireballs occurred at low wind speeds. The overpressure generated by the flames were also measured. The maximum observed fell from some 3 bar at 20 m from the release point to about 0.8 bar at 100 m.

Other tests were done with horizontal releases. One of the features measured in these trials was the distance reached by the flame. Figure 66.47 gives the relation between the mass flow and the impingement distance of the flame for a 50-mm-diameter pipe. In one of the trials in which a 35-m-long jet flame from a full bore release of 7.9 kg/s from a 50 mm pipe at pressure of 13 bar. The combustion energy was 365 MW. The maximum surface emissive power was 250 kW/m^2 and occurred 25 m from the release point and just before the flame underwent transition from the momentum-dominated to the buoyancy-dominated condition. However, for such full-scale bore discharges the heat radiation within the flame was complex, and steady heat fluxes were mainly in the range of 50–220 kW/m^2 and depended on the discharge conditions and the target distance. The maximum temperature occurred at a distance of 4 m and had a value of 1570 K.

Brzustowski [100] considered a flare (in the presence of high crosswind) as a uniformly radiating cylinder. He observed that the thermal radiation flux given by the point source model is similar to those predicted using a cylindrical source model except at distances very close to the source. Brzustowski [100] also computed radiation heat flux for vertical elements parallel and perpendicular to the wind direction and has concluded that the corrected point source model and the uniform cylinder radiation model essentially yield very similar results.

Brzustowski et al. [81] carried out small- and pilot-scale experiments to study the radiative characteristics of turbulent flares using commercial-grade methane and propane. Small-scale test data were taken at jet velocities from 6.8 to 70 m/s with jet Reynolds numbers from 7500 to 94,000, and ratios of crosswind velocity to jet velocity from 0 to 0.113. Pilot-scale experiments were conducted on an outdoor site

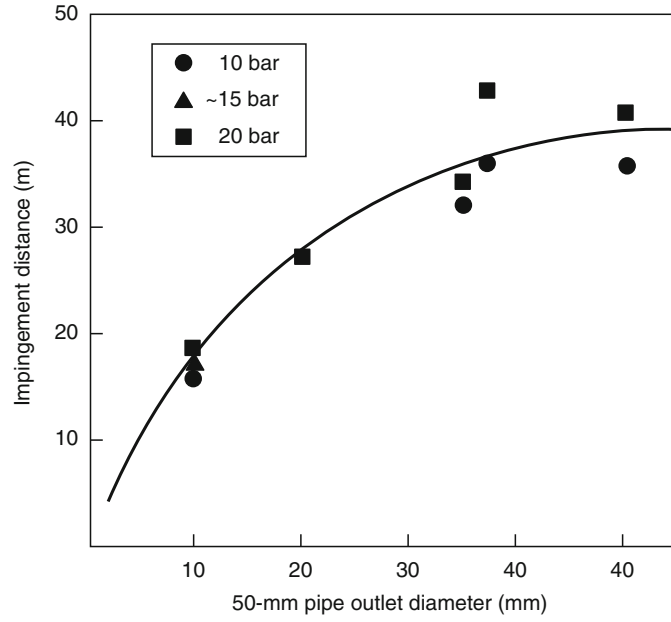

Fig. 66.47 Jet flames: flame impingement distance versus mass flow for propane [60]

with the flare modeled by a vertical 25 mm inner-diameter pipe 1.5 m high. In these tests, provisions were made for injecting steam into the gas below the tip of the flare. The incident heat flux at various distances was measured with and without steam.

Oenbring and Sifferman [101] compared the point source model predictions with full-scale measurements. The full-scale data consisted of radiation measurements in the Oenbring and Sifferman [101] studies that were conducted at the oil refinery facility in Conoco's Ponca City, Oklahoma, and in the Gillis gas plant facility in Los Angeles, California. The Gillis flare stack was 40 cm (16 in.) in diameter and 23 m high. The gas velocity ranged from a Mach number of 0.2 to 0.49. All test data indicate that the inverse square law predicts the thermal radiation accurately.

Radiative Fraction for Jet Flames

In order to predict the incident heat flux accurately, it is necessary to determine the fraction of total combustion energy resulting in thermal radiation. In general, the fraction of heat radiated depends on the efficiency of combustion and soot formation and on the heat lost by convection to the entrained air.

Most thermal radiation prediction models tends to ignore the details of the combustion process and concentrate on the overall combustion efficiency, or fraction of the energy that is radiated to the environment. Markstein [7] conducted a series of radiation measurements on propane turbulent diffusion flames. The total radiative powers of the flames were determined using wide-angle radiometer. The flow rates varied from 44 to 412 cm^3/s. A collimated beam radiometer was used to measure the radiation characteristics of different parts of the flames. Based on these measurements, Markstein [7] concluded that the thermal radiation from diffusion flames is at a maximum at approximately the center of the flame and tapers off on either side, forming a Gaussian distribution. The total radiative power of the flame was observed to be directly proportional to the total heat release rate. Figure 66.48 shows that the fraction of combustion energy released in the form of radiation is approximately 20 % for the propane diffusion flames. Burgess and Hertzberg [36] measured the fraction of combustion energy radiated to

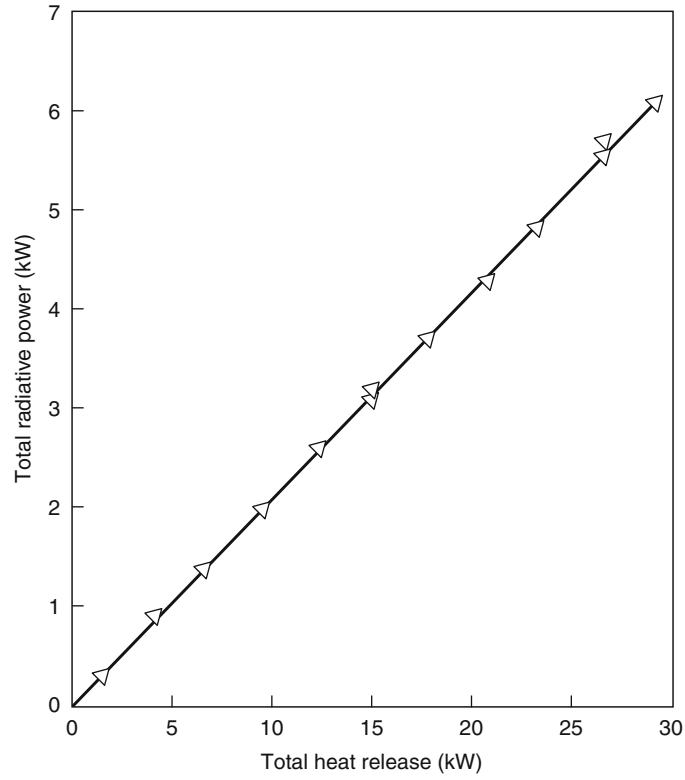

Fig. 66.48 Radiative power for propane diffusion flames [7]

Table 66.14 Comparison of radiative fraction, χr of various fuels

Fuel	f_s	χ_r Brzustowski [100]	χ_r Burgess and Hertzberg [36]	χ_r Tan [102]	χ_r Kent [103]	χ_r McCaffrey [89]
Hydrogen	1.0	0.2	0.17	–	–	–
Methane (C_1)	0.189	0.2	0.23	0.20	0.19	0.22
Ethylene (C_2)	0.170	0.25	0.36	0.26	0.25	0.38
Propane (C_3)	0.176	0.30	–	0.32	0.32	0.302
Butane (C_4)	0.175	0.30	0.30	0.37	0.37	–
C_5 and higher	–	0.40	–	–	–	–

the surroundings for several gaseous fuels. Tan [102] and Kent [103] have also suggested values for the radiated energy for a variety of fuels.

Table 66.14 compares the values of radiative fraction, χ_r, suggested by various investigators. The parameter f_s in Table 66.14 represents the fuel mass fraction at which carbon particles begin to form. For any hydrocarbon fuel, C_nH_m burning in air, the fraction f_s is given by

$$f_s = \frac{12n + m}{12n + m + [n/2(137.3)]} \tag{66.59}$$

For the same entrainment/mixing history, a gas with a higher value of f_s has less tendency to form solid carbon particles than a gas with a lower value of f_s. Higher values of f_s, therefore, correspond to lower radiation levels.

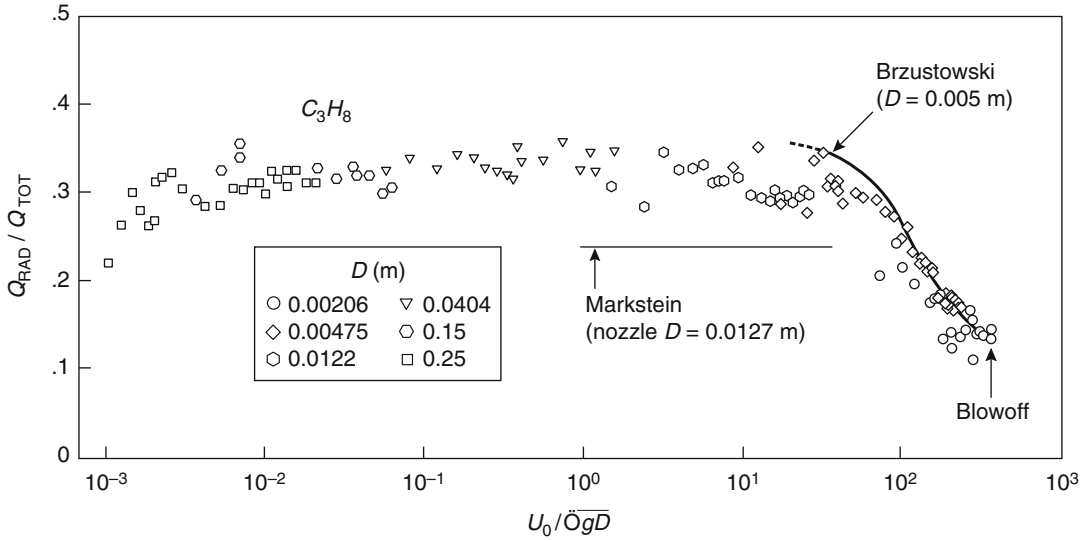

Fig. 66.49 Radiative fraction measured by McCaffrey [89]

Examination of Table 66.14 shows good qualitative agreement. Propane and butane have similar values of f_s, and their χ_r values are comparable. Methane and hydrogen have lower values of χ_r and higher f_s values. But ethylene has a lower value of f_s and, except in one study by Burgess and Hertzberg [36], the χ_r values are also lower. This may be partially due to straight molecular weight corrections applied by Tan [102] and Kent [103].

The intensity of flame radiation may be affected by the medium through which it passes. An appreciable attenuation may occur when radiation is transmitted from a source to a target through the atmosphere. The values of radiative fraction χ_r in Table 66.14 are properties of the fuel only. They do not take into account the variation of the operating parameters such as stack exit velocity, crosswind velocity, and the presence of air steam. However, these parameters have a profound influence on the temperature profiles and affect the fraction of combustion energy radiated, χ_r.

Figure 66.49 shows the radiative fraction measured by McCaffrey over six decades: $u/\sqrt{gDs}$. Comparing this figure with Fig. 66.42 shows that the radiative fraction is constant in the buoyancy-controlled regime, but for momentum-controlled jet flames, the radiative fraction decreases until blow-off occurs.

Evans and Pfenning [104] and McCaffrey [105, 106] have studied jet flame extinction via water spray. They also document significant reductions in flame radiation at subsuppression water spray addition rates of up to 50 %.

Brzustowski et al. [82] conducted a series of laboratory-scale tests on the effects of jet velocity and free stream velocity on the fraction of energy radiated, χ_r, from the turbulent flames. Figure 66.50 shows the effect of jet velocity on radiation in the absence of crosswind for methane and propane flames. Also drawn in Fig. 66.50 are the suggested values of radiative fraction χ_r from Tan [102] and Kent [103]. As can be seen from Fig. 66.50 the fraction of energy radiated, χ_r, is strongly dependent on jet velocity and decreases with increasing jet velocity. Figure 66.51 shows the effects of crosswind velocity on the radiant energy. In general, increasing crosswind velocity appears to increase the fraction of energy radiated, χ_r.

The significant departures of measured values of χ_r from the values previously published (which do not take into account the aerodynamic effects) can be understood in relation to variation of the

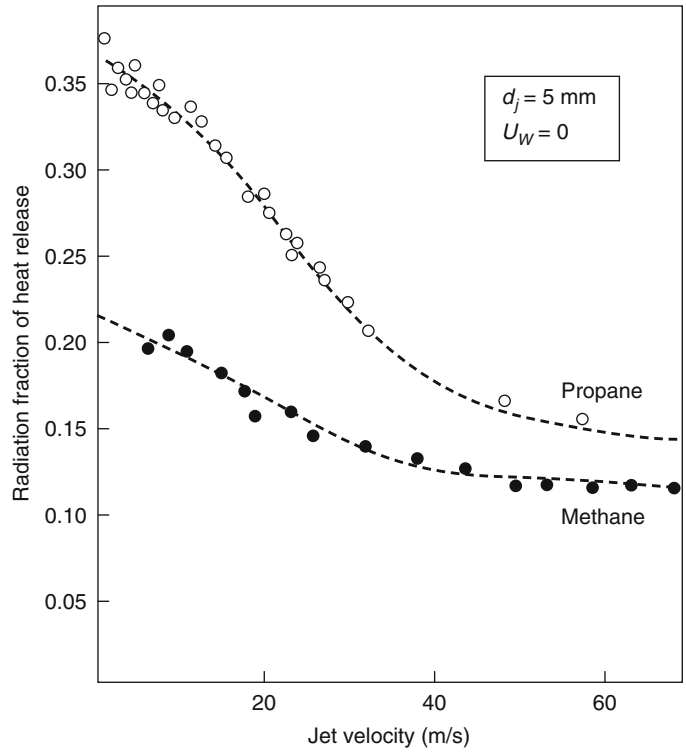

Fig. 66.50 Effect of jet velocity on radiated fraction of combustion energy [82]

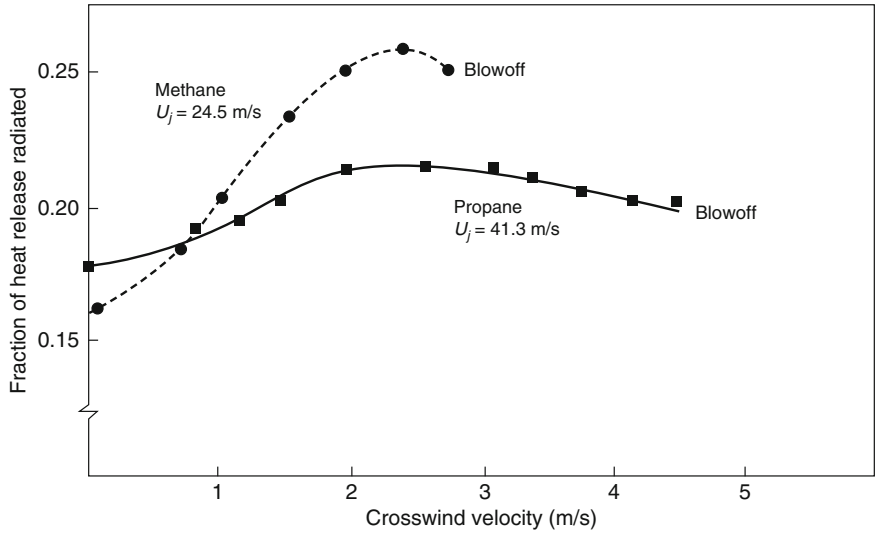

Fig. 66.51 Effect of crosswind velocity on radiated fraction of combustion energy [82]

detailed temperature profiles in the flames. The underlying explanation deals with the competing processes by which the products of hydrocarbon pyrolysis near the flare stack oxidize directly or form soot that burns in the downstream portion of the flames. Quite obviously, predictions based on the traditional values of χ_r would have overestimated the thermal radiation in all

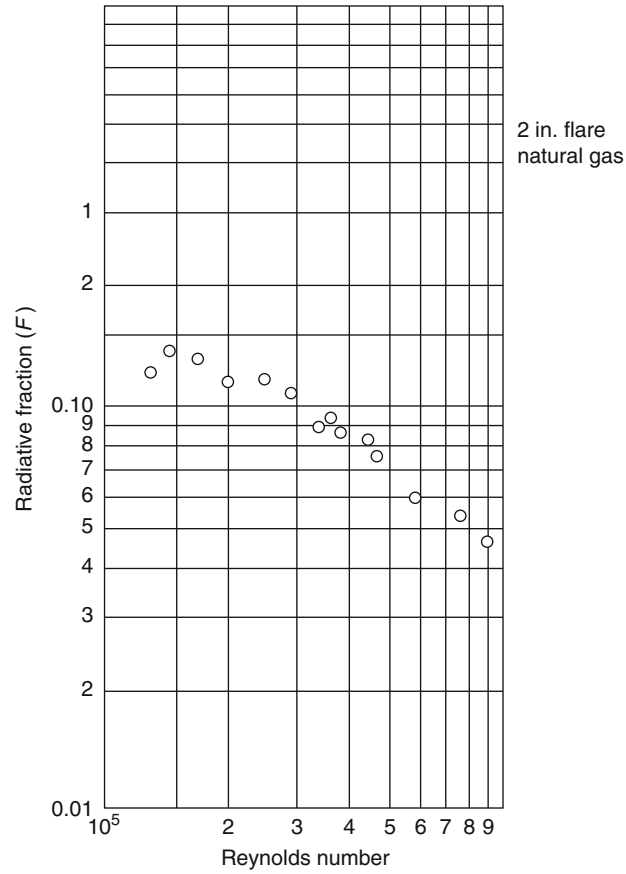

Fig. 66.52 Radiative fraction for natural gas flames full-scale tests [107]

these laboratory-scale experiments. Brzustowski et al. [82] also measured thermal radiation from a full-scale flare. The 0.406-m-diameter flare was operating at about 25 % of the design flaring rate. The best estimates of jet velocity and wind velocity were 28 and 4 m/s, respectively. The flame length was measured to be 25 m and flame tip was about 10 m above the flare tip level. The value of χ_r calculated from the radiation measurements at two ground sections 0.223 was about 30 % lower than the values predicted using the Tan [102] and Kent [103] approaches.

Figure 66.52 shows the fraction of net heat release radiated as a function of the flare Reynolds number for a 5 cm (2 in.) natural gas flare from Straiz et al. [107]. The Reynolds numbers in these tests are comparable to full-scale Reynolds numbers (of the order of 10^5–10^6). The fraction of energy radiated, χ_r, shows a significant departure at higher Reynolds numbers from its traditionally assumed value of 0.2.

It is quite evident that the aerodynamics of the flow have a significant effect on the radiation from a large turbulent diffusion flame. However, the radiation data described above were obtained on the laboratory-scale experiments, and their validity for large flames encountered in an offshore environment cannot be taken for granted.

Line and Cylinder Models for Jet Flame Radiation

As mentioned in the previous section, a point source model is a simple representation of a jet flame and applies only at large distance from the fire. The point source model can be inaccurate for target positions close to the fire. This is

particularly important when one is evaluating safe separation distances for storage of hydrocarbon fuels.

The tilted cylinder model discussed in the pool fire section can be used to overcome the inaccuracy of the point source model to determine the thermal radiation from large diffusion flames. This model assumes that the fire can be represented by a solid body of a simple geometrical shape, and all thermal radiation is emitted from its surface.

The incident radiation per unit area per unit time is given by

$$\dot{q}'' = FE\tau \tag{66.60}$$

where

E = Surface emissive power of flame, kW/m^2

F = Configuration factor

τ = Atmospheric attenuation factor (transmissivity)

The configuration factor is the fraction of the radiation falling directly on the receiving target. The shape or configuration factor depends on the shapes of the fire and receiving target, and on the distance between them.

The surface emissive power is the total radiative power leaving the surface of the fire approximated by the following equation [108]:

$$E = E_{bb}\left(1 - e^{-\kappa L}\right) \tag{66.61}$$

where

E_{bb} = Equivalent blackbody emissive power, kW/m^2

κ = Extinction coefficient, m^{-1}

L = Effective pathlength, m

The blackbody emissive power, E_{bb}, can be calculated by

$$E_{bb} = \sigma T_f^4 \tag{66.62}$$

where σ is the Stefan-Boltzmann constant (5.67×10^{-11} kW/m^2·K^4) and T_f is the flame temperature (K).

Fumarola et al. [109] suggested a line source model to compute radiation from jet flames. An elemental length of the flame is assumed to radiate similar to a point source model. The total incident heat flux at any observer location is computed by integrating the heat flux due to an elemental source over the flame length. They compared their results with Brzustowski [100] and the Oenbring and Sifferman model [110] and observed that their model predicted lower-incident heat fluxes at ground level.

Galant et al. [111] proposed a three-dimensional numerical model to estimate the flame geometry and thermal radiation from large diffusion flames. The model considers the variation in flow conditions based on a pseudo-stream-function formulation and includes effects of turbulence, combustion, and soot concentration. The model has been validated with field experiments of up to 254-mm (10-in.) diameter methane jets and agreement between predicted and measured heat flux is within 15 %.

Jet Fire Impingement Exposure

The severity of the thermal exposure from impinging jet flames far exceeds that observed for pool fire exposures. Heat fluxes of up to 250 and 300 kW/m^2 for two phase LP-gas and sonic natural gas jets, respectively, have been measured in large-scale jet flame tests (e.g., Cowley and Prichard [112]). In these tests where the flame fully engulfed a cylindrical target, heat fluxes averaged over the impingement area were 200 kW/m^2 for sonic natural gas jets and were 150 kW/m^2 for two phase LP-gas jets.

The severity of jet flame impingement exposures results from highly radiative, optically thick flames with high convective heat fluxes. The radiative and convective components of the total heat flux tend to be roughly equal in the high heat flux regions of the target (Parker [113]). Wighus and Dransgsholt [114] report temperatures as high as 1200 °C and impingement velocities of up to 80 m/s in gaseous propane jet flames. They also found that the temperatures observed at the location of peak velocity were lower for higher gas velocities. For instance, they measured 1150 °C at 30 m/s and 650 °C at 80 m/s. They measured heat fluxes as high as 340 kW/m^2 in some tests, and

the radiative fraction of the total heat flux tended to be about 2/3. Their results would indicate that differences found by Cowley and Prichard [112] for natural gas and two phase LP-gas flames were primarily the result of the two phase nature of the LP-gas release rather than differences between natural gas and propane gaseous flame properties.

Unsteady Thermal Radiation Analysis

Liquefied fuel gases having boiling points below normal ambient temperatures have come to be stored and transported in large quantities. Liquefied natural gas (LNG) is stored for peak demand use. It is also transported by sea in bulk carriers designed for cryogenic cargos. Liquefied petroleum gas (LP-gas) is stored under pressure and is transported by trucks, railroad tank cars, and by sea in bulk carriers. Although liquefied hydrogen has been used in limited quantities as a rocket fuel, serious consideration is being given to its use as a fuel for aircraft and possibly highway vehicles. Because volatile fuels are being transported in rapidly increasing volumes, speculation is being devoted to the kinds of accidents that could result from the release of these fuels.

The failure of a container carrying a pressurized cargo will result in the flash evaporation of a portion of the released liquid and the sudden formation of a vapor cloud from the evolved vapors. Upon contact with an ignition source, one of two situations may occur: the generation of a propagating plume flame, or the formation of a fireball. If the vapor puff is ignited immediately after its formation, it may burn as a rising sphere, usually referred to as a *fireball*. The rapid combustion of vapor clouds in the form of fireballs has been observed in several accidents involving vehicles carrying liquid propane. Here some of the accidents where a fireball has been reported to be observed are reviewed.

In the General Accounting Office report to the U.S. Congress regarding liquefied energy gases safety, an accident is cited involving a tractor-semitrailer carrying 34 m^3 (9000 gal) of LP-gas. About 2 min after the accident, a fireball of about 123 m (135 yd) in diameter was observed. The radiant heat from the fireball burned several people, a house, several other buildings, and some 12 acres of woods.

The National Fire Protection Association has maintained descriptions of several accidents involving LP-gas where a rising fireball was observed. One such accident happened in Oneonta, New York, where a freight train derailed involving 27 cars, 7 of which contained 120 m^3 (33,000 gal) of liquid propane. Seconds after the derailment, a huge fireball erupted from the area where the tank cars were piled up. It is believed that this fireball was the result of ignition of LP-gas when one of the tank cars split open. The fireball heated other tanks carrying LP-gas, which resulted in several BLEVEs (boiling liquid expanding vapor explosions).

One of the most cited fireballs occurred in Crescent City, Illinois, when a freight train carrying 15 cars derailed, 10 of them containing 130 m^3 (34,000 gal) of LP-gas each. One of the derailed tank cars rode up and over the pile and tore a hole in another tank car containing propane, causing the release of gas that produced the first fireball. There were several subsequent explosions that lasted for hours and destroyed 24 individual living quarters and 18 businesses.

The fireballs resulting from such accidents are large—usually of the order of about 100 m in diameter. The duration of the fireball is on the order of a few seconds because of rapid mixing with the surrounding air. During this brief period, a fraction of the combustion energy present in the initial mass of vapor is radiated as thermal energy to the surroundings. The adverse effect of this thermal radiation to population and property depends on the intensity and the duration of the radiation.

If, however, the vapor cloud is allowed to travel with the wind and is ignited at a location away from the source, the resulting vapor fire assumes the form of a propagating plume flame. In both cases, an unsteady diffusion flame is produced. However, the flame geometry is defined by the particular mode of burning. Accordingly, the levels of resulting thermal radiation differ significantly for each

mechanism. The unique behavior of these vapor cloud fires is discussed in this chapter. The following sections present an analysis of burning vapor clouds that define a plume fire; a discussion of the formation and burning of a hydrocarbon fireball; and a sample calculation procedure for burning of a vapor cloud in the form of a fireball.

Thermal Radiation from Burning Vapor Clouds

Estimating the thermal radiation field surrounding a burning vapor cloud involves geometric characterization of the cloud, that is, the time-averaged size of the visible envelope. It also requires estimation of the radiative properties of the fire, that is, the average emissive power, and so forth. Finally, the radiant intensity at a given location must be determined. Because the burning behavior of a moving vapor cloud can be best described as unsteady, the standard equations for pool fires do not apply. In the discussion that follows, the flame geometry and effective thermal radiation parameters that characterize a burning vapor cloud are identified.

Given a spill of a volatile, flammable chemical, initially a pool is formed. As the pool vaporizes due to heat transfer from the medium surface (land or water), a vapor cloud is formed above the pool. These vapors are entrained by the ambient wind and are dispersed in the downwind direction. Two conditions must be met for a burning cloud to be produced; first, there must be an ignition source located away from the spill point; second, the concentration within the vapor cloud must be within the flammability limit range for that material. Assuming these conditions exist, the fire that results is in the form of a propagating plume flame.

Based on experiments with spills of LNG on water, Mudan [115] and Raj et al. [33] identified three stages of vapor fire development. First, a transient turbulent flame spreads through the cloud. The flame propagates in both upwind and downwind directions. The second stage in the development of a vapor fire is the steady-state propagation toward the liquid pool. At this location, there appears to be a stationary diffusion flame. The third and final stage of burning results in a small pool fire at the source location. Based on limited experimental data on vapor cloud fires, the burning behavior and resultant flame geometry can be analyzed.

Flame Propagation Velocity Within a few seconds after ignition, flames tend to spread quickly both upwind and downwind of the ignition source. Flame travel in both directions is consistent if the ignition occurs after the flammable vapor cloud travels over it. The flames are initially contained within the cloud, but subsequently extend in the form of a flame plume above the cloud. This is consistent with premixed burning of the regions in the cloud that are within flammable limits prior to flame arrival, followed by diffusive burning of the richer regions in the cloud. After consuming the flammable vapors downwind of the ignition source, the downwind edge of the flame starts moving toward the spill point. Generally, the flame zone is normal to the wind direction.

During this transient flame growth, an *average* flame propagation velocity with respect to the ground can be determined by noting the location of the upwind edge of the flame at various time intervals. The flame speed with respect to gases may be obtained by adding the wind speed to the flame speed with respect to the ground. The initial, rapid propagation of the flame in the premixed vapor cloud can also be measured by the same technique.

Wind speed plays a significant role in the vapor cloud propagation. The flame velocity tends to increase with wind speed. Also, an increase in wind velocity increases the dispersion process. The ignition delay is also affected by the wind speed. Clearly, for a fuel-rich vapor cloud, an increase in mixedness will increase the flame propagation velocity. However, if the fuel concentration is well below stoichiometry, a further increase in ignition delay may, in fact, cause a decrease in flame propagation speed.

Mizner and Eyre [35] conducted vapor fire tests with propane spilled on water. The spill

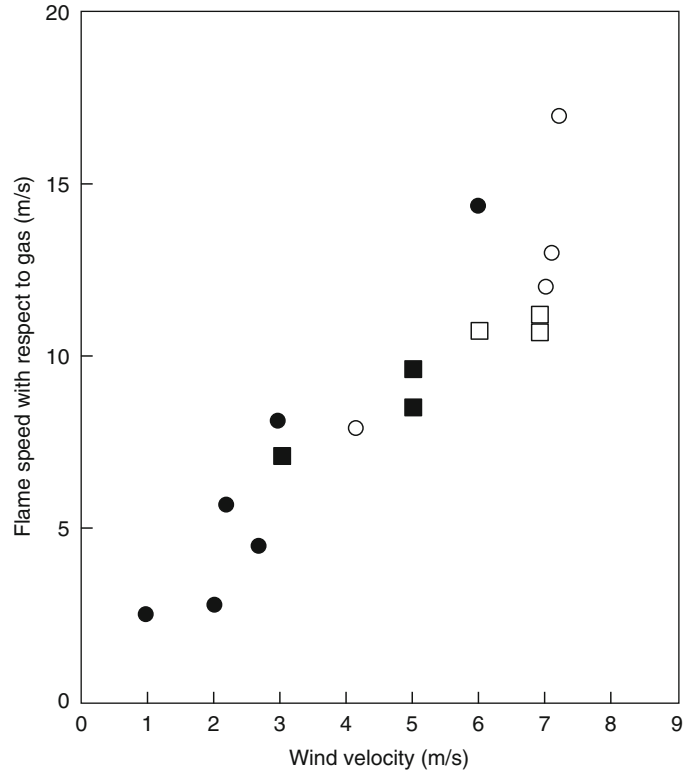

Fig. 66.53 Flame propagation velocities for LP-gas and LNG vapor fires [115]

rates of propane varied from 2.1 to 5.6 m^3/min and the ignition source was located approximately 130 m from the spill point. The wind speeds varied between 6 and 7 m/s. The flame propagation velocities were measured by locating the upwind edge of the flame as a function of time. Their analysis indicates that the flame propagation velocity (with respect to the ground) varies between 3.75 and 4.8 m/s.

In Fig. 66.53 the measured flame propagation velocities (with respect to unburnt gases) are shown for various wind speeds. The data indicate that there is no significant variation in the flame propagation velocities for methane (LNG) and propane (LP-gas). The maximum laminar burning velocity for methane is 0.45 m/s; laminar flame speed is 3.5 m/s; and the typical expansion ratio is 7.4. The corresponding properties for propane are 0.52, 4.0, and 7.6 m/s, respectively. Because these properties are somewhat similar for methane and propane, it is reasonable to expect the turbulent flame propagation velocities to be similar.

Flame Geometry Model Fay and Lewis [116] proposed a model for unsteady burning of unconfined fuel vapor clouds. Based on small-scale experiments with methane, ethane, and propane, and a simple entrainment model, they gave expressions to compute the maximum diameter, height, and duration for complete combustion. The model suggested by Fay and Lewis [116] assumes that the unsteady, turbulent diffusion flame is in the form of a fireball. The correlations given by the authors are validated over a range of small-scale experimental data (up to 200 cm^3) with methane, ethane, and propane gases at room temperature. However, experiments conducted with cold propane vapors ignited in an open environment do not show evidence of a fireball. In fact, the experiments performed by Shell [35] with LNG and LP-gas, and earlier tests involving LNG vapor fires, fail to confirm Fay and Lewis's [116] proposition that diffusive burning in unconfined vapor clouds takes place only in the form of a fireball.

Raj and Emmons [117] presented a theoretical analysis to estimate the ground level width of a large combustible vapor cloud. The model is based on the principle that the plume above a heat source is characterized by the strength of the heat source. In the case of a burning vapor plume, the rate of burning controls the plume characteristics, and the rate of burning itself is a function of the gas velocity within the plume.

The essential features of the Raj and Emmons [117] model are illustrated in Fig. 66.54. The assumptions made in the model development are as follows:

1. The geometry of the burning vapor cloud is two dimensional.
2. The burning is controlled by natural convection (buoyancy).
3. The flame propagation velocity with respect to unburnt gases is relatively constant.
4. The depth of the vapor cloud is uniform and is not affected by the flame.
5. The variation of the depth of vapor in the preburning zone is linear.
6. The steady-state turbulent flame correlation for the ratio of visible flame height to base width is valid.

Using experimentally derived values for flame height-to-width ratio and flame propagation velocity, Raj and Emmons [117] gave the following equation to determine the flame width as a function of time:

$$\tau = \left(\frac{\mathrm{Fr}_f}{\mathrm{Fr}}\right)^{1/3}\left\{\frac{\pi}{3\sqrt{3}} + \frac{2}{3}\ln\left[\frac{\sqrt{\chi^2+\chi+1}}{(1-\chi)}\right] - \frac{2}{\sqrt{3}}\tan^{-1}\left[\frac{2}{\sqrt{3}}\left(\chi+\frac{1}{2}\right)\right]\right\} \tag{66.63}$$

and

$$\chi = \left[\left(\frac{\mathrm{Fr}}{\mathrm{Fr}_f}\right)^{1/3}\xi\right]^{1/2}$$

where

$\xi = W/\delta$

$\tau = 2\ St/\delta$

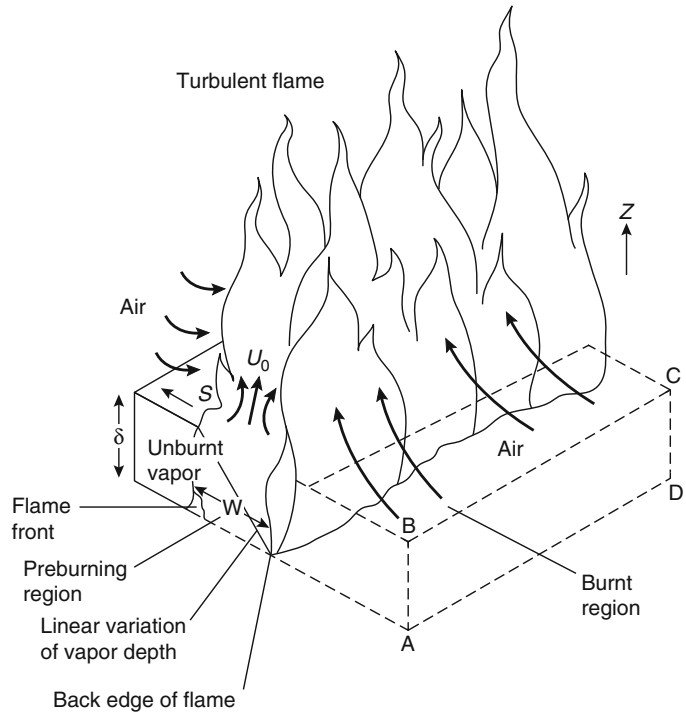

Fig. 66.54 Schematic diagram showing the unconfined burning of a pure flammable vapor cloud

$\mathrm{Fr}_f = S^2/g\delta$ = Flame Froude number
Fr = Froude number = U_0^2/gW
S = Flame propagation velocity, m/s
g = Acceleration due to gravity, m/s^2
δ = Unburnt vapor cloud thickness, m
U_0 = Upward velocity at flame base, m/s
W = Flame width, m

Raj and Emmons [117] estimated the Froude number based on Steward's [88] data on flame heights for hydrocarbon diffusion flames. The analysis indicates the following relationship for the flame height in a linear heat source.

$$\left(\frac{H}{W}\right)_{\text{stoichiometric}} = 4.98 N_{\text{CO}}^{1/3} \tag{66.64}$$

where N_{CO} is the combustion number defined as follows:

$$N_{\text{CO}} = \mathrm{Fr}\frac{\rho_0' 2\omega\left[r + \omega/\rho_o'\right]^2}{(1-\omega)^3} \tag{66.65}$$

where
ρ_0' = Density ratio = Density of vapor at flame base/density of air.
R = Stoichiometic air-fuel mass ratio
ω = Inverse volumetric expansion ratio and is defined as follows:

$$\omega = \frac{1}{\left(1 + Q_c/rC_pT_a\right)} \tag{66.66}$$

where
Q_c = Heat of combustion, J/kg
C_p = Specific heat, J/kg·K
T_a = Ambient temperature, K

The maximum width of the vapor fire is given by the following equation:

$$\xi_\infty = \frac{W_\infty}{\delta} = \left(\frac{\mathrm{Fr}}{\mathrm{Fr}_f}\right)^{-1.3} \tag{66.67}$$

Steward's [88] data indicate that nearly 400 % excess air is entrained in the fire plume. The typical height-to-width ratios measured in Steward's [88] data range between 5 and 50. Raj and Emmons assumed a height-to-width ratio of 2 for LNG vapor fires and demonstrated that Equation 66.67 predicts the observed behavior of flame width.

Experimental data on methane and propane vapor fires indicate that the flame width varies as the cloud propagates back to the spill point. Typically, it has been observed that the flame width increases as a function of time until all the flammable vapor is consumed. The width of the fire reduces to the dimension of the pool. That rate of increase in flame width appears to be slightly less than the flame propagation velocity (with respect to the ground).

The flame length variation can also be estimated as a function of flame width. It is interesting to note that flame length also increases slightly with time, but the ratio of the flame length to flame width is relatively constant. A plot of flame length-to-width ratios for propane vapor flames is shown in Fig. 66.55 [115]. In general, flame length is about 40 % of the flame width. The data of Mizner and Eyre [36] show that the typical flame length-to-width ratio varies between 20 % and 40 %. It is worth noting that vapor fire flame length-to-width ratios are significantly less than flame height-to-diameter ratios for pool fires.

The time-dependent flame width may be calculated using Equation 66.67. Figure 66.56 compares the computed flame width to measured flame widths as a function of time. Although there is considerable scatter in the data, the overall agreement between predicted and observed growth rates is good.

Thermal Radiation The incident flux received by a stationary observer from a propagating vapor is a complex function of several factors. First, the emissive power, which defines the radiative properties of the fire, should be determined. Because the duration of a vapor fire is short, and the steady burning period is even shorter, it is difficult to assign an averaging time for determining emissive powers and average incident fluxes. There is, however, a short period over which the thermal radiation appears to have less fluctuation. This duration can be used in determining average incident fluxes and corresponding emissive powers.

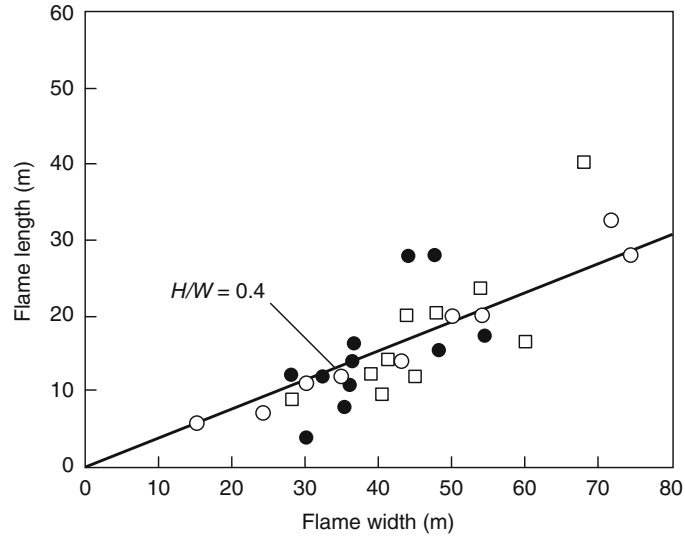

Fig. 66.55 Flame length as a function of flame width [118]

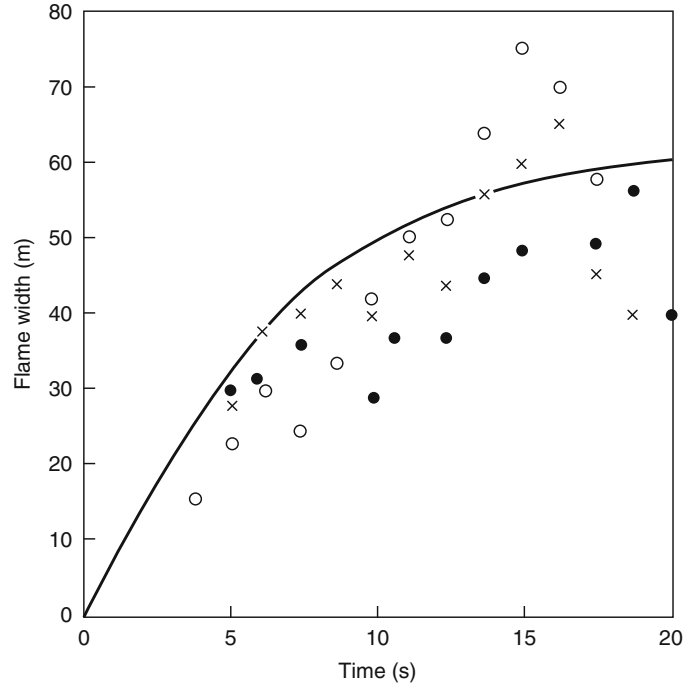

Fig. 66.56 Comparison of predicted and measured flame widths for LP-gas vapor fires [115]

Another important geometrical parameter influencing the thermal radiation from vapor fires is the area of the visible flame. If the flame is optically thick, the thermal radiation increases with an increase in the flame surface area. The area increases rapidly immediately following ignition because both the flame width and flame height increase with time. Therefore, the flame area increases approximately like the square of time. Once the flammable vapors are consumed, the flame area decreases rapidly. The incident flux also increases rapidly due to increasing flame area and drops off as the burnout process begins. The distance to the flame surface is also a

key parameter. Because the flame is in motion, the distance varies continuously until the cloud approaches the spill points where a pool fire is formed. Coupled with the variation in distance is the changing effect of absorption by the water vapor and carbon dioxide in the atmosphere. And finally, the geometry of the flame relative to the observer influences the view factor, that is, that portion of flame "seen" by the observer. Therefore, it is evident that the transient nature of the burning process, affected by the changing geometry, severely limits a detailed characterization of thermal radiation from a vapor cloud fire.

For a simple rectangular flame geometry, the centerline horizontal and vertical view factors can be determined using the following equations [2]:

$$F_h = \frac{1}{2\pi}\left(\tan^{-1}\gamma + \frac{X}{\sqrt{1+X^2}}\tan^{-1}\frac{Y}{\sqrt{1+X^2}}\right) \tag{66.68}$$

$$F_v = \frac{1}{2\pi}\left(\frac{X}{\sqrt{1+X^2}}\tan^{-1}\frac{Y}{\sqrt{1+X^2}} + \frac{Y}{\sqrt{1+Y^2}}\tan^{-1}\frac{X}{\sqrt{1+Y^2}}\right) \tag{66.69}$$

where X = flame length divided by observer distance, and Y = flame width divided by observer distance.

For asymmetric configurations, trigonometic variations of Equations 66.68 and 66.69 can be used to determine the appropriate view factors. The leading edge of the flame (with respect to the observer) may be calculated using the ignition location and the flame propagation velocity. The time-dependent flame width may be calculated using Equation 66.67. Because flame height is related to flame width, the crosswind radiation may be calculated using appropriate view factors. The incident thermal flux is given by the following equation:

$$\dot{q}''_{\text{crosswind}} = EF_{V,H}\tau \tag{66.70}$$

where τ represents the atmospheric transmissivity.

A similar procedure may be adopted to calculate incident thermal radiation in the downwind direction. Here the flame is moving away from the observer at flame propagation speed. Therefore, the downwind incident flux will be at its maximum at the time of ignition (assuming ignition occurs at the downwind edge of the cloud) and will decrease rapidly.

Because of the complex phenomena of a vapor fire, a simple calculation procedure cannot be developed to determine the incident thermal flux. A numerical program based on equations described in this section may be used to determine the time-dependent thermal flux.

Thermal Radiation from Hydrocarbon Fireballs

Fireball combustion occurs when volatile hydrocarbons are released and rapidly ignited. In order to characterize the radiation from fireballs, it is necessary to define the size and dynamics of the fireball and then to assess the radiation based on these results.

Fireball Size and Dynamics

The maximum size of a fireball is governed primarily by the mass of the fuel released and vaporized. Although the fireballs are rarely spherical, an equivalent spherical volume is widely used to characterize the size of a fireball. The maximum diameter of the equivalent spherical fireball is given by

$$D = 5.8\ \text{m}^{1/3} \tag{66.71}$$

where D is the maximum diameter in meters and m is the mass of fuel in kilograms. This expression was synthesized by Roberts [119] from prior work and has been adopted by others since that time (see CCPS [118]). The maximum fireball diameter is independent of the initial pressure of the fuel so long as the pressure and temperature are sufficient to vaporize the fuel. Hasegawa and

Sato [120, 121] suggest that for propane at or above normal ambient temperature (20 °C) complete vaporization will occur.

Although the maximum size of the fireball is independent of the release pressure, the dynamics of the fireball are dependent on the momentum of the release, which results from the flash evaporation of the fuel. For momentum-dominated fireballs, the burning duration is given by

$$t_d = 0.45m^{1/3} \tag{66.72}$$

(see CCPS [118]), where t_d is in seconds and m is in kilograms. For buoyancy-dominated fireballs, such as would be expected for atmospheric pressure releases, the burning duration is given by

$$t_d = 2.6m^{1/6} \tag{66.73}$$

(see CCPS [118]) where t_d is in seconds and m is in kilograms. Not only do burning durations differ for momentum-dominated and buoyancy-dominated fireballs, but the growth histories of the fireballs over their lifetime also differ. For momentum-dominated fireballs, the maximum fireball diameter is reached quickly with the fireball diameter growing initially as the one-fourth power of time (see Fig. 66.57). The fireball diameter remains approximately constant over its lifetime. Conversely, the size of a buoyancy-dominated fireball initially grows as the square of time, controlled by buoyant entrainment processes (Fay and Lewis [116]).

Comparing the above fireball duration equations, it becomes clear that for large fuel masses, the momentum-dominated duration exceeds the buoyancy-dominated duration. Because buoyancy is ever present, the duration should never exceed the buoyancy-dominated duration. As such, even pressurized releases will be dominated by buoyancy for very large masses (greater than about 30,000 kg), and the buoyancy-dominated expression should be used.

For buoyancy-dominated fireballs, not only is the entrainment rate lower, but the fireball rises during its lifetime. As such, during its lifetime the fireball lifts off from the ground. Roberts [119] adopts the correlation of Hardee and Lee [122] for the time to fireball liftoff:

$$t_e = 1.1m^{1/6} \tag{66.74}$$

where t_e is in seconds and m is in kilograms. As one would expect, the liftoff time scales in the same manner as the buoyant fireball duration,

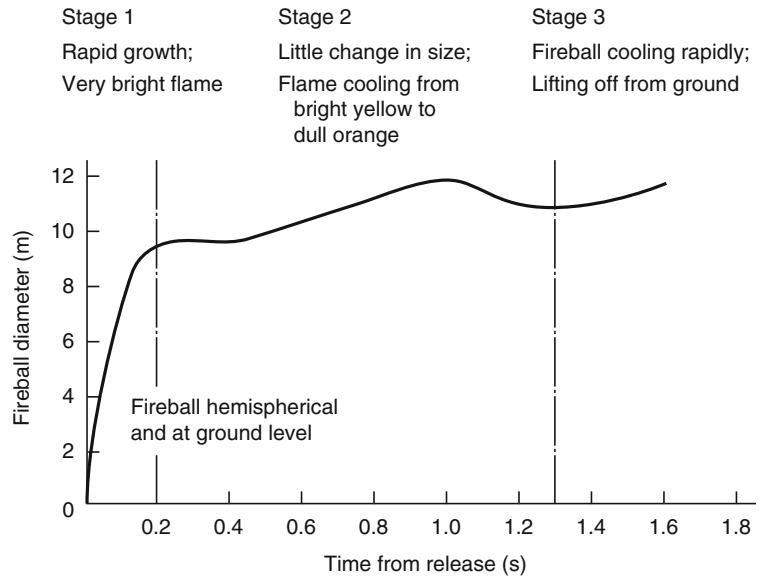

Fig. 66.57 Fireball development as a function of time; 7.5 kg LP-gas released from cylinder bursting [119]

with the liftoff time being about 40 % of the burning duration. Based on the work of Fay and Lewis [116], the maximum rise height of a buoyancy-dominated fireball is approximately five-thirds of the maximum fireball diameter. As such, the maximum rise heights range from one- to five-thirds of the maximum fireball diameter for both momentum- and buoyancy-dominated fireballs.

Fireball Radiation

Radiation models for fireballs use either the point source or spherical source model. The expressions are essentially equivalent under the simplest conditions but vary with geometric conditions where the target cannot view the entire fireball.

Point Source Fireball Model

For the point source model, the incident radiant flux, q, is given by

$$q = \tau \chi_R \cdot \frac{\dot{Q}}{4\pi L^2} \cos\theta \tag{66.75}$$

where
τ = Atmospheric transmissivity
χ_R = Radiative fraction
$\dot{Q}$ = Heat release rate
L = Distance from the target to the point source location
θ = Angle of the target relative to the line of sight connecting the source and target

The heat release rate is normally estimated by assuming that the total heat content of the fireball, Q, is released uniformly over the fireball duration.

$$\dot{Q} = \frac{Q}{t_d} \tag{66.76}$$

The radiative fraction is generally in the range 0.1–0.4. Roberts [119] correlated the data of Hawegawa and Sato [120, 121] to obtain the following correlation for the radiative fraction as a function of the fuel vapor pressure:

$$\chi_R = 0.27P^{0.32} \tag{66.77}$$

where P is the storage pressure (in MPa), and the original data included vapor pressures from 0.2 to 1.4 MPa.

The distance from the point source to the target is given by simple geometry as

$$L = \sqrt{R_T{}^2 + \left(Z_p - H_T\right)^2} \tag{66.78}$$

where
R_T = Horizontal distance from the release to the target
H_T = Target height
Z_p = Height of the point source

The appropriate selection of Z_p is the average height of the center of the fireball. This can range from $D/2$ for high-momentum releases with no buoyancy effects to 5/6 D for buoyancy-dominated releases.

Spherical Fireball Model

The spherical fireball model assumes that the fireball can be characterized as having an average fireball surface emissive power, E, and a diameter, D. The incident radiant flux to a target outside the fireball is given by

$$q = \tau E F \tag{66.79}$$

where τ is the transmissivity of the atmosphere between the fireball and the target and F is the configuration factor.

The configuration factor is strictly a geometric factor. Figure 66.58 shows the relevant geometric details required for the determination of the configuration factor where ϕ is the half-angle subtended by the fireball; θ is the angle of the normal to the target relative to the axis to the fireball; L is the separation of the target from the fireball center; and r is the fireball radius ($r = D/2$) [118]. When $\theta < \pi/2 - \phi$ the configuration factor is simply

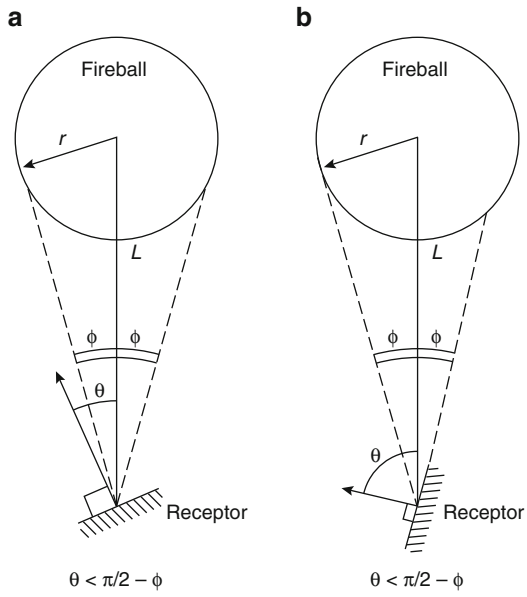

Fig. 66.58 Geometry of a radiative sphere (fireball). (**a**) Receptor "sees" the whole fireball. (**b**) Receptor "sees" part of the fireball

$$F = \left(\frac{r^2}{L^2}\right)(\cos\theta) \quad \text{for } \theta < \frac{\pi}{2} - \phi \tag{66.80}$$

When $\theta > \pi/2$—ϕ, portions of the fireball are not visible to the target and the configuration factor is more complex.

$$F = \frac{1}{2} - \frac{1}{\pi}\sin^{-1}\left[\frac{\left(L^2 - r^2\right)^{1/2}}{L\sin\Theta}\right] + \frac{r^2}{\pi L^2}\cos\Theta\cos^{-1}\left[\frac{\left(L^2 - r^2\right)^{1/2}}{r}\cos\Theta\right] - \frac{1}{\pi L^2}\left(L^2 - r^2\right)^{1/2}\left(r^2 - L^2\cos^2\Theta\right)^{1/2} \quad \text{for } \Theta > \frac{\pi}{2} - \Phi \tag{66.81}$$

where

r = Radius of fireball ($r = D/2$), m
D = Diameter of fireball, m
L = Distance to center of sphere, m
Θ = Angle between normal to surface and connection of point to center of sphere, rad
2Φ = View angle, rad

The appropriate selection of Z_p is the average height of the center of the fireball. This can range from $D/2$ for high-momentum releases with no buoyancy effects to $5/6D$ for buoyancy-dominated releases.

The emissive power of the fireball surfaces have been measured by several investigators and have been found to be in the range of 100–450 kW/m^2. Pape et al. [123] have correlated the data of Hasegawa and Sato in a form similar to the radiative fraction correlation by Roberts [119].

$$E = 235P^{0.39} \tag{66.82}$$

where E is the emissive power in kW/m^2 and P is the vapor pressure in MPa. Measurements by Johnson et al. [124] for 1000 and 2000 kg butane and propane releases at 0.75 and 1.6 MPa yielded surface emissive powers in the range of 320–370 kW/m^2. An emissive power for large-scale releases of 350 kW/m^2 is widely used.

Thermal Radiation Hazards to Personnel

Thermal radiation from hydrocarbon fires may pose significant hazards to both personnel and property. Hazards to personnel result from exposure to intense thermal radiation, causing severe burn injury. In the following subsection the criteria for thermal radiation hazard assessment for determining safe separation distances for personnel are discussed. Discussions of the effects on combustibles and structures can be found elsewhere in the handbook (see Chap. 21).

A comprehensive treatment of skin burn injury calculations is provided by the SFPE [125] and additional information is available in the Institution of Chemical Engineers monograph [126]. The thermal radiation from a fire may cause skin burns if the intensity of radiation and duration of exposure are sufficiently high. Skin burns occur over a continuous range of severity, starting from a burn so minor that the skin is barely damaged and extending

through complete destruction of all skin layers to the underlying tissues or bone. Several classifications of skin burn severity have been proposed, each depending on the degree of skin damage. The most familiar classification is to divide skin burns into three degrees. Even with these three degrees, there are several recognized sublevels. For present purposes, the following levels of burn severity can be used, with the attached simple descriptions:

1. *First degree*. The mildest level of skin burn, characterized by erythema (reddening), but no formation of blisters. The mildest of first-degree burns are not particularly painful and commonly present no medical problem. They may, in fact, not even cause symptoms other than a mild impression of warmth. More severe first-degree burns will produce some pain, but no permanent damage. Flaking or scaling of the skin will occur several days after exposure because of damage to the outer skin layer.
2. *Second degree*. An intermediate level of skin burn, characterized by formation of blisters. Blister depth may be shallow, with only the surface layers of the skin damaged, resulting in a moderate second-degree burn, or with nearly the full depth of the skin destroyed, that is, a severe second-degree burn.
3. *Third degree*. Deep burns, characterized by destruction of all skin layers. The underlying tissue may also be destroyed.

The medical problems of burns covering large areas of the body include the severe loss of fluid and the extreme potential for infection following the loss of a large portion of the protective layers of the skin. Survivability among burn patients has improved over recent decades due to improvements in treatment methods. Survivability of first-degree burns is excellent. Survival of individuals experiencing second-/third-degree burns varies with age, percent of body burned, and preexisting conditions [126–129]. For exposures to radiation from hydrocarbon fires at a distance, it is unlikely that the area of exposure will be below 20 % so that second-degree burns should be regarded as producing significant injury and likely death. Little credit can be taken for reduction of burn hazards by ordinary clothing not designed as thermal protection gear.

Pain and tissue damage are both related to heating of the skin. The skin consists of two main layers: the epidermis, which is a thin (0.05–0.1 mm) outer layer, and the dermis, which is an inner layer (1–2 mm thick). Although the skin is a complex system, models can be used as an aid in predicting skin response to heating. The simplest analysis begins with the assumptions that the skin and underlying tissue behave as a one-dimensional medium with constant thermal properties and heat transfer is due to conduction only.

The data of Buettner [130] and Hardy [131] obtained by having volunteers expose their forearms to varying degrees of thermal radiation, indicate that the threshold pain is felt by human beings when the average temperature of 0.1 mm depth of skin is increased to about 45 °C. They found the critical heat flux for initiation of pain was 1.4–1.7 kW/m^2 (the solar constant is about 1 kW/m^2 on a clear summer day). Hardy artificially varied the initial skin temperature and found that the temperature threshold for pain remained the same and the critical radiant flux for pain was reduced by increased initial skin temperature. Examining the data available in the literature, it was found that the time required for pain at normal initial skin temperatures (~32.5 °C) can be correlated with the intensity of radiation by the following equation [125, 130–133]:

$$t_p = \left(\frac{35}{\dot{q}''_r}\right)^{1.33} \tag{66.83}$$

where t_p is the time to produce pain in seconds, and $\dot{q}''_r$ is the incident radiant flux in kW/m^2. Equation 66.83 applies only at heat fluxes above the critical heat flux for pain of 1.4–1.7 kW/m^2 and normal skin temperature (32.5 °C).

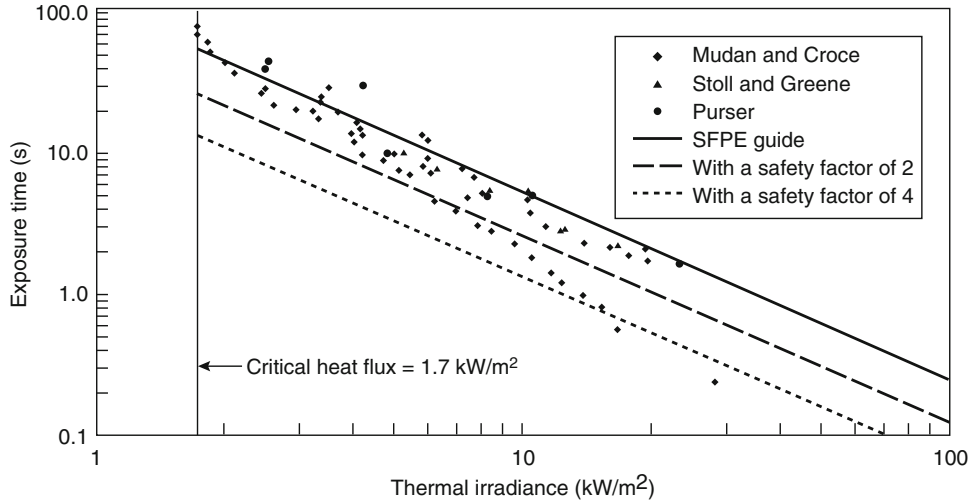

Fig. 66.59 Time for pain on a plot of exposure time versus thermal irradiance [125]. Individual data are shown as points and curve fits to data are shown as *thin lines*

In Fig. 66.59 the time required to cause pain is shown as a function of the incident thermal flux. The figure includes Equation 66.83 as well as curves reflecting factors of safety of 2 and 4 [125]. The sources of data used in Fig. 66.59 include Buettner [130], Hardy [131], Bigelow et al. [132], and Stoll and Greene [133]. The SFPE guide recommends a safety factor of 2 below 6 kW/m^2 and 4 above 6 kW/m^2.

Correlations of the onset of second-degree burns due to radiant heating have also been developed. The SFPE guide [125] recommends the following for second-degree burns:

$$t_B = \left(\frac{300}{\dot{q}_r''}\right)^{-1.46} \tag{66.84}$$

where t_B is the time in seconds to second-degree burns, and q_r'' is the radiant flux in kW/m^2. In Fig. 66.60 the time required to cause second-degree burns is shown as a function of the incident thermal flux. The SFPE guide recommends a safety factor of 1.5. Wieczorek and Dembsey [134] have examined the variability of the exposure required to produce burns based on conditions of exposure.

Correlations of this type are useful for scoping calculations, but because they assume a constant radiant flux, they are not applicable to more realistic time-dependent problems. More detailed methods have been developed, which include different thermal properties for each skin layer, blood profusion, and metabolic heat generation. In addition to more detailed treatment of heat transfer effects, these models also include burn damage to the skin via simple Arrhenius chemical kinetics, denoted the *damage integral*. This approach was developed by Henriques in the late 1940s. This damage integral reaches a value of one at the indicated burn level at the depth within the skin for which the damage has been determined. Mehta et al. [135], Dillon et al. [136], Torvi and Dale [137], Diller and Hayes [138], and Bamford and Boydell [139] are examples of such models. The SFPE guide includes discussion of the damage integral approach.

The *United States Federal Safety Standards for Liquefied Natural Gas Facilities* (49 *CFR*, Part 193, 1980) suggest an acceptable level of 5 kW/m^2 for direct exposure of human beings. At this incident flux, exposure time on bare skin

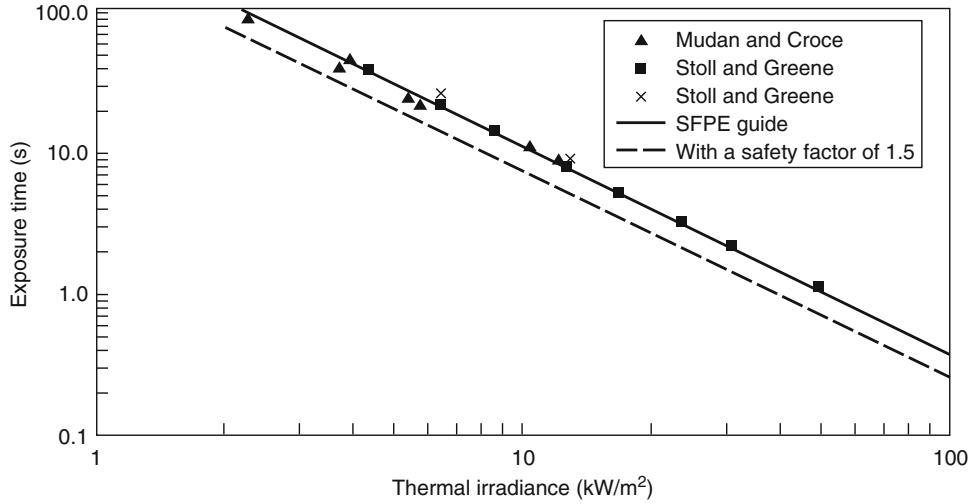

Fig. 66.60 Time for superficial second-degree burn on a plot of exposure time versus thermal irradiance [125]. Individual data are shown as points and curve fits to data are shown as *dashed lines*

before unbearable pain is about 13 s and second-degree burns may occur in about 40 s. This level can, therefore, be used as a criterion for injury for short-duration fireball exposures. Lower radiant flux criteria would be expected for pool or jet fires where the exposure durations can be significantly longer (as low as 1.4–1.7 kW/m^2, the threshold for pain and injury).

Summary

In the previous sections, we have given detailed techniques for computing impacts of large, open hydrocarbon fires. In particular, we have addressed steady-state thermal radiation from pool fires and flame jets and unsteady-state thermal radiation from vapor fires and fireballs. Particular emphasis has been placed on supporting the assessment methodology with available experimental data. These models can be used to appropriate impact criteria to evaluate the fire and flammability hazards associated with hydrocarbon releases.

Vapor Clouds

67

Nicolas F. Ponchaut, Francesco Colella, and Kevin C. Marr

Introduction

Vapor cloud explosions can be devastating events that result in significant damage to property and loss of life. Although vapor cloud explosion hazards are more common for oil and gas facilities, vapor cloud explosion incidents have occurred at other industrial facilities, such as chemical waste and water treatment plants [1, 2]. Analysis of vapor cloud explosions presents many challenges to engineers and investigators and requires an understanding of several issues. Some of these issues include the potential phase change of the source via condensation or flashing, dispersion characteristics of the vapor due to atmospheric conditions, and effects of buildings and structures on cloud dispersion and flame front propagation. The scope of this chapter is to discuss several of these key issues and present practical tools that can be used in vapor cloud explosion investigations or hazard analyses. Owing to the potentially large scale of vapor clouds, representative experimental testing is limited and often impractical. Therefore, this chapter focuses on analytical and computation methodologies that have been validated using experimental tests, and notes several standardized tests that can be used to quantify specific vapor cloud hazards. It is important to note that these methodologies only provide order of magnitude estimates and analysis, and therefore careful interpretation is required. Engineering experience often serves as the most important element to a successful vapor cloud explosion analysis.

In general, four main criteria are required for a vapor cloud explosion—a vapor source, or leak, must occur, the vapor must disperse and form a flammable vapor cloud, the vapor cloud must be ignited by a competent source, and an overpressure must be large enough to produce a pressure wave. This chapter is divided into three main sections—*Vapor Cloud Source*, *Vapor Dispersion*, and *Vapor Ignition*. The *Vapor Cloud Source* section discusses various types of vapor sources and methods to estimate the amount of source fuel. The *Vapor Dispersion* section provides an overview of the fundamentals of vapor dispersion that are useful in determining the size of the vapor cloud. Both sections introduce practical analytical methods and computational models. The *Vapor Ignition* section discusses analytical methods to determine the flammable portion of the vapor cloud, ignition sources, and estimates of the strength of resultant pressure or blast waves. Analyses of hazard scenarios where one or more of these criteria is not met, i.e. BLEVEs (boiling liquid expanding vapor explosions), flash fires and fireballs, are discussed in Chap. 71.

The general procedure for a vapor cloud explosion analysis is to estimate the vapor source, determine the size of the flammable cloud, determine the ignition scenario, and estimate the characteristics of the resultant blast wave. Conceptually, this procedure is straightforward.

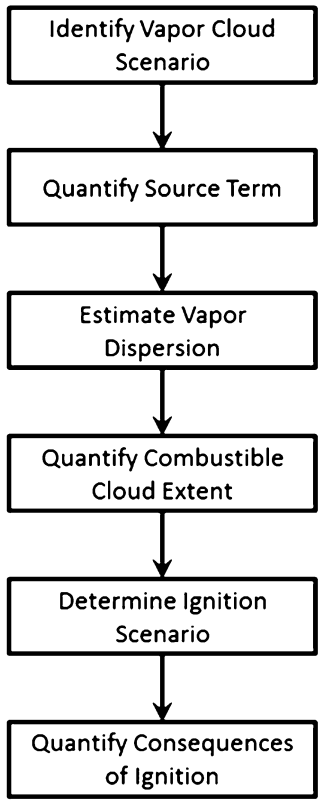

Fig. 67.1 Steps required for a vapor cloud explosion analysis

However, in practice, vapor cloud explosions are complicated events where each scenario consists of several linked events that are influenced by a variety of factors. Depending on these factors, different methods may be required. For example, a gasoline spill may require pool evaporation calculations, whereas a pipe leak may require an orifice flow calculation. Furthermore, variations in atmospheric conditions can affect estimates of cloud size, which in turn affect the magnitude of the resulting blast wave. Figure 67.1 shows a flow chart that organizes the various steps required in performing a vapor cloud explosion analysis. The individual elements of the flow chart are discussed in the subsequent sections in this chapter.

Vapor Cloud Source

Before estimating the extent and the hazard of a vapor cloud, it is first required to evaluate its source. The source of vapor clouds can be sorted in four categories depending on the properties of the involved substance:

- **Gas source:** when the substance is in vapor form both at ambient conditions and inside the leaking system (e.g. natural gas leak);
- **Liquid source:** when the substance is in liquid form, both at ambient conditions and inside the leaking system (e.g. leak of gasoline);
- **Liquefied gas source:** when the substance is in vapor form at ambient conditions but is in liquid form inside the leaking system (e.g. leak of Liquefied Natural Gas or of pressure liquefied propane)
- **Condensing vapor source:** when the substance is in liquid form at ambient conditions (boiling point is above ambient temperate) but is in vapor form inside the leaking system (e.g. in some industrial processes)

A summary of the different types of vapor sources is given in Fig. 67.2.

Gas Source

In the case of a Gas Source, the vapor is released through an orifice and the mass flow rate can be estimated using orifice flow equations. For a compressed vapor at pressure P_1, and density ρ_1, discharging to an ambient pressure P_a, through an orifice opening of area A (see Fig. 67.3), the vapor source mass flow rate can be estimated as

$$\dot{m} = CA\sqrt{2P_1\rho_1\frac{\gamma}{\gamma-1}\left(\frac{P_a}{P_1}\right)^{\frac{2}{\gamma}}\left[1-\left(\frac{P_a}{P_1}\right)^{\frac{\gamma-1}{\gamma}}\right]} \quad \text{if } \frac{P_a}{P_1} > \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$$

$$\dot{m} = CA\sqrt{\gamma P_1\rho_1\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}} \quad \text{if } \frac{P_a}{P_1} < \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}} \text{ (choked flow)}$$

where C is a discharge coefficient that is typically assumed to be lower than but close to 1 (typically around 0.98) [3]. The constant γ is

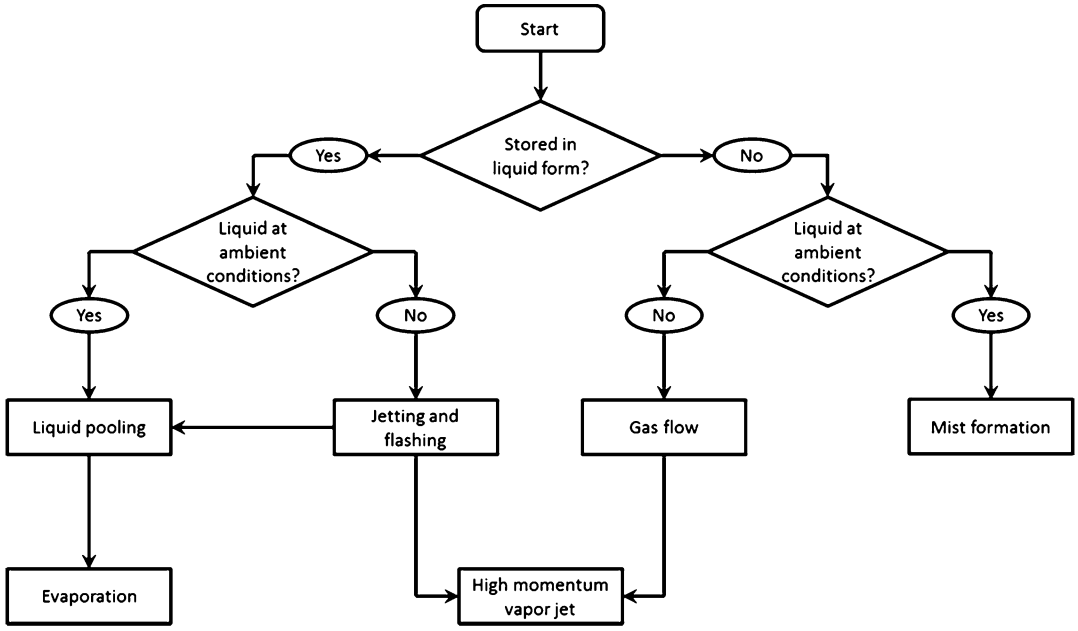

Fig. 67.2 Flowchart of vapor source scenarios

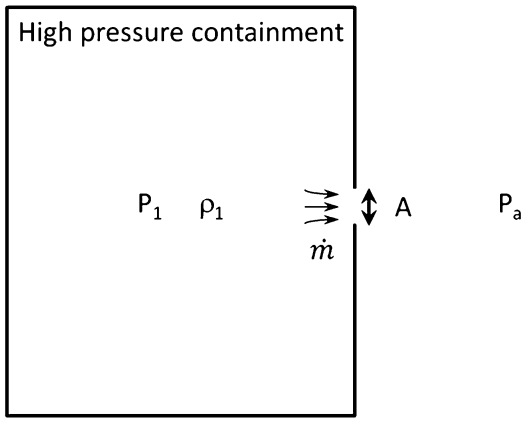

Fig. 67.3 Nomenclature for high pressure gas source

the ratio of specific heats (c_p/c_v), which depends on the gas properties. Values of γ range from 1.00 to 1.67, with more complex molecules leading to lower values. Example values of the ratio of specific heats are given in Table 67.1. Combustible vapors have γ ranging from 1.00 to 1.40. Also included in Table 67.1 is the critical pressure ratio, Above which the flow is choked.

Note that absolute pressures are used in the orifice formula. The vapor leaking through the orifice forms the vapor cloud immediately starting at the orifice.

Liquid Source

When the source is in liquid form and remains liquid when spilled on the ground, a three-step procedure is required to estimate the Vapor Cloud Source. The first step is to determine the spill rate of the substance on the ground or in the containment structure. The second step is to determine how fast the liquid pool is growing, while the third step is to calculate how quickly the pool vaporizes.

Although the evaporation of the pool can influence its growth, for most practical applications the effect of the vaporization rate on pool growth is small. Considering that the pool grows as if it were not evaporating leads to a slight overestimate of its size and therefore produces slightly overestimated evaporation rates.

Table 67.1 Specific heat ratio (γ) for various gases at ambient conditions [4]

Gas	Ratio of specific heat (γ)	Critical pressure ratio $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$
Monoatomic gas (Ar, He, Ne, Xe)	1.67	0.4867
Diatomic gas (Air, H_2, O_2, N_2, CO)	1.40	0.5283
Carbon dioxide (CO_2)	1.29	0.5475
Ammonia (NH_3)	1.31	0.5439
Methane (CH_4)	1.32	0.5421
Ethane (C_2H_6)	1.19	0.5664
Ethylene/ethene (C_2H_4)	1.24	0.5568
Acetylene (C_2H_2)	1.25	0.5549
Propane (C_3H_8)	1.13	0.5785
Propylene/propene (C_3H_6)	1.15	0.5744
Butane (C_4H_{10})	1.10	0.5847

Spill Rate Estimate

The spill rate can be estimated in various manners, depending on the situation. Some examples of spill scenarios are provided in the following list:

- A valve remaining unintentionally open would spill liquid on the ground at a rate determined by a pump or by the pipe system upstream of the valve (e.g. for a gasoline spill from a dispenser in a gas station, the flow is typically <10 gpm);
- For a pressurized liquid spilling through a breach, the orifice flow equation for liquid can be used to determine the spill rate. For a liquid of density ρ, pressurized to a pressure P_1, at an elevation h above the orifice and spilling into an ambient pressure P_a through an orifice opening of area A (see Fig. 67.4), the vapor source mass flow rate can be estimated as

$$\dot{m} = CA\sqrt{2\rho(P_1 - P_a + \rho g h)}$$

where C is a discharge coefficient that is typically assumed to be around 0.60 [4–6], and g is the acceleration due to gravity (9.81 m/s^2).

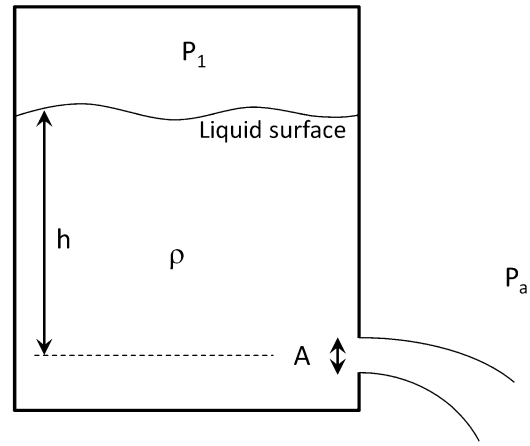

Fig. 67.4 Nomenclature for a pressurized liquid source

- For a liquid container spilling through a pipe system, the leak rate can be estimated using methods such as the K-factor, the equivalent L/D, the Crane or the 3-K (Darby) methods (for example, see [5–8], as well as Chap. 41).

Liquid Pool Growth

Once the spill rate has been identified, the growth of the liquid pool can be estimated. Various methodologies can be used depending on the ground layout and the properties of the fluid. Generally, a conservative assumption is to assume that the liquid spreads instantaneously either to cover the entire containment area or, when the spill is uncontained, to reach a minimum pool thickness. In other words, the area of the pool is:

$$A = \min\left(\frac{V_{\text{Spill}}}{h_{\min}}, A_c\right)$$

where V_{spill} is the spill volume, A_c the containment area, and $h_{\min}$ is the minimum pool thickness that depends on both the liquid and substrate properties: [9]

$$h_{\min} = \max\left(\sqrt{\frac{2\,\sigma\,(1-\cos\theta)}{g\,\rho}}, \varepsilon\right)$$

where σ is the surface tension at the air/liquid interface, θ is the contact angle (i.e. the angle of

the air/liquid interface where it meets the ground), and ε is the roughness of the substrate. The first term in the parentheses represents the thickness of a pool on a flat surface due to its surface tension, while the second represents the effect of surface roughness. In most practical applications, spills occur on concrete or on soil, and the surface roughness dominates any surface tension effects ($h_{\min} = \varepsilon$). A few examples of minimum pool thicknesses are given in Table 67.2.

Assuming that the pool spreads instantaneously leads to an upper bound on the vapor source rates. When a more refined analysis is required, such as a finite pool growth analysis, numerical models should be used. A non-exhaustive list of available model types is presented below in order of increasing complexity and accuracy:

- **Integral models**: In these models, the pool is assumed to spread axisymmetrically and its size and thickness are stretched according to energy and mass balance equations. The axis of symmetry of the pool coincides with spill location. The pool depth is usually either uniform or has a quadratic profile. This quadratic profile is based on a theoretical solution of the spread of a pool profile on *liquid* substrate as obtained by Hoult [11]. The edge of the pool has a typical thickness $h(t)$ and moves at a velocity $U(t)$ such that

$$U(t) = \sqrt{K\, g \max(0, h(t) - h_{\min})}$$

for spills on solid substrates;

$$\sqrt{K\, g \left(1 - \frac{\rho_{\text{Spill}}}{\rho_{\text{Substrate}}}\right) \max(0, h(t) - h_{\min})}$$

for spills on liquid substrates.

In this equation, K is a constant with a value between 1.16 and 2.0, depending on the software that is used [12]. Because of the assumptions used in integral models, features such as hydraulic jumps that are clearly observed for example when a garden hose is pointed at a wall are not considered. An anomaly of these models is that changes of leak rate affect the entire pool instantaneously. These models can only be used in axisymmetric geometries with flat ground and no obstacles. Integral models are used in GASP (Gas Accumulation over Spreading Pools), SuperChems, Breeze and PHAST [10, 11, 13–16].

- **One-dimensional—"shallow water equations"**: These models are best suited for pools that spread in a single direction such as round pools with radial spread or flow in long trenches. The effect of a sloped ground is included in some models. The models do not assume that the pool is of predefined thickness and can therefore capture most of the details of the pool. [17] These models cannot model the flow through trench branches or elbows (that slow down the liquid spread). Packages such as LSMS (Liquid Spill Modeling System) and ESM (Exponent Spill Model) use this type of model. [17, 18]
- **Two-dimensional—"shallow water equations"**: These models are suited for most pool scenarios and ground configurations. They can represent most of the flow features. The only drawback is their inability to model three dimensional effects such as step changes in ground height or vortices behind obstacles and trench corners. This type of model is used in the Computational Fluid Dynamics (CFD) software FLACS [19, 20].
- **Full three-dimensional models**: Modern CFD (Computational Fluid Dynamics) models can represent virtually any geometries and obstacles. They solve the full three-dimensional flow and are therefore the most accurate method to predict pool growth, but can be computationally intensive. The

		Molecular mass MW	Vapor p ressure P_v	Liquid heat capacity c	Latent heat of vaporization ΔH_v
n-Pentane	C_5H_{12}	72	50.0 kPa	2.33 kJ/kg-K	357 kJ/kg
n-Hexane	C_6H_{14}	86	14.3 kPa	2.24 kJ/kg-K	335 kJ/kg
n-Heptane	C_7H_{16}	100	5.35 kPa	2.20 kJ/kg-K	316 kJ/kg
iso-Octane	C_8H_{18}	114	4.88 kPa	2.15 kJ/kg-K	272 kJ/kg

Volume Of Fluid (VOF) model is typically used to track the interface between the pool and the ambient air. Both the spilled substance and the ambient air flows are solved in the simulations. Commercially available software such as Fluent [21] and Star-CCM+ [22] are examples of Computational Fluid Dynamics models that can be used for such simulations.

Pool Evaporation

Once the evolution of the pool size has been estimated, the evaporation can be modeled. Since the substance is in liquid form at ambient conditions, the vaporization is heavily dictated by the vapor pressure of the spilled substance, P_v (see Table 67.3 for typical vapor pressures). The higher the saturation pressure, the faster the evaporation. While the vapor is at saturation conditions right above the surface of the pool, the surroundings are not. This leads to diffusion of the vapor from the pool surface to the atmosphere.

The vapor pressure is highly dependent on temperature and can be easily estimated using the Clapeyron-Clausius equation

$$P_v = 133.3 \times 10^{-0.2185\frac{E}{T}+F}$$

where P_v is the vapor pressure in Pa, T is the temperature in K, and E and F are constants. Example values of the constants E and F are provided in Table 67.4 along with the temperature range in which the equation is applicable.

The evaporation rate of a liquid pool in ambient air, $\dot{m}$ (in kg/s), can be estimated by the Mackey and Matsugu model:

Table 67.4 Clapeyron-Clausius equation constants for common organic compounds. [24]

		E	F	Temperature range
n-Pentane	C_5H_{12}	6595.1	7.4897	−77 °C to 191 °C
n-Hexane	C_6H_{14}	7627.2	7.7171	−54 °C to 209 °C
n-Heptane	C_7H_{16}	8928.8	8.2585	
iso-Octane	C_8H_{18}	8548.0	7.9349	−36 °C to 99 °C

$$\dot{m} = 0.00482\, A_p\, Sc^{-0.67} u_{10}^{0.78}\, l^{-0.11} \frac{P_v\, MW}{\overline{R}\, T}$$

where A_p is the pool area in m^2, u_{10} is the wind speed measured 10 m above the ground in m/s, P_v and MW are the vapor pressure in Pa and the molecular mass of the spilled substance (in kg/kmol), and T is the pool temperature in K [25, 3, 26]. l is the characteristic length of the pool in m (i.e. the diameter in the case of a circular pool and the length along the wind direction for a rectangular pool). Finally, $\overline{R}_r$ is the universal gas constant (8314 Pa-m^3/kmol-K) and Sc is the Schmidt number of the substance. The Schmidt number for gases and vapors is typically around 0.8, which simplifies the Mackey and Matsugu model to [15].

$$\dot{m} = 6.73 \text{ x } 10^{-7}\, A_p\, u_{10}^{0.78}\, l^{-0.11} \frac{P_v\, MW}{T}$$

Note that at vapor pressures above 0.2 atm, the air over the pool starts to contain a significant amount of vapors affecting the thermodynamic properties of the surrounding air. For this reason, for vapor pressures above 0.2 atm, several authors recommend that the vapor pressure P_v be replaced by [16]

$$P_a \ln\left(\frac{P_a}{P_a - P_v}\right)$$

Since vapor pressures are heavily dependent on temperature, it is often required to evaluate the evolution of the pool temperature as it evaporates. The temperature of the pool is primarily influenced by an energy balance accounting for:

- Heat transfer with the ground that can supply or remove heat depending on temperature;
- Heat transfer due to the wind blowing over the pool and, when applicable, due to sun radiation;
- Heat sink due to the vaporization itself that removes energy directly from the pool.

For a pool of evolving mass m, the average pool temperature changes according to:

$$\frac{dT}{dt} = \frac{1}{m\, c_l}\left(\dot{Q}_c + \dot{Q}_g - \dot{Q}_v + \dot{Q}_r\right)$$

where c_l is the heat capacity of the liquid (see Table 67.3). In this equation, the different heat contributions, $\dot{Q}_c$ are the following:

– $\dot{Q}_c$ is the heat transferred from the atmosphere to the pool due to convection

$$\dot{Q}_c = \frac{A_p\, k_a}{l}\,(T_a - T)\left(0.037\left(\frac{\rho_a\, u_{10}\, l}{\mu_a}\right)^{0.8} - 871\right) Pr_a^{1/3}$$

where the values of the thermal conductivity and the viscosity of air are given in Table 67.5. More detailed convection correlations are provided in Chap. 3.

– $\dot{Q}_g$ is the heat transferred from or to the ground. Since the ground temperature evolves over time, the time from when the liquid first wet the ground is an important parameter. This time parameter differs for different parts of the pool due to the finite growth of the pool. At the center of the pool the ground is wetted earlier than near its leading edge. The following equation should be used [25, 28]

$$\dot{Q}_g(t) = \frac{k_g}{\sqrt{\alpha_g\, \pi}}\,(T_g - T)\int_0^{A_p(t)} \frac{dA_p}{\sqrt{t - \tau(A_p)}}$$

where $A_p(t)$ is the area of the pool at time t, $\tau(A_p)$ is the time at which the pool has grown to an area A_p, k_g is the ground thermal conductivity, and α_g is the ground thermal diffusivity. Typical values for ground thermal properties are provided in Table 67.6.

Table 67.5 Thermal properties of air at ambient temperatures. [27]

Air properties at 10 °C		
Density	ρ_a	1.293 kg/m^3
Thermal conductivity	k_a	0.02492 W/m-K
Dynamic viscosity	μ_a	1.71×10^{-5} kg/m-s
Prandtl number	Pr_a	0.71

Table 67.6 Thermal properties of various ground substrates at ambient temperature. [25, 27, 17]

Substrate material	Thermal conductivity k_g	Thermal diffusivity α_g
Concrete	1.35 W/m-K	5.2×10^{-7} m^2/s
Aerated concrete	0.28 W/m-K	2.6×10^{-7} m^2/s
Soil (average)	0.96 W/m-K	4.6×10^{-7} m^2/s
Soil (sandy, dry)	0.26 W/m-K	2.0×10^{-7} m^2/s
Soil (sandy, 8 % moist)	0.59 W/m-K	3.3×10^{-7} m^2/s
Carbon steel (1 %)	45.8 W/m-K	1.27×10^{-5} m^2/s

This formula can be simplified in the case where the pool wets the entire area instantaneously at time $t = 0$, leading to:

$$\dot{Q}_g = \frac{A_p\, k_g}{\sqrt{\alpha_g\, \pi\, t}}\,(T_g - T)$$

Note that that the two equations above assume that the temperature difference between the pool and the ground remains much larger than the temperature variation of the pool; a more accurate analysis should be performed when this approximation is invalid.

– $\dot{Q}_v$ is the heat taken away from the pool due to vaporization:

$$\dot{Q}_v = \dot{m}\, \Delta H_v$$

Where ΔH_v is the heat of vaporization of the substance being evaporated (see Table 67.3).

– $\dot{Q}_r$ is the heat exchanged by radiation. This includes direct radiation from the sun (which typically involves consideration for solar angle and cloud coverage), radiation between the pool and the atmosphere and, if applicable, radiation from the flames if the pool is involved in a fire.

It is important to realize that in the case of liquid spills, the vapor cloud source can last for much longer than the spill itself. For clouds forming outside of buildings or in well ventilated locations, vapors will continue to form for as long as there is liquid on the ground.

Liquefied Gas Source

The liquefied gas source refers to substances stored in liquid form that vaporize at ambient conditions. The gas can be liquefied in two different ways. In the pressure liquefied gas case, the substance is pressurized in the system to stay in liquid form at a temperature above its boiling point at ambient conditions (e.g. propane or butane bottles). In the subcooled gas case (refrigerated liquid), the gases are kept sufficiently cold to be in liquid form (e.g. cryogenic liquids, LNG—Liquefied Natural Gas).

When contained under pressures above ambient, the liquefied gas source leak creates a two phase jet that is commonly referred to as "jetting and flashing." A portion of the liquid ejected through the breach flashes immediately and becomes vapor, while the remainder remains liquid and forms small droplets that can either remain suspended and evaporate before reaching the ground or rain-out and pool on the ground (see Fig. 67.5). The speed of the jet and the amount of flashing depends on the pressure at which the liquid is stored and on the size of the breach.

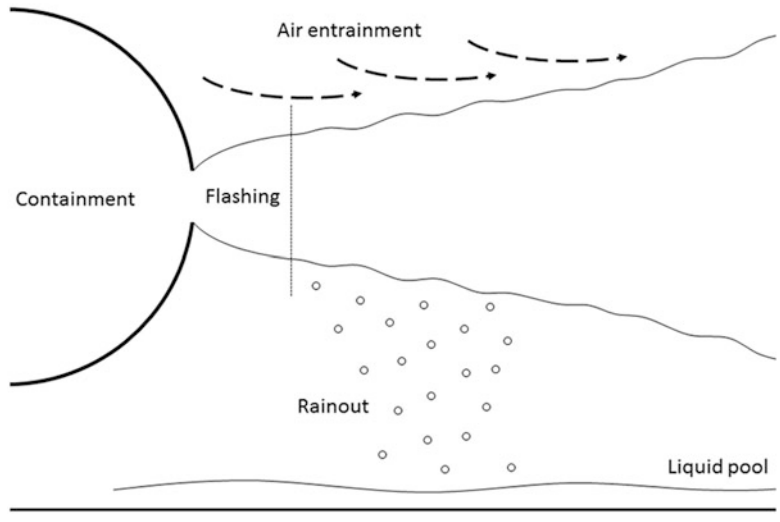

Fig. 67.5 Schematic of a jetting and flashing event

Pressure Liquefied Gas

In the case of a pressure liquefied gas source, a portion will vaporize as the pressure drops across the breach. The liquid will start vaporizing within the breach, and as a result, the orifice flow equations need to be adjusted. In particular, Leung [25] found that for a substance stored at an absolute temperature, T_0, and pressure, P_0, expanding through an orifice to an ambient pressure, P_a, a correlating parameter ω can be defined as

$$\omega = c_l \, T_0 \, P_0 \, \rho_l \left(\frac{\frac{1}{\rho_v} - \frac{1}{\rho_l}}{h_v - h_l} \right)^2$$

where all the properties are taken at T_0 and P_0. The subscripts l and v refer to saturated liquid and vapor properties, respectively; c, ρ and h are the specific heat, the density and the enthalpy of the substance. Using the parameter ω the critical pressure ratio P_c/P_0 can be obtained using Fig. 67.6.

If the critical pressure P_c is above the ambient pressure P_a, the flow through the breach is choked. In this case, the substance does not expand completely in the breach, but continues to flash away from the orifice until the substance reaches the ambient pressure. The choked flow rate can be estimated as

$$\dot{m} = A \, P_c \sqrt{\frac{\rho_l}{P_0 \, \omega}}$$

If the flow is not choked, i.e. if the critical pressure is below ambient, the flow is estimated by

$$\dot{m} = A \, P_a \sqrt{\frac{\rho_l}{P_0 \, \omega}}$$

As a result of this change of phase, the jet cools down. If the jet does not cool sufficiently to reach the boiling temperature at ambient pressure, all the substance turns into vapor immediately (i.e. there is no pooling on the ground). However, if the jet cools down sufficiently to reach its boiling temperature, the vaporization stops and a portion of the substance remains in liquid droplet form inside the cloud or forms a cold pool on the ground. Note that the jet entrains surrounding air which provides additional heat to the jet, resulting in additional vapor formation.

Refrigerated Liquid

In the case of a refrigerated liquid source, most of the phase change process is a result of temperature differences rather than of a pressure change. The flow through the breach can therefore be estimated using the orifice flow for liquid sources. Once the liquid has gone through the

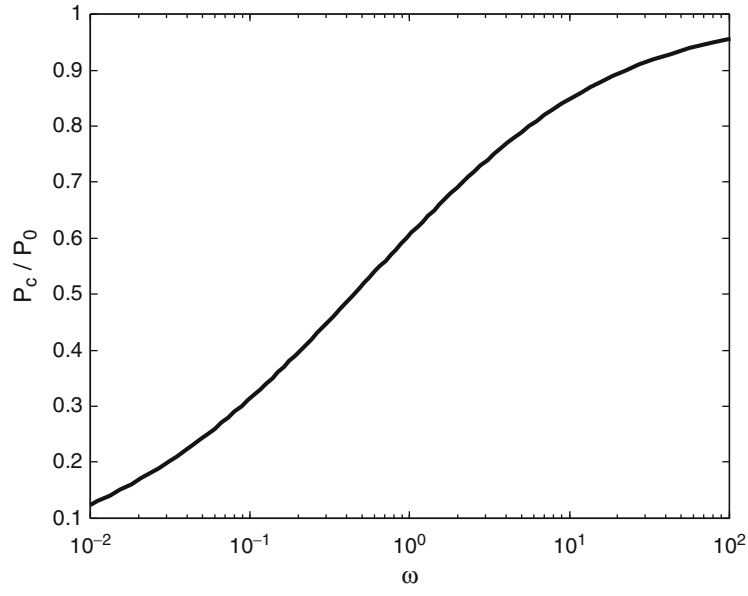

Fig. 67.6 Pressure ratio at critical flow

breach, it mixes with the surrounding air due to turbulence. The ambient air provides the heat required to vaporize the substance. If the mixing is sufficiently strong compared to the leak rate, the gas vaporizes completely. If it does not, a portion of the jet will remain in liquid form (i.e. droplets or pool on the ground).

Vaporization

Both pressure liquefied gas and refrigerated liquid leaks can lead to pooling of the substance at its boiling temperature. Once the leak rate through the breach has been obtained, the expansion of the jet due to flashing can be estimated. Software such as PHAST and FLASH (sub routine of the FLACS software) can be used to estimate the proportion of the substance that vaporizes immediately and the amount of liquid that pools on the ground. Such software relies on conservation of mass, momentum and energy, but also includes empirical correlations to estimate the amount of air entrained into the jet, the jet cone angle and the droplet size.

In addition to the portion of the jet that vaporizes immediately, the resulting droplets will continue to vaporize as the cloud mixes with warm ambient air. As for the liquid portion pooling on the ground, since it is at its boiling temperature, the vaporization rate is only limited by the amount of heat that the pool can extract from its surrounding. As a result, the following vaporization rate can be used

$$\dot{m} = \frac{\dot{Q}_c + \dot{Q}_g + \dot{Q}_r}{\Delta H_v}$$

Where $\dot{Q}_c$, $\dot{Q}_g$, and $\dot{Q}_r$ are the heat fluxes due to wind convection, ground conduction and radiation, respectively. The temperature of the pool stays constant at its boiling point.

Note that when pool is much colder than ambient temperature (i.e. in the case of a spill of a refrigerated liquid such as a cryogenic liquid), the conduction from the ground is by far the dominant heat source term. In such cases, convection and radiation can be ignored [18].

Condensing Vapor Source

When the substance has a boiling point that is above ambient temperature and is stored and/or utilized as a vapor, any release will cause it to condense when it comes in contact with ambient air. Under these conditions, the vapor source flow rate can be estimated as a gas source. However, once the vapors mix with air, they condense to form small droplets that may either pool on the ground or stay in suspension and evaporate particularly if the vapor pressure of the substance is high.

The proportion of droplets that would be light enough to stay in suspension depend on the pressure of the source and the velocity at the point of release and also require empirical correlations and the knowledge of the ambient conditions (i.e. wind). Condensing vapor sources are not common but can occur in industrial settings under very specific conditions. Detailed analysis of the behavior of condensing vapor source clouds is beyond the scope of this chapter.

Vapor Dispersion

The accidental release and ignition of flammable gases can result in hazards associated with heat exposure (i.e. in case of flash fires) or structural damage due to overpressure (i.e. in case of a vapor cloud explosion). The dispersion process of vapor or gas clouds is a complex phenomenon that is controlled by several variables including geometry and nature of the leak (see Chap. 71), atmospheric conditions, terrain features and the presence of obstacles and obstructions. The atmospheric variables that affect the cloud dispersion process include atmospheric stability, wind velocity and direction as well as humidity and temperature.

Determination of the Atmospheric Stability

Atmospheric stability is a measure of the tendency of the atmosphere to enhance or to decrease the vertical displacement of air parcels

and can be interpreted as a measure of atmospheric vertical mixing. A detailed description of the physical aspects of atmospheric stability is beyond the scope of this chapter and can be found in Hanna [29].

Atmospheric stability is usually classified according to the Pasquill and Gifford scheme. Stability classes A through C refer to unstable conditions and are characterized by significant vertical mixing. These conditions are generally encountered during the daytime hours where strong movements of upward convected air are generated due to ground heating from strong solar radiation. Stability classes E and F refer to stable conditions and generally occur during night time hours. In these conditions, the ground cools due to radiant heat transfer to the atmosphere, and atmospheric turbulence is suppressed due to the formation of stable density stratification. Stability class D represents neutral stability conditions and can be assumed for overcast conditions during day or night regardless of the wind speed.

Several methods have been developed for the determination of the atmospheric stability conditions. They are based on detailed temperature profiles or vertical wind speed measurements. A review of the different classification schemes is given by Woodward [30]. The simplest method for the evaluation of the atmospheric stability based on simple observable quantities (wind speed and sun radiation) has been developed by Gifford [31] and is summarized in Table 67.7.

According to Turner [32], night refers to the period from 1 hour before sunset to 1 hour after sunrise. Turner specifies that the neutral class D can be used for overcast conditions during day or night regardless of the wind speed. The categories of "strong" and "slight" solar radiation are typically associated with clear skies and solar altitude above the horizon greater than 60° and between 15° and 35°, respectively. Daytime cloudiness will reduce "strong" solar radiation to "moderate" with broken middle clouds (5/8 to 7/8 cloud cover) and to "slight" with broken low clouds.

It should be noted that the above methodology applies to open flat terrain and rural areas and is less accurate for urban areas due to the increased surface roughness and non-uniform temperature distribution. In these conditions, alternative methods would provide more accurate estimations [30].

Determination of the Wind Conditions

Wind direction information can be obtained by wind rose diagrams. These are polar diagrams in which the length of the sections is proportional to the frequency of particular wind directions and speeds. The shape of the vertical wind profile is dictated by the presence of an atmospheric boundary layer that reflects the gradual rise in wind velocity above the ground. There are two common approaches used for the definition of the wind profile in the lowest 1000 m of the atmosphere: the logarithmic and the power law profiles [30].

Table 67.7 Determination of the atmospheric stability as function of wind speed and solar radiation according to Gifford [31]

	Day			Night	
	Incoming solar radiation				
Surface wind speed (at 10 m) [m/s]	Strong	Moderate	Slight	Thinly overcast or ≥4/8 low cloud	≤3/8 cloud cover
<2	A	A–B	B	E	F
2–3	A–B	B	C	E	F
3–5	B	B–C	C	D	E
5–6	C	C–D	D	D	D
6	C	D	D	D	D

According to the power-law profile, the wind speed at different heights from the ground can be correlated as:

$$u = u_{10}\left(\frac{z}{z_{10}}\right)^{\alpha}$$

where u is the wind velocity at the height z, u_{10} is the wind velocity at the height of 10 m and α is a coefficient that depends on the atmospheric stability class and the terrain roughness. Some variability has been observed in the literature on the value of the power-law exponent α [33]. Table 67.8 contains some typical power law exponents as a function of the atmospheric stability class and the type of environment.

The alternative form for the wind profile is based on the logarithmic law

$$u = \frac{u_*}{\kappa}\left[ln\left(\frac{z}{z_0}\right) - \Psi\left(\frac{z}{L}\right)\right]$$

where u_* is the friction velocity, κ is the Von Karman constant (equal to 0.40), z_0 is the surface roughness length, L is the Monin-Obukov length scale, and Ψ is a function of the height z, the Monin-Obukov length scale L and the atmospheric stability class. The friction velocity u^* is determined from substituting a reference height and the actual wind velocity at the reference height for z and u in Equation X. Typical a reference height of 10 m is chosen.

Table 67.8 Power law exponent dependence on stability atmospheric stability class and the type of environment [33]

	Stability class	α Urban environment	α Rural environment
Very unstable	A	0.15	0.07
Unstable	B	0.15	0.07
Slightly unstable	C	0.20	0.10
Neutral	D	0.25	0.15
Stable	E	0.40	0.35
Very stable	F	0.60	0.55

The Monin-Obukov length scale represents the approximate height at which the production of turbulent kinetic energy due to buoyancy and shear forces are comparable [34]. The atmospheric stability conditions and the Monin-Obukov length scale are correlated as follow:

- $L > 0$ stable
- $L < 0$ unstable
- $L = \infty$ (practically $>10^5$) neutral

An estimation of the typical roughness length for various types of environments is provided in Table 67.9.

The most immediate calculation of L is based on a set of interpolation functions that have been proposed by Spicer and Havens (see [36]) in order to fit meteorological data from Pasquill [37]. The interpolation functions relate L to roughness height z_0 using the following power law equation:

$$L = cz_0{}^b$$

The curve fitting coefficients, c and b, for each atmospheric stability class are summarized in Table 67.10.

An alternative method proposed by Golder [38] relates the atmospheric stability class and the local surface roughness length to the Monin-Obukov length scale. Golder's results were presented in graphical form (see Fig. 67.7). Ana-

Table 67.9 Roughness length of various types of environments [35]

Terrain	z_0 [m]
Open water (at least 5 km)	0.0002

[a]Note: the Monin-Obukov length scale is infinite for Neutral stability

lytical expressions have been derived and can be found in [35].

According to Spicer and Havens the term $\Psi\left(\frac{z}{L}\right)$ can be evaluated as follows [36]:

$\Psi = 2\ln\left(\frac{1+a}{2}\right) + \ln\left(\frac{1+a^2}{2}\right) - 2tan^{-1}(a) + \frac{\pi}{2}$ Where $a = \left(1 - 15\left(\frac{z}{L}\right)\right)^{1/4}$	For stability A, B and C
$\Psi = 0$	For stability D
$\Psi = -4.7\left(\frac{z}{L}\right)$	For stability E and F

The interested reader can refer to [34] for a complete description of the procedure or for the calculation of the temperature profile in all stability classes.

Types of Vapor Clouds

The cloud dispersion behavior strongly depends on the characteristics of the leak—material released, nature of the release (low momentum release or high speed jet)—and on the atmospheric condition. Several research papers and reports on the atmospheric dispersion of vapor clouds have been published in the last few decades. The interested reader should refer to Hanna et al. (1982) [29], Britter and McQuaid (1988) [39], Britter (1989) [40], Spicer and Havens (1989) [36], Luketa-Hanlin (2006) [41], and Koopman and Ermak (2007) [42] for a complete review of the subject.

Classification

All the above mentioned references propose a classification of vapor clouds based on some sort of release Richardson number. One of the most comprehensive vapor cloud classification procedures has been proposed by Spicer and Havens [43]. The authors defined the release Richardson number as

$$Ri_c = \frac{g}{u_*^2}\left(\frac{\rho_i - \rho_a}{\rho_a}\right)\frac{\dot{m}}{\rho_i u_{10} D}$$

where $\dot{m}$ is the release rate, ρ_i is the initial density of the flammable gas, D is the diameter of the source, u_{10} is the wind velocity at 10 m elevation, u_* is the friction velocity, ρ_a is the ambient density and g is the acceleration due to gravity. Depending on the Richardson number, the release, and the wind velocity, four different regimes can be identified [36]:

- **Negative buoyancy dominated flows**: In this regime, typical dense gas features such as gravity induced slumping and lateral spreading of the cloud can be observed. This regime is typically observed when $Ri_c > 30$ and $\left(\frac{u_0}{u_*}\right)^2 < 10\,Ri_c$, where u_0 is the estimated release velocity at the leak location.
- **Stably stratified shear flows**: In this regime, the cloud is embedded in the mean wind flow and the density stratification tends to damp turbulence and reduce vertical mixing. This regime is typically observed when $1 < Ri_c < 30$ and $\left(\frac{u_0}{u_{10}}\right) < 16/(19 + Ri_c)$
- **Passive dispersion regime**: This regime is typically observed when $Ri_c < 1$ and $\left(\frac{u_0}{u_{10}}\right) < 0.8$. In the passive dispersion regime the dense gas effects are negligible and can be ignored.
- **High momentum release (jets)**: Any release not falling in one of the three categories above should be classified as high momentum release. In these cases the vapor dispersion process is strongly influenced by the jet induced turbulence. In comparison to the other cases, high momentum jets entrain

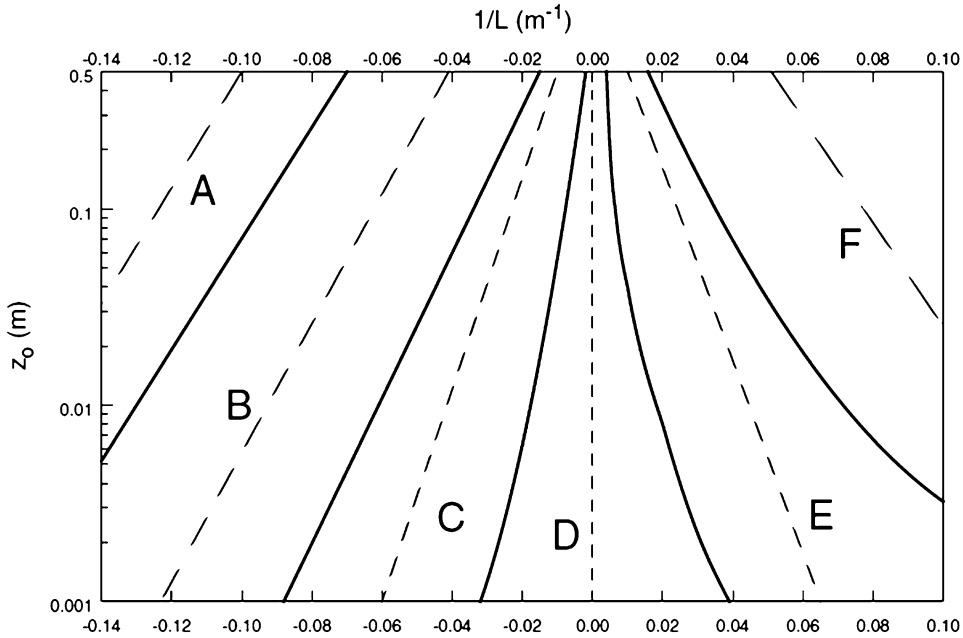

Fig. 67.7 Graph proposed by Goldner [38] for the evaluation of the Monin-Obukov length scale as function of the stability class and local surface roughness

more air and typically lead to a rapid reduction of the vapor concentration very close to the leak. High momentum releases will gradually transition to low momentum releases (one of the three other cases) as the distance from the source increases.

Release types can also be classified according to the duration in continuous and instantaneous releases. In general, the following classification can be adopted:

- A release is instantaneous when the release time is shorter than the time required by the vapor cloud to reach a given location.
- A release is continuous when the release time is longer than the time required by the vapor cloud to reach a given location.

Therefore, a given release will be classified as continuous or instantaneous depending on the relative position of the observer. According to the criteria proposed by Britter and McQuaid [39] and described by Casal [33], a release is considered continuous at a downstream location x, when

$$\left(\frac{u\,t_r}{x}\right) \geq 2.5$$

where t_r is the duration of the release, and u is the wind speed. A release will be classified as instantaneous when

$$\left(\frac{u\,t_r}{x}\right) \leq 0.6$$

Releases with intermediate duration should be analyzed as both instantaneous and continuous where the smaller resulting concentration should be taken as upper bound [33].

Characteristics of Vapor Clouds

This section provides an overview of the different release types: (1) dense gas clouds, (2) jets, and (3) neutral clouds.

Negative Buoyancy Dominated and Stably Stratified Shear Flows

Dense gas clouds are generated by the release of vapor or gas characterized by a density sufficiently larger than the ambient density. The

density of the cloud will be determined by both the molecular properties of the cloud chemical compounds and its temperature. According to Britter [40], dense gas clouds can be classified in the following categories:

- Clouds containing high molecular weight compounds (e.g. chlorine clouds)
- Clouds containing low molecular weight compounds at low temperature (e.g. LNG cloud generated by the evaporation of an liquid LNG pool onto a warm surface)
- Clouds containing low molecular weight compounds whose vapor at the boiling temperature is less dense than the environment but includes liquid droplets. The presence of the liquid droplets as well as their evaporation result in an increased cloud density (e.g. ammonia).
- Clouds containing chemical compounds that react with the ambient water vapor resulting in high density clouds (e.g. nitrogen Tetroxide (N_2O_4) and hydrogen fluoride (HF)).

Dense vapor clouds are characterized by phenomena that are radically different from those observed for positively buoyant or momentum driven clouds:

- Reduction of the vertical turbulent mixing due to the generation of a stable stratified environment;
- Generation of horizontal spreading currents controlled by the density difference between the cloud and the environment.

Due to the above effects, negatively buoyant clouds are characterized by a lower average cloud height and larger width compared to neutral clouds. The low-level dispersion process is therefore particularly sensitive to artificial and natural obstacles, which has driven the effort of the international community to study the interaction between dense vapor clouds and a variety of obstacles [40].

Several field experiments have shown a de-coupling between the dense gas dispersion process and the actual ambient atmospheric conditions [42]. In this scenario, the dense vapor cloud displaces the wind field resulting in a stably stratified density distribution that can reduce or entirely inhibit turbulent mixing. As a result, dense-gas clouds can manifest significant lateral and upwind spread. In addition, dense clouds tend to follow down-hill slopes almost independently of the atmospheric conditions and stagnate in valleys or in lower altitude regions.

The horizontal spreading of the cloud is determined by the hydrostatic pressure difference between the leading edge of the vapor cloud and the ambient. The movement of the dense cloud edge results in an intense mixing between the ambient air and the dense cloud localized at the cloud leading edge. The mixing mechanism, similar to that observed in Kelvin-Helmholtz instability problems, is induced by light fluid ingested underneath the leading edge that rises due to buoyant forces and is carried forward by the motion of the cloud. The resulting leading edge is characterized by a lobe and cleft structure. Additional mixing induced by shear layer instability at the leading edge interface enhances growth of finite amplitude billows [44].

De-stratification within the cloud results from heat transferred from the ground, which leads to a decreasing density and enhanced turbulent mixing across the interface. However, it has been observed for LNG clouds that the increased gas temperature is not sufficient for the cloud to transition to a buoyant regime within a short distance from the release point [42].

Jets and Pluncs

Vapor dispersion from high momentum jet releases is mainly controlled by the property of the jet itself. The momentum transfer between the ambient and the high speed release results in entrainment of ambient air into the jet, which reduces the jet velocity and concentration. Purely buoyant jets (or plumes) are generated from sources with low or negligible initial momentum (i.e. heat diffuser, chimneys, pool fires). Positively buoyant jets are characterized by a lower than ambient density (i.e. hot flue gases from a stack). Negatively buoyant jets are characterized by a higher than ambient density (i.e. high speed release of dense gases).

Chen and Rodi showed that both buoyant and non-buoyant jets have the tendency to become self-similar in the flow regions where either the

inertial forces or the buoyancy forces dominate the fluid-dynamic behavior [45]. Note that self-similarity does not exist in intermediate regions where the plume transitions from inertia to buoyancy domination. In particular, it has been shown that in self-similar regions, the spanwise profiles (i.e. velocity, concentration, jet width) at any distance along the axis of the jet become self-similar if scaled with an appropriate similarity variable. An overall review of similarity and scaling laws for jet releases is beyond the scope of this work. The interested reader should refer to [45] for a comprehensive monographic review that includes a wide review of experimental data as well as scaling constants, and range of validity of each scaling law.

Passive Dispersion Regime

Passive clouds are observed for releases of chemical compounds with molecular weight similar to that of the air, or of dense vapor clouds that have been sufficiently diluted due to ambient air entrainment. This is also the case with releases of air that contain low concentrations of a specific species. The dispersion of neutral clouds is mainly controlled by the atmospheric turbulence which in turn will be a strong function of the atmospheric stability class.

Modeling

Accurate and reliable predictions of vapor cloud dispersion are an important part of fire safety engineering for the design of new infrastructure. Current international standards are trending toward performance-based design, which allows engineers and hazard analysts to deal with innovative industrial design solutions.

Historically, the analysis of vapor cloud dispersion has made use of both experiments and computational modeling. For example, vapor dispersion experiments have been conducted since the 1970s at both small scale and field scale [42]. Typically, field experiments require measurements of weather conditions including wind speed and direction, turbulence, humidity, solar radiation, as well as vapor dispersion parameters such as concentration and temperature in various downwind locations and at different elevations. Although, full scale experiments and high fidelity diagnostics require large financial investments, they provide unique and valuable data that is useful for developing a phenomenological understanding of the dispersion mechanisms and are required for benchmarking computational models.

With recent developments in computation models, analyses of vapor dispersion scenarios can be performed on a single workstation. Computational modeling is more economical and time efficient, and can be used as a predictive tool. Different modeling approaches can be used depending on the accuracy required and the resources available. Typically, hazard calculations require quantitative knowledge of the evolution of the vapor cloud, in terms of variables such as:

- Distance to a given concentration (e.g. lower flammability limits *LFL* or *1/2 LFL*);
- Size, composition and shape of the cloud, which are required to predict thermal radiation estimates in case of combustion or for vapor cloud explosion modeling.
- Mass of vapor within the upper and lower flammability limits, which are used in the TNT Equivalency Method or the TNO multi-energy method.
- The time-dependent concentration in a specific location for the evaluation of toxicity effects.

Rather than presenting a comprehensive review of individual models for vapor dispersion, a review of the main model types is presented. Vapor dispersion modeling can be generally classified into categories of increasing complexity: simplified empirical models, one-dimensional integral models, shallow layer models, Lagrangian models and Navier-Stokes based models. This section will describe the main features of each of the categories including typical assumptions, limitations and accuracy achieved. This section also provides examples of models in each category.

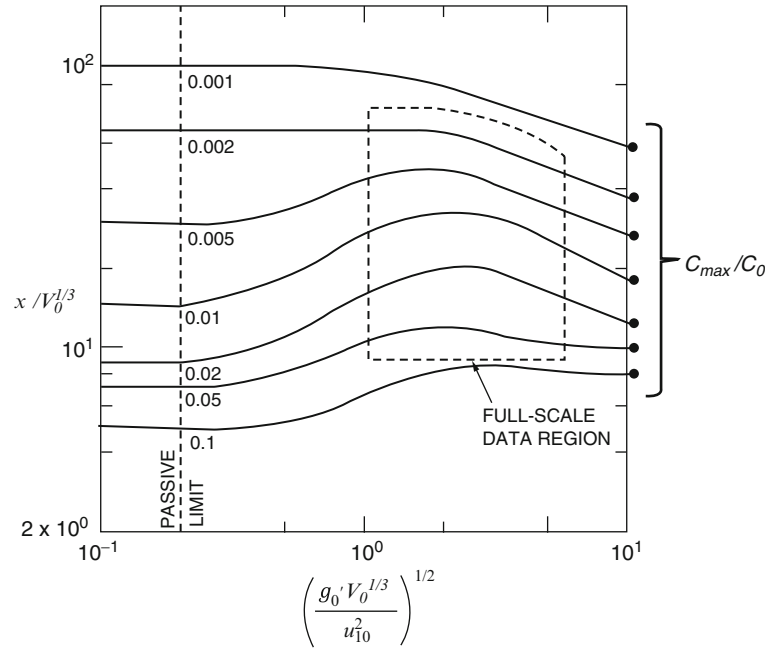

Fig. 67.8 Nomogram for instantaneous releases according to [39] (Note: the *curves* correspond to the indicated value of c_{max}/c_0)

Simplified Semi-empirical Models

Britter and McQuaid Model for Dense Clouds

The Britter and McQuaid model is based on a series of empirical correlations describing the main properties of a dense gas cloud generated at ground level and dispersing over a flat terrain. The model allows for the estimation of average concentration along the plume axis for a continuous release and the maximum concentration along the downwind direction for an instantaneous release. The model does not account for atmospheric stability class nor for terrain roughness. The model relies heavily on nomograms derived from large scale test data and from wind tunnel data [39].

Instantaneous Releases

For instantaneous releases, the model uses a set of curves or nomograms for downwind maximum concentration (expressed as c_{max}/c_0) representing the correlation between two functional groups $x/{V_0}^{1/3}$ and ${u_{10}}^2/({g_0}'V_0)^{1/3}$ where x is the downwind distance, V_0 is the initial volume of the release, u_{10} is the mean wind velocity at 10 m height, and ${g_0}'$ is the effective gravitational constant at the source. The effective gravitational constant can be estimated as

$$g_0' = \frac{g(\rho_0 - \rho_a)}{\rho_a}$$

where ρ_a and ρ_0 are the ambient and release source densities, respectively.

The determination of the iso-concentration contours for instantaneous releases is based on the following 3 steps:

1. Determine the downwind distance x to a given concentration for a particular iso-contour (e.g. LFL) using the nomograms from Fig. 67.8.
2. Calculate the cloud arrival time t at the downwind position x from the correlation

$$x = 0.4u_{10}t + b(t)$$

where $b(t)$ is the cloud radius at the time t to be estimated as

$$b(t) = \sqrt{b_0^2 + 1.2t\sqrt{{g_0}'V_0}}$$

where b_0 is the cloud radius at the source. The mean height of the cloud at a given time can be estimated as

$$h(t) = \frac{c_0 V_0}{\pi b(t)^2 c_{max}(t)}$$

Continuous Releases

For continuous releases, the model uses a set of curves or nomograms for downwind mean concentration (expressed as c_{mean}/c_0) representing the correlation between two functional groups

$$x\sqrt{\frac{u_{10}}{\dot{V}_0}} \text{ and } \left(\frac{g_0^{'2}\dot{V}_0}{u_{10}^5}\right)^{1/5}$$

where x is the downwind distance, $\dot{V}_0$ is the volume flow rate, u_{10} is the mean wind velocity at 10 m height, and $g_0^{'}$ is the effective gravitational constant at the source. The mean concentrations refer to long time average (calculated over 10 min). Greater concentrations can be observed for short durations due to turbulent fluctuations. According to [39] short term concentrations can be as high as 1.6 times the long term average values.

The determination of the iso-concentration contours for continuous releases is based on the following three steps:

1. Determination of the downwind distance x to a given concentration for a particular iso-contour (e.g. LFL) using the nomograms from Fig. 67.9.
2. Determination of the plume upwind extension x_u (see Fig. 67.10) as

$$x_u = b_0 + 2L_b$$

where b_0 is the source radius and L_b is given by

$$L_b = \frac{\dot{V}_0 g_0^{'}}{u^3}$$

3. The downwind half width b (see Fig. 67.10) of the plume can be estimated as

$$b(x) = 2b_0 + 8L_b + 2.5{L_b}^{1/3}x^{2/3}$$

The height of the plume at a downwind distance x can be obtained as

$$h(x) = \frac{\dot{V}_0}{2\,u\,b(x)}$$

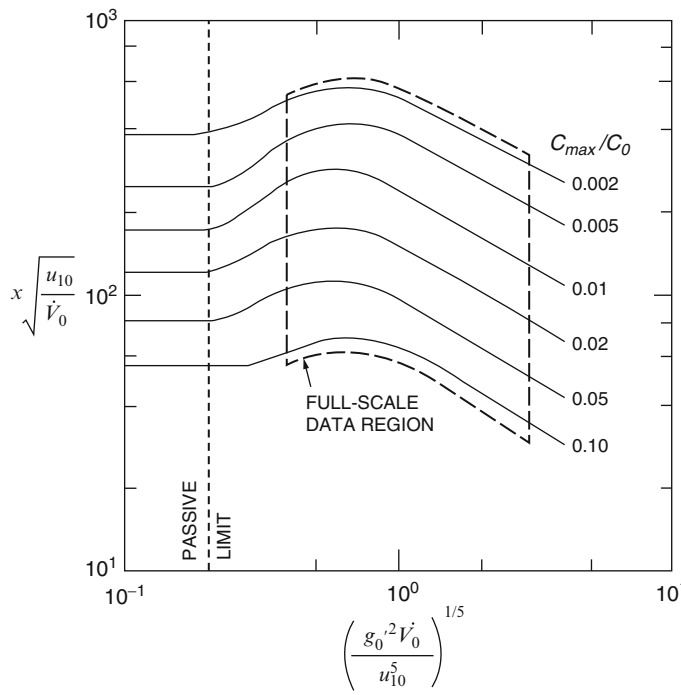

Fig. 67.9 Nomogram for continuous releases according to [39] (Note: the *curves* correspond to the indicated value of c_{mean}/c_0)

Intermediate Releases

According to [39], releases that cannot be classified as instantaneous or continuous should be studied using both approaches. The smaller of the concentration estimates should provide the upper bound for an intermediate duration release. The same authors recommend using the release duration as a time scale for converting the total leak volume V_0 into volume flow rate $\dot{V}_0$

Gaussian Plume for Passive Clouds

Under homogeneous turbulence and wind speed, the dispersion of passive clouds can be reasonably well described by Gaussian dispersion models. Gaussian dispersion models are based on the assumption that the cloud is essentially neutral (i.e. no gravitational effects are present), the meteorological conditions are constant during the release, the ground is flat, the surface roughness is constant and there are no obstacles near the release [33].

Depending on the release type (i.e. continuous or instantaneous) the concentration of a released compound (in kg/m^3) can be described using the following Gaussian plume models:

- $c(x,y,z) = \frac{\dot{m}}{2\pi u \sigma_y \sigma_z} exp\left(\frac{-y^2}{2{\sigma_y}^2}\right) exp\left(\frac{-(z-H)^2}{2{\sigma_z}^2}\right)$ for continuous release
- $c(x,y,z,t) = \frac{\dot{m}}{(2\pi)^{3/2}\sigma_x \sigma_y \sigma_z} exp\left(\frac{-y^2}{2{\sigma_y}^2}\right) exp\left(\frac{-(z-H)^2}{2{\sigma_z}^2}\right) exp\left(\frac{-(x-ut)^2}{2{\sigma_x}^2}\right)$ for instantaneous release

where $c(x, y, z)$ is the concentration at the x, y, z location defined according to Fig. 67.11, q and Q are the release rate and the total mass released (in kg/s and kg), u is the wind velocity (at the height of the plume centerline) at which the cloud is convected and H is the effective height of the plume centerline. The constants σ_x, σ_y, and σ_z represent the Gaussian plume dispersion parameters in the cross wind directions (σ_y, and σ_z) and along the wind direction (σ_x). They are functions of the downwind distance from the release and the ground roughness (i.e. release in rural or urban areas). At a certain distance downwind from the source, the plume may have spread enough to interact with the ground. In this condition, the vertical spread on the bottom side of the plume is inhibited resulting in what is known as ground reflection. In order to account for ground reflection additional terms have to be included (see [33]).

The effective height of the plume centerline H should be calculated accounting for the geometric height of the release source h (i.e. stack

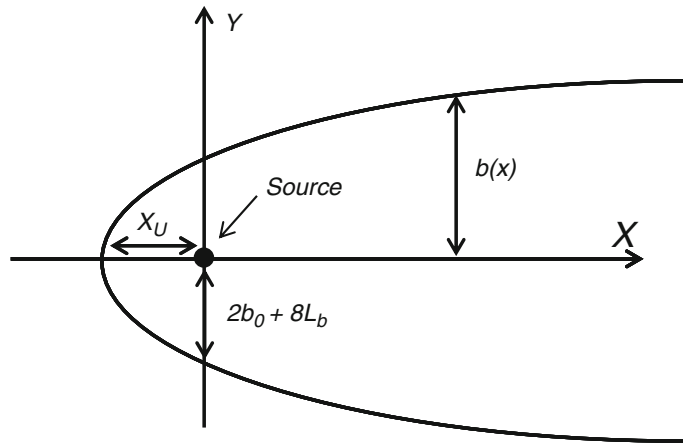

Fig. 67.10 Approximations of iso-concentration contours for a continuous release according to [39] (plan view). Wind blows in the positive x direction

height) and for the initial rise of the release due to the inertial and buoyancy forces ΔH. The latter can be computed according to the Holland equation [46]

$$\Delta H = \frac{u_0}{u} b_0 \left[1.5 + 2.68 P_a b_0 \left(\frac{T_0 - T_a}{T_0} \right) \right]$$

where u_0 is the vertical discharge velocity (in m/s), u is the wind velocity at the stack height (in m/s), b_0 is the internal diameter of the stack or leak (in m), P_a is the atmospheric pressure (in bar) and T_0 and T_a are the source and atmospheric temperatures (in K). Other methods for the calculation of the initial plume rise are summarized.

The Gaussian dispersion parameters can either be calculated by using parametric plots (see [32] or [33]) or by using the following correlations for continuous sources proposed in [35]:

- $\sigma_y = e\, x^m$ (in m)
- $\sigma_z = f\, x^n$ valid for distances from the release between 100 m and 10,000 m (in meters)

where the constants e, m, f and n are defined in accordance with Table 67.11. For distances smaller than 100 m, a linear interpolation between 0 and the σ values at 100 m should be performed. Additional corrections of σ_z as a function of the surface roughness can be included and are given in [35].

For instantaneous releases, the dispersion parameters can be evaluated as

- $\sigma_x = 0.13\, x$ (in meters)
- $\sigma_y = \frac{e}{2} x^m$ (in meters)
- $\sigma_z = f\, x$ (in meters)

where, coefficients e, f and m are the same as those previously defined in Table 67.11. The flammable mass between the LFL and the UFL for passive releases can be easily calculated using numerical integration procedures. Approximate analytical solutions for the estimation of the flammable mass and ground distance to LFL can be obtained following the procedures that

Table 67.11 Curve fitting constant for the evaluation of Gaussian dispersion parameters σ_y and σ_z [35]

	Stability class	e	m	f	n
Very unstable	A	0.527	0.865	0.28	0.90
Unstable	B	0.371	0.866	0.23	0.85
Slightly unstable	C	0.209	0.897	0.22	0.80
Neutral	D	0.128	0.905	0.20	0.76
Stable	E	0.098	0.902	0.15	0.73
Very stable	F	0.065	0.902	0.12	0.67

Note: Valid for $z_0 = 0.1$ and h <20 m; σ_y to be considered as a 10-min average

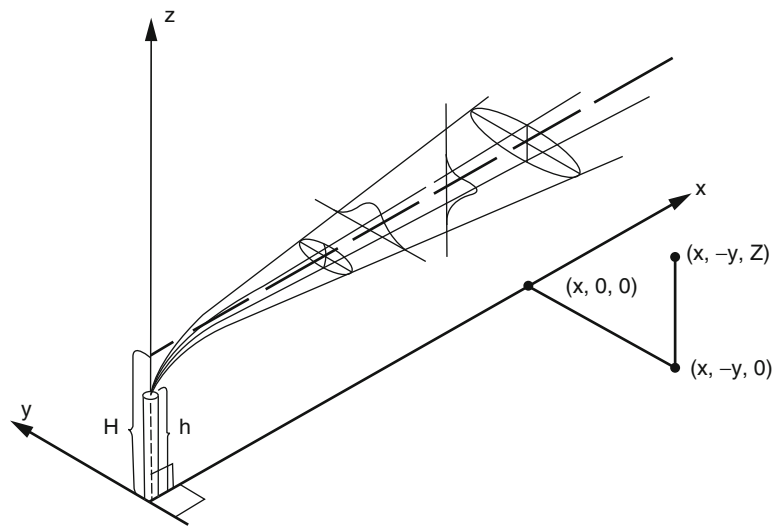

Fig. 67.11 Coordinate system used for the definition of the Gaussian plume model [32]

are described in [35] and [30]. However, the solutions are complicated and not practical for general use. In most cases, numerical integration or dedicated dispersion models are preferred.

TNO Method for Turbulent Jets

The flammable mass contained in free turbulent jets can be calculated using the TNO method for turbulent incompressible jets in a quiescent environment. The TNO method applies to axisymmetric, continuous releases with radius b_0, uniform concentration c_0 and uniform velocity u_0 in a quiescent environment [35]. The model is applicable for all cases where inertial forces are dominant compared to buoyant forces.[1] The last constraint limits the applicability of the model to the region characterized by an axial distance from the source x

$$x \leq 0.5\, b_0 \sqrt{Fr}\left({}^{\rho_0}/_{\rho_a}\right)^{1/4}$$

where Fr is the densimetric Froude number, defined as

$$Fr = \frac{\rho_0}{|\rho_a - \rho_0|}\frac{u_0^2}{2b_0 g}$$

ρ_a and ρ_0 are the ambient air density and the source density and g is the gravitational constant. The quiescent environment assumption can be relaxed by assuming that the jet velocity is atleast one order of magnitude larger than the ambient wind condition at the height of the release. If any of the above mentioned assumptions are not valid or in the presence of obstacles or complex terrain features, the TNO method is likely to provide incorrect results. More refined calculation techniques based on integral models or three-dimensional CFD models should be adopted.

The TNO model is based on the experimental observation that, after the potential core of the jet has disappeared at a distance x_s from the source, the velocity and concentration profiles assume the following Gaussian distributions:

[1] This method is limited to incompressible jets where u_0 is lower than 1/3 of the speed of the sound at ambient pressure.

Table 67.12 Empirical constants for the non-buoyant jet model defined in accordance with [47]

Non-buoyant empirical parameters	Value
C_u	6.2
C_c	5
C_{yu}	94
C_{yc}	57

$$\frac{u(y/x)}{u_c(x)} = e^{\left(-C_{yu}(y/x)^2\right)}$$

$$\frac{c(y/x)}{c_c(x)} = e^{\left(-C_{yc}(y/x)^2\right)}$$

where y is a radial coordinate, x is the axial coordinate, $u_c(x)$ and $c_c(x)$ are the jet centerline velocity and concentration values (function of the axial distance from the source) and C_{yu} and C_{yc} are empirical constants determined according to [47] (Table 67.12). It should be noted that the concentrations are expressed in parts per unit volume. The potential core represents the core region of the jet located immediately downstream of the release point where the fluid is not affected by the shear with the quiescent air and maintains the initial velocity u_0. An estimation of the extension of the potential core for non-buoyant plumes can be approximated by $25b_0$. A schematic showing the main features of a turbulent jet along with the main parameters is shown in Fig. 67.12.

For non-buoyant and buoyant jets, it has been observed that the origin of the axial coordinate x should be taken at a distance $-x_0$ from the real source (i.e. see discussion on the virtual point source Chap. 13). As a first order approximation it can be assumed that the virtual point source and the real source coincide (i.e. x_0 equal to zero).

For non-buoyant and buoyant jets, the centerline properties can be calculated as

$$\frac{u_c(x)}{u_0} = \sqrt{\frac{\rho_0}{\rho_a}}\frac{C_u b_0}{x}$$

$$\frac{c_c(x)}{c_0} = \sqrt{\frac{\rho_a}{\rho_0}}\frac{C_c b_0}{x}$$

where C_u and C_c are empirical constants determined by [47].

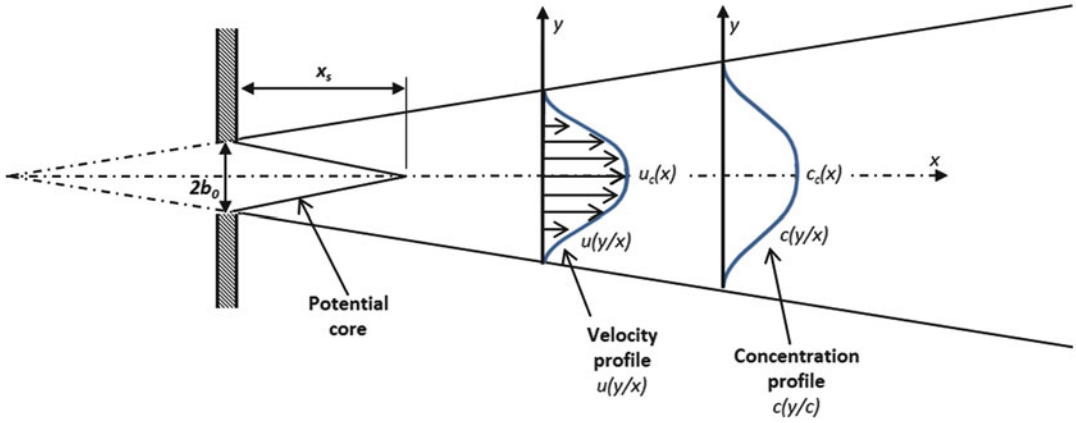

Fig. 67.12 Development of a turbulent jet in a quiescent environment (not to scale)

For negatively buoyant jets the above correlations are valid as long as x is lower than x_h, the maximum height reached by the jet before it falls back. An estimation of x_h can be obtained from

$$x_h = 4.11\sqrt{Fr}b_0$$

The maximum axial distance to the LFL concentration (expressed in parts per unit volume) can be conservatively assumed to be equal to

$$x_{LFL} = min\left(\sqrt{\frac{\rho_a}{\rho_0}}\frac{C_c b_0 c_0}{c_{LFL}}; x_h\right)$$

At axial distances larger than the length of the jet potential core, the radial position of the LFL concentration contours is given by

$$y_{LFL}(x) = \frac{x}{\sqrt{C_{yc}}}\sqrt{ln\left(\frac{b_0}{x}\sqrt{\frac{\rho_a}{\rho_0}}C_c\frac{c_0}{c_{LFL}}\right)}$$

The mass content of the chemical compound between the UFL and the LFL can be obtained by integrating the concentration profiles over the volume. The flammable mass can be estimated as

$$M = \frac{\pi\rho_0 {b_0}^3 c_0}{6C_{yc}}\frac{{\rho_a}^{3/2}}{\rho_0}{C_c}^3\left[\left(\frac{c_0}{c_{LFL}}\right)^2 - \left(\frac{c_0}{c_{UFL}}\right)^2\right]$$

A calculation method for under-expanded fuel-gas and volatile liquid-fuel jets with positive or negative buoyancy has been proposed by Epstein and Fauske [48]. These methodologies will not be presented here, but interested readers should refer to Epstein and Fauske for a complete overview.

Integral Models

Integral models are based on a limited number of equations that describe the overall properties (integral properties) of a flow. The literature over the last few decades contains many examples of integral models for vapor dispersion. Some of these examples include SLAB [49], HEGADAS [50], DEGADIS [36] and DRIFT [51], GASTAR [52].

Integral models are based on the solution of ordinary differential equations representing the evolution of the cloud average properties. Once the average properties are calculated, pre-determined profiles are used to obtain a three-dimensional distribution. For example, the DEGADIS and the HEGADAS models use a modified Gaussian profile with a flat middle portion in the cross-wind direction, and a power law concentration distribution in the vertical direction [53]. Integral models describe the horizontal cloud spread using common formulations for gravity currents. The ambient air entrainment into the cloud is quantified by entrainment velocities calculated as functions of the Richardson number. Integral models also account for different atmospheric conditions (wind speed and stability class) as well as surface roughness. They are formulated to simulate

continuous buoyancy-dominated, dense, or neutral gas releases. Dispersion of momentum driven releases (jets) is also accounted for.

Integral models are not suitable for modeling releases on terrains with sloping ground, complex topography or in the presence of buildings. Despite the effort to extend the applicability of integral models to non-idealized release scenarios (i.e. in the presence of variable terrain roughness, solid and porous obstacles, i.e. in GASTAR) accurate experimental validation is required to verify the model accuracy.

Shallow Layer Models

Shallow layer models have been applied to heavy gas dispersion modeling and represent a compromise between the simplicity of integral models and the computational complexity associated with full three-dimensional CFD models [54]. The TWODEE model [55], the SLAM model [56], and the DISPLAY-2 model [57] are examples of shallow layer models.

The use of shallow layer approximations to model heavy gas dispersion is appropriate because dense gas clouds typically have a low aspect ratio, *i.e*. the height of the cloud is typically much smaller than the horizontal spread of the cloud. In these models, the low aspect ratio allows for the fundamental conservation equations that describe the flow behavior to be simplified in a depth-averaged fashion. However, empirical correlations are still required to include the ambient air entrainment into the dense cloud.

In comparison to integral models, shallow layer models can accommodate the effects of complex or sloping terrains. The locally enhanced entrainment is included by adding an obstacle characteristic velocity to the base entrainment velocity [59]. Despite many advantages associated with shallow layer models, they are predominately used as a research tool and have not been extensively used for industrial hazard analyses.

Lagrangian Puff/Plume Models

Historically, Gaussian puff models have been used for buoyant or neutral cloud dispersion [58–60]. These models are generally based on the Gaussian formulation and describe the concentration field as the sum of a collection of discrete vapor/gas parcels or puffs. Each puff is allowed to be convected by the ambient wind and to evolve in size. The final concentration in a given position will be generated by the superposition of independent Lagrangian puffs.

The application of Lagrangian puff models to strongly buoyancy driven flows (i.e. dense vapor cloud dispersion) requires extreme care because in reality, the dynamics of one puff can be strongly coupled to other puffs. Dense cloud effects are taken into account in the SCIPUFF model where the puffs are convected and distorted in agreement with buoyancy driven dynamics [61]. The model has been developed to capture the flow patterns associated with the interaction between the dense cloud and the terrain that generates reduction of the vertical turbulent mixing and horizontal gravity spreading currents.

Given the low computation time associated with Lagrangian puff models, they are well suited for situations in which a wide range of atmospheric conditions have to be investigated as is the case in preliminary screening studies or emergency response applications.

Full Three-Dimensional CFD Models

Three dimensional computational fluid-dynamics (CFD) models are the most robust tools for the analysis of vapor cloud dispersion. The vapor dispersion dynamics are simulated by solving three-dimensional conservation equations for mass, momentum, energy and chemical species both in transient or steady state fashions.

Given the inherently turbulent nature of vapor cloud dispersion processes, the fundamental transport equations are averaged and complemented with the transport equations of several turbulent quantities (i.e. mainly turbulent

kinetic energy k and dissipation rate ε). The turbulence models implemented in CFD tools are optimized to account for the suppression of the turbulent mixing due to stable vertical density gradients as observed in dense vapor clouds. The entire set of transport equations is discretized on a grid of cells (mesh) and solved using highly sophisticated numerical algorithms.

The most advanced CFD codes are able to deal with very complex geometry which allows for the representation of arbitrary geometries, obstacles or complex terrain features.

There are several CFD codes that are specifically developed for vapor dispersion simulations. The two most well-known CFD dispersion tools are FEM3C developed at the Lawrence Livermore National Laboratory [62] and FLACS developed by GEXCON [20]. General purpose CFD software packages can also be used for vapor dispersion simulations. FLUENT developed by ANSYS [21] and Star-CCM+ developed by CD-Adapco are two examples of such general purpose CFD software. The application of general purpose CFD codes requires additional efforts to implement specific features that are built-in in dedicated vapor dispersion software. These include the implementation of specific atmospheric boundary layer models that account for the atmospheric stability class as well as appropriate routines to simulate two-phase flashing, droplet transport and evaporation, and pool evaporation [34, 63, 64].

CFD models have been remarkably successful given their flexibility and the wide range of possible scenarios that can be analyzed. Given the computational complexity associated with CFD models, they are better suited for design verification of specific scenarios or for post-incident analysis. Despite the wide range of applicability of CFD models for comprehensive hazard calculations, they are still limited by the inherently long run time, even when run on modern workstations (2013).

Vapor Ignition

For a vapor cloud explosion to occur, a competent ignition scenario must exist. However, to determine the likelihood of competent ignition, it is not sufficient to simply identify an ignition source. Other factors, including ignition source energy and presence of inert species, must also be considered to adequately determine not only the likelihood of ignition but also the hazards associated with the resultant ignited vapor cloud explosion. The following sections give a brief overview of some of the main contributing factors associated with vapor ignition and practical methodologies to quantify and access potential vapor ignition hazards.

Flammable Limits

For a vapor cloud to ignite, a portion of the vapor cloud must be within the flammable limits of the particular vapor/air mixture. For vapor clouds consisting of single common fuel species, the flammability limits are well defined in literature. A list of upper and lower flammable limits for several common fuel species can be found in Chap. 17. These limits are for mixtures of single fuel species and air. The presence of multiple fuel species or inert gases in the vapor cloud will affect the flammable regime.

Flammability Diagram

Flammability diagrams are often used to show the flammable regime of a particular fuel. A more detailed discussion of flammability diagrams can be found in Chap. 17. Here, a brief overview is given. Figure 67.13 shows an example of a flammability diagram. The upper and lower flammable limits are defined by the upper and lower portions of the thumb curve, respectively, where the regime inside the thumb curve is flammable. The flammability limits listed in Chap. 17 are represented by the points on the air line. As the oxygen concentration decreases, the two flammable limits approach one another. The point where the two portions of the curve meet is defined as the limiting oxygen concentration (LOC)—mixtures with oxygen concentrations lower than the LOC are not flammable. For most vapor cloud scenarios, vapor is released into atmospheric air. In these cases, there is always sufficient air available to

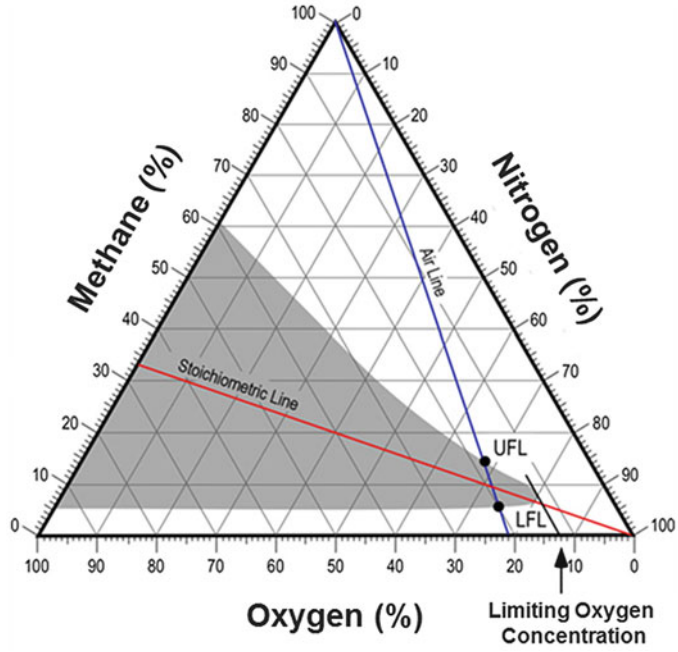

Fig. 67.13 Flammability diagram for methane

mix with the fuel vapor, and the lower flammable limit is more relevant in determining the flammable region. In general, elevated or reduced oxygen conditions are limited to enclosed chambers or buildings, such as hyperbaric chambers, and at high elevations. For example, the oxygen level in mountainous areas can be 15–20 % lower than the oxygen level at sea level.

Analytical Methods for Estimating Flammable Limits for Mixtures

Although vapor clouds often consist of single fuel species, there are scenarios, such as leaks from petroleum refineries, which may involve a complex mixture of combustible and inert species. Although flammable limits have been measured for some mixtures of common fuels [65, 66], flammable limits for a particular multi-species mixture of interest may not be readily available in literature. The presence of inert species, most commonly water vapor, carbon dioxide, nitrogen or argon, will also affect the flammable limits. Figure 67.14 shows the effect of several inert species on methane flammability. In general, the lower flammable limit is less

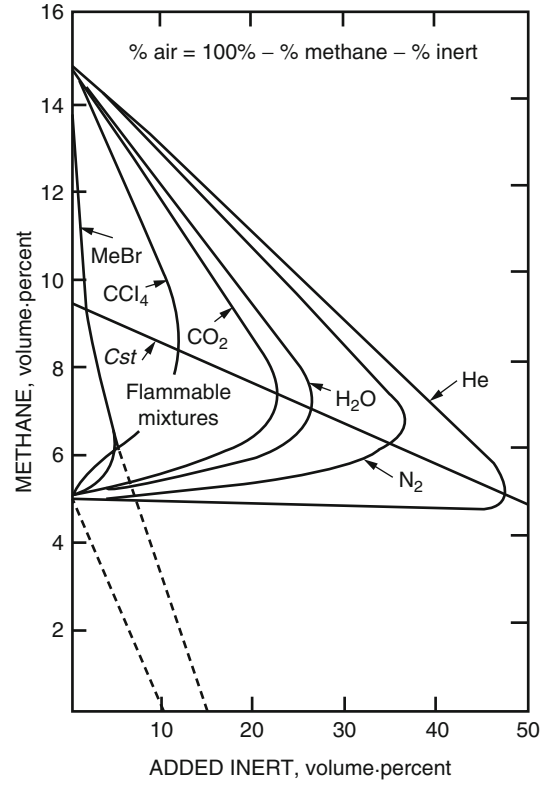

Fig. 67.14 Effect of various inert species on flammability limits of methane [66]

affected by inert species than the upper flammable limit. The sources of accidental vapor releases do not commonly contain inert species. However, even for releases of purely combustible vapors, mitigation techniques such as sprinklers and water hoses can introduce water vapor into the vapor cloud.

In practice, the most reliable method is to experimentally determine flammable limits for a particular fuel mixture. However experimental determination of flammable limits for mixtures with many species may not be practical. Several analytical correlations have been proposed to determine flammable limits. Although the accuracy of analytical methods may vary depending upon the mixture, these methods can be useful in obtaining engineering estimates of the flammable limits.

Le Chatelier's Principle

As discussed in Chap. 17, one common method to estimate upper and lower flammable limits is to apply Le Chatelier's principle, which is often used in determining physical properties of gas mixtures. Expressions for the lower flammable limit are reproduced below. Similar expressions for the upper flammable limit can be obtained by replacing the lower flammable limit with the upper flammable limit in the following equations. Applying Le Chatelier's principle, the lower flammable limit of the mixture in percent volume, LFL_{mix}, is determined by the following equation:

$$LFL_{mix} = \frac{1}{\sum_{j=1}\left(\frac{\chi_j}{LFL_j}\right)} \tag{67.1}$$

where χ_j and LFL_j are the respective molar concentration and lower flammable limit of each individual species, j. Although Le Chatelier's principle was originally intended for binary mixtures of combustible species, Equation 67.1 can be generalized to mixtures of multiple combustible species mixtures.

Le Chatelier's principle can be further generalized to include inert species. The simplest method is to artificially impose that the lower flammable limit of any inert gas approaches infinity [67]. In this limit, summation terms in the denominator of Equation 67.1 associated with inert species are zero. There is some evidence that this method provides a reasonable prediction for fuel mixtures with nitrogen. However, as seen in Fig. 67.14, the effect of inert species on flammable limits depends on the specific species. To address the behavior of various inert species, a nitrogen equivalency factor can be defined for non-nitrogen inert species. This method is described in detail by Molnarne et al. [68]. Applying nitrogen equivalency factors to Equation 67.1, the lower flammable limit of the mixture with any inert can be calculated by the following equation:

$$LFL_{mix} = \frac{1}{\sum_{j=1}\left(\frac{\chi_j}{LFL_j}\right) - \sum_{k=1}(N_{e,k} - 1)\chi_k} \tag{67.2}$$

where χ_k and $N_{e,k}$ are the respective molar concentrations and coefficients of nitrogen equivalency for inert species, k. Recommended coefficients of nitrogen equivalency for mixtures of water and carbon dioxide with a single fuel species are listed in Table 67.13. For multi-species fuel mixtures, an effective coefficient of nitrogen equivalency, $N_{e,k,eff}$, for each inert species can be determined by molar averaging the individual coefficients listed in Table 67.13 as follows:

$$N_{e,k,eff} = \sum_{i=1}(\chi_i N_{e,k,i}) \tag{67.3}$$

where the subscript k indicates the specific inert species and the summation subscript i indicates the single fuel species.

Table 67.13 Nitrogen equivalency coefficients for water and carbon dioxide [68]

Combustible species	$N_{e,H2O}$	$N_{e,CO2}$
Methane	1.87	2.23
Ethane	1.40	1.87
Propane	1.51	1.93
Ethylene	1.68	1.84
Propylene	1.36	1.92
Hydrogen	1.35	1.51
Other combustibles	1.50	1.87

Thermal Balance Method

A more rigorous method to estimate flammable limits for complex mixtures was proposed by Ma [69]. In this approach, the flammability of a mixture is derived from a balance between heating and quenching potentials. The upper and lower flammable limits for a single fuel species can be represented by the heating, H_F, and quenching, Q_F, potentials as follows:

$$LFL = \frac{1}{1 + H_F - Q_F} \tag{67.4}$$

$$UFL = \frac{0.2095H_0 - 1}{0.2095H_0 - 1 + Q_F} \tag{67.5}$$

where the constant 0.2095 is the mole fraction of oxygen in air. For elevated or limited oxygen scenarios, the appropriate mole fraction of oxygen would be used. The heating and quenching potentials are defined as follows:

$$H_F = C_0 H_0 \tag{67.6}$$

$$Q_F = 1 - \frac{1}{LFL} + C_0 H_0 \tag{67.7}$$

where C_0 is the number of moles of oxygen required for stoichiometric combustion of one mole of fuel, and H_0 is the heating potential of oxygen based on air, which is defined as

$$H_0 = \frac{UFL - LFL}{C_0(UFL)(LFL) - 0.2095(1 - UFL)LFL} \tag{67.8}$$

Equations 67.4, 67.5, 67.6, 67.7, and 67.8 are for single species fuels. To generalize the equations to multi-species fuel mixtures, the input parameters, H_F, H_0, Q_F, Q_0, and C_0 can be determined by mole averaging in a similar manner to Equation 67.3, where the effective parameter for the mixture is determined by summing the product of the molar concentration and the input parameter for the individual species.

The advantage of the thermal balance method is that the effect of inert species can be incorporated directly. The general forms of Equations 67.4 and 67.5 become

$$LFL_{mix} = \frac{1}{1 + \left(\frac{1}{1+R}\right)H_{F,mix} - \left(\frac{1}{1+R}\right)Q_{F,mix} - \left(\frac{R}{1+R}\right)Q_{D,mix}} \tag{67.9}$$

$$UFL_{mix} = \frac{0.2095H_{0,mix} - 1}{0.2095H_{0,mix} - 1 + \left(\frac{1}{1+R}\right)Q_{F,mix} + \left(\frac{R}{1+R}\right)Q_{D,mix}} \tag{67.10}$$

where the $H_{0,mix}$, $H_{F,mix}$, $Q_{F,mix}$ are the respective heating potential of oxygen, heating potential of the fuel, and quenching potential of the mixture. The ratio R is defined as the ratio between the molar concentrations of the inert and the fuel species. The effect of inert species is accounted by incorporating the quenching potential, $Q_{D,mix}$, of inert species. Similar to Equation 67.3, the quenching potential for multiple inert species can be determined by molar averaging to obtain an effective quenching potential for the inert mixture as follows:

$$Q_{D,mix} = \frac{\sum_{k=1}\left(\chi_{D,k}\, Q_{D,k}\right)}{\sum_{k=1}\chi_{D,k}} \tag{67.11}$$

where $\chi_{D,k}$ and $Q_{D,k}$ are the molar concentration and quenching potential for inert species k.

Quenching potentials depend on the adiabatic flame temperature. For most hydrocarbons, the flame temperature is approximately 1600 K. Quenching potentials for common inert species are listed in Table 67.14. Figure 67.15 shows a comparison of the predicted and measured flammable limits with dilution of carbon dioxide and argon for methane and ethane. The concentration of inert species at which the curves predicted by Equations 67.9 and 67.10 cross is often referred to as the inertion or inertization point. The error observed in the inertion point region arises due to several factors including incomplete reaction and decreased flame temperature. Corrective scaling for better prediction of the nose region of the flammability plot is discussed in Ma [69].

Testing Methodologies

When practical, flammable limits of a flammable vapor are best determined through testing. In certain cases where the composition of the vapor may be unknown, testing may be the only viable method. Relevant standardized tests for gas or vapor flammability are listed below:

- *ASTM E681 Standard Test Method for Concentration Limits of Flammability of Chemicals* (*Vapors and Gases*).
- *ASTM E918 Standard Practice for Determining Limits of Flammability of Chemicals at Elevated Temperature and Pressure*
- *ASTM E2079 Standard Test Methods for Limiting Oxygen* (*Oxidant*) *Concentration in Gases and Vapors*

Table 67.14 Quenching potentials for common inert species at an adiabatic flame temperature of 1600 K [69]

Inert species	Q_D
Helium	0.642
Argon	0.642
Nitrogen	0.992
Oxygen	1.046
Carbon dioxide	1.603
Air	1.000

Ignition Sources

Determining potential ignition sources is a crucial element in both fire and explosion investigation and hazard analysis of vapor cloud explosions. Because the minimum ignition energy required to ignite gases or vapors is on the order of tenths of millijoules, many potential competent ignition sources may exist in nearly all vapor cloud scenarios. In addition to the obvious sources such as open flames or fire in furnaces or heaters, sparks from electrical equipment, static discharges, or even friction from a cutting wheel can provide sufficient energy to ignite vapors.

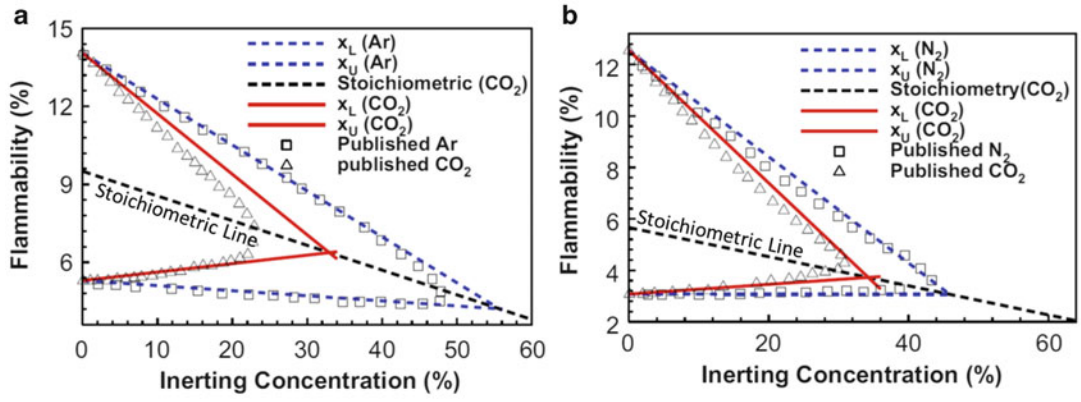

Fig. 67.15 Measured and predicted flammability diagrams for (**a**) methane and (**b**) ethane [69]. Reprinted from Fire Safety Journal, Vol. 46, T. MA, "A thermal theory for estimating the flammability limits of a mixture," pp. 558–567, Copyright (2011), with permission from Elsevier.

Table 67.15 Minimum ignition energy for common hydrocarbon-air mixtures [70]

	Minimum ignition energy (mJ)	
Gas mixture	Deflagration	Detonation
Acetylene-air	0.01	1.8×10^5
Propane-air	0.25	4.1×10^8
Methane-air	0.21	9.9×10^{10}
Hydrogen-air	0.016	5.2×10^6

Minimum Ignition Energy

The minimum ignition energy (MIE) for vapors is low and even weak sparks from static discharges may be strong enough to ignite a vapor cloud. The type of combustion mode ignited by a source can be either a deflagration a detonation, or both further discussion on the characteristics of deflagrations and detonations is discussed in later sections. However, the difference in minimum ignition energy for deflagrations compared to direct detonation is worth mentioning here. Table 67.15 lists the minimum ignition energy for select fuel-air mixtures for deflagration and detonation. The MIE required for a deflagration is on the order of 10^{-4} J, whereas the MIE required for a direct detonation is at least on the order of 10^2 J. Owing to the large amount of energy required to directly initiate a detonation, the vast majority of vapor cloud explosions begin as deflagrations.

Mechanical Sparks and Static Discharges

Mechanical sparks from process equipment and static discharges are common ignition sources for vapor cloud explosion. For example, the use of sparking tools in areas with flammable vapors can lead to a vapor cloud ignition. Other common ignition sources are static discharges, which can be classified as follows:

Spark Discharge. Spark discharges occur as a result of charge accumulation on a conductive object. When the potential between two conductive objects exceeds the dielectric strength of the gas between the conductive objects, a spark discharge will occur. Spark discharges transfer up to 10 J, which is large enough to ignite vapors and dusts. Spark discharges commonly arise as a result of improper grounding of ducts or pipes.

Brush Discharge. Brush discharges can occur between a conductive object and a charged non-conductive object. For example, a brush discharge can occur when a conductive sampling probe is lowered into a tank with a charged liquid. The energy transferred by brush discharges can be up to 4 mJ.

Propagating Brush Discharge. When an insulating layer with high resistance and dielectric strength is placed between two conductive surfaces, a propagating brush discharge can occur if the potential difference between the conductive surfaces is sufficiently large. Most often, only one conductor is in contact with the insulating layer. It is possible for propagating brush discharges to occur when filling epoxy-coated tanks or pipes. The energy transferred by propagating brush discharges can be up to 2 J.

Cone Discharge. Cone discharges can occur when a large vessel is rapidly filled with a high resistivity bulk product. A static discharge results from charge accumulation in the bulk product. The energy transferred by a cone discharge can be up to 1 J.

Corona Discharge. A corona discharge is the result of ionization of fluid surrounding an electrically energized conductor. Corona discharges are highly diffuse. A common example is dissipation of charge from fine wires or conductive threads. The energy transfer from a corona discharge is typically less than 0.1 mJ, which is less than the MIE of most flammable gases with the exception of lower MIE gases such as hydrogen or acetylene.

In fire and explosion investigation, static discharges and sparks often do not leave behind conclusive evidence. Evidence such as arcing on wires or improper grounding of electrical equipment is often used to support the possibility of static ignition. However, these types of evidence do not provide irrefutable proof that that the ignition was the result of a static discharge, since arcing can often occur post ignition. On the other hand, the lack of observed arcing on wires or surfaces and other circumstantial evidence is useful to eliminate the possibility of

spark ignition. A more detailed discussion of ignition hazards due to static discharges can be found in [71].

Autoignition Temperature and Hot Surface Ignition

Flammable mixtures can also be ignited if the gas temperature is sufficiently high. Although most common hydrocarbon fuels and hydrogen have autoignition temperatures greater than 400 °C, the autoignition temperature for some gases can be as low as 150 °C. The autoignition temperatures for many single species have been determined experimentally. Chapter 17 gives a table of autoignition temperatures for various gas species. For mixtures of gases, it is common to use the lowest autoignition temperature of the individual species in any vapor cloud ignition analysis to provide a conservative estimate. In cases where the autoignition temperature of a vapor cloud of unknown composition or of a vapor cloud with suspended dust particles, the autoignition temperature may be determined experimentally. Typically, testing standards for determining autoignition temperatures are related to dusts and liquid chemicals. Although these standards are not specific to vapors, they can be used as guidelines for developing specialized testing protocols. The testing standards for determining autoignition temperature include:

- *ASTM E659 Standard Test Method for Autoignition Temperature of Liquid Chemicals*
- *ASTM E1491 Standard Test Method for Minimum Autoignition Temperature of Dust Clouds*

Ignition of flammable mixtures can also result from sufficient heat transfer from hot surfaces. Unlike autoignition, the ignition of a gas by a hot surface depends on the temperature of the surface and on several additional parameters. The ignition of a flammable gas mixture that comes in contact with a heated surface depends on the energy that is transferred from the surface to the gas mixture, which depends on the fluid dynamics of the gas as it comes in contact with the surface. In practice, the autoignition temperature of the gas can be used as a conservative lower bound to assess explosion hazards from hot surfaces. Note that the ignition of flammable gases due to hot surfaces is different than the hot surface ignition of flammable liquids. The scope of this section is to address vapor cloud explosions. Hot surface ignition of flammable liquids is discussed in Chap. 18.

Deflagrations and Detonation

Vapor cloud explosions are characterized by a rapid increase in pressure. The rapid pressure rise is the result of rapid heating due to a deflagration or detonation. In this section, a brief overview of the fundamentals of deflagrations and detonations is given. The primary focus of this section is to discuss the application of these fundamental principles to vapor cloud explosions. For hazard assessment and mitigation related to deflagrations and detonations see Chap. 69.

Deflagrations

As discussed previously, the majority of vapor cloud explosions can be characterized as deflagrations. Nearly all vapor cloud explosions begin as a deflagration. A deflagration is characterized by subsonic propagation of the flame away from the ignition source. The flame propagation is the result of heat produced by the chemical reaction in the flame being transported into the unburned fuel-air mixture. As a result, the fuel-air mixture just ahead of the flame is preheated, which enables the flame to propagate into the unburned fuel-air mixture. This propagation will terminate once the flame reaches a fuel-air mixture that is not within the flammable limits or as a result of the reaction being quenched by turbulence generated by obstructions or by the expansion of the flame front itself, or some other heat loss mechanism.

In general, immediately after a vapor cloud ignites, the initial flame propagation is dominated by molecular diffusion and radiation, which results in laminar flame propagation. In most practical scenarios, flame propagation will increase in speed due to interaction with a turbulent flow field. In general, the source of turbulence is a combination of the following phenomena:

Table 67.16 Maximum laminar flame speed for common fuel-air mixtures at 25 °C [72]

Fuel	Flame speed (cm/s)
Methane	44.8
Ethane	47.6
Propane	46.4
n-Butane	44.9
Acetylene	155
Ethylene	73.5
Hydrogen	325

- Flow field turbulence of the unburned mixture;
- Turbulence generated from flow past obstacles;
- Turbulence generated from the expanding flame front itself.

The turbulence interacts with the flame front by wrinkling the flame. The wrinkling effectively enhances the combustion rate, and thus increases the flame propagation speed. The acceleration of the flame front results in a positive feedback mechanism where the turbulence generated by the flame front increases as the flame speed increases.

Historically, flame speeds have been measured experimentally. Several methods have been used including Bunsen burners and flat flame burners. Descriptions of these methods can be found in several combustion reference texts [72–74]. Table 67.16 shows laminar flame speeds for several common fuels. Flame speeds can also be computed numerically using commercially available combustion kinetics software such as Chemkin and DARS, which can account for parameters such as turbulence intensity, fuel mixtures, inert species, and elevated or reduced temperature and pressure. However, numerical computation of flame speed is limited to the accuracy of the assumed kinetics for the specific fuel of interest. Chemical kinetics are reasonably well defined for several common fuels including methane, propane, butane and some jet fuels.

Detonations

If the flame propagation accelerates to supersonic speeds, the propagation is referred to as a detonation and results in a shock wave. The detonation velocity can be derived from Chapman-Jouget (C-J) theory. Details of the derivation can be found in Glassman [72]. The detonation velocity, u_{det}, is as follows:

$$u_{det} = \frac{\gamma_b + 1}{\gamma_b}\sqrt{\frac{\gamma_b \overline{R} T_b}{MW_b}} \tag{67.12}$$

where $\overline{R}$ is the universal GAS constant, and where γ_b, T_b, and MW_b are the respective ratio of specific heats, temperature and molecular weight of the burned gases.

As discussed previously, significant energy is required to immediately initiate a detonation, and therefore immediate detonations are uncommon. The more common detonation scenario occurs when a deflagration continues to accelerate and abruptly transitions to a detonation. As discussed previously, a deflagration will accelerate due to turbulence interactions. Because these interactions result from many possible mechanisms, it is not feasible to generalize a theory for the acceleration phase of a deflagration-to-detonation transition (DDT) event. It is the combination of turbulent mechanisms—flow-field turbulence in the unburned mixture, turbulence generated from obstacles, and induced turbulence from the flame front itself—that augment the flame propagation speed and can result in a transition to detonation. Experimental data shows that in practice, augmentation of the flame speed to levels approaching detonations requires spaced obstacles and partial confinement of the vapor cloud [70]. Examples of such scenarios include obstacles such as process equipment, railcars, and industrial structures as well as tunnels, bridges or crowded parking lots. For vapor cloud explosions, detonations are not commonly observed, and it has been suggested that the inhomogeneity of the fuel-air mixture in a vapor cloud is the dominant limiting condition for self-sustaining detonations [70].

In theory, an analysis of a possible DDT event in a vapor cloud explosion can be performed using computational simulations. Several of the commercial software packages discussed in this chapter—Fluent, Star-CCM+, etc.—include combustion models that can be used to predict

DDT for simple geometries. In practice, current computing power is not sufficient to spatially resolve the flame front in a vapor cloud explosion, while having a sufficiently large computational domain to include an entire cloud, which can be up to several kilometers in size. In the future, as computing power increases, simulating full scale vapor clouds with complex geometries may become more feasible. Irrespective of computational resources, computational predictions are limited to the fidelity of the combustion model and must be used with caution. To extract the most value from a computational simulation of DDT, careful interpretation is required.

Blast Waves

The rapid heat released from a deflagration or a detonation results in the expansion of high temperature combustion products. Through this thermal expansion mechanism, a portion of the chemical energy generated by the fuel-air reaction is converted into mechanical energy in the form of a blast wave. The blast wave is characterized by a rapid increase in pressure, density and local fluid velocity followed by a less rapid decay to sub-atmospheric pressure conditions and an even slower recovery to atmospheric conditions. The shape of the blast wave is unique and dependent on the conditions of the explosion. Figure 67.16 shows examples of blast wave shapes. As discussed previously, a detonation of a vapor cloud is highly unlikely. However, overpressure due to a confined or partially confined deflagration can result in blast waves that approach detonation levels.

Analytical Methods

Although vapor cloud explosions are typically deflagrations rather than detonations, analyzing the detonation scenario is important because it provides the worst-case scenario. Also, pressure waves produced by an accelerating deflagration can potentially coalesce to form a shock. Determining worst-case scenario conditions is not only important in back-of-the-envelope analysis, but can also serve as an upper bound when interpreting results from computational simulations. The two most common analytical methods for predicting vapor cloud explosions are the TNT equivalency method and the TNO multi-energy method.

TNT Equivalency Method

The TNT-equivalency method is the simplest analytical procedure to analyze vapor cloud explosions. Physically, the TNT-equivalency method represents the efficiency of the conversion of chemical energy into mechanical energy. The conversion of available energy for the mass of a particular fuel, W_f, to an equivalent charge weight of TNT, W_{TNT}, is defined as follows:

$$W_{TNT} = \alpha_e \frac{W_f H_f}{H_{TNT}} = \alpha_m W_f \qquad (67.13)$$

where the TNT equivalency coefficients α_e and α_m are based on energy and mass, respectively. The energy and mass based TNT equivalency coefficients are related by the ratio of heat of

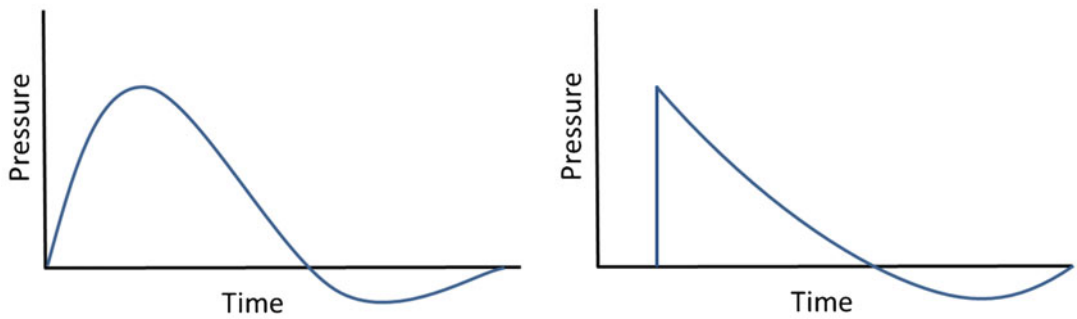

Fig. 67.16 Blast wave shapes for a deflagration (*left*) and a detonation (*right*)

combustion of the fuel, H_f, and the TNT blast energy, H_{TNT}. Once the equivalent charge weight of TNT is determined, blast parameters as a function of distance from the explosion can be determined based on empirical data and are commonly represented graphically. Common blast parameters of interest include the peak side-on overpressure, and the arrival time and duration of the blast wave.

Several TNT-equivalency methods have been proposed by various studies [75–80]. Although the details for each particular method differ slightly, the basis for these TNT-equivalency methods is similar. The TNT equivalency and blast energy are determined from statistical descriptions of historical vapor cloud explosions. The value of TNT equivalency energy coefficients proposed by various sources may range from 1 % up to 20 % and are shown in Table 67.17. In general, the TNT blast energy is assumed to be between 1800 and 2000 Btu/lb (4.19–4.65 MJ/kg) [70]. Because TNT-equivalency methods are reliant on a wide range of previous incidents—the graphical representations of the relationship between fuel and equivalent charge weight of TNT are effectively an average of historically significant vapor cloud explosion events—the accuracy of the TNT-equivalency predictions is limited to the scatter in the historical data. In fact, the scatter in the data contradicts the proportionality assumption between the fuel and equivalent charge weight of TNT, and thereby inherently limits the predictive accuracy of TNT-equivalency methods. TNT-equivalency methods tend to over predict the blast overpressure and under predict the duration. However, the advantage of TNT-equivalency methods is that they provide a simple, direct empirical relationship between a charge weight of TNT and the resulting structural damage. For hazard analyses, TNT-equivalency methods can be useful in determining potential structural damage and can give reasonable estimates of far-field blast effects as long as the actual explosion conditions are similar to an "average" historical event.

	0.15 (Class II)
British Gas [80]	0.2

[a]Class I—low reactivity materials (e.g. propane, butane, other ordinary flammable liquids)
Class II—moderately reactive materials (e.g. ethylene, diethyl ether, acrolein)
Class III—highly reactive materials (e.g. acetylene)

A commonly used TNT-equivalency method was proposed by U.K. Health & Safety Executive (HSE). In the HSE method, the fuel source is assumed to be liquid fuel that flashes to form a vapor cloud. The flash fraction of fuel, F, is estimated based on thermodynamic data as follows:

$$F = 1 - exp\left(\frac{-C_p \Delta T}{\Delta h_v}\right) \tag{67.14}$$

where the mean specific heat, C_p, and latent heat of vaporization, Δh_v, are defined for the specific fuel, and ΔT is defined as the temperature between the liquid fuel temperature in the storage vessel and the boiling temperature of the fuel at ambient pressure. The mass of the fuel is determined from the flash fraction and the mass of fuel released, m_f, as follows:

$$W_f = 2Fm_f \tag{67.15}$$

The multiplicative coefficient of two is included to account for spray and aerosol formation. Note that the maximum possible W_f is the amount of fuel released. The mass of fuel determined in Equation 67.15 is then used in Equation 67.13 to determine W_{TNT}. The values for α_e and H_{TNT} are assumed to be 0.03 and 4.68 MJ/kg, respectively. Once W_{TNT} is determined, the blast parameters can be determined directly from Fig. 67.17, where the x-axis is a scaled distance, z, that is defined as the real distance from the explosion, r, divided by the cubic root of W_{TNT}. The y-axis parameters, are also scaled by the cubic root of W_{TNT}.

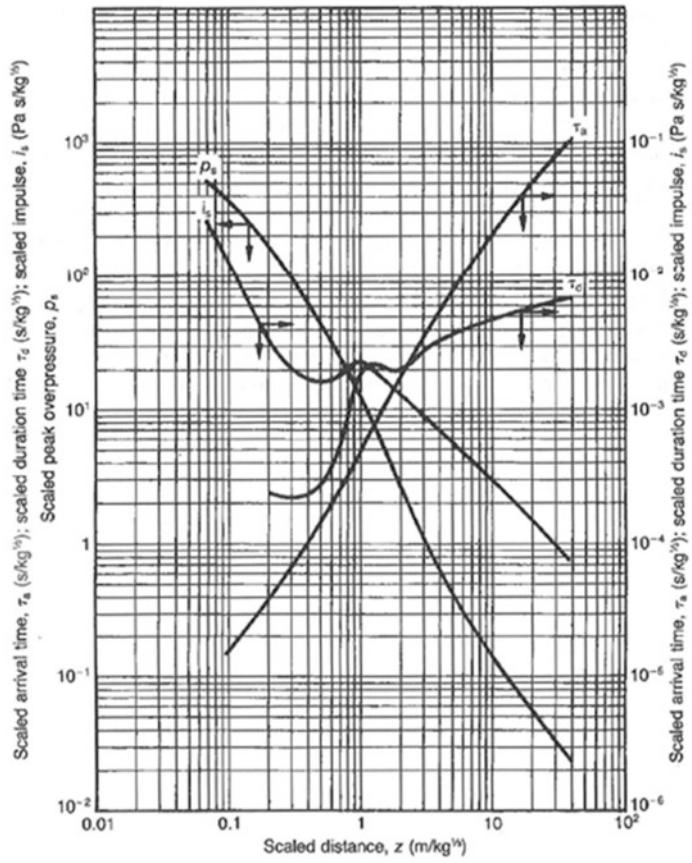

Fig. 67.17 Side-on blast parameters for a TNT hemispherical surface burst [70]

TNO Multi-energy Method

The multi-energy method is based on experimental observation that only a portion of the vapor cloud contributes to the blast [81, 82]. In the multi-energy approach, the blast wave is assumed to be produced by the portion of the vapor cloud that is partially confined or obstructed. Several experimental studies have shown that the unconfined or non-obstructed portion of the vapor cloud does not contribute to the blast [83]. In other parts of the vapor cloud where turbulence may have been generated at the time of ignition, blast generating conditions may also exist. An example of such a source is a highly turbulent jet resulting from a high pressure fuel release. The vapor cloud explosion is then viewed as an aggregate of sub-explosions from various sources in the cloud.

The multi-energy method is similar to TNT-equivalency methods in that the blast parameters are directly read off a blast chart. Figures 67.18 and 67.19 show multi-energy blast charts for side-on blast overpressure and duration curves. The method includes 10 blast classes (see Table 67.18), each one represented by separate curves in the figures. The axes variables are non-dimensional parameters. The combustion energy-scaled distance, $\overline{r}$, on the x-axes, the normalized side on overpressure, $\overline{\Delta P_s}$, and the normalized duration, $\overline{\tau}$, are defined as follows:

$$\overline{r} = \frac{r}{(E/P_a)^{1/3}} \tag{67.16}$$

$$\overline{\Delta P_s} = \frac{\Delta P_s}{P_a} \tag{67.17}$$

$$\overline{\tau} = \frac{\tau C_0}{(E/P_a)^{1/3}} \tag{67.18}$$

where the dimensional distance from the charge, r, and duration, τ, are normalized by the cube root of the available combustion energy, E,

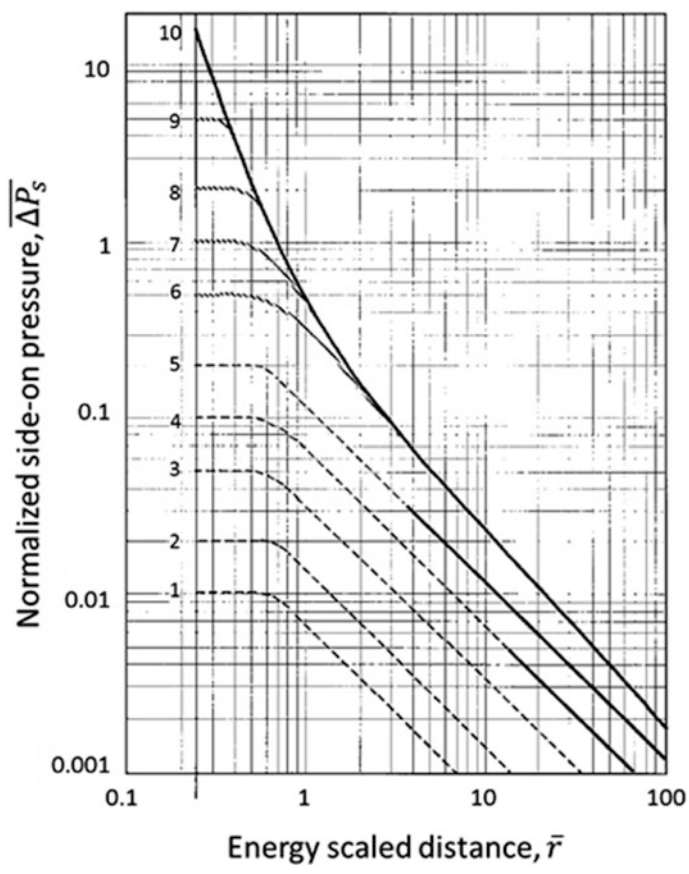

Fig. 67.18 Multi energy method side-on blast overpressure curves [86]

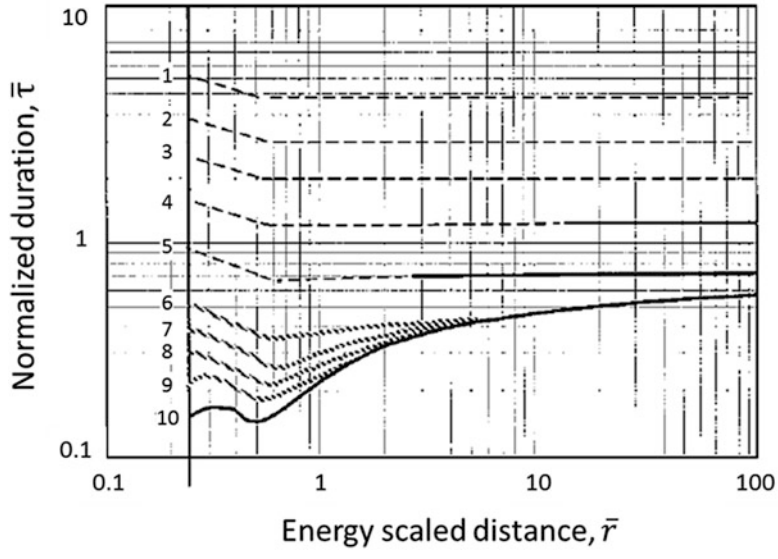

Fig. 67.19 Multi energy method blast duration curves [86]

Table 67.18 Initial blast strength index [87]

Blast strength	Ignition energy	Obstruction	Confinement	Class
1	High	High	Parallel plane	7–10
2	High	High	Unconfined	7–10
3	Low	High	Parallel plane	5–7
4	High	Low	Parallel plane	5–7
5	High	Low	Unconfined	4–6
6	High	None	Parallel plane	4–6
7	Low	High	Unconfined	4–5
8	High	None	Unconfined	4–5
9	Low	Low	Parallel plane	3–5
10	Low	Low	Unconfined	2–3
11	Low	None	Parallel plane	1–2
12	Low	None	Unconfined	1

divided by the atmospheric pressure, P_a. The side on overpressure, ΔP_s, is normalized by the atmospheric pressure. The symbol C_0, is the speed of sound of atmospheric air. The numbered curves indicate the class of blasts with strengths rated from 1 (weak) to 10 (detonation strength). For blast with strengths above 6, the curves approach the detonation limit as $\bar{r}$ increases.

The multi-energy method is not nearly as simple and direct as the TNT-equivalency method. A more detailed step-by-step discussion of the multi-energy method is given in Mercx and van den Berg [83]. An overview of the steps of the multi-energy method is given below.

1. ***Understand the applicability of the method***. The multi-energy method is applicable to unconfined vapor cloud explosions and is a conservative approach. It does not take into consideration directional effects due to non-uniform distribution of obstacles or confinement.
2. ***Determine the size of the cloud***. The multi-energy method requires an estimate of the size of the flammable cloud. For simple geometries or back-of-the-envelope estimates, the flammable region of the cloud can be determined from scaling laws [84] for plumes or jets and flammable limits for the fuel as discussed earlier in this chapter. For more accurate analyses, dispersion models as discussed previously may be employed.
3. ***Identify potential blast sources***. Engineering judgment must be used to properly determine the potential source of the blast. Some examples of common locations where blast sources can initiate include process equipment at chemical plants or refineries, space between extended parallel walls or barriers, spaces in tunnels, corridors or covered conveyor belts, and intense turbulent fuel-air mixture due to high pressure releases.
4. ***Define obstructed regions***. In addition to the blast source, the multi-energy method also incorporates sub-blasts due to obstructions. Below is a procedure given by Mercx and van den Berg to determine obstructed regions [83].
   (a) Approximate the structures as basic geometrical shapes.
   (b) Determine the obstacle orientation by taking the smallest dimension, D_1, oriented perpendicular to the assumed flame propagation direction. The dimension parallel to the flame propagation is identified as D_2.
   (c) Define an obstructed region as a group of obstacles that are located within a $10D_1$ or $1.5D_2$ radius from the center of the region. Note that D_1 and D_2 are dimensions for any obstacle in the region. Exclude any obstacle that has an outer boundary 25 m or further from the outer boundary of the obstructed region.
   (d) Determine the free volume of the obstructed region by subtracting the volume of the obstacles from the volume of the box. Note that the obstructed region can also be defined by multiple boxes to get a more accurate estimate of the free volume.
5. ***Determine the unobstructed volume***. Subtract the free volume of obstructed regions that are within the cloud from the total cloud volume.

6. ***Calculate the available combustion energy for the obstructed and unobstructed regions***. The combustion energy, E, can be determined by multiplying the volume of a region by the heat of combustion (volume basis) for the particular fuel. Conversely, the calculation can also be determined from the heat of combustion (mass basis) and the mass of the region.
7. ***Estimate the blast strength of each region***. A conservative approach would be to assign a blast class of 10 to any obstructed region and a class of 1 for unobstructed regions. In the case of turbulence in an unobstructed region due to, for example, the momentum of a fuel release, a blast class of 3 is recommended. Alternatively, blast class can be determined from Table 67.18 [84]. Definitions of the selection criteria are given below.
   (a) ***Ignition Energy***. An example of a *high* ignition energy source is a confined vented explosion. An example of *low* energy sources are sparks, flames, hot surfaces, etc.
   (b) ***Obstruction***. Obstructions are considered *high* if the ratio of total volume of the obstructions to the total volume of the obstructed area is greater than 0.3 and the spacing between obstacles is less than 3 m. If the obstacles in an area do not meet these criteria, the obstructions are considered *low*. *None* refers to the absence of any obstructions.
   (c) ***Confinement***. Confinement is considered a *parallel plane* confinement if a part of the vapor cloud is confined by barriers or walls on two or three sides. Confinement is considered *unconfined* if the gas vapor is only confined by the ground.
8. ***Multiple obstructed regions***. For cases where there is more than one obstructed region, define a single equivalent blast source by combining the combustion energy for all the regions and defining the center of the blast source as the energy weight-averaged location.
9. ***Blast source location of the unobstructed region***. If there are separate unobstructed regions, the source location of the unobstructed region of the cloud can also be determined by an energy weighted average of the separate unobstructed regions.
10. ***Calculate blast parameters***. For each source, use the estimated combustion energy to determine blast parameters from Figs. 67.18 and 67.19 and Equations 67.16, 67.17, and 67.18. If the distance between blast sources is small, the far-field blast parameters can be determined by assuming the blast sources are initiated simultaneously and the combustion energy for the sources can be summed.

Although, the multi-energy method will provide more accurate predictions than TNT-equivalency methods, it still has limitations and constraints. The multi-energy method assumes blast strengths of the blast sources, uses generalized criteria for defining obstructed regions, and assumes that the blast sources do not interact. Understanding how these assumptions affect the accuracy of the predicted results is essential in any vapor cloud explosion investigation or hazard analysis. In light of recent increases in computational power, computational codes are beginning to replace the tedious analytical approach of the multi-energy methods. Although computational codes such as FLACS provide higher fidelity analysis, analytical methods can still provide valuable insight when interpreting the results of computational simulations. Analytical methods can also be a more cost effective options when conducting a process hazard analysis where safety precautions are based on worst-case scenario conditions and the higher fidelity of computational codes are not required.

Computational Methods

Although analytical methods are useful tools for evaluating vapor cloud explosions, their limitations often require the use of computational tools. Several of the commercial software packages discussed in this chapter—FLACS, PHAST, Fluent, Star-CCM+, etc.—can be used

to analyze vapor cloud explosions. FLACS was developed specifically for vapor cloud explosion applications. FLACS simulations can predict several parameters, including overpressure due to blast waves and flame propagation, and can account for complex geometries. Several studies have been performed to validate FLACS with experimental results from medium to large scale tests [85–87].

Vapor cloud explosion scenarios may include complicating factors that analytical methods are unable to address. One such example is the explosion that occurred at the Buncefield Oil Storage Depot in Hertfordshire, England in 2005 that resulted from a gasoline leak from an overfilled tank [88]. Approximately 10 % of the oil turned into vapor and mixed with the ambient air to form a vapor cloud that appeared to have ignited and initiated a blast wave near a parking garage located west of the site. The Buncefield explosion was unique because the observed damaged due to the blast wave suggested that the overpressure was much higher than that expected for the low congestion levels dictated by the physical structures and equipment located at the site. Analyses showed that to predict an overpressure consistent with the observed damage, the computations needed to include the foliage of the surrounding trees [89]. Testing used to validate the simulations demonstrated the acceleration of a flame front as it passed along a row of dense tree foliage. Although computational methods can give insightful results, care must be taken when interpreting any computational simulation. In practice, careful validation with experimental results, physical observations, or analytical methods is essential in developing confidence in simulation results.

Nicolas F. Ponchaut performs hazard and process safety analyses related to fires, explosions, chemical releases, and equipment failures. He has been involved in numerous analyses including hazard quantification of LNG spills, the dispersion of flammable vapor clouds, and of pollutants resulting from flaring operations, and the thermal behavior and failure of large battery packs.

Francesco Colella specializes in the area computational fluid-dynamics, heat transfer, and computational fire

modeling. His professional expertise encompasses fire safety evaluations for industrial plants and LNG terminals, as well as failure analysis of industrial equipment, consumer products, and battery packs. Dr. Colella is principal member of the NFPA 502 committee on tunnel fire protection and his expertise includes life safety evaluations for underground structures such as car parks and tunnels.

Kevin C. Marr specializes in engineering analysis of physical phenomena related to heat transfer, fluid mechanics, multi-phase flow, combustion, and fire science. Dr. Marr has conducted several origin and cause investigations of fires and explosions at residential, commercial and industrial facilities and has conducted process hazard analyses for combustible dust and chemical releases from industrial facilities.

Effects of Thermal Radiation on People: Predicting 1st and 2nd Degree Skin Burns

68

Christopher J. Wieczorek and Nicholas A. Dembsey

Introduction

The human body can not tolerate elevated temperatures for any long duration of time. Pain and damage to the skin, i.e., skin burns, begins to occur when the temperature at the basal layer exceeds 44 °C [1]. The amount of damage is a function of both the skin temperature and duration of time for which the temperature is elevated above 44 °C. Previous studies on the effects of thermal radiation on the skin have led to empirical models, graphical techniques, and simple algorithms to predict the temperature-time histories of the skin and the degree of damage due to a constant radiative exposure. All of the methods discussed in this chapter are limited to predicting ONLY 1st and superficial 2nd degree burns. For more severe burns engineering guidance is not currently possible due to the lack of reliable data. Although this chapter provides guidance on calculating the onset of pain from empirical studies it does not include any prediction of humane response to pain as it relates to fire safety decision.

The Skin

The largest human organ is the skin. Skin represents approximately 15 % of the total weight of an average adult and has a surface area of 1.7 m^2 [2]. The skin serves in many different capacities that are essential to life. These include "(1) protection of underlying tissues from physical, chemical, and thermal trauma; (2) thermal regulation by sweating, heat conduction (insulation), and control of blood flow to a profuse plexus of minute surface vessels; (3) impermeability to both tissue fluids and environmental chemicals; and (4) sensory perception of touch, pain, and temperature."[2] As with the many functions which it serves the physiology of the skin is equally as complex.

For the purpose of this chapter it is not necessary to provide a full clinical definition of the skin. Understanding the complexity of the structure and functions of the skin is not required in order to predict and evaluate the severity of skin burns. It should be noted however that due to the complexity of the skin, simplified models and algorithms only provide an estimation of the skin damage.

A glossary of medical definitions can be found at the end of this chapter. An attempt has been made to define key terms within the body of the text to maintain a continuity of flow when reading.

The skin is composed of three primary layers: the epidermis, dermis (or corium), and hypodermis

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,

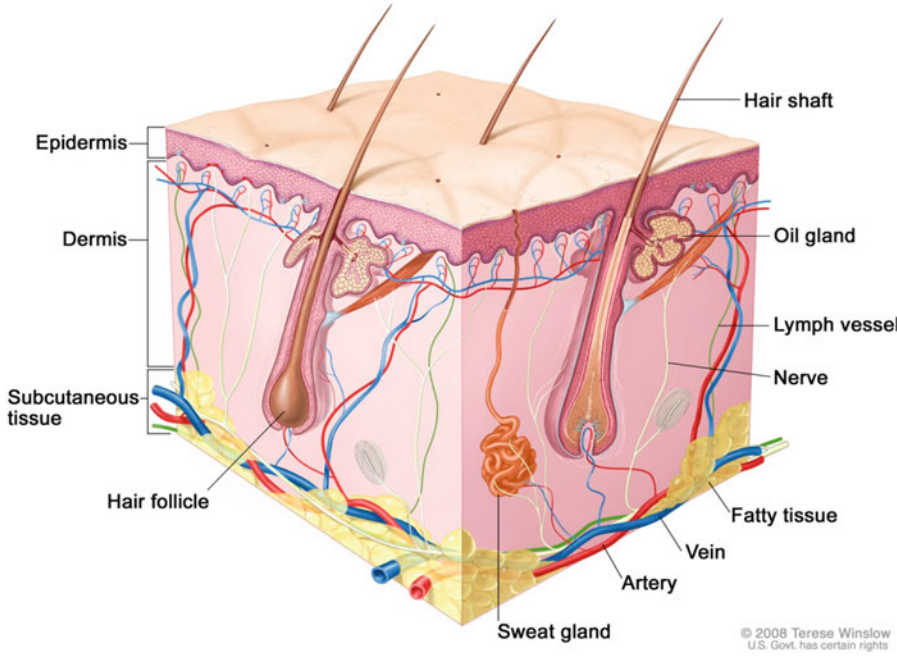

Fig. 68.1 The human skin. The skin is composed of three primary layers: the epidermis, the dermis, and hypodermis (subcutaneous fatty tissue)

stratum corneum stratum lucidum	stratum corneum
stratum granulosum	stratum granulosum
stratum germinativum	prickle layer
	basal layer

Fig. 68.2 Subdivisions of the epidermis

(or subcutaneous fatty tissue), Fig. 68.1 [3]. Each of these primary layers are further subdivided into other layers, all of which serve a different function.

The epidermis is divided into four layers. These layers are from top to bottom, the stratum corneum, stratum lucidum, stratum granulosum, and stratum germinativum [4, 5]. Other authors have defined the four primary layers as the stratum corneum, stratum granulosum, prickle layer, and basal layer [2]. Based on these definitions Fig. 68.2 was developed to illustrate the divisions of the epidermis from top to bottom.

Of these layers the stratum corneum is the only non-living layer of cells, the cells are considered dead or horny. The stratum lucidum and stratum granulosum are layers of cells "in transition between dead or dying squamous cells and the basal cells."[4] Also depending on the location either one or both of these layers may be absent [5].

The stratum germinativum or prickle layer is a "three-dimensional network of irregular interpapillary convolutions that afford a large surface area between the" epidermis and the dermis [2]. The basal cells form the lower layer of the stratum germinativum and are "arranged in a palisade-like manner over the dermis." [4] "Cells are generated in this layer and gradually extend toward the skin surface" forming the various layers of the epidermis as they begin and proceed to die [2].

The epidermis varies in thickness between 75 and 150 μm, except in the palms and soles where it varies between 0.4 and 0.6 mm [4]. It contains no blood vessels, lymphatic or connective tissue, and obtains all of its nourishment from the dermis[2]. The outermost layer, stratum corneum, of the epidermis contains approximately 10–20 % water, this percentage varies depending on whether or not the skin was dried, at which point it cracks,

or if it was soaked in water, resulting in wrinkling. The stratum germinativum contains approximately 70 % water and aids in the body's heat regulation [2, 5].

The dermis or corium is divided into two layers, the subepithelial or papillary layer and the reticular layer. The important feature of the dermis is the presence of the mastocyte cell. This type of cell contains large quantities of histamine and heparin. Histamine is defined as "a substance in the body found wherever tissues are damaged. Red flush of a burn is due to the local production of histamine; product of histidine catabolism." [6]

The dermis is approximately 1–4 mm thick. It contains the vascular, nervous, lymphatic and supporting structures of the skin. The dermis is approximately 10–30 % fibrous protein, most of which is collagen fibers. The remainder of the dermis is a complex of polysaccharide existing in the form of a viscoelastic gel. Along with enclosing the fibers in the dermis, it also contains proteins, electrolytes, tissue fluid and a mucinous material, which are all essential to the existence of the dermis [4].

> The papillary layer is a superficial layer of the corium, lying adjacent to the epidermis. It consists of numerous small, vascularized, and highly sensitive protuberances called papillae, which rise perpendicularly from its surface. The papillae are minute conical eminences with rounded or blunted extremities that are received into corresponding pits of the undersurface of the epidermis. Each papilla has many very small and closely interlaced bundles of finely fibrillated tissue, with a few elastic fibers and a single blood capillary loop.
>
> The blood supply to the skin accounts for nutritional supply, cellular and humoral defenses, and a major portion of the thermal regulatory function. The vasculature is highlighted by the presence of a rich network of branching arterial and venous arcades that are interconnected in a regular pattern. Small arteries entering the subcutaneous tissue form a system of long arterioles about 50 μm in diameter as the subdermal plexus. Adjacent links of the arteriolar system branch off to form the dermal plexus, which in turn forms a mesh of much finer arcuate capillaries, the subpapillary plexus. The capillaries combine into an even more complex venular mesh.
>
> An important and unique aspect of the skin circulation is the presence of a large number of direct shunts from arteries to veins, called arteriovenous (AV) anastomoses. Activation of these AV shunts enables nearly all blood flow to be diverted past the capillaries to increase the effective thermal insulation between the subcutaneous tissue and the environment. On the other hand, this complex and vast vascular bed can accept up to 20 % of the total cardiac output when the subpapillary plexus becomes engorged with blood. The small blood vessels of the skin have extensive sympathetic innervation and are highly responsive to neurogenic constrictor and dilator influences arising from various forms of local and systemic stress. This responsiveness is known to play an important role in the human thermoregulatory mechanism [2].

The dermis also contains hair follicles, located approximately 2 mm below the skin surface [7]. "Hair follicles play an important role in the re-growth of skin after severe burns because they are lined with epithelial cells which act as growth points. If the skin burn depth is greater than the follicle depth then re-growth is slow or even impossible." [7]

"The subcutaneous tissue below the skin consists of fat followed by muscle. Bundles of fat are bound together by collagen fibrils. It is not necessary to have muscle below the fat in all skin sites. Only in special parts of the body does subcutaneous muscle exist, e.g., in face and neck etc. The thickness of subcutaneous fat is of great importance in maintaining body temperature. Although this fat is not part of the skin proper, it exerts a great influence on the conductance of the body surface. The thickness of fat varies from virtually zero in some areas to 1.5–2.0 cm in others, the thigh being the fattest." [4] "Individual and anatomical differences in this fat deposition are very large and can play a major role in determining the degree of injury for a severe thermal insult." [2]

Human Variability

Sensation of Pain

The sensation of pain is believed to be a function of pain receptors, which are free nerve endings located throughout the body [8]. The number of pain receptors varies from one location to

Table 68.1 Number of pain receptors per square centimeter at various locations on the human body [8]

Location	Number of skin receptors for pain per cm^2
Tip of nose	44
Sole of foot	48
Ball of thumb	60
Scalp	144
Eyelid	172
Buttocks	180
Forehead	184
Back of hand	188
Inside forearm	203
Shoulder blade	212
Bend of elbow	224
Neck region	228
Back of knee	232

another. The number of receptors per centimeter squared, listed in Table 68.1, causes different parts of the body to be more or less sensitive to pain.

From Table 68.1 it can be seen that the least sensitive locations are the tip of the nose and the sole of the foot; while the back of the knee, neck region, and bend of the elbow, all contain more than 220 pain receptors per centimeter squared making them the more sensitive areas. The inside of the forearm contains 203 pain receptors per centimeter squared. Many of the initial studies performed to determine pain from thermal radiation consisted of exposing the forearm to the thermal source [9]. Therefore, the experimental time to pain values can be considered conservative when compared to most other locations on the body.

Along with the physical aspect of pain, the sensation of pain is also psychological. "...much depends on a person's attitudes, previous experiences, and culture. For example, athletes often report not feeling the pain of an injury until after the competition has ended. Some cultures are more stoical about pain and teach individuals to endure individual suffering; in Western cultures, there is the widespread illusion that pain and suffering are ennobling. Also, boys and girls within Western cultures are often taught to respond differently to pain."[8]

Table 68.2 Skin temperature at various locations on the body

Region	Surface area m^2 [10]	Temperature °C [11]	Temperature °C [10]
Head/ forehead	0.20	34.7	33.4

Initial Skin Temperature

The initial skin temperature of individuals varies significantly. Factors affecting the skin temperature include age, sex, personal habits, i.e., smoking versus non-smoking, occupation, physical activity, and even pregnancy. In addition to variations between individuals, the skin temperature at different locations on the body varies as well. Millington and Wilkinson state "measurement of skin temperature reveals significant differences between one part of the body surface and another." [10]

The skin temperatures for various locations on the body are shown in Table 68.2 [10, 11]. The skin temperature across the body varies between 28.6 °C and 34.7 °C. The data from both sources were taken with subjects at rest. The ambient temperature for one study[10] was provided as 23 °C, no ambient temperature was given for the other study.

The ambient temperature has two different effects on the skin temperature. First, "At ambient temperatures between 10 °C and 20 °C the range and distribution of skin temperatures are

Table 68.3 Seasonal effects including the ambient temperature (T_{amb}) and relative humidity (R.H.) on the skin temperature (T_{skin}) [12, 13]

Gender	N	Age	T_{amb} (°C)	R.H. (%)	Month	Number of sites	T_{skin} (°C)	Ref.

Female	22					Dorsal	30.6 ± 2.7

n = number of test subjects

[a]T_{amb} and R.H. are the ambient temperature and relative humidity respectively during the test

more variable (±10 °C) than they are in a warmer environment. At about 32 °C, a thermally neutral condition, both adults and infants have an overall temperature range of only 4 °C."[10] In addition to affecting the range of skin temperatures, the ambient temperature also affects the mean skin temperature as well. Studies have been performed to determine the effect of seasonal temperature changes and elevated ambient temperatures on the skin temperature for subjects during rest. The results from these studies are shown in Table 68.3 [12, 13].

Another study indicated that an individual's occupation also affects the skin temperature. A study of employees in seven different occupations was performed; skin temperature measurements were made at two locations, the volar and dorsal side, of the index finger [14]. The results from the study are shown in Table 68.4.

Employees in the fish processing industry had the lowest skin temperatures, on average 17 °C, while office workers and metal workers had the highest skin temperatures of approximately 32.7 °C. The temperature measurements in the study were performed on the index finger of the test subjects, this was shown previously, Table 68.2, to be the location at which the lowest skin temperatures on the body were measured. Also, a skin temperature of 17 °C is on the verge of the threshold of pain, which is listed as 16 °C in;

Table 68.9 therefore, it is believed that the skin temperatures at other locations of the body were higher than those reported for the tip of the finger.

A person's personal habits and health also affect the initial skin temperature. Studies have shown that a person who smokes or chews nicotine gum will have an increase in skin temperature of 0.62 °C [15]. Also, women who are pregnant have an increase in skin temperature of 2 °C above their normal skin temperature.

Skin Thickness

Determining skin thickness accurately is difficult since it is difficult to define clear boundaries between the different layers. Various techniques have been developed in an attempt to provide the best values. "While there are no great changes in skin thickness demonstrated by these methods, it is possible to show that the thickness of male and female skin, when young, is significantly different, but because the natural scatter of the data increases with age, it is doubtful whether the differences above the age of 65 years are real. Indeed, large variability in the measurement of skin thickness has been a feature in older people."[10] Differences in the forearm skin thickness among males and females of various ages are shown in Table 68.5.

As can be seen from Table 68.5 there is a significant difference between the skin thickness of males and females between the ages of 24 and 37, the male forearm skin is approximately 25 % thicker than the female's. The variation for all individuals below the age of 65 decreases to a difference of only 3 %, while the difference between males and females above the age of 65 is approximately 10 %.

The depth of the basal layer, which is the lowest layer of the epidermis, is critical in determining superficial 2nd degree burns. The reference state of the skin assumes that the basal layer is located at a depth of 80 μm. Millington and Wilkinson state however: "The measurement of epidermal thickness presents further difficulties, since the dermal papillae and rete ridges give an undulating lower surface."[10] They further state that: "It is now well established, however, that epidermal thickness varies considerably over the whole body surface and variation at comparable sites between individuals is also high."[10] The mean values for full epidermal thickness at 13 different sites of the body are shown in Table 68.6.[10]

As can be seen in Table 68.6, only three sites, the palm, fingertip, and back of hand have an epidermal thickness greater than 80 μm. The surface area encompassed by these three locations is only 3.5 % of the total skin surface area.

Table 68.5 Forearm skin thickness for four different age groups measured using different measurement techniques

Sex of subjects	Age group	Type of measure	Range (mm)	Average thickness (mm)	Mean value (mm)
Male	Under 65	X-ray	1.0–1.7	1.3	1.3
	Under 65	X-ray	1.1–1.8	1.43	
	24–37	X-ray	0.9–1.19	1.1	
	24–37	Ultrasound	1.0–1.16	1.12	
Female	Under 65	X-ray	0.9–1.4	1.1	1.26
	Under 65	X-ray	1.0–1.7	1.34	
	28–37	X-ray	0.82–0.95	0.88	
	28–37	Ultrasound	0.75–0.92	0.83	
Male	Over 65	X-ray	0.7–1.2	0.9	1.1
		X-ray		1.19	
Female	Over 65	X-ray	0.6–1.2	0.9	1.0
		X-ray		1.06	

The range of skin thickness and average for each study are listed along with the mean value of all studies in each group [10]

Table 68.6 Mean values for full epidermal thickness at thirteen different locations on the body [10]

Body site	Mean thickness (μm)
Palm	429.0
Fingertip	369.0
Back of hand	84.5
Forearm	60.9
Upper arm	43.9
Thoracic region	37.6
Abdomen	46.6
Upper back	43.4
Lower back	43.2
Thigh	54.3
Calf	74.9
Forehead	50.3
Cheek	38.8

The remaining 96.5 % of the body has a mean epidermal thickness of less than 80 μm. The values listed in Table 68.6 are mean values; at some locations the variations among different individuals can be significant. For example the epidermal thickness of the abdomen and thorax have been published to vary between 16 and 50 μm.[10]

Skin Burns

Thermal damage to the skin has been evaluated over the years in a number of ways. The most common scheme for evaluating thermal injury is ranking the burns as 1st, 2nd, or 3rd degree. Other methods include classifying the burns as partial or full thickness burns or using the University of Rochester's grading system.

The traditional ranking system of 1st, 2nd, or 3rd degree burns is dependent on the level of necrosis and the depth of damage. First-degree burns are superficial burns. Only the epidermis is affected. The skin is typically red and painful and does not blister. The epidermis often flakes off in the subsequent days or weeks [16]. Severe sunburns are the most common form of 1st degree burns [16].

A second-degree burn is indicative of complete necrosis of the epidermis. If no damage to the dermis occurs it is considered a superficial 2nd degree burn. Visually the skin is blistered, a moist bright pink-red mottled coloration and very painful [4]. If minor damage to the dermis has occurred it is considered a deep 2nd degree burn. The skin is blistered and is a very pale white or mottled color under the blisters [16].

A third-degree burn is complete necrosis of the dermis, extending and possibly including the subcutaneous fat. ASTM C 1055 defines complete or significant necrosis of the dermis as 75 % destruction of the dermis [17]. Other considerations include cell destruction below the depth of the hair follicles, approximately 2 mm [7]. With third-degree burns the skin rarely blisters [16]. The skin is dry, gray and charred and may feel leathery [7, 18]. Usually there is no feeling and no possibility for natural skin regeneration.

Additional levels of burns include 4th, 5th, and 6th degree burns. "Fourth-degree burns require skin grafts. Fifth- and sixth-degree burns involve destruction of muscle and/or bones, respectively." [19]

The criticism behind the traditional ranking system includes the lack of correlation between the initial surface appearance and the depth of injury. The depth of injury is the most reliable measure of burn severity [18]. "Short duration contact with a very hot object can cause immediate necrosis in the outer layers of the epidermis, giving the appearance of a third-degree burn without the injury penetrating to the underlying dermis. In contrast, longer-duration exposures to lower temperatures can cause a burn through the dermis without any immediate apparent surface necrosis."[18]

Based on this information a second classification of burns was developed and originally described by Zawacki [18] This method uses two categories of burns, partial thickness and full thickness. "A partial-thickness burn occurs when cell necrosis has proceeded part way through the dermis. A full-thickness burn occurs when the cells have been destroyed through the depth of the dermis. Under this categorization, a first degree burn is considered below the burn threshold, while a minimum severity partial-thickness burn occurs when the heat transfer is sufficient to

destroy cells at the base of the epidermis."[18] Other authors use the terms deep dermal and full thickness burns interchangeably [7].

The University of Rochester developed a classification system in which burns were evaluated as 0, 1°, 2°, 3°, 4° and 5° [20]. These grades corresponded to the following visual appearances:

0. No burn visible
1. Erythematous burn
2. Patchy white burn
3. Uniform white burn
4. Blebbed white burn
5. Carbonized burn

"Each of the five major categories of burn severity was divided into mild, moderate, and severe, giving 16° of damage."[20]

Knox [21] later modified the grading system developed at the University of Rochester. This method not only uses burn depth, but also cellular change with or without acidophilism present to classify burn damage. Table 68.7 provides the grade, description and approximate depth of burn.

"A grade of zero was given to all tissue sections showing no thermal damage. Burned tissue was categorized into epidermal, transepidermal, dermal, and adipose. Epidermal burns were subclassified as to whether cellular change without acidophilism was present (grade 1), whether acidophilism was present involving only partial depth of the epidermis (grade 2), or all the epidermal depth (grade 3). Transepidermal burns (those showing separation between the epidermis and the dermis) were subcategorized as to whether the separation was focal (grade 4) or complete (grade 5). Dermal burns were classified as to whether the damage was superficial, mid, deep, or complete (grades 6, 7, 8, and 9 respectively). Grade 10 was assigned to burns extending beyond the dermis into the adipose tissue."[21]

Table 68.8 compares the various burn classifications. No one method has been shown

Table 68.7 University of Rochester burn depth grading system [21]

Grade	Description	Depth (μ)
0	No thermal damage	0
1	Cell damage without acidophilism	1–20
2	Partial epidermal acidophilism	20–50
3	Complete epidermal acidophilism	50–100
4	Partial dermal–epidermal separation	100–150
5	Complete dermal–epidermal separation	150–250
6	Superficial dermal	250–500
7	Mid dermal	500–1000
8	Deep dermal	1000–1500
9	Complete dermal to adipose border	1500–2000
10	Adipose	>2000

Table 68.8 Comparison of skin burn classifications

General	Reed [18]	Lawton [7]	Knox [21]
1st degree	Below threshold	Superficial	1 – Cell damage without acidophilism
			2 – Partial epidermal acidophilism
			3 – Complete epidermal acidophilism
2nd degree	Partial thickness	Partial thickness	4 – Partial dermal–epidermal separation
			5 – Complete dermal–epidermal separation
3rd degree	Full thickness	Deep dermal	6 – Superficial dermal
			7 – Mid dermal
			8 – Deep dermal
			9 – Complete dermal to adipose border
			10 – Adipose

to be substantially better than the others. For the purpose of this chapter the traditional classification of 1st, 2nd, and 3rd degree burns, as defined above, will be used.

Burn Statistics and Clinical Treatment Time

There is an estimated 1.25 million burn injuries per year (1992) in the United States alone [22]. These injuries are due to a number of sources including fire and flame, motor vehicle accidents, electricity, lightning, aircraft crashes and other fire and burn injuries [22]. The percentage of burns caused by radiation hazards is not known. A recent study of 6417 burn injuries between 1991 and 1993 indicated that only 10 were directly attributed to radiation; other sources included flames, scalding, contact, chemical, electrical, and other [23]. Treatment is largely a function of burn depth, while patient survivability is primarily a function of the location and amount of skin area damaged and age; secondary effects such as preexisting health conditions (cardiac, liver, or lung disease), obesity, alcohol abuse, and any number of burn effects such as shock, pulmonary edema, and infection are also important variables which effect a patients survivability [16, 23, 19, 24]. It has been shown [24] that withholding any secondary effects, the survivability of a patient is only a function of age and percent of the body area burned, younger individuals can survive a much larger burn area than older individuals. A study on the probability of survival indicated that for individuals between the ages of 0 and 19 there was a 90 % probability of surviving burns covering up to 42 % of their body, while for the same burn area the probability of individuals older than 65 surviving was only 10 % and there was no chance of survival for individuals older than 70 [24].

Treatment of patients is dependent on the degree of thermal injury. First-degree may not even require medical treatment. Medical treatment for superficial 2nd degree burns will be minimal, while severe 2nd degree burns and 3rd degree burns will require extended hospital time and autograft surgery [9].

Other very important considerations include the emotional and psychological impacts from burn injuries. 'The impact of a severe facial burn, especially with noticeable scarring, is hard to overestimate. The majority of patients report anxiety, depression, and withdrawal that may be life-long. Patients with severe facial burns are rarely noticed in public, because many avoid all outside contact except with family members. Even the arts and literature portray persons with facial burns as emotionally scarred or sinister (c.f. *Phantom of the Opera*, *Nightmare on Elm Street*, *Darkman*, *Man Without a Face*.) Few of us can comprehend the difficulty of re-integrating into society with cosmetically unacceptable facial scars.' [25]

Prediction of Skin Burns

The essential elements for injury are "exposure to heat, and elevation of the skin temperature to an injurious level for a sufficient time to produce damage."[5] Over the years a large database of irradiance verses exposure time for varying degrees of injury has been compiled. These data are essential in evaluating the risk of human injury due to radiation hazards. In conjunction with these data empirical equations, graphical methods, simple algorithms, and finite element models have been developed to predict the degree of human injury. Of these the latter is the only method which will not be discussed in detail, as it is beyond the scope of this chapter.

The normal human skin temperature is 32.5 °C [1, 26]. Damage to the skin increases logarithmically with a linear increase in skin temperature [1]. As the temperature of the skin is elevated, an individual begins to experience different sensations and physical damage to the skin occurs. Skin injury begins when the skin temperature is greater than 44 °C. The amount of damage is a function of the skin temperature and the period of time for which the temperature is greater than 44 °C, at a tissue temperature of approximately 72 °C the skin is

Table 68.9 Thermal sensations and other effects at various temperatures [5]

Sensation	Skin color	Tissue temperature °C	Tissue temperature °F	Process	Injury
Numbness	White			Protein coagulation	Irreversible
	Mottled red and white	72	162	Thermal inactivation of tissue constituents	Possibly reversible
		68			
		64			Reversible
Maximum pain Severe pain Threshold pain	Bright red Light red	60	140

Numbness	White	0	32	Protein coagulation	Irreversible
		−4	25		

destroyed virtually instantaneously [1]. The initial skin temperature is also a factor; even a 1 °C difference can produce significantly different results [26]. Table 68.9 indicates the various stages of thermal sensations and associated effects at different skin temperatures [5].

The recommended property values define the reference state for the skin and are shown in Table 68.10. The effects of changes in initial skin temperature, T_0, epidermal thickness, x_b, and pain receptor depth, x_p, due to human variation will be discussed below. Methods used to predict pain and superficial 2nd degree burns are presented here and are calibrated for a constant incident thermal radiative exposure against experimental data using a set of recommended properties for the skin.

Thermal damage to the skin can occur via conduction, convection or radiation. Only skin damage due to radiation will be addressed within this chapter. Unless otherwise noted all of the methods discussed assume the following parameters for the skin and source of thermal radiation. The thermal insult is a *constant infrared* source over the exposure time. The skin is opaque to infrared radiation and has an initial skin temperature of 32.5 °C.

As indicated in Table 68.9, the first substantial sensation experienced, as the skin temperature is elevated, is pain. Pain receptors are located at an approximate skin depth of 0.1 mm [26]. Threshold pain is felt by human beings when the average temperature at the pain receptor depth is increased to about 45 °C [27].

Prediction of Skin Burns: Simple Algorithms

Two models for predicting the thermal damage to the skin due to radiation have been developed. They are the damage integral model and the "critical energy model." For both of these models it is required to know the temperature-time history of the skin. Four algorithms have been

Table 68.10 Reference state properties for the skin

Property	Symbol	Value	Units
Thermal conductivity (heating)	k_h	0.5878	W/m-K
Thermal conductivity (cooling)	k_c	0.4518	W/m-K
Volumetric heat capacity	ρc	4,186,800	J/m^3-K

Initial skin temperature	T_0	32.5	°C

developed to model skin temperature over time, based on a square-wave pulse of radiant energy.

Each of these models assumes that the skin is a single layer, opaque semi-infinite solid. The complexities of the skin, i.e., its layered non-homogenous structure, blood perfusion, sweating, etc. are all ignored. The incident radiant flux to the skin surface is assumed equal to the net flux absorbed by the skin. This is a reasonable assumption considering the simplified view of the skin, the skin absorptivity, and the skin surface cooling. The skin absorptivity can be taken to be between 0.94 [28] and 0.99 [11] for infrared incident radiation. Based on a skin temperature of 72 °C and a convection heat transfer coefficient of 0.025 kW/m^2 K, the convective and radiative cooling at the skin surface is at maximum 1.3 and 0.80 kW/m^2 respectively. The skin is assumed to be exposed to a constant heat flux for an exposure time τ, after which the flux is removed.

Equation 68.1 is used to predict the temperature profile at depth x below the skin surface [27]. Equation 68.1 can only be used to predict the time to pain. Only the heating period of the skin is considered, the cooling period is not taken into account.

$$T = T_0 + \frac{\dot{q}''}{k}\left[\frac{2\sqrt{\alpha t}}{\sqrt{\pi}}\exp\left(-\frac{x^2}{2\alpha t}\right) - x\,erfc\left(\frac{x}{2\sqrt{\alpha t}}\right)\right] \tag{68.1}$$

At the surface of the skin Equation 68.1 reduces to:[27]

$$T_s = T_0 + \frac{2\dot{q}''\sqrt{t}}{\sqrt{\pi k \rho c}} \tag{68.2}$$

Where:

$\dot{q}''$ = incident thermal radiation (W/m^2)
t = time (sec)
x = depth below the surface of the skin (m)
T = temperature at time t, and distance x below the skin surface (K)
T_0 = initial skin temperature (K)
T_S = temperature of the skin surface (K)
α = k/ρc = thermal diffusivity (m^2/s)
c = specific heat (J/kg-K)
k = thermal conductivity (W/m-K)
ρ = density (kg/m^3)

Damage to skin occurs whenever the skin temperature is above 44 °C, therefore it is important to include the relaxation or cooling period. At low irradiances as much as 10 % of the thermal damage occurs during the cooling period, at higher irradiances the damage during cooling can be as much as 35 % [29]. "This accounts for the well-known prevention of a blister by prompt application of ice to an exposed area. If this is done soon enough, a third of the injury can be eliminated. "[29] Three algorithms were developed which include relaxation or cooling of the skin. The first is shown as Equation 68.3 [30].

$$T = T_0 + \frac{2\dot{q}''}{\sqrt{k\rho c}}\left[\sqrt{\tau}\ ierfc\left(\frac{x}{2\sqrt{\alpha t}}\right) - \sqrt{t-\tau}\ ierfc\left(\frac{x}{2\sqrt{\alpha(t-\tau)}}\right) S(t)\right] \quad (68.3)$$

Where:
$\dot{q}''$ = incident thermal radiation (W/m^2)
t = time (sec)
x = depth below the surface of the skin (m)
S(t) = step function where S(t) = 0 if t < τ and S(t) = 1 if t ≥ τ
T = temperature at time t, and distance x below the skin surface (K)
T_0 = initial temperature (K)
α = k/ρc = thermal diffusivity (m^2/s)
k = thermal conductivity (W/m-K)
ρc = volumetric heat capacity (J/m^3-K)
τ = exposure time (sec)

The second is shown as Equation 68.4 [28].

$$T = T_0 + \frac{\dot{q}''}{k}\left[\frac{2\sqrt{\alpha t}}{\sqrt{\pi}}\exp\left(-\frac{x^2}{4\alpha t}\right) - x\left(1 - erf\left(\frac{x}{2\sqrt{\alpha t}}\right)\right)\right] - \frac{\dot{q}''}{k}\left[\frac{2\sqrt{\alpha(t-\tau)}}{\sqrt{\pi}}\exp\left(-\frac{x^2}{4\alpha(t-\tau)}\right) - x\left(1 - erf\left(\frac{x}{2\sqrt{\alpha(t-\tau)}}\right)\right)\right] \quad (68.4)$$

Where:
$\dot{q}''$ = incident thermal radiation (W/m^2)
t = time (sec)
x = depth below surface (m)
T = temperature at time t, and distance x below the skin surface (K)
T_o = initial skin temperature (K)
α = k/ρc = thermal diffusivity (m^2/s)
c = specific heat (J/kg-K)
k = thermal conductivity (W/m-K)
ρ = density (kg/m^3)
τ = exposure time (sec)

"Assuming constant heat flow and initial isothermal conditions, Equation 68.4 has two parts: First during the heating phase t ≤ τ the first two terms are real and the third term is imaginary. Second during the cooling phase t > τ all three terms are real. As time approaches infinity T approaches T_o. The third term is a Laplace solution for a negative $\dot{q}''$ input in the interval τ < t ≤ infinity so that the effective heat input is zero." [28]

Equations 68.3 and 68.4 are equivalent. Using the following relationships between the error function (erf), complimentary error function (erfc) and the integral of the complimentary error function (ierfc), Equation 68.3 can be transformed into Equation 68.4. Similarly, Equation 68.1 is equivalent to the first two terms of Equation 68.4 if similar substitutions are made.

$$\begin{aligned} &\text{erfc}\ \beta = 1 - \text{erf}\ \beta \\ &\text{and} \\ &\text{ierfc}\ \beta = \frac{1}{\sqrt{\pi}}e^{-\beta^2} - \beta\ \text{erfc}\ \beta \end{aligned} \quad (68.5)$$

The final algorithm, Equation 68.6, developed to model the temperature-time history of the skin assumes that the temperature profile in the semi-infinite slab is linear with a slope equal to the slope of the actual temperature profile at the surface [27]. Also, the model only predicts the temperature at the skin surface and not at a depth below the surface.

$$T(t_2) = T_0 + [T(t_1) - T_0]\sqrt{\frac{t_1}{t_2}} + \frac{\left[\dot{q}''(t_2) + \dot{q}''(t_1)\right](t_2 - t_1)}{2\sqrt{k\rho c\, t_2/\pi}} \quad (68.6)$$

Where:
$\dot{q}''(t_2)$ = incident thermal radiation at the current time step (W/m^2)
$\dot{q}''(t_1)$ = incident thermal radiation at the previous time step (kW/m^2)
t_1 = previous time (sec)

t_2 = current time (sec)
$T(t_1)$ = surface temperature at previous time step (K)
$T(t_2)$ = surface temperature at current time step (K)
T_o = initial skin temperature (K)
α = thermal diffusivity (m^2/s)
c = specific heat of skin (J/kg-K)
k = thermal conductivity of the skin (W/m-K)
ρ = density of skin (kg/m^3)

Thermal properties for the skin are required to solve the algorithms. Values for skin properties, although similar, vary from source to source. Table 68.10 contains the recommended values for the required properties.

The thermal conductivity was found to vary with temperature and whether or not the skin is being heated or cooled. It was determined that a constant value for the thermal conductivity during heating provided satisfactory results as compared to experimental data. During the cooling period however, the same constant value did not provide a satisfactory representation. To achieve a good fit to the experimental data, the thermal conductivity during cooling was stepped down by increments of -4.186×10^{-6} W/m-K at each time step [28]. For the purpose of this chapter it was determined that taking an average of these values provided an acceptable fit to the data. Figure 68.3 shows the experimental temperature-time history at a skin depth of 80 μm, the basal layer, for a heat flux of 15.7 kW/m^2 and an exposure time of 5.55 s. Superficial second-degree burns are obtained under these conditions. Also included in Fig. 68.3 are the histories predicted by Equations 68.4 and 68.6. The values indicated in Table 68.10 were used for the thermal properties of the skin, constant values for the thermal conductivity of 0.5878 and 0.4518 W/m-K were used for the heating and cooling phases respectively (Fig. 68.3).

An excellent correlation, for the basal layer temperature, between the experimental and theoretical values predicted by Equation 68.4 can be seen. Due to the level of agreement between Equation 68.4 and the experimental data at the basal layer, Equation 68.4 was used to predict the temperature of the skin at the skin surface.

The values predicted by Equation 68.6 are at a maximum 40 % greater than the surface temperatures predicted using Equation 68.4. The peak surface temperature is 74.4 °C. Instantaneous death to the skin occurs at a basal layer

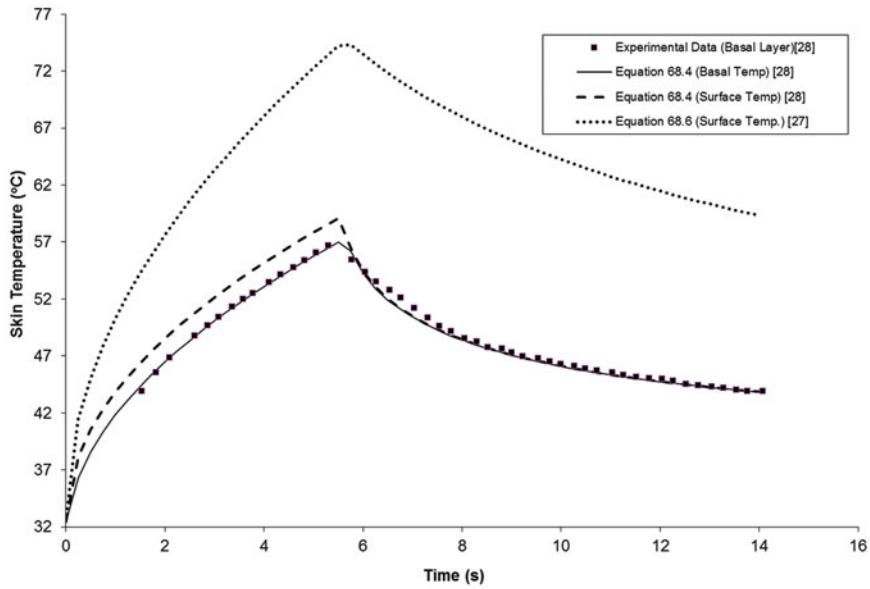

Fig. 68.3 Temperature-time history for the skin at the surface and basal layer caused by a thermal irradiance of 15.7 kW/m^2 for a duration of 5.55 s

temperature of 72 °C [1]. A surface temperature peak of 74.4 °C will produce burns significantly greater than superficial second-degree. It is not recommended that Equation 68.6 be used to model the skin temperature.

The rate at which epidermal injury occurs can be "modeled as a rate process governed by an activation energy and pre-exponential constant:", [31, 32]

$$\frac{d\Omega}{dt} = P \exp\left(\frac{-\Delta E}{RT}\right) \tag{68.7}$$

Where:

dΩ/dt = rate at which Ω, an arbitrary function of the epidermal injury as determined by histologic examination, is produced

T = basal epidermal layer temperature (K)

R = universal gas constant (8314 J/kmol-K)

P = pre-exponential term determined from experimental data (1/s)

ΔE = activation energy determined from experimental data (J/kmol)

By integrating Equation 68.7,

$$\Omega = \int_0^t P \exp\left(\frac{-\Delta E}{RT}\right) dt \tag{68.8}$$

the cumulative damage to the skin is determined. The severity of the burn injury is determined based on the quantitative values of the injury parameter Ω shown in Table 68.11.

The pre-exponential term and activation energy were originally determined to be 3.1×10^{98} 1/s and 6.28×10^{8} J/kmol respectively [32]. Later, application of the damage integral to include the cooling period lead to new values for these terms [28, 31]. Also, new numerical methods and techniques lead to more accurate curve fits to the original data providing even further revision to the terms [31]. Table 68.12 contains the various values for the pre-exponential and activation energy and the temperature range for which each is appropriate.

Table 68.11 Injury parameter values [31]

Injury parameter (Ω) value	Level of injury
0.53	First degree burn
1.0	Superficial second-degree burn

The values listed in Table 68.12 for the activation energy and the pre-exponential constant vary by several orders of magnitude between the different models. These variations are attributed to the numerical methods used to determine the values from the original experimental data. A recent study indicated that the values determined by Henriques could not be duplicated [31]. It was also indicated that use of these models "outside of the range of times and temperatures for which the model coefficients are verified by correlation with experimental data are likely to issue in injury values of questionable value."[31]

Table 68.13 lists the values predicted by each set of parameters for first (Ω = 0.53) and superficial second-degree (Ω = 1) burns. For each of the thermal irradiances indicated the temperature-time histories at the basal layer were determined using Equation 68.4. The exposure time was varied until the desired values for Ω were achieved.

It can be seen that at the lower fluxes, less than 20 kW/m^2, predictions by Weaver and Stoll are lower than those by the other models for both 1st and superficial 2nd degree burns. At the higher fluxes all of the models predict approximately the same time to injury. These predictions are compared to the pain and superficial 2nd degree burn data which will be presented later, see Figs. 68.4 and 68.5. Although a first-degree burn is not equivalent to pain, as a consistency check, the predictions are included with the pain data, see Fig. 68.4. As can be seen, all of the model's predicted times to 1st degree injury are above that of time to pain. The time to pain (time at which the basal layer temperature reaches 44 °C) based on Equation 68.1 is also included in Fig. 68.4; the Equation 68.1 predictions fall between Equation 68.9 values and the Equation 68.11 (safety factor of 4) values. Finally, the predicted time to superficial 2nd degree injury lies in good agreement with the experimental data shown in Fig. 68.5.

Safety factors need to be incorporated into Equations 68.1, 68.4 and 68.8, for predicting

Table 68.12 Activation energy and frequency factors for different models [4, 31, 35]

Model	Temperature range °C	Activation energy, ΔE J/kmol	Pre-exponential, P 1/s
Weaver & Stoll	$44 \leq T \leq 50$	7.72×10^8	2.185×10^{124}
	$T > 50$	3.25×10^8	1.823×10^{51}
Fugitt	$44 \leq T \leq 55$	6.27×10^8	3.1×10^{98}
	$T > 55$	2.96×10^8	5.0×10^{45}
Takata	$44 \leq T \leq 50$	4.18×10^8	4.322×10^{64}
	$T > 50$	6.69×10^8	9.389×10^{104}
Wu	$44 \leq T \leq 53$	6.27×10^8	3.1×10^{98}
	$T > 53$	6.27×10^8–5.10×10^5 (T-53)	3.1×10^{98}
Henriques	All T	6.27×10^8	3.1×10^{98}
Diller and Klutke	$44 \leq T \leq 52$	6.04×10^8	1.3×10^{95}
Mehta and Wong	All T	4.61×10^8	1.43×10^{72}
Torvi & Dale	$44 \leq T \leq 50$	7.82×10^8	2.185×10^{124}
	$T > 50$	3.27×10^8	1.823×10^{51}

Table 68.13 Predicted time to first and superficial second-degree burns

Irradiance ($KW/m^{2)}$	Weaver & Stoll (sec)	Fugitt (sec)	Takata (sec)	Wu (sec)	Henriques (sec)	Diller & Klutke (sec)	Mehta & Wong (sec)
$\Omega = 0.53$

40	1.4	1.9	1.5	1.2	1.4	1.4	1.5
50	0.94	1.4	0.95	0.91	0.94	0.93	1.1

time to pain, time to superficial 2nd degree burns, and the degree of thermal injury. The recommended safety factor to be used with Equation 68.1, for predicting time to pain, is 2. By dividing the time to pain values from Equation 68.1, by the safety factor of 2, the predicted values will be consistent with those of Equation 68.11. No safety factor can be recommended for the prediction of 1st degree burns due to the lack of data for comparison. Superficial 2nd degree burns predicted using Equations 68.4 and 68.8 should be done using the pre-exponential and activation energy constants given by Weaver and Stoll. The recommended safety factor to be used, with these equations, is 1.6. Dividing the predicted times by 1.6 is consistent with the values predicted by Equation 68.14. (See Fig. 68.5.)

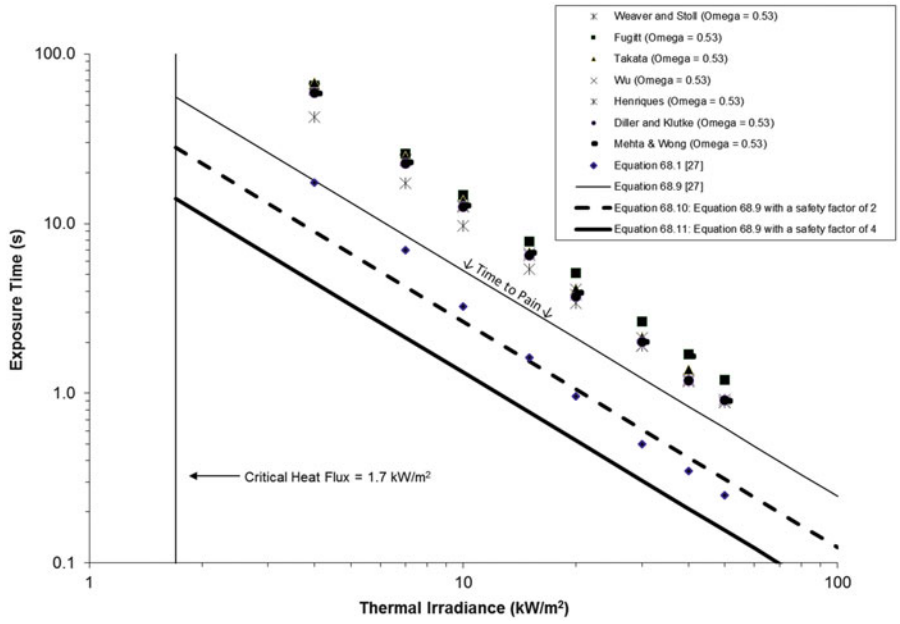

Fig. 68.4 Calculated exposure times to first-degree burns and pain on a plot of exposure time versus thermal irradiance

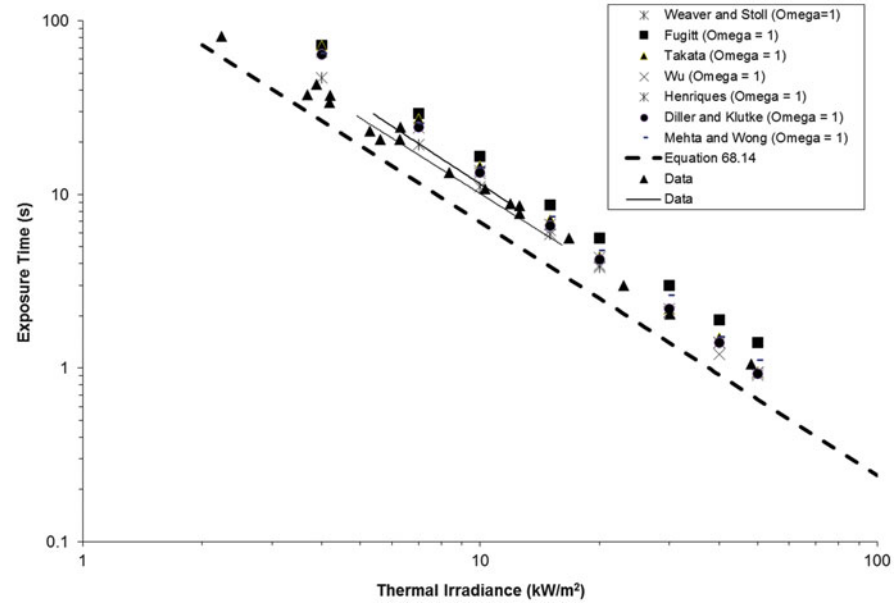

Fig. 68.5 Calculated exposure times to superficial second-degree burns on a plot of exposure time versus thermal irradiance. Values determined using the Henriques damage integral are compared to the data

The recommended safety factors need to be used in the proper manner depending on what calculation is being performed. Calculations in which the thermal irradiance is used to determine the time to injury, the resulting time is DIVIDED by the recommended safety factor. When calculating the degree of thermal injury (Ω value) using a thermal irradiance and an exposure time, the exposure time is MULTIPLIED by the recommended safety factor.

Using the damage integral to predict burn levels beyond superficial 2nd degree burns ($\Omega = 1$) should NOT be done. A recent paper stated "little difference in times to second-degree burn resulted from changing the values of the pre-exponential factor and activation energy for this range of heat fluxes [24–166.4 kW/m^2]."[30] Similar results were discussed above. "The effect of changing the values on third-degree burn predictions was much larger than with the second-degree burn times. As the times to third-degree burn are much longer, this would be expected. It is often difficult to distinguish between deep second degree, and third-degree burns. Therefore, it would be difficult to get accurate values for the pre-exponential factor and activation energy in third-degree burn experiments than in first and second-degree burn experiments."[30]

Another method developed for determining the amount of thermal damage to the skin is the "critical energy model." "The critical energy model states that the severity of the burn depends upon the amount of energy that is absorbed by the skin after the surface temperature reaches 55 °C. If the amount of excess energy is 41.9 kJ/m^2, pain or mild second-degree burns will be experienced. For an additional exposure of more than 83.8 kJ/m^2, a blister or severe second-degree burn will become evident. Finally, for an exposure of greater than 162.5 kJ/m^2, severe third-degree burns will result in permanent injury."[27] This model "was based on no physical reasoning whatsoever, and as such was completely empirical; moreover, only one burn level, namely, 2° mild burn was correlated."[4] Due to the limited applications and verification, this method is NOT recommended.

Comparison to More Complex Models

A brief discussion on the validity and prediction accuracy of the single layer model of the skin as compared with more complicated models needs to be included. Several large assumptions are made in the above equations and therefore incorporated into the later simplified equations. As stated previously the skin is a complicated structure. Both single layer, constant property models, such as Equations 68.1, 68.4 and 68.8, and more complex multiple layer, variable property finite element models have been developed. A sensitivity study using a finite element model indicated that variations in skin properties had minimal effects on the time to superficial 2nd degree burns [30]. Comparisons between the single layer and the multiple layer models for predicting times to 2nd degree burns for low intensity continuous exposures and high intensity short duration exposures (3 s) were also made. For continuous low intensity exposures the single layer model predicted times slightly higher than the multiple layer model, better agreement between the two was seen at higher irradiance levels, about 42 kW/m^2 [30]. Results between the models for predicting superficial 2nd degree burns from flash fires, i.e., high intensity short duration exposures showed that both the single layer model and the multiple layer model predicted the same times to 2nd degree burns [30]. Agreement between the predicted times to second degree burns between the single layer model and multiple layer model is expected since superficial 2nd degree burns only involve a single layer of the skin, the epidermis. Blood perfusion can be ignored since the epidermis contains no blood vessels; in addition it has been shown that it takes about 20 s for the skin to react by increasing the blood flow [30]. Most damage to the skin occurs before the increase in blood flow occurs [30].

Prediction of Skin Burns: Empirical Equations and Graphical Methods

Equation 68.9 is a correlation between the incident thermal radiation and the time to pain [27].

$$t_p = \left(\frac{35{,}000}{\dot{q}''}\right)^{1.33} \tag{68.9}$$

Where:
t_p = time required for pain (sec)
$\dot{q}''$ = incident thermal radiation (W/m^2)

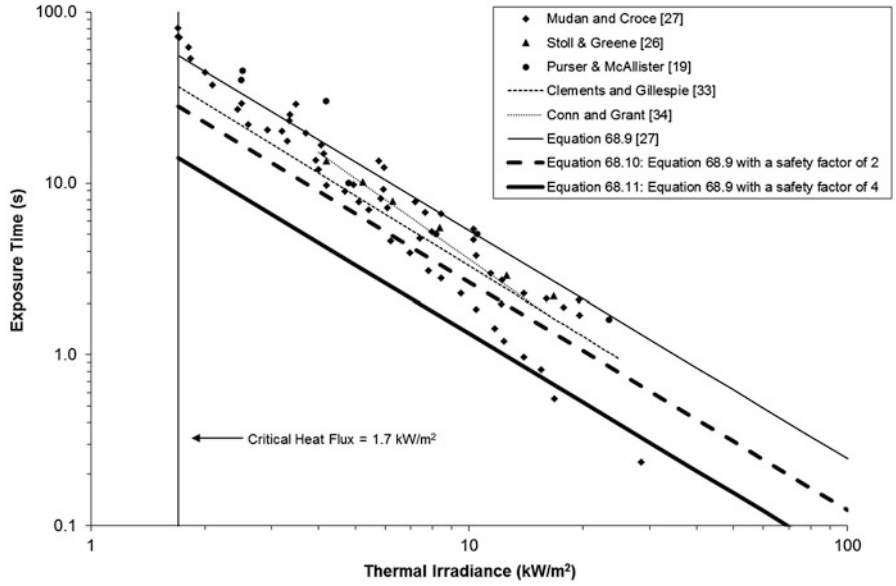

Fig. 68.6 Time for pain on a plot of exposure time versus Thermal irradiance. Individual data are shown as points and curve fits to data are thin lines

Figure 68.6 shows the time to pain on a plot of exposure time verses thermal irradiation [19, 26, 27, 33, 34]. The data were compiled from a variety of sources and includes both "prickling" and "threshold" pain [27]. The data are shown as individual data points in addition to exposure time verses irradiance curves, indicated as thin lines.

In one study, no pain was experienced by any test subject below an incident heat flux of 1.7 kW/m^2, no matter what the time duration [27]. This is considered the critical heat flux required to cause pain. From Fig. 68.6 it is also seen that Equation 68.9 predicts the time to pain well at the lower fluxes and over predicts the time at higher heat fluxes. A conservative approach would be to use a safety factor of 2; i.e., divide the predicted time by 2. As can be seen a larger percentage of data is encompassed with the second curve. The equation still over predicts the time to pain for some data at heat fluxes greater than 6000 W/m^2. A larger factor of safety, factor of 4, should be used for heat fluxes greater than 6000 W/m^2. The final recommended equations are,

$$t_p = \frac{1}{2}\left(\frac{35{,}000}{\dot{q}''}\right)^{1.33} \qquad \dot{q}'' \le 6{,}000 \text{ W/m}^2 \tag{68.10}$$

and

$$t_p = \frac{1}{4}\left(\frac{35{,}000}{\dot{q}''}\right)^{1.33} \qquad \dot{q}'' > 6{,}000 \text{ W/m}^2 \tag{68.11}$$

If the initial skin temperature is not between 32.5 °C and 33 °C then the exposure time for pain can be "corrected" for the initial temperature variation using [26].

$$t_{P2} = t_{P1}\left(\frac{44 - T_{02}}{44 - T_{01}}\right)^2 \tag{68.12}$$

Where:

t_{P1} = exposure time to pain at initial skin temperature T_{01}

t_{P2} = exposure time to pain at initial skin temperature of the given case T_{02}

T_{01} = initial skin temperature as given for chart (32.5 °C or 33 °C)

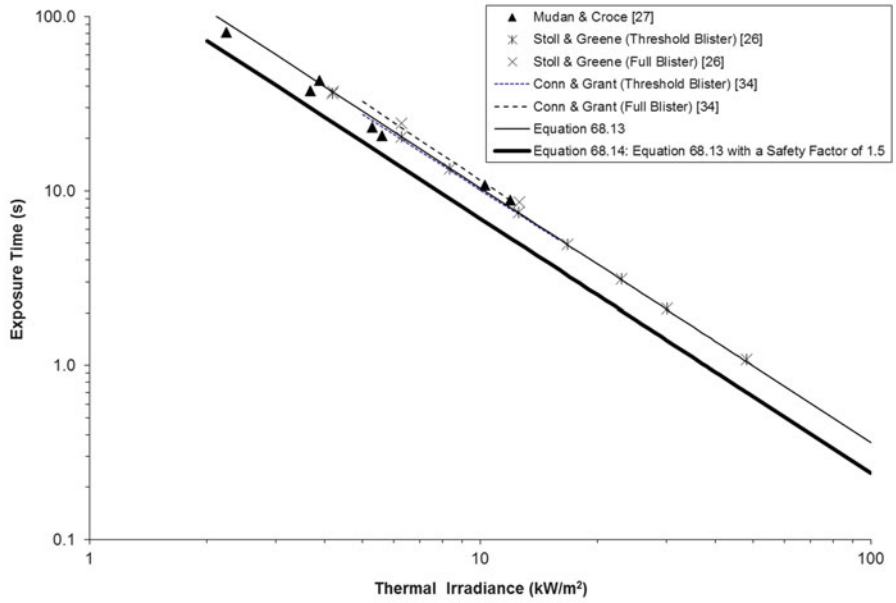

Fig. 68.7 Time for superficial second-degree burn on a plot of exposure time versus thermal irradiance. Individual data are shown as points and curve fits to data are thin lines

T_{02} = initial skin temperature for the given case (°C)

A blister is the separation of the epidermis from the dermis. The base of a blister forms at the basal layer, approximately 80 μm below the surface of the skin.[5] Figure 68.7 shows the time to blister (superficial 2nd degree burn) on a plot of exposure time verses thermal irradiance [26, 27, 34]. The experimental data are shown as provided in literature, either as individual data points or as exposure time versus thermal irradiance curves indicated as thin lines. All of the data are in excellent agreement. "Threshold" blister data and "Full" blister data are both included in the figure, as can be seen there is an insignificant difference between the two.

Equation 68.13 is a curve fit to the data.

$$t_B = 300\left(\frac{\dot{q}''}{1{,}000}\right)^{-1.46} \tag{68.13}$$

Where:

t_B = time to blister (sec)

$\dot{q}''$ = incident thermal radiation (W/m^2)

Equation 68.13 provides a good estimation of all the data shown. Using a safety factor of 1.5, which encompass all of the experimental data, Equation 68.13 becomes:

$$t_B = 200\left(\frac{\dot{q}''}{1{,}000}\right)^{-1.46} \tag{68.14}$$

It is recommended that Equation 68.14 be used to predict the time to blister.

Data beyond full blisters is almost nonexistent. Figure 68.8 was developed based on "the relation between thermal radiation intensity and burn injury for nuclear explosions at different yields."[27] The figure includes the significant injury, 1 %, 50 %, and 100 % fatality curves. Also, included in the figure are data by Mixter [36]. Mixter's data are for second-degree burns caused by a carbon arc source. Data of this nature was not included in the other figures since the carbon arc source is of a shorter wavelength than the radiation hazards addressed in this chapter. In all instances however, the carbon arc searchlights produced time to pain and time to blister results that exceeded the values obtained with the infrared radiation.

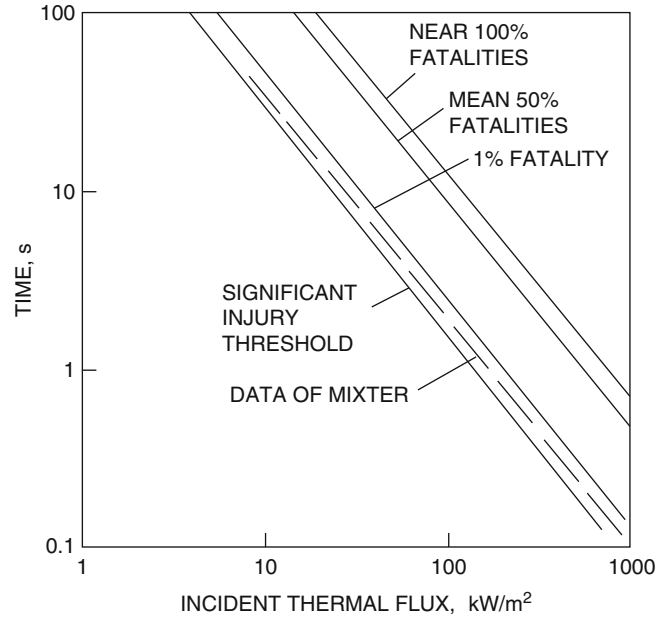

Fig. 68.8 Time required for 1 %, 50 %, and 100 % fatalities due to exposure to thermal radiation

New Simplified Methods

The use of either Equation 68.1 for determining the time to pain; or the use of Equation 68.4 and Equation 68.8 for determining the time to superficial 2nd degree burns although not difficult requires the use of a simple computer code or spreadsheet to do the calculations in an efficient manner. In an effort to simplify the calculations, two correlations, one for time to pain, Equation 68.15, and another for time to superficial 2nd degree burns, Equation 68.16, were developed. The units for time to pain, t_p, and time to superficial 2nd degree burns, t_{2b}, are seconds. The units for the incident thermal radiant heat flux, $\dot{q}''$, are kW/m^2.

$$t_p = 125\ (\dot{q}'')^{-1.9} \tag{68.15}$$

$$t_{2b} = 260(\dot{q}'')^{-1.56} \tag{68.16}$$

Equation 68.15 was developed by calculating the time to pain at the reference state properties of the skin, Table 68.10, using Equation 68.1 for incident thermal radiation levels between 1.7 kW/m^2 and 20 kW/m^2. The form of Equation 68.15 shown was specifically developed for levels of 1.7 kW/m^2 to 10 kW/m^2 and confirmed for levels of 10 kW/m^2 to 20 kW/m^2. This range of irradiances corresponds to the levels Equation 68.1 was calibrated for within this chapter. The lower thermal irradiance of 1.7 kW/m^2 is the critical heat flux, below which no pain is experienced no matter how long the duration of the exposure [9]. Equation 68.16 was developed by solving Equations 68.4 and 68.8 at the reference state properties of the skin, Table 68.10, to calculate the time to superficial 2nd degree burns for incident thermal radiation levels between 2 kW/m^2 and 50 kW/m^2. The range of values chosen in developing Equation 68.16 was selected based on the range of irradiance levels for which Equations 68.4 and 68.8 were calibrated for within this chapter.

Equations 68.15 and 68.16 are based on the reference state properties for the skin listed in Table 68.10 and are only functions of the incident thermal radiation. Neither equation takes into account any human variation in skin temperature or skin thickness. The reference state values may provide erroneous results depending on the target population for which the

calculations are being performed. Variations in these properties among different individuals and at different sites of the body exist. These variations can be accounted for by use of appropriate correction factors with Equations 68.15 and 68.16.

Equations similar to the new simplified equations presented here have been developed in the United Kingdom based on dose-response criteria [24]. The thermal dose is defined as $\dot{q}''^{4/3}t$, where the units of $\dot{q}''$ are kW/m^2 and the units of t are seconds. Pain results when the dose reaches 92 (kW/m^2)$^{4/3}$ s and a superficial 2nd degree burn results when the dose reaches the range of 210–700 (kW/m^2)$^{4/3}$ s. The thermal dose equations can be arranged to take the form $t = A(\dot{q}'')^{-4/3}$ where A is a constant. For pain the constant is 92 while for superficial 2nd degree burns the constant ranges between 210 and 700. Mudan and Croce have also used the above form of the thermal dose equation to predict time to pain; their recommended value for the constant A is 113 (kW/m^2)$^{4/3}$ s [27]. None of the equations incorporate safety factors. Therefore for comparative purposes if the safety factors are removed from Equations 68.15 and 68.16, they become:

$$t_p = 250\ (\dot{q}'')^{-1.9}. \tag{68.15a}$$

$$t_{2b} = 416\ (\dot{q}'')^{-1.56}. \tag{68.16a}$$

For a heat flux range of 4–18 kW/m^2 (which is the range used to develop the thermal dose equation), Equation 68.15a and $t_p = 92\ (\dot{q}'')^{-4/3}$ differ in magnitude on average by 1.2 s, while the deviation in magnitude in predicted times of 1.4 s is seen if the coefficient is 113, as recommended by Modan and Croce [27] Equation 68.16a and $t_{2b} = 210\,(\dot{q}'')^{-4/3}$ over the heat flux range of 14–50 kW/m^2 differ in magnitude by less than 1 s. For heat fluxes between 2 and 14 kW/m^2 Equation 68.16a gives times to superficial 2nd degree burns greater than $t_{2b} = 210\,(\dot{q}'')^{-4/3}$ but well less than $t_{2b} = 700(\dot{q}'')^{-4/3}$. Equations 68.15a and 68.16a then are very consistent with the thermal dose equations. Based on the discussion within this chapter it is believed that safety factors should be incorporated into the calculated times to pain and superficial 2nd degree burns, therefore further discussion within this chapter will be based on Equations 68.15 and 68.16 which incorporate the necessary safety factors.

Human Variability Correction Factors

The data presented in the previous sections clearly indicates that the reference state values for the initial skin temperature and epidermal thickness may not be valid in every situation. To use the simplified methods of Equations 68.15 and 68.16 correction factors are needed to account for variations in properties of human skin. The data presented previously allows a range of values for the initial skin temperature and epidermal thickness to be defined for a diverse population, see Table 68.14. The temperature values were selected based on typical values listed in the tables above. Although cooler skin temperatures are listed in the tables a minimum value of 27 °C was selected since the cooler temperatures are for very limited cases. The typical values for the epidermal thickness were taken as the minimum and maximum values listed in the literature. The minimum value is the published value for the abdomen and thorax, and the maximum value is that for the palm.

There are no data, known to the authors, that define the variation of pain receptor depth with age or body site location, therefore the pain receptor depth will be assumed to be fixed as defined by the reference state.

The effect of the initial skin temperature on the time to pain was studied using Equation 68.1 and varying the initial skin temperature between the values listed in Table 68.14. The results from the parametric study are shown in Fig. 68.9.

Table 68.14 Range of values for skin temperature and epidermal thickness for a diverse population

Property	Minimum value	Maximum value
Skin temperature	27 °C	38 °C
Epidermal thickness	16 μm	430 μm

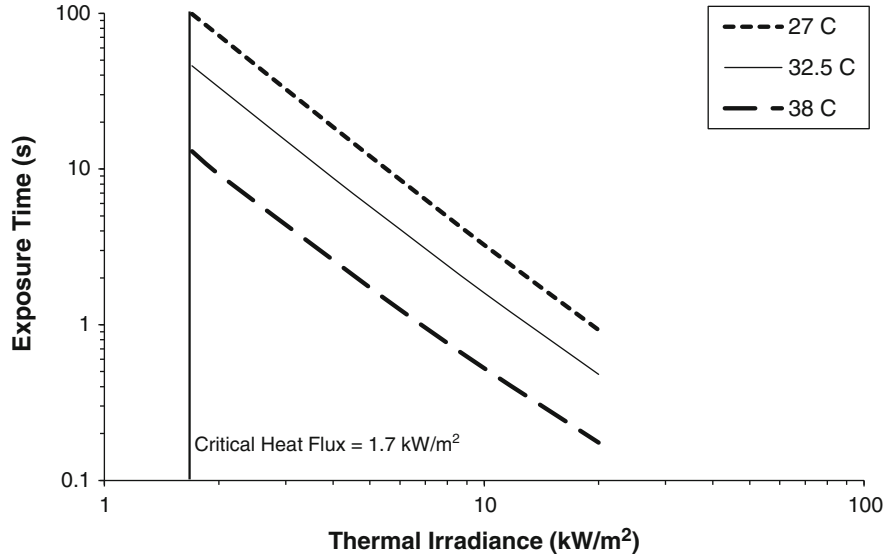

Fig. 68.9 Time to pain (exposure time) versus incident thermal radiation for the reference state initial skin temperature (32.5 °C) in comparison to initial skin temperatures of 27 °C and 38 °C. The temperature range represents a diverse population, see Table 68.14

The initial skin temperature has a significant effect on the time to pain. As the initial skin temperature is decreased there is an increase in the time to pain, while for elevated initial skin temperatures the time to pain decreases. For example, for irradiance levels of 1.7, 10, and 20 kW/m^2 the times to pain at the reference state are 46, 1.6, and 0.48 s respectively. At an elevated skin temperature of 38 °C the times to pain for the three irradiance levels respectively decreases to 13, 0.52, and 0.18 s, while at a lower skin temperature of 27 °C the times increase to 99, 3.3, and 0.18 s.

A correction factor, CF_p, for use with Equation 68.15 to account for the variation in initial skin temperature based on the results shown in Fig. 68.9 is,

$$CF_p = 3.7\ \beta^2 - 12.2\ \beta + 9.5 \qquad (68.17)$$

Where β is $T_{act}/32.5$, T_{act} is the actual initial skin temperature in °C and $0.83 < \beta < 1.17$. The time to pain calculated from Equation 68.15 is multiplied by the correction factor to account for variation in initial skin temperature from the reference state.

Equation 68.17 is similar to a correction factor that can be developed based on the work of Stoll and Greene [26]: $CF_{Stoll} = (3.8 - 2.8\beta)^2$. For initial skin temperatures above 32.5 °C Equation 68.17 is on average 6.4 % higher. For skin temperatures lower than 32.5 °C Equation 68.17 is 7.8 % lower on average.

For determining superficial 2nd degree burns variation in two skin properties, initial temperature and epidermal thickness, must be examined. Examining the effect of initial skin temperature using Equations 68.4 and 68.8 it is seen that the variation in the initial skin temperature has a similar effect on the time to 2nd degree burns as previously discussed for pain, see Fig. 68.10. The times to superficial 2nd degree burns for irradiance levels of 2, 10, and 50 kW/m^2 are 95, 6.9, and 0.6 s respectively for the reference state. If the initial skin temperature is decreased to 27 °C then the times to 2nd degree burns for the same irradiance levels increase to 158, 10, and 0.8 s respectively. Conversely, as the skin temperature is increased to 38 °C the times to 2nd degree burns decrease to 48, 4.3, and 0.42 s for irradiance levels of 2, 10, and 50 kW/m^2 respectively.

The time to superficial 2nd degree burns based on the reference state, calculated using

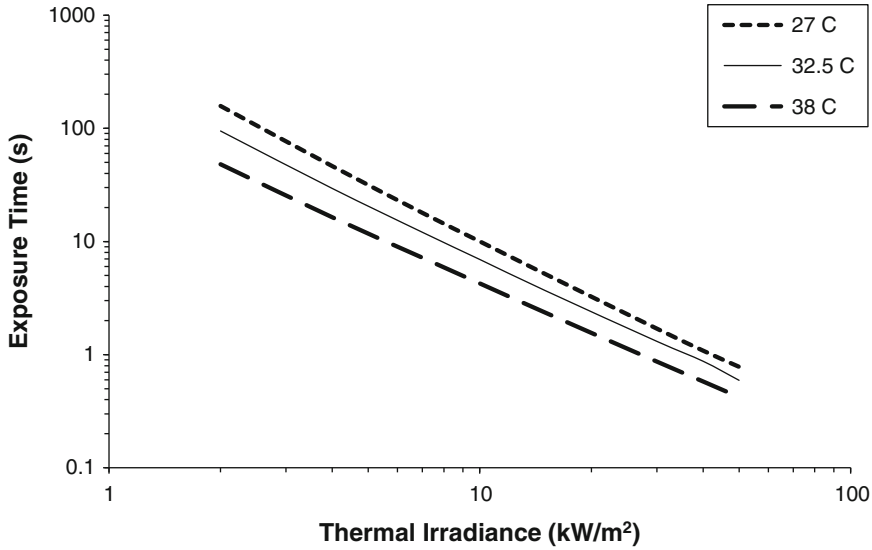

Fig. 68.10 Time to superficial 2nd degree burn (exposure time) versus incident thermal radiation for the reference state initial skin temperature (32.5 °C) in comparison to initial skin temperatures of 27 °C and 38 °C. The temperature range represents a diverse population, see Table 68.14

Equation 68.16, can be adjusted for variation in initial skin temperatures by multiplying the calculated time by the correction factor, CF_T, determined using Equation 68.18, where $0.83 < \beta < 1.17$,

$$CF_T = -4.4\ \beta^2 + 6.6\beta - 1.2 \qquad (68.18)$$

The second parameter that affects the time to superficial 2nd degree burns is the epidermal thickness (basal layer depth). The effect as calculated from Equations 68.4 and 68.8 of variation in thickness between the minimum and maximum values listed in Table 68.14 and the reference state depth is shown in Fig. 68.11. The time to superficial 2nd degree burns for the reference state were listed above as 95, 6.9, and 0.6 s for irradiance levels of 2, 10, and 50 kW/m^2 respectively. If the only variable to change is the basal layer depth the times to 2nd degree burns increase to 103, 9.0, and 1.2 s for a basal layer depth of 430 μm and decrease to 93, 6.4, and 0.48 s for a basal layer thickness of 16 μm. As can be seen, at lower incident radiation levels the epidermal thickness does not have as large effect on the time to superficial 2nd degree burns, as the radiation levels increase the effect of the basal layer depth increases.

The time to 2nd degree burns based on the reference state, calculated using Equation 68.16, can be adjusted for variation in epidermal thickness by multiply the calculated time by the correction factor, CF_d, determined using Equation 68.19,

$$CF_d = 0.000020\ (\dot{q}'')^2\ (1-\gamma) + 0.0060\ \dot{q}''\ (\gamma - 1) + 0.013\gamma + 0.99 \qquad (68.19)$$

Where γ is $x_{act}/80$, x_{act} is the actual epidermal thickness in μm and $0.20 < \gamma < 5.38$. The incident thermal radiation, $\dot{q}''$, in Equation 68.19 has units of kW/m^2. For time to superficial 2nd degree burn calculation using Equation 68.16, if both the initial skin temperature and epidermal thickness are different from the reference state then both correction factors need to be calculated, using Equations 68.18 and 68.19, and multiplied by the time from Equation 68.16.

A comparison between the predicted times to pain and superficial 2nd degree burns using Equations 68.1, 68.4, and 68.8, and the corresponding simplified equations with the correction factors was undertaken. The comparison for time to pain was conducted at heat fluxes of 1.7 kW/m^2, 10 kW/m^2 and 20 kW/m^2 for three

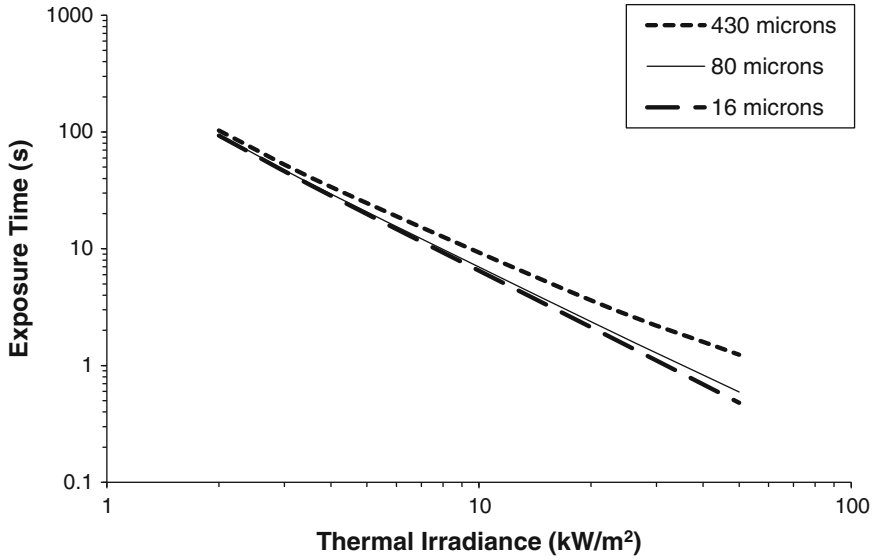

Fig. 68.11 Time to superficial 2nd degree burn (exposure time) versus incident thermal radiation for the reference state epidermal thickness (80 μm) in comparison to epidermal thickness of 16 to 430 μm. The thickness range represents a diverse population, see Table 68.14

values of $\beta = 0.83, 1, 1.17$ resulting in 9 points of comparison. For superficial 2nd degree burns the comparison was conducted at heat fluxes of 2 kW/m^2, 10 kW/m^2 and 50 kW/m^2 for three values of $\beta = 0.83$, 1, 1.17, and for three values of $\gamma = 0.20, 1, 5.38$ resulting in 27 points of comparison. The ranges of values for $0.83 < \beta < 1.17$ and $0.20 < \gamma < 5.38$ are based on the limit values for the skin temperature and epidermal thickness, Table 68.14, used to develop the correction factors CF_p, CF_T and CF_d. The range of heat fluxes covers the range used to develop the simplified equations.

The magnitude of the difference between Equation 68.1 and the simplified equations for the times to pain at 20 kW/m^2 is on average 0.08 s with a standard deviation (SD) of 0.04 s. At 10 kW/m^2 the average is 0.1 s with a SD of 0.1 s. At 1.7 kW/m^2 the difference for $\beta = 1$ and 1.17 is less than 0.5 s, and for $\beta = 0.83$ it is 11.8 s or 12 %. The magnitude of the difference between Equations 68.4 and 68.8 and the simplified equations for the times to superficial 2nd degree burns at 50 kW/m^2 is on average 0.1 s with a SD of 0.1 s. At 10 kW/m^2 the average is 0.7 s with a SD of 0.3 s. At 2 kW/m^2 the difference for $\beta = 1$ and 1.17 (all γ) is on average 5 s with a SD of 2 s, and for $\beta = 0.83$ (all γ) is on average 46 s or 29 %. For all the 1.7 kW/m^2 and 2 kW/m^2 cases the simplified equations for pain and superficial 2nd degree burns predict shorter times than do Equations 68.1, 68.4 and 68.8, respectively.

The range of values for the skin temperature and epidermal thickness listed in Table 68.14, $0.83 < \beta < 1.17$ and $0.20 < \gamma < 5.38$ respectively were then used to determine the minimum and maximum values for the correction factors shown in Table 68.15. Since the correction factor for skin thickness is a function of non-dimensional depth and the irradiance level, three irradiance values are shown.

The non-dimensional temperature coefficient, β, represents a variation from the reference state temperature of 32.5 °C. For the minimum and maximum temperatures listed in Table 68.14 there is a ±17 % deviation from the reference state, see Table 68.15. The equal negative and positive change in temperature does not produce an equal effect on the time to pain and superficial 2nd degree burns. A 17 % decrease in the initial skin temperature produces a 92 % increase in the time to pain and a 25 % increase in the time to superficial 2nd degree burns, and a 17 % increase in skin temperature

Table 68.15 Range of values for correction factors for pain and superficial 2nd degree burns based on initial skin temperature and epidermal thickness ranges shown in Table 68.14

Correction factor	$\beta = 0.83$	$\beta = 1.17$	$\gamma = 0.20$	$\gamma = 5.38$
Pain				
CF_p	1.92	0.29	–	–
2nd degree burns				
CF_T	1.25	0.50	–	–
CF_d ($\dot{q}'' = 2$ kW/m^2)	–	–	0.98	1.11
CF_d ($\dot{q}'' = 10$ kW/m^2)	–	–	0.95	1.31
CF_d ($\dot{q}'' = 50$ kW/m^2)	–	–	0.76	2.35

Initial skin temperature and epidermal thickness are represented via the non-dimensional parameters β and γ respectively

produces a 71 % decrease in the time pain and a 50 % decrease in the time to superficial 2nd degree burns, see Table 68.15.

The effect of a 1 °C change in the initial skin temperature on the time to pain and superficial 2nd degree burns can be examined as well. For a 1 °C (3 %) decrease in the skin temperature there is a 15 % and 6.4 % increase in the time to pain and superficial 2nd degree burns respectively. A 1 °C (3 %) increase in skin temperature produces a 14 % decrease in the time to pain and 7 % decrease in the time to 2nd degree burns.

The deviation in the basal layer depth from the reference state is represented by γ. The minimum epidermal thickness of 16 μm is an 80 % decrease from the reference state thickness of 80 μm and the maximum skin thickness of 430 μm is a 438 % increase, see Table 68.14 and Table 68.15. These large changes in epidermal thickness have a smaller effect on the time to superficial 2nd degree burns for low irradiance levels. For example an irradiance level of 2 kW/m^2 results in a 2 % difference between the calculated reference state burn time and the 16 μm burn time, and a 11 % difference between the reference state and the 430 μm burn time. As the irradiance level increases to 10 kW/m^2 a 5 % difference results between the calculated reference state burn time and the 16 μm burn time, and a 31 % difference results between the reference state and the 430 μm burn time. As the irradiance level increases further, up to 50 kW/m^2, the deviation from the time calculated at the reference state changes by 24 % and 135 % for the 16 μm and 430 μm states respectively, see Table 68.15.

Examples

Sample problems for three thermal irradiances will be shown and solved using the discussed methods. Values of 4 kW/m^2, 10 kW/m^2 and 20 kW/m^2 are assumed to have been determined based on previous methods [37]. The values were chosen to represent the lower limit for pain and skin damage, 4 kW/m^2, a typical value for wood based ignition, 10 kW/m^2, and a typical value for flashover, 20 kW/m^2.

Example 1 An individual is exposed to an incident heat flux of 4 kW/m^2 for a duration of 30 s. At what time will pain be experienced assuming an initial skin temperature of 1.) 32.5 °C 2.) 30 °C and 3.) 34 °C? What degree of damage will occur?

Since the thermal irradiation is less than 6 kW/m^2, Equation 68.10 is used to predict the time to pain. For case 1, an initial skin temperature of 32.5 °C, the time to pain is:

$$t_p = \frac{1}{2}\left(\frac{35{,}000}{\dot{q}''}\right)^{1.33}$$

$$t_p = \frac{1}{2}\left(\frac{35{,}000}{4{,}000}\right)^{1.33}$$

$$t_p = 9.0 \text{ sec}$$

For case 2 and 3, Equation 68.12 is used to "correct" the time for the variation in initial skin temperature. The time to pain for case 2 then becomes:

$$t_{P2} = t_{P1}\left(\frac{44 - T_{02}}{44 - T_{01}}\right)^2$$
$$t_{P2} = 9.0 \cdot \left(\frac{44 - 30}{44 - 32.5}\right)^2$$
$$t_{P2} = 13.3 \text{ sec}$$

and for case 3, the time to pain is,

$$t_{P2} = t_{P1}\left(\frac{44 - T_{02}}{44 - T_{01}}\right)^2$$
$$t_{P2} = 9.0 \cdot \left(\frac{44 - 34}{44 - 32.5}\right)^2$$
$$t_{P2} = 6.8 \text{ sec}.$$

Equation 68.1 is also be used to determine the time to pain.

$$T = T_0 + \frac{\dot{q}''}{k_h}\left[\frac{2\sqrt{\alpha_h t}}{\sqrt{\pi}}\exp\left(-\frac{x^2}{2\alpha_h t}\right) - x\,erfc\left(\frac{x}{2\sqrt{\alpha_h t}}\right)\right]$$

The values for the skin properties found in Table 68.10 are used. Since Equation 68.1 only takes into account the heating phase the thermal conductivity for heating is used. Equation 68.1 is solved by using a spreadsheet or simple computer code to calculate the skin temperature over time.

Case 1: Initial skin temperature of 32.5 °C

Step 1: Set the initial parameters.

Initial skin temperature, T_0:	305.5 K
Depth below surface, x:	8.00E-05 m
Effective radiation, $\dot{q}''$:	4000 W/m^2
Volumetric heat capacity, ρc:	4,186,800 J/m^3-K
Thermal conductivity during heating, k_h:	0.5878 W/m-K
Thermal diffusivity during heating, α_h:	1.40 E-7 m^2/s

Step 2: Set time interval for the calculations.

To obtain an appropriate resolution it is recommended that 0.1-s be used.

Step 3: Solve Equation 68.1 at each time interval until the skin temperature is 44 °C.

Step 4: Incorporate the recommended safety factor of 2. Since an irradiance is used to determine a time, the time is DIVIDED by the safety factor.

$$t_p = \frac{t}{Safety\ factor}$$
$$t_p = \frac{17.50}{2}$$
$$t_p = 8.8 \text{ sec}.$$

For case 2 and 3 the same procedure is used with the appropriate values for the initial skin temperature.

For case 2 the calculated time to pain is:

$$t_p = \frac{t}{Safety\ factor} = \frac{25.6}{2} = 12.8 \text{ sec},$$

and for case 3:

$$t_p = \frac{t}{Safety\ factor} = \frac{13.4}{2} = 6.7 \text{ sec}.$$

All of the methods for predicting the time to pain produce similar values.

Based on Equation 68.14 the time to blister is determined to be,

$$t_B = 200\left(\frac{\dot{q}''}{1{,}000}\right)^{-1.46}$$
$$t_B = 200 \cdot \left(\frac{4{,}000}{1{,}000}\right)^{-1.46}$$
$$t_B = 26.4 \text{ sec}.$$

Therefore, from the 30-s exposure a superficial 2nd degree burn is expected.

An alternative method for determining the degree of damage is to determine the temperature-time history of the skin and calculate the Henriques' damage function. This solution will require the use of a spreadsheet or simple computer program.

Step 1: Set the initial parameters. Use the values listed in Table 68.10 for skin properties.

Initial skin temperature, T_0:	305.5 K
Exposure time, τ:	30 s
Exposure time with safety factor of 1.6, τ:	$30 \cdot 1.6 = 48$ s
Depth below surface, x:	8.00E-05 m
Effective radiation, $\dot{q}''$:	4000 W/m^2
Volumetric heat capacity, ρc:	4,186,800 J/m^3-K
Thermal conductivity during heating, k_h:	0.5878 W/m-K
Thermal conductivity during cooling, k_c:	0.4518 W/m-K
Thermal diffusivity during heating, α_h:	1.40 E-7 m^2/s
Thermal diffusivity during cooling, α_c:	1.08 E-7 m^2/s

The recommended safety factor is MULTIPLIED by the exposure time, because the thermal irradiance and exposure time are used to determine the degree of thermal injury.

Step 2: Set time interval for the calculations.

To obtain an appropriate resolution it is recommended that for low thermal irradiances, $\dot{q}'' \leq 10$ kW/m^2, a 1-s time interval be used, and for thermal irradiances greater than 10 kW/m^2 a time interval of 0.25-s or less be used.

Since $\dot{q}'' = 4000$ W/m^2, 1-s time steps will be used.

Step 3: Calculate the skin temperature, T.

For the heating period, $t \leq \tau$, the first two terms of Equation 68.4 are used.

$$T = T_0 + \frac{\dot{q}''}{k_h}\left[\frac{2\sqrt{\alpha_h t}}{\sqrt{\pi}}\exp\left(-\frac{x^2}{4\alpha_h t}\right) - x\left(1 - erf\left(\frac{x}{2\sqrt{\alpha_h t}}\right)\right)\right]$$

During the cooling period, $t > \tau$, all three terms are used.

$$T = T_0 + \frac{\dot{q}''}{k_c}\left[\frac{2\sqrt{\alpha_c t}}{\sqrt{\pi}}\exp\left(-\frac{x^2}{4\alpha_c t}\right) - x\left(1 - erf\left(\frac{x}{2\sqrt{\alpha_c t}}\right)\right)\right] - \frac{\dot{q}''}{k_c}\left[\frac{2\sqrt{\alpha_c (t-\tau)}}{\sqrt{\pi}}\exp\left(-\frac{x^2}{4\alpha_c (t-\tau)}\right) - x\left(1 - erf\left(\frac{x}{2\sqrt{\alpha_c (t-\tau)}}\right)\right)\right]$$

It is important that the proper values for the thermal conductivity and thermal diffusivity be used during the heating and cooling periods.

Step 4: Set the pre-exponential constant and activation energy according to the skin temperature at each time interval, using the values of Weaver and Stoll.

If 44 °C $\leq$ T $\leq$ 50 °C,

$\Delta E = 7.78 \times 10^8$ J/kmol

$P = 2.185 \times 10^{124}$ 1/s

and if T > 50 °C,

$\Delta E = 3.25 \times 10^8$ J/kmol

$P = 1.823 \times 10^{51}$ 1/s.

Step 5: Since Equation 68.8 can not be solved directly, numerical techniques are required to solve for the damage function, Ω. First Equation 68.7,

$$\frac{d\Omega}{dt} = P\exp\left(\frac{-\Delta E}{RT}\right),$$

needs to be solved at each time interval. Then a numerical integration technique such as the trapezoidal rule needs to be used to integrate the function over time. The trapezoidal rule for this application is:

$$I_1 = \sum_{i=1}^{n-1} \frac{\left(\left(\frac{d\Omega}{dt}\right)_i + \left(\frac{d\Omega}{dt}\right)_{i+1}\right)}{2} (t_{i+1} - t_i) \tag{68.20}$$

Applying Equation 68.20 to all times for which T is greater than 44 °C, the value for the damage function is determined to be 1.13. Comparing the calculated result to the values for the damage function listed in Table 68.11 it is seen that a superficial 2nd degree burn will occur.

Example 2 An individual is exposed to an incident heat flux of 10 kW/m^2 for a duration of 10 s. If the initial skin temperature is 32.5 °C, at what time will pain be experienced and what degree of damage will occur?

Since the thermal irradiation is greater than 6 kW/m^2, Equation 68.11 is used to predict the time to pain.

$$\begin{aligned} t_p &= \frac{1}{4}\left(\frac{35{,}000}{\dot{q}''}\right)^{1.33} \\ t_p &= \frac{1}{4}\left(\frac{35{,}000}{10{,}000}\right)^{1.33} \\ t_p &= 1.3 \text{ sec} \end{aligned}$$

Applying the method discussed above for solving Equation 68.1, the time to pain is determined to be:

$$t_p = \frac{t}{Safety\ factor} = \frac{3.2}{2} = 1.6 \text{ sec}.$$

Both Equations 68.11 and 68.1 predict similar results.

Based on Equation 68.14 the time to blister is determined to be,

$$\begin{aligned} t_B &= 200\left(\frac{\dot{q}''}{1{,}000}\right)^{-1.46} \\ t_B &= 200 \cdot \left(\frac{10{,}000}{1{,}000}\right)^{-1.46} \\ t_B &= 6.9 \text{ sec}. \end{aligned}$$

The 10-s exposure will produce AT LEAST a superficial 2nd degree burn.

Following the same procedure described in the previous example, the damage integral is determined to be 7.7. This also indicates that AT LEAST a superficial 2nd degree burn will occur. It is important to understand that once Ω exceeds 1, the function has NO meaning relative to additional burn injury.

Example 3 An individual is exposed to an incident heat flux of 20 kW/m^2 for a duration of 5 s. At what time will pain be experienced and what degree of damage will occur, for an initial skin temperature of 32.5 °C?

Since the thermal irradiation is greater than 6 kW/m^2, Equation 68.11 is used to predict the time to pain.

$$\begin{aligned} t_p &= \frac{1}{4}\left(\frac{35{,}000}{\dot{q}''}\right)^{1.33} \\ t_p &= \frac{1}{4}\left(\frac{35{,}000}{20{,}000}\right)^{1.33} \\ t_p &= 0.5 \text{ sec}. \end{aligned}$$

Solving Equation 68.1 using the methodology discussed above, the time to pain is determined to be:

$$t_p = \frac{t}{Safety\ factor} = \frac{1.0}{2} = 0.5 \text{ sec}.$$

Again, the values determined using Equations 68.11 and 68.1 are comparable.

Based on Equation 68.14 the time to blister is determined to be,

$$\begin{aligned} t_B &= 200\left(\frac{\dot{q}''}{1{,}000}\right)^{-1.46} \\ t_B &= 200 \cdot \left(\frac{20{,}000}{1{,}000}\right)^{-1.46} \\ t_B &= 2.5 \text{ sec}. \end{aligned}$$

The 5-s exposure will produce AT LEAST a superficial 2nd degree burn.

Following the same procedure described in Example 1, the damage integral is determined to be 124.1 indicating AT LEAST a superficial 2nd degree burn. It is important to understand that once Ω exceeds 1, the function has NO meaning relative to additional burn injury.

Conclusions

Thermal damage to the skin is a function of skin temperature and the time duration for which the basal layer temperature is greater than 44 °C. Various models and techniques have been developed to predict the time and degree of damage due to a constant thermal irradiance. Methods for determining the time to pain, 1st degree burns and superficial 2nd degree burns have been evaluated and discussed with regards to appropriate applications and limitations.

A summary of the recommended techniques and equations for determining each condition follows:

Simple Algorithms

Simple algorithms which can be used to predict the degree of thermal damage, time to pain and superficial 2nd degree burns, exist but require the use of a spreadsheet or simple computer code to perform the calculations efficiently.

The time to pain is determined using Equation 68.1. The recommended safety factor of 2 is included in the calculation by DIVIDING the calculated time to pain.

The degree of damage produced by a thermal irradiance of a given duration is determined using the Henriques damage integral (Equation 68.8). Calculation of the damage function, Ω, requires that the temperature-time history of the skin be known. It is recommended that Equation 68.4 be used to determine the temperature-time history since it incorporates both the heating and cooling phases of the skin. When solving Equation 68.4 it is important to use the proper properties for the heating and cooling periods. The recommended skin properties are listed in Table 68.10.

The Henriques' damage integral, Equation 68.8, needs to be solved using numerical integration techniques; the trapezoidal rule provides a reasonable solution to the integral and can easily be programmed in a spreadsheet. The pre-exponential and activation energy constants provided by Weaver and Stoll should be used. The safety factor of 1.6 is used by MULTIPLYING the exposure time.

Proper use of the safety factors is required to obtain accurate results. Calculations in which the thermal irradiance is used to determine the time to injury, the resulting time is DIVIDED by the recommended safety factor. When calculating the degree of thermal injury (Ω value) using a thermal irradiance and an exposure time, the exposure time is MULTIPLIED by the recommended safety factor.

In an effort to simplify the calculation procedure, the algorithms were solved for a large number of incident thermal radiation levels and a reference state condition of the skin. Based on the results two simplified equations, Equations 68.15 and 68.16, were developed which predict the time to pain and superficial 2nd degree burns which are only a function of the incident thermal radiation. The simplified equations were compared to thermal dose equations recommended in the United Kingdom [24] for predicting pain and superficial 2nd degree burns, and an equation recommended by Mudan and Croce[27] for pain. When the safety factors which were incorporated into the Equations 68.15 and 68.16 are removed, they predict times that are consistent with those predicted using the thermal dose equations.

Graphical Methods

Figures 68.6 and 68.7 can be used to determine the time to pain and superficial 2nd degree burns respectively.

Empirical Equations

The time to pain is calculated for thermal irradiances less than or equal to 6 kW/m^2 using Equation 68.10 and for higher irradiances using Equation 68.11. If the initial skin temperature is not within the range of 32.5 °C and 33 °C, the

time to pain needs to be corrected for the temperature variation using Equation 68.12. Equation 68.12 can only be used to correct for time to pain and NOT time to blister.

It is recommended that Equation 68.14 be used to determine the time to superficial second-degree burns.

The simplified equations neglect any variation in the physical parameters of the skin among different individuals. Three important skin properties are the pain receptor depth, the initial skin temperature, and the epidermal thickness (basal layer depth). Little information is available in literature on pain receptor depth and therefore the effect of variation in the depth could not be studied. A literature study of how the initial skin temperature and basal layer depth vary, among individuals and at different sites of the body, was performed. The effect of age, sex, occupation, and personal habits on these parameters was examined. Based on a parametric study involving Equations 68.1, 68.4, and 68.8, correction factors were developed to adjust the times to injury calculated using the simplified equations. The correction factors, Equation 68.17, 68.18, and 68.19, are a function of non-dimensional temperature (β) and depth (γ) coefficients and the irradiance level. The difference in the times to pain and superficial 2nd degree burns between the simplified equations with correction factors and Equations 68.1, 68.4, and 68.8 was found to be negligible for heat fluxes greater than 10 kW/m^2. At low heat fluxes (1.7 kW/m^2 and 2 kW/m^2), the difference was found to be up to 30 % with the simplified equations predicting shorter times.

It was found that the initial skin temperature typically varies between 27 °C and 38 °C; this is a deviation of ±5.5 °C (±17 %) from the reference state temperature of 32.5 °C. The deviation in initial skin temperature can have effects as high as 92 % on the time to pain, and as high as 50 % on the time to superficial 2nd degree burns, this can mean the difference between no sensation and a 2nd degree burn for the same exposure.

The variation in basal layer depth (epidermal thickness) was found to be between 16 and 430 μm depending on an individual's age and sex, and depending on the body site. The reference state defines the basal layer depth as 80 μm. Examination of how the skin thickness affects the calculations showed that the variation was not simply a function of the skin thickness but the irradiance level as well. At lower irradiance levels the skin thickness has a smaller effect on the calculated times, in most instances less than 31 %; however, at higher irradiance levels (greater than 10 kW/m^2) there is a significant difference, in as much as 135 %, in the calculated times to superficial 2nd degree burns.

The simplified equations, along with the correction factors, allow the practicing fire protection engineer to evaluate the degree of thermal injury that can be expected by individuals in a hazardous situation. These tools can be incorporated into life safety models and risk assessment analyses without any difficulty in the calculation procedure.

Nomenclature

$\dot{q}''$	Incident thermal radiation (W/m^2)
t	Time (sec)
x	Depth below the surface of the skin (m)
ΔE	Activation energy deGlossaryTermined from experimental data (J/kmol)
P	Pre-exponential GlossaryTerm deGlossaryTermined from experimental data (1/s)
R	Universal gas constant (8314 J/kmol-K)
S(t)	Step function
T	Temperature at time t and distance x below the skin surface (K)
α	k/ρc = thermal diffusivity (m^2/s)
c	Specific heat (J/kg-K)
k	Thermal conductivity (W/m-K)
ρ	Density (kg/m^3)
ρc	Volumetric heat capacity (J/m^3-K)
τ	Exposure time (sec)
Ω	Henriques' damage function

Subscripts

c	Cooling
h	Heating
o	Initial
p	Pain
s	Surface
2b,B	Blister
1	Previous time
2	Current time

Definitions[1]

Acidophilism	Capable of being stained by acid stains such as eosin.
Acidosis	A disturbance in the acid-base balance of the body in which is an accumulation of acids or an excessive loss of bicarbonate.
Adipose	Fatty; pertaining to fat.
Basal	Pertaining to the base of anything; the base.
Bullae	A large blister or skin vesicle filled with fluid.
Collagen	A substance existing in the various tissues of the body, as in the white fibers of connective tissue.
Cutaneous	Pertaining to the skin.
Edema	A condition in which the body tissues contain an excessive amount of tissue fluid. It may be local or general.
Erythema	A form of macule showing diffused redness over the skin. Caused by capillary congestion, usually due to dilation of the superficial capillaries as a result of some external influence, such as heat, sunburn, etc.
Fibril	A small fiber. A very small filamentous structure, oftentimes the component of a cell or a fiber.
Heparin	A complex organic acid found especially in lung and liver tissue and having the ability in certain circumstances to prevent the clotting of blood.
Histamine	A substance in the body found wherever tissues are damaged. Red flush of a burn is due to the local production of histamine; product of histidine catabolism.
Histidine	An amino acid, $C_6H_9N_3O_2$, obtained by hydrolysis from tissue proteins and necessary for tissue repair and growth.
Horny	A cutaneous outgrowth composed chiefly of keratin. A horn-like projection.
Macule	Discolored spot or patch on the skin neither elevated nor depressed, of various colors, sizes and shapes.
Matrix	The intercellular substance of a tissue.
Melanin	The pigment which gives color to hair, skin and the choroid of the eye, and it is present in some cancers, as in melanoma.
Melanocyte	A phagocyte which has ingested melanin.
Necrosis	Death of areas of tissue or bone surrounded by healthy parts; death in mass as distinguished from necrobiosis, a general degeneration.
Papillary layer	The layer of the corium which adjoins the epidermis.
Petrolatum	

[1] (All definitions are taken from reference 6 unless otherwise noted.)

	A purified semi-solid mixture of hydrocarbons obtained from petroleum.
Phagocyte	A cell which has the ability to ingest and destroy particulate substances such as bacteria, protozoa, cells and cell debris, dust particles, and colloids.
Pulmonary	Concerning or involving the lungs.
Skin temperature	Surface temperature of the skin [26].
Squamous cells	Flat, scaly, epithelial cell.
Stratum	A layer.
Subcutaneous	Beneath or to be introduced beneath the skin.
Tissue temperature	Temperature at a depth approximately 80 μm below the skin surface [26].

Flammable Gas and Vapor Explosions 69

Robert Zalosh

Pertinent Gas and Vapor Flammability Properties

Flammable gases and vapors can produce an explosion when they are ignited while at a concentration between their lower and upper flammable limits, usually in a confined volume. Values of the lower and upper flammable limits for a particular flammable gas or vapor depend on the oxidant and inert gas in the mixture, as well as the mixture temperature. Flammable limits for gas-air mixtures are listed in Chap. 17 and Appendix 3. A more extensive compilation is available in the Zabetakis Bureau of Mines Report [1].

Ignition of the flammable mixture results in flame propagation away from the ignition site, and the expansion of the burned gases behind the propagating flame front. Confinement creates a restraint of this expansion and a resulting increase in pressure within the enclosure. When this pressure increase becomes large enough to create a structural damage potential, the result is an explosion. In the case of the NFPA standards, the term explosion is defined as the bursting or rupture of an enclosure or container due to the development of internal pressure. However, in this chapters an explosion will be regarded as a rapid potentially damaging pressure rise, whether the enclosure remains intact or breaches. In fact, some gas explosions can occur outside an enclosure if the flame speed becomes sufficiently rapid to produce compression waves and potentially damaging pressures with little or no confinement, as discussed at the end of this chapter.

When the flame propagates through the gas-air (or gas-oxidant) mixture at a speed lower than the speed of sound in the unburned gas mixture, the explosion is a deflagration. On the other hand, if and when the flame speed increases so that it is faster than sound speed in the unburned gas mixture, the explosion is called a detonation. The pressures produced in a detonation are substantially higher than those in a deflagration, and the detonation pressure increase occurs as a shock wave whereas the pressure rise in a deflagration occurs more gradually.

The flame speed, v_f, measured in a fixed reference frame, is given by the following equation:

$$v_f = S_u + v_u \tag{69.1}$$

where S_u is the burning velocity of the fuel-oxidant mixture, and v_u is the unburned gas velocity ahead of the propagating flame front. In the absence of turbulence, S_u is called the fundamental or laminar burning velocity of the mixture, and depends on the fuel/oxygen ratio as well and the oxygen/diluent ratio. As described in Chap. 12, the value of the laminar burning velocity is related to the mixture combustion kinetics and flame temperature, and varies inversely as the characteristic combustion reaction time. Tabulated values of S_u, such as those in Table 69.1, refer to the highest measured value of

Table 69.1 Deflagration parameters for flammable gases and vapors in air

Gas or vapor	P_{max} (bar g)	Laminar burning velocity (cm/s)
Acetylene	10.6	166
Ammonia	5.4	13[a]
n-Butane	8.0	45
Diethyl ether	8.1	47
Ethane	7.8	47
Ethanol	7.0	41[b]
Ethylene	8.0	80
Hydrogen	6.8	312
Isopropyl alcohol	7.8	41
Methane	7.1	40
Methyl alcohol	7.5	56
n-Pentane	7.8	46
Propane	7.9	46
Toluene	7.8	41

Values taken from Annex D and E of NFPA 68-2007 [2] except for ammonia and ethanol
[a]Value from C. Duynslaegher [3]
[b]Value from Takashi and Kimitoshi [4]

S_u for a particular fuel, oxidant, and diluent, over the entire range of flammable concentrations. This maximum mixture burning velocity often occurs at a concentration slightly richer than the stoichiometric concentration. Representative values for the alkanes and several other hydrocarbons are 40–47 cm/s. Double and triple bond hydrocarbons have significantly higher burning velocities due to their much faster combustion reaction rates.

Most combustion and fire dynamics textbooks, e.g. Drysdale [5], contain theoretical derivations of equations for the laminar burning velocity in terms of gas mixture thermochemical properties. These equations show that S_u is proportional to the mixture thermal diffusivity because it depends on the conduction of heat from the combustion products to the reactants. Since turbulence augments the thermal diffusivity by enhanced mixing of combustion products and reactants, turbulent burning velocities are usually significantly greater than laminar burning velocities, as discussed later in the section on explosions in elongated and obstructed enclosures.

Britton [6] has offered the following empirical equation for estimating laminar burning velocities from the gas-air mixture heat of combustion and the stoichiometric oxygen/fuel ratio.

$$S_u = 1666.1 - 34.228(-\Delta H_c/X_{OF}) + 0.18039(-\Delta H_c/X_{OF})^2 \quad (69.2)$$

where S_u is in cm/s, and
ΔH_C = Heat of combustion of the fuel, kcal/mole
X_{OF} = Stoichiometric ratio of oxygen to fuel.

For example, in the case of methane, $-\Delta H_C = 192$ kcal/mol, and $\chi_{OF} = 2$. In this case, Equation 69.2 yields $S_u = 42.7$ cm/s. This is about 7 % higher than the measured value of 40 cm/s listed for methane in Table 69.1.

The unburned gas velocity in Equation 69.1 depends on the gas mixture geometry and ignition location. For example in the case of a pipe with one closed end, ignition towards the closed end of the pipe will produce a much higher unburned gas velocity than ignition at the open end because the closed end restrains unburned gas motion induced by hot gas expansion. In unrestrained flame propagation, the unburned gas velocity causes the flame speed to be larger than the burning velocity by a factor equal to the ratio of the flame temperature to the unburned gas temperature.

Closed Vessel Deflagration Pressures and Pressure Rise Times

Ignition of a gas-air mixture in an unvented compact enclosure will usually result in a deflagration that produces a pressure increase because of hot gas and unburned gas confinement. The pressure developed in the enclosure is dependent on the extent of flame propagation and the temperature and composition of the burned gas. If the flame has propagated throughout the enclosure, the ratio of the deflagration pressure to the initial pressure in the enclosure can be obtained from the ideal gas equation as it applies to the post-deflagration and pre-deflagration gas-air mixtures, both of which occupy the same enclosure volume. Thus

$$\frac{P_m}{P_0} = \frac{n_b T_b}{n_0 T_0} \quad (69.3)$$

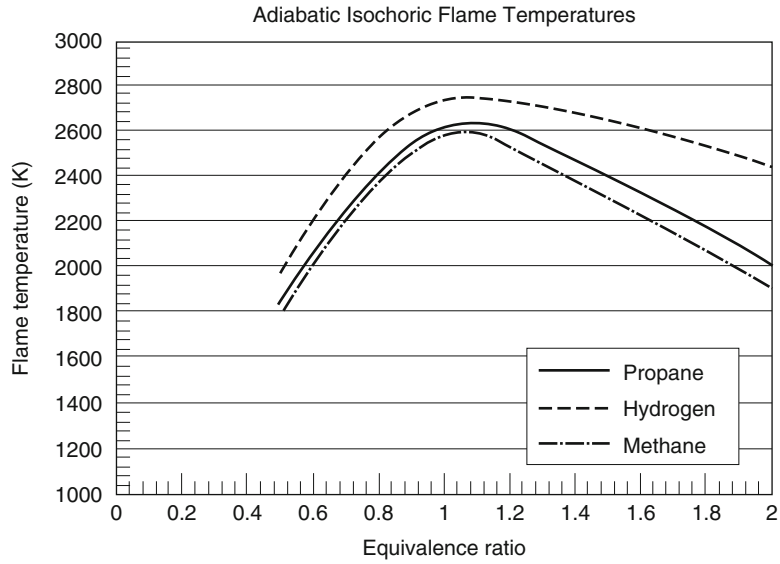

Fig. 69.1 Calculated adiabatic, constant volume flame temperatures as a function of equivalence ratio

where

P_m = Pressure developed at the completion of a closed vessel deflagration

P_0 = Initial pressure in the enclosure

n_b = Number of moles of burned gas at the completion of the deflagration

n_0 = Number of moles of gas-air mixture initially in the enclosure

T_b = Temperature of the burned gas at the completion of the deflagration

T_0 = Initial temperature of the gas-air mixture

Conservative estimates of burned gas temperature and composition can be obtained using the assumption that combustion occurs adiabatically at constant volume. Thus, the calculation of deflagration pressures becomes an exercise in thermochemical equilibrium in which the initial fuel-oxidant mixture is specified to react adiabatically at constant volume. Chemical equilibrium calculation principles and examples are described in Chap. 6. Various computer codes can be used to do these calculations as described below.

Calculated results obtained with the STANJAN code (written and distributed by Professor William Reynolds of Stanford University) are shown in Fig. 69.1 for the adiabatic constant-volume flame temperature, for methane-air, propane-air, and hydrogen-air mixtures of varying concentrations. The fuel concentration used in Fig. 69.1 is the equivalence ratio, defined as the fuel-to-air ratio divided by the stoichiometric fuel-to-air ratio. In terms of fuel volume fraction, x, the equivalence ratio is equal to $[x(1–x_{st})]/[x_{st}(1–x)]$, where x_{st} is the stoichiometric volume fraction of fuel. The stoichiometric fuel volume fraction for methane-air is 0.095, for propane-air, 0.040, and for hydrogen-air, 0.296. The calculated adiabatic constant-volume flame temperatures shown in Fig. 69.1 are generally 200–400 °C higher than the corresponding adiabatic, isobaric flame temperatures for the same fuel-air concentrations.

Although STANJAN is no longer easily available, similar calculations of adiabatic flame temperatures and pressures and combustion products can now be conducted using the GASEQ computer program available for downloading from http://www.arcl02.dsl.pipe.com. Output from GASEQ can also be used for the shock wave and detonation calculations described later in this chapter.

Calculated adiabatic constant-volume deflagration pressures for the same fuel-air mixtures are shown in Fig. 69.2. The maximum pressures for each flammable gas occur at fuel equivalence ratios in the range 1.1–1.2 (i.e., at slightly richer than stoichiometric concentrations). These worst-case deflagration pressures are in the

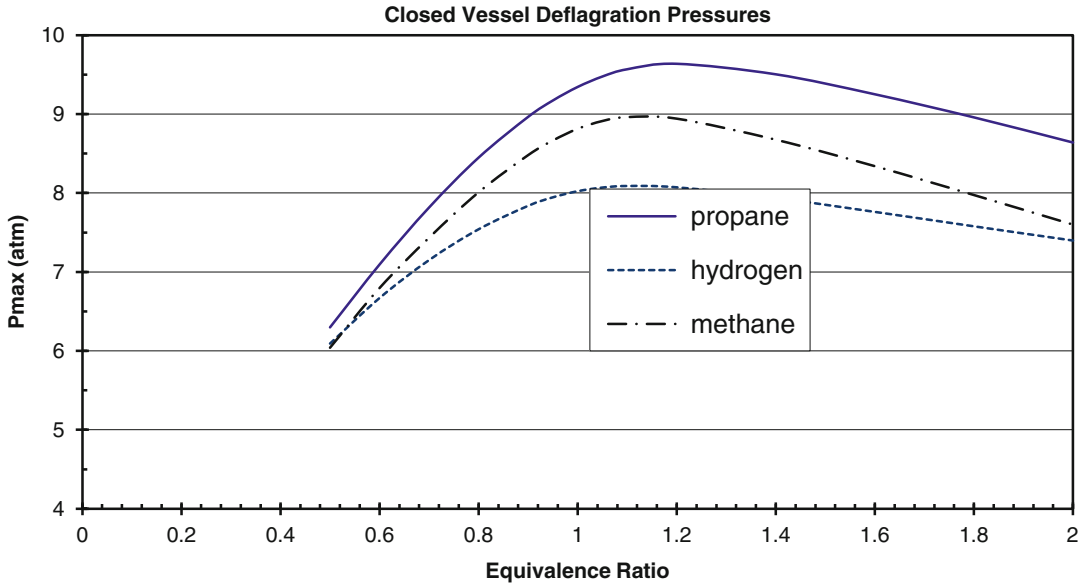

Fig. 69.2 Flammable gas-air deflagration pressures as a function of fuel equivalence ratio

range 8–9.6 atm abs. Theoretical values of P_m at an equivalence ratio of 0.5, which corresponds to the lower flammable limit for methane and propane, are in the range 6–6.5 atm abs. Experimental measurements of closed vessel deflagration pressures agree well with the theoretical values of P_m at near-stoichiometric concentrations but are significantly less than the theoretical values at concentrations near the lower and upper flammable limits. The reasons for the deviation at near-limit concentrations are (1) incomplete combustion due to flame propagation through only a portion of the enclosure and (2) slow flame propagation allowing time for heat losses from the burned gas mixture to the enclosure walls. As an example of the incomplete combustion, extensive deflagration testing of lean hydrogen-air mixtures has shown that the fraction of hydrogen burned ranges from zero to one as the hydrogen concentration increases from its lower limit of 4–8 vol.%, and remains equal to approximately one (complete combustion) as the hydrogen concentration ranges from 8 vol.% to about 40 vol.% (equivalence ratio of 1.6).

Measured values of $P_{\max}$ (worst-case P_m) are shown in Table 69.1 for 14 flammable gases and vapors. All but two values are in the range 6.8 bar–8.1 bar g. The two exceptions are acetylene ($P_{\max} = 10.6$ bar g) and ammonia ($P_{\max} = 5.4$ bar g).

The rate of pressure rise during a deflagration is primarily dependent on the rate of flame propagation and the vessel size, as well as the flame temperature. Theoretical calculations are usually based on the following assumptions. First, it is assumed that the flame speed is small in comparison to sound speed so that the pressures in the enclosure are spatially uniform at any given time during the deflagration. The rate of flame propagation relative to the unburned gas ahead of the flame front is the same burning velocity, S_u, *discussed above*. The mass burning rate is

$$\frac{dm_b}{dt} = -\frac{dm_u}{dt} = \rho_u \chi S_u A_f \qquad (69.4)$$

where

m_b = Mass of burned gas in enclosure at time t
m_u = Mass of unburned gas in enclosure at time t
ρ_u = Density of unburned gas at time t
A_f = Surface area of flame front at time t
χ = Ratio of turbulent burning velocity to laminar burning velocity

Flame propagation into a near-stoichiometric gas-air mixture will occur as an expanding

spherical flame until the flame approaches the walls of the enclosure. Expansion of the burned gas, and the corresponding motion of the unburned gas away from the ignition site as the flame propagates, causes the actual flame velocity relative to a fixed observer (i.e., the flame speed) to be significantly larger than the burning velocity. Before any compression occurs, the flame speed is $(T_b/T_0)S_u$, which is equal to 350–440 cm/s for many hydrocarbons at near-stoichiometric concentrations. Turbulent motion of the unburned gas can further increase the burning velocity and flame speed, as represented either by the augmentation factor χ, or by generating wrinkled or distorted flames with corresponding larger flame surface areas, A_f.

A second key assumption invoked in most theoretical models of closed vessel deflagrations is that the fractional pressure rise at any time during the deflagration is equal to the fraction of the total mass burned, that is,

$$\frac{P - P_0}{P_m - P_0} = \frac{m_b}{m_0} \tag{69.5}$$

where
P = Deflagration pressure at time t
m_0 = Total mass in the enclosure

The justification for Equation 69.5 is that it has been verified by more complicated models, such as the Complete Computer Solution described by Bradley and Mitcheson [7] as well as by experimental data reported in that paper and in Lewis and von Elbe [8]. Equation 69.5 can also be used to calculate the maximum pressure developed in enclosures that are partially filled with fuel-air mixtures (i.e., partial volume deflagrations), as described below in Example 3. Other analytical equations for partial volume deflagrations have been reported by Ogle [9] for a homogeneous pocket of gas and by Jo and Park [10] for a Gaussian gas concentration distribution within the enclosure.

The third assumption needed for a closed vessel deflagration model is the type of thermodynamic process undergone by the unburned gas as it is compressed. The most common assumption is that the unburned gas is compressed isentropically, that is, $P/P0 = (\rho/\rho_u)^{\gamma}$, where γ is the ratio of specific heats of the unburned gas (1.4 for most flammable hydrocarbon-air mixtures). Although it is not necessary, it is also common to assume the flame continues to propagate spherically such that its radius at any time t is r_b in a vessel of radius a. The resulting equations for $P(t)$ and $r_b(t)$ are

$$\frac{dP}{dt} = \frac{3\chi S_u}{a}\left(\frac{P}{P_0}\right)^{1/\gamma}(P_m - P_0)\left(\frac{r_b}{a}\right)^2 \tag{69.6}$$

$$\left(\frac{r_b}{a}\right)^2 = \left\{1 - \left(\frac{P_0}{P}\right)^{1/\gamma}\left[\frac{P_m - P}{P_m - P_0}\right]\right\}^{2/3} \tag{69.7}$$

Equations 69.6 and 69.7 can be solved simultaneously starting from the initial condition that $r_b/a = \varepsilon$ at $t = 0$, where ε is some small number $<<1$ representing the kernel of flame at ignition. An example solution for P(t) and $r_b/a(t)$ for the case $S_u = 45.5$ cm/s, $\chi = 1$, $P_m = 640$ kPa g, $a = 7.15$ m, is shown in Figs. 69.3 and 69.4. The curve in Fig. 69.3 labeled "numerical solution" refers to the numerical integration of Equation 69.6. The curve labeled "analytical approximation" refers to the following simplified solution for P(t) early in the deflagration when $\frac{P-P_0}{P_0} << 1$.

$$\frac{P - P_0}{P_0} = \left[\frac{1}{\gamma} + \frac{P_0}{P_m - P_0}\right]^2\left(\frac{P_m - P_0}{P_0}\right)^3 \times \left(\frac{\chi S_u t}{a}\right)^3 << 1 \tag{69.8}$$

The analytical approximation in Fig. 69.3 is virtually identical to the numerical solution when $P < 2$ psig, and only differs by about 20 % up to $P = 8$ psig. The flame radius at the time $P = 2$ psig is equal to half the enclosure vessel radius, and it is equal to 80 % of the vessel radius when $P = 16$ psig. Since the pressure ultimately increases to 93 psig in this particular deflagration, it is clear that most of the pressure increase occurs when the flame has propagated very close to the enclosure wall, such that the entire enclosure is almost filled with flame.

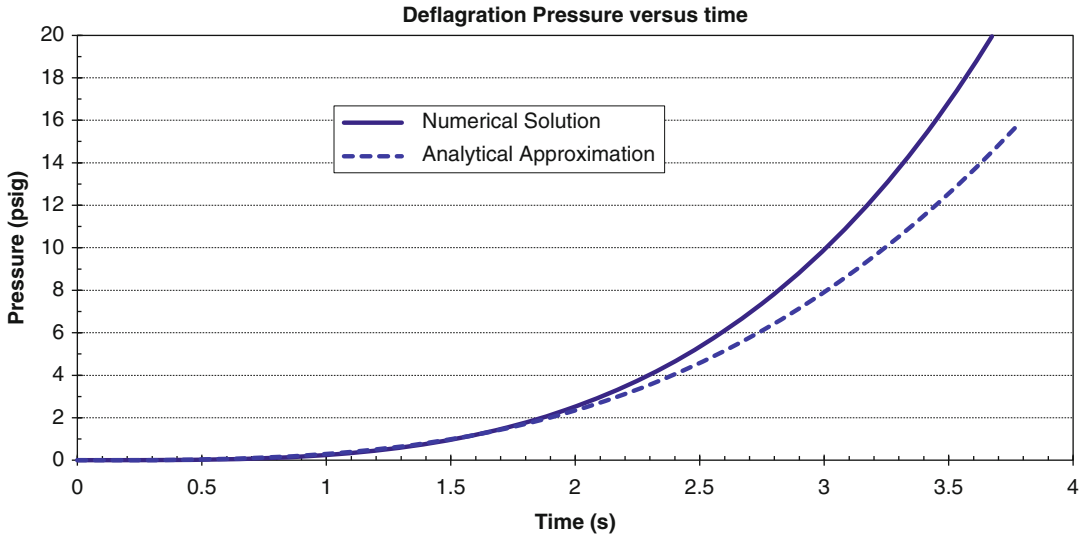

Fig. 69.3 Pressure versus time for a closed vessel deflagration with $S_u = 45.5$ cm/s, a = 7.15 m, and $P_m = 640$ kPa g

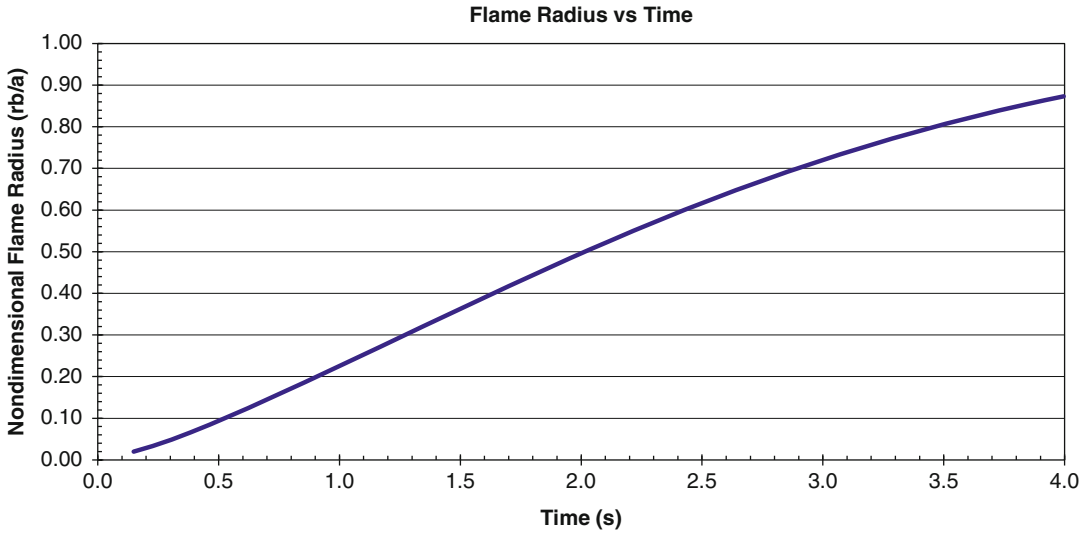

Fig. 69.4 Calculated nondimensional flame radius during deflagration

The continued integration of Equation 69.6 up to $P = P_m$ would require an empirical correlation to account for the variation of S_u with increased pressure and temperature of the unburned gas as it is compressed. Bradley and Mitcheson [7] have carried out non-dimensionalized solutions using such correlations. Their results indicate that the time, t_m, at which P reaches P_m, can be approximated as $t_m = \frac{a}{0.3 S_u}$, where the burning velocity is the mean value of the burning velocities at the beginning and end of the deflagration, i.e., when $P = P_0$ and $P = P_m$. In other words, the mean flame speed, a/t_m, during the deflagration is equal to 3.3 times the mean burning velocity.

Experimental measurements of the rate-of-pressure-rise in a closed vessel explosion are often characterized in terms of the parameter, K_G, defined as

$$K_G = \left(\frac{dP}{dt}\right)_{\max} V^{1/3} \qquad (69.9)$$

where V is the vessel volume, and the maximum rate of pressure rise is measured at the inflection point in the P versus time curve. Theoretically, there is no inflection point (because there is no heat loss or other mechanism to decelerate the flame), and $(dP/dt)_{max}$ occurs when $P = P_m$. Based on Equation 69.5, the theoretical relationship between K_G and S_u is

$$K_G = 4.84\chi S_u \left(\frac{P_m}{P_0}\right)^{1/\gamma} (P_m - P_0) \qquad (69.10)$$

Experimentally determined K_G values have been used in some gas explosion venting guidelines, such as the high strength enclosure method in NFPA 68-2007 [2, 11]. However, the experimental determination of K_G is scale dependent (as described in NFPA 68-2007 Annex D) because the turbulence parameter χ is scale dependent as well as dependent on the possible effects of various flame instabilities.

Partial Volume Deflagrations: Minimum Amount of Flammable Gas to Produce Possible Explosion Hazard

A partial volume deflagration is a deflagration in an enclosure that is only partially filled with a flammable mixture. This is much more likely than having a uniform mixture in flammable gas or vapor release incidents, particularly in large enclosures. A frequent question in these partial volume deflagration scenarios is how much pressure to expect from the burning of the flammable mixture associated with a limited amount of flammable vapor in the enclosure. The following example illustrates a worst-case answer to this question.

Example 1 Approximately 200 g of n-butane are released into an aerosol can-filling room due to a valve misalignment on one large deodorant can. A butane-air mixture forms around the filler as shown in Fig. 69.5. Suppose the butane mixes in stoichiometric proportions with air in this flammable region, and there is no butane in the rest of the 4 × 4 × 3 m room. If the stoichiometric n-butane-air mixture is subsequently ignited, what will the peak pressure be in the absence of any explosion venting?

Solution Equation 69.5 can be used to solve this problem if we first calculate the mass of butane needed to fill the entire room with a stoichiometric butane-air mixture. We can do this calculation in terms of the mixture density, ρ_0, and the butane mass fraction as follows.

$$m_0 = \left(\frac{x_{but} M_{but}}{M_{mix}}\right) \rho_0 V$$

where the mixture molecular weight, M_{mix}, is calculated based on the stoichiometric concentration of butane (3.1 v%).

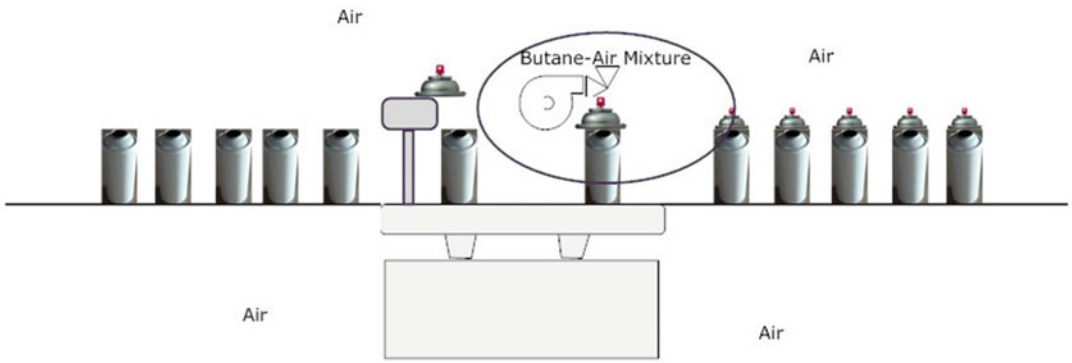

Fig. 69.5 Butane-air mixture formation around aerosol can filler

$$M_{mix} = x_{but}\,M_{but} + (1 - x_{but})M_{air}$$
$$= (0.031)(58) + (1 - 0.031)(28.8) = 29.7$$

The mixture density (which is not much different than air density) is calculated from the ideal gas equation:

$$\rho_0 = \frac{M_{mix}\,P_0}{R\,T_0} = \frac{(29.7\,kg/kmol)\left(101\,x\,10^3\,Pa\right)}{(8314 J/kmol - {}^\circ K)(298\,{}^\circ K)}$$
$$= 1.21\,kg/m^3$$

Therefore,

$m_0 = \left(\frac{(0.031)(58)}{29.7}\right)(1.21\,kg/m^3)(48\,m^3) = 3.52\,kg$

and $m_b/m_0 = (0.20\text{ kg})/(3.52\text{ kg}) = 0.057$.

Using the value for $P_m - P_0$ for n-butane in Table 69.4, $P - P_0 = (8.0\ bar\,g)(0.057) = 0.456\,bar\,g = 6.6\,psig$

We note that since this pressure is greater than the strength of rooms in industrial facilities, some form of explosion venting or explosion suppression would be needed. We also note that this scenario is entirely possible even though the 200 g of n-butane released would be too small to form a flammable mixture if it was dispersed uniformly throughout the 48 m^3 enclosure.

More general partial volume deflagrations calculations have been reported by Ogle [9] for stoichiometric mixture partial volumes and by Jo and Park [10] for Gaussian distribution flammable mixtures. The Ogle result is equivalent to Equation 69.5. Assuming the flammable mixture and air densities are equal, Equation 69.5 can be rewritten as

$$\frac{V_f}{V} = \chi_{st}\frac{P_{dam} - P_0}{P_m - P_0} \tag{69.11}$$

where V_f is the volume of fuel gas or vapor that creates a flammable mixture at stoichiometric concentration, x_{st}, in the enclosure volume V, and P_{dam} is the enclosure structural damage threshold pressure. Jo and Park [10] present the following more alternative equation for V_f/V assuming constant volume combustion to pressure P_m followed by isentropic expansion to pressure P_{dam}.

$$\frac{V_f}{V} = \frac{\chi_{st}}{\omega}\left[\frac{1 - \left(\frac{P_m}{P_0}\right)^{1/\gamma}}{1 - \left(\frac{P_{dam}}{P_0}\right)^{1/\gamma}}\right] \tag{69.12}$$

The parameter ω in Equation 69.12 is the fraction of flammable gas at concentrations between the lower and upper flammable limit. Jo and Park state that the maximum value of ω for their assumed Gaussian concentration distribution is

$$\omega_{max} = \text{erf}\sqrt{\left[\left(ln\left(x_{ufl}/x_{lfl}\right)\right]\right.} \tag{69.13}$$

where erf [ ] denotes the error function, and x_{ufl} and x_{lfl} denote the upper and lower flammable limit volume fraction concentrations, respectively. The value of ω_{max} for most flammable gases is in the range 0.9–1.0, implying that almost all the released gas is in the flammable range in the Jo and Park gas release scenario.

Damage threshold values pertinent to room and building construction and relatively slow pressure rise times (compared to structure characteristic deformation or vibration times) are listed in Table 69.2. The values show that a pressure of 7 kPa (0.07 bar, 1 psig) corresponds to shattering of all windows and the threshold for wood and aluminum panels to start failing. A pressure of about 23 kPa (0.23 bar, 3.3 psig) corresponds to major damage or destruction of typical steel panel industrial buildings.

Table 69.3 shows the values of V_f/V, i.e. flammable gas partial volume fraction,

Table 69.2 Pressure damage thresholds for buildings

Pressure (kPa)	Damage description[a]
3.5–7	Small and large windows usually shattered
7–15	Wood and aluminum panels fasteners fail; panels buckle or blow out
15–20	Unreinforced concrete and cinderblock walls shattered
20	Steel frame buildings distorted and pulled away from foundations
20–28	Self-framing steel panel building demolished
35–50	Nearly complete destruction of houses

[a]From Table B-2 of the CCPS Guidelines for Evaluating the Characteristics of Vapor Cloud Explosions, Flash Fires, and BLEVEs, AIChE 1994

Table 69.3 Partial volumes to produce minor and moderate building damage

Gas or vapor	X_{lfl} (v%)	V_f/V (v%) for $P_{dam} = 7$ kPa	V_f/V (v%) for $P_{dam} = 23$ kPa
Acetylene	2.5	0.051	0.168
n-Butane	1.8	0.027	0.090
Ethanol	3.3	0.048	0.158
Ethylene	2.7	0.057	0.188
n-Hexane	1.2	0.017	0.057
Hydrogen	4.0	0.304	0.998
Methane	5.0	0.083	0.273
Propane	2.1	0.036	0.117
Propylene	2.4	0.036	0.118

calculated from Equation 69.11 to produce the two aforementioned structural damage levels for an assortment of flammable gases and vapors. In the case of the 7 kPa damage level, the fuel partial volume fraction ranges from 0.017 to 0.304 v%. These values are one-to-two orders-of-magnitude lower than the lower flammable limits for the corresponding flammable gases. The V_f/V values reported by Jo and Park [10] are even lower than those in Table 69.3. Thus the common practice of alarming at a flammable gas concentration of one-fourth of the LFL does not necessarily prevent a deflagration if the vapor disperses so as to produce a near stoichiometric concentration in a small portion of the enclosure volume away from the gas sensor location.

Accident scenarios involving flammable liquid spills or heavy flammable vapor releases near floor level produce layered flammable mixtures above the floor. DeHaan et al. [13] conducted experiments with liquid hexane spills, and Tamanini and Chaffee [14] reported on experiments with propane floor layers. The hexane spills in the unventilated enclosure were ignited with an ignition source at an elevation of 5 cm above the floor when the ambient temperature was in the range 11–26 °C, and 20 cm above the floor when the ambient temperature was 33–34 °C. Ignition sources at higher elevations did not produce any ignitions in the 2.4 m high enclosure. Pressure increased as a quadratic function of time rather than the cubic variation indicated in Equation 69.8 because the thin floor layer only allowed cylindrical flame propagation rather than the more spherical flame propagation that occurs with larger or deeper flammable mixtures. Explosion pressures caused explosion vents to open at a pressure of 5–6 kPa.

Some of the propane floor layer ignition tests were conducted in an unvented 64 m^3 enclosure. Flammable mixture volumes occupied from 1.5 % to 7.15 % of the enclosure volume. In some tests ignition occurred while a significant portion of the floor layer had propane concentrations above the upper flammable limit, and flame expansion induced some of the fuel rich propane to mix with air and also contribute to the peak pressure rise. Calculated pressures based on Equation 69.11 (including an attempt to account for the rich mixture fill fraction contribution) agreed to within 9 % of the measured peak pressures in four of the six tests, and were 15–31 % higher than the measured pressures in the other two tests. Thus, Equation 69.11 can be used to obtain reasonably conservative estimates of partial volume deflagration pressures as long as there is some way to estimate the contribution of the fuel rich vapors. Examples of calculation methods for flammable liquid evaporation and stratified layer formation are described by [15] and in the CCPS Guidelines for Use of Vapor Cloud Dispersion Models [16].

Buoyant flammable gas releases form ceiling layers that also produce partial volume deflagrations when and if they are ignited. The partial volume equations are applicable providing the flame propagates through the buoyant ceiling layer, and providing flame accelerations do not produce shock waves. In the case of hydrogen ceiling layers, several test series have been conducted by Kuznetsov et al. [17] to delineate the conditions required for flame propagation with and without shock wave formation. Their results for a 60 cm deep uniform hydrogen ceiling layers in an unobstructed channel showed that hydrogen concentrations of about 15 v% and larger would produce propagation and flame acceleration along the length of the channel. This concentration corresponds to a laminar burning velocity of about 40 cm/s. The magnitude of the acceleration

was even greater when there was a concentration gradient even though the maximum hydrogen concentration at the top of the ceiling layer was no greater than that for a uniform layer. When there were obstructions simulating ceiling beams in a 24 cm deep layer, accelerating flame propagation was observed by Grune et al. [18] with hydrogen concentrations as low as 11 or 12 v%, corresponding to a laminar burning velocity of about 20 cm/s. The flame accelerations produced shock waves at hydrogen concentrations greater than 16–20 v% depending on the layer depth and type of obstructions.

Gas Explosions in Elongated and Obstructed Enclosures

Flame accelerations and corresponding high deflagration pressures are more likely in elongated enclosures, including pipes, and in highly obstructed areas. In both cases the flame accelerations are primarily due to flame stretch and turbulence effects. These effects are more pronounced in reactive mixtures with high burning velocities and flame temperatures (which produce larger burned gas to unburned gas expansion ratios).

Flame acceleration and flame stretch in a pipe are illustrated conceptually in Fig. 69.6. Ignition in the pipe interior produces a near spherical initial flame shape as represented at time t1 in the diagram. At time t2 the flame surface appears like a parabola with the leading edge at the center of the tube where the highest unburned gas velocities are located due to the induced flow ahead of the flame. At time t3 a turbulent boundary layer adjacent to the pipe wall has increased the rate of mixing and heat transfer between burned and unburned gas such that flame acceleration in the region near the wall has caused the flame to stretch in that region to propagate ahead of the flame on the centerline of the pipe. At time t4 the flame is more stretched and fully turbulent and is thicker than the laminar flames. At time t5 the turbulent boundary layer at the wall has caused a significant flame stretch with the leading edge at the wall. Compression waves ahead of the propagating flame have steepened to form a shock at time t5. The advancing compression waves and shock waves can cause the deflagration pressure to be greater than the constant volume deflagration pressures shown in Table 69.1 and Fig. 69.2. Propagating flame and shock wave images corresponding to the diagram in Fig. 69.6 can be found in the textbooks by Strehlow ([19], p. 435) and Lewis and von Elbe ([8], p. 299).

The magnitude of the flame acceleration depends on the pipe/tube dimensions and ignition location and the gas mixture reactivity. For example, Bartknecht [20] obtained the flame acceleration data shown in Fig. 69.7 illustrating the effects of ignition location and pipe end conditions for methane-air flames in a 40 m long pipe. When ignition occurred at the open end, there was virtually no flame acceleration at all because the burned gas expanded out of the pipe rather than inducing a flow toward the opposite end. When ignition occurred in the pipe with both ends closed, the flame accelerated to a maximum speed less than 100 m/s before decelerating and being quenched at the end wall. When ignition was at the closed end and the other end was open, the flame continued to accelerate to a speed of about 250 m/s at the open end of the pipe. Andrews et al. [21] did similar closed pipe experiments on a smaller scale with a range of methane-air concentrations. The highest flame speeds were obtained with near-stoichiometric concentrations, but the maximum flame speed reached in the 7.6 cm diameter pipe closed at both ends (about 37 m/s) was less than Bartknecht observed in the larger pipe. This demonstrates that the turbulence induced flame acceleration is scale dependent such that higher

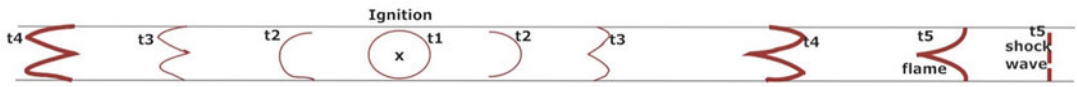

Fig. 69.6 Flame propagation in a tube or pipe

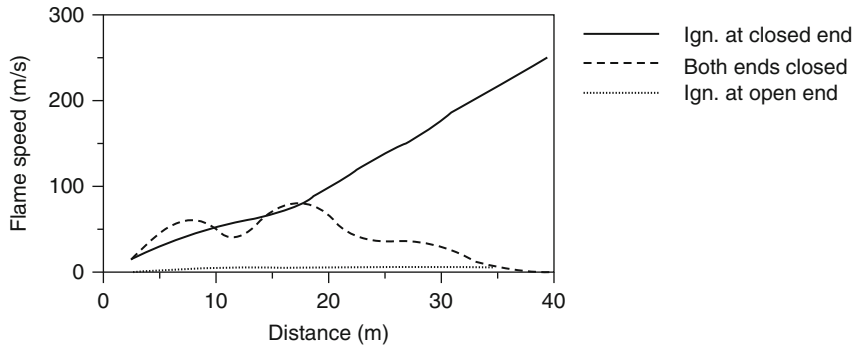

Fig. 69.7 Methane-air mixture flame acceleration in a 1.4 m diameter pipe (From Bartknecht [20])

flame speeds are observed in larger scale pipes and elongated enclosures.

The following linear acoustic relationship between flame speed and deflagration pressure has been shown by Richmond and Liebman [22] and Sapko et al. [23] to be a good approximation for planar flame propagation in pipes and mine galleries.

$$\Delta P = \rho_0 a_0 v_f \tag{69.14}$$

where ΔP is pressure at the flame front, ρ_0 the unburned gas density, a_0 is sound speed in the unburned gas, and v_f is the flame speed. The value of c_0 can be calculated from the following equation

$$a_0 = \sqrt{\frac{\gamma R T_0}{M_0}} \tag{69.15}$$

where γ is the ratio of specific heats, R is the universal gas constant, T_0 is the unburned gas mixture absolute temperature, and M_0 is the unburned gas molecular weight. The acoustic approximation implies that flame speeds are much less than sound speed for Equation 69.14 to be applicable. Equation 69.14 is not applicable when high vent flow velocities near an open pipe or gallery induce high flame speeds at lower pressures than those given by Equation 69.14.

Flame accelerations in elongated enclosures are enhanced by the presence of repeated obstacles in the enclosure because the obstacles stretch the flame and create turbulent wakes as the unburned gas mixture flows around them ahead of the flame. Extensive testing has been conducted with different shaped obstacles that produce various blockage ratios defined as the obstacle area divided by the pipe or channel cross-sectional area. As an example, the circular shaped obstacle blockage ratio effect on the maximum ethylene-air mixture flame speed for propagation in an 11 m long channel and the same length wedge shaped test sector is shown in Fig. 69.8. In the case of the wedge sector, the flame speed increases by an order-of-magnitude as the obstacle blockage ratio increases from zero to about 0.50 and higher.

Figure 69.9 shows the maximum explosion pressures measured in two hydrogen deflagration test programs in obstructed elongated enclosures. The tests in a 5 cm diameter tube with repeated orifice rings were reported by Lee et al. the data obtained with the 0.44 blockage ratio rings are shown in Fig. 69.9. The measured peak pressures were much lower than the constant volume deflagration pressures (Equation 69.3) when the hydrogen concentration was less than 13 vol.%, but were larger than the constant volume deflagration pressure at hydrogen concentrations of 13 vol.% and greater. This clearly demonstrates that the repeated obstacles are particularly important for reactive mixtures with relatively high laminar burning velocities. The laminar burning velocity for a 15 % H_2 in air mixture is about 40 cm/s, and for a 30 % (near-stoichiometric) hydrogen concentration the mixture burning velocity is about 210 cm/s ([24], p 44).

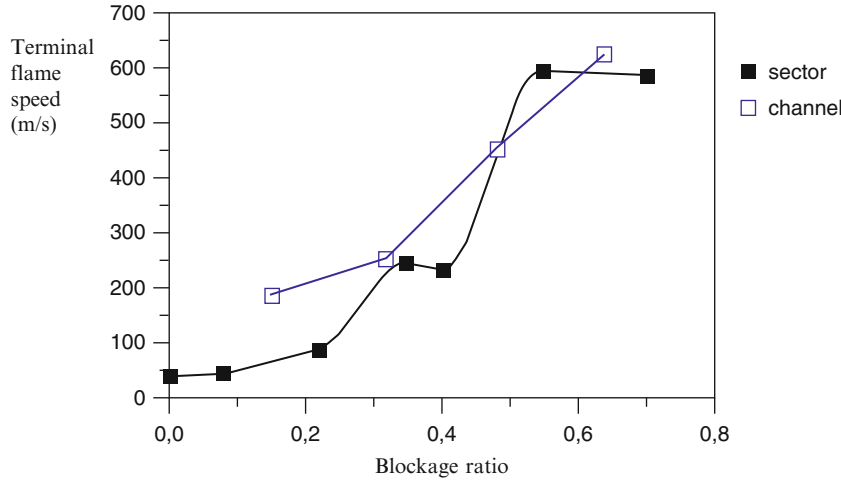

Fig. 69.8 Obstacle blockage ratio effects on ethylene-air mixture flame speeds in a channel and wedge sector (From GexCon Online Gas Explosion Handbook)

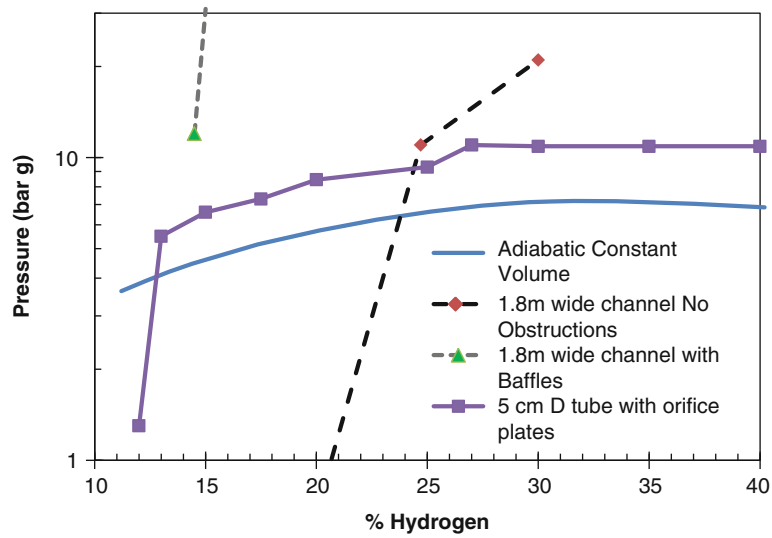

Fig. 69.9 Pressures measured during hydrogen flame propagation in tubes and channels

Qualitatively similar results on a much larger scale were obtained by Sandia National Laboratories [25] in hydrogen-air mixture tests in their FLAME test structure which is a 30.5 m long channel with a 1.83 × 2.4 m cross-section. As shown in Fig. 69.9, without any obstacles in the channel, the pressures were much less than the adiabatic constant volume pressure for hydrogen concentrations less than about 25 %, but exceeded the constant volume pressures at 25 % and above. When equally spaced vertical obstructions with a 0.33 blockage ratio were installed in the channel, the measured peak pressures were much larger than the adiabatic, constant volume pressures in both tests with hydrogen concentrations of about 15 %. Additional data not shown in Fig. 69.9 were obtained with higher concentrations, but with part of the obstructed channel roof removed to allow for venting. Most, but not all of those tests resulted in pressures well below the constant volume pressures.

Repeated obstacles can also induce large flame accelerations and potentially damaging deflagration pressures in large open and partially confined applications. However, for a given flame speed and gas mixture, the pressures developed are lower as the degree of confinement decreases. As in the completely confined situation, the magnitude of the flame acceleration is scale dependent, and also dependent on the characteristics of the turbulent flow ahead of the propagating flame. The two independent characteristics of this turbulence are the integral length scale, $\underline{L}$, and the root-mean-square (rms) turbulent velocity fluctuation, u'. In the case of repeated obstacles, the turbulence length scale is some fraction of the obstacle characteristic dimension, and the rms turbulence velocity is some fraction of the unburned gas velocity ahead of the propagating flame. In the case of fan induced turbulence, the integral length scale is some fraction of the fan blade length, and the rms turbulent velocity is some fraction of the blade tip speed.

In principle, the effects of turbulence on flame propagation speed can be expressed in the following functional form.

$$\frac{S_t}{S_u} = f\left(\frac{u'}{S_u}, Re_{\underline{L}}, Le\right) \tag{69.16}$$

where S_t is the gas mixture turbulent burning velocity, S_u is the previously discussed mixture laminar burning velocity, and $Re_{\underline{L}} = \frac{u'\underline{L}}{\nu}$, $Le = \frac{k}{\varrho_u c_p \mathcal{D}}$. The unburned gas property values in $Re_{\underline{L}}$ and Le are ν, the kinematic viscosity, k, the thermal conductivity, c_p, the specific heat, and $\mathcal{D}$ is the diffusion coefficient of the reactant (oxygen or flammable gas) whose concentration is less than stoichiometric. Abdel-Gayed et al. [26] have developed graphical correlations representing Equation 69.16 for laboratory data on fan stirred closed vessel explosions and turbulent burner flames. Their correlations show S_t/S_u increases with increasing values of u'/S_u and also increasing values of $Re_{\underline{L}}$. For example, a maximum value for S_t/S_u of about four occurs when u'/S_u is in the range 5–8 and $Re_{\underline{L}}$ is 100, but S_t/S_u can be as large as 10 when $Re_{\underline{L}}$ is equal to 1000. Thus, accounting for the turbulent burning velocity is a key factor in any realistic estimate of enhanced flame speeds due to repeated obstacles and other sources of turbulence. This is also one of the primary considerations governing the accuracy and reliability of current Computational Fluid Dynamics computer code calculations for explosions entailing turbulent flame propagation.

Two other considerations pertinent to understanding and assessing explosions in obstructed and complex geometries are flame instabilities and flame quenching. Flame instabilities generate increases in the flame surface area due to wrinkling and distortions caused by various hydrodynamic and thermo-diffusive mechanisms. The increased flame surface area causes increases in the burning rate, as indicated by Equation 69.4, and associated rates of pressure rise. Flame quenching can occur due to heat losses from the reacting gases, and also when the turbulence becomes so great that the gases pass through the reacting region before the combustion reaction is complete. In turbulence parlance, the chemical reaction time becomes larger than the turbulent eddy (where mixing of burned and unburned gases occurs) time scale. Abdel-Gayed and Bradley [27] have developed criteria for flame quenching due to excessive turbulence.

Detonations

A detonation is an explosion in which the combustion wave (i.e., flame) propagates at supersonic speeds through the unburned fuel. Detonations are fundamentally different than the closed vessel deflagrations described in the previous section of this chapter. Since flames in a deflagration propagate at speeds well below the speed of sound (which is about 340 m/s in room temperature air), the pressure increase during a deflagration occurs virtually uniformly throughout the enclosure as the explosion evolves. In contrast, the pressure rise during a detonation is highly non-uniform and occurs virtually instantaneously as the shock wave propagates through the gas-air mixture. If the flame speed is slightly

less than the speed of sound, such that the pressure rise is non-uniform but shock waves do not occur, the explosion is called a quasi-detonation.

The practical significance of this fundamental difference between detonations and deflagrations is that they require different approaches to explosion protection. The sudden, spatially non-uniform pressure rise during a detonation or quasi-detonation precludes the use of explosion venting or explosion suppression systems. Furthermore, the high-peak, short-duration detonative pressure loads warrant special considerations in the evaluation of structural resistance.

The peak pressure during a detonation can be calculated from the classical Chapman-Jouguet theory, which is a combination of thermochemical equilibrium and gas dynamic conservation equations across the detonation front [8, 19]. Figure 69.10 shows calculated detonation pressures as a function of fuel concentration for seven different flammable gases. Chapman-Jouguet calculations for these and other mixtures can be conducted with both the GASEQ and CET89 computer codes mentioned previously for deflagration calculations. Burgess et al. [28] and others have suggested that a good approximation to the Chapman-Jouguet detonation pressure, P_{CJ}, P_{CJ} is $= 2P_m$ (i.e., twice the closed vessel deflagration pressure). This approximation represents a much simpler alternative to the Chapman-Jouguet theory of calculating detonation pressures. As indicated in Fig. 69.10, P_{CJ} for a near-stoichiometric gas-air mixture initially at atmospheric pressure is in the range 16–20 atm.

The pressure distribution behind the C-J detonation front is shown in Fig. 69.11 for the case of a detonation wave propagating in both directions away from the initiation site in a tube. Behind the propagating detonation front the pressure decreases to a plateau value equal to about 0.35 P_{CJ}. The speed of propagation is equal to the C-J Mach number times the speed of sound in the unburned gas-air mixture. If the tube has one or more closed ends, the detonation wave will be reflected and propagate in the reverse direction with increased amplitude. If the end wall is rigid, the reflected shock wave for many gas-air mixtures is equal to 2.76 P_{CJ}. If the end wall is open, the detonation wave will be reflected as a rarefaction wave propagating back toward the detonation initiation site.

The structural load associated with a detonation wave depends on the impulse, I_D, per unit area, where

$$I_D(x,t) = \int_{t_a}^{t} [p(x,t) - p_a]\,dt$$

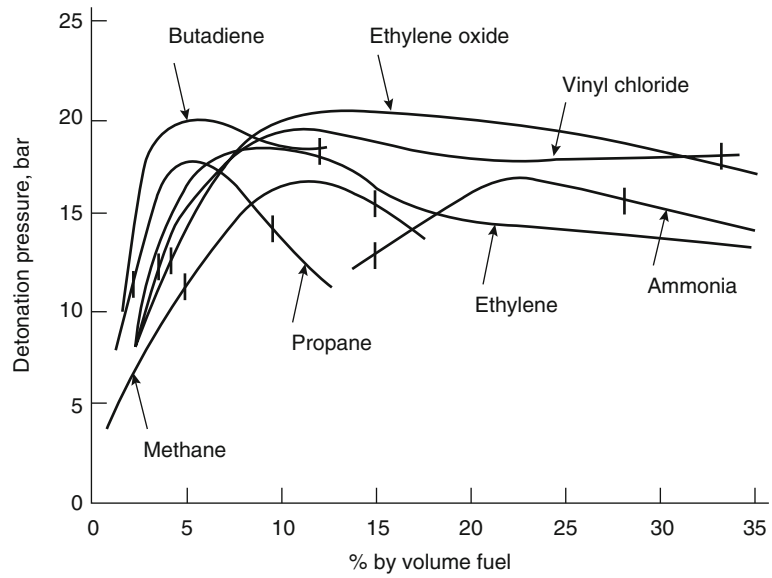

Fig. 69.10 Chapman-Jouget detonation pressures

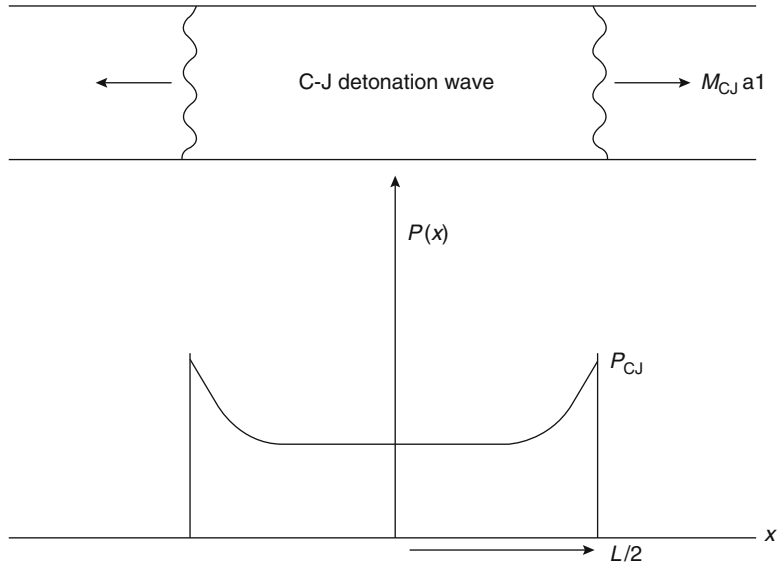

Fig. 69.11 Detonation wave propagation and pressure distribution in a pipe

The detonation front arrival time, t_a, is equal to $\frac{x}{M_D a_1}$, where x is the distance from the detonation initiation site, M_D is the detonation Mach number, and a1 is the speed of sound in the unburned gas-air mixture.

Neglecting any reflected waves, Sichel [29] has shown that a good approximation for I_D is

$$I_D = \frac{0.35 \rho_1 a_1 M_D x}{(\gamma_2 + 1)} \qquad (69.17)$$

where γ_2 is the ratio of specific heats in the burned gas; in many cases γ_2 is equal to 1.2. The C-J detonation Mach numbers for several stoichiometric gas-air mixtures are listed in Table 69.4. They are in the relatively narrow range 4.9–5.5. The unburned gas sound speed for most stoichiometric hydrocarbon-air gas mixtures is in the narrow range 330–350 m/s, while for hydrogen it is 403 m/s.

An interesting aspect of Equation 69.17 is that the specific impulse is linearly proportional to the distance from detonation initiation site. Burgess et al. [28], note that pipeline detonations often cause periodic ruptures along the pipeline length, with each break serving as a pressure relief expansion, requiring the pressure duration/impulse to rebuild to the structural failure threshold again by propagating over another length of pipe. Methods to assess the structural damage potential from these impulsive loads generated during detonations are described by Baker et al. [30]. One after-the-fact indication of structural failure due to detonative loads is the occurrence of fragmented structural debris associated with brittle failure, as opposed to the bulging and more ductile failure of structural steel subjected to deflagration pressures beyond the yield point.

In view of the drastically different explosion protection considerations for detonations, it is important to assess the potential for a detonation

Table 69.4 Detonation Mach numbers and cell sizes for stoichiometric gas-air mixtures

Gas	C-J Mach number[a]	Cell width (cm)[b]
Acetylene	5.46	0.98
n-Butane	–	5.0–6.2
Ethane	–	5.4–6.2
Ethylene	–	2.8
Hydrogen	4.89	1.5
Hydrogen sulfide	–	10
Methane	5.17	28
Propane	5.38	6.9
Propylene	–	5.4

[b]Detonation cell width data is from Sulmistras et al. [12]

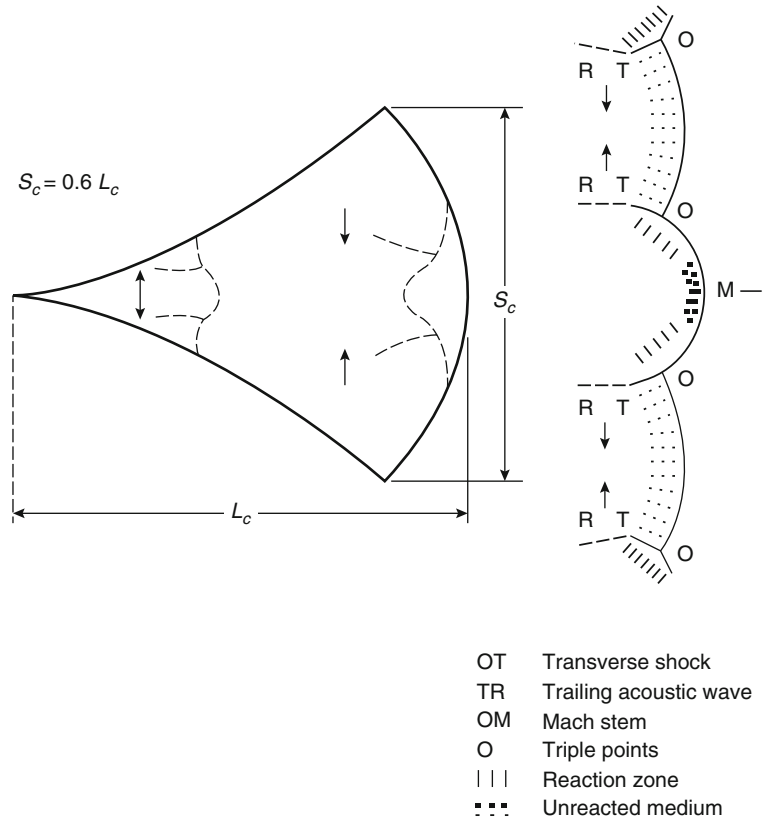

Fig. 69.12 Detonation cell structure

to occur as opposed to a deflagration. Some guidance, as described below, can be offered for this assessment, but there are no exact criteria to provide an unequivocal answer.

The detonability length scale is the detonation cell width, S_c, shown in Fig. 69.12. As indicated in Fig. 69.12, the detonation front consists of a complicated network of curved shock segments that propagate transversely to the detonation propagation direction. The transverse wave structure includes curvilinear triangles with a width S_c. If a smoke foil is inserted on the inner wall of a detonation tube, the detonation cells create a diamond or fish-scale shaped pattern on the smoke foil. Detonation cell widths are measured from the traces deposited on these smoke foils as described, for example, by Gelfand et al. [31].

Detonation cell widths can also be correlated with the detonation reaction zone length in a one-dimensional representation of the shock wave initiated chemically reacting flow behind the leading edge of a detonation. This model, which is called a ZND model (the initials stand for three original model developers), requires some chemical kinetics data as well as an assumption about heat losses and drag associated with the tube wall. The calculations and their relationship to cell size are described by Gelfand et al. [31], by Shepherd [32], and by Stamps et al. [33].

Detonation cell widths measured/calculated for nine different stoichiometric gas-air mixtures are listed in Table 69.4. Values range from about 1 cm for acetylene to about 28 cm for methane. These values were obtained at atmospheric pressure and room temperature. Higher initial pressures and temperatures would result in smaller cell widths. Furthermore, some of the gases listed in Table 69.4 have smaller cell widths at some fuel-rich concentrations, with minimum values for a given fuel being as

much as 40 % smaller than the values shown in the table.

A sustained detonation can only occur if the characteristic length scale of the gas-air mixture is greater than some multiple of the detonation cell width. The value of the multiplication factor depends on the geometry. In the case of a pipe, the detonation will not propagate down the pipe if the pipe diameter is less than about $S_c/3$. The detonation will not propagate from open end of the pipe into the surrounding gas mixture if the pipe diameter is less than 13 S_c.

What is the likelihood of a detonation occurring in an enclosure or cloud larger than the critical size indicated by the detonation cell size? The answer depends on the strength of the ignition source and the presence of either a highly elongated enclosure geometry or an exceptionally high level of turbulence for promoting flame acceleration. The minimum ignition source energy required for the direct initiation of a detonation ranges from a low of about **5** kJ for acetylene and hydrogen in air to a high estimated to be 93,000 kJ for methane. Since these initiation energies are many orders-of-magnitude larger than the energies associated with accidental ignition sources, direct initiation can be precluded from almost all accident initiation scenarios.

In the case of an accidental ignition source in a pipe or some other elongated enclosure, the deflagration-to-detonation transition (DDT) distance depends upon the following parameters.

Mixture Reactivity: The more reactive the mixture, the more rapid is the flame acceleration to DDT.

Enclosure or pipe wall roughness and the possible presence of obstruction: The rougher the pipe interior surface or the more obstructions present, the shorter is the transition length to DDT.

Enclosure or pipe diameter: The larger the pipe or enclosure diameter, the shorter is the transition to DDT.

Initial pressure and temperature: The higher the initial temperature and pressure, the shorter is the transition length to DDT.

Initial turbulence level: The more turbulence or initial gas velocity in the enclosure, the shorter is the DDT transition length.

Figure 69.13 illustrates how mixture reactivity influences the DDT length/diameter ratio for the case of a smooth walled 2-in. (5-cm) diameter pipe [34]. The ratio of DDT transition length to pipe diameter is plotted as a function of the ratio of nitrogen/oxygen concentration for methane, for ethane, and for propane at near-worst-case

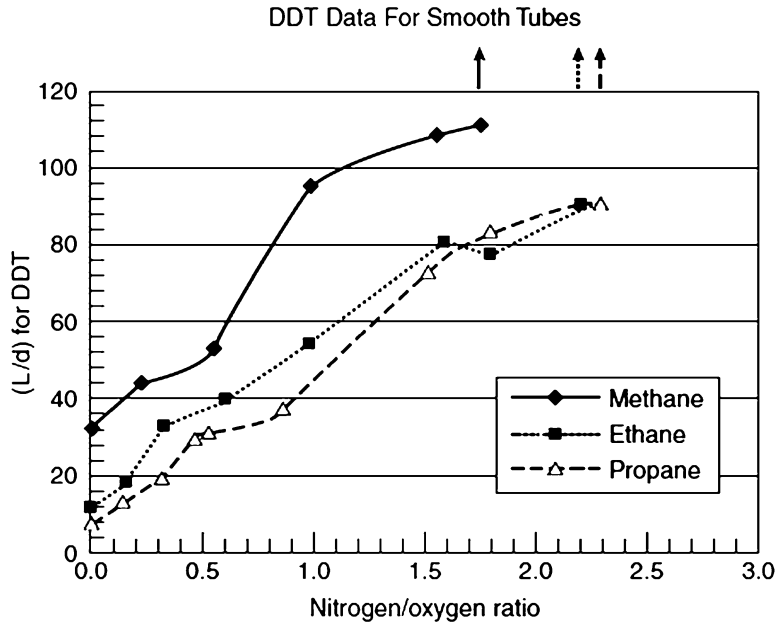

Fig. 69.13 Detonation run up L/D in smooth tubes

fuel/oxygen ratios that produce stoichiometric combustion with CO formation instead of CO_2. The L_{DDT}/diameter ratio increases rapidly as the nitrogen/oxygen ratio increases for all three alkanes, with the transition length being shortest for propane and longest for methane. In these experiments, the largest N_2/O_2 ratio at which transition occurred (last data point on each curve) was less than the 3.76 ratio corresponding to air. In other words, the L_{DDT}/diameter ratio for these alkanes in air (at a 2-in. pipe diameter) is larger than the largest ratio (120) measurable in these experiments. The three arrows in the graph represent the absence of transition at the indicated N_2/O_2 ratio. This data is consistent with the experimental observations of Flessner and Bjorklund [35], who did not see DDT with gasoline-air mixtures in a 15 cm-diameter, 16 m long smooth wall pipe, but saw DDT at a distance of 74 pipe diameters when they inserted an expanded metal liner in the pipe entrance to simulate a rough wall section.

Hydrogen-air mixtures are susceptible to DDT in both smooth and obstructed pipes and channels providing the hydrogen concentration is sufficiently high. The data in Fig. 69.9 provide a good indication of the minimum hydrogen concentration for DDT in the presence of obstructions in small diameter (5 cm) piping, and for smooth and baffled large width (1.8 m) channels. The flame speeds measured in the 1.8 m wide channel confirm DDT at hydrogen concentrations that produced peak pressures well above the adiabatic constant volume deflagration pressures. In the case of highly obstructed channels and piping, the critical hydrogen concentration for DDT seems to be 13–14 %. In case of large unobstructed channels, the critical concentration appears to be about 25 %.

Near stoichiometric concentration hydrogen-air mixture smooth pipe Length-to-diameter ratios needed for DDT were measured by Blanchard et al. [36] in a 16 cm diameter pipe. The DDT run up distance depended on the igniter location relative to the pipe end wall. The shortest measured DDT length was 8 m, corresponding to a L_{DDT}/diameter ratio of 50.

Sherman and Berman [37] have developed a semi-quantitative methodology to categorize the probability of detonations occurring in specific industrial accident scenarios by subjectively extrapolating the experimental data on the various effects mentioned above. They categorize gas mixture reactivities on the basis of detonation cell size, and they categorize enclosure geometries on the basis of size, confinement, level of obstructions, amount of venting, etc. They have applied their methodology to the case of a possible hydrogen detonation during hypothesized severe accident scenarios in one particular nuclear plant containment building.

Although most accidental explosions are deflagrations, there are some occasional well-documented accounts of detonation incidents. One excellent example is the Jacobs et al. [38] description of a particularly destructive detonation in a section of a petroleum refinery in which a gas mixture of 3 % naptha, 19 % oxygen, and 78 % inert gas at 105 psig was accidentally allowed to enter several large pieces of process equipment connected by over 1000 ft of piping. Their account of the incident includes a description of the flame propagation path and associated pressures (3000–4000 psi in some locations) developed.

Example 2 A large process oven is heated with a burner utilizing a 1-cm-diameter, 5-m-long fuel line containing a stoichiometric propane-air mixture. What is the likelihood of a detonation occurring in the oven and the fuel line as a result of a delayed ignition after the oven has been inadvertently filled with a fuel-air mixture? How would the situation change if a stoichiometric hydrogen-air mixture replaced the propane-air mixture in the fuel line?

Solution From Table 69.4 $Sc = 6.9$ cm for a stoichiometric propane-air mixture. Thus, the minimum pipe diameter for detonation propagation in this case is $Sc/3 = 2.3$ cm. Therefore, a sustained propane-air detonation will not propagate through the 1 cm fuel line. If the propane is replaced by hydrogen, $Sc/3 = 0.50$ cm, and a fuel line detonation would be possible,

particularly in view of the 500:1 length to diameter ratio.

In order for the detonation to be transmitted into the oven, the fuel line would have to be larger than 13 $Sc = 20$ cm for hydrogen. Thus, the oven should not experience a detonation. Explosion venting could be a viable form of explosion protection for the oven.

Example 3 If a detonation did propagate through a stoichiometric hydrogen-air mixture in the fuel line, what would the specific impulse be on the pipe wall. Neglect any reflected shock wave effects, and use a sound speed of 400 m/s for the unburned stoichiometric hydrogen-air mixture.

Solution Before using Equation 69.11 to evaluate the specific impulse, we need to calculate the molecular weight and density of the stoichiometric hydrogen-air mixture.

$$\rho_{mix} = \frac{M_{mix}}{M_{air}}\rho_{air} = \frac{[(0.295)(2) + (1 - 0.295)(28.8)}{28.8}\left(1.2\,kg/m^3\right) = 0.87\,kg/m^3$$

Using the C-J detonation Mach number for stoichiometric hydrogen-air listed in Table 69.4,

$$I = \frac{0.35(0.87\,kg/m^3)(400\,m/s)(4.89)(5\,m)}{(1.2+1)}$$
$$= 1354\,Pa - s$$

If we assume the pressure is effectively relieved when the detonation reaches the open end of the tube, the detonation duration in the 5 m long pipe is $\frac{5m}{4.89\,(400\,m/s)} = 2.56\,m\,\mathrm{sec}$. The average pressure exerted on the pipe wall is $I/t_{dur} = 530$ kPa = 77 psig. This value is about one-third of the C-J detonation pressure. Structural analysts familiar with dynamic loadings can use these values and the pipe wall properties to determine whether the fuel line should survive the detonation.

Blast Waves and Vapor Cloud Explosions

Blast waves are the explosion pressure disturbances that propagate away from the energy source. In the case of flammable gases and vapors, the energy source is usually the combustion energy. However, in the case of pressure vessel bursts, the blast energy is due to the compressed gas expansion energy released upon vessel rupture. The blast wave will propagate into the surrounding atmosphere and will decay with distance from the enclosure. A common question with regard to explosion protection is whether the blast wave at a particular location will be sufficiently strong to cause damage or injury. Simplified methodology to address this question is presented here along with reference citations for more thorough and extensive analyses.

If we confine our attention to distances that are large in comparison to the characteristic diameter of the breached enclosure or the energy deposition spatial scale, we can often deal with relatively simple far-field blast wave scaling correlations. The characteristic shape of the far-field blast wave is shown in Fig. 69.14. It consists of a shock wave with a pressure rise, P_S, followed immediately by a rarefaction wave in which the pressure decays to some value below atmospheric pressure, and then a gradual recovery to atmospheric pressure, P_0. Sometimes the final pressure recovery occurs in the form of a second shock, and the shape takes the form of a slightly deformed letter N, thus leading to the term *N wave*.

Blast wave correlations are often in the form of a non-dimensional pressure $(Ps - P_0)/P_0$ and a non-dimensional distance from the blast source. The non-dimensional distance, $\overline{R}$, is defined as:

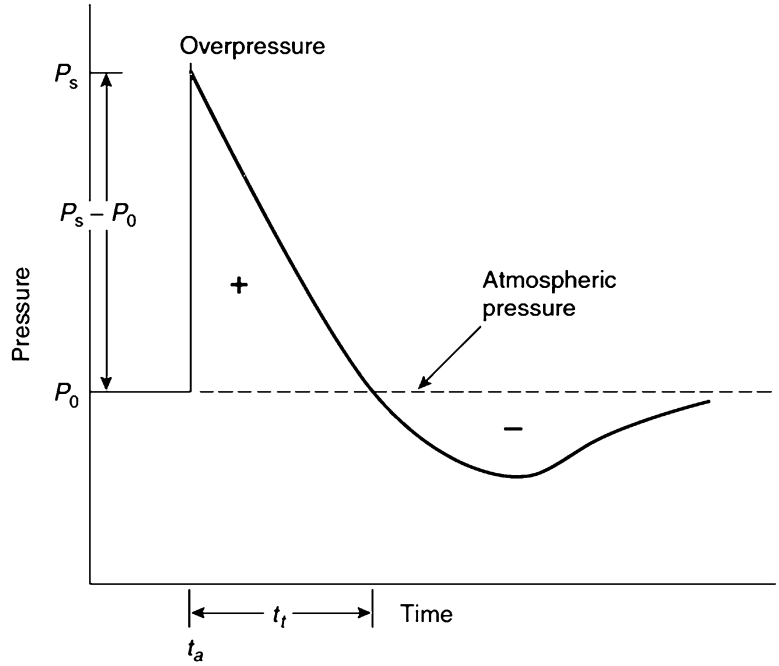

Fig. 69.14 Blast N-wave pressure vs time

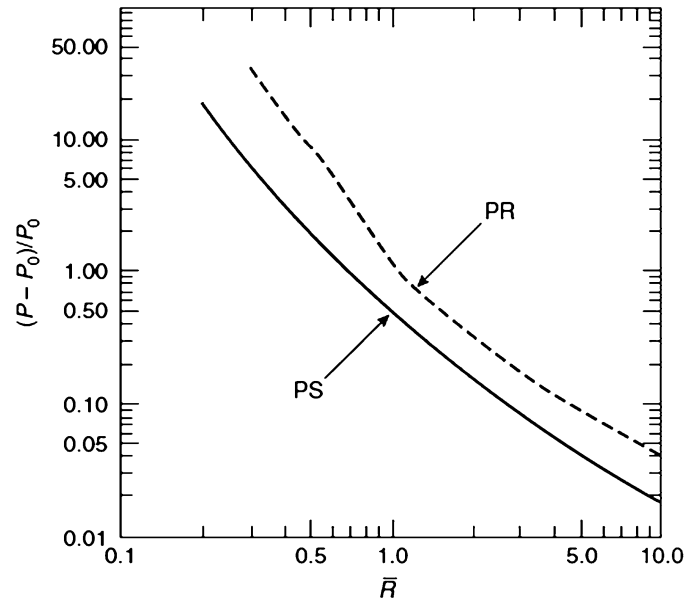

Fig. 69.15 TNT equivalent blast wave pressure versus energy scaled distance

$$\overline{R} = R\left(\frac{P_0}{E}\right)^{1/3} \tag{69.18}$$

where R is the actual distance from the blast source (m), E is the blast wave energy (J), and P_0 is in Pa.

The correlation for non-dimensional pressure versus $\overline{R}$ is shown in Fig. 69.15. The curve labeled PS in Fig. 69.15 refers to the incident overpressure, and the curve labeled PR refers to the reflected blast wave pressure resulting from a blast wave being reflected head-on from a rigid

wall. Neither curve in Fig. 69.15 accounts for the reflection of the shock wave off the ground surface. The usual procedure for including ground surface reflection is to use twice the calculated blast wave energy when using the correlations in Fig. 69.15.

The implication in this type of blast wave scaling correlation is that the blast wave is characterized by only one parameter, the blast energy, E. In the early theoretical models of blast wave pressure, the energy is assumed to be released instantaneously, at a single point. This approach is called ideal blast wave theory. The correlations for ideal blast waves are based on a combination of theory and test data from condensed phase, compact explosives. Baker et al. [30] describe the development of these correlations, which include non-dimensional blast wave impulses, positive-phase durations, and many other parameters. The impulse is particularly important for doing dynamic structural response analyses, such as those described by Kinney and Graham [39].

Can the blast waves from various accidental explosions be predicted from these ideal blast wave correlations? In some cases the answer is unequivocally yes. A good example is the blast wave from a ruptured pressure vessel containing a gas that is not ignited upon release.

The energy associated from this type of physical explosion is the energy of expansion of the gas as it goes from an initial pressure, P_1, to atmospheric pressure. Perfect gas isentropic expansion representations of this energy is

$$E = \frac{(P_1 - P_0)V}{\gamma - 1} \qquad (69.19)$$

where V is the vessel volume and γ is the gas ratio of specific heats. Other approaches to this problem including the assessment of vessel fragment shrapnel effects are described in the AIChE Consequence Analysis Guidelines [40].

If the breached vessel fails as a result of an internal combustion explosion, of if the vessel is vented per explosion venting guidelines, the blast wave analysis is considerably more complicated because there is a combustion energy contribution to the total blast wave energy. Correlations to predict blast waves from vented explosions are contained in NFPA 68 [2]. More detailed equations, including two-dimensional considerations, are described by Forcier and Zalosh [41].

Another special consideration in breached vessel blast waves is the blast wave and fragment shrapnel released when a liquefied gas undergoes a Boiling Liquid Expanding Vapor Explosion (BLEVE) as a result of severe fire exposure. Correlations for BLEVEs, and some of the research leading to these correlations, is described in the AIChE Center for Chemical Process Safety *Guidelines for Evaluating the Characteristics of Vapor Cloud Explosions, Flash Fires, and BLEVEs* [42].

Another very important special consideration is the blast wave associated with vapor cloud explosions. These explosions occur when a very large cloud of flammable gas or vapor is ignited in a highly obstructed environment such as a chemical or petrochemical plant with a high density of process/storage equipment and piping. The strength of the blast wave that occurs in a vapor cloud explosion is dependent on the flame speed that develops and the degree of confinement in and around the vapor cloud.

In some extreme cases of repeated obstructions, vapor cloud detonations can occur with blast wave pressure transients similar to the ideal blast wave shape shown in Fig. 69.14. More often, the flame speed is subsonic and the blast wave pressure transient appears as shown in Fig. 69.16, i.e. without a leading edge shock wave. The pressure rise time in these vapor cloud deflagrations depends on the flame speed and distance from the flammable cloud, with high subsonic flame speeds producing relatively steep compression waves ahead of the flame front.

There are separate impulses, I_+ and I_- associated the areas under the portions of the curve with positive pressures relative to atmospheric pressure, and with sub-atmospheric pressures. The blast wave scaling of these impulses is given by the following equation.

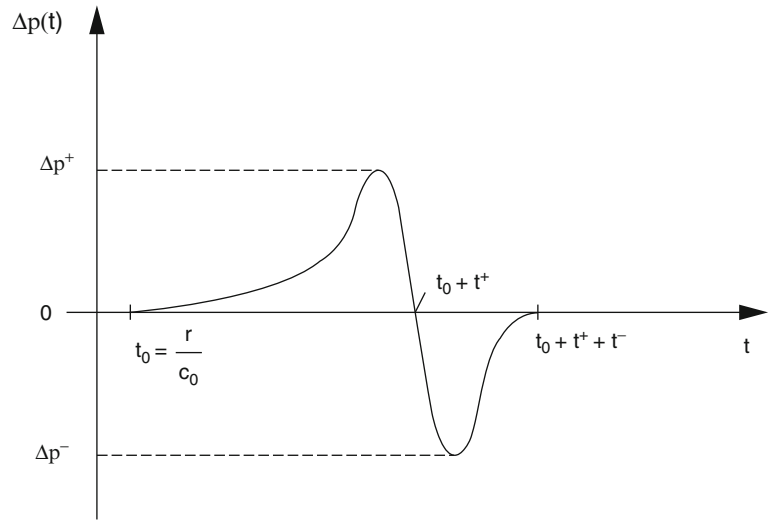

Fig. 69.16 Blast wave pressure transient for subsonic flame propagation in vapor cloud (From Souchet [43])

$$\bar{I}_+ = \frac{I_+ a_0}{p_0^{4/3} E^{1/3}} \tag{69.20}$$

where $\bar{I}_+$ is the non-dimensional impulse, and a_0 is sound speed in air.

The vapor cloud explosion blast wave energy is usually calculated from the volume of flammable gas in the obstructed or partially confined region of a facility. If we denote this volume as V_{vc}, and conservatively assume that the gas concentration in the cloud is the stoichiometric concentration, x_{st}, the vapor cloud explosion energy is

$$E = \rho_g V_{vc} x_{st} \Delta H_c \tag{69.21}$$

where the heat of combustion, ΔH_c, is now on a per unit fuel mass basis. If a vapor dispersion analysis is conducted, the resulting average flammable gas concentration in the obstructed region can be used instead of x_{st}.

Early assessments of vapor cloud explosion blast waves were conducted using the idealized blast wave type correlations described here, along with some rough guess at the energy yield (i.e., the fraction of the available combustion energy actually contributing to the blast wave). However, these early efforts were not very successful because (1) most of the interest is in the near field rather than the far field, and (2) even the far-field assessments were not accurate because the vapor cloud explosion blast wave strength and impulse decay much less rapidly than that of an ideal blast wave. Therefore, three other types of blast wave models are utilized now for vapor cloud explosions.

The mostly used approach is the use of numerical solutions to the full set of compressible gas conservation equations assuming one-dimensional (usually spherical) flame propagation at some assumed constant flame speed through a size vapor cloud of specified radius. The flame speed is usually expressed as a Mach number, $M_f = v_f/a_0$, (where a_0 is ambient air sound speed) and the computational results are presented in non-dimensional form using blast wave scaling. Figures 69.17 and 69.18 are the plots developed by Baker et al. [44, 45] for non-dimensional pressure and impulse versus energy scaled distance from the center of the vapor cloud. The maximum pressures in Fig. 69.17, corresponding to small values of $R\left(\frac{P_0}{E}\right)^{1/3}$, are the pressures developed within the cloud itself. They can be estimated with the following equation from Tang and Baker [46].

$$\frac{P_{max} - P_0}{P_0} = 2.4 \frac{M_f^2}{1 + M_f} \tag{69.22}$$

After comparing calculated pressures with pressures measured in medium scale vapor

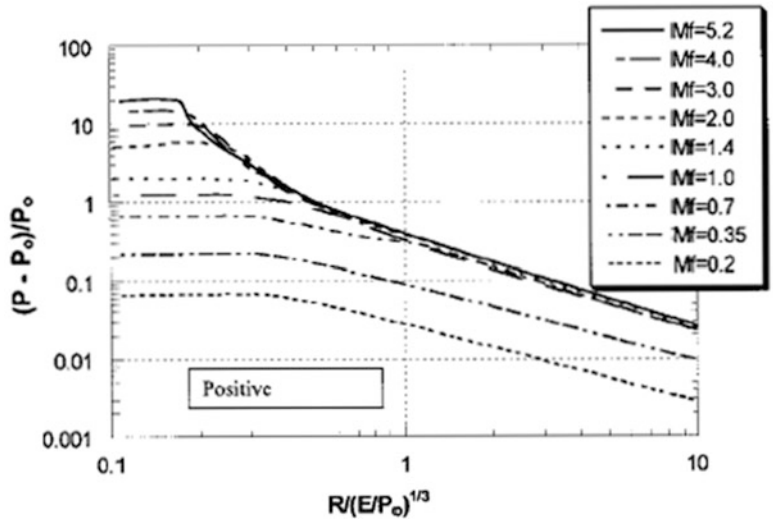

Fig. 69.17 Baker-Strehlow-Tang vapor cloud explosion pressure versus distance (From Pierorazio et al. [44])

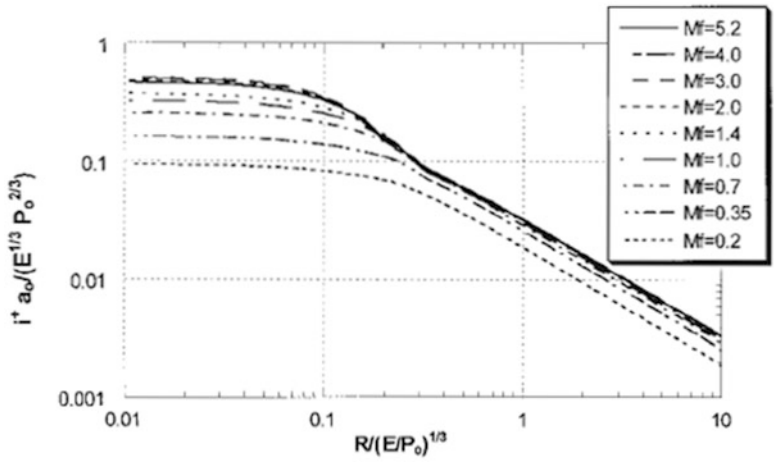

Fig. 69.18 Positive phase blast wave impulse versus energy-scaled distance (From Pierorazio et al. [44])

cloud explosion tests, Perorazio et al. [44] offer Table 69.5 as guidance in selecting the appropriate flame Mach number. The gas reactivity categories of Low, Medium, and High are designated based on the flammable gas laminar burning velocity as follows.

- Low reactivity refers to gases and vapors with S_u <40 cm/s
- Medium reactivity refers to gases and vapors with 40 cm/s < S_u <75 cm/s
- High reactivity refers to gases and vapors with S_u >75 cm/s.

Table 69.5 Flame speed Mach number selection table

		Congestion		
Confinement	Reactivity	Low	Medium	High
2-D	High	0.59	DDT	DDT
	Medium	**0.47**	0.66	**1.6**
	Low	0.079	0.47	0.66
2.5D	High	**0.47**	**DDT**	**DDT**
	Medium	**0.29**	0.55	1.0
	Low	0.053	0.35	**0.50**
3-D	High	**0.36**	**DDT**	DDT
	Medium	**0.11**	**0.44**	**0.50**
	Low	0.026	**0.23**	**0.34**

The 2-D confinement category was based on cylindrical flame propagation numerical calculations, and corresponds to flame propagation between the ground and a ceiling, in the absence of any confining wall. The 3-D confinement category corresponds to spherically symmetric flame propagation calculations with the premise that twice the energy should be used for hemi-spherical flame propagation associated with unconfined clouds on the ground. The 2.5-D confinement category was developed by averaging the results from 2-D and 3-D numerical calculations. According to Pierorazio et al. [44] the 2.5-D confinement category is "to be used in cases where the confinement is made of either a frangible panel or by a nearly solid confining plane (e.g., pipe rack where the pipes are almost touching)."

The Low, Medium, and High equipment Congestion categories can be selected by comparison of an application with the following table characterizing the level of pipe-like blockages used in the testing described by Pierorazio et al. Figure 69.19 shows a plan view representation of these three prototypical obstruction configurations.

The European approach that is equivalent to the Baker-Strehlow-Tang method and results in Figs. 69.17 and 69.18 is the so-called Multi-Energy method. It is described by van den Berg and Lannoy [47]. Taveau [48] has described the application of both the Baker-Strehlow-Tang method and the Multi-Energy method to the Buncefield tank farm vapor cloud explosion.

The second approach to Vapor Cloud Explosion blast pressure estimation is to use either empirical equations or analytical equations based on idealized geometries and assumed flame speeds. Dorofeev [49] offered the following empirical equation as a fit to many of the numerical calculations and experimental measurements of blast pressures.

$$\frac{P - P_0}{P_0} = \frac{0.34}{\overline{R}^{4/3}} + \frac{0.062}{\overline{R}^2} + \frac{0.033}{\overline{R}^2} \quad \text{for } 0.21 < \overline{R} < 3.77 \tag{69.23}$$

Two of the analytical solutions to the spherical flame or piston propagation conservation equations have been described by Souchet [43]. In the thin region near the propagating flame front ($R \approx R_f$) the following solution to the incompressible gas flow equations is applicable.

$$P - P_0 = 2\rho_a v_f^2 \left[1 - \frac{\rho_b}{\rho_a}\right] \left(\frac{R_f}{R}\right) \left[1 - \frac{1 - \frac{\rho_b}{\rho_a}}{4} \left(\frac{R_f}{R}\right)^3\right] \tag{69.24}$$

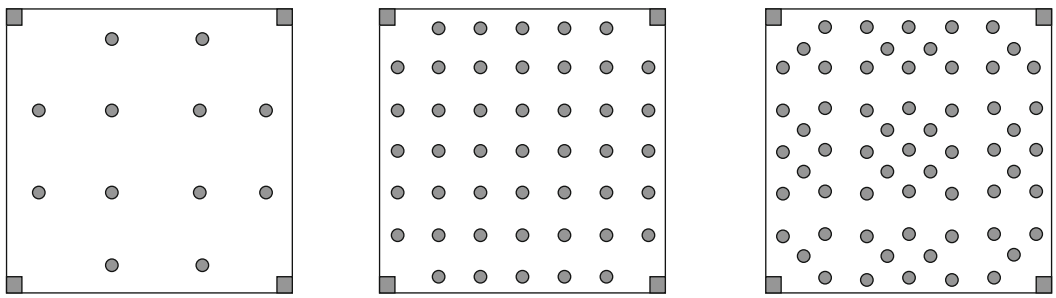

Fig. 69.19 Plan view of obstructions in vapor cloud explosion tests reported by Piezoranio et al. [44]

where the density ratio is approximately equal to the temperature ratio T_a/T_f for most flammable gases with stoichiometric concentrations less than 0.10.

In the far field where $P\text{-}P_0 << P_0$, the following acoustic flow solution is applicable.

$$P - P_0 = 2\rho_a v_f^2 \left[1 - \frac{\rho_b}{\rho_a}\right] \left(\frac{R_f}{R}\right) \left[1 - \frac{R}{a_0 t}\right] \text{ for } R < a_0 t \text{ and } R >> R_f \tag{69.25}$$

The third current approach for vapor cloud explosion calculations is to utilize CFD models of the actual two-dimensional or three-dimensional flame propagation, in which the flame speed and acceleration are calculated as part of the solution. The models used for this approach are also capable, in principle, of doing the vapor cloud dispersion calculations to determine the mass of flammable gas in and beyond the obstructed region. Although full CFD simulations of potential vapor cloud explosions are few and far between, their use may increase with increasing availability of faster and more powerful computers, along with the education of potential users of these sophisticated models. In a sense, this issue is only a microcosm of the more general question of what level of modeling will be utilized for performance based explosion hazard assessments.

Example 4 Figure 69.20 is an aerial view of a natural gas fueled power generation facility that was in the final stages of construction when it suffered an explosion when a flammable gas

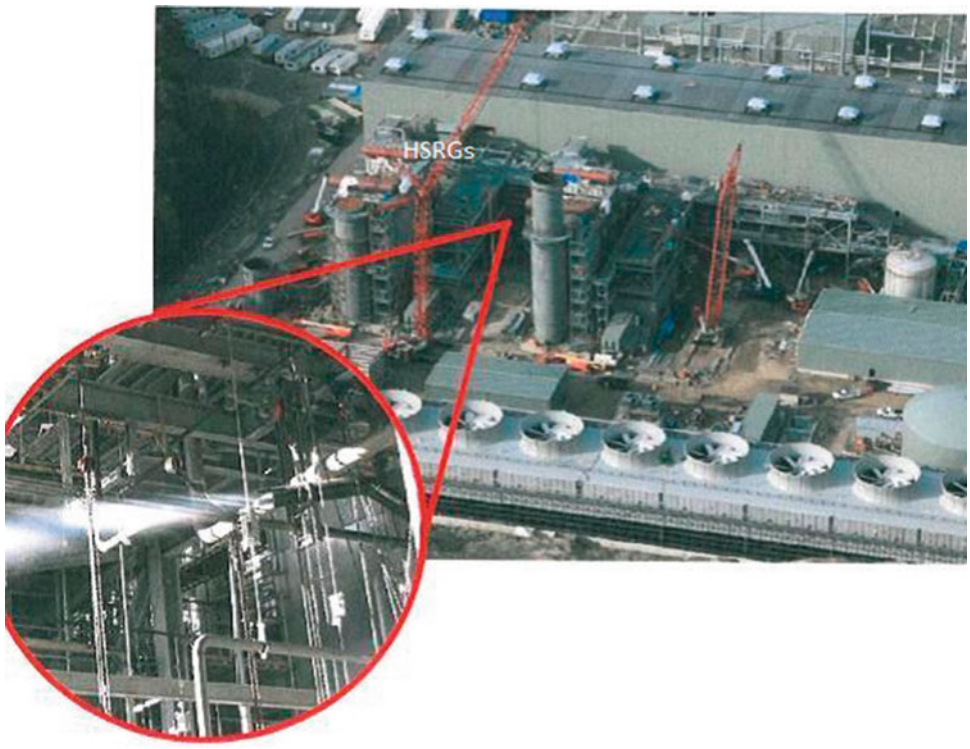

Fig. 69.20 Natural gas release sites in Kleen Energy explosion incident (From Chemical Safety Board Presentation)

cloud was ignited in the area of the Heat Recovery Steam Generators (HSRGs). The insert photo shows a similar gas release in the obstructed, semi-confined area between the two HSRGs. Assuming that the gas cloud volume within the area of the HSRGs is 7700 m^3, use the Baker-Strehlow-Tang method to estimate the vapor cloud explosion pressures that would be generated within the obstructed HSRGs. If the blast wave pressure at which about 10 % of windows are broken is 0.3 psig (0.021 barg), estimate the distance corresponding to this pressure for a vapor cloud explosion of the natural gas that accumulated in the HSRG area.

Solution Natural gas is composed primarily of methane, which is the prototype upper end of the Low Reactivity gas in the B-S-T method. The Confinement Level in this example is either 2-D or 2.5-D depending on whether there is some type of wall or barrier around the HSRGs at the time of the explosion. If we assume there was some type of soft or frangible wall, then this is a 2-D application. The Congestion Level can be estimated by making a rough estimate of the area blockage ratio of the structures and piping shown in the insert. This estimate is probably in the range 10–20 %, corresponding to either a Low or Medium Congestion level by comparison to the values in Table 69.6. A similar categorization would result from comparison of the insert photo to the diagrams in Fig. 69.19.

Looking at the Table 69.5 Mach Numbers for 2-D confinement and a Low Reactivity gas, we would specify 0.079 for Low Congestion and 0.47 for Medium Congestion. In view of the large difference in Mach numbers and the uncertainty in Congestion Categorization, the prudent approach would be to choose the Mach number of 0.47 to avoid a significant underestimate of blast wave pressures. Using this value of M_f in Equation 69.22, results in a calculated $(P_{max}–P_0)/P_0$ of 0.36. This corresponds to a $P_{max}–P_0$ of 5.3 psig, which is above the threshold for significant damage to steel panel industrial buildings. Indeed, the large power generation building behind the HSRGs in the photograph did suffer significant damage, as apparently did steel panels within the HSRGs.

Table 69.6 Congestion categories used in vapor cloud explosion tests

Congestion level	Obstruction pitch to diameter ratio	Obstruction area blockage ratio (%)	Volume blockage ratio (%)
Low	7.6	13	1.5
Medium	4.3	23	4.3
High	3.1	23	5.7

To determine the distance corresponding to a far-field blast wave pressure of 0.3 psig, we first calculate $(P–P_0)/P_0 = 0.3/14.7 = 0.020$. The corresponding value of $\bar{R}$ in Fig. 69.16 is found by interpolating between the $M_f = 0.35$ and $M_f = 0.7$ curves, i.e. between 5 and 10. The approximate result is $\overline{R} = 5 + (0.47 - 0.35) \times 5/(0.7 - 0.35) = 6.7$. The conversion from $\bar{R}$ to the actual distance R requires calculating the blast wave energy, $E = (7700\,m^3)\,(0.10\,m^3\,\text{methane}/m^3)*(0.71\,\text{kg–methane}/m^3\text{–methane})\,(50\,\text{MJ/kg} - \text{methane}) = 27.3\times 10^3\text{MJ}$. The methane density of 0.71 kg/m^3 is based on an assumed gas temperature of 0 °C (273 K) since there is substantial cooling of the gas blown down from a much higher pressure. The resulting R value is

$$R = 6.7\left(27.3 \times 10^9 J/1.01 \times 10^5 N/m^2\right)^{1/3} = 433\,m.$$

A value of R for $(P - P_0)/P_0 = 0.02$ can also be obtained from the acoustic approximation represented by Equation 69.25 at time $t >> R/a_0$. Using a value of $v_f = 0.47*340 = 160\,m/s$, and $R_f = (3*7700)/(4\pi)^{1/3} = 12.2\,m$, the calculated R is 332 m. Since the volume surrounding the HSRGs is shaped more like a box than a sphere, the choice of R_f would be different in the three directions, such that the largest R_f is about 33 m, and the corresponding value of R is about 930 m. This value is in better agreement with news media accounts of isolated window breakage in some homes away from the explosion site.

Dust Explosions

70

Robert Zalosh

Introduction: Dust Explosibility

Fine particulates of combustible materials can pose a dust flash fire hazard when dispersed as a cloud and ignited. If the suspended dust concentration is sufficiently high, a flame will propagate through the dust cloud. The dust flash fire hazard can escalate into a dust explosion hazard when there is confinement that restrains the dust laden air flow induced ahead of the propagating flame front such that potentially damaging pressures are developed.

For many materials, there is no doubt about whether the powder or dust form of the material is explosible. If a material is combustible in the sense that it poses a fire hazard, that material will also pose a dust explosion hazard if the characteristic particle size is less than roughly 500 micrometers (μm). However, the inverse is not necessarily true, i.e. some materials that do not normally pose a fire hazard can pose a dust explosion hazard. For examples, many metal dusts and powders can be oxidized rapidly enough when suspended in air to be explosible. Of course materials that are either already fully oxidized or inherently inert are neither combustible nor explosible.

Although 420–500 μm has been a traditional rule of thumb for the limiting particle size for a combustible material to also be explosible, the actual value depends on the material reactivity and the particle morphology. Weakly combustible materials such as polyvinyl chloride and iron need to be much smaller than 420 μm to be explosible, whereas test data for reactive materials such as stearic acid show they explosible at a median particle size greater than 1,000 μm ([1], p. 620). Elongated particles such as wood, paper fibers, and flock are also explosible even though their longest dimension is significantly larger than 1,000 μm.

Laboratory screening tests have been developed to determine whether a particular dust sample is explosible. The screening test described in ASTM E1226 [2] is now used by most commercial laboratories in the U.S. doing combustible dust testing. Figure 70.1 is a diagram of the test apparatus used in ASTM E1226 testing. The explosion test vessel has an internal volume of at least 20 L, and is either spherical or cylindrical with a length to diameter ratio of approximately 1. The vessel is equipped with electrically triggered pyrotechnic ignitors and pressure sensors to measure the explosion pressure development. Figure 70.2 is a photograph of a 20 l sphere in a commercial testing laboratory.

A pre-weighed dust sample is loaded into the dust container prior to the test. The explosion chamber is pre-evacuated so that the injection of the dust sample using compressed air will bring the test vessel pressure back to approximately 1 atm at the time of ignition. The dust is injected through the rebound nozzle shown at the bottom of the vessel in order to produce a near uniform distribution of dust at a concentration

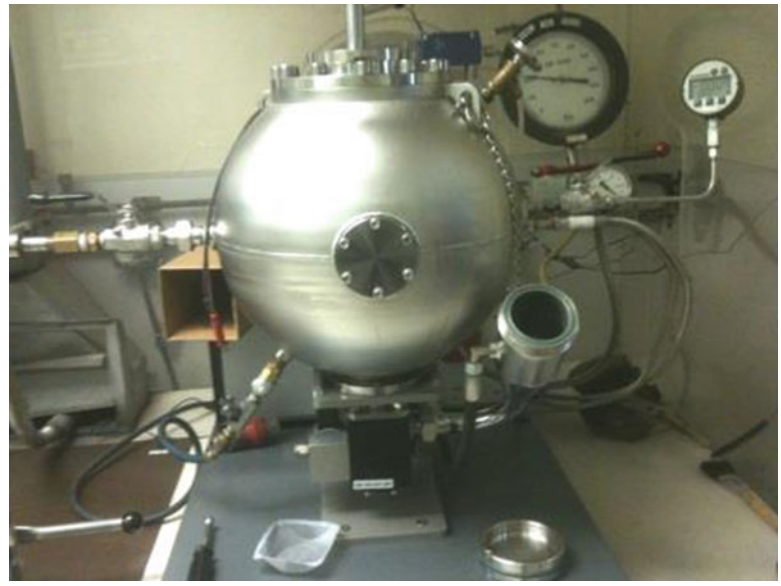

Fig. 70.2 20-l sphere test vessel

equal to the mass of the dust sample divided by the 20-l vessel volume. The time delay between the beginning of injection and ignition is an important parameter that is controlled by an automated timing circuit. The value of the time delay is selected by calibrating the test apparatus against benchmark data obtained for two particular dusts used in round robin tests.

Section 13 of ASTM E1226-10 specifies that screening tests be conducted using a 5 kJ or greater energy igniter and dust concentrations of 1,000 and 2,000 g/m^3. The dust samples are to have a moisture content no greater than 5 wt%, and usually have a particle size distribution corresponding to at least 95 wt% smaller than 75 μm. The test results are classified as combustible if either of the

two tested concentrations results in a pressure ratio, PR, greater than 2, where PR is defined as follows.

$$PR = \frac{P_{ex} - \Delta P_{ign}}{P_{ign}} \qquad (70.1)$$

where P_{ex} is the absolute explosion pressure measured for each concentration, P_{ign} is the absolute pressure in the vessel at the time the igniters are fired, and ΔP_{ign} is the pressure increase in the vessel due only to the firing of the igniter.

There are several variations of the ASTM E1226 screening tests. The Occupational Safety and Health Administration (OSHA) Salt Lake Tech Center's tests to determine if a dust sample is explosible are conducted with an igniter energy of 2.5 kJ, and a longer time delay than the ASTM testing. Comparison tests conducted in a 20-l sphere and a 1-m^3 test vessel have shown that ignition energies of 5 and 10 kJ in the 20-l sphere can sometimes cause over-driven explosions in the sense that the large ignition energies heat all the dust particles to the point that they start burning because of the igniter rather than because of flame propagation through the dust cloud [3]. The OSHA laboratory use of a 2.5 kJ igniter and the European standard (EN 14034-3) use of 2 1-kJ igniters avoid this problem. The European standard uses a minimum explosion pressure of 0.5 barg as the explosibility criterion, which corresponds to a pressure ratio of 1.3 in their tests [4]. After analyzing the effects of various ignition energies on the pressure ratios obtained for three different dust materials at various concentrations, Kua et al. [4] have concluded that there is an optimum ignition energy that produces neither over-driven explosions nor under-driven explosions in which too small a fraction of the dust is heated to produce flame propagation [4]. Their results indicate that the optimum ignition energy is 5–7 kJ for carbonaceous dusts that devolatilize before burning, and 2–5 kJ for metals that burn without vaporization.

Besides the choice of ignition energy used in testing, dust explosibility determinations can also depend on the selection and conditioning of the dust test sample. Dust composition may depend on the possible presence of contaminants in the sample or upon normal variations in composition due to variable process and feedstock conditions. Likewise the particle size distribution can be sensitive to the sample location, e.g. finer particles of fugitive dust usually settle upon surfaces at higher elevations than larger dust particles. In the case of metals, significant delays between sample acquisition and testing can result in particulate surface oxidation that can cause misleading negative results. Therefore, the choice of sample location and sample conditioning prior to testing are important considerations that can influence the results of explosibility determinations, as well as the deflagration parameter values described in the next section of this chapter.

Closed Vessel Deflagration and Ignition Parameters

The potential consequences of a dust explosion involving a particular material with a particular particle size distribution are best represented by the maximum explosion pressure, P_{max}, and the maximum rate-of-pressure-rise, $(dP/dt)_{max}$. The ISO 6184-1 [5] and ASTM E1226-10 test methods, which are virtually identical, are often used for such determinations. These methods have been developed on the premise that standardized testing and appropriate scaling laws can produce laboratory data that can be scaled up to much larger applications. Specifically, the value of P_{max} should be independent of test vessel size providing a minimum test volume of 20 l is used in a near spherical geometry. The value of $(dP/dt)_{max}$ is presumably inversely proportional to the characteristic vessel length scale, such that a material constant, K_{st}, is defined as:

$$K_{st} = (dp/dt)_{\max} V^{1/3} \qquad (70.2)$$

where $(dP/dt)_{max}$ is the maximum slope of the measured pressure versus time curve in tests in a vessel of volume V.

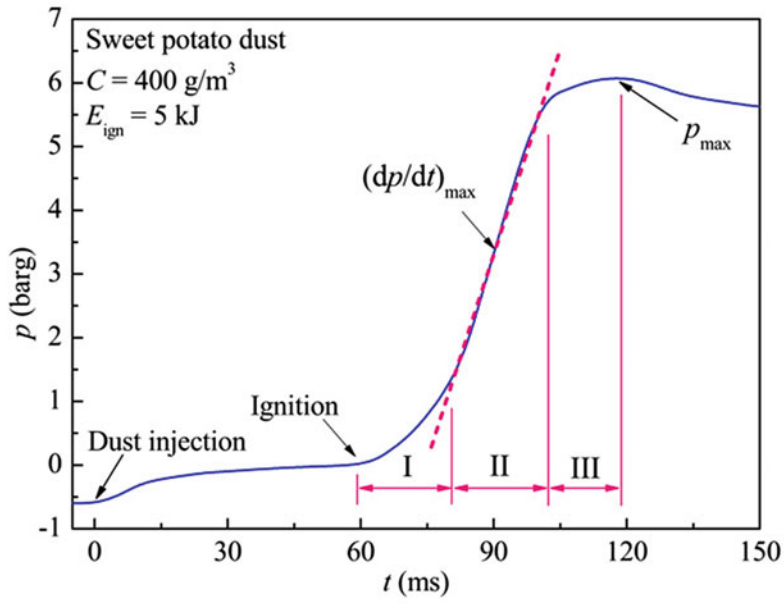

Fig. 70.3 Typical ISO 6184 test pressure transient (From Kuai et al. [4])

A typical ISO 6184-1 [5] transient pressure measurement is shown in Fig. 70.3. The vessel pressure gradually increases from about −0.6 to 0 barg as the dust sample is injected with the compressed air in the sample load chamber. After a 60 msec delay from the start of dust injection, the 5 kJ igniter is fired to start the beginning of the first period of the dust combustion process. During this first period, also called the induction period, the igniter is causing the burning of a sufficient number of dust particles to initiate flame propagation. The second period, also caused the period of steady state flame propagation, has a characteristic linear increase of pressure with time. This is the period in which $(dp/dt)_{max}$ is measured at the test concentration. The third period, which begins at the inflection point where the slope starts to decrease and ends at the time the maximum pressure occurs, might also be called the burnout period because the flame front has already reached the vessel wall and the dust behind the flame front is burning [4].

The ASTM E1226 and ISO 6184-1 test methods entail running three series of tests at varying dust concentrations, with measurements of the p_{max} and $(dp/dt)_{max}$ at each concentration. A typical set of results is shown in Fig. 70.4. In this set, the maximum pressure occurred at a concentration of 1,500 g/m^3 and the maximum rate-of-pressure rise occurred at a concentration of 1,000 g/m^3.

ASTM E1226 specifies that the value of P_{max} for the tested dust sample is calculated as the average of the three measured values for the three dust series after subtracting the pressure at ignition. The value indicated by the asterisk for the data in Fig. 70.4 is 6.6 barg. Similarly, the average of the three highest $(dP/dt)_{max}$ values shown in Fig. 70.4 is 480 bar/s. The corresponding value of K_{st} calculated using the 0.020 m^3 vessel volume is 130 bar-m/s.

Values of P_{max} and K_{st} for an assortment of combustible dust samples are shown in the last two columns of Table 70.1. The median dust particle size is listed along with the generic material.

Aluminum powder has the highest K_{st} value (515 bar-m/s) of the materials listed in Table 70.1, whereas aluminum shavings with a median particle size of 240 μm, are not even explosible. This illustrates the importance of particle size and morphology on dust explosion test parameter values. Most of the materials listed in Table 70.1 have a K_{st} value well below 200 bar-m/s. This is also true for the larger assortment of dust materials listed in Eckhoff's book [1].

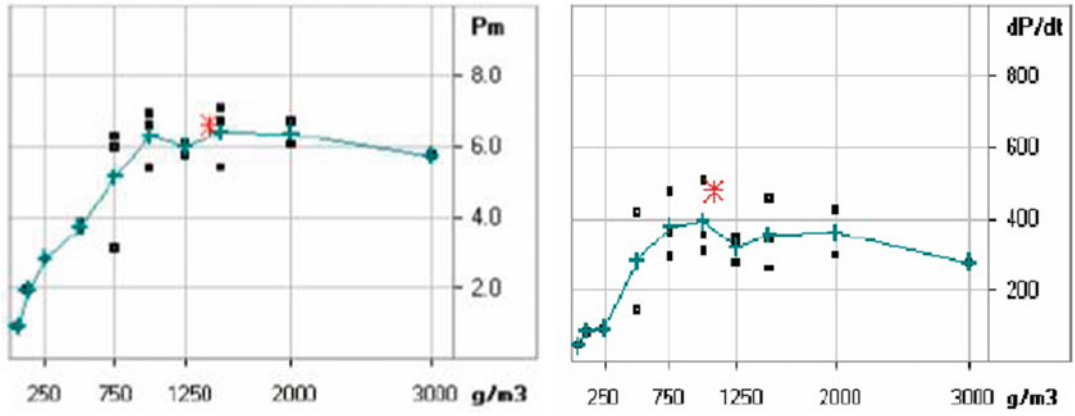

Fig. 70.4 Maximum pressure and maximum rate-of-pressure-rise versus dust concentration

Table 70.1 Explasibility data for representative powders and dusts[a]

Material	Median particle size (μm)	Minimum explosive concentration (g/m^3)	Min cloud ignition temp (°C)	Min layer ignition temp (°C)	Min ign energy (mJ)	P_{max} (bar g)	K_{ST} (bar-m/s)

[a]Data from R. Eckhoff, *Dust Explosions in the Process Industries*, Butterworth-Heinemann

[b]This MEC for polyethylene was determined in a 1.2 l cylinder

The Minimum Explosible Concentration (MEC) values listed in Table 70.1 are based on the same 20-l sphere standard test methodology described above. The ASME E1515 [6] determination of MEC entails conducting tests with lower and lower dust concentrations until the pressure ratio, PR, falls below 2, i.e. the same criterion as for dust explosibility. Preceding comments about the effects of the igniter energy and the turbulence level at ignition, as controlled by the time delay between dust injection initiation and igniter firing are also applicable to the MEC determination [4]. MEC values listed in Table 70.1 range from 15 g/m^3 for phenolic resin to 500 g/m^3 for iron dust.

When the dust concentration is significantly higher than the MEC, the P_{max} value is not sensitive to the characteristic particle size, but the K_{st} value does increase significantly with decreasing particle size. Since the particle size effect is due to the variation of particle surface area, the more general effect of particle size on rate-of-pressure-rise can be presented in terms of the particle surface area per unit mass. This effect is shown in Fig. 70.5 for aluminum particles, which often have flat or flake-like shapes.

Table 70.1 lists data for three dust ignitability parameters. The minimum dust cloud ignition temperature is determined by injecting dust samples into an oven, and repeating this test at various oven air temperatures [7]. The dust layer hot surface ignition temperature [8] is determined by placing a 1.27 cm deep layer of dust on an electrical hot plate, and slowly increasing the hot plate surface temperature until there is an indication of ignition either visually or from a thermocouple embedded in the dust layer. The dust cloud Minimum Ignition Energy (MIE) is determined in a 1.2 l cylindrical test apparatus equipped with spark electrodes energized by a circuit with adjustable voltage and/or capacitance, so as to produce adjustable spark discharge energies [9] generated upon injecting dust at varying concentrations into the test cylinder.

Dust cloud minimum ignition temperatures listed in Table 70.1 range from a low of 280 °C for sulfur to a high of 790 °C for activated carbon. Most values are in the much narrower range from 420 to 580 °C The value for a given material increases slightly with increasing dust characteristic particle size.

Most of the dust layer hot surface ignition temperatures listed in Table 70.1 are at least 100C lower than the corresponding dust cloud minimum ignition temperature. This is primarily due to the increased time available for the dust material to be heated to be heated to its ignition temperature. The dust layer ignition temperature test has a duration of 30 min, while the dust cloud ignition temperature test duration is effectively equal to the dust cloud settling time in the test chamber, which is usually on the order of a few seconds. The dust layer surface ignition temperature test is not applicable to thermoplastics since they melt and flow prior to ignition. One other pertinent ignition temperature test is the heated

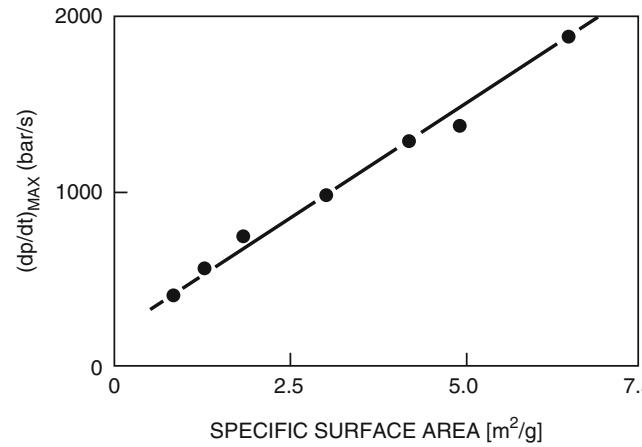

Fig. 70.5 Effect of specific surface area on $(dP/dt)_{max}$ (From Eckhoff [1])

air over dust layer. This test, which does not have an ASTM standard, usually produces ignition temperatures even lower than the dust layer surface ignition temperature because dust ignition usually occurs near the layer top surface (where there is ample oxygen to support ignition) and heating from below causes a decrease in layer temperature with elevation above the heated surface. The dust layer hot surface ignition temperature deceases with increasing layer thickness so that a safety margin is needed in establishing safe surface temperatures for equipment subject to layer accumulations deeper than the 12.7 mm thickness in ASTM E 2021, or the 5.0 mm thickness in IEC 61241-2-1 test method.

MIE data for the dust samples in Table 70.1 range from less than 1 mJ to more than 2,000 mJ. For a given material, the MIE is known to be influenced by the following parameters:

- The MIE decreases as the spark duration increases due to the presence of either inductance or resistance in the capacitive discharge circuit. For example, adding a series inductance in the range 0.1–1.0 H, or a series resistance in the range 10^4–10^5 Ω, decreases the MIE by an order-of-magnitude. The practical significance of this is that it takes more spark energy for an electrostatic (capacitive) discharge to ignite a dust cloud than for a spark in electrical equipment due perhaps to actuation of an electromechanical switch. The MIE data in Table 70.1 were obtained with long duration inductive discharges.
- The MIE decreases as the dust median particle size increases; Siwek and Cesana [11] show that the variation is to the −2.5 power of particle diameter.
- The MIE varies with dust concentration, but the most sensitive concentration depends on the particular material. The data in Table 70.1 are for the most sensitive concentration.
- The MIE decreases with increasing air-dust temperature.
- The MIE and the MIT increase with increasing velocity of the dust-air mixture such as might occur in a pneumatic transport piping or dust collection ducting.

The theoretical spark energy can be calculated for simple electrical discharges. For example, the energy (J) in a purely capacitive discharge is $½CV^2$, where C is the capacitance (farads), and V is the stored voltage prior to discharge. In the case of a purely inductive circuit, the theoretical spark energy is $½Li^2$, where L is the circuit inductance, and i is the current (A). The inductance spark energy can be compared directly to the MIE for a particular dust to assess the likelihood of ignition; the capacitive spark energy comparison should account for the higher ignition energies associated with short duration capacitive discharges. The energy associated with mechanical friction and impact sparks is much more difficult to determine.

Partial Volume Deflagrations in Equipment and Rooms

Since a suspended dust cloud is needed at a concentration above the measured MEC in order to have a dust deflagration, hazard assessments often entail estimating the average dust concentration in operating equipment. Although this type of estimate is applicable to powder and dust transport piping and ducts because there usually is a continuous near-uniform dust concentration in the pipe or duct, it is not applicable to equipment in which there is an inherently non-uniform suspended dust/powder concentration. One example of such equipment is the spray dryer shown schematically in Fig. 70.6.

The typical spray dryer consists of a large cylindrical upper chamber and a smaller conical lower chamber. Wet product sprayed through nozzles at the top of the dryer encounters a swirling heated air flow and gradually dries as it falls into the conical lower chamber. Dried product is removed at the bottom of the drier. The outlet air flow often contains fine particulates which are often removed in a dust collector. If the product is a combustible powder, dust explosion hazards exist in both the drying chamber and the dust collector.

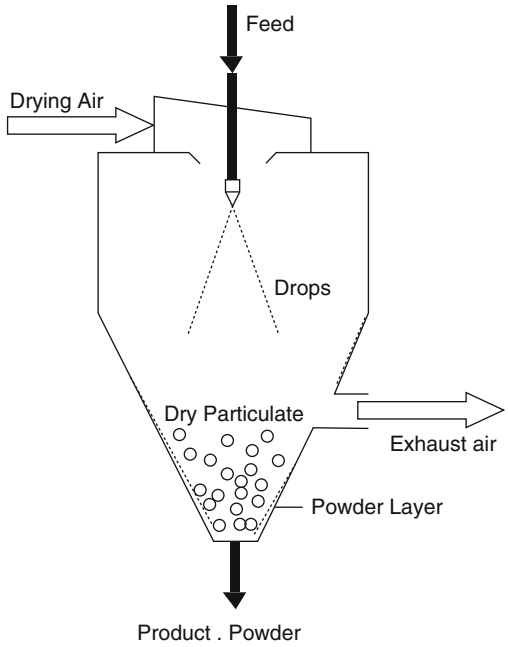

Fig. 70.6 Simplified spray dryer diagram

Siwek et al. [12] have conducted powder concentration measurements in various operating spray dryers. Their results for three different products show that the concentration decreases with distance above the dryer outlet such that concentrations above the MEC only exist in the lower section of the dryer. The average concentration in that region is reported to be less than 100 g/m^3. Similarly, the dust concentration in baghouses is highly non-uniform with the maximum concentrations occurring near the bags when they are pulsed. However, in both the spray dryer and the baghouse, there are often substantial layers of dust/powder on the walls and, in the case of the baghouse, on the filter bags. Tests conducted by Siwek et al. [12] in a vented spray dryer with and without dust layers showed that the dust layer can cause the pressure in the vented explosion to be 3–4 times as high as the same explosion in a dryer without any dust layer.

In view of the highly non-uniform nature of the dust in process equipment and the common occurrence of dust layers on the equipment surfaces, the NFPA 654-2013 standard [13] has the following criteria to determine if a dust explosion hazard exists in process equipment. According to paragraph 6.1.7 of NFPA 654-2013, an explosion hazard exists if there is a sufficient quantity of combustible dust to cause equipment rupture if the dust is suspended and ignited, and if there is a means of suspending the dust within the equipment. These conditions do in fact exist in most spray dryers, baghouses, and many other process equipment.

The pressure developed in a partial volume closed vessel dust explosion can be estimated by assuming that the dust concentration in the partial volume is equal to the worst case concentration, c_w, corresponding to the measured P_{max} value for the dust material, and that the flame propagates through the dust cloud until it reaches the perimeter of the dust cloud. This hypothesis leads to the following equation for the unvented enclosure partial volume pressure, P_{pv}.

$$P_{pv} = P_{\max}\frac{m_{dust}}{V\ c_w} \tag{70.3}$$

where V is the equipment total volume, and m_{dust} is the mass of suspended dust and suspendable layered dust, i.e.

$$m_{dust} = m_{susp} + \eta\ m_{layer} \tag{70.4}$$

The nomenclature for Equation 70.4 is m_{susp} is the mass of dust normally in suspension in the equipment, m_{layer} is the mass of accumulated dust in layers within the equipment, and η is the fraction of layered dust that can be lifted either due to some disturbance or to the initial flame propagation following ignition of the suspended dust.

The partial volume calculation approach represented by Equations 70.3 and 70.4 has been incorporated into NFPA 654 [13] for the determination of the maximum allowable amount of accumulated dust in a room or building such that a partial volume deflagration will not produce a pressure than can damage or blow out a portion of the room/building walls or ceiling. Section 6.1 of NFPA 654-2013 requires that a facility dust

explosion hazard area assessment be conducted with one of four alternative methods for calculating the maximum allowable accumulation. The most general of the four methods has the following equation for the maximum allowable amount of dust, M_{exp}, in a room or single dust hazard area based on pressure produced from a partial volume explosion not exceeding the enclosure strength.

$$M_{\exp} = \left[\frac{P_{es}}{DLF}\right] \cdot \left[\frac{C_w}{P_{\max}}\right] \cdot \frac{A_{floor} \cdot H}{\eta_D} \qquad (70.5)$$

M_{exp} = threshold dust mass kg based on building damage criterion

P_{es} = enclosure strength evaluated based on static pressure for the weakest building structural elements not intended to vent ot fail (bar g) per NFPA 68

DLF = dynamic load factor, the ratio of maximum dynamic deflection to static deflection per NFPA 68

C_w = Worst-case dust concentration (Kg/m3) at which the maximum rate-of-pressure-rise results in tests conducted per ASTM E 1226

P_{max} = maximum pressure (bar g) developed in ASTM E 1226 tests with the accumulated dust sample

A_{floor} = enclosure floor area (m2)

H = enclosure ceiling height (m)

ν_D = entrainment fraction = 0.25

A conservatively high value of 1.5 for the Dynamic Load Factor can be used in lieu of structure dynamic response analysis. When and if the accumulated mass of combustible dust in the room or area exceeds M_{exp}, NFPA 654-2013 section 6.1 requires that the dust be cleaned or that building deflagration venting be implemented to prevent the deflagration pressure from reaching the enclosure strength. There is also a flash fire hazard evaluation equation to determine when and if a flash fire hazard exists due to the potential lifting and ignition of a fraction, η_D, of the accumulated combustible dust.

EXAMPLE 1 Calculate the partial volume deflagration pressure in a powdered milk spray dryer with a suspended powder concentration of twice the powder MEC in the conical section of the dryer and a 3 mm layer of powder on the cone interior surface. The dryer cylindrical section is 6 m in diameter and 5 m high, and the conical section is 4 m high. The bulk density of the powder milk layer is 300 kg/m^3, the worst case dust concentration is 750 g/m^3 and a layer entrainment coefficient of 0.25 can be assumed.

SOLUTION The dryer volume is equal to $\pi\,(6)^2(5)/4 + \pi\,(6)^2\,(4)/12 = 141\ \text{m}^3 + 37.7\ \text{m}^3 = 179\ \text{m}^3$. The cone surface area is equal to $\pi\,(6/2)\quad (4^2 + 3^2)^{1/2} = 15\pi = 47.1\quad \text{m}^2$. From Table 70.1, the MEC for powdered milk is 60 g/m^3, so the concentration of suspended powder ignited in the conical section of the dryer is 120 g/m^2. From Equation 70.4,

$$m_{dust} = (0.120\ \text{kg/m}^3)(37.7\ \text{m}^3) + 0.25(300\ \text{kg/m}^3)(0.003\ \text{m})(47.1\ \text{m}^2) = 15.1\ \text{kg}$$

P_{max} for milk powder (from Table 70.1) = 8.1 barg. The volume fraction of milk powder in the dryer is

$m_{dust}/(c_w V) = 15.1\ \text{kg}/[(0.75\ \text{kg/m}^3)\,47.1\ \text{m}^3] = 0.113$. From Equation 70.3, $P_{pv} = 8.1(0.113) = 0.92$ barg.

This value of P_{pv} is comparable or higher than the strength of many spray dryers. A still higher value would have resulted from use of a higher layer entrainment coefficient or consideration of accumulations higher in the dryer. Therefore, explosion protection is probably needed.

EXAMPLE 2 A wood cabinet manufacturing plant has a 60 m by 40 m room for cutting chipboard panels. The room, has a 7 m ceiling supported by steel beams which will fail at an internal pressure on the roof panels of 75 lb/ft^2 = 0.036 bar. Chipboard dust samples have undergone ASTM E 1226 explosibility tests that resulted in a P_{max} of 9.2 bar and a worst-case suspended dust concentration of 600 g/m^2. What is the maximum allowable mass accumulation of sawdust in the room? Assuming that this accumulation occurs over 10 % of the floor area, and the sawdust bulk density is 218 kg/m^3, what is the maximum allowable accumulated dust layer thickness.

SOLUTION Substitution of the given parameter values into Equation 70.5,

$$M_{\exp} = \frac{(0.036\ bar)\left(0.60\frac{kg}{m^3}\right)(60m)(40m)(7m)}{1.5(9.2\ bar)(0.25)}$$
$$= 105\ kg$$

The corresponding maximum allowable dust layer thickness is equal to $M_{exp}/(\rho_b A_{dust})$ = 105 kg/[(218 kg/m^3) (0.10) (2400 m^2)] = 0.002 m = 2 mm. An alternative maximum dust layer thickness criterion in NFPA 654-2013 paragraph 6.1.3.1 for this material is 0.8 mm (1200 kg/m^3)/(218 kg/m^3) = 4.4 mm. However this layer thickness is only allowed over a maximum of 93 m^2 of floor area. Since the dust in the room accumulates over a 240 m^2, the allowable thickness must be scaled down to 4.4 mm (93 m^2)/(240 m^2) = 1.7 mm, which is very close to the 2 mm maximum allowable layer thickness calculated above from the value of M_{exp}.

Dust Explosion Propagation Phenomena

The dust explosion propagation process through a cloud of particles at a concentration above the MEC has some similarities and important differences from the corresponding process for a flammable gas mixture. As with flammable gas flame propagation, the flame heats the unburned fuel ahead of it to its ignition temperature, and the rate of flame propagation is governed by the rate of heat transfer and the fuel combustion reaction time. Similarly, the expansion of the burned gases due to its flame temperature induces a flow of the fuel-air mixture ahead of it.

One important difference between dust and gas flame propagation is that the dust combustion zone or flame thickness is significantly larger, being at least 10–100 mm [1] because the time scale for the dust particle to burn completely is usually significantly larger than the gas combustion reaction time. The dust combustion time scale depends on the dust particle combustion mechanism. Many dust materials undergo pyrolysis and devolatilization prior to combustion. Other materials, such as most combustible metals, undergo a combustion reaction at their surface. The rate of the combustible metal surface reaction depends on the rate of gaseous oxygen diffusion through the surface oxide layer.

Another difference between dust and gas flame propagation is that the dust flame is almost always turbulent with an irregular apparent flame surface that can be a collection of mini flames associated with the burning of individual particles or groups of particles. Figure 70.7 is a schematic representation of the turbulent dust flame propagation process showing the relative velocities of the flame, and the dust particles and air ahead of the propagating flame.

The flame heat transfer to the unburned dust particles is predominantly by flame radiation, as opposed to the convection and conduction associated with flammable gas flame propagation. Flame radiation is enhanced in the case of combustible metals with high flame temperatures reported by Cashdollar and Zlochower [14].

The air velocity induced ahead of a propagating dust explosion will lift at least some of any settled dust on the floor ahead of the flame. This phenomenon is illustrated in Fig. 70.8, which also shows a non-uniform cloud of lifted dust particles in front of the propagating flame.

In the case of dust explosion propagation down a gallery or duct, several test programs have been conducted to determine the minimum

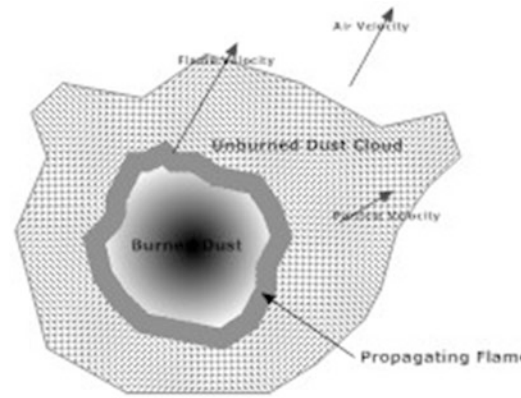

Fig. 70.7 Dust flame propagation schematic

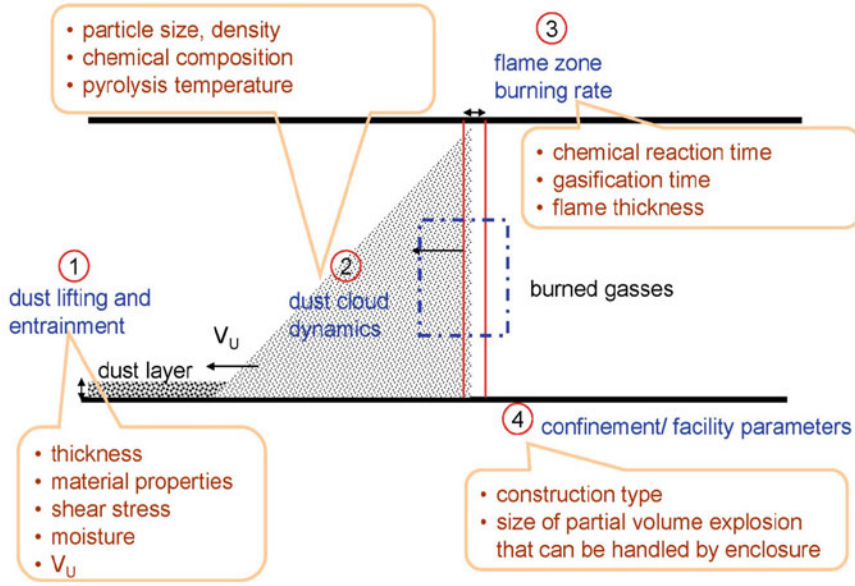

Fig. 70.8 Lifted dust forms cloud ahead of propagating flame (From A. Rangwala 2011)

dust layer equivalent concentration (dust loading per unit gallery length divided by gallery cross-sectional area) that will support the continuing propagation of a dust explosion initiated at one end of the gallery/duct. This question is critical to assessing the amount of accumulated dust needed for dust explosion propagation in coal mines and grain elevator conveyor galleries. Lebecki et al. report [15] that the minimum corn starch concentration required for explosion propagation in a 100 m long, 2 m diameter, gallery is 75 g/m^3 when a methane explosion initiates propagation, and 50 g/m^3 when the initial methane explosion is enhanced with an extra load of grain dust near the initiation site. When the equivalent accumulated corn starch concentration is 150 g/m^3 or greater, the flame accelerates and the peak pressure increases with distance away from the explosion initiation site. Flame speeds for the 150 g/m^3 dust loading reached 330 m/s at the far end of the gallery, and peak pressures reached 4 barg. Significantly higher flame speeds and pressures were measured for tests with a dust loading of 200 g/m^3. Dust-free gallery segments 20 m in length did not prevent flame propagation to the downstream dust laden remainder of the gallery.

Tamanini reported [16] on corn starch explosion propagation tests in 6 m length and 24.4 m length galleries with a larger cross-section primary explosion chamber attached to one end and open to the atmosphere at the other end. Flame propagation down the length of the galleries was observed in all tests with floor dust loadings as low as 50–77 g/m^3, but the flame only occupied the lower one third of the gallery cross-section, and there was no increase in explosion pressure with distance along the gallery. When baffles (flow obstructions) were installed in the gallery, the entrained dust cloud and flame extended to the gallery ceiling.

Another type of dust explosion propagation application is the propagation from one enclosure to another via a connecting pipe or duct. This is a common configuration both in powder production facilities and in facilities with dust collectors connected to dust generating equipment. An explosion in one vessel produces a pressure and temperature increase in the second vessel, such that an explosion in the second vessel will be initiated at a higher temperature and pressure than the initial explosion. This is sometimes called pressure piling. The resulting pressure of the second explosion

can be significantly higher than the P_{max} values measured in single vessel standard tests such as the ASTM E1226 tests, particularly when the second vessel is smaller than the first vessel.

Lunn et al. [17] presented test results and theoretical calculations demonstrating the increase in pressure in the second vessel when the ratio of the second vessel volume to the first vessel volume is less than 4. When the ratio is less than 0.5, the second vessel explosion pressure could be greater than twice the P_{max} value measure in standard 20-l sphere tests. Lunn et al. found that the diameter and length of the interconnecting pipe did have a significant effect on whether the flame from the first vessel would propagate into the second vessel to ignite the suspended dust cloud there. Explosion propagation was not observed in small pipe diameters (15 cm and less) with lengths of at least 5. CFD simulations conducted by Kosinski and Hoffman [18] showed that the percentage of still burning dust particles entering the second vessel was less than 20 % for a duct height of 15 cm, but was at least 75 % for a 50 cm high duct. Thus, explosion propagation between enclosures is more likely when the explosion is initiated in the larger enclosure, and when the interconnecting pipe or duct is greater than approximately 15 cm. Additional observations are presented in the section on explosion isolation.

Secondary Dust Explosion Hazards

Most of the serious injuries and fatalities resulting from dust explosions occur when a primary explosion in some type of process equipment produces a blast wave and burning dust cloud in an area occupied by personnel. The casualties can be great if fugitive dust near the primary explosion is lifted and ignited so as to produce either a large flash fire or a secondary dust explosion. Examples of combustible dust incidents where this has occurred are listed in Table 70.2. The incidents listed in Table 70.2 are described in the Chemical Safety Board's 2006 combustible dust incidents survey report [19] and Imperial Sugar incident report [20]. In many of these incidents victims were situated far away from the primary explosion, but there were extensive fugitive dust accumulations that extended far beyond the area of origin.

The initiating explosion blast wave causes an air velocity that decreases with distance from primary explosion site. Fugitive dust will be lifted if the air velocity exceeds a threshold value, U_t, that Ural [21] has approximated with the following simple equation.

$$U_t = 0.46\ \rho_p^{1/3} \tag{70.6}$$

where ρ_p is the dust particle density (kg/m^3) and U_t is in m/s. The mass flux of dust entrained

Table 70.2 Examples of dust explosion incidents with secondary dust explosions or flash fires

Type of plant	Primary explosion location	Combustible dust for secondary explosion or flash fire	Injuries	Fatalities
Textile mill	Flocking machinery	Nylon fibers	37	0
Power plant	Boiler	Pulverized coal	36	6
Iron foundry	Gas-fired oven	Phenolic resin	9	3
Rubber recycling	Dryer & bagging bin	Rubber	7	5
Rubber compounding	Space above suspended ceiling	Polyethylene	38	6
Acoustic insulation	Curing oven	Phenolic resin	37	7
Sugar refinery	Belt conveyor	Sugar	36	14

locally into the air flowing at velocity U is given by the following equation in the Research Foundation report [21].

$$m'' = 2\rho_a U \left(U^{\frac{1}{2}} - \frac{U_t^2}{U^{\frac{3}{2}}} \right) \qquad (70.7)$$

where m'' is in g/m^2-s, ρ_a is ambient air density (1.2 kg/m^3), and U and U_t are in m/s. These equations can be used for a scenario specific calculation of the local dust layer mass fraction entrained, as an alternative to using the NFPA 654 default value of 0.25 described previously.

Since many combustible metals have large bulk densities and high flame temperatures and P_{max} values, the allowable accumulation thicknesses based on Equation 70.5 and the NFPA 654-2013 equivalent for flash hazards are very thin. The NFPA Combustible Metals standard [22] does not allow any dust accumulation for certain extremely explosible metals such as magnesium. This implies immediate cleanup of any visible dust. NFPA 484 and NFPA 654 and the other NFPA combustible dust standards describe recommended cleanup methods to minimize the chances of creating a dust cloud and/or introducing an ignition source during cleanup. These measures include the use of portable vacuum cleaners certified for use in Class II (combustible dust) hazardous locations, which implies that they have been tested to verify that they are dust-ignition-proof for the particular combustible dust category (Group E, F, or G) for which they are listed. Of course, hand shoveling and sweeping are also viable cleaning methods. The NFPA Guide to Combustible Dusts [23] has descriptions and examples of the various recommended combustible dust cleaning equipment and tools.

Other important aspects of reducing the secondary dust explosion/fire hazard are training of personnel and development of documented cleaning schedules and reports. FM Loss Prevention Data Sheet 7-76 [24] states that a rule of thumb is to use a dust thickness of 1.6 mm (1/16th inch or the thickness of a quarter coin) is cause for cleanup of many dusts with bulk densities similar to that of wood. It also provides guidance on estimating the amount of surface area that may have accumulations of at least this depth, so that a dusty area in excess of 5 % of the room floor area would be a cleanup trigger. The NFPA Guide [23] includes examples of housekeeping data collection sheets to be completed and signed by plant personnel or contractors. It also has an example of a tabulated fugitive dust collection report showing the amounts of dust cleaned in various plant areas.

Dust Explosion Scenario Examples

Various categorized tabulations of dust explosion incidents, such as those in FM Data Sheet 7-76 [24] and the CCPS Guidelines for Powders and Bulk Solids [25], show that the equipment involved in many incidents include dust collectors, hammermills and similar size reduction equipment, storage silos and attached product conveying equipment, and ovens and dryers. Examples of dust cloud formation and ignition scenarios in this equipment are presented here.

In the case of the spray dryer shown schematically in Fig. 70.6, the hottest areas are the nozzles and walls in the upper section of the dryer. The hot air surrounding the nozzles often enters the dryer at a temperature above the powder hot surface ignition temperature or the hot air over layer ignition temperature so that product accumulations on the spray nozzles and the upper wall area are heated sufficiently to initiate burning of the accumulated product. If the burning product in the upper section of the dryer is lodged, it will fall toward the conical region where there may be a sufficient suspended dust cloud concentration to support a partial volume deflagration. The deflagration can then propagate to downstream process and dust collection equipment and cause other fires and explosions in that equipment.

Rotating drum dryers have also been the site of dust explosions and flash fires. Some of these incidents have occurred because of the inadvertent recycling of already dried product. This is particularly hazardous in direct fired dryers where the internal temperature can be above the

dust cloud auto-ignition temperature. In the case of steam tube dryers, the tubes can be dried product accumulation sites with hot surface temperatures above the dust layer hot surface ignition temperature.

Grinders, hammermills, and other size reduction equipment inherently dissipate large energy inputs required to break up the particles. This energy dissipation inevitably causes heating of the particles and metal surfaces. One scenario that produces particularly high temperatures is the inadvertent entrance of tramp metal into the mill. High concentration powder/dust clouds are an inherent result of hammermill operation, and they can be readily ignited by the hot hammer surface.

Figure 70.9 shows evidence of the frictional or impact heating of hammers in a hammermill used to produce powdered sugar. The heating of sugar and metal in that vicinity of the mill ignited a sugar dust explosion that burned the hammermill operator who was responding to the sound of severe vibration due to tramp metal or a broken hammer in the mill.

Recommendations in the CCPS Guidelines book [25] for preventing grinder/pulverizer dust explosions include monitoring the mill motor current and having an interlock shutdown upon high current draw, use of magnetic separators to find and remove tramp metal before it enters the mill, and use of special enclosed mills to allow inerting of powders with extremely low MIE and AIT values.

Possible reasons for the high occurrence of dust collector explosions are (1) they are almost always in particulate handling facilities, (2) they inherently concentrate the smaller particles which are easier to ignite than the mostly larger particles in other equipment, and (3) by being downstream of other process equipment they

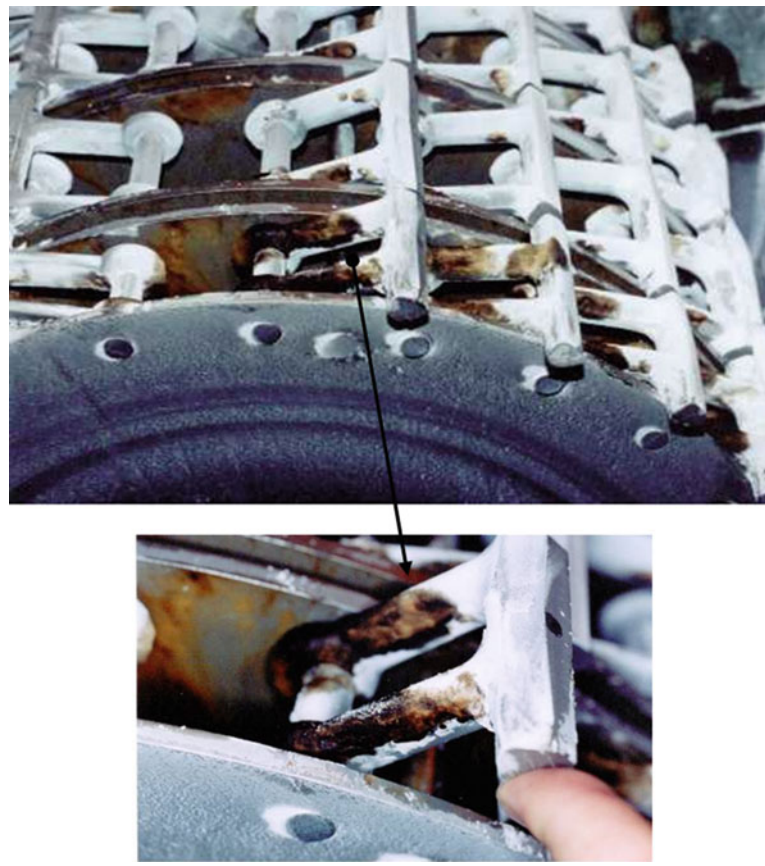

Fig. 70.9 Evidence of scorch marks in a sugar hammermill

often receive transported ignition sources as well as dust. Data from a German compilation of dust explosions cited by Eckhoff [1] indicate that the most frequent ignition sources have been mechanical sparks (41 %), burning embers and particle agglomerations (11 %), electrostatic discharges (10 %), and mechanical heating via friction (7 %).

Zalosh et al. [26] describe a dust explosion that occurred when some steel bolts accidentally entered and became trapped in a hammermill such that they became sufficiently hot to ignite the pharmaceutical powder in the mill. When the burning powder was conveyed to the dust collector, it ignited an explosion when the bags were pulsed. Other dust collector explosions described by Zalosh et al. [26] involved electrostatic discharge ignitions due to electrostatic charging of powder (tantalum) in one case and an ungrounded drum under the collector hopper in another case.

Figure 70.10 shows the burned and ruptured ducting attached to a roof mounted cyclone dust collector that was the site of an explosion due to burning fine particulate resulting from a fire in a rotating drum dryer upstream of the cyclone. The return air duct from the cyclone allowed the explosion to propagate back into the process building where it caused a secondary dust explosion.

Several dust collector explosions occur during maintenance and repair operations. One example is the double fatality explosion that occurred when a pipefitter was attempting to clear a clogged rotary valve at the outlet of a cyclone collector at an aluminum powder production facility [26]. Another example is the aluminum cuttings fire in abandoned dust collection ducting that had not been cleaned and checked before starting hot work to cut down the ducting. The discharge of a Halon fire extinguisher onto the burning aluminum cuttings caused an explosive reaction that resulted in a fatality.

A coal dust explosion occurred in a dust collector that was shut down to replace broken dry pipe sprinkler piping in which water inadvertently entered during a period of extremely cold weather. Scaffolding had to be erected in the dust collector hopper to reach the broken piping above the hopper. Vibrations caused by the

Fig. 70.10 Evidence of dust explosion and fire in cyclone collector and ducting

Fig. 70.11 Dust collector hopper in which coal dust explosion occurred

erection of the scaffolding caused dust to be dislodged from the many bags above the hopper, and the descending dust cloud was ignited by a halogen light bulb. Figure 70.11 shows the 28-in. (71 cm) diameter access opening in the hopper through which the injured scaffolding crew had to escape. Portions of some dust collector bag cages and some scaffold piping, as well as a pile of burned coal dust, are visible inside the hopper.

Other examples of dust explosion scenarios can be found in various Chemical Safety Board reports [19, 20] and British Health and Safety Executive reports.

Dust Explosion Venting and Suppression

The two most common forms of dust explosion protection for equipment are deflagration venting and suppression systems. The actions associated with both protection measures are initiated after the dust cloud starts burning in the enclosure and are intended to prevent the explosion pressure from reaching the enclosure damage threshold pressure. In the case of explosion venting, the protection action is the sudden opening of a vent closure to allow burning and unburned dust and combustion products to be vented at a rate sufficient to prevent damaging pressures from developing. In the case of explosion suppression systems, an extinguishing agent is rapidly injected into the enclosure so as to prevent additional burning of the dust cloud.

NFPA explosion venting design, installation, and maintenance requirements are described in NFPA 68 [27]. The NFPA 68 minimum required vent area, A_v in units of square meters, is calculated from the following basic equation.

$$A_v = 1 \times 10^{-4} \left(1 + 1.54 {P_{stat}}^{4/3}\right) K_{ST} V^{3/4} \sqrt{\frac{P_{max}}{P_{red}} - 1} \tag{70.8}$$

where

P_{stat} is the vent deployment pressure (bar g) in response to a slowly increasing (static) pressure,

V is the enclosure volume in m^3,

P_{red} is the reduced pressure (less than P_{max}) in the enclosure because of venting. NFPA 68 specifies that the value of P_{red} shall be no greater than 2/3rd the enclosure strength based either on incipient permanent deformation or actual enclosure (structural member) rupture, at the discretion of the facility owner.

In the limit of P_{red} approaching P_{max}, the vent area calculated from Equation 70.8 approaches zero because no venting is needed to prevent enclosure damage. In the other limit of $P_{red} << P_{max}$, the vent area varies as $1/\sqrt{P_{red}}$, which is the limit corresponding to incompressible gas flow through the vent.

Equation 70.8, which is applicable to compact enclosure with $L/D \leq 2$, and lightweight vent disks/panels, was developed by the NFPA Explosion Protection Technical Committee as a modification of a similar analytical approach to dust explosion venting derived by Tamanini and Valiulis [28] for FM Global applications.

The original development of the 2002 version of Equation 70.8 is described by Ural [29]. The coefficients and exponents in Equation 70.8 are empirical values selected to obtain agreement with large-scale dust explosion venting test data.

The test data used to refine and validate Equation 70.8 come from several European test programs in a variety of test vessels with a variety of combustible dusts. Since the dust concentration and turbulence level in the enclosure at the time of ignition significantly affect the rate of burning and associated rate-of-pressure-rise, the dust cloud generation and ignition in almost all these tests were set up to match the corresponding dust K_{ST} values measured in 1-m^3 and 20-l standardized closed vessel laboratory tests. The level of agreement between calculated values of A_v to obtain the P_{red} value measured in the tests with a given A_v is shown in Fig. 70.12. Test series 1 indicated in Fig. 70.12 was conducted in a 18.5 m^3 vessel with dusts having a range of K_{ST} values from 144 to 630 bar-m/s. Test series 2 was conducted with several different test vessels ranging in volume from 2.4 to 250 m^3, and with dusts having K_{ST} values in the range 206 to 322 bar-m/s. Test series 3 was conducted in a 10 m^3 test vessel using dusts with K_{ST} values between 130 and 280 bar-m/s. Thus, Equation 70.8 calculated results have been checked against dust with moderate to high K_{ST} values, but not yet with low K_{ST} dusts.

Vent areas calculated using Equation 70.8 are increased per NFPA 68 prescriptions for the following conditions: (1) large enclosure length-to-diameter ratios, (2) heavy vent panels, and (3) vent ducts used to direct the burning dust out of the building in which the equipment is located. The prescriptions for the first two factors are based on empirical correlations, whereas the vent duct vent area increase is based primarily on the pressure drop due to the vent flow in the vent duct.

NFPA 68-2013 has a provision for using less explosion vent area when the worst-case explosion scenario involves a dust cloud in only part of the enclosure volume. The ratio of the partial volume vent area to the full volume vent area is calculated from the following equation.

$$\frac{A_{pv}}{A_v} = X_f^{-1/3}\sqrt{\frac{X_f - \Pi}{1 - \Pi}} \quad \text{for} \quad X_f > \Pi\,, \tag{70.9}$$

where A_{pv} is the vent area required for a partial volume deflagration,

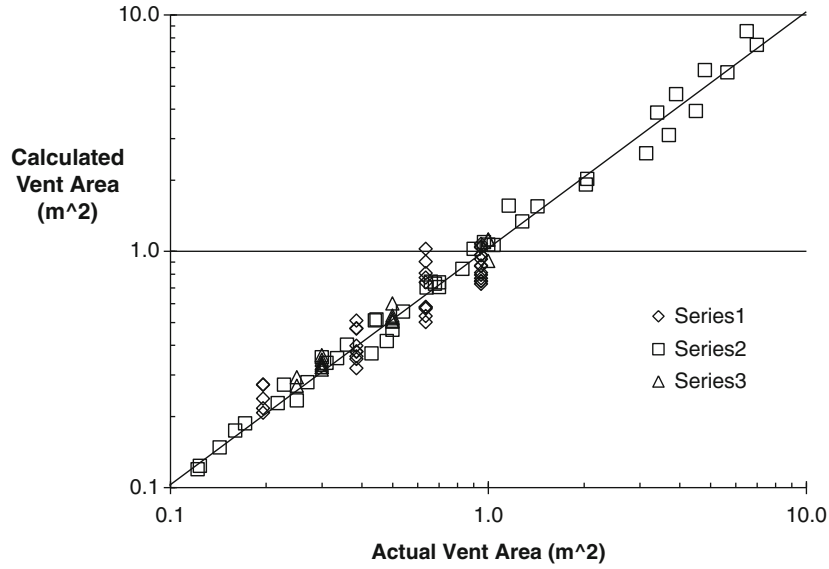

Fig. 70.12 Comparison of calculated and actual dust explosion test vent areas

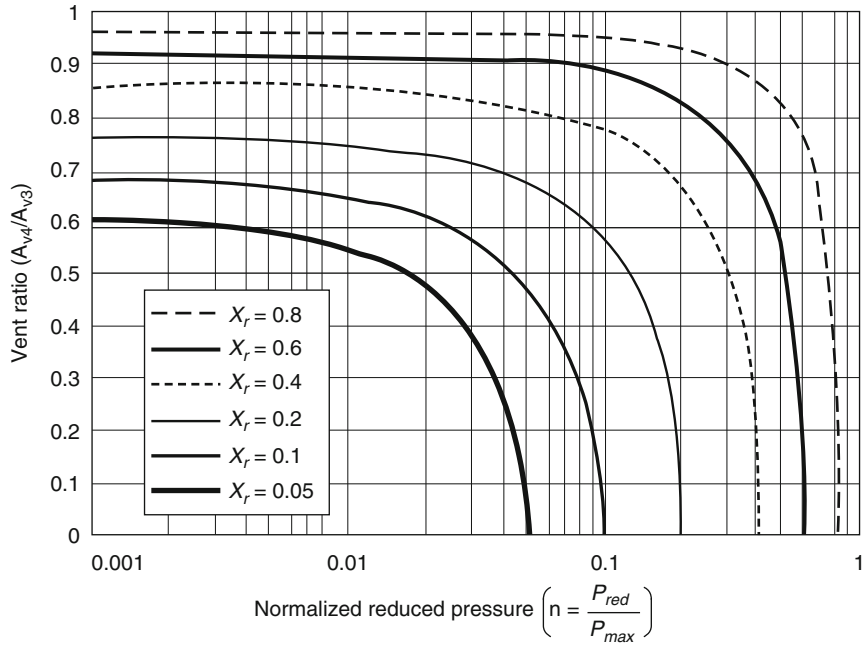

Fig. 70.13 Partial volume explosion vent area ratio versus P_{red}/P_{max} (From NFPA 68)

A_v is the vent area calculated from Equation 70.8 and any increase for enclosure L/D and vent panel mass,

X_f is the partial volume fill fraction in the enclosure,

$\Pi = P_{red}/P_{max}$.

As in Equation 70.3, the partial volume to be used in Equation 70.9, is m_{dust}/c_w, where m_{dust} is determined by Equation 70.4. Figure 70.13 shows the ratio A_{pv}/A_v, as a function of the pressure ratio, P_{red}/P_{max}, for various values of the partial volume fill fraction, X_f. The ratio is greater than 0.90 for pressure ratios less than about 0.1 combined with X_f values greater than 0.5. As the fill fraction tends toward Π, the required vent area decreases sharply toward zero since no venting is needed when $X_v \leq \Pi$. Some of the applications in which the partial volume approach is explicitly permitted per NFPA 68 are spray dryers (where the partial volume is based on measurements) and building dust explosions. The use of partial volume explosion venting is particularly advantageous for buildings because NFPA 68-2013 requires a 70 % increase in the vent area calculated from Equation 70.8 to account for potential secondary dust explosion scenarios with flame jet ignition of dust clouds generated from the primary explosion.

Although flameless explosion vents are now available for dust explosion protection, an explosion suppression system often becomes more pragmatic when explosion protection is required for equipment located far from an external wall or for materials that cannot be vented outside. The conceptual design of an active explosion suppression system is illustrated in Fig. 70.14. The three primary components of the system are (1) a pressure detector, (2) a control panel, and (3) one or more suppressant agent discharge containers. An incipient explosion is detector by the pressure sensor and the control cabinet actuates the high-speed discharge of suppression agent from the agent container(s). The component actuation times shown in Figure are just examples since the actual actuation times depend on the application, particularly the rate of explosion pressure rise.

One of the primary suppression system design considerations is the choice and quantity of

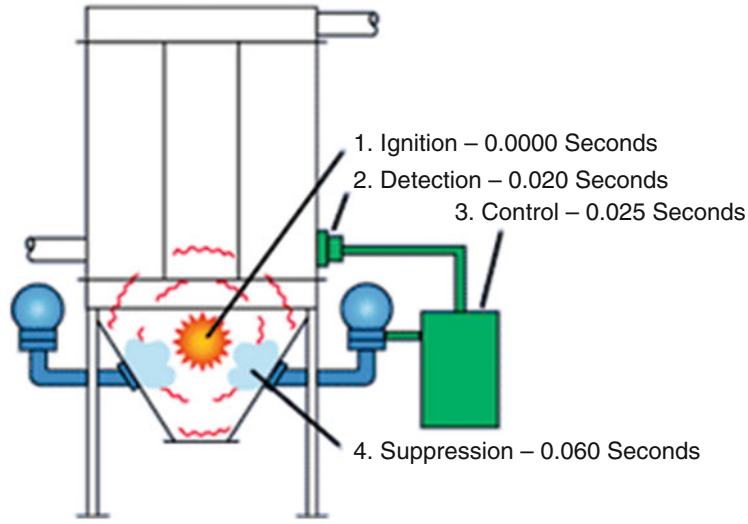

Fig. 70.14 Conceptual layout of an explosion suppression system (From Fenwal/IEP)

suppression agent. The most commonly used agent by U.S. suppression system designers is sodium bicarbonate with additives to prevent clumping and promote rapid discharge. Sodium bicarbonate (SBC) absorbs heat from the developing explosion as it starts to decompose via the following reaction.

$$2\,NaHCO_3 \rightarrow Na_2CO_3 + H_2O + CO_2$$

European suppression systems often use monoammonium phosphate (MAP), which also decomposes upon heating. The amount of SBC or MAP needed to achieve suppression depends on the combustible dust properties, e.g. flame temperature, ignition temperature, and K_{ST}, as well as the enclosure size and configuration. Experiments reported by Chatrathi and Going [30] determined the pre-ignition concentrations of SBC and MAP needed to provide inerting for explosions of various dusts in a 1-m^3 chamber using the ASTM E1226 standard igniter and ignition delay. Their results are listed in Table 70.3. The minimum required inerting concentrations generally increase with dust K_{ST}, but the relative increase is different for the two agents. Aluminum, which required the highest agent concentrations, has the highest flame temperature and probably the highest K_{ST} of the five dusts tested.

Since the suppression agents are supplied in pressurized containers, the amount of agent needed for a suppression system depends on the container size, pressure, and discharge characteristics, as well as the agent discharge actuation pressure. Suppression test data reported by Chatrathi and Going for sodium bicarbonate and potassium bicarbonate agents show that the Total Suppressed Pressure (TSP, maximum pressure developed in a test with a suppression system) was sensitive to the system actuation pressure, particularly when trying to suppress dusts with K_{ST} values of 300 bar-m/s and greater.

Explosion suppression test data reported by Bartknecht [10] indicate that the number of suppression agent filled containers required for suppression of a given dust in different size enclosure volumes varies as $V^{2/3}$ rather than being linearly proportional to V, which would be the case if there was just a required agent concentration in the enclosure. This implies that suppression is not just due to inerting of the dust, but to a dynamic balance proportional to the total surface area of the injected agent. This also suggests that agent particle size and rate of mixing with the burning particulate play significant roles in determining suppression system effectiveness.

Each suppression system provider has developed its own proprietary software tool to guide

Table 70.3 Minimum agent concentrations for inerting dust explosions

Combustible dust	K_{ST} (bar-m/s)	Min SBC concentration (g/m^3)	Min MAP concentration (g/m^3)
Pittsburgh seam coal	116[a]	550	125
Cornstarch	220	625	875
Polyethylene	240–280[a]	1,000	NA
Anthraquinone	Not reported[a]	1,750	>1,500
Aluminum	300	>2,750	>2,750

From Chatrathi and Going [30]

[a]K_{ST} values for these dust samples were not reported by Chatrathi and Going but can be estimated based on published data. Data for anthraquinone in Eckhoff [1] are in the range 94–364 bar-m/s

the design of system parameters for various customer applications. Going [31] has suggested that one of the equations in the Fike software tool to account for the parameters besides the required amount of agent is of the following form.

$$TSP = f\left(K_{ST}^{a} V^{b} Throw^{c} P_{act}^{d}\right) \qquad (70.10)$$

where Throw is the agent throw distance and P_{act} is the system actuation pressure as triggered by the pressure detector. This inclusion of throw distance in this functional form demonstrates that the location of the agent containers, so as to achieve complete coverage of the entire enclosure, is another important suppression system design consideration. Since the TSP value calculated from equations functionally similar to Equation 70.10 has to be less than the pressure resistance of the enclosure, the effectiveness and viability of explosion suppression systems are dependent on the margin between P_{act} and the enclosure strength.

Chapter 10 of NFPA 69 [32] describes the NFPA requirements for explosion suppression systems. One requirement is that the system design basis and range of applicability have been supported by testing and verified by an independent third party acceptable to the Authority Having Jurisdiction. One such independent third party is FM Global, which approves explosion suppression systems per Approval Standard 5700 [33]. FM Approval is contingent upon FM review of the system design software and the conducting of both unsuppressed and suppressed explosion tests in a vessel with a minimum volume of 1 m^3. The tests are conducted with a dust having the highest K_{ST} value for which the suppression system provider wants the FM Approval to be applicable. Other independent third parties doing certification testing are the various European notifying bodies that conduct examinations per the European ATEX Directive 1999/92/EU. Their examination and certification is presumably in accord with the CEN standard for explosion suppression systems [34]. This standard requires that at least 95 % of all suppression test pressures, i.e. measured TSP values, be less than the corresponding values calculated by the system designer's software.

Dust Explosion Isolation Devices and Combined Protection Systems

Dust explosion isolation devices are intended to prevent or interrupt the propagation of a deflagration through a duct or pipe connected to an enclosure in which a dust explosion originates. These devices can be divided into two categories: passive isolation devices and active isolation devices. Passive devices, described in Chap. 12 of NFPA 69-2008, function without the need for any separate deflagration sensor, control hardware, or actuation device. Active isolation devices use auxiliary sensors and controls and are electrically actuated upon deflagration detection.

Two examples of passive isolation devices are known generically as float valves and flap valves. Diagrams for these devices are shown in Figs. 70.15 and 70.16.

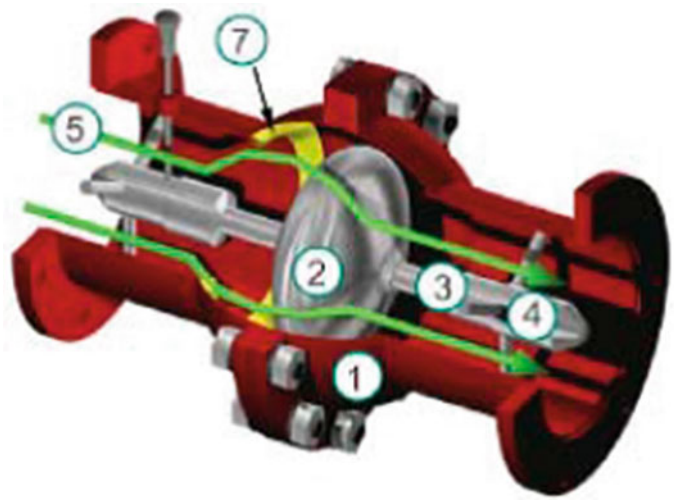

Fig. 70.15 Float isolation valve schematic (From Fike data sheet)

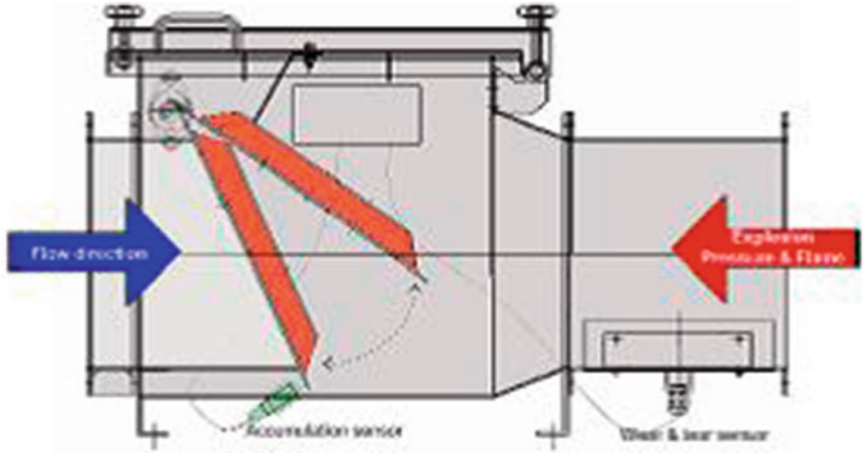

Fig. 70.16 Flap isolation valve schematic (From Fenwal/IEP)

The float component (# 2 in Fig. 70.15) in the float isolation valve slides within guide vanes (# 3 in Fig. 70.15) in the valve body such that a spring (# 5 in Fig. 70.15) holds the float in the open position during normal air flow through the valve. The back pressure wave caused by a propagating deflagration overcomes the spring force and causes the float to side shut against the valve seat (# 7 in Fig. 70.15). One manufacturer's valve requires a minimum deflagration pressure of 0.05 bar to close the valve. This valve comes in a double acting version in order to provide protection for a deflagration propagating in either direction.

The flap isolation valve shown in Fig. 70.16 relies on the normal air flow (typically a minimum air velocity of 15 m/s) to push open the hinged flap and allow powder/dust transport through the valve. A back pressure caused by a propagating deflagration overcomes the normal air flow pressure and forces the flap to slam shut. Since powder/dust accumulations on the valve bottom can prevent complete closure of the flap, there is often a dust accumulation sensor to provide a notification alarm when the accumulation reaches a level that might compromise isolation effectiveness.

In order to be effective, both the float valve and the flap valve must be fully closed before the deflagration flame front reaches them. Therefore the valves have to be located some minimum distance, l_{min}, from the pipe/duct connection to the enclosure in which the primary explosion occurs. The value of l_{min} depends on the flame velocity and the valve closing time. On the other hand, if the valves are located too far from the pipe/duct connection the propagating deflagration can accelerate and develop pressures that exceed the strength of the pipe/duct and valve. Therefore, as Fig. 70.17 indicates, there is also a maximum distance of the valve from the pipe/duct entrance. Siwek [35] has provided empirical prescriptions for l_{min} and l_{max} as a function of pipe diameter and maximum pressure in the protected equipment. Later proprietary guidelines by system designers also account for dust K_{ST} value.

Another type of passive explosion isolation device is the diverter valve shown in Fig. 70.18. It is configured to direct the normal air/product flow up and then back down into the horizontal pipe or duct. A hinged closure cap at the top of the diverter valve rapidly opens in response to an abnormal pressure caused by the propagating dust explosion. The suddenly opened valve then channels the burning dust and flame up out of the pipe or duct. This type of valve is suitable for

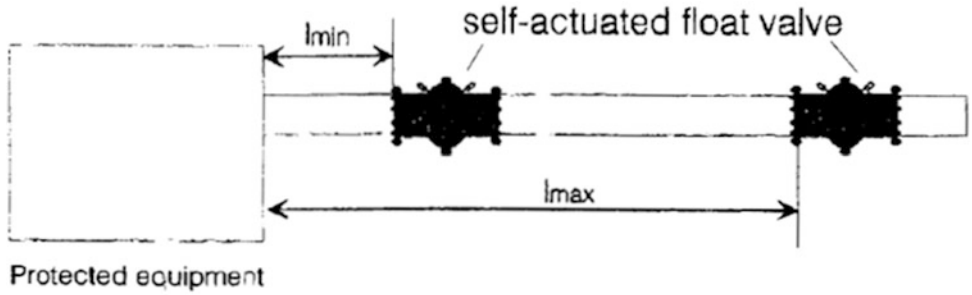

Fig. 70.17 Minimum and maximum distances for isolation device location (From Siwek [35])

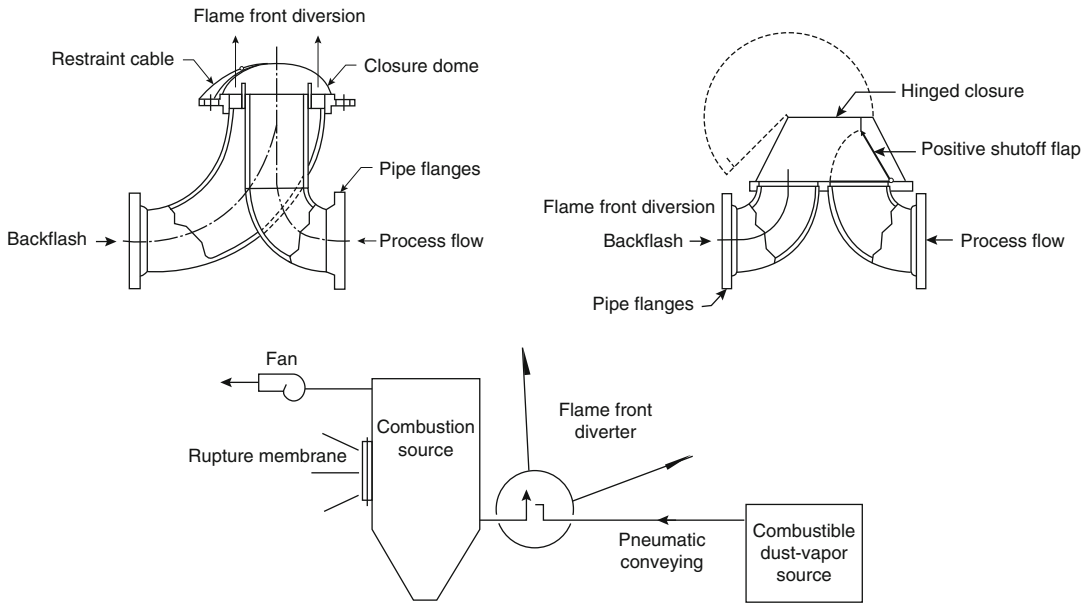

Fig. 70.18 Diverter explosion valve (From NFPA 69)

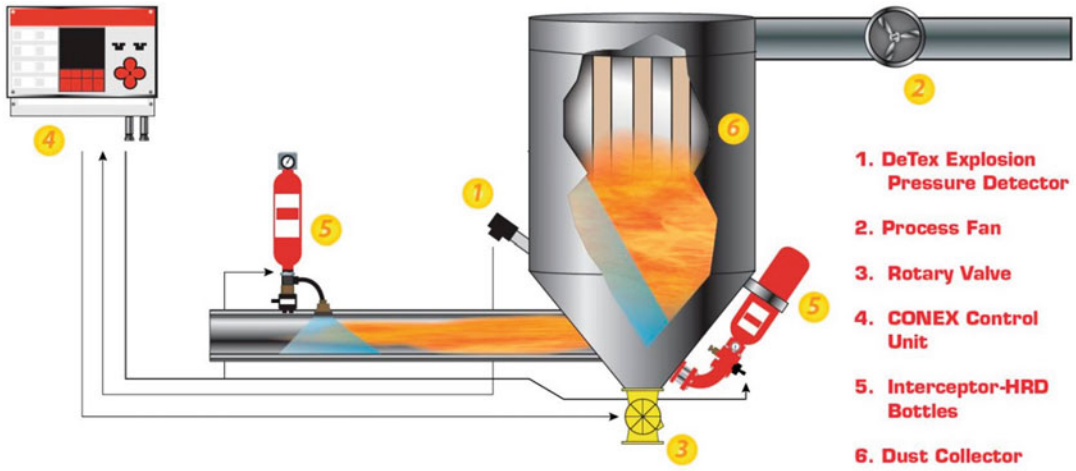

Fig. 70.19 Combined chemical isolation and suppression system (From CV Technology)

outdoor ducts and pipes where the burning dust discharge does not endanger personnel.

The most common active isolation device entails the triggered injection of a suppression agent into the pipe/duct before the propagating flame reaches that location. Since the agent is often triggered by a pressure sensor installed in the connected equipment, chemical isolation systems are commonly coupled with explosion suppression systems. Figure 70.19 is a conceptual layout of this combined system for the protection of a dust collector and the attached inlet duct. The suppression and isolation agent bottles (items # 5 in figure) are fired simultaneously by the control unit (item # 4).

Another type of active isolation device is a fast acting mechanical gate valve such as illustrated in Fig. 70.20. The electric initiator on the valve is actuated by a control panel wired to some type of deflagration detector located between the isolation valve and the enclosure in which an explosion is anticipated.

The float valve described above as a passive isolation device is also made as an externally actuated valve in which the float closure is driven by gas jets actuated by a separate deflagration detector. The advantage of this active isolation version of the float valve, shown in Fig. 70.21, is that it can be closed at a lower pressure than the passive, self-actuated version.

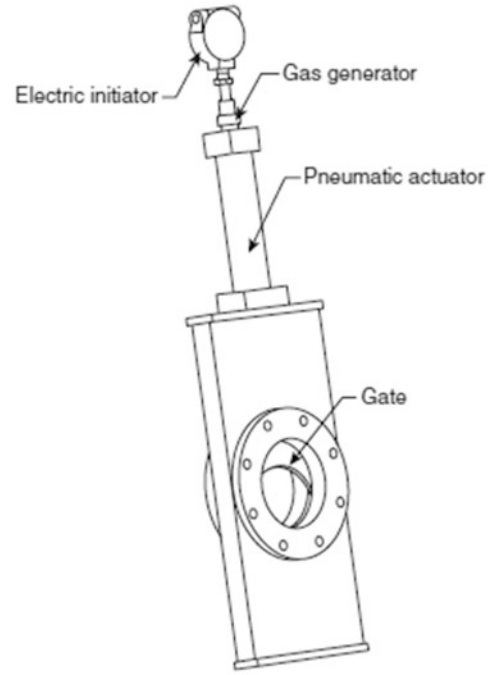

Fig. 70.20 Fast-acting, pneumatically actuated mechanical isolation valve (From NFPA 69)

Still another type of active isolation valve is the externally actuated pinch valve. As the cutaway diagram in Fig. 70.22 indicates, the valve interior has an elastomeric pinch that is normally open but can be closed by rapid compression via

an air line connected to the valve air chamber. The attached pressurized air source and actuation component are not shown in the figure.

NFPA 69 requires that both active and passive explosion isolation devices be tested and be certified by an independent organization. The European Community standard for such certifications is EN 15089 [36]. The standard has three types of testing requirements; explosion resistance testing, flame transmission testing, and functional testing. There are also requirements for optical and pressure detectors and control and indicating equipment used in active isolation devices. Certification documentation includes minimum and maximum isolation device installation distances, l_{min} and l_{max}, pressures developed on both sides of the isolation device, and commissioning and maintenance requirements. NFPA 69 requires quarterly inspections of isolation and suppression systems.

Fig. 70.21 Externally actuated float isolation valve (From NFPA 69)

The complexity of dust explosion suppression and isolation systems, and their potential deterioration in harsh powder/dust processing environments, has generated concern about their long term reliability. In order to address these reliability issues, Date et al. [37] have developed a mathematical reliability analysis for applications of these explosion protection systems. They describe the application of their analysis to an exemplar spray drying system shown in Fig. 70.23. The dryers are protected by explosion suppression systems and the cyclones are protected by explosion vents. There are also chemical and mechanical explosion isolation valves on the piping to and from the fluidized bed dryers. Actuation of the various devices is controlled by three control panels, one for each zone indicated in the diagram.

Date et al. [37] assigned nominal mean-times-to-failure for each of the explosion protection devices and control panel zones indicated in Fig. 70.23. Their lowest mean-times-between-

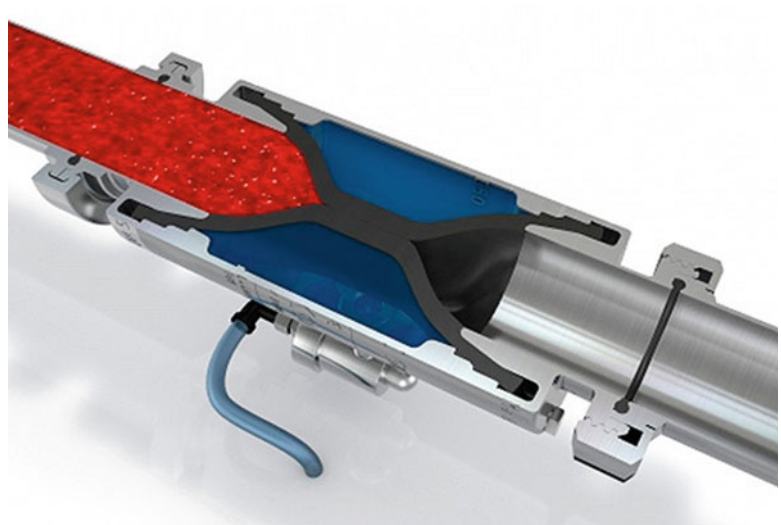

Fig. 70.22 Pinch isolation valve (From solidsonline.com AKO Web page)

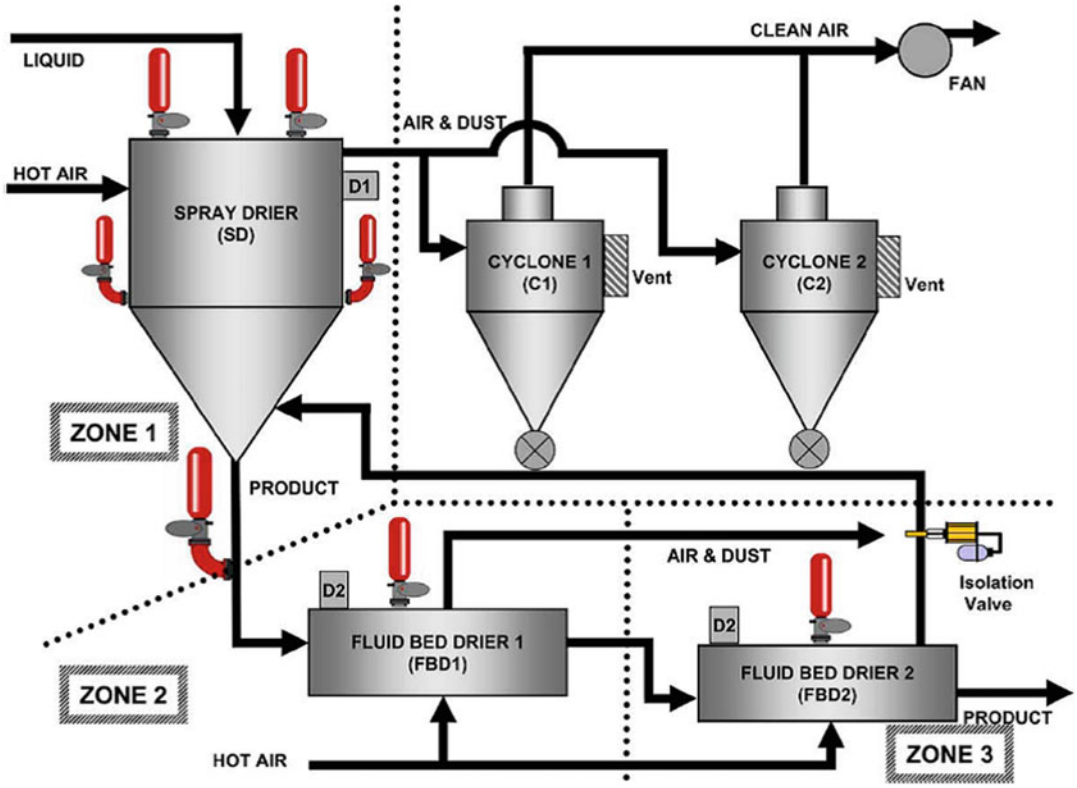

Fig. 70.23 Spray drying system used in Date et al. reliability analysis example (from Date et al.)

failures (MTBFs) were for the detectors (4,000 h) and the isolation devices (2,000 h). They converted the component MTBFs to corresponding component failure rates (without explicitly accounting for effects of maintenance and inspection intervals), and combined these with probabilities of flame propagation and vessel explosion pressures exceeding the vessel strengths. Date et al. used probability equations to calculate the probability of vessel failures and the overall system residual risk, i.e. the annual probability of explosion protection system failure. They also showed how the residual risk could be significantly reduced by combining Zones 2 and 3 so that an explosion in either fluidized bed dryer would trigger the simultaneous discharge of the suppression systems and isolation devices in both dryers, and thereby reduce the probability of late system actuation or the systems being overpowered by flame jet ignition associated with propagation between the two dryers.

Although quantitative evaluations of explosion protection reliability are not commonly conducted, there is growing concern for protection system reliability as well as system cost and installation priorities. These concerns can best be addressed by informed evaluations of dust explosion risks and the effectiveness and limitations of the various options for explosion protection.

BLEVES and Fireballs

71

Alfonso Ibarreta, Hubert Biteau, and Jason Sutula

The storage of flammable liquids and vapors in closed vessels can lead to a catastrophic failure of the vessel during a fire. When a vessel explosion involves a flammable substance, it is usually followed by a fireball [1]. If the flammable material is stored as a pressure liquefied gas, a sudden failure of the storage vessel may result in a **B**oiling **L**iquid **E**xpanding **V**apor **E**xplosion (BLEVE). A BLEVE event will result in a sudden conversion of stored thermal energy into mechanical energy in the form of a pressure wave. Additionally, the rupture of a compressed gas storage vessel may also result in a pressure wave.

A sudden energy release from a compressed vessel failure will result in damage associated with the pressure wave and the impact of missiles displaced by the explosion. In the case of a vessel filled with a flammable gas or liquid, the sudden ignition of the material can result in a fireball that travels upward while burning. This fireball may cause additional damage due to the associated flame radiation.

The following chapter discusses these types of events, the potential mitigation strategies, and the calculation of total energy released.

BLEVEs

A BLEVE is one of the major container and gas storage hazards within the chemical process industry and industry in general. In brief, a BLEVE consists of the rupture of a pressurized vessel containing a liquid that is above its atmospheric boiling point [2]. The consequences of a BLEVE can be substantial, even if the stored liquid is non-flammable. If the liquid is flammable, the hazards can be the fragmentation of the vessel, a pressure wave, and a secondary fireball. If the liquid is non-flammable, the main hazard will be associated with an overpressure event [2].

One of the most frequently cited BLEVE events took place in Crescent City, Illinois in 1970. A freight train with 15 cars derailed. Ten of the rail cars were tank storage cars carrying liquefied propane gas. At the start of the derailment, one of the liquefied propane gas cars collided with another, tearing a large rupture into one of the other tanks. The result was a large initial fireball and subsequent sustained fire. Five of the liquefied propane gas cars achieved a BLEVE in the first 4 h [2]. Nearby structures sustained severe damage and 66 injuries were reported as a result [2].

The BLEVE acronym was coined in 1957 by researchers from Factory Mutual Research Corporation [2]. J. B. Smith, W.S. Marsh, and W.L. Walls proposed the acronym after an in-house incident involving the rupture of a phenol reservoir that had become superheated [3]. Walls followed up the initial use of the

DOI 10.1007/978-1-4939-2565-0_71, © Society of Fire Protection Engineers 2016

acronym by defining a BLEVE as "a failure of a major container into two or more pieces, occurring at a moment in time when the contained liquid is at a temperature well above its boiling point at normal atmospheric pressure" [4, 5].

Birk and Cunningham redefined the BLEVE in a 1994 study as "the explosive release of expanding vapor and boiling liquid when a container holding a pressure liquefied gas fails catastrophically" [6]. More recently, the current definition that is in the greatest use stems from the Center for Chemical Process Safety and is given as "an explosion resulting from the failure of a vessel containing a liquid at a temperature significantly above its boiling point at normal atmospheric pressure" [2].

Description of a BLEVE Event

A BLEVE event begins when a pressurized container that is filled with a liquid at a temperature above its boiling point at normal atmospheric pressure undergoes an impairment that results in the rupture of the container. The rupture can be caused either thermally or mechanically. In the thermal case, the heating of the container is responsible for the mode of failure. In the mechanical case, the container rupture is due to an impact or other event that causes a portion of the container to be breached. When the container is breached, the vapor of the liquid expands while the liquid becomes superheated. The superheating of the liquid results in flashing of the liquid. Additionally, a pressure wave is generated at the time of rupture and release, which can lead to the fragmentation of the container and the production of missiles. If the liquid in the container is flammable, a premixed system of fuel and air will develop which may result in a fireball [7].

Abbasi and Abbasi [7] provided a summary of the steps observed in a typical BLEVE event by collating the works of McDevitt et al. [8], Prugh [9, 10], Leslie and Birk [11], Lees [12], Birk and Cunningham [6, 13], Casal et al. [14], Venart [15], Reid [16], Shebeko et al. [17], and Birk et al. [18]:

(A) **A container holding a pressurized liquefied gas receives a heat load or mechanically fails due to the impact of a missile, fatigue, or corrosion.** Heating from an exterior source to a container holding a pressurized liquefied gas will be problematic. As the heat loading increases, the pressure inside the container will begin to rise. Eventually, the pressure will increase to the point that a pressure relief valve will activate. If the container is not completely filled with liquid, the open pressure relief valve will allow for vapor to escape. Over time, the liquid level within the container will fall. As the liquid level falls, the cooling effect of the liquid on the metal walls of the container will be reduced. The heat exposure on the uncooled metal will lead to weakening and, eventually, a rupture of the container. This failure mode can occur even when the pressure relief valve has operated normally [7].

Missiles from the violent failure of other containers can result in the weakening or damage to nearby containers. Additionally, aging of a particular container can result in metal fatigue or corrosion, which can also lead to a more rapid failure when the container is exposed to exterior heat sources [7].

(B) **The container fails.** Containers that are designed to hold pressurized liquids can withstand pressures up to the set pressure for the relief valve. The expectation is that this set pressure would be achieved at room temperature. Heating of the container due to an exterior heat source (e.g., a nearby fire) immediately exposes the container to an environment that it was not designed to handle. If the temperature of the metal walls of the container increases sufficiently, the metal will lose strength and eventually rupture. Steel is commonly used in the construction of liquefied propane containers. These vessels will typically fail when the metal walls achieve a temperature of approximately 650 °C and a pressure of approximately 15 atm [7].

(C) There **is an instantaneous depressurization of the container and an explosive event.** Once a container has ruptured, the pressure within the container drops nearly instantaneously from a high pressure to atmospheric pressure. The temperature of

the pressurized liquefied gas remains well elevated above the liquid's boiling point. This is commonly referred to as a superheated liquid. Every liquid will have a unique superheat limit temperature, which is a property of the liquid. This temperature is a measure of how much superheating a particular liquid can withstand. When a liquid is stored at pressure, is above its superheat limit temperature, and a failure of the container occurs, the liquid will undergo an instantaneous and homogenous nucleation. The result is a rapid flashing of the liquid into a vapor, which can produce the BLEVE effect [7].

It is possible to produce the BLEVE effect if the liquid is below its superheat limit temperature, but still in a significant superheat condition. Several other conditions must be present for this to occur, which have been researched by Yu and Venart [19].

(D) **The container sustains pressure wave damage resulting in fragmentation of the container.** The near instantaneous transition of the liquid to a vapor produces an expansion on the order of several hundred to over a thousand times the original volume of the liquid. Additionally, the pressurized vapor within the container also expands rapidly. This rapid change produces a powerful overpressure blast wave that can fragment the container into various sized pieces that are propelled outward from the area of origin.

Fragments from the shattered container become missiles as they move away from the initiation point and move at high velocities in all directions. It is very common for these missiles to collide with other nearby containers, damaging or weakening them enough to allow for additional cascading BLEVE events to occur [7].

(E) **A resulting fireball or toxic dispersion is produced.** The final marker of a BLEVE event is the production of a fireball or the dispersion of a toxic substance. If the liquid in the container is non-toxic, such as water in a boiler, the only hazards will be the resulting pressure wave and missiles from the fragmentation of the container. If the liquid is flammable, the release of the flammable vapor will result in the mixing of the vapor with air into a flammable range that may ignite and produce a fireball. A fireball produced in this manner can be substantial in size and produce large amounts of thermal radiation.

BLEVEs that occur with toxic chemicals that are not flammable can create hazardous conditions through the rapid dispersion of the chemical. Chlorine has been involved in a number of historical BLEVE events where the dispersion has resulted in fatalities due to exposure from a toxic cloud [7].

Theory of BLEVE Precipitation

The main theory behind the precipitation of a BLEVE event was first put forth in 1979 by Reid [16]. This theory was centered around the idea of the superheat limit temperature. In this case, the superheat limit temperature was defined as the maximum temperature that could be achieved before a liquid must transition to a gaseous state. The superheat limit temperature is a unique property of a fluid and is pressure dependent.

The Superheat Limit Theory

The superheat limit theory for the initiation of a BLEVE event is described by the following chronology. First, a vessel that contains a pressure liquefied gas ruptures. Second, the vapor, which was previously in equilibrium with its liquid, begins to blow off. Third, the resulting liquid pressure drops rapidly and the liquid becomes superheated as the temperature of the liquid is now far above its boiling point at the reduced pressure [16].

The superheat limit for a given liquid can be reached by one of two means. First, at a constant pressure, the temperature of a liquid can be increased until a threshold value is achieved. This threshold value is the minimum temperature at

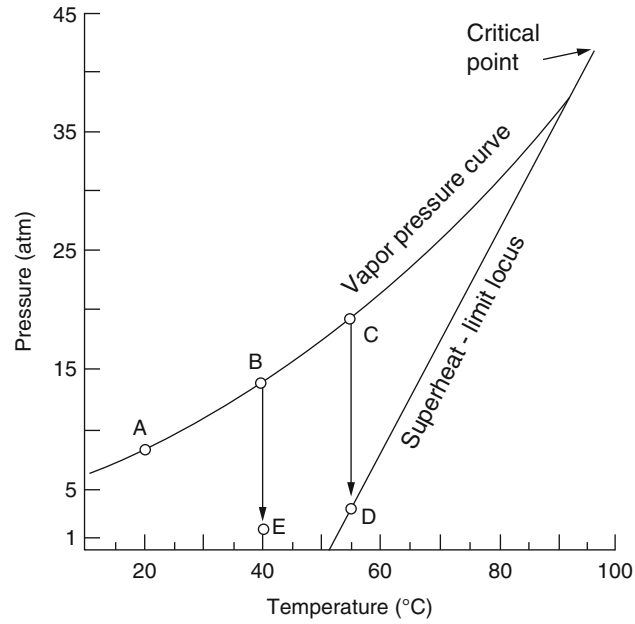

Fig. 71.1 Propane saturated vapor pressure and superheat limit [16]

which the liquid becomes homogenously nucleated in the absence of nucleation sites [7]. Second, at a constant temperature, the superheat limit is achieved if a container with a pressure-liquefied gas is rapidly depressurized [7].

In both of these pathways, there exists an instantaneous liquid to gas phase change of a portion of the liquid, resulting in a superheated liquid vapor explosion. The timing of these transitions is on the order of a few milliseconds, which allows for an extremely large increase in the volume of the system over a very small time scale. The combination of the newly created vapor with the expansion of the compressed vapor results in a strong pressure wave. An explosion produced in this fashion will be of high order and can shatter the storage container in multiple pieces, which will be thrown outward from the origin location [7].

The BLEVE pathways can be visually expressed in terms of the pressure and temperature evolution of the system. Figure 71.1 shows an example of how the superheat limit changes as a function of pressure and temperature for propane.

In examining Fig. 71.1, point A represents a system under a pressure of 9 atm and at ambient temperature. Once a thermal loading is applied on the container, both the pressure and temperature inside the container will increase following the saturation vapor pressure curve to maintain equilibrium of the liquid-vapor system. This is represented by points B and C. Upon containment failure (e.g., rupture of the vessel), the pressure drops rapidly as seen in the transition lines from B to E and C to D. The rapid depressurization transition allows for superheated liquid conditions as now the liquid is well above its boiling point (point D) [3].

Abbasi and Abbasi [7] illustrated the superheat limit theory by also presenting superheat temperature data on ammonia, chlorine, and butane, which is reproduced in Fig. 71.2. All three gases demonstrate typical superheat behavior, with the variation of the vapor pressure curve and the superheat limit a function of the type of fluid.

Determination of the Superheat Limit Temperature

Both experimental and theoretical approaches have been followed to determine the superheat limit temperature for a given fluid. While the complete knowledge of a particular superheat

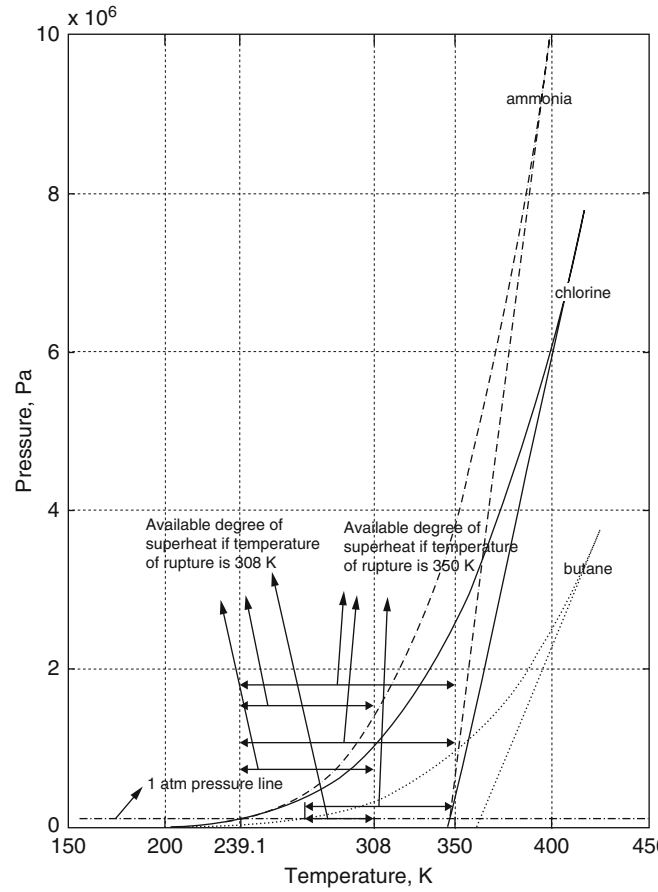

Fig. 71.2 Pressure-temperature curves and superheat limit loci for ammonia, chlorine, and butane, showing degrees of superheat at different stages of container rupture [7]

limit temperature would be a boon to industrial fire safety design, no approach to date has been performed that does not have some limitations.

The most widely used experimental approach for the determination of the superheat limit temperature is a droplet explosion technique first proposed by both Moore [20] and Wekeshima and Takata [21]. The experimental approach is conducted by injecting small droplets of the test liquid in a column filled with a different liquid that is less volatile relative to the test liquid. A temperature gradient is produced throughout the column with cooler temperatures at the base of the column and higher temperatures toward the top. As the droplet rises through its host liquid, it undergoes heating until the liquid droplet transitions to the gas phase. The temperature within the column where this rapid phase change occurs is recorded as the superheat limit temperature [7].

There are several limitations that must be considered when using this approach to determining a superheat limit temperature. First, at a molecular level, unstable bubble nuclei can reach sizes near the molecular level. At these scales, small fluctuations can initiate the formation of a nucleus bubble at temperatures below the actual superheat limit temperature. Errors using this method can also be compounded by the heat transfer dynamics to the droplet. Droplet size, the velocity of the droplet as it rises through the column, column temperature, and heat diffusivity of the droplet liquid can all influence the results of the testing method [7].

A second experimental approach utilizes a hot wire method. In this case, the test liquid sample

surrounds a very thin wire. The wire is rapidly heated, allowing for a temperature measurement of the liquid as it gasifies around the wire. The accuracy of this method is highly dependent on the rapidity of the temperature measuring device as well as the geometry of the wire surface, which can influence the nucleation of the liquid. Of the two experimental methodologies, the column method is considered to be the most accurate [7].

From the theoretical side, the superheat limit temperature can be explained utilizing the "homogeneous nucleation theory" by Gibbs [22]. Gibbs explored the factors that precipitate homogeneous nucleation in a superheated liquid and described the minimum amount of work required for the formation of vapor voids in a given liquid. Historically, this is now referred to as the classical theory, and it can be used to explain the fundamental mechanisms of explosive boiling in liquids. The theory can also be used to predict the steady-state rate of nucleation within the liquid and the expected size of bubble formation [22].

The theoretical approach for the superheat limit temperature varies from the data obtained through the experimental approaches. When accounting for the errors generated in the experimental approaches and additional research expanding on the homogeneous nucleation theory [23–28], the difference between the experimental data and theory suggests that the underlying fundamental mechanisms for the prediction of a superheat limit temperature are not yet completely understood.

Alternative Theory

Birk et al. [29] demonstrated that BLEVEs can occur at temperatures lower than the superheat limit temperature. In their study, they sub-divided a BLEVE into two types: a "hot BLEVE" and a "cold BLEVE". A cold BLEVE was defined as a BLEVE that occurs prior to a liquid reaching its superheat limit temperature. A hot BLEVE was defined similarly to the common BLEVE definition. Figure 71.3 depicts a flow diagram of the BLEVE process as defined by Birk et al. [29].

In describing the process in Fig. 71.3, Birk et al. [29] observed that cold BLEVEs typically occur in weaker containers, which fail at lower pressures. The consequences of these types of BLEVE events are correspondingly not as severe. Hot BLEVEs, then, occur with stronger containers. The delayed failure allows for a much larger pressure increase in the container and a correspondingly more severe event at the moment of failure.

Venart [30] also presented a modified theory to the work of Reid [16]. Venart introduced a new acronym called a BLCBE or Boiling Liquid Compressed/Collapsed Bubble Explosion. The BLCBE begins with a small failure in the vapor space of the container. The energy created by the failure is not sufficient to propagate the failure crack along the entire length of the container vessel. A vapor jet develops at the small breach, which allows for a pressure drop in the container. As the pressure drops, the liquid starts to boil, creating a two-phase flow within the vessel. As the liquid continues to boil, the pressure begins to increase once again within the container. The pressure increase leads to a bubble collapse, which results in a power amplified shock wave. Rapid destruction of the container ensues, with an explosive dispersal of the remaining liquid as fine droplets. Figure 71.4 shows a schematic of the BLCBE process. Figure 71.5 depicts a graph of the pressure change at the top of a container during a BLCBE event.

Time to BLEVE

Estimating the time to achieve a BLEVE for a given system is of great interest to industry and safety professionals. Unfortunately, a general methodology for predicting the time at which a particular vessel that is filled with a pressure liquefied gas will produce a BLEVE has not been currently developed. This is due to the complexity of the problem when examining the variables that effect whether or not a BLEVE will occur.

Birk and VanderSteen [32] conducted BLEVE experimentation with nine 1.8 m^3 propane tanks. Each tank was filled to 80 % capacity at approximately 10–20 °C. The results of the

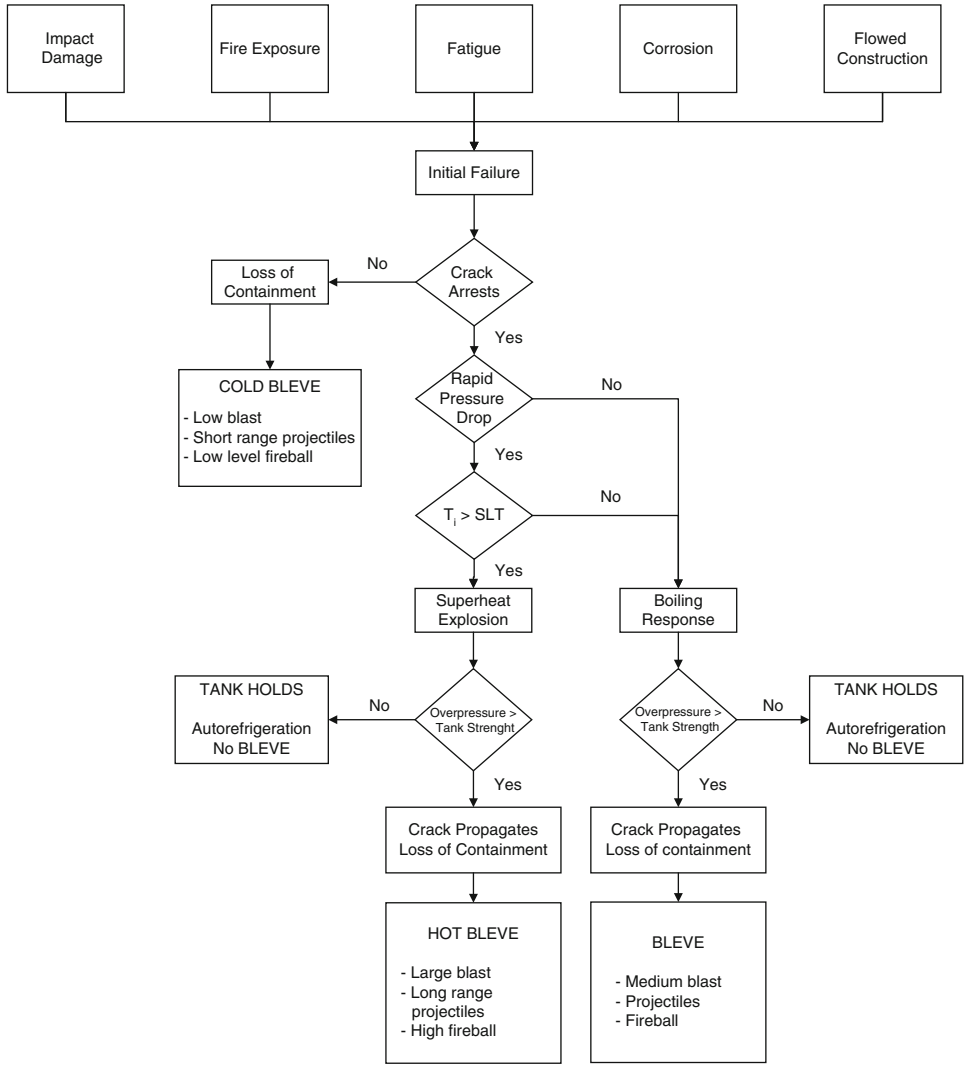

Fig. 71.3 Flow diagram of the BLEVE process by Birk et al. [29]

testing helped to provide some general insight into determining the time necessary for the initiation of a BLEVE event. The findings can be summarized as:

(A) The time needed to achieve an initial rupture of a particular container filled with a pressure liquefied gas is dependent on the type of pressure liquefied gas, overall geometry of the vessel, type of vessel material, manufacturing of the vessel, and pressure relief system of the vessel.

(B) If a failure of containment occurs in a vessel that is near or at its superheat limit temperature, it may not always precipitate a BLEVE. For a BLEVE to occur, the container must be weakened enough to open completely.

(C) When the vapor space of a particular vessel is severely heated, a critical length of that vapor space can be determined where the probability of a BLEVE event becomes highly likely over a large range of fill conditions.

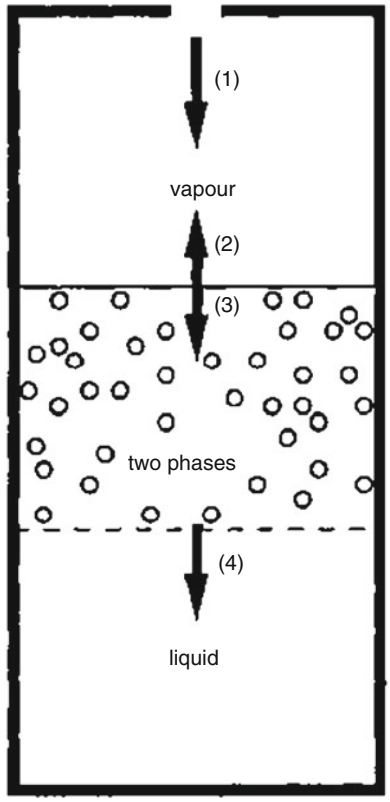

Fig. 71.4 Schematic diagram of BLEVE/BLCBE process in a vessel [19]

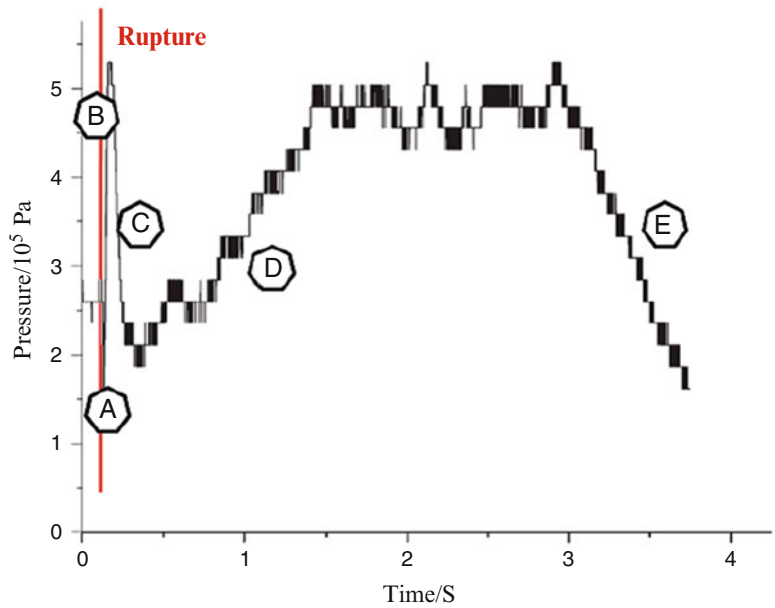
These generalities can be expanded to most pressure liquefied gases and vessels of all sizes.

Vessel-specific experimental studies have been conducted by numerous authors [33–35]. Blything and Reeves [33] examined horizontal cylinders filled 75 % with butane that were exposed to jet flame impingement and partial fire engulfment. The observed time to a BLEVE event ranged from 4 to 48 min.

Selway [34] examined 1000 t LPG storage spheres when exposed to full fire engulfment, partial fire engulfment, and jet flame impingement. For full fire engulfment, the time to BLEVE ranged from 7 to 11 min. For partial fire engulfment, Selway observed a range of 25–38 min. For jet flame impingement, times ranging from 5.5 to 7 min were recorded.

Roberts et al. [35] tested four 2-t propane vessels by exposure to a jet fire. Each of the vessels was fitted with a pressure relief value set at 17.24 barg. After 1–2 min of direct flame impingement, the pressure relief valves opened. Within an additional 3 min, a BLEVE event ensued.

Fig. 71.5 Pressure change at the top of a container during rupture [31]



Calculating the Energy Release

Failure of a vessel containing a pressure liquefied gas will induce one of the two scenarios [36]:

- Partial failure of the container with a finite rupture and single or two phase jet release;
- Complete failure with total loss of containment and BLEVE;

The evolution to one scenario or the other depends on the fluid storage conditions, the conditions the vessel is exposed to, as well as its ability to withstand external and internal mechanical or thermal aggressions. The outcome of a pressurized vessel failure is strongly related to the vessel properties as well as the amount of potential energy stored in the container.

Birk et al. conducted several series of testing on propane fuel tanks [6] exposed to various fire conditions. The failure process began with the formation of a crack in the vapor space. Once the crack appeared, propane vapor vented from the vessel. Three different types of development followed the original crack:

i. The crack stopped and a jet release was observed;
ii. The crack did not stop and a transition to BLEVE was observed;
iii. The crack stopped; a jet release was observed. Shortly after, the crack further expanded and a transition to BLEVE occurred.

Birk et al. [6] stated that a BLEVE takes place if the vessel undergoes a total loss of containment. A total loss of containment is witnessed when the stresses in the vessel exceed the level required to propagate a crack along its entire length. There is a coupling between the vessel failure and the fluid properties. The expanding fracture acts as a relief valve and creates a pressure drop in the tank. The liquid in the vessel undergoes flashing [36]. Vapor is suddenly released and produces a shock wave. The sudden expulsion of the vapor space causes the liquid phase to transition to a superheated state. It undergoes flashing and generates a BLEVE.

The energy necessary to generate a BLEVE is provided by the vapor and liquid phases of the tank. Energy from the vapor phase is available as soon as the failure process initiates. However, the liquid energy becomes only available after a phase change (i.e., flashing or boiling). Under rapid depressurization, large superheats can occur, resulting in very energetic boiling. According to Birk et al. [36], BLEVEs of weak vessels are of short duration and are driven by energy stored in the vapor phase. Longer duration BLEVEs of stronger vessels have been observed. Energy stored in the vapor phase plays a key role in the formation of the initial failure. However, Birk et al. observed that if the energy stored in the vapor phase was insufficient to obtain a total loss of containment through the initial failure, the crack could stop. Depressurization through the latter could stimulate a boiling response to the liquid. The pressure gradient may be large enough to expand the initial crack and cause a total loss of containment and a BLEVE.

Prior to failure and venting, the pressure in the vessel equals the vapor pressure at the liquid temperature. The energy release during a BLEVE is produced in the transformation of internal energy into mechanical energy. The intensity of the blast overpressure is correlated to the available internal energy. An expression of the total expansion energy E_{av} [kJ] is given in the 'Yellow Book' [37] as:

$$E_{av} = M_{liq}\left(u_{liq,1} - u_{liq,2}\right) + M_{gas}\left(u_{gas,1} - u_{gas,2}\right) \tag{71.1}$$

Where M_{liq} and $u_{liq,i}$ are, respectively, the mass of liquid (kg) and the internal energy of the liquid phase at state i (kJ.kg^{-1}) and M_{gas} and $u_{gas,i}$ are, respectively, the mass of gas (kg) and the internal energy of the gas phase at state i (kJ.kg^{-1}).

Roberts [35] corrected the previous formula to account for the fraction of liquid that flashed to vapor:

$$E_{av} = M_{liq,1}\,u_{liq,1} + M_{gas,1}\,u_{gas,1} - M_{liq,2}\,u_{liq,2} - M_{gas,2}\,u_{gas,2} \tag{71.2}$$

With

$$M_{liq,2} = (1-\chi_f)M_{liq,1} + \left(1-\chi_g\right)M_{gas,1} \tag{71.3}$$

$$M_{gas,2} = \chi_f M_{liq,1} + \chi_g M_{gas,1} \tag{71.4}$$

And,

$$\chi_f = \frac{s_{liq,1} - s_{liq,2}}{s_{gas,2} - s_{liq,2}} \tag{71.5}$$

$$\chi_g = \frac{s_{gas,1} - s_{liq,2}}{s_{gas,2} - s_{liq,2}} \tag{71.6}$$

Where X_f is the fraction of the initial liquid mass that flashes to vapor, $s_{liq,i}$ the specific entropy of the liquid phase at state i (kJ.kg^{-1}.K^{-1}) and $s_{gas,i}$ the specific entropy of the gas phase at state i (kJ.kg^{-1}.K^{-1}), while X_g is the fraction of the initial vapor mass that does not condense during the expansion.

Prugh [9] proposed a different expression for the expansion of the vapor in the vessel. The vapor is assimilated as an ideal gas and the expansion is assumed adiabatic and reversible (isentropic process). The expansion energy is given by:

$$E_{av} = \int PdV \tag{71.7}$$

Considering an isentropic process, the following relationships can be assumed for two given states 1 (initial) and 2 (final):

$$P_1V_1^{\gamma} = P_2V_2^{\gamma} = constant \tag{71.8}$$

$$\frac{V_1}{V_2} = \left(\frac{P_2}{P_1}\right)^{\frac{1}{\gamma}} = \left(\frac{T_2}{T_1}\right)^{\frac{1}{\gamma-1}} \tag{71.9}$$

Where γ is the ratio of specific heats $\left(\gamma = \frac{C_p}{C_V}\right)$.

By integrating Equation 71.7 and introducing the relationships (71.8) and (71.9), the energy release can be expressed as,

$$E_{av} = \frac{PV}{\gamma-1}\left(1-\left(\frac{P_{atm}}{P}\right)^{\frac{\gamma-1}{\gamma}}\right)\cdot 10^{-3} \tag{71.10}$$

Where, P is the pressure in the vessel just before the expansion (in Pa), P_{atm} is the atmospheric pressure (101,325 Pa), V is the initial volume of vapor (in m^3).

The energy can also be expressed as TNT equivalent. The conversion factor is given as 4680 J/g of TNT by Planas-Cuchi et al. [38],

$$W_{TNT} = \frac{PV}{\gamma-1}\left(1-\left(\frac{P_{atm}}{P}\right)^{\frac{\gamma-1}{\gamma}}\right)\cdot\frac{1}{4.68} \tag{71.11}$$

Where W_{TNT} is in equivalent mass of TNT (kg).

Equations 71.10 and 71.11 are relevant for gas filled vessels. If the vessel contains a pressurized liquid, the energy release can be approximated using the same method. The fraction of liquid that will flash must be accounted for in the calculation. The volume of liquid vaporized must also be added to the volume of vapor considered in (71.10) and (71.11).

$$V^* = V + fV_{liq}\left(\frac{\rho_{liq}}{\rho_{gas}}\right) \tag{71.12}$$

Where, V_{liq} is the volume of liquid in the vessel before the expansion (in m^3), f is the fraction of liquid that vaporized and ρ_{liq} (ρ_{gas}) the density of the liquid (gas) phase (in kg.m^{-3}). Prugh [9] and Van den Berg et al. [39] derived an expression of the vaporized fraction from the following heat balance:

$$M_{liq}C_{p,liq}dT = LdM_{liq} \tag{71.13}$$

Where M_{liq} is the liquid mass (kg), $C_{p,liq}$ is the specific heat of the liquid phase (kJ/kg.K^{-1}), and L is the latent heat of vaporization (in kJ.kg^{-1}).

The vaporized fraction is obtained by integrating Equation 71.13:

$$f = 1 - e^{-\frac{C_{p,liq}(T_o - T_B)}{L}} \tag{71.14}$$

With T_o, the temperature of the liquid phase at the time of the expansion (K); T_B is the boiling temperature of the liquid at the atmospheric pressure (K).

Equation 71.14 becomes inapplicable for a temperature T_o close to the critical temperature or above it. At the critical temperature, the latent

heat of vaporization is equal to zero while the specific heat tends toward infinity. Prugh [9] corrected the latter equation by introducing pertinent approximations of $C_{p,liq}$ and L:

$$f = 1 - e^{-2.63\left(C_{p,liq}/L\right)(T_c - T_b)\left(1-((T_c-T_0)/(T_c-T_b))^{0.38}\right)} \tag{71.15}$$

Where T_c is the critical temperature of the liquid (K). Finally, a corrected expression of the energy release equation is provided by Plans-Cuchi et al. [38],

$$W_{TNT} = \frac{PV^*}{\gamma - 1}\left(1 - \left(\frac{P_{atm}}{P}\right)^{\frac{\gamma-1}{\gamma}}\right) \cdot \frac{1}{4.68} \tag{71.16}$$

In 2004, Planas-Cuchi et al. [38] stressed that the assumption of an isentropic expansion was an ideal case. The release energy models based on this assumption overestimate the expansion. Planas-Cuchi et al. proposed that the real expansion energy ranges between two extreme values: the expansion energy based on the isentropic assumption and the expansion energy based on an adiabatic and irreversible expansion where the only expansion work is given by $-P_{atm}\Delta V$, where ΔV is the variation in volume of the whole content of the vessel when it changes from the explosion state to the assumed final state.

For an adiabatic process, the expansion work is equal to the variation of internal energy. Consequently,

$$-P_{atm}\Delta V = \Delta U \tag{71.17}$$

(71.17) is solved graphically by plotting on the same figure, the variation in work $-P_{atm}\Delta V$ and the variation in internal energy ΔU for different liquid-vapor equilibrium conditions corresponding to different vapor fraction values [38]. Equation 71.17 can also be solved analytically by using mass and energy balances:

$$\begin{aligned} -\Delta U = {} & x\ M_{total}\left(u_{liq} - u_{gas}\right) \\ & - M_{total}\ u_{liq} + U_i \end{aligned} \tag{71.18}$$

$$-P_{atm}\Delta V = P_0\left(x\left(v_{liq} - v_{gas}\right)M_{total} + M_{total}\, v_{liq} - V_i\right) \tag{71.19}$$

Where x is given by,

$$x = \frac{P_{atm}\ v_{liq}\ M_{total} - V_i\ P_{atm} + + M_{total}\ u_{liq} - U_i}{\left[\left(u_{liq} - u_{gas}\right) - \left(v_{gas} - v_{liq}\right)P_{atm}\right]M_{total}} \tag{71.20}$$

With u_{liq} and u_{gas}, respectively, the internal energy of the liquid and the vapor at the final state of the irreversible process (kJ/kg); v_{liq} and v_{gas}, respectively, the specific volume of the liquid and the vapor at the final state of the irreversible process ($m^3.kg^{-1}$); M_{total} the overall mass in the vessel (kg); U_i the overall internal energy of the system just before the expansion (kJ); V_i the volume of the vessel (m^3).

Equations 71.19 and 71.20 are used to estimate the change in internal energy, ΔU. The TNT equivalent mass is given by:

$$W_{TNT} = \beta\frac{1}{4.68}\Delta U \tag{71.21}$$

Where W_{TNT} is in kg and β is the fraction of the energy released converted into the blast wave.

In 2008, Genova et al. [40] proposed a different model to estimate the amount of energy release during a blast-wave overpressure. The authors assumed that flashing of the liquid generated most of the expansion work. They considered that the excess of heat stored in the liquid allowed the initiation and propagation of flashing. The heat stored in the liquid was expressed as follows:

$$Q = M_{liq}\ C_{p,liq}(T - T_B) \tag{71.22}$$

Where T is the temperature of the overheated liquid (K) and T_B is the boiling temperature of the liquid at atmospheric pressure (K). Changes in the heat capacity with temperature are assumed negligible. The authors assumed a high level of vessel filling and thus neglected the contribution of the vapor to expansion. The energy release is then modeled as follow:

$$E_{av} = \alpha\ Q = \alpha\ M_{liq}\ C_{p,liq}(T - T_B) \tag{71.23}$$

Where α is the fraction of excess heat stored in the liquid and converted into expansion work. Genova et al. [40] estimated α to be equal to 0.07 based on the analysis of experimental results.

Percent of Stored Energy Transferred to Blast Wave

Another critical parameter of the BLEVE intensity is the percentage of released energy that is transferred to the blast wave. When a vessel bursts, several phenomena take place. Each of them dissipates fractions of the energy release through:

- The energy of the blast wave;
- The kinetic energy of the different fragments;
- The potential energy absorbed by the fragments;
- The heat released in the surrounding atmosphere.

The exact distribution between the different phenomena depends on the incidental conditions of the BLEVE. Casal et al. [14] indicated that a critical condition is the type of failure (fragile or ductile). According to the authors, in the case of a fragile failure of a vessel, 80 % of the energy released contributes to the pressure wave. In comparison, they state that in the case of a ductile failure, only 40 % of the energy released is transferred to the pressure wave. Identical results are provided by Genova et al. [40].

Calculation of Blast Overpressures

The form of a blast wave is not simple to predict. One needs to account for the non-spherical shape of the vessel as well as reflecting phenomena from the ground and other objects. For instance, in the case of a vessel located slightly above ground, the ground will reduce the expansion volume by half which doubles the energy release. The ground also reflects the incident wave. The reflected wave can be two times stronger than the incident one. If the vessel is cylindrical, the blast has a stronger intensity on its sides than on the ends [36].

The blast overpressure is calculated based on the energy release estimation. Birk et al. [36] as well as the 'Yellow Book' [37] proposed a procedure to determine the blast overpressure.

i. Effective Blast Wave Energy

As mentioned previously, the energy release should be corrected to only account for the energy converted into expansion work. Additional corrections such as the presence of a reflecting ground surface need to be accounted for.

The effective blast wave energy is given by the following formula,

$$E_{ex} = \varepsilon \; E_{av} \tag{71.24}$$

Where ε takes into account the presence of a reflecting ground surface. If the vessel is high in the air, then $\varepsilon = 1$. $\varepsilon = 2$ when the vessel is less than 15 degrees above the horizon, as seen from the target [37].

ii. Estimation of the scaled distance

Explosive scaling is used to relate physical variables between different masses of an explosive material. For two explosive charges of a material, exploded in atmospheres with pressure P_1 and P_2, the Sachs scaling for distance is given by the following formula [41]:

$$\frac{R_1}{R_2} = \left(\frac{E_1}{E_2}\right)^{1/3} \left(\frac{P_2}{P_1}\right)^{1/3} \tag{71.25}$$

The Sachs scaled distance, $\overline{R}$, is derived from the previous expression:

$$\overline{R} = r\left(\frac{P_{atm}}{E_{ex}}\right)^{1/3} \tag{71.26}$$

With r the distance from the explosion source (m).

iii. Estimation of the overpressure of the blast wave

According to the value of $\overline{R}$, the peak overpressure P_S is evaluated differently.

- For $\overline{R} \geq 2$ the distance from the source is long enough to be considered in the far-field. Empirical relations are available to predict far-field pressure wave. Once

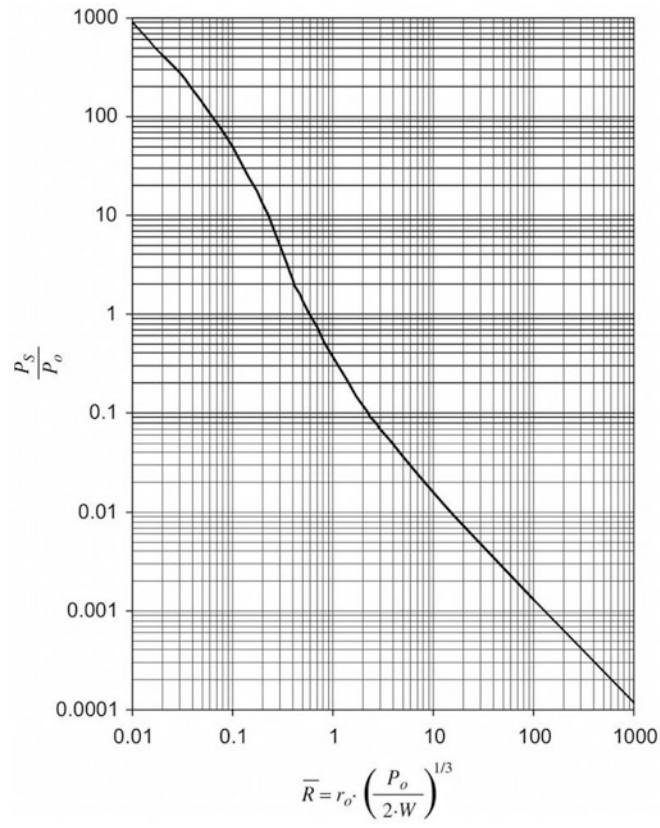


Fig. 71.6 Scaled-overpressure vs. scaled-distance curve [37]

the scaled-distance has been estimated, the peak overpressure P_S can be evaluated using scaled-overpressure vs. scaled-distance curves [37] as the one shown in Fig. 71.6.

- For $\overline{R} < 2$, the distance from the source is small enough to consider a near-field explosion. The same procedure as above would provide overly conservative approximations of the overpressure. In the near-field, high explosives generate higher overpressures than bursting vessels. A refined method is necessary to predict the blast overpressure [37].

This method assumes that the blast wave is symmetrical. The burst of a hemispherical vessel just above ground would create such a blast. Consequently, a hemispherical vessel is used calculation purposes. The hemispherical vessel's radius, r_0, is given by the following expression:

$$r_0 = \left(\frac{3V_g}{2\pi}\right)^{1/3} \tag{71.27}$$

With V_g, the volume of gas-filled part in the vessel (m^3). The non-dimensional starting distance is estimated using $r = r_0$ in Equation 71.26:

$$\overline{R_o} = r_0 \left(\frac{P_{atm}}{E_{ex}}\right)^{1/3} \tag{71.28}$$

For the near-field explosion, the initial shock overpressure at the vessel wall is given by,

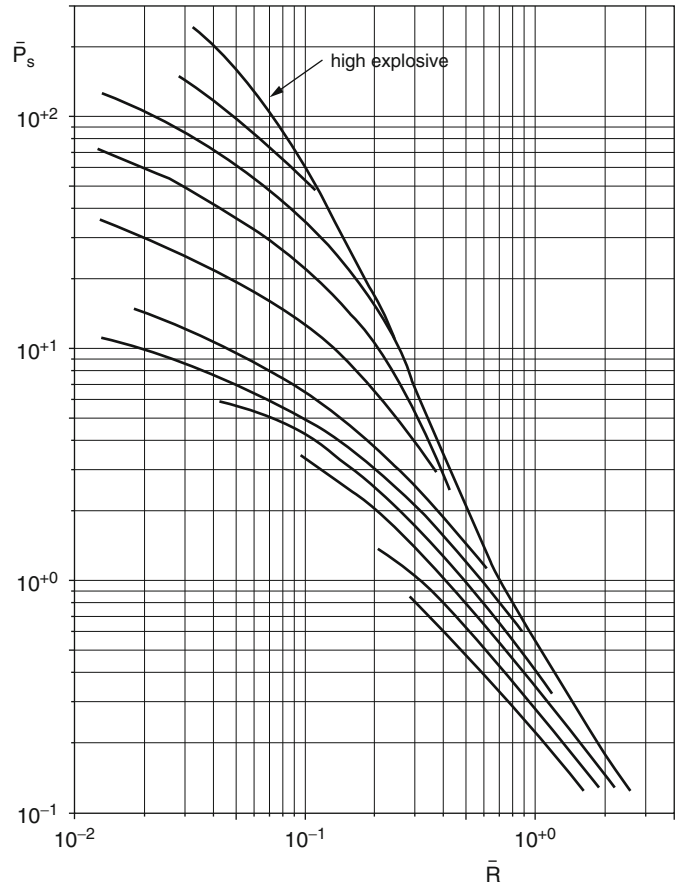

Fig. 71.7 Scaled-overpressure vs. scaled-distance curve [37]

$$\frac{P_1}{P_{atm}} = \frac{P_{so}}{P_{atm}}\left(1 - \frac{(\gamma_1 - 1)\left(\frac{a_0}{a_1}\right)\left(\frac{P_{so}}{P_{atm}} - 1\right)}{\sqrt{2\gamma_0\left(2\gamma_0 + \left((\gamma_0 + 1)\left(\frac{P_{so}}{P_{atm}} - 1\right)\right)\right)}}\right)^{\frac{-2\gamma_1}{\gamma_1 - 1}} \tag{71.29}$$

With, P_1, the pressure in the vessel (Pa), P_{so} the air shock overpressure (Pa), γ_1 the ratio of specific heats of compressed gas, γ_0 the ratio of specific heats of ambient air, a_0 the speed of sound in ambient air (m.s^{-1}) and a_1 the speed of sound in compressed gas (m.s^{-1}).

The ratio $\frac{a_0}{a_1}$ is calculated using the following expression:

$$\frac{a_0}{a_1} = \frac{\gamma_1 T_1 M_1}{\gamma_0 T_0 M_0} \tag{71.30}$$

Where, T_1 and M_1 are respectively the temperature (K) and the molar mass (g.mol^{-1}) of the compressed gas; T_o and M_0 are respectively the temperature (K) and the molar mass of ambient air (g.mol^{-1}).

Equation 71.29 is solved using an iteration procedure. The pressure of the blast wave decreases as it spreads further from its source. Estimations of $\overline{R_o}$ and P_{so} provide the initial conditions for the blast wave. Using Fig. 71.7 and given that $\overline{P_{so}} = \frac{P_{so}}{P_{atm}} - 1$, the pressure

curve of interest is the one containing the point with coordinates $\left(\overline{R_o}, \overline{P_{SO}}\right)$. Once the correct curve is identified, the blast overpressure P_s is found by reading the ordinate $\overline{P}_S$ of the point taken from the curve with abscissa $\overline{R}$ (estimated using Equation 71.26) and by using the following expression:

$$P_S = P_{atm}\left(\overline{P}_S + 1\right) \tag{71.31}$$

iv. Adjustment of the overpressure value
The previous methods presented for the estimation of P_S are based on the assumption of a perfectly symmetrical blast wave that would result from the burst of a hemispherical vessel above ground or a spherical vessel in the air. Since vessels are often cylindrical or spherical and slightly above ground, adjustments are necessary to the methods introduced previously. Adjustment factors are given in Table 71.1.

Table 71.1 Adjustment factors for the non-dimensional blast overpressure $\overline{P}_S$ [37].

	$\overline{R}$	Multiply $\overline{P}_S$ by
Cylindrical vessel	$\overline{R} < 0.3$	4
	$\overline{R} \in [0.3 - 1.6]$	1.6
	$\overline{R} \in [1.6 - 3.5]$	1.6
	$\overline{R} > 3.5$	1.4
Vessel slightly elevated above ground	$\overline{R} < 1$	2
	$\overline{R} \geq 1$	1.1

Consequence of Overpressures

Damages resulting from blast waves have been historically associated with the peak overpressure. Overpressure-damage criteria can be found in the literature [42–44]. Table 71.2 summarizes the information found in the previous references.

It is critical to stress that the values associated with the correlations peak overpressure—Damage indicated in Table 71.2 correctly approximate the magnitude of large explosions with long blast wave duration times. These criteria ignore the blast wave duration and the blast impulse. Consequently, they should not be used for blast waves with relatively small yields and/or short duration times. In these cases, use of Table 71.3 is advised.

Table 71.2 Blast damage—overpressure correlation

Type of damage	Pressure (kPa)
Minimum damage to glass panel [42]	0.1–0.3
Typical window glass breakage [42]	1–1.5
Windows shattered, plaster cracked, minor damage to buildings [42]	3.5–7.5
Person knocked down [42]	7–10
Panel of sheet metal buckled [42]	7.5–12.5
Failure of wooden siding in conventional homes [42]	7.5–15
Failure of walls constructed of concrete blocks or cinder blocks [42]	12.5–20
Oil storage tanks ruptured [42]	20–30
Utility poles broken off [42]	30–50
Serious damage to buildings with structural steel framework [42]	30–50
Reinforced concrete structures severely damaged [42]	40–60
Railroad cars overturned [42]	40–60
Probable total destruction of most buildings [42]	200–500
Wood roof joist, 13 ft. span [43]	3
Brick wall—minor damage [43]	5
Brick wall—major damage [43]	14
Wood frame building collapse [44]	20–31
Cladding of light industrial buildings ruptured [44]	27
Steel towers blown down [44]	205
Crater damage [44]	606

Table 71.3 Blast damage—impulse correlation [43]

Type of damage	Impulse (kPa–msec)
Brick wall—minor damage	110
Brick wall—major damage	295
Wood frame building collapse	248
Overturning of 10 ft. high truck	758

Sample Cases

Water Tank BLEVE

In January 1982, at the Star Elementary School of Spencer, OK, shortly after 12:00 p.m. as the students were eating lunch, a water heater exploded. Six children and 1 teacher were killed and 33 people were injured. The explosion blew up the concrete wall that separated the lunch room from the kitchen. The 300 l (0.3 m^3, 10.6 ft^3) water tank was propelled 41 m (135 ft.) away from its original location [45, 46].

The Fire Marshall's investigation revealed that some time before the explosion occurred, the temperature gauge indicated that the water temperature was 104 °C (220 °F) instead of 82 °C (180 °F) under normal operation. It also stressed that the pressure relief valve supposed to open at 8.6 bar (125 psig) was faulty. Later testing revealed that the valve did not open below 9.2 bar (133 psig) [45].

Based on the previous information, an estimation of the explosion overpressure can be obtained using expressions (71.10) from Prugh [9] and 71.23 from Genova et al. [40].

Prugh's Method

The calculation assumptions are the following:

- The pressure of the water inside the tank: $P_{water} = 917$ kPa;
- The temperature of the water inside the tank: $T_{water} = 377$ K;
- The density of liquid water: $\rho_{liq} = 1000\,kg/m^3$;
- The density of water vapor: $\rho_{vap} = 0.804\,kg/m^3$;
- The heat capacity of liquid water: $C_p = 4.2\ kJ.kg^{-1}.K^{-1}$;
- The heat capacity ratio of water: $\gamma = 1.329$;
- The latent heat of vaporization of water: $H_v = 2257\ kJ.kg^{-1}$;
- The critical temperature of water: $T_{crit} = 647$ K;
- The boiling temperature of water at atmospheric pressure: $T_{boil} = 373$ K;
- The total volume of the tank: $V = 0.3\ m^3$;
- The percentage of filling level of the tank was assumed to be 80 %;

The vaporization fraction f was calculated using Equation 71.15 and was found to be approximately, $f \sim 0.0074$. Expressions (71.10) and (71.12) are used to estimate the energy release:

$$E_{av} = \frac{PV^*}{\gamma - 1}\left(1 - \left(\frac{P_{atm}}{P}\right)^{\frac{\gamma-1}{\gamma}}\right) \cdot 10^{-3} \sim 2.67\,MJ$$

Assuming a ductile fracture, the energy in the pressure wave was taken as 40 % of E_{av}, approximately 1.07 MJ.

The scaled distance $\overline{R}$ was then calculated based on Equation 71.26, assuming the boiler was about 4 m away from the collapsed concrete wall,

$$\overline{R} \sim 1.45$$

Using the chart of Fig. 71.6, for scaled overpressure, gives a ratio $\frac{P_s}{P_{atm}} \sim 0.18$, hence a peak side on overpressure $P_s \sim 18$ kPa (2.6 psig).

Genova's Method

Based on the same assumptions as provided above, Equation 71.23 can be rewritten for water as,

$$E_{av} = 294\,M_{water}(T_{water} - T_{Boil}) \qquad (71.32)$$

$$E_{av} \sim 0.3\,MJ$$

And

$$\overline{R} \sim 2.17$$

Using the chart of Fig. 71.6, for scaled overpressure, gives a ratio $\frac{P_s}{P_{atm}} \sim 0.11$, hence a peak side on overpressure $P_s \sim 11$ kPa (1.6 psig).

Although a discrepancy is observed between the two methods, their order of magnitude is the same. While Prugh bases his calculation on the

assumption on the pressure, Genova's calculation uses the liquid temperature.

Testing of the relief valve stressed that it would not open below 920 kPa but it is possible that the burst pressure was under this value. Similarly, the last witnessed water temperature on the tank temperature gauge was 104 °C but the temperature might have continued to rise.

Despite the discrepancy between the two overpressure values, based on Table 71.2, their estimated magnitude could generate failure of a concrete wall.

Propane Railcar BLEVE

It would be of interest to have an estimation of the pressure inside a vessel prior to its transition to a BLEVE. In the case of road or rail car tanks, it is unlikely that the pressure gets recorded and in-vehicle pressure gauges might not be found after the explosion. Nevertheless, an approximation of the energy release can be obtained from the damages observed.

Assume a cylindrical rail car tank with a diameter of 2.5 m (8.2 ft) and a length of 20 m (65.6 ft) with a volume of 100 m^3 (3,531 ft^3). This tank is filled with LPG at 80 % of its total capacity. The temperature of the LPG is 22 °C (72 °F) and the pressure 8.7805 bar.

Due to excessive speeding, the train violently came off the track, tipped over and finally came to a halt. Immediately, flames appeared under the car. A few minutes after, a large explosion occurred. The glass windows of a house located approximately 250 m (820 ft) away did not break. Based on this information and using Table 71.2, one can determine that the peak overpressure was below 1.5 kPa (0.22 psig). By using Fig. 71.6, the scaled distance $\overline{R}$ is estimated to be:

$$\overline{R} \sim 10.3$$

Assuming a ductile fracture, the energy release can be estimated from Equation 71.26,

$$E_{av} = \left(\frac{r}{\overline{R}}\right)^3 \frac{P_{atm}}{0.8} \sim 1811.10^3 \text{ kJ}$$

By using an inverse approach on Equation 71.10, and with the following assumptions,

- The density of liquid propane: $\rho_{liq} = 582 \text{ kg/m}^3$;
- The density of gaseous propane: $\rho_{vap} = 2.423 \text{ kg/m}^3$;
- The heat capacity of liquid propane: $C_p = 2.72 \text{ kJ.kg}^{-1}.\text{K}^{-1}$;
- The heat capacity ratio of water: $\gamma = 1.1344$;
- The latent heat of vaporization of propane: $H_v = 425.31 \text{ kJ.kg}^{-1}$;
- The critical temperature of propane: $T_{crit} = 367 \text{ K}$;
- The boiling temperature of propane at atmospheric pressure: $T_{boil} = 231 \text{ K}$;

the pressure P prior to explosion can be estimated to be approximately 67 bars (972 psig).

Fireballs

The 'Yellow Book' [37] defines fireball as 'a fire, burning sufficiently rapidly for the burning mass to rise into the air as a cloud or ball.' A fireball takes place when a flammable liquid, gas or dust cloud is suddenly released and has limited mixing with air prior to ignition. This event differs from a flash fire or vapor cloud explosion in that the flammable release ignites prior to mixing with the outside air. The fireball combustion event therefore involves entrainment and mixing with the surrounding air as it burns. Burning occurs primarily in the outer layer of the fireball, where the fuel-rich cloud mixes with the surrounding air. As the gases inside the fireball are heated, buoyancy increases, and the fireball rises as it expands [47].

There are a number of scenarios that can lead to a fireball, including [48]:

- The ignition of a flammable release during a BLEVE event.
- The ignition of a fuel-rich vapor cloud.
- The ignition of a release of a liquefied gas pipeline, where the jet flame is preceded by a fireball.
- An ignition of a sudden flammable release following a boilover event.
- A release of flammable vapors into a building and subsequent ignition.
- Ignition of explosives or propellants.
- Venting of a deflagration inside an enclosure.

This type of combustion is relatively slow, since the speed of combustion is limited by the air entrainment and mixing time. There is, therefore, no associated blast wave. The fireball, however, poses a radiation hazard, as the thermal energy release during combustion is emitted radially.

Description of a Fireball Originating from a BLEVE

About 80 % of all BLEVEs involve flammable materials [7]. When a BLEVE is the result of an external fire, the ignition of the flammable release is an inevitable consequence, and will result in the formation of a fireball. If a tank containing a pressurized flammable gas or liquid is heated due to an external fire, two things will happen: (1) the pressure inside the vessel will increase due to either heating of the gas or an increase in the saturation pressure of the liquid and (2) the vessel walls will weaken as the temperature increases. If the heating continues and the vessel is not able to vent adequately, the walls of the vessel will fail at some point, resulting in a sudden release of the flammable material which will likely be ignited. The fireball event will initiate at the level of the release. After ignition, the volume of burning gas will increase and it will rise, producing a wake [1].

The fireball size and duration will directly depend on the amount of fuel that is burned within the fireball. A simple and conservative approach is to assume that the entire vessel's flammable contents are consumed in the fireball. In a realistic BLEVE scenario, however, a portion of the vessel contents will instantly flash due to the temperature of the liquid at the time of vessel failure (isentropic flash fraction), a portion of the liquid will form fine droplets that will vaporize as they fall and during the formation of the fireball, and a portion will rainout and form a pool on the ground that will be consumed as a pool fire. Hasegawa and Sato [49] showed that once the isentropic flash fraction equals 36 % or more, all of the fuel in the vessel is consumed in the fireball. Therefore, the assumption can be made that during a BLEVE event, the amount of fuel that will contribute to the subsequent fireball is three times the isentropic flash fraction, up to a maximum of 100 % of the liquid contained in the vessel [2].

There are physical models that can be used to calculate the motion, air entrainment and temperature of a fireball [50]. Alternatively, a number of experiments have been performed and analyzed over the years to come up with empirical relations of the fireball size and duration as a function of fuel mass consumed. These models are exponential relationships based on the flammable mass consumed. The variability on the empirical models is relatively small, and is related to the range in the scale of the experiments considered. As described in Chap. 66, the maximum diameter, D, of a spherical fireball originating from a BLEVE can be calculated as:

$$D = 5.8\,m^{1/3}$$

Similarly the duration of the fireball can be estimated from the flammable mass as [2]:

$$t_d = 0.45\,m^{1/3} \quad \text{for} \quad m < 30{,}000\,kg$$

$$t_d = 2.6\,m^{1/6} \quad \text{for} \quad m > 30{,}000\,kg$$

The duration of the fireball as a function of flammable mass is shown in Fig. 71.8. The figure shows how the fireball is a transient event lasting only seconds. The total radiation reaching nearby objects during such an event is less than that associated with a longer-lasting flammable liquid pool fire, limiting its potential hazard [50].

The fireball will quickly expand to its maximum diameter, D, as it rises. The fireball normally ascends at a constant rate from a height of $D/2$ to approximately $3D/2$. The maximum height of the fireball is reached in the last two-thirds of its duration [1]. Figure 71.9 shows the fireball height as a function of time. If an average fireball height is used, it can be estimated as 0.75 D.

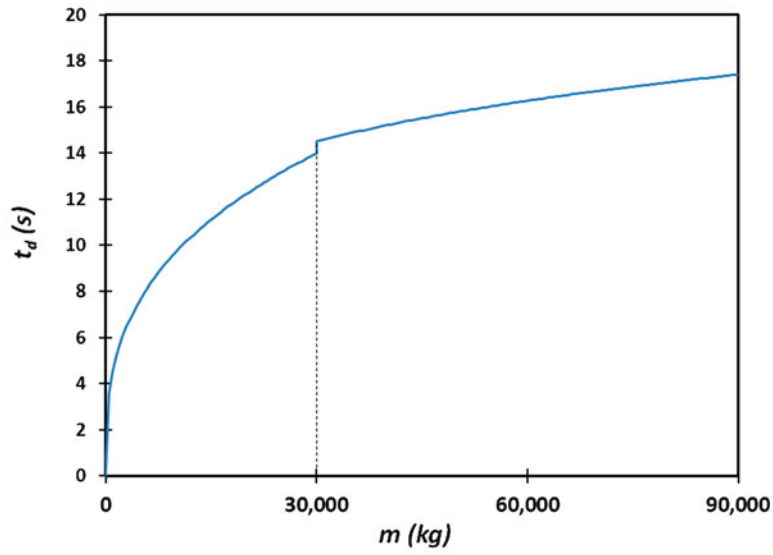

Fig. 71.8 Fireball duration as a function of flammable mass

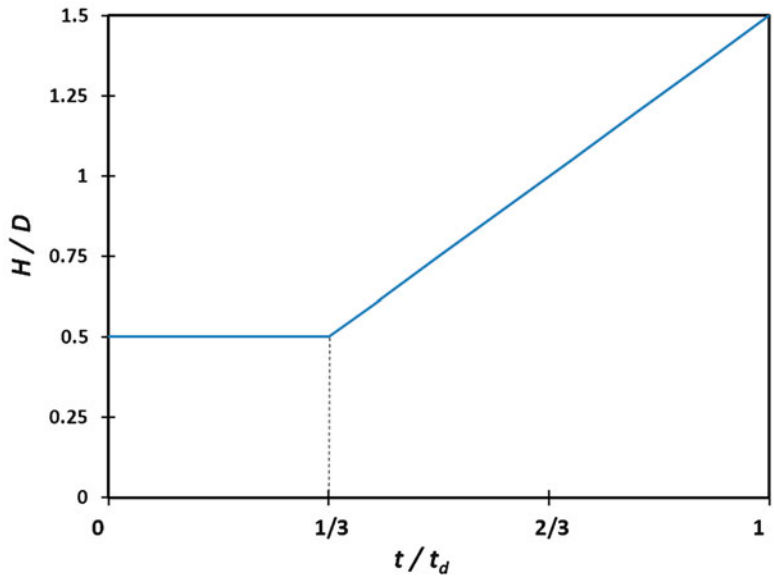

Fig. 71.9 Fireball height as a function of time

Fireball Radiation

The damage caused by the fireball comes from either flame impingement or radiant heat. The structural damage caused by a BLEVE blast wave and impact of missiles is limited to the near-field. In comparison, the radiation effects of the resulting fireball can often extend over much greater distances [2]. About one fourth of the energy released during the combustion of the fireball is transferred as radiant energy [7]. The burning rate is equal to the total amount of flammable material divided by the duration of the fireball [37].

There are three basic methods of calculation the radiation emitted by a fireball [48]:

1. Calculating the heat release rate of the fireball and the fraction of heat radiated.

2. Calculating the fireball flame surface temperature and emissivity.
3. Estimating the fireball surface emissive power.

The first method, which calculates the fraction of the heat release that is radiated, is used in conjunction with a point-source radiation model. The fraction of the energy released that goes into the radiant heat transfer varies, and it is one of the largest uncertainties in the fireball radiation models. The radiant energy fraction varies from 0.13 to 0.4, depending on the study [14].

The second and third methods, which determine the fireball surface emissive power, are used in conjunction with the solid flame radiation model. The third method, using empirically determined surface emissivity values or correlations, is discussed herein and detailed in Chap. 66. Using this method, a solid flame model can be used in order to calculate the radiation received by an object or surface located a certain distance away. This requires knowledge of the flame emissive power, view factor, the atmospheric transmissivity and the distance between the flame and the target [1]. The view factor can be calculated from the geometry of the fireball, the emissive power is dependent on the vapor pressure of the fuel involved, and the transmissivity can be estimated from the atmospheric conditions. The amount of radiation absorbed by a target is therefore dependent on the fireball duration, diameter and height [1]. The shape of the fireball can vary according to the type of tank failure. Rapid failures produce nearly-spherical fireballs, while slower releases tend to produce cylindrical releases with high lift-offs [1]. Most fireball radiation models assume the fireball is shaped as a perfect sphere.

Methods used to calculate the radiation exposure from a fireball formed during ignition of a hydrocarbon are detailed in Chap. 66, using both a point source and solid flame model. Experimental measurements of full-scale butane and propane fireballs have estimated their emissive power as 320–370 kW/m^2 [51]. An emissive power of 350 kW/m^2 is often used as a reasonable estimate for hydrocarbon fireballs involving a flammable mass of 1000 kg or more [2]. Most models assume that the fireball radiation is constant during the event. This simplification tends to over-estimate the amount of radiation observed by a target, and therefore over-estimates the extents of the radiation hazard zone. New techniques have been developed to account for variations in radiation levels during the duration of the fireball [1, 52].

Potential fire damage to buildings can be minimized using the following mitigation strategies [47]:

- Increasing the separation distance between the building and potential release locations of flammable storage vessels.
- Applying fireproofing to the exterior of buildings.
- Using water sprays or a water deluge system to cool exposed surfaces.

Fireballs Resulting from Deflagration Venting (NFPA 68)

Fireballs can be formed during explosion venting of a deflagration inside an enclosure. Explosion vents are commonly used to protect equipment and enclosures containing combustible gases and dusts. The NFPA 68 Standard for Explosion Protection by Deflagration Venting describes in detail how explosion vent systems should be designed and operated [53]. The vents are designed to open at relatively low pressures and allow the expanding gas to exit the enclosure during the deflagration. This reduces the maximum overpressure observed during a deflagration inside the protected vessel or enclosure.

During a deflagration in a vessel or enclosure protected by explosion vents, the unburned gases first exit the volume, followed by the flame. The combustible material is ejected some distance away from the protected vessel and combusts outside of the enclosure. The venting of the explosion produces both a pressure wave and a radiating fireball.

Explosion venting can be used to protect buildings and equipment, but can lead to a number of hazards that need to be addressed [54]:

- The ejection of flames and burning material, in the form of a fireball, from the vent opening.
- Emission of blast waves from the vent opening.
- Reaction forces on the enclosure.
- Emission of missiles (vent panels or other objects)
- Emission of toxic combustion products.

According to NFPA 68 (2013) §A.7.7 and §A.6.6 [53]:

> The fireball from a vented gas or dust deflagration presents a hazard to personnel in the vicinity. People caught in the flame itself will be at obvious risk from burns, but those who are outside the flame area can be at risk from thermal radiation effects. The heat flux produced by the fireball, the exposure time, and the distance from the fireball are important variables to determine the hazard.
>
> Flames and pressure waves that emerge from an enclosure during the venting process can injure personnel, ignite other combustibles in the vicinity, result in ensuing fires or secondary explosions, and result in pressure damage to adjacent buildings or equipment. The amount of a given quantity of combustible mixture that is expelled from the vent, and the thermal and pressure damage that occurs outside of the enclosure, depends on the volume of the enclosure, the vent opening pressure, and the magnitude of the vented overpressure, P_{red}. In the case of a given enclosure and a given quantity of combustible mixture, a lower vent opening pressure results in the discharge of more unburned material through the vent, resulting in a larger fireball outside the enclosure. A higher vent opening pressure results in more combustion taking place inside the enclosure prior to the vent opening and higher velocity through the vent. (See 6.2.3.) The fireball from vented dust deflagrations is potentially more hazardous than from vented gas deflagrations, because large quantities of unburned dust can be expelled and burned during the venting process.
>
> Deflagration venting generates pressure outside the vented enclosure. The pressure is caused by venting the primary deflagration inside the enclosure and by venting the secondary deflagration outside the enclosure.

The NFPA 68 standard provides an empirical correlation to predict the maximum size of a fireball produced during venting of a deflagration. According to §7.71 of NFPA 68, for venting of gas explosions, the axial extent of the hazard area from the vent location can be calculated as:

$$D = 3.1 \cdot \left(\frac{V}{n}\right)^{0.402}$$

Where V is the volume of the vented enclosure (m^3), and n is the number of evenly distributed vents. In the case of venting of dust explosions, the fireball hazard area distance can be calculated as (see §8.9.2 of NFPA 68):

$$D = K \cdot \left(\frac{V}{n}\right)^{1/3}$$

Where K is equal to 10 for metal dusts and 8 for chemical and agricultural dusts, D is the axial distance from the vent (m), V the volume of vented enclosure (m^3) and is the number of evenly distributed vents. The maximum distance, D (m), is limited for venting of combustible dusts to 60 m. The width and height of the projected fireball is taken as D. The fireball hazard area is described as a cone, as described in Fig. 71.10.

Personnel should be prevented from entering this hazard area during normal operation [55]. In addition, a separate hazard area associated with overpressures experienced during venting is defined in NFPA 68. The maximum overpressure immediately outside the vented enclosure is:

$$P_{max,a} = 0.2 \cdot P_{red} \cdot A_v^{0.1} \cdot V^{0.18}$$

Where P_{red} is the maximum overpressure inside the protected enclosure during venting (bar), Av is the vent area (m^2), and V is the volume of the protected enclosure (m^3). The maximum pressure as a function of radial distance from the vent, r (m), is shown graphically in Fig. 71.11 and is defined in NFPA 68 as:

$$P_{max,r} = P_{\max,a} \cdot \frac{(\alpha \cdot D)}{r}$$

Where α is 0.20 for horizontal vents and 0.25 for vertical vents. The external overpressure near the vent, up to a distance of $\alpha \cdot D$ (m), is constant and equal to $P_{max,a}$ (bar).

Sample Cases

LPG Release in Italy

During the transfer of LPG at an unloading facility from a 13 m^3 (459 ft^3) tanker truck to an underground tank, a release of LPG occurred from the back of the truck [56]. The tanker at the time was carrying approximately 4200 kg (9259 lb) of liquid LPG. The leak of LPG ignited, forming a pool fire under the tanker, while the tanker continued to leak fuel. After 25 min of continued burning, the tanker ruptured and

underwent a BLEVE. Witnesses described a fireball that was 20–25 m (65–82 ft) from the ground. No one was injured up to a distance of 100 m (328 ft) from the fireball. Calculations demonstrated that at the time of the BLEVE, the tanker held 250–600 kg (551–1323 lb) of fuel which was consumed during the fireball.

LNG Release in Spain

On 22 June 2002, a tanker truck carrying approximately 20 t of LNG overturned [57]. A fire ensued, enveloping the tank. The tank burst 20 min after the start of the incident. The driver was killed and two people were burned approximately 200 m (656 ft) from the truck. Calculations showed that the resulting fireball would have had a diameter of 150 m (492 ft), located 113 m (371 ft) above ground, and lasted 12 s [58]. The authors estimated a surface emitted flux of 260 kW/m^2.

Nomenclature

A_v	Vent area (m^2)
C_p	Specific heat at constant pressure (kJ·kg^{-1}· K^{-1})
C_v	Specific heat at constant volume (kJ·kg^{-1}· K^{-1})
D	Fireball diameter (m)
E_{av}	Total expansion energy (kJ)
L	Latent heat of vaporization (kJ · kg^{-1})
m	Flammable mass (kg)
M_{liq}	Liquid mass (kg)
P	Pressure (Pa)
R	Distance from explosive material (m)
S	Specific entropy (kJ·kg^{-1} · K^{-1})
T	Temperature (K)
t_d	Duration of the fireball (s)
u	Internal energy (kJ.kg-1)
V	Vessel volume (m3)
W_{TNT}	Equivalent mass of TNT (kg)
X_f	Mass fraction of the initial liquid mass that flashes to vapor
X_g	Mass fraction of the initial vapor mass that does not condense during expansion

Greek Letters

β	Fraction of energy released converted into the blast wave
γ	Ratio of specific heats $\left(\gamma = \frac{C_p}{C_v}\right)$
ν	Specific volume (m3 · kg^{-1})
ρ	Density (kg · m^{-3})

Subscripts

atm	atmospheric
gas	Gas
liq	Liquid

Dr. Jason Sutula is a Senior Fire Protection Engineer at Jensen Hughes. His main focus is the forensic analysis of fire and explosion losses.

Introduction to Fire Risk Analysis

72

John M. Watts Jr. and John R. Hall Jr.

Introduction

The risk assessment chapters in this section describe concepts and methods to be used in answering the three questions: What could happen? How bad would it be? How likely is it? This chapter in particular is intended to provide an overview of fire risk analysis as a whole, indicating how the subsequent chapters fit together and how a completed fire risk analysis connects to other evaluative and management activities. The purpose of this introductory chapter is threefold:

1. Introduce some generic terminology and fundamental concepts (building on the three questions raised above)
2. Provide an overview of the other chapters in this section
3. List some broad resources for conducting fire risk analysis (FRA)

What Is Risk?

Risk has always been a part of human endeavor, and for much of human history, the notion that risk could be actively controlled or prevented would have been considered mad or even blasphemous. Even today, when we increasingly expect protection against risk and use codes, regulations, insurance provisions, built-in and planned response mechanisms, and incentives, all to control or reduce risk, very few of our risk reduction and risk management actions proceed from a formal or quantitative risk analysis.

This aspect, too, is changing. Governments around the world are mandating risk analyses in areas of health and safety. Computations of the odds of harm are becoming a powerful force in decisions about activities involving risk.

Every decision related to fire safety is a fire risk decision, whether it is treated as such or not. And so, as our scientific understanding and our suite of quantitative engineering tools have rapidly expanded, we have discovered that we cannot make our fire safety decision-making process more scientific and quantitative unless we first place our new engineering tools into an appropriate fire risk analysis context. To do otherwise is to make many implicit assumptions about patterns of danger and preferences for certainty and for safety versus other human wants and needs.

Basing decisions on fire risk not only requires the challenging technical steps of fire risk estimation but also requires the identification of an acceptable level of risk, which is more a philosophical task than a technical one. Consider, for example, the recent fire loss experience of any country. Does this experience represent a level of fire risk acceptable to the citizens of that country? If the answer is no, then why is there so little attention paid to the problem? If the answer is

yes, meaning we accept certain losses, then why is there a great clamor for change following every serious fire?

Accepting a level of risk requires a value judgment, and people have different value judgments. Consider four perspectives on the value of residential sprinklers: technical, societal, enforcer, and managerial.

Technical value judgments are made by experts based on the available technical information and their acquired expertise. Experts pretty much agree that residential sprinklers can significantly reduce the calculated fire risk. The experts most aware of the risk reduction potential of sprinklers are also most likely to evaluate the attractiveness of sprinklers based on that potential, more than on other bases. They may embrace residential sprinklers with great enthusiasm on that basis.

Societal value judgments are the judgments of ordinary people balancing benefits, costs, and risks of the full range of activities and events that affect their daily lives. Their estimation of the benefits and the negative side effects of sprinklers may be based on folklore more than the best thinking of the experts, and they are likely to attach more importance to costs and to other hazards and needs than the experts—having a specific focus—do. Currently, it appears that the reduced fire risk produced by a residential sprinkler system is not valued as highly by the average citizen as is the increased benefit of a new car.

Enforcer value judgments are the judgments of a few professionals who are asked by society to protect their interests in a specific area. Enforcers are a special group within the larger group of individuals who provide *fire risk management*. An engineer performing a fire risk analysis will usually be working on behalf of a client with fire risk management responsibility, but the engineer cannot base his or her analysis on the values of the client alone. Instead, the fire risk analysis will need to address the client's values and also societal values. Enforcers are often seen as the interpreters and guardians of societal values, but at the same time, their technical expertise and focused mission of providing fire safety give them a distinctive set of values. Their estimation of benefits and side effects are likely closer to those of the experts, but their evaluation of those benefits and side effects are likely closer to those of the general public, embodied in societal value judgments. And because they directly incur neither the costs nor the benefits of their decisions, they must factor in some other considerations having to do with when it is acceptable to dictate safety choices to people. Is it equitable to require automatic sprinklers in *all* residences? How can cost be fairly distributed? Who is responsible for system reliability? Should production, installation, and maintenance of sprinklers be regulated?

Managerial value judgments are the judgments of all the other professionals with special responsibilities relevant to fire risk management, which for residential fire sprinklers would include such groups as architects, builders, managers of hardware retail chains, and so forth. Their estimation of the benefits and side effects of sprinklers may be similar to the general public's, their estimation of the costs is probably more accurate than that of any other group, and, most important, they themselves are likely to be directly affected by those costs more than by the benefits or side effects. Different information and different goals and values are likely to lead to a different assessment—though still risk based like all the others—of the attractiveness of residential sprinklers.

The chapters of this section are designed to provide the practicing engineer with the contextual tools and supplementary information that will permit him or her to use the knowledge and tools embedded in all the earlier sections and to produce a sound evaluation of alternative choices.

Fire risk estimation is the scientific process of answering three questions: (1) What could happen? (2) How bad would it be if it did happen? (3) How likely is it to happen? Or, to put it another way, risk has two essential components: exposure and undesired consequences. Exposure is a potential risk that becomes real with uncertainty, and so exposure refers to the likelihood or probability of experiencing a destructive event, for example, fire. Undesirable consequences,

ranging from deaths or dollars of property damage, to significant intangible losses such as business interruption, mission failure, environmental degradation, and destruction of cultural artifacts, are also potential risks. They become real if exposure occurs. Thus when we speak of fire risk, we are referring to the uncertainty of loss.

Let's return to the three questions that opened this chapter.

What could happen? can refer to a sequence of events ending in a fire loss, the sequence as a whole being called a *scenario,* or to an object or other entity having the potential for a sequence of events ending in a fire loss. A *hazard* is such an object, and *hazard* itself is the potential for loss. *Fire hazard analysis* is a term often used to refer to analyses of what could happen and how bad it would be, without analysis of likelihood.

How bad would it be if it did happen? is often called *consequence* and sometimes called *hazard,* in the sense of a specific measure of potential for loss. The measure of consequence can be direct (e.g., property is damaged) or indirect (e.g., the company is out of business for several days). It can be objective (e.g., replacement cost in monetary units) or subjective (e.g., pain and suffering effects of injury, utility measures of damage).

How likely is it to happen? is usually called *probability*. Probability can be relative (e.g., likelihood of this loss is how much greater or smaller than likelihood of that loss) or absolute (e.g., how many times a year, given a population of people or property). Probability can be regarded as objective and measured objectively (e.g., how many occurrences per year in a recent period of time). It can be regarded as objective but measured subjectively (e.g., how many occurrences do we estimate will occur next year, given data on the number of occurrences last year and impressions on what has changed since last year). It can be regarded as and measured subjectively.

Both consequence and probability can be either explicit in a formal fire risk analysis or implicit and unquantified in a more simplified fire risk analysis (e.g., *fire risk index*).

For purposes of use by fire protection engineers, we assume that fire risk analysis is a scientific process, closely linked to calculations based on proven relationships and the collection and analysis of valid and appropriate data, to describe the form, dimension, and characteristics of the fire risk. Fire risk analysis can take different approaches depending on the purpose and scope of the analysis or assessment. Some assessments look back to try to infer probabilities and other risk-related measures based on practices and fire loss experience after an event such as the introduction of home smoke alarms. Other assessments look ahead and try to predict what the practices and fire loss experience would be after an event such as legislating residential sprinklers in homes.

The approach taken to fire risk analysis can also differ based on the availability—quantity, quality, and detail—of data for the purpose. Assessing the fire risk for U.S. residences, for example, one is able to draw on a very large number of documented fire events but with limited detail. Assessing the fire risk for U.S. nuclear power plants, by contrast, has far fewer fire events to draw upon but much more detail on each such event. And assessing the fire risk in any specific existing building will involve very few events in that building and questions of relevance for data from any other building or group of buildings.

In fire safety engineering, risk analysis is most generally used to evaluate fire protection strategies for a particular application or for a class of facility or operation. In other words, there are a sizeable number of buildings and some considerable relevant fire loss history to draw upon.

Terminology and Concepts

The terminology of fire risk analysis is not consistent. For example, a committee of the Society for Risk Analysis identified 17 different definitions of *risk* [1]. If one considers risk to be the full probability distribution of hazardous events and loss consequences associated with a

building, product, or other entity to be studied, then all 17 definitions can be seen as alternative summary measures taken from that common distribution. The important point, however, is that for many people, a summary measure is not just a summary measure related to risk, useful for analysis; it *is* the risk. As another example, the terms *analysis* and *assessment* are often used interchangeably, yet some sources make sharp distinctions. We will provide distinct definitions.

The rest of the chapters in this section also show some inconsistencies in definitions and concepts. These are largely a function of differences in the authors' backgrounds, topics, resources, and intents. In general, the definitions and concepts used are similar, even when they are not identical.

An overview of terms is best presented in the form of a glossary, but the list below is presented in what is meant to be a logical sequence, rather than alphabetically. More extensive glossaries can be found in Grose [2] and Rowe [3].

Hazard A hazard is a chemical or physical condition that has the potential for causing damage to people, property, or the environment [4]. Hazard is any situation that has the potential for causing injury to life or damage to property and the environment [5].

Risk Risk is the potential for realization of unwanted, adverse consequences to human life, health, property, or the environment. Estimation of risk (for an event) is usually based on the expected value of the conditional probability of the event occurring times the consequence of the event given that it has occurred [6]. It follows that risk for a building, a product, or some other entity would be the probability distribution of events and associated consequences relevant to that building, product, or entity.

Probability According to the frequency interpretation, probability is the proportion of the time an event will occur in the long run. According to the subjective interpretation of probability, it is a measure of the strength of a person's belief concerning the occurrence or nonoccurrence of an event [7]. Probabilistic analysis is not well established in fire protection engineering, where empiricism, heuristics, and, more recently, physics-based modeling are principally used to make decisions. Probabilistic analysis is more established in fields such as decision analysis, management science, operations research, industrial and systems engineering, and systems safety. The mathematics of probability allow us to formulate engineering models which recognize uncertainty and deal with it quantitatively and consistently. Probability and statistics are covered in Chap. 73.

Consequence Consequence is a measure of the expected effects of an incident outcome case [4].

Perceived Risk Any measure of risk preferences in which the scale is not fully explainable by some objective measure of loss, direct or indirect, may be a measure of perceived risk. Studies of risk perception have identified a number of factors that consistently cause objectively equal risks to be perceived differently, including preferences for more certainty over less certainty (i.e., *risk aversion*), familiar over unfamiliar risks, voluntary over involuntary risks, readily detectable risks over undetectable or hidden risks, and common or ordinary risks over dramatic or memorable risks. The field of *risk communication* is devoted, in part, to finding ways for individuals and groups with differing ways of perceiving risks to communicate effectively, understand one another, and collaborate on mutually acceptable analyses and decisions.

Risk Analysis Risk analysis is the detailed examination, including risk assessment, risk evaluation, and risk management alternatives, performed to understand the nature of unwanted, negative consequences to human life, health, property, or the environment. Risk analysis is an analytical process to provide information regarding undesirable events, and it is the process of quantification of the probabilities and expected consequences for identified risks [6].

Risk Assessment Risk assessment is the process of establishing information regarding acceptable levels of a risk and/or levels of risk for an individual, group, society, or the environment [6].

Risk Estimation Risk estimation is the scientific determination of the characteristics of risks, usually in as quantitative a way as possible. These characteristics include the magnitude, spatial scale, duration, and intensity of adverse consequences and their associated probabilities as well as a description of the cause and effect links [6]. One complication is that a totally objective or scientific way to measure fire risk does not exist. Problem identification, data collection and reduction, and integration of information are all replete with subjective evaluations.

Risk Evaluation Risk evaluation is a component of risk assessment in which judgments are made about the significance and acceptability of risk [6].

Risk Identification Recognizing that a hazard exists and trying to define its characteristics is called risk identification. Often risks exist and are even measured for some time before their adverse consequences are recognized. In other cases, risk identification is a deliberate procedure to review, and, it is hoped, to anticipate possible hazards [6].

Acceptable Risk A value judgment applied to a particular scale for the measurement of risk yields a definition of acceptable risk. It therefore requires a prior decision on the scale and method used to estimate or measure risk and a second decision on the person or group whose views on acceptability are to be used. For a practicing engineer, acceptable risk is likely to be risk acceptable to the client. For an authority having jurisdiction (AHJ) or anyone answerable to an AHJ, acceptable risk is meant to be acceptable to society in general or to a particular community.

It is an axiom of fire risk analysis that zero risk is not an achievable goal. There are no risk-free alternatives available to individuals or organizations. No technology is 100 % reliable or totally immune to misuse, and even if technological risk could be eliminated, natural catastrophes such as lightning strikes, wildland fires, earthquakes, and wind storms include the potential for fire loss. An important corollary is that reducing fire risk may increase other forms of risk. An obvious case is the potential damage to the ozone layer from use of halon.

The goal that comes closest to being practical and yet striving for zero risk is to require that risk be as low as is technically possible. For fire protection engineering, this goal may take the form of accepting the residual risk after all identified risk reduction strategies and choices have been adopted. Or, for individuals with special preferences for particular fire protection strategies (e.g., active systems over product or material requirements, or vice versa, and either over education and training), acceptable risk may be the residual risk after favored choices are in place. One complication is that the residual risk in these cases may be perceived as zero, implying no prior acceptance of the nonzero risk that actually remains.

A Universally Acceptable Level of Fire Risk Does Not Exist No matter how one defines the term *acceptable level of fire risk,* it will be dependent on the problem context and on the individual judging acceptability, that is, on the alternatives and objectives. Individuals and organizations are inconsistent in their risk aversion. Surveys show wide variations with respect to factors such as voluntary versus involuntary risk and perceived versus calculated risk.

One contention is that the present public fire risk situation must be acceptable since otherwise there would be greater concern and call for action. This view is not a fully reliable generalization. People may have "accepted" the current risk because they believed it to be lower than it really is, believed no technically feasible alternative existed (which can change because technology changes or because perceptions of technology change), or saw no politically effective way to make their lack of acceptance known. Moreover, the current situation is a compromise among the greatly differing preferences of many

individuals and groups, whose relative influence on the process of choice may also change. More elaborate discussion of the issues associated with acceptable risk can be found in Lowrance [8] and Fischoff et al. [9].

Vulnerability The susceptibility of life, property, and the environment to injury or damage if a hazard manifests its potential is vulnerability [5].

Methods of Fire Risk Analysis

Fire risk analysis is basically a structured approach to decision making under uncertainty. Within this general structure, there are many techniques or approaches to both qualitative and quantitative fire risk analysis. For each application, consider the level of mathematical sophistication appropriate to meet objectives.

A generalized concept of fire risk analysis has these steps:

1. Identify fire hazards.
2. Quantify the consequences and probabilities of the fire hazards.
3. Identify hazard control options.
4. Quantify the effects of the options on the risks of the hazards.
5. Select the appropriate protection.

At each of the two stages of quantification, there is a wide range of possibilities of depth and detail, and the actual quantification can take place anywhere on a spectrum from a principal basis in hard data and established science to a principal basis in expert judgment.

Fire risk analysis begins—and for some applications may end—with the identification of fire hazards. A preliminary assessment of areas of potential concern in facility design and operational concepts may be organized by location (e.g., area of a plant) or by activity (e.g., manufacturing versus office functions, wherever they occur). This identification provides a structure for subsequent estimates of the probability of occurrence of the events in each possible accident sequence and thereby of each possible deleterious consequence.

Formal fire risk assessment evolved with the insurance industry in the nineteenth century. Methods of fire risk analysis may be classified into four categories: (1) checklists, (2) narratives, (3) indexing, and (4) probabilistic methods [10]. Checklists and narratives are nonquantitative approaches that may address steps 1, 3, and 5 above while bypassing steps 2 and 4. Indexing is a thorough quantification method that is heuristic rather than fundamentally based. Probabilistic methods have grown in use over the last third of a century but remain rare even today.

Checklists are a common accessory of fire safety consisting of a listing of hazards, usually with recommended practices. A checklist is usually less generic than a model code or standard. It may even be so specific that it is intended to apply to a single class of buildings under management of a single owner, reflecting the special concerns of that owner.

A checklist is a practical tool to support analysis of a building relative to a code or standard that forms the basis for the checklist. It is very seldom that all criteria in a code or standard apply to a single building. The fire protection engineer must focus on only those requirements that are applicable to a specific project. A checklist can aid in this process. It also makes requirements easier to read, understand, and track to compliance.

Checklists face a trade-off between practicality and ease of interpretation. A long checklist might list 50 fire safety factors, with each item described in a manner that is readily visible or measurable, but those 50 items are not all likely to be comparably important. A short checklist, on the other hand, is usually composed of conceptual features of fire safety, which may all be very important but may all require interpretation to be made measurable.

Moreover, checklists do not capture the interaction of fire risk factors, including the manner in which the importance of one fire risk factor will change as a function of performance on another factor. For example, the relative value of hydrants, sprinklers, and extinguishers is not constant but a function of other features of a structure's form and utility.

Narratives consist of a series of recommendations—things to do and not do—related to fire risk and safety. They are probably the earliest approach to fire risk assessment, stemming from the observation that fire is capable of destroying certain materials, such as wood, fur, and flesh. This realization would have led to a communication from parent to child on the avoidance of these fire dangers. In this earliest form, narratives were much simpler and less finished than checklists. They were not comprehensive with regard to hazards, and so they did not support a thorough review.

As the piecemeal parent's advice format evolved over the years, the narrative approach developed into the present multivolume set of the NFPA *National Fire Codes*® 2000 edition [11]. These contain the bulk of our present-day wisdom on fire safety. The information is presented in the form of descriptions of various hazardous conditions and ways to reduce or eliminate them. In this modern form, narratives are often more finished than checklists, which may be developed as simplified, practical tools to serve the more basic narratives.

Like checklists, narratives do not attempt to evaluate the fire risk quantitatively. A risk is judged acceptable if it is addressed in accordance with published recommendations. The criterion is one of pass or fail, and the residual risk remaining if you pass is never quantified or evaluated. Also like checklists, narratives cannot hope to cover the myriad conditions of human activity. While there is much common ground among different fire hazard situations, there is considerable variation in detail.

Indexing is representative of the quantitative fire risk assessment that originated with the insurance rating schedule. The approach has broadened to include a wide variety of applications. In general, fire risk indexing assigns values to selected variables based on professional judgment and past experience. The selected variables represent both positive and negative fire safety features and the assigned values are then operated on by some combination of arithmetic functions to arrive at a single value. This single value can be compared to other similar assessments or to a standard to rank the fire risk. Chapter 82 covers this subject.

Some measures used in fire risk analysis, such as *probable maximum loss* (PML), sound more fundamentally grounded than fire risk indexes but may actually be less so. There is no established consensus on how improbable a loss must be to be ineligible as the probable maximum loss, and the designation is sometimes given without benefit of any explicit or formal analysis. The resulting subjectivity of such a determination suggests that this value is more of an ordinal label than a quantitative measure of risk (which is not to say that it does not have usefulness).

Matrices and *contours* are methods that can fall between indexes and full-fledged probabilistic methods. A risk matrix typically provides a discrete partitioning of relative consequences along one dimension and relative likelihood along the other. The entry in each matrix cell may include a description of hazards known or believed to have that combination of consequence severity and likelihood, and may also be used to record judgments on the acceptability of such risks and/or recommendations on steps to take to reduce such risks. A risk contour is a continuous analogue to a risk matrix. Curves are drawn on a two-dimensional graph with one axis for consequence and one for probability, with a curve representing types of hazards or technically achievable states.

Probabilistic methods are the most informative approaches to fire risk assessment in that they produce quantitative values, typically produced by methods that can be traced back through explicit assumptions, data, and mathematical relationships to the underlying risk distribution that all methods are presumably seeking to address. Most of the chapters in this section of the handbook are devoted to engineering methods of use in executing a formal probabilistic analysis of fire risk. Some common, generic methods of fire risk analysis follow.

Event Tree An event tree is a graphical logic model that identifies and quantifies possible outcomes following an initiating event [4]. The

tree structure is organized by temporal sequence. Probabilities can be calculated from the tree, and consequences are typically assigned to the end states but may cumulate along the tree.

Fault Tree A fault tree is a method for representing the logical combinations of various system states that lead to a particular outcome [4]. The tree structure is organized by logical dependency. Probabilities can be calculated from the tree. Consequences are typically defined in an either/or form (success or failure) so that the probabilities suffice to calculate the risk, as defined.

Decision Tree A decision tree is a method for representing the possible outcomes following a succession of events, combining points where the ensuing path is subject to choice and points where it is not. The analysis operates similarly to an event or fault tree, and the simplest decision trees consist of a set of initial choices and an event or fault tree associated with each.

Influence Diagram An influence diagram is a graphical representation of the relationship of the decisions and uncertainties in a decision problem [12, 13]. The diagram is more flexible and less unidirectional than any type of tree diagram. It is designed to focus more on the elements of decision making and less on relevant underlying physical phenomena.

Overview of the Section

This section of the handbook is organized into three broad areas that progress from the general to the specific. There are some basic tools that most approaches to fire risk analysis should consider if not incorporate. There are some examples of generic models applied to fire safety problems, and there are detailed descriptions of fire risk analysis procedures that have been adopted in several areas of application.

The most common use of fire risk analysis is as a basis from which to make choices. The choice may be between two alternative designs for a building or two alternative formulations for a model code or standard. The choice may be whether to tighten requirements on product type A or product type B. Chapter 77 describes *decision analysis,* a generic field on forms of analysis that support this kind of decision making. *Cost-benefit analysis* is a specific type of decision analysis, in which a fire risk analysis provides estimates for some of the benefits, and other analysis quantifies corresponding costs.

Chapter 74 addresses *reliability*. Fire risk analysis depends upon many types of probabilities. One is fire scenario probability, the estimation of likelihood for the initial conditions and ensuring major events in fire development. Another group of probabilities might be transitory conditions related to people, such as the locations and capabilities of occupants when a fire begins. A critically important set of probabilities have to do with status and capabilities of fire protection equipment, features, and arrangements. Is the battery working in the smoke alarm? Is the sprinkler valve open or closed? Is the fire door working or blocked open? These are all questions of reliability addressed in Chap. 74.

Chapter 76 addresses *uncertainty*. Early on, the comment was made that the term *fire risk* refers to the uncertainty of loss. The concept of safety itself is one of uncertainty. There is no such thing as absolute safety; human activity will always and unavoidably involve risks. Chapter 76 addresses a narrower definition of uncertainty—not the uncertainty of the potential victim regarding the fact of fire loss but the uncertainty of the engineer or decision maker regarding estimates of the magnitude of fire risk.

Uncertainty may be caused by imprecision or bias in our techniques of observation or calculation, a lack of clarity in our goals, uncontrollable technological variation, or variations of natural phenomena, to name only the major components. The concept of fire is also uncertain. Unwanted combustion is perhaps the least predictable common physical phenomenon. Uncertainty analysis is the scientific calculation procedure that should underpin choices of *safety factors* and *safety*

margins. It is central to the valid use of fire risk analysis—or any other form of engineering analysis—for code equivalency, design approval, or any other important decision in the real world.

Chapter 78 addresses *data sources* for engineering analysis, particularly data useful for calculating scenario probabilities, reliability probabilities, or any other probabilities needed for fire risk analysis.

Chapter 79 addresses the *measurement of consequences in economic terms*. This measurement includes indirect losses, economic measures of the value of a lost life or of an injury, and the use of utility measures to capture people's desire to avoid uncertainty about loss, as well as loss itself, the implications for people's risk aversion for the basic mathematics of insurance, and so on. The common theme is treating consequences comprehensively and in a form that captures people's real preferences and can be readily compared to the costs of alternative choices. Chapter 81 addresses *other economic topics* that arise in the practice of engineering analysis, with particular emphasis on monetary valuations over time (e.g., rate of return, interest, discounting).

Chapter 80 describes techniques and available models using *computer simulation,* with special emphasis on those having a fire risk analysis basis, such as state-transition models. Chapter 82 describes less-quantified methods of fire risk analysis, involving *fire risk indexing*. Fire scenarios play an important role in many aspects of fire safety engineering. Significant among these is fire risk analysis, hence Chap. 38 describes methods of scenario development and quantification. This is a task that applies to all applications of fire risk analysis, though it tends to take a different form specific to each application, but is not required in this form or detail in other types of fire protection engineering analysis.

Chapters 75 and 83, respectively, describe general techniques and available methods for fire risk analysis of buildings and processes. Chapter 89 describes the specific methods tailored to application where the use of fire risk analysis is far more common than in others, namely, nuclear power plants. Chapter 90 describes applications for transportation vehicles. Chapter 84 presents the means to use fire risk analysis in the evaluation of the safety of consumer products. Chapter 85 shows applications to *health care facilities*.

Activities and Resources

Every major group involved in guidance related to fire safety now has a committee or a publication devoted to fire risk analysis, and the emphasis on risk-based or risk-informed approaches to decision making is growing rapidly. Thus, in addition to the many sources of specific models and methods mentioned in the subsequent chapters, there are a growing number of sources for generic work and guidance. Among the more important activities are the following:

- SFPE has added the *SFPE Engineering Guide to Fire Risk Assessment* to its growing collection of practice guides. In addition, fire risk analysis is addressed in context in a more limited form in the SFPE publication on an overview of performance-based design, the *SFPE Engineering Guide to Performance-Based Fire Protection.*
- NFPA's Technical Committee on Fire Risk Analysis, whose purpose is to provide assistance and guidance to other committees on methods and concepts in fire risk analysis, published NFPA 551, *Guide for the Evaluation of Fire Risk Assessments,* in 2004. The same committee now maintains NFPA 550, *Guide to the Fire Safety Concepts Tree,* 2002 edition, one of the most widely cited and used fault tree formats in fire risk analysis. Development of fire risk analysis methods for general and specific purposes has been a recurring emphasis of projects organized by NFPA's Fire Protection Research Foundation.
- ASTM maintains Standard E 1776, *Standard Guide for the Development of Fire-Risk-Assessment Standards,* to guide the writing of fire risk assessment standards for burnable products.

- The International Organization for Standardization (ISO) TC 92/SC 4 has published Technical Specification 16732, *Guidance on Fire Risk Assessment*. This international document is compatible with but much less detailed than the SFPE guide, which was published later.
- The Society for Risk Analysis is the principal worldwide professional organization devoted to risk analysis. It devotes comparatively little emphasis to engineering applications and to acute outcomes, instead focusing more on long-term chronic illness consequences.
- The Institute for Operations Research and the Management Sciences (InFORMS) has areas of emphasis in decision analysis and applies and develops risk analysis concepts and methods through that activity.

John M. Watts Jr. holds degrees in fire protection engineering, industrial engineering, and operations research. He is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. Dr. Watts also serves as editor of NFPA's *Fire Technology*.

John R. Hall Jr. is assistant vice president for fire analysis and research at the National Fire Protection Association. He has been involved in studies of fire experience patterns and trends, models of fire risk, and studies of fire department management experiences since 1974 at NFPA, the National Bureau of Standards, the U.S. Fire Administration, and the Urban Institute.

Probability and Statistics

73

John R. Hall Jr. and Francisco Joglar

Introduction

This chapter introduces the basic definitions and methods of probability and statistical analysis, which are the foundation for the reliability, and fire risk analysis, and other topics presented in this section. With increased availability of sizeable quantities of reliable data on a whole range of topics related to fire protection engineering, it is essential that the analysis of this data be based on sound mathematical principles from probability and statistical theory. The chapter is divided into two main sections: probability theory, and statistics.

Basic Concepts of Probability Theory

Probability Theory

Probability theory is the branch of mathematics dealing with the modeling of uncertainty through measures of the relative likelihood of alternative occurrences, whether specifically or generally defined. The term "set" is often introduced when describing probability theory from a classical perspective.

J.R. Hall Jr.
National Fire Protection Association

Set

A set is a collection of elements. For a set to be well-defined, it must be possible to identify with certainty whether any object is or is not an element or part of the set.

Set Theory

The theory of sets is the most fundamental branch of mathematics and is relevant to probability theory, because all probabilities are built up from sets.

Subsets

A set, A, that consists entirely of elements that are also contained in set B is called a subset of B. Each element in a set may also be considered a subset of that set.

Set Operators

There are three basic operators essential to the algebraic manipulation of sets:

Complement (~): The complement operator applies to a single set A and produces the set of all elements that are *not* in A. Such an operator is always applied relative to some specification of the set of all elements,

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_73, © Society of Fire Protection Engineers 2016

which is called the *universal set* (∪). The complement of the universal set is the *null set* (Ø) or *empty set,* the set with no elements.

Union (∪): The union operator is applied to two sets, as in $A \cup B$. It produces the set consisting of all elements that are members of *either* A or B or both.

Intersection (∩): The intersection operator is applied to two sets, as in $A \cap B$. It produces the set consisting of all elements that are members of *both* A and B.

Relationships Among the Operators

$$\sim (A \cup B) = \sim A \cap \sim B$$
$$\sim (A \cap B) = \sim A \cup \sim B$$
$$(A \cup B) \cap C = (A \cap C) \cup (B \cap C)$$
$$(A \cap B) \cup C = (A \cup C) \cap (B \cup C)$$
$$(A \cup B) \cup C = A \cup (B \cup C)$$
$$(A \cap B) \cap C = A \cap (B \cap C)$$

Venn Diagrams Venn diagrams are a graphical technique for displaying relationships among sets (represented by circles) and operators, within a rectangle that represents the universal set, ∪ (Figs. 73.1, 73.2, and 73.3).

Sample Space

Sample space is a set of mutually exclusive elements, each representing a possible outcome or occurrence and collectively representing all possible outcomes or occurrences for the experiment or problem under consideration. Mutually exclusive elements refer to those elements with no common outcomes (i.e., no intersection between them). A sample space must also have the property that the set operators defined previously, if applied to the subsets of the sample space in any combination, will always produce subsets of the sample space. Subsets of a sample space are called *events*.

Probability Measure

A probability measure is a mathematical function, P, defined on the subsets (events) of a sample space, U, and satisfying the following rules:

1. $P(A) \geq 0$ for any A, where A is an event subset of U.
2. $P(\text{Ø}) = 0$.
3. $P(U) = 1$.
4. If $A \cap B = \text{Ø}$, then $P(A \cup B) = P(A) + P(B)$.

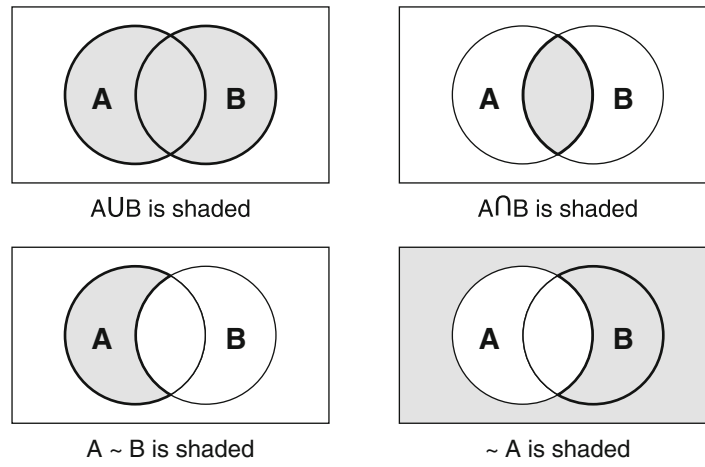

Fig. 73.1 Examples of set operators using shading for display

In the classical theory of probability, it was assumed that all probability measures must be based on experiments (actual or at least imaginable) which could be run repeatedly, so that for each outcome e (an element of the sample space of possible outcomes), $P(e)$ would be given asymptotically as the ratio between the number of times outcome e occurs and the number of times the experiment is performed. This interpretation is called the *frequency interpretation of probability*. More recently, theorists associated with the Bayesian school of statistical inference have argued for the interpretation of probability only as a measure of the individual's strength of belief in the likelihood of an outcome. This interpretation is called *subjective probability*. Each of these two schools represents both an underlying conceptual model and an approach that makes practical sense in some but not all situations. In assigning probabilities to the outcomes of heads and tails for a single coin, for example, a relatively brief frequency experiment is easy to conduct. In assigning probabilities to the possible values of the annual inflation rate for next year, the requisite experiment cannot be performed repeatedly. The mathematics of probability theory applies regardless of the source of the probability measure.

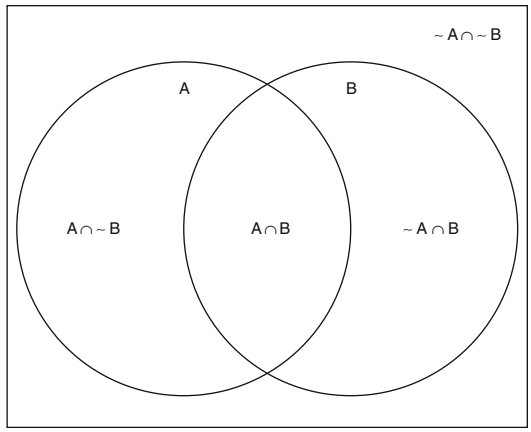

Fig. 73.2 Example of set operators applied to two sets

Probability Formulas Related to Set Operators

1. $P(A \cup B) = P(A) + P(B) - P(A \cap B)$
2. $P(\sim A) = 1 - P(A)$

These two formulas state, respectively, that (1) the probability that either (inclusive version) of two events will occur is equal to the sum of the probabilities that each event will occur minus the

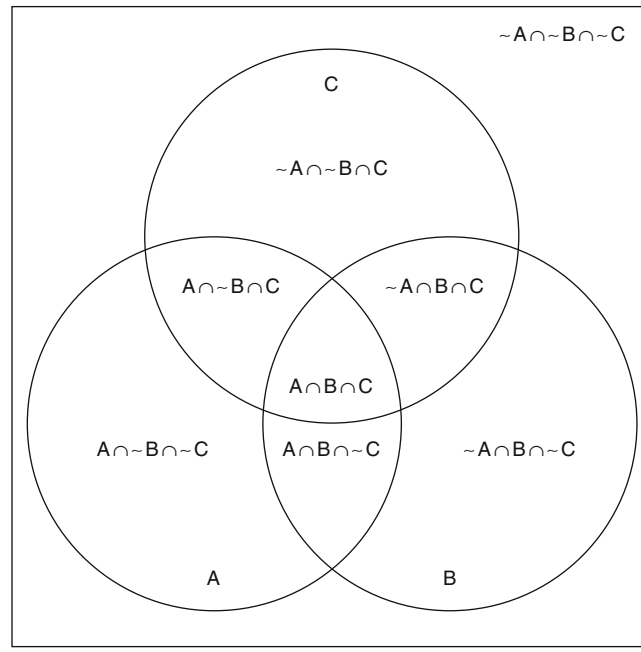

Fig. 73.3 Example of set operators applied to three sets

probability that both will occur; and (2) the probability that an event will not occur is equal to one minus the probability that it will occur.

Independence and Conditionality

The two events, A and B, are called *independent* if $P(A \cap B) = P(A) \times P(B)$. Two events that are not independent are called *dependent*.

The *conditional probability of A given B*, $P(A|B)$, is defined as $P(A \cap B)/P(B)$. It is normally interpreted to mean the probability that A will occur, given that B has occurred or will occur. If A and B are independent, then $P(A|B) = P(A)$ and $P(B|A) = P(B)$; in other words, the occurrence of A does not affect the likelihood of B, and vice versa.

It is important to note that two events may be dependent without either being the cause of the other and without any apparent logical connection. A common phenomenon involves two apparently unrelated variables (e.g., annual fire department expenditures on gasoline, annual sales revenue from plastics and petrochemicals) that are dependent because each is related in an understandable way to a third variable (e.g., price per barrel of oil).

Bayes's law (also called *Bayes's theorem* and *Bayes's formula*) states that

1. If B_i, $i = 1, \ldots, N$, are sets (events), and
2. If $B_1 \cup B_2 \cup \ldots \cup B_N = U$, and
3. If $B_i \cap B_j = \emptyset$ for all $i \neq j$ between 1 and N, and
4. If $P(B_i) \neq 0$, $i = 1, 2, \ldots, N$

then

$$P(B_i|A) = \frac{P(B_i) \times P(A|B_i)}{\left[P(B_1) \times P(A|B_1) + P(B_2) \times P(A|B_2) + \cdots + P(B_N) \times P(A|B_N)\right]}$$

Bayes's law is a particularly powerful consequence of the laws of conditional probability and is the foundation for modern statistical decision theory. What makes it so powerful is this application. Suppose $P(B_1), \ldots, P(B_N)$ represent the current best estimates of the probabilities of various events of interest prior to the performance of an experiment (or the collection of some data on experience). These are called *prior probabilities*. Suppose A is a possible outcome of that experiment whose probability of occurrence, given each of the events $B_1, \ldots, B_N$, can be derived. Then Bayes's law can be used to develop a new set of probabilities, $P(B_1 \mid A), \ldots, P(B_N \mid A)$ that incorporate the information provided by the experiment. These are called *posterior probabilities* because they are probabilities calculated *after* the gathering of information (e.g., through an experiment).

Example Suppose you have ten coins, nine of which are fair (0.5 probability of heads) and one of which is fixed (1.0 probability of heads). Choose one coin. With no other information, the probability that you have a fair coin (B_1) is 0.9 and the probability that you have the fixed coin (B_2) is 0.1. Suppose you flip the coin once.

If it comes up tails, you know it is a fair coin and Bayes's law confirms this. Let A be the event of getting tails on the one coin flip. Then

$$P(A|B_1) = 0.5 \quad \text{and} \quad P(A|B_2) = 0$$

Therefore,

$$P(B_1|A) = \frac{(0.5)(0.9)}{(0.5)(0.9) + (0)(0.1)} = 1$$

If the coin comes up heads, you still do not know whether it is the fixed or a fair coin. Since

heads is more likely with the fixed coin, the evidence points slightly in that direction. Let A' be the event of getting heads on the single coin flip. Then

$$P\left(A^{'}\middle|B_1\right) = 0.5 \quad \text{and} \quad P\left(A^{'}\middle|B_2\right) = 1$$

Therefore,

$$P\left(B_1\middle|A^{'}\right) = \frac{(0.5)(0.9)}{(0.5)(0.9) + (1.0)(0.1)} = 0.82$$

Thus the result of flipping the coin once and obtaining heads has lowered the estimate of the probability that you hold a fair coin from 0.9 to 0.82; correspondingly, your estimate that you hold the fixed coin has risen from 0.1 to 0.18.

Random Variables and Probability Distributions

A *random variable* is a real-number-valued function defined on the elements of a sample space. In some cases, the elements of a sample space may lend themselves to association with a particular random variable (e.g., the sample space consists of outcomes of tossing a die; the random variable is the number of spots on the exposed face). In other cases, the random variable may be only one of many that could easily have been associated with the sample space (e.g., the sample space consists of all citizens of the United States; the random variable is the weight to the nearest pound).

Each value of a random variable corresponds to an event subset of the sample space consisting of all elements for which the random variable takes on that value. The *probability of a value of the random variable,* then, is the probability of that event subset.

A *discrete probability distribution* is one for which the random variable has a finite or countably infinite number of possible values (e.g., values can be any integer from 0 to 10; values can be any integer).

A *continuous probability distribution* is one for which the random variable can take on an uncountably infinite number of possible values (e.g., values can be any real number from 0 to 10; values can be any real number).

A *probability distribution function* (also called *probability density, probability density function,* and *probability distribution*) is a mathematical function that integrates to 1.0, *f,* that gives the probability associated with each value of a random variable, $f(y) = P(x = y)$. The term *density* is usually reserved for random variables that can take on an uncountably infinite range of values, so that the probability of a range of values of the variable must be computed through integral calculus.

Because each value, *y,* of a random variable, *x,* is associated with a subset of the sample space, $f(y) \geq 0$ for all y.

Because no element of a sample space can take on two or more values of a random variable and each element must take on some value, the values of the random variable collectively correspond to a set of mutually exclusive subsets that exhaust all elements of the sample space, and so

$$\sum_{\text{all } x} f(x) = 1$$

for discrete probability distributions, and

$$\int_{\text{all } x} f(x)dx = 1$$

for continuous probability distributions.

A *cumulative distribution* is a mathematical function that, for each value of a random variable, gives the probability that the random variable will take on that value or any lesser value

$$F(y) = P(x \leq y) = \sum_{x \leq y} f(x)$$

for discrete probability distributions, and

$$F(y) = \int_{x \leq y} f(x)dx$$

for continuous probability distributions.

Note that some references use the term "probability distribution" to refer to the cumulative distribution function, *F,* of a continuous probability distribution, while referring to the

probability density function, *f,* only as a probability density function.

A *survival function* is a mathematical function that, for each value of a random variable, gives the probability that the random variable will exceed that value

$$S(y) = P(x > y) = \sum_{x>y} f(x)$$

for discrete probability distributions, and

$$S(y) = \int_{x>y} f(x)dx$$

for continuous probability distributions.

Therefore, for any probability distribution function $P(x)$ and any value y, the cumulative distribution and the survival function based on sum to one for all values of y.

$$F(y) + S(y) = 1$$

A *multivariate probability distribution* gives the probability for all combinations of values of two or more random values, for example, $f(u, v) = P(x = u \text{ and } y = v)$.

Key Parameters of Probability Distributions

Certain key parameters of probability distributions are of use because (1) they help to provide essential summary information about the random variable and its probability distributions and (2) they are included in the functional forms of certain probability distributions that are of use in many practical situations.

The mean, μ, of a random variable (also called its *expected value* or *average*) is defined as

$$\mu = \sum_{\text{all } x} xf(x)$$

for discrete probability distributions, and

$$\mu = \int_{\text{all } x} xf(x)dx$$

for continuous probability distributions. Notice that the mean is the center of mass of a probability distribution. Recall that the center of mass of a two-dimensional shape single rigid body (in this case the probability distribution function) is the point in the x axis where the distribution "balances" itself (i.e. the weighted relative position of the distributed mass sums to zero) and the average of the weighted position coordinates of the distributed mass defines its value. It is also written as $E(x)$, which stands for *expected value of x*. This is the most commonly used of several parameters that relate to some concept of the most typical or average value of a random variable.

The expected value can also be calculated for a function of the random variable, as follows:

$$E[g(x)] = \sum_{\text{all } x} g(x)f(x)$$

for discrete probability distributions, and

$$E[g(x)] = \int_{\text{all } x} g(x)f(x)dx$$

for continuous probability distributions. In Microsoft Excel, the expected value of a given sample size can be calculated using the "=AVERAGE(Sample_Range)" function, where the Sample_Range input is the group of cells containing the sample data.

The *variance,* σ^2, of a random variable is a measure of the likelihood that a random variable will take on values far from its mean value. It is a parameter used in the functional form of some commonly occurring probability distributions.

$$\sigma^2 = \sum_{\text{all } x} (x - \mu)^2 f(x)$$

for discrete probability distributions, and

$$\sigma^2 = \int_{\text{all } x} (x - \mu)^2 f(x)dx$$

for continuous probability distributions. In Microsoft Excel, the variance of a given sample size can be calculated using the "=VAR (Sample_Range)" function, where the

Sample_Range input is the group of cells containing the sample data. The function "=VARP(Sample_Range)" can be used for calculating the variance of an entire population.

The variance can also be expressed as the expected value of a function of the random variable, as follows:

$$\sigma^2 = E\left[(x-\mu)^2\right] = E\left(x^2\right) - \mu^2$$
$$= E\left(x^2\right) - [E(x)]^2$$

The variance is expressed as σ^2 because most calculations use the square root of the variance, which is called the *standard deviation,* σ. In practical terms, the standard deviation is the average of the distances of the different observations in sample to the sample mean. In Microsoft Excel, the standard deviation of a given sample size can be calculated using the "=STDEV(Sample_Range)" function, where the Sample_Range input is the group of cells containing the sample data. The function "=STDEVP(Sample_Range)" can be used for calculating the standard deviation of an entire population.

Example Suppose that ten experiments are conducted to evaluate the heat release rate of new product. Table 73.1 lists that resulting heat release rate values. The average, variance and standard deviation functions in Microsoft Excel are used to evaluate the statistics from the experimental results. Table 73.1 also indicates the Excel functions used for calculating the values. Notice that the function argument E5:E14 is the range of cells where the data is stored in the Excel worksheet.

The *moments* of a probability distribution are defined as the expected values of powers of the random variable. The *n*th moment is $E(x^n)$. Thus, the mean is the first moment, and the variance is the second moment minus the square of the first moment. The value given by $E[(x - \mu)^n]$ is defined as the *n*th moment about the mean.

The function defined by $E[e^{\theta x}]$ is called the moment generating function because it is equivalent to an infinite series whose terms consist of, for all *k,* the *k*th moment of *x* times $(\theta^k/k!)$.

Table 73.1 Heat release values from repeated experiments

Iteration	Sample (kW)	
1	652	
2	649	
3	671	
4	535	
5	583	
6	710	
7	652	
8	649	
9	683	
10	659	
Average (kW)	645	=AVERAGE(E5:E14)
Variance	2250	=VAR(E5:E15)
Standard deviation (kW)	50	=STDEV(E5:E14)

Percentiles refer to the value of the random variable where a specific amount of probability is accumulated. For example, the 5th percentile is the value of the random variable where 5 % of the area under the probability distribution curve is located. In mathematical form, the ith percentile P_i of a distribution can be found solving the integral of the distribution for its upper limit of integration. That is, the equation:

$$P_i = \int_{-\infty}^{x} f(x)dx$$

is solved for x. Recall that x represents the value of the random variable where the area under the distribution curve from $-\infty$ is equal to i. For continuous probability distributions, the median is that value, *y,* for which the cumulative distribution, $F(y)$, is equal to 0.5. For discrete probability distributions, the median is that value, *y,* for which $f(x < y) = f(x > y)$. If the random variable can take on only a finite number of values, the median may not be uniquely defined. The median is less sensitive than the mean to extreme values of the random variable and is the "average" of choice for certain kinds of analyses.

From a discrete perspective, the function "=PERCENTILE(Sample_Range, k)" in

Microsoft Excel can be used for determining the k^{th} percentile of a value in a data sample.

Skewness refers to the symmetry of a probability distribution function around its mean. The median is not equal to the mean in a skewed distribution. An age distribution of fire department uniformed personnel will be skewed, for example, because the small number of personnel in their 50s and 60s will raise the average (mean) age well above the typical age (middle to late 20s). The term is used more frequently than is any specific measure of it. A symmetric distribution has a skewness of zero, no matter how skewness is measured.

Kurtosis is a rarely used term for the relative flatness of a distribution.

Degrees of freedom is the term given to certain parameters in many commonly used distributions (e.g., Student's t, chi-square, F). The distributions that use these parameters are used in tests of the variance of samples. In those tests the parameters always correspond to positive integer values based on the size of the sample (e.g., n, $n-1$, $n-2$). Since increasing sample size gives the sample more freedom to vary, it is natural to call those parameters measures of the "degrees of freedom" to vary in the sample.

Conditional Distributions

From the general definition of conditional probability, the probability of random variable is larger than a conditional value x_o is given by:

$$F(x|x > x_o) = \frac{\Pr(x \le X/x > x_o)}{P(x > x_o)} = \frac{F(x) - F(x_o)}{1 - F(x_o)}$$

where x is the random variable. Figure 73.4 provides a conceptual representation of this formulation. The numerator represents the area under the curve between the variables x_o and x (shaded). The denominator is the area under the curve after the variable x_o (Fig. 73.4).

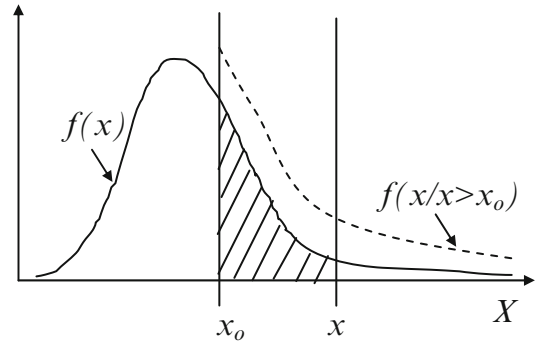

Fig. 73.4 Conceptual representation of the conditional probability of failure

Differentiating with respect to x, the conditional density function is obtained (see Papoulis, "Probability, Random Variables, and Stochastic Processes", 1991).

$$f(x|x > x_o) = \frac{f(x)}{1 - F(x_o)}$$

This conditional density, which is a function of x_o and x will be applied later in the chapter in the analysis of repairable systems. The denominator is by definition a number between 0 and 1, which forces the integral of the function from x_o to infinity to be 1.0. As illustrated by the dashed line in Fig. 73.4, the normalizing factor shifts the function upwards after x_o, but the shape of the distribution remains the same after that point. Again, the area under the curve of the conditional distribution after x_o is 1.0.

Commonly Used Probability Distributions

Uniform and Rectangular Distributions

These distributions give equal probability to all values. The term *rectangular distribution* is reserved for the continuous probability distribution case. It is used to characterize random variables with identical probabilities throughout its range. As a simple example of its discrete form, consider the outcome of rolling a fair dice. Clearly, the outcome is one of six numbers,

each with identical probability of one sixth. Notice that the uniform distribution is "uninformative" over its range. That is, it only suggests a finite range of possible values with equal probability.

1. $f(x) = 1/N$, for $x1, \ldots, x_N$, if $f(x)$ is a discrete probability distribution over N values of a random variable.
2. $f(x) = 1/(b-a)$, for $a \le x \le b$, if $f(x)$ is a continuous probability distribution over a finite range.

Multivariate versions of the uniform distribution can be readily constructed for both the discrete and the continuous cases.

The uniform and rectangular distributions are used when every outcome is equally likely. As such, they tend to be useful, for example, as a first estimate of the probability distribution if nothing is known; that is, if nothing is known, treat every possibility the same. In

Example 1 One of the 30 fire protection engineers in a firm is to be selected at random to accompany the local fire department on a fire code inspection. Each engineer is assigned a playing card, the reduced deck of 30 cards is shuffled and cut several times, and the top card is selected. Here, N is 30, so $f(x) = 1/30$ for each engineer.

Example 2 When the winning engineer arrives at the fire department, a random procedure is used to select one point on the city map. Whatever point is selected, they will inspect the buildings on the property of which that point is part.

Suppose A is the total area of the city. Then $f(x) = 1/A$, for every point in the city. For a given occupancy B, whose lot has area a, the probability of the event of choosing B (which corresponds to choosing any point on B's property) is equal to

$$\int_{\text{all points in } B} \left(\frac{1}{A}\right) dx = \frac{a}{A}$$

Note that although this is a uniform (rectangular) distribution over all *area* in the city, it is not a uniform distribution over all occupancies of the city, because an occupancy's probability of being chosen will be proportional to the size of its lot. In any analysis, there may be several different, incompatible ways of treating all possibilities "equally."

Normal Distribution (Also Called Gaussian Distribution)

The normal distribution, the familiar bell-shaped curve, is the most commonly used continuous probability density function in statistics; its density is a function of its mean, μ, and standard deviation, σ, as follows:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right] \text{ for } -\infty < x < +\infty$$

The *Central Limit Theorem* establishes that for *any* probability density function, the distribution of the sample mean, $\bar{x}$ of a sample from that density asymptotically approaches a normal distribution as the size of the sample increases. This means that the normal distribution can be used validly to test hypotheses about the means of any population, even if nothing is known or can be assumed about the population's underlying distribution. Also, the *Law of Large Numbers* establishes that the standard deviation of the distribution of the sample mean is inversely proportional to the square root of the sample size, which means that larger samples always produce more precise estimates of the sample mean. These two results are the cornerstones of sample-based statistical inference.

In addition to proving a valid distribution for sample *means* in all situations, the normal distribution also directly characterizes many *populations* of interest, including experimental measurement errors and quality control variations in materials properties.

A sample size of at least 30 should be used to obtain an acceptable fit of the sample mean distribution to the normal distribution.

The standard tables of the normal distribution are for a random variable with mean 0 and variance 1. They can be used for values from any normal distribution by subtracting the mean, then dividing the result by the standard deviation. The standardization equation is:

$$z = \frac{x - \mu}{\sigma}$$

Where z is the random variable from the standard normal distribution, and x, μ and σ are the random variable mean and standard deviation of the normal distribution.

The multivariate form of the normal distribution is also commonly used. Its parameters are given by a vector of the means of all the variables and a matrix with both the variances of all the variables and the covariances of pairs of variables (which are functions of the variances and the correlation coefficients).

In Microsoft Excel, the functions "=NORMDIST(x, μ, σ, cumulative)", "=NORMINV(p,μ, σ)", and "=STANDARDIZE(x, μ, σ)", are commonly used to plot and solve the normal distribution. The function NORMDIST solves for the function f(x) described earlier in this section, where x is the random variable, μ and σ are the mean and standard deviation of the normal distribution and the "cumulative" input (which is a Boolean input) is set to FALSE. Setting the "cumulative" input to TRUE returns the value of the cumulative distribution function F(x) instead of f(x). The NORMINV function returns the value of the random variable x that follows a normal distribution that is associated with a probability p. That is, the function solves for the integral equation for percentiles described earlier in this chapter. Finally, the STANDARDIZE function returns the standardized value of the random variable x, which is often characterized with the letter "z". The value of z follows a standard normal distribution.

Example As an example, consider the normal distribution with mean 650 and standard deviation 100 plotted in Microsoft Excel using the function NORMDIST described earlier (See Fig. 73.5). The profile with the square markers is the cumulative function and is obtained setting the cumulative argument to TRUE. The values for this function are read in the rightmost y axis (secondary axis). Notice that the distribution reaches the value of 1.0 when the full range of the distribution is covered. The profile with the diamond markers is the probability density function. Most distribution functions in Microsoft excel are plotted the same way.

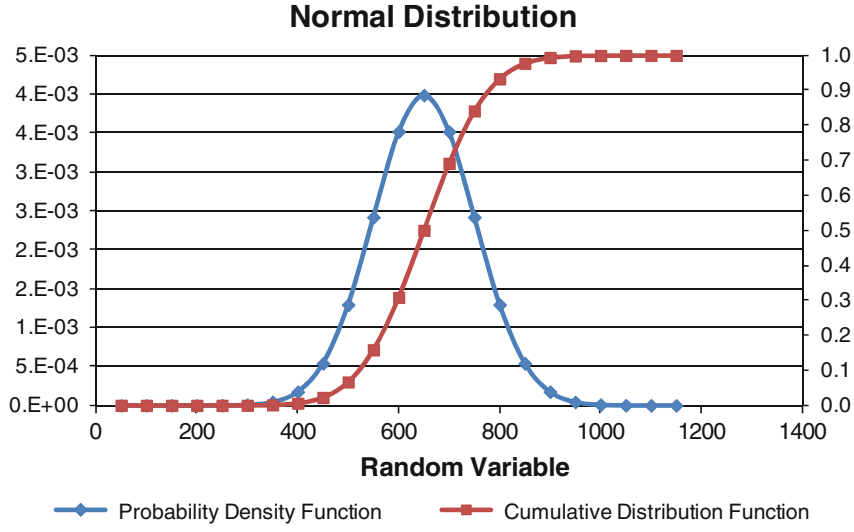

Fig. 73.5 Normal distribution

Example 1 The promotional examination for lieutenant is taken by 100 fire fighters, whose test scores, shown in Table 73.2, fit a normal distribution with mean score of 50 and standard deviation of 15. The fit is not exact because strictly speaking, the 100 scores comprise a discrete distribution, not a continuous distribution, and the possible scores are bounded by 0 and 100. Also, with only 100 scores, the fit to a normal distribution can be seen in this grouped data but might not be apparent if every score had its own frequency entered separately (Fig. 73.6).

Example 2 Suppose the widths of U.S. adults, fully clothed (including overcoats), at their widest points are normally distributed with mean 0.5 m and standard deviation of 0.053 m. Then, a door width equal to the mean (0.5 m) would accommodate 50.0 % of the population $[F(x \leq \mu) = 0.50]$. A door width equal to the mean plus one standard deviation (0.553 m) would accommodate 84.1 % of the population $[F(x \leq \mu + \sigma) = 0.841]$. A door width equal to the mean plus two standard deviations (0.606 m) would accommodate 97.7 % of the population $[F(x \leq \mu + 2\sigma) = 0.977]$.

But some buildings hold 10,000 persons, so suppose it is desired to construct a door width that will be too narrow for only one of every 20,000 persons. Then the value of a is desired, such that $F(x \leq \mu + a\sigma) = 0.99995$. That value of a is 3.87, which translates to a door width of 0.705 m, or more than 40 % wider than the door width that sufficed for one-half the population.

All basic statistics texts contain tables of the cumulative distribution function for the normal distribution.

In engineering practice, the primary use of the normal distribution will be in estimation of parameters. For example, an estimate of a burning characteristic of a product or material can be derived from a series of experiments or tests by calculating the mean value from the test, then

Table 73.2 Normal distribution sample test scores

Score	Number of fire fighters receiving that score
0–9	1
10–19	2
20–29	7
30–39	15
40–49	25
50–59	25
60–69	15
70–79	7
80–89	2
90–100	1

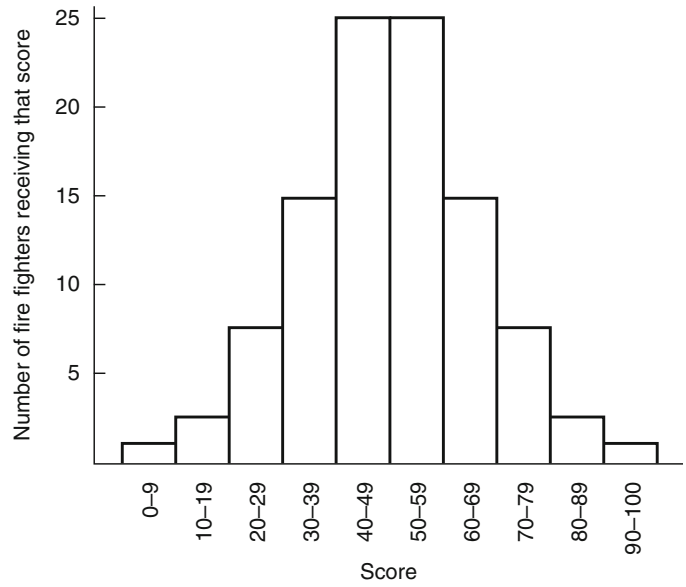

Fig. 73.6 Illustrative frequency bar chart

confirming that the test measurements reasonably fit a normal distribution around the mean. This latter step confirms that the errors are normally distributed, which means the sample mean is an unbiased best estimate of the underlying characteristics.

Example 3 The critical temperature for a steel beam is assumed to be normally distributed with mean = 550 °C and standard deviation of 40 °C. A fire protection engineer is evaluating the potential hazard of a fire below the beam, which will subject it to fire plume temperatures. Based on the heat release rates generated by the type and configuration of combustibles in the location, calculated fire plume temperatures range from 250 to 475 °C. Considering that the evaluation may not have included the lowest and highest heat release rates, the analysts assumes a normal distribution for the plume temperature with a 5th percentile = 250 °C and a 95th percentile = 475 °C. Since the normal distribution is symmetrical, the percentile values can be used for determining the mean of the distribution as follows: 250 + (475–250)/2 = 362.5 °C. Using the = NORMINV(0.05, 0, 1) = −1.64 function in excel for the standard normal distribution returns the random variable value for a probability of 0.05. We can now solve for the standard deviation of the normal distribution for temperature using the standardization formula as follows:

$$-1.64 = \frac{250 - 362.5}{\sigma}$$

The resulting normal distribution has a mean of 362.5 °C and a standard deviation of 68.6 °C.

Log-Normal Distribution

It is not unusual to deal with random variables whose logarithms (to any base) are normally distributed. In such cases, the original variables are said to be log-normally distributed. The log-normal distribution is defined for positive values only. The distribution is particularly appropriate for random variables constrained by zero that can assume few very large values. Equipment down time and failure times, fire load density (i.e., mass of combustibles per unit floor area) among others. The log-normal distribution results from the transformation x = ln (t) where the random variable x is normally distributed with mean μ and standard deviation σ. The mathematical form of the distribution is:

$$f(t) = \begin{cases} \frac{1}{\sqrt{2\pi}\sigma t} e^{\frac{-1}{2}\left(\frac{\ln(t)-\mu}{\sigma}\right)^2} & t \geq 0 \\ 0 & otherwise \end{cases}$$

where μ and σ are the mean and standard deviation of the normally distributed random variable x. The cumulative distribution function F(t) is obtained by a numerical integration of f(t).

The expected value and the variance of t can be obtained with the following equations:

$$E(t) = e^{\mu + \frac{\sigma^2}{2}}$$

$$V(t) = e^{2\mu + 2\sigma^2} - e^{2\mu + \sigma^2}$$

If E(t) and V(t) are known instead, μ and σ can be calculated using the equations above.

In risk analysis and reliability studies we often use the term "error factor" to characterize log-normal distributions. The error factor, EF, is defined as the ratio between the 95th and 50th percentiles of the distribution. Equivalently, it can be also defined as the ratio between the 50th and 5th percentiles of the distribution. It is also useful to note that the μ and σ parameters of the normal distribution can be obtained using the following relationships:

$$\sigma = \log(EF)/1.645$$

$$\mu = \log(mean) - \frac{\sigma^2}{2}$$

where the variable "mean" is the mean of the lognormal distribution.

The log-normal distribution has also been confirmed as a good fit for the distribution of magnitude of monetary loss, [1] which makes it a good choice for estimating extreme-event probabilities. In particular, this permits estimation of the probability or magnitude of the

maximum probable loss, an essential measure in insurance analysis, even if no such large losses have ever been documented.

The log-normal and Weibull distributions are popular choices to represent any skewed dataset when there is no fundamental or established basis for selecting a particular distribution. These distributions are both used, for example, to model occupant premovement times.

In Microsoft Excel, the functions "=LOGNORMDIST(t, μ, σ)", and "=LOGINV (p, μ, σ)", are commonly used to plot and solve the lognormal distribution. The function LOGNORMDIST solves for the function F(t) described earlier in this section, where ln(t) is the random variable, and μ and σ are the mean and standard deviation of the normally distributed ln(t). The LOGINV function returns the value of the random variable t that follows a lognormal distribution that is associated with a probability p. That is, the function solves for the integral equation for percentiles described earlier in this chapter.

Distributions for Significance Tests

The Student's *t,* chi-square, and *F* distributions are the workhorses for statistical hypothesis testing. They are used to determine that two or more objects are or are not clearly different from each other.

Student's *t* Distribution

For small samples, the distribution of the sample mean is not well approximated by the normal distribution. Even for somewhat larger samples, the population variance is typically not known, and the sample variance must be used instead. The Student's *t* distribution may be used instead of the normal distribution, but it does assume that the population is normally distributed. Its distribution is a function of its degrees of freedom, *m*.

$$f(t) = \frac{[\Gamma(m+1/2)]\left[(1+t^2/m)^{-(m+1)/2}\right]}{\sqrt{\pi m}[\Gamma(m/2)]} \quad \text{for} \quad -\infty < t < +\infty$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1}e^{-y}dy$$

Expressed in this standard form, the *t* distribution has a mean of zero and a variance of $m/(m-2)$. Since the Student's *t* distribution is used primarily in statistical testing, an example of its use is included in Chap. 42, "Automatic Sprinkler System Calculations."

In Microsoft Excel, the functions "=TDIST(t, deg_freedom, tails)", and "=TINV(p, deg_freedom)", are commonly used to plot and solve the student's t distribution. The function TDIST solves for the function f(t) described earlier in this section, where t is the random variable, the "deg_freedom" input refers to the number of degrees of freedom characterizing the distribution and the input "tails" is a value of 1 or 2 specifying if the results are for one-tailed or two-tailed distribution. The TINV function returns the value of the random variable t that follows a student's t that is associated with a probability p. That is, the function solves for the integral equation for percentiles described earlier in this chapter.

Chi-Square Distribution

Whereas the normal and *t* distributions may be used to test hypotheses about means, the chi-square distribution may be used to test hypotheses about variances or entire distributions. Its density is a function of its degrees of freedom, *m*.

$$f(x) = \frac{x^{(m-2)/2} e^{-x/2}}{2^{m/2}\Gamma(m/2)} \quad \text{for } x \geq 0$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1} e^{-y} dy$$

Expressed in this standard form, the chi-square distribution has its mean equal to m, the number of degrees of freedom, and its variance equal to $2m$.

In Microsoft Excel, the functions "=CHIDIST(x, deg_freedom)", and "=CHIINV (p, deg_freedom)", are commonly used to plot and solve the chi-square distribution. The function CHIDIST solves for the function f(x) described earlier in this section, where x is the random variable, and the "deg_freedom" input refers to the number of degrees of freedom characterizing the distribution. The CHIINV function returns the value of the random variable x that follows chi-square distribution that is associated with a probability p. That is, the function solves for the integral equation for percentiles described earlier in this chapter.

F Distribution

Whereas the normal distribution may be used to test hypotheses about the means of samples of a single random variable, the F distribution permits simultaneous testing of hypotheses about the means of samples reflecting several random variables, each with its own variance, and each pair of variables correlated to some unknown degree. Its density is a function of two non interchangeable degrees-of-freedom parameters, m_1 and m_2 .

$$f(x) = \frac{(m_1/m_2)^{m_1/2} x^{(m_1-2)/2} \{\Gamma[(m_1+m_2)/2]\}}{[\Gamma(m_1/2)][\Gamma(m_2/2)]\left[(1+m_1 x/m_2)^{(m_1+m_2)/2}\right]}$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1} e^{-y} dy$$

The mean of the F distribution is $m_2/(m_2 - 2)$, and the variance is given by

$$\sigma^2 = \frac{2m_2^2(m_1+m_2-2)}{m_1(m_2-2)^2(m_2-4)} \quad \text{if } m_2 > 4$$

In Microsoft Excel, the function "=FDIST(x, deg_freedom1, deg_freedom2)", is commonly used to plot and solve the F distribution. The function FDIST solves for the function f(x) described earlier in this section, where x is the random variable, and the "deg_freedom" inputs refer to the two values of degrees of freedom characterizing the distribution.

Distributions for Reliability Analysis

Exponential Distribution

The exponential distribution is the simplest distribution for use in reliability analysis, where it can be used to model the time to failure. Its density is a function of a parameter, θ, that is equal to its mean and its standard deviation.

$$f(x) = \left(\frac{1}{\theta}\right) e^{-x/\theta} \quad \text{for } x \geq 0$$

Its hazard rate is a constant, 1/θ, so the exponential distribution is the one to use if the expected time to failure is the same, regardless of how much time has already elapsed. This distribution also is commonly used to represent the time required to serve customers waiting in a queue.

The exponential distribution is useful as a starting point in any attempt to model the length of a time interval in a sequence of time intervals. For example, the exponential distribution has been used to model the time between successive evacuating occupants leaving a building [2]. The exponential distribution also has been used to model the probability that a fire is still burning, as a function of time after ignition. In most cases, the exponential distribution will be abandoned in favor of more complex distributions once there is sufficient fundamental understanding, or sufficient data, to point to a specific better-fitting distribution.

In Microsoft Excel, the function "=EXPONDIST(x, Lambda, cumulative)" is commonly used to plot and solve the exponential distribution. The function EXPONDIST solves for the function f(x) described earlier in this section, where x is the random variable, and Lambda is the distribution parameter. Readers should notice that the parameter Lambda in excel equals 1/θ in the function above. The "cumulative" input to the function is a Boolean term used to specify if the function solves the density (set to FALSE) or the cumulative (set to TRUE) distribution function.

Example A smoke alarm is installed in a private home and is powered by a battery from a lot with average life of 6 months. Suppose the time until the battery dies can be represented by an exponential distribution. (In practice, retailed batteries have a more complex failure rate function.) Then the time until failure might look like that shown in Table 73.3.

Table 73.3 Example of exponential distribution (smoke alarm batteries)

Months old	Probability of failure by this age (i.e., this soon or sooner)
0–1	0.154
1–2	0.283
2–3	0.393
3–4	0.487
4–5	0.565
5–6	0.632
6–7	0.689
7–8	0.736
8–9	0.777
9–10	0.811
10–11	0.840
11–12	0.865
Over 12	1.000

Note that there is a high probability of failure in the first month and a high probability of survival past 1 year

Example A review of impairment data on smoke detectors in a specific facility indicates that a smoke detector device fails on average once every 5 years for various reasons. Upon failure, the detectors are replaced with a new device. Determine the probability that a smoke detector will last: (1) at least 10 years, (2) at most 10 years, and (3) between 5 and 10 years.

Solution From the available data, the parameter λ is estimated as $\lambda = 1/5 = 0.2$ years^{-1}. The probabilities are calculated integrating the exponential distribution as follows:

Probability of the detector lasting at least 10 years:

$$\Pr(t \geq 10) = \int_{10}^{\infty} \lambda e^{-\lambda t} dt = 1 - \int_{0}^{10} \lambda e^{-\lambda t} dt = e^{-0.2(10)} = 0.135$$

This can easily be solved in Microsoft Excel using the function "=1-EXPONDIST(10,0.2, TRUE) = 0.135

Probability of the detector lasting at most 10 years:

$$\Pr(t \leq 10) = \int_{0}^{10} \lambda e^{-\lambda t} dt = 1 - 0.135 = 0.865$$

This can easily be solved in Microsoft Excel using the function "=EXPONDIST(10,0.2, TRUE) = 0.865

Probability of the detector lasting between 5 and 10 years:

$$\Pr(5 \leq t \leq 10) = \int_{5}^{10} \lambda e^{-\lambda t} dt = 0.23$$

This can easily be solved in Microsoft Excel using the function "=EXPONDIST(10,0.2, TRUE)—EXPONDIST(5,0.2,TRUE) = 0.23

The process for computing probabilities would be identical if a different probability distribution is selected provided that the distribution parameters are known.

Poisson Distribution

If a system has exponentially distributed time to failure with mean time θ, then the distribution of the total number of failures, *n,* in time, *t,* has a Poisson distribution. Its distribution is given by a parameter, λ, that is equal to both its mean and its variance.

$$f(n) = \frac{\lambda^n e^{-\lambda}}{n!}$$

for

$$n = 0, 1, 2, \ldots, + \infty$$

where

$$\lambda = \frac{t}{\theta} \quad \text{and} \quad n! = n(n-1)(n-2)\cdots(3)(2)(1)$$

This distribution also is commonly used to represent the number of customers entering a queue for service in a unit of time. It assumes that the expected number of arriving customers in any short interval of time is proportional to the length of time. As a further example of the linkage between exponential and Poisson distributions, if the exponential distribution is used to model the time between evacuating occupants leaving a building, then the Poisson distribution can be used as the distribution for the total number of occupants who have left the building [2].

In Microsoft Excel, the function "=POISSON (x, mean, cumulative)" is commonly used to plot and solve the poisson distribution. The function POISSON solves for the function f(n) described earlier in this section, where x is the random variable, and "mean" is the mean of the poisson distribution. The "cumulative" input to the function is a Boolean term used to specify if the function solves the density (set to FALSE) or the cumulative (set to TRUE) distribution function.

Example Using the smoke alarm scenario in the previous example, suppose each time the battery fails, it is detected immediately and immediately replaced with a new battery of similar expected life. Then the number of times the batteries will fail in the first year is given by a Poisson distribution (Table 73.3). Here t is 12 months and θ is 6 months, so λ is 2. With this information, lets calculate the probability that no more than 1 failures are observed in 10 months using the function in Microsoft Excel. The function "=POISSON(1, 2, TRUE)" will add the probabilities of observing zero and one failure respectively. The numerical results is "=POISSON(1, 2, TRUE) = 0.406" with is equivalent to adding the first two probabilities listed in Table 73.3.

Gamma Distribution (Also Called Erlang Distribution)

The gamma distribution is also commonly used to represent time to failure for a system, particularly in a situation where m independent faults, all with identical exponential distributions of time to occur, are required before the system fails. Its density is a function of two parameters, m and θ, which must both be greater than zero; m need not be an integer.

$$f(x) = \frac{x^{m-1} e^{-x/\theta}}{[\theta^m \Gamma(m)]} \quad \text{for } x \geq 0$$

where

$$\Gamma(m) = \int_0^\infty y^{m-1} e^{-y} dy$$

The mean is $m\theta$ and the variance is $m\theta^2$, which makes it convenient to calculate the values by matching moments with the mean and variance from a sample or population.

In Microsoft Excel, the functions "=GAMMADIST(x, alpha, beta, cumulative)", and "=GAMMAINV(p, alpha, beta) are commonly used to plot and solve the normal distribution. The function GAMMADIST solves for the function f(x) described earlier in this section, where x is the random variable, alpha and beta are the parameters of the gamma distribution and the "cumulative" input (which is a Boolean input) is set to FALSE. Setting the "cumulative"

input to TRUE returns the value of the cumulative distribution function F(x) instead of f(x). Notice that the input alpha is the same as the m parameter used in the equation above and the input beta is equivalent to the θ parameter used in the equation. The GAMMAINV function returns the value of the random variable x that follows a normal distribution that is associated with a probability p. That is, the function solves for the integral equation for percentiles described earlier in this chapter.

Example A set of fire tests for peak heat release rates suggest a sample mean of 1100 kW with a standard deviation of 300 kW. Since the normal distribution has tails extending into the negative range, it may not be a good selection for representing this sample. Lets try to fit a gamma distribution to the data. By matching moments, we can set $1100 = m\theta$ and $300^2 = m\theta^2$ and solve the system of two equations for m and θ, which are the parameter of the gamma distribution. The resulting values are m = 82 (the beta value), and θ = 13 (the alpha value). Using these values, the gamma distribution can be plotted for a range of heat release rate values as inputs to x and the following function "=GAMMADIST(x,13,82, FALSE)", where x are the values listed under the column HRR (kW) in Fig. 73.7.

Weibull Distribution

The most popular complex distribution used in reliability studies to represent time to failure, the Weibull distribution is flexible enough to permit failure rates that increase or decrease with system age. Its density is a function of two parameters, a and b, which must both be greater than zero.

$$f(x) = abx^{b-1}e^{-ax^b} \quad \text{for } x \geq 0$$

$$\mu = a^{-(1/b)}\Gamma\left(\frac{b+1}{b}\right)$$

$$\sigma^2 = a^{-(2/b)}\left\{\left[\Gamma\left(\frac{b+2}{b}\right)\right] - \left[\Gamma\left(\tfrac{b+1}{b}\right)\right]^2\right\}$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1}e^{-y}dy$$

The cumulative distribution can be expressed in closed form, as follows:

$$F(x) = 1 - e^{-ax^b}$$

Therefore, the failure rate has a simple form

$$h(x) = abx^{b-1}$$

The failure rate increases with x (e.g., system age) if $b > 1$ and decreases if $b < 1$. If $b = 1$,

HRR (kW)	PDF
0	0.0E+00

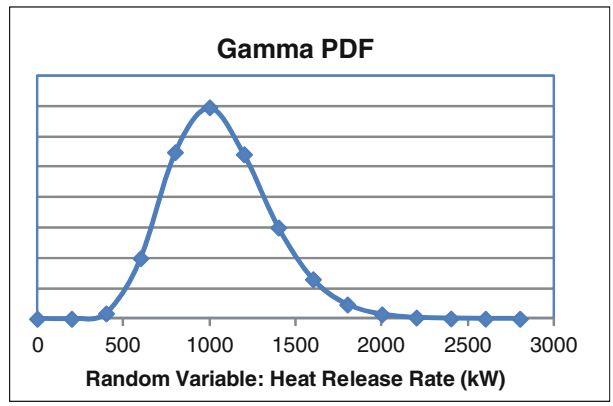

Fig. 73.7 Gamma distribution

the Weibull distribution becomes an exponential distribution, with $\theta = 1/a$.

The Weibull distribution, like the log-normal distribution, is popular to represent skewed datasets about which little is known. For example, the Weibull distribution has been used to represent premovement times of occupants [2].

The Weibull distribution will often provide good results for any phenomenon that resembles a reliability problem. For example, glass breaking in fire may be considered the end result of a number of micro-failures or changes. The Weibull distribution has been shown to work well as the distribution for breaking stress required to break windows [3].

In Microsoft Excel, the function "=WEIBULL (x, Alpha, Beta, cumulative)" is commonly used to plot and solve the weibull distribution. The function WEIBULL solves for the function f (x) described earlier in this section, where x is the random variable, and alpha (variable b used in the equation) and beta (which is represented as 1/a in the equation above) are the distribution parameters. The "cumulative" input to the function is a Boolean term used to specify if the function solves the density (set to FALSE) or the cumulative (set to TRUE) distribution function.

Example Suppose the example in Table 73.2 is modified to show the time to failure for the smoke alarm batteries as having a Weibull distribution. Suppose $\alpha = 1/6$. Then if $b = 1$, the Weibull distribution will be the same exponential distribution shown in Table 73.2. If $b < 1$, early failures are less likely, and if $b > 1$, early failures are more likely. Some examples are shown in Table 73.4. Note that it is not necessary to reduce b in order to make early failures unlikely. An exponential distribution with a higher θ (or Weibull distribution with a lower α) will also make early failures unlikely (Table 73.5).

Extreme Value Distributions

Extreme value distributions are used primarily to develop appropriate probabilistic models for rare events. In other words, extreme value distributions are probabilistic functions for the largest, or smallest, observation in a sample. As a conceptual example, consider a probability distribution f(x). Now let's generate N samples from that distribution. Each of these samples will have a maximum and a minimum value. If we group the maximum and minimum values from the N samples respectively, the resulting data sets can be described by extreme value distributions. Fire protection is an area of application of extreme value distributions where these functions can be use for predicting the behavior and statistics of the tails of for example fire losses.

Specifically, the largest member of a sample (i.e., the maximum) of size n has what is known as Type I largest extreme value distribution. This is also called the Gumbel, distribution, regardless of the probability distribution for the parent population. Two conditions however must be

met: The parent probability distribution needs to have a decreasing unbounded tail, and the distribution needs to have finite moments. A normal distribution for example would meet these criteria, where the right tail is decreasing and the mean and standard deviation are known. The mathematical structure for the largest extreme value distribution (LEV) is:

$$f(x|\theta_1,\theta_2) = \frac{1}{\theta_2}\exp(-z-\exp(-z))$$

where $z = \dfrac{x-\theta_1}{\theta_2}$ and θ_1, θ_2 are the location and scale* parameters, respectively, and $\theta_2 > 0$.

In the case of the minimum values from a parent distribution, the *smallest* member of each of the N samples can be modeled with the smallest extreme value distribution (SEV), also referred as Type I smallest extreme value distribution, with density

$$f(x|\theta_1,\theta_2) = \frac{1}{\theta_2}\exp(z-\exp(z))$$

as n increases. The parameters are similar to those described for the largest extreme value function.

In practice, the extreme value distributions "alter" the parent distribution to model the corresponding left or right tails (i.e. smallest or largest values of the random variables). As a conceptual example, let's assume the parent distribution is normal with mean and standard deviation 2000 and 400 respectively. In this case, the values of θ_1 and θ_2 are the mean and standard deviation of the normal distribution- which are the scale and shape parameters for the parent (i.e. normal) distribution. Plotting the parent normal distribution, and the smallest and largest extreme value distribution we can understand the behavior of these functions. Notice that the largest extreme distribution has higher cumulative probabilities in the right tail compared to the parent one. Similarly, the smallest extreme distribution has higher cumulative probabilities in the left tail compared to the parent one (Fig. 73.8).

A similar example is developed assuming the parent distribution is an exponential probability density function. In this case of the exponential distribution, the scale and shape parameters θ_1 and θ_2 are the same value. Notice that the same behavior observed for the normal distribution is also observed for the exponential density (Fig. 73.9).

There are cases however, where not all distribution moments are know. Two other extreme value distributions are available. The Type II or Frechet distribution can be used to model the largest observation. Mathematical the Frechet extreme value distribution is defined as:

$$f(x) = \frac{\alpha}{\beta}\left(\frac{\beta}{x}\right)^{\alpha+1}\exp\left(-\left(\frac{\beta}{x}\right)^{\alpha}\right)$$

where α is the shape parameter $(\alpha > 0)$, and β is the scale parameter $(\beta > 0)$. This distribution is bounded on the lower side $(x > 0)$ and has a

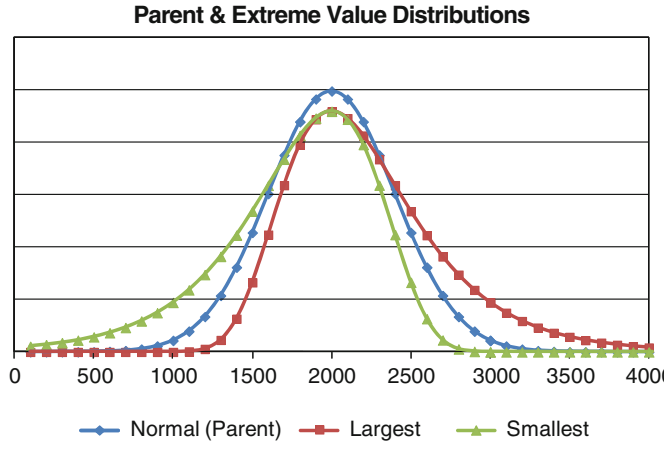

Fig. 73.8 Parent and extreme value distributions

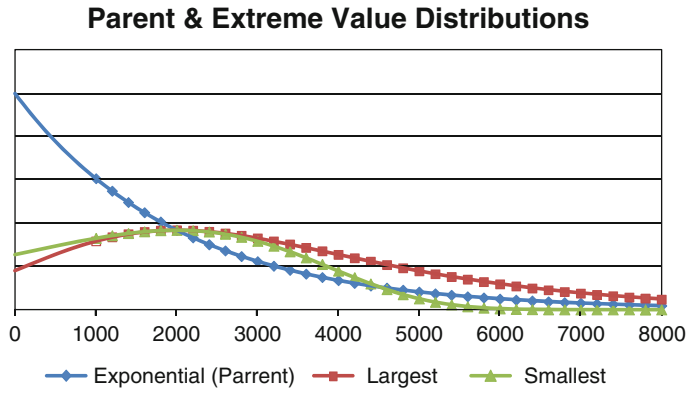

Fig. 73.9 Exponential parent and extreme value distributions

heavy upper tail. Finally, if the parent distribution function has a bounded tail, the smallest observation in a sample of size n, can be modeled with a Type III, or Weibull (described earlier in this chapter) distribution for the minimum. This distribution is routinely used in reliability engineering. It should be noted that the largest value distributions are seldom used for reliability analysis

Pareto Distribution

The Pareto distribution is not as commonly used but does provide a simple form for a distribution whose failure rate decreases with system age. Its density is a function of two parameters, a and b, which must both be greater than zero.

$$f(x) = ab^a x^{-(a+1)} \quad \text{for } x > b$$

$$\mu = ab/(a-1)$$

$$\sigma^2 = ab^2/\left[(a-1)^2(a-2)\right]$$

$$F(x) = 1 - b^a x^{-a}$$

$$h(x) = a/x$$

The parameter a must be greater than 2 for the mean and variance to converge to the values shown above. In general, a must be greater than k for the kth moment to converge.

Note that the formula for probabilities in a Pareto distribution includes only power-law relationships (i.e., the random variable x appears only *with* an exponent, never *in* an exponent or an additive term). This distinguishes the Pareto distribution from other major distributions, such as the Weibull distribution.

Tillander and Keski-Rahkonnen have refined traditional power law formulas for estimating ignition probability as a function of floor area [4]. Their proposed distribution uses both Pareto and log-normal distributions. Under special conditions, this formulation reduces to a simpler power law or sum of power laws formulation, which is the form previous analysts had developed.

Discrete Probability Distributions

A family of distributions exists to address calculations of the probability that a certain number of trails will have a common characteristic. Very few fire protection engineering calculations or models use these distributions. More commonly, individual probability values are chained together in fault trees, event trees, network models, or Markov processes, each of which connects states of the model by using probabilities to determine which of two or more alternative paths from one state will be followed.

Bernoulli Distribution

The Bernoulli distribution is the most basic of the discrete probability distributions and it represents a single trial or experiment in which there are only two possible outcomes—success

(with probability p) and failure. The random variable is the number of successes.

$$f(x) = px(1-p)(1-x) \quad \text{for } x = 0, 1$$

Therefore $f(x) = p$ if $x = 1$ and $f(x) = (1-p)$ if $x = 0$. The mean is p and the variance is $p(1-p)$.

Example Suppose there are 100 fire fighters in a department, 15 of whom are minorities. If all fire fighters are equally qualified, the probability that a minority fire fighter will be chosen as the next lieutenant is give by a Bernoulli distribution, with $p = 15/100 = 0.15$.

Binomial Distribution

The binomial distribution is the probability distribution for the number of successes in n independent Bernoulli trials, all having the same probability of success.

$$f(x) = \binom{n}{x} p^x (1-p)^{(n-x)} \text{ for } x = 0, 1, \ldots, n$$

where

$$\binom{n}{x} = \frac{n!}{x!(n-x)!}$$

and

$$x! = x(x-1)(x-2)\ldots(3)(2)(1)$$

The mean is np and the variance is $np(1-p)$.

The use of *factorials* (e.g., $x!$) can lead to time consuming calculations. It is possible for large values of n to approximate the binomial distribution by a normal distribution [with $\mu = np$ and $\sigma^2 = np(1-p)$]. This approximation will work acceptably if $np \geq 5$ and $n(1-p) \geq 5$. For small values of p, μ and σ^2 become very close, and one can approximate the binomial distribution by a Poisson distribution (with $\lambda = np$). This works acceptably if $n > 100$ and $p < 0.05$.

In Microsoft Excel, the function "=BINOMDIST(number_s, trials, probability_s, cumulative)" is commonly used to plot and solve the binomial distribution. The function BINOMDIST solves for the function f(x) described earlier in this section, where x is the random variable, number_s is the number of successes in the trails, trails is the number of trials, and probability_s is the success probability. The "cumulative" input to the function is a Boolean term used to specify if the function solves the density (set to FALSE) or the cumulative (set to TRUE) distribution function.

Example Suppose in the fire fighter promotion example just used, five lieutenants have been selected sequentially. Also suppose that each time a fire fighter is promoted to lieutenant, that slot is filled with another fire fighter of the same race before the next lieutenant is selected. Under these conditions, the five promotions represent five Bernoulli trials, all having the same probability that a minority fire fighter will be promoted. The number of minority fire fighters promoted will then be governed by a binomial distribution, as shown in Table 73.6.

Example How many fires in 1 year raise suspicion of arson?

Periodically, insurance companies or prosecutors will be tempted to infer a likelihood of arson from no more evidence than a history of multiple fires attached to a particular party in a limited period of time. The probability question underlying this line of reasoning is a binomial distribution question, specifically, the probability that one household will have n or more fires in a period when there were N total fires. Each fire is a "trial," as the term is used here, and each fire involving the one household of interest may be called a "success."

Table 73.6 Example of binomial distribution

Number of minority fire fighters promoted	Probability
0	0.444
1	0.392
2	0.138
3	0.024
4	0.002
5	0.000

Suppose the allegation is that no one could have three unintentional home structure fires in 2 years. In very rough terms for easy calculation, there are about 100 million U.S. housing units (occupied year-round) and 400,000 home structure fires per year, of which roughly 40,000 are intentional. Therefore, $n = 720{,}000$ (each fire is a trial and the annual fire toll is counted over 2 years) and $p = 1/100$ million (each fire could occur in any household). Using the Poisson approximation for ease of calculation, $np = 7.2/1000$.

$$P(k \text{ Successes}) = (7.2/1000)^k \left(e^{-7.2/1000}\right)/k!$$

The probability of three fires exactly will then be 6.2/100,000,000, and the probability of three or more fires will be slightly higher but will round to the same value. This is a very low probability, but applied to 100 million occupied housing units, it translates into an expectation of six housing units somewhere in the United States that will have three or more reported unintentional structure fires in a 2 year period.

Sometimes, allegations like these are buttressed by reference to brush fires, outdoor trash fires, car fires, or even public building fires that are linked to the same individual or household. However, such an allegation brings more fires into the mix, and the probability for a given number of fires in a given period of time will go up.

Geometric Distribution

In the case of a potentially unlimited number of independent Bernoulli trials with identical probabilities of success, the geometric distribution gives the distribution of the trial on which the first success will occur.

$$f(x) = p(1-p)^{(x-1)} \text{ for } x = 1, 2, 3, \ldots, +\infty$$

The mean is $(1/p)$ and the variance is $(1-p)/p^2$.

Example Continuing the example of serial promotions in which each open slot is filled by a new fire fighter of the same race, the geometric distribution would give the probability of which of the promotions will be the first to involve a minority fire fighter (Table 73.7).

Table 73.7 Geometric distribution with serial promotion example

First promotion to involve a minority fire fighter	Probability
First	0.150
Second	0.128
Third	0.108
Fourth	0.092
Fifth	0.078
Sixth	0.067
Seventh	0.057
Eighth	0.048
Ninth	0.041
Tenth	0.035
Later than tenth	0.196

Note the high probability that chance alone will delay the first minority promotion past the tenth promotion

Negative Binomial Distribution (Also Called Pascal Distribution)

This generalization of the geometric distribution gives the probability distribution for the trial on which the kth success will occur.

$$f(x) = \binom{x-1}{k-1} p^k (1-p)^{-(x-1)}$$

$$\text{for } x = k, k+1, k+2, \ldots, +\infty$$

where

$$\binom{x-1}{k-1} = \frac{(x-1)!}{(k-1)!(x-k)!}$$

and

$$x! = x(x-1)(x-2)\ldots(3)(2)(1)$$

Hypergeometric Distribution

The hypergeometric distribution is a variation on the binominal distribution that applies to cases where the initial probability of success, p, reflects

a fixed number of total successes and failures, N, available for selection so that each trial reduces either the number of successes remaining or the number of failures remaining. (For example, imagine an urn filled with balls of two different colors. If each trial consists of removing a ball, then replacing it in the urn, the binomial distribution applies. If each trial consists of removing a ball and keeping it out, the hypergeometric distribution applies.)

$$f(x) = \frac{\binom{Np}{x}\binom{N(1-p)}{n-x}}{\binom{N}{n}} \quad \text{for } x = 0, 1, 2, \ldots, n$$

where

N is the total number of successes and failures possible, $n \leq N$. Np and $N(1 - p)$ are integers

$$\binom{m}{y} = \frac{m!}{y!(m-y)!}$$

and

$$y! = y(y-1)(y-2)\ldots(3)(2)(1)$$

The mean is np and the variance is $np(1–p)[(N–n)/(N–1)]$. For very large values of N (relative to n), the hypergeometric distribution asymptotically approaches the binomial distribution.

In Microsoft Excel, the function "=HYPGEOMDIST(sample_s, number_sample, population_s, number_pop)" is commonly used to plot and solve the hypergeometric distribution. The function HYPGEOMDIST solves for the function f(x) described earlier in this section, where x is the random variable, sample_s is the number of successes in the sample, number_sample is the size of the sample, population_s is the number of successes in the population and number_pop is the population size.

Example Continuing the fire fighter promotion example, suppose five promotions are carried out all at once (Table 73.8). The hypergeometric distribution then gives the probability distribution for the number of minorities promoted; note how its probabilities differ from those generated by the binomial distribution.

Table 73.8 Example of hypergeometric distribution

Number of minority fire fighters promoted	Probability
0	0.436
1	0.403
2	0.138
3	0.022
4	0.001
5	0.000

For example,

$$0.436 = \frac{\binom{15}{0}\binom{85}{5}}{\binom{100}{5}} = \frac{[15!/(15!0!)][85!/(80!5!)]}{[100!/(95!5!)]} = \frac{(85)(84)(83)(82)(81)}{(100)(99)(98)(97)(96)}$$

Multinomial Distribution

The multinomial distribution is a generalization of the binomial distribution that addresses the case where there are more than two possible outcomes. Given k possible outcomes, such that the probability of the ith outcome is always p_i and the p_i collectively sum to unity, then for a series of n independent trials

$$f(x_1, \ldots, x_k) = \frac{n!}{x_1!x_2!\ldots x_k!} p_1^{x_1} p_2^{x_2} \cdots p_k^{x_k}$$

for all cases of $x_1 = 0, 1, 2, \ldots, n$, for $i = 1, 2, \ldots, k$, subject to

$$\sum_{i=1}^{k} x_i = n$$

$$\mu_i = n p_i$$

$$\sigma_i^2 = n p_i (1 - p_i)$$

Example Continuing the fire department example, suppose that the department's 100 fire fighters include 15 black fire fighters and 5 female fire fighters, none of whom is black. Suppose two

Table 73.9 Example of multinomial distribution

Number of fire fighters promoted			
Minority males	Female	White males	Probability
0	0	2	0.640
0	1	1	0.080
0	2	0	0.002
1	0	1	0.240
1	1	0	0.015
2	0	0	0.023

promotions are made, and the slot vacated for the first promotion is filled by a fire fighter of the same race and sex before the second promotion is made. Then the multinomial distribution (Table 73.9) describes the possible outcomes of interest.

For example, this is the probability that the promotions will go to one white male and one white female:

$$0.080 = \frac{2!}{0!1!1!}(0.15)^0(0.50)^1(0.80)^1$$
$$= 2 \times 0.05 \times 0.80$$

Beta Distribution

In Bayesian statistical inference, if the phenomenon of interest is governed by a Bernoulli distribution, then one needs a probability distribution for the parameter, p, of that Bernoulli distribution, and a Beta distribution is typically used.

$$f(p) = \frac{\Gamma(a+b)}{[\Gamma(a)][\Gamma(b)]} p^{a-1} 1 - p^{(b-1)}$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1} e^{-y} dy$$

The mean is $a/(a + b)$ and the variance is given by

$$\Gamma_2 = \frac{ab}{(a+b)^2(a+b+1)}$$

If $a = b = 1$, this becomes a *uniform distribution*. Larger values of b correspond to smaller variances, hence tighter confidence bands around the mean estimate of the parameter.

In Microsoft Excel, the functions "=BETADIST(x, alpha, beta, a, b)", and "=BETAINV(p, alpha, beta, a, b) are commonly used to plot and solve the beta distribution. The function BETADIST solves for the function f(x) described earlier in this section, where x is the random variable, and alpha and beta are the parameters of the gamma distribution (represented with the variables a and b in the function above). Notice that the next two parameters in the Excel function, a and b, are not included in the equation above. These parameters are the minimum and maximum range value for the random variable. Consequently, the equation above has a range between zero and one. In practice these two parameters shift and expands the distribution between the values a and b.

Frequency Histograms

It is practical and convenient to discuss frequency histograms before describing applications of probability theory. A frequency histogram is a bar chart depicting the number of occurrence of events in different intervals. A *histogram* is a technique of exploratory data analysis for displaying the frequency of occurrence of a finite set of data. The data values are arrayed along the x-axis of a graph, and the y-axis is used to plot the frequency, usually as number of occurrences or percentage of total occurrences.

As suggested in this section, frequency histogram are a useful tool for providing a general idea of how the probability distribution may look like, and serve as the first step for determining which distribution represents the random variable. Consider as an example the duration of fire events of a specific type recorded in sample of similar industrial facilities listed in Table 73.10. There are a total of 49 events.

Treating the duration of the fire as a random variable, we are interested in identifying an appropriate probability distribution for the fire

duration. As a first step, let's develop a frequency histogram. Microsoft Excel provides a relatively easy way of building frequency histograms by using the = FREQUENCY(data array, bins array) array function. The data array input is an array of data from which the histogram will be developed. The bins array is an array of intervals in which the data will be classified. Notice that FREQUENCY is an array function. An array function in excel provides an output in more than one cell. Therefore, the range of cells in which the output is desired needs to be highlighted before the function is typed/assigned to the top-left cell in the output array. The analyst will then need to press CTRL-SHIFT-ENTER for the function to calculate the output values. In the case of the FREQUENCY array function, the array output is always a one column table with the same number or rows as the bin array.

Table 73.10 Recorded fire durations

ID	Duration (min)	ID	Duration (min)	ID	Duration (min)
1	120	18	0	35	2
2	25	19	1	36	10
3	25	20	0	37	76
4	20	21	7	38	2
5	25	22	15	39	10
6	10	23	2	40	2
7	5	24	6	41	2
8	10	25	59	42	10
9	39	26	2	43	10
10	5	27	5	44	2
11	11	28	7	45	10
12	15	29	24	46	2
13	10	30	5	47	2
14	10	31	5	48	10
15	1	32	3	49	17
16	10	33	7		
17	50	34	2		

In this particular example, the data array is the duration of the events. The bin array is a user defined column of time intervals. Figure 73.10 illustrates two sample histograms for the fire duration data listed above. The left most histogram groups the data in 10 min bins. Consequently, the FREQUENCY function calculates 35 fire events with durations between zero and 10 min. The right most histogram classifies the data in 10 min intervals. Consequently, there are 14 events with durations between zero and 2 min.

It was mentioned earlier that frequency histograms are a good first step in determining an appropriate probability distribution. By inspecting the histograms depicted in Fig. 73.10, the following preliminary observations can be made:

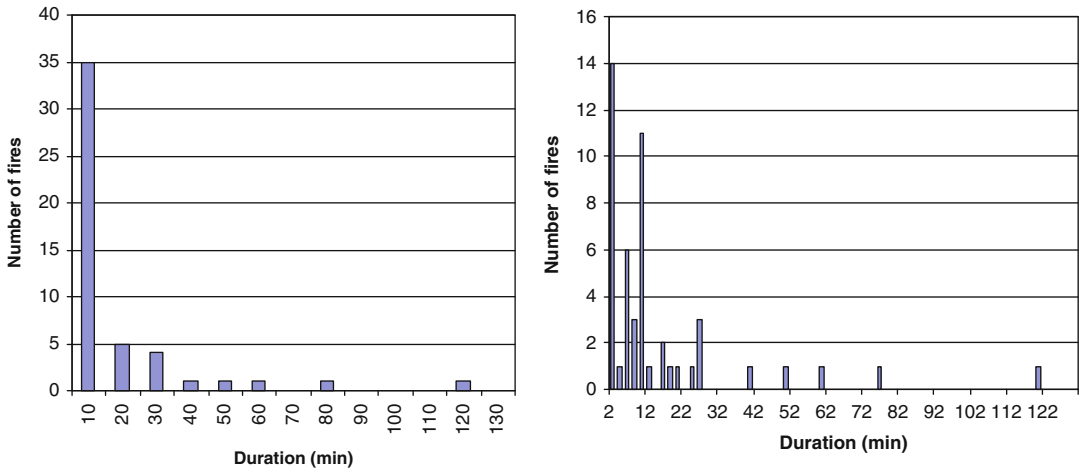

Fig. 73.10 Frequency histograms for the recorded fire durations

1. The probability distribution for fire events duration in the collected sample is not symmetric. It appears to be skewed to the left as most of the events lasted less than 30 min.
2. The fire durations are within the same order of magnitude. That is, the events lasted with 10–100 min. There are no events lasting high hundreds, or thousands of minutes.
3. There are no negative values in the fire durations.

These observations help us narrow the parametric probability distributions that may govern the data.

1. Two arguments may dismiss the use of the normal distribution. First, it does not appear this would be a symmetric distribution. Second, since most of the events are near the origin, the normal distribution is likely to have tails expanding to negative values, which are not "physical".
2. Since the fire duration data is within the same order of magnitude, the use of the lognormal distribution is not appropriate.
3. The histogram suggests the shape of an exponential distribution.

Random Number Generation

It is often necessary in applications of probability theory to generate random numbers from specific probability distributions. Uncertainty propagation is an example of these applications. Algorithms for generating random numbers from different probability distributions are described in numerous simulation and probability text books. Furthermore, these algorithms are readily available for use in most spreadsheet and mathematical computer packages. Since a detail explanation of most of these algorithms is out of the scope of this chapter, only a conceptual description of the process of generating random numbers based on the inversion method. This method can be used for generating numbers by analytically solving the probability distribution for its random variable or using the predefined inverted functions in Excel. Readers are encourage and expected to become familiar with random number generator functions a computer package of their choice since they are necessary for solving some of the exercises in this and future modules.

Inversion Method

Let's say we are interested in generating a random vector of size n for the uncertain variable t. In this example, t has units of time and follows an exponential distribution $f(t) = \lambda\exp(-\lambda t)$ where λ is known.

First, the cumulative distribution function for the exponential distribution is determined.

This example is relatively simple because the cumulative distribution function for the exponential distribution can be solved analytically and solved for the variable t. That is, the cumulative distribution function for the exponential distribution is

$$\int \lambda e^{-\lambda t} dt = e^{-\lambda t}$$

Then a random number from the uniform distribution U(0,1) is generated and set equal to the cumulative distribution, which represents an area under the curve of f(t) to the left of the value t.

$$u = e^{-\lambda t}$$

The random number is finally obtained solving for t as follows:

$$t = -\frac{\ln(u)}{\lambda}$$

This process is repeated for as many random numbers are necessary. Let's assume $\lambda = 0.2$ and 10 random numbers are necessary. Table 73.11 lists the uniform random numbers and the corresponding values for the variable t.

This process is conceptually represented in Fig. 73.11.

In most cases however the distributions do not have closed form integrals that can be inverted, requiring additional numerical methods and/or techniques for generating the random vectors. Another alternative is to use the inverted

probability distribution functions in Microsoft Excel. Some of these functions are listed in Table 73.12.

Basic Concepts of Statistical Analysis

Having discussed the basic principles of probability theory, this chapter now focuses on statistical analysis. Statistical analysis is basic to all aspects of fire protection engineering that involve abstracting results from experiments or real experience. Statistical analysis is the applied side of the mathematics of probability theory. Let's start first with some basic definitions.

Table 73.11 Random numbers for the exponential distribution

	λ	0.2
Iteration	U(0,1)	t
1	0.9	0.6
2	0.2	7.3
3	0.2	8.8
4	0.2	8.8
5	0.8	1.4
6	0.7	1.9
7	0.1	10.9
8	0.7	1.5
9	0.5	3.1
10	0.4	4.2

Perhaps the best way to visualize the "t" column in Table 73.1 is using a histogram. This can be done in Excel using the = Frequency() function. Notice that this is an "array" function, i.e., the output of the function is not a single cell

Statistic

A statistic is (a) any item of numerical data, or (b) a quantity (e.g., mean) computed as a function on a body of numerical data, or the function itself.

Statistical Analysis

Statistical analysis is the use of mathematical methods to condense sizable bodies of numerical data into a small number of summary statistics from which useful conclusions may be drawn.

Statistical Inference

Statistical inference is statistical analysis that consists of using methods based on the mathematics of probability theory to reason from properties of a body of numerical data, regarded as a sample from a larger population, to properties of that larger population.

In *classical statistical inference,* a single best estimate of each statistic of interest is developed from available data, the uncertainty of that statistic is estimated, and hypotheses are tested and conclusions drawn from those bases. Notice that

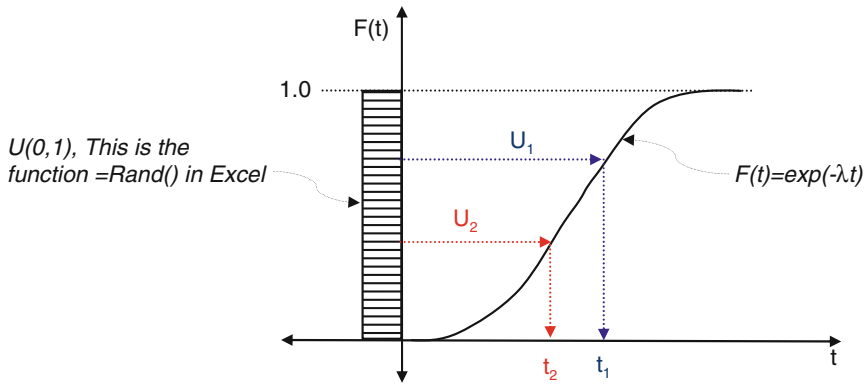

Fig. 73.11 Conceptual representation of the process of generating random numbers

Table 73.12 Microsoft excel functions

Distribution	Parameters	Random number generator	In microsoft excel
Uniform	A, B	Mathematical, statistical and spreadsheet software packages include pre-programmed functions for generating random numbers form a u(0,1) distribution	=Rand() for u(0,1) random numbers =A + Rand()*(B-A) for u(A,B) random numbers
Normal	μ, σ	Box Muller method for generating a pair of random variables from the standard normal distribution: 1. Generate 2 random numbers form the u (0,1), u_1, and u_2 2. Set $x = 2u_1 - 1$ and $y = 2u_2 - 1$ 3. If $q = \sqrt{x^2 + y^2} < 1$, set $z = \frac{x}{q}\sqrt{-4\ \ln(q)}$ and $w = \frac{y}{q}\sqrt{-4\ \ln(q)}$ Where z and w are standard normal random variables 4. Reject x and y and start over if the condition is not met	=Norminv(p,μ,σ) Where p is the cumulative probability, μ is the mean and σ is the standard deviation of the normal distribution
Lognormal*	μ, σ	The random number $z = \exp(\mu + \sigma \cdot r)$ follows a lognormal distribution where r is a standard normal random variate and μ and σ are the parameters of the lognormal distribution	=Loginv(p,μ,σ) Where p is the cumulative probability, μ is the mean of ln(x) and σ is the standard deviation of ln(x)
Exponential	λ	The random variable $z = -\frac{\ln(u)}{\lambda}$ follows an exponential distribution where u is a random number from the u(0,1) and λ is the parameter of the exponential distribution	N/A, but can be easily programmed in the spreadsheet
Chi-Square	ν	The random variable $z = \sum_{i=1}^{\nu} n(0,1)_i^2$ follows a Chi-Square distribution where n(0,1) is a random number from the standard normal distribution and ν is the parameter of the Chi-Square distribution Perhaps a prefered alternative is to use the Wilson-Hilferty transformation: $z = \nu\left[n\sqrt{2/9\nu} + 2/9\nu + 1\right]^3$ Where n is a random n(0,1,) variable and ν is the parameter of the Chi-Square distribution	=Chiinv(p,ν) Where p is the cumulative probability and ν is the parameter of the Chi-Square distribution
Gamma	α, β	The random variable $z = \sum_{i=1}^{\alpha} -\beta\ \ln(u)$ follows a gamma distribution where u is a random number from the u(0,1) and α and β are the parameters of the gamma distribution. The parameter alpha must be an integer	=Gammainv(p,α,β) Where p is the cumulative probability and α and β are the parameters of the gamma distribution
Beta	A, B, α, β	See rejection algorithm in this section	=Betainv(p,α,β,A,B) Where p is the cumulative probability and α, β, A, and B are the parameters of the Beta distribution
Weibull	α, β	The random variable $x = \alpha[-\ln(u)]^{1/\beta}$ follows a weibull distribution where u is a random number from the u(0,1), and α and β are the parameters of the Weibull distribution	N/A, but can be easily programmed in the spreadsheet

this is consistent with the classical or frequentist definition of probability provided earlier in this chapter.

In *Bayesian statistical inference,* a probability distribution for each statistic of interest is developed, using a form that permits new information, when it is acquired, to be used to adjust that distribution. Bayes's law, which was described in earlier in this chapter is used to adjust the distribution in light of the new information. Notice that this is consistent with the Bayesian or subjective definition of probability.

Conceptual Example: Suppose an engineer needs to develop a probability distribution for fuel load likely to be encountered in a new high-rise office building, to support estimation of fire growth and intensity in a full-floor burnout scenario. Fuel load would be measured in energy per unit area, such as BTUs per square meter. Suppose a field survey has been conducted that provides fuel load energy and areas for 400 rooms or areas in existing similar office properties.

Obviously, the most difficult task in this analysis would be to conduct such a field survey and convert its results to the indicated form. This will probably involve (1) estimating the mass of each item of contents and furnishings in each office or area assessed, (2) converting those estimates to estimates of total mass by category of material for each office or area assessed, (3) using existing or new test results to convert estimates' mass by material into estimates of energy content by material, and (4) summing the energy estimates into combined estimates for the room. With so many estimates required, it is likely that the data for each room will be in the form of a minimum, a maximum, and a best estimate and not just a point estimate.

Development of the probability distribution will then need to reflect the variation in fuel load from room to room, as reflected in part by the variation in best estimates across rooms, and the uncertainty in room fuel load estimates, as reflected by the minimums and maximums. A good situation would be data supporting the proposition that the variation in fuel load across rooms and the error in fuel load estimates for individual rooms both fit normal distributions. Other distributions (such as a lognormal distribution for the variation and a normal distribution for error) would still be mathematically tractable, though any such calculations go well beyond the guidance provided in this chapter.

Exploratory Data Analysis

Exploratory data analysis is the development of *descriptive statistics,* that is, statistical analysis that does not make inferences to a population.

Key Parameters of Descriptive Statistics

The *mean, median, variance,* and *standard deviation,* as described earlier in this section, can all be applied here, using the relative frequency of occurrence of each value in the body of data to define a discrete probability distribution.

The *mode* is the value that occurs most frequently, that is, the value of x for which $f(x) > f(y)$ for all $y \neq x$.

A body of data is called *unimodal* if $f(z) < f(y)$ in all cases where $|z - x| > |y - x|$, that is, if the probability distribution function steadily decreases as one moves away from the mode.

A body of data is called *multimodal* if it is not unimodal. In such cases there will be two or more values of x for which $f(x) > f(y)$ for all $y \neq x$ and $|y - x| < \varepsilon$, where ε is some small value. Although there may be only one mode in the sense of a most frequently occurring value, the existence of local maximums in the probability distribution function is sufficient to make the distribution multimodal. Multimodal data usually occur when data are combined from two or more populations, each having an underlying unimodal distribution. For example, if data were collected on the lengths of fire department vehicles, it probably would be multimodal, having one peak each for automobiles, ambulances/vans, engines, and ladders.

A *geometric mean* is another type of average:

$$\text{G.M.} = (x1x2x3 \ldots xn)^{1/n}$$

The geometric mean is useful in averaging index numbers reflecting rates of change. For example, suppose a, b, and c are annual rates of increase in the fire department budget for three successive years. Then $A = 1 + a$, $B = 1 + b$, and $C = 1 + c$ would be index numbers reflecting those three rates. The index number, D, reflecting the cumulative increase over all 3 years, would be given by $D = ABC$, and so an index number yielding an "average" rate of inflation for the 3-year period would be given by $(ABC)^{1/3}$, or the geometric mean of the index numbers. This geometric mean is the index number that could be compounded over the 3 years to obtain the actual cumulative increase. Note that the geometric mean is equivalent to computing the arithmetic mean of the logarithms of the data values, then exponentiating the result, that is, using the result as an exponential power to be applied to the base used in computing the logarithms. In Microsoft Excel, the function "=GEOMEAN(range)" calculates the geometric mean, where in the parameter "range" is the cells containing the relevant data.

Example In a fire risk analysis, the frequency of fires (i.e., the ignition frequency) is often considered a random variable that is characterized with a probability distribution. In a specific application, relevant fire events data is collected for determining the ignition frequency of specific equipment in a facility. The results of the collection process suggest that there is no data for some of the potential sources of ignition identified in the facility. For those sources of ignition, the analysis team decides to characterize their frequency with a lognormal distribution. The analysis team considers that the 5th and 95th percentile of the distribution are 1 event every 25 years and 1 every 5 years respectively. The mean for this lognormal distribution is then calculated using the geometric mean as follows: "=GEOMEAN(1/25, 1/5) = 0.089" events per year.

The *harmonic mean* is a less commonly used average that consists of the reciprocal of the arithmetic mean of the reciprocals of the data values. For example, suppose $V1, \ldots, Vn$ are a set of n values of the speed achieved by an engine company on a set of test runs from the firehouse to a single location. Then these speeds can also be represented as $d/t1, d/t2, \ldots, d/tn$, where d is the constant distance and $t1, \ldots, tn$ are the times of the n runs. The average speed would be given by $nd/(t1 + t2 + \cdots + tn)$, or total distance divided by total time. That value will also be given by the harmonic mean of the speed values. This example also helps illustrate why the harmonic mean is rarely used. It is likely that anyone who had access to the speed values would also have access to time values, $t1, \ldots, tn$, and could compute the average more quickly by using them directly.

The *range* is the difference between the highest and lowest values, or the term may be used to refer to those two values and the interval between them. In Microsoft Excel, the "=MIN (range)" and "=MAX(range)" functions can be used for determining the minimum and maximum value of a sample respectively.

Quartiles, deciles, and *percentiles* are useful measures of the dispersion of the data. If the data are arranged in ascending or descending order, the three quartiles, $Q1$, $Q2$, and $Q3$, are the values that mark off 25 %, 50 %, and 75 %, respectively, of the data set. In other words,

$Q1$ is chosen so that $F(Q1) = 0.25$

$Q2$ is chosen so that $F(Q2) = 0.50$; $Q2$ is also the median

$Q3$ is chosen so that $F(Q3) = 0.75$

In Microsoft Excel, the functions "=PERCENTILE(array, k)" and "=QUARTILE (array, quart)" can be used for determining the percentile o quartile of a range of data respectively. The parameter k is the percentile value expressed in a number from 0 to 1. The parameter quart refers to the first, second, third or fourth quartile.

Deciles and percentiles are defined analogously so as to divide the data set into tenths or hundredths, respectively, rather than fourths. Like the second quartile, the fifth decile equals the median. The *interquartile range,* or $Q3 - Q1$, is an alternative to the full range that is less sensitive to extreme values.

A *scatter plot* or *scatter diagram* is a technique of exploratory data analysis for displaying the patterns of a finite set of bivariate data. Each pair of data values is plotted on an (x,y) graph. This technique works best if both dimensions of the data are continuous so that the same pair of values does not occur more than once.

The *coefficient of variation* is given by the standard deviation divided by the mean. When the result is multiplied by 100, it gives the scatter about the mean in percentage terms relative to the mean.

Correlation, Regression, and Analysis of Variance

Correlation analysis and (linear) regression analysis are the two most basic and most common forms of analysis of variance, a collection of statistical analysis techniques that also includes experimental design and discriminant analysis.

Correlation

In qualitative terms, correlation refers to the degree of association between two or more random variables. Random variables with discrete and continuous probability distributions were defined earlier in this chapter.

The most common quantitative measure of correlation specifically addresses the extent to which two random variables are linearly related.

Correlation Coefficient (Also Called the Pearson Product-Moment Correlation Coefficient)

Let two discrete random variables, X and Y, have a joint probability distribution given by f (xi, yj) = probability ($X = x$i and $Y = y$j).

Then the correlation coefficient of X and Y is given by

$$\rho_{XY} = \frac{\left[\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}(x_i-\mu_X)(y_i-\mu_Y)f\left(x_i,y_j\right)\right]}{\sqrt{\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}\left[(x_i-\mu_X)^2 f\left(x_i,y_j\right)\right]}\sqrt{\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}\left[y_i-\mu_Y)^2 f(x_i,y_i)\right]}}$$

where

$$\mu_X = \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} x_i f\left(x_i,y_j\right)$$

and

$$\mu_Y = \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} y_i f\left(x_i,y_j\right)$$

Let two continuous random variables, X and Y, have a joint probability density function given by $f(x,y)$ such that

$$\int_{-\infty}^{y}\int_{-\infty}^{x} f(u,v)du\,dv = \text{probability}(X \le x \text{ and } Y \le y)$$

Then the correlation coefficient of X and Y is given by

$$\rho_{XY} = \frac{\left[\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(x-\mu_X)(y-\mu_Y)f(x,y)dxdy\right]}{\sqrt{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(x-\mu_X)^2 f(x,y)dxdy}\sqrt{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(y-\mu_Y)^2 f(x,y)dxdy}}$$

where

$$\mu_X \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} xf(x,y)dxdy$$

and

$$\mu_X \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} yf(x,y)dxdy$$

If $y = ax + b$, then $\rho = 1$ if $a > 0$ and $\rho = -1$ if $a < 0$.

It is possible for one variable to be a function of another, yet have zero correlation with it (e.g., $y = x$ for $x \geq 0$ and $y = -x$ for $x < 0$).

If two random variables are independent, they will have zero correlation. However, zero correlation can occur without independence.

Even if two variables are highly correlated, it is not necessary for either to be the cause of the other. Many so-called spurious correlations occur. An example is a case of two variables (e.g., sales of fire extinguishers, sales of chewing gum) that are both strongly influenced by a third variable (e.g., disposable income) and so will be highly correlated with each other because each is correlated with the third variable.

In the case of a multimodal joint probability distribution, the correlation may be quite different at a macro- and a microlevel. Consider the variables of fire rate per household and average income per household with regard to census tracts in a city. A small number of tracts typically will have high fire rates and low incomes; the rest will have low fire rates and high incomes. The two variables will be highly correlated if all census tracts are considered together, but if the two relatively homogeneous areas are analyzed separately, there may be little correlation.

If a sample of size n consists of pairs of values (xi, yi), then the sample correlation coefficient is

$$r_{XY} = \frac{\sum_{i=1}^{\infty} (x_i - \overline{x})(y_i - \overline{y})}{\sqrt{\sum_{i=1}^{n} (x_i - \overline{x})^2} \sqrt{\sum_{i=1}^{n} (y_i - \overline{y})^2}}$$

Example Suppose the scores of ten fire fighters on a promotional exam are compared to their numbers of years with the fire service, with results shown in Table 73.13 and in Fig. 73.12.

Table 73.13 Distribution of test scores

Age	Score
18	54
20	85
20	62
20	60
22	66
25	70
25	75
28	88
29	70
30	90

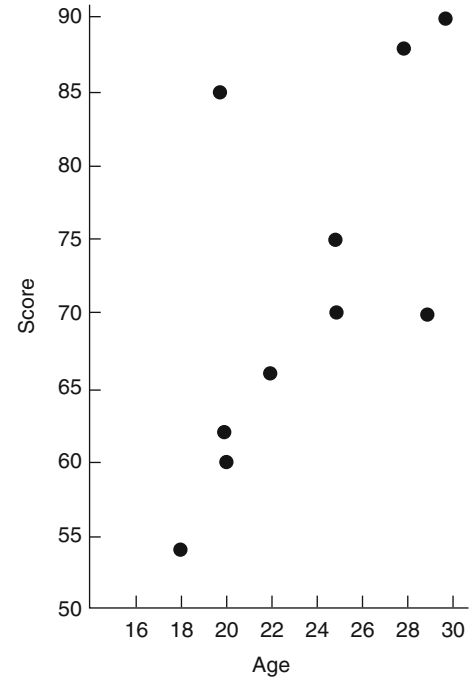

Fig. 73.12 Distribution of test scores

Using Microsoft Excel, then the mean age is "=AVERAGE(Age range)" = 23.7 and the mean score is "=SCORE(Score range)" =72, where the parameters age range and score range are the corresponding data sets listed in Table 73.1. The correlation coefficient can be also calculated using Microsoft Excel as follows: "=CORREL(Age range, Score range)" =0.67, indicating moderate correlation. If the second individual's score, which is the farthest from the group pattern, were changed from 85 to

60, the correlation coefficient would rise to 0.89, indicating high correlation.

The *coefficient of determination* (also called the *percentage of variation explained*) is given by the square of the correlation coefficient.

Regression

Regression analysis consists of fitting a relationship, usually but not limited to a linear relationship ($Y = aX + b$), to two random variables, X and Y. The term *regression* is left over from one of the findings in one of the earliest applications of the theory, where it was discovered that heights of parents are good predictors of heights of children but that heights of children tend to "regress" toward the mean. (In other words, for this problem, the best fit was $Y = a(X - \mu_x) + \mu_y$, where $a < 1$.)

Method of Least Squares

The method of least squares assumes that the best fit is obtained by minimizing the weighted sum of the squared differences between predicted and observed values of Y. In other words:

For two discrete random variables, X and Y, with joint probability distribution $f(xi, yj)$, choose a and b to minimize

$$\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}(y_i - ax_i - b)^2 f\left(x_i, y_j\right)$$

For two continuous random variables, X and Y, with joint density function $f(x, y)$, choose a and b to minimize

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(y - ax - b)^2 f(x, y)dx\ dy$$

For a sample of size n of pairs of values (xi, yi), choose a and b to minimize

$$\sum_{i=1}^{n}(y_i - ax_i - b)^2$$

The method of least squares is the best method if the deviations between observed and expected values of Y are themselves normally distributed, independent random variables. This condition would be satisfied, for example, in most experiments if the only source of deviation were error in reading a measuring device. The deviations are also called *residuals*.

Analysis of patterns in residuals can be done to confirm the normality assumptions cited above. Also, data points may be selected with extremely large residuals and studied for common characteristics as a means of trying to identify other factors that may be correlated to the outcomes, y. These results, in turn, may lead to a more sophisticated, multivariate regression analysis.

Regression Coefficients

The least-squares fit of a relationship of the form $Y = aX + B$ will be given by

$$a = \frac{\rho_{xy}\sigma_y}{\sigma_x}$$
$$b = \mu_y - a\mu_x$$

For a sample of size n of pairs (xi, yi), the formulas are

$$a = \frac{\left(n\sum_{i=1}^{n}x_i y_i\right) - \left[\left(\sum_{i=1}^{n}x_i\right)\left(\sum_{i=1}^{n}y_i\right)\right]}{\left(n\sum_{i=1}^{n}x_i^2\right) - \left[\left(\sum_{i=1}^{n}x_i\right)^2\right]}$$

$$b = \frac{\left[\left(\sum_{i=1}^{n}x_i^2\right)\left(\sum_{i=1}^{n}y_i\right)\right] - \left[\left(\sum_{i=1}^{n}x_i\right)\left(\sum_{i=1}^{n}x_i y_i\right)\right]}{\left(n\sum_{i=1}^{n}x_i^2\right) - \left[\left(\sum_{i=1}^{n}x_i\right)^2\right]}$$

Example Reexamine the case of age versus test score examined earlier under the discussion of correlation. In that case, as noted, the correlation coefficient was 0.67, the mean age was 23.7, and the mean score was 72. The ratio of standard deviations can be calculated as 2.87. Therefore, $a = 1.92$ and $b = 26.5$. This means that the predicted score for age 20 would be 64.9, compared to the 60, 62, and 85 scored by persons of that age, whereas the predicted score for age 30 would be 84.1, compared to the 90 scored by the person of that age. The values of a and be can be calculated using the array function in Microsoft Excel "=LINEST(known_y's, known_x's, const, stats). The known_y's and known_x's parameters are the array of data for the y values (dependent variable), and the x values (independent variable) respectively. The parameters const and stats are optional and not used in this example. As an array function, LINEST must be specified selecting first two adjacent cells in excel and using CTRL-SHIFT-ENTER to solve it. Readers are encourage to review all the technical description and examples of this function in the corresponding Microsoft Excel help file.

Continuing with the example, this regression line tends to overpredict scores for younger persons because the line is tipped as it tries to accommodate the 85 score achieved by one 20-year-old. If that score had been a 60, then as noted the correlation coefficient would be 0.89; also, the mean score would be 69.5 and the ratio of standard deviations would be 2.78. Therefore, a would be 2.47 and b would be 11.0. The predicted score for age 20 would change from 64.9 to 60.4, and the predicted score for age 18 would change from 61.1 to 55.5, much closer to the score actually achieved by the 18-year-old.

Although it is theoretically (i.e. mathematically) possible to fit any relationship, not just a linear one, between X and Y, it is rarely possible to develop least-square formulas for a and b if the relationship is not linear. A simple scatter plot would suggest if the relationship with the data is linear. If it's not linear, the analyst will usually want to try to transform problems into linear regression problems. For example, if the true relationship is believed to be of the form $y = c^{(x+d)}$, one would set up a linear regression of $\log y$ versus x. Then $d \log c = b$ and $\log c = a$.

Example 5: Developing Empirical Correlations One of the most widely used empirical correlations is the McCaffrey-Quintiere-Harkleroad (MQH) correlation of temperature rise (dT) with heat release rate (Q) and height above heat source (z):

$$dT \propto Q_{2/3} z_{5/3}^{-}$$

Although this relationship was developed from energy balance fundamentals and other established theory, such a correlation could emerge as an empirical finding from experiments. In fact, the three authors for whom the correlation is named took such an approach in a 1981 paper [1]. One analysis of data from 112 experiments produced an inferred exponent of 0.624 for Q (compared to the 0.667, or 2/3, in the correlation as it is best known) and an associated r-squared value (percentage of variation explained) of 92 %. A second analysis of the same data cited in the same paper used a slightly different setup for the modeling parameters and derived a best-estimate exponent of 0.650 for Q with an r-squared value of 90 %.

The procedure for such an analysis begins with conversion of the hypothesized relationship to a general linear model:

$$\begin{aligned} \log\ dT &= \log\left[(\text{Proportionality constant}) Q^{\mathrm{A}} z^{\mathrm{B}}\right] \\ &= A\ \log\ Q + B\ \log\ z + C \end{aligned}$$

where C is the logarithm of the proportionality constant (not shown) in the MQH correlation.

The method of least squares calls for the analyst to produce values of A, B, and C that minimize the sum of squares of differences between the terms to left and right of the equal sign. By taking the partial derivatives with respect to A, B, and C of the sum of squared differences and setting those derivatives equal to zero (in order to solve for the minimum), one obtains three linear equations in three unknowns and can solve for A, B, and C:

$$U = \sum_i (\log\ dT_i - A\ \log\ Q_i - B\ \log\ z_i - C)_2$$
$$\partial/\partial A\ \ U = \sum_i (-2 \log\ Q_i)(\log\ dT_i - A\ \log\ Q_i - B\ \log\ z_i - C) = 0$$
$$\partial/\partial B\ \ U = \sum_i (-2 \log\ z_i)(\log\ dT_i - A\ \log\ Q_i - B\ \log\ z_i - C) = 0$$
$$\partial/\partial C\ \ U = \sum_i (-2)(\log\ dT_i - A\ \log\ Q_i - B\ \log\ z_i - C) = 0$$

where *i* refers to the *i*th experiment in the series of 112 experiments.

It is possible to produce not only best (maximum likelihood) estimates—which is what 0.624 and 0.650 presumably are—for the exponent for *Q* but also confidence ranges for the values, which would probably be very tight given the *r*-squared values of 92 % and 90 % and the fact that the data set contained more than 100 experiments. Of greater interest would be an analysis of the MQH correlation, with its 0.667 exponent, as given. One can conduct a goodness-of-fit chi-square analysis using the same experimental data set. The authors did not take their analysis in that direction, at least for their article.

Regression analysis assumes that an error in one observation (temperature change vs. heat and height) is independent of an error in any other observation. It is important to take steps to make sure this assumption is reasonably true of the data set. For example, the assumption will not be true of observations over time, where a phenomenon called "autocorrelation" is of concern. Any deviation or error in temperature at time *t* can be expected to influence temperatures at later times.

Hypothesis Testing in Classical Statistical Inference

Hypothesis and Test

A statistical *hypothesis* is a well-defined statement about a probability distribution or, more frequently, one of its parameters. A classical *test* of a statistical hypothesis is based on the use of several concepts to organize the uncertainty inherent in any probabilistic situation.

The hypothesis being considered is called the *null hypothesis* and implies a probability distribution. Classical statistical inference asks whether the probability of having obtained the statistics actually collected, given the null hypothesis, is so low that the null hypothesis must be rejected.

The test works on the basis of a statistic computed from a sample. That statistic is compared to a reference value. If the statistic falls to one side of the reference value, then the null hypothesis is rejected; if the statistic falls to the other side, then the null hypothesis is not rejected.

For the reasons given above, a statistical test resolves doubts in favor of the null hypothesis. Therefore, an analyst may choose to say that the null hypothesis was "not rejected" rather than say it was "accepted." The analogy is to a criminal trial, which may find a defendant "not guilty" but does not make findings of "innocent."

A *Type I error* occurs when the null hypothesis is really true, but the test says that it should be rejected. A *Type II error* occurs when the null hypothesis is really false, but the test says it should not be rejected. (Informally, many analysts use the term *Type III error* to refer to analyses that set up the initial problem incorrectly, thereby producing results that, however precise, are irrelevant to the real issue.)

A *confidence coefficient,* or measure of the *degree of confidence,* is used to indicate the maximum acceptable probability of Type I error. In most cases, the null hypothesis corresponds to a single, well-defined probability distribution. Therefore, the probability of the sample statistic falling on the reject side of the reference value can be calculated precisely, and the reference value can be selected so as to set that probability equal to the confidence coefficient.

One way of using the confidence coefficient is to set *confidence limits* or define a confidence

interval. These limits or internal boundaries are set so that if the null hypothesis is true, then the probability of obtaining a sample whose test statistic is outside the limits (or interval) is equal to the confidence coefficient. These confidence limits indicate to the user how precisely the probability distribution or its parameter can be defined, given the size of the sample and its variability.

The value of the confidence coefficient can be set at any of certain standard levels (90 %, 95 %, and 99 % are often used), or it can be derived from an analysis that seeks to balance Type I and Type II errors. The latter approach is more comprehensive, but it is much more difficult because the alternative(s) to the null hypothesis rarely correspond(s) to a single probability distribution. In a typical case, the null hypothesis states a single value for a population parameter ($\mu = a$) and the alternative corresponds to all other values ($\mu \neq a$). Each specific alternative defines a specific probability distribution with a specific probability of Type II error. The *power function of the test* is that function that gives the probability of *not* committing a Type II error for each parameter value covered by the alternative(s) to the null hypothesis.

As the parameter value approaches the value in the null hypothesis (e.g., $\mu \rightarrow a$), the power of the test drops toward the confidence coefficient.

Test of Mean: *z* Test

If a sample has been collected from a population with known standard deviation σ, the central limit theorem indicates that the sample mean has an approximately normal distribution about the true population mean μ_0.

Let

$$z = \left(\sqrt{n}\right)(\overline{x} - \mu_0)\sigma$$

where
n = Sample size
μ_0 = Hypothesized true value of μ
$\overline{x}$ = Sample mean

Let z_α be the value for which $F(z_\alpha) = 1 - \alpha$, where F is the cumulative distribution function of a normal distribution with mean zero and variance one (Note that $z_{1-\alpha} = -z_\alpha$.).

A *two-sided test* presumes that, if the true population mean is not μ_0, then it is equally likely to be greater than or less than μ_0. In that case, positive and negative values of z are treated the same and the confidence coefficient must be divided between the two sides of the confidence interval. Then if α is the confidence coefficient, the two-sided test says accept the null hypothesis if

$$-z_\alpha/2 \leq z \leq z_{\alpha/2}$$

A *one-sided test* presumes that if the true population mean is not μ_0, then it must be greater than (or less than) μ_0. If α is the confidence coefficient, then the one-sided test says accept the null hypothesis if

$$z \geq -z_\alpha \text{if the alternative to } \mu = \mu_0 \text{is } \mu < \mu_0$$

or

$$z \leq z_\alpha \text{if the alternative to } \mu = m_0 \text{is } \mu > \mu_0$$

The value

$$\frac{\sigma}{\sqrt{n}}$$

is called the *standard error of the mean*. In Microsoft Excel, the function "=ZTEST(Array, x, sigma)" can be used for calculating the one tail p value of a z test. In statistical hypothesis testing, the p-value is the probability of obtaining a test statistic at least as extreme as the one that was actually observed, assuming that the null hypothesis is true [1]. One often "rejects the null hypothesis" when the p-value is less than the significance level α, which is often 0.05 or 0.01. When the null hypothesis is rejected, the result is said to be statistically significant. The parameter Array is the sample data. The parameter x is the tested value. Finally, the parameter sigma is optional- it's the standard deviation for the population if the value is known. If left blank, the function will use the sample standard deviation.

Test of Difference Between Two Means: *z* Test

If two samples from populations with known standard deviations, σ_1 and σ_2, have been collected, a null hypothesis might be that they are from the same population, which means their means would be the same ($\mu_1 = \mu_2$). Then a two-sided test is applied, using the following statistic:

$$z = \frac{(\overline{x}_1 - \overline{x}_2)}{\sqrt{\sigma_1^2/n_1 + \sigma_2^2/n_2}}$$

where $\overline{x}$, σ_{i2}, and n_i are the sample mean, population variance, and sample size, respectively, of the *i*th sample. In Microsoft Excel, this statistical test is available in the Data Analysis tools under Data/Data Analysis. Readers are referred to the help file for information about how to install the Data Analysis as it is not usually installed by default. It should be also noted that the Data Analysis tools are not typical Excel functions like the ones that have been discussed earlier in this chapter. These functions provide solutions only "once", and these solutions are not live in the spreadsheet. That is, the solutions are not updated with inputs parameters change unless the functions are run again through the Data Analysis dialog box.

For this specific test, the Data Analysis dialog box requires the following input

- Variable 1: Range Enter the cell reference for the first range of data that you want to analyze. The range must consist of a single column or row of data.
- Variable 2: Range Enter the cell reference for the second range of data that you want to analyze. The range must consist of a single column or row of data.
- Hypothesized Mean Difference: Enter the number that you want for the shift in sample means. A value of 0 (zero) indicates that the sample means are hypothesized to be equal.
- Variable 1: Variance (known) Enter the known population variance for the Variable 1 input range.
- Variable 2: Variance (known) Enter the known population variance for the Variable 2 input range.
- Labels: Select if the first row or column of your input ranges contains labels. Clear this check box if your input ranges have no labels. Microsoft Office Excel generates the appropriate data labels for the output table.
- Alpha: Enter the confidence level for the test. This value must be in the range 0...1. The alpha level is a significance level that is related to the probability of having a type I error (rejecting a true hypothesis).
- Output Range: Enter the reference for the upper-left cell of the output table. Excel automatically determines the size of the output area and displays a message if the output table will replace existing data.
- New Worksheet Ply: Click to insert a new worksheet in the current workbook and paste the results starting at cell A1 of the new worksheet. To name the new worksheet, type a name in the box.
- New Workbook: Click to create a new workbook in which results are added to a new worksheet.

Test of Proportion: *z* Test

If a sample has been drawn from a population governed by a binominal distribution, then the normal approximation gives the following statistic, to be used in one- or two-sided tests

$$z = \frac{n(\overline{p} - p_0)}{\sqrt{p_0(1 - p_0)}}$$

where p_0 is the hypothesized true proportion and p is the sample proportion.

Test of Difference Between Two Proportions: *z* Test

Again the normal approximation to the binomial distribution gives the test statistic

$$z = \frac{(\overline{p}_1 - \overline{p}_2)}{\sqrt{[\overline{p}_1(1 - \overline{p}_1)/n_1] + [\overline{p}_2(1 - \overline{p}_2)/n_2]}}$$

Test of Mean: *t* Test

The z tests assume known variance(s), so if variances are not known, a test based on Student's t distribution must be used. Let $t_{\alpha,\mathrm{m}}$ be defined such that $F(T_{\alpha,\mathrm{m}}) = 1 - \alpha$, where F is the cumulative distribution function for a Student's t distribution with m degrees of freedom. Note that $t_{(1-\alpha),\mathrm{m}} = -t_{\alpha,\mathrm{m}}$. Then

$$t = \frac{\sqrt{n}(\bar{x} - \mu_0)}{s}$$

where
n = Sample size
μ_0 = Hypothesized population mean
s = Sample standard deviation

A two-sided test says accept the null hypothesis if

$$-t_{(\alpha/2),(n-1)} \leq t \leq t_{(\alpha/2),(n-1)}$$

Note that the number of degrees of freedom is one less than the sample size. An informal method of remembering this is that 1 degree of freedom is used to estimate the standard deviation.

A one-sided test says accept the null hypothesis if

$t \geq -t_{\alpha,(\mathrm{n}-1)}$ if the alternative to $\mu = \mu_0$ is

$\mu < \mu_0$ or

$t \leq -t_{\alpha,(\mathrm{n}-1)}$ if the alternative to $\mu = \mu_0$ is

$\mu < \mu_0$ A test of differences between two means is constructed analogously.

In Microsoft Excel, the function "=TTEST (Array1, Array2, Tails, Type)" can be used for solving the t test. The Arrays input parameters are the first and second data sets respectively. The Tails input parameter specifies the number of distribution tails to return: a value of 1 can be use for the one-tailed distribution, the value of 2 can be used for the two tailed distribution. The Type parameter refers to the type of tests. A value of one is used if the test is paired. (Paired samples t-tests typically consist of a sample of matched pairs of similar units, or one group of units that has been tested twice -a "repeated measures" t-test. A typical example of the repeated measures t-test would be where subjects are tested prior to a treatment, say for high blood pressure, and the same subjects are tested again after treatment with a blood-pressure lowering medication.) A value of three is used two samples with unequal variances. A value of three is used for two samples with unequal variances.

The Data Analysis tools (see the discussion of Data Analysis tools under the z-test provided earlier in this chapter) also have functions to solve the following t – tests: (1) paired two-sample for means, (2) two-sample assuming equal variances, and (3) two-sample assuming unequal variances.

Example This example will illustrate all the tests described thus far. Suppose there are two fire departments, each of which has given promotional tests to 100 fire fighters. Scores can range from 0 to 100, and the passing score is 70. The actual distributions of scores are shown in Table 73.14 and Figs. 73.2 and 73.13.

Suppose that nationwide the standard deviation for this test is 17.45, the mean score is 50, and the proportion who pass is 0.17. Is

Table 73.14 Distribution of test scores

	Number of fire fighters with that score in	
Score	Department A	Department B
10	0	5
20	6	5
30	5	10
40	20	20
50	29	25
60	20	20
70	9	10
80	5	3
90	3	2
100	3	0
Total	100	100
Sample mean	53.2	48.2
Sample standard deviation	17.54	17.34
Proportion of sample passing	0.20	0.15

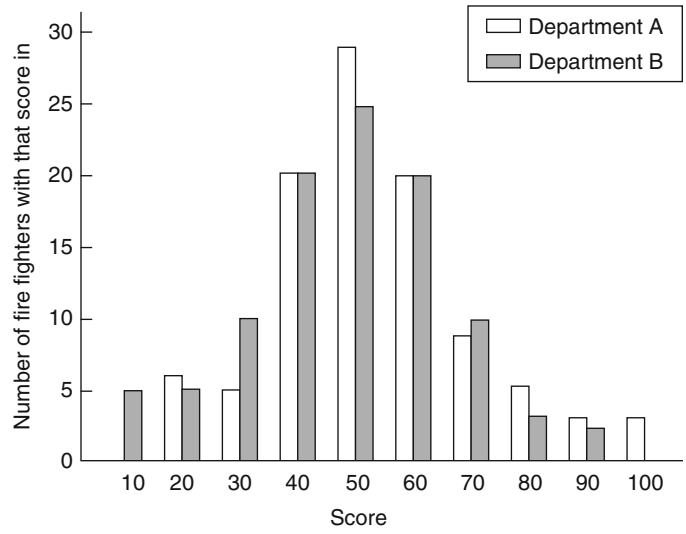

Fig. 73.13 Distribution of test scores in two fire departments

Department A an average department? This suggests a two-sided test of the mean score, using the z test because the standard deviation is known. Let α be 0.05, so $z_{\alpha/2} = 1.96$. The z statistic for the test is

$$\frac{\left(\sqrt{100}\right)(53.2 - 50)}{17.60} = 1.83$$

which is between −1.96 and +1.96 so the null hypothesis is accepted. Department A is average.

Suppose it is asked instead whether Department A is a better-than-average department. This formulation suggests a one-sided test of the mean score, again using the z test because the standard deviation is known. Again, let $\alpha = 0.05$, so $Z_{\alpha/2} = 1.64$. The z statistic for the test is again 1.83, which is greater than 1.64, so we reject the null hypothesis and conclude that Department A is above average.

The results for these two tests seem contradictory because one concludes that Department A is average and the other concludes that Department A is above average. Such discrepancies are inherent to statistical tests. They can be sensitive to the choice of α. (If α were 0.10, both null hypotheses would be rejected, whereas if α were 0.01, both null hypotheses would be accepted. In either case, the two tests would give consistent results.) They can be sensitive to how the alternatives were posed, as was true here.

Suppose it is asked whether Departments A and B have significantly different mean scores. This formulation suggests a z test of the difference between two means. In this case the standard deviations are the same and the sample sizes are the same, so the z statistic reduces to

$$\frac{53.2 - 48.2}{\sqrt{2 \times 17.45/100}} = 8.46$$

The two-sided test reference value of 1.96, calculated earlier, is easily exceeded, and we conclude that the two departments do have statistically significant differences in their mean scores.

Suppose it is asked whether Department A's proportion of students passing (0.20) is statistically significantly greater than the overall average of 0.17. This formulation calls for a z test of a proportion, and the z statistic is

$$\frac{\left(\sqrt{100}\right)(0.20) - 0.17}{\sqrt{(0.17)(0.83)}} = 0.80$$

This result is not statistically significant under either a one-sided or a two-sided test.

Are the proportions passing in Departments A and B different? This formulation suggests a z test of the difference between two proportions, and the z statistic is

$$\frac{0.20 - 0.15}{\sqrt{[(0.20)(0.80)/100] + [(0.15)(0.80)/100]}} = 0.93$$

Even though the average scores for Departments A and B were found to be different by a statistically significant margin, their percentage of test takers passing were not found to be significantly different.

Suppose the value of the overall standard deviation for the test was not known, or it was not known whether it applied to these departments, but it was known that the overall average score was 50. Is Department A's score significantly better? This formulation suggests a one-sided t test. The t statistic is

$$\frac{\sqrt{100}(53.2 - 50.0)}{17.54} = 1.82$$

For a one-sided t test with a 0.05 confidence level and 99 degrees of freedom, the reference value is the same as for a one-sided z test with a 0.05 confidence level, namely 1.64. Because the sample standard deviation is also nearly equal to the overall standard deviation used earlier, the test results are virtually the same, and the null hypothesis is rejected. This would not have been the case if the sample size had been considerably smaller, leading to a larger reference value. The smaller the difference you are examining, the larger the sample size required to be sure that difference is real and not just the result of random variation.

Test of Variance: Chi-Square Test

Assuming a normal population, one can test the hypothesis $\sigma = \sigma_0$ with the following:

$$\psi_2 = \frac{(n-1)s^2}{\sigma_0^2}$$

where n is the sample size and s_2 is the sample variance.

A two-sided test accepts the null hypothesis if

$$\psi^2_{(1-\alpha/2),(n-1)} \leq \psi^2 \leq \psi^2_{(\alpha/2),(n-1)}$$

where ${\psi_{\alpha,m}}^2$ is the value such that $F\left(\psi^2_{\alpha,m}\right) = 1 - \alpha$, where F is the cumulative distribution function of a chi-square distribution with m degrees of freedom. Note that the degrees of freedom used in the test are one less than the sample size. One-sided tests can be constructed analogously.

Test of Goodness of Fit to a Distribution: Chi-Square Test

The Chi-Square (χ^2) is the distribution of the sum of squares of a number of normal random variables. If for example a theoretical model is compared with experimental data, the difference (i.e., the error) between the model output and the data is assumed normal. This "error" is often squared to eliminate any negative sign. Therefore, the χ^2 distribution can be used to test the goodness of fit between the observed data points and the values predicted by the model, subject to the difference been normally distributed.

The Chi-Square test is often used to test distributions when a relatively large sample size is available (i.e., sample sizes $\geq$30). The test can be summarized as follows: the expected number of events per bin in a histogram is compared to the number of events resulting from the probability distribution that is been tested. If both frequencies are relatively similar throughout the range of the random variable, then the distribution may be a good fit.

A special use of the test of variance is to test how well a set of experimental data fit a presumed theoretical probability distribution. Suppose the distribution in question is represented as a set of k values or ranges of values for the random variable. Let p_{i} , . . . , p_{k} be the hypothesized probabilities for those k values or ranges; let p_{i} , . . . , p_{k} be the sample estimates of those probabilities; and let n be the sample size. Then the statistic is

$$\psi^2 = \sum_{i=1}^{k} \left\{ \frac{[u(p_i, \overline{p}_i, n)]^2}{n p_i} \right\}$$

where

$$u(p_i, \overline{p}_i, n) = \begin{cases} 0 & \text{if } -\frac{1}{2} \le n p_i - n\overline{p}_i \le \frac{1}{2} \\ n p_i - n\overline{p}_i - \frac{1}{2} & \text{if } n p_i - n\overline{p}_i > \frac{1}{2} \\ n\overline{p}_i - n p_i - \frac{1}{2} & \text{if } n\overline{p}_i - n p_i > \frac{1}{2} \end{cases}$$

This process of reducing the gap between np_i and $n\overline{p}_i$ by ½ is called the *Yates continuity correction,* and it compensates for the fact that the chi-square distribution, a continuous function, is being used to approximate a discrete probability distribution. Also, to apply this test validly, one must make sure that the k classes are grouped sufficiently that $np_i \ge 5$ for all $i = 1, \ldots, k$.

The null hypothesis says this sample came from the distribution represented by $p_1, \ldots, p_k$. That hypothesis is accepted if

$$\psi^2 \le \psi^2_{\alpha, j}$$

where j is at most $k - 1$ and may be less if the p_i are based in part on the sample.

For example, suppose an analyst wishes to test goodness of fit to a binomial distribution but has no prior estimate of which binomial distribution should be used. The analyst would select the particular binomial distribution that has p equal to the sample proportion. In that case one parameter has been estimated from the sample, and j would be reduced by one to $(k - 2)$. If the analyst were testing goodness of fit to a normal distribution and estimated both mean and variance from the sample, then j would drop by two to $(k - 3)$.

Example In the frequency histogram example described earlier in the Frequency Histogram section, each bin had a size of 10 min. There were 35 fires in the first bin, 5 fires in the second, etc. Each of this values would be compared with the events predicted by the probability distribution been tested to determine the "goodness of fit". This statistical test can best described in seven steps. The seven steps are best described using the example above as follows:

Step 1: Given a sample data of size n, determine the number of intervals

The number of intervals is equivalent to the bins in a frequency histogram. Consequently, this step consists of determining the bins in which the classified data will be compared with the value suggested by the probability distribution. For best results, it is recommended that the number of data points in each bin be equal or larger than five.

Let's consider the left most histogram in Fig. 73.10, which was developed with a bin size of 10 min. The first bin has 35 fires. The second bin has 5 fires. All other bins have less than 5 fires. Therefore, these bins can be combined for the purposes of the test. See Table 73.15:

In summary, the chi-square test will have three intervals for this example.

Table 73.15 Number of intervals for Chi-Square goodness of fit test example

Bin interval	Number of fires
0–10	35
10–20	5
20–120	9[a]

[a]This interval groups durations from 20 to 120 min to capture the remaining fire events so that the number of fires is equal or larger than 5

Step 2: Choose a distribution for testing

The second step is to determine which distribution will be tested. The distribution parameters should be also identified.

Following our histogram example above, it was preliminarily concluded that the gamma distribution was a good candidate for testing. Recall that the parameters of the gamma distribution are α and β.

Step 3: Estimate the distribution parameters

Using the data available (e.g., the data use for developing the histogram), the distribution parameters should be estimated. For some distributions, parameters can be estimated using closed form algebraic equations. In some other distributions however, numerical methods are necessary for solving a system of simultaneous equations to calculate the corresponding parameters.

We know that $E(x) = \mu = \alpha \cdot \beta$, and $V(x) = \sigma^2 = \alpha \cdot \beta^2$. Therefore, the expected value (e.g., using the average( ) function in Excel) and variance (e.g., using the Var( )) function in Excel) can be directly obtained from the available data in order to obtain α and β from solving the system of simultaneous equations. The resulting system of equations is:

$$E(x) = \mu = \alpha \cdot \beta = 14.44$$
$$V(x) = \sigma^2 = \alpha \cdot \beta^2 = 471.2$$

Solving the above system, the α and β parameters are 0.44 and 32.6 respectively. Let's super-impose the gamma distribution in the histogram to start assessing if our preliminary judgment of the gamma distribution is appropriate. This comparison is depicted in Fig. 73.14. By visual examination, the gamma distribution approximates to the frequency histogram, which suggests that it is a good candidate for quantitative testing.

Step 4: Calculate the expected frequency

This step consists of calculating the expected number of events in each bin.

The following is a description of the columns in Table 73.16.

1. The first column is the bin interval as described earlier. Notice that in this example there is a total of three bins.
2. The second column, observed frequency, lists the counted number of fire events per bin. For example, there are 35 fire events with durations between zero and 10 min.
3. The third column is the probability associated with each bin. This probability

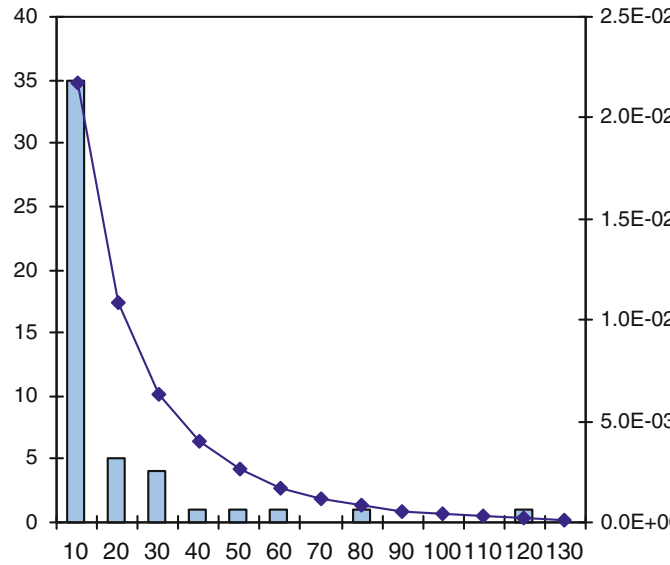

Fig. 73.14 Comparison of frequency histogram (*bars*) and gamma distribution function (*line*)

Table 73.16 Observed and expected frequency for χ^2 goodness of fit analysis

Bin interval	Observed frequency	Probability	Expected frequency
0–10	35	0.61	30.07
11–20	5	0.15	7.51
20–120	9	0.23	11.17

Table 73.17 Observed and expected frequency for χ^2 goodness of fit analysis

Bin interval	Observed frequency	Probability	Expected frequency	Calculated χ^2
0–10	35	0.61	30.07	0.81
11–20	5	0.15	7.51	0.84
20–120	9	0.23	11.17	0.42
			Total	**2.07**

is calculated using the distribution that is been tested, in this case, the gamma distribution. The probability is the area under the distribution curve within the bin interval.

4. The expected frequency column lists the expected frequency within the bin. This frequency is calculated by multiplying the probability by the total number of observations. In this example, there are a total of 49 observations. See Table 73.16. Therefore, the expected frequency for the first interval is $0.61 \times 49 = 30.07$.

Step 5: Calculate the χ^2 value

The calculated χ^2 value is obtained from:

$$\chi^2 = \sum_{i=1}^{k} \frac{(F_e - F_o)^2}{F_e}$$

where k is the number of intervals evaluated, F_e is the expected frequency for each bin, and F_o is the observed frequency for each bin. Notice that the equation consists of a sum of the square of the differences between the theoretical value and the observed values. The calculated values in our example are listed in Table 73.17 under the calculated χ^2 column. The shaded cell is the sum of the calculated χ^2 values for the individual bins.

Step 6: Identify the critical χ^2 value

The critical χ^2 value is compared with the calculated one to determine if the null hypothesis can be accepted or rejected. The determination of the critical value requires: (1) the determination of the degrees of freedom (which is the parameter of the chi-square distribution), and (2) a confidence level α. For the goodness of fit test, the degrees of freedom ν is simply k-1, where k is the number of bins used in the test. The confidence level α suggests that the random variable of the χ^2 will be within (1-α) range of the distribution.

The critical χ^2 value can be obtained from χ^2 tables in the back of probability and statistics books, or preferably, calculated using the = CHIINV( ) (i.e., inverse of the chi-square) function in Excel. In this particular example, the Excel function is = CHIINV (0.05,2), where 0.05 is the confidence level $\alpha = 5.99$ and 2 are the degrees of freedom.

Step 7: Final Decision

The null hypothesis is not rejected if the calculated χ^2 value is less than the critical one. Finalizing our example, it is then concluded that the gamma distribution is a good fit for the experimental data. Properly stated, there is no evidence to reject the gamma distribution as a good fit for the data.

Contingency Test of Independence: Chi-Square Test

A special case of the goodness of fit test is a test of the hypothesis that two random variables are independent, in which case the goodness of fit

test is displayed in a *contingency table,* as follows:

Let $X_1, \ldots, X_m$ be the m values or subranges of a random variable, X; and let $Y_1, \ldots, Y_k$ be the k values or subranges of a random variable, Y.

Let p_i be the estimated probability of X_i, for $i = 1, \ldots, m$; and let q_i be the estimated probability of y_j, for $j = 1, \ldots, k$.

Let n be the size of a sample such that, for each sample entry, a value of X and a value of Y are provided. (Be sure $np_iq_j \geq 5$ for all i and j.)

Let r_{ij} be the number of sample entries for which $X = X_i$ and $Y = Y_j$.

Therefore

$$\sum_{i=1}^{m}\sum_{j=1}^{k} r_{ij} = n$$

Then the sample will provide estimated values of p_i and q_j as follows

$$p_i = \frac{\left(\sum_{j=i}^{k} r_{ij}\right)}{n}$$

and

$$q_i = \frac{\left(\sum_{i=j}^{m} r_{ij}\right)}{n}$$

If the two random variables are independent, then the expected values for r_{ij} are given by np_iq_j.

The test statistic, therefore, is given by

$$\psi^2 = \sum_{i=1}^{m}\sum_{j=1}^{k}\left\{\frac{\left[u\left(r_{ij}, p_i, q_j, n\right)\right]^2}{np_iq_j}\right\}$$

where

$$u\left(r_{ij}, p_i, q_j, n\right) = \begin{cases} 0 & \text{if } -\frac{1}{2} \leq r_{ij} - np_iq_j \leq \frac{1}{2} \\ r_{ij} - np_iq_j - \frac{1}{2} & \text{if } r_{ij} - np_iq_j > \frac{1}{2} \\ np_iq_j - r_{ij} - \frac{1}{2} & \text{if } np_iq_j - r_{ij} > \frac{1}{2} \end{cases}$$

The null hypothesis of independence is accepted if

$$\psi^2 \leq \psi^2_{\alpha,[(m-1)(k-1)]}$$

The number of degrees of freedom comes from the formula given for goodness of fit tests. One begins with $mk - 1$ degrees of freedom. There are m values of p_i, but they sum to one, so only $m - 1$ need be estimated from the sample, and similarly $(k - 1)$ values of q_j must be estimated. Therefore the degrees of freedom for the test equal $(mk - 1) - (m - 1) - (k - 1) = (m - 1)(k - 1)$.

Nonparametric Tests

There are a large number of nonparametric tests, so called because they use no sample or population parameters and make no assumptions about the type of probability distribution that produced the sample.

Sampling Theory

A *random sample* is a sample chosen in accordance with a well-defined procedure that assures (a) each equal item (e.g., each person) has an equal chance of being selected; or (b) each value of a random variable (e.g., height) has a likelihood of being selected that is the same as its probability of occurrence in the full population. A sample that is selected with no conscious biases still may not be truly random; the burden of proof is on the procedure that claims to produce a random sample. A random sample may not be as representative as a sample that is chosen

to be representative, but a sample chosen to be representative on a few characteristics may not be random and may not be representative with respect to other important characteristics.

In addition to requiring that each item have an equal chance of being selected, a random sample must assure that every combination of items also has an equal chance of being selected. For example, a random sample of currently married couples would not be a random sample of currently married persons, because spouses would be either selected or not selected together in the former but not necessarily in the latter.

A *sampling frame* is a basis for reaching any member of a population for sampling in a way that preserves the randomness of selection. An example would be a mailing list, although if it had missing names or duplicate names it would be deficient as a sampling frame, because each equally likely name would not have an equal chance at selection. A *sample design* is a procedure for drawing a sample from a sampling frame so that the desired randomness properties are achieved.

A *simple random sample* is a sample that is drawn by a procedure assuming complete randomness from a population all of whose elements are equally likely. If they are not all equally likely, a procedure that assures complete randomness is called a *probability sample*.

A *stratified random sample* is a sample that achieves greater precision than a simple random sample by taking advantage of existing knowledge about the variance structure of subpopulations. By concentrating a disproportionate share of the sample in subpopulations that account for disproportionate shares of the total variance, a stratified random sample produces lower total variance for a given sample size. The annual National Fire Protection Association survey of fire departments that produces the annual estimates of total U.S. fire loss is a stratified random sample.

A *cluster sample* is a sample that randomly selects certain subpopulations, then samples only them. This approach often involves subpopulations that consist of geographical areas, in which case it is also called an *area sample*. The purpose of cluster sampling is to hold down the cost of sampling. It is not as statistically acceptable as a simple or stratified random sample.

A *systematic sample* begins with a listing of the population, then random selection of the first sample member, and finally selection of the remaining members at fixed intervals (e.g., every *k*th name on the list). This approach is simpler than true random sampling but not as acceptable.

A *representative sample* is one chosen to guarantee representation from each of several groups. If properly designed, it is a special case of stratified random sampling, but often the term is used for samples where the need for representation is the only part of the procedure specified. If the size of the representation is also specified, it is called a *quota sample*. The statistical properties of a sample constructed in this way cannot be determined, and nothing useful can be said about its accuracy or precision. That is also true of a *judgment sample,* in which the only rules governing sample selection are the statistician's judgments.

Characterization of Data from Experimentation or Modeling

Data Variability

Any data source is subject to variability for reasons other than those with substantive importance. Results of a test of burning behavior of a material may vary because of the ambient temperature or humidity. Such variation can be virtually eliminated through careful experimental controls. Results may vary because of naturally occurring variations in the composition of the material or human variability in the production process. Such variation can be reduced through careful controls, and it may be possible to measure the variation that cannot be eliminated. Test results may vary because of moment-to-moment variations in airflow or in the heat output of the heating apparatus or in many other physical conditions and characteristics. Such variation

can be reduced through careful controls, but residual variation may be difficult or impossible to measure. And because test results may vary as a result of standardization and care, or the lack thereof, it is also true that test results may vary with the laboratories, organizations, and people conducting the tests.

Interpretation of test results—or of modeling results based on input test data—must take account of data variability from causes other than those of interest. Such variability is often called "error" in statistical terminology, where the term *error* is used to refer to all deviations between predicted and actual results, not just to deviations involving improper human behavior. Standards for test methods typically have sections for what is called *precision* and *bias* information. Precision refers to the magnitude of error. Bias refers to the symmetry of error. Precision asks, "Are large differences possible even if there is no difference in the characteristics we intended to test for?" Bias asks, "Are we more likely to err in one direction than in another?"

Precision and bias sections are often lacking in test method documentation—or at least lacking in detail. For laboratory testing the principal source of precision and bias information is interlaboratory studies. Through reported experiments at each of several laboratories under what are intended to be identical testing conditions, one can quantify the magnitude of variation from one run to the next in a single laboratory (called *repeatability*) and of variation between laboratories (called *reproduceability*).

There are standard statistical methods for assessing such variation, but the work is expensive, which accounts for the scarcity of such data. Also, the results, when published, are attached to a test method but may show more precision than a user will obtain in another application (e.g., different material) or in a laboratory without the heightened attention to precise controls that one expects in an interlaboratory evaluation. (No laboratory wishes to be found less precise, or less capable generally, than its competitors, but in most day-to-day work, there is no expectation of such calibration of performance, and people may relax.)

One might think that inherently statistical databases—such as fire incident databases—would be easier to assess, and it is true that precision can be readily calculated based on sample size. However, bias depends on the adequacy of the sampling—is the sample truly random and so representative of its universe?—and most statistical databases are not truly random. The National Fire Incident Reporting System (NFIRS) captures nearly a million fire incidents a year, typically close to half the total fires reported to fire departments. The precision of NFIRS is outstanding, on that basis. However, national estimates of specific fire problems project and calibrate NFIRS using a smaller database, the NFPA annual fire experience survey, and so reflect that smaller database's lesser (though still excellent) precision. More importantly, NFIRS is not a true random sample (although the NFPA survey is), and so its bias cannot be calculated from any standard statistical methods. Instead, NFIRS users note the large share of total fires it represents and the absence of any obvious sources of significant bias. (For example, NFIRS is believed to be less represented in rural or large urban areas but is well represented in both.)

In the end, engineering analysis must consider and address data variability issues but typically cannot hope to fully quantify or resolve them.

Testing Models for Goodness of Fit

Earlier in this chapter, the use of the chi-square test to assess goodness of fit was described for a statistical distribution. The same method can be used to assess goodness of fit between any set of model predictions and laboratory data. In essence, this statistical test assumes that each laboratory data point is equally likely. If there are n data points, then the test is based on

$$\psi^2 = \sum_{i=1}^{n} \frac{\left(x_{i,\text{measured}} - x_{i,\text{predicted}}\right)^2}{x_{i,\text{predicted}}}$$

This method is a one-sided test using $n - 1 - k$ degrees of freedom, where k is equal to the number of model parameters estimated from the data. (The more the data are used indirectly to predict themselves, the less variation one would expect to see.)

The more common practice in assessing goodness of fit is to "eyeball" the two curves, that is, be guided by an impression of proximity. This can be highly misleading. The eye tends to measure distances between two curves as the shortest distance between the curves, whereas accuracy of prediction is based on differences in predicted versus actual y-axis values for given x-axis values. These differences can be very large between two curves with steep slopes that look close together, and steep slopes are commonplace in curves for variables that describe fire development and related environmental conditions.

On the other hand, sometimes the most relevant and appropriate measures of the correspondence between two curves lie in the correspondence between key summary measures and not in the exactness of the correspondence between the full curves. For example, the timing of the transition from smoldering to free burning is not well described by any model and is subject to enormous variability. However, this should not be allowed to obscure the agreement of model with empirical data during the free-burning stage.

One way to adjust the comparison so that it excludes the smoldering phase is through recalibration of the curve. Set the timing and fire conditions at the onset of free burning for the model equal to the timing and fire conditions from the lab data. Then, use formal statistical methods to assess how well the model predicts the data from that point on. Note, however, that the steepness of the curves makes it quite possible that calculated agreement will be poor even with this adjustment.

Another way to adjust the comparison is to compare the timing of transition points (also called *inflection points* in calculus), such as time from the onset of free burning to flashover; and appropriate maximums (e.g., peak heat release rate) and minimums (e.g., oxygen concentration). The problem with this approach is that there may not be simple statistical tests, such as the chi-square test for goodness of fit of whole curves, that will indicate how much difference in timing of transition points or in other summary measures can be expected statistically due to measurement error or other normal variability and how much difference is significant. There needs to be an extended dialogue between fire protection engineers and statisticians to determine which statistical bases for evaluating goodness of fit of models to empirical data are both executable as statistical tests and meaningful to the modelers.

Example The first example in this chapter discussed statistical inference of a best probability distribution to describe fuel load (as energy per unit area). However, that example assumed that the form of the distribution was already known, possibly from fundamentals, possibly from past empirical studies. Only the parameters needed to be estimated. Suppose that is not the case.

One way to select a best form for the distribution is to identify candidate distributions (e.g., normal, log normal, exponential, Weibull, uniform) and then conduct a chi-square goodness of fit assessment of each, using comparable setups. Use the techniques discussed to develop best sample-based estimates of the parameters for each distribution (e.g., the two parameters of normal, lognormal, and Weibull distributions; the one parameter of exponential, Poisson, or uniform distributions). Then convert each distribution into a histogram-style discrete probability distribution for a set of intervals. For example, set up 20 intervals, where the first interval begins at zero (the lowest value fuel load can take) and the last interval includes all the highest fuel load values that may occur.

Use these same intervals in evaluating each distribution. Convert the empirical data (which in the earlier example came from analysis of 400 rooms or areas) to a set of measured probability values, which will be the same for every distribution. Then convert the candidate distribution with its sample-based parameters to a set of predicted probability values for each interval. Also, take account of differences in degrees of freedom. A distribution with two inferred parameters (e.g., lognormal) will have one less degree of freedom than a distribution with one inferred parameter (e.g., exponential), which means the same chi-square statistic will be more significant in the latter case as compared to the former case.

Reliability, Availability, and Maintainability

74

Francisco Joglar

Introduction

Many engineering fields can benefit from reliability, availability, and maintainability, concepts and techniques. Fire protection engineering is not an exception. For example, fire protection engineers may be interested in estimating the number of failures of fire pumps under their watch. Other practical applications may include increasing the reliability and/or availability of a fire protection system, optimizing inspection, testing and maintenance intervals and calculating probabilistic values for a fire risk assessment. As the use of risk-informed, performance based methods increases, fire protection researchers and engineers continue to improve and apply reliability, availability, and maintainability methods and techniques in the field.

The primary objective of a reliability analysis is the prediction of failures by monitoring equipment condition as a function of time. Consequently, the fundamentals of reliability analysis can be found primarily in probability and statistical theory and in the physical characterization of the failure mechanisms. In principle, failures can be predicted either by statistical analysis of reliability data or by physical models simulating corresponding failure mechanisms. In some applications however, it is necessary to use both approaches simultaneously given the specific characteristics and complexity of the system or components under analysis. Because the physical modeling of each possible failure mechanism (e.g., simulating corrosion inside a sprinkler system pipe) can be a field of study by itself, this chapter concentrates on the statistical methods for analyzing reliability data in which time is considered an aggregate agent of failure.

This chapter provides an overview of basic concepts and analytical methods associated with reliability, availability, and maintainability. Such concepts are necessary since reliability analysis not only applies to simple replaceable components but also to repairable items that may undergo routine inspections, testing, and maintenance and complex systems including hardware, software, and human interaction. The material includes treatment of repairable and replaceable components, system reliability analysis, and a general description of human and software reliability. The chapter includes enough theoretical background and practical examples so that fire protection engineers can perform the suggested calculations with a good understanding of the advantages and limitations of the selected analysis. The solution of some practical problems requires the use of numerical methods for solving them and the use of mathematical software packages is recommended.

Basic Concepts

This section provides a qualitative overview of reliability, availability, and maintainability analysis with a process for conducting such analyses.

Reliability, Availability, and Maintainability

Reliability, represented by the letter R, is the probability of an item functioning after a predefined time, T. This definition introduces the concept of probability in reliability analysis. As such, the time to failure of a system or component is considered a random variable characterized by a probability distribution. The curve in Fig. 74.1 represents the probability distribution characterizing the time to failure. The reliability of the system is the area under the probability distribution to the right of time T. The unreliability of a system or component, represented by the letter F, is simply $F = 1 - R$. That is, the unreliability will be the area under the curve to the left of time T. Figure 74.1 illustrates this concept.

Maintainability refers to the analysis of downtime, that is, the times that a system or component may not be operational due to an inspection, testing, or preventive or corrective maintenance activities. Consequently, maintainability analysis includes the statistical techniques necessary to characterize inspection, testing, and preventive and corrective maintenance times. As in the case of times to failure in reliability analysis, the times to repair are assumed random in maintainability analysis.

The concept of availability is somewhat different. Availability is the probability that an item will be operational at a predefined time, T. It is important to stress the difference between reliability and availability. Recall that reliability is the probability of an item functioning *after* time, T. Availability refers to the probability of the item being operational *at* time, T. Availability analysis is important because it incorporates the concepts of uptime and downtime of systems and components, which for the most part are associated with repairable items or items that undergo inspections, testing, and maintenance activities. Fire protection systems are good examples of such items.

Individual Components

In the context of this chapter, components are those items that are analyzed as individual units with no direct consideration to interaction between different subcomponents, including software and human actions. Components can be broadly classified as repairable and nonrepairable (i.e., replaceable).

Nonrepairable components are those that are replaced after a failure (e.g., a sprinkler head). Consequently, the concepts of availability and maintainability are not relevant in the analysis of individual nonrepairable components. Once an item is determined to be (or assumed to be) nonrepairable for the purpose of a particular analysis, the problem reduces to determining failure modes, collecting reliability data, and performing reliability modeling.

The reliability modeling can be approached from two different perspectives: (1) assuming

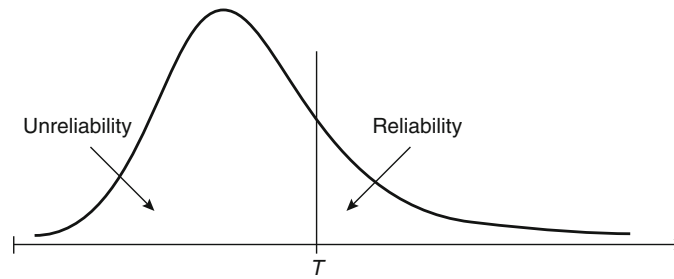

Fig. 74.1 Conceptual representation for the definition of reliability and unreliability

time is an aggregate agent of failure, which requires the collection of time to failure data; or (2) a probabilistic modeling of the physical stress and strength associated with the component. In the former, the reliability modeling usually includes the determination of an appropriate probability distribution for the time to failure and the calculation of the mean time to failure (MTTF) or other relevant probability metric. In the latter, reliability modeling requires the characterization of the physical stress affecting the component as a probability distribution. The capacity of the component to withstand the stress, referred to as the strength, is also characterized as a probability distribution.

Repairable items are those that are returned to operation after a failure. Depending on the analysis objectives, and the duration of repair times relative to operational times, the concepts of maintainability and availability may be fully applicable since repairable items can be routinely inspected, tested, and subjected to preventive or corrective maintenance activities. Consequently, the reliability, maintainability, or availability analysis becomes relatively complex, often requiring numerical methods for the solution. Typical reliability studies for repairable items involve the analysis of mean time between failures (MTBF), trend analysis, mean time to repair (MTTR), the prediction of failures in a predefined period of time, and the determination of optimum inspection and maintenance intervals.

Systems

Many professionals in the fire protection engineering field have the responsibility of maintaining in optimal condition fire protection systems such as detection systems, halon and CO_2 systems, and so on. Fire protection features can be either in standby mode or in continuous operation. Most of these systems consist of electronic, electrical, and mechanical devices working together. Although an entire system can be treated as an individual component lumping together all failure modes, it is often necessary to characterize individual subcomponents in order to analyze their effect on the overall system.

Systems are classified in this chapter as hardware systems or complex systems. Hardware systems are those consisting only of electronic, electrical, or mechanical components. Complex systems are those operating based on interactions between hardware, software, and human actions. Today, more and more systems are complex. The need for modeling the reliability/availability of such systems has generated considerable research in the area of software and human reliability. Readers should appreciate that fire, as a common cause failure mode, can impact the operation of complex systems such as the space shuttle or a commercial nuclear power plant.

In general, system analysis requires the individual treatment of subcomponents and a logic model connecting such subcomponents. Once the reliability or availability of each individual subcomponent is properly characterized, the overall system reliability or availability can be calculated.

Finally, system models are usually top-bottom models in which the events leading to the failure of interest are logically deduced from the failure itself. The most common modeling approach is the fault tree. Currently, fault trees are developed to include hardware, software, and human action, as well as considerations for common cause failures.

Conducting a Reliability, Availability, or Maintainability Analysis

The process of conducting a reliability, availability, or maintainability analysis consists of the following general steps:

1. Definition of system boundaries
2. Failure mode analysis
3. Collection of reliability data
4. Selection of appropriate modeling method or technique
5. Quantification
6. Documentation

In some cases, steps 3 and 4 may switch in order or be conducted in parallel since the required inputs to the selected model are usually generated from data. A qualitative discussion of each step follows.

Step 1: Definition of System Boundaries The first step, definition of system boundaries, refers to the identification of which subcomponents will be included and the resolution of each component or system. This may be a trivial step in the case of a simple replaceable component. At the same time, it can also require careful consideration in the case of complex systems such as the space shuttle, a nuclear reactor, and so on. In practice, the definition of system boundaries involves evaluating each component of the system and determining if it should be part of the analysis or not. There are usually good economical and technical reasons whether or not to include the component. Notice also that this evaluation may include software and human elements in the system. Some general characteristics to consider may include the following:

- Is the item repairable or nonrepairable?
- For repairable systems:
  - Is the item subjected to routine inspections?
  - Is the item subjected to preventive maintenance?
  - What is the typical duration of inspection and maintenance activities?
- Should the item be treated as an individual component or a system?
- Does the item involve only hardware component(s) or a combination of hardware, software, and human elements?
- What is the main objective of the system and which subsystems are critical to accomplishing such objectives?

Another important consideration is the level of resolution that can be supported with reliability data. For example, a fire pump may be modeled as an individual component or as a system of interconnected subcomponents. In the latter case, reliability data describing each of the subcomponents and a logic model integrating all of the subcomponents will be necessary.

Step 2: Failure Mode Analysis At this point, the concept of failure mode must be introduced. A *failure mode* is the way in which a particular system or component can fail. The term failure mode should be distinguished from the term *failure mechanism*, which refers to the fundamental chemical or physical effect responsible for a particular failure mode.

Once the system or component has been defined, it is important to understand the different failure mechanisms that will eventually suggest the different failure modes for which reliability data will be collected. Depending on the complexity of the system or component, the identification of failure modes of a system often requires input from experts involved in its design, operation, inspection, testing, and maintenance. As in step 1, the ability to collect reliability data also influences the level of resolution at which the failure modes are identified or quantified.

A tool that is regularly used for analyzing failure modes is the Failure Modes and Effects Analysis or FMEA [1]. The FMEA is a bottom-up (inductive) analysis that identifies failure modes in the system. The term *bottom-up* refers to identifying failure modes starting from the component level of a system. As such, FMEA is a very methodical tool that looks at every component in the system and then identifies the failure modes. As the failure modes are identified, the effects of such failure modes in the system are also assessed. The information resulting from a FMEA analysis is tabulated using a relatively rigorous table structure. The table includes the component or system name, failure mode, effects, and so on. Another alternative is the use of top-bottom (deductive) methods for identifying relevant failure modes (e.g., fault trees).

Step 3: Collection of Reliability Data Reliability or availability calculations using statistical methods will ultimately depend on the collection of reliability data. Reliability data are collected once the failure modes are identified. In most cases, reliability data will suggest the rate of

occurrence of the different failure modes. The data typically required for reliability studies include times to failure, inspection and test durations, duration of preventive or corrective maintenance, and so on.

Among others, Ebeling [2] (p. 284) suggests the following classification of reliability data:

1. Operational versus test-generated data
2. Complete versus censored data

Operational data are collected in the field by monitoring the operation of the system or component. In contrast, test-generated data are collected from controlled experiments designed to imitate the operational condition of an item. This step is usually necessary during the design stage before the release of new products. In some cases, accelerated testing techniques are necessary when failures of the system and components may take long times. As stated by Nelson [3], accelerated testing consists of a variety of test methods for shortening the life of products or hastening the degradation of their performance.

The concept of complete and censored data is best explained with an example. Consider a simple experiment consisting of ten lightbulbs in operation with the objective of recording the time to failure. A complete data set would include the times to failure of each of the ten lightbulbs (failure-terminated test). In a censored data set, the test would have been stopped some time before the failure of all the lightbulbs (a time-terminated test). Therefore, the censored data set will include some number of bulbs lasting longer than the duration of the test.

Finally, data collection may be a continuous effort if reliability, availability, and maintainability techniques are used for a continuous monitoring of equipment conditions. In this case Bayesian methods can be used to update previously recorded data with new information.

Step 4: Selection of Appropriate Modeling Method or Technique The selection of an appropriate modeling method or technique largely depends on the type of system and the supporting reliability data. The analysts should carefully consider the assumptions governing the different modeling tools to determine applicability to the system or component being analyzed.

A number of these methods or techniques are currently included in software packages in which the user inputs the data and selects the type of analysis. At the same time, the use of these software packages requires understanding of the fundamental assumptions governing the analysis and expertise in the interpretation of the results.

In some cases, however, preprogrammed software packages may not offer the modeling capabilities required by the system or component under analysis. In that case, analysts may need to develop their own models or combine capabilities from different software packages in order to obtain the desired solution. For example, different tools may be used for the statistical analysis of reliability data and for prediction of failures in a specified period of time.

Step 5: Quantification Quantification refers to exercising the selected modeling tool or technique in order to obtain quantitative results. As in the case of the collection of reliability data, the quantification process may be a one-time exercise or may consist of a continuous process of monitoring equipment condition.

Step 6: Documentation The final step is documentation. The documentation of a reliability, availability, or maintainability analysis should include detailed descriptions of the five steps documented earlier.

The remaining sections in this chapter describe selected quantitative techniques in support of the steps listed previously.

Reliability Analysis of Nonrepairable Items

Recall that nonrepairable items are those that are replaced upon failure. As such, this section describes analytical techniques for evaluating the reliability and predicting the time to first failure of components. The most common approach for quantifying the reliability of

nonrepairable items is treating the time to failure, t, as a random variable governed by a probability distribution $f(t)$. Consistent with the definition of reliability provided earlier, the reliability can be expressed as

$$R(t) = \int_{T}^{\infty} f(t)dt = 1 - \int_{0}^{T} f(t)dt \qquad (74.1)$$

The MTTF is, therefore, the expected value of t, which is represented as

$$\text{MTTF} = E(t) = \int_{0}^{T} t \cdot f(t)dt \qquad (74.2)$$

As shown in Papoulis [4] (p. 166), it can be proven that

$$\text{MTTF} = E(t) = \int_{0}^{\infty} R(t)dt \qquad (74.3)$$

since $R(t)$, which is the reliability of the system, tends to zero as time goes to infinity. It can be proven also that

$$R(t) = \exp\left[-\int_{0}^{t} h(x)dx\right] \qquad (74.4)$$

where $h(x)$ is the conditional failure rate or hazard rate of the system. The concept of hazard rate is described later in this chapter.

Probability Distributions

A probability distribution, or probability density function (PDF), is a mathematical function governing the probability of a random variable over its physical range. Any equation whose area under the curve is exactly 1.0 is a probability distribution. A number of distributions have been identified as practical for different engineering applications. That is also the case for reliability engineering.

Consider the failure history illustrated in Fig. 74.2. The round markers indicate the failure times of equipment measured from time 0. Given this failure history, one or more probability distributions representing the data could be identified, as represented by the different curves in Fig. 74.2. The shape and scale of the selected distribution are important factors to consider in the analysis.

This section describes the most common distributions used in reliability applications for representing the random nature of times to failure. These distributions are the exponential, Weibull, log-normal, and empirical distributions. Depending on the specific application, other distributions not covered in this chapter may be also selected.

Exponential Distribution The exponential distribution is routinely used in reliability analysis for nonrepairable items. The distribution is used as a model for determining the probability of times between successive events. In fire protection engineering applications, times between successive events can be (but are not limited to) the times between failures of a fire protection system, times between fires in a facility, or times between 9-1-1 calls to a fire department.

The exponential PDF is a one-parameter distribution, which is usually represented by the symbol λ and should be interpreted as the constant rate (units of 1/time) at which a given event

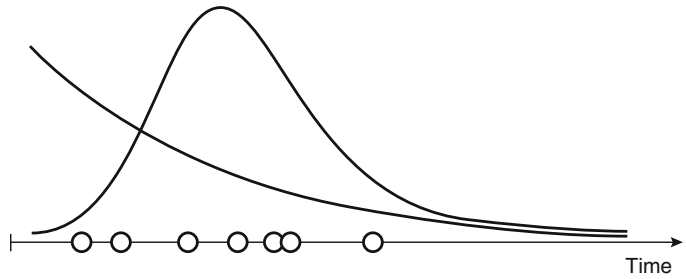

Fig. 74.2 Conceptual representation of a failure history represented by probability distributions

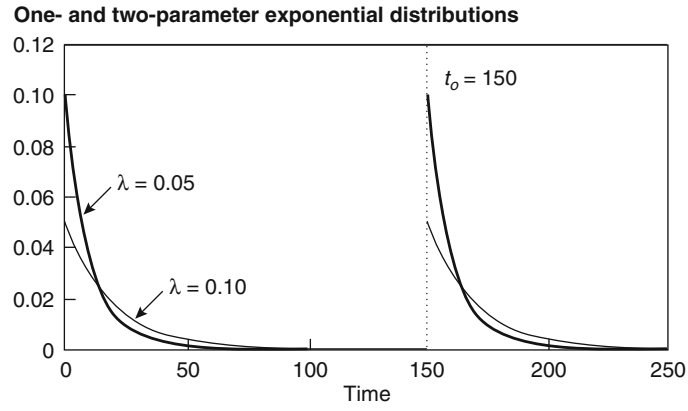

Fig. 74.3 Example representations of the exponential distribution

occurs. The mathematical form of the distribution is

$$f(t) = \begin{cases} \lambda e^{-\lambda t} & t \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{74.5}$$

where t is the random variable, usually time, and λ is the parameter characterizing the distribution. The mean and standard deviation of the exponential distribution is $1/\lambda$.

The exponential distribution can be easily integrated to obtain the following cumulative distribution function (cdf):

$$F(t) = \begin{cases} 0 & t < 0 \\ 1 - e^{-\lambda t} & \text{otherwise} \end{cases} \tag{74.6}$$

And from Equation 74.1, $R(t) = e^{-\lambda t}$. The exponential distribution always starts at $t = 0$. This origin can be shifted using the two-parameter exponential distribution

$$f(t) = \begin{cases} \lambda e^{-\lambda(t-t_0)} & t \geq t_0 \\ 0 & \text{otherwise} \end{cases} \tag{74.7}$$

where t_o represents the minimum life of the component.

Figure 74.3 illustrates examples of shapes and locations the exponential distribution can assume. Notice two identical groups of distributions. The only difference between the two groups is the use of the one- or two-parameter exponential distribution. The λ value is the same for both groups.

Weibull Distribution Another distribution that is widely used for representing the time to failure of a component is the Weibull distribution. The mathematical form of the distribution is

$$f(t) = \begin{cases} \dfrac{\beta t^{\beta-1}}{\alpha^{\beta}} e^{-\left(\frac{t}{\alpha}\right)^{\beta}} & t \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{74.8}$$

where β is the shape parameter and α is the scale parameter. The Weibull distribution reduces to the exponential distribution if $\beta = 1$ and $\lambda = 1/\alpha$. The cdf for the Weibull distribution is

$$F(t) = \begin{cases} 1 - e^{-\left(\frac{t}{\alpha}\right)^{\beta}} & t \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{74.9}$$

From Equation 74.1, $R(t) = e^{-\left(\frac{t}{\alpha}\right)^{\beta}}$. The mean and variance of the distributions are given by the following expressions:

$$E(t) = \alpha \cdot \Gamma\left[\frac{\beta+1}{\beta}\right] \tag{74.10}$$

$$V(t) = a^2\left(\Gamma[(b\ +\ 2)/\beta]\ -\ \{\Gamma[(\beta +\ 1\ )/\beta]\}^2\right) \tag{74.11}$$

where $\Gamma(\cdot)$ is the gamma function.

In every Weibull distribution, 63.2 % of all the probability under the curve will occur at $t = \alpha$. In other words $Pr(t < \alpha) = 0.632$.

For values of $\beta < 1$, the shape of the distribution is similar to an exponential distribution. For values of β between 1 and 3, the distribution is skewed to the left. Finally, with β values larger than 3 the distribution will start to approach a bell shape.

The origin of the two-parameter Weibull distribution is always 0. In cases where it is necessary to shift the origin to $t_o > 0$, the three-parameter Weibull distribution can be used. In this distribution, the parameter t_o would represent the minimum life of a component. That is, no failures are expected before t_o.

$$f(t) = \begin{cases} \dfrac{\beta(t-t_o)^{\beta-1}}{\alpha^{\beta}} e^{\left(\frac{t-t_o}{\alpha}\right)^{\beta}} & t \geq t_o \\ 0 & \text{otherwise} \end{cases} \tag{74.12}$$

Figure 74.4 illustrates examples of shapes and locations the Weibull distribution can assume. Notice two groups of distributions. The only difference between the two groups is the use of the two- or three-parameter Weibull distribution. The α and β values are the same for both groups.

Log-Normal Distribution Similar to the Weibull, the log-normal distribution is defined for positive values only. This characteristic makes it a suitable selection for probabilistic distribution of failures. The distribution is particularly appropriate for random variables constrained by zero that can assume few very large values. Equipment downtime may be a good example. The log-normal distribution results from the transformation $x = \ln(t)$ where the random variable x is normally distributed with mean μ and standard deviation σ. The mathematical form of the distribution is

$$f(t) = \begin{cases} \dfrac{1}{2\pi\sigma t} e^{\frac{-1}{2}\left(\frac{\ln(t)-\mu}{\sigma}\right)^2} & t \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{74.13}$$

where μ and σ are the mean and standard deviation of the normally distributed random variable x. Figure 74.5 provides an example of the log-normal distribution. The cumulative distribution function $F(t)$ as well as the reliability function $R(t)$ are obtained by a numerical integration of $f(t)$.

The expected value and the variance of t can be obtained with the following equations:

$$E(t) = e^{\mu+\frac{\sigma^2}{2}} \tag{74.14}$$

$$V(t) = e^{2\mu+2\sigma^2} - e^{2\mu+\sigma^2} \tag{74.15}$$

If $E(t)$ and $V(t)$ are known instead, μ and σ can be calculated using Equations 74.14 and 74.15.

Empirical Distribution Sometimes the use of an empirical distribution is necessary since the collected data may not follow any known parametric probability distribution. According to Modarres [5] (p. 286), for a complete set of data (see definition of complete data in the reliability data section) and a small sample size

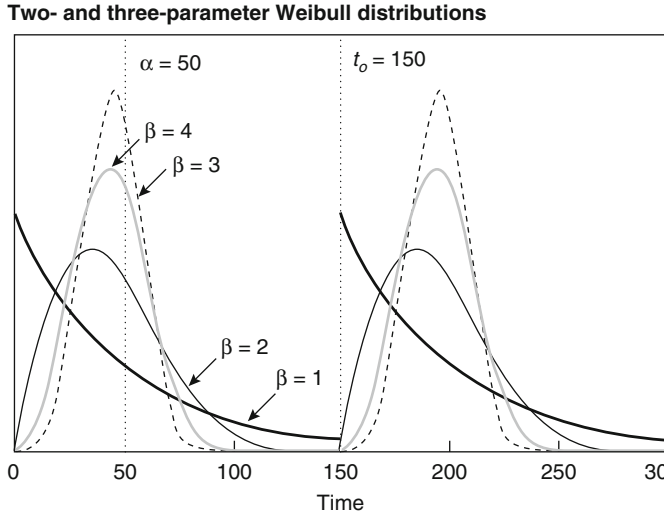

Fig. 74.4 Example representations of the Weibull distribution

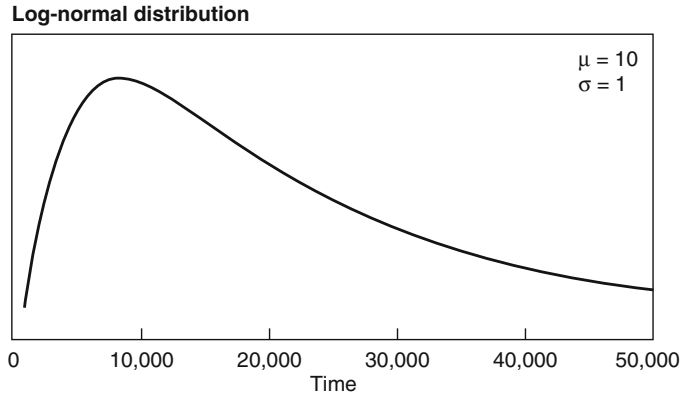

Fig. 74.5 Example of the log-normal distribution

($n < 15$), the empirical distribution function for times to failures t_i, t_{i+1},,. . ., t_n has the following mathematical form:

$$\hat{f}(t_i) = \frac{1}{(n+0.25)(t_{i+1} - t_i)}, \quad i = 1, 2, \ldots, n-1 \tag{74.16}$$

The symbol "^" indicates that the estimate is obtained from sample data. The reliability function is, therefore,

$$\hat{R}(t_i) = 1 - \hat{F}(t_i) = \frac{n + 0.625 - i}{n + 0.25}, \quad i = 1, 2, \ldots, n \tag{74.17}$$

This empirical formulation implies that the same number of failures is expected between two failure times (t_i, t_{i+1}). Finally, the sample expected value and variance of the failure data can be calculated using

$$\hat{E}(t) = \sum_{i=1}^{n} \frac{t_i}{n} \tag{74.18}$$

$$\hat{V}(t) = \frac{\sum_{i=1}^{n} t_i^2 - n\hat{E}(t_i)^2}{n-1} \tag{74.19}$$

Example 1 A review of impairment data on smoke detectors in a given facility indicates that a smoke detector device fails on average once every 5 years for various reasons. Upon failure, the detectors are replaced with a new device. Determine the probability that a smoke detector will last (1) at least 10 years, (2) at most 10 years, and (3) between 5 and 10 years.

Solution From the available data, the parameter λ is estimated as $\lambda = 1/5 = 0.2$ years^{-1}. The probabilities are calculated integrating the exponential distribution (Equation 74.5) as follows:

Probability of the detector lasting at least 10 years:

$$Pr(t \geq 10) = \int_{10}^{\infty} \lambda e^{-\lambda t} dt = 1 - \int_{0}^{10} \lambda e^{-\lambda t} dt = e^{-0.2(10)} = 0.135$$

Probability of the detector lasting at most 10 years:

$$Pr(t \leq 10) = 1 - \int_{10}^{\infty} \lambda e^{-\lambda t} dt = 1 - 0.135 = 0.865$$

Probability of the detector lasting between 5 and 10 years:

$$Pr(5 \leq t \leq 10) = \int_{5}^{10} \lambda e^{-\lambda t} dt = 0.23$$

The process for computing probabilities would be identical if a different probability distribution is selected. Readers are referred to the section on parameter estimation later in this chapter for methods for calculating parameters for the probability distributions described earlier.

Failure No.	Time to Failure (Days)	$\hat{R}(t_i) = \frac{n + 0.625 - i}{n + 0.25}$
1	42	$\frac{4 + 0.625 - 1}{4 + 0.25} = 0.85$
2	296	$\frac{4 + 0.625 - 2}{4 + 0.25} = 0.62$
3	467	$\frac{4 + 0.625 - 3}{4 + 0.25} = 0.38$
4	596	$\frac{4 + 0.625 - 4}{4 + 0.25} = 0.15$

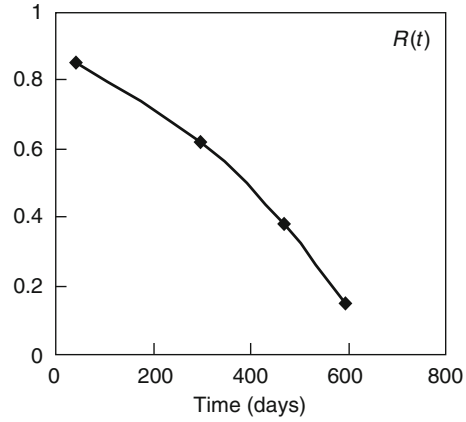

Fig. 74.6 Numerical solution for Example 2

Example 2 Plot the reliability curve for the following times to failure (in units of days) using the empirical distribution 42, 296, 467, 596.

Solution Before Equation 74.17 is used to calculate the reliability, the failure times must be in ascending order. In this case $n = 4$. Results are presented in Fig. 74.6.

Conditional Distributions and Hazard Rate

From the definition of conditional probability, the probability of a system functioning at time t_o fails before time $t > t_o$ is expressed as

$$F(t|t>t_o) = \frac{Pr(t \le T/t>t_0)}{P(t > t_0)} = \frac{F(t) - F(t_o)}{1 - F(t_o)} \qquad (74.20)$$

where t is the random variable for time. Figure 74.7 provides a conceptual representation of this formulation. The numerator represents the area under the curve between the variables t_o and t (shaded). The denominator is the area under the curve after the variable t_o, which is also the reliability of the system.

Differentiating with respect to x, the conditional density function is obtained [4].

$$f(t|t>t_o) = \frac{f(t)}{1 - F(t_0)} \qquad (74.21)$$

This conditional density, which is a function of t_o and t, will be applied later in the chapter in the analysis of repairable systems. The denominator is by definition a number between 0 and 1, which forces the integral of the function from t_o to infinity to be 1.0. As illustrated by the dashed line in Fig. 74.4, the normalizing factor shifts the function upwards after t_o, but the shape of the distribution remains the same after that point. Again, the area under the curve of the conditional distribution after t_o is 1.0.

The value of the conditional density function at $t_o = t$ is a function only of t. This function, which is usually denoted as $h(t)$, is called the conditional failure rate or hazard rate of a component. The hazard rate is found by dividing the PDF of the component by its reliability at time t. From Equation 74.21,

$$h(t) = \frac{f(t)}{1 - F(t)} = \frac{f(t)}{R(t)} \qquad (74.22)$$

Accordingly, the product $h(t) \cdot dt$ represents the conditional probability that a component surviving at time t, will fail between time t and $(t + \Delta t)$ for the first and only time. The component will then be replaced. Although $h(t)$ equals the value of the conditional density for times $t_o = t$, it is not a probability distribution because the area is not

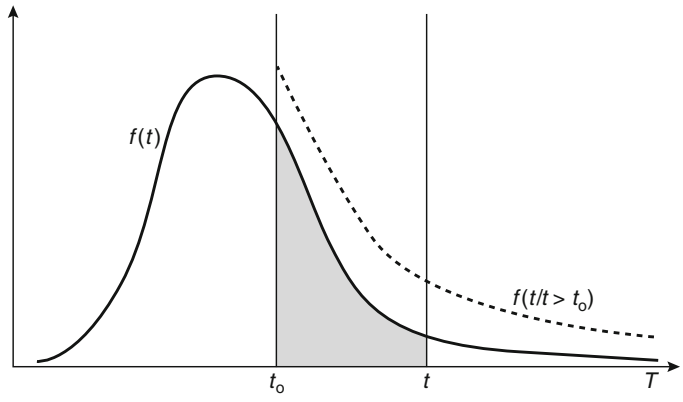

Fig. 74.7 Conceptual representation of the conditional probability of failure

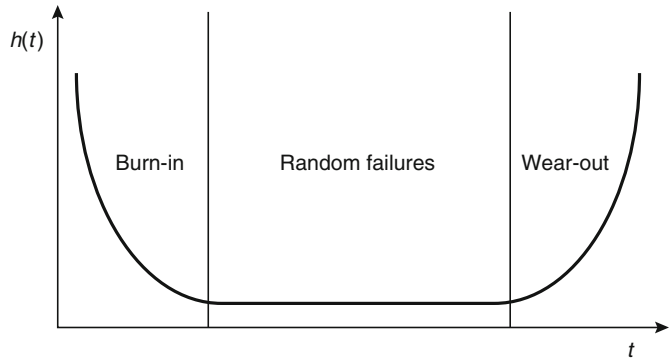

Fig. 74.8 Typical bathtub curve

1.0. However, the hazard rate is an important function in reliability analysis since it shows changes in the probability of failure over the lifetime of a component.

A representative shape of $h(t)$ is the *bathtub* curve for replaceable items. A typical bathtub curve is shown in Fig. 74.8. This bathtub curve is divided in three regions: burn-in, random failures, and wear-out. The *burn-in* region is characterized by a decreasing failure rate due to improvements in early failures attributable to defects in design, manufacturing, or construction. The *random failure* region is characterized by a constant failure rate. As the system or component ages, it starts to exhibit an increasing failure rate. This increasing failure rate characterizes the *wear-out* region.

Exponential Distribution The failure rate of an exponential distribution is independent of time (constant failure rate). It empirically fits the experience of many systems and components over the random failure region of the bathtub curve. The inherent characteristic of a constant failure rate limits the application of the exponential distribution as will be described later in the chapter. From Equation 74.22, the conditional probability distribution $f(t/t > t_o)$ and hazard function $h(t)$ for the exponential distribution are

$$f(t|t>t_o) = \frac{f(t)}{1-F(t_o)} = \frac{\lambda e^{-\lambda(t+t_o)}}{e^{-\lambda t_o}} = \lambda e^{-\lambda(t)}$$

and

$$h(t) = \frac{f(t)}{1-F(t)} = \frac{\lambda e^{-\lambda t}}{e^{-\lambda t}} = \lambda$$

Notice that the latter is independent of time. This result demonstrates one very important characteristic of the exponential distribution for reliability applications: its memory-less property. In other words, the distribution of the remaining lifetime (the conditional distribution) of a component is independent of the current age or what is equivalent, identical to the exponential PDF. At

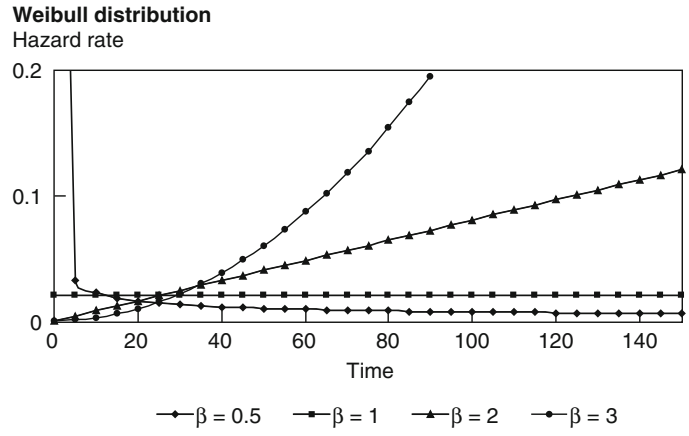

Fig. 74.9 Examples of Weibull distribution hazard rates

each point in time, a given component shows no effect of wear.

Weibull Distribution A more general distribution for representing probability of failures in increasing (wear-out region), decreasing (burn-in region), and constant failure rate conditions is the Weibull distribution. The conditional probability distribution and hazard rates are

$$f(t|t>t_o) = \frac{f(t+t_o)}{1-F(t_o)} = \frac{\frac{\beta t^{\beta-1}}{\alpha^{\beta}} e^{-\left(\frac{t+t_o}{\alpha}\right)^{\beta}}}{e^{-\left(\frac{t_o}{\alpha}\right)^{\beta}}} = \frac{\beta t^{\beta-1}}{\alpha^{\beta}} e^{\left(\frac{t_o}{\alpha}\right)^{\beta}-\left(\frac{t+t_o}{\alpha}\right)^{\beta}} \tag{74.23}$$

$$h(t) = \frac{f(t)}{1-F(t)} = \frac{\frac{\beta t^{\beta-1}}{\alpha^{\beta}} e^{-\left(\frac{t}{\alpha}\right)^{\beta}}}{e^{-\left(\frac{t}{\alpha}\right)^{\beta}}} = \frac{\beta t^{\beta-1}}{\alpha^{\beta}} \tag{74.24}$$

Clearly $h(t)$ is a function of time. Figure 74.9 illustrates various examples of $h(t)$. Notice that the function is decreasing for β values less than 1, constant for β values approximately equal to 1, and increasing for β values greater than 1. Therefore, β values other than 1.0 are an indication of increasing or decreasing hazard rates as a function of time. As mentioned earlier, a β value of 1.0 results in the exponential distribution, which has been demonstrated to have a constant hazard rate.

Log-Normal Distribution The hazard rate of the log-normal distribution does not have a close-form mathematical expression and, therefore, has to be evaluated numerically. In general it is an increasing function followed by a decreasing one. Ebeling [2] suggests that this is an uncommon hazard rate behavior for most components. The conditional distribution and the hazard rate can be expressed as

$$f(t|t_o) = \frac{\frac{1}{\sqrt{2\pi}\sigma t} e^{\frac{-1}{2}\left[\frac{\ln(t+t_o)-\mu}{\sigma}\right]^2}}{1-\int_0^{t_0} \frac{1}{\sqrt{2\pi}\sigma t} e^{\frac{-1}{2}\left[\frac{\ln(t)-\mu}{\sigma}\right]^2} dt} \tag{74.25}$$

And

$$h(t) = \frac{\frac{1}{\sqrt{2\pi}\sigma t} e^{\frac{-1}{2}\left[\frac{\ln(t)-\mu}{\sigma}\right]^2}}{1-\int_0^{t} \frac{1}{\sqrt{2\pi}\sigma t} e^{\frac{-1}{2}\left[\frac{\ln(t)-\mu}{\sigma}\right]^2} dt}$$

where the integral in the denominator needs to be evaluated numerically. Figure 74.10 illustrates an example of the log-normal hazard rate.

Empirical Distribution The hazard rate for the empirical distribution, which assumes a complete data set, can be found using Equations 74.16 and 74.17 [5]. That is,

$$\hat{h}(t) = \frac{\hat{f}(t)}{\hat{R}(t)} = \frac{1}{(t_{i+1}-t_i)(n+0.624-i)}, \quad i = 1, 2, \ldots, n-1 \tag{74.26}$$

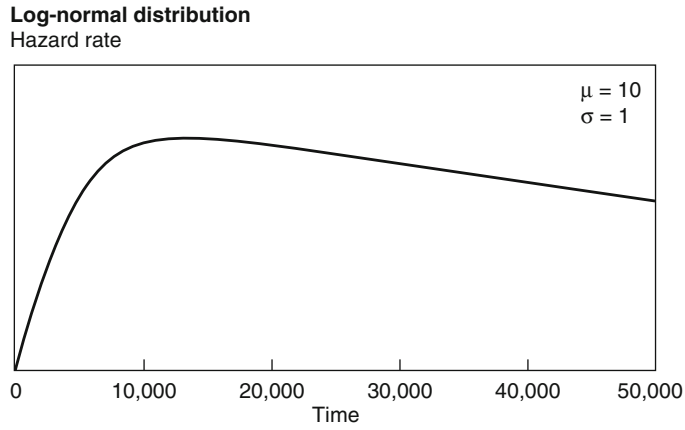

Fig. 74.10 Sample hazard rate of the log-normal distribution

Stress and Strength Interference Model

As suggested by Wulpi [6], "All fractures are caused by stresses, and a version of the 'weakest link' theory applies: fracture will originate wherever the local stress first exceeds the local strength." Expanding this concept from fractures to failures in general, the stress and strength interference model can be formulated for calculating probabilities of failure. In this context, Ebeling [2] (p. 12a) defines *stress* as any load that produces a failure. The *strength* is the capacity of a system or component to withstand the stress. A failure will occur if the stress exceeds the strength of a system or component. The stress-strength interference model can be considered a static reliability model. That is, the probability of failure is based on the comparison of instantaneous loads placed on the system or component with its ability to withstand that load rather than based on past failure profiles.

It is important to clearly identify the stress and strength that will be evaluated since there may be many different types of stresses and strengths in any given system. Some stresses may not be obvious as, for example, residual stresses in metals. Ebeling [2] lists four major categories of stress: electrical, thermal, mechanical, and chemical. Mechanical failures may include fractures or distortions. Corrosion is an example of a chemical failure. These stresses may occur as the system interacts with environmental conditions (fire or corrosion) or may be due to operating conditions (vibration). To predict the reliability of a system or component, the nature of both the stress and the strength must be known. In most situations, physical models describing both the stress and the strength are necessary.

As a conceptual example, consider the case of a steel beam heated by fire plume conditions. Assuming steady-state conditions, the stress-strength interference model can be formulated in terms of temperature. The plume temperature at the location of the steel element would represent the thermal load on the steel element. The ability to withstand the thermal load would be represented by the damage temperature of the steel.

The following general stress-strength combinations can be analyzed: (1) random stress–fixed strength, (2) fixed stress–random strength, and (3) random stress–random strength. A random stress or strength refers specifically to a probability distribution describing, respectively, the load or the capacity to withstand that load. In contrast, a fixed stress or strength refers to a deterministic magnitude of the load or capacity to withstand it, respectively.

The reliability in Case 1 is the area under the curve of the stress distribution $f(s)$ to the left of the strength limit S_o. In Case 2, the reliability is the area under the curve of the strength distribution $f(s_o)$ exceeding the stress limit S. In these cases, the probabilities of failure are calculated by integrating the probability distribution for stress or strength with the corresponding limits

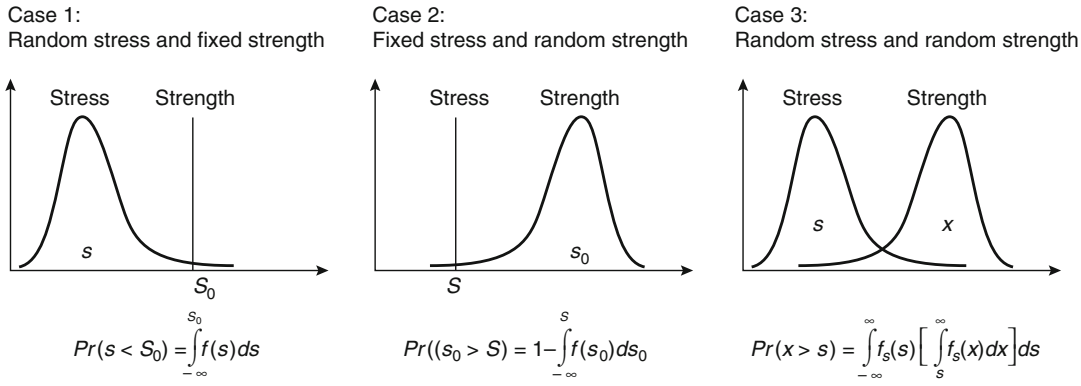

Fig. 74.11 Summary of stress-strength interference models

of integration. The integral equations are shown in Fig. 74.11.

In Case 3, where both stress (s) and strength (x) are random variables represented by probability distributions, the overlap area between the two curves is an indicator of the probability of failure. Notice that in this case the probability of failure is not the overlap area as illustrated in a two-dimensional graphical representation. The reliability calculation must consider the combinations of all the values assumed by the random variables s and x. The probability of the strength being larger than a given value of s, say S, is given by

$$R = Pr(x>S) = \int_{S}^{\infty} f_x(x)dx \qquad (74.27)$$

where $f_x(X)$ is the probability distribution for the strength. This probability corresponds to one and only one possible value of the random variable S. By definition, the probability of observing the value S is $f_s\,(S) \cdot ds$, where $f_s\,(s)$ is the probability distribution for the stress. Therefore, the probability of the stress assuming the value s and the strength exceeding it is the multiplication

$$f_s(s)ds \cdot \int_{S}^{\infty} f_x(x)dx \qquad (74.28)$$

assuming both stress and strength are independent random variables. Finally, since the reliability estimate must consider all possible values of s,

$$R = \int_{-\infty}^{\infty} f_s(s) \cdot \left[\int_{s}^{\infty} f_x(x)dx\right] ds \qquad (74.29)$$

Again, Fig. 74.11 provides a summary of the stress-strength interference cases.

Applications in Fire Risk Analysis A recent fire risk assessment methodology [7] defines the concept of severity factor as the probability of a fire with the duration and heat release rate necessary to generate target damage. In this application, a target is any item selected for evaluation in a postulated fire scenario that can be subjected to fire damage.

The severity factor is calculated as described in Case 1 in Fig. 74.11. That is, the stress is the probability distribution for the heat release rate and the fixed strength is the heat release rate necessary for generating target damage. Therefore, the probability is the severity factor, which represents the fractions of fire intensities capable of generating target damage.

Additional Applications: Probabilistic Safety Factors and Safety Margins The safety factor, sf, is defined as $sf = x/s$, where both x and s are random variables. Propagating the uncertainty from x and s, the probability distribution for sf, as shown in Papoulis [4] (p. 138, footnote 4), is given by

$$f_{SF}(sf) = \int_{-\infty}^{\infty} |s| f(sf \cdot s, s) ds \qquad (74.30)$$

Notice that $f(sf \cdot s, s)$ is the joint probability distribution of x and s where $x = sf \cdot s$.

The safety margin, sm, is defined as $sm = x - s$. Again, both x and s are random variables. The probability distribution for sm is given by the following expression:

$$f_{sm}(sm) = \int_{-\infty}^{\infty} f(sm + s, s) ds \qquad (74.31)$$

In this case, $f(sm + s, s)$ is the joint probability distribution of x and s where $x = sm + s$. In this context, the probability of failure is $Pr(sm < 0)$ or

$$1 - \int_{0}^{\infty} f_{sm}(sm) dsm \qquad (74.32)$$

Example 3 The critical temperature[1] for a steel beam is assumed to be normally distributed with mean = 550 °C and standard deviation of 40 °C. A fire protection engineer is evaluating the potential hazard of a fire below the beam, which will subject it to fire-plume temperatures. Based on the heat release rates generated by the type and configuration of combustibles in the location, calculated fire-plume temperatures range from 250 to 475 °C. Since the evaluation may not have considered the lowest and highest heat release rates, the fire protection engineer assumes a normal distribution for the plume temperature with a 5th percentile = 250 °C and a 95th percentile = 475 °C. The resulting normal distribution has a mean of 362.5 °C and a standard deviation of 68.6 °C. Based on this hazard analysis, calculate the probabilistic safety factor and safety margin.

[1] The critical temperature for a steel member is defined as the temperature at which the material properties have decreased to the extent that the steel structural member is no longer capable of carrying a specified load or stress level (*SFPE Handbook of Fire Protection Engineering*, 3rd ed., p. 4–230).

Solution The first step in solving this problem consists in identifying the stress and the strength. The stress is generated by the fire plume, which subjects the beam to elevated temperatures. Such stress is characterized by a normal distribution with a mean of 362.5 °C and a standard deviation of 68.6 °C. The strength is the damage temperature of the beam. It is characterized by another normal distribution with a mean of 550 °C and standard deviation of 40 °C. The two normal distributions are illustrated in Fig. 74.12a. Notice some overlap between the two curves. This overlap indicates that there is some probability of the fire damaging the beam. Solving Equation 74.29 numerically (Case 3 in Fig. 74.11), the reliability of the beam is $Pr(x > s) = 0.991$.

The distribution for the safety factor, calculated with Equation 74.30, is illustrated in Fig. 74.12b. The mean safety factor is 1.6. Finally, the safety margin can be obtained using Equation 74.31. The safety margin is plotted in Fig. 74.12c. The mean of the safety margin is 187 °C. The probability of failure using the safety margin is $Pr(sm < 0) = 0.009$.

Generic Reliability Values for Fire Protection Systems

Various studies have been conducted for assessing generic reliability values for fire protection features. This section provides a summary of the scope and findings of some of these studies.

Bukowski et al. [8] documented a detailed study for assessing the operational reliability of automatic sprinklers and smoke detectors. A large literature review was conducted as part of this study, including national fire incident database reports, U.S. Department of Defense safety records, industry and occupancy specific studies, insurance industry historical records, inspection reports documented in the open literature, and experimental data.

The reliability values for automatic sprinklers (mean and 95 % confidence intervals) resulting from this study are listed in Table 74.1 for

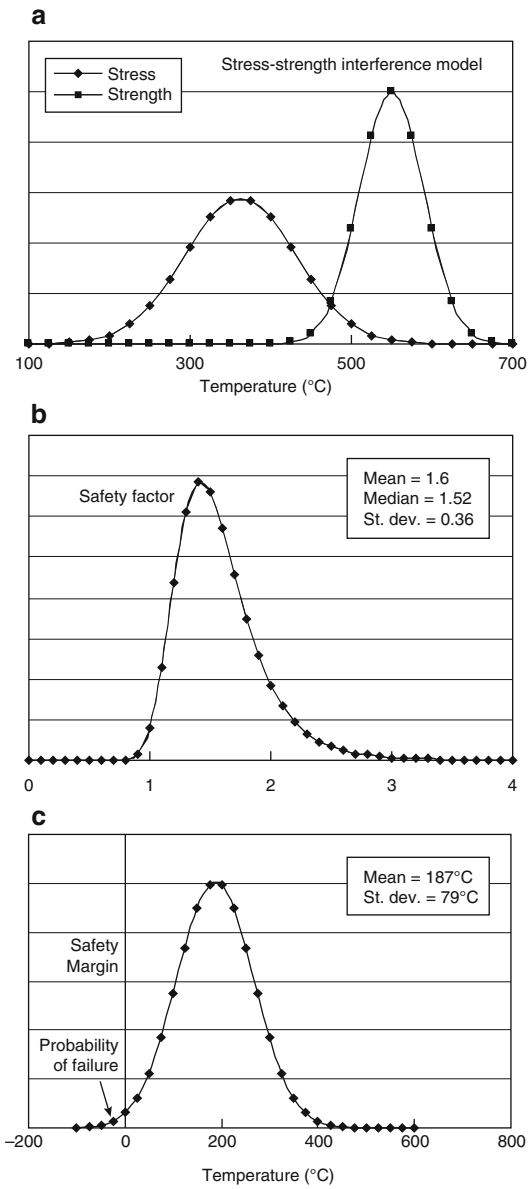

Fig. 74.12 Stress-strength interference model, safety factor, and safety margin for Example 3

different occupancies. These reliability values are unconditional of a fire event and represent the probability that the sprinklers will not fail dangerous (fail at the time of a fire). In the discussion, the authors provide a careful description of the type and biases of the reliability data, which included different reporting periods, types of occupancies, level of detail regarding types of fires, and sprinkler system design. In addition, the inspection, testing, and maintenance activities varied among the different sets of data collected. It should be noted that most of the sprinkler systems involved in the documented incidents included standard spray systems. Finally, the authors stress that the use of these reliability values should consider the confidence interval instead of a point estimate.

In the case of smoke detectors (Table 74.2), the available data had larger sample sizes and were collected in a period of 10 years. The data analysis suggested significantly different reliability values for different occupancies. The authors indicate that the resulting reliabilities should be used only after examining the referenced studies and determining their applicability to the particular safety strategy employing the analyzed system.

Another set of generic reliability values for fire protection systems is reported in Appendix P, NUREG/CR-6850 [7]. These values are based on an earlier study conducted by EPRI [9]. for determining suppression reliability values for nuclear power plant fire risk analyses. The values, as reported, are the following [7]:

- Carbon dioxide = 0.96
- Halon systems = 0.95
- Wet pipe sprinkler systems = 0.98
- Deluge or preaction sprinkler systems = 0.95

These estimates do not include maintenance contributions to unavailability, credit for manual actuation of the system, dependent failures, and plant specific data. It should be noted that fire protection systems in commercial nuclear power plants are subjected to an aggressive inspection and testing program [10].

Although generic reliability values such as the ones listed in this section are available, they usually do not capture important factors affecting individual fire protection systems. These factors include specific environmental conditions, inspection, testing and maintenance procedures, and system design features. Therefore, collection of operational data and analysis for specific systems should provide better insights than the use of generic reliability values. At the same time, if the use of generic values is necessary, the use of confidence intervals, as recommended in Bukowski et al. [8], is important in order to capture differences in the data selected for the

Table 74.1 Generic reliability values for automatic sprinklers [8]

estimation of the generic values. In addition, it is recommended that the reliability analysts provides technical justification that any generic value used provides good representation of the systems or components under analysis.

Reliability Analysis of Repairable Items

Recall that a repairable system is one that is brought back to operation after a repair. A repairable system or component may be brought back to operation in any of the following states [11]:

1. As good as new (also referred to as "as new" or "same as new")
2. As bad as old (also referred to as "same as old")
3. Better than old but worse than new
4. Better than new
5. Worse than old

Current probabilistic models used in the analysis of repairable items can account for these five after-repair states. The two most common assumed states are "as good as new" and "as bad as old." Under the "as good as new" assumption, the repair is considered perfect and the item is restored to as new condition. In contrast, the "as bad as old" assumption refers to a minimal repair. In this state, the item is brought back to the condition it had just before the failure.

Perhaps the most important concept in predicting failures in repairable systems is the concept of trend. The term *trend* refers to the behavior of the failure rate as a function of time. A constant failure rate, which results in identical MTBF, shows no trend. This is the "as good as new" after-repair state. In contrast, equipment in which the failure rate is either increasing or decreasing as a function of time does show trend. Once a trend is identified, the appropriate statistical model for predicting failures of repairable systems can be selected.

This section describes models for predicting failures and calculating the reliability of repairable systems under the assumption of the first two after-repair states listed previously: "as good as new" and/or "as bad as old." The probabilistic analysis of the remaining three after-repair states provides failure predictions similar to those obtained under the "as good as new" and "as bad as old" assumptions at least for the immediate future (next few failures) [12]. Given that conclusion and the additional technical complexities associated with those after-repair states, models supporting the last three after-repair states are out of the scope of this chapter.

Probabilistic Models for Failure Predictions

Ascher and Feingold [13] suggest a general strategy for analyzing repairable systems. This strategy is simplified to account for the techniques within the scope of this section only. The strategy is summarized in Fig. 74.13.

The first step in the flowchart consists of ordering the data in chronological order. This is necessary for conducting the trend analysis. Once the failure behavior of the component in terms of trend has been established, the analysis can proceed using the renewal process (RP) or nonhomogenous (NHPP) Poisson process accordingly.

In general, the RP and NHPP are stochastic processes. The term *stochastic process* refers to a random variable as a function of time, or $f(T, t)$, where T is the random variable for time to next

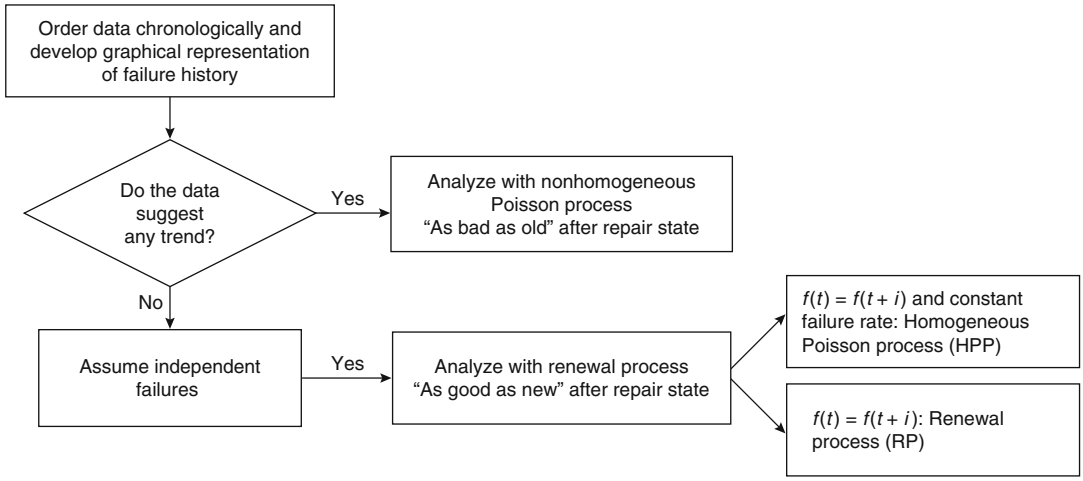

Fig. 74.13 Simplified strategy for analyzing repairable systems

failure. Notice that at a given time t, $f(T)$ is a probability distribution for the time to next failure. Cox and Lewis [14] describe a Poisson process as ". . . a mathematical concept and no real phenomena can be expected to be exactly in accord with it. Whether or not a particular series is in reasonable agreement with a Poisson process is ultimately an empirical matter, even though the key assumptions have varying degrees of plausibility in different applications" (p. 18). The RP assumes failures are independent of each other. This assumption is captured in the analysis by setting $f(T_i) = f(T_{i+1}) = \ldots = f(T_n)$. That is, the probability distributions for the times between failures are identical. In the special case of a constant failure rate, the RP becomes the homogeneous Poisson process (HPP). That is, the HPP is a renewal process where the number of events in a time interval is a random variable following a Poisson probability distribution (the times between failure are exponentially distributed).

In the case of the NHPP, failures are dependent. As a result, the NHPP is characterized by each failure having a different $f(T)$. In practice, each $f(T)$ is modeled using a conditional distribution of the form $f(t_i / t_i > t_{i-1})$ where t_i is the time to next failure and t_{i-1} is the time of the last failure. Clearly, the failure rate changes as a function of time.

The numerical techniques for estimating the number of failures of a repairable item discussed in this chapter assume that the repair time is significantly smaller than the operating time. Under that assumption, repair times are not considered in the analysis. The following subsections describe the flowchart in Fig. 74.13 in detail.

Order Data Chronologically with Graphical Representation of Failure History The first step in the flowchart is to organize the data in chronological order. This exercise, although simple, results in a very useful visual tool for identifying failure trends when plotted in a failure number versus cumulative operating time format in linear paper. Depending on the resulting shape of the plot, the three distinct trends illustrated in Fig. 74.14 can be identified.

A straight line, labeled Case A in Fig. 74.14, is an indication of constant times between failures. Case B, which has a concave down shape, represents increasing times between failures. Case C has a concave up shape, indicating that the times between failures are decreasing.

The Laplace or Centroid Test The Laplace or centroid test can also be used for determining trends in the data by comparing the centroid of the observed times with the midpoint of the period of observation. This test is described in detail in Cox and Lewis [14]. The test consists of calculating the value of u using the following equation for a "failure-terminated" analysis:

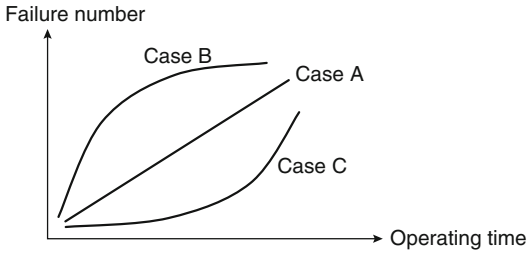

Fig. 74.14 Summary of general trends observed in repairable systems

$$u = \frac{\dfrac{\sum_{i=1}^{n-1} t_i}{n-1} - \dfrac{t_o}{2}}{t_o\sqrt{1/(12/n-1)}} \qquad (74.33)$$

where t_o is the time of the last failure, t_i are the failure times (i.e., $t_i - t_{i-1}$ is a time between failures), and n is the total number of failures. In the case of a "time-terminated" analysis, in which the observation is terminated sometime after the last failure, t_o is the time when the observations were terminated and the $n - 1$ terms in the numerator and denominator should be replaced by n. In commenting on the use of the Laplace test, Modarres [5] indicates that if u is close to 0, there is no evidence of trend in the data. If $u < 0$, the trend is decreasing. Finally, $u > 0$ suggests an increasing trend. Since u follows a standard normal distribution, the following statistical test can be formulated:

H_o: The data show no trend

H_a: The data show trend

Arbitrarily choosing a confidence level α of 0.9, the 5th and 95th percentiles of the standard normal distribution are, respectively, –1.64 and 1.64. Therefore, if u is outside those percentiles, there is evidence to reject the null hypothesis of no trend in the data (i.e., there is a trend).

Example 4 An industrial facility has recorded the following data (Table 74.3) for electrical cabinets of the same type over a period of 10 years (from 1/1/1990 to 12/31/1999). A fire protection engineer is interested in determining if specific changes implemented in the second half of the 1990s in the cabinet maintenance activities performed to the cabinets have made a difference in the number of fires. Do the failure data suggest any trend?

Solution The problem states that the trend analysis should be performed over a period of 10 years. Therefore, this is a time-terminated analysis. In this case, $t_o = 10$ years, $n = 7$ failures, and $\sum t_i = 33.63$ years. With these input values, u is calculated as

$$u = \frac{\dfrac{\sum_{i=1}^{n-1} t_o}{n} - \dfrac{t_o}{2}}{t_o\sqrt{1/(12/n)}} = \frac{\frac{33.63}{7} - \frac{10}{2}}{10\sqrt{1/(12/7)}} = \frac{-0.2}{7.63} = -0.026$$

Since $u \approx 0$, it can be concluded that the data present an almost negligible decreasing trend. The engineer should conclude that the implemented maintenance activities are still not producing the expected effects. Furthermore, −0.026 is inside the 10 % (two-side test) confidence range for the standard normal distribution, which suggests that there is no evidence to reject the hypothesis of no trend in the data.

The Renewal Process (RP) In an RP, the different times to failure are considered independent and identically distributed random variables (a stationary stochastic process), which is consistent with the primary underlying notion of this process that assumes that the system is restored to its original ("as new") condition following a relatively short repair action. The mathematical formulation follows from the failure history depicted in Fig. 74.15.

Consider a new repairable item starting its operating life at $t = 0$. The probability distribution for the first failure, occurring at time T_1, is $f(T_1)$. Assuming a short repair action between failures, the age of the equipment after n failures can be generalized as

Table 74.3 Electrical cabinet failures due to ignition of internal components

Date	Days between failures	Years between failures
1/1/1990		
4/30/1990	119	0.33
11/2/1990	186	0.51
10/12/1992	710	1.95
7/25/1993	286	0.78
10/15/1996	1178	3.23
8/16/1999	1035	2.84
8/24/1999	8	0.02
		0.34[a]

[a]0.34 years since last failure in 10-year period of analysis

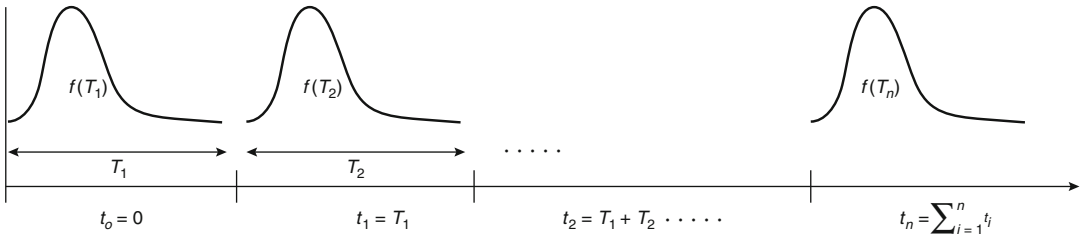

Fig. 74.15 Conceptual representation of the renewal process

$$t_n = \sum_{i=1}^{n} T_i$$

where n is the total number of failures. Notice that T_i is the time between the $i-1$ and the ith failure and t_i represents the age of the item after the ith failure. Both of these variables are random. Since t is a linear combination of random variables, its probability distribution after the ith failure, $f^{(i)}(t)$ is the convolution of $f^{(i-1)}(t)$ and $f(t)$. Recall that the $f(t)$'s in the renewal process are identical. The convolution integral is

$$f^{(i)}(t) = \int_0^t f^{(i-1)}(t-s) \cdot f(s)ds \qquad (74.34)$$

Integrating Equation 74.34 over t, the following cumulative distribution function is obtained:

$$F^{(i)}(t) = \int_0^t F^{(i-1)}(t-s) \cdot f(s)ds$$

Clearly, $F^{(i)}(t) = P[T_1 + T_2 + \ \ldots \ + T_n \leq t]$. From this formulation and the fundamental definition as found in Nelson [3] (p. 186)

$$P[N(t) = n] = F^{(n)}(t) - F^{(n+1)}(t)$$

where $N(t)$ is the number of failures at time t. The following expressions for the expected number of failures (or renewals) can be formulated as

$$W(t) = F^{(1)}(t) + \int_0^t W(t-s)f(s)ds \qquad (74.35)$$

$$\frac{dW}{dt} = w(t)$$

$$= f^{(1)}(t) + \int_0^t w(t-s)f(s)ds \qquad (74.36)$$

The terms of these equations can be explained as follows: $w(t)\Delta t$ is the probability that a failure (and, therefore, a renewal) occurs in the interval $(t, t + \Delta t)$. This event can occur in either of two mutually exclusive ways: (1) the first item that was placed in operation fails in $(t, t + \Delta t)$, or (2) a renewal took place at $(t - s)$, $0 < s < t$, and the unit placed in operation fails in $(t, t + \Delta t)$. These two events have probabilities equal to the first and second term of the right side of the renewal equation, respectively.

Equation 74.36 has a closed-form solution if $f(T)$ is exponential. Specifically, if $f(T) = \lambda e^{-\lambda \cdot T}$, the convolution integral is solvable through the Laplace transform and yields $W(t) = \lambda \cdot t$. This is the HPP described earlier, which is a sequence of independent and identically distributed random failures *with a constant failure rate*, λ. Furthermore, a number of numerical solutions exist for the Weibull, truncated normal, gamma, and log-normal distributions [11].

The applications of the RP model are limited. Krivtsov [11] and Ascher and Feingold [13] suggest that the RP is a poor model for a repairable system, unless the system consists of one nonrepairable component in a socket. Furthermore, Ascher and Feingold [13] (p. 59) argue that the RP is "not necessarily the appropriate model even for a socket." The reasons provided by Ascher and Feingold in support of this statement include (1) externally induced stress on the socket may change over time, (2) stress on the part in the socket at time t may have been affected by damage to other parts caused by failures in that socket before time t, and (3) in the real world, the replacement components may not come from the same population.

The Superimposed Renewal Process In a superimposed renewal process (SRP), it is assumed that n renewal processes are operating independently. The SRP is then formed collecting the failures (or renewals) from each independent process in a single history. Figure 74.16 illustrates this process. The failures in each of the three renewal processes illustrated in Fig. 74.16 are depicted with different markers. The failure history labeled SRP is the collection of the three RP failure histories.

The SRP is in general not a renewal process since the distributions for failure times are not identical. However, the superimposed failure history can be analyzed assuming an NHPP as described in the following section.

The Nonhomogeneous Poisson Process (NHPP) The NHPP relaxes the necessary assumption characterizing the RP, which states that the probability distributions for the time to next failure are identical. As a result, the probability distributions governing the time to next failure can be different to the one governing the previous failure (a nonstationary stochastic process). This flexibility offered by the NHPP is particularly appropriate for the analysis of repairable components since it is expected that, on average, the times to next failure will decrease as the equipment ages. Notice, however, that the NHPP is not only applicable to the analysis of components with increasing failure rates. The process applies to components characterized with constant or decreasing failure rates as well.

The Weibull is perhaps the most common probability distribution selected for the NHPP. Recall that the Weibull distribution has the flexibility of characterizing times to failure for components with constant, increasing, or decreasing failure rates.

A common formulation of the NHPP for reliability applications can be conceptually described as the following:

- The time to first failure, T_1, follows the probability distribution $f(t)$.
- The times for subsequent failures, $T_{2,\,3,\ldots n}$, is governed by the conditional probability distribution $f(t_i / t_i > t_{i-1})$.

Recall from Fig. 74.15 that T_i is the time between failures, and t_i is the equipment age at the time of failure i. This formulation is governed by the following assumption: the equipment condition is assumed "as bad as old" after each

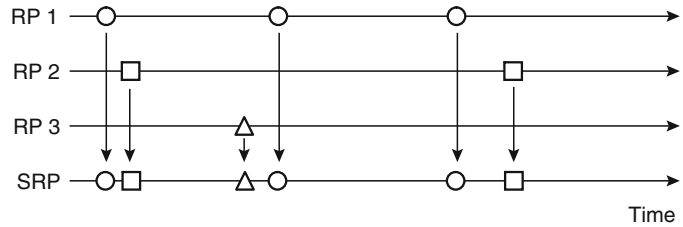

Fig. 74.16 Conceptual representation of the superimposed renewal process

failure. The use of the conditional distribution after the first failure not only suggests that the equipment is modeled as having survived up to failure time $t_i (i > 1)$ but also that the equipment was subjected to a "minimal repair." A minimal repair is one that restores the equipment to the condition it had just before the last failure.[2]

Assuming that the times to failure follow a Weibull distribution, the distribution for the first failure is (Equation 74.8)

$$f(s) = \frac{\beta t_1^{\beta-1}}{\alpha^{\beta}} e^{-\left(\frac{t_1}{\alpha}\right)\beta}$$

For the subsequent failures, the probability distribution function is conditional as follows (see Equation 74.23):

$$f(t_i|t_i > t_{i-1}) = \frac{\beta t_i^{\beta-1}}{\alpha^{\beta}} e^{\left(\frac{t_{i-1}}{\alpha}\right)^{\beta}\left(\frac{t_i}{\alpha}\right)^{\beta}}$$

Numerical Algorithm for Predicting Failures of Repairable Systems Krivtsov [11] describes a very useful algorithm for determining the expected number of failures of a repairable system by solving the process described previously. It can be used for the RP or the NHPP. Figure 74.17 depicts the flowchart for the algorithm. The algorithm calculates the expected number of failures using a Monte Carlo simulation. The formulation consists of generating n number of failure histories for a given repairable item. A failure history refers to the number of failures experienced by the repairable item in a period of analysis t_f.

For each failure history H, the time accumulator is set to 0 and failure times are generated using a random number generator from a corresponding probability distribution. Notice that any applicable distribution can be used and the parameters of the distribution are provided as inputs to the algorithm (see section on "Data Analysis and Parameter Estimation" later in this chapter for details). For any failure history, the algorithm determines if the failure j is the first in the history. If $j = 0$, then the distribution $f(T)$ is used to generate the time for this first failure. The time for the second failure ($j \geq 1$) is generated using the conditional distribution $f(T_i/T_i > T_{i-1})$ for the nonhomogeneous Poisson process or $f(t)$ for the renewal process. The process continues by generating additional failures with their corresponding times. The failure times are accumulated until $t > t_f$. At this point, the number of failures in the history is stored for future use, and the generation of the next failure history begins. Once the n failure histories have been generated, there are n calculated number of failures. Finally, the number of failures in each history are averaged and reported as the expected number of failures for the repairable item.

An important assumption in this algorithm is that the times to repair are neglected. That is, they are considered short when compared with the times to failure. The algorithm, however, can account for repair times by adding them to the time accumulator. Repair times can be generated from a probability distribution, as described in the "Maintainability" section later in this chapter, after each failure. The impact of the repair time in the algorithm can be twofold depending on the governing assumptions. First, it will increase the amount of time the item is not operating. Second, it can affect the condition at which the item is returned to service. The "as good as new" and "as bad as old" assumptions are still applicable as long as the repair time is not included in the conditional distributions for time to failure.

Example 5 Continuing with Example 4, how many failures are expected by 12/31/2003? Let us apply the algorithm in Fig. 74.17 assuming the times between failures follow a Weibull distribution. For illustrative purposes, failure predictions are made assuming an NHPP and an RP. Recall that this is a time-terminated analysis. Therefore, Equations 74.59 and 74.60 are used for calculating the parameters of the Weibull distribution.

[2] This assumption can be relaxed implementing the concept of virtual age [15]. The virtual age is calculated as $A = q \cdot \sum_{i=1}^{n} t_i$. A q value of 0 indicates that the equipment is new. A q value of 1 indicates that the equipment is as old as the last failure, which is the assumption of the NHPP. A q value between 0 and 1 indicates that the equipment is worse than new but better than old. An NHPP developed using the concept of virtual age is described in Krivtsov [11], Hurtado et al. [12], and Yanez et al. [16].

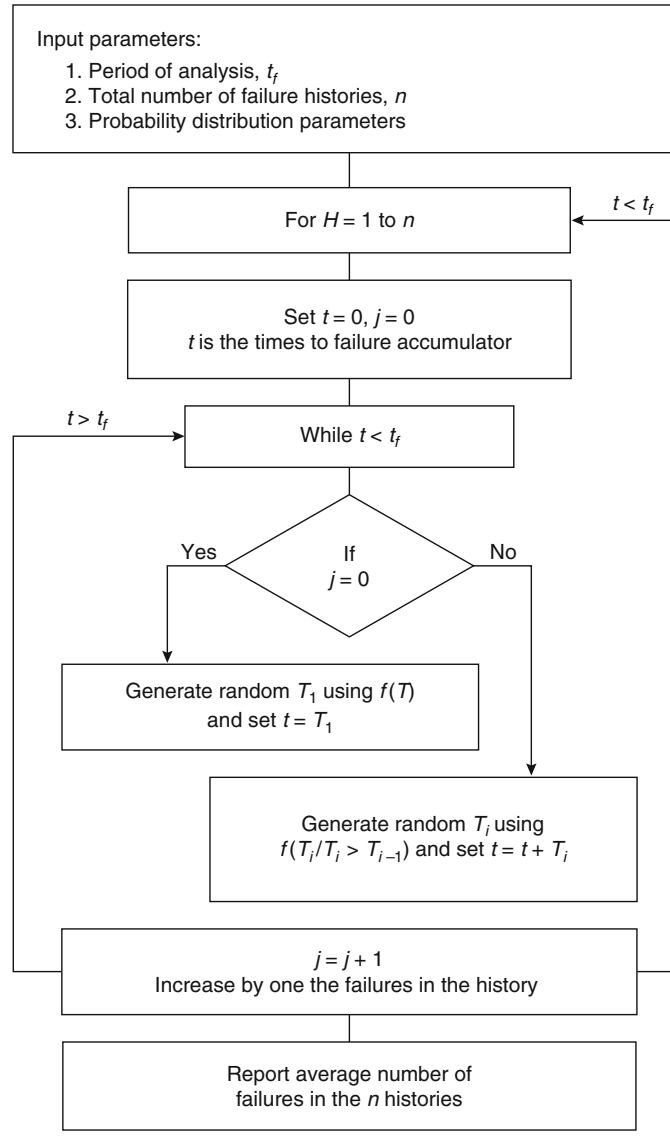

Fig. 74.17 Flowchart describing the algorithm for calculating the expected number of failures of a repairable system

The following values are obtained: $\alpha = 288.8$, and $\beta = 0.75$ for the NHPP. Notice a β value lower than 1.0, suggesting a decreasing failure rate. This is consistent with the results of Example 4. In the case of the RP, Equations 74.56 and 74.57 suggest $\alpha = 282.3$, and $\beta = 0.9$. A β value close to 1 suggests an almost constant failure rate.

Solution Solving the algorithm for a period of 13 years, the solution plotted in Fig. 74.18 is obtained. Figure 74.18 illustrates both the failure data and the predictions up to approximately 13 years. The NHPP model is predicting a total of eight failures by the 13th year. That is only one additional failure from the ones recorded so far. In contrast, the RP predicts ten failures; an additional three failures to the ones recorded so far.

Finally, the shapes of the RP and NHPP predictions are consistent with Cases A and B, respectively, in Fig. 74.14. This example illustrates the effects trend has on failure

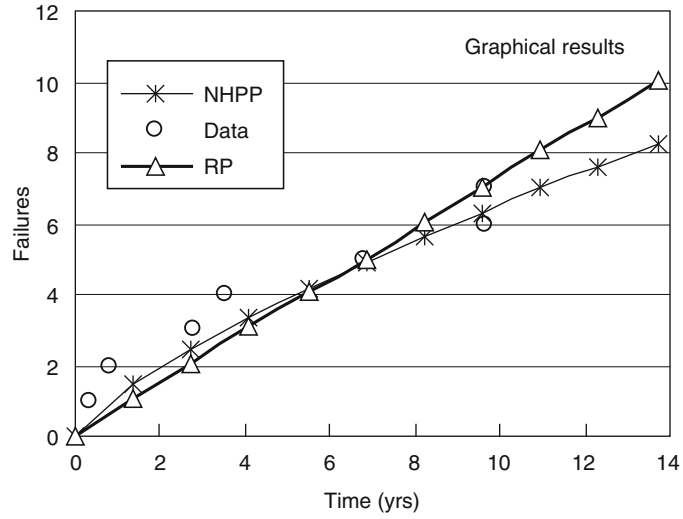

Fig. 74.18 Graphical solution for the prediction of failures using the algorithm in Fig. 74.17 assuming Weibull distribution

predictions and, therefore, the importance of model selection.

Maintainability

In repairable or replaceable systems, particularly in those where the repair or replace time is not negligible (i.e., long relative to the operational time) downtimes should be properly characterized. Maintainability refers to the probabilistic characterization of such downtimes. As described later in this chapter, downtimes can be an important factor in availability calculations.

For the purpose of this chapter, maintainability includes the inspections, testing, and maintenance activities to which an item is subjected. As indicated in SAND 95-1361, "It is clear that most fire protection system failures are discovered during testing and maintenance activities and not when the fire protection systems are required to actuate [10]." NFPA 25, *Standard for the Inspection, Testing and Maintenance of Water-Based Fire Protection Systems*, defines inspections as "visual examinations of a system or portions thereof to verify that it appears to be in operating condition and is free of physical damage [17]." NFPA 25 also defines testing as "a procedure used to determine the status of a system as intended by conducting periodic physical checks." In fire protection systems, testing may include water flow tests, fire pump tests, alarm tests, and so on. Testing is particularly important in standby systems such as those required to operate in emergency situations. Finally, NFPA 25 defines maintenance as a work performed to keep equipment operable or to make repairs [17].

Maintenance activities can be preventive or corrective. Preventive maintenance refers to the actions taken to retain an item at a specified level of performance. It has the potential of reducing failure rate. Corrective maintenance represents actions taken to restore a machine to an operational state after it is disabled due to a part of system failure.

Most fire protection engineering systems are subjected to scheduled inspections, testing, and maintenance activities. NFPA standards, devoted to specific suppression systems, include specific inspection, testing, and maintenance recommendations. Some examples are the following:

- NFPA 25 [17] provides specific recommendations for inspection, testing, and maintenance schedules and procedures for sprinkler systems, standpipe and hose systems, private fire service mains, fire pumps, water storage tanks, and valves,

among others. The scope of the standard also includes impairment handling and reporting.
- *NFPA 72®, National Fire Alarm Code®* [18], provides specific recommendations for inspection, testing, and maintenance activities for the different elements of fire detection systems including control equipment, generators, uninterrupted and standby power supplies, batteries, annunciators, initiating devices, communication equipment, and so on.
- NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems*," [19] provides specific recommendations for inspection, testing, and maintenance of clean agent fire suppression systems.

Additional examples include NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems*, for CO_2 systems; NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems*, for Halon systems; and NFPA 17, *Standard for Dry Chemical Extinguishing Systems*, for dry chemical systems. Ultimately, the selection of inspection, testing, and maintenance strategies will depend on existing regulations, adopted standards, cost, and the type of system. Most of these inspection, testing, and maintenance strategies can be quantified and included in maintainability and availability studies.

Maintainability Quantification

As suggested earlier, maintainability refers to the probabilistic characterization of downtimes. Factors affecting downtime include activities before and after failure.

Before a failure occurs, consider the following:

1. *Inspection time*. Although inspections are usually quick, some systems may require relatively longer inspection times. Usually, inspections do not require the system to be down and, consequently, this time is not considered in maintainability studies.
2. *Testing time*. The time required for system testing. This time is only considered in maintainability studies if the system is down during the test.
3. *Preventive maintenance time*. The time required for preventive maintenance activities. As in the case of testing time, this time is only considered in maintainability studies if the system is down during the maintenance.

After the failure occurs, the following corrective maintenance-related activities are usually conducted [20]:

1. Realization time—the time to detect a failure. In some systems or components, this time can be minimized with relevant alarms.
2. Access time—the time to isolate the system before any diagnosis or repair activities can begin. Some mechanical design considerations can reduce the access time. For example, access time can be reduced if the system components with the highest failure rates are accessible.
3. Diagnosis time—the time required for identifying the specific components that should be replaced or repaired in the system.
4. Logistic time—refers to the time taken to develop a repair strategy and assemble required parts/components, equipment, and personnel.
5. Repair/replacement time—the time required to repair the failure. As in the case of the access time, it can be minimized with a good mechanical and human factors design.
6. Checkout time—refers to the time taken to verify that the failure no longer exists.

The preceding classification suggests two general downtime characterizations: (1) before failure occurs, which is dominated by testing and preventive maintenance activities; and (2) after the failure occurs, which can be influenced by many factors depending on the type of system and the availability of parts and personnel to perform the repair. These two downtime classifications can be considered random

and, therefore, represented with probability distributions.

In practice, downtimes are often characterized using the exponential distribution. By using the exponential distribution, downtimes can be readily included in availability analyses using Markov models (as discussed later in the chapter).

The most common parameter used to characterize repair times is the mean time to repair (MTTR). Assuming that the distribution for the repair time is $g(t)$, the MTTR is defined as

$$\text{MTTR} = \int_0^\infty t \cdot g(t)dt \tag{74.37}$$

Availability

The analysis for repairable systems described so far assumes relatively short repair actions. In practice, this assumption simplifies the analysis by not considering the inspection, testing, and/or the repair time. In some applications, however, the quantification of equipment downtime is necessary. Accordingly, the scope of the analysis is not about calculating the probability of the equipment successfully operating after time t, but the probability that the system is available over a specified period of time. The latter is referred to as an availability analysis. As an example, consider a room protected with a CO_2 system. For life safety reasons, the system may be taken out of service some periods of time. As a result, the probability of the system being available is affected by the time it is out of service.

The term *availability* is defined as the probability that an item, when used under stated conditions, will be operational at a given time. Notice the difference between the concept of reliability and availability. Recall that the former refers to the probability of a continuous operation over a time interval. The complement of the availability is termed *unavailability* or $U = 1 - A$. A very simple mathematical expression capturing this definition is

$$\text{A} = \frac{u}{u+d} \tag{74.38}$$

$$U = \frac{d}{u+d} = 1 - A \tag{74.39}$$

where u is the uptime, and d is the downtime during a predefined period of time T.

The concept of availability can be extended further considering the terms *instantaneous* and *average availability*. The instantaneous availability is the probability that the system is operational at a specific time t. The average availability, on the other hand, is defined for a fixed period of time T as

$$\overline{A} = \frac{1}{T}\int_0^T a(t)dt \tag{74.40}$$

where $a(t)$ is the availability as a function of time.

Both of these terms are important. That is, two systems may have the same average availabilities, but the instantaneous values may suggest periods of time when the unavailability is high. Consider as a conceptual example Fig. 74.19, which illustrates the behavior of the unavailability of a system as a function of time. Notice how the unavailability grows to the limit where the system is fully unavailable and needs repair. The repair returns the unavailability to low levels and the cycle starts again.

Reliability engineers have developed computer programs that follow and quantify the cycle described in Fig. 74.19 (see, for example, NUREG/CR-1924 [21]). Also relatively simple mathematical expressions for calculating availability in systems with different inspection and repair schedules are available. Modarres [5] (p. 205) lists the equations in Table 74.4.

The equations listed in Table 74.4 assume a constant failure rate λ (1/h). T_m is the mission length (hour), τ is the average downtime MTTR (hour), T is the test interval (hour), T_R is the average repair time (hour), T_t is the average test duration (hour), f_r is the frequency of repair per test interval, and T_o is the operating time (uptime) $= T - T_R - T_t$. Notice that these simple

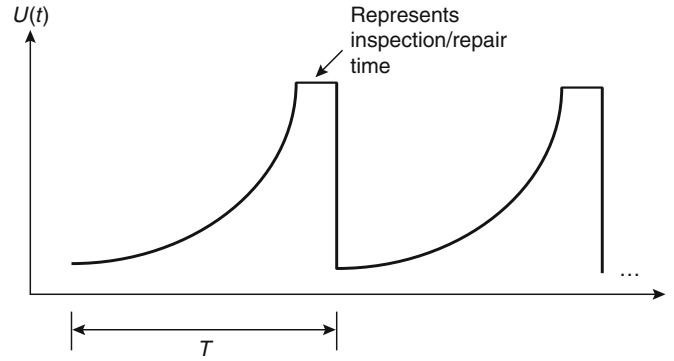

Fig. 74.19 Conceptual representation of system unavailability as a function of time

Table 74.4 Summary of equations for availability calculations

Type	Average availability
Time independent (constant)	A
Nonrepairable	$\overline{A} = \frac{1}{T}\int_0^T a(t)dt = \frac{1}{T}\int_0^T (1-\lambda t)dt = 1 - \frac{1}{2}\lambda T_m$*
Repairable (failures immediately detected)	$\frac{1}{T+\lambda t}$ (from solution to Markov model, Case 2 with $\mu = 1/\tau$)
Repairable (periodically tested)	$1 - \frac{1}{2}\lambda T_o - f_r\frac{T_R}{T} - \frac{T_t}{T}$

*$a(t) \approx 1 - \lambda t$ (for $\lambda t < 0.1$). This is an approximate form of the availability as a function of time, which assumes perfect repair and very short repair and test durations (their contribution is neglected in the unavailability calculation)

equations are for very specific applications. Another alternative for calculating availability is using Markov modeling.

Use of Markov Modeling for Determining System Availabilities

Markov modeling refers to a simulation based on the different *states* a system may be in time. As such, it is particularly appropriate for solving availability problems in which the main interest is to calculate the probability of an item being operational at a given time t.

There are three general classes of Markov processes: [4] (1) discrete time–discrete state, (2) continuous time–discrete state, and (3) continuous time–continuous state. In most reliability engineering applications, states are discrete. Therefore, this section focuses on the first two classes only. These two classes apply nicely to the failure/repair process because combinations of failure create discrete system states. Furthermore, the failure/repair process moves between discrete states only as a result of current state and current failure [19].

The following characteristics of Markov models are important:

- Markov models are stochastic processes developed and solved based on the assumption that the probability of being in state i depends only on the state $i - 1$ (i.e., the previous state). In other words, the future state of the system is determined by the present state but is independent of previous states. This is consistent with the memory-less property of the exponential distribution previously described in this chapter.
- Identified states should be mutually exclusive. That is, the system can be in only one state at a given time. States are usually represented graphically as circles.
- Once the states have been determined, transitions between states must be established.

Each transition is characterized by a probability in the case of discrete time models or a constant rate of transition in the case of continuous time models. A transition is represented graphically with an arrow starting at the current state and pointing to the state to which the system might change. The exponential distribution characterizes the transition times between states since the rates of transitions are constant.

- A state can transition to itself. This is represented with an arrow leaving the state and pointing to the same state.
- Absorbing states are those from which there is no transition out. If the system reaches an absorbing state, it will remain in that state.

Developing the Markov Model The first step in developing a Markov model of a system is determining the system states over time. Typical states in reliability engineering may include the following:

- Operational, which refers to a system operating in normal conditions
- Failure, which refers to a system that has failed and is not operating
- Degraded, which refers to an item that can achieve its operational goals without being in optimal operational conditions
- Repair, which refers to a system that is undergoing repair activities
- Inspection, which refers to a system that is undergoing inspection
- Testing, which refers to a system that is undergoing testing activities
- Standby, which refers to a system operating in standby mode

Consider as examples the Markov models summarized in Fig. 74.20. The simplest (and also trivial) example is the case of a nonrepairable item, which is characterized by two states: operational and failed. Obviously, the item will change from an operational state to a failed state as represented in Case 1 of Fig. 74.20. In this example, the transition can be defined by a probability of failure (discrete model) or a failure rate (continuous model). Notice that the failure state is absorbing.

The simplest Markov model for a repairable system is depicted in Case 2 of Fig. 74.20. Notice that in this case an additional transition is included from the repair state to the operational one. This transition is defined by the repair probability or a repair rate.

Case 3 of Fig. 74.20 consists of a repairable system subjected to scheduled testing. The system is represented with three states: operational, test, and repair. The system may transition from the operational state to the repair state with a probability of failure P_f or a failure rate λ. It can also transition from the repair state to the operational state with a probability of repair P_r or a repair rate μ. Due to the scheduled tests, the system will move to the test state with a probability P_i or a test rate τ. Once in the test state, it may return to operation if no degraded condition requiring repair is found. That transition is represented with the probability P_s or the rate ψ. Finally, if a degraded condition requiring repair is found during the inspection, the system transitions to the repair state with probability P_r or a rate γ.

Case 4 of Fig. 74.20 represents a standby system. That is, one component of the system is operational and an identical component serves as a backup. The system is designed so that if the operating component fails, the backup component automatically starts. In this example, the system is considered operational if one of the two components is operating. The Markov model of this system consists of four states, labeled for clarity States 1, 2, 3, and 4, respectively. State 1 represents both the primary and backup components operating. In this state, the backup components will operate if the primary fails. Transitions from this state may occur to State 2, 3, or 4. In State 2 the backup has failed, leaving the system with no redundancy. In State 3, the primary component has failed and the system is operating with the backup one. The transition from State 1 to State 4, where both the primary and the backup have failed, can occur, for example, due to a common cause failure (see discussion on common cause failure later in the chapter) or failure to the switching device. If repairs in State 2 or 3 have not been

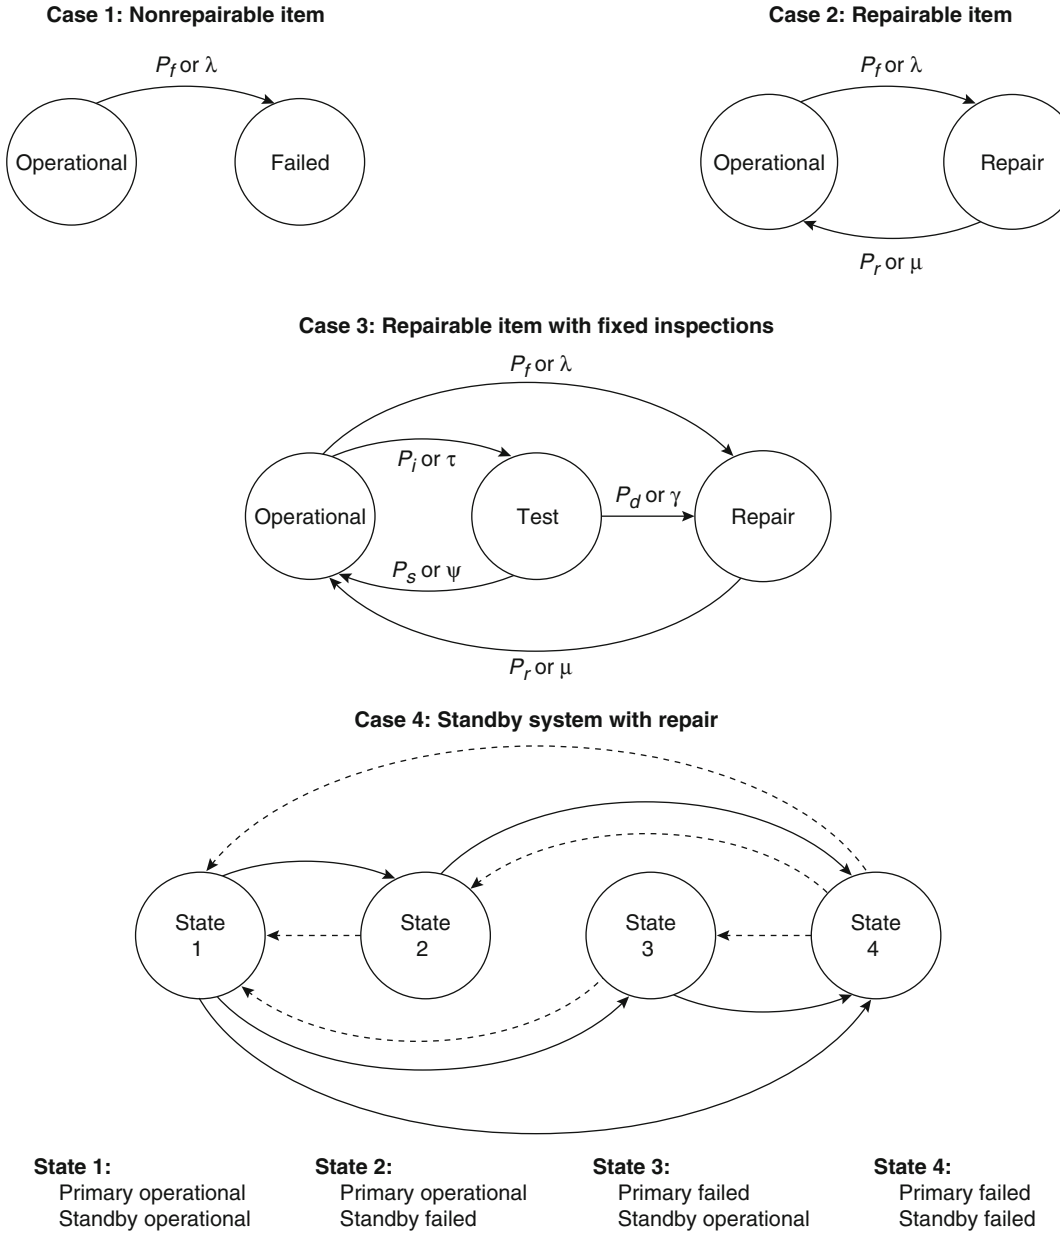

Fig. 74.20 Four Markov models for selected systems or components

made on time, a failure of the only operating component will force a transition to State 4 also. Notice that if no repairs are considered, State 4 becomes an absorbing state. On the other hand, if repair transitions are included, as illustrated with dashed lines in Case 4 of Fig. 74.20, the system will eventually return to State 1, 2, or 3 when the corresponding repairs are completed. Notice also that repair transitions have been included from States 2 and 3 to State 1.

The transition matrices and availability solutions for the systems described in Fig. 74.20 are discussed in the following sections.

Transition Matrix The transition matrix, T, summarizes all transition probabilities or rates

in a Markov model. It is a square matrix with n rows and columns where n is the number of states in the model. For clarity purposes, the matrices in the section have an additional row and column for identifying the corresponding state.

In a discrete time Markov model analysis, the transition matrix will include probability values representing the transition from one state to the other. In the case of a continuous time analysis, the transition matrix will include rates of transitions from one state to the other. To add the probabilities or rates in the matrix, start from the first state in the first column. From that state, add transition probabilities or rates to the state in the first row of the different columns. Continue this process until all the states in the different rows have been completed. In the case of discrete time Markov models, the values in each row must add to 1.0. No transitions are characterized by a 0 numeric value. Tables 74.5 and 74.8 are the transition matrices that correspond to the four Markov models listed in Fig. 74.20.

Case 1, shown in Table 74.5, consists of only one transition from operational to failure. The failure state is absorbing. As such, the transition matrix includes only the failure probability or rate from operational to failure, P_f or λ. In Case 2, however, there are no absorbing states. Notice that the transition matrix in Table 74.6 includes both the failure rate or probability characterizing the change of state from operational to repair (P_f or λ) and the repair probability or rate characterizing the change of state from repair to operational (P_r or μ).

As shown in Table 74.7, Case 3 consists of a larger matrix since it has three states. The transition from operational to test states is characterized by the inspection probability or rate, P_i or τ, respectively. Similarly, the transition from operational to repair states is characterized by the failure probability or rate, P_f or λ. Those two transitions complete the first row of the matrix, since there are only two arrows moving out of the operational state. The test state is evaluated next. From this state, there are transitions to the operational and repair states.

Table 74.5 Transition matrix for Case 1 of Fig. 74.20

	Operational	Failure
Operational		P_f or λ
Repair		

Table 74.6 Transition matrix for Case 2 of Fig. 74.20

	Operational	Repair
Operational		P_f or λ
Repair	P_r or μ	

These two transitions are characterized by the variables (P_s or ψ) or (P_d or γ), respectively. Finally, there is only one transition out of the repair state. This transition is characterized by P_r or μ, which is the probability or rate of moving from repair to operational states.

The transition matrix for Case 4 is illustrated in Table 74.8. Recall that this case consists of four states, labeled State 1, State 2, State 3, and State 4. The process to complete this matrix is identical to the one described for the earlier matrices. As such, the transition from State 1 to State 2 is characterized by the failure of the standby system. A transition from State 1 to State 3 is characterized by the failure of the primary system. The transition from State 1 to State 4, which would include the failure of both components at the same time, is characterized by a common cause failure probability or rate. Notice that there are transitions from States 2 and 3 to State 4, which represent failures of the primary and standby components when the other has already failed. In contrast, the transitions from States 2 and 3 to State 1 represent the repair of the primary or standby component, respectively, when the other is operating. Finally, transitions out of State 4 represent repairs. These repairs can move the system to any of the first three states.

Solving the Discrete Time Markov Model Recall that in a discrete time Markov model there is a state transition at every time step according to the transition matrix. At this point in the analysis, the Markov model and the transition matrix are developed. From this

Table 74.7 Transition matrix for Case 3 of Fig. 74.20

	Operational	Test	Repair
Operational		P_i or τ	P_f or λ
Test	P_s or ψ		P_d or γ
Repair	P_r or μ

State 4	P_s or μ_s	P_r or μ	P_r or μ	

information, the steady-state probabilities of being in each of the states can be calculated.

When a discrete time Markov model starts at time 0 in a particular state, the probabilities of being in state i will vary with time. Since the transition matrix shows probabilities for moving from any one state to another in one time interval, the matrix can be multiplied by itself to obtain transition probabilities for multiple time intervals. For example, when the transition matrix is squared, the result is another $n \times n$ matrix that gives probabilities of going between states in one time step [22]. Mathematically, these transition probabilities as a function of time are represented as

$$T^{t+1} = T\tilde{n}T^t \tag{74.41}$$

where $\boldsymbol{T}$ is the transition matrix and t is the time step. After some number of matrix multiplications, these resulting transition probabilities will reach steady state or $T^{t+1} \approx T^t$.

Let us also define a vector of initial conditions, that is, the state of the system at time 0. This vector is a $1 \times n$ matrix (recall that n is the number of states in the system) and is identified with the letter L. In most practical applications, it has a value of 1.0 in the initial state and 0 in the others. The value of 1.0 for state i is the probability of the system in state i at time 0. The probability of a system in state i after t number of transitions can be calculated multiplying $\mathbf{L}$ by the corresponding T matrix. Mathematically this is expressed as

$$\mathrm{L}^t = \mathrm{L}^{t=0}\,\tilde{n}\,T^t$$

In the long run, as $t - \infty$, $\mathbf{L}^{t+1} = \mathbf{L}^t \cdot \boldsymbol{T} = \mathbf{L}^t$. In other words, the state probabilities captured in the vector $\mathbf{L}$ will not change. Although the process of matrix multiplication is relatively easy, there is a straightforward technique for calculating the steady-state probabilities. The technique consists of determining the normalized eigenvector for the eigenvalue 1.0 of the transposed transition matrix [23] (pp. 393–394). In practice, this technique reduces to solving for the vector $\mathbf{X}$ in the following equation:

$$\left(T^T - \mathrm{I}\right)\tilde{n}\,\mathbf{X} = 0 \tag{74.42}$$

where $\boldsymbol{T}^T$ is the transposition of $\boldsymbol{T}$, and $\mathbf{I}$ is the unit vector. Again, vector $\mathbf{X}$ is the steady-state probabilities. As an example, consider the following transition probabilities for the Markov models presented in Fig. 74.20.

CASE 1 Since there is only one transition, and the failed state is absorbing, the steady-state probabilities for the system being operational and failed are 0 and 1.0, respectively.

CASE 2 Let us assume the following values for the transition matrix:

$$T = \begin{vmatrix} 0.99 & 0.01 \\ 0.75 & 0.25 \end{vmatrix}$$

The values should be interpreted as follows:

- 0.01 is the transition probability from the operational to the repair state. Consequently, $1-0.01 = 0.99$ is the probability of not transitioning to the repair state.
- 0.75 is the transition probability from the repair state to the operational state. Consequently, $1-0.75 = 0.25$ is the probability of not transitioning from the repair state to the operational state.

The steady-state probabilities of state are the nontrivial solution ($\mathbf{X} \neq 0$) of Equation 74.42, which is a normalized eigenvector of $\boldsymbol{T}^T$ for the eigenvalue 1. The system of equations from Equation 74.42 is

$$(0.99\ \ 1)x_i + (0.75\ \ 0)x_2 = 0$$
$$(0.01\ \ 0)x_1 + (0.25\ \ 1)x_2 = 0$$

where

$$T^t = \begin{vmatrix} 0.99 & 0.75 \\ 0.01 & 0.25 \end{vmatrix}$$

and

$$\mathrm{I} = \begin{vmatrix} 1 & 0 \\ 0 & 1 \end{vmatrix}$$

The foregoing system must be solved with the restriction that $x_1 + x_2 = 1$. The solution can be also found directly from the normalized eigenvector for the eigenvalue 1.0 of the transposed transition matrix. The resulting steady-state probabilities are 0.987 and 0.013 of being in the operational and repair states, respectively. Notice that the availability of the system is 0.987.

CASE 3 In Case 3, the following transition probabilities are assumed.

$$T = \begin{vmatrix} 0.1 & 0.5 & 0.4 \\ 0.9 & 0 & 0.1 \\ 0.75 & 0 & 0.25 \end{vmatrix}$$

The transition probabilities should be interpreted as follows:

- The probability for transitioning from the operational state to the test state is 0.5. The transition probability from the operational state to the repair state is 0.4. Consequently, the probability of not transitioning from the operational state is 0.1.
- The probability of transitioning from the test state to the repair state is 0.1. This value represents cases where a degraded condition in the fire pump has been identified. The transition probability from the test to the operational state is 0.9. This value represents the case in which the inspection found the fire pump in good operational condition and, therefore, it is returned to service. At the same time, there is no probability of staying in the inspection state. The pump will eventually return to service or will be sent to repair.
- The probability of transitioning from the repair state to the operational state is 0.75. There is no probability of transitioning from the repair state to the test state. Consequently, there is a 0.25 probability of not transitioning from the repair state.

The normalized eigenvector for the eigenvalue 1.0 of the transposed transition matrix suggests steady-state probabilities 0.476, 0.238, and 0.286 of being in the operational, inspection, and repair states, respectively. Notice that the availability of the system is 0.476. The unavailability of the system is the sum of the probabilities of being in the test and repair states or 0.238 + 0.286 = 0.524.

CASE 4 The transition probabilities for Case 4 are summarized in the following matrix.

$$T = \begin{vmatrix} 0.6 & 0.2 & 0.15 & 0.05 \\ 0.4 & 0.4 & 0 & 0.2 \\ 0.4 & 0 & 0.4 & 0.2 \\ 0.3 & 0.3 & 0.3 & 0.1 \end{vmatrix}$$

The following interpretation should be given to the transition probabilities:

- From State 1, in which both batteries are operable, there are transition probabilities to States 2, 3, and 4. As such, the probability of not transitioning from State 1 is 0.6.
- From State 2, there are transition probabilities to State 1, when the backup battery is replaced, to State 4, if the primary battery also fails before the backup is replaced. There is no probability of transitioning to State 3, since the backup battery would need to be replaced first. Consequently, there is a probability of 0.4 of staying in State 2 (1−(0.4 + 0.2 = 0.4)).
- The transition probabilities from State 3 are similar to those in State 2. The only difference, of course, is that transitions start from State 3. As such, there is no probability of transitioning to State 2, since the primary battery would need to be replaced first.
- There are equal probabilities of 0.3 of transitioning from State 4 to any of the first three states. That is, the probability of replacing one or two batteries is 0.3. Consequently, the probability of not transitioning from State 4 is 0.1.

The normalized eigenvector for the eigenvalue 1.0 of the transposed transition matrix suggests steady-state probabilities 0.486, 0.22, 0.179, and 0.115 of being in States 1, 2, 3, and 4, respectively. Notice that the availability of the system is 0.486 + 0.22 + 0.179 = 0.885. The unavailability of the system is 0.115.

Solving Continuous Time Markov Modeling Solving continuous time Markov models requires the development of a system of ordinary differential equations. Depending on the number of states and different transitions, the system may have an analytical solution. However, it is often practical to input the system of equations in a differential equation solver available in most mathematical software packages, which provides numerical answers in seconds. These systems can be also solved using Monte Carlo simulation.

As mentioned earlier, in the case of continuous time Markov models the transition probabilities are substituted by a constant rate of transition. This is because the rate of the exponential distribution equals the instantaneous probability as in the time interval $(t, t + \Delta t)$ as Δt goes to 0. The development of the system of differential equations is best described using the four cases listed in Fig. 74.20.

CASE 1 Recall that this is a trivial case included for explanatory purposes. In this case, there is only one differential equation. The probability of being in the operational state, L_O,, at time $t + \Delta t$ is

$$L_O(t + \Delta t) = L_O(t)\ \tilde{n}\ (1 - \lambda \Delta t)$$

where the term on the right-hand side is the probability of being in the operational state at time t times the instantaneous probability of no failure in time interval $(t, t + \Delta t)$. Rearranging, dividing by ΔT, and taking the limit as $\Delta t \to 0$, the equation can be written as

$$\frac{dL_O(t)}{dt} = -\lambda \tilde{n} L_O(t)$$

and as expected, solving the differential equation, $L_O\ (t) = \mathrm{e}^{-\lambda t}$. Notice that this is the reliability of a nonrepairable component.

CASE 2 This is the simplest model for a repairable item. One ordinary differential equation should be written for each of the two states. For the operational state

$$L_O(t + \Delta t)\ = L_O(t)\ \tilde{n}\ (1\ - \lambda \Delta t)\ + L_R(t)\ \tilde{n} \mu \Delta t$$

The first term on the right-hand side represents the probability of being in the operational state at time t and a failure doesn't occur. The second term in the right-hand side is the probability of being in the repair state at time t and a repair occurs. For the repair state

$$L_R(t + \Delta t) = L_R(t) \tilde{n} (1 - \ \mu \Delta t) + L_O(t) \tilde{n} \lambda \Delta t$$

Rearranging, dividing by ΔT and taking the limit as $\Delta t \to 0$ in both equations, the resulting system is

$$\frac{dL_O(t)}{dt} = -\lambda \cdot L_O(t) + \mu\ \tilde{n}\ L_R(t)$$

$$\frac{dL_R(t)}{dt} = -\lambda \cdot L_O(t) - \mu\ \tilde{n}\ L_R(t)$$

Solving the foregoing system of equations results in the probability of being in the operational and repair states as a function of time. These are the availability and unavailability values, respectively. The analytical solutions are

$$a(t) = \frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu} \mathrm{e}^{-(\lambda + \mu)t} \qquad (74.43)$$

$$u(t) = \frac{\lambda}{\lambda + \mu} - \frac{\lambda}{\lambda + \mu} \mathrm{e}^{-(\lambda + \mu)t} \qquad (74.44)$$

These equations can be reduced to the first term on the right-hand side, respectively, since the exponential term approximates to 0 for large values of t. The step-by-step analytical result of this system is documented in a number of reliability engineering textbooks [5] (p. 208) and is not reproduced here.

CASE 3 A system of three differential equations must be developed for Case 3, one equation for each of the three states: operational, test, and

repair. For the operational state, the probability of being in state L_O at time $t + \Delta t$ is

$$L_O(t+\Delta t) = L_O(t) - \lambda \Delta L_O(t) - \tau \Delta t L_O(t) + \psi \Delta t L_I(t) + \mu \Delta t L_R(t)$$

The terms on the right-hand side in the preceding equation are

- The probability of being in L_O at time t (first term)
- Minus the probability of transition to the repair state (second term)
- Minus the probability of transition to the test state (third term)
- Plus the probability of being in the test state and transition to operational state (fourth term)
- Plus the probability of being in the repair state and transition to the operational state (fifth term)

Rearranging, dividing by ΔT, and taking the limit as $\Delta t \to 0$, the resulting equation is

$$\frac{dL_O(t)}{dt} = \psi L_I(t) + \mu L_R(t) - \lambda L_O(t) - \tau L_O(t)$$

The process is similar for developing the differential equation for the test state:

$$L_T(t+\Delta t) = L_T(t) + \tau \Delta t L_O(t)\ \psi \Delta t L_T(t) + \gamma \Delta t L_T(t)$$

Rearranging, dividing by ΔT, and taking the limit as $\Delta t \to 0$, the resulting equation is

$$\frac{dL_T(t)}{dt} = \tau L_O(t) - \psi L_T(t) - \gamma L_T(t)$$

Finally, for the repair state:

$$L_R(t+\Delta t) = L_R(t) + \lambda \Delta t L_O(t) + \gamma \Delta t L_I(t) - \mu \Delta t L_R(t)$$

Rearranging, dividing by ΔT and taking the limit as $\Delta t \to 0$, the resulting equation is

$$\frac{dL_R(t)}{dt} = \lambda L_O(t) + \gamma L_I(t) - \mu L_R(t)$$

Example 6 Consider the case of a fire pump subjected to weekly testing as recommended in NFPA 25. The duration of the test is approximated to 1 day. In addition, reliability data for the pump suggest an MTBF of 36 months, and a 5 % chance that the inspection and testing activities will find pump problems requiring repair. Finally, the pump's MTTR is 1 week. What is the availability of the pump?

Solution The problem statement suggest the following rates: (1) the failure rate λ is 1/36 months^{-1}, (2) the repair rate μ is 1/0.25 months^{-1} (approximating 1 week as 0.25 months), (3) the inspection rate τ is also 1/0.25 months^{-1}, (4) the rate at which the pumps return to service after inspection and testing is 1/0.033 months^{-1}, approximating 1 day as 1/30 months, and (5) rate at which pump problems requiring repair are detected during inspection and testing is $0.05 \cdot \tau$. These values are summarized in the transition matrix shown in Table 74.9.

Solving the foregoing system of differential equations numerically with the values in Table 74.9, the state probabilities plotted in Fig. 74.21 are obtained. The steady-state probability of being in the operational state is 0.873. This example was solved assuming the system starts at time 0 in the operational state.

CASE 4 In Case 4, the system consists of four differential equations, one of each of the four states in the Markov model. For State 1,

$$L_1(t+\Delta t) = L_1(t) - \lambda_{sb}\Delta t L_1(t) - \lambda_{cc}\Delta t L_1(t) - \lambda_p \Delta t L_1(t) + \mu \Delta t L_2(t) + \mu \Delta t L_3(t) + \mu_s \Delta t L_4(t)$$

Rearranging, dividing by ΔT, and taking the limit as $\Delta t \to 0$, the resulting equation is

$$\frac{dL_1(t)}{dt} = \mu \cdot L_3(t) + \mu \cdot L_2(t) + \mu_s L_4(t) - \lambda_{sb} L_1(t) - \lambda_{cc} L_1(t) - \lambda_p L_1(t)$$

For State 2,

Table 74.9 Transition matrix for Example 6 (all units in months^{-1})

	Operational	Test	Repair
Operational		$\tau = 1/0.25$	$\lambda = 1/36$
Test	$\psi = 1/0.033$		$\gamma = 0.05 \cdot \tau$
Repair	$\mu = 1/0.25$		

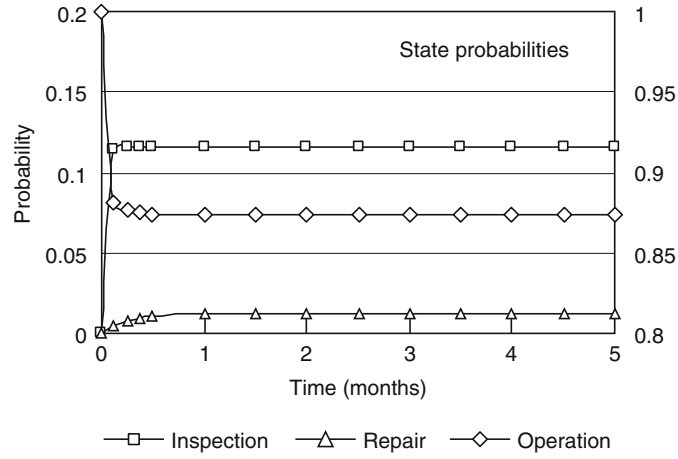

Fig. 74.21 Graphical solution for Example 6. Steady-state probabilities: operational = 0.873 (read in the right y-axis), inspection = 0.116, repair = 0.012

$$L_2(t+\Delta t) = L_2(t) + \lambda_{sb}\Delta t L_1(t) + \mu\Delta t L_4(t) - \mu\Delta t L_2(t) - \lambda_p \Delta t L_2(t)$$

Rearranging, dividing by ΔT, and taking the limit as $\Delta t \to 0$, the resulting equation is

$$\frac{dL_2(t)}{dt} = \lambda_{sb} \cdot L_1(t) + \mu \cdot L_4(t) - \mu L_2(t) - \lambda_p L_2(t)$$

For State 3,

$$L_3(t+\Delta t) = L_3(t) + \mu\Delta t L_4(t) + \lambda_p \Delta t L_1(t) - \lambda_{sb}\Delta t L_3(t) - \mu\Delta t L_3(t)$$

Rearranging, dividing by ΔT, and taking the limit as $\Delta t \to 0$, the resulting equation is

$$\frac{dL_3(t)}{dt} = \mu \cdot L_4(t) + \lambda_p \cdot L_1(t) - \lambda_{sb} L_3(t) - \mu L_3(t)$$

For State 4,

$$L_4(t+\Delta t) = L_4(t) + \lambda_{cc}\Delta t L_1(t) + \lambda_{sb}\Delta t L_3(t) + \lambda_p \Delta t L_2(t) - \mu\Delta t L_4(t) - \mu\Delta t L_4(t) - \mu_s \Delta t L_4(t)$$

Rearranging, dividing by ΔT, and taking the limit as $\Delta t \to 0$, the resulting equation is

$$\frac{dL_1(t)}{dt} = \lambda_{cc} \cdot L_1(t) + \lambda_{sb} \cdot L_3(t) + \lambda_p L_2(t) - \mu L_4(t) - \mu L_4(t) - \mu_s L_4(t)$$

Example 7 Consider a water-based fire protection system designed with redundant pumps. Based on reliability and maintainability data collected over a period of time, the following rates have been calculated:

- The MTBF of the primary pump is 24 months. Therefore, the failure rate, λ_p, is 1/24 months^{-1}.
- The MTBF of the standby pump is 36 months. Therefore, the failure rate, λ_{sb}, is 1/36 months^{-1}.
- The MTTR of either the primary or the standby pump is 2 weeks. Therefore, the repair rate, μ, is 1/0.5 months^{-1}.
- The mean time to common cause failure is 60 months. Therefore, the failure rate, λ_{cc}, is 1/60 months^{-1}.
- The MTTR of both pumps is 3 weeks. Therefore, the repair rate, $\mu_{s,,}$ is 1/0.75 months^{-1}.

Solution The information provided in the problem statement is summarized in the transition matrix in Table 74.10.

Solving the foregoing system of differential equations numerically with the values in Table 74.7, the state probabilities plotted in Fig. 74.22 are obtained. The steady-state probability of being in the operational state is 0.958 + 0.016 + 0.023 = 997. This example was solved assuming the system starts at time 0 in the operational state.

Inspection, Testing and Maintenance Schedules for Achieving Target Availability

Availability is interpreted as the probability of success on demand (i.e., the system is available at the time of the fire). As discussed earlier, fire protection systems are required to be subjected to inspection, testing, maintenance activities with the purpose of increasing the system's availability. Given the requirements for inspection, testing and maintenance, it can be qualitatively argued that such activities will have a positive impact on systems availability. However, a qualitative argument is often not enough to provide fire protection professionals with flexibility to manage inspection, testing and maintenance activities on a performance based/risk informed regulatory framework. The ability to explicitly incorporate these activities into a quantitative model taking advantage of the existing data infrastructure based on current requirements on documenting impairment, provides can quantitative approach for managing fire protection systems.

Table 74.10 Transition matrix for Example 7 (all units in months^{-1})

	State 1	State 2	State 3	State 4
State 1		$\lambda_{sb} = 1/36$	$\lambda_p = 1/24$	$\lambda_{cc} = 1/60$
State 2	$\mu = 1/0.5$			$\lambda_p = 1/24$
State 3	$\mu = 1/0.5$		$\mu = 1/0.5$	$\lambda_{sb} = 1/36$
State 4	$\mu_s = 1/0.75$	$\mu = 1/0.5$		

In practical applications, quantitative availability models are based on performance data generated over time from maintenance, inspection and testing activities. Once explicitly modeled, decision can be made based managing maintenance activities with the goal of maintaining or improving target availability values. Examples include:

- Performance data may suggest key system failure modes that could be identified in time with increased inspections (or completely corrected by design changes) preventing system failures or unnecessary testing.
- Time between inspections, testing and maintenance activities may be able to be increased without affecting the system unavailability

The examples above stress the need for an availability model based on performance data. Consider as an example the Markov models Cases 3 and 4 discussed in examples 6 and 7 earlier in this chapter. The model includes three states: operational, testing and repair. Performance data on the system can be used for determining if random system failures generate to increase or decreased schedule inspections and maintenance activities without affecting the availability values. For a number of systems, the availability models are relatively easy to develop and solved. At the same time, the model inputs are based on the ability to obtain and maintain quality reliability and availability data for characterizing the system.

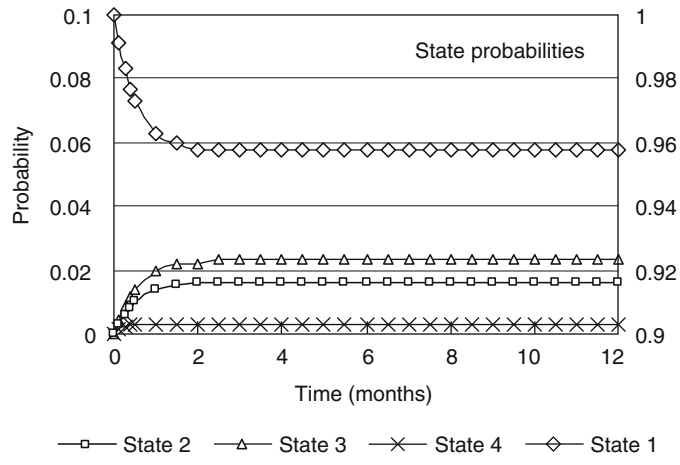

Fig. 74.22 Graphical solution for Example 7. State probabilities: State 1 = 0.958 (read in the right y-axis), State 2 = 0.016, State 3 = 0.023, State 4 = 0.0032

Data Analysis and Parameter Estimation

Statistical data form the basis for most reliability, availability, and maintainability analyses. The collected data are used for estimating the parameters of the appropriate statistical model. This section describes the process of collecting and classifying reliability data and selected statistical techniques for parameter estimation.

Collection of Reliability Data

Reliability data can be obtained from laboratory tests or field observations. Other sources may include generic handbook data or expert judgment. One of the defining attributes of the method of observation is the way the beginning and the end of observation are defined. Ebeling [2], (p. 284) suggests the following classification of reliability data:

1. Operational versus test-generated data
2. Complete versus censored data

Operational versus test-generated data refers to the source of the data. Operational data are usually less expensive and reflect actual operation conditions. On the other hand, test-generated data may be expensive and are usually generated in controlled environments. There are situations, however, where the use of test-generated data is unavoidable. A typical example of this situation is in the testing of a new product where no operational experience is available. Once the data are gathered, it is usually necessary to structure the data such that the data provide the maximum amount of information and are usable in the maximum number of applications for the minimum amount of cost in time and expense.

Complete versus censored data refers to how the data were recorded. A complete data set is one in which all the tested items failed. That is, the time to failure of all tested items is known. Much life data, however, are incomplete [3] (p. 13). In contrast, a censored data set is one in which not all the tested items failed. Specifically, Nelson [3] offers the following classification of censored data:

1. Singly censored data: All units have identical test time, and the test is terminated before all units fail.
   (a) Censored on the left: The failure time is known to be before a specific time.
   (b) Censored on the right: Not all items failed at the end of the test. Consequently, the time to failure of the resulting operating items is known only to be beyond the end of the test. Resulting operating items are usually referred to as survivors or suspensions.
      i. Type I censoring (or time terminated): The data collection process has a predefined duration.
      ii. Type II censoring (or failure terminated): The data collection process ends after a fixed number of failures has occurred.
2. Multiply censored data: Test times or operating times differ among the censored units.

Parameter Estimation: The Maximum Likelihood Estimator

The maximum likelihood (ML) is a method that is often used for estimating probability distribution parameters in most applications. It is most efficient if used with relatively large data samples. To obtain estimates of the distribution parameters, the following likelihood function is developed:

$$L(t,\theta) = \prod_{i=1}^{n} f(t_i,\theta) \tag{74.45}$$

where t_i is the data sample of size n, and θ is the parameter(s) of the probability distribution $f(t)$. The log-likelihood function is a convenient way of representing Equation 74.45.

$$L(t,\theta) = \ln f(t,\theta) = \sum_{i=1}^{n} ln[f(t_i,\theta)] \quad (74.46)$$

For singly censored data, the likelihood function can be modified as follows:

$$L(t,\theta) = \prod_{i=1}^{r} f(t_i,\theta)^{\delta_i} \cdot [1 - F(t_i,\theta)]^{1-\delta_i} \quad (74.47)$$

where δ is 1 for exact failure times and 0 for right-censored data, and $1 - F(t)$ is the probability that the censored units do not fail before the termination of the test. Assuming identical components, the second term in Equation 74.47 can be simplified as follows:

$$[1 - F(t_i,\theta)]^{1-\delta_i} = [R(T_e)]^{n-r} \quad (74.48)$$

where $n - r$ are the censored units and T_e is the test duration for either Type I or Type II data.

Notice that the likelihood function represents the probability distribution $f(x)$ expressed as a function of θ. Therefore, the value of θ that maximizes the function $L(x, \theta)$ can be obtained differentiating Equation 74.46 with respect to θ, setting it to zero, and solving for θ. In the case that $f(x)$ has more than one parameter (let us assume m parameters), a system of m equations resulting from the partial derivative of $L(x, \theta)$ with respect to each of the parameters will need to be solved simultaneously (in most cases using numerical methods).

In the following subsections, the ML method is used for estimating the parameters of the probability distributions discussed previously in the chapter.

Estimating Parameters of the Exponential Distribution Recall that the exponential distribution has only one parameter, λ. Assuming n exact failure time observations (complete data),

$$L(t,\lambda) = \prod_{i=1}^{r} \lambda e^{-\lambda t_i} \quad or \quad \ln[L(t,\lambda)] = \sum_{i=1}^{n} \ln\left[\lambda e^{-\lambda t_i}\right]$$
$$= \sum_{i=1}^{n} [\ln(\lambda) - \lambda t_i] = n\ln(\lambda) - \sum_{i=1}^{n} \lambda t_i$$

From differentiating and setting the resulting function to zero, the following estimate for λ is obtained:

$$\frac{\partial}{\partial \lambda} = \frac{n}{\lambda} - \sum_{i=1}^{n} t_i - 0$$
$$\hat{\lambda} = \frac{n}{\sum_{i=1}^{n} t_i} \quad (74.49)$$

In the case of singly censored data,

$$L(t,\lambda) = \left\{ \prod_{i=1}^{n} \lambda e^{-\lambda t_i} \right\} \left(e^{-\lambda T_e}\right)^{n-r} \quad (74.50)$$

Expressing Equation 74.50 in logarithmic terms, differentiating with respect to λ, and setting the differential to 0 results in (see derivation in Ebeling [2])

$$\hat{\lambda} = \frac{r}{\sum_{i=1}^{r} t_i + (n-r)T_e} \quad (74.51)$$

Estimating Parameters of the Weibull Distribution If the times between failures follow a Weibull distribution, the ML is

$$L(t,\alpha,\beta) = \prod_{i=1}^{n} \frac{\beta t_1^{\beta-1}}{\alpha^{\beta}} e^{-\left(\frac{t_i}{\alpha}\right)^{\beta}} \quad (74.52)$$

Expressing Equation 74.52 in logarithmic terms, differentiating with respect to α and β, setting the two differential equations to 0, and solving the system of equations produces the following estimates [24]:

$$\alpha = \left[\frac{\sum_{i=1}^{n} t_i^{\beta}}{n} \right]^{1/\beta} \quad (74.53)$$

$$\beta = \frac{n}{(1/\alpha)\sum_{i=1}^{n} \left[t_i^{\beta} \ln(t_i)\right] - \sum_{i=1}^{n} \ln(t_i)} \quad (74.54)$$

Notice that this system of equations must be solved simultaneously. In the case of singly censored data

$$L(t,\alpha,\beta)=\left\{\prod_{i=1}^{n}\frac{\beta t_1^{\beta-1}}{\alpha^{\beta}}e^{-\left(\frac{t_i}{\alpha}\right)^{\beta}}\right\}\left(e^{-(T_s/\alpha)^{\beta}}\right)^{n-r} \tag{74.55}$$

Expressing Equation 74.55 in logarithmic terms, differentiating with respect to α and β, setting the two differential equations to 0, and solving the system of equations produces the following estimates (see derivation in Ebeling [2]):

$$\alpha=\left[\frac{(n-r)\cdot t_s^{\beta}\sum_{i=1}^{r}t_i^{\beta}}{r}\right]^{1/\beta} \tag{74.56}$$

$$\frac{1}{r}\sum_{i=1}^{r}\ln(t_i)+\frac{1}{\beta}=\frac{(n-r)t_s^{\beta}\ln(t_s)+\sum_{i=1}^{r}\left[t_i^{\beta}\ln(t_i)\right]}{(n-r)t_s^{\beta}+\sum_{i=1}^{r}\ln(t_i)} \tag{74.57}$$

where t_s is $\sum_{i=1}^{r}t_i+(n-r)T_e$.

Estimating Parameters of the Log-Normal Distribution From the transformation of the normal distribution, the parameters of the log-normal distribution μ and σ are

$$\mu=\frac{1}{n}\sum_{i=1}^{n}\ln(t_i),\ \text{and}\ \sigma^2=\left(\frac{1}{n-1}\right)\sum_{i=1}^{n}[\ln(x_i-\mu)]^2$$

Ebeling [2] describes a numerical algorithm for the estimators for singly censored data of the normal and log-normal distribution.

Estimating Parameters of the Renewal Process In the renewal process, the times between failures are identically distributed. If these times are exponentially or Weibull distributed, the distribution parameters can be obtained using the ML method as described earlier in this section. Specifically, the parameter for the exponential distribution is obtained from Equations 74.49 or 74.50. The parameters for the Weibull distribution can be obtained from Equations 74.53 and 74.54 or 74.56 and 74.57. A similar procedure would need to be followed if failure times are characterized by a different distribution.

Estimating Parameters of the Nonhomogeneous Poisson Process Recall that in the nonhomogenous Poisson process, the first failure is represented with a probability distribution $f(t)$. Subsequent failures are then represented by the conditional distribution $f(t_i/t_i > t_{i-1})$. As an example, the parameters for the nonhomogeneous Poisson process are estimated assuming the failure times follow a Weibull distribution. A similar procedure would need to be followed if failure times are characterized by a different distribution.

For a time-terminated evaluation (e.g., predicting the next failure considering that the item has been operating for some time after the last failure)

$$L(t,\alpha,\beta)=\frac{\beta t_1^{\beta-1}}{\alpha^{\beta}}e^{-\left(\frac{t_1}{\alpha}\right)^{\beta}}\cdot\left\{\prod_{i=2}^{n}\frac{\beta t_i^{\beta-1}}{\alpha^{\beta}}e^{\left(\frac{t_{i-1}}{\alpha}\right)^{\beta}-\left(\frac{t_i}{\alpha}\right)^{\beta}}\right\}\cdot R(T_e/t_n) \tag{74.58}$$

The first term in the right-hand side is the Weibull distribution for the first failure. The second term in the right-hand side, which is inside the product, is the conditional Weibull distribution for failures 2 to n. Finally, the third term in the right-hand side is the probability that the item will not fail before the test is terminated. This last probability is calculated using the conditional Weibull from the time of the last failure until time T_e.

Expressing Equation 74.58 in logarithmic terms, differentiating with respect to α and β, setting the two differential equations to 0, and solving the system of equations produces the following estimates:

$$\alpha=\frac{t_n}{n^{1/\beta}} \tag{74.59}$$

$$\beta = \frac{n}{\sum_{i=1}^{n} \ln\left(\frac{t_n}{t_i}\right)} \tag{74.60}$$

Failure-terminated evaluation:

$$L(t, \alpha, \beta) = \frac{\beta t_1^{\beta-1}}{\alpha^{\beta}} e^{-\left(\frac{t_1}{\alpha}\right)^{\beta}} \cdot \prod_{i=2}^{n} \frac{\beta t_i^{\beta-1}}{\alpha^{\beta}} e^{\left(\frac{t_{i-1}}{\alpha}\right)^{\beta} - \left(\frac{t_i}{\alpha}\right)^{\beta}} \tag{74.61}$$

The first term in the right-hand side is the Weibull distribution for the first failure. The second term in the right-hand side, which is inside the product, is the conditional Weibull distribution for failures 2 to n.

Expressing Equation 74.61 in logarithmic terms, differentiating with respect to α and β, setting the two differential equations to 0, and solving the system of equations produces the following estimates:

$$\alpha = \frac{t_n}{n^{1/\beta}} \tag{74.62}$$

$$\beta = \frac{n-1}{\sum_{i=1}^{n} \ln\left(\frac{t_n}{t_i}\right)} \tag{74.63}$$

Parameter Estimation: Bayesian Analysis

Bayes theorem provides a very useful tool for estimating and updating probability distribution parameters. It should be mentioned that reliability-engineering applications represent a small sample of the universe of applications of Bayes theorem. In general terms, Bayes theorem is expressed as

$$\pi(\lambda/E) = \frac{L(E/\lambda)\pi_o(\lambda)}{k} \tag{74.64}$$

where

$\pi(\lambda/E)$ is the posterior probability of λ given the evidence E, $L(E/\lambda)$ is likelihood function, $\pi_o(\lambda)$ is the prior distribution, and k is a normalizing factor so that the function $\pi(\lambda/E)$ integrates to 1.0 over the appropriate range. Mathematically,

$$k = \int_{-\infty}^{\infty} L(E/\lambda)\pi_o(\lambda)d\lambda$$

The posterior distribution includes two sources of information: (1) the prior distribution, which captures any prior knowledge on the parameter λ; and (2) the likelihood function, which captures the available evidence. The ability to estimate parameters updating prior knowledge as evidence becomes available is a key advantage of using Bayes theorem.

The prior distribution captures any prior knowledge on the parameter λ. In the cases where there is no prior knowledge about λ, the prior distribution can be represented with a uniform probability distribution. Depending on the application, the prior distribution can be developed based on expert judgment.

The likelihood function usually captures the available evidence. It is the probability of the evidence E assuming the value of the unknown quantity is λ.

The posterior distribution $\pi(\lambda/E)$ is a probability distribution for the parameter λ itself. Notice that λ is treated as a random variable. Calculating the mean or median of the posterior distribution would provide a point estimate of λ.

Example 8: Applications to Updating Failure Rates Generic industry data suggest that a diesel generator in an industrial facility can experience three small fires over a period of 5 years due to leaking oil in contact with a hot surface. The same type of diesel generator was installed in a facility 3 years ago. In 3 years of operation, no fire associated with the diesel generator has been recorded. Calculate an updated failure frequency of diesel generator failures due to ignition of oil due to contact with a hot surface.

Solution The posterior distribution represents the updated failure rate. In order to obtain the posterior distribution, the prior distribution and the likelihood function must be identified first. In the case of the prior distribution, a very useful

option for representing the failure rate as a distribution is described in this example in addition to the Bayesian approach.

The prior information consists of a failure rate of $\lambda = 3/5 = 0.6$ failure per year. This value needs to be represented as a probability distribution. Epstein [25] suggests that the random variable $x = 2\lambda T$ follows a chi-square distribution with $\nu = 2r$ degrees of freedom if λ is assumed constant. The variable r is the number of failures and T is the time in which the failures were observed. By transformation $\lambda = x/2T$ (see Papoulis [4], p. 93), a probability distribution for λ can be found from the chi-square distribution for x. In general, the distribution for λ, which is the prior distribution, is

$$\pi_o(\lambda) = \frac{x^{\nu/2-1}\mathrm{e}^{-x/2}}{2^{\nu/2}\Gamma(\nu/2)} \cdot 2T \qquad (74.65)$$

where x is $2\lambda T$, ν is $2r$, and the term $2T$ results from the transformation from x to λ.

The likelihood function incorporates the new evidence into the analysis. In this case, the new evidence is no fires in 3 years. The Poisson distribution as stated in Papoulis [4] (p. 57) is a likely choice to capture evidence in this form. Accordingly,

$$L(\lambda) = \mathrm{e}^{-\lambda T_a}\frac{(\lambda T_a)^k}{k!} \qquad (74.66)$$

where k is the number of failures observed in period T_a. In this example, $k = 0$ and $T_a = 3$. Solving Equation 74.64 numerically as a function of λ using Equations 74.65 and 74.66 as inputs, the mean and median for the posterior are 0.38 and 0.33 fires per year, respectively. These values are lower than the 0.6 and 0.54 fires per year for the mean and median of the prior distribution. The reduction in the mean and median is consistent with the evidence of no fire in the subsequent 3 years. The prior and posterior distributions are plotted in Fig. 74.23.

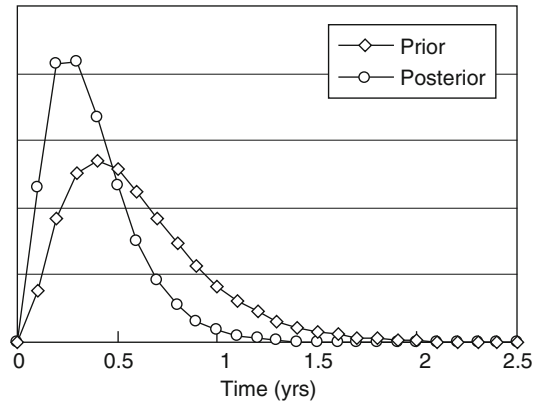

Fig. 74.23 Prior and posterior distribution in Example 8

Accelerated Testing

As stated by Nelson [3], "Accelerated testing consists in a variety of test methods for shortening the life of products or hastening the degradation of their performance. The aim of such testing is to quickly obtain data which, if properly modeled and analyzed, yields desired information on product life and performance under normal use."

Accelerated tests can be broadly classified in two groups: accelerated degradation tests and accelerated life tests. Both of them shorten the time to degradation or failure, respectively, of the tested element. These two broad categories of accelerated tests are further classified in different types of testing methods (see, for example, Nelson [3]). The accelerated life or degradation tests are used to estimate reliability by conducting tests at increased levels of stress. That is, the tested element is evaluated at different stress levels, which at the same time fit a stress life distribution (life-stress relationship model). In the case of accelerated life tests, the main goal is to accelerate the failure of a product. In the case of accelerated degradation tests, the interest is in evaluating predetermined performance measures in the product. Examples of degradation processes may include crack grow/propagation, corrosion, and so on.

Perhaps the most important aspect of accelerated testing is the identification and characterization of the stresses affecting the operating environment of the component. A component can be stressed by increasing its usage rate, increasing the aging rate, or increasing the level of stress affecting any of its failure

mechanisms. Stresses may vary in type and in time. Examples of stresses are temperature, usage rate, loading, and so on. Furthermore, stresses can be constant, progressive, cyclic, and so on. It is important to choose accelerating variables that correspond to the failure mechanism. Once the stress has been identified, a life-stress relationship model can be developed.

Life-stress relationship models can be physical or empirical. Physical models are used for well-understood failure mechanisms. These models are based on physical/chemical theory that describes the failure-causing process. The advantage of physical models is that they may be used for extrapolation. Empirical models are used when there is little understanding of the chemical and physical processes describing the failure mechanisms. Empirical models may often provide an excellent fit to available data but may not be used for extrapolations. Figure 74.24 illustrates a conceptual representation of a life-stress relationship model. A physical or empirical model defines the life expectancy of an item subjected to a given stress level. There is a probability that the item will fail given a stress level. This probability is represented by a distribution reflected on the *y*-axis.

Some Popular Models

The following subsections briefly describe two popular life-stress models and the process of characterizing probability distributions for different stress levels.

The Arrhenius life-temperature relationship: Perhaps the most common model for predicting an item's life as a function of temperature is the Arrhenius life-temperature relationship. This relationship is used to describe products that fail as a result of degradation due to chemical reactions or metal diffusion. According to this relationship, the rate of reaction is given by

$$\text{Rate} = A' e^{-E/kT} \tag{74.67}$$

where E is the activation energy (usually in electron volts), k is the Stefan Boltzmann constant ($8.6171 \cdot 10^{-5}$), T is the absolute temperature, and A' is a constant usually obtained from data. Considering that the reaction rate is inversely proportional to the item's life, the Arrhenius life-temperature relationship is

$$t = Ae^{-E/kT} \tag{74.68}$$

Example: Application in Fire Testing NUREG/CR-5546 [26] describes an investigation of thermal aging on the fire damageability of electric cables. The investigation consisted in subjecting energized cables to high-temperature environments in a chamber. Previous to the experiments in the chamber, the Arrhenius model was utilized to account for the thermal aging of cables. A thermal oven was used to provide a constant elevated aging temperature for a period of 28 days. It was determined that the 1-month aging temperature was equivalent to a 40-year life. The aging temperature was calculated as follows:

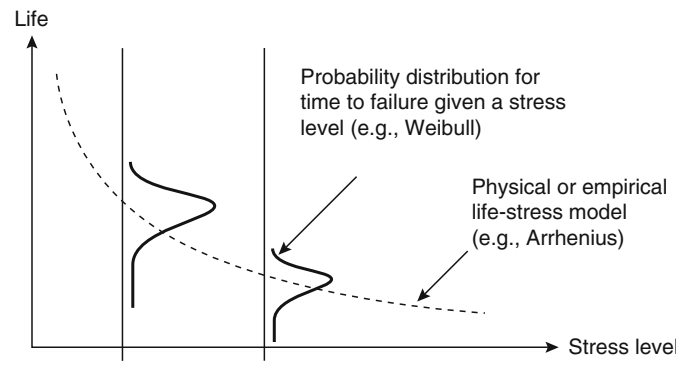

Fig. 74.24 Conceptual representation of a life-stress relationship model

$$\frac{t_o}{t_a} = \frac{A\mathrm{e}^{-E/kT_{\mathrm{amb}}}}{A^{-E}\mathrm{e}^{kT_{\mathrm{oven}}}}$$

where T_{amb} is the "real" temperature at which the cables are usually exposed, T_{oven} is the aging temperature at which the oven is going to be set, t_o is 40 years, and t_a is 28 days. Assuming $E = 0.83$ eV, and $T_{\mathrm{amb}} = 59$ °C, A cancels resulting in $T_{\mathrm{oven}} = 150$ °C. That is, according to the Arrehnius life-temperature relationship model, having cables in a 150 °C thermal environment for 28 days is equivalent to having cables in a 59 °C thermal environment for 40 years.

The Inverse Power Relationship In the case of the inverse power relationship (or inverse power law), the item's life is associated with an accelerated stress. This relationship has been found to be empirically adequate for many products including ball and roller bearings, flash lamps, and so on.

For an accelerated stress variable S, the item's life t is approximated with the inverse power relationship as

$$t(S) = \frac{A}{S^{\gamma}} \qquad (74.69)$$

where A and g are constant parameters obtained from the data.

Probabilistic life-stress relationships: As suggested earlier in this section, the probabilistic life-stress relationship, such as the one depicted in Fig. 74.24, requires two general elements: (1) a physical or empirical model, and (2) a probability distribution. In addition to those two elements, experimental data are usually required to find the correlating constants in both the model and the distribution.

Example: Application: The Arrhenius-Weibull Model. Let us assume that after careful evaluation, temperature has been identified as an important factor affecting a product's life and the Arrhenius relationship has been selected as the model for associating operating temperature and life. Let us further assume that under a given operating temperature, the item's life follows a Weibull distribution:

$$f(t) = \begin{cases} \dfrac{\beta(t-t_o)^{\beta-1}}{\alpha^{\beta}}\mathrm{e}^{-\left(\frac{t-t_o}{\alpha}\right)^{\beta}} & t \geq t_o \\ 0 & \text{otherwise} \end{cases}$$

Since α is the location parameter, it is set equal to the Arrhenius life-temperature model.

$$\alpha = A\mathrm{e}^{-E/kT}$$

Substituting in the Weibull distribution,

$$f(t,T) = \begin{cases} \dfrac{\beta(t-t_o)^{\beta-1}}{\left(A\mathrm{e}^{-E/kT}\right)^{\beta}}\mathrm{e}^{-\left(\frac{t-t_o}{A\mathrm{e}^{-E/kT}}\right)^{\beta}} & t \geq t_o \\ 0 & \text{otherwise} \end{cases}$$

Assuming a known activation energy, the parameters t_o, β, and A can be obtained from experimental data using methods such as the maximum likelihood estimator. As constants, these parameters are independent of temperature.

Other Probabilistic Life-Stress Relationships The Arrhenius-Weibull relationship is only one in many relationships that have been and can be developed. In general, this combination of physical or empirical models governing the behavior of an item under stress and probability distribution can be a useful tool for considering uncertainty in failure predictions.

Examples of other combinations available in the accelerated testing literature are Arrhenius–log-normal, inverse power–Weilbull, and inverse power–log-normal.

Cautionary Remarks

Three general assumptions govern the foregoing accelerated testing discussion:

1. Only a transformation of time will be observed due to elevated stresses.
2. Failure or degradation times are accelerated.
3. No new failure modes are introduced.

These assumptions, however, may not be applicable to all products. The following cautionary remarks are important to consider:

1. It may be argued that accelerated tests do not reflect actual use conditions of the product in

the field. As an example, consider the case of some levels of an accelerating factor increasing (instead of shortening) the life of a product. Such an argument stresses the importance of careful selection and evaluation of accelerating factors.
2. High levels of stresses may introduce new failure modes not observed under "normal" operating conditions. Also, high stress levels may change the life-stress relationship model.
3. Some products are characterized by multiple and relatively equally likely failure modes. In those cases, life-stress relationships should capture both failure modes so that life predictions result from a contribution of the modeled failure modes.

Software Reliability

Software reliability is a relatively young field. At the same time, the need for estimating software reliability is growing, as longer and more complex software is available for different applications. Treatment of software failures may be critical in some applications where computer programs perform important tasks. At the same time, software reliability applications in fire protection engineering are limited. Some applications may include the development process of computer fire models, treatment of fire protection system failures due to software errors, and treatment of software failures in fire risk assessments.

The following definitions are important in the field of software reliability:

- *Software reliability*. The probability that the software will be operational during a predefined period of time
- *Software maintainability*. The probability that the software will be restored to working condition in a given period of time
- *Software availability*. The probability that the software is operational (not failed) at a given time t
- *Bug*. A software design flaw that will result in symptoms exhibited during testing or normal operation
- *Software error*. An error made by the programmer (e.g., typographical error, omission, or incorrect numerical value [constant])
- *Software fault*. Software defect that causes a failure
- *Software failure*. A software failure occurs when the user perceives that the output of the program is incorrect, that is, an unacceptable departure of a program operation from program requirements

Notice that most of these definitions are consistent with the reliability, availability, and maintainability analysis of hardware items. In fact, some of the modeling techniques are similar, including (but not limited to) the failure data collection during tests, the determination of software failure rates, and the failure prediction using the nonhomogenous Poisson process. Pham [27](p. 4) indicates that there are more than 50 models for quantifying software reliability. Currently, the field has matured to the point that models can be applied in practical situations providing meaningful results. At the same time, there is no one model that is best for all situations.

From a reliability point of view, software is different from hardware in the sense that it does not degrade or wear out because of time. The failure mechanisms are different. The majority of hardware faults are physical faults due to inherent material defects or the interaction of materials with the environment. In the case of software, most of the faults are design faults, which are introduced by humans during the development process. Software deterioration may also occur in the process of upgrading it due to the introduction of new programming errors. This characteristic is conceptually captured in Fig. 74.25, which presents a conceptual hazard rate curve for software.

Another important difference between hardware and software failures is that the latter often do not provide any warnings.

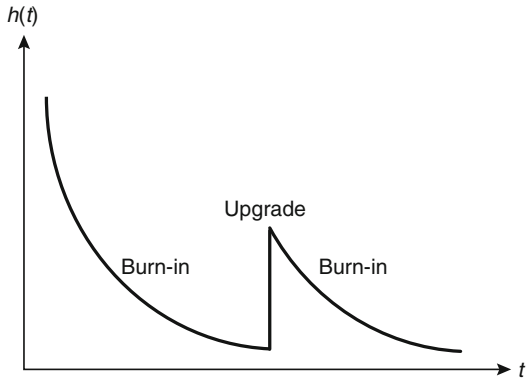

Fig. 74.25 Conceptual hazard rate curve for software

Software Reliability and Fire Risk Assessment

Currently, even detailed fire probabilistic risk assessment methodologies [7] do not include specific qualitative or quantitative treatment of software failures. Instead, software-related failure modes are assumed to be part of a broader hardware system failure or initiating event. That is, the system model is not developed to a resolution in which software failure modes are explicitly modeled. However, the explicit treatment of software failures may eventually be incorporated in fire risk assessments as the interest in detailed fire risk analysis grows.

Software Verification and Validation

The subject of software verification and validation (V&V) of fire models is closely related to the software reliability field. The main difference between software reliability and software V&V is that the former is intended for the evaluation of the probability of software failures and the latter can be considered a rigorous software quality check.

In the case of a computer fire model, software verification refers to a detailed evaluation of the computer implementation. Verification includes activities such as verifying that the selected algorithm for solving a system of equations is correctly programmed. In general terms, a software verification process is intended to check that the software product meets the designed specifications.

On the other hand, software validation refers to an assessment of the predictive capabilities of the model. In the case of a computer fire model, a validation process includes activities such as comparing model results to experimental data. In general terms, a software validation process is intended to check that the software can be used for its intended applications.

ASTM E1355-05, *Standard Guide for Evaluating the Predictive Capability of Deterministic Fire Models* [28], documents guidelines for performing a fire model V&V analysis. It recommends the following steps for conducting a software V&V:

- Define the model and scenarios for which the evaluation is to be conducted.
- Assess the appropriateness of the theoretical basis and assumptions used in the model.
- Assess the mathematical and numerical robustness of the model.
- Validate the model by quantifying its accuracy in predicting the course of events for intended fire scenarios.

It should be stressed that ASTM E1355-05 recommends a quantitative assessment of the predictive capabilities of the model under evaluation.

Human Reliability

Human reliability analysis (HRA) is a structured approach used to identify potential human error events and to systematically estimate the probability of those errors using data, models, or expert judgment [7]. *Notice that this definition is perhaps more appropriate to the term "Human Unreliability Analysis" as it refers to calculating human error probabilities*. Nevertheless, this structured approach enables analysts to incorporate the impact of human actions on the quantitative reliability analysis of complex systems that may support a risk assessment.

Human behavior in fire has always been an important aspect of fire protection engineering. Traditionally, fire protection engineers have

considered human behavior and human factors in fire department or fire brigade activities, life safety, egress, and fire protection system designs. However, the current knowledge in human behavior in fire and human response to fire events has not been formalized as a quantitative model for identifying and evaluating human errors. Although a specific model for fire HRA may not be available, the current HRA technology can be very helpful in the following areas:

- *Quantitative fire risk analysis*. Human error probabilities may be explicitly included in the basic events of logic models such as fault trees. Consequently, a logic model quantification process will require a numerical representation of the human error events.
- *Risk reduction potential*. In contrast with a quantitative risk assessment, which may be used for supporting regulatory decisions, human reliability analysis can be used for determining risk reduction potential. In this case, human error events expressed in relative terms as the resulting risk values are only compared with each other and not against regulatory criteria.
- *Prevention of industrial accidents*. This is mostly a qualitative assessment generally intended for identifying and protecting against consequences generated by human errors. In the case of fire protection engineering, this may include (1) preparing inspection and maintenance procedures such that human errors are minimized, (2) identifying human errors that may generate a fire event, and/or (3) identifying human errors that may affect (delay or prevent) the timely response to a fire

Qualitatively, identifying conditions that can lead to erroneous actions (human error events) in work operations requires a systematic evaluation of the system under analysis. The process of identifying human error events requires a team with expertise in cognitive science, psychology, human factors, and the operations under evaluation. In some cases, particularly during the design stage, such conditions can be corrected or improved with relatively small amount of resources.

The quantitative aspect of HRA builds on the qualitative analysis of work operations where human errors are identified. In practice, probabilities are calculated for the identified human error events. The actual process of calculating probabilities may have different levels of complexity depending on the selected model, the nature of the human error events, and the conditions leading to those errors. Available HRA models (discussed briefly later in this section) usually provide relative indicators or error likeliness, which are very useful in determining areas where improvements to tasks or procedures can be made.

Some Relevant Definitions

Let's start our brief discussion of human reliability by considering some useful definitions. It should be noted that recent HRA literature suggests that there is still disagreement within the community in the use of some key terms and definitions [29]. Considering any disagreement still present in the field, the following definitions can be helpful in understanding different HRA methods (the definitions were compiled from a number of sources):

Human factors	The study of how humans behave physically and psychologically in relation to particular environments, products, or services.
Human action	The motion(s), decision(s), or thinking of one or more people required to complete a postulated mission defined in a scenario.
Human error	Failure of a postulated human action in a given scenario.
Human error probability (HEP)	The probability of a human error.

Error of commission	Manifestation of an unintended or unplanned action; in other words, an incorrect action was performed.
Error of omission	Failure to perform an action; an omission is registered if the appropriate action was not carried out when required.
Extraneous error	Refers to a wrong (or unrequired) action performed.
Latent error	Those errors committed pre-event initiation and whose effects are not realized until the event occurs. Latent conditions influencing an accident event can be present for long periods of time before combining with other workplace factors including active errors to produce the accident.
Active error	Those errors resulting in accident initiations, or those that occur in response to an accident.
Cognition	Refers to the conscious process to obtain knowledge, think, decide, and learn, considering aspects such as situation awareness, perception, reasoning, and judgment.
Cognitive error	The cause for the manifestation of either errors of omission or commission. The potential for cognitive errors may increase if, for example, an operator needs to rely on theory or abstract knowledge to make a decision.
Human failure event (HFE)	In risk analysis, a human failure event is a basic event in a logic model (see the discussion on fault trees later in this chapter).
Performance shaping factor	A factor influencing the probability of human error. Typical performance shaping factors include: available time to complete the task, stress (e.g., mental stress, excessive workload, physical stress), environmental conditions (e.g., noise, toxicity), task complexity, experience and/or training conducting the task, available procedures for completing the task, ergonomics and/or human-machine interactions, and fitness for duty.
Error-forcing context	The situation that arises when particular combinations of performance shaping factors and situation conditions create an environment in which unsafe actions are more likely to occur.
Action	An activity, typically observable and usually involving the manipulation of equipment, that is carried out by an operator(s) to achieve a certain outcome. The required diagnosis of the need to perform the activity; the subsequent decision to perform the activity; obtaining any necessary equipment, procedures, or other aids or devices necessary to perform the activity; traveling to the location to perform the activity; implementing the activity; and checking that the activity has had its desired effect are all

	implied and encompassed by the term *action*.
Available time (or time available)	The time period from a presentation of a cue for an action to the time of adverse consequences if the action is not taken.
Diagnosis time	The time required for an operator(s) to examine and evaluate data to determine the need for, and to make the decision to implement, an action.
Implementation time	The time required by the operator(s) to successfully perform the manipulative aspects of an action (i.e., not the diagnosis aspects themselves, but typically as a result of the diagnosis aspects), including obtaining any necessary equipment, procedures, or other aids or devices; traveling to the necessary location; implementing the action; and checking that the action has had its desired effect.
Mental model	From a system operations perspective, a mental representation that integrates a person's understanding of how systems and plants work. A mental model enables a person to mentally simulate plant and system performance in order to predict or anticipate plant and equipment behavior.
Situation assessment	Situation assessment involves developing and updating a mental representation of the factors known or thought to be affecting the current set of conditions at a given point in time.
Situation model	A mental representation of the current set of conditions, and the factors thought to be affecting these conditions, resulting from the operator's situation assessment. The situation model is created by an interpretation of operational data in light of the operator's mental model. An operator's situation model is usually updated constantly as new information is received.

Some Human Error Examples

NUREG/CR-6738, "Risk Methods Insights Gained from Fire Incidents" [30] summarizes the following examples of human errors associated with fire events in commercial nuclear power plants (see NUREG/CR-6738 for additional details on the events). The following human errors occurred after the fire ignition:

- Waterford (1985): A main feedwater pump caught fire. The plant operator at the scene called the control room with the wrong pump tag number. This error resulted in the undamaged pump being shut down from the control room.
- Robinson (1989): During an outage a maintenance crew connected a hydrogen source to the plant compressed air system in error. The compressed air system was operating at a lower pressure than the hydrogen source. Hydrogen entered the compressed air system, was distributed to pipes throughout the plant, and exited the system at several locations (wherever the compressed air system was being used within the plant). The escaping

hydrogen caught fire at various points where ignition sources were present.
- Waterford (1995): During a switchgear fire, operators failed to promptly declare the event. The plant procedures apparently did call for operators to verify the presence of flames before declaring a fire emergency. However, the failure to declare a fire given the reports of "heavy smoke" issuing from the switchgear room is considered a human error event in the context of a fire probabilistic risk assessment. This error led to a substantial delay in activating the fire brigade.

The following examples, also listed in NUREG/CR-6738, suggest errors that led to a fire or compromised the response to the fire:
- At Browns Ferry (1975), the fire was ignited by a technician who allowed the lit candle he was carrying near penetration seals to touch unprotected seal material. Several fires involving the same ignition scenario, albeit all of no significant consequence, had occurred prior to the incident on March 22, 1975. Plant management and operators failed to take note of the earlier events and to disallow further usage.
- At Armenia (1982), the fixed suppression system for the cable gallery where the fire started was switched to the manual actuation mode (disabling automatic initiation) prior to the event. Fire damage to associated system cables rendered the system inoperable relatively early in the incident. Repeated attempts to manually actuate the system failed.
- At South Ukraine (1984), the fixed fire suppression system for the containment had been switched to the manual actuation mode (disabling automatic initiation) sometime before the fire occurred. Plant personnel apparently also failed to switch the system back to its automatic mode or to manually actuate the system after the existence of the fire was verified.

It is interesting to note that some of the human error scenarios described above (Robinson, 1989, and Waterford, 1985) can be categorized as errors of commission. That is, the operators took an action that further complicated the situation or created a new undesired condition for the plant. The remaining case examples involved errors of omission. That is, operators failed to take an action that would have contributed to mitigation of the incident.

The HRA Process

This section describes in very general terms a process for conducting human reliability analysis. Not all the steps may be necessary in a given application. At the same time, it should be noted that a comprehensive HRA may require expertise in more than one HRA method or a team of experts in relevant technical areas.

Problem Definition Kirwan [31] suggests the following two questions should be answered in defining the HRA problem:
1. Should the HRA be qualitative or quantitative?
2. How far should the scope of the HRA analysis extend?

The latter question refers to which specific tasks or events within the process or accident under analysis will require quantification of human error probabilities. In answering these two questions, analysts often compromise between the ideal outcome of the analysis and any availability constraints (e.g., available data, available resources, analytical capabilities, etc.).

Notice that the process or accident under analysis may consist of relatively complex interactions between operators and hardware and software systems associated with multiple human error events. In such cases, it may not be feasible or desirable to analyze all possible tasks that may be undertaken. Consequently, the HRA analyst must set the scope of the analysis in a way that offers an appropriate and reasonable level of investigation, assessment of the system vulnerability to human errors, and human error quantification.

Qualitative Analysis The qualitative analysis consists primarily of (1) identifying human error events in the scenarios or tasks under analysis, (2) determining the appropriate performance shaping factors affecting the human error probabilities, and (3) determining how the human errors will be represented in the quantitative risk assessment.

Identifying human errors (*task analysis*). Generally, the process of identifying human error events consists of

- Developing a description (or reviewing existing procedures) of typical expected steps to be followed in the tasks under analysis, for example, in response to a fire event
- Understanding the impact of specific trainings offered for conducting the tasks under analysis

The process of identifying human errors may need to incorporate (1) operators or personnel with expertise performing the tasks under analysis; (2) experts in cognitive science, psychology, and human factors; and (3) interviews and simulations of the corresponding tasks. Such activities should be focused on understanding the human thought process before and after conducting an action. Particular attention should be given to the interaction between the human(s), the procedures being followed, the system response to operator actions, and the environmental conditions. Specifically, errors could be identified by postulating what operators are likely to think and do, what types of actions they may take in a given situation, and how the system or sequence of events may be affected by such actions.

As an example, consider a procedure requiring an operator to read information from an interface [32]. Some considerations that should be evaluated in determining if such an activity may result in an erroneous action include (but may not be limited to):

1. Can the display be read with sufficient accuracy from different viewing positions?
2. Is the information in the display presented in an appropriate form for an operator to use it effectively?
3. Can the display be located easily?
4. Can the display be confused with other nearby information?
5. Does the information processing impose an unacceptable memory load?
6. Does the information require interpretation from the operators?

The answers to these questions may suggest different types of errors that may need to be included in a logic model and quantified. Kirwan [31] offers the following classification of basic error modes:

- Errors of omission
  - Omits an entire task or omits steps in a task
- Errors of commission
  - Time errors: errors too early or too late
  - Latent error prevents execution
  - Qualitative errors: too much of an action, too little from an action, action repeated
  - Selection errors: right action on wrong object, wrong action on right object, wrong action on wrong object
  - Wrong information or communication error
  - Sequence errors: incorrect sequence
- Extraneous errors
  - Rule violations

Performance Shaping Factors Many, if not most, HRA methods use performance shaping factors (PSF) information in the estimation of human error probabilities. In general, performance shaping factors may enhance the degree of realism present in HRA analysis. It is important to understand which performance shaping factors are within the capabilities of the selected quantitative model and how they should be specified. The following list provides examples of performance shaping factors [33].

- *Available time*. Refers to the amount of time available for an operator or a crew to diagnose and act upon an abnormal event. A shortage of time can affect the operator's ability to think clearly and consider alternatives. It may also affect the operator's ability to perform.

- *Stress/stressors*. Stress has been broadly defined and used to describe negative as well as positive motivating forces of human performance. Stress can include mental stress, excessive workload, or physical stress (such as that imposed by difficult environmental factors). Environmental factors often referred to as stressors, such as excessive heat, noise, poor ventilation, or radiation, can induce stress in a person and affect the operator's mental or physical performance.
- *Complexity*. Refers to how difficult the task is to perform in the given context. Complexity considers both the task and the environment in which it is to be performed. The more difficult the task is to perform, the greater the chance for human error. Similarly, the more ambiguous the task is, the greater the chance for human error. Complexity also considers the mental effort required, such as when performing mental calculations; the memory requirements; the process of understanding the underlying model of how the system works; and the reliance on knowledge instead of training or practice. Complexity can also refer to physical efforts required, such as physical actions that are difficult because of complicated patterns of movements.
- *Experience and training*. Refer to the experience and training of the operator(s) involved in the task. Included in this consideration are the years of experience of the individual or crew and whether or not the operator or crew have been trained on the type of accident, the amount of time that has passed since training, and the systems involved in the task and scenario. Another consideration is whether the scenario is novel or unique (i.e., whether the crew or individual has been involved in a similar scenario, in either a training or an operational setting).
- *Procedures*. Refers to the existence and use of formal operating procedures for the tasks under consideration. Common problems seen in event investigations for procedures include situations where procedures give wrong or inadequate information regarding a particular control sequence. Another common problem is the ambiguity of steps.
- *Ergonomics and HMI*. Ergonomics refers to the equipment, displays and controls, layout, quality and quantity of information available from instrumentation, and the interaction of the operator or crew with the equipment to carry out tasks. Aspects of human-machine interaction (HMI) are included in this category. The adequacy or inadequacy of computer software is also included in this PSF.
- *Fitness for duty*. Fitness for duty refers to whether the individual performing the task is physically and mentally fit to perform the task at the time. Factors that may affect fitness include fatigue, sickness, drug use (legal or illegal), overconfidence, personal problems, and distractions. Fitness for duty includes factors associated with individuals but not related to training, experience, or stress.
- *Work processes*. Refer to aspects of doing work, including interorganizational, safety culture, work planning, communication, and management support and policies. How work is planned, communicated, and executed can affect individual and crew performance. If planning and communication are poor, then individuals may not fully understand the work requirements. Work processes include consideration of coordination, command, and control. Work processes also include any management, organizational, or supervisory factors that may affect performance.

In the specific case of fire risk analysis, research is still needed for further developing some of the performance shaping factors listed above to account for fire-generated conditions. Notice that performance shaping factors for fire risk analysis applications should include those (1) associated with humans in direct contact with fire-generated conditions (e.g., a control room operator performing a task with smoke migrating into the control room) or (2) those associated with humans making decisions and performing actions in response to the fire but away from

the fire-generated conditions. NUREG/CR-6850 [7] lists various performance shaping factors associated with fire events. These performance shaping factors are developed for commercial nuclear power plant applications where operators must monitor and control the plant while keeping track of fire suppression activities. Furthermore, the shaping factors for fire applications have not been numerically characterized yet and are not included in any quantitative HRA method.

- *Available staffing resources*. Fire can introduce additional demands for staffing resources beyond what is typically assumed for handling accidents not involving fire. These demands can take the form of needing to use and coordinate with more personnel such as the fire brigade and/or local fire department personnel.
- *Applicability and suitability of training and experience*. The familiarity and level of training (e.g., types of scenarios, frequency of training, or classroom discussions or simulations) for addressing the range of possible fires and potential actions.
- *Suitability of relevant procedures and administrative controls*. Depending on the fire, the operators may need to use other procedures or controls than those typically used in response to accidents not involving fires. This could lead to less familiarity or even confusion with regard to implementing different or multiple procedures simultaneously.
- *Availability and clarity of instrumentation* (*cues to take actions as well as confirm expected plant response*). Fires can introduce multiple spurious events and indications unlike that expected in other accidents not involving fires. This can add confusion with regard to the true plant status and the subsequent actions for operators to take as they sort out what is false from what is actually happening, as well as the need to address unwanted spurious events (e.g., spurious closing of an injection valve). This sorting-out process can, at best, add to the time to perform necessary actions and, at worst, cause the operators to not take appropriate actions at all or perform procedure-directed actions under the wrong circumstances or at the wrong time (e.g., by procedure, shut down an otherwise operable pump because of a spurious high-temperature alarm).
- *Time available and time needed to complete the act*, *including the effect of concurrent and competing activities*. Many of the other PSFs may influence the overall estimate of the time available and needed to complete desirable actions. For example, spurious closure of a valve used in the suction path of many injection paths may need quick detection and response by the crew. Use of less familiar or otherwise different procedure steps and sequencing could change the anticipated timing of actions in response to a fire. Interfacing with the fire brigade may delay performing some actions. The desired actions may be more complex and necessitate an increased workload than for internal events response (e.g., disable an equipment item before repositioning it, as opposed to simply repositioning it during an internal event). Accessibility issues, harsher environments, the need for other special tools, and so on, may also impact the overall timeline of how quickly actions normally addressed in response to internal events can be performed under fire conditions. Furthermore, potential fire growth and suppression could alter equipment failure considerations from those considered for internal events. The timing of important actions needs to be reconsidered with the fire and its effects.
- *Environment in which the act needs to be performed*. Fires can introduce new environmental considerations not normally experienced in the response to internal events. These include heat, smoke, the use of water or other fire-suppression agents or chemicals, toxic gases, and different radiation exposure or contamination levels. Any or all of these may affect the accomplishment of the desired action.

- *Accessibility and operability of equipment to be manipulated*. Fires and their effects (e.g., environment) could eliminate or at least delay the ability to take actions otherwise credited in other types of accidents because the location is inaccessible. Additionally, fires can cause failure of equipment used in the desirable action (e.g., irreversible damage) so that it should be considered inoperable, even manually.
- *The need for special tools* (*keys*, *ladders*, *hoses*, *clothing to enter a radiation area*, etc.). Fires may cause the need for special tools or clothing (e.g., breathing gear, protective clothing) not otherwise considered in response to internal events. The accessibility of these tools or clothing needs to be checked so that the desired actions can indeed be performed in a fire situation. Furthermore, the level of familiarity and training on using these special tools need to be assessed.
- *Communications*. Necessary communications to carry out the desired actions may or may not be available in some fires. This needs to be checked, as does the level of familiarity and training to use any special communication devices.
- *Special fitness needs*. Should the fire and its effects cause the need to consider actions not previously considered under accidents not involving fires, or changes to how previously considered actions are performed, checks should be made to ensure unique fitness needs are not introduced.

Depending on the HRA model selected, performance shaping factors such as the ones listed above are numerically characterized in one form or another in the quantification process.

Representation of Human Error Events in a Quantitative Risk Assessment Finally, human error events usually need to be included in a system model as part of a quantitative risk assessment. To do so, it is necessary to incorporate them in the logic model so that the operation of the system is accurately represented. In very general terms, the human events can be modeled using fault trees and event trees considering the capabilities of each tool. For example, an event tree is probably more appropriate to capture the sequential order of human actions. At the same time, the event tree will only capture dependencies between events by probability point values in the branch lines.

Quantitative Analysis A comparison between the nature of the human actions under analysis and the capabilities of specific HRA methods will ultimately suggest an appropriate method to use. Quantitative HRA methods can be generally classified as simulation models, expert judgment methods, and analytical methods. Simulation models are those that primarily rely on computer methods to mimic human behavior under certain conditions. Expert judgment methods may be necessary where there is little or no useful human error data for supporting a quantitative analysis. Finally, analytical methods generally use a model based on a number of parameters to provide an estimate of human reliability. It should be noted that analytical methods are often used in quantitative risk assessments in the commercial nuclear industry.

Documentation Documentation is particularly important in HRA since a number of technical aspects in the analysis may be on the analysis team judgment. The following aspects of the analysis should be carefully documented: (1) the analysis team, (2) the task analysis including the identified human errors, (3) specification of performance shaping factors, (4) quantification of human error probabilities, (5) representation of human errors in a quantitative risk assessment, and (6) data sources.

HRA Models

HRA methods have evolved over the past 30 years in response to the need to improve the understanding of human performance in the behavioral sciences and to improve human error probability estimates in a quantitative risk assessment. Simple

modeling and quantitative techniques developed more than 25 years ago continue to be used today. At the same time, newer methods try to better incorporate the conditions under which human actions could be performed.

Specifically, there are a number of HRA models available. Swain [34] (p. 306), for example, lists 15 of them. In discussing the limitations of HRA, Swain indicates that there is a "wide disparity in the use of HRA methods." Swain's paper [34] also lists references for the 15 models. Hollnagel [29], for example, describes and discusses some of these methods. Furthermore, NUREG-1842, "Evaluation of Human Reliability Methods Against Good Practices" [35] presents a comparison among some of the available methods and models. Given the status of the technology, describing each model is out of the scope of this section. Instead, this section briefly describes general trends, strengths, and limitations of some of these models.

HRA models can be classified as first or second generation. This classification is not based on the chronological order in which they were developed but in the explicit consideration of the human decision-making process. The first generation of HRA methods consider a safety-related human action to be similar to a component or system that either succeeds or fails in its intended function. In the second generation, methods explicitly incorporate some kind of a model of human cognitive behavior that takes into account advances in behavioral sciences. This is intended to provide a much richer description of the human-system interactions, which considers, among other issues, the context in which the human makes decisions.

Another practical classification is in terms of the model capabilities for qualitative and quantitative analysis. That is, some methods and models have capabilities for identifying human error events and searching for the most relevant human performance factors, and others only address the quantification aspects of the analysis.

There are strengths and limitations in every HRA model. Perhaps the most important limitation is the lack of validation data. Curiously, this is a limitation present in the first generation models that the second generation models did not address. To the contrary, second generation models may need even more data for validation. Nevertheless, HRA practitioners are continuously trying to collect relevant data and improve available methods models to expand the application of human reliability analysis to different fields (such as fire risk assessment) and to generate probabilities that best represent the identified human errors.

System Modeling and Analysis

A system is a collection of items (e.g., subsystems, components, etc.) whose proper coordinated function leads to the proper functioning of the system itself. As mentioned by Vesely [36], the primary objective of system analysis is not to develop a system model but to gain information about it. In system analysis, it is important to model the proper relationship between subsystems and components as well as the reliability or availability of the individual items to determine the reliability or availability of the system as a whole.

Perhaps the first step in developing a system model is to determine its boundaries. System boundaries refer to the number of subsystems to include and the resolution of each subsystem (i.e., which component to include). The determination of system boundaries usually considers economic resources and the level of sophistication the model needs to have in order to support practical applications.

Subsystems or components are not limited to hardware items. They may include software or human actions necessary for the successful operation of the system. Ultimately, the hardware and software elements of the system, as well as the human actions, are represented as probabilities in the overall system model.

There are several system modeling schemes for reliability or availability analysis. Two of the most common ones are the reliability block diagrams and the fault tree. The use of reliability block diagrams is usually appropriate for relatively simple systems. For complex systems,

such as those including numerous interactions between components, those including the role of humans, and common causes failures, the use of fault trees (or other logic models) is usually more appropriate.

Block Diagrams

Reliability block diagrams are frequently used to model the effects of items failing (or functioning) on system performance. The diagrams often correspond to the physical arrangement of the components in the system. Block diagrams can be classified as series, parallel, standby, share loads, or other.

Series Systems In a system consisting of individual components in series, the failure of one component results in the failure of the system. Accordingly, all components in a series system must work for the intended mission of the system in order for it to be operational. Figure 74.26 illustrates a system with two components in series.

The reliability function for a system of n units in series is the multiplication of the reliability of the individual units. This is expressed as

$$R_s(t) = \prod_{i=1}^{n} R_i(t) \qquad (74.70)$$

where R_i is the reliability of the ith unit. The hazard rate of the system is

$$h_s(t) = \sum_{i=1}^{n} h_i(t)$$

or in the case of a constant failure rate $\lambda_s = \sum_{i=1}^{n} \lambda_i$

Consequently, for the case of the exponential distribution,

$$R_s(t) = \exp\left(-\sum_{i=1}^{n} \lambda_i\right) \cdot t, \text{ and the}$$

$$\text{MTTF}_s(t) = \frac{1}{\lambda_s}$$

Parallel Systems A reliability block diagram is in parallel configuration (Fig. 74.27) if the failure of one of all units in the system results in the system failure. Accordingly, success of only one unit would be sufficient to guarantee the success of the system.

According to the definition of a parallel system, failure of all units results in the failure of the system. Therefore, for a set of n items in parallel,

$$R_s(t) = 1 - \prod_{i=1}^{n} [1 - R_i(t)] \qquad (74.71)$$

Analytical expressions for the hazard rate and MTTF of the systems are rather complex. However, these values can be found numerically from Equations 74.3 and 74.22 presented earlier in the chapter. In general, the design of an active parallel system results in an MTTF exceeding that of an individual unit. However, the contribution from the second unit, the third unit, and so on would have a diminishing return as the number of units in parallel increases. Notice that there would be an optimum number of units in the system for which the designer would balance cost and reliability in its life cycle.

A more general form of a series and parallel system is the so-called k-out-of-N system. In this type of system, if any combination of k-out-of-N independently working units are operational, it guarantees the success of the system. Assuming that all units are identical, the reliability of the

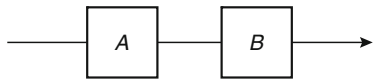

Fig. 74.26 Reliability block diagram for two components in series

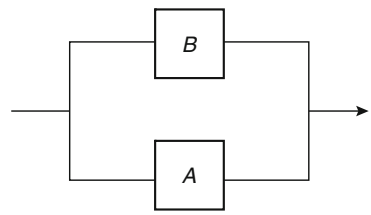

Fig. 74.27 Reliability block diagram for two components in parallel

k-out-of-N system can be represented using the binomial distribution as follows:

$$R(t) = \sum_{r=K}^{n} \binom{n}{r} [R(t)]^r [-R(t)]^{n-r}$$
$$= 1 - \sum_{r=0}^{k-1} \binom{n}{r} [R(t)]^r [-R(t)]^{n-r}$$

Standby Systems In a standby system, some of its units remain idle until they are called for service by a sensing and switching device. The idle unit operates when the failure of the primary unit is detected. Clearly, the reliability of the system should include considerations for the primary and standby units, as well as for the sensing and switching device.

According to the foregoing definition, the mathematical function for the reliability of the standby system shown in Fig. 74.28 can be expressed as

$$R_s(t) = R_A(t) + R_{ss}(t_1) \cdot R'_B(t_1) \cdot R_B(t - t_1) \cdot \int_0^t f_A(t_1) dt_1 \qquad (74.72)$$

where $f_A(t)$ is the probability distribution function for the time to failure of unit A, $R_{ss}(t_1)$ is the reliability of the sensing and switching device, $R'_B(t_1)$ is the reliability of unit B in the standby mode, and $R_B(t - t_1)$ is the reliability of unit B after it started to operate at time t_1. As for the case of the parallel system, the hazard rate and MTTF values can be found numerically from Equations 74.3 and 74.22 presented earlier in the chapter.

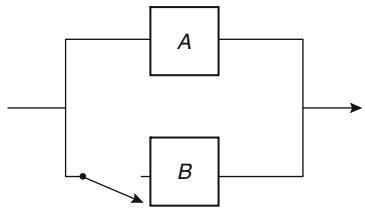

Fig. 74.28 Reliability block diagram for two-component standby system

Share Load Systems A share load system refers to a parallel system whose units equally share the system function. Consider as an example the case of a set of two parallel pumps delivering x gpm of water to a fire protection system. Each pump delivers $x/2$ gpm. If one of the pumps fails, then the second pump must provide the total amount of water. For a share load system to work, both units have to supply $x/2$ gpm, or in the case either unit fails, the operating unit must supply x gpm. Accordingly, the mathematical expression is

$$R_s(t) = [R_h(t)]^2 + 2 \cdot \int_0^t f_h(t_1) R_h(t_1) R_h(t - t_1) dt_1 \qquad (74.73)$$

The first term in the right-hand side represents the contribution of both units working successfully with each carrying a half load. The second term represents the two equal probabilities that unit 1 fails first and unit 2 takes the full load at time t_1, or vice versa. If there are switching mechanisms involved in the shift from a half to a full load, its reliability should also be incorporated in the equation. As for the case of the parallel system, the hazard rate and MTTF values can be found numerically from Equations 74.3 and 74.22 presented earlier in the chapter.

Other Systems There are systems that are not in series or parallel. In fact, most practical systems are not in parallel or series but exhibit some hybrid combination of the two. For those systems with combinations of series and parallel subsystems (series-parallel systems), each subsystem can be reduced to an equivalent component with R_s given by the equations listed previously for series or parallel systems, respectively. Eventually, the reliability function for the entire system can be developed by a systematic combination of the reliability functions for series or parallel subsystems. A conceptual example of such a system is presented in Fig. 74.29. Notice that there is a group of three units in series and another group of three units in parallel. Representing the reliability of the parallel group

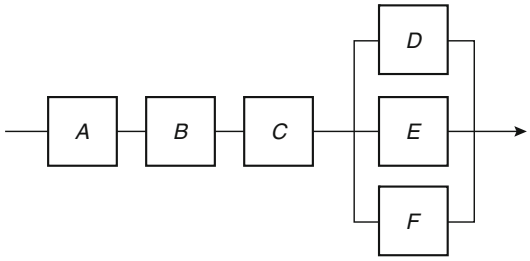

Fig. 74.29 Reliability block diagram for system with series parallel groups

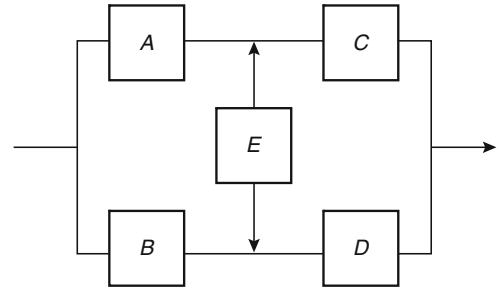

Fig. 74.30 Reliability block diagram for system not having units in series or in parallel

with an equivalent reliability function using Equation 74.71 results in a system of four units in series.

In the case of systems with units that are not in series or parallel, other analytical methods must be used for developing the reliability function. A conceptual example of such a system is presented in Fig. 74.30. Notice that the individual units are not in series or in parallel.

Depending on the number of units in the system, methods for calculating reliability can become computationally intensive, often requiring the use of a computer and software with capabilities for developing and analyzing system models.

Cut Sets and Path Sets Cut sets and path sets are computationally intensive methods of determining the reliability of systems. As suggested in the previous section, the method can be applied by hand if the number of units in the system is relatively small. At the same time, as the number of units in the system increases, the use of a computer becomes necessary. Path sets are a group of units that connect the input and output of a system when traversed in the direction of the arrows in the reliability block diagram. Therefore, a path set is actually a path through the diagram. A minimal path set is a path set that would not provide a connection between input and output if any of the units fail or were removed. For example, the minimal path sets in Fig. 74.30 are (*A*-*C*), (*B*-*D*), (*A*-*E*-*D*), and (*A*-*E*-*B*). If at least one of the items in each path set is removed, there would be no path from input to output.

If a system has n minimal path sets, denoted as $P_1, P_2 \ldots P_n$, the reliability can be expressed as follows:

$$R_s(t) = Pr(P_1 \cup P_2 \cup \ldots \cup P_n) \qquad (74.74)$$

where each path set P_i represents the event that units in path set i work. That is, the system will be operational as long as at least one of the path sets is operational. Notice, however, that in many cases, the P_i's are not mutually exclusive, which complicates the calculation of the system reliability. Assuming mutually exclusive path sets, Equation 74.74 offers an upper bound of the system reliability:

$$R_s(t) \leq Pr(P_1) + Pr(P_2) + \ldots + Pr(P_n) \qquad (74.75)$$

It should be stressed that the assumption of mutually exclusive path sets is a limitation in the use of the equation. The equation may provide useful answers when used with small reliability values and is usually not a good bound for practical applications.

A cut set is a set of units that interrupts all possible connections between input and output points. A minimal cut set is the smallest set of units needed to guarantee an interruption of the flow. In the case of Fig. 74.30, the cut sets are (*A*-*B*), (*C*-*D*), (*C*-*E*-*D*), (*A*-*E*-*B*), (*B*-*E*-*C*), and (*A*-*E*-*D*). The system reliability can be also calculated using the cut sets as follows:

$$R_s(t) = 1 - Pr(C_1 \cup C_2 \cup \ldots \cup C_n) \quad (74.76)$$

where C_n represents the event that units in the cut set fail sometime before the mission time. The probability term on the right-hand side represents the probability that at least one of the minimal cut sets exists before time t. Thus, the reliability is obtained by subtracting this term from 1.0. Since the cut sets are not usually mutually exclusive, Equation 74.76 provides the following lower bound for reliability:

$$R_s(t) \geq 1 - [Pr(C_1) + pr(C_2) + \ldots + Pr(C_n)] \quad (74.77)$$

This bounding technique yields a much better representation of the reliability because most engineering units have reliabilities much greater than 0.9 over the mission time, making the use of Equation 74.77 appropriate.

Fault Trees

The most popular logic model is the fault tree. A fault tree is a graphic model of the various parallel and sequential combinations of faults that will result in the occurrence of the predefined, undesired event. The faults can be events that are associated with component hardware failures, human errors, or any other pertinent event, which can lead to an undesired event [36]. Fault trees are very powerful as a qualitative analysis tool but can be quantified. In reliability engineering, this quantification results in the calculation of the probability of failure of the system captured in the fault tree logic.

A fault tree is not a model of all possible system failures or all possible causes for system failures. Instead, a fault tree is developed based on a top event and, thus, includes those failures contributing to the top event only. The events are connected with gates that provide the logic interactions between the events. Tables 74.11 and 74.12 list the most common event and gate symbols used in fault trees and the corresponding description [36].

It is important to stress also that fault trees do not capture the dynamic interactions of the different events. Dynamic interactions are changes in the system as a function of time or other physical parameters such as temperature, humidity, and so on.

Example 9 An automatic CO_2 fire suppression system (total flooding) provides protection to a relatively small cable room in a commercial power plant. The CO_2 system includes the following components:

- A detection system consisting of a panel, two heat detection devices, and an alarm
- One CO_2 storage tank that has an actuator valve connected to the panel and a cylinder valve
- One discharge nozzle
- One manual pull station

The detection system is connected to a power supply and has a backup battery. Upon a detection signal, the alarm sounds and after a 60-s delay, the actuator valve operates releasing the CO_2 into the room. The manual pull station can be used to release the CO_2 any time. The manual actuation will also trigger the alarm and the 60-s delay time. It is assumed that the system will suppress the fire if the CO_2 is released at the proper concentration and that the concentration is maintained for a predefined period of time.

Develop a fault tree for the top event "CO_2 suppression system fails to suppress fire in the cable room before damage occurs." In this case, damage refers to any postulated scenario consequence.

Solution The event tree is depicted in Figs. 74.31 and 74.32. Notice that Fig. 74.32 is a continuation of the main fault tree in Fig. 74.31. The continuation node is represented by a triangle. The top event is "CO_2 suppression system fails to suppress the fire before damage occurs," assuming a fire in the cable room, failure of the CO_2 system if the fire is not detected, or the fire is not suppressed. These two events are connected with an OR gate to the top event.

The event "failure to detect the fire" is further developed in the events "failure of the automatic

Table 74.11 Summary of typical events in fault trees

Events	Symbol	Description
Basic event		A basic initiating fault requiring no further development
Conditioning event		Specific conditions or restrictions that apply to any logic gate (used for priority AND and INHIBIT)
Undeveloped event		An event that is not further developed either because it is of insufficient consequences or because information is unavailable
External event		An event that is normally expected to occur
Intermediate event		A fault event that occurs because of one or more antecedent causes acting through logic gates

Table 74.12 Summary of typical gates used in fault trees

Events	Symbol	Description
AND		Output fault occurs if all the input faults occur
OR		Output fault occurs if at least one of the input faults occurs
Exclusive OR		Output fault occurs if exactly one of the input faults occurs
Priority AND		Output fault occurs if all the input faults occur in a specific sequence (as described by the conditioning event)
INHIBIT		Output fault occurs if the single input fault occurs in the presence of an enabling condition (as described in the conditioning event)

detection system" and "failures of any other means of detection." The latter event is intended to account for detection means such as personnel detecting the fire. The failure of the automatic heat detection system is also further developed to consider failure of the detection devices or the panel. Failure of the detection devices can occur due to failures of the detectors, or a fire not large enough to be detected before damage. Notice that there is an element of time, "before damage," that is not explicitly captured in the fault tree. Failure of the panel can occur due to failures in the primary and backup systems or other panel failure.

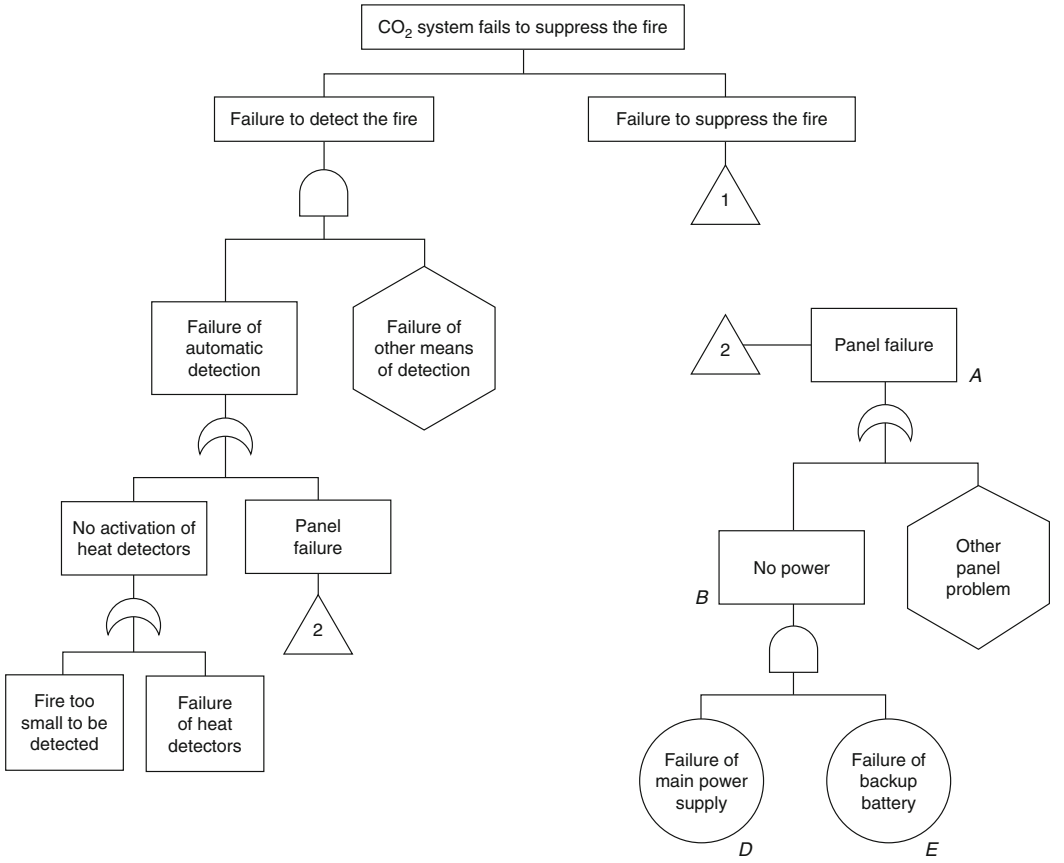

Fig. 74.31 Fault tree for Example 9

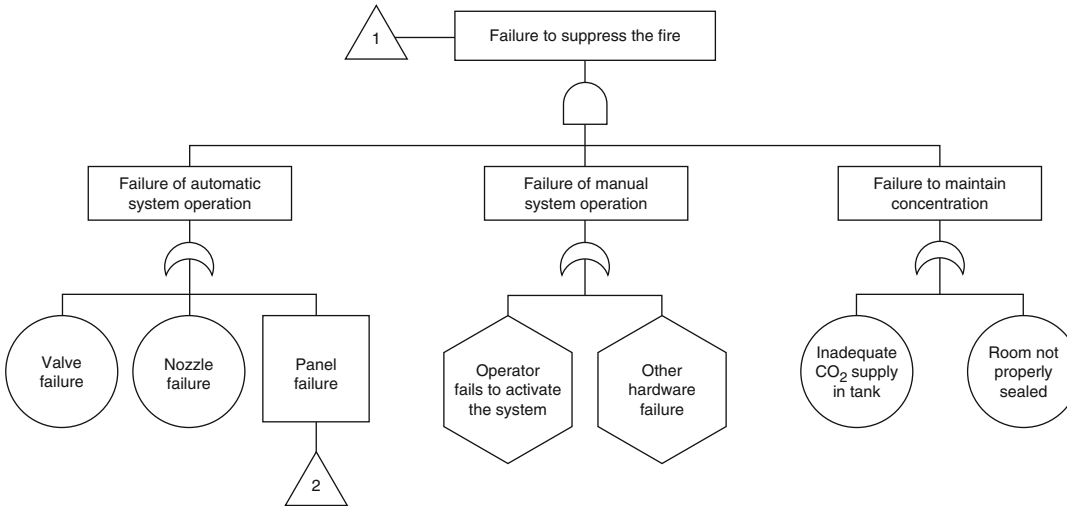

Fig. 74.32 Fault tree for Example 9

In terms of failure of the suppression system, the event tree considers failures of the automatic system, failure of a manual activation of the system, or failure to maintain CO_2 concentration in the room. Notice again the element of time that is not explicitly captured in the fault tree. That is, failure to automatically or manually activate the system can include cases in which the activation worked, but it was activated too late to prevent any fire damage. These three events are further developed to consider hardware failures, room leakages, and manual actions.

Fault Tree Quantification

The quantification of fault trees, which refers to the probability of the top event, given the logic relationships and the probabilities of the basic events, can be solved by hand or using computer programs. In practice, a solution by hand is usually time consuming and limited only to relatively small trees. Fault trees for most complex systems would need to be quantified using a computer.

In solving fault trees by hand, the use of the rare event approximation and Boolean algebra are necessary. In the rare event approximation, the term $Pr(A \cap B)$ in $Pr(A \cup B) = Pr(A) + Pr(B) - Pr(A \cap B)$is assumed to be a very small contributor and, therefore, is neglected. For example, if $Pr(A) = Pr(B) = 0.1$, then $Pr(A)Pr(B) = 0.01$, which is an order of magnitude less. The rare event approximation provides an upper bound that is reasonable if the probabilities of the individual events are small. Once the fault tree has been developed, the quantification process consists of the following steps:

1. Determine the probability or frequency of the basic events. These probabilities or frequencies are the input parameters for the analysis.
2. Starting from the top, write the Boolean expression for each level of the fault tree.
3. Combine the Boolean expressions for the different levels.
4. The resulting cut set combination can be used for determining the probability or frequency of the top event using Equation 74.77.

Example 10 Using the subtree 2 in Example 2, determine the reliability of the panel. For simplicity, the events in the fault tree have been labeled with letters A to E.

Solution Let us follow the four steps listed previously in order to solve this example. The first step is to determine probabilities of the basic events. In this case, the fault tree has two basic events and one undeveloped event at the lowest level. Let us assume the probabilities for the basic events are $D = P_1$ and $E = P_2$ and for the undeveloped event is $C = P_3$.

The second step is to write a Boolean expression for each fault tree level. Starting from the top,

$A = B + C$, notice the use of the rare event approximation

$B = D \cdot E$

The third step is to combine the Boolean expressions. Accordingly,

$$A = D \text{ñ} E + C$$

Finally, the foregoing expression suggests the cut sets of the tree. There are two cut sets, C and DE. These cut sets are easy to identify even by visual inspection of the fault tree. From Equation 74.77, the reliability of the panel is

$$\begin{aligned} R &\approx 1 - [Pr(C_1) + Pr(C_2) + \ldots + Pr(C_n)] \\ &\approx 1 - [Pr(D) \cdot Pr(E) + Pr(C)] \\ R &\approx 1 - [P_D \cdot P_E + P_C] \end{aligned}$$

Dependent and Common Cause Failures

Dependent failures are events in which the probability of each failure is dependent on the occurrence of other failures. For simplicity, let us assume that the failures of items A and B are dependent. The probability of failure of the two items can be expressed as

$$P(AB) \neq P(A) \text{ñ} P(B)$$

where in general $P(AB)$ is greater than $P(A)P(B)$. That is, the probability of failure of the two items is usually, but not always, greater than the failure of the two items assuming independence. Mosleh

et al. [37] classifies dependencies as intrinsic and extrinsic. Intrinsic dependencies are those in which the functional status of a component is affected by the functional status of another. These dependencies are usually due to the physical configuration of the component. Some examples may include dependencies such as "B is not needed when *A* works." Extrinsic dependencies are those in which the dependency is due to external factors not considered in the designed functional characteristics of the system. Examples of extrinsic dependencies may include environmental factors and human interactions (maintenance activities, etc.). Notice that fire-generated conditions can be considered an extrinsic dependency.

Intrinsic dependencies are usually explicitly captured in logic system models such as fault trees. At the same time, extrinsic dependencies are often not included in such models. The term *common cause failures* (CCF) is intended to capture those dependencies, for the most part extrinsic, that are not known or are difficult to explicitly include in a system model. Mosleh et al. [33] defines CCF as ". . . a subset of dependent events in which two or more component fault states exist at the same time, or in a short time interval, and are direct results of a shared cause." According to Modarres [5], CCFs have been shown by many reliability studies to contribute significantly to the overall unavailability or unreliability of complex systems.

Mosleh et al. [37] suggest that CCFs are due to a particular root cause and a coupling factor. The coupling factor makes the root cause of the failure common to all the dependent components. Coupling factors are classified as hardware based, operation based, and environment based [37]. Examples of hardware-based coupling factors include the same component internal parts and the same maintenance/test/calibration characteristics. In terms of operation-based coupling factors, examples include the same operating staff, procedures, or schedules. Finally, environment-based coupling factors refer to similar location.

As a conceptual example, consider a scenario involving a fire damaging control cables for two motor-operated valves. In a particular room, the cables are routed in different cable trays in the same stack. The root cause of the valve control system failure is the actual failure of the control cables. The coupling factor is location. Since the cables are in the same room and cable tray stack, fire conditions affect both cables at the same time.

Modeling Common Cause Failures

Modeling common cause failures in fault trees have the potential of increasing the size of the tree considerably. Typically, the process involves screening steps for determining which common cause groups impact the overall reliability of the system. Mosleh et al. [37] describes both qualitative and quantitative screening steps.

The actual modification of a fault tree to include common cause failure is best described considering the basic events of a fault tree as illustrated in Fig. 74.33a. In this example, the system fails if any of the three basic components fails. Figure 74.33b depicts an expanded fault tree considering common cause failures. Each basic event in Fig. 74.33a is further developed in four basic events in Fig. 74.33b (the only development of event *B* fails is presented). The four basic events are (1) "*B* fails," which refers to the independent failure of component *B*, (2) components *A* and *B* fail due to common cause, (3) components *B* and *C* fail due to common cause, and (4) components *A*, *B*, and *C* fail due to common cause.

The Boolean representation of the total failure of the components is $F(B) = F(B) + F(AB) + F(BC) + F(ABC)$. Similar expressions can be written for components *A* and *C*. The cut sets for the tree are $(A_i \cdot B_i \cdot C_i)$, $(A_i \cdot BC)$, $(B_i \cdot AC)$, $(C_i \cdot AB)$, and (ABC). The subscript *i* refers to the independent failure of the component. That is, the first cut set is the independent failure of the three components. The second cut set is the independent failure of component *A* and failure of components *B* and *C* due to common cause. The

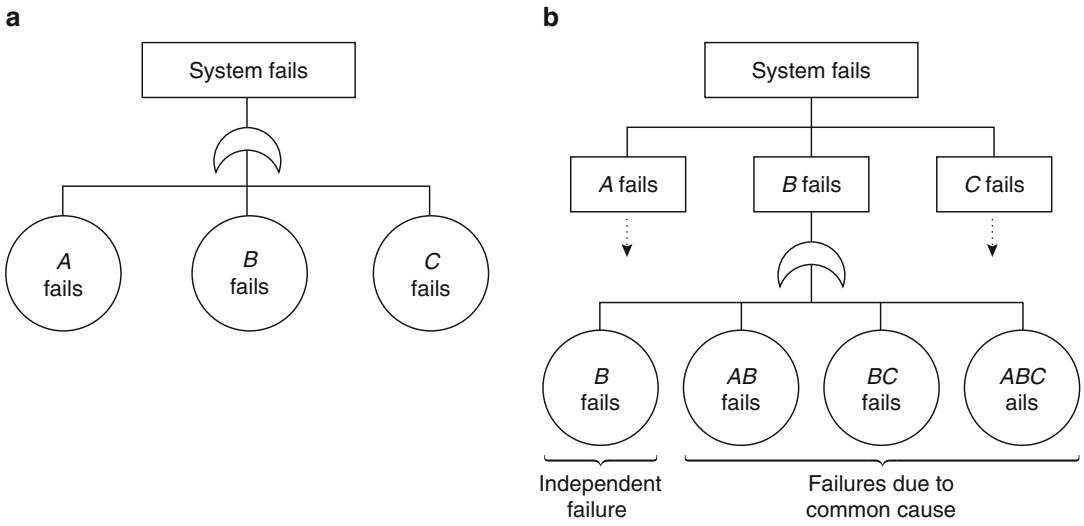

Fig. 74.33 Pictorial representation of a fault tree considering common cause failures

last cut set is the failure of the three components due to common cause. At this point, readers should appreciate how considerations for common cause failures can significantly increase the size of the logic models. If common cause failures are not considered, only the first cut set would be necessary. Applying the rare event approximation,

$$Q_s = Pr(A_i) \cdot Pr(B_i) \cdot Pr(C_i) + Pr(A_i) \cdot Pr(BC) + Pr(B_i) \cdot Pr(AC) + Pr(C_i) \cdot Pr(AB) + Pr(ABC)$$

Assuming components A, B, and C are identical,

$$Q_1 = Pr(A_i) = Pr(B_i) = Pr(C_i)$$
$$Q_2 = Pr(BC) = Pr(AC) = Pr(AB)$$
$$Q_3 = Pr(ABC), \text{ and}$$
$$Q_s = Q_1^3 + 3 \cdot Q_1 \cdot Q_2 + Q_3$$

Mosleh et al. [37] recommend the representation of the Q_k values with quantifiable parameters for practical purposes. One of the most common models is the alpha factor (α-factor) model. The α-factor model develops common cause frequencies from a set of failure ratios and the total component failure rate Q_T . In very general terms, $Q_k = \alpha Q_T$,, where Q_T represents total frequency including independent and common cause events, and α is the fraction of the total frequency involving the failure of k events. The description of the specific details of this model (or other parametric models for CCF) is out of the scope of this chapter.

Summary

This chapter summarizes reliability engineering topics relevant to fire protection engineers. In most cases, reliability engineering offers statistical models that can be used by fire protection practitioners in support of their day-to-day activities. Examples of such activities may include improving maintenance practices for fire protection systems, developing fire risk assessments, identifying failure modes of a fire protection system, improving the reliability and availability of a particular fire protection system design, improving operator procedures, and so on.

Most of the statistical models require the collection of data for calculating relevant parameters. In some applications, the data

collection process can be a challenging task. However, even with limited data or values based on expert judgment assessments, the statistical models described in this chapter can be used for obtaining a better understanding of failure modes and failure likelihoods of systems and components through time. Such an understanding usually provides insights on how to better manage or improve the reliability and availability of fire protection systems, components, and procedures.

Nomenclature

A	Availability
A	Empirical variable (in Arrhenius life-time relationship)
C_i	Cut set i
d	Downtime in availability analysis
E	Activation energy (in Arrhenius life-time relationship)
$E(t)$	Expected value of variable t
$f(t)$	Probability distribution function for random variable t
$F(t)$	Cumulative distribution function for random variable t
fr	Frequency of repair per test interval (in availability analysis)
$g(t)$	Probability distribution for the repair time
$h(t)$	Hazard rate of variable t
I	Unit vector (in Markov analysis)
k	Normalizing factor in Bayesian analysis
k	Number of events in Poisson probability distribution
k	Stefan Boltzman constant (in Arrhenius life-time relationship)
L	Vector of initial state conditions (in Markov analysis)
$L(t,\theta)$	Likelihood function for parameters t and θ.
L_i	State i (in Markov analysis)
MTTF	Mean time to failure
MTTR	Mean time to repair
N, n	Counter variable usually for number of failures
P_i	Path set i
$R(t)$	Reliability as a function of time
$R(t)$	Reliability function
S	Stress variable (in inverse power law relationship)
S, s	Stress variable or random variable for stress (stress and strength analysis)
sf	Probabilistic safety factor
s_m	Probabilistic safety margin
T	Test interval (in availability analysis)
T	Transition matrix (in Markov analysis)
T	Absolute temperature (in Arrhenius life-time relationship)
T, t	Time variable or random variable for time
T_m	Mission time length (in availability analysis)
To	Uptime (in availability analysis)
T_R	Average repair time (in availability analysis)
T_t	Average test duration (in availability analysis)
u	Laplace or centroid trend indicator (for Laplace or centroid test)
U	Uptime in availability analysis
U	Unavailability
$V(t)$	Variance of variable t
$W(t)$	Expected number of failures as a function of time
X	Vector to be solved for (in Markov analysis)
X, x	Strength variable or random variable for strength (stress and strength analysis)

Greek Letters

α	Weibull distribution location parameter
$\alpha(t)$	Availability as a function of time
β	Weibull distribution shape parameter
λ	Constant failure rate and exponential distribution parameter

μ	Normal distribution mean
ν	Degrees of freedom in chi square distribution
$\pi(\lambda)$	Posterior distribution in Bayesian analysis
$\pi_o(\lambda)$	Prior distribution of variable l in Bayesian analysis
σ	Normal distribution standard deviation

Building Fire Risk Analysis

75

Brian J. Meacham, David Charters, Peter Johnson, and Matthew Salisbury

Introduction

The aim of building fire risk analysis is to gain insight into and characterize fire-related risks to better inform the wide range of decisions that must be made as part of building design, construction, and operation. As used in this chapter, risk is defined as the possibility of an unwanted outcome in an uncertain situation, where the possibility of the unwanted outcome is a function of three factors: loss of or harm to something that is valued, the event or hazard that may occasion the loss or harm, and a judgment about the likelihood that the loss or harm will occur [1]. Specifically, fire risk is the possibility of an unwanted outcome in an uncertain situation, where fire is the hazard that may induce the loss or harm to that which is valued (e.g., life, property, business continuity, heritage, the environment, or some combination of these). Building fire risk analysis, then, is the process of understanding and characterizing the fire hazard(s) in a building, the unwanted outcomes (relevant losses or harm) that may result from a fire, and the likelihood of fire and unwanted outcomes occurring.

Building fire risk analysis must consider several factors. Some of these factors are familiar to fire protection engineers and some perhaps are not. For example, building fire risk analysis should consider (1) what the fire hazards are and how fires might occur; (2) how the unwanted outcomes (consequences) are valued and by whom (including offsetting benefits); (3) what differences in risk perception and valuation exist and how they should be treated (i.e., should high-consequence events be disregarded if the probability of occurrence is very low); (4) if there are any social or cultural issues that may be relevant; (5) if there are different stakeholder views on the likelihood of fire occurrence and of the resulting consequences; and (6) whether uncertainty, variability, and unknowns have been identified and appropriately addressed.

Evaluation of fire hazards is something that many (or generally) fire protection engineers do well, and for which numerous tools and methods exist (e.g., this handbook). The valuation of consequences, however, requires data, tools, and methods that differ from those used for fire hazard assessment. Valuation of consequences requires consideration of physical, economic, health, environmental, social, cultural, and psychological factors. In valuing life safety consequences, for example, many engineers consider only injury and loss of life to an individual. However, there are also such factors as reduced quality of life, the inability to continue to work, and the impact on family relationships. On property protection, factors such as smoke and water damage should be considered, in addition to thermal damage. On business continuity, there are long-term issues, such as loss of image and market share, in addition to the short-term monetary losses associated with downtime.

Much like the valuation of consequences, the issue of determining the likelihood of fire occurrence and of resulting consequences requires data, tools, and methods not typically used by fire protection engineers. In addition, there are two approaches to the concept of probability (likelihood): the frequentist approach and the subjectivist approach [1, 2]. In brief, the frequentist approach comes from classical statistics, which considers probability to be a property of a process that is ideally determined from an infinite population of data. It considers probability to be a measured value and that information needed to estimate it can come mainly from observing the process. (For example, one can determine the probability of a coin landing with "heads" up or "tails" up only by flipping the coin an "infinite" number of times.) The subjectivist view, however, holds that probability has a value at any time that represents the total available knowledge about the process at that particular time. (For example, one can look at a coin having a "head" and a "tail," assess whether it is well balanced, observe a single coin toss, and estimate the probability of getting a "head" or a "tail" if one flips the coin again.) In practice, the main difference in approach is often one of how nonstatistical information is treated in the risk analysis. The frequentist approach attempts to keep the statistical values unaltered in the analysis, while commenting on limitations and bias so that they can be considered in the overall evaluation of the risk at the end of the process. The subjective approach attempts to generate numerical values using nonstatistical information and integrate them directly into the risk calculation.

Regardless of the difference in approach, the availability of information to determine probabilities is critical, as is the applicability of the probability information to the problem at hand. For example, (1) what data are available (e.g., how many fire ignitions have there been in office buildings in the past 10 years that did not result in significant fire damage?); (2) how applicable are historical data as an indicator of future events (e.g., were fire loss data from cellulosic materials prior to 1960 an appropriate indicator of fire losses involving synthetic materials after 1960?); and (3) how might changes to the building or its contents in the future impact the likelihood of fire occurrence and/or magnitude and type of consequences?

It is difficult to provide comprehensive guidance on what obstacles one should look out for when using fire safety data for fire risk analysis. However, some simple questions can be used to assess the suitability of data for fire risk analysis. Suggested key points for reviewing data include

- What is the set of cases that the data are drawn from?
- What scenarios are the data measuring?
- How similar is the building being analyzed to the cases being considered?
- Especially if the data are from another country, how do definitions, thresholds, and other design and collection rules and practices affect the relevance to the building being analyzed?

Other considerations include

- How old are the data (are they still applicable, given changes that may have occurred since the data were obtained)?
- Are corroborative data available?
- Are the data from statistical studies or based on engineering judgment?

When reviewing the results of the analysis, consideration should include

- Do the answers look realistic when compared to historical data for similar events?
- How sensitive are the results to data?

The above points to a critical factor in building fire risk analysis: there will be uncertainty, variability, and unknowns in any risk problem. How these factors are identified and addressed will be critical to the risk analysis, especially with respect to the stakeholders involved in passing judgment on the "acceptability" of the risk. Should point values be used or are distributions preferable? How is the variability in parameters such as building occupant health and ability addressed in the analysis? These are just a few items that must be addressed.

Building fire risk analysis is one of the main ways of assessing uncertainty, sensitivity, and variability in unknowns in fire protection engineering; for example, will a particular system

operate in a fire, and what are the potential consequences and risk implications of system failure? Building fire risk analysis requires evaluation of the likelihood of fires occurring and the consequences that may result. Developing these evaluations requires significant information from numerous sources, including objective data (e.g., historical fire loss data), subjective judgment, and input from interested and affected stakeholders. To help the diverse stakeholders involved in building fire risk analysis better understand how each views each building fire risk problem, and to address the preceding issues, an understanding of risk characterization is needed.

Building Fire Risk Characterization

Risk characterization requires a well-defined problem that those involved agree with, a sound scientific base, the proper use of analytical techniques with proper consideration of uncertainties and unknowns, and sufficient discussion and deliberation so that everyone understands all of the issues [3]. The risk characterization process will likely require several iterations as new information and data become available and as participants gain better understanding and raise more issues. It should be an inclusive, informed, consensus-building process, and not one where one person or group dominates the deliberations and/or analysis and forces a solution.

To help characterize building fire risks, a number of questions need to be asked: [1, 3–6]

1. Who or what is exposed?
2. If it is people, what groups are exposed?
3. What is posing the risk?
4. What is the nature of the harm or loss?
5. What qualities of the hazard might affect judgments about the risk (e.g., voluntary/involuntary, known/unknown, etc.)?
6. Where is the hazard experience?
7. Where and how do hazards overlap?
8. How adequate are the databases on the risks?
9. How much scientific consensus exists about how to analyze the risks?
10. How much scientific consensus is there likely to be about risk estimates? How much consensus is there among the affected parties about the nature of the risk?
11. Are there omissions from the analysis that are important for decisions?

Various tools and methods exist to help obtain needed information for building fire risk characterization. Several of these are outlined in the following section. Detailed discussion on the above questions can be found in the literature [1, 4–6].

Methods for Gathering Building Fire Risk Information

To help obtain the necessary information regarding what is valued and how, the likely impacts of fire and fire effects, how particular fire hazard conditions may occur, and the likelihood of losses occurring, several tools, methods, and approaches are available. This section provides a brief overview of various tools, methods, and approaches available to fire protection engineers for the purpose of gathering needed information. This section does not constitute a comprehensive review, and readers are urged to consult the fire and risk literature for more tools, methods, and approaches and for more details on the approaches discussed herein.

As part of a risk analysis, one should identify what is of value, assess the hazards that may result in harm or loss to that which is valued, and make an estimate regarding the likelihood of the loss occurring. In building fire risk analysis, life safety, property protection, business continuity, the environment, and/or heritage are the value foci. To determine how they are valued and the associated levels of unacceptable impact (damage, injury, or failure), consequence analysis is used. To determine the extent of exposure from potential hazard situations, fire hazard assessments are undertaken. To complete the risk analysis, evaluation of the likelihood of hazard events occurring and their levels of impact that result in unacceptable or intolerable levels of risk is required.

Consequence Analysis

To determine how a hazard may occasion loss or harm to that which is valued, some form of consequence analysis is required. Consequence analysis, a key component of risk characterization, is concerned with determining the potential impacts of a hazard event without consideration of the likelihood of the consequences occurring. Consequence analysis is more difficult than hazard assessment, in that it may not always be clear in what ways and to what extent something is valued and how the loss should be characterized. For life safety, the line may be drawn simply between life and death, or may be extended to cover quality of life, pain and suffering, and/or rehabilitation after a fire-induced injury. For property protection, it may not always be clear to the interested and affected parties where, how, and how much damage may occur. Some may not realize that code compliance, for example, can be significantly different than protecting their building, process, contents, or other assets of value. The issues can get even more complex for assessing potential business continuity impacts and damage to historically important buildings or contents. Nonetheless, such differences are important for characterizing risks, determining tolerable impacts, and selecting acceptance (damage, failure) criteria, and are why interested and affected parties must be involved in the process.

The nature of consequence analysis will vary based on the risk problem, with the issues of what is valued and how it is valued being two central foci. Determination of what is valued and how it is valued may require facility surveys, research into the impact of fire effects on that which is valued, an understanding of the state of knowledge for assessing impacts on that which is valued, and discussions with a wide variety of interested and affected parties. Uncertainty, variability, and unknowns will be key factors in many consequence analyses, especially as related to such factors as available data, randomness in affected populations, selection of acceptance criteria, selection of methods for assessing the impacts, and values of the affected and interested parties. (See Chap. 76 for discussion on uncertainty, variability, and unknowns.)

In the taxonomy of performance-based fire safety design, consequence analysis is often described in terms of establishing fire safety goals, objectives, and criteria; and tools, methods, and approaches to determining fire safety performance can be found in pertinent references [7–10]. Although such documents contain some guidance on selecting acceptance (performance) criteria, there is often a need to refer to more specific resources for details on particular physiological thresholds, material failure points, and related impact-related criteria (e.g., see pertinent chapters in this handbook). For monetary valuation equivalents, guidance can be found elsewhere in this handbook (see Chap. 79 by Ramachandran and Hall) as well as in the general risk literature [11–13]. It is worth noting, however, that valuation in terms of monetary worth can be difficult to achieve. This is especially true for life safety, where identifying a value for human life can be difficult (if not impossible) and sometimes controversial [14–21]. Discussions on monetary valuation for the purpose of insurance/no-insurance trade-offs can also be found in the literature [22, 23].

One way of potentially addressing this controversy is to try to quantify the risk/cost effectiveness of alternative life safety solutions in terms of "cost per life saved," "cost of premature death averted," or similar approach. By using such approaches, risk/cost effectiveness can be compared without placing a value on human life. See Chap. 81 for discussion on benefit-cost analysis and related monetary valuation issues.

Hazard Assessment

The purpose of a fire hazard assessment is to identify possible sources of fire ignition and various conditions that may result from the fire without consideration of the likelihood of occurrence. Fire hazard assessments typically involve surveys of facilities or processes to obtain such information as potential ignition sources, potential fuel sources, arrangement of fuel packages,

building and compartment configurations, and presence of fire safety features. Armed with this information, one either assumes ignition or established burning and estimates or predicts the fire growth, spread, and impact under a variety of fuel, compartment, and fire protection systems configurations. Identification of ignition sources requires knowledge of how ignition can occur (see Chap. 18 in this handbook) and often involves simply a visual survey. However, visual inspections may be supplemented by general or facility-specific loss data, material hazard data sheets, and other sources of information as appropriate. This latter point is important, as a review of historical loss data can help minimize the chance of focusing too closely on unique hazards, while overlooking more common, but equally important, hazards.

There are a number of tools and methods available to the fire protection engineer for the purpose of fire hazard assessment. Checklists are often used as a quick method to verify compliance with codes, standards, or recommended practices. They can be as simple or as detailed as needed, and can provide a good foundation for inexperienced persons to gain an understanding of potential hazards by making them focus on areas of concern. They can be used during design, as part of an approval process, and/or as part of an inspection and maintenance program. A potential downside is that too much focus on the checklist can lead to other hazards or potentially hazardous conditions being ignored. In addition, the user, if inexperienced, may not understand the relative importance of one item on the checklist over another, or how the hazard condition could manifest itself.

Safety reviews are typically performed for existing facilities and involve regularly scheduled visual inspections [24]. The primary purpose is to identify conditions or procedures that could lead to accidents (initiating events), illness, injury, or damage (consequences). As with a checklist, the scope of the review can be as simple or complex as deemed necessary. It may be simply a walk-through or may require review of material safety data sheets (MSDSs), testing of systems, or other safety-related functions. Checklists and a routine schedule are often helpful components of a safety review.

A "what if" analysis is primarily a conceptual divergent thinking process used to help identify areas of concern for use in checklists, safety reviews, and the following tools and methods [24]. It involves people asking "what if" about potential situations or scenarios that could arise, such as "what if the pump fails?" or "what if the operator mistakenly activates switch A instead of switch B?" "What if" analysis is typically informal and is used as a basis for initiating more detailed analyses.

Checklists and "what if" analyses can be combined as part of hazard and operability (HazOp) studies [24]. A HazOp study primarily involves taking a checklist, an MSDS, a system flow or operation chart, or other document about a process or system and systematically asking questions aimed at determining outcomes for specific actions. For example, if a valve on a drawing is labeled "flow," the question might be asked, what happens when there is "no flow"? Where the answer is unknown or unsatisfactory, additional analysis is undertaken. HazOps tend to be quite formal.

More formal approaches include failure modes and effects analysis (FMEA) and failure modes and effects and criticality analysis (FMECA) [24]. FMEA and FMECA require a tabulation of equipment, components and systems, their failure modes, the effect of the failure, and the criticality of the failure (in a FMECA). These analyses typically focus on single-mode failures and usually do not include human failure analysis.

If, after application of one of the above methods, a potential failure mode or hazard condition is deemed to require more detailed analysis, fault tree analysis (FTA) or event tree analysis (ETA) is often used [24]. FTA is essentially a "reverse thinking" or "top down" deductive technique that focuses on one particular event that could (or did) occur (typically an accident) and provides a structure for evaluating the potential causes of the event (e.g., given failure X, what could have been the cause). It does this by providing a structure, in the form of a graphic representation of a logic model, that

an analyst uses to display various events, conditions, actions, and outcomes. The output of an FTA is a set of combinations of root or initiating events that could lead to (or could have lead to) a failure and may include component, equipment, system, operating and/or human actions, failures, or errors. Although FTA may be a qualitative tool as used in hazard assessment, it can be used as a quantitative risk assessment tool if probabilities or frequencies are assigned to the various initiating or root causes.

Fault tree analysis (FTA) can be used to predict the probability or frequency of an event's outcome by combining the probabilities or frequencies of initiating events using logic gates (primarily AND gates and OR gates), as illustrated in Fig. 75.1. Use of an AND gate implies that all branches leading into the upper event must happen for the event to occur. In Fig. 75.1, using a hospital as an example, "failure to detect a fire on a ward within 5 min of ignition" is expected to occur only if "failure to detect by automatic fire detection system" AND "failure by staff to observe (detect) fire" conditions are met. Use of an OR gate implies that only one of the connected branch events must occur. For example, "failure to detect by automatic fire detection system" could result if either "no automatic fire detector present" OR if "failure of automatic detector to detect fire" occurs. By assigning a probability or frequency associated with each event in the tree, and combining the probabilities or frequencies according to the AND and OR gates, the probability or frequency of the top event can be estimated [25].

Whereas FTA begins with a failure and provides a structure to look for potential causes, event tree analysis (ETA) provides a structure for postulating an initiating event and analyzing the potential outcomes. The principal tool is a decision tree (as used in decision analysis) with branches for success or failure (yes or no, or other binomial output). The basic approach is to identify an initiating event, identify systems or strategies intended to mitigate the event, and ask the "success or failure" question for each system or strategy, building the tree in the process. As with FTA, ETA is primarily a qualitative tool as used in hazard assessment but is often used as a quantitative risk assessment tool by assigning probabilities, much the way probabilities are used in a decision tree (see also Chap. 83 and other sources [26–28]).

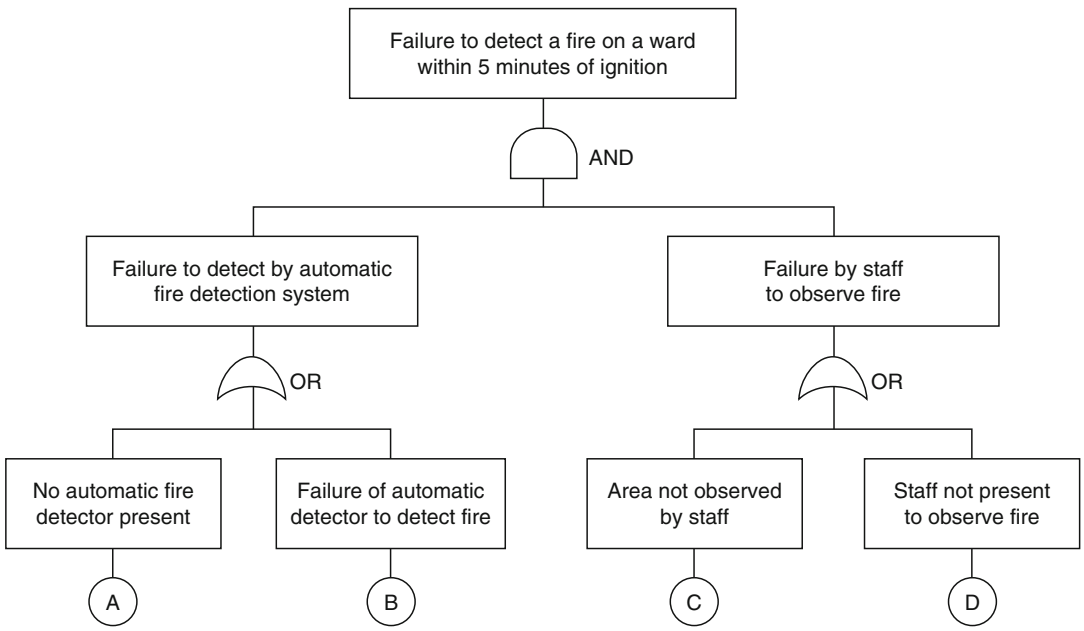

Fig. 75.1 Simple fault tree—fire detection in a hospital ward

For example, consider the simple event tree in Fig. 75.2. The initiating event is "ignition inside hospital ward" and the aim is to assess the probability or frequency of that ignition resulting in a "small fire" or a "fully developed fire" (more developed trees could include other options, such as "self-termination"). For each question (statement, or intervention), either a probability of occurrence or frequency can be assigned (e.g., the probability of fire growth is *X*, or fire growth has been observed to occur *Y* times per year for similar occupancies). If taking a probability approach, conditional probabilities for each factor can be estimated using a combination of historical data and expert judgment, as appropriate, resulting in a probability estimate for a specific outcome (scenario). By assessing the likelihood of the initial event in conjunction with the probabilities of the various factors, the frequency of the outcomes (scenarios) can likewise be estimated [25].

The data for event trees can be taken from fire statistics and other observations and measurements [29]. The effectiveness of an event tree in representing real fire events can be undertaken by quantifying the conditional probabilities for all fires in a type of building and then comparing the predicted outcome frequencies with the frequencies of deaths and injury in real events in that data set [30].

Cause-consequence analysis combines the forward thinking concept of ETA with the reverse thinking concepts of FTA to provide a more broadly encompassing picture of possible sequences of events [24]. Although primarily a qualitative tool as used in hazard assessment, it can be overlaid with frequencies or probabilities where used as a quantitative risk assessment tool.

Human error analysis describes a group of task-analysis-based qualitative techniques used to better understand the types of errors people might make and under what circumstances. Although helpful in better understanding potential sources of error, it has been noted that some such analyses treat human error and reliability in much the same way as mechanical systems, and it is argued that "desirable systems states" may be a more appropriate model [31]. In essence, "desirable systems states" focus on the goals that systems are aiming to achieve; and with why, what, and how questions, focus in on the potential for errors in various states of the system. Where people are part of the system, this approach highlights areas of concern and uncertainty related to human reliability and error.

In addition to the above methods, a variety of analytic tools, such as models, are used to assist in the hazard assessment. As Britter [32] points out, models are useful for a variety of tasks, including

- A means of summarizing extensive analytical and experimental results in order to assist in the transfer of that knowledge and to focus attention on deficiencies in the knowledge base

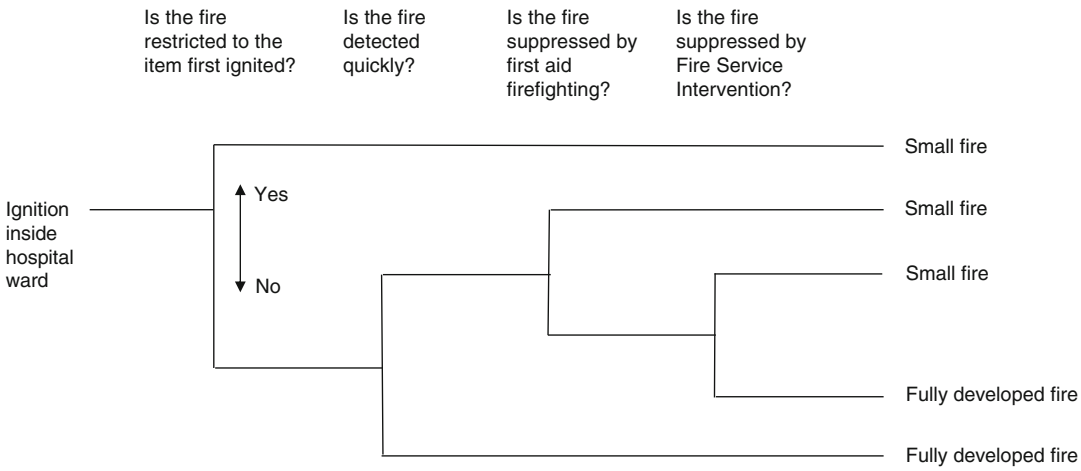

Fig. 75.2 Simple event tree—fire extinguishment in a hospital ward

- A means to provide knowledge in a form accessible to users with varying levels of expertise in the subject area
- A means to highlight the sensitivity of the output to the various input parameters
- Predictive tools for various scenarios of interest that have not, themselves, been tested

As used here, models can be mathematical or physical. Mathematical models include empirical models (based on correlation), models based on fundamental equations, analytical models (exact or approximate solutions to a set of equations in closed form), and numerical models (computational models). Physical models (simulations) rely on actual physical representations, often at a reduced scale (e.g., a wind tunnel), and sometimes with the actual material of concern (e.g., air movement in a wind tunnel), and sometimes with different materials with similar properties. Models are widely used to support fire hazard assessment. Details on fire effects modeling are provided elsewhere in this handbook and can be found throughout the fire literature. It is worth noting here that, regardless of the model one uses for fire hazard assessment or risk analysis, one must understand its uses, applications, and limitations; and appropriately account for the sources of uncertainty and variability that matter (see Chap. 76 for more details).

Causal Relationship of Initiating Events, Hazards, and Consequences

In addition to being viewed as separate components, consequence analysis and hazard assessment can be thought of as two parts of a process for identifying and evaluating the potential for unwanted consequences (loss or harm of something that is valued) given some initiating event. This definition implies that an event without unwanted consequences does not constitute a hazard and that there is a causal relationship between initiating events and unwanted consequences. One way to assess the potential for some initiating event to result in unwanted consequences is to view the situation in terms of a causal sequence, which looks at the situation as starting with some basic human need and ending in some consequence(s) [33]. The basic causal structure is illustrated in Fig. 75.3.

In brief, there are a variety of basic human needs, such as shelter, companionship, and love, which in turn lead to wants or desires. These wants or desires often result in the application of some technology to address the want. Unfortunately, the choice of technology can result in an outcome that exposes someone or something to loss or harm, resulting in some potential for unwanted consequences. To change the potential for unwanted consequences, one can modify the causal sequence by initiating one of six alternatives: modify wants, alter technology, block events, block outcomes, block the exposure, or block the consequence. This can be illustrated by example.

One basic human need is protection from the elements. To address this need, humans want shelters that provide protection from things such as rain, snow, and cold temperatures. To address this want, they may choose to live in structures that provide protection from rain and snow and can be heated to a comfortable temperature. Furthermore, they may choose to build

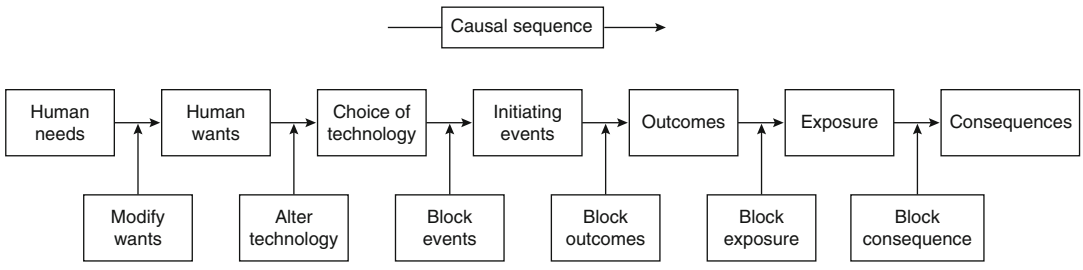

Fig. 75.3 Causal sequence [33]

these structures out of wood and to use an open fire as a source of heat. Under "normal" circumstances, everything could work fine, and the choice of technologies would provide the desired benefits. However, there could be some event, such as the blocking of a ventilation opening or too much fuel being put on the fire, that could lead to potentially unwanted outcomes. These outcomes, such as the presence of smoke, CO, or excessive temperatures in the structure, could then lead to exposures to people and property and ultimately result in unwanted consequences. Such a sequence can be illustrated diagrammatically, as shown in Fig. 75.4.

By applying an assessment methodology such as the causal sequence, one is able to visualize events, outcomes, exposures, and consequences in a systematic manner. The application can be as simple or as complex as needed, with the addition of multiple events, outcomes, exposures, and consequences and the addition of feedback loops providing further detail. Furthermore, the approach is compatible with various other hazard assessment techniques, as outlined previously, that may be more focused on specific parts of an overall assessment problem. This is illustrated in Fig. 75.5.

As can be seen in Fig. 75.5, numerous methods and approaches can be used for specific hazard assessments. Although some are applicable to a variety of problems, many are intimately associated with specific characteristics of the hazard, the type of risk problem, the current state of knowledge, and the available technology. For example, most health hazard and risk assessments (toxicological, physiological, cancer, disease) rely heavily on epidemiological studies and dose-response relationships and models [34–38]. In these cases, a causal relationship is often sought between exposure to a substance and unwanted outcomes (e.g., exposure to asbestos and the causation of cancer). Such approaches may be considered if an incapacitation assessment is being undertaken. For technology-related hazard and risk assessments, the focal point is typically the relationship between initiating events and outcomes (through to consequences). For these analyses, methods such as those outlined previously, like failure mode and effects analyses, fault tree analyses, and event tree analyses, are often used [2, 24, 39–43].

Fire Safety Concepts Tree

A useful tool for fire hazard and consequence analysis is the *fire safety concepts tree* [44]. The fire safety concepts tree is a graphical

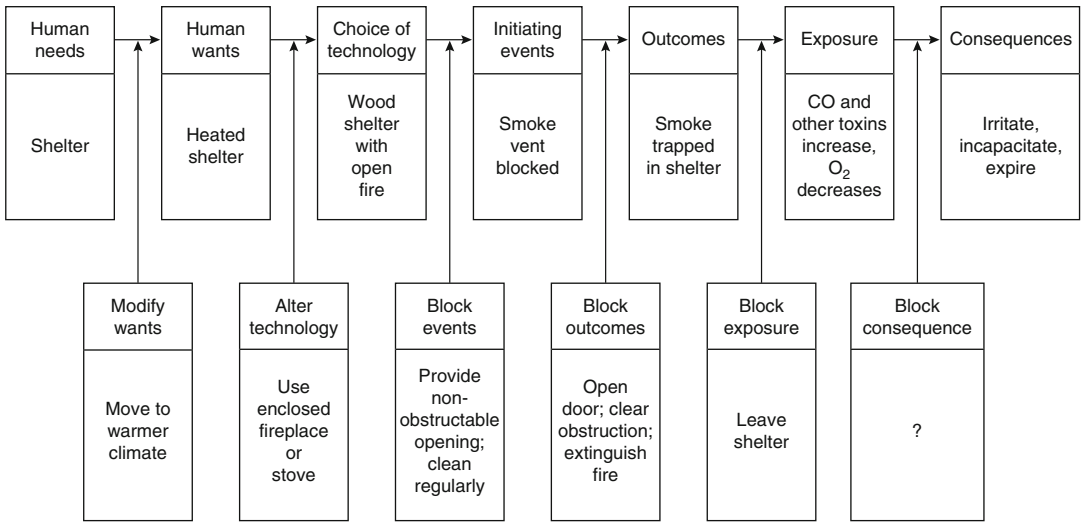

Fig. 75.4 Illustration of potential unwanted fire-related consequences

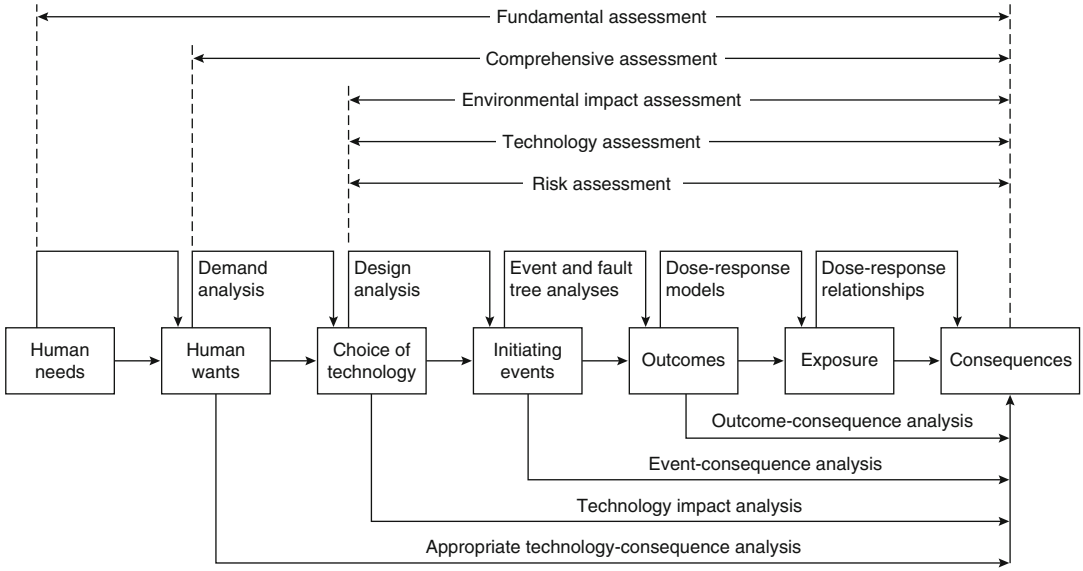

Fig. 75.5 Modes of analysis compatible with the causal structure [33]

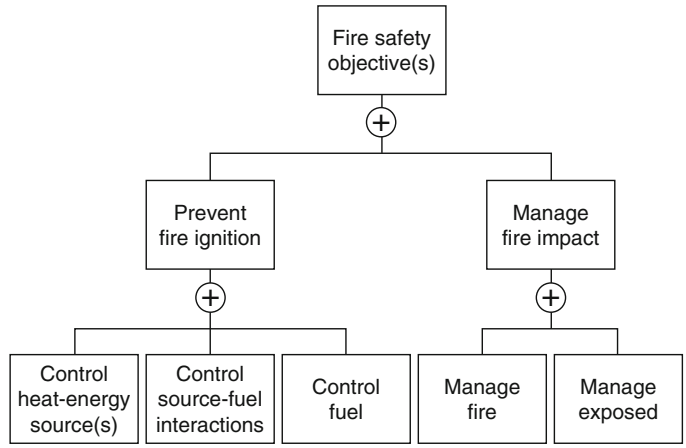

Fig. 75.6 Top branch of the fire concepts tree [44]

representation of the deliberations and professional judgments of the NFPA Technical Committee on Systems Concepts for Fire Protection in Structures, and represents one way in which building fire safety can be viewed [45]. It is divided into two primary branches, "prevent fire ignition" and "manage fire impact," with the concept being that one or the other must be accomplished in order to meet one's fire safety objectives. One can use the tree as a guide to evaluate potential fire impacts in those cases where a building fails to meet the criteria of one or more branches (e.g., if ignition is not prevented, one can evaluate the ability of the building's systems to manage the fire impact). One can also modify the fire safety concepts tree into the form of an event tree or a decision tree for risk analysis.

A portion of the fire concepts tree is provided in Fig. 75.6, which shows the top-level choices, "prevent fire ignition" or "manage fire impact." A complete version of the event tree can be found in NFPA 550, *Guide to the Fire Safety Concepts Tree* [44].

Assessing the Likelihood of Occurrence

Thus far, the risk analysis components of determining what is valued and assessing the hazard conditions that may occasion the loss or harm have been discussed. The final component is concerned with obtaining a judgment on the likelihood of specific losses occurring to what is valued. The concepts of frequency, probability, and the differing views of probability are important to this discussion.

One dictionary defines probability as the likelihood of an occurrence expressed as the ratio of the number of actual occurrences to that of possible occurrences, and frequency as the rate of occurrence [46]. Inherent in the latter definition is the concept of events per unit time. Thus, a frequency of fire ignitions during a specific period of time, on its own, is not an indication of the probability of fire ignition. To obtain a probability of fire ignition, an estimate of the number of possible occurrences is required as well. For example, a hypothetical statistic of 20 fires per year occurring in toasters as they are switched on is a *frequency*. To estimate the *probability* of a fire in a toaster when it is switched on, one would also need data on the total number of times toasters are switched on per year. If one had data that indicated that toasters are switched on 20 million times per year, one could then estimate the probability of fires in toasters as they are switched on as 20 fires per 20 million toaster starts per year, or one in a million per year.

Probability theory is a branch of mathematics that deals with the modeling of uncertainty through measures of relative likelihood of alternative occurrences [47].

This is one place where the differing approaches of objectivism and subjectivism come into play: the estimation of the likelihood of occurrence. As noted earlier in this chapter, some approaches tend to give more weight in the analysis to data from observed events with a narrative to address the effects of current state of knowledge to inform a judgment, whereas other approaches tend to utilize the current state of knowledge coupled with judgment to modify data from observed events as part of the analysis. This distinction is important to remember when certain high-consequence fire events are relatively rare and thus data are somewhat limited. In addition, people can change the nature of the fire hazard over time (e.g., by reconfiguring buildings, changing contents); and the material composition of building products and contents will likely change, making the ability to predict future hazards or risks challenging at best.

Such conditions provide an argument for the use of subjective probability measures over objective measures for building fire risk analysis. Because data are often scarce, and actual occurrences and possible occurrences may not be precisely known, it is often necessary to make estimates. At issue is how one chooses to make the required estimates [48]. For example, whereas one may have frequency data on fire ignitions in a particular class of buildings, a subjective judgment relative to the number of possible future occurrences may be more appropriate than a judgment based on statistical treatment of limited and potentially highly uncertain data.

Regardless of the differences in philosophy between objectivism and subjectivism, data are needed. Sources of fire loss data, including fire frequency data, can be found in Chap. 78 by Hall and Ahrens, as well as in various other publications, including annual [49] and periodic [50, 51] journal articles, NFPA reports [52], government reports [53], and handbook appendices [10, 54, 55]. Likewise, approaches which illustrate how data are used in different ways for evaluating and characterizing risk can be found in the literature [56–60]. In addition, it should be clear that the concepts of uncertainty, variability, and unknowns, by the nature of the problem, are critical concerns in risk analysis and must be appropriately addressed (see the following section as well as Chap. 76).

FN Curves

In managing building fire risks, it is important to differentiate between high-frequency/low-consequence events and high-consequence/

low-frequency events. This is important because society tends to be less tolerant of high-consequence events (consequence aversion), and the means for managing risks may be affected by the nature of their frequency and consequence.

FN curves were developed in the nuclear industry in the 1960s [61] as a means of analyzing and communicating the different levels and natures of risks, particularly those with the potential for high consequences but with low frequencies.

Figure 75.7 [62] shows an FN curve for multifatality accident rates. It is possible to see that road fatalities are the highest level of risk, but are at the high-frequency/low-consequence end of the graph; whereas aircraft crashes risks are higher at the high-consequence/low-frequency end of the graph, where society tends to show greater concern.

Figure 75.8 shows how FN curves can be used to compare levels of fire risk in different parts of a building or indeed in different buildings [63].

As Low as Reasonably Practicable (ALARP)

One way of testing risks that are neither negligible nor intolerable is the principle of as low as reasonably practicable (ALARP). That is, if the cost of risk reduction or the benefits of the activity grossly outweigh the risks, then the level of risk can be said to be ALARP [64]. The degree to which a risk is ALARP is usually calculated using cost-benefit analysis.

EXAMPLE: Financial Risk Assessment Using Cost-Benefit Analysis

Concern was expressed by a major bus operator with respect to the risk to business from fires in bus garages. In particular, the operator was interested in whether or not it should install sprinkler systems in its existing bus garages or take some action. Obviously, the cost of this would be considerable, and so the bus operator commissioned

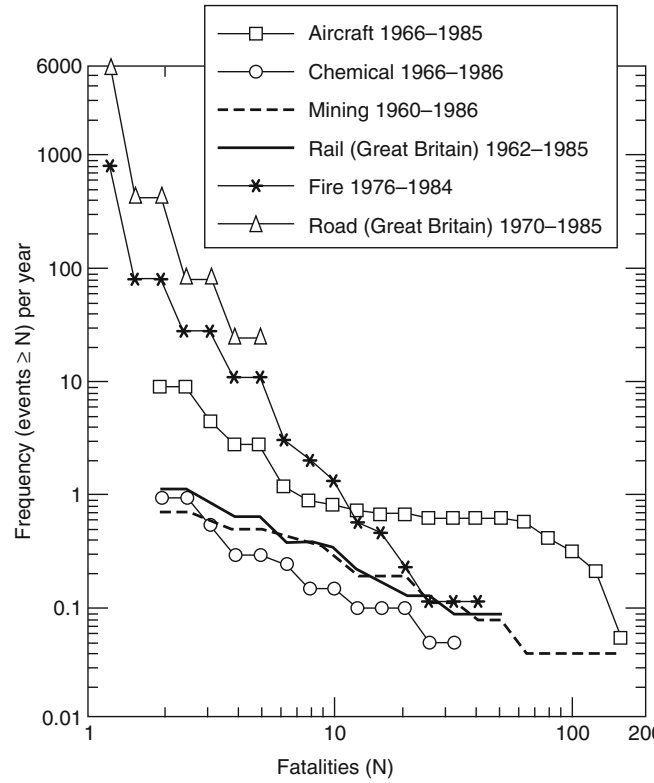

Fig. 75.7 Frequency of multiple fatality accidents in the United Kingdom [62]

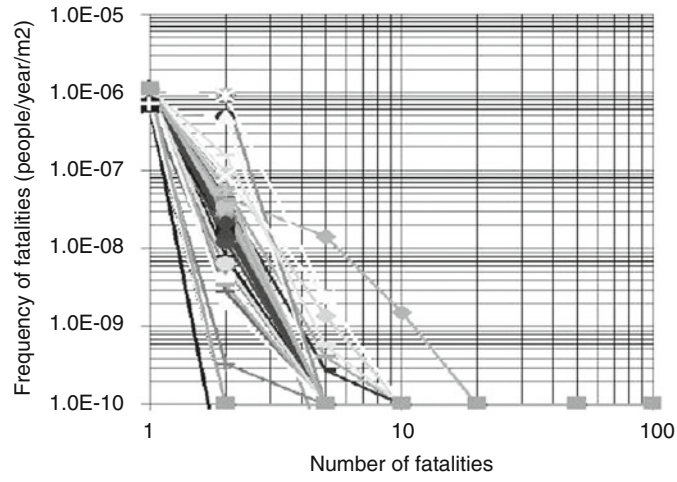

Fig. 75.8 Example of FN curves for fire risk/occupant year in a building [63]

a study to quantify the benefits in terms of property protection [65].

This risk assessment involves

1. Identifying events that could give rise to the outcome of concern
2. Estimating how often the events happen
3. Estimating what the severity of the outcome of those events would/will be
4. Assessing the implications of the level of risk

Identifying Events

The events of concern are fires causing significant damage to vehicles and property in bus garages. From operating experience, fire safety judgment, and full-scale fire tests, these events were narrowed down to one "reasonable worst case" event:

A seat fire at three points on a double-deck bus parked among others.

The risk parameter chosen for the study was the cost of fires per calendar year. This could allow the bus operator to put these risks in context with historical data on other risks.

Estimating the Frequency of Events

To estimate how often the fire event happens, historical data were collected on how often fires occur on buses in garages. Because large fires on buses are relatively infrequent, there was insufficient information to directly estimate how often these severe events occur. Therefore, an event tree was constructed to help generate the missing information.

An event tree was constructed to predict the possible outcomes from an initial event (Fig. 75.9). For example, an initial event of "Seat fire in the lower saloon of a double-deck bus" may have outcomes of "Damage less than £200,000" and "Damage greater than £500,000." The likelihood of each outcome depends on other factors such as "Is the fire noticed at an early stage of development?" "Does the fire spread to neighboring buses?" or "Is the fire extinguished using fire extinguishers?"

The conditional probability of each of these other factors is estimated using historical data and informed judgment. Therefore, using the likelihood of an initial event and the probabilities of the other factors, an estimate can be made of how often an event occurs.

Estimating the Severity of the Outcome

There are several ways to estimate the severity of the outcome: using historical information, using simple analytical methods, using computer models, and/or using full-scale tests. Each approach has its advantages and disadvantages. Historical data describe what the outcomes have been in the past but may not be complete or relevant. Simple analytical methods can predict

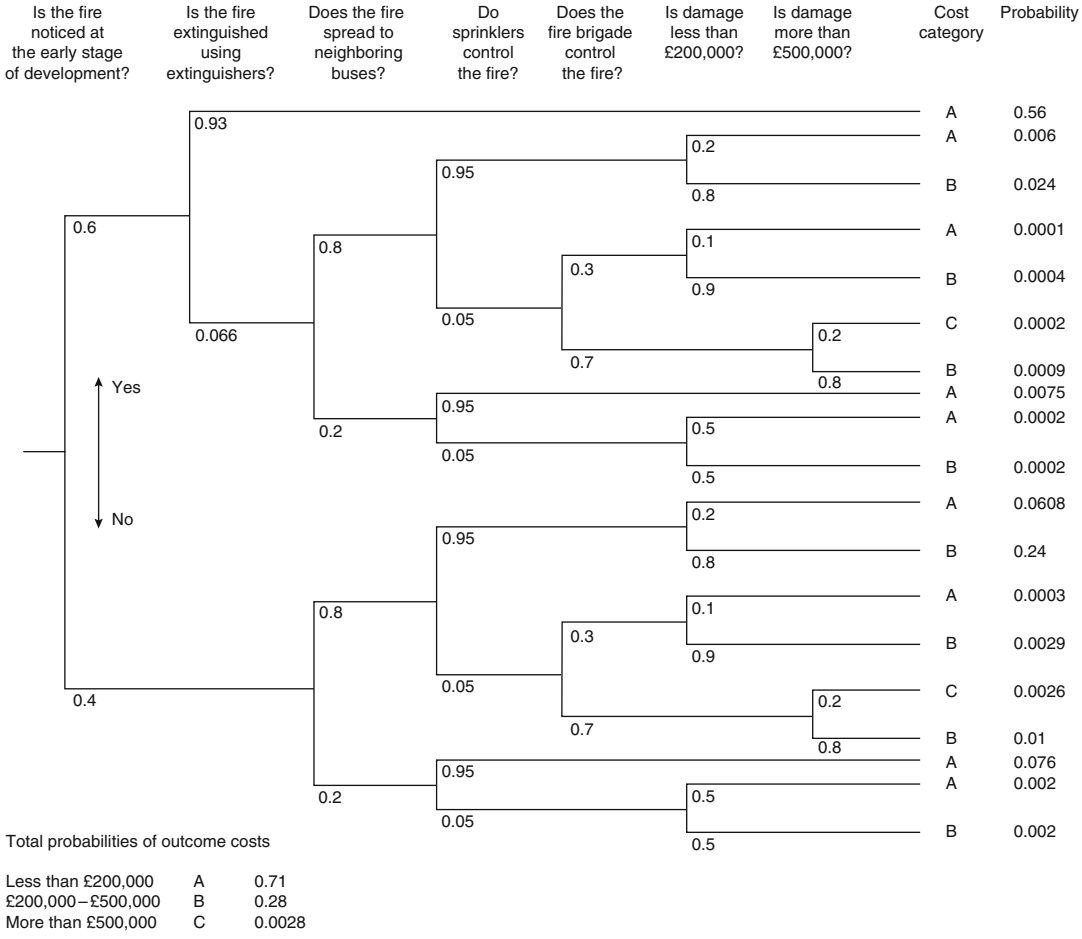

Fig. 75.9 Simplified event tree for bus garage fires with sprinklers installed [65]

the severity of outcomes cost effectively, but the answer is only as good as the assumptions made. Computer models can predict the severity of outcomes more closely but can be expensive and time consuming. Full-scale testing probably gives the most accurate assessment of the severity of outcomes, but it is usually even more costly and time consuming.

In this case the severity of the outcome (i.e., losses due to damaged buses/garage) depended heavily on the spread of fire from bus to bus and the effective spray density of different sprinkler systems. Therefore, a combination of full-scale testing and computer modeling was used to predict fire growth, fire spread, and the effectiveness of sprinklers.

Results

The risk assessment indicated that, for the event identified, a higher than ordinary level of sprinkler spray density was necessary to prevent fire spread from bus to bus. The frequencies of fires in bus garages was about 0.1 per garage year. The fire risk was then calculated for the bus garages with and without sprinklers. The difference between the two figures is the benefit rate from reduced property losses by fitting sprinkler systems, and this was of the order of £2000 per year (but this varied with the size of garage).

Historical accident data indicate that the predicted risk of damage is pessimistic; very few records of such fire damage could be found. Having quantified the benefits of sprinklers in

reducing risks in bus garages, cost-benefit analysis was used to assess whether they would represent a good investment in fire safety.

Cost-Benefit Analysis

The first step was to determine the total costs of the sprinkler installation. This not only included the initial installation costs but also covered the annual running costs. The following list, although not meant to be exhaustive, covers the main costs included in this case:

- Design fees
- Installation/construction
- Commissioning/training of staff
- Maintenance/running and so forth

The capital cost for the sprinkler system was £25,000 with an annual maintenance cost of £100. The benefits of the new installation are then listed, including

- Reduced property loss
- Reduced consequential losses
- Reduced insurance premiums
- Improved life safety and so forth

The benefit rates from the quantified fire risk assessment were added to the difference in insurance premiums to give the total benefit rate of £2500 per garage year.

This is the figure used in the investment appraisal. Table 75.1 shows the discounted cash flow over a 30 year period. The discount factor used is 10 %; this is the norm for commercial premises and is spread over a 30 year life span (because of the life of the sprinkler system). The financial data in Table 75.1 do not represent those of any particular garage or operator but may be typical of some circumstances.

The cost-benefit analysis showed a small positive net present value at the end of 30 years. The positive figure indicated that, strictly speaking, the installation of bus garage sprinkler systems did not represent a good investment. However, the smallness of the value indicated that this was a marginal case. In the light of the risk assessment, the bus operator decided that it had sufficient redundancy and diversity of bus supply through ownership (in several garages), leasing and buying, and insurance not to require bus garage sprinklers. However, the risk assessment had highlighted several other risk management issues, such as fire safety management and the separation of the information technology (IT) center, where risk reduction was much more cost effective.

Study Conclusions

A study to assess the benefits of installing sprinkler systems in bus garages [65] indicated that there were business continuity and property protection benefits to the operator. However, the cost-benefit analysis and the operator's contingency plans meant that there was no cost-benefit or consequence case for installing sprinklers in bus garages. As a result of the risk assessment,

Table 75.1 Discounted cash flow for Bus garage sprinkler system [60]

Year	Capital cost (£)	Annual cost (£/year)	Total cost (£/year)	Savings (£/year)	Net costs/ savings (£/year)	Discount factor (9 %)	NPV of costs/ savings (£)	Cumulative NPV
0	25,000	–	25,000	0	25,000	1	25,000	25,000
1		100	100	–2,500	–2,400	0.9091	–2,182	22,818

the operator did implement other safeguards and fire precaution measures.

Uncertainty, Variability, and Unknowns

The extent of literature on the topics of uncertainty, variability, and unknowns indicates that identifying, understanding, and addressing these are clearly critical issues. For example, these issues pervade discussions of acceptable risk [66–69], risk characterization [3], risk assessment [42, 70–74], and decision analysis [11, 13, 75–78]. However, as one can see from a review of the various reference sources, there seems to be little consensus regarding how to treat these factors. There are several reasons for this, many of which impact building fire risk analysis and even drive the need for risk analysis, including

- The risk problem may not be clearly understood or sufficiently well defined [3, 68]. Any uncertainty in the problem definition will be propagated throughout the risk assessment and management process. If this uncertainty is large (i.e., if the stakeholders do not agree on key issues or parameters of the problem), the uncertainty in any proposed solution will be some factor greater.
- There are many types of uncertainties that go unrecognized or ignored [3, 68, 71, 73]. These include uncertainties in variables that are built into analytical tools and methods; uncertainties associated with criteria selected for assessing acceptability; and uncertainties in human behavior, attitudes, and values.
- There may be variability that is treated as uncertainty [36, 73, 74]. If the risk problem relates to the human population, for example, it should be recognized that both uncertainty and variability exist, and that they need to be addressed differently. It may not be known how many people may be exposed (uncertainty), and for any population postulated to be exposed, there will be differences among the individuals (variability). Uncertainty and variability become important when discussing issues such as using the entire population or some subset of sensitive or vulnerable persons, and if the latter is selected, what defines the subset.
- There may be unknowns that are treated as uncertainties [3, 79–81]. In some cases, it is impossible to accurately predict some event that may happen far into the future, or to control the circumstances on which certain assumptions are based. If these indeterminate events are treated as events that can be accurately predicted, the uncertainties in any solution could be significant (see Stern and Fineburg [3]).
- There may be disagreement regarding how to address uncertainties of different types. First, the differences between uncertainty, variability, and indeterminacy need to be identified [74]. Then one needs to identify appropriate mechanisms to address the uncertainty, variability, or indeterminacy. For example, Morgan and Henrion [71] argue that the only type of quantities whose uncertainty may be appropriately represented in probabilistic terms are empirical quantities. However, there are other types of quantities, such as model domain parameters, decision variables, and value parameters. For these, parametric or switchover analysis (or other) may be needed.
- There may be disagreement on a quantitative methodology (or set of quantitative methodologies) for treating uncertainty. Even if it is decided to perform a probabilistic analysis on an empirical quantity, there may be disagreement as to an appropriate approach to apply. For example, probabilistic approaches range from classical, statistical-based analyses to subjective, Bayesian analyses, with other types of quantitative or qualitative analyses scattered in between [3, 48, 82, 83]. To complicate the issue, frequentists often reject the Bayesian approach, and vice versa.
- There is concern that the data, mathematical rigor, and expertise needed to conduct a quantitative uncertainty analysis would render such an analysis impracticable in many situations, and as a result, the analysis would

not be undertaken or would be performed incorrectly [84].

To help people better understand the complex issues surrounding uncertainty, variability, and unknowns (hereafter lumped as uncertainty for convenience), various taxonomies and treatments have been suggested [3, 7, 68, 72, 85, 86]. Regardless of specific differences, much of the literature identifies the following areas as requiring consideration: scientific uncertainty; human factors uncertainty; uncertainty in risk perceptions, attitudes, and values; and decision-making uncertainty.

Scientific uncertainties result from lack of knowledge (either obtainable through further study or due to random chance and variations) and from necessary approximations. They are often among the most readily recognizable and quantifiable uncertainties and can be grouped into five subcategories: theory and model uncertainties, data and input uncertainties, calculation limitations, level of detail of the model, and representativeness [7, 32, 85, 86].

Theory and model uncertainties may arise when physical processes are not modeled due to a lack of knowledge about them or about how to include them, when processes are modeled based on empirically derived correlation, and/or when simplifying assumptions are made. Data and input uncertainties arise from inaccuracies in data collection and reporting, incomplete knowledge of specific input values and variations in those values as a function of confounding factors, and input errors made by the modeler. Calculation limitations encompass such factors as the control volume selected for modeling, the level of detail of the model, and the model-domain parameters specified. Representativeness relates to how well the modeled situation reflects reality.

In considering human factors, uncertainty and variability are present in several modes. There is uncertainty regarding who might be affected and how. That is, it is not always known who will be impacted (uncertainty or indeterminacy), and within the population affected, there will be physiological uncertainties and variability. There are also uncertainties and unknowns related to how people will react in different situations, especially under stress.

As discussed earlier, there can be significant differences in the ways people perceive and value risk, as well as in their attitudes about risk. Differing perceptions give rise to both variability and uncertainty, and capturing these differences is important. There will be situations in which age, family, infirmity, or other factors or conditions will impact perceptions of risk. There may be social, economic, philosophical, religious, or cultural differences in people's values systems. In addition, some people are risk tolerant, whereas others are risk averse. It is important to recognize these differences exist, and thus reduce uncertainty and unknowns, and better understand and address variability where it exists. Also important are the perceptions and issues of equity, efficacy, and fairness—issues of importance in risk characterization and management [78]. Here again, social, economic, or cultural differences of the interested and affected parties may play a major role.

There is also uncertainty in the decision-making process, including uncertainty about how to best define the decision problem, difficulties in assessing the facts of the matter, difficulties in assessing relevant values, uncertainties about the human element in the decision-making process, and difficulties in assessing the quality of the decisions that are produced [68].

All of these factors should be considered and appropriately accounted for when undertaking a building fire risk analysis. For more details on uncertainty and its treatment, see Chap. 76.

Building Fire Risk Analysis Approaches, Methods, and Models

This section provides a brief overview of various qualitative and quantitative risk analysis approaches, tools, and methods available to fire protection engineers. This section does not constitute a comprehensive review, and readers are urged to consult the fire and risk literature for more approaches to risk analysis and for more details on the approaches discussed herein.

Magnusson [27] suggests that there are two primary approaches to risk analysis: the single

scenario, analytic safety index ß approach, and the multiscenario, event tree approach. In the single scenario, analytic safety index ß approach, there is a single-limit state described by an analytical expression developed from physically derived correlation (e.g., mass flow in plumes, smoke-filling times, radiation from flames) or from response surface equations describing output from a computer program. The design problem is formulated in terms of the limit state function, G, as $G(X_1, X_2, \ldots, X_n) = 0$. The parameters X_i are stochastic parameters describing the system, such as fire growth rate and response time of occupants. The goal is to find a solution given the constraint that $P(G < 0) < P_{\text{target}}$.

Challenges and limitations to the use of this approach include difficulty in developing appropriate analytical expressions, difficulty in developing uncertainty factors, and the limitation of being a single scenario application. Nonetheless, this approach is useful for some applications, and details can be found in the literature [26–28]. Although not developed, it has been suggested that this basic approach can be applied more broadly to the building fire problem as well [87, 88].

A response surface approach to probabilistic assessment of risk to life from fire as presented by Albrecht [89, 90] is similar to the probabilistic scenario and event tree risk assessment methodology outlined by Magnusson et al. [27] in which the probability (P), and a safety index (β), respectively, of a limit state violation is calculated as

$$P(\Omega_f) = \Phi(-\beta),$$

where Ω_f is the failure domain of the limit state function, for example

$$\Omega_f = \mathrm{G(X)} \leq 0,$$

and $\Phi(\cdot)$ is the function of the standardized normal distribution.

Since probabilistic calculations usually require a high number of evaluations of the underlying limit state it is usually not feasible to use numerically expensive models. Hence, so far only plume formulations or zone models have been utilized within those uncertainty calculations [27, 86, 91]. Yet, for performance-based life safety risk analysis it is nowadays inevitable to use state-of-the-art simulation models, such as computational fluid dynamics (CFD) or microscopic evacuation models for each scenario within a system of various possible scenarios.

In order to bypass the high numerical cost and to allow for probabilistic calculations using advanced and complex numerical models, an adaptive response surface algorithm was developed that uses so-called moving least squares (MLS) [92] with an interpolating weighting function [93] instead of the traditional global linear or quadratic regression functions [94]. These response surface formulations provide a good surrogate model with a comparably low number of required evaluations of the numerically expensive models and thus allow for a fast and accurate overall computation. The calculation of the failure probabilities is performed by exploiting the surrogate with an optimized adaptive importance sampling Monte Carlo algorithm (AIS) [95] which additionally allows to compute sensitivities to identify the highest contributors to the overall variance, i.e. the most relevant input parameters. The complete algorithm flowchart is shown in Fig. 75.10 and is described in detail in reference 89, Chap. 6.

The derived failure probabilities were then be compiled into event trees [26–28, 94, 96, 97] to perform a holistic system failure analysis. The advantage of the event tree analysis can be the identification of the most influential scenario by looking at the highest product of each scenario probability and the expected outcome if the scenario occurs. This constitutes the classic approach to quantitative risk analysis [94, 96, 97].

Another area of application of event tree analysis is the possibility to quantify the effect of fire protection systems on the safety level considering their potential failure. This can be achieved by comparing the two scenarios with and without the chosen fire protection system being functional while incorporating its probability of malfunction. Values for these failure probabilities can be found, for example, in the British

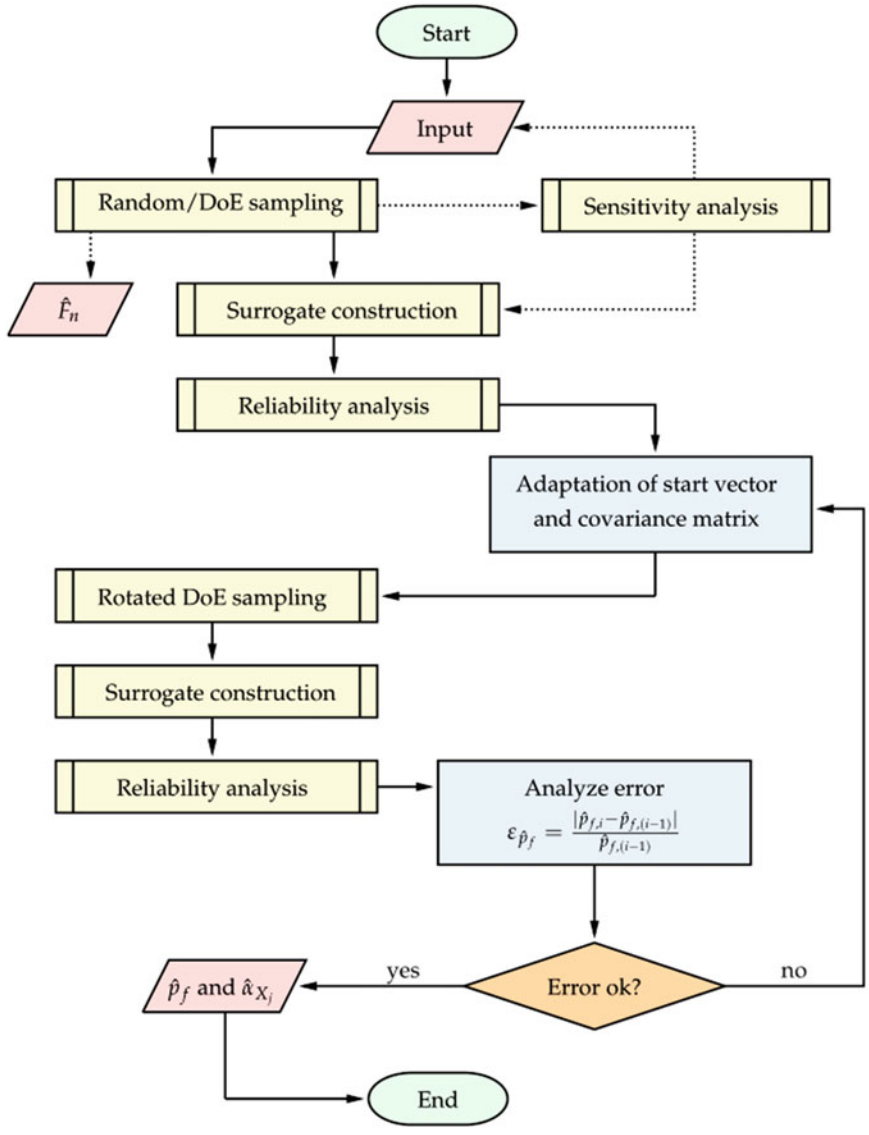

Fig. 75.10 Flowchart of the IMLS response surface Algorithm [89]

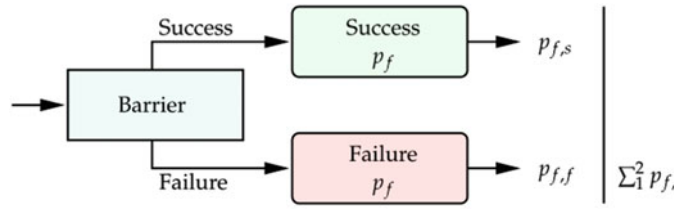

Fig. 75.11 Modeling of fire protection barriers within an event tree considering their possible failure to assess the overall impact on the safety level [89]

Standard 7974 [98]. The sub-event tree for this analysis is shown in Fig. 75.11. Further branches can be added to analyze, for example, interaction effects between various fire protection systems, such as sprinklers and ventilation systems. A comprehensive application with various scenarios and different fire protection systems can be found in reference 89, Chap. 7.

The combination of full probabilistic, performance-based scenario analysis and system analysis with state-of-the-art numerical simulation tools in fire protection engineering yields valuable quantitative information which can be used to identify the most critical scenarios and to quantify the effect of fire protection systems and thus provide a risk-optimized as well as cost-benefit optimized solutions.

To simplify this rather mathematical approach for practical application, it is possible to derive semi-probabilistic safety concepts as has been proposed [99] for the Eurocode structural fire protection where safety factors for one or multiple input parameters are derived that implicitly fulfill the required target reliability when applied. In order to develop such a safety concept for life safety analysis, for example a semi-probabilistic safety factor γ for ASET $\geq \gamma$(RSET), those target reliabilities would have to be agreed upon first.

Event tree analysis (ETA) is often used to analyze complex situations with several possible scenarios, where several fire or life safety systems are in place or are being considered. In brief, event trees are developed for a scenario, and probabilities and frequencies for components are applied (see previous discussion on ETA). In the *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings* [10], the method for quantifying fire risk from multiple fire scenarios is given as

$$\sum \text{Risk}_i = \sum (\text{Loss}_i \cdot F_i)$$

where

Risk_i = Risk associated with scenario i
Loss_i = Loss associated with scenario i
F_i = Frequency of scenario i occurring

This relationship is similar to the earlier general discussion on engineering risk analysis; but in this case, the term *loss* is used instead of *consequence*, and the summation indicates "total" risk from multiple scenarios. This type of risk analysis, commonly referred to as probabilistic risk assessment (PRA), is widely used in the chemical process industry (see Chap. 83) and for fire safety assessments of nuclear facilities [41], and is beginning to see broader application in fire protection engineering applications [10, 26–28, 43].

Although ETA-based risk analyses methods are applicable to multiscenario situations, it does not mean such approaches are necessarily simple. This can be illustrated using a three-room example. Figure 75.12 shows an event tree for a three-room building that is compartmented as shown. For this example, the fire scenario frequency, F_i, is assumed to be uniformly distributed across the three rooms, and the consequence of a single room loss is $C/3$ (i.e., the consequence of losing all three rooms to a fire would be C) [10].

If the probability that the fire will be contained in one room is P_c, and that it is prevented from propagating to the third is P_f, then the overall risk as shown in Fig. 75.10 can be estimated as

$$\begin{aligned} R = {} & \frac{C}{3}(F_i P_1 P_c) + \frac{2C}{3}\left[F_i P_1 (1-P_c) P_f\right] \\ & + C\left[F_i P_1 (1-P_c)(1-P_f)\right] + \frac{C}{3}(F_i P_2 P_c) \\ & + \frac{2C}{3}\left[F_i P_2 (1-P_c) P_f\right] + C\left[F_i P_2 (1-P_c)(1-P_f)\right] \\ & + \frac{C}{3}(F_i P_3 P_c) + \frac{2C}{3}\left[F_i P_3 (1-P_c) P_f\right] \\ & + C\left[F_i P_3 (1-P_c)(1-P_f)\right] \end{aligned}$$

where P_1, P_2, and P_3 are the probabilities that a fire will start in room 1, 2, or 3, respectively.

With some mathematical manipulation, the above equation simplifies to the following:

$$R = \frac{CF_i}{3}\left(3 - 2P_c - P_f + P_c P_f\right)$$

For this example, P_c and P_f can be interpreted as the success probabilities of the fire barriers. To place these results in context, numeric values will be added. If P_c and P_f are both equal to 0.1 (i.e., fire propagates 9 in 10 times), then the *risk* is

$$R = \frac{CF_i}{3}[3 - 2(0.1) - (0.1) + (0.1)(0.1)] = 0.90CF_i$$

If P_c and P_f are both equal to 0.9 (i.e., fire propagates 1 in 10 times), then the *risk* is

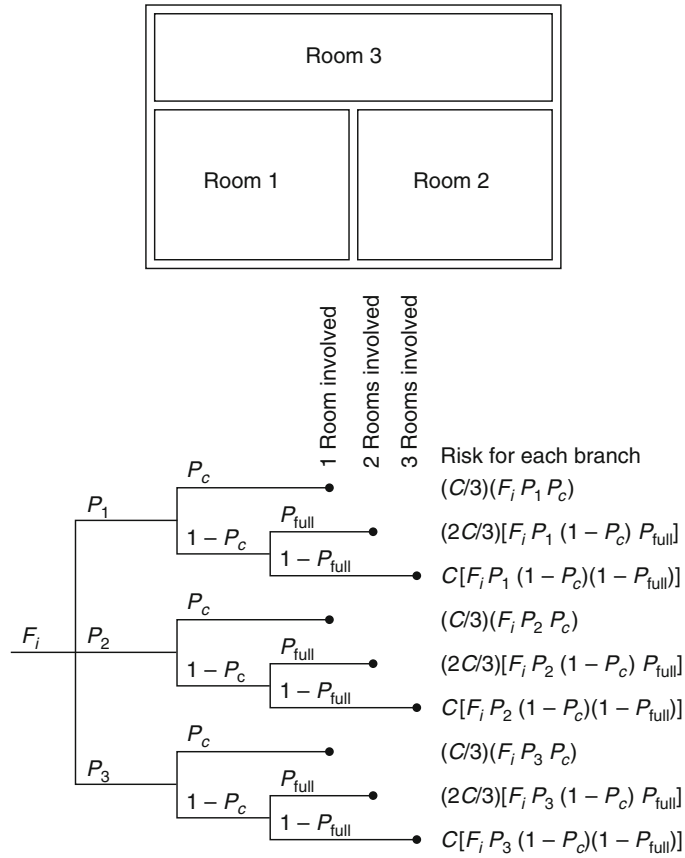

Fig. 75.12 Event tree for three-room fire risk analysis [10]

$$R = \frac{CF_i}{3}[3 - 2(0.9) - (0.9) + (0.9)(0.9)]$$
$$= 0.37CF_i$$

If P_c and P_f are set to unity (i.e., fire barriers never fail), then the *risk* is

$$R = \frac{CF_i}{3}[3 - 2(1) - (1) + (1)(1)] = \frac{CF_i}{3}$$
$$\simeq 0.33CF_i$$

Although this example is very simplified, it suggests how complicated a classical ETA-based engineering risk analysis can be. For each fire protection feature considered, the number of branches (i.e., potential outcomes) in the event tree will increase. Given that this increase is usually geometric, the analysis can become quite complex.

The above example also illustrates an important concept in risk-based calculations. The bounding risk for this problem would be CF_i (i.e., complete facility loss). This is the risk if all fire protection features are assumed to always fail. The risk when the fire protection features are always assumed to work (i.e., the fire barriers never fail, thus P_c and P_f are set to unity) is the lower bound risk. Thus, the potential range for the calculated risk is bounded between $0.33CF_i$ and CF_i. The better the protection, the closer the risk will approach $0.33CF_i$.

The above example can also be used to illustrate the difference between fire scenarios (all possible scenarios that could occur) and design fire scenarios (that subset of fire scenarios selected for design purposes) [10]. For example, the total range of fire scenarios for the above example could consider various room-to-room sequences (e.g., starts in room 1, then goes to

room 2 and finally to room 3). If this is done, one finds that there are a total of 15 possible paths of fire propagation:

1. Starts in room 1 and is contained in room 1
2. Starts in room 1 and propagates to room 2, but not to room 3
3. Starts in room 1 and propagates to room 3, but not to room 2
4. Starts in room 1 and propagates to room 2 and then to room 3
5. Starts in room 1 and propagates to room 3 and then to room 2
6. Starts in room 2 and is contained in room 2
7. Starts in room 2 and propagates to room 1, but not to room 3
8. Starts in room 2 and propagates to room 3, but not to room 1
9. Starts in room 2 and propagates to room 1 and then to room 3
10. Starts in room 2 and propagates to room 3 and then to room 1
11. Starts in room 3 and is contained in room 3
12. Starts in room 3 and propagates to room 1, but not to room 2
13. Starts in room 3 and propagates to room 2, but not to room 1
14. Starts in room 3 and propagates to room 1 and then to room 2
15. Starts in room 3 and propagates to room 2 and then to room 1

If simultaneous propagation to the second and third rooms were considered a significant threat, there would be three additional scenarios. This brings the total scenarios to 18 before considering details such as doors being open or closed, whether people of various characteristics are in the rooms, and whether they are sleeping.

It is also important to address the fact that fire protection systems may not always be operational. As such, the concepts of availability and reliability should be addressed. A system is considered available when it is ready and able to perform its intended function (e.g., a smoke detection system is installed and working). If a system is taken out of service, even temporarily (e.g., it is undergoing maintenance), it is unavailable. A risk-based approach should consider some probability that a system will be unavailable if it is a possibility. A system that is available but not functional is considered unreliable (e.g., the smoke detection system is installed but the smoke detector opening is blocked with duct tape). Probabilities can be developed for evaluation of system availability and reliability. Availability and reliability are reported or derived as a composite value. (When the latter is the case, it should be made explicit.)

Risk-Cost Assessment Model

Because of the complexity of ETA-based risk analysis, computers are often used to enable multiple scenarios to be evaluated in relatively short time frames. Two such models, FIRE-RISK (formerly known as CESARE-Risk) and FiRECAM, are based on a fire risk and cost assessment model developed by Beck [100–102] and expanded collaboratively by Beck and Yung [102, 103].

A brief description of the current risk-cost assessment model and its submodels is given in this section [104]. More detailed descriptions are given for the design fire submodel, the fire growth submodel, and the smoke movement submodel. As for the other submodels, more details can be found in other publications [101, 103, 105–107].

The risk-cost assessment model employs an event-based modeling approach in which events are characterized by discrete times and probability of occurrence. The event-based approach is used to define the outcomes of fire growth and spread scenarios in terms of the times of occurrence of untenable conditions. The consequence of these outcomes is in terms of the number of people exposed to untenable conditions.

The risk-cost assessment model for office and apartment buildings assesses the fire safety performance of a fire protection design in terms of two decision-making parameters: (1) the expected risk to life (ERL) and (2) the fire-cost expectation (FCE). The ERL is the expected number of deaths over the lifetime of the building divided by the total population of the

building and the design life of the building. The FCE is the total fire cost, which includes the capital cost for the passive and active fire protection systems, the maintenance cost for the active fire protection systems, and the expected losses resulting from fires in the building. The ERL is a quantitative measure of the risk to life from all probable fires in the building, whereas the FCE quantifies the fire cost associated with the particular fire safety system design.

To calculate the ERL and FCE values, the risk-cost assessment model considers the dynamic interaction between fire growth, fire spread, smoke movement, human behavior, and the response of fire brigades. These calculations are performed by a number of submodels interacting with each other, as shown in the flowchart in Fig. 75.13. In Fig. 75.13, the term *submodel* has been abbreviated as *model*.

The FIRE-RISK model, like FiRECAM and other more complex risk-cost models, is at present suited only to fire research or for use in assessment of building code requirements by researchers. These models are not currently well suited to use by fire protection engineers for individual building design, although that could be the ultimate aim.

FIRE-RISK has been used to assess building code requirements in Australia for Class 2 apartment buildings [108]. In particular, the current prescriptive requirements in the Building Code of Australia (BCA) have been evaluated in terms of the risks to life safety due to fire using this risk-cost model. Fatality rates per 1000 fires have been estimated for occupants in the apartment of fire origin (AFO) and in the apartments of nonfire origin (ANFO). Results of this research are shown in Table 75.2.

The lower rates for high-rise apartment buildings are likely to reflect the more stringent fire protection provisions required for buildings over 25 m under the BCA. It is suggested by Thomas et al. [108] that these results reflect the fatality rates from fire statistics for this class

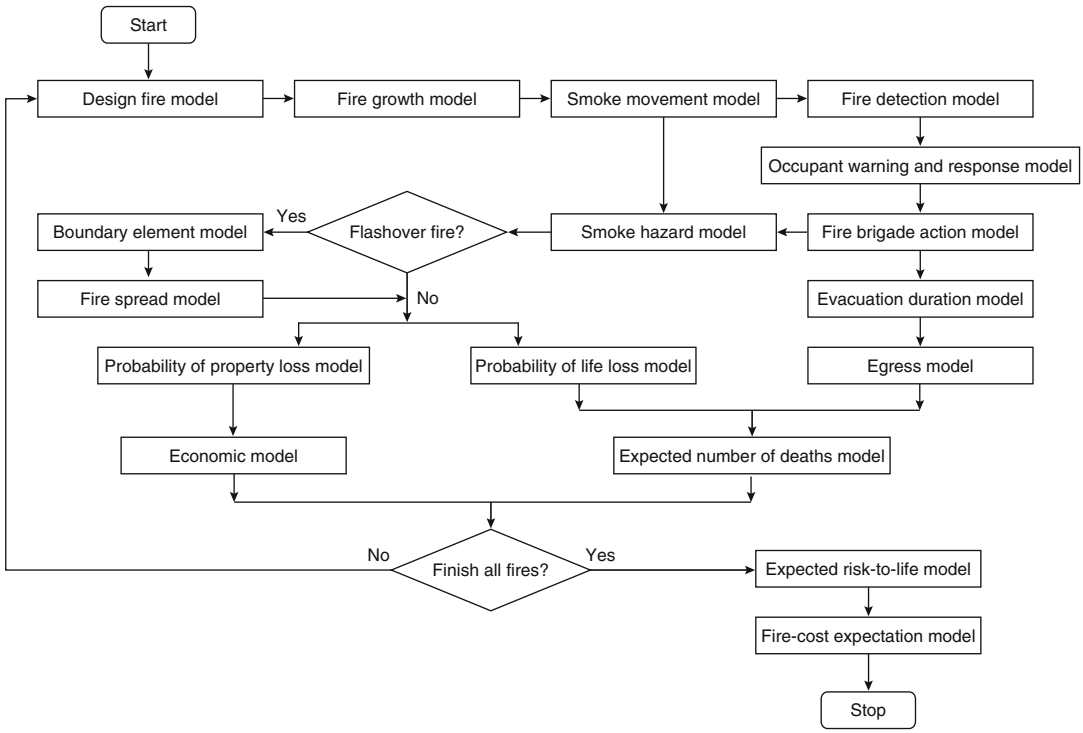

Fig. 75.13 Risk-cost assessment model

Table 75.2 Average ANFO fatality rates using CESARE-risk [92]

Building height	Fatality rate	
Low rise (<4 stories)	<0.2	ANFO fatalities/1000 fires
Medium rise (<25 m, >4 stories)	3.3–3.4	ANFO fatalities/1000 fires
High rise (>25 m)	1.7–2.1	ANFO fatalities/1000 fires

of buildings, which lends credibility to this approach.

The next step in the Australian process is to evaluate alternative fire safety solutions from those currently prescribed as deemed-to-satisfy solutions within the BCA. This would allow other prescriptive solutions to be developed and included in the BCA, which could provide building owners and designers with more flexibility to choose from a wider set of agreed prescriptive design solutions.

The risk-cost assessment model uses six design fires in the room of fire origin, and the subsequent fire and smoke spread, to evaluate life risks and protection costs in office and apartment buildings. The six design fires, representing the wide spectrum of possible fire types, are

1. Smoldering fire with room entrance door open
2. Smoldering fire with room entrance door closed
3. Flaming nonflashover fire with room entrance door open
4. Flaming nonflashover fire with room entrance door closed
5. Flashover fire with room entrance door open
6. Flashover fire with room entrance door closed

The probability of occurrence of each design fire, given that a fire has occurred, is based on statistical data. For example, in Canada, statistics show that 18 % of all apartment fires reach flashover and become fully developed fires, 63 % are flaming fires that do not reach flashover, and the remaining 19 % are smoldering fires that do not reach the flaming stage [109]. If sprinklers are installed, the model assumes that some of the flashover and nonflashover fires, depending on the reliability and effectiveness of the sprinkler system, are rendered nonlethal.

The risk-cost assessment model evaluates the effects of various fire scenarios that may occur in the building during its life. For example, in an apartment building, one fire scenario is the fire and smoke spread resulting from one design fire in any one of the apartment units in the building and during a time when the occupants are either awake or asleep. The number of fire scenarios, therefore, is the product of the number of design fires, the number of apartment units, and whether the occupants are awake or asleep.

The fire growth submodel [110] predicts the development of the six design fires in the room of fire origin. The submodel calculates the burning rate, the room temperature, and the production and concentration of toxic gases as a function of time. With these calculations, the model determines the time of occurrence of five important events: (1) time of fire cue, (2) time of smoke detector activation, (3) time of sprinkler activation, (4) time of flashover, and (5) time of fire burnout. The first three detection times are used by the evacuation duration submodel to estimate the time available for evacuation; the flashover time is used by the fire brigade action submodel, in combination with the arrival time of the fire brigade, to evaluate the effectiveness of fire fighting; and the burnout time is used by the smoke hazard submodel as part of the calculation for the maximum smoke hazard. The submodel also predicts the mass flow rate, the temperature, and the concentrations of CO and CO_2 in the hot gases leaving the fire room. This latter information is used by the smoke movement submodel to calculate the spread of smoke to different parts of the building as a function of time.

The smoke movement submodel [111] calculates the spread of smoke and toxic gases to different parts of the building as a function of time. The submodel also calculates the critical time when the stairs become untenable, which is considered to be the time when the occupants are

trapped in the building. This critical time is used later by the evacuation duration submodel to calculate the time available for evacuation.

The fire detection submodel calculates the probabilities of detection at the first three detection times mentioned under the fire growth submodel, based on the probabilities of detection by smoke detectors, sprinklers, and occupants. This information is used by the occupant warning and response submodel to calculate the probabilities of response of the occupants.

The occupant warning and response submodel calculates the probabilities of warning and response at the first three detection times mentioned under the fire growth submodel. This information is used by the fire brigade action submodel to calculate the probability of response of the fire brigade, and by the egress submodel to model the evacuation of the occupants.

The fire brigade action submodel calculates the probability and time of arrival of the fire brigade. This submodel also evaluates the effectiveness of fire fighting, based on the flashover time from the fire growth submodel and the arrival time of the fire brigade. The information on arrival and effectiveness of the fire brigade is used by the smoke hazard submodel to calculate the maximum smoke hazard to the occupants, and by the fire spread submodel to calculate the probabilities of fire spread.

The smoke hazard submodel calculates the maximum smoke hazard to the occupants based on the burnout time from the fire growth submodel and the arrival time and effectiveness of the fire brigade from the fire brigade action submodel. This information is used by the life loss submodel to calculate the probabilities of life loss.

The evacuation duration submodel uses the three fire detection times from the fire growth submodel and the critical time in the stairs from the smoke movement submodel to calculate three durations available for evacuation. This information is used by the egress submodel to model the evacuation of the occupants.

Based on the evacuation time available and the probability of response of the occupants, this submodel calculates the number of occupants who have evacuated the building and the number trapped in the building. This information is used by the expected number of deaths submodel to calculate the expected number of deaths.

The boundary element submodel calculates the probabilities of failure of the boundary elements (walls, floors, doors, etc.) when they are subjected to fully developed, realistic fires. The submodel comprises the following probabilistic models: fire severity, temperature distribution, thermomechanical material properties, failure performance for each limit state, and overall probability of failure.

Based on the probabilities of failure of the boundary elements, this submodel calculates the probabilities of fire spread to each part of the building given a fully developed fire in any enclosure. A probabilistic network of the building is developed where nodes represent building volumes, links represent boundary elements between volumes, and probabilities of failure of the boundary elements are assigned to links. Allowance is made for the effectiveness of the fire brigade. The probability of fire spread information is used by both the property loss submodel and the life loss submodel to estimate fire losses and life loss.

Based on the probabilities of smoke hazard from the smoke hazard submodel and fire spread from the fire spread submodel, this submodel calculates the probabilities of life loss.

Based on the probabilities of life loss from the life loss submodel and the number of occupants trapped in the building from the egress submodel, this submodel calculates the expected number of deaths in the building.

Based on the probabilities of fire spread from the fire spread submodel, this submodel calculates the expected property loss.

Based on the expected property loss and the capital and maintenance costs of the fire protection systems, this submodel calculates the expected fire costs.

The expected risk-to-life submodel calculates the overall expected risk to life (ERL) by summing the expected number of deaths in the

building for each fire scenario and the probability of each fire scenario.

The fire-cost expectation submodel calculates the fire-cost expectation (FCE) using the capital and maintenance costs of the fire protection systems, the expected fire loss for each fire scenario, and the probability of each fire scenario.

In the risk-cost assessment model, due to the complexity and the lack of sufficient understanding of fire phenomena and human behavior, certain conservative assumptions and approximations were made in the mathematical modeling. In addition, not all aspects of the risk-cost assessment model have been fully verified by full-scale fire experiments or actual fire experience. Only some of the submodels have been verified by experiments or statistical data.

As a result, the predictions made by the model can be considered as only approximate. The model, therefore, should not be used for absolute assessments of life risks and protection costs. For comparative assessments of life risks and protection costs, and for the selection of a cost-effective fire safety system design solution, the model is considered to be reliable.

As in many computer models, the model uses certain input parameters to describe the characteristics of various fire safety designs. These include the fire resistance rating of boundary elements, the reliability of smoke alarms and sprinklers, the probability of doors open or closed, and the response time of fire brigades. The sensitivity of these parameters on the predicted risks has been checked and found to be reasonable [112].

FRAMEworks

Another computer-based risk assessment model, *FRAMEworks*, was developed through a collaborative effort between the National Institute of Standards and Technology (NIST), the NFPA Fire Analysis & Research Division, and the private consulting firm of Benjamin/Clarke Associates [113, 114]. The goal of this effort was to develop an objective, comprehensive, generally applicable, and widely recognized fire risk assessment methodology for products that go into buildings. The result was a method for quantifying the fire risk associated with a specific class of products in a specified occupancy.

FRAMEworks is similar in many respects to the fire risk and cost assessment model of Beck described above. It combines a quantitative (fire effects modeling) method to evaluate specific products in specific fire scenarios with a statistical method of relating fire deaths to the specific scenarios in order to establish a death rate baseline for the scenarios. The impact of new or replacement products can then be evaluated against the baseline scenarios to determine if the risk is comparatively higher or lower with a change of product(s).

The modeling sequence to compute fire risk in *FRAMEworks* is illustrated in Fig. 75.14. A more detailed description of the model can be found in the NFPA *Fire Protection Handbook*® [114].

CRISP

A computer-based fire risk assessment model is also under development in the United Kingdom by the Building Research Establishment, Fire Research Station. This model, called CRISP (Computation of Risk Indices by Simulation Procedures), is similar to the Beck model in that it provides a Monte Carlo simulation of entire fire scenarios but is an object-oriented model as opposed to a state transition model [115, 116]. The basic concept of the CRISP approach is that the building-contents-people system is treated as a collection of objects, represented by a section of the program that defines the objects' behavior in response to stimuli (input data). The objects may interact in a number of ways, depending on the information exchanged between them, but data associated with an object cannot be changed by another object (only by changing that object's code). Thus, for any given scenario, the objects will interact with each other but not change each

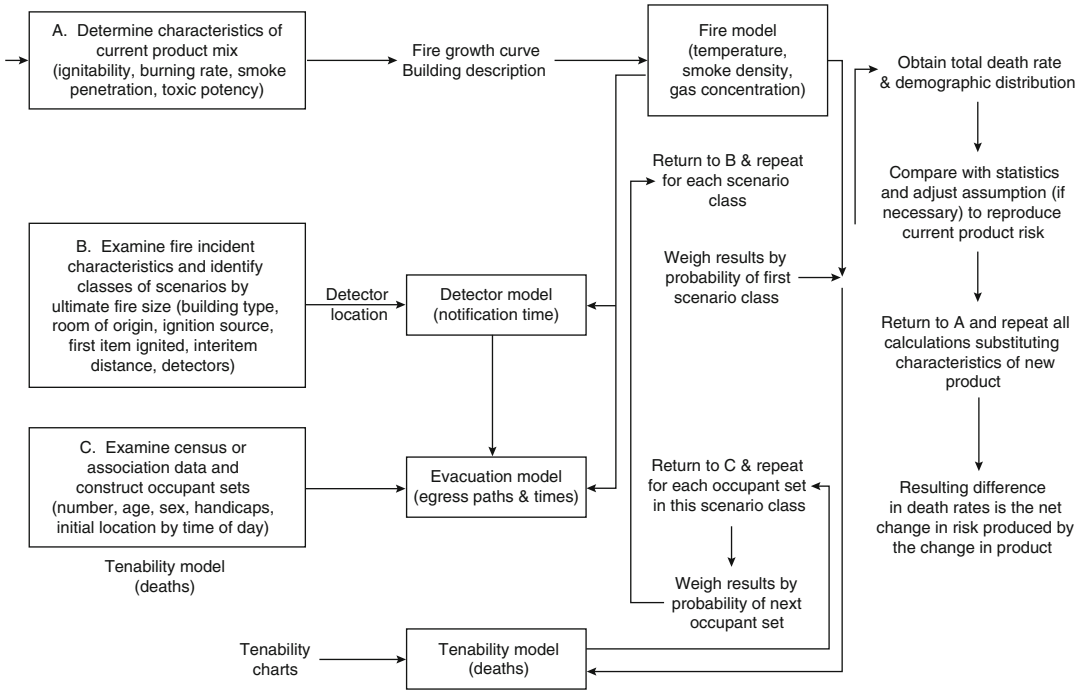

Fig. 75.14 Modeling sequence to compute fire risk in FRAMEworks [113]

other, based on the associated object definition and input parameters.

The types of objects modeled include furniture, hot and cold gas layers, vents, walls, rooms, alarms, occupants, and fire fighters [115]. The actions of the objects are governed by physical relationships (e.g., fire growth) and tables of rules (e.g., for people). For each run, various conditions, contents, and occupant characteristics are randomly selected and probabilities are assigned. Once the conditions have been defined, the simulation predicts how a scenario develops with time until the fire is out or the occupants are dead or have escaped.

Thus far, the scope of CRISP runs has been limited to two-story residential occupancies, and has been used to evaluate such trade-offs as fire detection installation versus the need for additional passive fire protection, and caution has been urged relative to the model's use in more complex buildings [105].

FRIM-MAB

A fire risk index method has been developed for multistory apartment buildings (FRIM-MAB) [117]. The approach uses a semiquantitative approach to characterize the fire risk associated with timber-frame buildings common within the Nordic countries of northern Europe.

Specific fire-related parameters such as apartment linings, smoke detection, escape routes, and the like are defined, with supporting decision tables to allow consistent evaluation of each parameter. The parameters are indexed based, for example, on the type of suppression system provided. The whole building is then assessed using a semiquantitative method. A comparative risk value is then determined for each building. This approach provides a consistent method for categorizing the risk within buildings. The approach has been supported by more complex modeling using quantified risk assessment

(QRA) techniques. The risk index provided has been shown to be consistent with the calculated expected risk from using QRA; however, it is noted the risk determined is not quantitative but provides valuable comparison between buildings assessed with the same method.

Of particular interest is the ability to provide repeatable and consistent evaluations of risk. The approach has been validated via assessment of separate buildings by independent engineers, evaluating the buildings with identical information. The results show, for the sample buildings assessed, that a consistent answer can be provided.

BuildingQRA

BuildingQRA [141] is a software package developed to help assess safety and financial risks associated with fires in buildings. An event tree structure is used. Scenarios are solved probabilistically for the event tree using Monte Carlo analysis. The software includes options assessment and cost-benefit prioritization. Multiple scenarios assessments are based either on discrete hazard (smoke) and egress analysis using zone models or user defined values. Specific event trees can be developed. Distributions are used for input parameters. Other user defined functions, including fault trees, are available as well.

B-RISK

B-RISK is a fire simulation model and software program comprising a fire risk simulator for generating probability distributions for relevant model outputs, given that the statistical distributions to key input parameters are assigned [142]. Central to B-RISK is an underlying deterministic fire zone model, BRANZFIRE [143], for which the physics have been expanded, and a new tools for users has been implemented which allows for a better understanding and description of the uncertainty and risk associated with fires in building enclosures. The B-RISK model may be used for both single deterministic runs as well as for multiple iterations of a scenario for the purpose of sensitivity analysis or for producing probabilistic descriptors of fire risk under defined conditions.

CUrisk

A quantified risk assessment (QRA) program is being developed at Carlton University, CUrisk [118], to evaluate the fire safety designs, predominantly for timber-framed commercial buildings. Risk, in this instance, is determined with the use of an overriding system model, providing an event tree, with supporting submodels used to determine fire growth and smoke movement, boundary failure and fire spread, occupant response and evacuation, and building cost and economic loss.

The model uses deterministic analysis of separate fire scenarios to calculate, for example, smoke temperatures and toxic smoke concentrations within the fire compartment and neighboring compartments. The approach uses an advanced occupant evacuation model to determine the time taken for occupants to evacuate including a "rule-based" behavior system and random procedures within the decision-making process.

The results provide the expected risk to life (ERL) and the expected risk injury (ERI), based on the tenability criteria to yield both death and also incapacitation. The expected annual financial cost of fire within the building can also be determined.

Structured Technical Analysis of Risks from Fire (STAR-Fire) and Simplified Approach to Fire Risk Assessment (SAFiRE) Methods

Structured Technical Analysis of Risks from Fire (STAR-Fire) [119] and Simplified Approach to Fire Risk Assessment (SAFiRE) methods [120] were first developed following analysis of the King's Cross Underground Station fire. The approaches are based on the risk assessment

methods first developed in the nuclear industry and further developed in the offshore and transport industries, modified to provide quantified fire risk assessment for the design of buildings. These methods can address life safety, property protection, and business continuity fire safety objectives, with selection dependent on user needs, and can be used for both new and existing buildings. To date, a large cross section of building types has been assessed using these methods, including retail, public, transport, education, and industrial facilities [58, 120, 121].

Generic fault and event trees, and balanced modeling of frequency and consequence, are used in each approach [121, 122]. Individual and societal risk to life can be assessed, and average or distributional representations of financial loss measures can be used, with results presented in either tables or FN curves. The outcomes can then be used for absolute risk assessment, using risk criteria agreed on by stakeholders, or, comparatively, benchmarking to the risk levels associated with a code compliant design or other agreed benchmark (the latter being the preferred approach).

In these methods, individual fire events are defined by their frequency and their consequences. Scenarios are defined by fault and event tree analysis, with Monte Carlo analysis of highly variable parameters (e.g., number of people in the building at the time of ignition). Input data include geometry of spaces and escape routes, fire growth, detection, occupant number, premovement time and velocity/flow, frequency of ignition, and probabilities of failure of fire protection systems, with probability distributions being calculated for the most variable parameters; and evacuation time, tenability time, and statistical analysis of some scenarios being generated. Simulation of one million fire scenarios requires on the order of 1–2 h. Uncertainty, safety factors, sensitivity, precision, and bias are addressed through a qualitative narrative.

Hazard and Risk Matrices

In addition to the more complicated single-scenario and ETA-based engineering approaches and computer-based risk modeling, various risk analysis alternatives exist that combine hazard analysis, consequence analysis, and judgments about likelihood of events in less quantitatively rigorous manners. This does not imply the methods are less rigorous, or less appropriate, but that they are simply easier to apply. In many cases, such simplified approaches will be more widely accepted by interested and affected parties, as the concepts may be familiar.

One such approach is the hazard matrix [123], or risk matrix approach [10, 124]. This approach is simpler to apply than a classical engineering risk analysis approach, as the importance of identifying all possible outcomes is less critical. In essence, it works by quantifying the consequences of the most severe events anticipated and coupling these with approximate event frequencies. The result is a quantified approximate risk estimate. In this approach, a maximum consequence for each type of loss is identified (life safety, property, business interruption, environmental damage, etc.) that represents the largest realistic event of each type. Each maximum consequence is then ranked. Table 75.3 provides an example of possible consequence ranking thresholds (i.e., negligible, low, medium, and high) that may be selected. For these estimates, the consequence predictions should bound all possible event outcomes at the 95th percentile or better [10]. The 95th percentile value is suggested because it has gained ready acceptance in other engineering fields, and by using such a standard value, it may be possible to compare different analyses. If it is desired to use a different bounding level, all stakeholders must agree. An extensive analysis can often be avoided when selecting the maximum consequence if the total replacement costs are assumed to be the maximum consequence.

The frequencies must also be ranked in this type of analysis. Here, the frequencies should be for exceeding a specific loss (i.e., consequence) rather than for a specific scenario, as frequencies based solely on a specific scenario can be misleading. For example, a scenario may have a frequency of 10^{-7} per year, leading one to the conclusion that fire is not a concern. However, the reported fire risk should actually represent

Table 75.3 Possible consequence ranking criteria [10]

Consequence level	Impact on populace	Impact on property/operations
High (H)	Immediate fatalities, acute injuries—immediately life threatening or permanently disabling	Damage > $XX million—building destroyed and surrounding property damaged
Moderate (M)	Serious injuries, permanent disabilities, hospitalization required	$YY < damage < $XX million—major equipment destroyed, minor impact on surroundings
Low (L)	Minor injuries, no permanent disabilities, no hospitalization	Damage < $YY—reparable damage to building, significant operational downtime, no impact on surroundings
Negligible (N)	Negligible injuries	Minor repairs to building required, minimal operational downtime

Table 75.4 Example frequency criteria used for probability ranking [10]

Acronym	Description	Frequency level (median time to event)	Description
A	Anticipated, expected	$>10^{-2}$/year (<100 years)	Common incidents that may occur several times during the lifetime of the building
U	Unlikely	$10^{-4} < f < 10^{-2}$/year (100–1,0000 years)	Events that are not anticipated to occur during the lifetime of the facility. Natural phenomena of this probability class include UBC-level earthquake, 100-year flood, maximum wind gust, etc.
EU	Extremely unlikely	$10^{-6} < f < 10^{-4}$/year (1,0000–1 million years)	Events that will probably not occur during the life cycle of the building
BEU	Beyond extremely unlikely	$<10^{-6}$/year (>1 million years)	All other accidents

the frequency of multiple fire scenarios, so if 30 specific scenarios are developed, each at 10^{-7} fires per year, the net effect is 3×10^{-6} fires per year. Table 75.4 provides a specific example for frequency ranking [10, 122]. As with consequence ranking, alternate frequency rankings (bins) from those presented in Table 75.4 can be developed provided that all interested and affected parties agree. It is also possible to add additional layers of ranking where desirable.

Once the bounding consequences and their respective frequencies have been estimated, they must be converted to an estimate of risk. An estimation is accomplished by plotting the consequence-frequency combination in a matrix, as shown in Fig. 75.15 (the numbers in boxes are for identification purposes and do not imply a ranking). The stakeholders assign each consequence-frequency combination, and the resultant risks are considered bounding risks. After this analysis, events that meet a certain risk criterion may be considered "acceptable" based on the objectives and input from the interested and affected parties (e.g., the interested and affected parties may consider moderate, low, and negligible risk events acceptable).

Performance Matrix

A concept similar to that of the hazard and risk matrices approach described above has been developed for use in building and fire safety regulations [1, 4, 5, 125–128]. This approach establishes a performance matrix that compares performance groups (building types grouped by like performance expectations) by magnitude of design events (probabilistic or deterministic descriptions of hazard event). Within the

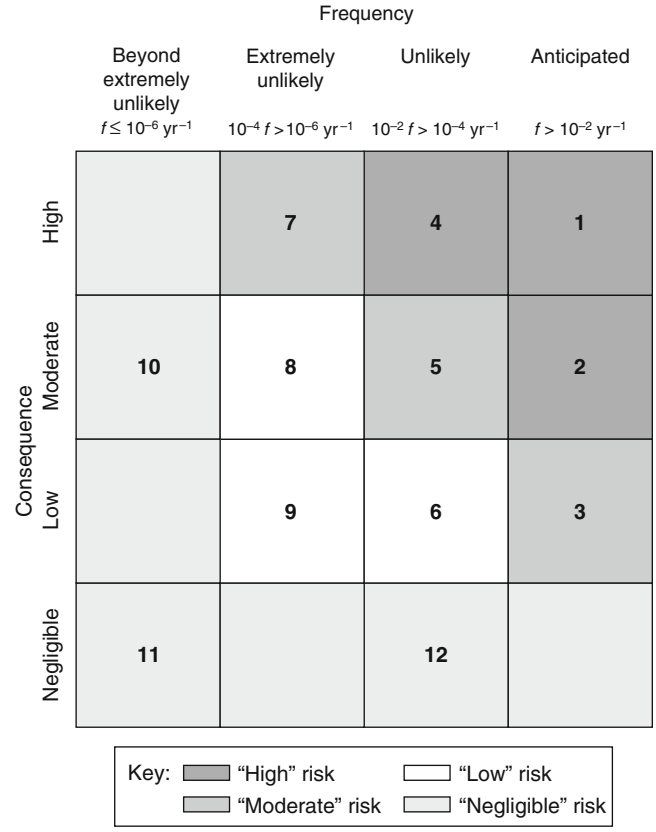

Fig. 75.15 Example risk ranking matrix [10]

performance matrix, instead of having risk bins (groups), there are tolerable levels of impact (reflecting the amount of damage expected for buildings within different performance groups given specific magnitudes of design events). As the performance group increases from Group I to Group IV, the level of required performance increases, as do the corresponding levels of tolerable impact. This is illustrated in Fig. 75.15.

Within the performance matrix, tolerable levels of impacts reflect various limit states of damage, injury, or loss that can be estimated, measured, and/or calculated when subjected to design loads of various magnitudes. As the impacts get larger, it is expected that more damage will occur, unless a higher level of performance is desired. In this manner, the levels of impact are inversely proportional to building performance: less impact means better performance. Establishment of these levels of tolerable impact requires a balance of technical knowledge and ability and societal values. The term *tolerable* is used to reflect the fact that absolute protection is not possible, and that some damage, injury, or loss is currently tolerated in structures, especially after a hazard event. The term *impact* is used as a broad descriptor of loss.

If one so chooses, one can overlay probabilities and consequences on the performance matrix in a manner similar to the hazard and risk matrices discussed previously. In the performance matrix (Fig. 75.16), the magnitudes of design event can be overlaid with probabilities (or frequencies) of event occurrence, from high at the bottom to low at the top. For all high-probability events, the allowable magnitude of impact (consequences) is either mild or moderate depending on the performance group. For low-probability events, the allowable magnitude of impact can be moderate, high, or severe depending on the performance group. This approach allows for decisions to be made on the

required level of building performance for low-probability, high-consequence events, based on the performance group to which a building is designated.

Performance groups are simply consolidations of use groups with common performance requirements. They are developed as part of the risk characterization process, considering such issues as numbers of people in a building, sensitive or vulnerable populations, the hazards posed by the building, its contents or processes, and essential facilities and services [126]. The number of performance groups that is required should be based on an analytical-deliberative risk characterization process as described previously. The following definitions of performance groups represent one example, as used in the *International Performance Code for Buildings and Facilities* [125].

Performance Group I is intended to cover those buildings or facilities, such as utility sheds, where the failure of such buildings poses a low risk to human life. Performance Group II is intended to be the minimum for most typical buildings, such as business, mercantile, or storage uses. Performance Group III includes building and facilities with an increased level of societal benefit or importance. These structures and classes of structures require increased levels of performance as they house large numbers of people, vulnerable populations, or occupants with other risk factors; or they fulfill some role of increased importance to the local community or to society in general. Examples include post-disaster command control centers, acute-care hospitals, or a school used as an emergency shelter. Performance Group IV contains building uses or facilities that have an unusually high risk. Such facilities may include nuclear facilities or explosives storage facilities. For specific facilities, for specific jurisdictions, or in countries outside of the United States, other definitions for the performance groups may be appropriate.

Fig. 75.16 Performance matrix [1, 125]

Magnitude of design event Increasing magnitude of event	**Increasing level of building performance** Performance groups			
	Performance group I	Performance group II	Performance group III	Performance group IV
Very large (very rare)	**Severe**	**Severe**	**High**	**Moderate**
Large (rare)	**Severe**	**High**	**Moderate**	**Mild**
Medium (less frequent)	**High**	**Moderate**	**Mild**	**Mild**
Small (frequent)	**Moderate**	**Mild**	**Mild**	**Mild**

Likewise, the number of tolerable levels of impact can be selected based on the level of detail deemed appropriate by interested and affected parties. One possibility is the use of four levels: mild, moderate, high, and severe [128]. The definition of each level would reflect the tolerability limits as developed by a risk characterization effort. For example, a moderate level of impact may be defined as follows (remember that levels of impact are inversely proportional to levels of performance, and that these are design goals):

- There is moderate structural damage that is repairable; some delay in reoccupancy can be expected due to structural rehabilitation.
- Nonstructural systems needed for normal building use are fully operational, although some cleanup and repair may be needed. Emergency systems remain fully operational.
- Injuries to building occupants may be locally significant, but generally moderate in numbers and in nature. There is a low likelihood of single life loss and a very low likelihood of multiple life loss.
- Damage to building contents may be locally significant but is generally moderate in extent and cost.
- Some hazardous materials are released to the environment, but the risk to the community is minimal. No emergency relocation is necessary.

Associated with the tolerable levels of impact is the actual hazard event. One way to look at the hazard event is in terms of its size, or magnitude. The magnitude of a hazard event can be represented deterministically or as a frequency of occurrence. When characterizing the magnitude of hazard events, it is important to remember that (1) they are on a continuum and are compartmentalized for ease of analysis and design; and (2) they should be considered "design loads" and not as a reflection of the actual magnitude of event that could impact a building.

As with tolerable levels of impact, the number of magnitude of event levels can be established by the interested and affected parties. For example, four categories of event magnitude (design loads) can be selected: small (frequent), medium (occasional), large (rare), and very large (very rare). To understand how the magnitudes can be described, consider earthquake loads and fire loads, where earthquake loads are shown in terms of their mean return period, and fire loads are shown deterministically in terms of extent of flame spread.

Earthquake loads (mean return period)	
Frequent	72 years
Occasional	225 years
Rare	474 years
Very rare	2475 years
Fire loads (deterministic)	
Small	Contained to object of origin
Medium	Contained to room
Large	Contained to floor
Very large	Contained to building

There is often correlation between frequent, occasional, rare, and very rare; and small, medium, large, and very large; in that frequent events tend to be small, whereas very large events tend to be very rare. Also, it is often the very large or very rare events that are of particular concern, as it is these events for which providing high levels of protection against is costly and may not be considered reasonable or cost-effective for all buildings.

The Building Fire Safety Evaluation Method (BFSEM)

Another approach to identifying hazards and consequences, for obtaining judgments on the likelihood of events occurring, and for characterizing risk, is the *Building Fire Safety Evaluation Method* (BFSEM) [129–133]. The BFSEM can be used to analyze an existing building or a proposed new building. A primary goal is to understand how the building will perform for credible diagnostic fire scenarios. Describing expected risk characterizations are another part of a complete BFSEM analysis. One can perform either a holistic analysis or an individual component analysis.

Figure 75.17 illustrates the scope of fire performance and risk characterizations [132]. After one understands the building's performance and can characterize the associated risks, an integrated design or risk management program can be developed.

The system of building-fire behavior is dynamic. Therefore, time links all parts of the system. The method's organization provides a way to coordinate dynamic fire changes and fire defense operations. An analysis incorporates time-based changes in component performance by adapting conventional event trees of risk analysis. Performance evaluations for any instant of time adapt conventional fault tree analysis. Component interactions are incorporated into evaluations.

The method is based on deterministic analyses of the fire defense components. An analysis uses modules that are obtained by decomposing the complete functional system of fire and buildings and repackaging the components into analytical networks. Adapting techniques of failure analysis to additional decompositions provides a basis for evaluating events that are critical to performance.

Time-based relationships can be captured in an *Interactive Performance Information* (IPI) chart, which orders and records important information for performance evaluations and risk characterizations. It allows one to observe changes in any component over time as well as to examine the status of any or all components at any instant of time. An IPI chart is illustrated in Fig. 75.18 [132]. In Fig. 75.18, the diagnostic fire scenario and each of the major fire defense parts are shown by the horizontal rows. Each of these rows describes an event tree adapted from conventional risk analysis. The status of the events

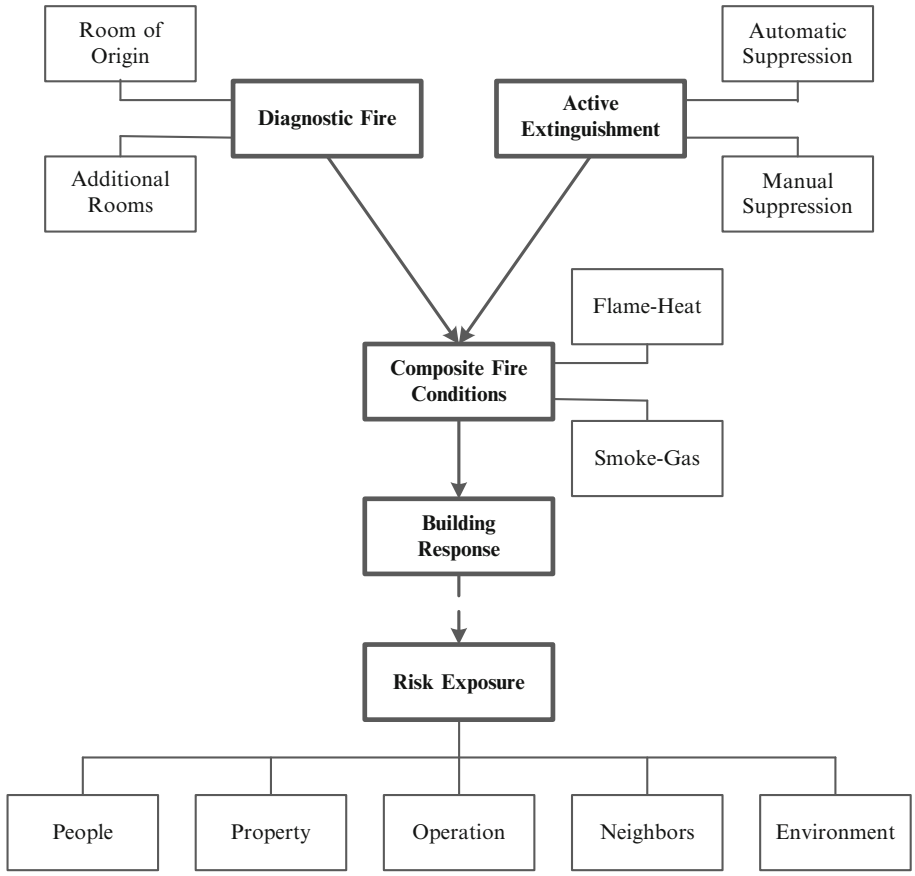

Fig. 75.17 Fire risk characterization in the BFSEM [132]

changes over the duration of the fire. The vertical columns identify time steps from ignition to extinguishment. The component events in a column are based on fault tree analysis.

The horizontal rows (event trees) are analogous to a continuous video of the operation of the major fire defenses and their major components. If we were to "stop the world" at an instant of time (i.e. examine the events in a single vertical column), the status of each component could be described and their interactions with other parts of the dynamic building-fire system would be recognized. This is analogous to examining a group of still photographs all taken at that time. For any fire scenario, each cell of the IPI chart is effectively a cell of a spreadsheet. A broad range of attributes, including a description of performance, can be shown for each instant of time.

A relatively narrow window of functional operation exists for each component of Fig. 75.18. One part of a performance analysis coordinates the time durations to understand the impact of functional operation sequencing for the building fire scenario. Each building has unique features that distinguish its fire performance from that of others. Thus, IPI charts provide a means to compare risks and the effectiveness of design improvements.

Performance quantification is deterministic. However, today's state of the art of fire technology is inadequate to quantify the performance of all components and their interactions. Consequently, evaluations incorporate Bayesian techniques to describe expected performance. This enables the contributions of other components at that instant of time to be incorporated into an evaluation. The process enriches performance understanding and communication by expressing results in terms of a probabilistic degree of success. This use of probability should not create the impression that the method is probabilistic. To the contrary, the method is deterministic, but uses Bayesian theory to bridge the gap between "benchmarks" of known behavior.

Application of the BFSEM provides a comprehensive method for identifying factors that affect the fire safety performance of a building. The method has been widely used, including being adapted by the U.S. Coast Guard to become its ship fire safety engineering methodology (SFSEM) [133].

Guidance Documents for Fire Risk Assessment

Given the growing interest in the use of risk assessment techniques for building fire safety evaluation, a number of organizations have prepared guidance documents that are useful to designers and approval authorities (i.e., AHJs) in relation to buildings.

These guides are not risk assessment methodologies or risk analysis techniques. Rather they are directed at assisting practitioners in selecting the appropriate methodology for any given building and ensuring that the process of risk assessment and approval is undertaken in a proper engineering manner.

SFPE Engineering Guide—Fire Risk Assessment

The *SFPE Engineering Guide*: *Fire Risk Assessment* [134] is aimed at those qualified practitioners undertaking design and evaluation of buildings and/or process fire safety. The document provides guidance on the selection and use of risk assessment techniques and provides a recommended process to follow.

The *SFPE Guide* does not specify particular risk assessment methods or techniques. However, it highlights

- A recommended process for fire risk assessment (Fig. 75.19)
- Tools that may be used for hazard identification
- Sources of data for risk assessment
- Approaches to consequence modeling
- Methods for calculating fire risk
- Documentation of fire risk assessment

The *SFPE Guide* is structured to follow the flowchart represented in Fig. 75.19, providing guidance and information association with each

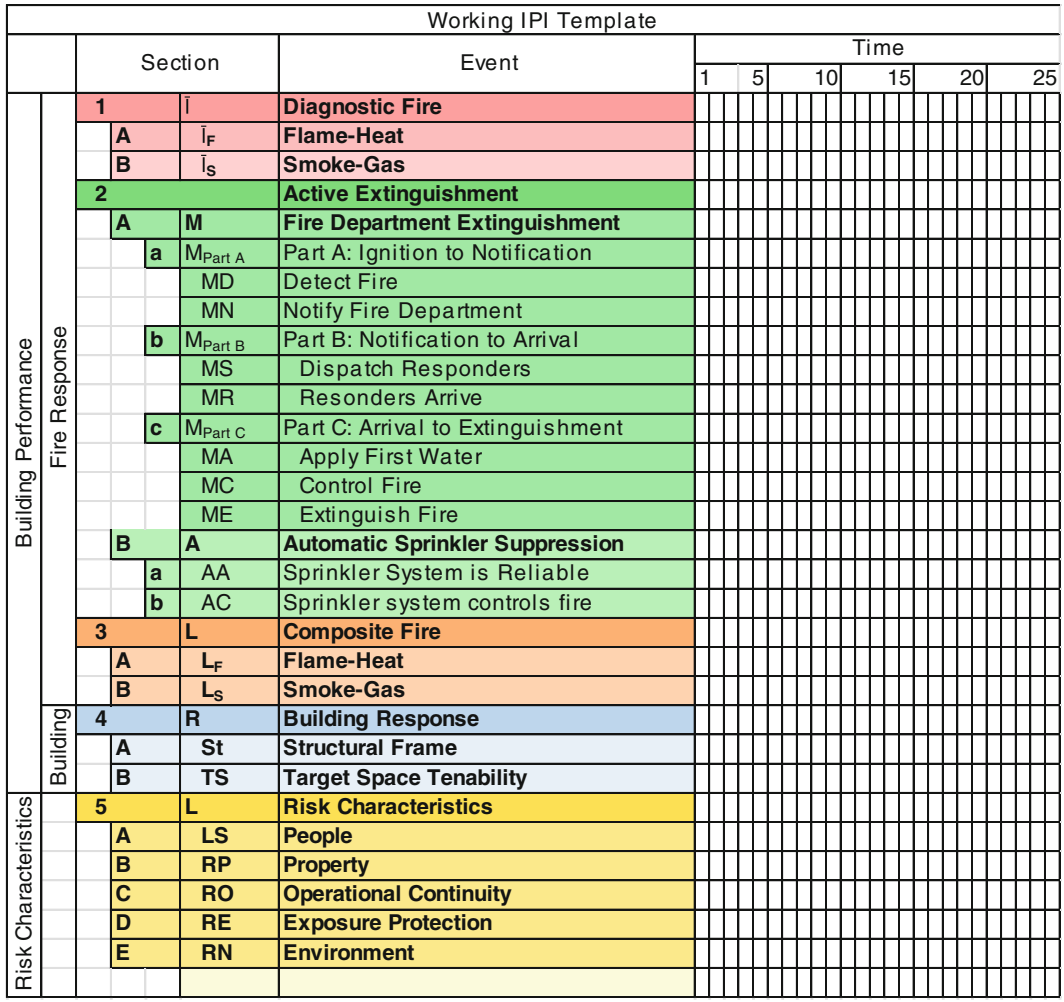

Fig. 75.18 Interactive Performance Information (IPI) chart representation of BFSEM [132]

step in the process. This information is supported with many references and a comprehensive list of information sources for further reading for each step of the risk assessment process. An overview of the SFPE process can be found in reference [135].

NFPA 551, *Guide for the Evaluation of Fire Risk Assessments*

NFPA 551, *Guide for the Evaluation of Fire Risk Assessments* [136], was developed in the United States in recognition of the fact that fire risk assessment methods are increasingly being used in developing fire and life safety solutions for buildings and other facilities.

This guidance document is directed at those responsible for approving or evaluating fire and life safety solutions based on a fire risk assessment. It provides a framework that describes the properties of a fire risk assessment, particularly where it is being used in a performance-based regulatory framework. As a result, this guide is suited to a building or fire official or other authority having jurisdiction required to evaluate or approve a building design where the design is being supported by a fire risk assessment.

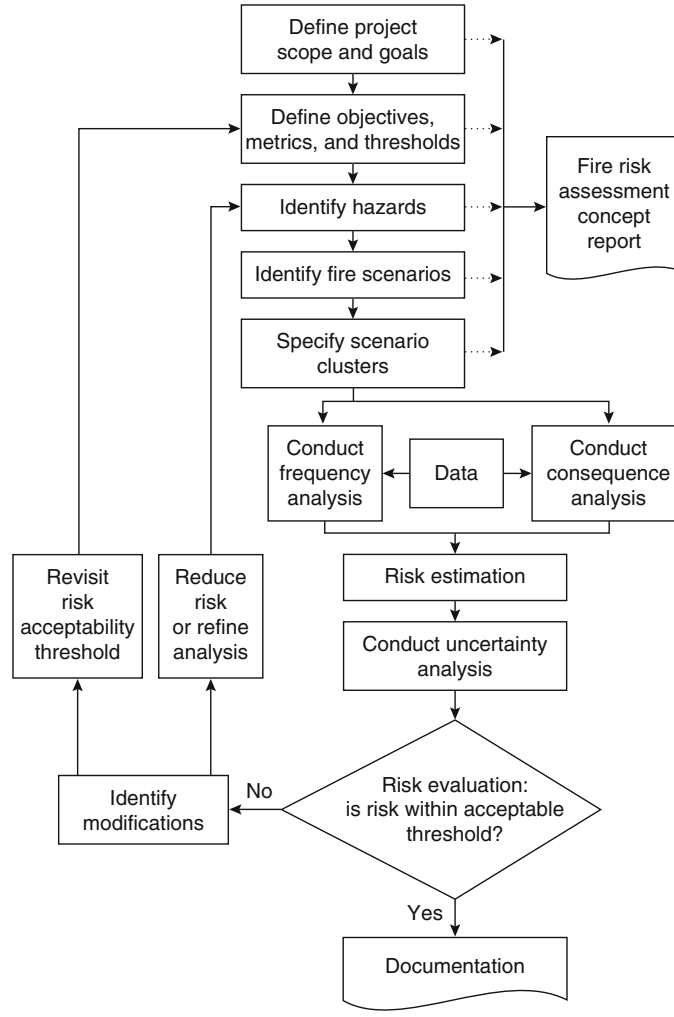

Fig. 75.19 Fire risk assessment flowchart [134]

Like the *SFPE Guide* referenced above, NFPA 551 neither specifies particular fire risk assessment methods nor attempts to set acceptance criteria. Rather it sets out the technical review process and documentation that should be used by those evaluating or approving. The review process is illustrated in Fig. 75.20.

NFPA 551 defines five categories of fire risk assessment methods in order of increasing complexity, namely

- Qualitative methods
- Semiqualitative criteria-based methods
- Semiqualitative consequence methods
- Quantitative methods
- Cost-benefit risk methods

It highlights the importance of identifying the objectives of any fire risk assessment and other factors that should be considered by those undertaking fire risk assessments. For each of the five categories of methods, the characteristics of each approach are identified, and issues of inputs and outputs, assumptions and limitations, selection of fire scenarios, and uncertainty are discussed.

BS 7974-7, *Probabilistic Risk Assessment*

The British Standards Institute (BSI), the National Standards Body of the United Kingdom (U.K.), provides a number of fire-related design

standards. A framework for the application of fire safety engineering principles for the design of buildings is provided within BS 7974. This document is supported by the Published Document series PD 7974 Parts 0 to 7. The final document, Part 7, provides guidance for the probabilistic risk assessment of buildings [137].

The document provides a framework for risk assessment commensurate with a number of approaches within this handbook. Specifically, the document provides guidance with regard to acceptance criteria for life safety and financial assessments, which may use either comparative or absolute methodologies. The absolute criteria for individual risks and societal risk are provided. The logic tree is illustrated using both event trees and fault trees. An assessment methodology using *complex* analysis techniques is also provided, whereby risk is evaluated understanding the reliability of systems, use of stochastic models to evaluate the spread of fire within a building, Monte Carlo analysis used to evaluate a random distribution of variables addressing low-probability scenarios, and safety factors.

The annex to this document provides very useful guidance about the probability of fire starting dependent on the type and use of the building. Further, the average area damaged and the distribution of damage are provided. There are also valuable statistics on the frequency distribution of the numbers of deaths attributed to fire, the probability of flashover, and reliability data concerning active and passive fire safety systems.

These data are principally based on U.K. fire statistics recorded over a representative sample period and as such are considered a valuable

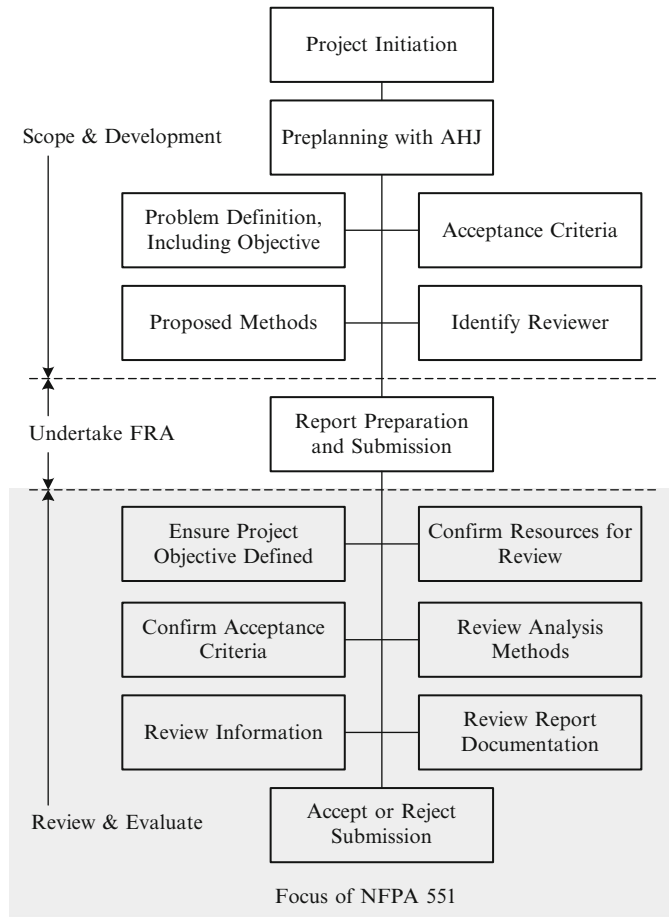

Fig. 75.20 NFPA 551 review process [136]

source of information, although generally applicable to U.K. projects. The data, for example, illustrate fire damage for an 8000-square-meter textile industry building is twice as large for a nonsprinkled building when compared to a sprinkler protected building.

ISO 16732-1:2012 *Fire Safety Engineering—Fire Risk Assessment*

ISO 16732-1:2012 provides the conceptual basis for fire risk assessment by stating the principles underlying the quantification and interpretation of fire-related risk [138]. The principles and concepts outlined in the standard can be applied to any fire safety objectives, including safety life, conservation of property, business continuity, preservation of heritage and protection of the environment. The fire risk principles discussed in the standard apply to all fire-related phenomena and user applications, which means that the principles can be applied to all types of fire scenarios.

In ISO 16732-1:2012, principles underlying the quantification of risk are presented in terms of the steps to be taken in conducting a fire risk assessment. These quantification steps are initially placed in the context of the overall management of fire risk and then explained within the context of fire safety engineering. The use of scenarios and the characterization of probability (or the closely related measure of frequency) and consequence are then described as steps in fire risk estimation, leading to the quantification of combined fire risk. Guidance is also provided on the use of the information generated, i.e., on the interpretation of fire risk. Finally, there is guidance on methods of uncertainty analysis, in which the uncertainty associated with the fire risk estimates is estimated and the implications of that uncertainty are interpreted and assessed.

As described by ISO 16732-1:2012, risk management includes risk assessment, but also typically includes risk treatment, risk acceptance, and risk communication (see Fig. 75.21).

In this approach, fire risk assessment is part of a larger process, which starts with setting fire risk goals and objectives, and where risk acceptance marks the conclusion of the assessment. If risk is not accepted, another risk assessment is necessary, and risk treatment is an option after each risk assessment. Risk communication is conducted after risk acceptance.

The component of fire risk assessment is defined as a procedure for estimation of fire risk for a built environment and evaluation of estimated fire risk in terms of well-defined acceptance criteria [138]. Fire risk assessment is can be used to quantify the risk associated with specific scenarios, but can also be used to assess alternative designs, prior to selecting a specific design or making changes to that design to achieve compliance with the acceptance criteria.

Fire risk assessment begins with the fire risk goals and objectives and a proposed design specification for the structure or other part of the built environment to be assessed. The risk associated with the design specification is estimated and then evaluated. Risk evaluation consists of comparison of the estimated risk for the design to the acceptance criteria.

Fire risk estimation begins with the establishment of a context. The context provides a number of quantitative assumptions, which are required with the objectives and the design specifications to perform the estimation calculations. Figure 75.22 describes the sequence of steps involved in fire risk estimation as it is conducted when the scenario structure is explicit and when frequencies and consequences are explicitly calculated in quantitative form (other sections of the standard describe the use of risk curves, risk matrices and other techniques for which the flow chart is not fully applicable in detail).

The standard goes on to describe in some detail the components in the fire risk estimation, as well as the role of uncertainty in the fire risk assessment process. Examples of application of fire risk assessment are also included.

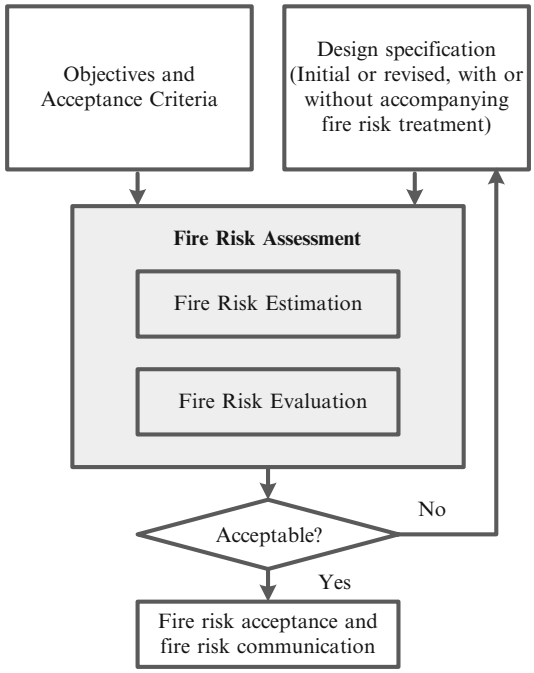

Fig. 75.21 Fire risk management concept [138]

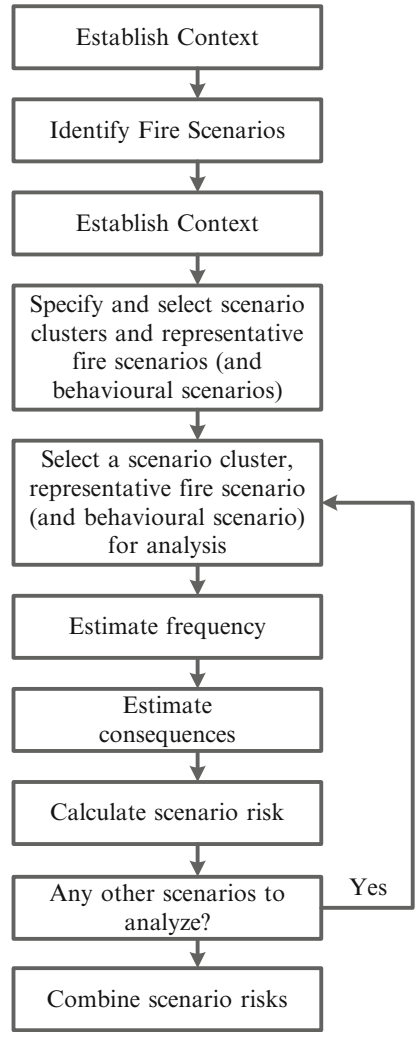

Fig. 75.22 Risk estimation [138]

Textbooks

As noted in the previous section, there has been a growing interest in fire risk assessment over the last two decades, which has prompted the development of several guidance documents and standards on fire risk assessment. In addition, there have been new chapters added to the SFPE Handbook on various aspects of fire risk assessment, e.g. by industry, occupancy type and sector (built environment, transportation), with each new edition. As another indicator of the growing interest in fire risk assessment, and the desire for information relative to tools and techniques for fire risk assessment, there have been a number of textbooks published in the last decade, with others in development. It is worth noting these as additional resource for fire protection engineers, with the hope that this section continues to expand in future editions.

Published in 2004, *Evaluation of Fire Safety* [139], while not strictly a text on fire risk assessment, includes many aspects of fire risk assessment throughout. Written by a collection of five leading authorities in fire safety engineering, the text includes chapters on sources of statistical fire loss data, measurements of fire risk, various fire risk evaluation methods (e.g., point systems, logic tress, stochastic fire risk modeling and the fire safety concepts tree and derivative approaches). It provides a comprehensive suite of information for anyone embarking on fire safety evaluation of the built environment.

Following the tragic events of September 11, 2001, the text *Extreme Event Mitigation in Buildings*: *Analysis and Design* [140] was published to provide a resource for understanding and assessing building performance under

extreme events. While not focused solely on fire, the text provides information on assessing likelihood of occurrence, potential impacts, and strategies for mitigation for a wide range of extreme events—natural, technological and deliberate, while aiming to achieve a balance of acceptable levels of risk, performance and cost. The text outlines how risk-informed performance-based analyses can be used to help make important risk mitigation decisions.

In 2007, a trio of risk experts from Australia published the book, *Risk Analysis in Building Fire Safety Engineering* [94]. As the title implies, this text is focused on tools and techniques that are fundamental to applying risk concepts in fire safety engineering. It starts with elements of probability theory required for the understanding of risk analysis, then transitions into various tools for risk analysis, including the beta reliability index, Monte Carlo Analysis, Event Tree and Fault Tree analysis, and cost-benefit analysis. Several chapters are then provide relative to modeling the probabilistic and stochastic aspects of fire safety systems. Case studies are provided to illustrate the application of these concepts in performance-based fire safety design.

2008 saw the publication of a text focused on building fire risk assessment, *Principles of Fire Risk Assessment in Buildings* [96]. This text is presented in two parts: Part I overviews simple approaches to fire risk assessment, and Part II outlines a fundamental approach to fire risk assessment, considering fire growth, smoke spread, occupant response and other factors using fire risk assessment concepts. Like the text above, this was authored by an expert in the field who has developed models for fire risk assessment described earlier in this chapter.

Most recently, two renowned fire risk experts from the UK collaborated on the 2011 text, *Quantitative Risk Assessment in Fire Safety* [97]. This text presents a broad ranging discussion of qualitative, semi-quantitative and quantitative risk assessment techniques, discussing sources of data, structuring of the assessment technique, assessment and evaluation. Probabilistic and stochastic analysis of fire development and spread and response of fire safety systems is also provided. Reliability of fire safety systems, performance of people and effectiveness of the fire services is also presented.

These texts, as well as others written for specific industries, hazards and risks, provide fire protection engineers with additional resources for tackling the challenges of building fire risk analysis.

Summary

Building fire risk analysis is a complex subject. This chapter has provided a brief overview of key issues in the subject area, including discussions on difficulties in defining risk, on risk characterization, on tools and methods to help identify hazards and consequences, and on building fire risk analysis methods. Given the complexities involved in building fire risk analysis, it is intended that this chapter provide a starting point rather than an end point. With this in mind, extensive references and sources for further reading are provided for additional information. A review of other risk-related chapters in this handbook, such as those by Hall; Notarianni and Parry; Ramachandran and Hall; Watts; Barry; and Siu, Hyslop, and Nowlen is a good place to start. In addition, in the post-9/11 environment, building fire risk analysis should consider extreme fire and other events and be part of the overall risk assessment for the building [140]. Finally, it is important to remember that when embarking on a building fire risk analysis effort, one should take care to identify and involve the interested and affected stakeholders, carefully consider the range of risk issues involved, and seek the most appropriate approaches, tools, methods, and data for the problem.

Brian J. Meacham is an Associate Professor at Worcester Polytechnic Institute (WPI) in the United States. He has more than 30 years of professional experience as a consultant, researcher and educator in the areas of risk-informed and performance-based fire engineering and regulation. He is a licensed Professional Engineer (US), a Chartered Engineer (U.K.), a Fellow of the Society of

Fire Protection Engineers, and a Fellow of the Institution of Fire Engineers.

David Charters is with the specialist risk management consulting and training company Risktec Solutions in the U.K. He has more than 25 years of professional experience as a consultant, research and educator in fire risk analysis and engineering. He is a Chartered Engineer (U.K.), a Professional Member of the Society of Fire Protection Engineers, and a Fellow of the Institution of Fire Engineers.

Peter Johnson is a Principal and Fellow with the global engineering consultancy and design firm Arup and is based in Melbourne, Australia. He has had 40 years of professional fire engineering experience involving fire testing, education, and design of buildings and transport infrastructure. He is an Arup Fellow and a Fellow of the Society of Fire Protection Engineers.

Matthew Salisbury is a practicing Fire Engineer with Michael Slattery Associates. He has 15 years of fire engineering experience, is a Chartered Engineer (U.K.), a Member of the Society of Fire Protection Engineers and a Member of the Institution of Fire Engineers. He has developed a number of fire engineering software packages, including BuildingQRA.

Uncertainty

76

Kathy A. Notarianni and Gareth W. Parry

Introduction

To provide fire protection engineering decisions that are meaningful and defendable, the practitioner must understand and be able to characterize the impact of uncertainty on fire safety engineering calculations. This requirement is true for all fire safety engineering calculations, whether conducted to meet a performance-based code, to aid in the establishment of a prescriptive requirement; to compare a performance option to its prescriptive counterpart; or as part of a fire risk analysis used in managing a complex facility, such as a nuclear power plant. At present, however, there is no clear guidance for the treatment of uncertainty in the use of fire safety engineering calculations to support decision making. Development of such guidance will assist engineers and architects in the design process; assist code officials by increasing confidence in the acceptance of a performance calculation; aid researchers in prioritizing enhancements to both the physics and structure of fire models; and aid policy makers by incorporating scientific knowledge and technical predictive abilities in policy decisions. It is essential for the application of risk analysis in the regulation and management of complex facilities.

The overarching objective of this chapter is to provide guidance on, and examples of, addressing uncertainty in the use of fire safety engineering calculations and to document the latest research relating to uncertainty. The chapter consists of ten sections. The first part of the chapter, sections "Understanding and Identifying Uncertainty", "Uncertainties in the Design Process: Problem of Switchover", "Treatment of Uncertainty with Safety Factors", and "Techniques for the Quantitative Treatment of Uncertainty" focus on increasing awareness of uncertainties and providing methods by which to treat uncertainty. Section "Understanding and Identifying Uncertainty" covers basic concepts of uncertainty and variability in order to develop a common language for discussion among fire safety professionals. It includes identification of various sources of uncertainty in Fire Protection Engineering. Section "Uncertainties in the Design Process: Problem of Switchover" provides a motivating example that shows the importance of dealing with uncertainty in the application of our scientific tools. The example shows how variations in analysis parameters, assumptions, or model inputs can lead to changes in the acceptability of a fire safety design, which is termed *switchover* [1]. The treatment of uncertainty with both implied and explicit safety factors, the use of safety factors in both prescriptive and performance-based codes, and guidance on selecting an appropriate factor of safety and on combining safety factors is given in section "Treatment of Uncertainty with Safety Factors." Section "Techniques for the Quantitative Treatment of Uncertainty" introduces many

techniques and methods for treating uncertainties in measurement; in analysis parameters, assumptions, and values; and in complex fire models.

The middle part of the chapter, sections "Application of Uncertainty Analysis to Fire Safety Engineering Calculations", "Application of Uncertainty to Cost-Benefit Models, Improving Regulation, and Overall Decision Making", and "Uncertainty in Probabilistic Risk Assessment", tackles the important applications of uncertainty analysis. Section "Application of Uncertainty Analysis to Fire Safety Engineering Calculations" outlines a procedure for applying uncertainty analysis to a fire safety engineering calculation. It shows how results of this type of analysis are used to create distributions of time to untenability, to demonstrate the effect of selecting various sets of performance criteria, to compare two designs, and to provide insight to model development. Section "Application of Uncertainty to Cost-Benefit Models, Improving Regulation, and Overall Decision Making" uses a case study to look at the application of Uncertainty to Cost-Benefit Models and Decision Analysis Models and Section "Uncertainty in Probabilistic Risk Assessment" covers "Uncertainty in Probabilistic Risk Assessment." Probabilistic risk assessment (PRA) is an analytical tool that provides for the analysis of uncertainty in a comprehensive manner. This is illustrated by an example of the way in which uncertainty is addressed in the context of risk-informed regulatory decision making for nuclear power plants, with an emphasis on the fire-related aspects. This example, although specific to nuclear power plants, serves to illustrate many of the principals involved in the analysis of uncertainty. The third and final part of the chapter documents recent research that explores uncertainty as it applies to fire modeling and egress modeling (section "Uncertainties in Fire Modeling and Egress Modeling"), Measurements and Test Standards (section "Uncertainties in FPE Measurements and Test Standards"), and Determining Effectiveness (section "Use of Uncertainty to Determine Effectiveness"). In summary, a lot of good work on uncertainty has been done recently.

Understanding and Identifying Uncertainty

Uncertainty is a broad and general term used to describe a variety of concepts including but not limited to lack of knowledge, variability, randomness, indeterminacy, judgment, approximation, linguistic imprecision, error, and significance. These and many other facets of uncertainty are discussed in more detail in Chapter 4 of the book *Uncertainty* [1]. Examples of sources of uncertainty are discussed below.

Sources of Uncertainty

Uncertainty is often discussed as though it were synonymous with measurement uncertainty, that is, doubt about the validity of the result of a measurement. Measurement uncertainties are characterized both from a statistical analysis of a series of observations (to determine the random error) and from systematic effects associated with corrections and reference standards (to determine the systematic error). The total error is defined as a combination of random and systematic errors. Much work has been done to reach an international consensus on the evaluation and expression of measurement uncertainty. General rules for evaluating and expressing uncertainty in measurement are provided in a guide published by the American National Standards Institute and the National Conference of Standards Laboratories [2]. An example of dealing with measurement uncertainty in fire protection engineering can be found in a study of the uncertainty surrounding the use of thermocouples to measure temperature [3].

Uncertainty can arise because of disagreement among information sources. Rates of generation of products of combustion per gram of fuel burned vary from study to study and even from test to test in the same study using the same instruments.

Uncertainty can arise from a lack of complete knowledge. For example, what is the heat release rate or radiative fraction of a mixed-fuel

package? We have not measured and cannot reliably predict the value of these quantities for all potential fuel packages. Furthermore, the heat release rate and radiative fraction vary with parameters such as geometry, source and strength of ignition, and ventilation conditions. Uncertainty may also arise from *randomness*, such as where and how the fire will start.

Uncertainty in predictability results from *variability*; for example, the ambient temperature and the total number of deaths from fire. These quantities vary in time by season, month, and day. They also vary in space by regional location and community size. Even if we have complete information, we may be uncertain because of simplifications and approximations introduced due to computational limitations.

Uncertainty may arise from *indeterminacy*, defined as the inability to know what will happen in the future. For example, building occupancy and furnishings may differ 10 or 20 years after they were first constructed. Or uncertainty may arise due to the unpredictability of human behavior. It is unknown what actions each occupant will take when discovering a fire or hearing an alarm.

Other sources of uncertainty are related directly to the determination of the acceptance criteria for any decision made using the results of the analysis. Uncertainty may arise from difficulties in defining the problem. For example, a goal may be established to provide an equivalent level of fire safety. However, equivalency may be defined as providing the same time available for egress, providing the same level of property protection, providing the same level of fire safety for fire fighters entering the building, or all of the above.

Uncertainty in defining the problem may also arise from *linguistic imprecision*. For example, a goal stated as "flame spread should be limited" is not well defined. There are also important questions related to understanding uncertainties in perceptions, attitudes, and values toward risk. "In addition to being uncertain about what exists in the external world, we may be uncertain about individual preferences, uncertain about decisions relating to potential solutions, and even uncertain about the level and significance of our uncertainty" [1].

Uncertainties inherent in the performance-based analysis and design process are discussed in *Introduction to Performance-Based Fire Safety* [4].

Uncertainty and Variability

Understanding the level and significance of our uncertainty is crucial to making good fire safety design decisions. The variety of different uses of the term *uncertainty*, along with the absence of agreed-upon terminology, can generate considerable confusion in the fire protection engineering world. However, in the context of the performance and use of fire safety engineering calculations in decision making, it has become increasingly common practice to classify uncertainty into two major categories, namely aleatory and epistemic uncertainty [5, 6].

- *Aleatory uncertainty* is uncertainty associated with randomness. It is manifested, for example, in the unpredictability of the time at which a particular event will occur, whether that event is the failure of an operating component or the occurrence of a fire, or whether a particular component will operate as required when demanded. As discussed in more detail below, fire models of complex facilities are built up from events that are random and unpredictable. Randomness is, therefore, an essential element of a fire model of the system under analysis.
- *Epistemic uncertainty* is uncertainty associated with incompleteness of the analyst's state of knowledge. For example, as with any model, a fire safety engineering model is an approximation of reality. Because the analyst's state of knowledge is incomplete, there will be uncertainty about how best to model the system and its behavior. Furthermore, it is usually necessary to make simplifications or approximations so that the model can be solved in an efficient and timely manner. Therefore, the results of the model are subject to epistemic uncertainty.

In addition, as discussed earlier, there is uncertainty related to the choice of acceptance criteria associated with a decision.

Both types of uncertainty are addressed mathematically using probability theory, but it is important to maintain the distinction between them. An essential difference between aleatory and epistemic uncertainties is that the latter are, in principle, reducible through the collection of more knowledge, whereas the former are not: they represent a property of the system being analyzed in the following sense. The probabilities of events generated by probability models essentially represent the relative fractions with which various outcomes would be expected given that populations of identical replications of the system of concern were hypothetically to be observed a large number of times [7].

What these fractions represent is not necessarily an "inherent" randomness in the system behavior, but the fact that, at the level at which the events are defined, there is hidden variability that is accommodated in the model as if the events were random processes. There is variability in underlying conditions that has an impact on the behavior of individuals in the population who are not being explicitly accounted for. Instead the impact of the variability is implicit in the use of the probability models used for the events. Thus, the relative fractions are parameters of a model of the world [5] in which groups of components are regarded as being members of the same population.

A different model of the world can lead to different sets of variables being suppressed, different definitions of basic events, and different probability models. Because the models of concern are models of complex systems or complex phenomena, of necessity they involve approximations. In making these approximations, the distinction between the aleatory and epistemic uncertainties can become confused, particularly since the mathematics of probability is used to address both types. However, it is important to maintain the distinction because the interpretation of the results of the analysis and their use in decision making are a function of the nature of the uncertainty [8].

In summary, aleatory uncertainty is embedded in the structure of the model, whereas epistemic uncertainty is associated with the confidence that can be associated with the results of that model. The principal focus of this chapter is the treatment of epistemic uncertainty.

Identifying Sources of Uncertainty in Fire Protection Engineering

Scientific Uncertainties Scientific uncertainties are due both to lack of knowledge (e.g., in the underlying physics, chemistry, fluid mechanics, and/or heat transfer of the fire process) and to necessary approximations required for operational practicality of a model or calculation. Of the many types of uncertainty found in performance-based fire safety design calculations, scientific uncertainties are typically the most easily recognizable and quantifiable. The many types of scientific uncertainties can be roughly divided into five subcategories: (1) theory and model uncertainties, (2) data and input uncertainties, (3) calculation limitations, (4) level of detail of the model, and (5) representativeness of the design fire scenarios.

Theory and model uncertainties arise when physical processes are not modeled due to lack of knowledge of how to include them, processes are modeled based on empirically derived correlations, and/or simplifying assumptions are made. These types of uncertainties are present in most compartment fire models, where each of these factors leads to uncertainties in the results. Most compartment fire models are zone models, which make the simplifying assumption that each room can be divided into two volumes or layers, each of which is assumed to be internally uniform, and that changes in energy or state are implemented immediately throughout the layers. Current zone models do not contain a combustion model to predict fire growth, forcing the model user to account for any interactions between the fire and the pyrolysis rate. Many compartment fire models also use an empirical correlation to determine the amount of mass moved between the layers.

Data and input uncertainties arise from both lack of knowledge of specific input values and variations in input values as a function of many factors, such as time, temperature, or regional location. For example, the rate of heat release of a three-cushion upholstered sofa may be uncertain due to lack of available data for sofas with the same dimensions, stuffing, and cover materials. It may also be uncertain because the test method by which the heat release rate was measured could not specify all combinations of ignition source and strength and because there are inaccuracies inherent in the instrumentation used in the test. Other inputs, such as concentrations of toxic gases produced, vary with time as the fire develops and are uncertain. The species production rates used to predict concentrations are a function of the material or combination of materials actually burned. This is unknown a priori at the design stage.

For most fire models and calculation procedures, very different answers can result depending on the calculation limitations, control volume selected for modeling, the level of detail of the model, and the model-domain parameters specified. Model-domain parameters set the scope of the system being modeled and define the model's level of detail and/or baseline properties. Though these parameters or quantities are often ignored during uncertainty analysis, they have the potential for considerable impact [1]. This has been shown for fires in high bay spaces. Differences in the outcome criteria, such as maximum temperature and time to activation of fire detectors and sprinklers, are found when a large space is modeled with a simple zone fire model versus a more detailed computational fluid-dynamics model [9]. Differences in the outcome criteria are also found when a large space, which is typically subdivided by draft curtains,[1] is modeled. If a control volume is drawn around a single draft-curtained area (as opposed to drawing the control volume around multiple draft-curtained areas or around the entire building), higher temperatures and faster activation times of installed fire protection devices will be predicted. Also significant to the uncertainty in the outcome parameters are the index variables of the model. Index variables are used to identify a location in the domain of a model or to make calculations specific to a population, geographic region, and so forth.

Uncertainty arises in both the number and type of design-fire scenarios that need to be modeled for a given design/building. There may be significant differences between reality and the design-fire scenarios that were used to judge the adequacy of the performance-based design. Variations in the ignition source, rate of growth, and/or the materials burned affect confidence in the results. It is unclear whether all statistically significant fire scenarios must be modeled or whether worst-case or reasonable-worst-case scenarios are adequate. Furthermore, a worst-case scenario may be defined in terms of many different variables. A scenario may be the worst case because it is most likely to cause death, because it has potential for large property loss, or for other reasons.

Uncertainties and Variability in Behavior Human behavior can affect the likelihood of ignition, the choice of actions when confronted with a fire, and the effectiveness or ineffectiveness of both those actions and the passive and active features and systems installed to provide protection for occupants. Human behavioral uncertainties can apply to any of these factors and may affect different steps in the design process (e.g., definition of project goals, selection of performance criteria, and development and evaluation of trial designs). Human behaviors can range from predictable with low uncertainty to predictable with high uncertainty. Behavioral scientists tell us that actions are likely to be more effective and predictable with less uncertainty when choices are limited, procedures are practiced, the situation is not novel, and little chaos is present. Unfortunately, during a fire, few if any of these conditions occur. Any modeling that assumes these conditions are present when

[1] A draft curtain is a barrier that extends a certain vertical distance down from the roof or ceiling. Draft curtains are installed to subdivide a large area with the intent of corralling the heat and smoke.

they are not is likely not only to understate the uncertainty but also to over-estimate the likely effectiveness of the actions. Brannigan discusses what he calls *intentional uncertainty* in relationship to human behavior [10]. Brannigan states, "Human decision making does not follow the same kind of well understood rules that control the physical science variables used in models. Human decisions represent intentional uncertainty."

Human behavior in response to a fire alarm must be modeled in terms of time to respond to the alarm and type of response. Does the person immediately begin evacuating the building? Does he or she take the stairs or the elevator? What factors into that choice? Does the person try to fight the fire? Does the person stop to gather personal possessions or call a neighbor? Another area of human behavior relevant to performance-based calculations is behavior during egress. Do people use the best exit or the most familiar one? How long do people take to start to exit?

Human factors also affect the analysis needed for identifying goals and objectives and developing performance criteria. Fire safety goals typically include levels of protection for people, with performance criteria being a further refinement of these objectives. Performance criteria are numerical values to which the expected performance of trial designs can be compared. What range of occupant characteristics, such as age or disability, should be considered? How do human behaviors, for example, during egress influence the numerical values chosen for performance criteria?

When developing and evaluating trial designs, the efficacy of the proposed fire safety measures mitigating all likely fire scenarios should be determined. This determination involves varying human behavioral elements. For instance, two very different fire scenarios could develop from the same cooking-initiated design fire: (1) a grease fire from cooking sets off a smoke alarm, which alerts the occupant, who reacts quickly and then properly extinguishes the fire while it is still small; or (2) the same grease fire sets off the same smoke alarm, but the occupant has left the cooking unattended and taken a sleep aid so that he is not awakened by the smoke alarm and the fire is able to spread to adjacent items. The First International Symposium on Human Behaviour in Fire was held in 1998. Proceedings from this conference are illustrative of a body of literature, course curricula, and standards that should be considered when delving into this topic [11].

Uncertainties and Variability in Risk Perceptions and Values People perceive and value risk with both variability and uncertainty. Capturing differences that people have in their perceptions of risk and values related to risk is a necessary step in the design process. Research has shown that, although people typically view consequences from voluntary risks less severely than equal consequences resulting from an unknown and/or involuntary risk, variability exists [12]. For example, although some people would agree that an increase in risk to fire fighters (people who accept risk as part of their job) is justifiable if a corresponding decrease in risk to the public could be achieved, others would not. Few studies have been conducted that clearly demonstrate how society values fire safety risks at the level needed to support performance-based trade-offs. Work on incorporating risk concepts and identifying levels of acceptable risk is discussed in Chap. 75. It is important to identify where value judgments enter into a performance-based calculation and to make any assumptions explicit regarding values and the impact of different values on the final design.

Another important factor is the concept of *equivalency*. Equivalency can mean different things to different stakeholders. For example, one person may determine that noncombustible construction is equivalent to an installed sprinkler system if they are both shown to provide time to fully egress the building. Another may argue that they are not equivalent—that the sprinkler system is less reliable. Designs may be equivalent in terms of life safety, property protection, business interruption, injuries, and/or prevention of structural collapse, but they are most likely not equivalent in all regards.

It is, therefore, important to make explicit the assumptions on which equivalency depends.

Uncertainties Related to the Life-Cycle Use and safety of Buildings Many factors change over the lifetime of a building. The uncertainties surrounding future use, occupancy, and other factors contribute to the difficulty in conducting a structured, performance-based design. Even daily fluctuations in these design parameters can affect the safety of a building. For example, a building or area of a building that is normally occupied 24 h per day may become unoccupied (or occupied by very different people) for extended periods of time due to extraneous factors (e.g., business closing, maintenance, renovation). The characteristics of the different occupants can lead to very different design considerations. Other changes that may affect the life-cycle safety of the building are fire service characteristics such as location, expected response time, and operating procedures and capabilities.

Uncertainties Related to Providing for Equity and Incorporation of Societal Values Providing for equity and incorporating societal values involves determining what is important to the stakeholders and to what degree protection should be provided. A mechanism should be provided to ensure equal outcomes for subgroups. Since most projects have many stakeholders, such as building owner, design engineer, architect, code official, and the public (users of the building), it is difficult to assign worth to the usefulness or importance of something and apply it across all individual and societal issues. The key here is that decisions that change when a value, attitude, or risk perception varies must be made explicit in the design. Agreement on these key decisions by all stakeholders is critical to the success of a performance-based design.

Relation to Steps in the Design Process Several types of uncertainty will be encountered at each step in a performance-based design process or during the process of setting a new prescriptive requirement. For example, when developing performance criteria, one will have to deal with scientific uncertainty, such as determining what level of carbon monoxide will cause unacceptable consequences and how to account scientifically for interactions among products of combustion. One will also have to deal with issues of equity and societal values. At present, performance criteria are not established or agreed on. Changes to the set of performance criteria selected could cause the same design for the same building to be deemed acceptable in one jurisdiction and unacceptable in another. Uncertainties related to life-cycle use and safety of buildings also arises when selecting performance criteria. Over the life cycle of the building, many factors, such as use and occupant characteristics, change.

Uncertainties in the Design Process: Problem of Switchover

Of practical significance is the fact that direct measurement of the fire safety performance of a building or building system is not usually possible; therefore, we must rely on the technical predictive ability of scientific tools, such as existing fire models. The problem is this: the numerous uncertainties in the application of these fire safety design tools often go unrecognized or ignored. Many of these uncertainties are inherent in the design process itself. Variations in analysis parameters, assumptions, or model inputs may cause output criteria to change. *Switchover* occurs when outcome criteria change enough so as to cause a change in the design decision (e.g., the acceptability of a final design). It is critical to know if different sets of reasonable inputs, scenarios, or parameters used in a fire safety engineering design have potential to cause switchover and lead to different acceptable designs.

The Society of Fire Protection Engineers *SFPE Engineering Guide to Performance-Based Fire Protection* details several steps in the design process [13]. These are shown in Fig. 76.1, adapted from the SFPE engineering guide. The stated intent of the guide is to

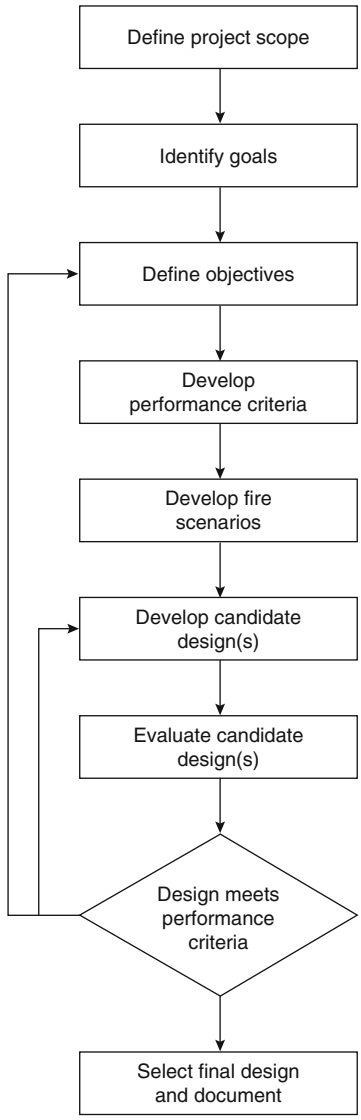

Fig. 76.1 Overview of the performance-based design process

"provide guidance that can be used by both design engineers and approving authorities as a means to determine and *document achievement of agreed upon levels of fire safety* for a particular project."

A review and analysis were conducted of the performance-based design process for fire safety engineering outlined in the guide along with a review of several case studies of performance-based, fire safety engineering designs for actual buildings [14]. This review uncovered seven major barriers to determining and documenting achievement of agreed-upon levels of fire safety for a particular project. All seven barriers involve various types of uncertainty. Thus there is a well-defined and strong role for uncertainty analysis in improving the ability to document achievement of agreed-upon levels of fire safety. The seven barriers identified are presented here along with a discussion of how they might lead to switchover of a design from acceptable to unacceptable.

1. **Performance criteria are not established or no agreement exists:** There is uncertainty in the selection of performance criteria. In fact, performance criteria have not been established or agreed upon by the fire safety community, and current policy allows the stakeholders themselves to select the criteria to be used for each design. Discussions occur around questions such as the following: Is the set of performance criteria sufficient? What do the numerical values actually represent? Should different criteria be used for different subpopulations, such as for people who are sick, elderly, or have disabilities? At one recent international conference, two engineers presented their performance-based case studies conducted for real clients on actual buildings. They had each followed the current design guidelines; however, they had selected very different performance criteria [15, 16]. Differences existed on three levels: (1) the parameters included in the set of performance criteria, (2) numerical values selected as the critical or cutoff values for these parameters, and (3) the presence or absence of a time element for reaching the cutoff values. Since predictions of fire models are compared to selected performance/life-safety criteria in order to determine if a design is acceptable, variations in criteria can cause the same design to pass or fail.
2. **The design fire selection process is unspecified:** Design fires are descriptions of fire events (e.g., a grease fire on the stove, a smoldering cigarette fire on the sofa). Along with design fires, several fire scenarios, or descriptions of possible fires that could occur, are developed. For each design fire

evaluated, the goal is to provide a fire safety design that would prevent unwanted fires from developing.

Because it is impossible to evaluate physically the performance of building systems in response to all design fires that might occur, the design fires and the resulting fire scenarios chosen may not adequately represent the range of fires that might occur in the building. Usually a designer will try to select worst-case or reasonable worst-case scenarios.[2] However, it is not always intuitive which scenarios present a worst-case situation or how likely (or unlikely) a particular scenario is. It is debatable whether we should be designing for the one-in-a-million fire and how many design fires and fire scenarios are sufficient. A methodology is needed that would incorporate the likelihood of a design fire and/or associated design fire scenario. It is easy to see how the same design may be deemed acceptable if based on a limited number and type of design fires or deemed unacceptable if based on an expanded set of scenarios or a different set of scenarios.

3. **Assumptions are made about human behaviors during fire:** During several critical steps in the design process, assumptions are made about human behaviors during fire. For example, some egress models used by fire protection engineers to predict the time required for safely evacuating a building (or part of a building) make many assumptions about how humans behave. Two assumptions are stated in one internationally used egress model: (1) 100 % of the occupants are readily mobile, and (2) occupants begin leaving the building immediately on hearing an alarm [17]. Experience demonstrates that these assumptions often are not the case [18, 19].

   Other behavior assumptions may not be explicitly stated but can be inferred from an analysis of model outputs. For example, results from a recently published study of a performance calculation using the egress model in FASTlite reveal that assumptions are made about human behavior during fires [17]. A decrease in the number of exits by one-third increases the egress time by exactly one-third, which suggests an implied assumption that an equal number of people egress through each available exit. More typically, the different exits will not be used equally. Some may be more familiar because they are used for normal entering and exiting, and some may be better marked or more visible or easier to get to. As a result, significant differences in exit use are not only possible but likely. Existing egress calculations and models need to be evaluated so that unrecognized and/or unstated uncertainties resulting from assumptions regarding human behavior can be identified. Once revealed, the implications of these assumptions need to be explored quantitatively.

4. **Predictive fire models have limitations that are not well documented or widely understood:** Fire models and other calculation methodologies are often inappropriately used to develop and evaluate trial designs for buildings and/or scenarios outside the predictive capabilities of the models. This occurs because limitations of fire models are not well documented or widely understood. For example, computer fire models do not model fire directly and only predict fire effects based on user-selected input data. Because many existing fire model and calculation methodologies were originally developed as research tools, model conditions, defined as "fundamental requirements for the model's validity," [10] are often unknown or unstated. Estimates provided by a model are technically credible only when model conditions have not been violated.

5. **Outputs of fire models are point values that do not directly incorporate uncertainty:** Even when the model is used within its intended limitations, fire model outputs are point values that do not reflect inherent input uncertainties (e.g., fire growth rates, initial

[2] The term *worst-case scenario* is used in this chapter to represent both worst-case and reasonable worst-case scenarios as understood in the fire protection design field.

conditions). Without knowledge of the uncertainty surrounding a prediction, it is impossible to be certain of a design's acceptability. One example is modeling the response of fire protection equipment such as sprinklers, heat detectors, and smoke detectors. Predictions of the time to activation of such devices would specify, for example, 121 s. However, the actual time to activation may be higher or lower depending on uncertain inputs or on any number of factors not modeled, such as individual detector characteristics and distance below the ceiling.

6. **The design process often requires engineers to work beyond their areas of expertise:** Problems can also occur when fire protection engineers are required to work in domains outside their expertise. Conservative assumptions made by well-intentioned engineers may not be as conservative as intended. For example, a design engineer intending to be conservative may assume that tenability would be violated if, out of a set of criteria, any one particular criterion, such as temperature or carbon monoxide, exceeded its minimum value. However, toxicity experts might argue that temperature and gas interactions cause tenability to be violated even when every individual species is in acceptable ranges. Likewise, a design engineer may assume that the time needed for a resident to react to an alarm be conservatively set equal to the travel time needed to go from one remote corner of the unit to the other most remote corner of the same unit. However, this may not be that conservative, since even a fully ambulatory occupant may stop to gather belongings, rescue a pet, call a neighbor, and so forth.
7. **No standardized methods exist to incorporate reliability of systems:** The last barrier identified is the uncertainty surrounding both the reliability of a given fire protection device, system, or characteristic and the lack of a standardized method to incorporate reliability into performance-based engineering calculations and decisions based on these calculations. We may be uncertain about the reliability of a given fire suppression system. Sometimes a fire suppression system is proposed as an alternative to passive fire protection, such as compartmentalization. However, these two alternatives have different reliabilities. There is uncertainty (e.g., no agreement) on how to account for these differences.

These seven barriers to determining and documenting achievement of agreed-upon levels of fire safety for a particular project must be addressed fully in order for all stakeholders to have a known level of confidence in the science-based predictions and the resulting final design. All seven barriers involve various types of uncertainty. Thus there is a well-defined and important role for uncertainty analysis in fire safety engineering calculations. Although this clear role for uncertainty in improving the development and implementation of performance-based fire safety regulations exists, uncertainty analysis is clearly an uncomfortable topic for many of the stakeholders in the process.

Difficulties with Uncertainty Analysis and Complexity

Discussion of the proper treatment of uncertainty in a fire safety engineering calculation is difficult for several reasons:

1. *Magnitude of the problem.* It is widely assumed that a mixture of conservative assumptions and factors of safety can be used to explain away uncertainties. However, the magnitude of the problem is not clearly understood. Factors of safety that are applied at various stages of the analysis are not necessarily linearly related to the critical output parameters, potentially resulting in a reduced (or nonexistent) factor of safety in the results.
2. *Uncertainties that go unrecognized or ignored.* These types of uncertainties include those in variables hardwired in scientific tools, those in tenability/performance criteria, those surrounding the selection of design fires, and those in human behaviors and values.
3. *Effect on the implementation of performance regulations.* It is feared that identification and

treatment of uncertainty would show that our current ability to predict the buildup of heat and toxic products of combustion is not accurate enough to judge the acceptability of a proposed design with a high enough confidence level. This would delay implementation of the entire performance process until predictions of critical outcome criteria can be more certain.

4. *Quantitative methodology*. No quantitative methodology exists for treating uncertainty in performance-based designs. A methodology is needed that is both rigorous and user-friendly.
5. *Impracticality*. It is feared that the mathematical rigor needed to conduct such an analysis would render the process impractical.
6. *Paucity of data*. To quantify uncertainty adequately, a large quantity of data would be needed to determine ranges of values for input parameters, such as heats of combustion, rates of production of various gaseous species, and other important inputs. A large quantity of data would also be needed to validate predicted values with empirical data from real burn scenarios.

It should be pointed out that these are real and valid concerns due to the combination of poorly defined and unstructured problems, and the lack of a user-friendly methodology. Current common practice for conducting uncertainty analyses involves completing a series of single-variable sensitivity studies. Application of these techniques to a complete performance-based design containing hundreds of variables is impractical. Later sections focus on practical ways to identify and account for uncertainties in fire protection engineering design.

In conclusion, *uncertainty* is a broad and general term used to describe a variety of concepts, including, but not limited to, lack of knowledge, variability, randomness, indeterminacy, judgment, approximation, linguistic imprecision, error, and significance. Many of these uncertainties are inherent in the design process itself. Variations in analysis parameters, assumptions, or model inputs may cause output criteria to change. Switchover occurs when outcome criteria change enough so as to cause a change in the design decision (e.g., the acceptability of a final design). It is critical to know whether different sets of reasonable inputs, scenarios, or parameters used in a fire safety engineering design have potential to cause switchover and to lead to different acceptable designs. This section on identifying sources of uncertainty provided an overview of terminology used to describe uncertainty, described aspects of the design process that introduce uncertainty, and presented a taxonomy useful as an aid in identifying uncertainties.

Treatment of Uncertainty with Safety Factors

When considering uncertainty in a fire protection engineering calculation, fire protection engineers typically consider first the uncertainties associated with the calculation inputs, usually empirically measured quantities, such as heat release rate. However, there are many other types of uncertainty integral to fire safety engineering design.

In a complete uncertainty analysis, not all uncertain parameters are treated quantitatively, only parameters or combinations of parameters with the potential to cause switchover in the final decision on the acceptability of a design. Others are negligible and best-guess values of these parameters can be used in the calculations. Still others, such as societal values, become policy or regulatory issues, not engineering issues. The intelligent use of safety factors can often cover more than one type of uncertainty. Still, it is useful to first identify sources and types of uncertainty from a broad perspective. Without first adequately identifying the sources of uncertainty, we cannot understand how best to handle them.

Safety factor and *margin of safety* are two commonly used terms in the field of engineering. The dictionary defines *factor of safety* in terms of stress: "The ratio of the maximum stress that a structural part or other piece of material can withstand to the maximum stress estimated for it in the use for which it is designed." Safety factors do not apply only to stress, however.

The idea of a safety factor is that the design values are multiplied by the factor of safety, and the design is checked to ensure that the design is safe at the larger value (i.e., the product of the design value and the safety factor). Safety margin is a slightly different concept. A safety margin is additive and not multiplicative. A *safety margin* is defined as the difference between the design value and the value that would no longer be safe.

Implied Versus Explicit Safety Factors

Safety factors are used with both prescriptive and performance codes. These factors of safety can be implied or explicit. Implied safety factors generally are found at various sub stages or components of a design. Implied safety factors provide for an extra margin of safety simply attributable to the choice of a component of a system. Implied safety factors may also take the form of conservative assumptions or worst-case scenarios. Explicit safety factors are multipliers applied to critical analysis parameters, often (and preferably) the final outcome criteria used to judge the acceptability of a design. Both types of safety factors are used to increase safety by lowering the probability that critical values of analysis parameters will be reached or exceeded.

Use of Safety Factors in Prescriptive and Performance Codes

An example of an implied safety factor in a prescriptive code is use of a pipe material or thickness that exceeds the strength and durability needed to meet the requirements of a sprinkler system. Pipe schedules have implied safety factors. An example of an explicit safety factor incorporated into a prescriptive code provision is a requirement to use a sprinkler flow density of 1.5 or some other multiple higher than the minimum shown experimentally to control a given type of fire. In this example, the safety factor is used to cover for uncertainties in the measurement of the needed flow density, variations in the actual fuel package versus the fuel package tested, and uncertainties and variations in geometry, building characteristics, and so forth. An example of an implied safety factor in a performance code is an assumption that the rate of production of carbon monoxide for a given fuel package is equal to the rate of production of the component fuel with the highest production. An example of an explicit factor of safety incorporated into a performance-based design is to directly multiply the time necessary for egress by a factor of 2.

Selecting an Appropriate Factor of Safety

The first step in the use of safety factors is to determine which analysis parameters would be appropriate for the application of a safety factor. When a factor of safety is applied to measures of the final outcome criteria, it is most clear what margin of safety has actually been achieved; however, it is least clear how to alter the design specifications when a higher factor of safety is desired.

Safety factors may also be applied to different analysis parameters at various stages of the analysis. Careful judgment must be used, however, when applying these intermediate safety factors, because the quantity to which they are applied may not be linearly related to the final outcome criteria. Even if the quantity is linearly related to the final outcome criteria, it may not possess a relationship. Specifically, a relationship exists when a unit change in the analysis parameter causes a proportional unit change in the outcome criteria. In fire protection engineering calculations, input variables and analysis parameters are not often linearly related to outcome criteria, such as upper-layer temperature. Also, they usually do not share common units of measure. In fire protection engineering calculations, time is the only common measure. It is likely that a safety factor of 2 applied to an intermediate quantity will not carry through the calculation and allow for a safety factor of 2 in the final design. In some cases, a safety factor of

2 applied to an intermediate quantity may not allow for *any* factor of safety design.

This lack of carry-through of the factor of safety is particularly true for implied factors of safety often found in the form of conservative assumptions. For example, an assumption that a fast growth rate fire is a worst-case scenario is not true in all cases. A fast-flaming fire may not pose the greatest danger if it activates the sprinkler more quickly. A more slowly developing fire may be more able to overpower the sprinkler in some circumstances, and a fire originating in an unprotected or shielded space, even though slower growing may also be more deadly. Therefore, if we wish to provide a safety factor of 2 to the time available to safely egress a building, we cannot assume that doubling the fire size (heat-release rate) will achieve this goal. Heat-release rate is not linearly related to time to critical temperature.

When an explicit factor of safety is applied, one may choose a value of 1.5, 2, or even higher. How much of a margin of safety is appropriate is as much a function of how much confidence we have in the predictive equations (i.e., are we using a factor of safety as a factor of uncertainty?) used in the calculations as it is of the stakeholders' risk tolerance. It should be noted, however, that increasing the margin of safety usually corresponds to an increase in cost of the project. When historical performance data are available, they can be used to set factors of safety. Otherwise, safety factors are usually set by expert judgment or mandated in policy. Safety factors are set to reflect confidence in the design equations as well as to reflect the stakeholders' acceptable risk tolerance. New specialized methods are being developed for deriving appropriate factors of safety.

Combining Safety Factors

First, it must be stated that there are no official rules for combining safety factors, i.e., none published and agreed on by the fire safety community at large. The following list of suggestions and potential pitfalls was compiled by the author. After a thorough review of the literature, specific numbers and justifications for safety factors were found lacking. To get good quantitative numbers for safety factors, historical data are needed.

Track the effect of each factor of safety: The effect of each factor of safety on the outcome criteria can be determined by changing the value of the safety factor and observing the net change in the outcome criteria relative to the net change in the safety factor. When the equations are not overly complicated, it may be possible to derive this relationship directly using partial derivatives. For conservative assumptions, the effect of the assumption should be tested by repeat calculations.

Watch for variance: If the normal variation in the population is sufficiently large, a factor of safety applied to the mean will not cover all or even most of the people who will be in the building. For example, if the baseline walking speed is estimated as the walking speed of a young, healthy individual and a safety factor of 2 is used, that would not cover the walking speed of an elderly person or person with physical disabilities if his or her speed was less than half the average.

Don't assume safety factors are additive: Factors of safety applied to two individual parameters in the analysis will not necessarily provide a total factor of safety equal to the sum of each individual safety factor. The total safety factor could be more or less than the sum of the two individual safety factors. As discussed earlier, analysis parameters are often not linearly related to outcome criteria. They are most likely in different units of measure, and analysis parameters are likely not linearly related to each other. For these reasons, safety factors cannot be assumed to be additive.

Account for both positive and negative effects on safety: An explicit factor of safety or design assumption may have either a positive or negative contribution toward safety. Careful thought, engineering judgment, and testing using the calculation procedure must be used to test for the effects of each factor of safety and/or design assumption made. For example,

doubling the heat of combustion may be conservative in predicting upper-layer temperature, whereas doubling the radiative fraction will have the opposite effect.

Evaluate for multiple performance criteria: Since most fire safety engineering designs are judged on multiple performance criteria, what might constitute an implied factor of safety for one outcome criterion might constitute a reduction in safety for another parameter. For example, if a soot yield value is conservative for smoke detector activation, then it could not simultaneously be conservative for life safety [20].

Realize effects may change with time: The relative importance of individual input variables, and thus the factors of safety applied to them, may be a function of time. In particular, variables may be limiting factors in the analysis during the time period of preflashover, and in the post flashover time period they may have little or no effect. In fire protection engineering we often deal with two distinct phases of the fire represented by different physics and mathematics; consequently we must be careful to be aware of changes in the effects of a parameter in these very different phases of fire development.

Derivation of Safety Factors

Researchers at the University of Lund [21, 22] have been conducting research on the application of the FOSM (first-order second-moment) methodology for fire safety engineering design. They have applied the FOSM method to derive safety factors for use in fire safety engineering design calculations. The safety index is represented by β, the distance from the origin to a failure line (limit state). β is also referred to as a reliability index, where reliability is defined as the probabilistic measure of assurance of performance. β can also be thought of as the overall safety factor for the design.

The overall concept for conducting a design is to specify input data, choose a target reliability index β (researchers suggest 1.4, which is approximately equivalent to a probability of failure of 8 % on condition that a fire has started), and vary the design parameters to be determined until the chosen value of β has been obtained. In this type of analysis, design parameters include design door width and time to detection [21].

Researchers have also applied the FOSM methodology to derive the safety factor, β, for a design. In this case, design parameters such as door widths and time to detection are already known. An example is worked out for a shopping center [34]. There are some admitted shortcomings to applying this methodology to an actual design problem. First, the importance of the uncertainties in the input parameters needs to be investigated via a sensitivity analysis. A method of incorporating this uncertainty would then need to be standardized.

Linking Safety Factor and Failure Probability

The concept of safety factors can be addressed in the context of assessing failure probability for fire safety engineering. The complete elimination of risk is impossible, but the traditional engineering approach can be improved by involving a probabilistic methodology H. Yaping, in his paper "Linking Safety Factor and Failure Probability for Fire Safety Engineering," *Journal of Fire Protection Engineering*, 2010 [23], gave three levels of treating uncertainties in engineering designs include (1) using a single characteristic value for a particular uncertain parameter due to a lack of knowledge about the parameter, (2) describing parameters by a mean and standard deviation, and (3) describing parameters by full probability distributions.

So called "evaluation parameters," such as ASET (A) and RSET (R), are determined by "design parameters," such as fuel load or detection time. Risk is defined as the expected loss and is the product of an event's consequence and probability. The safety margin, in this case the difference between ASET and RSET (W), is referred to as the "performance parameter," as it is used to evaluate the system performance.

The use of a safety factor is considered only a partial or first-order measure of failure probability. A more detailed analysis of the properties of the probability distribution that describes a performance parameter will provide a higher-order measure. ASET and RSET can be considered random variables. Likewise, the safety margin is a random variable. If A and R are normally distributed, their difference, W, will be as well. μ_W and σ_W can be determined from A and R, and the ratio $\beta_W = \frac{\mu_W}{\sigma_W}$ is defined as the safety index. It is a measure of the distance of μ_W from $W = 0$, the failure point, in terms of σ_W. An analysis of β_W demonstrates that, for a given safety factor, the safety index may still be small. Therefore, even a large safety factor may not guarantee a low failure probability. A similar approach can be used for log-normal A and R. The α-percentile approach may be appropriate especially when distributions of design parameters are not known, or distributions of ASET and RSET are difficult to obtain. In such a situation, the performance of a "worst-case" scenario may be evaluated. In order to avoid ambiguity in the definition of "worst-case," the α-percentile approach assigns a percentile ranking (α) to a particular fire scenario. Determination of W for associated α's will allow the calculation of μ_W and σ_W, and thus an assessment of failure probability. The greatest difficulty in this type of analysis lies in determining the choice of a percentile, α, for a given scenario. This will rely largely on the use of expert solicitation.

Techniques for the Quantitative Treatment of Uncertainty

It is important not only to recognize the various types of uncertainty but also the different types of quantities for which the uncertainty exists, since they need to be treated in different ways. There is a standard procedure for quantifying uncertainty in empirical quantities. This procedure, sometimes referred to as classical uncertainty analysis, is based on the mathematics of probability and statistics. However, as shown by the taxonomy, in any fire safety engineering calculation or decision there are many non-empirical parameters and assumptions used in the calculations. It is not always appropriate, meaningful, or even possible to treat the uncertainty in these non-empirical parameters by these same probabilistic methods. It has been argued that "probability is an appropriate way to express some of these kinds of uncertainty but not others" [1]. The next sections present quantitative methods appropriate for the expression of uncertainty in various types of quantities.

Techniques for Quantifying Measurement Uncertainty

Many calculation and model inputs are empirical in nature. To be empirical, variables must be measurable and have a true value. Empirical quantities in the domain of fire protection engineering include the heat-release rate, the burning rate, and the radiative fraction of a given fuel. Classical uncertainty analysis refers to a statistical method of determining the random and systematic errors (and from them the total error) for a set of measurements. Random error and statistical variation result because no measurement of an empirical quantity can be absolutely exact. Imperfections in the measuring instruments and observational technique will inevitably give rise to variations from one observation to the next. The resulting uncertainty depends on the size of the variations between observations and the number of observations taken.

Classical statistical techniques such as standard deviation, confidence intervals, and others can be used to quantify this uncertainty. These statistical techniques are presented in Chap. 73. A full discussion on uncertainty in measurement is found in the U.S./ISO guide [2] and in the NIST guide [24]. The NIST guide describes two types of evaluations of uncertainty. A Type A evaluation of standard uncertainty may be based on any valid statistical method for treating data. Three examples are (1) calculating the standard deviation of the mean of a series of independent observations; (2) using the method of least

squares to fit a curve to data in order to estimate the parameters of the curve and their standard deviations; and (3) carrying out an analysis of variance (ANOVA) in order to identify and quantify random effects in certain kinds of measurements.

A Type B evaluation of standard uncertainty is usually based on scientific judgment using all the relevant information available, which may include previous measurement data, experience, manufacturer's specifications, and calibration reports. There is not always a simple correspondence between the classification of uncertainty components into categories A and B and the commonly used classification of uncertainty components as random and systematic.

The nature of an uncertainty component is conditioned by the use made of the corresponding quantity, that is, on how that quantity appears in the mathematical model that describes the measurement process. When the corresponding quantity is used in a different way, a random component may become a systematic component and vice versa. The NIST guide also differentiates between uncertainty and error. It is assumed that a correction is applied to compensate for each recognized systematic effect that significantly influences the measurement result. The relevant uncertainty to associate with each recognized systematic effect is then the uncertainty of the applied correction.

Techniques for Assessing Uncertainty in Analysis Parameters, Assumptions, and Value Parameters

Probabilistic techniques used to quantify measurement uncertainties are not applicable to uncertainties in establishing performance criteria or uncertainties regarding values such as the value of life. These uncertainties should be evaluated with techniques that make explicit the effect of the uncertainty on the value of all decision variables. Decision variables in fire protection engineering include elements such as level of acceptable fire safety and installation of fire protection devices. If a quantity is a decision variable, then by definition it has no absolute, true value. It is up to the decision maker who exercises direct control to decide its value. Morgan and Henrion state that, "The question of whether a specific quantity is a decision variable, an empirical quantity, or some other type of quantity depends on the context and intent of the model, *and particularly who the decision maker is*" (emphasis added) [1]. For example, in performance-based design, the minimum, permissible escape time during a fire may be a decision variable for the regulatory body, but it may be an empirical quantity from the viewpoint of the fire protection engineer.

Value parameters represent preferences of individuals. One controversial value parameter is the value of premature death avoided, often referred to as the value of life. Another is risk tolerance or risk preference, a parameter used to specify a degree of risk aversion when comparing uncertain outcomes. The effect on the outcome of an analysis caused by differences in value parameters should be demonstrated explicitly. This is done by repeating the analysis for a range of possible inputs of the value parameter (s) to determine if a change in the outcome occurs that someone would care about. Several techniques that aid in the evaluation of uncertainty in these types of quantities are presented below. For all these techniques, the effect of various values of analysis parameters, assumptions, and value parameters is made explicit.

Bounding: Bounding is the evaluation of the extremes of the range of possible values of an uncertain quantity. If the extreme values at both ends are acceptable, a more complex and costly analytical uncertainty analysis may be avoided. For example, suppose we bound the ambient room temperature between a low and a high value. If we are trying to predict carbon monoxide buildup in a room, we may find that the results are either not sensitive to ambient temperature, or the range of predicted values of carbon monoxide, based on the range of ambient temperatures, is completely acceptable. We may either eliminate ambient temperature as a variable or set it to our best-guess estimate.

We do not need to quantify the uncertainty in the ambient temperature any further.

Sensitivity and sensitivity analysis: The sensitivity of a design to modest variability and uncertainty must be explicitly understood. Sensitivity analysis is useful in assessing the consequences of uncertainty in data and in assumptions. By testing the responsiveness of calculation results to variations in values assigned to different parameters, sensitivity analysis enables the identification of those parameters that are most important to the outcome criteria. It does not tell the decision maker the value that should be used, but it can show the impact of using different values.

Parametric analysis: A parametric analysis is a particular type of sensitivity analysis. In parametric analysis, detailed information is obtained about the effect of a particular input on the value of the outcome criterion. This is done by evaluating and plotting the outcome criterion for a sequence of different values for each input, holding the others constant.

Importance and importance analysis: An importance analysis is a particular type of sensitivity analysis that determines which of the uncertain input variables contributes most to the uncertainty in the outcome variable. The results are used to focus on getting more precise estimates or building a more detailed model for the one or two, or small group, of the most important inputs. Importance here is defined as the rank-order correlation between the output value and each uncertain input. Each variable's importance is calculated on a relative scale from 0 to 1. An importance value of 0 indicates that the uncertain input variable has no effect on the uncertainty in the output.

Comparative analysis: Comparative analysis is a technique used to evaluate risks, and the costs to mitigate them, by means of comparison with other similar risks. This technique is useful in evaluating perceptions of risk tolerance. Researchers [25] conducted a comparative analysis of the cost of mandating residential fire sprinklers with the cost of mandating other methods of reducing residential deaths, such as radon remediation and ground fault interrupters.

Expert elicitation: When hard data do not exist and are not possible to create experimentally, an expert elicitation is often conducted in order to obtain expert judgment of an uncertain quantity. An excellent discussion of the techniques for conducting an expert elicitation is provided in Chapter 6 of *Uncertainty* [1].

Switchover: Variations in analysis parameters, assumptions, or model inputs will cause output criteria to change. Switchover occurs when outcome criteria change enough so as to cause a change in the design decision (e.g., the acceptability of a final design).

Techniques for Assessing Uncertainty and Sensitivity in Complex Models

Several of the scientific uncertainties discussed in the taxonomy presented above can be evaluated only by examining the structure of the fire model. These include theory and model uncertainties, calculation limitations, and level of detail of the model. Uncertainties arise when physical processes (1) are modeled based on empirically derived correlations and/or (2) simplifying assumptions are made. Other physical processes are not modeled due to lack of knowledge of how to include them. As stated earlier, most compartment fire models are zone models, which make the simplifying assumption that each room can be divided into two volumes or layers, each of which is assumed to be internally uniform. Current fire models do not contain a combustion model to predict fire growth, and many compartment fire models use an empirical correlation to determine the amount of mass moving between the layers [26]. These modeling approximations introduce uncertainties.

Fire-Model Validation Because fire models have been relied on as a means of verifying that a fire safety engineering design meets a set of performance objectives, fire-model validation has become a much-discussed topic. Work is

being done to characterize the additional output uncertainty due to modeling approximations. Part of this work focuses on aiding the user in selecting a model, or set of models, appropriate to the type of prediction(s) needed. Some researchers have suggested a Bayesian framework, where each available model is treated as a source of information that can be used in a prediction [27, 28]. In addition, work is ongoing to evaluate computer fire models by comparing model predictions to predictions of other models or with experimental data. These comparisons are helpful to the user in determining the level of uncertainty likely from a model prediction for a similar set of conditions. However, these comparisons are difficult, since they involve comparing two time-series curves, the experimental measurements, and the predicted values. Historically these comparisons have been largely qualitative. The use of a branch of mathematics called functional analysis, to make comparisons of these time-series curves, is being investigated. This analysis enables lengths, angles, and distances between two arbitrary curves to be defined and quantified [29]. Further validation issues that must be addressed were discussed among various groups of fire safety professionals at the Conference on Fire Safety Design in the Twenty-First Century [30]. Jones discusses issues that must be addressed in *Progress Report on Fire Model Validation* [31]. Once a model is selected, it is useful to know the sensitivity of that model's output predictions to the values selected for the inputs.

Quantifying Model Bias and Standard Deviation Experimentally Independent of the errors associated with input parameters, numerical calculations also involve errors that are specific to the model itself. Sources include theoretical and numerical assumptions, numerical techniques, and user error. As the work of Lundin points out, most studies of model error with respect to fire safety design are qualitative in nature. However, a quantitative understanding of model error allows even models with significant error to be useful tools. Lundin's work [32, 33] utilizes a comparison between model outputs of the CFAST 2.0 two-zone model for smoke transport and experimental measurements. Lundin develops a systematic method for evaluating model error and applying this evaluation to future simulations to improve output values. For a model such as CFAST, model error varies both within a given fire scenario and between different scenarios. In order to generate a straightforward method for output adjustment, the different scenarios represent changes in parameters, such as room height within a limited range, such that the error predictions in each case are of the same magnitude. The method is applied to a particular set of scenarios, referred to as a scenario configuration.

This method uses a regression technique to evaluate both the systematic error (the curve of how error develops in a given scenario, such as error in upper layer temperature with the value of upper layer temperature) and the random error (variations about that curve). This is done for both the error in a particular scenario as well as the error between scenarios. The method is designed to create a prediction interval, the upper or lower bound of which can be used as the adjustment curve to create a more conservative estimate. The application of this method allows for a quantitative treatment of model error and subsequent adjustments in model outputs. However, the experimental scenarios used must have limited uncertainties in order to decouple model errors from those generated by poor input values.

Similar to Lundin, McGratten and Toman [34] have developed a method for quantifying model uncertainty. This approach relies only on model predictions and experimental measurements and can be easily understood by persons with limited modeling or uncertainty experience. Unlike Lundin, this method considers only the error at a single event in a fire scenario. The peak value of a particular parameter, such as upper layer temperature, is compared for a series of paired experiment and model simulations for similar scenarios. The similarity of particular fire scenarios, and hence their applicability to this method, must be determined by comparison of key non-dimensional parameters. McGratten and Toman show that, given a particular model

prediction, a normal distribution can be generated to represent the "true" value. This is given by the equation

$$\theta' \left| M' \sim N\left(\frac{M'}{\hat{\delta}}, \left(\frac{M'}{\hat{\delta}}\right)^2 \left(\frac{\hat{\omega}_M}{\hat{\delta}}\right)^2\right)\right.$$

where θ' is the true value, M' is the model prediction, and $\hat{\delta}$ and $\hat{\omega}_M$ are the model bias and relative uncertainty, which are derived using the relevant values from all of the scenarios considered and obtaining the relative experimental uncertainty ω_E. It should be noted that relative uncertainty refers to the uncertainty of a value with respect to that value. This method has the benefit of providing outputs as probability distributions without having to run a full Monte Carlo analysis. However, having a limited number of similar experimental and model comparisons has been shown to be problematic, particularly in determining the relative model uncertainty, where imaginary numbers may be obtained.

Sensitivity of Output Predictions to Input Values When selecting and using a fire model, it is important to know the sensitivity of the predicted outcome criteria to the model inputs. In order to facilitate this, several quantitative methods for determining the sensitivity of model predictions to model inputs are described below, along with a brief discussion of their positive and negative attributes and limitations of application. These methods are also discussed in ASTM 1355-92, *Standard Guide for Evaluating Predictive Capability of Computer Fire Models* [35].

A Differential/Direct Method For a system of time-dependent, ordinary differential equations, it is possible to solve directly for the partial derivative of the predicted values with respect to each input variable. This set of partial derivatives measures the sensitivity of the solution with respect to changes in the input parameters:

$$Y_I = f_I = (c_1, c_2, \ldots, y_1, y_2, \ldots, t)$$

where c_k are rate parameters.

We simultaneously solve for both y_I and a set of sensitivity functions, $\delta y_i/\delta c_k$, over all times t. These partial derivatives measure the sensitivity of the solution with respect to uncertainties in the parameters c_k and in initial conditions. Often these parameters are not accurately known. Dickson provides an example of a direct solution of a set of ordinary differential equations that composes a large computational model of atmospheric chemical kinetics [36].

Response Surface Replacement Multiple runs, n, of the computer model are made. The model output Y_i and inputs $X_{1i} \ldots, X_{ki}$, $I = 1, \ldots, n$ are used to estimate the parameters of a general linear model of the form:

$$Y = \beta_0 + \sum_i \beta_j X_j$$

The estimated model is known as a fitted response surface, and this response surface is used as a replacement for the computer model. All inferences with respect to uncertainty analysis and sensitivity analysis for the computer model are then derived from this fitted model [37]. Construction of a response surface without specification of the probability distributions for all input variables is discussed by Iman [38]. It is suggested, in fact, that when using certain sampling techniques to build a response surface, it may be desirable to ignore probability distributions and use only the ranges of the variables. Iman provides a good discussion of using a response surface method to conduct a sensitivity analysis and provide a ranking of input variables in a second paper [39]. Beller has discussed the use of response surfaces for modeling upper-layer temperature and layer height [40].

Monte Carlo Sampling In uncertainty analysis employing Monte Carlo sampling,[3] it is desired to estimate the distribution function and the

[3] There are many sampling techniques. Monte Carlo is a well-accepted sampling method that has certain statistical advantages but may not be the best choice in all cases.

variance for the particular output variables under consideration. The uncertainty surrounding each input is represented mathematically and often probabilistically by its individual distribution. When all probability distributions for all uncertain quantities are put together, a simulation model is built that is believed to capture the relevant aspects of the uncertainty in the problem. After running the simulation many times, an approximation of the probability distribution of the output variables is generated. The more simulations that are carried out, the more accurate the approximation becomes.

Comparison of Sampling-Based Uncertainty Analysis A model under consideration can be written as $\mathbf{x} = \mathbf{y}(\mathbf{x}) = \mathbf{f}(\mathbf{x})$ with $\mathbf{x} = [x_1, x_2, \ldots, x_{nX}]$ and $\mathbf{y} = [y_1, y_2, \ldots, y_{nY}]$. It is possible that the dimensions nX and nY are large, and the function $\mathbf{f}$ is complex. If model uncertainty is not considered, i.e., the "correct" value of $\mathbf{y}$ is generated from the appropriate value of $\mathbf{x}$, there are two aspects of the effect of uncertainty on $\mathbf{x}$ on $\mathbf{y(x)}$. The first aspect is the uncertainty in $\mathbf{y(x)}$ given the uncertainty in $\mathbf{x}$, and the second is the importance of the individual elements of $\mathbf{x}$ on the uncertainty in $\mathbf{y(x)}$. These are the uncertainty analysis and sensitivity analysis, respectively.

If the uncertainty of the individual elements of $\mathbf{x}$ is given by probability distributions, then a sample-based analysis is conducted by evaluating the pairs $[\mathbf{x}_k, \mathbf{y}(\mathbf{x}_k)], k = 1, 2, \ldots, nS$, where $\mathbf{x}_k = [x_{k1}, x_{k1}, \ldots, x_{knX}], k = 1, 2, \ldots nS$ represents nS samples from the distributions for each element of $\mathbf{x}$. Sampling from these distributions can be carried out by either a random method or another procedure, such as Latin-hypercube sampling. The work of Helton and Davis [41] demonstrates how correlation coefficients, partial-correlation coefficients, and standardized-regression coefficients can be used to assess the strength of a linear relationship between $\mathbf{x}_k$ and $\mathbf{y}(\mathbf{x}_k)$. Rank-correlation coefficients, standardized rank regression coefficients, and partial-rank correlation coefficients can be used to assess the strength of a monotonic relationship. Common means, common locations, common medians, and statistical independence can be used to assess nonlinear and nonmonotonic relationships. Methods for sampling based sensitivity analysis are tested for simple test problems and a more complex performance assessment of a radioactive waste disposal facility. Both parametric-regression procedures (linear regression, rank regression, and quadratic regression) and nonparametric procedures (locally weighted regression, additive models, projection-pursuit regression, and recursive-partitioning regression) are used. For correctly ordering the importance of inputs and the R^2 value, the recursive partitioning regression is found to the best of all those tested. However, it generally took longer to implement. The locally weighted and projection-pursuit methods used introduced some difficulties that might limit their usability.

Quantification of Margins of Uncertainty (QMU) Quantification of Margins and Uncertainties (QMU) is a broad methodology for obtaining critical information to be used in U.S. nuclear-weapon stockpile management [42]. QMU is a "decision-support methodology for complex technical decisions that are made under conditions of uncertainty and that center on performance thresholds and associated margins for engineered systems." Results may be expressed as a confidence ratio of margin to uncertainty (CR = M/U). However, this representation is of limited value, and a more rigorous study of uncertainty should be conducted. Three key elements of the performance characteristics are (1) identification and specification of performance thresholds, (2) identification and specification of associated performance margins, and (3) quantification of uncertainty in thresholds and margins. The underlying components of QMU are the scenario identification, the likelihood of scenarios, the consequence of scenarios, and the credibility of the evaluation of the first three components. Credibility is a driving factor when modeling and simulation are used in QMU. This can be assessed through verification and validation. Epistemic uncertainty is especially important and should be acknowledged and quantified separate from aleatory uncertainty.

Sensitivity analysis is also a vital aspect to QMU. Risk informed decision analysis (RIDA) utilizes the results of QMU along with considerations of other factors in order to make decisions. Schematically, this can be represented as $Decision = D\left[\frac{M_1}{U(M_1)}, \ldots, \frac{M_n}{U(M_n)};\ other\ factors\right]$. However, it is important to note that this representation is deceptively simplistic. The details of the uncertainty, the "other factors," and how other factors may also play into the ratios are all implicit in this form.

Helton offers a detailed overview of QMU, a form of risk-assessment that is applied to nuclear weapons stockpiles. He defines aleatory and epistemic uncertainty and presents examples of how to represent them mathematically. For analysis involving both types of uncertainty, final results should separate the effects of the two types. Additionally, documentation about the analysis should be highly detailed, and the presentation of results should be in a form that provides information about system behavior and the uncertainty involved in predicting that behavior.

Generalized Information Theory (GIT)

Oberhampf et al. offer a discussion of the differences between epistemic and aleatory uncertainty . They identify three different classes of information: (1) The classification strong *statistical information refers* to a large data set that can be used to derive or convincingly verify a particular statistical model. (2) *Sparse statistical information* refers to a small collection of data from which a statistical model must be indirectly inferred, and fitting will result in epistemic uncertainty. (3) *Intervals* refers to bounds or graded levels that typically form expert elicitation. Multiple sources may give conflicting data. The article gives essentially no information on what "general information theory," "possibility theory," "fuzzy set theory," or "evidence theory" are. It does provide "challenge problems" used in a workshop, as well as numerical inputs so that participants can compare.

Other investigators, such as Vasquez and Whiting [43], suggest that random errors on experimental measurements are often the only type considered, and that systematic errors (or bias) are often discounted. Systematic errors are often not reported, as there is a psychological perception that it diminishes the credibility of experimental results. However, such errors do exist and are not completely reducible. They offer a method utilizing Monte Carlo methods to separate and compare the effects of both random and systematic error on model outputs. Random errors are propagated by creating n pseudo-data sets, in which each particular datum is randomly sampled, according to the probability distribution with which it is associated, for each of the n sets. Systematic errors are propagated by creating n pseudo-data sets, in which the entire original set is randomly shifted within a defined bias range. This is often done by defining a uniform distribution for the mean value of each stochastic variable. However, bias adjustments may be dependent on the value of the variable (called a dynamic bias range), so proper probability distributions should be selected as appropriate. The effects of random and systematic errors can be assessed independently or simultaneously. By creating cumulative probability distributions of the outputs, comparisons can be made between the relative importance of random and systematic errors for a given model. In particular, the importance of systematic errors can be used to motivate more thoughtful experimentation, which attempts to quantify both error types adequately.

Advantages and Disadvantages of Each Technique

Iman and Helton state in their paper, *Investigation of Uncertainty and Sensitivity Analysis Techniques for Computer Models*, some of the characteristics of large and complex computer models [37]:

- There are many input and output variables.
- The model is time-consuming to run on the computer.
- Alterations to the model are difficult and time-consuming.
- It is difficult to reduce the model to a single system of equations.

- Discontinuities exist in the behavior of the model.
- Correlations exist among the input variables, and the associated marginal probability distributions are often nonnormal.
- Model predictions are nonlinear, multivariate, time-dependent functions of the input variables.
- The relative importance of the individual input variables is a function of time.

Fire models often possess many and sometimes all of these characteristics. Iman and Helton evaluated the above three techniques as applied to large, complex models having many of the listed characteristics. Their evaluation included ease of implementation, flexibility, estimate of the cumulative distribution function (CDF) of the output, and adaptability to different methods of sensitivity (analysis). Their findings clearly show that the technique that had the best overall performance was Monte Carlo sampling. They found that a differential analysis provides good local information about the inputs but does not extend well to a global interpretation. Also, a very real problem with differential analysis lies in the difficulty of implementation. Response surface replacements were not recommended because the underlying models are often too complex to be adequately represented by a simple function.

The following section describes a methodology for application of uncertainty analysis to fire safety engineering calculations. This methodology employs Monte Carlo sampling. It also incorporates many of the techniques described in previous sections for quantifying measurement uncertainty and assessing uncertainty in analysis parameters, assumptions, and value parameters.

Application of Uncertainty Analysis to Fire Safety Engineering Calculations

The fire safety community needs to begin to move forward from discussing a set of issues and concerns relating to uncertainty in fire protection engineering to agreeing as a community on practical steps to execute an uncertainty analysis. This section demonstrates a suggested methodology that quantitatively treats variability and uncertainty, and applies them to a complex fire protection engineering problem. The methodology suggested is a generic methodology that is applicable to a wide range of fire protection engineering calculations and fire safety design issues. For example, application of the methodology is appropriate for engineering calculations such as those that predict upper-layer temperatures and concentrations of products of combustion. The methodology may also be applied to calculations of time needed to egress. It ties together the issues discussed earlier regarding uncertainties in the design process and the problem of switchover. Here, a brief introduction to and overview of the methodology are presented. A full description of the methodology and a worked case study of an actual building can be found in Notarianni [44].

Overview of the Performance-Based Design Process with Uncertainty

The methodology is rigorous but comprehensible. It breaks up the process of conducting an engineering design calculation with uncertainty analysis into identifiable steps, each of which can be expanded or contracted to fit specific design problems. Table 76.1 shows the steps in conducting a performance-based fire protection engineering design. The column labeled Performance-Based Design Process lists the steps in the performance-based design process as detailed in the SFPE guide [13]. The right column lists the steps in the performance-based process with uncertainty. Steps or parts of steps in bold signify suggested modifications to the current design process. Steps 1–3 are modified by incorporating treatment of uncertainties noted in parentheses and detailed in the taxonomy presented earlier. The intent of each step does not change; however, the process is made explicit and standardized.

Table 76.1 Steps in the performance-based design process with and without uncertainty

Performance-based design process [13]		Performance-based design process with uncertainty [44]
Step 1	Define project scope	Define project scope **(uncertainties related to life-cycle use and safety of buildings)**
Step 2	Identify goals	Identify goals **(uncertainties related to equity and incorporation of societal values)**
Step 3	Define stakeholder and design objectives	Define stakeholder and design objectives **(uncertainties related to risk perception and values)**
Step 4	Develop performance criteria	Develop probabilistic statement of performance **(criteria, threshold, probability, time)**
Step 5	Develop design fire scenarios	**Develop a distribution of design fire scenarios**
		(a) **Select calculation procedure(s)**
		(b) **Identify uncertain input parameters**
		(c) **Generate a distribution of design fire curves**
		(d) **Define distributions of and model correlations among other input parameters**
		(e) **Select sampling method and determine number of scenarios**
Step 6	Develop candidate designs	Develop candidate designs
Step 7	Evaluate candidate designs	Evaluate candidate designs
		(a) **Calculate a set of values for each outcome criterion and create cumulative distribution functions**
		(b) **Determine sensitivity to elements of probabilistic statement of perfor**mance
		(c) **Evaluate base case (optional)**
		(d) **Determine effect of each candidate design on each of the scenarios**
		(e) **Evaluate uncertainty importance**
Step 8	Design meets performance criteria?	Design meets **all four elements of probabilistic statement of performance?**
Step 9	Select final design	Select final design
Step 10	Prepare design documentation	Prepare design documentation

The quantitative methodology for the application of uncertainty analysis is applied throughout Steps 4–8. In Step 4 a probabilistic statement of performance is developed. In Steps 5–7, candidate designs are developed, and a process for evaluating these designs through simulation with uncertainty analysis is described. Step 8 now includes a decision of acceptability that makes use of the results of the quantitative uncertainty analysis. Steps 9 and 10 remain the same. It should be noted that performance-based designs might require an iterative process. If, in Step 8, the candidate designs are deemed unacceptable, the process returns to Step 6 to develop new candidate designs. If no acceptable design is found to meet the goals and objectives, Steps 1–3 must be revisited.

Steps 1–3: Define Scope, Goals, and Objectives

Many of the types of uncertainties discussed in the taxonomy are important to consider during the process of setting the scope, goals, and objectives of a project. These three steps are described next; for each step, one example of a type of uncertainty to consider is provided.

The first step in the performance-based design process is to define the scope of the project. The project scope is an identification of the boundaries of the performance-based analysis or design. The SFPE guide suggests consideration of several aspects of scope, such as occupant and building characteristics, and intended use of the building. In the first section of this chapter, indeterminacy was discussed as well as

uncertainties related to the life-cycle use and safety of buildings. Indeterminacy affects the scope in that it is impossible to know what the occupancy and furnishings will be in a building at some point in the future. Therefore, when assumptions are made regarding occupant and building characteristics, some investigation of the sensitivity of the final design to changes in occupant and building characteristics should be made and documented. If switchover occurs for a particular value of one or a combination of analysis parameters, assumptions, or values, this switchover needs to be made explicit.

The second step in the design process is identifying and documenting fire safety goals of various stakeholders. These goals include levels of protection for people and property, and provide for continuity of operations, historical preservation, and environmental protection. For example, when identifying goals of various stakeholders, a mechanism needs to be provided to ensure equal outcomes for subgroups, including the building owner, design engineer, architect, code official, and the public (end users). Because it is difficult to assign worth in the usefulness or importance of something and apply it across all individual and societal issues, the key here is that decisions that change when a value, attitude, or risk perception varies must be made explicit in the design documentation.

The third step in the design process is the development of objectives, which are essentially the design goals that have been further refined into values quantifiable in engineering terms. Objectives might include mitigating the consequences of a fire expressed in terms of dollar values; loss of life; or maximum allowable conditions such as the extent of fire spread, temperature, or spread of combustion products. Uncertainties arise here in risk perceptions and values. There are both uncertainty and variability in the way people perceive and value risk.

Capturing differences people have in their perceptions and values related to risk is a necessary step in the design process. For example, it may be a goal of the stakeholders to protect historical features of the building or to protect against business interruption or loss of operating capability. Stakeholders with different values may see these needs differently. It is important to identify where value judgments enter into a performance-based calculation and to make any assumptions explicit regarding values and the impact of different values on the final design.

The following discussion focuses on incorporating uncertainty directly into Steps 4–8. Here we develop a probabilistic design statement, develop a distribution of statistically significant fire scenarios, calculate a set of values for critical outcome criteria, and evaluate each candidate design to determine whether the design meets the performance criteria within acceptable uncertainty bounds.

Step 4: Develop Probabilistic Statement of Performance

The fourth step in the design process is the development of a probabilistic statement(s) of performance, i.e., criteria by which to judge the acceptability of the design. These criteria are a further refinement of the design objectives and contain numerical values to which the expected performance of the candidate designs can be compared. Each probabilistic design statement contains a minimum of four elements: probability, time, performance criteria, and threshold value. For example, an objective may be to maintain tenable gas concentrations in the corridor. A corresponding probabilistic design statement for life safety might specify that the design must allow for a 0.9 probability of having 4 min or more before a temperature of 65 °C is reached in the corridor. Thus, all four elements are included: probability, time, performance criteria, and threshold value. A location is also specified.

There are many issues to be addressed when establishing probabilistic statements of performance. For example, which criterion should one evaluate? One could select, instead of or in addition to temperature, levels of carbon monoxide, heat flux, or obscuration. There is disagreement in the literature as to what values of each of these cause negative consequences. The negative consequences must be defined; i.e., should the threshold values represent incapacitation or lethality? Also, the probability element involves

determining the level of acceptable risk to the stakeholders, and establishing criteria for time to untenability involves understanding behavioral patterns of people in a fire as well as making value judgments as to which subpopulations to try to protect. The sensitivity of the design to each element of the probabilistic statement of performance is evaluated in Step 7b.

Based on this type of sensitivity analysis, a two-tiered probabilistic statement of performance may be developed based on any of the four elements as well as location. For example, the probabilistic statement of performance may say that the design must allow for a 0.9 probability of having 4 min or more before untenability based on a temperature of 65 °C is reached *and* a 0.9 probability of having 6 min or more before 100 °C is reached. The design statement may be specified in other ways, including the following:

- Include two probability levels, such as the design must have greater than or equal to a 0.95 probability of *X and* less than or equal to a 0.1 or more probability of *Y*.
- Provide a variation, such as the design must provide for a 0.9 probability of providing 4 min before untenability is reached and a 0.9 probability of having 8 min or more before untenable gas conditions are reached.

These are just a few of the possible specification options. Also, the location of evaluation matters. Untenability can be evaluated as a minimum anywhere in any room, including the room of origin, or it can be evaluated along the egress path. These two analyses may give different results in terms of acceptability.

Step 5: Develop a Distribution of Design Fire Scenarios

One of the most important pieces of the methodology is how to generate a set of realistic input scenarios. It is important that this set include a combination of scenarios that represents statistically both the types of fires and the frequency at which they occur in a given occupancy. The input scenario generator should integrate information about the uncertainty, variability, and correlational structure of the input parameters. Using an appropriate sampling method (e.g., Monte Carlo method), a set of any given number of fire scenarios may be constructed. This distribution of scenarios generated will contain the typical cases as well as the worst-case scenarios in the tails of the distribution. The steps involved in developing a distribution of design fire scenarios are (1) selecting a calculation procedure, (2) identifying the uncertain and crucial input parameters, (3) generating a distribution of design fire curves, (4) defining distributions of and modeling correlations among input parameters, and (5) selecting a sampling method and determining the number of scenarios.

Note: When selecting a design fire, a single choice is inadequate for PBD purposes. Monte Carlo is one possible simulation method for (1) propagating this uncertainty through a design calculation or fire model and (2) generating a cumulative distribution of outputs. However, for more complex fire models, conducting the necessary number of simulation iterations may be computationally prohibitive. An alternative method, using the Quadrature Method of Moments (QMOM), greatly reduces the number of simulations needed in order to create the CDF of an output variable. It should be noted that this approach is appropriate only when the uncertainty of only one input variable is being considered.

Upadhyay and Ezekoye [45] focus on a comparison of the QMOM method to the Monte Carlo method for both the ASET and CFAST models. The input value, heat release rate $\dot{S}$, is defined by a particular distribution $m(\dot{S})$. The output quantity of interest, the smoke layer height Z at some critical time t_{cr}, is described by a distribution $n(Z)$. The same analysis, however, can be carried out for any other input/output pair. The k^{th} moment of $n(Z)$ can be found by $M_k^{(Z)} \approx \sum_{n=1}^{N_0} Z(\dot{S}_n, t_{cr})^k W_n$ where $\dot{S}_n$ are the quadrature points and W_n are the quadrature weights obtained from the moments of $m(\dot{S})$. N_Q, the number of simulations needed, is typically 3 or 4, which greatly reduces the number of iterations from a Monte Carlo simulation. The moments of the output distribution, $n(Z)$, can be used to reconstruct a CDF.

Step 5a: Select a Calculation Procedure(s)

There is a range of calculation tools and models currently available from which to select the calculation procedure(s) to be used in the performance-based design. The *Fire Protection Handbook* provides a good overview of the various types of fire models [46]. Which model or type of model is selected depends on several factors, including the application of interest. Fire models can be used to predict a hazard, predict a risk, reconstruct a fire, interpolate between or extrapolate beyond test results, or evaluate a parametric variation. The application of fire models for each of these purposes is discussed by Nelson [47]. Each of these applications may have purpose at some stage of the performance-based design process.

Step 5b: Identify Uncertain Input Parameters

Once a calculation procedure is chosen and candidate designs have been selected, the input parameters necessary for the calculation are evaluated. Which input parameters will be treated as uncertain must be determined. Ideally, only parameters or combinations of parameters with uncertainty great enough to change decisions regarding the final design are treated as uncertain. These are referred to as the *crucial variables*. Unfortunately, we do not always know a priori which of the input parameters possess crucial uncertainty. Therefore, we must use a combination of judgment and results of previous analyses. The uncertainty importance of each of the uncertain input parameters is determined so that future analyses may be simplified. Eventually, only a few key parameters may be needed to capture the uncertainty in each calculation.

Step 5c: Generate a Distribution of Design Fire Curves

Design fire scenarios are made up of both possible fire events (heat release rate curves) and characteristics of the material burning, of the building, and other relevant information, such as weather conditions. A set of design fires is established to mimic the type and frequency of fires expected for that occupancy. These design fire curves are based on statistically collected data, judgments, and the goals of the design. Each design fire is assigned a likelihood of occurrence.

Step 5d: Define Distributions of and Model Correlations Among Other Input Parameters

The uncertainty and variability surrounding each variable must be captured in the mathematical description of that variable. Any and all available knowledge regarding the value of that parameter should be incorporated into the input scenario generator. This information includes empirically measured values, known variations, and statistically compiled data. For example, for a given occupancy type, the NFPA publishes statistical data on the percentage of fires that start in each potential room of fire origin. This information should be incorporated into the random scenario generator so that the generator mimics these statistics. Distributions can be constructed for variables such as temperature, wind, and relative humidity from regional data published by the National Weather Service. Methods for quantifying measurement uncertainty [2] are used to capture uncertainty and variability in empirically measured parameters, such as rates of production of products of combustion. In many cases, where hard data do not exist and are not possible to create, expert elicitation is needed to quantify the uncertainty.

When two or more variables are correlated, knowledge of the value of one variable tells something about the value of the other variable (s). Correlation among variables is modeled so that the input scenario generator will not generate unrealistic scenarios. For example, if the design incorporates a weather module, a month of the year would be randomly selected. For that given month, a value is sampled from an outdoor temperature distribution based on National Weather Service data for that region. Outdoor temperature is correlated to external pressure, wind, relative humidity, likelihood of windows/doors being open, indoor temperature and pressure, and initial fuel temperature. This information prevents the software from generating, for example, a scenario where there is a fire on a below-freezing

day in August in Southern California and all the windows are open.

Step 5e: Select a Sampling Method and Determine the Number of Scenarios

A sampling method, such as Monte Carlo, Latin Hypercube, or quasi-random, must be selected. By sampling a single value from each of the distributions in the input scenario generator and combining those numbers with the values of input parameters that are being treated as certain, any number of independent fire scenarios may be generated.

A large number of scenarios increases the statistical significance of the results. However, this relationship is dependent on the sampling method chosen and is not linear. Using 2000 runs may not provide any more insight than using 500. The number of scenarios chosen depends on (1) the number of uncertain input parameters, (2) the average calculation time per scenario for the calculation procedure chosen, and (3) the statistical significance needed. When conducting correlational analyses between inputs and outputs, one obtains importance or correlation coefficients, c, between 0 and 1. Hald provides a formula for determining the relationship between the number of runs, n, and the statistical significance (as measured by a t-test) of the correlation coefficient [48].

$$t = \frac{c}{\sqrt{1 - c^2}}\left(\sqrt{n - 2}\right)$$

The value for t is related to the confidence level, which is typically chosen as 95 %.

Step 6: Develop Candidate Designs

The candidate design is intended to meet the project requirements. A candidate design includes proposed fire protection systems, construction features, and operations that are provided in order to meet the performance criteria when evaluated using the design fire scenarios.

Step 7: Evaluate Candidate Designs

Each candidate design must be evaluated using each design fire scenario. The evaluations indicate whether the candidate design will meet the elements of the probabilistic statements of performance. Only candidate designs that meet the performance criteria may be considered as final design proposals. Without the quantitative treatment of uncertainties in the design, each calculation will provide a point estimate of only the important outcome criteria. For example, the performance criterion for a design may be a 100 °C maximum temperature reached in the upper layer. The time to an upper-layer temperature of 100 °C may be predicted as 175 s, and the time to activation of a sprinkler may be predicted as 171.2 s by a given computer model. Because the sprinkler is predicted to activate before the performance criteria is exceeded, this would be deemed an acceptable design. However, the uncertainty in the prediction of time to 100 °C may be ±20 s. This would mean that the temperature in the room may reach 100 °C at 155 s or before activation of the sprinkler. Also, the predicted time to activation of the sprinkler has an uncertainty surrounding it, as does the temperature at which untenability might actually occur.

The performance-based design process with uncertainty will aid in the calculation of a range of possible values for each key outcome criterion instead of a single point value. This methodology is useful for and may need to be applied to several parts of the design calculations. For example, it could be applied to the calculation of upper-layer temperatures, to the prediction of time to response of devices, and to the prediction of time needed to egress a building.

Step 7a: Calculate a Set of Values for Each Outcome Criterion

A single value will be determined for each outcome criterion calculated for each design fire scenario run. Much information can be obtained from observation of both the range of values for criteria of interest and from cumulative distribution functions generated from the set of all values.

If criteria are time-series values, each scenario will predict a different curve of the key outcome criteria versus time. For example, if upper-layer temperature is the criterion of interest, four

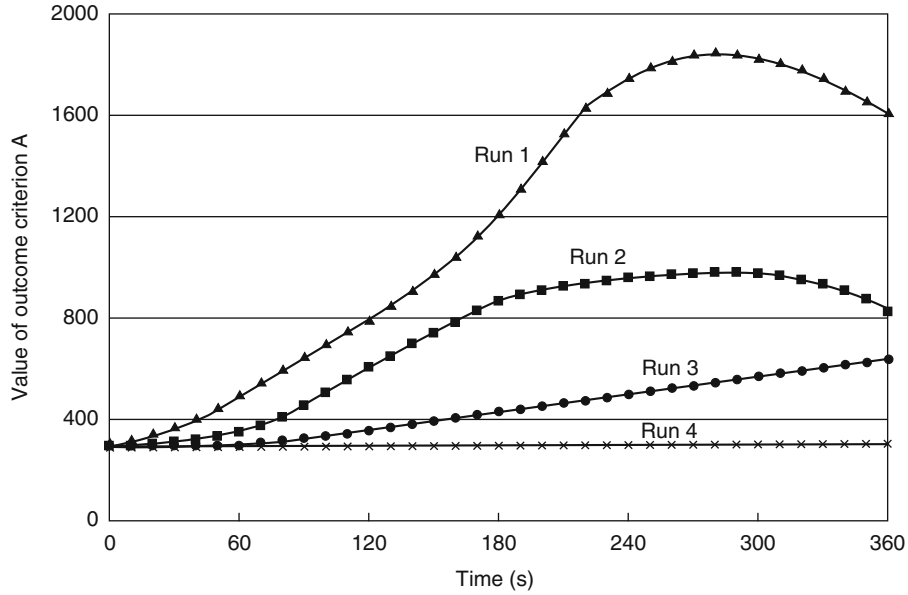

Fig. 76.2 Variation in prediction of time-series values of outcome criterion A

design fire scenarios would produce four curves of upper-layer temperature versus time. Figure 76.2 shows a representative graph of the value of outcome criterion A plotted against time from ignition (in seconds). For any given design, there will be as many curves as there are design fire scenarios calculated. One can see that the curves vary both in the magnitude of the peak value and in the time to the peak value.

The range of values predicted from the set of design fire scenarios represents the uncertainty in the value of the outcome criterion. From the set of predicted values of a single outcome criterion, a cumulative distribution function may be generated. This is done by graphing the value of the criterion against its rank order. For example, for n design fire scenarios, n values of a given criterion are generated. These values are then sorted in descending order. The largest value is graphed versus $1/n$, the second largest against $2/n$, . . ., and the smallest value against n/n or 1.

An example of a cumulative distribution function (CDF) is shown in Fig. 76.5. The time to reach a threshold value of 1 or more of the tenability criteria, that is, a value determined to cause injury or death, can be determined from the time-series predictions. The threshold value may be a particular temperature or carbon monoxide level or a parameter used to represent some synergistic effect of a combination of the tenability variables. One value of time to untenability is obtained for each scenario run. The set of all possible values provides a distribution of the outcome criteria.

Figure 76.3 shows that, for the distribution of design fire scenarios, there is almost a 1.0 probability that the time to a critical value of criterion A is 30 s or more. Likewise, there is a 0.75 probability that the time to this value is 120 s or more, a 0.50 probability that it is 180 s or more, and a 0.1 probability that it is 390 s or more.

Step 7b: Determine Sensitivity to Elements of the Probabilistic Statement of Performance

The sensitivity of key outcome criteria to each of the four elements of the probabilistic statement of performance on which a design is judged must be known before good policy and good design practice can be established. Elements such as criteria, threshold values, probabilities, and times are neither mandated nor agreed on by fire safety and health professionals or the public. Therefore, major conclusions of all designs

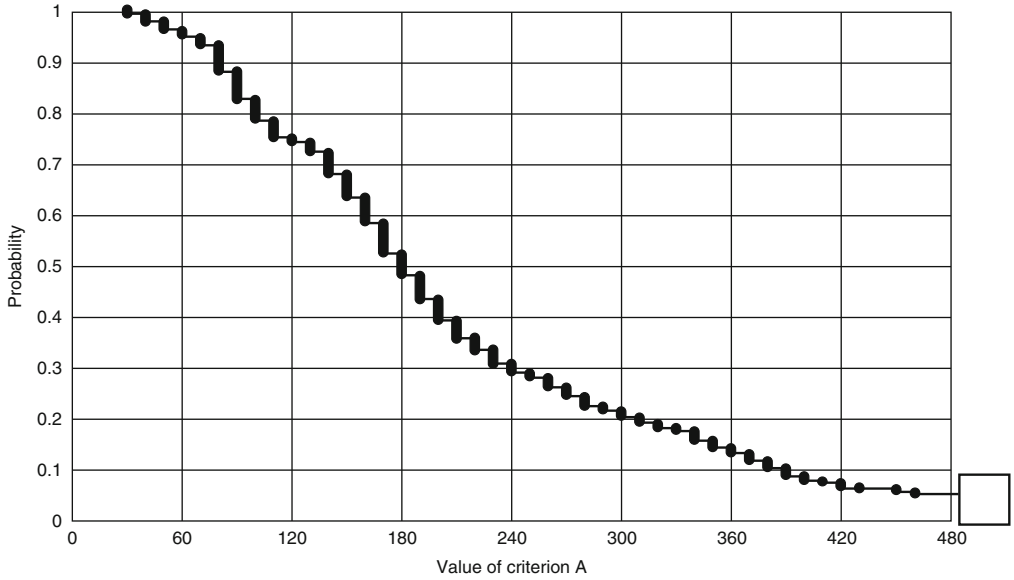

Fig. 76.3 Cumulative distribution function of time to the critical value of criterion A

should be checked in order to demonstrate the sensitivity to uncertainty in each of these elements. For example, checks should be made of times to untenable temperature, carbon monoxide, carbon dioxide, reduction in oxygen, and synergistic effects of the presence of these substances. It may also be appropriate to evaluate for heat flux and visibility.

The same design may be judged on two different performance criteria or by two different critical values of the same performance criterion. Figure 76.4 shows an example of time to untenability based on different values of upper-layer temperature. This type of presentation could also be used to determine the effect on time to untenability by selecting a group of tenability criteria or by including different sets of components in the specification of tenability criteria.

This type of evaluation is a good way to focus discussions among stakeholders on deciding which tenability criteria should be included, what effect the selection of different threshold values of tenability criteria has, what probability level is acceptable to the stakeholders, and how to select the final design. At the end of this step, final performance criteria must be selected for use in judging acceptability of designs and choosing a final design.

Step 7c: Evaluate the Base Case

Depending on the needs and the scope of the project, it is helpful to compare a candidate design to a base-case design. The base case can be the design that meets the prescriptive code, the design that includes the fire protection options currently in the building, or the design with no active fire-suppression systems. The purpose of having a base case is to benchmark the effects of fire on the building and on the building conditions against each of the designs.

In Fig. 76.5, the results of multiple scenario runs are used to show the probability of safe egress graphed against the time to untenable conditions for two different designs. Design 1 and Design 2 may represent two different performance designs or a performance design and a prescriptive design. Reiss discusses the need for this comparative approach [49]. The graph shows two design curves that exhibit crossover. Design 1 provides a higher probability of tenability out to 50 s. Design 2, however, provides a higher probability of tenability at longer times.

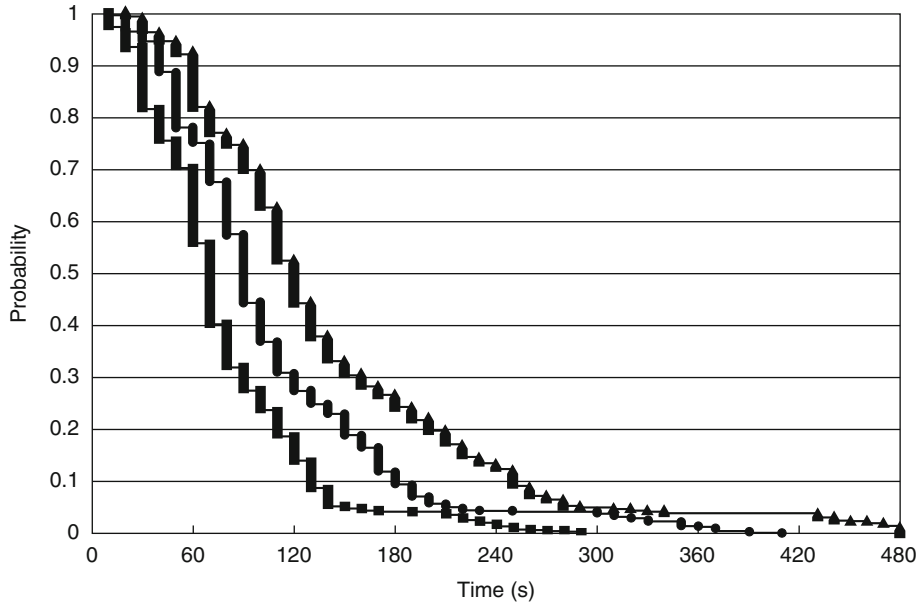

Fig. 76.4 Probability of having X seconds or more before untenable upper-layer temperatures are reached for three different values of untenable temperature

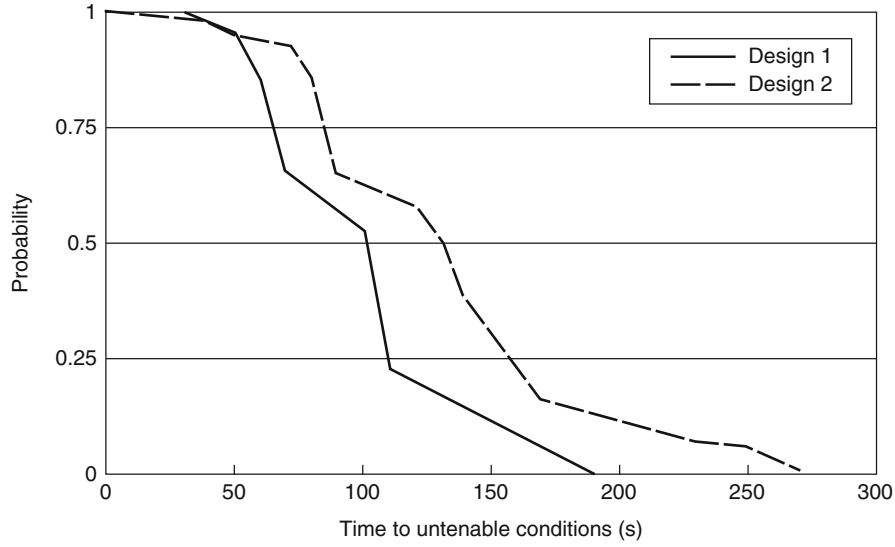

Fig. 76.5 Comparison of cumulative distribution functions of time to untenable conditions for two different designs

Another way that the acceptability of a design is judged is by comparing the level of safety provided with that provided by the corresponding prescriptive design. There is uncertainty associated with the prescriptive design also. The prescriptive code will mandate certain building materials and fire detection and suppression schemes. However, uncertainty and variability remain in the weather, ventilation conditions, human behavioral aspects, and where and how

the fire will start. Thus multiple scenarios can be constructed in a parallel manner to that shown above, holding as constants those factors required by the prescriptive code. Thus a CDF for the prescriptive code can be generated and compared with the CDF for the performance code.

Step 7d: Determine the Effect of Each Candidate Design on Each of the Scenarios

To compare two different candidate designs, we may want to look at the distribution of differences between the two designs based on the final selected performance criteria. One may consider differences between a design and the reference base case or differences in time to untenability provided by Design 1 versus Design 2. For example, Fig. 76.6 is a cumulative distribution function of the difference in time to untenability provided by Design 1 minus the time to untenability provided by Design 2.

Figure 76.6 shows that there is a 0.25 probability that Design 1 will provide a longer time-to-untenable conditions than will Design 2. Conversely, there is a 0.75 probability that Design 2 will provide a longer time to untenability than will Design 1 and a 0.25 probability that the difference will be 100 s or more. In selecting a final design, it may be helpful to investigate what factors might lead to Design 1 providing more time to untenability than Design 2, which could highlight ways to improve the design.

Step 7e: Evaluate Uncertainty Importance

An importance analysis is a particular type of sensitivity analysis that determines which of the uncertain input variables contributes most to the uncertainty in the outcome variable. The results are used to simplify future performance-based designs by identifying the one, two, or small group of most important inputs. Importance here is measured by the correlation between the output value and each uncertain input. Each variable's importance is calculated on a scale from 0 to 1 (or −1). A correlation of 0 indicates that uncertainty in the input variable has no effect on the uncertainty in the output parameter. The input parameters can be correlated to composite or derived outcomes (i.e., an outcome that is not directly an output of the model but one that is derived from the output data). Likewise, input variables can be combined (e.g., the volume of a room can be determined from the dimension).

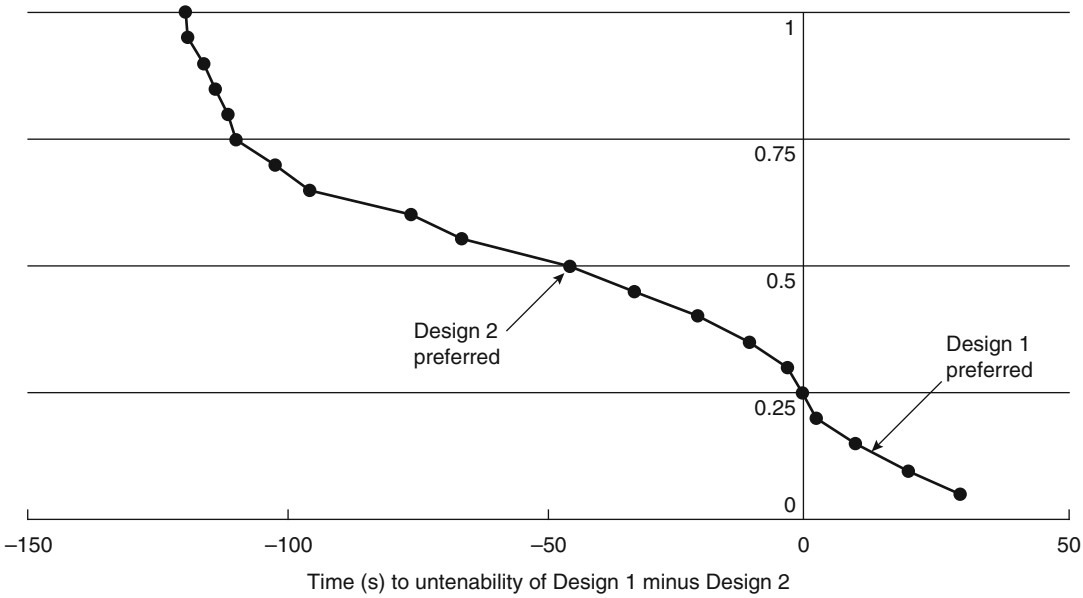

Fig. 76.6 Cumulative distribution function of time to untenability of Design 1—Design 2

Room volume may be correlated with key outcome criteria, for example, peak temperature or time to peak temperature.

Importance analysis can be used to simplify a future uncertainty analysis by determining the input uncertainties that are most crucial. This analysis can simplify the process for a class of buildings and can demonstrate where additional research would be effective in reducing uncertainty and ensuring a safer, more predictable building. It must be remembered, however, that correlation does not equal causation. Thus, any apparent, strong correlation that is counterintuitive should be investigated with good engineering judgment. Also, for each design, the value of the correlation coefficient that is statistically significant will depend on the number of scenarios run and the sampling method used.

Step 8: Judge a Design's Acceptability Based on All Four Elements of Probabilistic Statement of Performance

There are two ways to judge acceptability of a design. The first is based on the minimum time to untenability anywhere in the building, including the room of origin. The second is the time to untenability along the egress path. In general, for both cases, cumulative distribution functions are used to judge acceptability of a design. For example, Fig. 76.3 is a cumulative distribution function of the time to a specific value of criterion A in the room of origin. If the probabilistic statement of performance required a 0.9 probability of having 30 s or more before reaching this value, it can be determined from the CDF that this criterion is met. In fact, Fig. 76.3 shows that there is a 0.9 probability of having 80 s or more. However, if the probabilistic statement of performance requires a 1.0 probability of having 50 s or more, Fig. 76.3 shows that this criterion is not met because the CDF demonstrates a 1.0 probability of having only 30 s or more.

Another way of judging the acceptability of a performance-based design is with a time-to-egress analysis. The time needed to egress a building is often represented in the literature as the time to detect the fire, plus the time to react, plus the time to travel to a safe place. This analysis is represented mathematically as

$$\text{Time}_{\text{egress}} < \text{Time}_{\text{untenability}}$$

$$\text{Time}_{\text{egress}} = \text{Time}_{\text{detect}} + \text{Time}_{\text{react}} + \text{Time}_{\text{travel}}$$

One problem with this approach is that it is very difficult to predict human behavior in terms of reaction time and travel time during a fire. There are both variability due to age and health of the individual and uncertainty as to individual goals and concerns (e.g., will the person try to fight the fire, locate valuables, rescue pets, or notify other occupants about the fire?). The methodology described in this chapter may be applied to egress calculations. Because these are difficult to predict, however, it is suggested that perhaps these are best handled as societal and policy decisions. Regulatory decisions may be made as to the available, safe egress time. For example, more time may be mandated for a healthcare facility, where patients may be nonambulatory and/or asleep at the time of the fire, than in an office building, where occupants are generally awake and ambulatory.

Steps 9–10: Select a Final Design and Prepare Documentation

Candidate designs that satisfy the probabilistic design statement(s) may be considered for selection as the final design. When more than one candidate design meets all four elements of the probabilistic statement of performance, other factors, such as cost and preference, are considered. When considering multiple designs or designs with very different features, a multicriteria decision-analysis model may be developed to aid in selecting the final design.

Proper documentation of a performance design is critical and should be written so that all parties involved understand what is necessary for the design implementation, maintenance, and continuity of the fire protection design. The *SFPE Engineering Guide to Performance-Based Fire Protection* suggests that the documentation have four parts: the fire protection engineering design brief, the performance design

report, the detailed specifications and drawings, and the building operations and maintenance manual [13]. It is important that the performance-based design report convey the expected hazards, risks, and performance over the entire building life. It should include the project scope, goal, and objectives, the probabilistic design statements, a discussion of the design fires and design fire scenarios, and any critical design assumptions.

In conclusion, incorporating uncertainty in a fire safety engineering design calculation aids in ensuring performance. The methodology described in the foregoing section can be used in combination with standard performance-based design procedure. Each step in the methodology may be expanded or contracted to fit the needs of a given calculation. In the future, one may be able to construct libraries of models with families of input scenario generators and develop reusable models for classes of buildings. Ultimately, a fire safety engineering model should be developed that directly incorporates uncertainty.

Application of Uncertainty to Cost-Benefit Models, Improving Regulation, and Overall Decision Making

Decision Making Under Uncertainty

The importance of making good decisions under conditions of uncertainty is becoming better understood in many fields, including fire safety design. The recently released National Science Policy study, *Unlocking Our Future: Toward a New National Science Policy*, states, "Decision makers must recognize that uncertainty is a fundamental aspect of the scientific process." Good decisions can be made under uncertain conditions; however, one must capture the nature and magnitude of the uncertainty in order to make a good decision [50].

There is uncertainty involved in deciding among fire safety options, such as whether to install smoke detectors, sprinklers, or both. Another example is deciding whether the cost of redundant pumps or entire redundant systems is justified. These types of decisions are typically modeled using fire safety trees [51]. However, average or best-guess estimates typically are used for parameters in the decision model, and uncertainty and variability in these are rarely considered.

Decisions made by municipalities on whether to mandate fire safety systems, such as residential sprinklers, are likewise often made based on economic analyses using best-guess and national average values. Integration of uncertainty and variability into these types of cost-benefit studies would provide the decision maker more insights into the issues at hand. It would also highlight where engineering technology is able to reduce risks and where regulatory solutions might be more helpful.

This process is becoming more complex because implementation of any form of a performance-based standard will require more decisions to be made. These decisions will be more difficult, more complex, and more uncertain than under a prescriptive-based code. Robert Clemen discusses in his book, *Making Hard Decisions*, four reasons making decisions is so difficult [52].

- *First, decisions can be difficult simply because of their complexity*. In the case of decisions regarding fire protection features, one must consider the potential for property protection, life safety, injury mitigation, and business continuity. One must also consider the diverse impacts on people with special needs, such as the very young, the elderly, or persons with limited mobility.
- *Second, decisions can be difficult because the decision maker may be working toward multiple or competing objectives*. In fire protection analyses, typically competing objectives are low cost and high level of safety. Progress in one direction, such as installing automatic fire sprinklers for increased fire safety, may impede progress of a competing objective, such as designing an economical building.
- *Third, a problem may be difficult if different perspectives lead to different conclusions*. In a fire protection decision, the perspective of the

building owner, designer, and authority having jurisdiction may very well differ.

- *Finally, decisions can also be difficult because of the inherent uncertainty*. Uncertainties may arise in the model physics, the values of the inputs, the reliability of the devices, and the frequency of events. Yet a decision must be made without knowing for sure what these uncertain values will be. In fact, the most important decisions are often those that must be made under the greatest uncertainty, have the highest complexity, and involve multiple perspectives and goods.

The quantitative treatment of variability and uncertainty using the tools and techniques presented earlier in this chapter can help in identifying important sources of uncertainty and representing that uncertainty in a quantitative way.

The following section introduces an analytical approach that enables quantitative models and decision models to be built with the integrated treatment of uncertainty. The final section demonstrates how these tools were used in a cost-benefit model of the decision to mandate residential fire sprinklers from a municipal standpoint.

Available Software That Incorporates Uncertainty

Decision analysis applications often use generic modeling software, such as spreadsheets, statistics packages, and financial modeling languages. Specialized software is also available for modeling decision problems using decision trees, influence diagrams, belief networks, multiattribute utility functions, hierarchical value structures, Monte Carlo simulation, and multicriteria optimization.

Two of the many such pieces of software that allow for direct treatment of uncertainty are Analytica™ by Lumina and @RISK™ by Palisade. They are described here for informational purposes only, intended to provide the reader with an idea of the capabilities of currently available software. The reader is encouraged to evaluate the full range of available software before selecting a package.

@RISK is a risk-analysis and simulation add-in for Microsoft Excel or Lotus 1-2-3. @RISK adds the power of Monte Carlo simulation to spreadsheet models. It allows users to replace uncertain values in a spreadsheet with probability functions, which represent a range of possible values. @RISK can recalculate users' spreadsheets hundreds or even thousands of times, each time selecting random numbers from the functions entered. The result is distributions of possible outcomes and the probabilities of getting those results. This result identifies not only what could happen in a given situation but also how likely it is that it will happen.

Analytica is another program that allows for the direct treatment of uncertainty. A model built in Analytica uses a graphical interface that resembles an influence diagram. This diagram conveys the model structure. A complicated model can be easily organized into a hierarchy of comprehensible and simple modules. The influence diagram format easily distinguishes between decision variables (those you can control), chance variables (uncertain quantities that cannot be controlled), and objectives (criteria to maximize).

Other distinctive features of Analytica are what the company terms *intelligent arrays* and turnkey importance analysis. With intelligent arrays, data may be entered as an array indexed by several parameters. The software handles operations on these multidimensional values, such as adding, multiplying element by element, or summing over a dimension. Examples of intelligent arrays are presented in the following section.

In Analytica uncertainty can be treated explicitly with probabilities. The user can express uncertainty about any variable, selecting a probability distribution using a graphical browser; propagate uncertainties with the model using Monte Carlo sampling; and display uncertain results as standard statistics, probability bands, probability density functions, or cumulative probability functions. Analytica conducts rank-order and importance analyses. These tools help users decide which uncertainties make a

difference to help determine whether getting better data or expanding the model is worthwhile. Analytica also allows for parametric analysis by graphing model behavior as one or more inputs are varied.

Example of Cost-Benefit Model with Variability and Uncertainty

In the United States, approximately 3500 people die each year in residential fires. The number of residential fire deaths, however, varies with the type of housing, area of the country, and community size. The cost of installing residential fire sprinklers varies with areas of the country and house age. Thus, the true cost-benefit analysis will be different for each combination of the above parameters. However, cost-benefit models typically use average costs and probabilities and do not incorporate uncertainty.

A model was built using Analytica that incorporated variability and uncertainty to determine the societal benefits and costs of mandating residential sprinklers. A full description of the mathematical model and the results is beyond the scope of this chapter but can be found in "The Role of Uncertainty in Improving Fire Protection Regulation" [49]. A brief overview of that study is presented in order to demonstrate the techniques used in the treatment of variability and uncertainty and the implications for fire protection analyses.

Treatment of Variability and Uncertainty

Inter-year Variability in Fire Loss Statistics To conduct a cost-benefit study of residential fire sprinkler systems, many fire statistics (e.g., death rates, injury rates, and average direct dollar losses) are needed as inputs. National average values of these numbers are often used in these analyses. For example, the national average value for the residential death rate would be equal to the number of residential fire deaths nationally divided by the number of occupied residential units. The actual fire death rate will vary with a number of parameters.

The U.S. National Fire Protection Association publishes death rates discretized by three of four index variables: region of the country, community size, and house type [53]. The fourth index variable, house age, is accounted for in the cost functions, as it is more expensive to retrofit sprinklers than it is to install them during the construction phase. There are four regions of the country, eight community sizes, and three house types. Thus, the death rate used in these calculations is a $4 \times 8 \times 3$ matrix consisting of 96 values for death rate. Two examples would be the death rate in manufactured homes in a small community (2500 or less) in the South and the death rate in a one- or two-family dwelling in a community size of 25,000–50,000 in the West.

Yearly Variability in Fire Loss Statistics It is important to differentiate between variability and uncertainty. Variability in fire statistics from year to year arises because of the randomness of the occurrence of fires. For instance, in one particular year, several large-loss fires may occur followed by few or none the next year. In this study, since there is an interest in benefits and costs over the life of a fire sprinkler system, mean yearly values were chosen. Yearly variance in deaths, injuries, property loss, and indirect losses due to fires is thus accounted for by taking mean yearly values over a 5-year period. Mean values were calculated from the 1989–1993 data.

Uncertainty in the Fire Statistics Uncertainty in fire loss statistics exists due to the impossibility of a full and accurate accounting of all fires and all fire losses. Mathematical techniques are thus used to provide estimates [54]. Uncertainty in the fire data is represented as uncertainty about the mean values. An expert elicitation of the chief statistician of NFPA was conducted to set the uncertainty bands for the fire statistics [55].

Uncertainty in Other (Empirical) Model Inputs Uncertainty in the cost data and parameters, such as the sprinkler reduction factor, were determined by bounding. For example, uncertainty in the sprinkler reduction factor arises because of the small number of fires occurring in homes with automatic sprinklers installed. Data from other occupancies were used to bound the uncertainty.

Propagation of Uncertainty Once the uncertainties in the model inputs have been expressed, the question becomes how to propagate these uncertainties through the model to discover the uncertainty in the predicted consequences. In this analysis a Monte Carlo simulation was used. A value for each input is randomly selected from its actual probability distribution. From these values, a value for the outcome criteria is calculated. This process is repeated many times, resulting in a probability distribution for each outcome variable.

Value/Cost of Death Averted For any cost-benefit analysis regarding health and safety, one of the most highly contentious points is setting a value of life. Economists have come up with various ways of estimating the value of a life. These include willingness to pay for safety devices and income-based estimates [56]. All these methods are highly debated. For this study, the problem of establishing a value of life was avoided by means of careful selection of the outcome criteria. By selecting the outcome criteria to be dollars per premature death averted and dollars per life-year saved, no explicit value of life needs to be specified.

Results—National Average Calculation Versus Indexed Calculations When variability due to region, community size, house type, and house age is accounted for, the net cost of residential sprinklers varies tremendously. The net cost for installing residential sprinklers varies by greater than a factor of 35 times from a low of $1.4 million per premature death averted (for a new manufactured home in a small community in the South) to a high of $35.1 million (for a retrofit of a one- and two-family dwelling in a medium-size community in the Western U.S.). Based on a national average calculation, our model predicts that residential fire sprinklers have a median net cost of $7.3 million per premature death averted.

Comparison to Other Lifesaving Interventions An article in *Risk Analysis* identified over 500 lifesaving interventions, reporting their net cost in terms of dollars per life-year saved [57]. The accuracy of the results is limited by the accuracy of the data and assumptions in each original analysis, but the results are believable within an order of magnitude. In this study the cost per life-year saved for residential fire sprinklers was compared to the cost per life-year saved for chlorination of drinking water, banning urea-formaldehyde insulation in homes, installing oxygen depletion sensors for gas space heaters, conducting radon remediation, mandating child-resistant cigarette lighters, and installing ground fault interrupters. Figure 76.7 shows this comparison. The heights of the bars

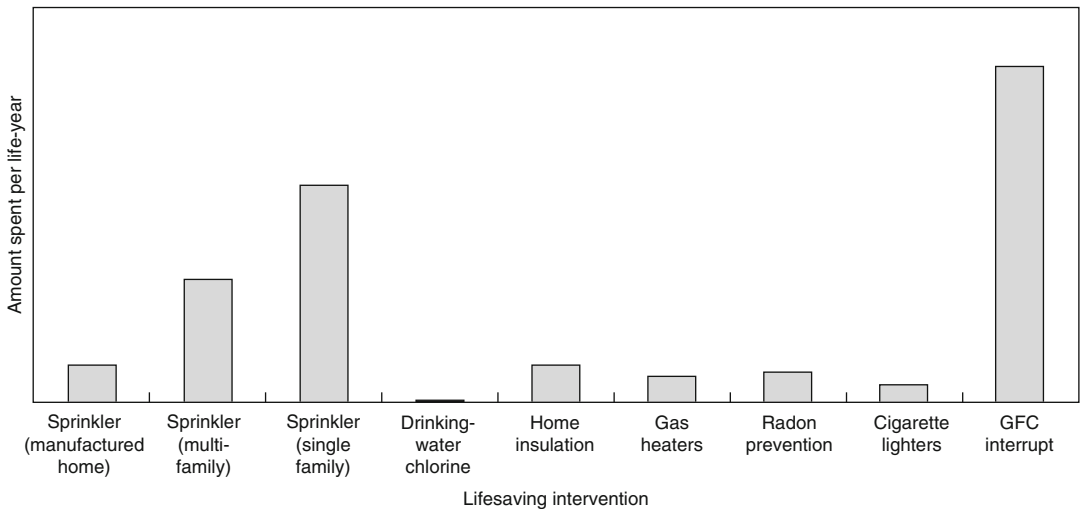

Fig. 76.7 Comparison of net cost of fire sprinklers in manufactured homes with other residential lifesaving interventions

represent the relative costs per life-year saved and have all been normalized to the cost of chlorination of drinking water.

Uncertainty in Cost-Benefit and Decision Analysis Models

This example demonstrates how uncertainty and variability may be treated in a cost-benefit or decision analysis model. It also shows that effectively treating variability and uncertainty and use of tools such as importance analysis and comparative analysis can lead to greater insights. The cost of mandating residential fire sprinklers in new manufactured homes is shown to be as low as five times less than the cost of mandating residential fire sprinklers using national average values for fire risk and costs. The cost of mandating residential fire sprinklers in existing single family homes is shown to be up to five times more than using national average numbers. The comparative analysis provides lawmakers with a frame of reference by comparing the cost of mandating residential fire sprinklers to the costs of mandating other residential safety options with lifesaving potential.

Uncertainty in Probabilistic Risk Assessment

Definition of the Problem

This example discusses an approach to a particular problem, namely decision making on the acceptability of changes to the licensing basis of a nuclear power plant using results from a probabilistic risk assessment (PRA), which includes contributions from accidents initiated by fires occurring within the plant. The licensing basis is a legal requirement that determines how the plant is built and operated. The elements of a PRA that can be used to investigate the risk from fires are discussed in Chap. 89 and in more detail in "EPRI/NRC-RES Fire PRA Methodology for Nuclear Power Facilities" [58].

Role of the PRA in the Decision

In order to use the results of any analysis, in this case a PRA, in decision making, the decision makers must first determine what role the analysis is to play in the decision and how it is going to fulfill that role. In this section, the approach taken by the U.S. Nuclear Regulatory Commission (NRC) for using results from PRAs in decision making is used as an example to illustrate this process [59]. The approach is described in detail in Regulatory Guide (RG) 1.174 [18]. Although RG 1.174 focuses on one type of application, namely changes to the licensing basis of an operating nuclear plant, the principles involved have been adopted in a more general way in the development of risk-informed regulatory decision making at the U.S. Nuclear Regulatory Commission.

In deciding how to use risk information in decision making, two approaches can be considered. The first, a *risk-based approach*, would use the risk results as the sole basis for the decision. The second, a *risk-informed approach*, would use risk information as one of the elements in making decisions. The recognition that the PRA, although a detailed model, is still a model, which is an approximation of reality, coupled with a recognition that there is an incompleteness of the collective state of knowledge about all the possible failure causes and mechanisms, led the NRC to adopt the use of risk-informed rather than risk-based decision making. To develop the concept further, it is necessary to define what other factors are to be taken into account in the decision. In RG 1.174, this effort led to the development of five principles of risk-informed decision making, all of which must be met for the proposed change to be accepted (Fig. 76.8). The incorporation of defense-in-depth and the use of safety margins have been an integral part of the design and operation of nuclear power plants and are significant defenses against unknown causes of failure. Similarly, the requirement to perform monitoring following a change is a response to

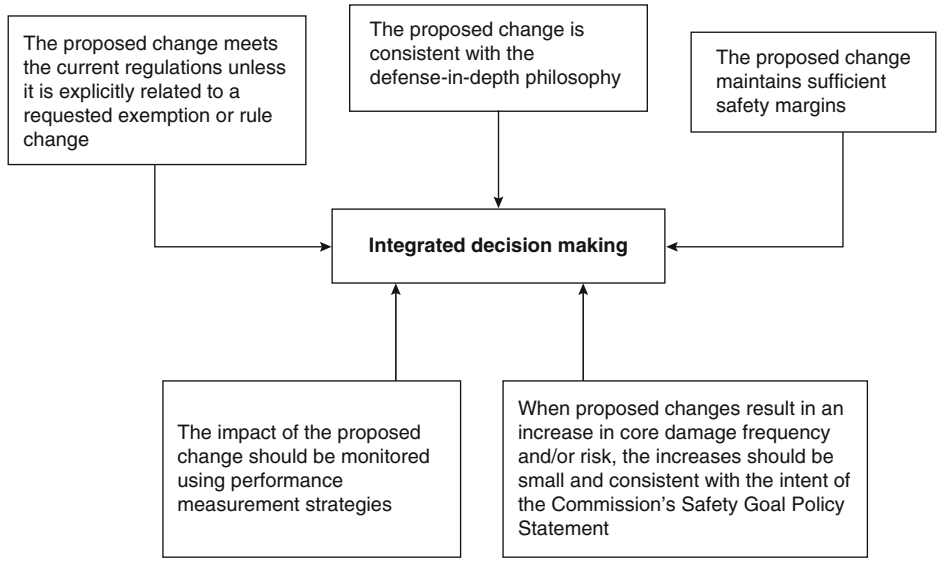

Fig. 76.8 Principles of risk-informed decision making

the potential for incompleteness in the analysis of the impact of the change.

In this example, the result of the engineering calculation, in this case the PRA, is one, but only one, input to the decision.

Acceptance Criteria Given that the role of risk information has been determined, it is necessary to develop criteria that can be used to determine when the results of the risk calculations are acceptable, which includes defining the following:

- Risk metrics to be used
- Decision criteria

In this particular application, the decision metrics were chosen to be the core damage frequency (CDF) and the large early-release frequency (LERF), both of which are results that can be obtained from PRA. The risk-acceptance criteria (one for each of CDF and LERF) were based on the impact on those metrics, measured as ΔCDF and ΔLERF, resulting from the proposed change. The acceptance criteria for CDF are included as Fig. 76.9.

When defining a decision criterion, it is crucial to define how uncertainty is accommodated by the choice of criterion, which to a large extent depends on how the uncertainties can be incorporated into the results of the analysis. This process will be discussed later, after the detailed discussion of the analysis of uncertainty.

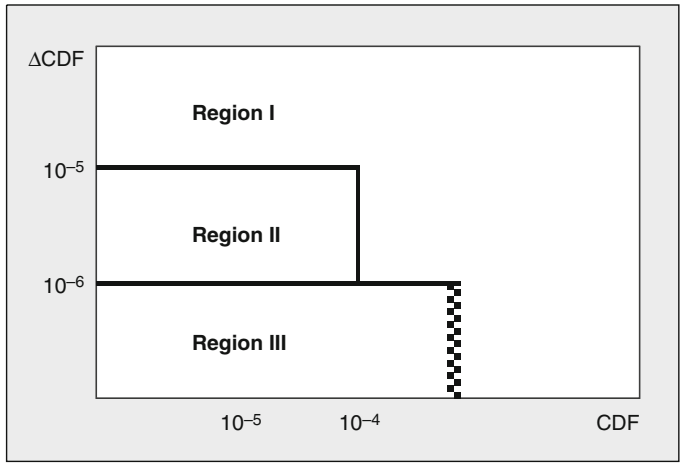
Analysis of Uncertainty

The steps needed to perform an analysis of uncertainty in the results of the analysis are the following:

- Identifying the sources of uncertainty.
- Characterizing the uncertainty on the individual inputs to the model.
- Propagating these uncertainties to obtain a characterization of the uncertainty on the output of the model.
- Interpreting the results in light of the uncertainty.
- Presenting the results in a way that is meaningful to the user (e.g., decision maker).

Before discussing the steps in more detail, we present a discussion of the fire PRA model as it relates to uncertainty. Much of the discussion here can be generalized to other types of fire safety engineering calculations.

Uncertainty in the Context of Developing Fire Risk Models In general terms, a model can be



1. Region I
—No changes
2. Region II
—Small changes
—Track cumulative impacts

3. Region III
—Very small changes
—More flexibility with respect to baseline
—Track cumulative impacts

Fig. 76.9 Acceptance guidelines for core damage frequency

described as an analyst's attempt to represent a system (using the term *system* in a very general way) in a form that can be used as an explanatory and an exploratory tool. In almost all cases, it is impossible to capture all the subtleties of the system behavior. Therefore, any model is, at best, an approximation. A model in the physical sciences or engineering disciplines is usually a mathematical model, which is to say that it has a mathematical form, and can produce numerical results that represent some observable aspects of system behavior. Such a mathematical model will generally have several parameters. Since any model is an approximate representation, it follows that there must be some uncertainty associated with the formulation and predictions of the model. For some models, however, this uncertainty is so small that it can essentially be ignored. For example, the mathematical formulation of many of the models created by physicists to explain natural phenomena is sufficiently well supported or verified that the models are very precise in their predictions, as long as they are used within their region of applicability.

In addition, many of the parameters are so well known that they can be thought of as universal constants. An example of one such model is Newtonian mechanics and Newton's law of gravity, which is capable of making very accurate predictions of such things as planetary motion and can be used to define the trajectories of planets or space vehicles with great accuracy. Not only is the model rather simple, but also the parameter of the model, the gravitational constant, is known very accurately. Of course, it is well known that, under specific boundary conditions and for particular problems, Newtonian mechanics breaks down and must be replaced with the general theory of relativity. Newtonian mechanics is an example of a deterministic model. However, a model need not necessarily be deterministic to be precise. Quantum electrodynamics (QED) is a model that is capable of making very accurate predictions. However, because of the quantum mechanical nature of matter in the small scale, it does so only in a probabilistic sense, making predictions about the average behavior of a population of events rather than about the outcome of a particular event. It is, therefore, a probabilistic model of the world. The uncertainty associated with this lack of predictability for single occurrences of events is an example of aleatory uncertainty.

As described in Chap. 89, a fire-risk model or a fire PRA is typically constructed using logic structures, such as event trees and fault trees, to identify the different combinations of more elementary events, called basic events, that could lead to undesired system states. What these logic models represent is a discretization of the potentially unlimited range of scenarios into a manageable set that are supposed to be representative of and encompass the range of consequences of that larger set.

The types of basic events found in fire PRAs include events that (1) represent the occurrence of a fire scenario, defined as a fire with specified initial conditions, type (e.g., cable fire, pool fire), and size in a specific location; (2) delineate the different levels of severity of fire damage, taking into account the potential for fire growth and the potential for fire suppression; and (3) events that represent failures or states of unavailability of components or human failures that contribute to the failure of the systems designed to protect against the undesirable consequences should the plant be damaged by fire. The occurrence of the fire scenarios is modeled as a random process, and a frequency of occurrence is associated with each fire scenario. The basic events in the third group discussed above are typically events such as the failure of a pump to start, the failure of a pump to run for 24 h, and failure of an operator to take the appropriate actions to prevent system damage. For the most part these basic events are also regarded as resulting from random occurrences with respect to the demand created by the initiating event and are described by probabilistic models.

The events that delineate the different levels of damage caused by a fire are chosen on the basis of an analysis using models of fire growth and damage, and models for the detection and suppression of fires. Some of these models are deterministic in nature, whereas others are probabilistic. For example, the time of successful fire suppression is treated as a random process in that the time of successful suppression is treated as a distributed variable. Typically, fire growth and cable damage are treated deterministically by creating a time line for the development of damaging conditions within a fire area and by defining failure as occurring after exposure to a specified temperature for a specified time, respectively. This model is recognized as an approximation, since fire growth and fire damage are essentially stochastic processes; there would in reality be variability in factors such as the precise location of the origin of the fire, for example. However, it is typically convenient to model this infinite variability by a set of representative fires and model their growth in an average way.

Therefore, a fire PRA is a probabilistic model of aleatory uncertainty. Unlike the physics models discussed above, however, there are significant epistemic uncertainties that must be recognized. The reasons for these uncertainties include the following:

- For many of the basic events of the PRA model, the associated probability models adopted are simple with only one or two parameters. Examples include the simple constant failure rate reliability model, which assumes that the failures of a component, while it is in standby, occur at a constant rate; and the uniformly distributed (in time) likelihood of a fire scenario. The model for both these processes is the well-known Poisson model. The parameter(s) of such models can be estimated using appropriate data, which in the examples above comprise the number of failures observed in a population of like components in a given time and the number of occurrences of a fire scenario in a given time, respectively. However, most of the events that constitute the building blocks of the risk model (e.g., the fire initiation) and the non-fire-induced equipment failures are rare events. Because the occurrences are rare, there are statistical uncertainties in the estimates of the parameters of the model.
- Events exist for which there may be uncertainties associated with interpreting the data to be used for estimation. For example, when collecting data on fire scenarios, there can be uncertainty on what data to collect. For example, should all fires be counted, or should minor fires that were self-extinguishing

or those that were suppressed quickly be excluded? Should historical fires that were not damaging be included in the count if in a different location they might have been significant? These and other issues are discussed in NUREG/CR-6850 [17]. As another example, when counting failures based on the review of maintenance records, it is not always clear whether the failure would have prevented the component from performing the mission required of it to meet the success criteria assumed in the risk model.

- There can also be uncertainty about the form of the probability model. Although the Poisson and binomial models are typically adopted for the occurrence of initiating events and for equipment failures, it has to be recognized that these are assumptions and may not be appropriate for all situations.
- The fire PRA model is also dependent on models of fire growth and damage and on models of fire detection and suppression. The modeling of fire growth, taking into account the geometry of targets and intervening combustibles, the influence of hot gas layers, and so on, is extremely complicated, and the models at best are approximate. For a detailed discussion see NUREG/CR-6850 [17]. The simplifications that are necessary to develop a model can produce conservative or nonconservative biases.
- Given that the form of the model has been decided on, there is an additional source of uncertainty associated with the parameters of those models (e.g., the temperature at which damage is assumed to occur).
- The number of potential fire scenarios is very large, and it is necessary to choose a representative set to model the impact. This sample also introduces uncertainty in the form of a potential bias, which is usually intended to be somewhat conservative.

As mentioned previously, the uncertainty associated with the structure of and input to the fire risk model could be in the choice of mathematical form of the input models, it could be in the values of its parameters, or both. To the extent that changes in the parameter values are little more than subtle changes in the form of the model, it could be argued that there is really no precise distinction between model uncertainty and parameter uncertainty. However, as discussed below, parameter uncertainties and model uncertainties are dealt with differently.

Identifying the Sources of Uncertainty It is helpful to categorize uncertainty into parameter and model uncertainties. As will be seen below, this is primarily because the methods for the characterization and analysis of uncertainty are different for the two types. However, it is also necessary to identify a third type of uncertainty, namely uncertainty about the completeness of the model, which while it cannot be handled analytically, must be taken into account when making decisions using the results of a risk analysis.

Parameter Uncertainty Parameter uncertainty is the uncertainty in the values of the parameters of a model, conditional on an acceptance of the mathematical form of that model. The uncertainty arises in different ways depending on how the data on which the parameter values are estimated are obtained.

For continuous variables, such as heat of combustion, which can be measured directly, there is measurement uncertainty, which is typically not a major source of uncertainty for the types of parameters found in risk models. However, the uncertainty in some variables, such as the temperature at which damage occurs, can have a significant impact. Although in principle it might be considered that such a variable is directly measurable, doing so can be challenging.

Statistical uncertainty occurs in two of the following ways:

- When a parameter (such as the temperature at which damage occurs) that can be measured directly is obtained from a series of experiments, and the phenomena being tested are random in the sense that the experiments cannot be strictly reproduced except in some overall sense, such as establishing gross boundary conditions. The measured value

will be variable from experiment to experiment and, in the foregoing example, will depend on such variables as where and how the temperature is measured. This variability can, in principle, be captured statistically in a probability distribution. This type of uncertainty could be embedded into the aleatory structure of the risk model if the model were intended to explicitly model that variability. However, because of the need to limit the granularity in the model, it is likely instead to be treated as an uncertainty on the representative value of the parameter. This case is an example of a gray area in terms of separating aleatory and epistemic uncertainty. Analysts should be particularly careful in defining their approach so that their intent in modeling is clear.

- When a parameter value is inferred from event data using a statistical process, as is the case with failure rates of components, for example.
- In many cases, data are limited, or may be only indirectly relevant. In such cases, expert judgment has to be applied to determine the value of the data.

Model Uncertainty Because of the potential for a large number of scenarios, the analysis of which would be prohibitive, as discussed previously, it is common to choose a small set of scenarios to analyze that is representative and bound or encompass the effects of all potential fire scenarios. The smaller the set of scenarios, the more approximate will be the results. Depending on the purpose of the analysis, different degrees of discretization may be appropriate. In developing the set of representative scenarios, fire models may be used to screen out a number of scenarios. Typically, it would be expected that the models used for this step would be conservative and fairly simple. However, the use of screening models is another source of uncertainty.

These representative scenarios are analyzed using models of fire growth, fire damage, and fire detection and suppression. As discussed earlier, the models used for fire growth and for fire damage are essentially deterministic. Because of the complexity of the physical phenomena involved, they are of necessity approximate. The models have limitations, and these must be recognized when using them. Some models are largely empirical, whereas other models, such as zone models, models based on computational fluid dynamics, and fire dynamics models, are analytical, with a variation in their degree of sophistication. These different models have different capabilities and will give different results when used in the same context. Thus the sources of uncertainty are not restricted to uncertainties in the parameters (e.g., heat-release rate) of those models, though these may be the easiest to deal with analytically. Typically the model limitations will produce results that are biased, and the biases have to be understood.

Completeness Uncertainty Completeness uncertainty can be thought of also as a type of model uncertainty. However, it is discussed separately here because it represents a type of uncertainty that cannot be quantified, because it represents those aspects of the real world that, either knowingly or unknowingly, are not addressed in the model. Incompleteness in the model, therefore, can be thought of as arising in two different ways:

- Some contributors/effects may be knowingly left out of the model for a number of reasons. There may currently be no analytical model for the particular issue (e.g., the impact of safety culture). Resources may not be available to develop a complete model, leading to a decision not to model certain contributors to risk (e.g., seismically induced fires).
- Some phenomena or failure mechanisms may be omitted because their potential existence has not been recognized.

For some of the known sources of incompleteness, the limitations may be recognized and the formulation of the models may be designed to address the issues by, for example, providing somewhat conservative results. This possibility is addressed under the

model uncertainty category. Some issues, however, cannot be compensated for in that way. An example in the area of nuclear power plant PRAs is that many of the models do not address the seismically induced plant disturbances. It is clear that, if something is not modeled, it cannot be addressed quantitatively in the same manner as those issues that are modeled. The true unknowns in particular (i.e., those related to issues whose existence is not recognized) cannot be addressed analytically. However, in the interest of making defendable decisions, they still have to be addressed during the decision making, as will be discussed later.

Characterization of Input Uncertainty Current practices for characterizing the different types of uncertainty are discussed below.

Parameter Uncertainty In most recent PRAs, the representation of uncertainty in parameter values has been accomplished by adopting a Bayesian or subjectivist framework [60]. In this framework, the uncertainty is characterized by a continuous probability distribution function on the value of the parameter, which is interpreted as being an expression of the analyst's degree of belief in the corresponding value as bounding the true value of the parameter. The representation of the uncertainty in the form of a probability distribution lends itself to propagation, so that the uncertainties on the constituent elements can be combined in a meaningful way. Whereas classical statistical methods can be used to provide a maximum likelihood estimate and associated confidence intervals on parameter estimates, the mathematical propagation of confidence intervals is difficult to perform and interpret [61].

As discussed earlier, for many of the basic events of the PRA model, the associated probability models are simple, with only one or two parameters. These models include the Poisson model and the binomial model. The parameter (s) of such models can be estimated using appropriate data, which in the example above comprise the number of events observed in a population of like components in a given time or in a given number of trials, respectively. The estimation of parameter values of simple reliability models and the characterization of their associated uncertainties have been addressed in many places. The most recent and comprehensive treatment can be found in NUREG/CR-6823 [62].

There are other parameters, such as the temperatures at which cables fail or heat-release rates, that are not based on simple counting statistics, as is the case for failure rates and initiating events. The characterization of these uncertainties should be compatible with the way in which they are to be formally propagated through the analysis of the likelihood of specific damage states resulting from a fire scenario to evaluate the probability of damage. The parameters associated with the models for fire growth, damage, and suppression will be discussed in the context of the model uncertainty.

Uncertainty in the Data Used to Estimate Parameters In some cases, although the underlying model may be simple, there may be uncertainties associated with interpreting the data to be used for estimation. Examples include the following:

- When estimating fire frequencies for use in risk models, the question arises whether all fires should be included or whether those that are extinguished early should be excluded.
- When considering the completeness of the data records, it is necessary to determine if the facilities required to report occurrences, whether they be fires or failures, do so in a consistent manner.
- When evaluating equipment "failures" identified from maintenance records, it is necessary to assess whether the need for maintenance constitutes a failure in the context of the success criteria used in the risk model.

The uncertainties associated with interpretation of data to apply to a specific model are not typically amenable to an analytical closed form. However, some idea of the uncertainty in the parameter value can be obtained by performing sensitivity studies. The difficulty with constructing a probability distribution is

that one would have to give a degree of belief to each sensitivity study. This would typically be a discrete distribution.

Model Uncertainty The characterization of model uncertainty is very much dependent on the way in which the uncertainty is manifested. Many of the models used are approximate and have certain biases. The key to dealing with such uncertainties is to understand the nature of the approximations and to try to understand the degree of conservatism or nonconservatism in the use of the models. Doing so is clearly difficult with models of very complex phenomena, as there can be no direct comparison with experiments. Some sources of uncertainty may be explored by varying the parameters in the model. When model complexity makes it not feasible to represent the uncertainty in a closed analytical form, it is acceptable to provide a range of potential results that can be used later to perform sensitivity studies to explore the impact of uncertainty on the results.

As discussed earlier, there is a range of models that could be used. Typically, an analyst will adopt one model for a specific application. However, since all the models presumably have some validity, the differences in their predictions represent a source of uncertainty. The only way to address this uncertainty explicitly is to perform the analysis using more than one model and use the results of the different models to develop a range of results for the analysis. These could be combined to give a probability distribution on the results of the analysis by assigning a probability to each model to represent the level of confidence in the different models. However, as discussed later, the approach in RG 1.174 would be to look at each analysis separately. However it is done, if there are models that could potentially produce significantly different results, it is important that there be confidence in the results from the model of choice.

Completeness Uncertainty Relating to things that are not included in the model, completeness uncertainty cannot be characterized in the same manner as input uncertainties. However, this uncertainty is important and must be recognized when using the results of the risk assessment.

Propagation of Uncertainty Propagation of uncertainty refers to the process of analyzing the impact of the input uncertainties on the results of the model. Typically, in the PRA literature this term has been used in the context of generating a probability distribution on the numerical results of the risk analysis.

Parameter Uncertainty Methods are relatively well established for the propagation of the uncertainty on the basic event probabilities that are characterized by probability distributions, through the quantification process, to generate a characterization of uncertainty on the output of the PRA [63]. Because epistemic uncertainties on parameters are generally characterized as probability distributions, whether the distributions are continuous or discrete, the most common technique is Monte Carlo analysis or variants thereof, such as the Latin Hypercube Sampling [64].

Model Uncertainty To the extent that the uncertainty in the modeling of fire growth, fire damage, and detection and suppression can be expressed as a probability distribution on the probability of a specific fire damage state, it can be treated as a parameter uncertainty as discussed above.

When more than one model is in common usage for a specific issue, such as fire growth, it is possible to represent the uncertainty as a discrete distribution over the results of the models and propagate that discrete distribution through the analysis to produce a potentially multimodal distribution on the results. This is not typically done and, in the interest of identifying what factors are determining the results, such an uncertainty is perhaps addressed better using sensitivity studies as discussed later [65, 66].

Interpretation of the Results of a PRA Interpreting the significance of the results of a PRA in the light of the uncertainties is important if the PRA results are to be applied to making meaningful decisions about changes in design or operating practices or if they are to

be used for economic decisions. Probability distributions on the numerical results, such as the core-damage frequency, can be used to calibrate the confidence level at which a safety goal is being met, for example. However, although it may be important to characterize the overall uncertainty, it is equally important to understand which factors drive the uncertainty. If the results of alternate models are included in the final PRA results, it is essential to be able to distinguish between the results of the alternate models [65, 66].

Several methods are available for identifying the drivers of uncertainty. The two principal tools are importance analysis and sensitivity analysis.

Importance Analysis Several different importance measures are in common usage. These include the Fussell-Vesely, Birnbaum, Risk Achievement Worth, and Risk Reduction Worth [67]. When applied to the results of a risk analysis, they measure the significance of a basic event to the overall result. Once identified as significant, the uncertainty associated with the evaluation of that basic event is also significant to the results.

Sensitivity Analysis Sensitivity analysis is a powerful tool for investigating the impact of uncertainty on results. To be meaningful, however, the sensitivity analyses must be chosen carefully and must represent reasonable alternatives to the model of choice. Because uncertainties can have synergistic effects on the results, it may be necessary to perform sensitivity analyses on more than one of the uncertain issues simultaneously.

Presentation of Results of Uncertainty Analysis The most appropriate way to present the results of an uncertainty analysis is a function of how the results are going to be used. Options include the following and combinations thereof:

- Continuous probability distribution on numerical results. This is feasible only when there is an analytical means of propagating uncertainty.
- Discrete probability distribution representing the impact of different models or assumptions. This is practical only when the analysts are willing to weigh their beliefs in the different models or assumptions that may be used.
- Bounds or ranges of results that represent the results of the extreme assumptions.
- Discrete set of results that represents the results of making different assumptions or using different models, or that represents the impact of varying key parameters in the model that have significant uncertainty.

However the results are presented, the analyst has to understand and be able to communicate what is driving the uncertainty.

Comparison of PRA Results with the Acceptance Criteria

The acceptance guidelines used in RG 1.174 for one of the metrics, core damage frequency (or CDF), is shown in Fig. 76.9. In RG 1.174 the acceptance guidelines are not intended to be interpreted as being overly prescriptive. They are intended to provide an indication, in numerical terms, of what is considered acceptable. This is largely because the state-of-knowledge, or epistemic, uncertainties associated with PRA calculations preclude a definitive decision with respect to which region the application belongs, based purely on the numerical results. In the case of RG 1.174, the term *acceptance guidelines* was used rather than acceptance criteria, primarily to recognize that not all of the analysis uncertainty was captured in the uncertainty distribution.

In the context of RG 1.174, the intent of comparing the PRA results with the acceptance guidelines is to demonstrate with reasonable assurance that the principle that requires the risk change to be small is indeed being met. This decision must be based on a full understanding of the contributors to the PRA results and the impacts of the uncertainties, both those that are explicitly accounted for in the results and those that are not. This is a somewhat subjective process, and the reasoning behind the decisions must be well documented.

As mentioned earlier in this section, when defining a decision criterion, it is crucial to define how the choice of criterion accommodates

uncertainty. When defining the acceptance criteria of RG 1.174, the following alternatives were discussed: (1) the mean value of the distribution representing the epistemic uncertainty should be used for comparison; and (2) some specified percentile of the uncertainty distribution, corresponding to a specified confidence level, should be used. The guidelines were chosen such that the appropriate measure for comparison is the mean value of the corresponding uncertainty distribution. The reason was to some extent historical, since the guidelines were based on prior guidelines that were to be compared to mean values. However, in addition, there is a philosophical problem associated with determining what would be the appropriate confidence level to choose if that route were taken. More details of the reasoning behind the approach can be found in Caruso et al. [68].

Because parameter, model, and completeness uncertainties are represented differently, different approaches were used to take them into account as discussed below.

Parameter Uncertainty Because of the way the acceptance guidelines were developed, the appropriate numerical measures to use in the initial comparison of the PRA results to the acceptance guidelines are mean values. The mean values referred to are the means of the probability distributions that result from the propagation of the uncertainties on the input parameters and those model uncertainties explicitly represented in the model. A formal propagation of the uncertainty is the best way to correctly account for state-of-knowledge uncertainties that arise from the use of the same parameter values for several basic event probability models [69]. Under certain circumstances, however, a formal propagation of uncertainty may not be required if it can be demonstrated that the state-of-knowledge correlation is unimportant. This will involve, for example, a demonstration that the bulk of the contributing scenarios (cutsets or accident sequences) do not involve multiple events that rely on the same parameter for their quantification.

Model Uncertainty Although the analysis of parametric uncertainty is fairly mature and is addressed adequately through the use of mean values, the analysis of the model and completeness uncertainties cannot be handled in such a formal manner. To address model uncertainty it is necessary to demonstrate that the choice of reasonable alternative hypotheses, adjustment factors, or modeling approximations or methods to those adopted in the PRA model would not significantly change the assessment. This demonstration can take the form of well-formulated sensitivity studies or qualitative arguments. In this context, "reasonable" is interpreted as implying some precedent for the alternative, such as use by other analysts, and also that there is a physically reasonable basis for the alternative. It is not the intent that the search for alternatives should be exhaustive and arbitrary. The alternatives that would drive the result toward being unacceptable should be identified and sensitivity studies performed or reasons given as to why they are not appropriate for the particular application or for the particular plant. In general, the results of the sensitivity studies should confirm that the guidelines are still met even under the alternative assumptions (i.e., change generally remains in the appropriate region). Alternatively, this analysis can be used to identify candidates for compensatory actions or increased monitoring.

Completeness Uncertainty Completeness is not in itself an uncertainty but rather a reflection of a limitation in the scope of the model. The result is, however, an uncertainty about where the true risk lies. The problem with completeness uncertainty is that, because it reflects an unanalyzed contribution, it is difficult (if not impossible) to estimate its magnitude. Some contributions are unanalyzed, not because methods are not available, but because they have not been refined to the level of the analysis of what is included in the model. Examples are the analysis of errors of commission, and the low-power and shutdown modes of operation. There are issues, however, for which methods of analysis have not been developed, and they have to be accepted as

potential limitations of the technology. Thus, for example, the impact on actual plant risk from unanalyzed issues, such as the influences of organizational performance, cannot now be explicitly assessed.

The issue of completeness of scope of a PRA can be addressed for those scope items for which methods are in principle available and, therefore, some understanding of the contribution to risk exists in a number of ways. For example, the out-of-scope items can be addressed by supplementing the analysis with additional analysis to enlarge the scope, by providing arguments that, for the application of concern, the out-of-scope contributors are not significant, or by designing the proposed change such that the major sources of uncertainty will not have an impact on the decision-making process. For example, in region III of the acceptance guidelines, where small increases are allowed regardless of the value of the baseline CDF or LERF, the proposed change to the licensing basis could be designed such that the modes of operation or the initiating events that are missing from the analysis would not be affected by the change.

The degree to which supplementary arguments can be used to support the claim that the uncertainties do not impact the decision depends on the proximity to the guidelines. When the contributions from the modeled contributors are close to the guidelines, the argument that the contribution from the missing items is not significant must be convincing and in some cases may require additional PRA analyses. When the margin is significant, a qualitative argument may be sufficient.

Incompleteness that is the result of unknown phenomena can clearly not be addressed in this way. It is to address this source of uncertainty that the principles of safety margins and defense-in-depth play such an important role.

This section has described an example of an approach to addressing uncertainty in a decision-making context. Although the example is specific to regulatory decision making for nuclear power plants, it serves to illustrate the essential elements of the approach that can be generalized to other applications. The example discussed later on the performance-based design process follows much the same approach.

Uncertainties in Fire Modeling and Egress Modeling

The Fire Protection community, especially the fire model developers and researchers, have begun over the past 8–10 years, to look more seriously at uncertainty in fire and egress modeling. In 2005, the International FORUM of fire research directors published a position paper on verification and validation of numerical models [70] and in 2012, the Standard Guide for Evaluating the Predictive Capability of Fire Models, was updated by ASTM E1355 [71].

Fire Dynamics Simulator (FDS)

In an attempt to characterize the ability of FDS to predict the response of thermal detectors, *Hurley and Munguia* place a heptane burner in a room [72]. Temperature measurements from thermocouples is soldered to brass disks to represent thermal detectors with known RTIs. The ceiling height is adjusted across a range from 3.0 to 12.2 m. The heat release rate is estimated to follow a modified t^2 curve, which is adjusted to account for limitations of the heptane flow control in the early stages of the fire. Quantitative uncertainty in temperature measurements is accounted for from three sources. These are the measurement capabilities of the thermocouples, the measurement capabilities of the flow controls, and the repeatability. Other sources, such as exact location of the burner, potential drafts, and the quality of the values used for combustion efficiency and radiative fraction, is not quantified. FDS results showed a trend of over-prediction of temperatures within the plume. However, it is determined that grid-insensitive convergence is not established in this region, so these values are not used in the final analysis. Comparisons are made of

measurements and predicted values at a radial distance of 2.2 m. It is determined that, at worst, FDS predicted temperature rise values within a factor of 1.9 of the measurements. An example is offered that, for simulating a device with a given activation temperature, the temperature rise should be multiplied by 1.9 and 1/1.9 and added to the ambient temperature. The modeler should then also determine the predicted activation time of a device with these two bounding activation temperatures in order to account for the range of model error.

CFAST

In 2002, W. D. Davis published his study, "Comparison of Algorithms to Calculate Plume Centerline Temperature and Ceiling Jet Temperature with Experiments," Journal of Fire Protection Engineering, 12(1), pp. 9–29 which covered some basic calculations for plumes and ceiling jets [73] and in 2007, Peacock and Reneake published, Verification and Validation of Selected Fire Models for Nuclear Power Plant Applications. Volume 5. Consolidated Fire Growth and Smoke Transport Model (CFAST) [74]. This study conducted an evaluation of the sensitivity and predictive capability of the CFAST model for nuclear risk calculations.

Using the methodology previously developed by Lundin, a quantitative analysis of the model error in the two-zone model CFAST can be used to evaluate the model, measure improvements in the model, assess predictive capabilities for uncertainty analysis, and make adjustments of model predictions. Error in model predictions is assumed to contain bias (which varied with the magnitude of the predicted value) and uncertainty (which was independent of the predicted value). Uncertainty is assumed to vary between different scenarios.

Lundin uses previous experimental data for model comparison for several distinct scenario configurations [74]. A scenario configuration, as defined previously, consists of a number of similar scenarios where parameters, such as ceiling height, are adjusted over a limited range. Direct comparisons are made between model predictions of upper layer temperature and experimental data. A linear regression method is used to develop an adjustment formula for predicted temperature $T\_adj = \beta T\_p + U\_adj$. The value of U_adj depends on whether one adjusts the line to either bound of a 95 % prediction interval in order to make more conservative adjustments for a particular application. β and U_adj are shown to differ between scenario configurations, demonstrating that the use of a single adjustment factor for all configurations would not be appropriate. Difficulties with defining the limits of a particular scenario configuration are acknowledged, especially as it is not practical to have a very large number of adjustment formulas for very specific scenario configurations. However, introducing more variability into a scenario configuration adds to uncertainty in model error assessment.

ASET-B

An assessment of the predictive capabilities of the computer fire model ASET-B can be made by comparing data from two full-scale tests. SFPE formed a computer fire model evaluation task group that follows the methodology of ASTM E-1355. This standard gives three methods for analyzing model predictive capabilities: blind calculations, specified calculations, and open calculations. Blind calculations provide the modeler with a basic description of the scenario to be modeled. For specified calculations, the modeler is given a complete description of model inputs. For open calculations, the modeler is given a complete description of the scenario and must choose the model inputs.

This work employed open calculations using previously published research. Model predictions of smoke filling were compared to a test in a $6 \times 6 \times 6$ m enclosure and rectangular barracks building. Assumptions were required in translating the scenarios to model inputs, specifically for - heat-release rates and heat-loss fractions. ASET-B was found to provide "reasonably accurate"

predictions of smoke layer temperatures, though no real quantitative assessment was made [75].

Heat Detector Models

The uncertainty and sensitivity of a classical deterministic heat fire detector activation model, as presented by Schifiliti et al., uses a Monte Carlo approach with LHS to (1) quantify both how uncertainties in inputs propagate through the model—uncertainty analysis—and (2) identify which uncertain inputs have the most significant impact on the result—sensitivity analysis. The model uses a lumped-mass formulation, ignores radiation and convection, and assumes a flat, large ceiling and a symmetrical plume. The study focused on a hypothetical one-story building. Seven input parameters were identified: fire growth rate, convective fraction, radial distance to the detector, height above the fire, detector RTI, detector response temperature, and ambient temperature. Distributions were assigned to each variable. The uncertainty analysis yielded CDFs of activation time for the specific scenario, which could be used to assess confidence intervals for design purposes. The uncertainty analysis focused on CCs, SRCs, PCCs, RCCs, SRRCs, and PRCCs, and their respective statistical significance. Analysis revealed that detector position and fire-growth rate had the most significant impact. Limitations of this approach were acknowledged, such as the fact that model uncertainty was not considered, and that the distributions used as inputs were assigned somewhat arbitrarily [76].

DETACT

Uncertainty in fire detection is evaluated using the deterministic fire detection model, DETACT. The formulation is similar to that evaluated by Kong et al.; however, the conduction losses are considered. A Monte Carlo approach with random sampling is used to adjust the input parameters based on defined distributions. Distributions of activation time are generated with uncertainty considered only in geometry-type inputs, only in fire-type inputs, only in detector-type inputs, and finally with uncertainty considered in all inputs. The distribution of outputs is examined for the particular scenario considered. As in the study of Kong et al., model uncertainty is not addressed. It is suggested that, in order to avoid the limitations of the semi-empirical nature of the model, the range of its assumptions should be applied [77, 78].

Uncertainties in Egress Modeling

Computer egress modeling is becoming widely accepted in building design. However, the inherent difficulties associated with the unpredictable nature of human behavior, as well as a general lack of data needed to calculate evacuation times, means that there is significant uncertainty associated with these models. Uncertain variables include occupant loads, occupant-movement characteristics, and pre-movement times. The work of Lord et al., represents one particular effort to quantify the effect of uncertainty in these models [79]. The goals are to (1) understand the sources of uncertainty and variability in egress models, (2) apply a method of uncertainty analysis to egress models, (3) identify significant variables which may have a "cross-over" effect, and (4) provide guidance for building engineers in the appropriate implementation of egress models. The egress model STEPS was used to simulate egress in a six-story office building in London, Ontario, Canada, for which evacuation data existed. Monte Carlo analysis was used to generate CDFs that represented the effect of adjusting different input variables on evacuation time. Variables such as occupant load, pre-movement time, walking speed, door flow rate, etc. were studied. Occupant loads, pre-movement times, queuing coefficient, and lock-solver depth were found to be significant. Lock-solver depth dictates how circular locks in the simulation are resolved.

Continuing the work presented above, the STEPS egress model is used to simulate egress in a 14-story apartment building in Calgary, for

which evacuation data exists. Monte Carlo analysis is used to generate CDFs that represented the effect of adjusting different input variables on evacuation time. Additionally, correlation coefficients (CC) are evaluated for the variables in question in order to test for a linear relationship. The magnitude, sign, and statistical significance of the coefficients are considered. Initial findings, showing differences in the properties of the CCs for the two buildings, indicate that a single set of uncertain variables may not be important for all building designs [80].

Similar to the study conducted for STEPS, a Monte Carlo analysis is carried out in order to quantify the effect of uncertain parameters for the FDS+EVAC evacuation model. Because FDS+EVAC employs a stochastic evacuation model, multiple simulations with the same inputs will not produce identical results. The effect of this aleatory uncertainty is reduced by running each iteration of the Monte Carlo analysis ten times and taking an average time to represent the particular scenario. Pre-movement time, the percentage of adults, the occupant density, and effective width are all specified by distributions. It should be noted that the standard deviation of the pre-movement time is studied, not the pre-movement time itself, and it is also specified by a distribution. Correlation coefficients are examined to assess the linear influence of the inputs, and rank correlation coefficients are examined to assess the monotonic influence of the inputs. Both coefficients indicate that the standard deviation of pre-movement time has the strongest influence on the output, followed by the effective width. It is suggested that for sufficiently large distributions of these two variables—variations in occupant density and occupant type—have minimal effects and can be ignored. It is also demonstrated that simply using the most likely values for the input parameters and applying a safety factor should be approached with caution. Using a safety factor of 1.5 is found to fail the performance criteria (which is chosen as the time of upper bound of the 95 % confidence interval for the Monte Carlo analysis), while a safety factor of two passes [81].

Uncertainties in FPE Measurements and Test Standards

Individual Measurements (HRR, Temperature, Burn Patterns)

The work of Zhao and Dembsey focuses on measurement uncertainty analysis for calorimetry, specifically using a Cone Calorimeter [82]. A lack of standardized methodology for this type of uncertainty analysis makes comparisons between data from different laboratories difficult. Uncertainties intrinsic to the device components and their calibration are considered. Other sources, such as drift, data reduction, or personal operation, are not included in the context of this study. Type A and B uncertainty are evaluated. Using ISO guides (guide to the expression of uncertainty in measurement) and NIST (guidelines for evaluating and expressing the uncertainty of NIST measurement results), a detailed study of the uncertainties of direct measurements in the Cone, such as mass or O_2 concentration, is carried out. Using the Law of Propagation of Uncertainty, direct measurement uncertainty is then used to evaluate the uncertainty in indirect measurements (such as HRR). Monte Carlo simulation is used to verify the 95 % confidence intervals calculated for the indirectly measured quantities. The intent of the work is to demonstrate a detailed methodology that could be applied to better quantify measurement uncertainty and improve the quality and applicability of reported fire test data.

Given the importance of heat release measurements in fire safety, the quantitative quality of quantitative reporting of the measurements is critical. Measurements using a gas burner in a large open hood, capable of measuring heat release rates up to 3 MW, are evaluated. Uncertainty for the value of input-heat release, based on the gas flow, and measured heat release, are both considered [83]. Similar to the study of Zhao and Dembsey, the uncertainty associated with independent direct measurements is evaluated first. In this study, the drift of the gas analyzer is also included. The uncertainty propagation of the individual variables in the equation for heat release is

then carried out. The standard deviation of repeat measurements is combined with the values from the uncertainty propagation to create a combined uncertainty. This methodology can be applied to a full-scale test facility to obtain a quantitative evaluation of uncertainty in measured values.

In 2003, Pitts, W. M.; Braun, E.; Peacock, R. D.; Mitler, H. E.; Johnsson, E. L.; Reneke, P. A.; Blevins, L. of NIST studied temperature uncertainties for Bare-Bead and Aspirated Thermocouple Measurements in Fire Environments. Temperature measurements were made for natural-gas and heptane fires in a reduced-scale enclosure using a variety of bare-bead and aspirated thermocouples in order to characterize the uncertainties. The focus is the role of radiative heat transfer and the effects of finite time response on the measurements. The findings show that significant errors are possible for all thermocouples considered. Aspirated thermocouples reduce, but do not eliminate, such uncertainties. An alternate approach, use of several bare-bead thermocouples with extrapolation to zero diameter, is not easily implemented in the time-varying temperature environments characteristic of fires [84].

A study carried out at NIST investigated the role of uncertainty in fire measurements when conducting fire pattern repeatability experiments [85]. Gypsum board is exposed to a fire from a natural-gas burner, a gasoline-pan fire, or a polyurethane foam fire, with each fuel type being tested multiple times. Confidence intervals of 95 % for heat release, temperature, and flame height are obtained through statistical analysis of the individual test results for each fuel type. Dimensions of burn patterns based on fuel type are also measured, and uncertainties are obtained through the same type of statistical analysis. The repeatability of the gas-burner tests is highest, due to their well-controlled nature. Conversely, the polyurethane foam has the lowest repeatability due to the inconsistent nature of the flame spread on the solid fuel. Comparisons repeatability of flame heights to burn pattern heights has the highest agreement for the gas-burner fuel.

Uncertainty in Fire Test Standards

In 2012, ASTM published a collection of 11 papers on uncertainty related to fire test standards, J. R. Hall, and A. D. Library led off the discussion with their paper, "Uncertainty in fire standards and what to do about it" [86]. Many of the papers addressed how different parties, such as testing laboratories, enforcement authorities, manufacturers, and practicing engineers, incorporate uncertainty into their use of results from fire safety tests and calculations. It also examines the larger implications of different approaches and provides overviews of some of the newest methods and approaches for handling uncertainty.

A distinction is made between measurement uncertainty and variability in uncontrolled variables for fire tests. The measurement uncertainty, as discussed in ISO 17025 (general requirements for the competence of testing and calibration laboratories), and addressed in the previously mentioned studies of small and large scale calorimetry, is represented as a range for a specific confidence interval and is quantitative in nature. Uncontrolled variability is related to uncertainty parameters, such as the arrangement of test components, laboratory drafts, specimen ignitability, specimen uniformity, and so on. The effects of such variability are not quantifiable in the same manner as measurement uncertainty, and Trevino and Curkeet [87] propose that the overall contribution to test variability from these factors is much more significant than from measurement uncertainty. An example is given in which HRR curves for identical mattresses are compared. The variability is much greater than the measurement uncertainty of the calorimeter, and it is attributed largely to differences in flame spread between the tests. A "precision" analysis, in which the repeatability (within a lab) and reproducibility (among multiple labs) of fire tests, is suggested as one way to quantify test variability. If the reproducibility of a particular test is shown to be good, it is suggested that the repeatability will also be, as it is almost always

preferable. Due to the fact that a full repeatability and reproducibility study for multiple fire tests would be a significant undertaking, a cost/benefit analysis should be carried out first.

The Steiner Tunnel, ASTM E84 offers techniques for understanding, improving, and controlling measurement uncertainty in a fire test [88]. Variation of test parameters is quantified using Statistical Process Control (SPC). Parameters that have variations falling outside of control limits can be identified, and necessary improvements can be made to individual elements of the test. Additionally, a "Poke-yoke," or "Go" and "No Go" technique is used. This involves a system for operator notification if a parameter is out of control limits based on SPC. A repeatability and reproducibility study of the improved tunnel test demonstrates that the approach is successful in controlling variability. The variation between test results is largely due to changes in the test material, and not the specific user or the test method itself. Thus confidence in the test is improved.

A round-robin repeatability and reproducibility study was conducted for cone calorimeter and intermediate-scale calorimeter (ICAL). A set of four laboratories participated in each round-robin (not the same set for cone and ICAL). Sixteen materials are tested with the cone (at 75 kw/m^2), and four materials are tested with ICAL (at 40 and 25 kw/m^2). The cone shows better overall repeatability and reproducibility than ICAL, though there is less difference in reproducibility between the two. The conclusion of this work, however, is that more work needs to be put into this type of analysis. A number of limitations could be improved in future studies, including the fact that the involvement of more laboratories would improve the statistical analysis, as would more materials. Additionally, assurance must be made that all laboratories strictly comply with the test standards, pre-round-robin calibrations are made, and any problems are identified and rectified. More detailed instructions on test configuration and measurement should be provided to the laboratories to ensure consistency. Though it does not provide a full quantitative treatment of uncertainty, it does characterize the repeatability and reproducibility of individual measurements.

Use of Uncertainty to Determine Effectiveness

Uncertainty in Estimating Effectiveness of Sprinklers for Fire Control

The assessment of sprinkler system effectiveness is important, particularly when evaluating performance-based design criteria. A study of data from the New Zealand Fires Service [89] incident reports was conducted in an effort to quantify uncertainty in sprinkler system effectiveness, rather than providing only a single figure. Effectiveness is considered to consist of both reliability (whether the sprinkler operated when a sufficient fire was present) and efficiency (whether the sprinkler suppressed or controlled the fire as expected). The available data is used to inform the creation of probability distributions for the different events in a sprinkler-system effectiveness decision tree. Monte Carlo analysis is then used to create distributions for reliability, efficiency, and effectiveness. A mean effectiveness of 86 % is found, which is lower than previously reported values. Limitations of the analysis are acknowledged, including the uncertainty inherent in the accuracy of incident reports. Additionally, the definition of "effectiveness" is not well established, and assumptions are required when assessing this performance of sprinklers for specific events.

Decisions on Needed Water Demand

A proposed model for estimating the quantity of water required for fire suppression assumes a t-squared fire growth curve $\dot{Q} = \alpha t_{in}^2$, where α is a growth coefficient and t_{in} is the time from fire ignition to the start of fire service intervention.

The mass of water needed is given by $m_c = 3 \times 10^{-4} \alpha t_{in}{}^1 t_s$, where t_s is the suppression time. Data from 100 incidents in Taoyuan County, Taiwan, R.O.C., are used to determine the variables. Growth coefficients are selected based upon the occupancy type for a particular incident. Comparisons between the calculated mass of water needed and the actual water used, which was determined by the number and size of responding vehicles, show that a suppression time of 20 min gives the best agreement. Distributions are used to introduce estimated uncertainty in the department time-to-intervention and the growth coefficient. Monte Carlo analysis reveals a standard deviation of ±30 % for calculations of required water for a particular incident. It is suggested that this fast calculation method can be coupled with GIS data on a particular occupancy to provide an assessment of required resources at the time an incident is reported to the fire service. Limitations of the model originate from the limited amount of reported data available. The 100 incidents used do not describe whether all the water sent to a scene is used or if additional water sources are utilized. The time from fire ignition to the reporting of a fire also must be assumed. The inclusion of additional data would assist in refining choices of the model parameters [90].

Summary

An understanding and characterization of the impact of the uncertainties on the results of fire safety engineering calculations are essential to ensuring that the decisions made using those results are meaningful and defendable. Distributions of outcomes are a much richer description of what is possible than the typical point value answers. Though stakeholders and/or policy decisions must still determine how much risk to accept, with thorough uncertainty analyses, this decision will be informed and free of the uneasiness that typically surrounds acceptance of a deterministic performance calculation. The information provided in this chapter is intended to help the fire protection community understand the nature and sources of uncertainty, aid in the selection of a calculation procedure, apply a methodology for the treatment of uncertainty, and incorporate uncertainty into cost-benefit models and decisions.

Kathy A. Notarianni is on the faculty of the Department of Fire Protection Engineering at Worcester Polytechnic Institute. She is an associate professor of fire protection engineering and an associate professor of both chemical and mechanical engineering. Her research has focused on topics such as smoke detection, water-based suppression, fire fighter safety and deployment of resources for the fire service, application of fire models, and uncertainty analysis.

Gareth W. Parry is a senior advisor on probabilistic risk assessment (PRA) in the Office of Nuclear Reactor Regulation at the United States Nuclear Regulatory Commission.

Decision Analysis

77

H.A. Donegan

Introduction

This chapter is devoted to some of the basic elements of decision analysis, a subject that has its roots firmly established in the area of management science, but now enjoys a much wider application. The present article, which is not intended as an exhaustive discussion paper, aims to introduce basic terminology and to illustrate some of the techniques that can be applied to situations in fire protection engineering, one of the many areas of application. The growth in application can be attributed to the significant developments that have taken place within information technology, particularly with regard to the ready availability of user-friendly decision support software. Practitioners interested in particular aspects of the subject and in software will find appropriate references listed in context. The reader should be aware at the outset that decision analysis is more general than risk analysis, which, in terms of fire protection, has its own extensive and highly specialized literature—see, for example, Castino and Harmathy [1], Gretener [2], Hall [3], Hirschler [4], Watts [5, 6].

The engineering of fire protection necessitates a high degree of decision making at all levels of application, and because of the capricious nature of unwanted fire, it involves a high degree of subjectivity and therefore uncertainty. In practically every aspect of fire protection, the practitioner is faced with choices when presented with options or alternative courses of action, each of which has one or more consequences. If a choice is subjective, then it can be made only when the following pieces of information are known to the decision maker:

1. An understanding of each possible consequence
2. The likelihood of occurrence of each consequence
3. The method for combining values and probabilities of consequences into a meaningful course of action

Sometimes the sheer number of options will limit the time that can be spent on evaluating each single option, as when one is faced with large product lists—for example, smoke alarms or fire-resistant doors. Or the possible consequences of a course of action are difficult to enumerate, as in the case of increasingly complex new technology. Often the value of a consequence can be estimated only on the basis of sample information, for example, studying a selection of literature. In other cases, the value of a consequence may depend on many dimensions, such as choosing where to live—taxes, transport, amenities, employment, and so on. Or there may be several possible consequences distributed over time, and it is difficult to predict which one of them will occur and at what time—typically when the fire brigade is attempting to suppress a raging fire.

In complex problems, decisions often have to be made when there are several sources of difficulty interacting or competing. For example, deciding whether or not to build a nuclear power plant instead of a conventional alternative in the face of increasing energy demands is perhaps typical. In this situation, the decision makers have to deal with short- and long-term multidimensional consequences; they know that despite extremely low outcome probabilities, a small number of uncertain events could lead to a catastrophe. With the benefit of hindsight, it is a chilling reality that Chernobyl is the epitome of the above scenario and therefore a timely reminder to those engaged in subjective decisions that impact on life safety.

Consequences are often a reflection of the mathematical modeling strategy that underpins many decisions and are therefore only as valid as the appropriateness of the chosen model or, inclusively, the reliability of its input data. Moreover, the fact that much of the data are subjective places the opinion experts at a key point in the chain of responsibility for good decision making (see Winkler and Murphy [7]). In what follows, it is assumed that methodologies under the various decision classifications are supported by the best efforts of practitioners and software designers.

Before proceeding to look at decision classifications, some key words that frequently appear in the literature of decision theory are now discussed. For example, in the above preamble, casual reference was made to the terms *subjectivity* and *uncertainty,* yet these are emotive words with a vast and formal literature—see, for example, Bunn [8], French [9, 10], Lindley [11], Raiffa [12], Viek and Wagenaar [13].

The concept of probability in decision theory embraces two distinct schools of probabilists—the frequentists and the subjectivists.

The *frequentists* believe that probability can only have meaning in the context of an infinitely repeatable experiment, in which the probability of an event A, namely $P(A)$, is taken to be its long-run relative frequency of occurrence in repeated trials of the experiment—termed *objective probability*. In the reality of risk assessment, approximations called actuarial estimates are used; the relative frequency of the number of times A has previously occurred in some finite experiment is taken as an indication of likely occurrences in the future. For example, if the statistics [14] of residential fire deaths in the sample period (finite experiment) 1983–1987 show that on average 47.8 % of the deaths are identified as occupants aged 65 years and over, then 0.478 is regarded as the probability that a fatal casualty in a residential fire is a person aged 65 or above. Approximations are common in production scenarios. For example, if A represents the event that a sprinkler head is defective, and during the inspection (finite experiment) of a random batch of 240 sprinkler heads 2 are found to be defective, then the chance of picking, at random, a faulty head from the batch is 2 in 240, yet $P(A)$ is stated in general as being 1/120 until revised in another finite experiment.

The *subjectivists* associate probability not with the system under observation, but with the observer of that system identifying probability as the degree or strength of belief that the system will adopt a certain state—termed *subjective probability*. For example, in the modeling of fire spread, the probability of flashover in the room of origin is a measure of opinion relating to the change of state from preflashover to postflashover. It would be decided by the modeler on the basis of experience regarding uncertainties associated with the fire variables in the room of origin. However, such decisions need considerable care; the article by Bunn [8] addresses some of the fundamental issues regarding the assessment of subjective probabilities. A highly pertinent article by Noonan and Fitzgerald [15] discusses the role of subjective probabilities in fire risk management studies.

Developments in artificial intelligence and in expert systems have shown that probability theory in itself is insufficient to cater to the advancement of theories relating to the management of uncertainty in knowledge-based systems. For example, lexical elasticity, which relates to the fuzziness of words in natural language, provides a clear example. A simple relation between X, Y, and Z expressed as

if X is small and Y is very large,
then Z is not very small

does not lend itself to a simple interpretation within the field of probability theory. This is by reason of the lexical elasticity of the predicates *large* and *small* [16]. Such developments have inspired the formation of a new school of practitioners focused on imprecision rather than uncertainty. The topics are rather specialized and outside the scope of the present article, but the interested reader will find appropriate background reading in Zadeh [17] and in Klir and Folger [18].

The term *uncertainty* is used prolifically in decision theory, and yet textbooks generally sidestep any attempt at a formal definition. This presentation will not dissent from that established pattern, but will nevertheless construct an interpretation from the axioms of probability. (The subject of probability is discussed elsewhere in this handbook). The axioms are restated here for convenience:

- Axiom 1: *Positiveness*—the probability of an event occurring must be nonnegative.
- Axiom 2: *Certainty*—the probability of an event that is certain to occur is 1.
- Axiom 3: *Addition*—if events A and B are mutually exclusive, then the probability

$$P(A \text{ or } B) = P(A) + P(B)$$

Axioms 1 and 2 imply that the probability of an event occurring must be at least 0 and no greater than 1. Hence uncertainty (for the purpose of this discussion) identifies with the probability of an event A such that $0 \leq P(A) < 1$. In a subjective environment, the location of $P(A)$ in the interval [0, 1] lies within a subneighborhood of uncertainty, which is clearly articulated by Bell et al. [19]. They point to the confrontation between abstract theory and realistic behavior, particularly when subjective assessments are required. Real people do not behave like the models say they should. For example,

- Many experts are willing to answer hypothetical questions about uncertain quantities.
- Lay people and indeed experts do not calibrate well. By and large, assessed probability distributions are too tight; people think they know more than they really know and are surprised far too often.
- Some assessment methods lead to less distortion than others.
- It is extremely difficult to assess small probabilities.
- Subjects can learn to calibrate better if they are given systematic feedback.

It is intended that these observations, which are highly pertinent in fire safety, will alert the reader to the realization that decision making is as much an art as it is a science.

Decision Classifications

Broadly speaking, decision classifications can be characterized by the qualitative knowledge spectrum shown in Fig. 77.1. Given that the spectrum ranges from ambiguous data to well-defined data, in

- Decision making under certainty—the data are known deterministically
- Decision making under risk—the data are described statistically
- Decision making under uncertainty—the data cannot be assigned relevant weights

Decision making under any condition involves alternatives whose payoffs (outcomes) depend on the states of nature, which may be random events. Specifically, the *payoff matrix* of a decision problem with m alternatives and n states of nature can be represented as in Fig. 77.2. The element a_i represents the alternative i, and the element s_j represents state of nature j. The payoff or outcome associated with a_i and sj is denoted by $v(a_i, s_j)$.

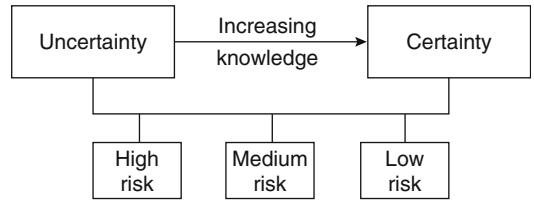

Fig. 77.1 Qualitative knowledge spectrum

Fig. 77.2 Payoff matrix

Alternatives a_i	States of nature s_j: s_1	s_2	s_n
a_1	$v(a_1, s_1)$	$v(a_1, s_2)$	$v(a_1, s_n)$
a_2	$v(a_2, s_1)$	$v(a_2, s_2)$	
a_m	$v(a_m, s_1)$		$v(a_m, s_n)$

Decision Making Under Certainty

Decision making under certainty means the decision maker knows with certainty the consequence of every alternative or decision choice. For example, a fire engineering consultant with resources to take on a single contract has the choice of two 1 year guaranteed contracts *A* and *B*, each with similar conditions and each capable of being carried out within the consultant's office environment. If the value of *A* exceeds that of *B* by $4000, then there is certainty that contract *A* will maximize the consultant's well-being. Of course, there is the classic and perhaps paradoxical phrase that accompanies any certainty, "all other things being equal." The payoff matrix would take the form shown in Fig. 77.3.

Alternatives	State of nature (event)	
	Contract *A*	$v(A) = v(B) + 4000$
	Contract *B*	$v(B)$

Fig. 77.3 Contract payoff matrix

Such matrices are clearly unnecessary for straightforward decision making. However, they offer decision makers a useful structure when the choice of alternative is compounded by more than one state of nature, as in decision making under risk or uncertainty.

Decision Making Under Risk

Decision making under risk assumes that the payoff (gain or cost) associated with each alternative, for a given state of nature, has an associated probability. The payoff is usually based on the expected value criterion, which seeks the maximization of expected (average) gain or the minimization of expected cost among the alternatives. The procedure stems from the concept of expectation, perhaps the most important concept in decision theory, which is discussed in elementary textbooks on probability.

Table 77.1 Probability distribution for a large, medium, or small fire

Probability of fire type	Large fire	Medium fire	Small fire
Pessimistic case	0.6	0.2	0.2
Optimistic case	0.4	0.4	0.2

Basically, *expectation* is a weighted average, and to compute its value, one takes the following steps:

1. List all possible alternatives a_i and states of nature (exclusive events) s_j together with the corresponding probabilities $P(s_j)$.
2. Relative to a given fixed state of nature, note the value of each alternative $v(a_i, s_j)$.
3. Calculate $P(s_j) \times v(a_i, s_j)$ as j ranges across all states for each fixed i.
4. Add and note the products for each alternative i.

Consider the situation where a building's lease has just been extended for a 10 year period, and although the building is fire-safety compliant, the management, in reviewing a number of factors, invite consultants to assess the fire risk with respect to stock. The results of their inquiry are summarized in Table 77.1, which reveals

Fig. 77.4 Payoff matrix showing various outcomes

		States of nature		
		Large fire	Medium fire	Small fire
		P(large fire)	*P(medium fire)*	*P(small fire)*
		0.5	0.3	0.2
Alternatives	UUS	24,000	16,000	8,000
	UWS	18,000	11,000	4,000
	REB	30,000	15,000	5,000

pessimistic and optimistic discrete probability distributions for large, medium, and small fires, conditional on there being a fire within the observed stock. The article by Noonan and Fitzgerald [15] discusses such a risk assessment for a warehouse.

The management, who have some understanding of decision theory, agree in the light of the consultant's report to examine the following alternatives:

- Upgrade using a sprinkler system (UUS).
- Upgrade without sprinklers (UWS).
- Retain the existing building (REB).

Increasing the degree of fire protection requires additional investment, and for simplicity it is assumed that a proportion of upgrade costs (dollars) are included in the potential loss values as estimated by management. Also, management, who are neither pessimistic nor optimistic, settle on the following mean probabilities of fire size risk: $P(\textit{large fire}) = 0.5$, $P(\textit{medium fire}) = 0.3$, and $P(\textit{small fire}) = 0.2$. The payoff matrix takes the form shown in Fig. 77.4.

Hence the expectation for each alternative is given by

$$\text{UUS} : 0.5 \times 24,000 + 0.3 \times 16,000 + 0.2 \times 8,000 = 18,400$$

$$\text{UWS} : 0.5 \times 18,000 + 0.3 \times 11,000 + 0.2 \times 4,000 = 13,100$$

$$\text{REB} : 0.5 \times 30,000 + 0.3 \times 15,000 + 0.2 \times 5,000 = 20,500$$

Based on this information, the management would opt for upgrading without sprinklers. The reader should note that the expected value for an alternative is the average cost to the company that would be expected if the decision were repeated a large number of times—it is not the value that would be returned every time. Clearly, if the decision is made only once, the loss could be any of the three values \$18,000, \$11,000, or \$4000.

Such problems can be represented using a decision tree, as shown in Fig. 77.5. Taha [20] recommends the following nodal notation—a square (□) to represent a decision point and a circle (○) to represent a chance event. Shields and Silcock [21] offer a tree structure in fire safety terminology. See also the *Guide to Fire Safety Concepts Tree,* NFPA 550 [22].

Decision Making Under Uncertainty

Decision making under uncertainty differs from decision making under risk in that in the probability distribution associated with the states of nature, s_j is either unknown or cannot be determined. To overcome this dearth of information, the following models have been developed:

- Laplace paradigm
- Wald (minimax/maximin) paradigm
- Savage paradigm
- Hurwicz paradigm

Each reflects the degree of conservation exhibited by the decision makers in the face of uncertainty.

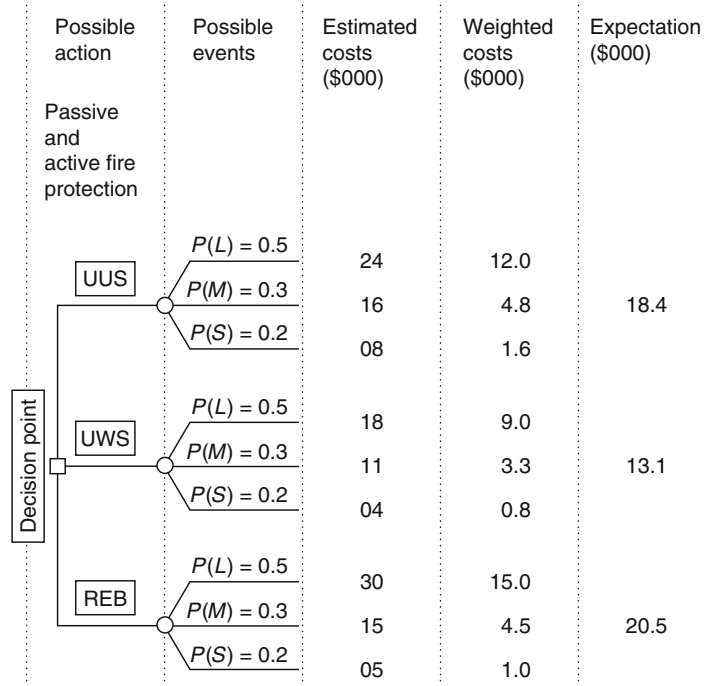

Fig. 77.5 Decision tree to illustrate decision making under risk

The Laplace Paradigm The Laplace paradigm [23] is based on the principle of insufficient reason [10]. This simply means that, because the probability distribution of the states of nature are not known, there is no reason to believe that they are different. Hence, the j alternatives are evaluated using the optimistic belief that $P(s_j) = 1/n$ where n is the number of states of nature. If the payoff $v(a_i, s_j)$ represents cost (as opposed to gain), then the best alternative is the one that yields

$$\min_{a_i}\left[\frac{1}{n}\sum_{j=1}^{n} v(a_i, s_j)\right]$$

with min changing to max in a gain situation.

The Wald (Minimax/Maximin) Paradigm The Wald paradigm [24] stems from the conservative attitude of caution—it is a pessimistic criterion of choice insofar as it assumes that the worst will happen. The paradigm aims to get the best out of the worst possible conditions. Given as before, that $v(a_i, s_j)$ is a cost, then the most appropriate alternative selected conforms to

$$\min_{a_i}\left\{\max_{s_j} v(a_i, s_j)\right\}$$

In a gain situation, the operators min and max are transposed.

The Savage Paradigm Often referred to as the Savage regret criterion, the Savage paradigm [25] aims at moderating the pessimistic outlook of Wald's paradigm. Here the payoff matrix $[v(a_i, s_j)]$ is replaced with a regret matrix $[r(a_i, s_j)]$, where the function r is defined as follows:

$$r(a_i, s_j) = \begin{cases} \max\limits_{a_k}\left[v(a_k, s_j)\right] - v(a_i, s_j) & \text{if } v \text{ is a gain} \\ v(a_i, s_j) - \max\limits_{a_k}\left[v(a_k, s_j)\right] & \text{if } v \text{ is a cost} \end{cases}$$

Regret is the difference between actual outcome and best possible outcome, as in the trivial example of a student who gets 85 % instead of 100 %; the student's regret is 15 %. Likewise, a home owner who pays $300 for house insurance, when a neighbor insures a similar house with a different company for $250, experiences a regret of $50.

The subtlety of moderation in the case of the Savage paradigm over the Wald criterion becomes clear in the following contrived situation. Consider a potential cost matrix where the choice is between a property with smoke alarms adjacent to the fire brigade (a_1) or one with smoke alarms but 50 miles from the fire brigade (a_2), and the states of nature are s_1 (alarm works) and s_2 (alarm fails) (see Fig. 77.6). It is clear from the minimax criterion that alternative a_2 with a definite loss of $20,000 is preferable. However, a_1 looks attractive if s_1 is realized with a chance loss of only $90. Clearly, the a_2 alternative is totally conservative.

Now, using Savage's paradigm, the regret matrix in Fig. 77.7 emerges. The minimax criterion applied to the regret matrix now selects a_1—the less pessimistic option.

The Hurwicz Paradigm The Hurwicz paradigm [26] reflects a range of attitudes from the most optimistic to the most conservative. Letting $v(a_i, s_j)$ represent a cost (or loss), and if t is an index of optimism such that $0 \leq t \leq 1$, then Hurwicz claims that the most appropriate alternative conforms to

$$\min_{a_i} \left\{ t \min_{s_j} v(a_i, s_j) + (1-t) \max_{s_j} v(a_i, s_j) \right\}$$

In a gain situation, the operators min and max are interchanged. If $t = 0$, the criterion reduces to the Wald condition, and when $t = 1$, the result is totally optimistic in selecting the best of the best. The decision maker has control over the choice of t, which, in the absence of strong feelings, is taken as 0.5.

	s_1	s_2	Row max	
a_1	90	21,000	$21,000	
a_2	20,000	20,000	$20,000	→ Minimax

a_2	20,910	0	$20,910	

Fig. 77.7 Regret matrix

Summary Example

The Faculty of Inferno Research Engineers (FIRE) is planning an international conference in Geneva, and FIRE estimates that there are 4 likely bands of attendance: 150, 200, 250, and 300 attendees. The cost of organization will be a minimum if FIRE can select a venue in Geneva that meets the demand exactly. Clearly, deviations above or below the demand levels incur additional costs resulting from unused seating capacity or lost income opportunities when some of the demand is not satisfied. At the proposed date set for the conference, the organizing committee of FIRE can select one of four appropriate venues that match the corresponding attendance bands. Letting a_1, a_2, a_3, and a_4 represent the alternative venues with respective seating capacities (150, 200, 250, and 300), and letting s_1 through s_4 represent the levels of attendance (150, 200, 250, or 300), the payoff matrix in Fig. 77.8 summarizes the relative seating and venue costs to FIRE in hundreds of dollars.

The organizing committee applies the above four methods with the results shown below.

- *Laplace paradigm.* If $E(a_i)$ denotes the expectation associated with a_i, then

$$E(a_1) = 1/4(4 + 9 + 17 + 24) = \$1350$$
$$E(a_2) = 1/4(7 + 6 + 11 + 22) = \$1150 \text{ (Optimum)}$$
$$E(a_3) = 1/4(20 + 17 + 11 + 20) = \$1700$$
$$E(a_4) = 1/4(28 + 22 + 18 + 14) = \$2050$$

		States of nature			
		s_1	s_2	s_3	s_4
Alternatives	a_1	4	9	17	24
	a_2	7	6	11	22
	a_3	20	17	11	20
	a_4	28	22	18	14

Fig. 77.8 Cost payoff matrix

Fig. 77.9 Matrix resulting from Wald's paradigm

	s_1	s_2	s_3	s_4	Row max	
a_1	4	9	17	24	$2400	
a_2	7	6	11	22	$2200	
a_3	20	17	11	20	**$2000**	(Optimum)
a_4	28	22	18	14	$2800	

Fig. 77.10 Regret matrix resulting from the Savage paradigm

	s_1	s_2	s_3	s_4	Row max	
a_1	0	3	6	10	$1000	
a_2	3	0	0	8	**$800**	(Optimum)
a_3	16	11	0	6	$1600	
a_4	24	16	7	0	$2400	

- *Wald paradigm*. See the matrix in Fig. 77.9.
- *Savage paradigm*. The regret matrix (Fig. 77.10) is determined by subtracting 4, 6, 11, and 14 from columns 1 through 4, respectively.
- *Hurwicz paradigm*. The data in Table 77.2 summarizes the picture for arbitrary t.

If you were chairman of FIRE, how would you interpret the above set of results and hence advise your committee on what decision to make?

Table 77.2 Outcome of the Hurwicz paradigm

Alternative	Row min	Row max	t(row min) + $(1-t)$(row max)
a_1	4	24	$24-20t$
a_2	6	22	$22-16t$
a_3	11	20	$20-9t$
a_4	24	28	$28-14t$

Multiobjective Decisions

The above classification examples have one property in common; they all belong to the class of problems where the desired alternative is chosen exclusively on the basis of a single objective—to either minimize cost or maximize gain. When a problem involves two or more objectives, the decision maker must decide on the relative importance of each before analyzing the merits of each alternative. Multiple objectives are often conflicting; for example, a fire authority, in citing a new fire station, might have to balance key objectives such as minimizing cost, minimizing risk, and minimizing travel distance. A problem of this kind never has a correct solution, but the nature of its analysis can offer the stakeholders considerable insight into the quality of any emerging decision.

Terminology

There is a profusion of terminology used in connection with such decision making. For instance, the formal literature uses the terms *multiattribute decision making*, *multiobjective decision making*, and *multicriteria decision making* (the terminology preferred by this author) almost interchangeably, and the inexperienced practitioner could well be forgiven for being confused. However, the following definitions should assist the reader who is trying to come to terms with multicriteria decision theory.

Objectives Objectives are task actions, such as

- To reduce the number of deaths due to unwanted fire

- To improve the level of fire safety in public assembly buildings
- To minimize the number of toxic hazards in the event of a fire
- To maximize the efficiency of fire modeling

French [10] claims that an objective has a dimension together with an indication of the "good" and "bad" ends of the dimension. Thus, to minimize toxic hazards is an objective that indicates that a reduced number of hazards is preferred. This concurs with Keeney and Raiffa [27], who described an objective as an indication of the preferred direction of change. The performance of a stated objective is measured by its attributes.

Attributes Synonymous with criteria, attributes are the dimensions of an objective along which alternatives are represented [10]. For example, if alternatives are to be judged against three attributes, picture these as the three axes X, Y, and Z. Then an alternative $\mathrm{a} = (a_1, a_2, a_3)$ is effectively a point in three-dimensional space such that a_1 is in the X dimension, a_2 is in the Y dimension, and a_3 is in the Z dimension. For example, Donegan et al. [28] list the attributes of domestic fire safety evaluation as Occupants, Doors, Communications, Internal Planning, Travel Distance, and Flues/Ducts. In mathematical terms, these represent a six-dimensional attribute space in which, for example, a domestic norm $\mathrm{n} = (n_1, n_2, n_3, n_4, n_5, n_6)$ can be used as a comparator against which to judge the m alternatives $\mathrm{a}^k = \left(a_1^k, a_2^k, a_3^k, a_4^k, a_5^k, a_6^k\right)$ where $1 \leq k \leq m$. It is not the intention of this article to dwell on mathematical formalism; the interested reader will find a full axiomatic treatment in French [10].

Value and Utility For each alternative facing a decision maker, it is conventional to measure the alternative's attractiveness by means of a numerical score aggregated from the attribute scores. If the decisions involve no element of risk or uncertainty, scores are described as *values* of the course of action; otherwise they are known as *utilities* of the course of action. This article, given its introductory status, will restrict its illustrations to the former. For an introduction to utility theory and an excellent account of its application in decision making, with special reference to insurance risk, see Ramachandran [29].

Weighting Although the decision maker has chosen, or agreed on, a set of attributes, it does not mean that each attribute has the same merit. Each attribute will rate a degree of importance, but the actual cardinal priority of the attributes is seldom obvious. Although a decision maker familiar with the task at hand might intuitively identify the ordinal priority, it is usually necessary to employ a formal process to arrive at credible weights. Such a process may be as informal as the Delphi method [30] or as formal as the eigenvector technique of the analytic hierarchy process [31]. More will be said of these processes later in this chapter. Figure 77.11 summarizes the problem environment.

Dominance An alternative X is dominated if another alternative Y is "better" in at least one attribute and performs equally with respect to the remaining attributes. This definition permits the initial screening of alternatives insofar as all dominated alternatives are discarded.

Satisficing The word *satisficing* is probably a contraction of *sufficient to satisfy* [32], although Watts [33] believes the term was coined by Simon [34] for identifying a solution that is good enough although not necessarily optimal. The method of satisficing, often referred to as the conjunctive method, is purely a screening technique. In order for an alternative to be acceptable, it must exceed stated performance thresholds for all attributes. This compares with the norm strategy used by Shields et al. [35] in their fire safety evaluation of public assembly buildings.

Disjunctive The term *disjunctive* also applies to screening. Disjunctiveness is the logical complement of satisficing in that an acceptable alternative must exceed a given performance threshold for at least one attribute.

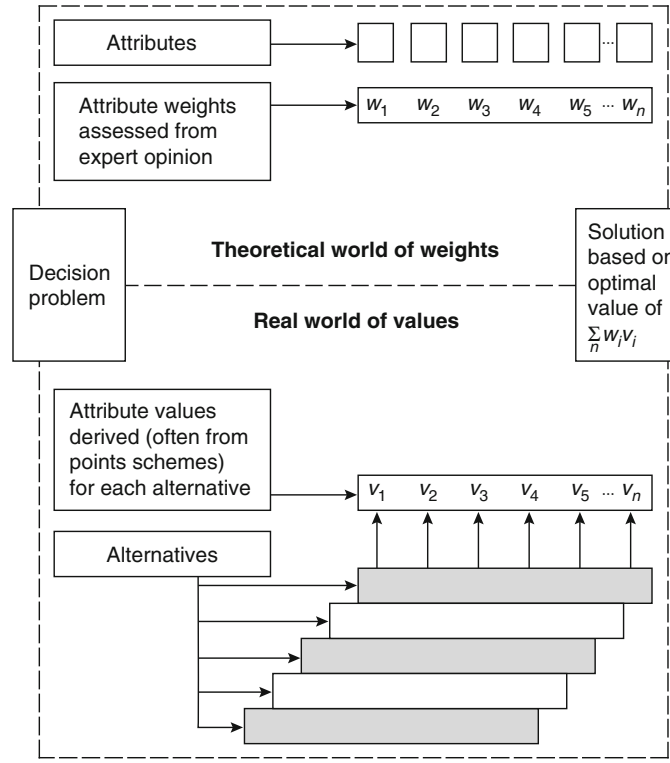

Fig. 77.11 Attributes, values, and weights

Additive Weighting The additive weighting method will be demonstrated later in this chapter. Basically, the score attached to an alternative is equal to the weighted sum of its attribute preference valuations (frequently, the generic term *utilities* is used, albeit in the absence of probability distributions). The weights are subjective percentages of importance given to each attribute label. The resulting weighted sums for each alternative can be used to rank, screen, or choose an alternative. It has been shown that, provided trade-offs among the attributes in any subset of the attributes do not depend on the levels of the remaining attributes, the additive weighting model can be applied without reservation. The trade-off proviso is described by Keeney and Raiffa [27] as preferential independence, which is neatly formalized in French [10].

Simple Multicriteria Illustration

Consider the situation where a new fire station is to be located in a large conurbation offering five potential sites—A, B, C, D, E. Deciding on the most appropriate site is a nontrivial matter, and as with any building project, there are costs and benefits to be considered. This illustration will focus only on the benefits of siting, with considerable simplification to ensure transparency of the methodology. The technique is based on the Simple Multi-Attribute Rating Technique (SMART) of Edwards [36], and the stages in the process are outlined as follows:

Nominate the Decision Maker(s) (DM) In this case, an architect is charged with this responsibility. Group decision making is possible (see Goodwin and Wright [37]).

Recognize the Alternatives The alternatives correspond to the siting locations A, B, C, D, E.

Identify the Attributes The attributes are usually finalized with the assistance of a value tree, such as Fig. 77.12. Here the architect identifies two main predesign attributes, called Site and Situation, and also specifies their

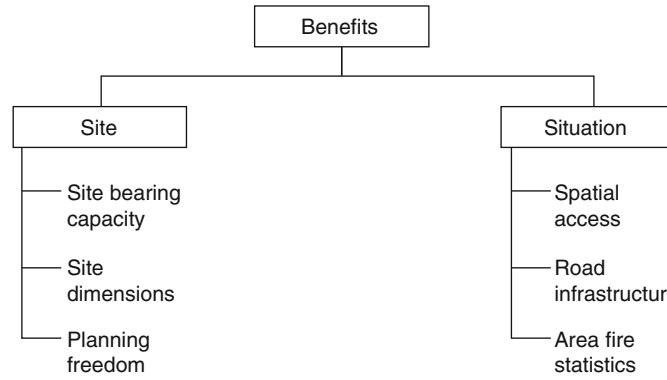

Fig. 77.12 Value tree for fire station location problem

Table 77.3 Architect's attribute-scale values

	A	B	C	D	E
Spatial access	70	75	65	45	55
Road infrastructure	95	15	75	65	35
Area statistics	25	95	05	25	55
Site dimensions	45	25	05	50	95
Bearing capacity	60	05	05	25	85
Planning freedom	75	25	95	85	65

subattributes, that is, criteria that can be readily assessed or valued with respect to each site—Spatial Access, Road Infrastructure, Area Fire Statistics, Site Dimensions, Site Bearing Capacity, and Planning Freedom.

Assess Each Alternative Using the six attribute labels, the architect assesses each site (alternative) and assigns to it a corresponding attribute value, v_i $(1 \leq i \leq 6)$. The valuation of site attributes can be carried out using direct measurement (if appropriate), a logical points scheme, or, as the architect chose to do in this case, a simple linear rating scale from 0, meaning horrible, to 100, meaning best possible. Attribute valuation using the linear rating scale approach is succinctly discussed in Edwards and Newman [38]. An interesting and instructive observation made by these authors is that a curved (nonlinear) value function almost never makes any difference to the decision. The architect's survey reveals the matrix of values shown in Fig. 77.13.

Determine a Weighting Factor $w_i(1 \leq i \leq 6)$ for Each Attribute The weighting factor could reflect the decision maker's point of view, or a consensus point of view derived from experts. In any event, there are a number of specialized techniques for obtaining such weights, and these will be discussed later in this article. Suffice for the present example that the architect has access to weights. Thus, Spatial Access (26 %), Road Infrastructure (34 %), Area Statistics (8 %), Site Dimensions (10 %), Bearing Capacity (19 %), Planning Freedom (3 %). Note that the weights are in percentages, which must sum to 100 %, or if stated in decimal format, they should sum to 1.

Take a Weighted Average of the Values Assigned to Each Site (Alternative) See Table 77.4. The weighted average will give the architect a measure of how well a particular site performs over all the attributes. The weighted average (aggregate benefit) is obtained from the sum $\sum_{i=1}^{6} w_i v_i$.

Table 77.4 Values and weights for each site

		Site				
Attribute	Weight	A	B	C	D	E
Road infrastructure	0.34	95	15	75	65	35
Spatial access	0.26	70	75	65	45	55
Bearing capacity	0.19	60	5	5	25	85
Site dimensions	0.10	45	25	5	50	95
Area statistics	0.08	25	95	5	25	55
Planning freedom	0.03	70	25	95	85	65
Aggregate benefits		70.50	36.4	47.10	48.10	58.20

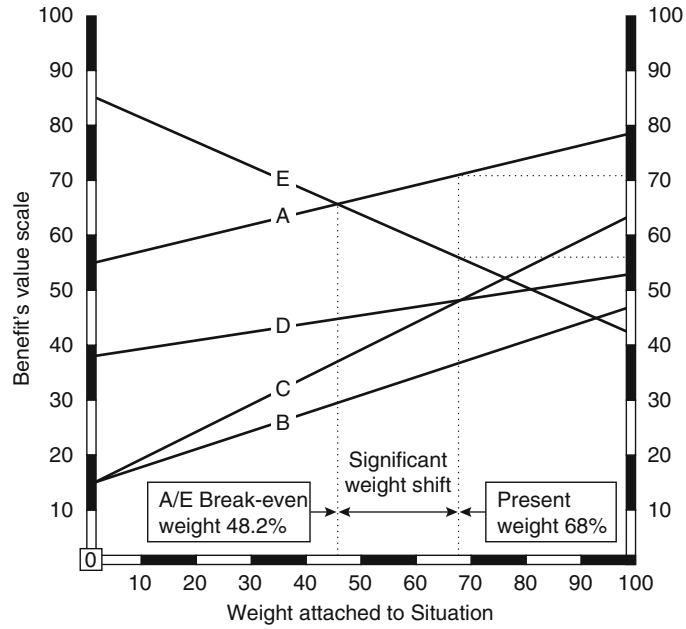

Fig. 77.13 Sensitivity analysis for weight attached to situation

Make a Provisional Decision The apparent answer is site A, but the architect must be reassured, and therefore must check the robustness of the results as follows.

Carry Out a Sensitivity Analysis to Test the Robustness of the Decision The sensitivity analysis is an important aspect of the analysis that is often overlooked in practice, yet it is perhaps the most revealing part of the process and can contribute significantly to the decision maker's understanding of the problem. It is imperative that the procedure not be haphazard. The following strategy is recommended in Goodwin and Wright [37].

The architect, upon reflecting on the above results, notices that the Situation attribute accounts for 34 % + 26 % + 8 % = 68 % of the benefit's weighting, whereas Site features account for the remaining 32 %. Accordingly, before giving a formal decision, the architect proceeds to investigate the consequences of varying the weight attached to Situation. Figure 77.13 summarizes how the value of benefits for the different sites varies with changes in the Situation weights. The graphical technique is based on the following proposition: If Situation, for example, had a weight of 0, this would imply that the three corresponding attributes (Spatial Access, Road Infrastructure, Area Statistics) would each

Table 77.5 Values and weights when situation is zero weighted

		Site				
Attribute	Weight	A	B	C	D	E
Road infrastructure	0.00	95	15	75	65	35
Spatial access	0.00	70	75	65	45	55
Bearing capacity	0.60	60	5	5	25	85
Site dimensions	0.31	45	25	5	50	95
Area statistics	0.00	25	95	5	25	55
Planning freedom	0.09	70	25	95	85	65
Aggregate benefits		56.25	13.00	13.10	38.20	86.30

have zero weights. Correspondingly, the weights of the six lowest attributes would be Spatial Access (0), Road Infrastructure (0), Area Statistics (0), Site Dimensions (10), Bearing Capacity (19), and Planning Freedom (3). When normalized and rounded, these amount to 0, 0, 0, 60, 31, and 9, respectively, as shown in Table 77.5. It is not difficult to draw the corresponding graphs for each site, as shown in Fig. 77.13.

It is evident from the graphs that a zero weighting on Situation would immediately elevate site E to priority status. This status would maintain so long as the weight attached to Situation is less than 48.2 %. However, this is clearly significantly lower than the professionally judged figure of 68 %. The tangibility of the attributes in this example provides little scope for opinion variance, particularly among experts, and therefore it is unlikely that the opinion swing required to put site E in the frontier of consideration is likely to happen. The architect would be justified in the recommendation of site A.

A similar approach could be taken with the lower-level weights. For example, the architect may be instructed to explore the effect of varying the weights attached to Road Infrastructure and Spatial Access while keeping the weight attached to Area Statistics constant. Such in-depth analyses are clearly worthwhile when large amounts of resources are being expended. The reader is reminded that this example dealt only with the multicriteria related to benefits; it did not address the issue of costs and the relationship between costs and benefits. A useful discussion on trade-off between costs and benefits, pitched at the level of this example, can be gleaned from Goodwin and Wright [37].

Fire Safety Attribute Weighting

Rational solutions for many of today's decision-making problems in fire safety evaluation are difficult to formulate. This is often due not only to the complexity of the problems themselves, but also to the vagueness (also referred to as "fuzziness") of certain concepts. Despite the increased accessibility of modern computing technology, the complexity factor can be handled only by the introduction of a multiattribute structure into the elements of a problem. Consistent judgments of weight and value must be made on individual fire safety attributes to enable an overall assessment, and it is important to distinguish the tasks involved (see Fig. 77.11). Finding attribute weights is a theoretical exercise that, for many evaluation problems, reduces to finding a cardinal ranking of criteria (see Watts [6]). On the other hand, finding the corresponding values for each alternative is a real-world exercise, which can involve complex points schemes and specialized economic functional analysis. The buoyant literature devoted to both tasks is conveniently reviewed by Watts [39]. Definitive articles are presented by Nelson and Schibe [40], Marchant [41, 42], Stollard [43], Shields et al. [44], and Dodd and Donegan [45, 46].

The generally accepted attribute levels—objectives, tactics, and components—are shown in Fig. 77.14, with nomenclature attributed to Marchant [41]. The levels conform to a

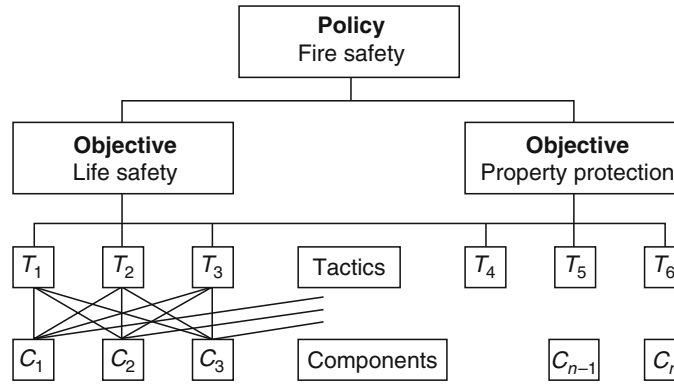

Fig. 77.14 Typical fire safety evaluation hierarchy

hierarchical structure with decreasing generality from the apex.

The Hierarchy Philosophy

The example in the preceding section, "Simple Multicriteria Illustration," did not discuss strategies for obtaining the weights of criteria or attributes. These strategies have a vast and specialized literature within the realm of decision theory, but the accepted nature of attribute decomposition within fire safety evaluation has enabled the following distillation of methods.

These all hinge on the structure of a fire safety evaluation hierarchy, shown in Fig. 77.14. Typically, if the key objective or policy is "fire safety," the next level of the hierarchy lists the secondary, or supporting, objectives—"to save lives" and "to protect property." Sometimes a third objective, "to prevent conflagration," is included, but this will be dictated by the environment of the problem. These objectives are very general, and their balance of importance can be crucial to the ranking outcome of a set of weights (see Dodd and Donegan [45]). The next reduced level of generality comprises the tactics that would be employed by a safety analyst in support of the objectives. For example, "to improve egress capability" or "to facilitate rescue" would be recognized tactics in support of "life safety." At the components level, usually the lowest level, the criteria are chosen to identify with the tactics, but at a much lower level of generality. Each component is seen as a pragmatic dimension to which an engineer can attach a value when surveying an alternative. Most components have long lists of subcomponents, which are useful when seeking an attribute value. The value emerges as a synthesis of scores or points attached in some logical manner to each subcomponent. A typical component could be "doors" and these would be valued on the basis of subcomponents such as "dimensions," "fire resistance," "glazing," or "intumescent stripping."

Effectiveness Matrices

Effectiveness matrices are opinion matrices. (The term *effectiveness matrix* is taken from Lai and Hopkins [47].) Already, it has been stated that attributes are dimensions along which alternatives can be represented. However, it is possible, as follows, to extrapolate this idea to cater for the cardinal ranking of fire safety components relative to the stated policy. Assume that there are m components, n tactics, and k objectives. A decision maker (DM) can represent each component as a vector of tactics, and, a fortiori, the set of components as an effectiveness matrix $[c_{ij}]_{m \times n}$ in which the rows represent components and the columns represent tactics. The element c_{ij} is the numerical equivalent of the DM's opinion as to the importance of the ith component relative to the jth tactic. Similarly, each tactic can be represented as a vector of

objectives, the set of tactics being represented by the effectiveness matrix $[t_{ij}]_{n \times k}$, where t_{ij} represents the importance of the *i*th tactic relative to the *j*th objective. Finally, DM declares the importance of each objective relative to the stated policy in the effectiveness matrix $[o_{ij}]_{k \times 1}$ (vector, since there is only a single policy). The product of the three effectiveness matrices,

$$\left[c_{ij}\right]_{m \times n} \times \left[t_{ij}\right]_{n \times k} \times \left[o_{ij}\right]_{k \times 1}$$

yields the components-to-policy vector, which, when linearly normalized gives the required attribute weightings.

The preceding numerical routine is the same for all weighting methods. Any differences in the routine relate to the determination of the effectiveness matrices. These are discussed in the next section using notation that has previously appeared in fire research literature.

Weighting Methods Used in Fire Safety Evaluation

The hierarchical model is amenable to either cross-impact analysis or analysis involving pairwise comparisons. These two analysis methods will be discussed in some depth. In either case, the aim is the attachment of subjective weights to all of the objectives, tactics, and components, so that in vector form, components are prioritized with respect to each tactic, tactics are prioritized with respect to each objective, and finally, objectives are prioritized with respect to policy. Ultimately, the decision weight vectors at each level are grouped in matrix format (effectiveness matrices) such that, if they are identified as

C/T—the components-to-tactics matrix
T/O—the tactics-to-objectives matrix
O/P—the objectives-to-policy matrix

then the matrix product **C/T** × **T/O** × **O/P** yields a components-to-policy vector that, when normalized, gives the desired prioritization weights.

Edinburgh Cross-Impact Analysis

The unformalized approach used in the Edinburgh model, attributed in the main to Marchant [41], is perhaps the most basic form of cross-impact analysis. The decision maker uses a pseudo Likert scale having values from 0 (least important) to 5 (most important). A Likert scale (named after its inventor) is used to measure a respondent's level of agreement on some issue. The values may be considered to be ordinal, ranging from least agreement to most agreement [48]. The decision maker uses the Likert scale to assess the importance of each element on a given hierarchical level relative to each element of the next-highest level, and produces a corresponding effectiveness matrix. When more than one decision maker is involved (as is usually the case), a consensus matrix that summarizes all the decisions can be calculated. The dimensions of all the resulting matrices for the complete hierarchy permit their consecutive multiplication, as shown in the previous section. It is noteworthy that Edwards et al. [49] have shown that judgments of magnitude, although amenable to semantic scaling (classical Likert), "are best when made numerically." This characterizes the pseudo Likert scale (see the discussion in the subsection titled "Interval Scale" later in this chapter).

The simplicity of the cross-impact approach has an obvious appeal because of its acquiescence with intuition. The input data are essentially bias-free, absolute values chosen from a Likert-type scale; there is no limit to the number of elements at a single level; and reasonable precision can be used in determining scores. The lack of uniformity among experts in their perceptions of component independence is accommodated by an *interaction percentage contribution matrix (IPCM)*. This is a component-to-component square matrix showing the degree to which the contribution of a component to fire safety is enhanced by the interaction of other components. The reader will find an example in Stollard [43].

Hierarchical Cross-Impact Analysis (HCIA) Methodology

Hierarchical cross-impact analysis (HCIA) is a multiattribute weighting strategy developed at the University of Ulster using a similar philosophy to the Edinburgh approach. The characterization of HCIA, fully developed by Donegan et al. [28], addresses the cross-impact approach at two levels—the fundamental level and the pragmatic level. In the *fundamental level*, a pseudo axiomatic approach is taken to

- Define a hierarchy in relation to fire safety
- Explain the meaning of interactive importance
- Propose the notion of a partial impact
- Define a total impact
- Introduce sequential perturbations

In the *pragmatic level,* a modeling approach is taken to

- Maintain the assessment interval through each stage of the quantification
- Stretch the component ranking intervals to enhance the important components and decrease the psychological significance of the less-important components
- Perturb consensus weightings with interaction noise

HCIA methodology formalizes many aspects of the Edinburgh approach. It uses a similar hierarchical cross-impact analysis over the different levels in the system, but allows for interactions between issues at the same level by the use of perturber matrices. Again, it can be used only for hierarchical networks.

Using the attribute terminology outlined above, the partial impact of tactic T_j on component C_i relative to the rth objective O_r is written and defined as

$$\partial I\left(C_i/T_j\right)_{O_r} = \left(C_i/Tj\right)\left(T_j/O_r\right)$$

The total impact of the collection of tactics on C_i relative to O_r is then defined as

$$\sum_{j=1}^{n} \partial I\left(C_i/T_j\right)_{O_r} = \sum_{j=1}^{n} t_{ij}\sigma_{jr}$$

which is clearly a matrix product. The elimination of the tactics collection of attributes is completed by defining the interaction

$$C_i/O_r = \sqrt{\frac{1}{n}\sum_{j=1}^{n} t_{ij}\sigma_{jr}}$$

thus giving a components-to-objectives interaction matrix. Similarly, the objectives collection of attributes is eliminated leaving a components-to-policy vector.

The pairwise comparison perturbation matrices, utilized at all the levels in the hierarchy to eliminate the problems of interdependence of issues, are symmetric and generally sparse. These adjust for "noise" in the system resulting from vagueness in the definitions of the attributes at each level.

While the forced stretching of the final vector as described in Donegan et al. [28] was purely subjective and appeared to have some significance at that time, it was recognized that such a strategy was contextually motivated and, unless unanimously adopted by the fire research community, could result in serious obfuscation. Research reported in Dodd and Donegan [45] points to indigenous stretching as a naturally occurring feature of some scales and therefore a factor in scale choice. Although research by Saaty and Vargas [50] illustrates how particular measurement techniques are more appropriate in certain situations, there is the concomitant psychological impact on scoring that results from the manner in which a question is posed—see, for example, the paper by Salo and Hämäläinen [51]. Insufficient contextual research to date leaves this psychological issue unresolved.

In spite of its formality, HCIA, just like its parent the Edinburgh model, suffers from one serious drawback—the absence of a consistency check. Even in the short time taken to score a set of issues, mood changes, tiredness, or lack of concentration can influence judgment. Short of an alternative to cross-impact analysis, no reliable quality measure has yet been devised to allay this shortcoming. It was this concern that

prompted Shields and Silcock [52] to consider using the analytic hierarchy process due to Saaty [31].

Analytic Hierarchy Process (AHP)

The analytic hierarchy process (AHP) is a procedure that has been widely recognized and used as a method of prioritizing the elemental issues in complex problems in a variety of applications (see, for example, Rahman and Frair [53], Liu and Xu [54], and Vachnadze and Markozashvili [55]). Unlike traditional multiattribute techniques, AHP permits the integration of alternatives into the hierarchy, a merging of the real and theoretical worlds depicted in Fig. 77.11, though this is not an essential requirement of the process. AHP can also be used as a means of weighting attributes, if desired; it is this latter option that is of concern here. The procedure entails the comparison of all the pairs of individual attributes at each level relative to each attribute in the superior level. The intrinsic complexity of the process prohibits a simple description.

The technique is based on the fact that for a square matrix, **C,** of nonnegative real numbers representing, for example, pairwise comparisons of the importance of component attributes of the hierarchy with respect to one element of the next-higher tactics level, there is a dominant eigenvalue, λ, and a corresponding right eigenvector, **x,** emerging from the characteristic equation $\mathbf{Cx} = \lambda\mathbf{x}$. Given that $\mathbf{C} = (c_{ij})$, where $c_{ij} > 0$ and $i, j = 1, 2, 3, \ldots, m$; and given that $c_{ij} = 1/c_{ij}$ and the consistency condition $c_{ik} = c_{ij} \times c_{jk}$: $i, j = 1, 2, 3, \ldots, m$ holds; then it is easily shown that $\lambda = m$ and, by virtue of the fact that **C** is of unit rank, the remaining m—1 eigenvalues are each zero. For such a matrix, any column is essentially the dominant right eigenvector of priorities (weights). In reality, it is unreasonable to expect decision makers to be perfectly consistent, although a fair degree of consistency is expected. Variations from perfect consistency in **C** perturb the eigenvalues such that l is greater than m [31], the proximity of the maximum eigenvalue to the order of **C** being an indication of the consistency.

The corresponding eigenvector is normalized and the procedure repeated for each tactic in the tactics collection. The set of dominant eigenvectors is considered as an effectiveness matrix of priorities (**C/T**) between components and tactics. Similarly, priority effectiveness matrices are established for tactics to objectives (**T/O**) and for objectives to policy (**O/P**). A combined matrix multiplication (**C/T**)(**T/O**)(**O/P**) yields a component-to-policy priority (weighting) vector. In the calculation of such priorities, the matrix entries are selected from a statistically optimized set of Saaty's weightings:

$$S = \left\{\frac{1}{9}, \frac{1}{8}, \frac{1}{7}, \frac{1}{6}, \frac{1}{5}, \frac{1}{4}, \frac{1}{3}, \frac{1}{2}, 1, 2, 3, 4, 5, 6, 7, 8, 9\right\}$$

AHP Example Consider, for example, the situation where five components, C_1–C_5, must be prioritized with respect to, say, tactic T_3. The decision maker indicates the relative importance of C_1 and C_2, C_1 and C_3, C_1 and C_4, and so on, on a scale of 1–9. A score of 1 on this scale implies that the two components being compared are "of equal importance," whereas a score of 9 signifies that one of the components is "of absolute importance" relative to the other. The intermediate scores indicate varying degrees of importance between the two extremes. Obviously, the importance of any component relative to itself is unity, and the law of reciprocity holds; that is, if C_1 rates a score of 3 against C_2, then C_2 rates a score of 1/3 against C_1, and so on. Thus, these pairwise criteria comparisons by the decision maker can be incorporated into a "positive reciprocal" (terminology used by Saaty [31]) decision matrix, as shown in Fig. 77.15.

Such a matrix is a typical response from a decision maker; if it were perfectly consistent, then the eigenspectrum would be {5,0,0,0}. However, a simple calculation shows the spectrum to have a right dominant eigenvalue, λ, of 6.7 and a corresponding normalized dominant right eigenvector of [0.25, 0.14, 0.19, 0.19,

	C_1	C_2	C_3	C_4	C_5
C_1	1	3	2	2	1
C_2	$\frac{1}{3}$	1	$\frac{1}{4}$	$\frac{1}{4}$	2
C_3	$\frac{1}{2}$	4	1	$\frac{1}{2}$	3
C_4	$\frac{1}{2}$	4	2	1	$\frac{1}{5}$
C_5	1	$\frac{1}{2}$	$\frac{1}{3}$	5	1

Fig. 77.15 Positive reciprocal decision matrix

0.24] in this case. Saaty [31] defines a consistency index,

$$CI = \frac{\lambda - k}{k - 1}$$

where k is the order of the matrix, and a corresponding consistency ratio

$$CR = \frac{CI}{\text{Random consistency number}}$$

Saaty [31] provides a list of random consistency numbers, which are reviewed and updated by Donegan and Dodd [56].

The consistency check is designed to provoke the decision maker into reconsidering the entries in the decision matrix should the consistency ratio be unacceptable—for example, greater than 10 %.

Difficulties with AHP The main user criticism that can be labeled against the procedure is the number of questions that must be posed to busy experts in the exhaustive completion of a questionnaire structured around a given hierarchy. This is particularly frustrating to a research manager who may experience attrition of experts on having to elicit expert opinions on a number of rounds in pursuit of consensus. The availability of convenient AHP analysis software such as Expert Choice (by Decision Support Software Inc., in Pittsburgh) does not reduce this particular inconvenience at present. Perhaps, with increasing World Wide Web facilities and new methods in survey computing, the problem will not be so manifest. Implicit in this main criticism is the problem associated with obtaining group consensus in AHP. The question of whether to obtain consensus among experts before inputting the data into AHP, or whether to seek vector consensus when each expert's weighting vector has been evaluated, is discussed with an illustration of both methods in Tung [57].

Criticisms of a theoretical nature continue to be debated in the technical literature stemming from the paper by Dyre [58], but these are really of academic interest only and should not inhibit the potential user. Perhaps the most abused criticism is that of *rank reversal,* which, among other things, refers to the possibility that ordinal changes can take place in a list of remaining attributes when one is removed from the analysis. The debate is far from being settled, but as AHP was developed by Saaty, it is not unreasonable to quote his view on the concept of rank reversal:

> An important question in decision making is whether adding new alternatives to a decision structure should or should not affect the rank of the old ones. It was once thought that irrelevant alternatives should not affect their rank. But experiments reported in the literature have shown that rank reversal can occur for many different reasons. The decision to preserve rank depends on whether the number of alternatives added, and how good they are, influences preference among the old ones. The AHP has a procedure to preserve rank, as in buying a best computer even if there are many like it, and another to allow rank to change, as in buying a beautiful tie if there are many like it. [59]

The different opinions and complex arguments are beyond the scope of this article, but users of proprietary AHP software will have a mode selection option that will facilitate either rank reversal possibilities or absolute rank preservation.

Measurement

Measurement is defined as the assignation of a number to the entity under consideration in accordance with a rule; this number then reflects the measured property of the entity [60]. In mathematical terminology, the measurement is the image under a *monotonic,* that is, order-preserving, mapping of the dimensional property into a real line.

Considerations

Measurement of the physical entities encountered in experimental work presents a large number of fundamental problems that must be recognized by researchers. For example, the precision of the result cannot exceed the precision of any of the data used in its calculation. Thus, a result to ten significant digits is pointless when even one item of the contributory data is approximated to two significant figures. This is why 10.000 is not the same as 10; the former indicates that the measuring equipment allowed for measurements of three decimal places, and the "correct" result is therefore between 9.9995 and 10.0005, whereas the latter shows much less precision—between 9.5 and 10.5.

Further allowance must be made for experimental error. Many external factors (e.g., heavy road traffic outside the laboratory) can introduce random elements into the measuring process. These factors, however small, must be taken into account in the result. Systematic errors, caused by a bias in the measurement process, assume an even greater significance with the introduction of opinions, which can compromise the work and should be eliminated. The opinion problem is present in most questionnaire design. These opinions, or psychological components, where linearity is less measurable, can jeopardize experimental results (see detailed discussion in Viek and Wagenaar [13]).

Scaling

The four types of scale most relevant to fire protection engineering are (1) nominal, (2) ordinal, (3) interval, and (4) ratio. Each scale, in order, represents progressively stronger properties [61].

Nominal Scale The values on a *nominal scale* classify or categorize the objects represented; in other words, no information on size is implied. For example, the number identifying food items on a menu or the room number in an office block might be regarded as nominal scales. The property common to such items is the *category property*. Many coding systems are nominal scales. For example, the computer system of a car dealer might store car type as a single digit: 01 for Ford, 02 for General Motors, 03 for Lincoln, 04 for Buick, and so on. Such a number does not reflect the size or power of the car; it merely indicates the manufacturer. Similarly, fire extinguishers might be classified by type: 1 for water, 2 for CO_2, 3 for halon, and so on. However, the numbers 1–3 have no implications with regard to quality.

Ordinal Scale The *ordinal scale* not only characterizes the entities represented, but also ranks or orders them. However, proportion is not necessarily maintained. This type of scale is exemplified by examination grades: in a descending scale, a grade 2 is better than a grade 3, but one cannot say by how much. Glenburg [61] offers the stripes on military personnel as an ordinal scale: a sergeant (three stripes) is "superior" to a corporal (two stripes), but it is nonsense to argue that the sergeant is one and a half times as authoritative. Ordinal scale examples abound in organizations; one example is the ranking of daily tasks in order of priority.

Interval Scale More mathematically tractable and, hence, of greater importance in quantitative assessments, the interval scale is a continuous scale between two points, for example, from 0 to 10, or 1–5. Relative difference is maintained; that is, equal intervals of the scale have the same meaning. For example, the effective difference between 1 and 2 is exactly the same as the effective difference between 4 and 5. An example of an interval scale is a ruler or similarly graduated device. Celsius and Fahrenheit temperature scales are interval, and the *equal intervals property,* or *relative difference property,* is essential when one scale is converted to the other. Arithmetic-based operations involving addition, subtraction, and multiplication by a scalar (a number with no units) can be used on numbers from an interval scale.

Not infrequently, the integer range from 0 to 5 has been used to assign relative values of importance to the attributes of a fire safety hierarchy. The adoption of this numerical range over a spectrum of attributes, described in the literature (e.g., Dunn Rankin [62] and Torgenson [63]) as a Likert-type scale, entails a consideration of its validity in terms of the measurement it achieves. Strictly speaking, the scale is ordinal since it cannot be taken for granted that the distances between attributes are equal. Kumar [64] states that a Likert scale is based on the assumption that each item (attribute) has a priori equal attitudinal value (importance or weight) in terms of reflecting an attitude (from 0 to 5) toward the issue in question, which in the context of fire safety attribute weighting is not the case. Nevertheless, the work of Schiebe et al. [30] has demonstrated that the error in assuming the equal interval property is not significant. Hence, the results obtained from such measurements can be used in combinatorial calculations.

Ratio Scale The *ratio scale* is an interval scale with the *absolute zero property;* in other words, one end is fixed so that the values on it are absolute rather than relative. For example, the Kelvin (K) scale relates temperature to absolute zero temperature, at which all motion ceases. This scale is fundamental to the operation of AHP (see the previous section titled "Analytic Hierarchy Process (AHP)"), and due consideration must be given to the entity of measurement. For example, a body having a temperature of 40 °C indicates twice the temperature of another body at 20 °C, but not twice the heat content, which must be referred to the absolute zero of temperature, −273 °C.

Panels of Experts

The development of expert systems and case-based reasoning tools implies an underlying assumption as to the meaning of expertness. Consequently the assessment of expert opinion using, for example, a Delphi process, may lead to conclusions that, without some formal insight, could on some occasions be considered ambiguous. A review of Delphi literature (Rowe and Wright [65]) will not solve this problem, since Delphi researchers fail to define the term *expert* as applied to their study. If, in simplistic terms, an expert is regarded as one practiced or skillful within the area of consideration, there is an intuitive extrapolation as to the notion of expertise, and the assessment of expert opinion relies to some extent on a global understanding of this extrapolation. In general, the expert response must conform to some form of measurement criterion in relation to consensus if any conclusion is to be reached on any issue that is the subject of expert opinion.

On the assumption that more heads are better than one in achieving a balanced view, many different forums for assessing group opinion have been utilized over the years (see Schiebe et al. [30]). Some of the most common means of assessing group opinion are discussed as follows.

Committee

The traditional method of forming group opinion is the committee. Under the guidance of a (impartial) chairperson, the issue is isolated (if necessary) and debated, with consensus determined by a majority vote. Besides the obvious discrepancy that a majority and consensus are not synonymous, the recognized difficulties with the method are the existence of one dominant member and group pressure upon an individual to conform (the herd instinct). Thus, the resultant group pronouncement may not be at all representative of the group.

Nominal Group

A committee is strictly a subgroup of a large organization from which its authority is derived. More relevant to a panel of experts, that is, the pooling of considered opinion, are nominal groups and variations thereof. In this situation,

the alternatives are created by the panel members when they are each outside the group context. The individual members' lists, circulated before meetings, are then pooled. Personality issues are reduced, the dominant member should be the member best prepared, authorship of ideas is on record and cannot be disputed, and preconsideration should reduce the herd instinct.

Delphi Panel

Of more rigorous delineation is the Delphi panel (Linstone and Turoff [66], Render and Stair [67], Rowe and Wright [65], Wheelwright and Makridakis [68]), devised as a method of obviating the practical difficulties inherent in the committee concept. In the Delphi panel, the group members never meet physically; all communication is through a group controller or coordinator who selects the members of the panel, presents the basic problem, and informs the individuals in the group of progress to date (feedback). When the atomic or elemental issues that constitute the main problem have been determined (the qualitative phase), consensus is sought on the quantitative value to be ascribed to each of these issues (statistical response).

A series of rounds of voting is held. After each round the group controller returns to each panel member his or her scores together with a measure of the group opinion on each issue. The panel members are then asked if they wish to revise their opinions. The process is repeated until group opinion has converged sufficiently to be described as consensus, or until it is recognized that a consensus is unattainable. Unanimity is less important in the method than the absence of group pressure.

The two essential characteristics in a Delphi panel are (1) the anonymity of panelists and (2) feedback (histograms, measures of central tendency, or analytic consensus). The former eliminates the problem of the dominant member and group pressure to conform. However, a new problem is introduced—a considerable time scale is involved in the sending and receiving of questions and answers. While this (at least) theoretically guarantees a considered opinion, a substantial attrition rate is almost inevitable. Members of the group lose interest, change jobs, or become otherwise indisposed. Also, the group controller has a role of far greater significance than a committee chairperson; only a high level of awareness on his or her part can prevent the unconscious bias that might be introduced. Other doubts about and difficulties with the method are summarized by Marchant [69], Shields et al. [70], Sackman [71], and Ayton et al. [72].

Computer Conferencing

Modern technology enables remote participation in group discussion. Participants input their views into a computer system, and their views are circulated to the other panelists for comment and reply. A suitable schedule allows either a quick result or a more leisurely, considered process. Anonymity is optional.

This concept can be combined with others, for example, the Delphi method, with a reduction of time scale and consequent diminishing of attrition (i.e., drop-outs). Further, if a computer system for analyzing these data exists, the results may be obtained almost instantaneously. Hence, the group may have access to the consequences of their polling before their views are forgotten. The almost universal availability of the Internet and ISDN developments in survey computing are already having a considerable impact on this type of conferencing.

DACAM Group

A DACAM group [73] is an alternative method of overcoming the problem with committees. Here, the group meets physically but is divided (usually systematically) into subgroups for discussion sessions. Between each session, representatives from the subgroups meet to compare progress and coordinate the agenda for the next session. In this way, the dominant member, being limited to one subgroup, is less influential on the group decision.

While this method guarantees a quick result (e.g., in a day), the facility to organize such a

group is dependent on at least substantial goodwill, if not considerable finance.

Consensus

The notion of consensus is very much an intuitive one. In politics, there is "consensus" on a policy that is acceptable to a majority. If no consensus exists, then it can often be achieved by broadening the policy. However, the concept is very largely negative in that the emphasis is on avoidance of what is intolerable to others.

The nature of consensus depends on the context or terms of reference of the problem. For example, the arrangement of a number of options in order of importance or preference (comparative consensus) is essentially different from assessing the importance of a single elemental issue within the problem (definitive consensus).

Definitive Consensus

Definitive consensus involves panel members who assign to each issue a score chosen from a Likert-type scale, that is, a range of values, such as (0,10) or (0,5). For example, one might say that a very definite consensus had been reached if a comfortable majority (say, 60 %) agreed on an exact value, or if a substantial majority (say, 75 %) agreed on a small range, or if all agreed to within a slightly larger range. Thus, there is a balance between the number conforming to the view and the range permitted.

The essential problem, however, is finding mechanisms for representing and assessing the opinions on each individual issue for the complete panel, in other words, mechanisms that provide the following for the set of scores for each issue:

- A profile of the scores
- A focal point of agreement (if any)
- A measure of the agreement at that point

Additional problems arise if the panel is divided into several groups, each of which is in internal accord. This is referred to as *split consensus,* or a *multimodal* situation. The interested reader will find a mathematical function (neighborhood consensus) that addresses these issues in Donegan and Dodd [74].

Traditionally, a histogram was generally used as a profile, and the presence or absence of consensus was determined by a statistical measure of dispersion. Chatterjee and Chatterjee [75] discuss mean- and median-based methods together with the compromises referred to as the trimmed and windsorized means. A *trimmed mean* excludes extreme values, and in a *windsorized mean,* the extreme values are replaced by the second-most extreme values. Some of the assumptions and drawbacks of these measures, for example, the nonrepresentativeness of the mean, the instability of the mode, and the inconsistency and precision-dependence of the median, are described in Dodd and Donegan [76].

It is worth pointing out here the difference between consensus and compromise. If on a scale of 0–5, one-half of a group selects 0 and the other half selects 5, then 2.5 is a compromise score. It would be inaccurate, however, to describe 2.5 as a consensus score, since this figure is not representative of any members of the group and, therefore, not a measure of the group itself. There is, in fact, no consensus among the group.

Alternative Stability Approach

A major problem with, for example, Delphi studies is that stability may set in before consensus has been achieved, and the latter might therefore never be reached. When seeking consensus on a large number of issues, this is highly likely for some of the issues and quite consistent with Delphi philosophy, which is more concerned with narrowing the spread of diverse opinions than enforcing an artificial consensus.

It is possible and perhaps simpler to use a definition of stability (based on a comparison of successful rounds) as the termination criterion for a Delphi panel. This would also allow item/individual/tactic/group stability to be considered. The definition of stability might be based on the

ratio of total scores for two rounds, for example, the average of the moduli of the differences between the rounds. Linstone and Turoff [66] suggest the quadratic mean as a refinement of this. Alternatively, if the data were normalized (i.e., translated and magnified to fit a uniform distribution), it might be simpler to use Pearson's correlation coefficient.

The principal advantage of the alternative stability approach is that stability is almost certain to be achieved, and fairly rapidly. It is generally recognized that stability is normally achieved within four polling rounds in most Delphi panels (see Render and Stair [67]).

Comparative Consensus

Comparative consensus involves a panel of individuals who must decide on an arrangement of *n* issues (or objects) in order of importance or merit. For the sake of simplicity, let the issue be a number from 1 to *n*. Each panel member decides on an arrangement that might be expected to differ from the arrangements of others. Two problems can arise—(1) establishing a universally acceptable arrangement, and (2) the amount of agreement among the panel. A typical example of this situation might be the selection of an agreed priority list from ten independent lists returned by experts whose task is to rank in order of importance the following safety features: fire extinguishers, smoke alarms, sprinklers, flashing lights, and direction signs.

Comparative consensus [77] also involves only the *ranking* of a number of issues (in contrast to the simpler notion of definitive consensus, as described above, in which the agreement of a panel on a single issue is assessed). The obvious question in the situation where several panelists judge several issues is whether (1) it is preferable to determine the agreement on each issue on the basis of scores and then determine rank on the basis of the consensus scores, or whether (2) each panel member should rank all the issues on the basis of his or her scores and subsequently look for consensus on the set of rankings. This has never been satisfactorily resolved.

Compound Consensus

Compound consensus arises when, for example, a panel is required to produce an agreed ranking (with weightings) for a set of issues. This type of consensus can occur when AHP is used by a relatively small panel to produce a set of rankings. The obvious question is whether it is better to (1) find (definitive) consensus among the panel on the issue and then rank the issue for the whole panel, or (2) let each panel member rank the issues and then seek (comparative) consensus on the rankings. Compound consensus allows a weighting of each of the issues to be taken into account.

Data for Engineering Analysis

78

Marty Ahrens and John R. Hall Jr.

Introduction

This chapter addresses sources of input data required for deterministic (e.g., fire hazard) or probabilistic (e.g., fire risk) engineering analysis, such as performance-based design, code change analysis, product evaluation analysis, or major fire reconstruction. An overview of types of analysis engineers may perform, with a brief discussion of the kinds of engineering problems that should be addressed using those kinds of analysis, is given in the list below. Table 78.1 shows the fire-related phenomena that must be characterized and types of data required to model the phenomenon for each type of analysis listed.

Types of Analysis and Data Needs

- (General) fire risk analysis refers to a comprehensive analysis of fire risk associated with a range of situations, whether or not there is a particular focus for the analysis, and is set up in a classic risk analysis format, using scenarios and scenario clusters in a scenario structure, and requiring data on probabilities for each scenario cluster and consequences for each scenario.
- Fire hazard or risk analysis of a burnable product is needed for evaluation and possibly certification for acceptability (possibly for equivalence to a product regulation) of a product, material, assembly, component, and so on whose role in fire is as something that burns, either the first item ignited or a major fuel source during fire development.
- Fire hazard or risk analysis of a design for an occupiable space is needed for assessment and possibly approval of a design for an entire building (possibly under equivalence or relative to a performance-based code).
- Fire hazard or risk analysis is also appropriate for evaluation and possibly approval of products whose roles in fire are as heat sources that initiate fires.
- Engineering analysis can be appropriately applied to the performance of automatic detection/alarm or suppression systems or of other active fire protection systems.
- Engineering analysis can be appropriately applied to the performance of passive fire protection, such as walls, doors, and structural members.
- Engineering analysis can be appropriately applied to the performance of features designed to ensure safe evacuation of occupants from a building with a developing fire.

As Table 78.1 shows, regardless of the type of analysis required, the same generic types of data are typically needed, which may be organized into these few sources:

- Fire incident and field observation (i.e., nonincident event) data
  Probabilities of ignition or of reliability, given naturally occurring variation in conditions

Table 78.1 Types of analysis and associated data needs

Type of analysis	Phenomena	Data needs
General fire risk analysis	Ignition—probability of fire, by scenario	Fire incident data, exposure data
	Consequence—measures of severity of fire, by scenario	Fire incident data, laboratory test results
Burnable product fire hazard or risk analysis	Ignition—probability of fire, by scenario, for different versions of the product	Laboratory test results (related to scenarios, including specific ignition sources), fire incident data, product usage data
	Burning characteristics of product once ignited—time curve for heat release rate, peak heat release rate, flame spread rate, effective heat of combustion, rate of production of smoke or toxic species	Laboratory test results
	Reliability of product—probability, mode or nature, and magnitude of "failure," defined as any deviation from nominal product performance	Field observations (e.g., probability of poor quality control in manufacture of product), usage data (e.g., age effects related to performance, degradation due to wear or vandalism)
	Contribution to harm to people—toxic species production by mass loss ratio or mass loss rate, toxic potency of species, time rate of production of vision-reducing products of combustion	Laboratory test results (of characteristics and effects of fire conditions produced when product burns)
	Contribution to harm to property—mass loss rate by combustion product, corrosivity or other chemical characteristics by combustion product	Laboratory test results (of characteristics and effects of fire conditions produced when product burns)
	Contribution to other harm—environmental impact, impact on heritage	
Design for occupiable space fire hazard or risk analysis	Ignition and burning characteristics	Laboratory test results (related to scenarios, including specific ignition sources), fire incident data, product usage data
	Transition to flashover	Design specifications (e.g., compartment dimensions, thermal properties of compartment surface linings, venting), laboratory test results, other measured or estimated conditions
	Burnout time	Field surveys (fuel load or fuel mass available, compartment geometry, ventilation), laboratory tests (mass burning rate, heat of combustion)
	Space to space fire spread—flame spread rate	Design specifications (e.g., measures of barrier integrity), laboratory test results, other measured or estimated conditions (e.g., paths of fire spread such as HVAC), fire duration (see burnout time)
	Structural performance—collapse or damage making use of building unsafe	Laboratory test results, field observations
	Contribution to harm to people	Same as for burnable product analysis
	Contribution to harm to property	Same as for burnable product analysis
	Contribution to other harm	Same as for burnable product analysis

(continued)

Table 78.1 (continued)

Type of analysis	Phenomena	Data needs
Heat source product fire hazard or risk analysis	Ignition—probability of fire, by scenario, for different versions of the product	Laboratory test results, fire incident data, product usage data
	Reliability of product—probability, nature, and magnitude of deviations from nominal product performance	Field observations (e.g., probability of poor quality control in manufacture of product, testing, and maintenance records), usage data (e.g., component failure due to age, degradation due to usage or vandalism)
Active fire protection performance	Time of activation	Laboratory test results (e.g., physical conditions leading to system activation), fire incident data
	System effect—measures of system output (e.g., sound, suppression agent)	Laboratory test results, fire incident data
	Reliability—probability, nature, and magnitude of deviations from nominal system performance	Field observations (e.g., probability of poor quality control in manufacture of product, testing, and maintenance records), usage data (e.g., component failure due to age, degradation due to usage or vandalism)
Passive fire protection performance	Time performing function (e.g., time blocking spread of fire, time providing structural integrity while subjected to fire conditions)	Laboratory test results (on passive fire protection element, reflecting materials, and type of design or construction), fire incident data, burnout time (see previous reference to burnout time as a phenomenon; it is a calculated time for fire duration exposing a passive fire protection element)
	Feature effect—degree to which function is performed (e.g., quantity of fire effects permitted to pass barrier)	Laboratory test results, fire incident data
	Reliability—probability, nature, and magnitude of deviations from nominal feature performance	Field observations (e.g., impairment prior to fire, such as poke- through holes in wall or doors blocked open, probability of poor quality control in manufacture of product), usage data (e.g., component failure due to age, degradation due to usage or vandalism), laboratory test results
Evacuation and other human behavior	Occupant characteristics	Field observations, laboratory test results, design specifications, and estimated conditions

Fire size and consequences, given specified values of certain conditions, factors, or characteristics of interest and naturally occurring variation in all others

Characteristics and behavior of people

- Usage or exposure data

  Denominators for probability calculations from event data (e.g., number of portable electric heaters versus wood stoves in use, to support estimates of fires per year per unit; number of gasoline service stations, to support estimates of probability of fire per service station per year; number of square feet of office space, to support estimates of probability of fire per square foot of office space per year)

- Laboratory test results

  Fire size (e.g., heat release rate) as a function of time, given planned variation in certain conditions (e.g., fuel load) and unplanned variation in those not recognized or measured (e.g., exact location of fuel items and their proximity to each other)

  Probabilities of ignition or of reliability, given planned variation in conditions (measured as numbers of ignitions or numbers of failures divided by numbers of trials, although fire and equipment failure tend to be such rare events that measurement of probabilities in the laboratory can be impractical)

Fire consequences, including specific effects on people (actually data for estimation of effects on people, for example, via animal tests or toxic effects models based on species concentrations and exposure times) or on property, as a function of time and of specified or measured conditions

Discussion of data types and sources will be organized, therefore, around incident data, field observation data, usage or exposure data, and laboratory test results. The last type will be addressed only briefly, as it is the type most familiar already to fire protection engineers and most thoroughly discussed in the other chapters of this handbook.

Incident Data

How often do certain items catch fire, or certain types of equipment start fires, or certain types of occupancies have fires? The first component in all these calculations is data on event frequencies per unit of time. Fire experience data will include a number of fires involving products, occupancies, or other subjects of analysis that are in widespread use and identified in a fire data collection system. These data can be combined with usage data to calculate event frequencies.

If the product, occupancy class, or circumstance is new or not identifiable in the data system, it will not be reflected in current fire experience data. Laboratory tests in a full range of relevant scenarios may be necessary to calibrate the likelihood of ignition for a new product against the likelihood of ignition for a typical established product or mix of products.

There are no standard test protocols for such a calibration. Because ignition is typically a rare event, it may be difficult and expensive to obtain test-based estimates of these relative likelihoods. Subjective estimation and interpretive judgment will likely be required and may in some instances be the only basis available for ignition probability estimates for new products. (For example, experts might agree that a new product will be roughly a third to a half less likely to be involved in fire ignitions than a typical product now in use.)

If fire experience history is relevant, it is important that estimates be drawn from suitable, statistically representative databases and procedures. In the United States, this means starting with national estimates derived from the detail in the U.S. Fire Administration's (USFA's) National Fire Incident Reporting System (NFIRS) and the estimated totals from the National Fire Protection Association's (NFPA) annual survey of fire departments for projection of NFIRS to national estimates [1–3].

National Fire Incident Reporting System

NFIRS Overview In the United States, local fire departments use NFIRS to document their responses. In the process, they function as data collectors for a system that enables analysis of local, state, and national fire problems. NFIRS captures data about the property use or occupancy where the fire occurred, the item first ignited and its composition, general type of equipment involved in ignition, heat source, factor contributing to ignition, number of stories, level of fire origin, and performance of automatic detection and suppression systems.

NFIRS is the largest and most detailed fire incident database in the world, capturing almost a million individual fire incidents a year in 2006–2010, or roughly two–thirds of the fires reported to local fire departments. In the 1980s and 1990s, NFIRS received data from some or all communities in roughly 40 of the 50 states, plus the District of Columbia, although not all participating communities or states were able to submit data every year. In 2010, the NFIRS database included at least some reports from all 50 states and the District of Columbia. Participation in NFIRS is voluntary at the federal level. Different states have different reporting requirements, ranging from mandatory reporting of all incidents or fires to mandatory reporting of just those fires resulting in a casualty or dollar loss of a certain size or to completely voluntary reporting. State resources can affect participation

even if local fire departments are completing the NFIRS reports. Participation rates in NFIRS and practices regarding the types and severity of incidents reported are not necessarily uniform across regions and sizes of community. Also, some incidents from participating departments are never submitted or have errors that prevent inclusion into the national database. Both region and community size, in turn, are correlated with frequency and severity of fires, which means NFIRS may be susceptible to systematic biases.

A 2005 NFPA survey of NFIRS participant communities versus nonparticipant communities found that participant communities tended to have statistically significant differences in annual rates of dwelling and other structure fires and in some other (but far from all) major measures of fire experience [4].

Version 5.0 of NFIRS Like most well-established data systems, NFIRS has had both major and minor revisions. The most extensive and last major revision was the introduction of Version 5.0, or NFIRS 5.0, in 1999. Due to the extensive changes in data elements, categories, and coding procedures, extreme caution must be used in comparing data from 1980 to 1998 with data from the later years. NFIRS 5.0 was adopted gradually, so the transition years of 1999–2002 are also volatile. More questions were added about automatic fire suppression and detection equipment, including presence, type, operation, effectiveness, and reasons for failure or ineffectiveness. Structure Status, which indicates if a property is normally occupied, idle, vacant, under construction, renovation or demolition, is another new data element. More choices were added for Equipment Involved in Ignition, which is no longer a required field. When equipment is involved, information on the power or fuel source is also requested. Other optional data elements collect information about On-Site Materials and Suppression Factors. NFIRS 5.0 dropped a few data elements, including Construction Type, Method of Alarm, and Method of Extinguishment, and greatly reduced the number of Property Use (occupancy) categories. Some fields, such as Factors Contributing to Ignition, On-Site Materials, Suppression Factors, and Actions Taken, allow multiple entries. A manual containing the NFIRS 5.0 data elements, code choices and coding rules is available online [5].

Some of the features of NFIRS 5.0 that make it easier for fire departments to document incidents can make data interpretation and analysis more challenging. Different analysts or organizations may choose to handle these features differently and consequently obtain different results.

The number of incident type choices has been greatly expanded. The structure fire incident types are shown Table 78.2. In NFPA's analyses, structure fires also include fires in mobile property used as a fixed structure, such as manufactured housing and portable buildings (incident types 120–123).

To ease the burden on the fire service, NFIRS now requires only minimal information on certain types of structure fires, collectively called "confined fires" (incident type 113–118), that did not spread beyond the object of origin, such as small cooking fires, chimney fires, confined fuel burner or boiler fires, and trash fires that did not spread to other contents or the structure itself. Note that these incident types may apply to fires that occur in mobile properties that are used as structures and would require less information to complete. Some jurisdictions and some fire officers do complete the entire report for these confined fires. This makes it possible to do some data analysis when the focus is on a large number of incidents. Because such data is not routinely provided, these estimates will be more volatile and more uncertain. Just as the operation of automatic detection or extinguishing equipment can mean that a fire that would have been reported to a fire department is handled by occupants and not reported, such equipment can also mean that a fire that would have grown and spread remains confined. In many confined fires, automatic detection equipment sounded an early warning. Some of these fires were quickly extinguished by one sprinkler. At the same time, a typical confined fire may be too small to activate an operational detector or an operational sprinkler.

Table 78.2 NFIRS 5.0 structure fire incident types

Structure fire
111. Building fire, excluding confined fires (113–118)
112. Fire in a structure other than a building, including fires on or in piers, quays, or pilings; tunnels or underground connecting structures,; bridges; trestles, or overhead elevated structures; transformers; power or utility vaults or equipment fences; and tents
113. Cooking fire involving the contents of a cooking vessel with fire extension beyond the vessel
114. Chimney or flue fire originating in and confined to a chimney or flue, excluding fires that extend beyond the chimney
115. Incinerator overload or malfunction with no flame damage outside the incinerator
116. Fuel burner or boiler fire or delayed ignition or malfunction where flames cause no damage outside the fire box
117. Commercial compactor fire that is confined to contents of compactor, excluding home trash compactors
118. Trash or rubbish fire in a structure with no flame damage to the structure or its contents
Fire in mobile property used as a fixed structure, including manufactured housing, mobile homes, motor homes and camping trailers
121. Fire in manufactured housing or mobile home used as a fixed residence, including units not in transit and used as a structure for residential purposes and manufactured homes built on a permanent chassis
122. Fire in a motor home, camper or recreational vehicle when used as a structure, including fires in motor homes when not in transit and used as a structure for residential purposes
123. Fire in a portable building when used at a fixed location, including portable buildings used for commerce industry or education and trailers used for commercial purposes
120. Fire in mobile property, used as a fixed structure, other

Any calculation of loss rates per fire or per 100 fires for purposes of assessing the impact of automatic fire protection equipment therefore should include confined fires that stayed small or were kept small.

When analyzing for other factors such as area of origin or equipment involved in ignition, some groupings are reasonable. NFPA groups incident type 114, confined chimney or flue fire, with fireplace or chimney fires, and confined fuel burner or boiler fire with central heating equipment fires. Confined cooking fires can be assumed to involve cooking equipment and to have usually occurred in a kitchen or cooking area.

The confined or contained trash fires pose the most problems because the scenario provides little information about cause or area of origin. Many such fires are intentional. They may be started by a discarded cigarette or fireplace ashes. A child could have been playing with fire. Omitting these fires could lead to underestimates of the problem. The downside to analyzing confined fires is that there is less usable data that is less representative.

Some analysts omit fires in structures other than buildings (incident type 112). However, many of the areas of origin entered for these fires appear to indicate that these "structures" are in fact parts of buildings, which would suggest they should be included in any analysis of building fires.

National Estimates from NFIRS and NFPA's Fire Department Experience Survey

Because of the differing reporting practices, NFIRS used alone does not provide accurate estimates of the size of the fire problem in general or of specific fire problems. The annual NFPA Department Experience Survey is a more traditional sample-based survey, allowing projections to be made. The NFPA survey is a stratified random-sample survey that captures roughly one-tenth of all U.S. fire departments, including most departments protecting a population of at least 50,000. This stratification preserves randomness, hence representativeness, in the sample while reducing total variance, for more precise answers with less sampling uncertainty. National estimates of the extent of the general fire problem are

projected from the survey results and published annually [6].

By dividing the projected totals from the NFPA survey by the reported totals in NFIRS, multipliers are obtained that can be applied to the NFIRS data to develop national estimates of specific fire problems, a method developed by analysts at the USFA, Consumer Product Safety Commission (CPSC), and NFPA [3].

This multiple calibration approach makes use of the annual NFPA survey where its statistical design advantages are strongest. There are separate projection formulas for four major property classes (residential structures, nonresidential structures, vehicles, and other) and for each measure of fire severity (fire incidents, civilian deaths, civilian injuries, and direct property damage).

For example, the scaling ratio for 2010 civilian deaths in residential structures is equal to the total number of 2010 civilian deaths in residential structure fires reported to fire departments according to the NFPA survey (2665) divided by the total number of 2010 civilian deaths in residential structure fires reported to NFIRS (1534). Therefore, the scaling ratio is $2665/1534 = 1.74$. However, note that the scaling ratios for fires, civilian deaths and injuries and direct property damage can differ markedly from each other. The scaling ratios for a particular loss measure also can differ markedly from one property class to another. The most stable scaling ratios will be the residential scaling ratios and the fire incident scaling ratios for any property class. The other scaling ratios will be more uncertain because they are based on smaller numbers and because the distorting effects of individual fires with high death tolls or large property loss are not smoothed out over a large number of total fires.

Most analyses of interest involve calculating not just the estimated total number of fires per year within a particular occupancy but more specifically the estimated number per year of a certain type of fire in the particular occupancy, most frequently those defined by some ignition-cause or property. The six cause-related characteristics most commonly used to describe fires are two characteristics related to the source of heat of ignition (Heat Source, Equipment Involved in Ignition), two characteristics related to the first fuel item ignited (Item or Type of Material First Ignited), the Factor(s) Contributing to Ignition by bringing the heat source and ignited material together, and Area of Origin. Other characteristics of interest involve fire protection, number of stories, and victim characteristics, such as ages of persons killed or injured in fire, victim location at ignition, and victim activity at time of injury.

In the next few sections of the chapter, nearly all the examples cited involve analyses of fire cause, which will tend to be of greatest value in analyses for public education or for evaluation of the fire performance of burnable products. Engineering analyses of candidate designs for whole buildings will depend more on analysis of other data elements, such as fire size and the performance of fire protection equipment. The points being made about good analysis practice transfer from the data elements used in the examples to all other NFIRS data elements.

Handling Unknown Data

Some fire incident reports may not include a particular characteristic of interest in NFIRS or may indicate that the information was undetermined or unknown. If the unknowns are not taken into account, then the propensity to report or not report a characteristic may influence the results far more than the actual patterns of that characteristic. For example, suppose the number of fires remained the same for several consecutive years, but the percentage of fires with cause unreported steadily declined over those years. If the unknown-cause fires were ignored, it would appear as if fires due to every specific cause increased over time while total fires remained unchanged. This, of course, does not make sense.

Consequently, most national estimates analyses allocate unknowns by using scaling ratios defined by NFPA survey estimates of totals divided by only those NFIRS fires for which the dimension in question was known and reported.

Inherent in this approach is the assumption that the fires with unreported characteristics, if known, would show the same proportions as the fires with known characteristics. For example, it assumes that the hotel fires with unknown Area of Origin codes contain the same relative shares of guest room fires, kitchen fires, laundry room fires, and so forth, as are found in the hotel fires for which the Area of Origin was reported.

There are more sophisticated statistical techniques for imputing missing values or for "raking" unknowns simultaneously in two or more dimensions, but these are rarely used in routine analysis.

Issues Regarding Unknown Data in NFIRS The confined-fire option with its very limited reporting requirements has also complicated the process of handling unknown or missing data. Analyses of heating equipment have historically been done by using data in the Equipment Involved in Ignition field. Code choices in this field include a range of codes corresponding to heating equipment, other ranges corresponding to other well-defined types of equipment, and some other codes indicating that the Equipment Involved in Ignition is completely or partially unclassified or unknown, or blank. The Equipment Involved in Ignition field is blank for most confined fires. For the few that are known, the heating equipment share will differ substantially by specific type of confined fire. When Equipment Involved is known, fires listed as confined to furnace or boiler will usually show some type of heating equipment with furnaces or central heating units dominating. Fires listed as confined to cooking vessel will occasionally show heating equipment. If confined and non-confined fires are analyzed together, the unknowns will be dominated by the confined-fire unknowns, which do not have the same equipment distribution as the non-confined-fire unknowns. If the analyst infers equipment from the dominant type for each type of confined fire, the pool of residual unknowns will be dominated by the non-confined-fire unknowns—the only ones remaining—and they will tend to be allocated based on the confined-fire shares of equipment. (Confined fires are dominated by confined cooking vessel fires, but non-confined fires are not so dominated by cooking equipment fires.) The best choices appear to be separate allocation of unknowns for confined and non-confined fires or allocation of unknowns for non-confined fires and inference for confined fires. But none of the choices are as clean or as logically appealing as the old simple rule of proportional allocation of all unknowns when the same fields were required for all incidents.

Version 5.0 also introduced new "skip patterns" so that certain data elements are required only when specific values are or are not entered into a different element. For example, information on the Type of Material First Ignited is no longer required for fires in which the Item First Ignited is blank, undetermined, or some type of "general material." General materials can include items as diverse as electrical wire or cable insulation; transformers or transformer fluids; conveyor, drive, or V-belts; tires; railroad ties; pyrotechnics; fences or poles; dust, fiber, or lint; books, magazines, or files; film residue; adhesive; rubbish; oily rags; and multiple items first ignited. One could reasonably assume that when the Item First Ignited was unknown or undetermined, then the Type of Material First Ignited was also. However, information about the Type of Material First Ignited could be inferred for many of the general items, so these are not always true unknowns. Because the Type of Material First Ignited is often supplied even when not required, any time the field is left blank NFPA now treats it as unknown.

NFIRS also has fields for the Item Contributing Most to Flame Spread and Type of Material Contributing Most to Flame Spread. Analysis of this field is complicated by a checkbox that is to be used to indicate any of the following conditions:

1. There was no flame spread;
2. The Item First Ignited was the same as Item Contributing Most to Flame Spread; or

3. The Item Contributing Most to Flame Spread was undetermined.

Sometimes the same item is entered despite the directions. "None" is a valid choice in several fields: Equipment Involved in Ignition, Fire Suppression Factors, and Factor Contributing to Ignition. For Factor Contributing to Ignition, it appears that "None" is greatly overused. NFPA treats "None" in this field as an unknown. For Equipment Involved in Ignition, a substantial share of incident reports indicate that no equipment was involved in ignition, but indicate that the Heat Source was some type of operating equipment. Some fire officials seem reluctant to list equipment involved when the equipment itself was operating correctly and user error was the greater issue. Electrical wiring is sometimes not perceived as equipment because it is not something that gets plugged in or turned on. When the Heat Source entry does not confirm that no equipment was involved in ignition, NFPA considers the Equipment Involved in Ignition to be unknown. If the Heat Source was entered as "Radiated or conducted heat from operating equipment," the Equipment Involved in Ignition would be considered unknown if entered as "none."

Errors and Uncertainty in NFIRS-Based National Estimates It may be useful at this point to summarize sources of error and uncertainty in NFIRS-based national estimates, both those that can be readily quantified and those that cannot:

- *Sample-size-based uncertainty*. Uncertainty due to sample size is negligible from NFIRS itself because of its enormous scope, unless the problem being examined accounts for hundreds of fires per year or less, and modest from the calibrating NFPA survey (about 10 % for deaths and much less for other measures of fire loss).
- *Sample-bias-based uncertainty*. The NFPA survey is designed to reduce sample bias; however, some may exist. For example, departments who submit all incidents to NFIRS may be better able to complete the survey, whereas other departments may report to the NFPA survey only what is required by their states' NFIRS programs. On the other hand, departments using NFIRS software from vendors who include the survey as an output report are more likely to respond to the survey. Some departments do not participate or may participate in some years but not others. NFIRS is not sample based, and it is hard to quantify the impact of reporting differences.

The completeness and quality of data also vary by jurisdiction.

- *Uncertainty due to missing data*. The percentage of NFIRS cases with blank or unknown data can be somewhat addressed, as noted above, by proportional allocation but can also be used to estimate the uncertainty, which, in the extreme, ranges from all the unknowns being relevant to none of the unknowns being relevant.
- *Uncertainty due to terminology or category choices*. Some of the choices in NFIRS do not use terms firefighters would know. When looking at home wiring fires, it might seem reasonable to look at fires involving either electrical branch circuit wiring and outlets or receptacles. However, many firefighters are not familiar with the term "branch circuit wiring". In 2006–2010, three times as many home fires involved "electrical wiring, other" as involved electrical branch circuits. Karyl Kinsey of the Austin Texas Fire Department found that almost one-third of Austin's fire reports that mentioned smoking as a fire cause and completed the Fire Module reported that the Heat Source was a hot ember or ash (43) rather than a cigarette or other form of smoking material (61–63) [7]. It is possible that the first entry that looks reasonable is chosen, even when it is not the most appropriate.
- *Uncertainty about what should be considered unknown*. When something is coded as "other" or "unclassified," particularly when used with a category, such as 'electrical distribution or lighting equipment, other," (Equipment Involved in Ignition 200) does it truly mean that the particular fire

circumstances do not fit into any of the choices? Is it more accurate to treat these as unknown or partially unknown? NFPA treats the "other" broad categories of equipment as partially unknown and distributes them across their respective categories. However, an absolute "other" is taken at face value. NFPA treats Heat Source 60 "Heat form open flame or smoking material, other" as a partial unknown and distributes these incidents proportionally across the other categories of smoking materials and open flames.

- *Uncertainty due to coding inconsistencies*. More difficult to address because few coding combinations are truly inconsistent (unusual fires are possible), coding inconsistency can be analyzed as with missing, blank, or unknown data by eliminating a range of suspect cases from consideration.
- *Uncertainty due to error in determining and recording the facts of the case*. If the initial investigation is flawed, resulting errors will be carried forward into the incident report. Data entry errors can also occur. Factual errors are unmeasureable in the absence of some indicator within the incident record (e.g., inconsistency in coding two or more data elements) or access to a more reliably accurate source of incident data; however, few incidents have a second source of data, and second sources of data are not necessarily more reliable.
- *The impact of inclusion or exclusion of unusually serious incidents on estimates*. The casualties and property damage from the events of September 11, 2001, were not included in NFIRS. NFPA made a conscious decision to exclude these deaths when calculating scaling ratios for national estimates. On a much smaller scale, NFPA is aware of some dormitory and fraternity fire deaths that were not reported to NFIRS. Trend tables show no deaths in these occupancies in those years. For most occupancies other than homes, fire deaths are very rare events, sometimes so rare that years may pass with no deaths reported to fire departments anywhere in the country. For such occupancies, single-year NFIRS-based national estimates are almost certain to miss the true values. If the only fatal fire that occurred was in the NFIRS sample, the estimating procedure will double or triple the number of deaths, producing an overly high estimate. If the only fatal fire was not in the NFIRS sample, the estimate will be zero, which is too low. In some years, NFPA is able to identify some fatal fires through news clips and confirm the deaths through fire departments even though those fire deaths are not part of the NFIRS sample, but this information cannot be used to adjust the NFIRS-based estimates because it is one-sided. Inserting events identified outside the sampling process undercuts the entire basis of sample-based statistical estimation. When the average number of deaths per year is this low, rolling multiyear averages are more appropriate. Even multi-year averages can give a misleading impression of confidence about patterns of fire death factors when the numbers are small and the portion with unknown data high. If one occupancy had six deaths in 5 years, based on projection from two deaths including in the NFIRS dataset, and the cause was known in only one death or both deaths occurred in the same fire, there would be a high degree of uncertainty if we followed our normal allocation of unknown data and conclude that all the deaths in this occupancy resulted from that one cause. At the same time, it would be misleading to treat all the deaths as having unknown cause, and it could be confusing to confine all the information on cause to a footnote.

Firefighters provide NFIRS data using a standardized coding system after a fire to complete an incident report. The strengths of the system are also limiting factors. By utilizing a standard classification system, with a limited number of standardized data elements and choices within each data element, to capture the circumstances at all types of fires, data can be captured easily and practically about a wide variety of events. The limited number of data

elements mean that the data will not be as detailed as many people would like. The fire service personnel collecting the data are generalists, not specialists. They can usually identify that a particular piece of equipment was the source of ignition, but they are unlikely to know which part of the equipment was involved. Information on brand, model, or component of equipment involved is not coded and is often not captured. Nor does NFIRS capture very specific types of equipment that are used in only a small number of industries. And even at the level of detail addressed by the database coding, there are many gray areas of interpretation.

If these weaknesses seem substantial, it may be useful to consider the much greater weaknesses of any other currently available statistical database. If one uses only data collected by experts and specialists, then the dataset will be small and is almost certain to be unrepresentative of the larger set of fires. If one uses data mining techniques to look for patterns in unstructured or narrative incident reports, then results can be distorted because many incident reports will not have included information on the characteristics selected for analysis by the data mining. If one withholds results unless certain standards of statistical significance have been met, then one will have no data-based estimates for many parameters necessary to engineering analysis.

It is possible to use Bayesian statistical analysis techniques to combine subjective estimates with limited or flawed datasets, but there are no well-known major examples of applying these techniques to NFIRS, let alone any solid guidance on how to set up engineering problems for this kind of analysis.

Going back to the limitations and complexities of NFIRS, consider this example of applying the data to a particular product, specifically, the steps required just to fully capture the detail available in NFIRS to estimate fires involving a particular type of carpet. Carpet is one of several products that falls within the NFIRS category of floor covering. The NFIRS Item Ignited code 14 for floor covering includes floor covering or surface rugs, carpets, or mats. The NFIRS database can be checked for number of fires coded as starting with floor covering. However, floor covering will also account for a proportional share of fires with Item First Ignited unknown. Floor covering may also account for a proportional share of fires under Item First Ignited code 10, which is other or unclassified structural component or finish. The standard references on developing national estimates provide guidance on these steps and the specific statistical methods needed to execute them.

To distinguish carpets from other floor coverings, consider the Type of Material First Ignited data. This data element has codes for several broad categories of fabrics and textiles, including code 71-fabric, fiber, cotton, blends, rayon, wood, or finished good, including yarn and canvas, but excluding fur and silk; code 74-fur, silk, or other fabric or finished goods excluding those included in code 71; code 77-plastic coated fabric, including plastic upholstery fabric and other vinyl fabrics; and code 70-unclassified fabric, textile, or fur. Carpets or rugs could be estimated by including only fires in which the Type of Material First Ignited was any one of the three codes for identifiable fabric-codes 71, 74, and 77. You might include all or a proportional share of fires coded as Type of Material First Ignited as code 70 (unclassified fabric, textile, or fur) as well as a proportional share of fires coded as totally unknown. This would properly separate carpet fires from hardwood or unfinished floors (Type of Material First Ignited codes in the 60–69 range, which is processed wood and paper) and from vinyl floor coverings (Type of Material First Ignited code 41-plastic; or perhaps code 81-linoleum; or code 80-unclassified materials compounded with oil). But what about fires classified as code code 51-rubber; code 54-hay or straw; code 50-unclassified natural product; code 76-human hair; or code 00-completely unclassified? If each of these possibilities corresponds to another real product—say, an exercise mat—then exclusion of these inappropriate codes makes sense. But any code that does not correspond to another real product is probably a miscoding and so is best

treated as another type of partial or complete unknown, to be proportionally allocated and so added to the estimated number of total carpet fires.

For example, gasoline (code 23) is in the top 15 most frequently reported Types of Material First Ignited for home floor covering fires. Gasoline clearly refers not to the floor covering but to a substance spilled or poured onto the floor covering. Should such fires be excluded because they clearly do not involve a true floor covering as the first item ignited? Or should they be included on the basis that the gasoline leads to accelerated early involvement of the real floor covering in fire, and so floor covering is the first true product involved in fire? Or should they be excluded on the basis that the burning properties of the floor covering are irrelevant to a fire started with gasoline? Or should they be included on the basis that the relative ability of different floor coverings to absorb gasoline could make a difference in fire development? No matter what the decision, it will not be a simple one.

The gasoline example illustrates another general point. It may be tempting, when constructing national estimates, to exclude certain types of fires as not being fair tests of the product or the building design. This practice is unsound, as all fires involving a product or occupancy are relevant to an overall description of the fire problem associated with it. Factors that make the fire challenge seem unfair can be properly addressed at the stage of analyzing how much fire probabilities can be reduced or interpreting whether a certain fire probability is acceptably low. But exclusions should occur at those points, not at the initial stages of analysis, or else the engineering analysis will be conducted against a misleadingly optimistic view of the size of the problem to be addressed.

The most detailed and appropriate estimate of the incident frequency derivable from NFIRS-based national estimates may have been obtained after these decisions have been made and steps completed. It is not possible to ascertain, for example, age, style, specific materials, or specific burning properties of carpet from NFIRS. In some cases, further refinement is possible based on differential patterns of usage and their implications for areas of origin or for exposure to certain heat sources. Further progress depends on inference from a combination of incident data, usage data, and laboratory test data. The inference rules will be discussed after those types of data have been reviewed and discussed individually.

For now, let us return to the earlier statement that valid analysis of incident rates requires the use of a statistically representative database, like NFIRS and the NFPA survey. Many other databases exist that are much more detailed than NFIRS but are either known to be statistically unrepresentative or at best not known to be representative. To see why it is imperative that analysts not sacrifice statistical validity for detail, it may be useful to review a number of half-truths and widely held myths surrounding databases.

Data Half-Truths and Myths

Someone Must Collect the Data I Need Why? Who would have that much interest? It takes time and resources to collect data. Any organization that collects data will have a reason to do so. And the data they collect will be the data *they* need. On the other hand, some databases were developed to serve diverse purposes and constituencies. In 1974, the National Fire Prevention and Control Act, Public Law 93-498, Section 9, established the National Fire Data Center to "provide an accurate, nationwide analysis of the fire problem, identify major problem areas, assist in setting priorities, determine possible solutions to problems, and monitor the effectiveness of programs to reduce fire losses." This act established the U.S. Fire Administration and the National Fire Incident Reporting System (NFIRS). As another example, the U.S. Consumer Product Safety Commission (CPSC) uses data from the sample-based National Electronic Injury Surveillance System (NEISS) [8], which CPSC created, to develop estimates of the

number of injuries associated with consumer products and treated at hospital emergency rooms. In 2000, NEISS was expanded to provide estimates of all injuries seen in emergency rooms, not just injuries associated with products.

NFIRS and NEISS are examples of event databases. Both were designed to help quantify a very wide variety of problems and were not designed to "prove" a particular point.

When considering the use of data from a particular source, it is wise to consider why the data collection effort was undertaken in the first place. Who paid for it? Would the sponsors have a vested interest in a particular outcome? In some cases, data may be collected to promote an agenda. Because leading questions or other methodological flaws may make the data virtually useless, it is often helpful to review the survey instrument or form.

Biases may be unintentional but still serious. Sometimes a data collection effort was designed to answer one specific question and the results would not be applicable in other settings. Rural and urban experiences may differ considerably from each other; a study of big-city fire problems could not be applied to rural settings without refinement or reconfirmation. Moreover, data collection budgets are typically small. Most databases are limited to data that are easy to obtain. Both the accuracy of the data and the representativeness of the incidents captured must be considered highly suspect in any so-called opportunity sample.

Even in a well-designed and adequately funded data collection system with no deliberate bias some biases arise because of the relative difficulty of obtaining reliable information and universal participation. For example, fires in fully sprinklered buildings or buildings with good detection/alarm systems are more likely to be discovered and controlled by on-site resources. No data collection system based in organizations like the fire service can expect to capture unreported fires. The national estimates of fire problems that are produced by combining NFIRS data and the results of the NFPA survey only reflect data reported to municipal fire departments and exclude those handled by private fire brigades, federal fire-fighting organizations, or the occupants themselves. Further increasing this bias is the fact that some occupancies, particularly high-hazard occupancies, are more likely to have fire brigades than others.

Data on heat release rates at key points during a fire could be quite useful. Unfortunately, no one has the technology to measure or estimate such data outside a laboratory. Suppose one asked for readily observable change points in the fire, such as spread to a new room or floor. No one can expect to be in position to observe such change points at most fires. Firefighters do not have the discretionary time during a fire to check specific times and record them. When seeking data, it is important to ask how the data collectors would be able to obtain the data and how reliable they would be.

Anecdotes Describe Typical Incidents This is often not true. *Anecdotes* are what statisticians call data points from a database that has not been designed to ensure statistical representativeness. The NFPA Fire Analysis and Research Division runs an anecdotal database called the Fire Incident Data Organization (FIDO). A clipping service identifies significant incidents (e.g., large loss, multiple deaths), and additional information is requested from the fire service and other sources. NFPA conducts follow-up surveys of state fire marshals to ensure that records of fire fighter fatalities and these very serious fires are complete. However, FIDO also captures well-documented fires on an opportunity basis, and for these fires, FIDO is only anecdotal.

From early in the twentieth century until the mid-1970s, NFPA collected information on sprinkler activations [5]. However, over time the easily available data sources became less and less reliable in capturing smaller fires. As FIDO's representativeness for smaller fires declined, so did its representativeness in capturing sprinkler successes. More and more such incidents were missed, and a disproportionate number of captured incidents therefore showed sprinkler problems.

Anecdotal information like that provided by FIDO, NFPA Fire Investigations, or CPSC's In-Depth Investigations file can indicate the range and diversity of fires that *can* happen. Anecdotes cannot be used to estimate incident rates or probabilities.

A Rose Is a Rose Is a Rose Anecdotes are relevant but may not be representative. It is also possible to have representative data that are not relevant, even though they appear to be, because of differing definitions for the same terms. For example, definitions of data elements may differ in different countries or even different data collection systems. In fire incident databases, *space heater* refers to a heater for a relatively small area. The U.S. Department of Energy's Energy Information Administration uses the term *space heater* to describe *all* heating systems, including furnaces and other central heating units, on the theory that all of them are heating space, as opposed to heating water or food [9]. However, the term *heating equipment* in fire incident databases includes not only equipment to heat spaces but also water heaters.

If Data Were Collected, They Must Be Available The analyst's life would be easier if this statement were true. Unfortunately, it's not. Some data, such as the detailed information collected by insurance companies, are proprietary and confidential. Corporations may maintain incident records when injuries or mishaps occur, but they are usually under no obligation to share that information with the general public. Information collected by the government *should* be available. The public can generally obtain copies of reports or files that already exist. However, data may not be kept indefinitely and older data may never have been entered into modern, electronically accessible media. Many computer systems have not been integrated so analyses that are theoretically quite easy may be impossible without major conversion efforts. However, these problems are usually not insurmountable. Some modifications may be needed and sources of uncertainty must be documented. Considerable data are available, as noted, which means estimates of sampling-based uncertainty can be readily constructed.

Field Observation Data

Switching now from fire incident data to other kinds of data based on observations in the field, Table 78.1 cites field observation data as relevant to reliability analysis, including instances of unavailability or failures to perform with full effectiveness when needed despite being available, and emergency evacuation analysis. The chapter on reliability (Chap. 74) elsewhere in this handbook provides an overview of issues in, data sources on, and mathematical methods for analyzing reliability. At present, data to support reliability analysis are very scarce. However, the five types of data sources listed below are also relevant to other aspects of engineering analysis:

- Judgments and opinions
- Inspection and testing
- Simulations and laboratory studies
- Incident and other field data on systems performance
- Product life tracking systems

Judgments and Opinions

In the absence of data from systematic field observations, one can use estimates from individuals whose work experience has provided them with a long period of nonsystematic field observations. Methods like Delphi panels try to eliminate bias from the group process of consolidating expert opinions into consensus estimates. (Modified Delphi panels have been used to specify many of the scoring parameters for NFPA 101A, *Guide on Alternative Approaches to Life Safety*, the alternative evaluation scheme to NFPA *101®*, *Life Safety Code®*.) But shared biases remain and are commonplace. In particular, the mix of observations that occur in the normal course of a job in fire suppression, fire reconstruction, design, and so forth, is subject to many biases that may not be recognized by the experts. (For example, new buildings are more likely to be designed for the affluent end of the general or business population, whereas fires are more likely to occur at the less affluent end,

but neither tendency is absolute.) In addition, there is a tendency for individuals to shade their recollections in favor of a pattern that is simpler than the often complex truth. Thus, a system or feature with relatively high reliability will have its reliability estimated even higher (sometimes called the *halo effect*), while a system or feature with relatively low reliability will have its reliability estimated even lower (sometimes called the *horns effect*).

Inspections and Testing

A program of routine inspection and testing can provide statistically representative data on failure frequencies and severities and is particularly useful for failures that are less than total or that otherwise may not draw attention to themselves when they occur. *Frequency* is how often failure occurs, and *severity* is how damaging failure is when it occurs, so frequency numbers are in fact relative to the failure severity level being tallied. However, inspection and testing-based databases are usually proprietary and so not available for routine engineering analysis. And even when available, they are subject to some critical gaps and biases.

First, the inspections that provide this kind of data tend to be part of a very advanced maintenance program, which provides the principal justification for the high cost of frequent inspection and testing. Frequent maintenance and inspection, in turn, are more likely to occur with a better-trained and more safety-conscious workforce, so human error reliability problems, which tend to dominate mechanical and electrical problems for most systems and features in practice, are likely to be sharply lower. The resulting reliability figures will therefore tend to be much better than those achieved for more typical properties that lack the maintenance to achieve high reliability and the inspections and testing to measure their reliability.

Second, this form of data collection can miss transitory failure conditions, such as blocking a door open, or vulnerability to extremely rare external events, such as earthquakes. In both cases, the sampling in time represented by the inspections and tests may not be sufficient to identify an important problem, in the former case because the sampling points are too far apart and in the latter case because the sampling does not (and perhaps could not) cover a sufficiently long period of time.

Finally, the process of inspection and testing is itself subject to error. If inspection is limited to observation only, without more active involvement as with testing, the probability of error in observation can be quite significant. Most databases derived from inspections or tests do not consider this type of error.

In 2012 NFPA's Fire Protection Research Foundation began a project to develop guidance on how to use risk and reliability data and modeling more frequently and more systematically in the specification of inspection, testing and maintenance programs. There may be additional resources available from this project.

Simulations and Laboratory Studies

Exit drills are a form of simulation or laboratory study that provides data on human reliability (and performance) with regard to a range of safety-related behaviors. They illustrate the larger point that simulations and related studies are particularly useful for studying human error reliability, a critical aspect that tends to be less well addressed by other controlled-study data sources.

However, simulations may be less than realistic as a result of simplifications done to make the experiment repeatable and manageable, as well as those made to avoid undue risks to participants. A bench-scale fire test cannot be readily scaled up to real-scale fire effects and will avoid the high flux levels of a fully developed fire, in part to avoid harm to operators and equipment, but in so doing may create a misleadingly mild picture of real fire conditions. Even a room-scale test is unlikely to be set up with accelerants, high wind-speed ventilation, conditions promoting backdrafts, or some other factors that can produce the most severe fire conditions.

An evacuation drill may avoid bad weather days to avoid injury to occupants, but this may paint an unrealistically optimistic picture of how slow and hazardous real evacuations may be.

The field of ergonomics provides design solutions to many of the people–equipment interaction problems that studies and data like these identify.

Incident and Other Field Data on Systems Performance

In theory, the most appropriate database on the reliability of a system or feature would capture every naturally occurring test of its availability and performance (i.e., unwanted fires) and every other activation of the system (e.g., unwanted alarms). In practice, this requires constant monitoring, which is almost always too expensive to be implemented. Attempts to approximate such a database using only fires reported to fire departments or, even worse, fires reported in the media, will miss most incidents and can give a misleadingly pessimistic picture of reliability.

NFIRS makes it possible to estimate the percentage of fires in a specific occupancy in which fire detection equipment operated. In homes that had smoke alarms and reported fires considered large enough to activate the alarms in 2005–2009, the smoke alarms operated 85 % of the time. When powered by batteries only, they operated only 77 % of the time, but when hardwired, they operated in 92 % of the fires. The leading reason they did not operate was a missing or disconnected power source [10]. It is generally *not* possible to tell from aggregated fire experience data the portion of fires occurring in properties that complied with a specific portion of any applicable codes. NFIRS collects more information on automatic detection type, power source and failure reason, but it does not indicate proximity to area of origin, type of sensor used, if smoke alarms were interconnected or if the detection system was monitored. Nor does it capture the performance of fire protection features triggered by fire detection systems.

NFIRS provides useful data on sprinkler reliability. After excluding confined fires, fires in properties under construction, and fires in which the reason for sprinkler failure to operate was "Not in area of fire," wet pipe sprinklers were found to have operated in 95 % of the 2006–2010 residential fires that were large enough to activate the system and in 91 % of such fires in all occupancies combined. The reason for 53 % of the residential failures and 60 % of overall failures was because the system had been shut off [11].

All the databases described here tend to focus on active systems and other fire protection equipment. Passive fire protection features, such as fire walls, are less likely to be captured, in part because their failures tend not to be time-specific events (e.g., when a smoke alarm has its battery removed or a sprinkler valve is shut off, both events occur at defined points of time) but rather partial deficiencies in performance (e.g., a door is normally left slightly ajar or a wall has a hole in it). A poke-through hole in a wall, for example, is not a total failure of the wall and does not appear as an event in the course of the fire. Although it may have played a role in extension of the fire, it is unlikely to be identified in a post-fire analysis. It also may not fit your definition of a reliability problem, but it is clearly a deviation from intended design that affects and degrades performance. No incident database routinely documents fire development and related factors in enough detail to capture this kind of problem.

Product Life Tracking Systems

Some buildings maintain comprehensive tracking systems for safety equipment or other equipment throughout their productive lives. There will be information on what was bought; when it was bought; when it was installed; when and how it was maintained; and often when, how, and why it failed. When such a system includes enough identical products—or is connected to a larger database, such as might cover all the buildings owned by a large corporation or government agency—it

can support the development of very detailed reliability statistical distributions.

Usage and Exposure Data

Engineering analyses require usage and exposure data at several points. First, if the analysis addresses fire risk, then usage or exposure data (e.g., number of units of product in use, number of establishments of a particular type, number of people using a product or occupying a building, number of square feet of space devoted to a type of occupancy) are needed to convert incident data to estimates of ignition probability or to convert failure event data to estimates of reliability. Many engineering analyses, however, frame problems in ways that do not require explicit, quantitative treatment of ignition or reliability. Even these analyses still need some usage and exposure data in order to define and specify transitory conditions, such as the numbers, locations, and capabilities of occupants, that affect the achievement of fire safety objectives and so the performance of a design. For risk calculation, the principal challenge is to find statistically representative numerator data with enough detail and data definitions that are consistent or compatible with the definitions used by the denominator incident or data.

Heating Example of Matching Coding Categories Between Databases

NFIRS Version 5.0 has the following codes for heating equipment

100 Unclassified heating, ventilation, or air conditioning equipment
112 Heat pump
120 Unclassified fireplace or chimney
121 Masonry fireplace
122 Factory-built fireplace
123 Fireplace insert/stove
124 Heating stove
125 Chimney or vent connector
126 Brick, stone, or masonry chimney
127 Metal chimney, stovepipe, or flue
131 Built-in furnace or local heating unit, including built-in humidifiers, but excluding process furnaces or kilns
132 Furnace or central heating unit, including built-in humidifiers, but excluding process furnaces or kilns
133 Boiler (power, process, or heating)
141 Heater, including floor furnaces, wall heaters, and baseboard heaters, but excluding catalytic heaters, oil-filled heaters, and hot water heaters
142 Catalytic heater
143 Oil-filled heater, excluding kerosene heaters
144 Heat lamp
145 Heat tape
151 Water heater, including sink-mounted hot water heaters and waterbed heaters
152 Steam line, heat pipe, or hot air duct, including radiators and hot water baseboard heaters

Some of these specific types of equipment are part of distribution and are not specifically linked to any particular devices. A chimney, chimney connector, vent pipe, steam line, or hot air duct could be associated with a variety of different types of heat-generating equipment. Code 100 covers equipment that is unclassified or unknown as to heating equipment versus air conditioning or venting equipment. Heat pumps appear to be positioned as air conditioning equipment, in that the codes numerically to either side of code 112 are for air conditioning equipment or fans, but heat pumps can be used for either heating or air conditioning.

These categories correspond reasonably well but not exactly with the categories used by the U.S. Department of Energy to organize information on household usage of heating equipment [9]:

- Heat pump
- Central furnace with ducts to individual rooms
- Steam/hot water system with radiators or convectors in each room or pipes in the floor
- Built-in electric units in each room installed in walls, ceilings, baseboard or floors
- Built-in floor/wall pipeless furnace

- Built-in room heater burning gas, oil, or kerosene
- Heating stove (burning wood, coal, or coke)
- Portable electric heaters
- Portable kerosene heaters
- Fireplace
- Some other equipment)

As noted earlier, the U.S. Department of Energy uses the term "Space Heating" to encompass equipment intended to heat the environment as opposed to cooking equipment or lighting which might also get hot.

Version 5.0 of NFIRS captures data on the equipment power source when equipment is involved in the ignition, as shown in the following list, which also shows the Department of Energy categories:

- Three categories of electric-powered equipment: electrical line voltage, including typical house current; batteries and low voltage (less than 50 V); and other electrical (compared to the single electricity category in the Department of Energy usage categories)
- Three categories of gas fuel: natural and other lighter-than-air gas; LP- or other heavier-than-air gas; and other gas fuels, (compared to natural gas vs. bottled LP or propane gas in the Department of Energy usage categories)
- Five categories of liquid-fueled equipment: gasoline; alcohol; kerosene, diesel fuel, or numbers 1 and 2 fuel oil including furnace and bunker oil; numbers 4, 5, and 6 fuel oils; and other liquid fuels (compared to fuel oil vs. kerosene in the Department of Energy usage categories)
- Four categories of solid-fueled equipment: wood or paper; coal or charcoal; chemical; and other solid fuels (compared to wood, the only solid fuel specifically identified in the Department of Energy usage categories)
- Eight other specific power sources may also be recorded: compressed air, steam, water, wind, solar, geothermal, nuclear, and fluid or hydraulic power source

This comparison will suffice to illustrate the point that even modestly detailed incident and usage databases can present a multitude of compatibility problems. Some problems can be solved by one-time special data collection efforts to devise assignment rules for estimation purposes Some problems can be solved by examination of the technology alternatives and by asking data collectors what rules they use to resolve questions in the field. Some problems can be addressed by expert judgment. And some problems create limits to the level of detail achievable in the data.

Occupancy Example of Matching Coding Categories Between Databases

Another example has to do with occupancies. *Occupancy* refers to the use made of a space, and "property use" is the NFIRS code that describes occupancy of a property, whether a building or part of a building (such as a restaurant in a mall or on the ground floor of a high-rise multiuse building). The North American Industry Classification System (NAICS) codes for establishments are designed to classify the primary activity or line of the business that owns or occupies the building. In pursuit of its primary activity, a business may require and oversee many types of occupancies, from manufacturing to sales to office to storage to public assembly. The codes for businesses also distinguish retail from wholesale sales, whereas the NFIRS codes for occupancies do not. Is a wholesale sales operation an office building or a mercantile occupancy? Or is it an office occupancy and a storage occupancy sharing a building? (Or the two parts might not be sharing a building).

There are far more storage occupancies than there are buildings housing businesses whose defining purpose is storage. This means that no matter how one groups fires in storage occupancies, it is not clear that the data will match the data on establishments. Some storage occupancy fires will be in storage businesses, but many, perhaps most, will involve storage buildings in complexes associated with stores,

factories, or even homes. Garages, sheds, fire stations, barns, docks and marinas are all considered storage properties in NFIRS.

Mixed use complexes, such as shopping malls and high-rise buildings may host retail establishments, restaurants, parking garages, and residential living space all in one structure. A fire that starts in one type of occupancy may impact other types within the same structure.

Even when major categorization mismatches are not an issue, minor ones can be. NAICS codes identify gasoline service stations as a type of retail business. Version 5.0 property use code 571 identifies public service stations, but that category also includes LP-gas stations with associated convenience stores. In NAICS, LP-gas (bottled gas) dealers are under a separate retail code for fuel dealers.

Storage Shed $\neq$ Warehouse

If all the matching issues are addressed, then one must still consider the measurement scales available. The business code categories are used to count establishments, which is probably the best measure of exposure but also mixes very large and very small buildings without distinction. A better measure for fire risk analysis would probably be square footage, but those data exist only for highly aggregated categories of buildings. Business-coded data also exist on numbers of employees and dollars of payroll, both already related to business size but not clearly relevant to exposure proportional to fire risk. NFIRS collects total square feet or dimensions for non-confined structure fires. Users of this data would need to establish ranges to make the number of choices manageable.

Occupant Characteristics

Occupant characteristics must also be considered. Engineering analysis is done using scenarios, whether in terms of fire hazard or full analysis of fire risk. Most fire safety objectives trace, directly or indirectly, to a goal of protecting people. Short of a highly conservative (and generally unachievable) objective of preventing any fire effects in any occupied area, engineering analysis will need to address the fates of occupants, explicitly and quantitatively. This, in turn, requires data on the occupants, effective when fire begins. How many are there, where are they, how will they act, and what are they capable of?

A wealth of information exists regarding household structures, which may be useful in defining *occupant sets*—alternative descriptions of occupants for analysis, analogous to fire scenarios—for homes. Information is much less detailed for occupants of any other occupancy, and these will tend to be the types of buildings where engineering analysis is sought. For those properties, one will need to seek data from industry sources and special surveys. Absent such data, it will be tempting, and possibly necessary, to use ad hoc, heuristic methods to shape subjective estimates. Certain cautions must be noted in so doing.

1. Occupants do not respond in an ideal or perfectly efficient manner. They do not react immediately to the first cues of fire, they do not evacuate on the basis of perfect knowledge of conditions throughout the building, and they may evacuate in accordance with their normal patterns of movement rather than along rarely used paths best designed for quick, safe evacuation. Occupants may try to defend in place when they should not or try to evacuate when it would be safer to defend in place. None of this is a matter of panic or of irrational behavior or choices. It is not even unusual conservatism. It is simply a realistic view of how people respond to fire. In her article about how people respond to fire alarms, Guylène Proulx wrote that fire alarms are intended to meet four objectives: (1) warning occupants, (2) getting them to respond immediately, (3) starting the evacuation process, and (4) providing enough time to escape. She found that, in practice, people who hear a fire alarm tend to seek the reason for the alarm rather than assuming that a fire is occurring. They seek other cues such as the smell of

smoke, the sound of sirens, etc. If they do recognize a fire, they may engage in other activities such as fighting the fire, calling the fire department before evacuating, collecting belongings, or warning others [12]. Some evacuation models incorporate best available data on typical behavior and the time it takes. Optimizing models do not.

2. The places that have the most fires differ, not in kind but to a significant degree, from the mix of places in general. States that have higher fire death rates tend to have larger percentages of the population who are poor and less educated. These factors can have implications for buildings whose design, maintenance, and operation may be less fire safe, reflecting the limitations of their occupants, managers, and owners [13]. If a larger percentage of the adult population smokes, that is also associated with higher death rates. In 2010, smoking materials caused 21 % of all home structure fire deaths [14].
3. There are little data on how best to reflect occupant characteristics, and some of them may be moot for an engineering analysis of a well-designed new building, but analysts are advised to shade their assumptions and parameters toward less capability for occupants than the norm and much less capability than engineers see in their own lives, since engineers, like all professionals, are more affluent and better educated than the national average.
4. There are far more people with limitations in the general population than ever before, if only because there are far more people in the older age groups. Buildings open to the general public will see more and more occupants with limitations of age. The Americans with Disabilities Act has facilitated access to workplaces and places of assembly for many more physically challenged individuals, and the deinstitutionalization of many people with chronic mental illness decades ago led to a larger share of occupants with mental or emotional limitations. The diversity of physical challenges is also increasingly recognized. Many people have some limitations (wear corrective eyeglasses or contact lenses, for example), and there may be less data with which to model the many moderately limited occupants than there is to model the much fewer severely limited occupants. Data on health status, hearing and vision impairment, and difficulties in physical function are captured by the Centers for Disease Control and Prevention's National Health Information Survey. In 2010, 9 % of noninstitutionalized U.S. residents 18 years and older found it very difficult or impossible to stoop, bend, or kneel. Among those at least 75 years old, the percentage increased to 26 % [15]. These individuals could find it difficult to get below a smoke layer in a fire situation. Similarly 5 % of the surveyed population could not climb at least 10 steps without resting; 20 % of those 75 or over could not do so. Data on going *down* stairs were not provided but would be unlikely to be much more favorable. Sixteen percent of those over 18 had hearing trouble if they were not using a hearing aid, and 9 % had vision trouble, even with glasses or contact lenses. For those 75 and over, these percentages increased to 45 % and 16 % respectively. These limitations have important implications for relaying emergency information.
5. Occupant profiles can often be specified by linkage to time of day. Fewer occupants are in homes during the day on weekdays, and a different mix of ages and roles is found among those home during the day than the mix of home occupants in the evening or at night. In the evening, people will tend to be awake, while at night, most will be asleep. The American Time Use Survey collects data about how Americans 15 or older spend their time and the times of day they are engaging in specific activities [16]. In office buildings, the number, location, and other characteristics of occupants are clearly different during normal working hours than outside them. In hotels, different times of day will find different mixes

of occupants in the guest rooms, the small meeting rooms, the large function rooms, and the recreational facilities.

6. Fire incidence and casualty data can and should be used as input to the process of setting occupant characteristics, but usually those data should not be used directly. Suppose you created a list of scenarios, each associated with a different family structure, and you assigned scenario probabilities so that every age group was weighted the same as its share of civilian fire deaths. In such a case, when scenario fires were run and analyzed, the high-risk age groups would receive additional weighting based on their higher rate of deaths per fire, and the net result would be an age distribution for deaths that would overstate the death rate for the high-risk groups and understate it for the low-risk groups. In essence, the higher risk for certain age groups would have been factored in twice. It is easier to fix this problem for ages, because data exist on the age distribution for the population. However, for many other factors of interest—such as the number of deaths or injuries in which physical disability or alcohol impairment played a role, both of which are captured in fire casualty records—there may be no general-population data available for specific occupancies.
7. It is dangerous to limit the challenge posed by occupant characteristics with an assumption of code compliance or compliance with the latest model codes. The most deadly fires in eating and drinking establishments have involved serious code violations, including severe overcrowding. Many deadly fires have occurred in facilities that were not designed, operated, or licensed to provide more than personal care services, but that nevertheless proved to have occupants with severe limitations when a fire occurred [17]. It is unreasonable to expect a building design to protect occupants from fire in the face of pervasive, serious code violations, but it is not unreasonable to conservatively plan for at least occasional, transitory, but possibly significant violations, such as overcrowding or deterioration of occupant capability below the minimum level that allowed them to be admitted for residency. Serious fires do not usually happen where everyone follows all the rules and best practices. A design should be robust enough to protect people even when challenged beyond the strict limits of what is supposed to be possible.

Laboratory Data

For laboratory data on physical properties of fire, products, buildings, and so on, you should start with the other chapters of this handbook, which identify the measures of interest, put them in context, and in many instances, provide or reference best available data. Also, read the Chap. 73 for general guidance on handling error and uncertainty in data. For guidance on error and uncertainty in data from particular test methods consult precision and bias statements in the standards for those test methods or consult ASTM E691, *Practice for Conducting an Interlaboratory Study to Determine the Precision of a Test Method*.

On a related point, read the other chapters closely for guidance, specific to each type of data, on what to do if your case does not exactly match the specifications for any available test data. For example, consider the following questions.

1. Is it best to choose the closest documented case, or is extrapolation or interpolation better? How do you determine what is the closest? How far outside tested values can you extrapolate with reasonable confidence?
2. What do you do if the tests do not align along any linear scale, making direct interpolation and extrapolation impossible? (For example, there may be one result for each of several materials). Are there scaled characteristics that can be used as a legitimate, if unproven, basis for interpolation or extrapolation?

3. Is linear interpolation or extrapolation appropriate, or would another functional form be more appropriate?
4. In addition to the characteristics of the object or space for which you need data, are the fire conditions you anticipate the same as those used in the available tests? If not, do the differences matter and can they be adjusted for?

When analyzing data, also keep the following points in mind:

1. Scale matters. Results from bench-scale fire tests cannot be assumed to reflect full-scale performance.
2. Interactions also matter. Fire performance of products that are composites or layered combinations of materials cannot be predicted from test data on their constituent materials.
3. Time and usage change things. Products may change chemically or be altered physically, up to and including vandalism. All such changes may affect the applicability of test data on new products. This is even more true if the laboratory tests were on prototypes—or even prototypes with simplified design features—rather than on actual products ready for use.

In addition to direct use of laboratory test data, such data can be combined with incident data to provide greater detail. Consider the use of laboratory test data to build on the ignition probability estimates developed earlier for a specific product in the carpet and rug class. Under the section headed "Incident Data," the discussion showed how to develop floor covering fire estimates and then fabric or textile floor covering fire estimates. Suppose this national estimates approach suffices to provide probabilities of ignition for a product class (e.g., carpet or rug) but not for any type, style, or brand of that product class.

First, the universe of products in use (not the universe of products currently offered for sale) must be divided into a small number of representative pieces such that every variation of product in use is represented by one of these reference pieces. Second, data must be developed on the share of current usage (not the current market share). Then, laboratory tests must be conducted to determine relative ignitability.

Let $i = 1,\ldots, n$ be designations for n different representative pieces. Let u_i be the collective share of total usage accounted for by the ith piece and all the pieces represented by the ith piece. Let p' be the probability of ignition, derived from fire incident national estimates for the product in all its variations. Let p_i be the proportion of laboratory trials of the ith piece in which ignition occurred. Then, with all variations of product represented and none double counted,

$$\sum_{i=1}^{n} u_i = 1$$

The usage-weighted average frequency of ignition for the tested pieces is proportional to the experience-derived overall ignition probability for the product class.

$$\sum_{i=1}^{n} u_i p_i \propto p'$$

Therefore, the best estimate of the ignition probability for a piece of type i is

$$\frac{p' u_i p_i}{\sum_{i=1}^{n} u_i p_i}$$

This formula uses the incident data to calibrate the laboratory test data, or it uses the laboratory data to subdivide the ignition probability for the product class into more product-specific ignition probabilities.

Data Sources

It is impossible to list all the data sources that may be useful for engineering analyses. However, a number of principal sources are listed below, and the organizations that provide those databases will often have leads to specialized databases for specific purposes.

Incident or Event Data

National (U.S.) estimates based on NFIRS and the NFPA survey of the frequency and severity of reported fires can be obtained from

One-Stop Data Shop
National Fire Protection Association
1 Batterymarch Park
Quincy, MA 02269-9101
Telephone: (617) 984-7451
Fax: (617) 984-7478
E-mail: osds@nfpa.org
Website: http://www.nfpa.org/research

The National Fire Incident Reporting System (NFIRS) itself is administered by the U.S. Fire Administration. The codes used by NFIRS may be downloaded from http://www.nfirs.fema.gov/documentation/reference. Specific questions about NFIRS and requests for raw data may be submitted online or addressed to
NFIRS Help Desk
U.S. Fire Administration
16825 South Seton Avenue
Emmitsburg, MD 21727
Telephone: (888) 382-3827
E-mail: FEMA-NFIRSHELP@fema.dhs.gov
Website: http://www.usfa.fema.gov/data/nfirs/support/

The U.S. Department of Labor's Bureau of Labor Statistics collects a wealth of data about industries, employees, occupational outlook, demographics, workplace injuries, illnesses and deaths, prices, wages, and time use. Data may be accessed at http://www.bls.gov/data/.

The Department of Labor's Occupational Safety & Health Administration (OSHA) has an online database of accident investigations that may be searched by keyword, the North American Industry Classification System (NAICS) code, or the older Standard Industry Classification (SIC) code. These reports may be useful in fleshing out scenarios. Associated inspection reports indicate the number of violations found. Data may be accessed at http://www.osha.gov/pls/imis/accidentsearch.html. Additional resources on the site let the user search by OSHA standard to determine which SIC groupings have the most violations of that standard or which OSHA standards had the most violations. Searches for specific establishments are also possible. See http://www.osha.gov/oshstats/index.html.

Four types of data can be ordered from the National Injury Information Clearinghouse, including

- Sample-based estimates of injuries treated at hospital emergency rooms, from the National Electronic Injury Surveillance System (NEISS)
- Summaries of death certificate data on product-related fatalities
- In-depth investigations of product-related injuries or incidents, from CPSC's special studies and ongoing program of investigations
- Summaries, indexed by product, of CPSC Hotline reports, product-related newspaper accounts, and medical examiner reports

The NEISS data and the death certificate data could be used for event data and can be obtained from

National Injury Information Clearinghouse
U.S. Consumer Product Safety Commission (CPSC)
Washington, DC 20207-0001
Telephone: (800) 638-2775
Fax: (301) 504-0025
E-mail: clearinghouse@cpsc.gov
Website: http://www.cpsc.gov/about/clrnghse.html

NEISS data may be queried and publications, investigations, and related materials may be found at http://www.cpsc.gov/en/research–Statistics/.
Australian injury data can be obtained from
The National Injury Surveillance and Prevention Project
Research Centre for Injury Studies
GPO Box 2100
Adelaide SA 5001
Australia
Telephone: +61 8 8201 7602
Fax: +61 8 8374 0702
E-mail: nisu@flinders.edu.au
Website: http://www.nisu.flinders.edu.au

Sources of Usage and Exposure Data

For every year through 2012, the Bureau of the Census has released an updated *Statistical Abstract of the United States*. This publication

contains close to 1400 tables on demographics and economic activity and is a compilation of data collected by the U.S. Census and other entities. Some of the data would help establish usage and exposure. The companion publications, *State and Metropolitan Area Data Book* and the *County and City Data Book* contain similar data on their respective jurisdictions. Due to limited funds, the Census Bureau has stopped collecting data for these publications. It is possible that a private company may do so. Table source notes will help users from the published editions can lead users to the original sources.

Tables and ordering information on these publications are available http://www.census.gov/compendia/statab

Sources for data in the *Statistical Abstract* are often worth checking for possible additional information that may or may not be published elsewhere. Much of the information was originally collected by the U.S. Census Bureau. The Census Bureau's Statistics of U.S. Businesses uses Business Register, the NAICS coding system, a file of business establishments maintained by the Bureau, with Company Organization Survey for multi-establishment businesses as well as records from other agencies [18]. The Economic Census, conducted every 5 years, measures business activity by establishment [19]. Data are available at http://www.census.gov/econ/.

The Bureau of the Census and the U.S. Department of Housing and Urban Development (HUD) together produce the *American Housing Survey*. Data on housing can be obtained from http://www.census.gov/programs-surveys/ahs/. Additional information may be obtained by e-mailing ahsn@census.gov or phoning 7-888-518-7365.

Demographic and economic (exposure and usage) data from countries in the European Union can be obtained from Eurostat at http://ec.europa.eu/eurostat.

The U.S. Department of Energy's Energy Information Administration (EIA) conducts energy consumption surveys of residential, commercial, and industrial users. These surveys provide valuable information on equipment and fuel usage. The EIA will also be conducting surveys on alternative-fueled vehicles. Information can be obtained by contacting the
Energy Information Administration
1000 Independence Avenue, SW
Washington, DC 20585
Telephone: (202) 586-8800
E-mail: InfoCtr@eia.gov
Website: http://www.eia.gov/consumption/

Data from roughly 100 U.S. agencies have been compiled and are accessible through FedStats. Many databases may be downloaded by the user at http://fedstats.sites.usa.gov/.

Laboratory Data

The National Institute of Standards and Technology's (NIST's) Building and Fire Research Laboratory (BFRL) maintains a number of databases with experimental data that may be useful for modeling. All can be accessed through http://fire.nist.gov/ by following the menu to the data listings. They include the following:

- Fire experiment results, emphasizing heat release rates, suitable for zone modeling
- Diffusion flame measurements
- Residential fire sprinkler tests done by BFRL
- Home smoke alarm tests conducted as part of the so-called Dunes II project
- Tests of rail vehicles and their interiors and contents
- Firefighting agents
- Tests of treated versus untreated vinyl siding in wildland/urban interface

John R. Hall Jr. is retired from his former position of division director for the Fire Analysis and Research Division at the National Fire Protection Association.

Measuring Consequences in Economic Terms

79

G. Ramachandran and John R. Hall Jr.

Introduction

In any fire risk analysis or risk-based assessment, valid measurements of the severity of the fire hazard—the consequences of fire, if it occurs—are of paramount importance. Most analyses are limited to simple outcome measures, such as numbers of deaths or injuries or direct property damage, defined as direct harm to property requiring repair or replacement.

Consequences have to be expressed in monetary values if the purpose of the analysis is to permit a decision maker to express and compare all relevant costs and benefits of different choices in comparable terms that truly capture what is important to the decision maker or the group represented (such as the general public).

The rapidly growing use of performance-based fire protection design exemplifies the need for these advanced methods of consequence measurement at the level of an individual building or product, just as the growing number of countries demanding cost-benefit analysis of proposed new national regulations illustrates the need for these methods of measurement at the level of national policy.

This chapter describes some of the oft-neglected aspects of consequence measurement in support of economic decisions about fire protection engineering choices, specifically

- An overview of the total cost of fire and of efforts to prevent or mitigate fire
- A discussion of how the relevant costs and benefits for the same choices may vary, depending on whether they are analyzed from the point of view of an individual, an organization, or society as a whole
- An overview of how costs and benefits are treated for insurance purposes
- Methods for translating nonmonetary consequences—notably deaths and injuries—into monetary equivalents for purposes of analysis
- Methods for estimating indirect losses—mainly business interruption costs—caused particularly by large fires
- Utility theory and its role in capturing people's preferences for certainty in outcomes

Principles of life-cycle costing are relevant but are covered at length in Chap. 81. Chapter 81 also provides additional material relevant to many of the subjects covered in this section. A more extensive treatment of these topics, with a range of examples, can be found in *The Economics of Fire Protection* by G. Ramachandran [1].

Components of Total National Fire Cost

For more than two decades, the World Fire Statistics Centre (WFSC) has issued periodic

G. Ramachandran (✉)
Operations Research Section at the Fire Research Station of the United Kingdom

J.R. Hall Jr.
Retired from National Fire Protection Association

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_79, © Society of Fire Protection Engineers 2016

studies with comparative statistics from 15 to 20 countries on the total cost of fire [2]. Their methods are the starting point for most national analyses, including more detailed analyses from the United States and Canada [3]. The WFSC methodology tracks deaths and injuries, which are not converted to monetary equivalents, but focuses on four core economic components:

- Damages due to fire, whether reported or unreported (for a fire service database), insured or uninsured (for an insurance database), direct or indirect (where indirect loss includes business interruption losses—also called consequential loss), temporary lodging, missed work, and other costs or lost income associated with recovery from a fire
- Costs of fire-fighting organizations, typically dominated by or limited to the costs of municipal career fire service organizations
- Incremental construction costs for buildings attributable to fire safety requirements or concerns
- Administrative costs of fire insurance, including profits

Table 79.1 shows these costs from 1980 to 2011 for the United States [4]. The reports of the World Fire Statistics Centre show comparable figures for many other countries, primarily in Europe but including Japan and Canada. Comparisons are made easier because all loss figures are also shown as percentages of national gross domestic product (GDP). The total U.S. percentage for these core components typically runs about 1 % of the GDP. The United States tends to have one of the lower percentages for fire damage and fire insurance administration (although the latter is especially hard to calculate and has proven quite volatile from year to year). The United States tends to have one of the higher percentages for costs of fire-fighting organizations and for fire-related costs of building construction (although the latter is a subjective estimate, based on some special studies).

Table 79.2 shows the relative importance of the four core components of total cost and how that relative importance has changed over the 32 years studied. The costs of fire-fighting organizations and building construction for fire protection—where the U.S. figures tend to represent one of the higher GDP percentages—are by far the two dominant components of the total cost core, and their dominance has been growing. Not shown in Tables 79.1 and 79.2 are two other important points. First, in nearly every country providing indirect loss figures, indirect losses tend to be less than 25 % of direct damages (notably excepting Switzerland at roughly 40 %). Second, the U.S. fire death rate, relative to national population, consistently ranks among the highest rates in the countries studied by the World Fire Statistics Centre.

Indirect Loss Estimation: NFPA Approach to U.S. Losses

NFPA did a special study to provide a better basis for calculating indirect loss for properties other than homes. It found that indirect loss varied considerably as a fraction of direct damage from one type of property to another. Based on analysis of 109 fires from 1989, indirect losses (principally business interruption costs) add the following amounts to direct loss, based on property class:

- 65 % for manufacturing and industrial properties
- 25 % for public assembly, educational, institutional, retail, and office properties
- 10 % for residential, storage, and special-structure properties
- 0 % for vehicle and outdoor fires

These percentages may appear low to anyone whose sense of indirect loss is based primarily on a few well-publicized incidents where indirect losses were much larger than direct damages. From a statistical standpoint, however, such incidents are more than offset by the far more numerous incidents where indirect loss is either small or nonexistent.

There remains the problem of quantifying indirect loss associated with properties that never reopen. Here again, the overall pattern is much more modest than some figures that have circulated. Each year, an estimated 2 % of reported nonresidential structure fires, excluding fires in storage facilities and special structures

Table 79.1 Estimated core total cost of fire in the United States (in billions of dollars)

Component of cost	1980	1985	1990	1991	1992	1993	1994	1995	1996
Economic losses	7.9	9.1	9.8	11.8	10.8	10.9	10.4	11.7	12.0
Reported	6.3	7.3	7.8	9.5	8.3	8.5	8.2	8.9	9.4
Unreported	0.3	0.4	0.6	0.8	0.7	0.9	0.8	0.9	1.0
Indirect	1.3	1.4	1.4	1.5	1.7	1.5	1.5	1.9	1.6
Career fire departments	5.7	8.5	13.2	13.8	14.4	15.4	16.1	17.1	17.7

Note: Sums may not equal totals because of rounding error. Figures are not adjusted for inflation except for total rows in 2011 dollars; other figures are as reported in those years. Some figures for earlier years have been changed from earlier total cost reports to reflect revisions shown in published sources. Net fire insurance includes the difference in economic losses between published insurance figures and the figures shown here. Economic losses in 2001 include the unique events of the 9/11 attacks

(e.g., vacant properties, properties under construction, structures that are not buildings), result in business closings. For NFPA's analysis of indirect losses in the United States, a closing is estimated to imply indirect losses equal to four times the reported direct loss in the fire.

These very rough calculations suffice to estimate indirect loss for purposes of a national analysis of total cost from society's point of view. They clearly are not sufficient to produce estimates suitable for insurance purposes or any other decision making at the level of an individual firm. Also, detailed estimates of consequential losses to the national economy should reflect several economic factors, including level of employment or unemployment, level of capacity utilization, volume of exports and imports, exchange rates, and performance of national and international competitors. Due to the interactions of these factors, a detailed evaluation of consequential losses to the national economy is a complex problem requiring the application of

Table 79.2 Changes in components of core of total cost of fire in the United States, 1980–2011

Component of cost	Percent change 1980–2011	1980 percent share	2011 percent share
Economic loss	+89	28	14
Career fire departments	+641	20	39
Net fire insurance	+392	14	19
Building construction for fire protection	+193	38	29
Total	+283	100	100
Consumer price index [a]	+173		

Sources: Table 79.1; consumer price index data from U.S. Bureau of the Census, Statistical Abstract of the United States, Washington, DC (1999–2013)

Note: Sums may not equal totals because of rounding error. The estimated core of total cost of fire has increased more from 1980 to 2011 (283 %) than the increase due to inflation for the same years (173 %)

[a]In other words, $1.00 in 1980 consumer goods would have cost $2.73 in 2011

econometric models, such as input-output analysis. These national factors do not apply to analysis at the level of an individual firm.

The effects of a fire on the earning capacity of a firm can be measured in terms of loss of profits during the period of interruption following the damage until the resumption of the activity in which the firm was engaged before the fire. Loss of profits is usually expressed as a percentage of loss of turnover. A cover against this loss can be obtained by purchasing a consequential loss insurance policy, the premium for which is a function of the period of indemnity. Loss of profits sustained by a supplier or customer of the firm that suffered the fire (called the "fire-hit firm" from here on) can be covered by a normal consequential loss policy based on reduction in turnover.

The form of insurance policy in more general use in the United States is known as business interruption insurance (BII). BII operates on lines similar to the U.K. contract of consequential loss insurance (CLI) with a turnover specification, though there are some differences. For private sector level insurance firms transacting BII or CLI, there are useful sources of data for estimating consequential losses due to fires in industrial and commercial premises. Organizations such as the Insurance Information Institute in the United States compile consequential loss data furnished by major insurance firms.

Indirect Loss Estimation: Unpublished U.K. Study

Returning to national- and society-level analyses of indirect or consequential loss, some now-old studies done in the United Kingdom illustrate how a more detailed analysis can be done. The U.K. government's Home Office carried out two research studies between 1970 and 1980 on consequential losses to the national economy. The first study adopted an input-output-type model in which all losses were considered output losses [5]. Losses were either (1) losses in the type of output actually hit by fire or (2) losses in some other output, because production factors (e.g., fixed assets, entrepreneurial effort, or labor) have been less effectively employed as a result of the fire. The effects of a fire were assumed to have the most impact on the fire-hit firm, the supplying firm, the purchasing firm, the parallel firm, and the rest of the economy. A fire-hit firm was defined as a compartment of production covering just that type of output hit by a fire and no other output. A parallel firm was defined as the compartment of a firm that produced in parallel to the fire-hit compartment (which might be in the same firm or in another firm). Any effects in a parallel firm or somewhere else in the rest of the economy were assumed to be included in the calculation of the effects in a fire-hit firm, in a supplying firm, or in a purchasing firm.

In this Home Office study, consequential losses were measured by the net present values of streams of annual outputs lost by the fire-hit firm, supplying firms, and purchasing firms. In regard to the fire-hit firm, it was necessary to determine a length of time over which fixed assets destroyed by fire were assumed not to be replaced by extra investment in the economy. This time choice had to depend on a view of the future course of the economy, which depended on unknown events and influences. Hence,

alternative calculations were produced based on the remaining lives of the assets and on a number of shorter periods. The net present values were corrected within the fire-hit firm, supplying firms, and purchasing firms for offsetting influences due to two factors. First, some production factors affected by fire might be used elsewhere in the economy. Second, production factors already employed elsewhere might be used more intensively. The extent of such offsetting influences would depend largely on the level of employment and the pressure of demand in the economy. Separate calculations were made for three alternative cases—slack, middle, and tight conditions in the economy. Results were given for each of 15 industries, including a factor by which a fixed assets valuation should be multiplied to give the sum of all the corrected output losses.

In order to verify the assumptions employed and results obtained in this study, the Home Office commissioned field research aimed at an in-depth investigation of a small sample of fires [6], which involved direct contact with fire-hit firms and concentrated on direct, consequential, and, hence, the total loss to the U.K. economy from industrial, distributive, and service sector fires. Consequential losses were considered to arise from loss of exports, extra imports, the diversion of resources from other productive activities, and reduction in the efficiency of resource use following the fire. The study assumed that there was full-capacity utilization of resources and that market values of the resources reflected their true worth. Insurance estimates of losses were used as measures of the assets destroyed in fires. Application of national capital output ratios translated these asset losses into losses of output from fire. Allowances were made for the secondary impact on suppliers and customers of fire-hit firms and for the impact of the level of capacity utilization. A correction factor was applied to account for the ability of the economy to "make good" the losses of the fire-hit firm by other firms.

The analysis produced estimates of the ratios of consequential to direct losses to the economy for "off-peak" and "peak" years and for each industry and service sector. The main conclusion was that most fires, except those in chemical and allied industries, produced no consequential losses to the national economy. Only in one sector (chemicals) was evidence found of a statistical link between consequential losses and direct losses. The study failed to estimate this link for other sectors and a number of other possible effects on consequential losses. Note the similarity of this conclusion to the results of the much smaller, rougher, and more recent NFPA study, leading to the indirect loss parameters still used in the United States.

Indirect Loss Estimation: Private Sector Level

A study by Hicks and Liebermann deals with costs and losses from the community and private perspective as they impact the fire victim [7]. The property class categories addressed in this study were commercial occupancies only, separated into four types: (1) mercantile, (2) nonmanufacturing, (3) manufacturing, and (4) warehouses. The authors considered first the following expression, based on a convenient formulation of the Cobb-Douglas production function [8]:

$$IL = ke^{rT}E^{a}X^{1-a} \tag{79.1}$$

where
IL = Indirect loss
K = Constant
r, a = Regression coefficients
E = Expenditure for fire protection (–)
X = Number of fires (+)
T = Time (surrogate for technological advance) (–)

The signs in parentheses relate to the expected values of the coefficients for the independent variables. The term ke^{rT} is a scalar factor in which r measures increases in fire department efficiency due to technological advances in suppression equipment, training, or facilities as well as altered building codes, smoke alarms, and the like. Equation 79.1 can be converted to a multiple-regression model by taking logarithms of terms on both sides.

In principle, the parameters r and a can be estimated but, in practice, sufficiently detailed statistics typically are not available. The authors therefore adopted the following, much more simplified, form:

$$IL = c(DL)^b \tag{79.2}$$

where DL is the direct loss and c and b are constants. Equation 79.2 is based on the assumption that very small fires typically generate small indirect losses while large fires produce larger indirect losses. If $b = 1$, this model reduces to the earlier-cited approach used by NFPA, wherein indirect losses are estimated as proportional to direct damages.

The results obtained by Hicks and Liebermann [7] are given in Table 79.3. Note that all values of the parameter b are near 1, which means the deviations from the even simpler model used by NFPA are modest. Statistical tests of significance showed that the regression model fitted well with the data in all the cases except warehouses. Since nationally aggregated data were utilized, it was recommended that the occupancy-specific models be used only at the national level and that any desired analysis of local impacts be accomplished using a local model. The value of parameter b has been estimated to be greater than unity for local and national levels and less than unity for the occupancy levels. For any increase in direct loss, the ratio of indirect to direct loss would increase if $b > 1$, and decrease if $b < 1$. The ratio would be a constant if $b = 1$. From the information given in the study, it was not possible to test whether the value of b was significantly different from unity for any of the six levels.

Table 79.3 Relationship between direct and indirect fire loss model parameters [7]

	Parameters (from Equation 79.2)	
Level	c	b
Local	0.203	1.146
National	0.015	1.245
Mercantile	0.109	0.889
Nonmanufacturing	0.069	0.874
Manufacturing	0.135	0.890
Warehouse	0.047	0.804

Indirect Loss: Illustrations from Some Major U.S. Fires

It is not difficult to identify large, well-publicized fires in which the cost of business interruption far exceeds direct property loss, such as a property that offers lodging or workspace and suffers so much damage that the slack capacity of the facility or even the community is not sufficient to absorb the displaced demand. An example is the MGM Grand Hotel fire, where the hotel claimed total direct damage and business interruption costs of $211 million, whereas NFPA's best information placed direct damage at $30–50 million [9].

Sometimes, though, it can be difficult to determine what the true net loss due to business interruption is—what constitutes an "interruption." Compare two large high-rise office building fires [10, 11]. Fire destroyed four floors of the 62-story First Interstate Bank building in Los Angeles in 1988 but also took the entire building out of service for 6 months—a true business interruption, because the property reopened after repairs.

By contrast, the 1991 One Meridian Plaza fire destroyed more floors in a shorter high-rise office building (38 stories) and the building never reopened. Dozens of firms, occupying nearly a million square feet of office space, had to seek new permanent homes, but the real estate community estimated, a year after the fire, that vacancy rates would still be 11–12 % *after* every displaced firm had been absorbed.

One Meridian Plaza represented an estimated 2.5 % of Philadelphia's office space, whereas the MGM Grand represented a larger share of Las Vegas area hotel rooms. These are all factors in determining how easily a market can compensate for interruption of capacity from one provider. Similar concerns arise for fires in any type of large multiunit residential or health care occupancy.

The most clear-cut examples of widespread vulnerability involve critical elements of the nation's infrastructure. Fears of great damage from a widely distributed computer virus have so far not materialized, and two major interruptions to the northeast electrical power

grid in the last third of the twentieth century were not due to fire. However, there have been two fires involving telephone exchanges, the more recent in Hinsdale, Illinois, in 1988 [12].

A total of 38,000 customers were served by the Hinsdale office. The majority were still without service 5 days after the fire, and some did not regain service until 9 days after the fire. An estimated 9000 businesses were affected, including a nationwide hotel chain's reservation service, a florist delivery service networked to 12,500 florists around the country, and communications between a Federal Aviation Administration control tower and both of Chicago's major commercial airports. The most conservative estimate of the costs of the associated delays and lost business would exceed the estimated $40–$60 million in direct damage.

Economic Costs Not Usually Calculated Within the Core

Several cost components have been estimated by Meade but cannot be readily estimated each year [3]. They totaled $27.8 billion in 1991 and consist of the following:

- Costs of meeting fire grade standards in the manufacture of equipment, particularly electrical systems equipment and "smart" equipment with its greater use of computer components ($18.0 billion)
- Costs of fire maintenance, defined to include system maintenance, industrial fire brigades, and training programs for occupational fire protection and fire safety ($6.5 billion)
- Costs of fire retardants and all product testing associated with design for fire safety ($2.5 billion)
- Costs of disaster recovery plans and backups ($0.6 billion)
- Costs of volunteer and paid activities involved in preparing and maintaining codes and standards ($0.2 billion)

The largest piece by far is the first one. Meade's study developed estimates, by industry, firm, or individual making the estimate, that ranged over two orders of magnitude, from 20 % to 2000 % add-on cost. He settled on 30 %, which seems conservative. However, out of the fraction of equipment that could be affected by these costs, his estimate of the share that is built to these more demanding standards is not conservative. His estimate raises the concern that the fire safety spending habits of industry's most fire-conscious companies have been treated as typical of all industry.

Based on the Consumer Price Index, the $27.8 billion estimated by Meade for 1991 would translate to $45.9 billion in 2011 in the United States. The NFPA now adds a figure for national and state fire agency costs, which was $3.0 billion in 2011.

Costs and Benefits Based on Level

The previous discussion noted that the calculation of indirect loss is done differently if the focus is on an individual firm or on the entire society. Any calculation of costs and benefits associated with fire, fire prevention, or mitigation activities and decisions will show differences based on level, because costs and benefits do not fall equally on all parties.

A fire that interrupts or destroys the ability of a single firm to offer its goods or services to the market results in devastating indirect loss to that firm. Society, however, may experience no discernable effect, provided that

1. The firm represents a small part of its industry, so that neither price nor availability of its products or services is affected by the removal of the firm.
2. The firm represents a small part of the employment opportunities in its community, so that its employees are able to find comparable work and income quickly and easily.

Conversely, a fire that results in little on-site damage but creates devastating environmental damage on the surrounding area, through air or water pollution, may represent a negligible cost to the firm, provided it is able to disown the off-site costs and pay minimal legal costs to do so. Meanwhile, the cost to society is enormous.

The second example cited above involves direct damage to property, and its central premise—that the firm could disavow off-site

damages if they were sufficiently difficult to measure and to trace to an event on the firm's site—is probably far-fetched in today's world. The first example cited above involves a major type of indirect loss, sometimes called business interruption loss or consequential loss, and that example is not at all unusual.

Analysis can be done at many different levels—the individual person, the individual firm, the individual community, the individual industry, the individual state or province, the individual industry plus all industries strongly dependent on it, the individual nation, the entire world—but for purposes of analyzing business interruption or consequential loss, it may be useful to focus on two major levels of economic activity: (1) private sector and community level and (2) national and societal level. The first level includes the fire-hit firm and the firms supplying to or purchasing from the fire-hit firm's materials, components, or services. Costs associated with moving, temporary accommodation, and lost profits are valid costs at the private sector level but not at the national level.

At the national level, the loss of a specific unit of productive capacity may be spread among the remaining capacity in the nation such that competitors may seize the opportunity to enter the market and maintain the national rate and volume of manufacture. In such cases, there may be little or no incremental loss to the national economy as a result of a fire in the premises of, for example, a manufacturing firm. Several studies by the now-defunct Insurance Technical Bureau (ITB) in the United Kingdom provide an indication of the various special factors one should consider in the evaluation of consequential losses due to fires and other hazards.

A small share of the total number of production lines in a plant manufacturing pharmaceutical products may generate a very large proportion of total gross profits [13]. Regulatory restrictions may limit possibilities for shifting manufacture to other plants or even to other lines in the same plant. Natural raw materials may be irreplaceable or out of season, creating another source of delay in recovery or another obstacle to meeting demand during the recovery process. Specialized plant equipment (e.g., tailor-made driers or centrifuges) may involve long delays for replacement. Loss of laboratory facilities may seriously interrupt testing and quality control programs.

The aerospace industry is another example where innovation driven by research creates a very short cycle time for the introduction of new products. In such cases there may be little redundancy in the supply of prototypes or other essential elements needed to keep the program on schedule [14]. Examples might include a new aircraft prototype assembly, untried or unproven research and development projects, or specimens for fatigue testing of aircraft structures. Loss of any of the above could result in a significant interruption to the program. In addition, the effect of delays in the development or supply of components or assemblies from specialist equipment manufacturers can be serious. The interactions of the many activities and firms involved in the manufacture of aerospace products makes for involved consequential loss considerations.

An example from the other end of the spectrum of industries would be resin, paint, and ink manufacture, which would not normally be expected to give rise to unduly high consequential loss [15]. Facilities are generally dispersed in small units throughout a given country, and there may be sufficient manufacturing capacity to absorb temporary loss at individual sites. Also few, if any, products are so special that they cannot be made elsewhere in the industry. Consequential loss, therefore, hinges primarily on the time for reinstatement of the plant and the ability of management to arrange for the supply of goods from other sources, pending a return to full production. Loss of raw materials or finished goods normally results in relatively short interruption periods. However, longer periods may be required for the replacement of tanks and pumps destroyed by fires, and for other hazards, such as explosion.

Due to high investment costs, specialized equipment (e.g., electronically or computer-controlled equipment) is generally used at full

capacity in some industrial processes. Continuous operation of these processes may reduce the chance of a fire spreading but provides no scope for making up for lost production following a fire. Specialized equipment damaged by fire cannot be replaced easily or quickly, especially if the assemblies or spare parts for them have to be imported. Industries using such equipment are liable to sustain high consequential losses.

Measurement Approaches in the Insurance Industry

Statistical (actuarial) techniques are well developed for calculating the insurance premium for loss of profits due to fire (e.g., see Benckert) [16].

The risk premium is a function of the period of indemnity and is generally expressed as the product of the loss frequency and the mean amount of loss. The loss frequency is assumed to be independent of the period of indemnity. The frequency function of the period of interruption following a fire has a log-normal distribution [16, 17].

An insurance company generally adds two types of loading to the risk premium to calculate the premium payable by a policyholder. First, a safety loading is added toward chance fluctuations of loss beyond the expected loss. Second, another loading is imposed to cover the insurer's operating costs, which include profits, taxes, and other administrative expenses. A number of texts have been published on different types of insurance and claims concerned with consequential losses (e.g., see Riley) [18].

Monetary Equivalents for Nonmonetary Costs and Consequences

Deaths and Injuries

Damage to life or health in terms of injuries and deaths is an important consequence in fire risk assessment and is usually the first priority consequence cited in national codes or regulations. Its importance is not in question. What is difficult is identifying a valid and acceptable method for estimating and comparing monetary equivalents of consequences of this type with costs and monetary equivalents of consequences of other types, such as property damage or indirect/consequential loss.

Insurance claims provide some data for the valuation of injury, though they are likely to be limited to costs mediated by the marketplace, such as treatment costs and the value of work time lost. Other costs, such as pain and suffering, are more difficult to evaluate.

The specification of a dollar equivalent for human losses, particularly for loss of life, remains an extremely controversial subject. It is important to emphasize that no one intends to suggest that there is an acceptable price for losing one's life. Rather, these figures are intended to reflect a social consensus on the value of changes in the risk of death by fire. For example, if most people say they would be willing to pay $1500 to reduce their lifetime risk of dying in a fire from, say, one chance in 500 to one chance in 1000, then a simple way of restating that is that people value a life saved at $1500 for 1/1000 of a life, or $1.5 million per life.

Four approaches to valuing human life have been identified. The first method is concerned with gross output based on goods and services that a person can produce if not deprived, by death, of the opportunity to do so. Sometimes gross productivity is reduced by an amount representing consumption (net output). Discounted values are generally taken to allow for the lag with which the production or consumption occurs. The output approach usually gives a small value for life, especially if discounted consumption is deducted from discounted production. This must be so since the community as a whole consumes most of what it produces. It is argued that when a person dies, although the community loses that person's future output, it also saves concurrent future consumption. The person's own consumption or the utility that would be derived if the person were alive is not counted as a loss. This approach received considerable emphasis, say, 30 years

ago, but not today. A variation of this approach is called the "livelihood approach" [19].

The second approach assumes that if an individual has a life insurance policy for $\$x$, then he or she implicitly values his or her life at $\$x$. Collection of necessary data from insurance companies is not a difficult task, and this is the major advantage in adopting the insurance method. There are, however, two drawbacks to this method. First, a decision whether or not to purchase insurance and the amount of insurance is not necessarily made in a manner consistent with one's best judgment of the value of his or her life. This decision depends largely on the premium the insured can bear from his or her income, taking into account family expenditures. Second, purchasing an insurance policy does not affect the mortality risk to an individual. This purchase is not intended to compensate fully for death or to reduce the risk of accidental death. Hence insuring life is not exactly a value tradeoff that is considered between mortality risks and costs.

The third method for assessing value of life involves court awards to heirs of a deceased person as restitution from a party felt to be responsible for the fatality. Here again, collection of necessary data is not a problem. Assessment of values of life could also be expected to be reasonably accurate since lawyers and judges have a massive professional expertise in the ex post analysis of accidents. The object of such an analysis is to discover whether the risk could have been reasonably foreseen and whether the risk was justified or unreasonable.

There are, however, a few problems in using court awards for valuing human life. The court should ideally be concerned with the assessment of suitable sums as compensation for an objective loss (e.g., loss of earnings of the deceased) as well as for a subjective loss (e.g., damages to spouse and children for their bereavement and grief). In some countries damages can include a subjective component for pain and suffering of survivors, but certain courts are generally against such compensation for subjective losses to persons who are not themselves physically injured, believing that bereavement and grief are not losses which deserve substantial compensation. It is also difficult to value the quality of a life that has been lost. People who themselves suffer severe personal injury, of course, qualify for substantial damages for subjective losses. Resource costs such as medical and hospital expenses are significantly higher for obvious reasons in serious injury cases than in fatal cases; hence, awards for subjective losses tend to be much larger and more important in serious nonfatal cases than in fatal cases. Some courts have also limited to very low levels the damages that may be awarded for reductions of life expectancy. Last, in court awards risks to individuals are considered relative to the plaintiff and costs to the defendant. However, value judgments are likely to vary according to whether the individuals making these judgments are associated with the plaintiff, the defendant, or the court.

The fourth approach is the one most widely adopted for valuing life. The willingness to pay is based on the money people are willing to spend to increase their safety or reduce a particular mortality risk [20, 21]. It is difficult to differentiate between the benefit from increasing people's feeling of safety and that from reducing the number of deaths. Anxiety is a disbenefit even if the risk is much smaller than believed. Likewise, a person who dies from something whose risk is not known to him or her still suffers a loss.

This approach to value of life rests on the principle that living is a generally enjoyable activity for which people would be willing to sacrifice other activities, such as consumption. The implied value of life revealed by a willingness-to-pay criterion would depend on a number of factors. The acceptable expenditure per life saved for involuntary risks is likely to be higher than the acceptable expenditure for voluntary risks, as people are generally less willing to accept involuntarily the same level of risk they will accept voluntarily. The sum people are prepared to pay to reduce a given risk will also depend on the total level of risk, the amount already being spent on safety, and the earnings of the individuals.

The theoretical superiority of the willingness-to-pay method begins with its connection to the

principle of consumer sovereignty, which says goods should be valued according to the value individuals put on them. Despite this individual-oriented underpinning, this approach can also be used to develop a general figure for a typical person, based on consensus patterns in the values individuals select. This, in turn, permits analysis of societal decisions using the willingness-to-pay principle.

Surveys have shown variability and inconsistencies in responses, because individuals have difficulty in answering questions involving very small changes in their mortality risks [22–24]. Due to insufficient knowledge about the risk, most people find it difficult to accurately quantify the magnitude of a risk. Also, the benefits are often intangible (e.g., enjoyment, peace of mind). It is difficult to put a monetary value on these factors.

Economists therefore use a variety of inferential methods to develop value of life and value of injury averted estimates for purposes of analysis. These include examination of patterns from the other three approaches—foregone future earnings, insurance policy amounts, and especially court judgments. It is also possible to develop an inferred value of life risk reduction from any action that has a cost and achieves such a reduction. Studies have been done of the implied value of life associated with hundreds of safety- and health-related regulatory actions. Studies could be done based on the price and demand curves for safety-oriented products, such as smoke alarms and child-resistant lighters.

It is useful to keep in mind the very wide variation in the estimates and valuations and the implied uncertainty as to what values are reasonable. For example, a landmark 1981 study cited sources for values of statistical life ranging from $50,000 to $8 million [25]. More recent valuations have been higher generally but still vary widely.

Economists at the U.S. Consumer Product Safety Commission (CPSC) have an ongoing program of studies of injury costs. Periodically, they review the literature, including their own studies, and select dollar values for use in policy analysis of fire safety and other product hazard analysis. The NFPA studies of the total cost of fire in the United States use values of $5 million per death and $166,000 per injury as 1993 values, then use the Consumer Price Index to calculate corresponding values for later years *for injuries only*, all in accordance with the practices of CPSC economists. Special studies have changed the NFPA methodology of estimating costs for injuries, adding a multiplier of 60% to civilian injuries, 30% to firefighter foreground injuries, and 10% to firefighter non-fireground injuries.

The total dollar equivalent for reported and unreported fire deaths and injuries in the United States, calculated in this way, was $31.7 billion in 2011 [4].

It is beyond the scope of this chapter or this handbook to review, even briefly, the many nuances, methods, and applications of value of life estimation. For those who wish to pursue the subject in more detail, several listed references are recommended [26–33].

Value of Donated Time

In the United States, the largest block of donated time for fire safety consists of that donated by the roughly 800,000 volunteer fire fighters who provide municipal fire protection to a sizeable fraction, mostly rural, of the U.S. population. One approach to valuing their donated time is to assume that costs are generated not so much by the workload of emergencies as by the need to provide coverage and readiness to respond for a certain area, that is, the ability to provide an effective response within a certain response time. If this approach is used, the primary factor in costs would not be workload, but geographical area. The low-density rural areas covered by volunteer fire departments would then require more personnel than would more compact areas of equal population covered by career fire departments.

Communities seeking to set such fire protection coverage at an appropriate level might begin with a response time objective. The part of response time that is most related to resource decisions is travel time, which may be treated

as proportional to travel distance. If one thinks of a typical response area as a circle with the fire station in the middle, one can see that travel distance is proportional to the square root of area. For example, if the distance from the fire station to the edge of the response area doubles, that is equivalent to doubling the radius of a circle, whose area then is quadrupled. This also means that if the same population is spread out over an area four times as large, it will need twice as many fire stations to provide equivalent travel times, which means the needed number of fire fighters may be treated as inversely proportional to the square root of the population density.

In 2000, the metropolitan statistical areas of the United States had 80.3 % of the U.S. population in 20.0 % of the area. If one assigns all the remaining area and population to volunteers (which is a rough approximation), then the metropolitan population density (proportional to 80.3 % divided by 20.0 %) exceeds the nonmetropolitan population density (proportional to 19.7 % divided by 80.0 %) by a factor of 16. The square root is 4.0, which is somewhat higher than the actual ratio in fire fighters (2.8:1 in 2002).

Using the 4:1 ratio for personnel needed, assuming their costs would be the same as in career fire departments, and again adjusting for nonpersonnel costs included in reported local fire expenditures, the result is $139.8 billion in 2011 for the value of time donated by volunteer fire fighters.

If this estimate of the value of donated time by volunteer fire fighters is combined with the earlier estimates of the core components of total cost of fire, the other economic components estimated from data that is not updated yearly, and the estimated monetary equivalent of deaths and injuries associated with fire, the resulting total is $329 billion for the United States in 2011. This is 2.1 % of the total U.S. gross domestic product, a figure that fully justifies appeals from the fire protection engineering community for more support of research seeking to reduce the total, either through improved safety or through sustained safety at reduced cost.

Utility Theory

Even after all costs and benefits (e.g., risk reduction) have been converted to monetary equivalents, an important aspect of people's preferences may be overlooked if expected-value techniques are used directly in a cost-benefit analysis of fire safety measures to include the certainty-equivalent of uncertain costs and benefits.

Suppose a person is offered a choice between $5 or a 50/50 coin toss wager between $10 and nothing. The expected values of the two choices are equal, assuming a fair coin. A person who prefers the sure thing is called *risk averse*. Most people are somewhat risk averse in some situations. Just how risk averse a person is can be measured by determining how low the sure-thing offer can be set before the person will choose the wager with the $5 expected value.

Fire loss is never a sure thing, and so people's risk preferences are always relevant to assessing their preferences for choices involving fire risk.

People differ not only in their degree of risk aversion but also as a function of the type of choice being offered. Some people may prefer to take risks in most situations. It also is not unusual to find that a person is a *risk preferer* for ventures involving small losses but a *risk avoider* for those involving large values.

Any pattern of risk preferences can be quantified by the use of *utility functions*. *Disutility*, the negative counterpart of utility, is the appropriate term in an analysis involving negative outcomes such as fire loss, cost of fire protection, and insurance premiums.

Consider a few more examples based on participation in a game of chance. Suppose a person is offered the following bet on the toss of a coin—to win $100 if the coin comes up heads or lose $75 if the coin comes up tails. If the coin is a fair coin, the $probability of heads or tails coming up is one-half. The expected payoff is

$$\frac{1}{2}(\$100) + \frac{1}{2}(-\$75) = \$12.5$$

if the person playing the game takes the bet and $0 if he or she does not take the bet. According to

the expected value criterion, the bet should be accepted because its expected value is greater than the expected value of not taking the bet.

Now suppose the amounts involved are $1,000,000 and $750,000 rather than $100 and $75. The expected payoff is now $125,000 if the bet is taken and $0 if the bet is not taken. Every value has been multiplied by 10,000. According to the expected value criterion, the bet should still be taken and is even more attractive. But would you take this bet? Probably not, unless you are wealthy enough that you could afford to lose $750,000. The possible gain of $1,000,000 is tempting, but losing could be devastating or even intolerable.

As another example, consider a choice between two bets. In the first bet, the person playing the game wins $2 million if a coin comes up heads and wins $1 million if the coin comes up tails. In the second bet $8 million can be won if the coin comes up heads, but nothing will be won if the coin comes up tails. The expected payoffs of the two bets are $1.5 and $4 million, respectively. The second bet has a much larger expected payoff than the first, and hence should be chosen on the basis of the expected value criterion. However, many would choose the first bet because they focus on the larger minimum gain—the closest thing to the "sure thing" in a choice between two bets. With the first bet, you are assured of at least $1 million. With the second bet, there is a 50 % chance of winning nothing.

Consider a third example, defined more directly in terms of fire safety. Suppose the owner of a home or other building faces a probability, p, of fire occurring in the coming year and a loss, L, in the event of a fire. (In this simplified example, only one kind and severity of fire is possible.) The expected annual loss due to fire in that building is pL, and it is a two-outcome bet, like a coin toss.

The sure-thing alternative, from the owner's point of view, can be achieved through insurance. The property owner has two options—to insure or not insure the building. The expected loss (cost) is equal to the insurance premium (call it I) if insured, and pL if not insured.

On the basis of the expected value principle, the owner should choose the insurance option only if I is less than pL. This condition will never be satisfied since an insurance firm would determine the premium, I, for a risk category by adding to the risk premium, pL, two loadings—a safety loading and another loading to cover the operating costs of the firm which include profits, taxes, and other administrative expenses. From the insurance company's point of view, it should offer the insurance only if I is greater than pL. How is it that insurance even exists under these conditions?

The risk aversion of most people provides the foundation for breaking this dilemma. Based on risk aversion, the building owner will accept a sure-thing loss of I even if I is greater than pL. The difference is typically large enough not only to make a mutually acceptable deal possible, but to allow I to be large enough to cover the two loadings mentioned above.

In practice, many different sizes and severities of fire are possible. For the smallest fires, the building owner's risk aversion will probably be much less pronounced, and insurance may seem unattractive. The creation of a deductible threshold solves that problem by allowing the insurance to be limited to losses large enough for the owner's risk aversion to be strong. If a very large fire occurs, the insurance company may be unable to cover the loss. This leads to reinsurance markets, particularly for properties with the potential for more than one very large loss in a short period of time. For smaller losses, the safety loadings on the risk premium would provide a safety margin for the insurance company, depending on its calculations of the probability distribution for the fire loss. There may also be an upper bound set on the maximum loss the insurance company can cover.

The preference for a small fixed loss over a risk of large loss originates primarily from an aversion to the psychological state of uncertainty. For the reasons mentioned previously, the expected monetary value is not a satisfactory criterion for decisions involving potential losses in ranges where risk aversion is an issue for many people. Note that the ranges of risk aversion can

depend on the size of the decision maker's resource base—how large a loss can be sustained at all, and how large a loss can be absorbed without serious inconvenience or harm—and on the number of "bets" undertaken. An insurance purchaser has one bet (at least one per year) going, so he or she is exposed to the full uncertainty of the risk. An insurance company with many customers has many bets going, so the company's annual loss experience will fit a much narrower range around the expected value, except in certain circumstances. If many customers are exposed to a common risk, such as will happen if many customers live in the same hurricane-prone region, the range of probable outcomes for the insurance company will be much wider. If the insurance company's evaluation of the probabilities and consequences is seriously deficient or simply outdated, then its exposure may be quite different than it believes.

Utility and Disutility

For positive outcomes (gains), *utility* means a measurement scale for desirability [34]. It is a number measuring the attractiveness of a consequence—the higher the utility, the more desirable the consequence. A utility function translates monetary consequences into a scale for which expected-value calculations accurately reflect the preferences of an individual, a firm, or a decision maker. For negative outcomes (losses and costs), *disutility* is a measurement scale for undesirability—the higher the disutility, the less desirable the consequence.

The examples given earlier illustrate the fact that, for a specific person, firm, or decision-making entity, the value of gaining x dollars (or consequence of losing x dollars) is not necessarily x multiplied by the value of gaining a single dollar (or consequence of losing a single dollar). Issues of certainty and of the ability to accept loss can cause substantial deviations from the simple multiplicative relationship.

If it were possible to measure the true relative values to the decision maker of the various possible payoffs in a problem of decision making under uncertainty, expected values could be calculated in terms of these true values instead of the monetary values. The theory of utility seeks to develop such values, permitting choices to be analyzed using the decision-making rule—the maximization of expected utility or minimization of expected disutility. Utility theory provides a means of encoding risk preferences in such a way that the risky venture with the highest expected utility or lowest expected disutility is preferred. Symbolically, if the monetary value of the ith outcome is X_i the utility corresponding to a gain X_i is $U(X_i)$ the disutility corresponding to a loss X_i may be denoted by $D(X_i)$.

Utility Functions

The mathematical structure of the function $U(X)$ is central to the application of utility theory. Figure 79.1 graphically shows three typical utility functions that are usually encountered in this analysis [35]. The utility function represented by the straight line A is appropriate for a decision maker operating on an expected monetary value (EMV) basis. This line satisfies the equation $U(X) = X$ and represents risk neutrality. The concave curve B corresponds to a risk-averse (or risk-avoiding) decision maker, and the convex curve C to a risk-prone (or risk-taking) decision maker. For a decision maker who is more risk prone than the EMV individual or who prefers a risk, the utility of a fair game exceeds the utility of not gambling and hence a fair game will always be played. On the other hand a decision maker who is more risk averse than the EMV person does not like or cannot afford risks and is a risk avoider.

Some individuals could have a sigmoid form of utility function as illustrated by Fig. 79.2. Such a person is a risk preferer for small values of X but a risk avoider for larger values.

Consider now a game with a 50 % chance of winning \$100 and a 50 % chance of winning nothing, which has the expected value \$50. The expected value line A in Fig. 79.1 connects the points [0, $u(0)$] and [100, $u(100)$]. To find the utility of the game for the risk avoider (curve B),

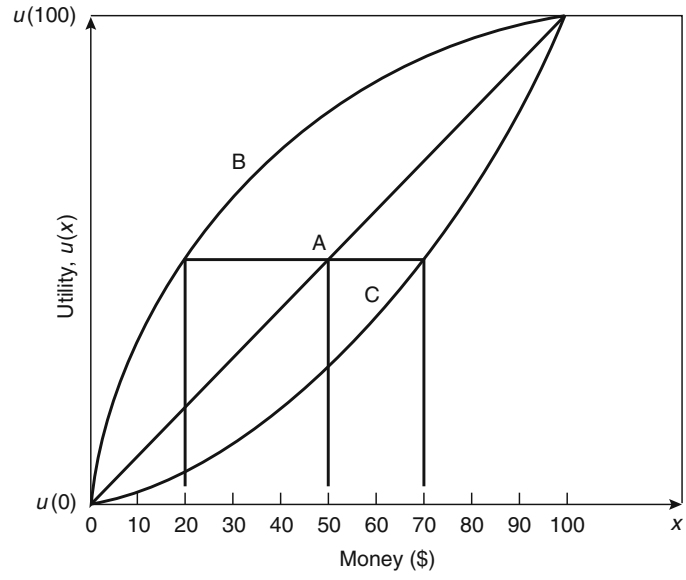

Fig. 79.1 Typical utility functions

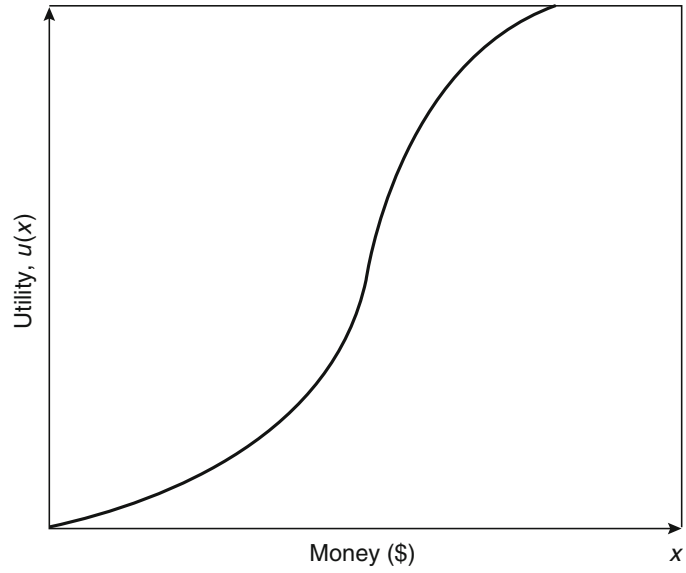

Fig. 79.2 Sigmoid utility function

find the utility value corresponding to the point on the straight line above the expected \$50 value of the game. By reading to the left, cutting curve *B*, this value is equal to *U*(\$20) so that the decision maker's cash equivalent (CE) for the game is \$20. He or she would be willing to pay up to \$20 to be able to participate in the game. This is still below the EMV of \$50 since the utility function *B* is that of a risk avoider.

The difference between the EMV and CE is the *risk premium*, which is \$30 in this example. The decision maker would be willing to pay \$30 to avoid the risk involved in participating in the game.

In the case of the risk taker denoted by curve *C*, the utility of the game is equal to *U*(\$70), so \$70 is the cash equivalent for the game. Although the expected value is only \$50, the risk taker is

willing to pay up to $70 to be able to participate in the game. Hence the risk premium is –$20. It is negative because the decision maker, instead of being willing to pay a premium to avoid the risk in the game, is willing to pay a premium (above and beyond the expected value) to be able to participate in the game.

The risk premium, RP, discussed above is the amount that a decision maker, on the basis of his or her utility function, is willing to pay to avoid or participate in a risky activity. For increasing utility functions such as those shown in Fig. 79.1, the risk premium for any risky venture is defined as

$$\mathrm{RP} = \mathrm{EMV} - \mathrm{CE}\,dx \tag{79.3}$$

where EMV is the expected monetary value and CE the cash equivalent. The parameter CE is also referred to as *certainty monetary equivalent*, CME, in the literature on utility theory [36].
