This edition of the SFPE Handbook of Fire Protection Engineering is dedicated to Philip DiNenno, who was the editor in chief for the first four editions of this handbook. In the mid-1980s, Phil DiNenno, Jack Watts, Doug Walton, Craig Beyler, and Dick Custer had an idea to create a collection of calculation methods for fire protection engineering. From this idea emerged the SFPE Handbook of Fire Protection Engineering, which was first published in 1988.

No other single event had as significant an impact on establishing the profession of fire protection engineering as the publication of this handbook. As Vyto Babrauskas said: "The field [of fire protection engineering] has made very gratifying progress in these last four decades. . .. The most remarkable positive achievement I think has been the SFPE Handbook, published first in 1988. . . . [W]ith the publication of the first edition of the SFPE Handbook in 1988, all of a sudden we could properly describe this as a science-based profession." [Babrauskas, V. "Some Neglected Areas in Fire Safety Engineering," Fire Science and Technology Vol. 32 No. 1 (2013) pp. 35–48.]

When they began creating the first edition, Phil and his colleagues had no model other than handbooks used in other professions. Phil contributed the leadership, vision, and motivation necessary to develop the handbook, and he did so using entirely volunteer resources. This would be an incredible accomplishment for anyone. Phil did it before he turned 35.

Foreword

This edition marks a passing of the torch for the *SFPE Handbook of Fire Protection Engineering*. All of the editors of the prior editions except for two (Jack Watts and John Hall) have retired, and a new editorial team has taken their place. Additionally, Springer has assumed the role of publisher beginning with this edition.

For the first four editions, the *SFPE Handbook of Fire Protection Engineering* was published by the National Fire Protection Association. The Society of Fire Protection Engineers owes a debt of gratitude to NFPA. Without their encouragement and confidence, this handbook might never have existed.

With a new editorial team emerge many changes. The chapters relevant to human behavior in fire have been significantly refocused and augmented. The fundamental engineering chapters have been revised to provide a better foundation for the chapters that follow. Many new chapters related to fire protection system selection and design have been added. The chapters associated with fire resistance design have been modified to reflect advances over the last decade. And, this edition includes several new chapters pertinent to industrial fire protection.

The editors owe a debt of gratitude to those whom they follow. Continuing a successful endeavor is much easier than launching it.

Metrication

The editors of the *SFPE Handbook of Fire Protection Engineering* have worked toward the expanded use of SI units for this fifth edition. In some instances, however, US customary units have been retained. For example, when equations, correlations, or design methodologies have input variables or constants that have been developed from data originally in US customary units, those units are retained. This is also the case for certain tables, charts, and nomographs. Where equations employing US customary units are used in worked examples, the results are presented as SI units as well.

Introduction to Fluid Mechanics

1

Bart Merci

Fluid Properties

In this section, a number of fluid properties are defined. An implicit assumption in the classical fluid mechanics is the 'continuum hypothesis', implying that we treat fluids as continuous media, not as an ensemble of individual molecules [1]. This is justified in 'normal' circumstances. This way, the fluid and flow quantities are continuous and local quantities to be interpreted as averages over a volume V^* which is very small (but still very large when compared to distances between molecules). This assumption allows to define local fluid and flow properties (e.g. velocity vectors). The continuum hypothesis is adopted here.

A fluid can be a liquid or a gas (vapour).

Density

The mass density is the amount of fluid mass inside a volume:

$$\rho = \frac{m}{V}. \tag{1.1}$$

Its unit is kg/m^3.

In a variable density flow, the density can vary in space and time and the local density at a certain time is defined as in Equation 1.1, taking the local limit for a small volume.

In an incompressible flow, the density does not vary. In general, liquids can be considered 'incompressible'. In gases, the density can vary due to variations in pressure or temperature (see below: ideal gas law).

The reciprocal of density is the 'specific volume' (m^3/kg).

Viscosity

Fluids can flow. The viscosity is the fluid property that indicates how easily molecules can move with respect to each other. Fluid particles with different velocity have the tendency to evolve to the same common velocity, through exchange of momentum. In other words, fluid layers with different velocities exert a shear stress τ onto each other. Most technically relevant fluids are 'Newtonian': the shear stress increases linearly with the strain rate (or velocity gradient):

$$\tau = \mu \frac{dv}{dy}. \tag{1.2}$$

The unit of τ is Pa (= N/m^2).

The proportionality factor, relating the velocity gradient to the shear stress, is the dynamic viscosity μ (unit: Pa.s).

In gases, μ typically increases with temperature, whereas in liquids it decreases with increasing temperature.

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_1, © Society of Fire Protection Engineers 2016

Sometimes, the kinematic viscosity is used:

$$\nu = \frac{\mu}{\rho}. \tag{1.3}$$

Its unit is m^2/s.

The shear stress, Equation 1.2, causes friction losses in case of flow. The higher the viscosity, the larger the flow losses become for the same velocity gradient. In other words, the resistance of the fluid against (imposed) flow increases with increasing viscosity.

The viscosity of a fluid is never zero. The important implication is that, whenever there is a solid boundary, this boundary always exerts an influence on the flow field (e.g. causing the development of a boundary layer).

Specific Heat

The specific heat or thermal capacity, c, is the amount of energy required to cause a temperature rise of 1 K (or 1 °C) in 1 kg of the fluid. Its unit is J/(kg.K).

In gases the value of the specific heat depends on the circumstances under which the energy is supplied. If the pressure is kept constant, the notation is c_p. If the volume is kept constant, the notation is c_v. The difference between the two values is called the gas constant R (also in J/(kg.K)):

$$c_p = c_V + R. \tag{1.4}$$

For liquids and solids, $c_p \approx c_v$.

Conduction Coefficient

The conduction coefficient expresses how easily heat flows inside a material. Its value indicates the heat flux per unit area (W/m^2) related to a spatial temperature gradient (K/m):

$$\vec{\dot{q}} = -k\nabla T = -\lambda\nabla T. \tag{1.5}$$

This is Fourier's law. The minus sign indicates that the heat flux is always from high temperature to low temperature.

The unit of the conduction coefficient (k or λ) is W/(m.K).

The conduction coefficient, specific heat and density can be combined to obtain the thermal diffusivity:

$$\alpha = \frac{k}{\rho c} \tag{1.6}$$

The unit of α is m^2/s.

Diffusion Coefficient

In a mixture of fluids (see below), one species can diffuse in the mixture due to concentration gradients of that species in the mixture. It is common practice to apply Fick's law for many flows:

$$\vec{J}_k = -\rho D_k \nabla Y. \tag{1.7}$$

The diffusion coefficient D thus provides the relation between the diffusion flux J_k ($kg/(m^2s)$) of species k and the spatial gradient of the local mass fraction Y_k (i.e. the amount of mass of species k per kg mixture) of that species. The minus sign expresses that the diffusion flux is always from higher concentration to lower concentration.

The unit of D is m^2/s.

Dimensionless Groups of Fluid Properties

By combining the fluid properties, dimensionless groups can be constructed. Indeed, the units of ν, α and D are the same (m^2/s). Physically, the interpretation is that ν tries to make the velocity field uniform inside a fluid

(through exchange of momentum), α tries to make the temperature field uniform (through heat exchange by conduction) and D tries to make the concentration field in a mixture homogeneous (through concentration gradient driven diffusion).

The resulting dimensionless groups read:

– The Prandtl number:

$$\mathrm{Pr} = \frac{\nu}{\alpha} = \frac{\mu c_p}{\lambda} = \frac{\mu c_p}{k}. \tag{1.8}$$

– The Schmidt number:

$$Sc = \frac{\nu}{D}. \tag{1.9}$$

– The Lewis number:

$$Le = \frac{\alpha}{D}. \tag{1.10}$$

Clearly, these numbers are connected: $Le = Sc.\mathrm{Pr}^{-1}$.

It is important to note that the dimensionless numbers Equations 1.8, 1.9, and 1.10 are still fluid properties, not flow properties.

As long as no mixtures are considered, the Prandtl number is the most relevant dimensionless fluid property, when heat transfer is an issue.

State Properties

State properties describe the state of the fluid, not the material properties of the fluid.

Pressure

The pressure (p) can be defined as the normal force per unit area at a certain point. The unit is Pa. Pressure differences are the driving force for fluid flows.

Temperature

The unit of temperature (T) is Kelvin (K). The temperature must not be confused with heat (the unit of which is Joule, J).

Internal Energy

The local motion of molecules in a fluid is related to the internal energy (e or u, with unit J/kg). This is a measure for the thermal energy.

Enthalpy

The quantity (static) enthalpy (h, with unit J/kg) is related to the internal energy through addition of pressure, divided by mass density:

$$h = u + \frac{p}{\rho} = e + \frac{p}{\rho}. \tag{1.11}$$

Entropy

The entropy is a measure for the disorder in the fluid. It is related to the second law of thermodynamics. This quantity is typically not particularly relevant for fire related issues.

Equation of State

Liquids

In liquids, the density is essentially constant, relatively very weakly dependent on pressure and temperature. Yet, the general expression that provides the equation of state defines the relation between density, temperature and pressure:

$$\rho = f(p, T) \tag{1.12}$$

Gases: Ideal Gas Law

In gases, it is common practice to specify Equation 1.12 as the 'ideal gas law':

$$p = \rho RT \tag{1.13}$$

For fire related flows, this is justified. Most gases behave as air would do and air behaves as an ideal gas (with the exception of extremely low or

high pressure or temperature, but this is not relevant for real-life fire applications). The gas constant R (J/(kg.K)) has been introduced in Equation 1.4 and the temperature T is expressed in Kelvin (K).

Mixtures

In fire related flows, the fluid can be a mixture. Obvious examples are smoke or flames. A distinction must be made between chemical and physical issues. If toxicity is an issue, chemical aspects are important. As long as the flow itself is concerned, the physical behaviour of many gaseous mixtures resembles very much the behaviour of hot air. One reason is that the species most often encountered, have comparable diffusivities (with the important exception of hydrogen, which has a much higher diffusivity). Another reason is that typically by far mixtures in fire related flows consist mainly of air.

As a consequence, the simplification is made very commonly to treat a mixture of hot gases as hot air, applying the ideal gas law (Equation 1.13) with the gas constant for air and using the (temperature dependent) viscosity for hot air. Therefore, mixtures of gases do not receive much attention when fluid mechanics aspects are considered in case of fire.

Yet, a few definitions are introduced here. The mass fraction Y_i of species i is the ratio of the local amount of mass of species i to the local amount of mass of mixture. It is therefore a non-dimensional quantity. Conservation of mass leads to the statement that, everywhere in physical space, the sum of all mass fractions of all species equals unity: $\sum_{i=1}^{N} Y_i = 1$.

Using the notion of mass fractions, the fluid properties of mixtures can be determined from the fluid properties of their constituent species. E.g. the specific heat becomes $c = \sum_{i=1}^{N} Y_i c_i$.

Also state properties can be defined as such. E.g. static enthalpy becomes: $h = \sum_{i=1}^{N} Y_i h_i$.

Conservation Equations

Figure 1.1 visualises a streamline through a surface of a (control) volume. This concept will be used to develop the conservation equations in the integral formulation. A streamline is defined such that locally the velocity vector is tangent to the streamline. A collection of streamlines is called a stream tube.

Conservation of Mass—Continuity Equation

Conservation of mass expresses the following principle:

The amount of mass that flows into a stationary volume per unit time, equals the outflow of mass per unit time out of that same volume plus the amount of mass accumulation per unit time in that same volume.

Mathematically, this is formulated as follows:

- The net outflow per unit time is given by a closed surface integral over the entire area of the manifold ∂V, enclosing the volume V: $\iint_{\partial V} \rho \vec{v}.\vec{n} dA$; in this expression, $\vec{v}$ is the local velocity vector at a certain position on ∂V, $\vec{n}$ the local normal vector on the surface (i.e. the vector with length equal to 1, locally perpendicular to the surface and pointed outward) and dA the area of an infinitesimal element

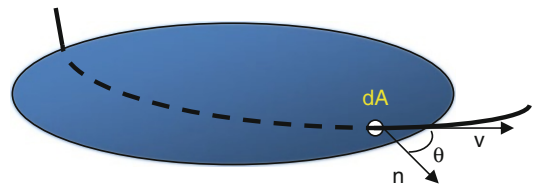

Fig. 1.1 Streamline through a surface. Notation: dA is the area of an infinitesimal part of the surface; n is the normal vector, with length equal to unity, perpendicular to dA and pointing 'outward' of the control volume, spanned by the surface; v is the local flow velocity vector at position dA; θ is the angle between vectors n and v

on the surface; note that the inner product $\vec{v}.\vec{n} > 0$ for outflow, while $\vec{v}.\vec{n} < 0$ for inflow;
- The accumulation of mass per unit time is obtained from a derivation with respect to time of the integral of the mass density over the entire volume: $\frac{\partial}{\partial t}\iiint_V \rho dV$.

The conservation of mass thus reads:

$$\frac{\partial}{\partial t}\iiint_V \rho dV + \iint_{\partial V} \rho \vec{v}.\vec{n} dA = 0. \tag{1.14}$$

This equation is also called the *continuity equation*.

An important simplification is found in the case of *permanent* (or '*steady*') *motion*. In that case, the time derivative disappears in Equation 1.14:

$$\iint_{\partial V} \rho \vec{v}.\vec{n} dA = 0. \tag{1.15}$$

A further simplification concerns *incompressible fluids* (e.g. water in a pipe under normal conditions). In that case, density does not change, so that not only Equation 1.15 applies, but it further simplifies to read:

$$\iint_{\partial V} \vec{v}.\vec{n} dA = 0. \tag{1.16}$$

A very simple illustration of Equation 1.15 is provided on the basis of Fig. 1.2. There is no flow through the solid boundaries (solid lines in Fig. 1.2), so the only contributions to $\iint_{\partial V} \rho \vec{v}.\vec{n} dA$ stem from surfaces 1 and 2. In surface 1, the velocity vector is pointing inward, while the normal vector is by definition pointing outward, so the contribution (under the simplified assumption of uniform flow through the cross-section) becomes: $-\rho_1 v_1 A_1$. On surface 2, the velocity and the normal vectors are pointing outward, leading to: $+\rho_2 v_2 A_2$. Equation 1.15 thus provides: $-\rho_1 v_1 A_1 + \rho_2 v_2 A_2 = 0 \rightarrow \rho_1 v_1 A_1 = \rho_2 v_2 A_2$. In case of incompressible flow (Equation 1.16) this further simplifies to: $v_1 A_1 = v_2 A_2$.

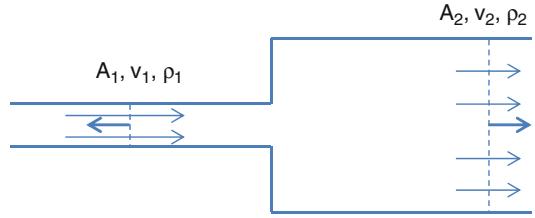

Fig. 1.2 Illustration of conservation of mass for steady flow (Equation 1.15) through a pipe expansion. *Dashed lines*: boundary of control volume. *Bold vectors*: normal vectors (unity length, perpendicular to surface and pointing outward). The other vectors indicate velocity vectors

The integral in Equation 1.14 in fact refers to the total net mass flow rate (kg/s) through a surface with area A:

$$\dot{m} = \iint_A \rho \vec{v}.\vec{n} dA \tag{1.17}$$

If the mass density is not included, the total net volume flow rate (m^3/s) through a surface with area A is found:

$$\dot{V} = \iint_A \vec{v}.\vec{n} dA. \tag{1.18}$$

Expression (1.14) can also be formulated in differential form, applying Green's theorem:

$$\frac{\partial \rho}{\partial t} + \nabla.\left(\rho \vec{v}\right) = 0. \tag{1.19}$$

The symbol ∇ is the divergence operator:

$$\nabla.\vec{v} = \left(\frac{\partial}{\partial x}\vec{1}_x + \frac{\partial}{\partial y}\vec{1}_y + \frac{\partial}{\partial z}\vec{1}_z\right).\left(v_x\vec{1}_x + v_y\vec{1}_y + v_z\vec{1}_z\right) = \frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z}. \tag{1.20}$$

In Equation 1.20, $\vec{1}_x$ is the notation for the unity vector, i.e. a vector with length equal to unity, in the x-direction.

Expression (1.15), for steady flow, reads in differential form:

$$\nabla.\left(\rho\vec{v}\right) = 0, \tag{1.21}$$

while expression (1.16), for incompressible fluids, becomes:

$$\nabla.\vec{v} = 0. \tag{1.22}$$

This shows that the velocity field for any flow of an incompressible fluid is 'divergence free', or 'solenoidal'.

Total Momentum

Now the integral formulation for the conservation of total momentum is discussed. Figure 1.1 again serves as the basic sketch.

Conservation of total momentum refers to the expression of Newton's second law, applied to flows. The net change in momentum of a system per unit time in a certain sense and direction equals the net force on that system in that sense and direction.

Expressed for a stationary volume, this becomes:

The total force onto a stationary volume equals the sum of the net outflow of momentum per unit time out of that same volume plus the accumulation of momentum per unit time in that same volume.

The local amount of momentum per unit volume is $\rho\vec{v}$ (kg/(m^{2}s)). Newton's second law thus reads:

$$\frac{\partial}{\partial t}\iiint_V \rho\vec{v}dV + \iint_{\partial V}\rho\vec{v}\left(\vec{v}.\vec{n}\right)dA = \vec{F}_{tot}. \tag{1.23}$$

Note that Equation 1.19 is a vector equation, i.e. the equation is valid for each component/direction individually.

For a permanent (or 'steady') motion, expression (1.19) simplifies to:

$$\iint_{\partial V}\rho\vec{v}\left(\vec{v}.\vec{n}\right)dA = \vec{F}_{tot}. \tag{1.24}$$

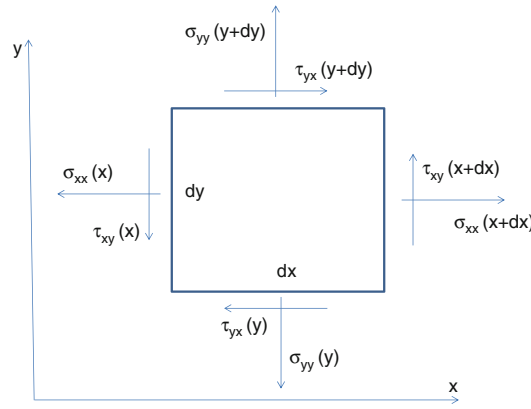

Fig. 1.3 Definition of normal stresses and shear stresses (2D)

The total force consists of:

- Surface forces:
  - Pressure (Pa);
  - Viscous stresses (Pa);
- Body forces:
  - Gravity (N);
  - Others (not relevant for fire related flows).

These forces are discussed now, in differential formulation:

$$\begin{cases} F_{tot,x} = \dfrac{\partial\sigma_{xx}}{\partial x} + \dfrac{\partial\tau_{xy}}{\partial y} + \dfrac{\partial\tau_{xz}}{\partial z} + \rho g_x \\ F_{tot,y} = \dfrac{\partial\tau_{yx}}{\partial x} + \dfrac{\partial\sigma_{yy}}{\partial y} + \dfrac{\partial\tau_{yz}}{\partial z} + \rho g_y \\ F_{tot,z} = \dfrac{\partial\tau_{zx}}{\partial x} + \dfrac{\partial\tau_{zy}}{\partial y} + \dfrac{\partial\sigma_{zz}}{\partial z} + \rho g_z \end{cases} \tag{1.25}$$

The final terms in Equation 1.25 refer to the gravity acceleration vector, multiplied with the local mass density. Figure 1.3 shows how the normal stresses and shear stresses are defined.

The shear stresses are found from Stokes' law:

$$\begin{aligned} \tau_{xy} &= \tau_{yx} = \mu\left(\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x}\right) \\ \tau_{xz} &= \tau_{zx} = \mu\left(\frac{\partial v_x}{\partial z} + \frac{\partial v_z}{\partial x}\right) \\ \tau_{yz} &= \tau_{zy} = \mu\left(\frac{\partial v_z}{\partial y} + \frac{\partial v_y}{\partial z}\right). \end{aligned} \tag{1.26}$$

The shear stresses are thus proportional to the dynamic viscosity and the local velocity gradients.

The normal stresses contain contributions from stresses due to fluid dilatation (for variable density flows only) and pressure:

$$\begin{aligned}\sigma_{xx} &= -p + \frac{2}{3}\mu\left(\frac{\partial v_x}{\partial x} - \frac{1}{3}\nabla.\vec{v}\right)\\ \sigma_{yy} &= -p + \frac{2}{3}\mu\left(\frac{\partial v_y}{\partial y} - \frac{1}{3}\nabla.\vec{v}\right)\\ \sigma_{zz} &= -p + \frac{2}{3}\mu\left(\frac{\partial v_z}{\partial z} - \frac{1}{3}\nabla.\vec{v}\right).\end{aligned} \tag{1.27}$$

The above results in the *Navier–Stokes equations*:

$$\begin{cases}\frac{\partial}{\partial t}(\rho v_x) + \rho v_x\frac{\partial v_x}{\partial x} + \rho v_y\frac{\partial v_x}{\partial y} + \rho v_z\frac{\partial v_x}{\partial z} = -\frac{\partial p}{\partial x} + \frac{2}{3}\frac{\partial}{\partial x}\left(\mu\left(\frac{\partial v_x}{\partial x} - \frac{1}{3}\nabla.\vec{v}\right)\right) + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} + \rho g_x\\ \frac{\partial}{\partial t}(\rho v_y) + \rho v_x\frac{\partial v_y}{\partial x} + \rho v_y\frac{\partial v_y}{\partial y} + \rho v_z\frac{\partial v_y}{\partial z} = -\frac{\partial p}{\partial y} + \frac{2}{3}\frac{\partial}{\partial y}\left(\mu\left(\frac{\partial v_y}{\partial y} - \frac{1}{3}\nabla.\vec{v}\right)\right) + \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yz}}{\partial z} + \rho g_y\\ \frac{\partial}{\partial t}(\rho v_z) + \rho v_x\frac{\partial v_z}{\partial x} + \rho v_y\frac{\partial v_z}{\partial y} + \rho v_z\frac{\partial v_z}{\partial z} = -\frac{\partial p}{\partial z} + \frac{2}{3}\frac{\partial}{\partial z}\left(\mu\left(\frac{\partial v_z}{\partial z} - \frac{1}{3}\nabla.\vec{v}\right)\right) + \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \rho g_z\end{cases} \tag{1.28}$$

Note that the presence of the gravity force is essential in order to account for the Archimedes force. This is essential for buoyancy-driven forces, which is important in the context of fire.

Also note that pressure gradients (or pressure differences) are the driving force for flows, not the absolute pressure level.

Energy

Conservation of energy refers to the first law of thermodynamics:

The change (*per unit time*) *of the total internal energy of a system equals the sum of the heat added* (*per unit time*) *to the system and the work* (*per unit time*) *exerted onto that system.*

The total internal energy consists of:

- Static internal energy e (J/kg) or ρe (J/m^3);
- Kinetic energy $\rho v^2/2$ (J/m^3).

The mathematical formulation of the first law of thermodynamics for a stationary open system can be found in many textbooks (e.g. [2–9]). It reads:

$$\begin{aligned}\frac{\partial}{\partial t}\int_V\left(\rho e + \frac{1}{2}\rho v^2\right)dV = &-\oint_{\partial V}\left(\rho e + \frac{1}{2}\rho v^2\right)\vec{v}.\vec{n}dS - \oint_{\partial V} p\vec{v}.\vec{n}dS + \oint_{\partial V}\left(\vec{\vec{\tau}}.\vec{v}\right).\vec{n}dS\\ &+\int_V \rho\vec{g}.\vec{v}dV + \int_V \rho S_h dV - \oint_{\partial V}\vec{q}.\vec{n}dS\end{aligned} \tag{1.29}$$

The terms on the right hand side are:

- First term: Net inflow of total internal energy into the control volume ('convection'); the minus sign is necessary to comply with the sign convection (see previous sections: the normal vector is pointing outward).
- Second term: Work of the flow against pressure. This is work from a force (pressure),

exerted onto the surface. The work by the pressure onto the flow is positive for inflow and negative for outflow, which explains the minus sign.
- Third term: Work by the viscous stresses. This is work from a force (viscous stresses, Equations 1.26 and 1.27, exerted onto the surface. With the sign conventions used (Fig. 1.3 and outward pointing normal vector), this is a term with a plus sign.
- Fourth term: Work by gravity. This is work by a volume force, exerted inside the volume. This work is positive for a downward flow, so that with $\vec{g} = -g\vec{1}_y$ no minus sign is required in this term (if the y-direction is positive vertically upward).
- Fifth term: Volumetric source term of heat / internal energy (e.g. radiation). This term can be positive or negative.
- Final term: Net incoming flux of heat/internal energy (e.g. conduction). The flux with the flow cannot be added to this term (as it is already included in the convection term).

The energy equation can also be formulated, using enthalpy Equation 1.11:

$$\frac{\partial}{\partial t}\int_{CV}\left(\rho h+\frac{1}{2}\rho v^2\right)dV=\frac{\partial}{\partial t}\int_{CV}pdV-\oint_{\partial CV}\left(\rho h+\frac{1}{2}\rho v^2\right)\vec{v}.\vec{n}dS+\oint_{\partial CV}\left(\vec{\vec{\tau}}.\vec{v}\right).\vec{n}dS$$
$$+\int_{CV}\rho\vec{g}.\vec{v}dV+\int_{CV}\rho S_h dV-\oint_{\partial CV}\vec{q}.\vec{n}dS. \tag{1.30}$$

In differential formulation, this reads:

$$\frac{\partial}{\partial t}\left(\rho h+\frac{1}{2}\rho v^2\right)+\nabla.\left(\rho\left(h+\frac{1}{2}v^2\right)\vec{v}\right)=\frac{\partial p}{\partial t}+\nabla.\left(\vec{\vec{\tau}}.\vec{v}\right)+\rho S_h+\rho\sum_{i=1}^{N}Y_i\vec{g}.\vec{v}_i-\nabla.\vec{q} \tag{1.31}$$

The (static) enthalpy is the mass-weighted sum of the enthalpies of species i:

$$h=\sum_{i=1}^{N}Y_i h_i. \tag{1.32}$$

The enthalpy h_i is the sum of a reference enthalpy (the chemical standard formation enthalpy of species i) and a 'sensible' (thermal) enthalpy [5–9]. For ideal gases this reads:

$$h_i(T)=h_{ref,i}+\int_{T_{ref}}^{T}c_{p,i}(T)dT, \tag{1.33}$$

with $c_{p,i}$ the specific heat of species i, defined above.

Note that in Equation 1.31, expressed in terms of enthalpy, the source term ρS_h contains e.g. radiation, but not a heat release rate due to combustion. Combustion reactions transform chemically bound enthalpy into sensible enthalpy and as such cause a temperature rise, but the sum of sensible and chemical enthalpy does not change locally. If the energy equation is expressed in terms of temperature (or sensible enthalpy), a source term due to the combustion heat release rate does appear.

The final term in Equation 1.31 reads:

$$\nabla.\vec{q}=-\nabla.(\lambda\nabla T)-\nabla.\left(\rho\sum_{i=1}^{N}h_i D_i\nabla Y_i\right)+D.E. \tag{1.34}$$

The abbreviation 'D.E.' stands for the 'Dufour effect', i.e. and additional enthalpy flux due to species concentration differences. This effect is

ignored in fire related flows. The first terms in Equation 1.34 refer to Fourier's law for heat conduction, Equation 1.5. The middle terms refer to an enthalpy flux due to diffusion, using Fick's law, Equation 1.7.

The general expression, Equation 1.31, can often be simplified. Many fire-induced flows are low-Mach number flows (note: this is not true for explosions). The time derivative of pressure can often be ignored. Also the work done by gravity, by the viscous shear stresses and by the normal stresses becomes very small and the kinetic energy is negligible. Using Equations 1.8 and 1.9, the energy equation becomes:

$$\frac{\partial}{\partial t}(\rho h) + \nabla.\left(\rho h \vec{v}\right) = \nabla.\left(\frac{\mu}{\mathrm{Pr}}\nabla h + \mu\sum_{i=1}^{N}\left(\frac{1}{Sc_i} - \frac{1}{\mathrm{Pr}}\right)h_i \nabla Y_i\right) + \rho S_h \tag{1.35}$$

For unity Lewis number ($Le_i = 1$ for all i, Equation 1.10) fluids, this further simplifies to:

$$\frac{\partial}{\partial t}(\rho h) + \nabla.\left(\rho h \vec{v}\right) = \nabla.\left(\frac{\mu}{\mathrm{Pr}}\nabla h\right) + \rho S_h. \tag{1.36}$$

Hydrostatics

Hydrostatics

From the general Navier–Stokes equations (1.28), the basic law for hydrostatics is immediately recovered. Indeed, setting all velocities in a certain environment equal to zero, the only terms remaining are:

$$\nabla p = \rho_{amb}\vec{g}. \tag{1.37}$$

Equation 1.37 is valid at any time (in the absence of motion). For the special case where $\vec{g} = -g\vec{1}_y$, with g = 9.81 m/s^2, Equation 1.37 reads (in the y-direction):

$$\frac{dp}{dy} = -\rho_{amb} g \tag{1.38}$$

Note that Equation 1.37 in such circumstances also implies that pressure does not vary in the horizontal directions.

Equation 1.38 can be integrated:

$$p = p_{ref} - \rho_{amb} g\left(y - y_{ref}\right). \tag{1.39}$$

Buoyancy

The main relevance of the fundamental law of hydrostatics, Equation 1.37, lies in the fact that in many fire related flows, buoyancy plays a dominant role. This can be learnt from the Navier–Stokes equations, Equation 1.28, combining the forces due to pressure gradients and gravity. In the vertical direction (still with $\vec{g} = -g\vec{1}_y$), using Equation 1.38, the resulting force per unit area reads:

$$-\frac{dp}{dy} - \rho g = (\rho_{amb} - \rho)g. \tag{1.40}$$

In the process of getting to expression (1.40), the implicit assumption is made that pressure differences in the horizontal directions are small.

Equation 1.40 reveals that the driving force in situations where buoyancy dominates, stems from density differences, in the presence of a gravity field. This is known as Archimedes' law. Note that, since gravity acts in the vertical direction only, buoyancy forces by definition also act in the vertical direction only.

For small density differences, the approximation $\rho \approx \rho_{amb}$ is typically made in the Navier–Stokes equations, except that the difference $(\rho_{amb} - \rho)$ is accounted for in combination with gravity (Equation 1.40). This is called Boussinesq's approximation. In the context of small density differences, expression (1.40) can be developed further, using a Taylor series

expansion: $\rho = \rho(T, p) \Rightarrow \rho \approx \rho_{amb} + \left(\frac{\partial \rho}{\partial T}\right)_p (T - T_{amb}) + \left(\frac{\partial \rho}{\partial p}\right)_T (p - p_{amb})$. Typically the pressure correction is much smaller than the temperature correction. Using the thermal volumetric expansion coefficient:

$$\beta = -\frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_p, \tag{1.41}$$

the Archimedes force becomes:

$$(\rho_{amb} - \rho)g = \rho_{amb}\beta(T - T_{amb})g \quad , \quad if \quad \beta(T - T_\infty) \ll 1. \tag{1.42}$$

The basic expression is thus Equation 1.40, based on density differences, while Equation 1.42 is only valid for small enough temperature differences.

Scaling Laws—Dimensionless Flow Numbers

In this section, starting from the governing equations, some scaling laws and non-dimensional flow numbers are introduced. The characteristic length scale is L, the characteristic velocity is u.

Dimensionless Flow Numbers

Examination of the terms in the Navier–Stokes equations, Equations 1.28 and 1.26, leads to the following proportionalities: $\frac{\rho u}{t} \sim \frac{\rho u^2}{L} \sim \frac{\Delta p}{L} \sim \Delta \rho g \sim \mu \frac{u}{L^2}$. Several non-dimensional flow numbers can be derived now, as follows. The importance of each of the numbers mentioned, depends on the importance of the corresponding terms in the Navier–Stokes equations. The convection term/inertia term is always important, as it characterizes the flow. Depending on the flow configuration, one or more terms are in competition with (or determine) the inertia term (or thus the flow). This is explained next.

When the viscous stresses prevail, the proportionality $\frac{\rho u^2}{L} \sim \mu \frac{u}{L^2}$ leads to the Reynolds number, which is the ratio of inertial forces to viscous forces:

$$\mathrm{Re} = \frac{\rho u L}{\mu} = \frac{uL}{\nu}. \tag{1.43}$$

The viscous forces tend to damp the inherent instabilities in the non-linear convection terms in the Navier–Stokes equations, while these instabilities can evolve towards fully-developed turbulence for large enough Reynolds number. This is addressed in the next section.

When buoyancy is dominant, the proportionality $\frac{\rho u^2}{L} \sim \Delta \rho g$ leads to the Froude number, which is the ratio of inertial forces to the Archimedes force:

$$\mathrm{Fr} = \frac{\rho u^2}{\Delta \rho g L}. \tag{1.44}$$

In the fire community, this is often simplified to:

$$\mathrm{Fr} = \frac{u^2}{gL}. \tag{1.45}$$

Expression (1.44) resembles the underlying physics more than Equation 1.45. On the other hand, the difference between expressions (1.44) and (1.45) is no more than a numerical factor, depending on the densities at hand. Moreover, in many experiments it is much more straightforward to measure velocities than mass densities, so that it is easier to characterize the experimental set-up through formulation (1.45). This explains why the use of Equation 1.45 is popular in diagrams and correlations.

If large (imposed) pressure differences occur, sometimes the Euler number comes into play, through $\frac{\rho u^2}{L} \sim \frac{\Delta p}{L}$:

$$Eu = \frac{\Delta p}{u^2}. \tag{1.46}$$

In fire related flows, this is often not relevant.

In buoyancy driven flows, applying Boussinesq's hypothesis, the driving force (Equation 1.42) can also be made dimensionless as:

$$Ra = \frac{L^3 g\beta\Delta T}{\alpha\nu}. \tag{1.47}$$

This is the Rayleigh number. Alternatively, the Grashof number can be used:

$$Gr = \frac{L^3 g\beta\Delta T}{\nu^2}. \tag{1.48}$$

The relation between the two is: $Ra = Gr.\mathrm{Pr}$, with the Prandtl number as defined in Equation 1.8. The Grashof number can be interpreted as a ratio of buoyancy forces (with Boussinesq's approximation) to the viscous forces. This is relevant in boundary layers (see below).

Scaling

In this section, scaling is briefly discussed in the context of fluid mechanics. As such, only the momentum equation is considered, albeit that at the end of this section, some remarks are formulated on the fire heat release rate (using the energy equation) and the study of unsteady phenomena (using the mass conservation equation). As a consequence, no comments are formulated on e.g. convective heat transfer or conduction through solids, nor on radiation. For an extensive discussion on scaling, the reader is referred to [10, 11].

The main non-dimensional numbers in low-Mach number flows are the Reynolds number Equation 1.43 and the Froude number Equation 1.44 (or Equation 1.45). Firstly, it is mentioned that the only way to preserve both numbers when scaling (up or down) a flow in a certain configuration, is through the use of different fluids. Indeed, assume that the fluid does not change (and that the densities do not change). Then preservation of Re reveals that: $\mathrm{Re}_1 = \mathrm{Re}_2 \Rightarrow \frac{u_1 L_1}{\nu} = \frac{u_2 L_2}{\nu} \Rightarrow u_2 = \frac{u_1 L_1}{L_2}$. Preservation of the Froude number (still with the assumption that densities do not change) leads to: $Fr_1 = Fr_2 \Rightarrow \frac{u_1^2}{gL_1} = \frac{u_2^2}{gL_2} \Rightarrow u_2 = u_1\sqrt{\frac{L_2}{L_1}}$. Clearly, this is inconsistent with the requirement, stemming from the preservation of the Reynolds number. Both numbers can be preserved if, starting from the requirement for preservation of the Froude number, the fluid's viscosity is modified such that also the Reynolds number is preserved. This is not straightforward.

Fortunately, both the Reynolds number and the Froude number have the property that, as soon as they are large enough, their actual value becomes irrelevant. In other words, as soon as they are sufficiently high, the qualification 'high' is sufficient, not the exact number. This is due to turbulence, overwhelming molecular phenomena (see next section). This can also be understood intuitively. The Reynolds number is the ratio of inertia to viscous damping forces. Either the damping force is strong enough to overcome the inherent instabilities in the non-linear convection terms in the Navier–Stokes equations (laminar flow), almost strong enough (transitional flow) or not strong enough (turbulent flow). When turbulence is fully developed, the strength of the viscous stress becomes irrelevant, i.e. the true value of the Reynolds number becomes irrelevant. For the Froude number, it is most instructive to examine expression (1.44). The driving force for buoyancy is in the denominator. If density differences become small, buoyancy becomes irrelevant and the Froude number is high. As such, high values of the Froude number implies that buoyancy is not important and thus that the error is small when the Froude number is not preserved (as long as it stays sufficiently high).

Knowing this, it is instructive to examine the order or magnitude of Reynolds number and Froude number in fire related flows. Indeed, if one of the numbers can be expected to be high,

that number need not be preserved in scaling. Typical dimensions are in the order of 1 m: $L = \mathrm{O}(m)$. Typical velocities are in the order of 1 m/s: $u = \mathrm{O}(m/s)$. Densities are in the order of 1 kg/m^3: $\rho = \mathrm{O}(kg/m^3)$. The dynamic viscosity in gases is in the order of 10^{-6} Pa.s: $\mu = \mathrm{O}\left(10^{-6} Pa.s\right)$. Using these numbers, the Reynolds number Equation 1.43 is: $\mathrm{Re} = \mathrm{O}\left(\frac{1.1.1}{10^{-6}}\right) = \mathrm{O}\left(10^6\right)$, while the Froude number Equation 1.44 is: $\mathrm{Fr} = \mathrm{O}\left(\frac{1.1}{1.10.1}\right) = \mathrm{O}(0.1)$. Obviously, these are rough order of magnitude analyses, but it is clear that in fire related flows, the choice will be made to preserve the Froude number, not the Reynolds number, when scaling is applied.

The energy equation also provides information regarding scaling laws. The simplified formulation (1.36) can be used for fire-related flows. Yet, temperatures are very important in fire related flows, so the energy equation should be interpreted in terms of sensible enthalpy, in which case the fire heat release rate ($\dot{Q}$, in W) comes into play. Knowing that, in terms of dimensions, (sensible) enthalpy differences can be re-written as the product of specific heat and temperature differences, Equation 1.36 leads to the following proportionalities: $\frac{\rho c_p \Delta T}{t} \sim \frac{\rho c_p \Delta T u}{L} \sim \frac{\dot{Q}}{L^3} \sim \frac{k \Delta T}{L^2}$.

This reveals that:

$$\dot{Q} \sim u \rho c_p \Delta T L^2. \tag{1.49}$$

It is common practice to scale configurations such that the temperatures remain the same. This also implies that densities do not change (if the same fluid is applied). As has just been explained, the Froude number Equation 1.44 is preserved, so that the velocity scales as $\sim \sqrt{L}$. As a consequence, the fire heat release rate scales as:

$$\frac{\dot{Q}_1}{\dot{Q}_2} = \frac{\sqrt{L_1} L_1^2}{\sqrt{L_2} L_2^2} \Rightarrow \dot{Q} \sim L^{5/2}. \tag{1.50}$$

Finally, it is noteworthy that the conservation of mass, Equation 1.19, reveals that:

$$t \sim L/u. \tag{1.51}$$

Applying Froude scaling, the velocity scales as $\sim \sqrt{L}$, so that expression (1.51) reveals that the temporal evolution of quantities (e.g. temperature) depends on the dimensions of the configuration as $t \sim \sqrt{L}$. This is relevant when unsteady phenomena are studied.

Turbulence

There are numerous text books on turbulence and turbulent flows, e.g. [12, 13]. Only some introductory comments are presented here.

Reynolds Number

In the previous section it has been mentioned that the Reynolds number Equation 1.43 is the ratio on inertia to viscous forces. It is well-known that the convection term in the Navier–Stokes equations (1.28) is inherently unstable and that the flow becomes turbulent when the viscous forces are not strong enough to damp the instabilities, i.e. when the Reynolds number becomes sufficiently high. Below a certain threshold number, the flow remains 'laminar'. There is no sudden change from 'laminar' to 'turbulent': there is a 'transition' zone in between.

Care must be taken in the definition of this 'critical' Reynolds number, in the sense that the length scale must be defined. In flows over flat plates, it is common practice to use the distance from the leading edge and Re_c is in the order of 500.000. In pipe flows, it is common practice to use the pipe diameter as characteristic length scale and Re_c is in the order of 2.000.

It is important to stress that the Reynolds number is a flow property, not a fluid property.

Turbulence is typically defined on the basis of a number of properties [13]:

- Randomness: there are fluctuations in the flow;
- Three-dimensionality: even if the mean flow is 2D or axisymmetric, the vortices or 'eddies' are always three-dimensional;
- There is a wide range of length scales and time scales in the flow. The largest scales are determined by the configuration at hand,

while the smallest scales are determined by the Reynolds number. The smallest scales can easily be 10,000 times smaller than the largest scales.
- Turbulent mixing is very effective.
- There is a lot of diffusion and dissipation. Turbulence dies out quickly if not sustained by velocity gradients in the mean flow.
- There is vortex stretching, transferring energy from the mean flow to turbulent fluctuations.

It is instructive to briefly explain the randomness in the flow. Indeed, knowing that the Navier–Stokes equations (Equation 1.28) are deterministic, one may pose the question how it is possible that randomness occurs when applying deterministic boundary and initial conditions. The reason is that there are always small fluctuations, i.e. the boundary and initial conditions are never known with infinite precision. Due to the unstable convection terms in the Navier–Stokes equations, turbulent flows are extremely sensitive to details and this creates randomness in the instantaneous flow fields. This makes it impossible to make long-term predictions of instantaneous turbulent flow fields and explains why turbulent flows are tackled in simulation through statistical approaches (see below). Obviously, the mean flow can still be deterministic (see below).

Reynolds Averaging

As mentioned in the previous section, the fluctuations in a turbulent flow make a direct analysis through the Navier–Stokes equations (Equation 1.28) impossible. Therefore, a statistical approach is adopted. The primary interest is often the mean flow. To that purpose, the Navier–Stokes equations are averaged. The concept of Reynolds averaging is explained first.

Consider a turbulent flow. Measuring a velocity component (or e.g. a temperature) at a certain location will then yield a fluctuating signal, as explained. One can now determine the 'average' of that signal. The true definition of a Reynolds average [12, 13] is that many realizations of the 'same' turbulent flow are made, repetitive measurements of the quantity are made at the same location, and the average value of the measurements is determined. In a simplified manner, though, one can think of this procedure as a time averaging, where the averaging period Δt is sufficiently long, compared to the largest turbulent time scales, but sufficiently short compared to time scales associated with possible variations in the mean flow:

$$\overline{v}_x(t) = \frac{1}{\Delta t}\int_{t-\Delta t}^{t} v_x(t)dt; \overline{T}(t) = \frac{1}{\Delta t}\int_{t-\Delta t}^{t} T(t)dt. \tag{1.52}$$

It is clear that this is only possible if the turbulent time scales are short, compared to time scales in the mean flow. The 'integral' turbulent time scale is typically less than 1 s, so in many fire related flows this concept of Reynolds averaging is possible.

Using Equation 1.52, the instantaneous value can be expressed as the sum of the (Reynolds) averaged value and the instantaneous fluctuation around that value:

$$v_x(t) = \overline{v}_x(t) + v_x'(t); T(t) = \overline{T}(t) + T'(t). \tag{1.53}$$

Note that:

$$\overline{v_x'(t)} = 0; \overline{T'(t)} = 0; \overline{\overline{v_x(t)}} = \overline{v_x(t)}; \overline{\overline{T(t)}} = \overline{T(t)}. \tag{1.54}$$

Applying this averaging technique to the conservation equations (1.19), (1.28) and (1.36), the equations are obtained for the Reynolds-averaged quantities. They are very similar to the instantaneous equations, but some additional terms appear:
- Reynolds stresses in the momentum equations;
- Turbulent heat fluxes in the energy equation.

This is explained next. For the sake of ease, the energy equation is simplified here: it is expressed in terms of temperature and no chemical reactions, nor radiation, are considered. The

averaging of the chemical and radiative source terms is a separate problem, not addressed here.

The additional terms appear as a consequence of the presence of products in the instantaneous Equations 1.28 and 1.36. The mean value of the product is not equal to the product of the mean values:

$$\begin{aligned}\overline{v_x v_y} &= \overline{\left(\overline{v}_x + v_x'\right)\left(\overline{v}_y + v_y'\right)} = \overline{\overline{v}_x}\,\overline{\overline{v}_y} + \overline{\overline{v}_x v_y'} + \overline{v_x' \overline{v}_y} + \overline{v_x' v_y'} = \overline{v}_x \overline{v}_y + \overline{v_x' v_y'} \\ \overline{v_x T} &= \overline{\left(\overline{v}_x + v_x'\right)\left(\overline{T} + T'\right)} = \overline{\overline{v}_x}\,\overline{\overline{T}} + \overline{\overline{v}_x T'} + \overline{v_x' \overline{T}} + \overline{v_x' T'} = \overline{v}_x \overline{T} + \overline{v_x' T'}.\end{aligned} \tag{1.55}$$

Simplifying further to a steady boundary layer flow of an incompressible fluid over a flat plate without external pressure gradient, the main remaining dominant terms are:

$$\begin{aligned}&\frac{\partial \overline{v}_x}{\partial x} + \frac{\partial \overline{v}_y}{\partial y} = 0 \\ &\overline{v}_x \frac{\partial \overline{v}_x}{\partial x} + \overline{v}_y \frac{\partial \overline{v}_x}{\partial y} = \frac{\partial}{\partial y}\left(\nu \frac{\partial \overline{v}_x}{\partial y}\right) - \frac{\partial}{\partial y}\left(\overline{v_x' v_y'}\right) \\ &\overline{v}_x \frac{\partial \overline{T}}{\partial x} + \overline{v}_y \frac{\partial \overline{T}}{\partial y} = \frac{\partial}{\partial y}\left(\alpha \frac{\partial \overline{T}}{\partial y}\right) - \frac{\partial}{\partial y}\left(\overline{v_y' T'}\right)\end{aligned} \tag{1.56}$$

Clearly, the final terms, stemming from turbulence, are similar in nature to the molecular viscous stresses and the molecular thermal diffusion terms. The main question is now what the turbulent correlations look like. Indeed, terms like $\overline{v_x' v_y'}$ are only non-zero if the velocity fluctuations in the difference directions are statistically correlated. This is the case, explained from Fig. 1.4, showing a situation in a flow with a mean velocity gradient. The discussion is given here for the top left eddy, but it prevails for all eddies. At the left side of the top left eddy, the instantaneous motion is downward, as indicated by the arrow. Knowing that the mean velocity in the vertical direction equals zero, this implies that $v' < 0$. In its downward motion, the eddy brings along fluid with a higher (mean) velocity in the horizontal direction into a region with lower (mean) velocity. Thus, the impact is a local increase in horizontal velocity, in other words $u' > 0$. Clearly, from a statistical point of view the velocity fluctuations in both directions are correlated, in such a manner that $\overline{u'v'} < 0$. At the right side of the top left eddy, the instantaneous motion is upward ($v' > 0$) and (in the mean) lower horizontal velocity is brought into a region with (in the mean) higher

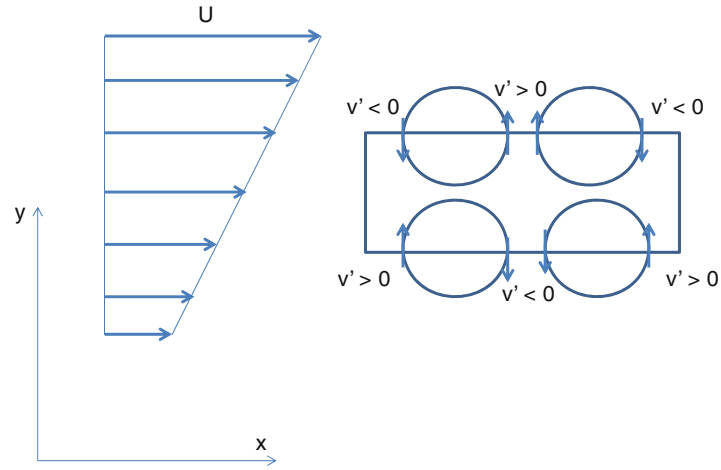

Fig. 1.4 Sketch of turbulent fluctuations (eddies) in a flow with a mean velocity gradient

horizontal velocity, causing u' < 0. Thus, again $\overline{u'v'} < 0$. A similar reasoning can be built up for the temperature fluxes.

Additionally, it is clear that the fluctuations, caused by the turbulent eddy motion, will be larger as the mean velocity (or temperature) gradients are larger.

The above led to the following 'eddy viscosity' modeling concept, introduced by Boussinesq:

$$-\overline{v_x' v_y'} = \nu_t \frac{\partial \overline{v}_x}{\partial y} \tag{1.57}$$

In other words, a 'turbulent' or 'eddy' viscosity is simply added to the molecular viscosity in Equation 1.56. This reflects the physical observation that momentum transfer increases in turbulent flows through the turbulent motion of eddies. These cause 'large scale' momentum transfer.

Similarly, this concept can be applied to the heat fluxes:

$$-\overline{v_y' T'} = \alpha_t \frac{\partial \overline{T}}{\partial y} \tag{1.58}$$

In other words, the addition of the turbulent thermal diffusivity to the molecular thermal diffusivity reflects the physical observation that heat transfer increases in turbulent flows through the turbulent motion of eddies. These cause 'large scale' heat transfer.

Turbulence Modeling

As mentioned above, there is always a wide range of length scales and time scales in turbulent flows. The higher the Reynolds number, the wider this range, because the smallest scales become smaller and smaller.

The largest turbulence scales are called the 'integral' scales. The smallest scales are called the 'Kolmogorov' scales. A detailed discussion of the spectrum is considered beyond the scope of this section, but it is important to appreciate that most of the turbulent kinetic energy is in the integral scale range ('energy containing range'), while turbulence is dissipated at scales around the Kolmogorov scales. Indeed, at those scales, viscous damping 'kills' turbulence, i.e. dissipates the turbulent kinetic energy into heat.

The notion of energy cascade, introduced by Richardson, is worth mentioning. The basic mechanism is as follows:

- Energy is taken from the mean flow and transferred to kinetic energy of turbulent eddies; this occurs around the integral scales;
- The turbulent eddies break up, transferring their energy to the eddies of smaller scale; only little energy is dissipated in this break-up process;
- The break-up process of eddies continues ('cascade process') until the eddies become so small that they cannot survive the damping action of viscosity anymore;
- The dissipation takes place at the smallest turbulence scales.

It is important to appreciate that, whereas the dissipation takes place at the smallest scales, the dissipation rate is determined by the production rate of turbulence from the mean flow in the energy containing range (in equilibrium conditions).

This phenomenology is reflected in the choice for turbulence modeling in CFD (Computational Fluid Dynamics). One extreme approach is not to model turbulence, i.e. to completely resolve all turbulent motions, down to the smallest scales. Knowing that these small scales can easily be in the order of 0.1 mm or less, and realizing that the computational mesh needs to be sufficiently fine to resolve the smallest eddies, it is immediately clear that this approach is not feasible in typical fire related flow simulations, where dimensions are in the order of 1 m. Worse than that, in addition to unacceptable computing time and memory requirements, most of the time and memory would be devoted to simulating the smallest scales [13], whereas the primary interest is typically in the large scale flow phenomena (or in the mean flow).

The other extreme is RANS (Reynolds-Averaged Navier–Stokes) turbulence modeling. In this approach, Reynolds averaging (see previous section) is applied and all turbulent motions, i.e. the entire turbulent spectrum, are modeled. Only the mean flow is resolved. The k-ε model

belongs to this class of models. The advantages of the RANS approach are clear: the computational mesh only needs to be fine enough to resolve the mean flows; the time step (in transient calculations) can be chosen on the basis of mean flow phenomena; one immediately gets a solution for the mean flow. There are major disadvantages, though. Firstly, all turbulence is modeled. Knowing that the largest turbulent scales are configuration dependent, it cannot be expected that a single RANS model can deal with arbitrary configurations in a reliable manner. Second, in fire related flows large scale flow unsteadiness often plays an important role, e.g. in the entrainment process of air into flames or smoke. Such unsteadiness is not captured in (unsteady) RANS and must be modeled. Again, being configuration dependent, RANS models cannot be expected to be as accurate as approaches where this unsteadiness is resolved.

This explains the popularity of the LES (Large-Eddy Simulations) technique in CFD for fire related flows. In this technique, the large scale eddies are resolved and only the effect of the small scale eddies is modeled. This technique offers the advantage of resolving the large-scale flow unsteadiness (and buoyancy effects). Also, the unacceptable fineness of the computational mesh as required in DNS is avoided. Yet, there is a very important caveat. Indeed, in order to guarantee the quality of LES results, 80 % of the turbulent kinetic energy must be resolved [13]. It is common practice to use the computational mesh as filter in the LES approach, i.e. the size of the computational mesh cells determines the size of the eddies still resolved. In many CFD simulations performed on today's computers, the mesh size is in the order of 10 cm or more. Very often, it cannot be guaranteed that 80 % of the turbulent kinetic energy is effectively resolved, so that care must be taken in the interpretation of the CFD results. In other words, blind belief in the exactness of under-resolved LES must be avoided. Also, it must be understood that if the computational mesh is used as filter for the instantaneous Navier–Stokes equations, as is common practice in the fire safety science community, no grid independent results can be expected from LES. Indeed, as the filter of the equations itself is modified, the results inevitably change. This is not the case in RANS simulations, where the results become independent of the mesh applied, provided it is fine enough.

For more discussion on turbulence modeling, in the context of reacting flows, the reader is also referred to [14].

Boundary Layers—External Flows

In section "Scaling", it was mentioned that the absolute value of the Reynolds number Equation 1.43 becomes irrelevant as Re becomes high. In other words, the flow can be considered 'inviscid', i.e. $\mu = 0$. Stated in another manner: viscosity becomes irrelevant in the Navier–Stokes equations. This, however, is only true in the absence of solid boundaries. Indeed, since viscosity is never really equal to zero, there is a 'no-slip' boundary condition at any solid boundary: due to the viscous forces, the fluid locally takes the velocity of the solid boundary, at the solid boundary. In fire-related flows, the solid boundaries typically stand still, so that the no-slip boundary condition implies that the fluid velocity equals zero.

In fire related flows, boundary layers appear as 'external' flows or in 'internal flows'. 'Internal' flows are discussed in the next section.

Examples of fire related boundary layers in external flows are: the flow over surfaces (horizontal or vertical) with e.g. flame spread, flow of smoke underneath a ceiling, atmospheric boundary layers in forest fires, etc. An 'external flow' is a flow where a 'free stream velocity' can be defined, i.e. a velocity that is not affected by the presence of the solid boundary.

Both the boundary layer flow itself and the corresponding (convective) heat transfer can be of importance in the context of fire.

Consider first the situation of a flow with free stream velocity U_∞ over a smooth flat plate, without external pressure gradient, schematically shown in Fig. 1.5. At the flat plate, $U = 0$ (no slip boundary condition), whereas 'sufficiently far away' from the plate $U = U\infty$. The notion

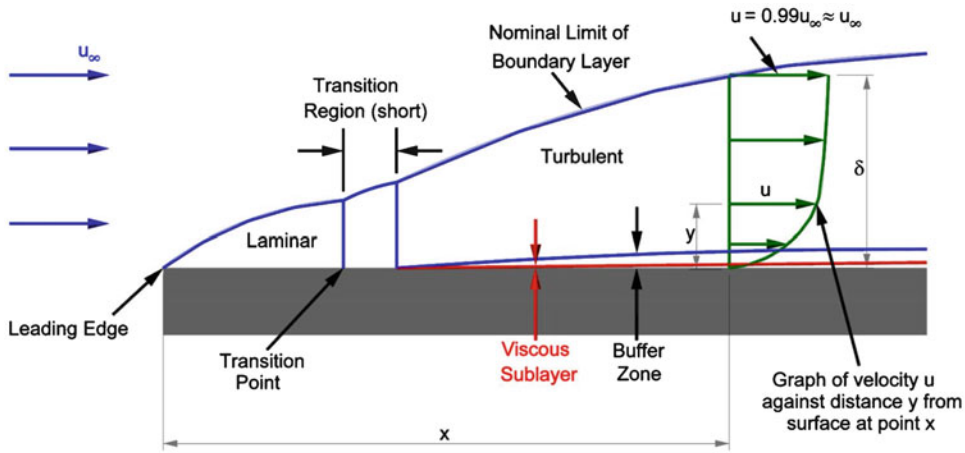

Fig. 1.5 Schematic representation of flow over a flat plate (Source: http://www.cortana.com)

'sufficiently far away' is related to the thickness of the boundary layer, which can be defined as:

$$y = \delta : v_x = 0.99U_\infty. \tag{1.59}$$

In words: the boundary layer thickness δ is the distance from the plate where the velocity equals 99 % of the free stream velocity. Other measures, such as displacement thickness and momentum thickness, can also be used to characterize the boundary layer thickness, but this is not essential for the present discussion.

Two flow regions can be defined:

- $y < \delta$: Strong velocity gradients and viscous shear stresses;
- $y > \delta$: Negligible velocity gradients and viscous shear stresses.

From an order of magnitude analysis, in the assumption that $\delta \ll x$, with x the distance from the leading edge of the flat plate, and in the assumption of laminar flow in the boundary layer, it can be shown that the boundary layer thickness grows as:

$$\delta_{lam} \sim \left(\frac{\mu x}{\rho U_\infty}\right)^{1/2}. \tag{1.60}$$

In words: the laminar boundary layer thickness grows with the square root of the distance from the leading edge. It is thicker as the kinematic viscosity is higher. The latter shows that the influence region of the flat plate is larger for fluids with higher viscosity.

Using x as characteristic distance, the following Reynolds number can be defined:

$$\mathrm{Re}_x = \frac{U_\infty x}{\nu}. \tag{1.61}$$

The viscous shear stress at the plate then becomes:

$$\tau_s = \mu\left(\frac{\partial v_x}{\partial y}\right)\Big|_{y=0} \sim \rho\nu\frac{U_\infty}{\delta} \sim \rho U_\infty^2\left(\frac{U_\infty x}{\nu}\right)^{-1/2}. \tag{1.62}$$

This can be expressed in a non-dimensional manner, by introducing the friction coefficient:

$$C_{f,x} = \frac{\tau_{s,x}}{\frac{1}{2}\rho U_\infty^2} \sim \left(\frac{U_\infty x}{\nu}\right)^{-1/2} = \mathrm{Re}_x^{-1/2}. \tag{1.63}$$

The 'Blasius' solution for laminar boundary layers over smooth flat plates indeed yields:

$$\delta_{lam} = 4.92x\mathrm{Re}_x^{-1/2}; C_{f,x.lam} = 0.664\mathrm{Re}_x^{-1/2} \tag{1.64}$$

However, as mentioned, there are inherent instabilities in the convection terms in the Navier–Stokes equations. These instabilities are damped near the flat plate, primarily due to the blocking effect and the viscous forces, so that turbulent vortices (eddies) cannot develop.

However, as the laminar boundary layer thickness grows with the distance from the leading edge (Equation 1.60), turbulence can start to develop. There is a critical Reynolds number $Re_{x,crit}$ (Equation 1.61) beyond which there is transition from laminar to turbulent flow. For a smooth flat plate, $Re_{x,crit}$ is in the order of 500.000.

As mentioned in the previous section, the momentum (and heat) transfer strongly increase in turbulent motions, as compared to the aligned laminar flow, since momentum (and heat) are transferred on a larger scale through the turbulent eddies. As a result, the surface friction (and heat transfer) increase and the boundary layer becomes thicker. It can be shown that:

$$\delta_{turb} = 0.37 x \mathrm{Re}_x^{-1/5}; C_{f,x,turb} = \frac{\tau_s}{\frac{1}{2}\rho U_\infty^2} = 0.0592 \mathrm{Re}_x^{-1/5}. \quad (1.65)$$

Thus, a turbulent boundary layer grows more rapidly than a laminar boundary layer.

Before discussing the turbulent boundary layer in more detail, it is worth mentioning that, very similar to boundary layers at the level of velocities, thermal boundary layers can be defined. Indeed, the thermal diffusivity α plays the same role for heat transfer as the kinematic viscosity ν does for momentum transfer, as mentioned before. The thermal boundary layer thickness is defined as:

$$y = \delta_T : T - T_s = 0.99(T_\infty - T_s), \quad (1.66)$$

with T_s the surface temperature at the flat plate.

The Prandtl number (Equation 1.8) then determines whether the thermal boundary layer is thicker or not than the flow boundary layer:

- $Pr = 1$: $\delta = \delta_T$;
- $Pr < 1$: $\delta < \delta_T$; example: air;
- $Pr > 1$: $\delta > \delta_T$; example: water.

Now the turbulent layer is discussed in more detail. Figure 1.6 presents a profile as measured in a pipe (which is in fact an internal flow, see next section), but the boundary layer near the solid boundary is very similar.

The results are expressed in a nondimensional manner, introducing the friction velocity:

$$u_* = \sqrt{\frac{\tau_s}{\rho}}, \quad (1.67)$$

and the non-dimensional distance from the solid boundary, expressed in 'viscous' units:

$$y^+ = \frac{y u_*}{\nu}. \quad (1.68)$$

Three regions can be distinguished inside the boundary layer:

- Laminar (or 'viscous') sub-layer, $y^+ < 5$: very close to the solid boundary, all turbulence is damped (due to blocking effect and viscous forces) and the flow is essentially laminar. The velocity increases linearly with the distance from the solid boundary.
- Logarithmic layer, $30 < y^+ < 300$: the motion is turbulent and there is a logarithmic relation between the mean velocity and the distance from the solid boundary.
- Buffer layer: $5 < y^+ < 30$: transitional region between the laminar sub-layer and the logarithmic layer.

It must be stressed that the discussion above refers to smooth surfaces. Roughness on a surface will affect the transition to turbulence and the turbulent boundary layer structures. This can be important, e.g. when the wind load on buildings is considered in built environment or when wind effects are considered in the context of e.g. forest fires. This, however, is considered beyond the scope of the present chapter.

Internal Flows—Flows in Pipes—Pressure Losses

A major difference from the previous section on external flows, is that in internal flows the notion 'free stream velocity' does not exist. In fully developed flow conditions, the flow is entirely affected by the presence of the solid boundary and, consequently, by the fluid's viscosity. The discussion is based here on flows through pipes, since pipes are a common configuration (e.g. water through pipes for sprinklers or water hoses in fire service intervention). Some comments are formulated for flows through ducts in the end.

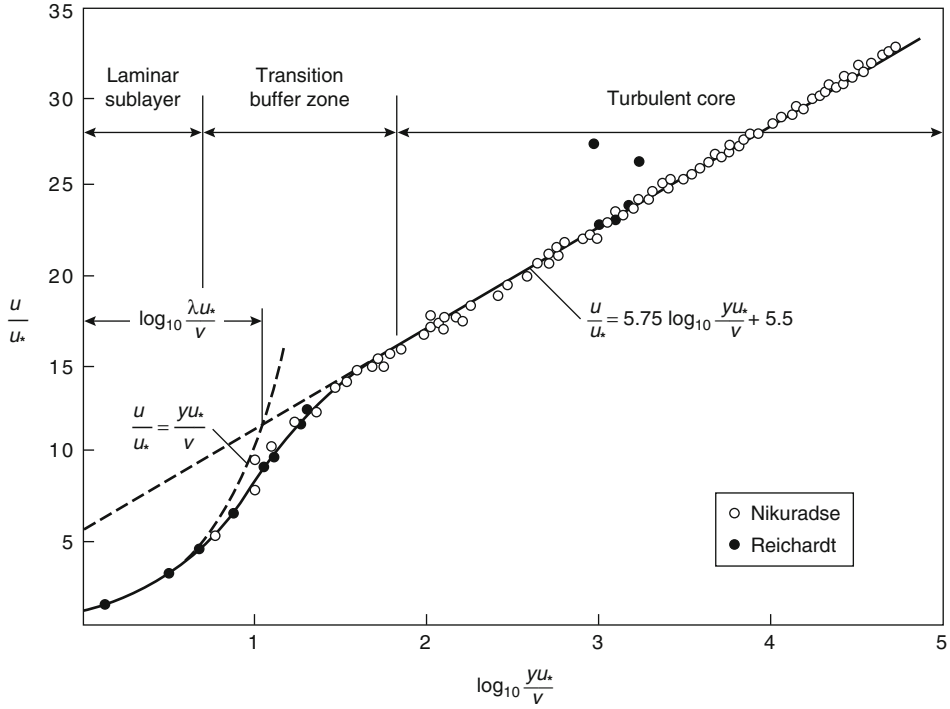

Fig. 1.6 Turbulent velocity profiles as measured in a pipe: different regions in boundary layer

When the entrance region of a smooth pipe is considered, a boundary layer develops from the solid boundary, very similar to what has been described in the previous section. However, since this boundary layer grows on the entire surface, there is a point where the entire cross-section is covered by a 'boundary layer'. This point determines the 'entrance length'. From that point onward, the boundary layers do not evolve and the flow becomes fully developed.

Depending on the Reynolds number, the flow is again laminar or turbulent. It is clear that the distance from the entrance is not a useful characteristic length, since in fully developed flow conditions, the velocity profiles are independent of that distance. Clearly, the pipe diameter is a useful quantity. At the same time, there is no free stream velocity. A mean velocity U_m can be computed from the volume flow rate and the cross-sectional area. Thus, the Reynolds number is now defined as:

$$\mathrm{Re} = \frac{U_m D}{\nu}. \tag{1.69}$$

The critical Reynolds number beyond which the flow becomes turbulent is around $\mathrm{Re}_{crit} = 2300$.

When the cross-section is not round, the diameter D is replaced by the hydraulic diameter D_h, defines as four times the cross-sectional area divided by the cross-section perimeter:

$$D_h = \frac{4A}{P}. \tag{1.70}$$

It is straightforward to show that for fully developed laminar flows, the following expressions hold (with R = D/2 the radius of the pipe and r the radial distance from the pipe symmetry axis):

- Parabolic velocity profile:

$$\frac{u}{U_m} = 2\left(1 - \frac{r}{R}\right)^2; \tag{1.71}$$

- Wall shear stress (friction):

$$\tau_{s,lam} = -\mu \frac{\partial u}{\partial r}\bigg|_{r=R} = 4\mu \frac{U_m}{R}; \tag{1.72}$$

- Friction factor:

$$f_{lam} = \frac{\tau_{s,lam}}{\frac{1}{2}\rho U_m^2} = \frac{16}{\mathrm{Re}_D}; \tag{1.73}$$

	∈ (ft)	∈ (mm)
Riveted steel	0.003–0.03	0.9–9.0
Concrete	0.001–0.01	0.3–3.0
Wood stove	0.0006–0.03	0.18–0.9

Commercial steel or wrought iron	0.00015	0.046
Drawn tubing	0.000005	0.0015

Fig. 1.7 Moody diagram

- Pressure loss over a distance L in the pipe:

$$\Delta p_{lam} = f_{lam} \frac{1}{2} \rho U_m^2 \frac{4L}{D}. \qquad (1.74)$$

Note that the pressure loss is linear with the length of the pipe and, with Equation 1.73, linear with the mean velocity and inversely proportional with the square of the pipe's diameter. Recall that this is only true for laminar flows.

For turbulent flows, the expressions become more complex. The velocity profile can be approximated as:

$$\frac{u}{U_{\max}} = \left(1 - \frac{r}{R}\right)^{1/7}, U_{\max} = \frac{U_m}{0.817}. \qquad (1.75)$$

Expression (1.74) still holds for the pressure losses, but the friction factor is no longer obtained from Equation 1.73. The Moody diagram [14] (Fig. 1.7) reveals that, for large enough Reynolds number, the friction factor is determined by the relative roughness of the pipe, independent of the Reynolds number. As a consequence, for turbulent flows, the pressure loss is still linear with the length of the pipe, but proportional to the mean velocity squared and inversely proportional with the pipe diameter.

In duct flows, essentially the same reasoning holds. The major difference is in the values for the friction factor f, important to estimate pressure losses. Secondary flows appear in the corners of duct, transporting momentum from the center to the corners and leading to a relative increase in velocity near the corners.

It is instructive to quantify pressure losses for internal flows as:

$$\Delta p_L = C_L \frac{1}{2} \rho U_m^2. \qquad (1.76)$$

The loss coefficient C_L must be defined, depending on the situation (geometry and flow type—laminar/turbulent). All pressure losses must be accounted for in the design. This holds for e.g. the design of the piping system for sprinklers (i.e. what pump must be chosen) or the design of a smoke extraction system

(i.e. what extraction fans are required to overcome all pressure losses, including the ones in the exhaust system).

Some examples are briefly mentioned here:

- Straight sections: Moody diagram, see above.
- Curves/bends: C_L is determined by the total angle and the radius of the bend (e.g. $C_L = 0.14$ for an angle of 90° with radius $2D$, but it is about 1.2 for the same angle of 90° but with radius = 0, i.e. a sharp bend). Curves and bends are always important to consider in calculations of pressure losses.
- Sudden pipe expansion: $C_L = \left(1 - \frac{A_1}{A_2}\right)^2$. A special case concerns the flow into a large space, i.e. $A_2 \to \infty$. Then $C_L = 1$.
- Sudden pipe constriction: the flow is constricted and then widens again behind the constriction. A good estimate for a sudden constriction is $C_L = 0.5$, while C_L goes down to 0 for a very gentle constriction.
- Flows through openings: C_L primarily depends on the edges of the opening. The most typical situation is that the edges are Sharp. In that case C_L typically varies between the values $C_L = 0.4$ and $C_L = 0.7$.

Bernoulli Equation

The Bernoulli equation is of fundamental importance. The equation, valid on any streamline, has been developed for incompressible flows (liquids). Yet, it can also be applied to low-Mach number flows where the density hardly changes (gas flows in fire related flows, as long as the density along the streamline does not vary strongly).

With the notation now that z is the height (i.e. the z-direction is vertically upward), Bernoulli's equation reads:

$$p + \frac{1}{2}\rho v^2 + \rho g z = const. \tag{1.77}$$

A few application examples are briefly mentioned.

Application Example 1: Velocity Measurement with a Pitot Tube Figure 1.8 shows the basic principle of a Pitot tube. The flow is stagnated. By measuring the pressure increase cause by this stagnation, the velocity can be computed. Indeed, applying Bernoulli's Equation 1.77 at constant height z yields:

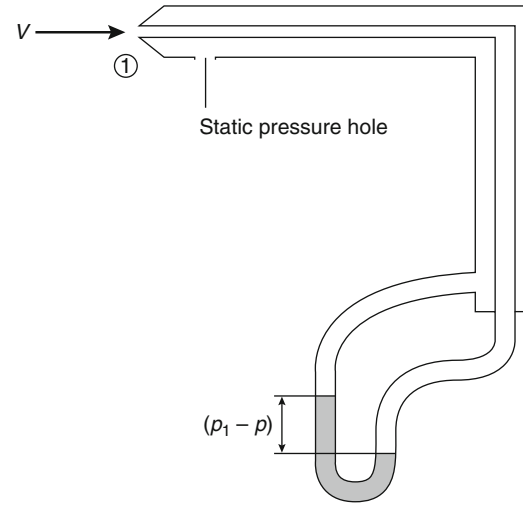

Fig. 1.8 Sketch of Pitot tube

$$p_{tot} + \frac{1}{2}\rho 0^2 = p_{stat} + \frac{1}{2}\rho v^2 \Rightarrow v = \sqrt{\frac{2(p_{tot} - p_{stat})}{\rho}}. \tag{1.78}$$

Application Example 2: Venturi Flowrate Meter Figure 1.9 shows the basic principle of a Venturi meter. It is essentially a converging cone, from which the flowrate through a pipe can be calculated. Indeed, applying Bernoulli's Equation 1.77 at constant height z yields:

$$p_1 + \frac{1}{2}\rho v_1^2 = p_2 + \frac{1}{2}\rho v_2^2. \tag{1.79}$$

Conservation of mass allows elimination of v1: $v_1 = v_2 \frac{A_2}{A_1}$. Insertion in Equation 1.80 and introducing $\dot{V} = v_2 A_2$ yields:

$$\dot{V} = A_2 \sqrt{\frac{2A_1^2(p_1 - p_2)}{\rho(A_1^2 - A_2^2)}}. \tag{1.80}$$

Application Example 3: Flow Out of a Large Tank Figure 1.10 sketches the situation. A large tank is considered, so that the liquid surface can be approximated as standing still, i.e. $v_1 = 0$.

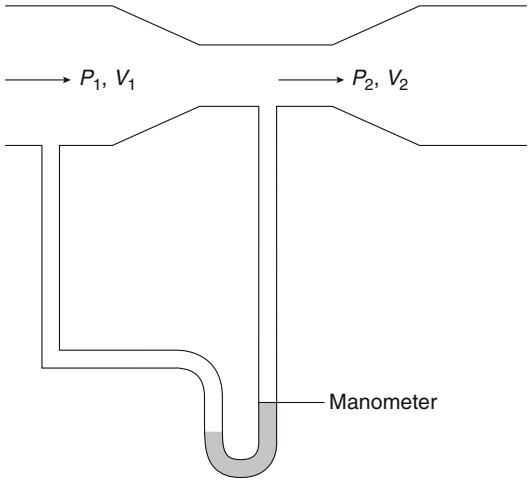

Fig. 1.9 Sketch of Venturi meter

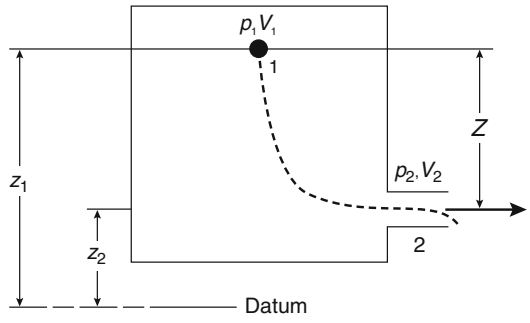

Fig. 1.10 Outflow out of a large tank

Approximating $p_1 = p_2 = p_{atm}$, the flow is generated by the gravity force:

$$\frac{1}{2}\rho v_2^2 = \rho g z \Rightarrow v_2 = \sqrt{2gz}. \tag{1.81}$$

The assumption $p_1 = p_2 = p_{atm}$ is a reasonable assumption if the tank is open and if the liquid density is much higher than the density of air (the latter is practically always fulfilled).

Application Example 4: Flow Through an Orifice In the previous example, the pressure driving the fluid out of the tank stems from gravity. In general, the pressure difference (Δp) over an opening determines the flow through the opening. From the (mean) velocity and the cross-sectional area (A) of the opening, the volume flow rate through that opening can be computed. A discharge coefficient C_d is introduced, though:

$$\dot{V} = C_d A \sqrt{\frac{2\Delta p}{\rho}}. \tag{1.82}$$

This can be interpreted as a 'correction' to the cross-section area that is effectively used for outflow (or inflow). For an orifice, the value of C_d is around 0.6 for e.g. open doors or windows, going up to about 0.7 for flows through small gaps [10].

Finally, it is mentioned that, when pressure losses are considered (see previous section), Bernoulli's equation can be extended to:

$$p_1 + \frac{1}{2}\rho v_1^2 + \rho g z_1 = p_2 + \frac{1}{2}\rho v_2^2 + \rho g z_2 + \Delta p_{L,1-2}. \tag{1.83}$$

In Equation 1.84, the final term reflects the pressure loss between points 1 and 2 on the streamline.

Wind

Wind is an important factor in fire protection engineering. An obvious example is the effect of wind on the development of forest fires, where convection strongly affects the direction and speed of fire spread. Another examples concerns smoke and heat control (SHC) in case of fire inside a building, where wind will exert a pressure load onto the building. The distribution of the load (positive and negative) affects the performance of the SHC system. The wind can also induce internal flows into the building, depending on leakages or open windows or doors.

It is common practice to consider steady wind conditions. Clearly, wind gusts can have an impact in the course of the fire. This is not considered in the discussion below.

Natural Wind Characteristics

A classical method to characterize the boundary layer, when there is no detailed information of surface roughness, is the use of a power law:

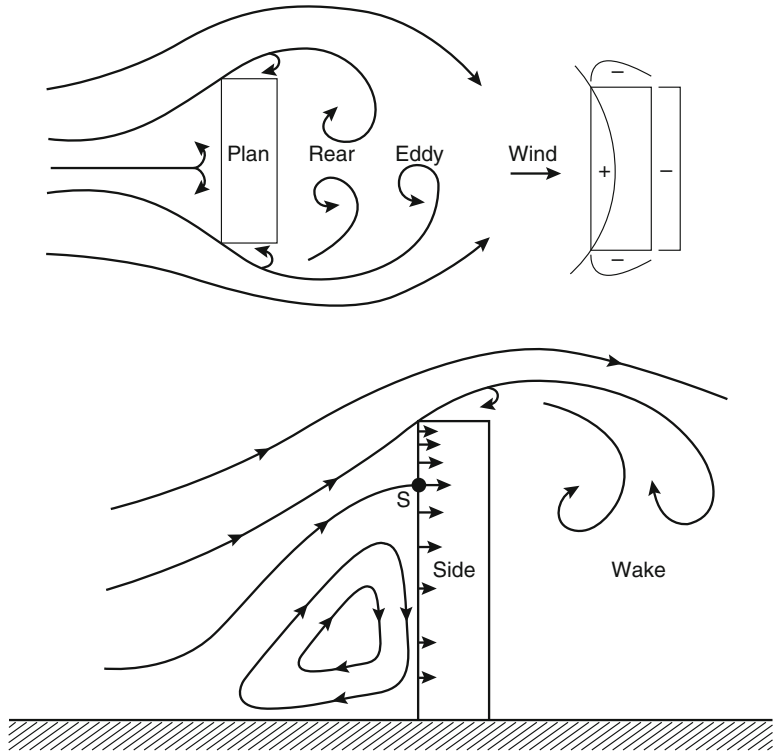

Fig. 1.11 Schematic representation of wind flow, interacting with a tall building

$$v(z) = v(z_{ref})\left(\frac{z}{z_{ref}}\right)^{\alpha}. \qquad (1.84)$$

The exponent α is given the value α = 1/7 for 'smooth' surfaces. This is related to turbulent boundary layer velocity profiles. Other values apply for 'rough' surfaces, i.e. when 'obstacles' such as trees or buildings disturb the boundary layer. An alternative option is then the use of a log law expression:

$$v(z) = \frac{v_*}{\kappa}\ln\left(\frac{z}{z_o}\right). \qquad (1.85)$$

In expression (1.86), v_* is the friction velocity Equation 1.67, κ is the von Karman coefficient ($\kappa = 0.4$) and z_o is the aerodynamic roughness length. The reader is referred to specialized literature for more details (e.g. [15]).

Interaction of Wind with Buildings

It is well-known that wind, impinging in a perpendicular direction onto a rectangular building, causes over-pressure on the windward side and under-pressure on all other sides (including the roof). This is illustrated in Fig. 1.11. This pressure load distribution affects the performance of SHC systems and can cause internal flows (e.g. through open windows or doors), as mentioned. However, it must be stressed that Fig. 1.11 is a strong simplification of reality. Not only is the wind assumed steady and perpendicular to one side of the building, it is also not supposed to be affected by the environment. In reality, tall buildings are situated in a built environment, so the oncoming wind profile need not obey expressions like (1.85) or (1.86) and need not be unidirectional. For obvious reasons, the direction of the oncoming wind, even if not disturbed by the environment, varies in time, depending on atmospheric pressure distributions. Finally, modern buildings are not necessarily rectangular in shape. All these factors indicate the need for either small-scale wind tunnel experiments or extensive CFD studies. For the time being, since it is necessary to consider many wind directions and velocities and the (built) environment can be complex and hard to characterize as boundary conditions in CFD simulations, wind tunnel experiments seem

preferable. The model scale can then be built on a table that can be turned around in the wind tunnel to examine various angles of oncoming wind.

To finalize this section, it is recalled that wind-induced over-pressure and under-pressure are proportional to the wind velocity squared. This is to be expected from Bernoulli's equation 1.77. Clearly, the flow does not stagnate entirely over the entire surface and thus pressure coefficients are introduced:

$$\Delta p_w = \frac{1}{2} C_w \rho_{amb} v_w^2. \tag{1.86}$$

The wind coefficient can be positive (over-pressure at the windward side) or negative (under-pressure). In e.g. [16] more info is found on this topic.

Nomenclature

A_v	Vent area (m^2)
C_p	Specific heat at constant pressure (kJ.kg^{-1}.K^{-1})
C_v	Specific heat at constant volume (kJ.kg^{-1}.K^{-1})
D	Fireball diameter (m)
E_{av}	Total expansion energy (kJ)
L	Latent heat of vaporization (kJ.kg^{-1})
m	Flammable mass (kg)
M_{liq}	Liquid mass (kg)
P	Pressure (Pa)
R	Distance from explosive material (m)
s	Specific entropy (kJ.kg^{-1}.K^{-1})
T	Temperature (K)
t_d	Duration of the fireball (s)
u	Internal energy (kJ.kg^{-1})
V	Vessel volume (m^3)
W_{TNT}	Equivalent mass of TNT (kg)
X_f	Mass fraction of the initial liquid mass that flashes to vapor
X_g	Mass fraction of the initial vapor mass that does not condense during expansion

Greek Symbols

β	Fraction of energy released converted into the blast wave.
γ	Ratio of specific heats $\left(\gamma = \frac{C_p}{C_v}\right)$
ν	Specific volume (m^3.kg^{-1})
ρ	Density (kg.m^{-3})

Subscripts

atm	Atmospheric
gas	Gas
liq	Liquid

Having completed a PhD (Ghent University, 2000) on turbulence modeling in CFD simulations of non-premixed combustion, he is an expert in fluid mechanics aspects in reacting flows, more particularly related to fire and smoke dynamics.

Conduction of Heat in Solids

2

Ofodike A. Ezekoye

Introduction

Heat transfer is an area of thermal engineering that focuses on the transport, exchange, and redistribution of thermal energy. The three modes or ways that heat can be transferred have been termed conduction, convection, and radiation. In this chapter, the basic physics associated with conduction heat transfer will be presented, and it will be shown through examples how the tools and analysis typically used for conduction problems can be applied to design and analysis when fire occurs.

Conduction heat transfer only occurs in a medium. This is a distinction between conduction and radiation, which does not require a medium. The medium or state of matter in which conduction takes place can be a gas, liquid, or solid. The distinction between conduction and convection heat transfer is associated with whether the medium has some ordered flow or bulk motion. Heat transfer, when there is a mass averaged velocity, is termed convection. Heat transfer that takes place in a stationary frame of reference is called conduction. More details will be presented on the mechanisms that allow heat transfer to occur in a stationary medium as we proceed through this discussion. Solutions will be provided for selected configurations and scenarios. The treatise of Carslaw and Jaeger [1] covers most solutions for conduction phenomena. Other useful texts that discuss conduction phenomena are readily available [2, 3]. It is useful to build up this discussion by first identifying where conduction heat transfer ties into overall energy conservation and energy transfer.

Energy Conservation

The fundamental laws that allow us to analyze and predict fire phenomena are often termed conservation laws. Conservation laws are essentially balance equations that allow us to model how variables that describe the physical world dynamically evolve. In fire systems, we typically model the physical world using mass conservation, momentum conservation, energy conservation, and chemical species conservation. For this chapter, we are interested in describing how heat is transferred in media that are not deforming (i.e., are in rigid body motion with no unbalanced forces) or reacting (fixed chemical species and mass). We do assume, however, that the medium can possibly have heat transferred to it either through interactions with its surrounding or through some other energy input into it. Also, we assume that the medium may have different amounts of thermal energy stored within it at different locations. To more precisely describe energy transfer processes, we rely on the first law of thermodynamics. The energy conservation principle is the basis for heat transfer.

Thermodynamic Properties

The first law of thermodynamics is a statement of energy conservation [4, 5]. It states that the change in energy for an identifiable set of matter can only result from heat transferred across the material's boundary or work done either by or on the material. The thermodynamic property or energy function that best describes the molecular, atomic, electronic, and nuclear energy of a material is the internal energy. In terms of the internal energy, U, the first law is

$$\frac{dU}{dt} = \dot{Q}_{net,in} + \dot{W}_{net,in}$$

U is the internal energy, Q is heat added to the system and W is work done on the system.

The total internal energy U is a system integrated value that represents the total thermal energy of the material system of interest. We can describe the local internal energy in terms of a mass specific internal energy, u, that is simply the total internal energy, U, for a region of matter divided by the mass of that region. The internal energy, like any other thermodynamic variable can be defined in terms of other thermodynamic variables. There is an approximation used in thermodynamics that states that the internal energy for an incompressible material can be specified in terms of the temperature. The thermodynamic property specific heat capacity at constant volume, c_v, relates differential changes in the mass specific internal energy to differential changes in temperature.

$$c_v = \frac{du}{dT} \text{ and } mc_v\, dT = dU$$

The mass is defined as the product of density and volume. The control-mass statement of the first law for a case with no net work done becomes:

$$\rho V c \frac{dT}{dt} = \dot{Q}_{net,in}$$

This form of the first law neither provides information about spatial variations in energy within the medium nor describes how energy is transferred. Experience tells us that the heat transfer into some identifiable mass element likely depends on temperature differences. It will be necessary to define the heat transfer rate in terms of temperature differences. The empirical law defining the heat transfer rate to a body immersed in a fluid is called Newton's law of cooling. When Newton's law of cooling is used, the heat transfer rate to the body is $\dot{Q}_{net,in} = hA(T - T_\infty)$ If we apply Newton's law of cooling to the first law, we arrive at a result called the lumped thermal approximation in conduction analysis.

Lumped Thermal Analysis

Briefly, the lumped thermal approximation allows one to model the overall transient thermal response of a body at some initial temperature subjected to either a change to the external fluid temperature or as a result of some local heating within the object. The validity of this approximation will be discussed in more detail in later sections. For the purposes of this discussion, we will say that the approximation is valid when the time scales for internal energy transfer and subsequent homogenization of the temperature field within an object are much smaller than the time scales for energy transfer from the surface of the body to an external thermal reservoir. In short, the lumped thermal approximation is reasonable when temperature differences within a body are relatively small when compared to temperature differences between the surface of the body and a characteristic temperature of the exterior fluid. It can be shown that a nondimensional heat transfer parameter called the Biot number (Bi) which represents the ratio of the internal conductive resistance to the external convective resistance should be small for the lumped thermal approximation to be valid. A mathematical statement of the energy equation in the lumped approximation is (Fig. 2.1):

$$\frac{dT}{dt} = -\frac{h_c A}{\rho V c}(T - T_\infty)$$

This first order ordinary differential equation can be integrated and one form of the solution is:

$$\frac{T - T_e}{T_0 - T_e} = e^{-(h_c A/\rho V c)t} = e^{-t/t_c}$$

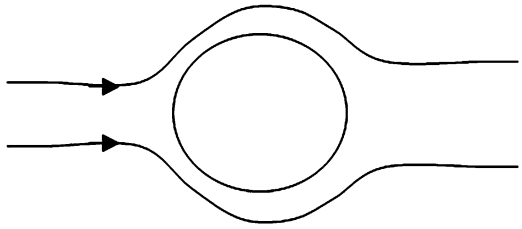

Fig. 2.1 Schematic showing convective flow over an object that will be analyzed using a lumped thermal approximation

In the above, T_0 is the initial temperature of the body and T_e is the external fluid temperature surrounding the object. There is a characteristic time in the problem defined as:

$$t_c = \frac{\rho V c}{hA}$$

The characteristic time provides an estimate of the time required for the nondimensional temperature to relax to its steady value. This relatively simple solution is useful in characterizing a large number of important problems in fire systems [6].

Example 1 The lumped thermal approximation is frequently used to analyze the response of a sprinkler head as it activates due to a change in the environment temperature because of a fire. A sprinkler head fuse can be modeled as a cylinder of diameter 4 mm and length 12 mm. The density can be approximated as being 1000 kg/m^3. The specific heat capacity is approximately 1 kJ/kgK. The heat transfer coefficient of the smoke gases is 20 W/m^{2}K. If the smoke gases are 200 °C and the fuse is initially at 20 °C, how long will it take for the fuse to open if the activation temperature is 80 °C?

The solution is arrived at from inverting:

$$\frac{T - T_e}{T_0 - T_e} = e^{-\left(\overline{h}_c A/\rho V c\right)t} = e^{-t/t_c}$$

$$t_{ACT} = \frac{\rho L c}{\overline{h}_c} \ln \frac{T_0 - T_e}{T_{ACT} - T_e}$$

For the values that we specified, we find that the fuse opens in 243 s. Chapter 3, shows that the heat transfer coefficient is proportional to the fluid velocity $h = Cu^{1/2}$. This results in:

$$\frac{t_{ACT} u^{1/2}}{\ln \dfrac{T_0 - T_e}{T_{ACT} - T_e}} = \frac{\rho L c}{C} = RTI$$

This combination of parameters is the well known response time index for sprinklers.

Fourier's Law of Conduction

As previously noted, the lumped approximation does not allow one to predict the spatial variation of temperature within a body. In some sense, it provides an average or lumped temperature response. To be able to predict the spatial variation of temperature, it is necessary to introduce another physical law that models how heat is transported when temperatures differences exist within a body. We expect heat to flow across a body in proportion to the temperature difference across the body, and perhaps inversely related to the distance across the body. Fourier's law states that the heat flux is proportional to the temperature gradient (the spatial derivative of the temperature). For a one dimensional homogeneous and isotropic object this reduces to the simple expression:

$$q'' = -k \frac{dT}{dx}$$

We use the notation q″ to indicate a heat transfer rate per unit area. The proportionality between the heat flux and the spatial derivative of temperature is the thermal conductivity.

Thermal Conductivity

For materials like air, water, glass, and copper, the thermal conductivity is isotropic (i.e., does not depend on orientation), but it has a temperature dependence. Under conditions in which the overall thermal conductivity difference across the body is small relative to the any particular value of the thermal conductivity in the body, we

can consider k to be essentially a constant. In fire applications, this is often not the case, but for the sake of analysis we will often use this approximation when generating analytical solutions.

There are materials for which the thermal conductivity depends both on the local temperature and also on the orientation. In contrast to isotropic materials for which there is no directional effect, anisotropic materials have this directional dependence. The most commonly encountered anisotropic material in fire applications is wood. The grain structure of wood is the source of the anisotropy. Practically, we would find that for the same temperature difference across a given thickness of wood, the heat transfer rate depends on whether this temperature difference is aligned with the grains or aligned perpendicular to the grains. Of course, as one heats wood, there are also chemical changes to the wood. So, the thermal conductivity depends on the temperature, composition, and orientation. For a simple analysis, the effects of decomposition are often neglected for the initial ignition process.

Again, Fourier's law states that the heat flux vector, $\vec{q}''$, is proportional to the temperature gradient, where the proportionality constant is the thermal conductivity, k. In general, k is a second order tensor and has different values depending on the face and orientation of a differential volume [1–3]. For a general anisotropic material

$$\vec{q}'' = -\begin{bmatrix} k_{xx} & k_{xy} & k_{xz} \\ k_{yx} & k_{yy} & k_{yz} \\ k_{zx} & k_{zy} & k_{zz} \end{bmatrix} \nabla T$$

This suggests that the component of the heat flux vector in the x-direction depends on all components of the temperature gradient.

$$q_x = -\left(k_{xx}\frac{\partial T}{\partial x} + k_{xy}\frac{\partial T}{\partial x} + k_{xz}\frac{\partial T}{\partial x} \right)$$

For some materials that are frequently dealt with in fire analyses, such as wood, there is some simplification in the dependence of thermal conductivity on orientation. Laminates like wood are said to be orthotropic. For an orthotropic material, the off-diagonal elements of the thermal conductivity tensor are zero and the diagonal elements are not equal to each other.

$$k = \begin{bmatrix} k_{xx} & 0 & 0 \\ 0 & k_{yy} & 0 \\ 0 & 0 & k_{zz} \end{bmatrix}$$

For metals, many crystalline solids, many amorphous solids, liquids, and gases, the conduction process is considered to take place in an isotropic medium. For such materials, the thermal conductivity can vary spatially and with temperature, but does not have an orientation effect.

$$k = k(T(x,y)) \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

Homogeneous Systems

Most obvious in gases, it is known that random molecular motion transfers heat from hot molecules to cooler ones. For solids other wave like effects are important. There is a relatively simple theory that describes the physics of thermal conductivity. Conduction heat transfer can be thought of in terms of a carrier particle with a characteristic velocity and characteristic length scale over which it acts. The development of this perspective of thermal conductivity, based on the properties of notional particles is described by Kaviany [7, 8]. In some sense, this description is a simple generalization of the kinetic theory description of thermal conductivity for gases. For gases, we understand that the kinetic theory of gases describes how k varies in terms of a characteristic gas velocity, u, the number density of molecules, n, the mean free path, l, and the molecular internal energy described by the molecular mass and heat capacity (mc).

$$k \cong \frac{1}{3} mc_v nul$$

In the following table adapted from Kaviany [7, 8], the characteristic parameters for various types of conduction systems are provided (Table 2.1).

Examples of Homogenous Materials

In fire analysis, most solid materials are approximated as being homogeneous. Examples of homogeneous systems in fire applications are

Table 2.1 Characteristic quantities used in microscale carrier model of conduction

Microscale carrier	Fluid particle (random motion)	Phonon (quantal lattice vibration)	Electron
Regimes	Dilute gases	Acoustic phonon and optical phonon	Free electrons and valence electrons
Mean free path	Interparticle spacing	Lattice dimension	Lattice dimension
Carrier concentration	Fluid density	Solid density	Free electron density
Carrier speed	Thermal speed	Speed of sound	Electron drift velocity

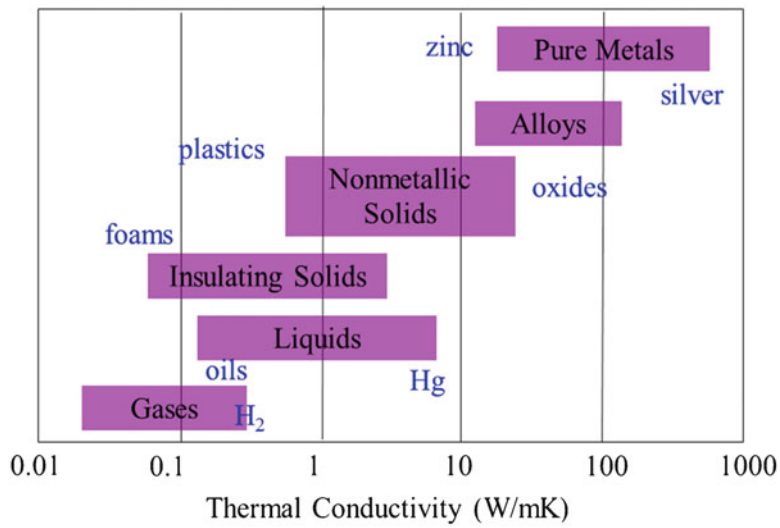

Fig. 2.2 Range of thermal conductivities for different materials (Adapted from [2])

simple polymeric materials, metals, and various types of insulating materials (Fig. 2.2).

Composite Systems

Treatment of composite material thermal conductivity is somewhat more complicated than the treatment for homogeneous materials. With increased use of composite materials like polymer impregnated concrete as structural components, it is useful to discuss how to construct an effective thermal conductivity for such materials. The key to constructing an effective thermal conductivity is to develop a meaningful way to average the thermal properties for the system. A representative averaging volume is the term used to describe the volume over which one can meaningfully average the properties of the composite in order to properly thermally characterize the material. The simplest treatments of composite media thermal conductivity use either series or parallel resistance models. For a mixed medium that is comprised of several different conducting elements, the parallel approximation provides an upper bound on an effective thermal conductivity, while the series approximation provides a lower bound.

Examples of Composite Materials

Examples of composite materials include many types of insulating materials in which at least two types of materials are mixed in various mass fractions. The mass or volume fractions of the constituents can then be used along with their individual conductivities to define an effective conductivity for the system. Various mixing rules have been developed for the effective thermal conductivity. Gebhart [9] discusses a general way of classifying the effective thermal conductivity of a binary system comprised of a matrix material a and added material b as:

$$\frac{k_e}{k_a} = f\left(\frac{k_b}{k_a}, \Phi_b, \frac{L_i}{L}, Bi\right).$$

Depending on the ratio of the thermal conductivities, the ratios of the characteristic lengths of the a and b segments within the medium, and the relative volumetric ratios, different correlations exist for the effective conductivity.

Kaviany [7] presents a correlation for the effective conductivity for random porous solids (e.g., continuous solid and fluid phases) as might occur for a wound insulation material,

$$\frac{\langle k \rangle}{k_f} = \left(\frac{k_s}{k_f}\right)^{0.280 - 0.757 \log(\varepsilon) - 0.057 \log\left(k_s/k_f\right)}$$

which is valid for fluid porosity (volume fraction) in the range of $0.2 < \varepsilon < 0.6$.

Heat Equation Formulations

The heat equation is the name given to the differential equation that models heat conduction in materials. The heat equation is most generally developed in a three dimensional, unsteady form. Depending on the scenario of interest, it is not always necessary to solve the full formulation of the heat equation. By formulating an appropriate reduced form of the heat equation, one can generally compute an accurate representation of the temperature profile and heat flux distribution in the material. In the following sections, several reduced model forms for the heat equation will be discussed.

Steady One Dimensional Models

Under conditions in which there is a primary heat transfer direction, it is appropriate to formulate a one-dimensional form of the heat equation. Further, when the time scale for changes in boundary conditions and sources are large relative to the time scale over which the thermal system equilibrates, the analysis can be treated as being steady. A discussion of how to define the time to equilibrate in conduction systems will follow in a later section.

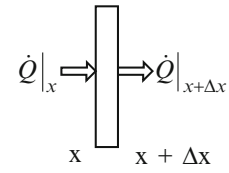

Fig. 2.3 Schematic of differential volume in which steady one dimensional heat equation is developed

To develop the one dimensional conduction model, we consider an elemental volume, ΔV, located between spatial locations x and x + Δx for a heat transfer process that is in steady state. We can apply the first law of thermodynamics to the elemental volume and consider a case in which there is no internal generation (Fig. 2.3).

$$\dot{Q}\big|_x = \dot{Q}\big|_{x+\Delta x} = \text{Constant}$$

$$\dot{Q} = q''A = -kA\frac{dT}{dx}$$

$$\frac{d}{dx}\left(kA\frac{dT}{dx}\right) = 0$$

Application of Fourier's law leads to an energy equation specified in terms of temperature gradients defined within the solid. The solution can be found by simple integration.

If the thermal conductivity, k, is nearly constant over the temperature range of interest to the problem, then we see that a very simple relationship holds between the temperature difference across the solid, the thermal conductivity, and the thickness of the solid. It is apparent that an analogy holds between this form and Ohm's law, where the heat transfer rate is identified as a current, the temperature difference, ΔT is identified as a potential change, and L/kA is identified as a generalized resistance.

Cylindrical Shells

This same type of analysis can be formulated for cylindrical shells. The difference in the analysis is that the cylindrical shell has variable surface area (Fig. 2.4).

Applying Fourier's law over concentric cylindrical elements yields

$$\dot{Q} = Aq = 2\pi rL\left(-k\frac{dT}{dr}\right)$$

Similar to the development for the planar slab geometry, an effective resistance can be defined for the cylindrical system. Integrating the equation twice yields:

$$\dot{Q} = \frac{2\pi kL(T_1 - T_2)}{\ln(r_2/r_1)}$$

We can extract a resistance from this expression to be:

$$R = \frac{\ln(r_2/r_1)}{2\pi kL}$$

Fin Approximation

The fin approximation refers to one dimensional conduction analysis where heat transfer has a predominant direction, there is no transverse temperature gradient, and the heat transfer in the transverse direction is simply defined through Newton's law of cooling. The simplest example of use of the fin approximation is in the development of the pin fin model. A pin fin is slender rod of length L and diameter D with convective heat transfer taking place over most of the rod's surface. At least one end of the rod is assumed to be fixed at a temperature different from the environmental fluid temperature. For one dimensional heat transfer to be valid, the length of the fin divided by the diameter should be large and a Biot number Bi = hD/k for the fin should be small. In a fire scenario, a fully exposed beam might be modeled as being a fin [10]. Development of the pin fin equation begins with a power balance on a differential section of the fin, as shown below (Fig. 2.5).

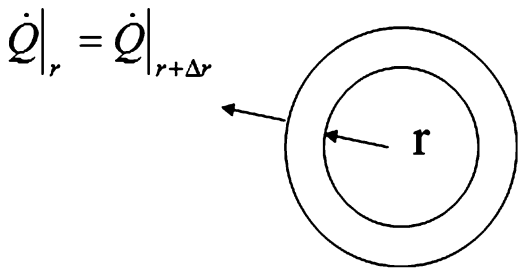

Fig. 2.4 Schematic of cylindrical shell in which one dimensional, steady cylindrical formulation of heat equation is developed

One dimensional analysis (radially lumped) is valid when d/L<<1 and Bi<<1.

The power balance on the differential element coupled with performing a limiting process as Δx approaches zero results in the pin fin equation shown below.

$$kA_c\frac{d^2T}{dx^2} - h_cP(T - T_\infty) = 0$$

This second order ordinary differential equation requires two boundary conditions (BCs). The base temperature is often specified as known (i.e., $T(x = 0)$). Typical BCs at $x = L$ are:

(a) Known tip temperature or Dirichlet condition (e.g., $T(L) = 20\ ^\circ\text{C}$)
(b) Known tip heat flux or Neumann condition (e.g., $q''(x = L) = 0$)
(c) Convection tip or Robin's condition (e.g., $-k\frac{dT}{dx}\big|_{x=L} = h(T(x = L) - T_\infty)$

Solutions and examples of use of the fin approximation will be provided in a later section. It is, however, useful to discuss one limiting case solution for the pin fin. A pin fin is said to be semi-infinite if the effect of the imposed temperature at the fin base does not affect the temperature distribution over the entire length of the fin.

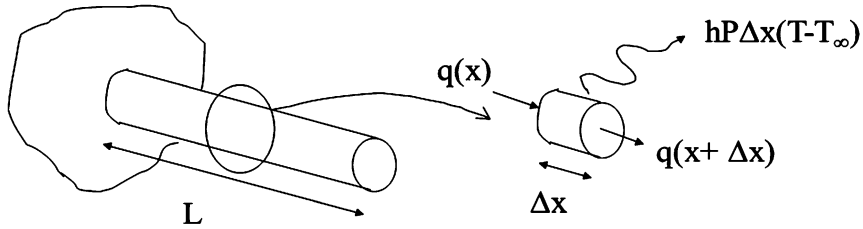

Fig. 2.5 Development of pin fin equation for cylindrical rod

Simple 1D Composite Systems

The simplest composite systems can be thought of in two limiting cases. One might imagine configurations with two different conductors either in a series or in a parallel configuration. For the simpler case, in which the conductors are in series, it is useful to discuss the nature of the interface between the two conductors. The idealized interface between surfaces is considered to be perfect contact in which the interface temperatures are the same on both surfaces. In contrast, an imperfect contact is said to have a contact resistance and there is a temperature discontinuity at the interface between the two surfaces (Fig. 2.6). In the equation shown below h_i is known as the interface conductance with the same units as the heat transfer coefficient (W/m^{2}K)

$$-k_A \left.\frac{dT}{dx}\right|_u = h_i(T_u - T_s) = -k_B \left.\frac{dT}{dx}\right|_s$$

Example 2 A composite wall for a furnace is made of two materials, an insulating material with thermal conductivity k_A and an exterior skin with thermal conductivity k_B. Within the furnace there is an internal heat transfer coefficient $h_{c,i}$ and internal temperature T_i. Outside of this wall there is a heat transfer coefficient hc,o and external temperature T_o. We can calculate the total heat flux (heat transfer rate per unit area) and also the intermediate temperatures (e.g., the interface temperature between the two materials) using a simple resistance analogy (Fig. 2.7).

By identifying a simple conductive resistance for the slabs we see that the heat transfer rate can be specified as

$$\dot{Q} = \frac{T_i - T_1}{1/h_{c,i}A} = \frac{T_1 - T_2}{L_A/k_A A} = \frac{T_2 - T_3}{L_B/k_B A} = \frac{T_3 - T_0}{1/h_{C,o}A}$$

The heat transfer rate can be thought of as being proportional to a potential difference (i.e., the

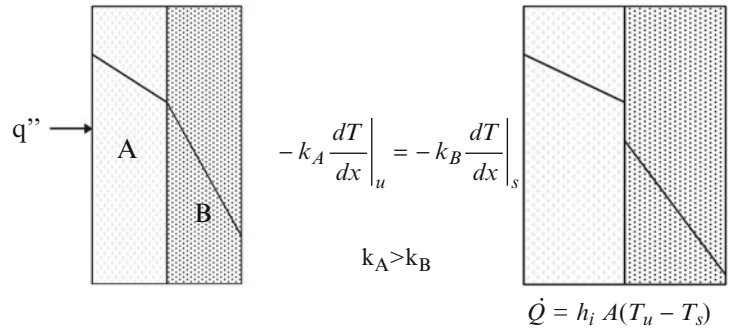

Fig. 2.6 Comparison of perfect and imperfect thermal contact showing contact resistance temperature jump for imperfect contact

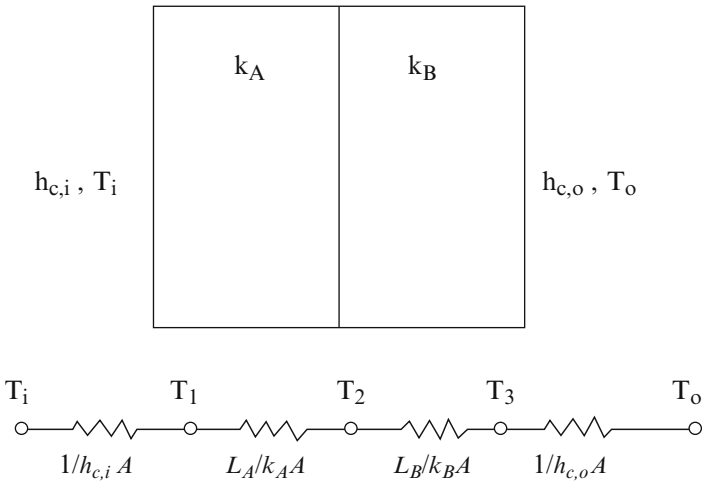

Fig. 2.7 Circuit analogy for conduction in two slabs

temperature drop) and inversely proportional to a resistance. We can use:

$$\dot{Q}R_i = \Delta T_i$$
$$\dot{Q}\sum R_i = \sum \Delta T_i$$

The sum of the individual potential drops equals the total potential difference across the system. Dividing by the sum of the resistances, we get:

$\dot{Q} = \frac{T_i - T_o}{\sum R_i}$ which on a per unit area basis becomes

$q'' = \frac{T_i - T_o}{\sum R_i''}$

For a case with $T_i = 1000\ ^\circ C$, $T_o = 300\ ^\circ C$, $h_{ci} = 30\ W/(m^2K)$, $h_{co} = 10\ W/(m^2K)$, $L_A = 2\ cm$, $L_B = 0.2\ cm$, $k_A = 1\ W/(mK)$, $k_B = 20\ W/(mK)$ we find that the equivalent resistance

$$R_{EQ}'' = \sum R_i'' = 0.153\frac{Km^2}{W}$$

The heat flux is $q'' = \frac{1000-300}{0.153} = 4.56 kW/m^2$. Check the magnitudes of all the resistance elements. If any of these is particularly small compared to the others, we can sometimes neglect that effect in our analysis.

Steady-Multidimensional Models

For problems in which the heat transfer processes internally equilibrate on time scales that are shorter than the times over which external time dependent processes and/or thermal forcing occur, the problem can be formulated as being steady. There are conditions in which there is not a dominant or preferred direction for heat flow for which a one dimensional formulation is inappropriate. For such problems a multidimensional model is required. The governing equation in this formulation is simply:

$$\nabla^2 T = \dot{Q}_v''' \Big/ k$$

Where $\dot{Q}_v'''$ is a volumetric source term. Problems can be set up in Cartesian or cylindrical or spherical coordinate systems depending on the particular type of problem of interest.

Boundary Condition Approximations and Assumptions

Boundary conditions are one of the three types that were previously identified in the fin discussion: prescribed temperature also known as Dirichlet conditions, prescribed flux also known as Neumann conditions, or mixed flux and temperature also known as Robins conditions. For Neumann type conditions, a so-called compatibility condition must hold for a steady formulation to be valid. In practice, this means that the next heat flux into the object must be zero to ensure that a steady solution exists. The three boundary conditions are stated mathematically below.

$$T|_{x=L} = T_s$$
$$-k\left.\frac{\partial T}{\partial x}\right|_{x=L} = q_s$$
$$-k\left.\frac{\partial T}{\partial x}\right|_{x=L} = h_c\left(T|_{x=L} - T_e\right)$$

Transient One Dimensional Models

For formulations in which transient effects must be included, there are conditions in which there is a predominant heat transfer direction. When there is a preferred direction for heat flow, the thermal forcing can either be from one of the boundaries or from an internal source. For most fire problems, the forcing will occur from a boundary or face. While all physical problems have some finite characteristic length, we will discuss an approximation that specifies the extent of the domain to be semi-infinite.

Thermally Thick and Thin Approximations

We can summarize studies of one dimensional unsteady conduction using a map of solution approximations in a Fourier number (Fo) and Biot number (Bi) space. The Fourier number

physically represents the thermal penetration thickness, δ, divided by the geometric dimension of the system, L.

$$Fo = \frac{\alpha t}{L^2} = \left(\frac{\delta}{L}\right)^2$$

As previously noted, the Biot number can be interpreted as a ratio of the conductive resistance to the convective resistance or as the ratio of the temperature differences in the solid to the driving convective temperature difference. Recall that a lumped thermal approximation is valid when Bi<<1.

The Biot number defined in terms of the true length scale of the object can be considered to be the global Biot number for the scenario. A local Biot number can be constructed using the thermal diffusion length as the characteristic length. In the following equation, it can be shown that the local Biot number is specified as the product of the global Biot number and the square root of the Fourier number [11].

$$Bi = \frac{hR}{k} = \frac{h\delta}{k}\frac{R}{\delta} = \frac{h\delta}{k} Fo^{-1/2}$$

$$\frac{h\delta}{k} = Bi\ \ Fo^{1/2} = \frac{T_w - T_o}{T_\infty - T_w}$$

This local Biot number can then be interpreted as an estimate of the temperature difference between the wall and interior temperatures relative to difference between the wall and fluid reservoir temperatures. Because it is a local Biot number and defined in terms of the thermal penetration depth, it also provides insight into what might be considered to be a semi-infinite domain. For small Fourier numbers, the thermal diffusion distance δ is smaller than the global or geometric length of the object. The map below can be used to characterize the various domains for which different types of approximations are valid. The diagonal line in the upper left hand quadrant represents the demarcation between a convective boundary condition and fixed surface temperature on a semi-infinite body (Fig. 2.8).

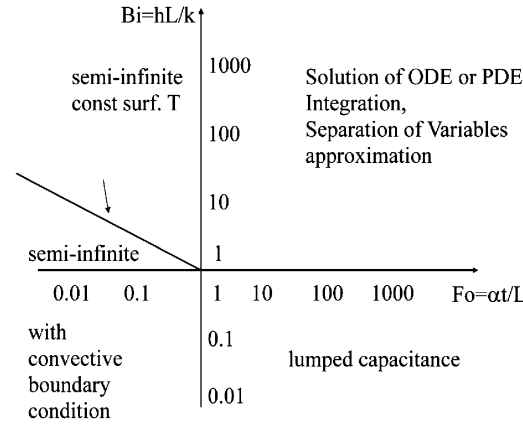

Fig. 2.8 Map identifying different conduction solution regimes as described by Biot and Fourier numbers (Adapted from [12])

Transient Multidimensional Models

For transient multidimensional cases, we rely on the full solution of the heat equation. For simple geometries, we can use analytical methods to construct the solutions. With increased geometrical complexity, computational methods are required. In later sections, both analytical and computational techniques for solving these problems will be detailed.

$$\rho c \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right) + \dot{Q}_v'''$$

Analytical Solutions and Examples

Despite the increased accessibility and power of computing devices, analytical models continue to be important in analyzing and characterizing conduction phenomena in fire systems. Analytical solutions are essential in the verification of computational models and are often used to provide back-of-the-envelope engineering guidance. In this section, solutions will be provided for some of conduction formulations that have been discussed.

Steady-One Dimensional Examples

Critical Thickness of Insulation

For the cylindrical system, we noted that the one dimensional steady form of the heat equation is:

$$\frac{d}{dr}\left(rk\frac{dT}{dr}\right)=0$$

Integrating twice, we derive the temperature solution.

$$\frac{T_1-T}{T_1-T_2}=\frac{\ln(r/r_1)}{\ln(r_2/r_1)}$$

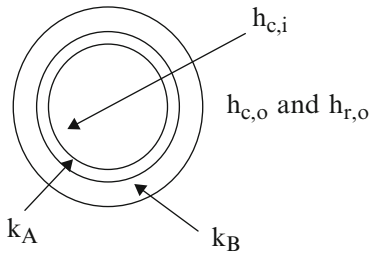
The heat transfer rate is given by:

$$\dot{Q}=\frac{2\pi kL(T_1-T_2)}{\ln(r_2/r_1)}$$

A resistance can be defined as:

$$R=\frac{\ln(r_2/r_1)}{2\pi kL}$$

Often in fire scenarios there is a desire to minimize heat transfer to a pipe or rod from the high temperature environment. Insulating the pipe or rod is one approach to minimize the heat transfer rate. The effect of insulating a pipe is explored in this discussion. A schematic of the system is shown below:



Consider that an internal heat transfer coefficient exists because of the fluid flow within a pipe. The pipe is made of material A and has a thermal conductivity, k_A. Insulation wrapped around the pipe has thermal conductivity, k_B. The fluid flowing in the pipe is at a temperature T_i. External to the insulated pipe is an environment at temperature T_o that interacts with the insulated pipe through convection and radiation. There is a convective heat transfer coefficient $h_{c,o}$ and the radiative transfer process is approximated using a radiation heat transfer coefficient. We can define an overall conductance for the system using the convective resistances and also the conductive resistance that we just developed for cylindrical systems.

$$\dot{Q}=UA(T_i-T_o)=\frac{T_i-T_o}{1/UA}$$

The overall conductance is modeled as $\frac{1}{UA}=\frac{1}{2\pi r_1 L h_{c,i}}+\frac{\ln(r_2/r_1)}{2\pi k_A L}+\frac{\ln(r_3/r_2)}{2\pi k_B L}+\frac{1}{2\pi r_3 L\left(h_{c,o}+h_{r,o}\right)}$ where r_1 is the inner radius of the pipe, r_2 is the outer radius of the pipe, and r_3 is the outer radius of the insulation. We can neglect the internal convection resistance and the conduction resistance of the pipe relative to the external convection resistance and the conduction resistance of the insulation when:

$$\frac{h_{c,o}r_3}{h_{c,i}r_1}<<1 \quad \text{and} \quad \frac{h_{c,o}r_3\ln(r_2/r_1)}{k_A}<<\frac{h_{c,o}r_3\ln(r_3/r_2)}{k_B}$$

For such a case, we find that the heat transfer rate is related to the driving temperature difference as:

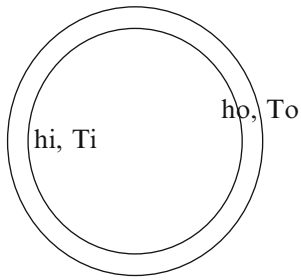
$$\dot{Q}=\frac{T_i-T_o}{R}=\frac{T_i-T_o}{\ln(r_o/r_i)/2\pi Lk+1/2\pi Lr_o h_o}$$

While we might assume that the addition of an insulating layer will always result in a decrease in the heat transfer rate, we can easily see that the denominator has a minimum value when there has been addition of insulation. This minimum value of resistance means that the heat transfer rate increases with the addition of some insulation. Taking the derivative of the denominator and identifying the extremum shows that when the insulating layer has a radius of

$$r_0=r_{cr}=\frac{k}{h_o}$$

the heat transfer has a maximum value.

Example 3 An exposed water sprinkler line is within a compartment on fire. The fire products are at a temperature of 1000 °C. We can assume that the heat transfer coefficient between the fire products and the pipe is 30 W/(m^{2}K). The pipe has a diameter of 5 cm, a thickness of 5 mm, and a thermal conductivity of 30 W/(mK). At one section of the pipe, the water has a mean temperature of 30 °C and an internal heat transfer coefficient of 100 W/(m^{2}K). We can calculate the heat flux at this section of pipe using a thermal resistance circuit.



$$q_i'' A_i = \frac{(T_i - T_o)A_i}{\sum R_i''} = \frac{T_i - T_o}{\frac{1}{h_i A_i} + \frac{\ln\left(\frac{r_o}{r_i}\right)}{2\pi k L} + \frac{1}{h_o A_o}}$$

Note that the radial location of the heat flux must be specified as the heat flux is different at the outer edge of the pipe from its value at the inner edge. The total heat transfer rate is 2.7 kW/m of pipe. The heat flux at the inner wall is 9.7 kW/m^2.

For an insulator with thermal conductivity of 1 W/(mK) and the same external heat transfer coefficient of 30 W/(m^{2}K), the critical radius $r_{cr} = \frac{k}{h_o}$ is 0.03 m or 3 cm. Thus, adding 1 cm of an insulator with a thermal conductivity of 1 W/(mK) to the pipe increases the heat transfer rate. We would have:

$$q_i'' A_i = \frac{(T_i - T_o)A_i}{\sum R_i''} = \frac{T_i - T_o}{\frac{1}{h_i A_i} + \frac{\ln\left(\frac{r_p}{r_i}\right)}{2\pi k L} + \frac{\ln\left(\frac{r_o}{r_p}\right)}{2\pi k L} + \frac{1}{h_o A_o}}$$

The total heat transfer rate increases to 2.9 kW/m. As previously noted, while we increased the conductive resistance by the insulation, we decreased the external convective resistance by increasing the area. The total resistance has decreased from 0.354 Km/W to 0.33 Km/W. The choice of insulator matters. The same thickness insulation, but with a thermal conductivity of 0.1 W/(mK) increases the equivalent resistance to 0.59 Km/W and decreases the total heat transfer rate to 1.6 kW/m.

Fin Model of a Beam Extending Between Two Walls

Frequently, engineers must evaluate the thermal response of beams and columns that are affected by high temperature gases associated with a fire [10]. Imagine that two walls of a compartment are at temperatures T_w and a high temperature gas flows around a fully exposed beam. We can evaluate the thermal response of the beam using a fin model (Fig. 2.9).

Earlier, we derived the constant cross-sectional area fin equation:

$$kA_c \frac{d^2T}{dx^2} - h_c P(T - T_\infty) = 0$$

Solutions to this equation are either in terms of exponential functions or hyperbolic sine and cosine. It is convenient to define an excess temperature in terms of the difference between the fin temperature and the fluid temperature (Fig. 2.10).

$$\frac{d^2\theta}{dx^2} - m^2\theta = 0$$
$$\theta = T - T_\infty$$
$$m^2 = h_c P / kA_c$$

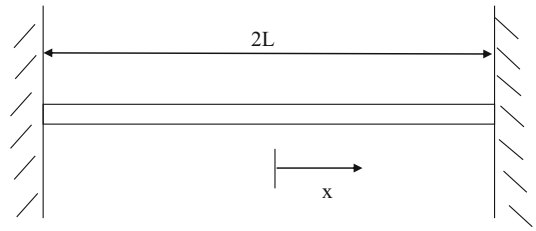


Fig. 2.9 Schematic of beam convectively heated between two walls

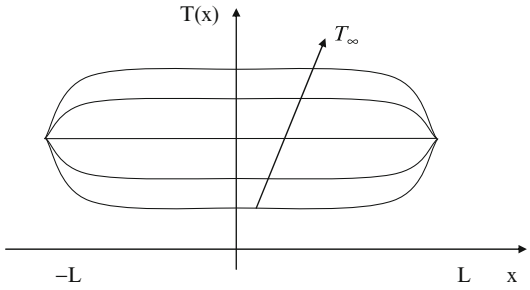

Fig. 2.10 Temperature profiles for suspended beam example showing effect of the gas to wall temperature difference on the temperature profile

For this case in which the walls are at the same temperature we arrive at a solution:

$$T = T_\infty + (T_w - T_\infty)\frac{\cosh(mx)}{\cosh(mL)}$$

If we had defined the origin for the x coordinate as being one of the walls, and if the parameter mL>>1, the exponential solution is appropriate and decays to zero at large x values.

$$\frac{\theta}{\theta_b} = e^{-mx}$$

Example 4 An unprotected round steel bar extends across two compartments. The bar has a diameter of 5 cm. One compartment is fully involved in fire with gas temperatures of 600 °C around the bar. The heat transfer coefficient is 30 W/(m^{2}K). The compartment temperature of the room that the bar extends into is at 20 °C. For convenience, we assume that the void space also has a air temperature of 20 °C and that the heat transfer coefficients are also 30 W/(m^{2}K) in the void space and in the nonfire compartment. We can estimate the temperature of the bar within the void space to see if it might pose an ignition hazard using fin analysis.

For a sufficiently long bar we can use the semi-infinite assumption which states that the temperature distribution in the fin has an exponential variation (Fig. 2.11).

$$\frac{\theta_C(x)}{\theta_{C,B}} = \frac{T(x^+) - T_{C,\infty}}{T_I - T_{C,\infty}} = e^{-mx^+} \text{ and } \frac{\theta_F(x)}{\theta_{F,B}} = \frac{T(x^-) - T_{F,\infty}}{T_I - T_{F,\infty}} = e^{-mx^+}$$

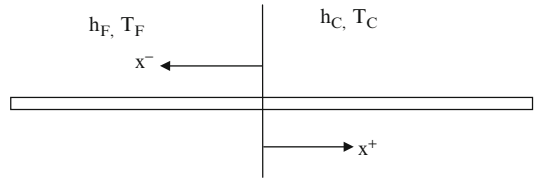

Fig. 2.11 Schematic diagram of a bar extending between two domains with different temperatures and different heat transfer coefficients

At the interface of the fire flow and the cold flow, the bar temperature is continuous and can be specified to be an interface temperature T_I. Also, the heat flux is continuous at the interface. Since the thermal conductivity does not change, we simply write this as:

$$\frac{\partial T}{\partial x^+} = -\frac{\partial T}{\partial x^-}$$

$$-(T_I - T_{C,\infty})\left(\frac{h_A P}{kA_c}\right)^{1/2} = (T_I - T_{F,\infty})\left(\frac{h_F P}{kA_c}\right)^{1/2}$$

$$T_I = \frac{m_F T_{F,\infty} + m_A T_{C,\infty}}{m_F + m_A}$$

For a case in which the heat transfer coefficient is the same on both sides of the interface, the interface temperature is 310 °C and is a simple average of the fire side gas temperature and the cold compartment air temperature. If the heat transfer coefficients had been different, the interface temperature is the weighted average of the two temperatures as shown above.

Flame Temperature Thermocouple Measurement

Consider a thermocouple that is modeled as a rod of diameter D, thermal conductivity k, and length L with half of the thermocouple length in air and the other half inserted into a pool fire flame. It is useful to determine if there is a conduction error in the thermocouple. There are several possible fin models that can be used to illustrate this effect. Here, we take an idealized scenario in which the thermocouple wire is modeled as being a fin with insulated ends in the hot fluid and also in the cold fluid. In reality, there is a convective end condition in the hot region (i.e., at the thermocouple junction) and the termination point in the cold region is often very far away

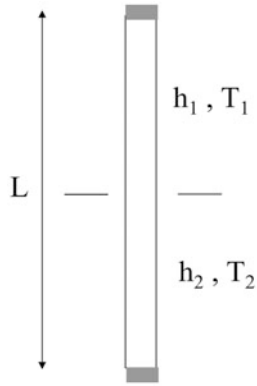

Fig. 2.12 Fin suspended across free surface in fluids with different temperatures and heat transfer coefficients

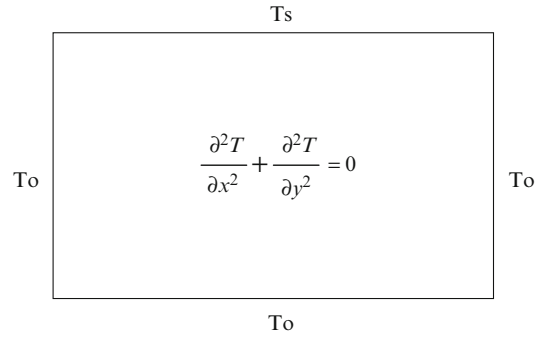

Fig. 2.13 Plate in which Laplace equation is to be solved to determine 2D temperature profile

from the point where the thermocouple is inserted into the flame. The question posed here is whether the temperature at the end placed into the hot fluid (i.e., the flame) reaches the hot fluid temperature (in which case, the thermocouple is measuring the correct temperature) or whether the conduction losses to the cold side are affecting the measurement. The insulated end solution for a rod of diameter D, thermal conductivity k, and length L suspended between two fluids/flows is

$$\frac{\theta_A}{\theta_{A0}}=\frac{T_A-T_{A\infty}}{T_{A0}-T_{A\infty}}=\frac{\cosh[m_A(L_A-x_A)]}{\cosh(m_A L_A)}$$

If the fin is not semi-infinite (i.e., mL is not large relative to unity), we need to use the full solution to get the interface temperature. The interface temperature (Fig. 2.12) is

$$T_{A0}=\frac{T_{A\infty}m_A\tanh(m_A L_A)+T_{B\infty}m_B\tanh(m_B L_B)}{[m_A\tanh(m_A L_A)+m_B\tanh(m_B L_B)]}$$

As we saw earlier, if the heat transfer coefficient is the same on the hot and cold sides, we get an interface temperature that is the simple mean value of the hot and cold temperatures. The error in the measured end temperature

$$\frac{T_A(L)-T_{A\infty}}{T_{A\infty}}=\frac{1}{2}\left(\frac{T_{B\infty}}{T_{A\infty}}-1\right)\left(\frac{1}{\cosh(m_A L_A)}\right)$$

For a case with an air temperature of 300 K and a flame temperature of 2000 K, if the thermocouple has a diameter of 2 mm, a heat transfer coefficient of 30 W/m^{2}K, thermal conductivity of 60 W/(mK), and a length of 6 cm equally split between the hot and cold fluids, we find that the interface temperature is 1150 K and that the tip temperature is 1751 K. This represents an approximately 12 % error in the predicted freestream temperature.

Steady Multidimensional Example

There are many heat transfer systems for which there is a need to generate multidimensional solutions. Often it is appropriate to model a two dimensional temperature variation for geometries in which two characteristic lengths are of comparable magnitude and the third characteristic length is significantly longer. For such geometries, if one is interested in specifying the temperature variation at a cross-section of the geometry at lengths far from the boundaries of the long direction, a two dimensional approximation often proves to be valid. In this section, we discuss the separation of variables approach to solving such problems.

Separation of Variables Applied to Two Dimensional Fin

Example 5 A very long rectangular bar has three sides maintained at temperature 20 °C and one side at temperature 120 °C (Fig. 2.13). Because the bar is very long, we can neglect the axial heat transfer problem and focus our attention on the heat transfer processes at some intermediate slice

within the bar. We are simplifying this three dimensional problem into a two dimensional problem. Further, we can define a new temperature, sometimes called the excess temperature, defined as the temperature subtracting off some reference value. For this problem, it is convenient to think of the 20 °C temperature as a reference value.

We define an excess temperature to be $\theta(x, y) = T(x, y) - 20$. In terms of the excess temperature, we have the following boundary conditions:

$$\begin{aligned} x &= 0, \;\; 0 < y < b; \;\; \theta = 0 \\ y &= 0, \;\; 0 < x < a; \;\; \theta = 0 \\ x &= a, \;\; 0 < y < b; \;\; \theta = 0 \\ y &= b, \;\; 0 < x < a; \;\; \theta = 100 \end{aligned}$$

We use a standard technique for the solution of finite domain partial differential equations called separation of variables to solve for the temperature distribution in the plate section. Separation of variables relies on expanding the dependent function θ(x,y) in terms of an appropriate set of basis functions. For this Cartesian coordinates example, the basis functions turn out to be sine and cosine functions. The members of the family of functions that constitute the set of basis functions are said to be orthogonal to each other in a weighted integral sense. There is a deep relationship between the process in separation of variables and the theory of Fourier series as well as many computational techniques for solving differential equations. One simple starting point for separation of variables solution is to assume a solution form of

$$\theta(x, y) = X(x)Y(y)$$

Upon substituting this solution form into the partial differential equation, one obtains two separable ordinary differential equations: $-\frac{1}{X}\frac{d^2X}{dx^2} = \frac{1}{Y}\frac{d^2Y}{dy^2} = \lambda^2$

The solution of the X(x) equation yields the trigonometric functions, while the solution of the Y(y) equation yields hyperbolic trigonometric functions sinh and cosh. Substitution of this form of solution into the PDE results in unique choices for the parameters λ and also presents an opportunity to define the so-called Fourier coefficients for the problem (Fig. 2.14).

$$\theta(x, y) = 100 \sum_{n=1}^{\infty} \frac{2[1 - (-1)^n]}{n\pi \sinh(n\pi b/a)} \times \sin\frac{n\pi x}{a} \sinh\frac{n\pi y}{a}$$

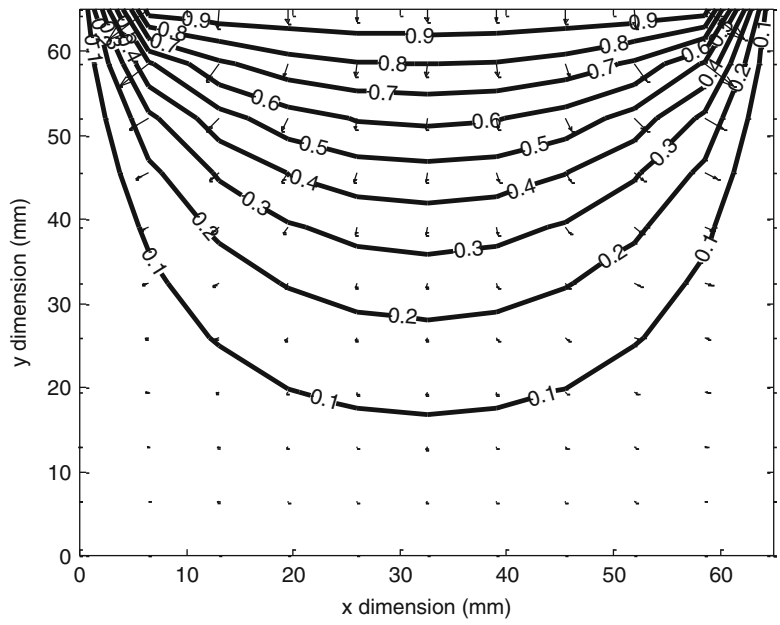

Fig. 2.14 Separation of variables solution ($\theta(x, y)$/100) for 2D plate conduction problem

Transient Lumped Examples with Time Dependent Forcing

Often the transient response of a thermal system must be evaluated. The lumped thermal approximation is valid when the internal conduction resistance is small relative to the external convective resistance.

$$\frac{\text{Internal conduction resistance}}{\text{External convection resistance}} \cong \frac{L/k_s A}{1/\overline{h}_c A} = \frac{\overline{h}_c L}{k_s}$$

Imagine a cold spherical heat sensor emersed in an initially cold gas for which the gas temperature is a linearly increasing function of time. It is useful to understand how the heat sensor's temperature will vary with time. Assume that Bi = 0.1 and Fo ~ 10. T(r,t = 0) = To.

The model used to characterize the temperature variation of the sphere is the same lumped thermal model previously discussed. The difference is that because the reservoir temperature is time varying, the temperature solution is no longer a simple exponential function (Fig. 2.15).

$$\rho V c \frac{dT}{dt} = -\overline{h}_c A (T - T_\infty)$$

$$\frac{dT}{dt} = -\frac{\overline{h}_c A}{\rho V c}(T - T_\infty) \quad \text{with} \quad T_\infty(t) = T_o + at$$

The solution (Fig. 2.16) with $\theta(t) = T - T_o$ is

$$\theta(t) = a\tau\left[\exp\left(\frac{-t}{\tau}\right) - 1\right] + at$$

$$= a\left[t - \tau\left(1 - \exp\left(\frac{-t}{\tau}\right)\right)\right]$$

We see in Fig. 2.16 that there is a time lag between the increasing temperature of the fluid and the increasing temperature of the detector. Additionally, we see that the detector temperature at any given time is always lower than the fluid temperature.

Laplace Transform Methods

The Laplace transform is one of several integral transform methods that can be used in conduction analysis [12]. For time dependent functions, the Laplace transform maps the time dependent derivative terms into algebraic terms that are

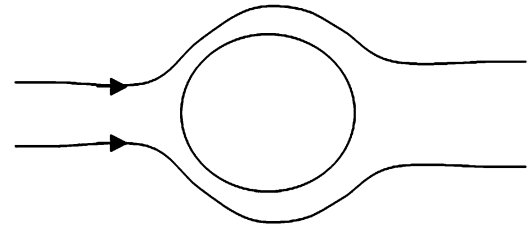

Fig. 2.15 Schematic showing convective flow over an object that will be analyzed using a lumped thermal approximation

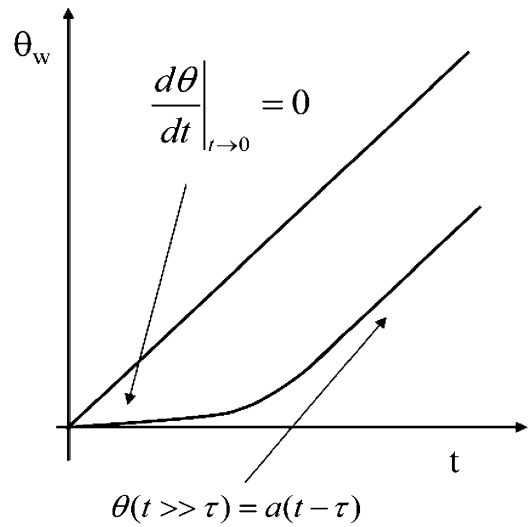

Fig. 2.16 Solution for lumped approximation problem in which fluid temperature is a linearly increasing function of time

parameterized by a new independent variable. For an ordinary differential equation (e.g., a thermally lumped system analysis), application of the Laplace transform yields an algebraic equation that can be solved for the transformed dependent variable. The time dependent form is retrieved using an inversion integral called the Bromwich integral. In the equation below, the Laplace transform integral operator is applied to a general temperature function that depends on time and spatial location. The definition of the Laplace transform is shown below.

$$\mathcal{L}(T) = \hat{T}(x,s) = \int_0^\infty T(x,t) e^{-st} dt$$

An example of the use of the Laplace transform is provided below. Consider the lumped analysis system that we have been using

$$\frac{dT}{dt} = -\frac{\overline{h}_c A}{\rho V c}(T - T_\infty)$$

Straightforward application of the transform yields:

$$s\hat{T}(s) - T(0) = -\frac{\overline{h}_c A}{\rho V c}\left(\hat{T}(s) - \frac{T_\infty}{s}\right)$$

Because the initial condition shows up in this transformation, it is often convenient to use superposition to force the initial condition to be zero. For such a case we have,

$$s\hat{\theta}(s) = -\frac{\overline{h}_c A}{\rho V c}\left(\hat{\theta}(s) - \frac{\theta_\infty}{s}\right)$$

Solving for the transformed temperature variable yields:

$$\hat{\theta}(s) = \frac{\theta_\infty}{\tau_c s\left(s + \tau_c^{-1}\right)}$$

Using any one of a number of inversion tables or online calculators, we retrieve the inverse of this function.

$$\theta(t) = \theta_\infty\left(1 - \exp\left(\frac{-t}{\tau_c}\right)\right)$$

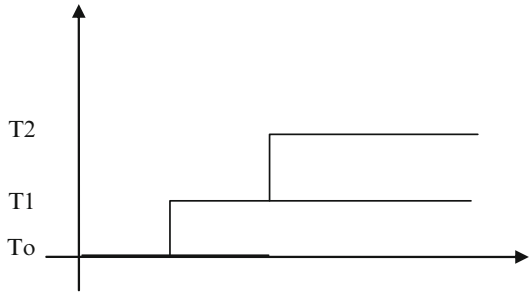
The result above is equivalent to the result shown earlier. The power of the Laplace transform method is that it can be applied to arbitrarily complex differential equations. The challenge of the method has typically been generating the inverse transform. With increasing accessibility of symbolic mathematical software tools, with some freely available online such as Wolfram Alpha, this particular challenge is no longer quite as severe.

Duhamel Integral Methods

The Duhamel integral is a method for generating a solution for an arbitrarily complex time dependent forcing of a conduction system using the solution for a step change. A simple case to present the ideas of this concept is the problem in which there is a step change in the external temperature of a reservoir in contact with a lumped thermal system. We know the solution from earlier sections.

$$\frac{dT}{dt} = -\frac{\overline{h}_c A}{\rho V c}(T - T_\infty)$$

Graphically, a series of external temperature step changes can be looked at as follows:



If we focus on the initial step change, this is no different from the original problem that we considered. The offset in time can be addressed using an offset in time. Simply by creating a new time variable, e.g., $s = t - t_1$, we create an offset time variable. To explore what is meant by a step change in the external temperature, we formally formulate the mathematical equation using the Heaviside step function.

$$\frac{dT}{dt} = -\frac{\overline{h}_c A}{\rho V c}(T - T_0 - (T_1 - T_0)H_s(t - t_1) - (T_2 - T_1)H_s(t - t_2))$$

If we now define a relative temperature $T - T_0$, we arrive at the equation

$$\frac{d\theta}{dt} = -\frac{\overline{h}_c A}{\rho V c}(\theta - \Delta\theta_1 H_s(t - t_1) - \Delta\theta_2 H_s(t - t_2))$$

To solve this equation, it is convenient to define a series of linear transformations and use superposition to solve this individual equations.

$$\theta = F + G$$

$$\frac{dF}{dt} + \frac{dG}{dt} = -\frac{\overline{h}_c A}{\rho V c}(F + G - \Delta\theta_1 H_s(t - t_1) - \Delta\theta_2 H_s(t - t_2))$$

$$\frac{dF}{dt} = -\frac{\overline{h}_c A}{\rho V c}(F - \Delta\theta_1 H_s(t - t_1))$$

$$\frac{dG}{dt} = -\frac{\overline{h}_c A}{\rho V c}(G - \Delta\theta_2 H_s(t - t_2))$$

Because $\theta(0) = 0$, we can enforce that both F and G are also equal to zero and have solutions of form:

$$F(t) = \Delta\theta_1\left(1 - e^{-(t-t_1)/t_c}\right)$$

The solution for the excess temperature is then:

$$\theta(t) = \Delta\theta_1\left(1 - e^{-(t-t_1)/t_c}\right) + \Delta\theta_2\left(1 - e^{-(t-t_2)/t_c}\right)$$

For a series of step changes, we can generalize this superposition of solutions to generate:

$$\theta(t) = \sum \frac{\Delta\theta_i}{\Delta\tau_i}\left(1 - e^{-(t-\tau_i)/t_c}\right)\Delta\tau_i = \int_0^t \frac{d\theta}{d\tau}\left(1 - e^{-(t-\tau)/t_c}\right)d\tau$$

We immediately see that for the case in which the freestream temperature is changing as a linear function of time $T_\infty(t) \quad = T_o + at$

We get

$$\theta(t) = \int_0^t a\left(1 - e^{-(t-\tau)/t_c}\right)d\tau$$

$$= at - ae^{-t/t_c}t_c\left(e^{t/t_c} - 1\right)$$

$$= at - at_c\left(1 - e^{-t/t_c}\right) = a\left[t - t_c\left(1 - e^{-t/t_c}\right)\right]$$

which is the same result that we arrived at using a much simpler analysis in an earlier section. The power of the Duhamel formulation is evident in problems like the semi-infinite slab problem for which the solution is expressed in terms of the error function. One interesting application of the Duhamel method that we will use in the section on inverse analysis is the determination of the heat flux from a temperature measurement. The generalization of the Duhamel form states that the time dependent variation of temperature can be defined in terms of an integral of the product of the step response solution, which is time dependent, and the time derivative of the unsteady effect.

Transient Semi-infinite (Thermally Thick) One-Dimensional Examples

For thermally thick problems in which the thermal penetration wave never reaches the back side, analytical solutions are available for a range of boundary conditions. These solutions are generally specified in terms of tabulated functions [13]. Useful approximate solutions can also be developed for these problems using integral approximations and the scaling properties of diffusive transport (Fig. 2.17).

For the thermally thick conduction problem, the solution is often described as being for a semi-infinite domain (Fo<<1). Using either a Laplace transform solution approach or any number of other approaches, one can arrive at the temperature variation for a constant surface temperature boundary condition.

$$\theta = \frac{T - T_0}{T_s - T_0} = 1 - \frac{2}{\pi^{1/2}}\int_0^\eta e^{-u^2}du = \operatorname{erfc}\left(\frac{x}{(4\alpha t)^{1/2}}\right)$$

We see that the solution is defined using the complementary error function (erfc). The surface heat flux variation with time is:

$$q_s = -k(T_s - T_0)\left[-\frac{2}{\pi^{1/2}}e^{-\eta^2}\frac{1}{(4\alpha t)^{1/2}}\right]_{\eta=0} = \frac{k(T_s - T_0)}{(\pi\alpha t)^{1/2}}$$

Interestingly, an approximation for the heat flux that depends on the thermal penetration depth does a reasonable job of predicting the overall trends.

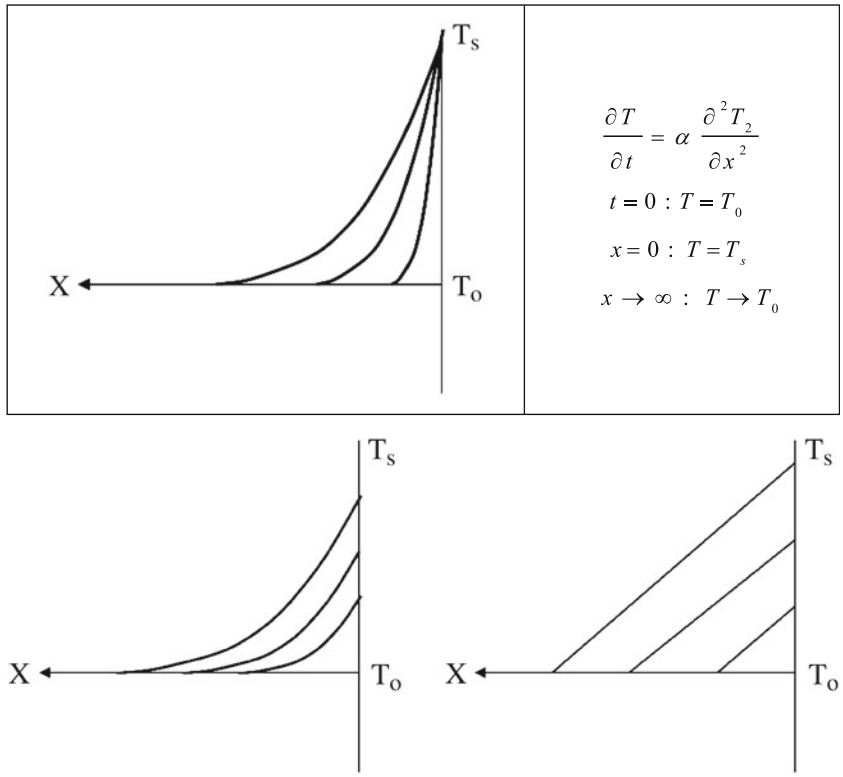


Fig. 2.17 Governing equation for semi-infinite model of conduction in a slab and associated temperature profiles

$$q_s \cong \frac{k(T_s - T_0)}{\delta(t)} = \frac{k(T_s - T_0)}{\sqrt{\alpha t}}$$

In the approximation, we have used the sing the simplified scaling law $\delta \approx \sqrt{\alpha t}$

A similar approximation can be used for the constant surface heat flux boundary condition. We recognize that the approximate variation is as follows:

$$T_s = T_0 + \frac{q_s\sqrt{\alpha t}}{k} = T_0 + \frac{q_s\sqrt{t}}{\sqrt{k\rho c}}$$

The surface temperature has $t^{1/2}$ dependence which we can compare to exact analytical result

$$T(x,t) = T_0 + \frac{q_s}{k}\left[\left(\frac{4\alpha t}{\pi}\right)^{1/2} e^{-x^2/4\alpha t} - x\,\mathrm{erfc}\frac{x}{(4\alpha t)^{1/2}}\right]$$

which at

$$\mathrm{x} = 0 \text{ is } T_s = T_0 + \frac{q_s}{k}\left[\left(\frac{4\alpha t}{\pi}\right)^{1/2}\right]$$

The Newton's law of cooling convective boundary condition case is analytically quite challenging, but can be reduced to a very simple form using the type of scaling previously described (Fig. 2.18).

We note that the internal heat flux can be approximated using a diffusion model and must be balanced by the Newton's law of cooling convection term.

$$q_s \cong \frac{k(T_s(t) - T_0)}{\delta} = h(T_e - T_s)$$

In solving for the wall temperature we arrive at:

$$\frac{T_s(t) - T_0}{(T_e - T_0)} = \frac{\frac{h\sqrt{\alpha t}}{k}}{\left(1 + \frac{h\sqrt{\alpha t}}{k}\right)}$$

At long time, we get constant surface temperature. We can compare this to the exact solution (Fig. 2.19):

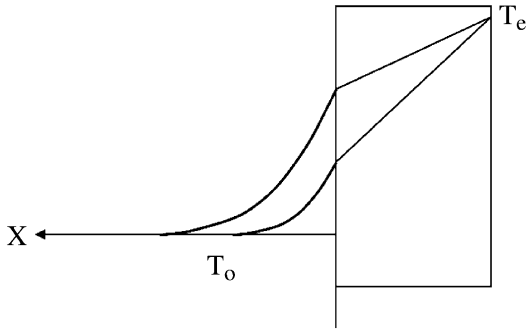

Fig. 2.18 Schematic of semi-infinite model of conduction in a slab with convective boundary conditions

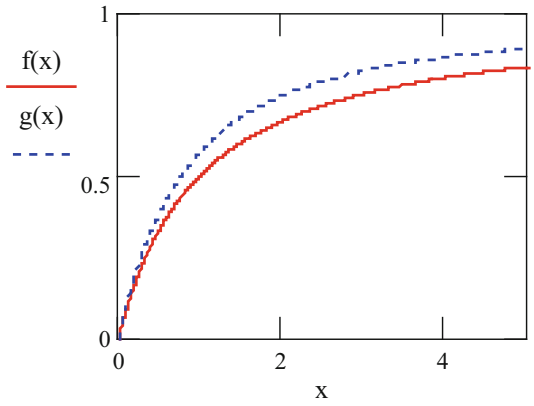

Fig. 2.19 Comparison of approximate and exact solution of semi-infinite model of conduction in a slab with convective boundary conditions

$$\frac{T_s - T_0}{T_e - T_0} = 1 - e^{(h_c/k)^2 \alpha t} \text{erfc}\left[\frac{h_c}{k}(\alpha t)^{1/2}\right]$$

Transient Multidimensional Examples

Multidimensional transient problems represent a class of problems that pose sufficient analytical complexity that we often revert to computational solutions for these systems. For some simple geometries, however, there are tabulated results that are useful for determining the overall

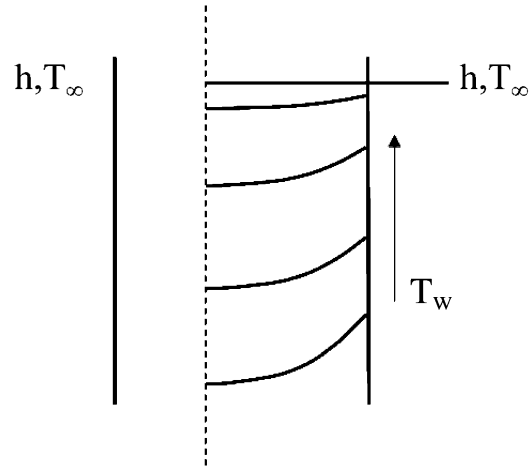

Fig. 2.20 Schematic of one dimensional conduction in a slab with convective boundary conditions

thermal behavior of such systems. The starting point for constructing such solutions is a one dimensional transient problem. As an example, for the slab/wall geometry for which there is convective heating on two sides, there is a separation of variables series solution for the problem. For relatively long times as is defined by the Fourier number (Fo>1), the series solution converges with a small number of terms. Physically, the temperature profile (i.e., the solution) becomes smoother with increasing time. Because so few terms are required to represent the temperature field evolution, it is possible to define the solution in terms of a simple product of a time dependent function and a spatially varying function (Fig. 2.20). The governing equation, initial condition and boundary conditions for the one dimensional problem are:

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial x^2}$$

$$t = 0: \quad T = T_0$$

$$x = 0: \quad \frac{\partial T}{\partial x} = 0$$

$$x = L: \quad -k\frac{\partial T}{\partial x} = h(T - T_\infty)$$

The solution of the one dimensional problem is:

$$\frac{T-T_\infty}{T_0-T_\infty}=\frac{\theta}{\theta_0}=\sum_{n=0}^{\infty} \times \frac{\sin(\lambda_n L)}{\lambda_n L+\sin(\lambda_n L)\cos(\lambda_n L)} \times e^{-\lambda_n{}^2 \alpha t}\cos(\lambda_n x)$$

The eigenvalues of the problem can be written as: $\lambda_n L = \mathrm{Bi}\cot(\lambda_n L)$. Also, the argument of the exponential function can be written as:$\lambda_n^2 \alpha t = (\lambda_n L)^2\left(\frac{\alpha t}{L^2}\right) = (\lambda_n L)^2\,\mathrm{Fo}$. This suggests that the solution is defined by the following parameters:

$$\mathrm{Bi},\ \mathrm{Fo},\ \frac{x}{L}$$

For long enough times, the one term expansion generates [2]:

$$\frac{T-T_\infty}{T_0-T_\infty}=\frac{\theta}{\theta_0}=\frac{\theta}{\theta_{CL}}\times\frac{\theta_{CL}}{\theta_0} = C(\mathrm{Bi})\ \ f(t)g(x)$$

The centerline temperature varies only with time, while the temperature at any location normalized by the centerline temperature is essentially a function of the spatial location.

It can be easily shown that the temperature within a block can be found as the product of the temperatures found from three separate one dimensional solutions (Fig. 2.21):

$$\theta(t,x,y,x)=P(x,t)P(y,t)P(z,t)$$

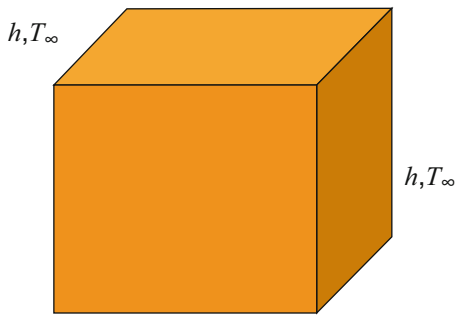

Fig. 2.21 Schematic diagram of cube with external convective heating

Overview of Computational Issues in Conduction

For complex geometries or for problems with nonlinear effects and multiple physical processes, analytical solutions are usually not easily found. For the majority of practical heat transfer processes in fire, a fire engineer will resort to the use of computational tools to characterize the system. Olenick and Carpenter [14] summarize the key features of a number of computational tools available for simulating thermal response associated with fire endurance testing. These tools use a variety of numerical discretization techniques. In the following section, we discuss the types of computational techniques most often used for fire problems and present simple examples for some of these cases to help clarify what underlying steps are taken in some of the tools and codes described in [14]. Useful reference texts for numerical solution of the differential equations associated with conduction are Shih [15] and Ferziger [16].

To start, we define a very simple conduction/diffusion problem with a source (S).

$$\Gamma\frac{d^2\phi}{dx^2}+S=0$$

The analytical solution can be easily found by integrating this equation twice. For the case of a constant source we get:

$$\phi = C_2 + C_1 x - \frac{S}{2\Gamma}x^2$$

Consider the case with boundary conditions:

$$\left.\frac{d\phi}{dx}\right|_{x=0} = 0 \text{ and } \phi(L)=0$$

C_1 is zero by the adiabatic condition, and $C_2 = \frac{S}{2\Gamma}$ such that;

$$\phi=\frac{S}{2\Gamma}(L-x^2)$$

We will compare this solution to those generated by the numerical solutions.

Finite Difference Approximations

The finite difference technique is used to solve differential equations by expanding the dependent variable, at specified positions in the computational space into a Taylor series, appropriately adding and subtracting terms from other series terms together to generate approximations for the derivative terms in the underlying differential equation. As an example, the dependent variable is expanded below in a Taylor expansion at locations 1 and 3 (Fig. 2.22).

$$\phi_1 = \phi_2 - \left.\frac{\partial \phi}{\partial x}\right|_2 \Delta x + \frac{1}{2}\left.\frac{\partial^2 \phi}{\partial x^2}\right|_2 \Delta x^2 + O\left(\Delta x^3\right)$$

$$\phi_3 = \phi_2 + \left.\frac{\partial \phi}{\partial x}\right|_2 \Delta x + \frac{1}{2}\left.\frac{\partial^2 \phi}{\partial x^2}\right|_2 \Delta x^2 + O\left(\Delta x^3\right)$$

By subtracting the two series from each other, we arrive at one representation for the derivatives at location 2.

$$\left.\frac{\partial \phi}{\partial x}\right|_2 = \frac{\phi_3 - \phi_1}{2\Delta x} + O\left(\Delta x^2\right)$$

$$\left.\frac{\partial^2 \phi}{\partial x^2}\right|_2 = \frac{\phi_3 - 2\phi_2 + \phi_1}{\Delta x^2} + O\left(\Delta x^2\right)$$

Substituting the approximations into the original differential equation then provides an algebraic rule by which to evaluate the values of the dependent variable at the prespecified (grid) points.

$$\Gamma \left.\frac{\partial^2 \phi}{\partial x^2}\right|_2 = \Gamma\left(\frac{\phi_3 - 2\phi_2 + \phi_1}{\Delta x^2}\right)$$

And the source term can be approximated as $S_2 = S(\phi_2)$

We see that the final form of the algebraic system of equations is

$$\Gamma\left(\frac{\phi_3 - 2\phi_2 + \phi_1}{\Delta x^2}\right) = -S(\phi_2)$$

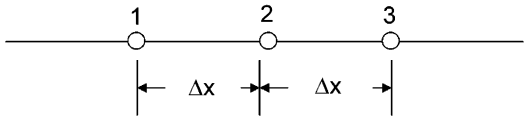

Fig. 2.22 Schematic of finite difference stencil

Symbolically, we can arrange the system of algebraic equations into a form shown below.

$$a_{i-1}\phi_{i-1} - a_i\phi_i + a_{i+1}\phi_{i+1} = b$$

$$a_{i-1} = \frac{\Gamma}{\Delta x}, a_{i+1} = \frac{\Gamma}{\Delta x}, a_i = \frac{-2\Gamma}{\Delta x}, b = -\overline{S}\ \Delta x$$

For the case in which $\Gamma = 0.2$, $0 < x < L$, and $S = 4$

We will use $N = 5$ grid points, $\Delta x = 0.25L$ for $L = 1$

$$a_{i-1} = 1, a_{i+1} = 1, a_i = -2, \quad b = 1$$

$$\begin{bmatrix} -2 & 2 & & & \\ 1 & -2 & 1 & & \\ & 1 & -2 & 1 & \\ & & 1 & -2 & 1 \\ & & & & 1 \end{bmatrix} \begin{bmatrix} \phi_1 \\ \phi_2 \\ \phi_3 \\ \phi_4 \\ \phi_5 \end{bmatrix} = \begin{bmatrix} -1 \\ -1 \\ -1 \\ -1 \\ 0 \end{bmatrix} \text{ with solution } \begin{bmatrix} \phi_1 \\ \phi_2 \\ \phi_3 \\ \phi_4 \\ \phi_5 \end{bmatrix} = \begin{bmatrix} 8 \\ 7.5 \\ 6 \\ 3.5 \\ 0 \end{bmatrix}$$

Which is exactly the same as the answer provided by the exact solution.

Finite Volume Approximation

An alternative way of generating algebraic equations representing the differential equation is the finite volume technique. The finite volume technique is closely related to Galerkin finite element techniques. Both are members of a family of solution techniques called method of weighted residuals. For both types of solution techniques, an integrated form of the underlying differential equation is used to develop the algebraic equations. In both types of techniques, one weights the equation before integrating. Because the weight in the control volume method is just equal to unity, the process to developing the algebraic equations has a simple physical interpretation. The finite volume technique is sometimes called the control volume technique or the subdomain method [17] (Fig. 2.23).

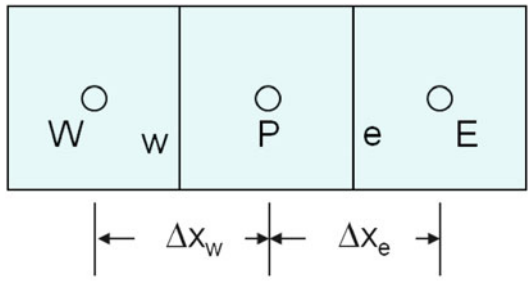

Fig. 2.23 Schematic of finite volume cells

Consider the diffusion equation in conservative form.

$$\frac{d}{dx}\left(\Gamma\frac{d\phi}{dx}\right)+S=0$$

The equation is integrated over the control volume

$\int_w^e \frac{d}{dx}\left(\Gamma\frac{d\phi}{dx}\right)+S\ dx=0$ to become

$$\left(\Gamma\frac{d\phi}{dx}\right)_e-\left(\Gamma\frac{d\phi}{dx}\right)_w+\int_w^e S\ dx=0$$

A linear profile assumption is made between cell centroids for ϕ. Assume S varies linearly over the control volume

$$\frac{\Gamma_e(\phi_E-\phi_P)}{\Delta x_e}-\frac{\Gamma_w(\phi_P-\phi_W)}{\Delta x_w}+\overline{S}\ \Delta x=0$$

Collecting terms and casting into an algebraic equation yields:

$$a_E\phi_E+a_P\phi_P+a_W\phi_W=b$$

$$a_E=\frac{\Gamma_e}{\Delta x_e}, a_W=\frac{\Gamma_w}{\Delta x_w}, a_P=\frac{-2\Gamma_w}{\Delta x_w},\quad b=-\overline{S}\ \Delta x$$

Again, for the case in which $\Gamma=0.25,\quad 0<x<L,$ and $\quad S=4$

We will use $N=5$ grid points, $\Delta x=0.25L$ for $L=1$

$$a_{i-1}=1, a_{i+1}=1, a_i=-2,\quad b=1$$

$$\begin{bmatrix}-2 & 2 & & & \\ 1 & -2 & 1 & & \\ & 1 & -2 & 1 & \\ & & 1 & -2 & 1\\ & & & & 1\end{bmatrix}\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\\ \phi_5\end{bmatrix}=\begin{bmatrix}-1\\ -1\\ -1\\ -1\\ 0\end{bmatrix}$$

This system of linear equations, written in matrix form has a banded structure and can be solved using a number of linear algebraic solution strategies. For tridiagonal matrices, an efficient algorithm exists (Thomas algorithm) for solving the system [18]. The solution is:

$$\begin{bmatrix}\phi_1\\ \phi_2\\ \phi_3\\ \phi_4\\ \phi_5\end{bmatrix}=\begin{bmatrix}8\\ 7.5\\ 6\\ 3.5\\ 0\end{bmatrix}$$

The solution is exactly the same as the answer provided by the exact solution.

Finite Element Approximations

This discussion is on Galerkin finite element techniques which are a subclass of the method of weighted residuals (MWR) [15, 17]. The method explicitly identifies an approximate solution to the governing equation, for which the approximate solution is generated from a broader class of functions than the true solution resides in. There is an approximation, $\widetilde{\phi}$, to ϕ that produces a residual in the solution of the diffusion equation when the approximation is used.

$$\Gamma\frac{d^2\widetilde{\phi}}{dx^2}+S=R$$

In MWR, the weighted average of the residual is zero, rather than the residual. The weight function is called W(x).

$$\int_{domain} R(x)W(x)dx=0$$

The approximating function is assumed to be expandable in a set of linearly independent "basis functions" $N_j(x)$.

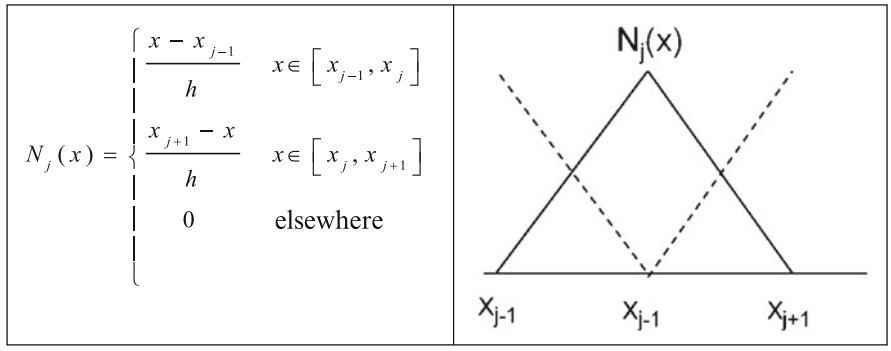

Fig. 2.24 Triangular basis functions and schematic of overlapping functions

$$\widetilde{\phi} = \sum \phi_j N_j(x)$$

In Galerkin FEM the weight function is specified to be the same as the basis function. $W_j(x) = N_j(x)$.

$$\int_{domain} R(x)W(x)dx = 0$$

Effectively, we are forcing the residual to be orthogonal to the basis functions. Properties of the basis function in terms of ease of evaluation, accuracy etc. suggest the use of polynomials.

An example of basis functions is shown below (Fig. 2.24).

The weighted residual becomes:

$$\int_a^b \left(\Gamma \frac{d^2\widetilde{\phi}}{dx^2} + S \right) N_j(x)dx = 0$$

While ϕ should be twice differentiable, the "weak form" allows a wider class of functions to be used. We integrate by parts. We get an equation in terms of integrals of basis functions and coefficients of the unknown function at nodal points.

$$A\phi_{j+1} + B\phi_j + C\phi_{j-1} + D_j = 0$$

Inverse Conduction Heat Transfer Approximations and Examples

Inverse analysis refers to a variety of approaches used to determine model parameters, boundary conditions, initial conditions, etc. The use of the term inverse relates to the idea that the analysis inverts the normal rules of causality in order to find an answer that best agrees with observations. In conduction problems, typical examples of use of inverse analysis are determining the heat flux on a slab given a limited number of interior temperature measurement or identifying material properties that allow a model to best match measured temperature data. There are many approaches to generating an inverse solution, and some of these techniques are essentially optimization methods. One might summarize optimization based analysis as the search for parameters that when used in a forward formulation of the problem of interest generate solutions whose deviation from experimental data is quantified., There are, however, specialized techniques that have been developed for inverse analysis that have not been specifically developed from an optimization perspective. These techniques generally require that the problem be formulated in an inverse sense. For problems formulated in an inverse sense, there ultimately becomes an ill posed mathematical problem. Ill posed problems [19] are those for which the solution is not unique or does not smoothly change relative to small changes in an input parameter. For such problems, there is a need to regularize the underlying system of equations.

If one considers the simple diffusion equation that has been presented in earlier sections and considers the need to specify the source in the medium given some number of temperature

measurements in the slab, the process to determine the source is an inverse analysis. An important fundamental consideration in inverse analysis is the notion that experimental noise exists in the measured data and that such noise corrupts the inversion process.

Given the ODE, we can formulate an integral equation for the temperatures using a delta function source [19, 20]. This is simply a Greens' function solution for the problem. In a forward analysis, we would simply integrate the source distribution in such a way as to generate a temperature at every point given the source distribution. The inversion requires an estimate of the source, given some measurements of temperature. Further, it is assumed that the temperature data are noisy. We see that for each temperature measurement, there is a corresponding quadrature rule that maps the integral equation to an algebraic equation. We see that this process results in a matrix equation in which the source description explicitly shows up as an unknown. Using typical linear algebra techniques, we find that the results for the source are quite noisy and not representative of the input source that was used to drive the forward solution. Note that for this exercise, synthetic measured data are sampled from the forward solution.

The Greens' function solution is constructed using a delta function source:

$$\Gamma\frac{d^2\phi}{dx^2} = -S'''(x) \text{ which for the Green's function is } \frac{\Gamma}{S_o''}\frac{d^2G}{dx^2} = -\delta(x-x_0)$$

Integrating the delta function yields:

$$\begin{aligned} G &= ax+b && x<x_0 \\ \Gamma\frac{dG}{dx}\Big|_{x_0-\varepsilon}^{x_0+\varepsilon} &= S_o'' H_s(x-x_0) \\ G &= Ax+B && x>x_0 \end{aligned}$$

For a case in which ϕ is zero at −L and L, we get the Green's function solutions to be:

$$G(x,x_0) = \frac{-S_o''L}{2\Gamma}(1-x_0/L)(1+x/L) \qquad x<x_0$$

$$G(x,x_0) = \frac{-S_o''L}{2\Gamma}(1+x_0/L)(1-x/L) \qquad x>x_0$$

The final solution for the dependent variable is

$$\phi(x_0) = \frac{L}{2\Gamma}(1-x_0/L)\int_{-L}^{x_0}(1+x/L)S_o''S'(x)dx + \frac{L}{2\Gamma}(1+x_0/L)\int_{x_0}^{L}(1-x/L)S_o''S'(x)dx$$

For the case of a constant source we can show that we retrieve the exact solution. For an inverse formulation, we can imagine that several experimental values of ϕ are assumed to be available through measurements. The linear algebraic system is then:

$$\vec{\phi}(x_i) = \frac{L}{2\Gamma}(1-x_i/L)\sum_{j=1}^{1+(x_i+L)/\Delta x}(1+x_j/L)S'''(x_j)\Delta x + \frac{L}{2\Gamma}(1+x_i/L)\sum_{j=1+(x_i+L)/\Delta x}^{N}(1-x_j/L)S'''(x_j)\Delta x$$

$$x_j = -L + \frac{2L}{N-1}(j-1)$$

$$\vec{\phi}_i = A_{i,j}\vec{S}_j$$

We see that the m×n matrix operator $A_{i,j}$ is not square when there are a limited number (m) of measurements $\vec{\phi}_i$ that require many more evaluations (n) of the source term. To overcome the sensitivity to the data noise and the limited number of available measurements, regularization methods are used to generate smooth approximations to inversely formulated problems. Examples of regularization methods include truncated singular value decomposition (TSVD), Tikhonov regularization, and conjugate gradient based approaches. More details can be found in Hansen [19] and Press et al. [18], on details of these methods. When applied to the example problem, TSVD regularization allows us to easily invert for the source profile.

For the case in which $\Gamma = 0.25$, $-L < x < L$, and $S = 4$, we assume that measurements are made at x = (−.67 L, −0.33 L, 0.33 L, 0.67 L). We will use N = 7 grid points to evaluate the integral in the Greens function solution. This results in a grid spacing of $\Delta x = 0.33L$. For this problem we add random noise to the measured $\vec{\phi}_i$ values to simulate measurement error.

The matrix operations are then

$$\begin{bmatrix} 0 & 0.37 & 0.296 & 0.222 & 0.148 & 0.074 & 0 \\ 0 & 0.296 & 0.593 & 0.444 & 296 & 0.148 & 0 \\ 0 & 0.148 & 0.296 & 0.444 & 0.593 & 0.296 & 0 \\ 0 & 0.074 & 0.148 & 0.222 & 0.296 & 0.37 & 0 \end{bmatrix} \begin{bmatrix} S_1 \\ S_2 \\ \vdots \\ S_6 \\ S_7 \end{bmatrix} = \begin{bmatrix} 4.94 \\ 7.13 \\ 7.61 \\ 4.47 \end{bmatrix}$$

The singular value decomposition of the matrix A results in $A = U\Sigma V^T$. The matrix Σ is a diagonal matrix with the singular values ordered from largest to smallest as the diagonal elements. The number of singular values provides an indication of the number of independent equations in the system of equations. Also the ratio of the largest singular value to the smallest singular value, called the condition number of the matrix, reflects how singular the matrix is and how much amplification of error might be associated with small perturbations propagated through the inversion. For this problem, the singular value decomposition is:

$$\begin{pmatrix} -0.357 & 0.5 & -0.61 & -0.5 \\ -0.61 & 0.5 & 0.357 & 0.5 \\ -0.61 & -0.5 & 0.357 & -0.5 \\ -0.357 & -0.5 & -0.61 & 0.5 \end{pmatrix} \begin{pmatrix} 1.358 & 0 & 0 & 0 \\ 0 & 0.444 & 0 & 0 \\ 0 & 0 & 0.178 & 0 \\ 0 & 0 & 0 & 0.148 \end{pmatrix} \begin{pmatrix} 0 & 0 & 0 & 0 \\ -0.317 & 0.5 & -0.632 & -0.5 \\ -0.516 & 0.5 & 0.258 & 0.5 \\ -0.516 & 0 & 0.258 & 0 \\ -0.516 & -0.5 & 0.258 & -0.5 \\ -0.317 & -0.5 & -0.632 & 0.5 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

The system of equations is inverted using the numerically accurate inversion (SVD pseudo-inverse) and also using a so-called truncated SVD (TSVD) pseudo-inverse. In the TSVD inversion, the smallest singular value (0.148) is not used in the inversion. The inversion is given by

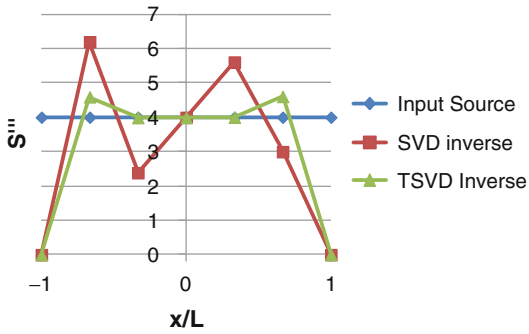

Fig. 2.25 Comparison of SVD inverse and TSVD inverse of noisy input data

$$\vec{S} = \sum_{i=1}^{k} \frac{\vec{u}_i \cdot \vec{\phi}}{\sigma_i} \vec{v}_i$$

In this expression the $\vec{u}_i$ and $\vec{v}_i$ are the column vectors of the U and V matrices in the SVD decomposition. The summation is over the total number of retained singular values. Figure 2.25 shows a comparison of the SVD and TSVD inversions of the noisy measurements. We see that there is considerably more variation and deviation from the exact source values for the SVD inversion relative to the TSVD inversion. The process of truncating the representation of the A matrix acts to smooth or regularize the solution.

This problem is only one example of the many types of techniques that can be applied in inverse heat transfer analysis. Many other types of inversion processes might be used for fire problems. There are many examples of time dependent inversion, as might be done to determine a surface heat flux when measuring internal temperatures that present many different solution approaches for inversion [21, 22]. An interesting analogy exists between the steady example using TSVD based inversion and some types of temporally evolving inverse problems. For linear time dependent problems, analytical solution forms exist for time dependent heating using the Duhamel integral formulation. A simple example from Beck et al. [21] shows the process for determining the heat flux when a single temperature measurement is made using a modification of the Duhamel integral. The Duhamel integral representation looks very much like the Greens function formulation that was detailed. In both cases, one is solving a Fredholm integral equation for some underlying system forcing.

Convection Heat Transfer

3

Arvind Atreya

This chapter is respectfully dedicated to the author's father, Dr. Dharam Dev Atreya.

Introduction

There are only two fundamental physical modes of energy transfer, conduction and radiation. In conduction, energy slowly diffuses through a *medium* from a point of higher temperature to a point of lower temperature, whereas in radiation, energy is transmitted with the speed of light by electromagnetic waves (or photons), and a transmitting medium is not required. Thus from a conceptual viewpoint, convection is not a basic mode of heat transfer. Instead, it occurs by a combined effect of conduction (and/or radiation) and the motion of the transmitting medium.

Nevertheless, convection plays a very important role in fires. It transports the enormous amount of chemical energy released during a fire to the surrounding environment by the motion of hot gases. This motion may be induced naturally by the fire itself (hot gases rise and cold air rushes to replace them) or by a source external to the fire, such as a prevailing wind. Based on this distinction, the subject of convective heat transfer is usually subdivided into *natural* (free) and *forced* convection. Obviously, both natural and forced convection may occur simultaneously, resulting in a mixed mode of convective heat transfer. A further subdivision based on whether the flow occurs inside (e.g., in a pipe) or outside the body under consideration is also often made. For application of convective heat transfer to fire science, natural convection around objects is clearly far more important than forced convection inside a pipe. Thus greater attention is devoted here to natural convective heat transfer and external flows.

The objective of this chapter is to provide a firm understanding of the physical mechanisms that underlie convective heat transfer, as well as to develop the means to perform convection heat transfer calculations. In the first section of the chapter, basic concepts and relations are developed; calculation methods are illustrated with the help of examples in the second section. Tables of empirical and theoretical results (including their range of applicability) are also provided for quick reference.

Concepts and Basic Relations

A simple, everyday problem of drying a wet body in a stream of warm dry air is shown in Fig. 3.1. From our knowledge of fluid mechanics, we expect the flow of air to slow down next to the surface of the wet body, thus transferring some of its momentum to the body. Conversely, the body will experience a drag force if it moves through stationary air. In addition to this exchange of momentum, the body also losses some of its moisture; that is, transfer of mass takes place

A. Atreya (✉)

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_3, © Society of Fire Protection Engineers 2016

from the wet surface to the warm air. Furthermore, for moisture to evaporate at the wet surface the necessary heat must also be transferred from the warm air to the wet body. Hence, the body experiences a simultaneous transfer of momentum, mass, and energy.

To obtain a quantitative description of the above process, note first that all the quantities (mass, momentum, and energy) being transported in the example are conserved, so conservation laws govern their rate of transfer.

These conservation laws need to be supplemented by basic or constitutive relations that relate the rate of transfer to the driving forces and fluid properties. These basic laws are: (1) Newton's law of viscosity, which relates the rate of change of momentum to velocity gradients; (2) Fourier's law of heat conduction, which relates the rate of heat transfer to temperature gradients; and (3) Fick's law of mass diffusion, which relates the rate of mass transfer to concentration gradients. With this framework of conservation and basic laws a majority of laminar convective heat transfer problems can be analyzed, at least in principle. For the turbulent case this framework provides guidance for developing useful empirical correlations.

This section covers the basic laws in the context of laminar flows and their relationships to the more familiar heat transfer coefficients. Later, we see how these heat transfer coefficients can be determined by the application of conservation laws. The effect of turbulence is also discussed and empirical correlations presented.

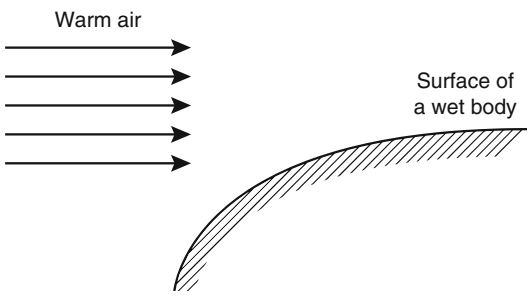

Fig. 3.1 Drying of a wet body in a stream of warm air

Basic Laws of Molecular Transfer

Newton's Law of Viscosity An isothermal system is shown in Fig. 3.2. It consists of a fluid trapped between two impervious flat plates that are infinite in extent and separated by a distance, δ. Experiments show that if the lower plate is fixed and the upper plate is moved at a constant velocity, u_∞, then the velocity of the fluid between the two plates varies from u_∞ near the top plate to zero at the fixed plate. Under steady laminar conditions, a linear velocity profile is established as shown in Fig. 3.2. The fluid thus exerts a shear force on the stationary plate. Experiments also show that τ, the shear force exerted on the bottom plate per unit area, is directly proportional to u_∞ and inversely proportional to the separation distance, δ; that is,

$$\tau \alpha \frac{u_\infty}{\delta} \quad \text{or} \quad \tau = \mu \frac{u_\infty}{\delta}$$

The constant of proportionality, μ, is called the dynamic viscosity of the fluid (units: N·s/m^2) and the force per unit area, τ, is called the shear stress. (In some texts a negative sign is introduced to emphasize the direction of net momentum transfer, i.e., from the fluid at higher velocity to the fluid at lower velocity.) Note that the shear stress τ exerted by the fluid on the fixed plate is in the positive x-direction and that exerted by the fixed plate on the fluid is equal and opposite in direction.) In differential form

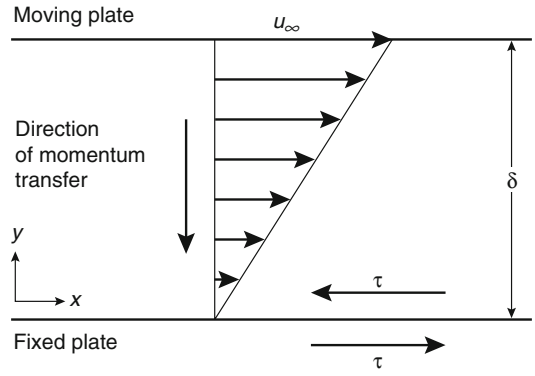

Fig. 3.2 Steady-state velocity distribution in a Newtonian fluid

this relationship expresses the shear stress at any location, y, in the fluid as

$$\tau = \mu \frac{du}{dy} \tag{3.1}$$

This is Newton's law of viscosity. Equation 3.1 states that the shear stress experienced by a fluid layer is directly proportional to the velocity gradient inside the fluid at that location.

Fluids that behave according to Equation 3.1 (i.e., τ is linearly related to the velocity gradient, du/dy, and μ is not a function of the velocity gradient) are called Newtonian fluids. Fortunately, all gases and most simple liquids such as water obey this simple law. For gases, μ roughly increases as the square root of temperature as predicted by the kinetic theory of dilute gases. Liquids, on the other hand, become "thinner" (less viscous), that is, μ decreases with increase in temperature. For non-Newtonian fluids (e.g., pastes, slurries, blood, etc.) the dynamic viscosity also depends on the velocity gradient or the rate of shear.

Fourier's Law of Heat Conduction Two stationary parallel plates separated by a distance, δ_t, are shown in Fig. 3.3. Let the temperature of the upper plate be T_∞ and that of the lower plate be T_s. Under steady conditions and for temperature independent properties of the trapped fluid, a linear temperature distribution as shown in Fig. 3.3 is obtained. Thus, as expected, heat is transferred by the stationary fluid from the hot to the cold plate. The heat flow per unit area per unit time through the fluid ($\dot{q}''$ J/m^{2}s) is found to be directly proportional to the temperature difference, $T_\infty - T_s$, and inversely proportional to the separation distance, δ_t; that is,

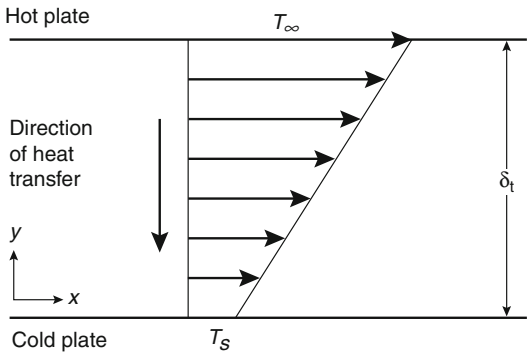

Fig. 3.3 Steady-state temperature distribution

$$\dot{q}'' \alpha \frac{T_\infty - T_s}{\delta_t} = -k \frac{T_\infty - T_s}{\delta_t}$$

The constant of proportionality, k, is called the thermal conductivity (units: J/mKs). The minus sign is a consequence of the second law of thermodynamics, which requires the heat to flow in the direction of decreasing temperature. In differential form the heat across any fluid layer is given by

$$\dot{q}'' = -k \frac{dT}{dy} \tag{3.2}$$

This is known as Fourier's law of heat conduction, which states that the heat flux is directly proportional to the temperature gradient and the heat flux vector is oriented in the direction of decreasing temperature. The thermal conductivity, k, like viscosity, μ, is a physical property of the fluid. The thermal conductivity of gases at low densities increases with increasing temperature (roughly as $\sqrt{T}$ according to the kinetic theory of dilute gases) whereas the thermal conductivity of most liquids decreases with increasing temperature.

Fick's Law of Mass Diffusion Once again, consider the parallel plate example. This time, there are no temperature gradients and no directed motion of the plates. Instead, the top plate is maintained at a higher concentration of species A ($C_{A\infty}$, kg of species A/m^3), assuming that it is wet, and the bottom plate is maintained at a fixed but lower concentration of species A (C_{AW}, kg of A/m^3). Then, under steady conditions a concentration profile, as shown in Fig. 3.4, is established. This nonuniform concentration field is the driving force for species A to diffuse from the top to the bottom plate. The mass flux of species A, $\dot{m}''$ (units: kg/m^{2}s), leaving the top plate and arriving at the bottom plate through the fluid, B, is found to be directly proportional to the concentration difference and

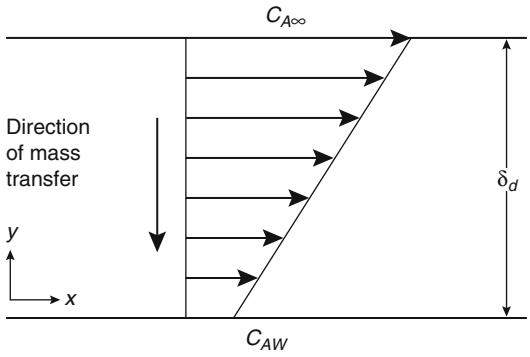

Fig. 3.4 Steady-state concentration distribution

inversely proportional to the separation distance δ_d, that is,

$$\dot{m}_A'' \alpha \frac{C_{A\infty} - C_{AW}}{\delta_d} = -D_{AB} \frac{C_{A\infty} - C_{AW}}{\delta_d}$$

The constant of proportionality, D_{AB}, is called diffusivity of species A through species B and has units of m^2/s. The negative sign once again indicates that the net mass transfer of species A occurs in the direction of decreasing concentration. In the differential form, the mass flux of species A across any layer of fluid B is given by

$$\dot{m}'' = -D_{AB} \frac{dC_A}{dy} \tag{3.3}$$

This is known as Fick's law of mass diffusion, which states that the mass flux across a fluid layer is directly proportional to the local concentration gradient. For binary gas mixtures, D_{AB} increases with increasing temperature roughly as three-halves power, as predicted by the kinetic theory of dilute gases.

Discussion Equations 3.1, 3.2, and 3.3 look very similar—they all relate the flux of the transported quantity to their respective local gradients. Actually, these equations may be considered definitions of the three macroscopic physical properties, μ, k, and D_{AB} of the fluid. In general, these properties are functions of temperature, pressure, and composition. As noted earlier, for low pressure binary gas mixtures (<10 atm) the pressure, temperature, and composition dependence of these properties can be approximately predicted by the kinetic theory of gases. In fact, the physical mechanism of all three transport processes is easily understood by considering the random motion of molecules in an ideal gas.

Molecules of a gas, even in the absence of bulk fluid motion, move around randomly at high speeds and bump into each other. Thus, a given molecule may be found anywhere between the two parallel plates. The problem, however, is how to distinguish one molecule from another. When the upper plate is moving relative to the bottom plate, the molecules adjacent to the upper plate attain a directed velocity over and above their random motion. Consequently, as the molecules near the upper plate find themselves in lower fluid layers (and vice versa) they exchange directed motion (or momentum) by bumping into each other. Similarly, the gas molecules near the hot upper plate are distinguished from those adjacent to the cold lower plate because they possess a higher kinetic energy. Once again, by virtue of random motion, these higher kinetic energy molecules find themselves near the cold plate and collide with low kinetic energy molecules (or vice versa), thus transporting energy. In the case of mass diffusion, the molecules are chemically labeled and their random motion results in mass transfer. Since increasing the gas temperature increases the random molecular motion, the transport processes become more efficient at higher gas temperatures. For gases, the macroscopic physical properties (viscosity, thermal conductivity, and diffusivity) that characterize momentum, heat, and mass transport must also increase with temperature.

Assuming constant properties, Equations 3.1 and 3.2 can be rewritten in the following forms:

$$\tau = \left(\frac{\mu}{\rho}\right) \frac{d(\rho u)}{dy} \tag{3.1a}$$

$$\dot{q}'' = -\left(\frac{k}{\rho c_p}\right) \frac{d(\rho c_p T)}{dy} \tag{3.2a}$$

Here, μ/ρ is known as the kinematic viscosity, ν, and has units of m^2/s. The product, ρu, has units of (kg m/s)/m^3; that is, momentum per unit volume. The quantity, $k/\rho c_p$, is known as the thermal

diffusivity, α, and it too has units of m^2/s. The product, $\rho c_p T$, then becomes enthalpy per unit volume and has units of J/m^3. Comparing these with Equation 3.3, where the mass diffusivity, D_{AB}, also has units of m^2/s and C_A is expressed in kg of species A/m^3, we find that the fluxes are related to their corresponding gradients of volumetric concentration. Furthermore, the ratios of various physical constants yield the familiar nondimensional numbers. These are

$$\text{Prandtl number, Pr} = \nu/\alpha$$
$$\text{Schmidt number, Sc} = \nu/D_{AB}$$
$$\text{Lewis number, Le} = \alpha/D_{AB}$$

Here, the Prandtl number compares the relative magnitude of momentum transfer to heat transfer, the Schmidt number compares momentum transfer to mass transfer, and the Lewis number compares heat transfer to mass transfer. The significance of these nondimensional numbers will become obvious when we discuss boundary layer transfer processes. The balance of this section will discuss primarily heat transfer. The treatment of mass transfer is similar and will not be discussed. However, since fluid motion is central to convective heat transfer, it is necessary to understand momentum transport to solve convective heat transfer problems.

Relationship of Basic Laws to Transfer Coefficients

A flow condition is shown in Fig. 3.5. A fluid of velocity, u_∞, and temperature, T_∞, flows over an arbitrarily shaped stationary surface of area, A_s.

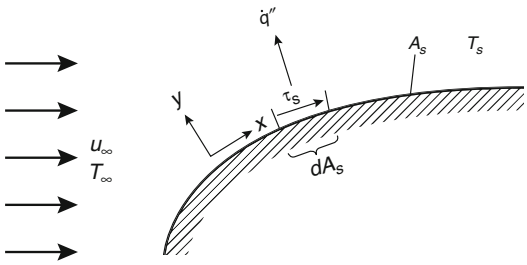

Fig. 3.5 Example of the convection heat transfer problem

If the surface conditions are such that $T_s \neq T_\infty$, we know that convection heat transfer will occur. The convection heat transfer problem is to relate the local heat flux, $\dot{q}''$, to its driving force, $T_s - T_\infty$. By expressing the heat flux as

$$\dot{q}'' = h(T_s - T_\infty) \tag{3.4}$$

the problem is reduced to determining h, which is called the heat transfer coefficient. From Equation 3.2 it is clear that the heat transfer coefficient may be expressed as

$$h = \frac{-k(\partial T/\partial y)\big|_{y=0}}{(Ts - T\infty)} \left(\frac{J}{m^2 s\ \text{K}}\right) \tag{3.5}$$

In Equation 3.5 the partial derivative is used because, in general, temperature is a function of x, y, z, and time. Thus, if the thermal conductivity of the fluid is known, the problem of determining the local heat transfer coefficient is reduced to that of determining the local temperature gradient in the fluid adjacent to the surface. This local temperature gradient can be experimentally measured or obtained theoretically from the solution of the conservation laws. Obviously, the temperature gradient will vary from point to point along the surface of the body. Often, such detail is not required and it may only be necessary to determine an average heat transfer coefficient, $\overline{h}$. This is obtained by integrating over the entire surface area, A_s. The total rate of heat transfer from the body to the fluid is given by

$$\dot{q}(\text{J/s}) = \int_{A_s} \dot{q}''\left(\text{J/m}^2\text{s}\right) \cdot dA_s\left(\text{m}^2\right) \tag{3.6}$$

Defining an average heat transfer coefficient, $\overline{h}$, as

$$\dot{q} = \overline{h} A_s (T_s - T_\infty) \tag{3.7}$$

The following is obtained from the use of Equations 3.4, 3.6, and 3.7

$$\overline{h} = \frac{1}{A_s(T_s - T_\infty)} \int_{A_s} h(T_s - T_\infty) dA_s \tag{3.8}$$

If the surface temperature, T_s, is held constant, then

$$\overline{h} = \frac{1}{A_s}\int_{A_s} h dA_s \left(\frac{\text{J}}{\text{m}^2\text{s K}}\right) \tag{3.9}$$

Similarly, the local shear stress at the surface, τ_s, can be related to its cause, the fluid velocity, u_∞. This relation is derived by defining a local nondimensional friction coefficient, C_f, according to the equation

$$\tau_s \equiv C_f\left(\frac{1}{2}\rho u_\infty^2\right) \tag{3.10}$$

Once again, the problem is reduced to the determination of C_f. Using Equation 3.1 we obtain

$$C_f = \frac{\mu(\partial u/\partial y)\big|_{y=0}}{(1/2)\rho u_\infty^2} \tag{3.11}$$

Thus, the local friction coefficient can be evaluated from the knowledge of the local velocity gradient in the fluid adjacent to the surface. The average friction coefficient can easily be obtained by integrating the local shear stress, τ_s, over the entire surface area, A_s. The total drag force, D, experienced by the body is given by the product of average shear stress, $\overline{\tau}_s$, and the surface area, A_s. In other words,

$$D \equiv \overline{\tau}_s A_s = \int_{A_s} \tau_s dA_s \tag{3.12}$$

Assuming u_∞ to be the same at all locations

$$\overline{\tau}_s = \frac{\left(1/2\rho u_\infty^2\right)}{A_s}\int_{A_s} C_f A_s \tag{3.13}$$

Defining the average friction coefficient, $\overline{C}_f$, as

$$\overline{C}_f \equiv \frac{\overline{\tau}_s}{\left(1/2\rho u_\infty^2\right)} \tag{3.14}$$

we get

$$\overline{C}_f = \frac{1}{A_s}\int_{A_s} C_f dA_s \tag{3.15}$$

To obtain h, $\overline{h}$, C_f, and $\overline{C}_f$ a knowledge of fluid properties and temperature and velocity gradients in the fluid adjacent to the surface is required. To obtain these gradients it is necessary to be more specific about the surface geometry and the flow conditions. The governing conservation equations for an arbitrary surface geometry will be first derived and then applied to a flat plate to illustrate the methodology.

Conservation Equations for Convection Heat Transfer

It has been shown that to determine the heat transfer and friction coefficients, the temperature and velocity distributions in the flow are needed. In principle, these may be obtained from the solution of the conservation equations with appropriate boundary conditions. Although in practice it is difficult, the very knowledge of conservation equations and their solutions for simple cases (such as a flat plate) provide considerable insight about the parameters influencing the heat transfer and friction coefficients. Thus, the necessary equations will be first developed and then applied to a flat plate.

Consider the flow over the surface shown in Fig. 3.6. To simplify the development assume two-dimensional flow conditions, for which x is the direction along the surface and y is normal to the surface. Extension of this to three-dimensional flows is available in the literature [1–5].

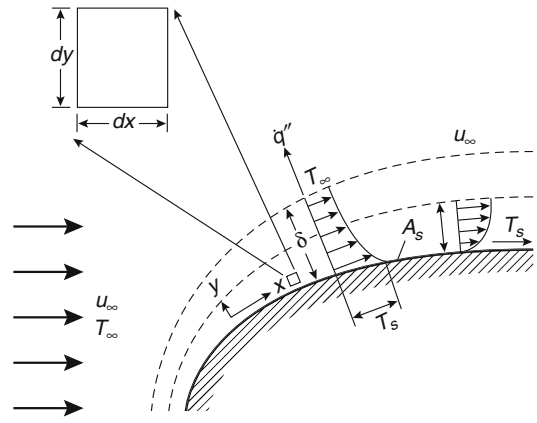

Fig. 3.6 Velocity and temperature distributions inside the fluid for flow over a hot surface

Conservation of Mass (Continuity Equation) The first conservation law that is pertinent to the problem is that matter is neither created nor destroyed. When applied to the differential control volume shown in Figs. 3.6 and 3.7 it states that the net rate of mass flow entering the elemental control volume in the x-direction, plus the net rate of mass flow entering the elemental control volume in the y-direction equals the net rate of increase of mass stored in the control volume. Mass enters and leaves the control volume exclusively through gross fluid motions. Such a transport is often referred to as convective transport.

For a control volume of unit depth in the z-direction, mass entering the left face per unit time, $\dot{M}_x$, is given by

$$\dot{M}_x = \rho\left(\mathrm{kg/m^3}\right) u(\mathrm{m/\ sec})\, dy(\mathrm{m}) \cdot 1(\mathrm{m})$$

Similarly, mass entering the bottom face per unit time, $\dot{M}_y$, is given by

$$\dot{M}_y = \rho \cdot v \cdot dx \cdot 1$$

where v is the fluid velocity in the y-direction.

Since ρu and ρv are continuous functions of x, y, and time, in general they will be different at different locations. To determine ρu at $(x + dx)$, expand ρu about the point x in the Taylor series as

$$\rho u(x + dx, y) = \rho u(x, y) + \left[\frac{\partial(\rho u)}{\partial x}\right]_{x,y} dx \tag{3.16}$$

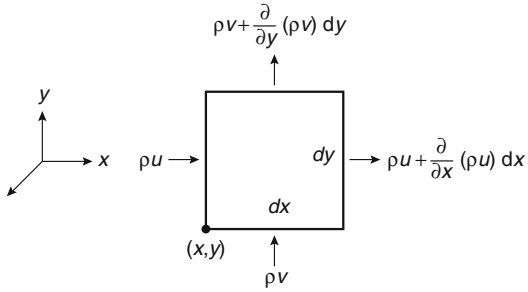

Fig. 3.7 Differential control volume for mass conservation in a two-dimensional flow

Similarly,

$$\rho v(x, y + dy) = \rho v(x, y) + \left[\frac{\partial(\rho v)}{\partial y}\right]_{x,y} dy$$

Thus, mass leaving the right face per unit time, $\dot{M}_{x+dx}$, is given by

$$\dot{M}_{x+dx} = \left[\rho u + \frac{\partial(\rho u)}{\partial x} dx\right] \cdot dy \cdot 1 \tag{3.17}$$

and mass leaving the top face per unit time, $\dot{M}_{y+dy}$, is

$$\dot{M}_{y+dy} = \left[\rho v + \frac{\partial(\rho v)}{\partial y} dy\right] \cdot dx \cdot 1 \tag{3.18}$$

Finally, the rate of increase (or decrease) of mass stored in the control volume, $\dot{M}_s$, is of the form

$$\dot{M}_s = \frac{\partial}{\partial t}(\rho \cdot dx \cdot dy \cdot 1) = \frac{\partial \rho}{\partial t} dxdy \tag{3.19}$$

Thus, conservation of mass requirement may now be expressed as

$$(\rho u)dy + (\rho v)dx - \left[\rho u + \frac{\partial(\rho u)}{\partial x} dx\right] dy - \left[\rho v + \frac{\partial(\rho v)}{\partial y} dy\right] dx = \frac{\partial \rho}{\partial t} dxdy \tag{3.20}$$

After canceling terms and dividing by $dx\, dy$

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} = 0 \tag{3.21}$$

This is the *continuity equation*, which is an expression of the overall mass conservation requirement and must be satisfied at every point in the flow. This equation applies for a single species fluid, as well as for mixtures in which species diffusion and chemical reactions may be occurring.

Conservation of Momentum The second conservation law pertinent to the convection heat

transfer problem is Newton's second law of motion. For a differential control volume in a flow field, this requirement states that the sum of all forces acting on the control volume must equal the rate of increase of the fluid momentum within the control volume, plus the net rate at which momentum leaves the control volume (outflow-inflow).

The forces acting on the fluid may be categorized into *body forces* that are proportional to the volume, and *surface forces*, which are proportional to the area. Gravitational, centrifugal, magnetic, and electric fields are familiar examples of body forces. Of these, gravitational body force is the most important from the fire science point of view. The x- and y-components of this body force per unit volume of the fluid will be designated as F_{Bx} and F_{By}, respectively.

The surface forces, F_s, acting on the fluid are called stresses (force/area). These are due to fluid static pressure, p, and viscous stresses. Since pressure is always normal to the surface, the viscous stresses are also resolved into normal stresses, σ_{ii}, which act normal to the surface, and shear stresses, τ_{ij}, which act along or parallel to the surface. Figure 3.8 shows the various viscous stresses acting on the surface of a differential control volume. A double subscript notation is used to specify the stress components. The first subscript indicates the direction of the outward normal to the surface, and the second subscript indicates the direction of the force component. Accordingly, the stress τ_{xy}, acting on the left face, corresponds to the viscous shear force per unit area in the negative y-direction on a face whose normal is in the negative x-direction—resulting in a positive shear stress. All the viscous stresses shown in Fig. 3.8 are positive according to the adopted convention. It should be noted that these forces act on the fluid inside the control volume and are caused by its interaction with the surrounding fluid. Thus, these viscous stresses will vanish if the fluid velocity, or more specifically the velocity gradient in the fluid, becomes zero. The normal viscous stresses shown in Fig. 3.8 must not be confused with static pressure, p, which does not vanish for zero velocity. Since these stresses are continuous functions of x, y, and time, the customary Taylor's expansion is used to express the stresses on the top and right faces of the control volume shown in Fig. 3.8. Thus, the net surface force in the x- and y-directions may be expressed as

$$F_{sx} = \left(\frac{\partial \sigma_{xx}}{\partial x} - \frac{\partial p}{\partial x} + \frac{\partial \tau_{yx}}{\partial y}\right) dxdy \qquad (3.22)$$

$$F_{sy} = \left(\frac{\partial \sigma_{yy}}{\partial y} - \frac{\partial p}{\partial y} + \frac{\partial \tau_{xy}}{\partial x}\right) dxdy \qquad (3.23)$$

To use Newton's second law, the time rate of change of momentum and the momentum influx and outflux must also be evaluated. To focus on the x-direction, the relevant momentum fluxes are shown in Fig. 3.9. The mass flux through the left face is ρu and hence the corresponding

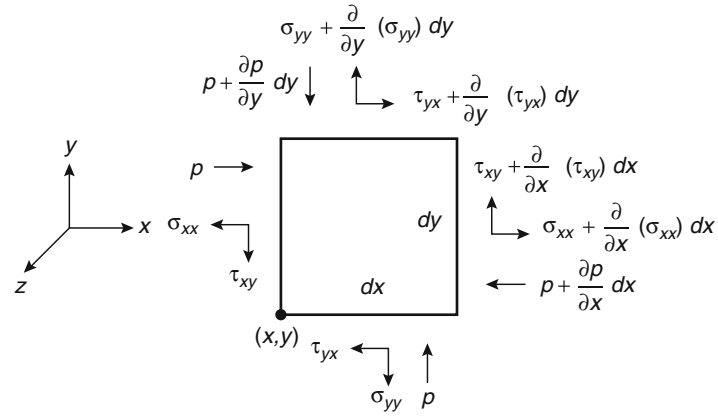

Fig. 3.8 Static pressure, p, and normal and shear viscous stresses acting on a differential control volume in a two-dimensional flow

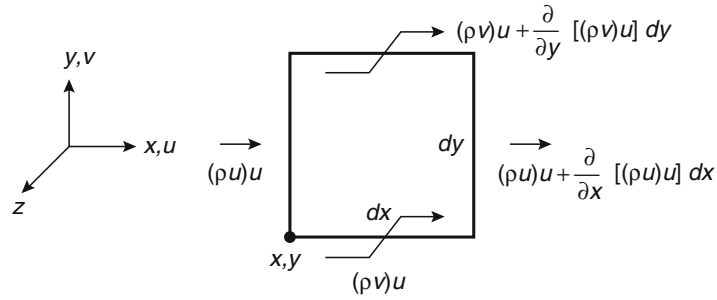

Fig. 3.9 Influx and outflux of x-momentum in the control volume

momentum flux is $(\rho u)u$. Similarly, the x-momentum flux due to mass flow in the y-direction through the bottom face is $(\rho v)u$. Thus the net rate at which momentum leaves the control volume is given by (x-momentum outflow − inflow)

$$\frac{\partial}{\partial x}[(\rho u)u]dx\,dy + \frac{\partial[(\rho v)u]}{\partial y}dy\,dx$$

In addition, the time rate of change of x-momentum of the fluid within the control volume is given by

$$\frac{\partial}{\partial t}(\rho u)dx\,dy$$

Equating the total rate of change in the x-direction to the sum of forces in the x-direction, we obtain

$$\frac{\partial(\rho u)}{\partial t} + \frac{\partial[(\rho u)u]}{\partial x} + \frac{\partial[(\rho v)u]}{\partial y} = \frac{\partial \sigma_{xx}}{\partial x} - \frac{\partial p}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + F_{Bx} \qquad (3.24)$$

By using Equation 3.21, Equation 3.24 may be expressed in a more convenient form as

$$\rho\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y}\right) = \frac{\partial}{\partial x}(\sigma_{xx} - p) + \frac{\partial \tau_{yx}}{\partial y} + F_{Bx} \qquad (3.25)$$

A similar expression is obtained for the y-direction. This is

$$\rho\left(\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y}\right) = \frac{\partial}{\partial y}(\sigma_{yy} - p) + \frac{\partial \tau_{xy}}{\partial x} + F_{By} \qquad (3.26)$$

In Equations 3.25 and 3.26, the first term on the left side represents the increase in momentum of the fluid inside the control volume, and the remaining terms represent the net rate of momentum efflux from the control volume. The terms on the right side of the equations account for the net viscous, pressure, and body forces acting on the control volume. These equations must be satisfied at every point in the fluid. A solution of Equations 3.21, 3.25, and 3.26 along with appropriate boundary conditions yields the velocity field needed to determine the friction coefficient.

Before a solution to the above equations can be obtained, it is necessary to relate the viscous stresses to the velocity gradients. For a one-dimensional flow of a Newtonian fluid, Equation 3.1 relates the shear stress to the velocity gradient in the fluid. For a two-dimensional flow of Newtonian fluid [2], the required stress-velocity gradient expressions are

$$\sigma_{xx} = 2\mu\frac{\partial u}{\partial x} - \frac{2}{3}\mu\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) \qquad (3.27)$$

$$\sigma_{yy} = 2\mu\frac{\partial v}{\partial y} - \frac{2}{3}\mu\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) \qquad (3.28)$$

$$\tau_{xy} = \tau_{yx} = \mu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) \qquad (3.29)$$

On substituting Equations 3.27, 3.28, and 3.29 into Equations 3.25 and 3.26, the desired form of the x- and y-momentum equations is obtained. These are

x-momentum equation

$$\rho\left(\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}\right)=-\frac{\partial p}{\partial x}+\mu\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right)+\frac{1}{3}\mu\frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)+F_{Bx} \tag{3.30}$$

y-momentum equation

$$\rho\left(\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}\right)=-\frac{\partial p}{\partial x}+\mu\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}\right)+\frac{1}{3}\mu\frac{\partial}{\partial y}\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)+F_{By} \tag{3.31}$$

For an isothermal system, Equations 3.21, 3.30, and 3.31 along with the equation of state ($p = \rho RT$ for an ideal gas) provide a complete set for determining the four dependent variables (u, v, p, and ρ) as a function of the three independent variables x, y, and t. However, for a nonisothermal system such as a fire, energy balance must also be considered.

Conservation of Energy The temperature field inside the fluid, $T(x, y, t)$, needed to determine the heat transfer coefficient is obtained by applying the first law of thermodynamics to the differential control volume shown in Fig. 3.6. Before writing the energy balance for this control volume, it is necessary to identify the items that must be included in the energy budget. These are:

1. The stored energy. This includes the specific internal or thermal energy, e; J/kg, and the kinetic energy of the fluid per unit mass, $V^2/2 = (u^2 + v^2)/2$. Potential energy is neglected because for most problems in convective heat transfer it is substantially smaller than thermal and kinetic energy. Hence, the total energy content per unit volume is given by: $\rho(e + V^2/2)$.
2. Conduction of thermal energy across the surfaces of the control volume. Here, the rate of energy transported per unit area per unit time across the control surface is given by Equation 3.2 as $\dot{q}''_x = -k\partial T/\partial x$ for the x-direction, and $\dot{q}''_y = -k\partial T/\partial y$ for the y-direction.
3. Energy generated per unit volume per unit time inside the control volume (Q watts/m^3). This may be due to chemical reactions (endothermic or exothermic) or may be caused by the radiative loss of heat. Although the specific form of Q will depend on the nature of the physical process, here we will treat it only as a rate of heat loss or gain per unit volume.
4. The rate of work done by surface or body forces. For surface forces, $\mathbf{F_S}$, it is given by: [$\mathbf{F_S}$ · (velocity vector)] (surface area); and for the body forces, $\mathbf{F_B}$, it is given by: [$\mathbf{F_B}$ · (velocity vector)] (volume). Both these expressions have units of watts or work done per unit time.

With these definitions, consider the control volume shown in Figs. 3.6 and 3.10. The conservation of energy for this control volume can be simply stated as

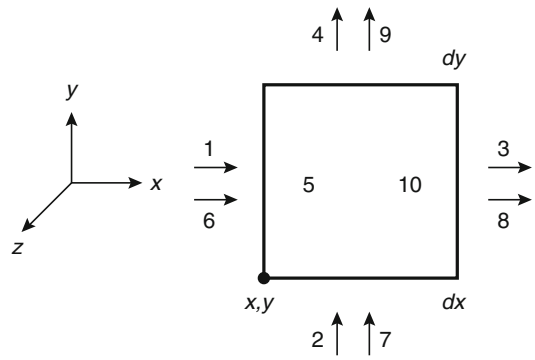

Fig. 3.10 A control volume showing the energy conducted and convected through its control surfaces

$$\begin{pmatrix}\text{Rate of increase}\\ \text{of energy inside}\\ \text{the control volume}\end{pmatrix} = \begin{pmatrix}\text{Net rate of energy flow}\\ \text{into the control volume}\\ \text{by bulk and fluid motion}\end{pmatrix} + \begin{pmatrix}\text{Flow of heat through}\\ \text{the control surface}\\ \text{by conduction}\end{pmatrix} + \begin{pmatrix}\text{Rate of work done by body}\\ \text{and surface forces}\end{pmatrix} + \begin{pmatrix}\text{Energy generated inside}\\ \text{the control volume}\end{pmatrix} \tag{3.32}$$

In Equation 3.32 the rate of increase of energy inside the control volume is given by

$$\frac{\partial}{\partial t}\left[\rho\left(e+\frac{V^2}{2}\right)\right]dxdy$$

The net rate at which the energy enters the control volume by convection or bulk fluid motion is obtained by subtracting the energy going out from that coming in, to yield

$$-\frac{\partial}{\partial x}\left[\rho u\left(e+\frac{V^2}{2}\right)\right]dxdy-\frac{\partial}{\partial y}\left[\rho v\left(e+\frac{V^2}{2}\right)\right]dxdy$$

Similarly, the heat flowing into the control volume by conduction is given by

$$-\left(\frac{\partial \dot{q}_x''}{\partial x}+\frac{\partial \dot{q}_y''}{\partial y}\right)dxdy=\left[\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right)\right]dxdy$$

Finally, the net rate at which work is done on the fluid inside the control volume (Fig. 3.11) is given by the expression

$$\left(uF_{Bx}+vF_{By}\right)dxdy-\left[\frac{\partial(pu)}{\partial x}+\frac{\partial(pv)}{\partial y}\right]dxdy+\left[\frac{\partial}{\partial x}\left(u\sigma_{xx}\right)+\frac{\partial}{\partial y}\left(v\sigma_{yy}\right)+\frac{\partial}{\partial y}\left(u\tau_{yx}\right)+\frac{\partial}{\partial x}\left(v\tau_{xy}\right)\right]dxdy$$

On substituting these expressions into Equation 3.32, simplifying and using Equations 3.27 through 3.31, we obtain

$$\rho C_p\frac{\partial T}{\partial t}+\rho uC_p\frac{\partial T}{\partial x}+\rho vC_p\frac{\partial T}{\partial y}=\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right)+\left(\frac{\partial p}{\partial t}+u\frac{\partial p}{\partial x}+v\frac{\partial p}{\partial y}\right)+\mu\Phi \tag{3.33}$$

In Equation 3.33, the thermodynamic definition of enthalpy ($i = e + p/\rho$ and $di = C_p dT$) has been used. Also, the term $\mu\Phi$ is called the viscous dissipation and is given by

$$\mu\Phi=2\mu\left[\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial v}{\partial y}\right)^2\right]+\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)^2-\frac{2}{3}\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)^2 \tag{3.34}$$

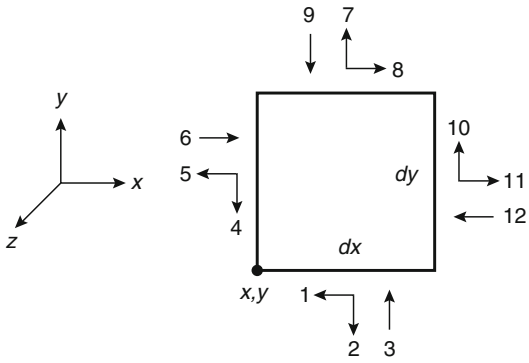

Fig. 3.11 Control volume showing the rate of work done by various surface forces. All units are in watts

Equations 3.21, 3.30, 3.31, and 3.33, along with the equation of state ($p = \rho RT$, for an ideal gas), provide a complete set for determining the temperature and velocity field [$T(x, y, t)$, $u(x, y, t)$, $v(x, y, t)$] inside the fluid. However, it is not possible to solve the above set of coupled nonlinear partial differential equations. Therefore, several simplifying approximations are made. These are discussed below.

Simplifications

1. *Low velocity*. For most problems encountered in convective heat transfer, the flow velocity is low enough (Mach number $< {}^1/_3$) to ignore the contribution of viscous work in the energy equation. This allows the term $\mu\phi$ in Equation 3.33 to be dropped.
2. *Incompressible flow*. Fluid density is assumed to be constant except in the buoyancy terms (F_{Bx}, F_{By}) of Equations 3.30 and 3.31. This is called the Boussinesq approximation and will be discussed later in greater detail.
3. *Steady flow*. This approximation allows all the time derivative terms in the above equations to be dropped.
4. *Constant properties*. Specific heat, thermal conductivity, and viscosity are all assumed to be constant; that is, independent of temperature and pressure.

With these simplifications and assuming that the body force is only due to gravity (i.e., $F_{Bx} = -\rho g_x$ and $F_{By} = -\rho g_y$), Equations 3.21, 3.30, 3.31, and 3.33 become

Continuity

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{3.35}$$

x-momentum

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \nu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) - g_x \tag{3.36}$$

y-momentum

$$u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \nu\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right) - g_y \tag{3.37}$$

Energy equation

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) + \frac{1}{\rho C_p}\left(u\frac{\partial p}{\partial x} + v\frac{\partial p}{\partial y}\right) \tag{3.38}$$

Often, the energy equation is further simplified by assuming that the terms ($u\ \partial p/\partial x$) and ($v\ \partial p/\partial y$) are negligible. This assumption is justified since most processes of interest are nearly isobaric. Thus the energy equation becomes

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) \tag{3.39}$$

Equations 3.35, 3.36, 3.37, and 3.39, along with the equation of state ($p = \rho RT$, for an ideal gas), provide a complete set for determining $u(x, y)$, $v(x, y)$, $T(x, y)$, $\rho(x, y)$, and $p(x, y)$. Once these dependent variables are known, the desired heat transfer coefficient and friction factor are obtained from Equations 3.5 and 3.11, respectively. However, the above equations are still too difficult to solve and a further simplification, known as the boundary layer approximation, is often made.

The Boundary Layer Concept

In 1904, Prandtl proposed that all the viscous effects are concentrated in a thin layer near the boundary and that outside this layer the fluid behaves as though it is inviscid. Thus, the flow over a body, such as the one shown in Fig. 3.6, can be divided into two zones: (1) a thin viscous layer near the surface, called the boundary layer, and (2) inviscid external flow, which can be closely approximated by the potential flow theory. As will be seen later, the fact that the boundary layer is thin compared to the characteristic dimensions of the object is exploited to simplify the governing equations and obtain a useful solution. This boundary layer approximation plays an important role in convective heat transfer, since the gradients of velocity and temperature at the surface of the body are required to determine the heat transfer coefficient and the friction factor.

To illustrate these ideas, consider fluid flow over a flat plate as shown in Fig. 3.12. The fluid particles in contact with the plate surface must assume zero velocity because of no slip at the wall, whereas the fluid particles far away from the wall continue to move at the free stream velocity, u_∞. The transition of fluid velocity from zero to u_∞ takes place in a small distance, δ, which is known as the boundary layer thickness and is defined as the value of y for which $u = 0.99u_\infty$. As is intuitively obvious, the thickness of the boundary layer increases with fluid viscosity and decreases with increasing free-stream velocity. By defining the Reynolds number, Re, as $\mathrm{Re} = u_\infty L/\nu$, where L is the characteristic length of the plate, the boundary layer thickness decreases with increasing Re. For most flows of practical interest, the Reynolds number is large enough such that δ is much less than the characteristic length, L ($\delta \ll L$).

Just as a velocity boundary layer develops because of viscous effects near the surface, a thermal boundary layer develops due to heat transfer between the free stream and the surface if their temperatures are different. The fluid particles that come into contact with the plate surface achieve thermal equilibrium at the plate's surface temperature. In turn, these particles exchange energy with those in the adjoining fluid layer, and temperature gradients develop in the fluid. As shown in Fig. 3.12, the region of the fluid in which these temperature gradients exist is the thermal boundary layer, and its thickness, δ_t, is defined as the value of y for which the ratio $[(T - T_S)/(T_\infty - T_S)] = 0.99$. The thermal boundary layer thickness increases with the thermal diffusivity, α, of the fluid and decreases with increasing free stream velocity. In other words, δ_t is inversely proportional to the product of the Reynolds number and Prandtl number ($\mathrm{Re}\ \mathrm{Pr} = (u_\infty L/\nu)(\nu/\alpha) = u_\infty L/\alpha$). For air, $\mathrm{Pr} \approx 0.7$ and the Reynolds number is sufficiently large for flows of practical interest, consequently $\delta_t \ll L$.

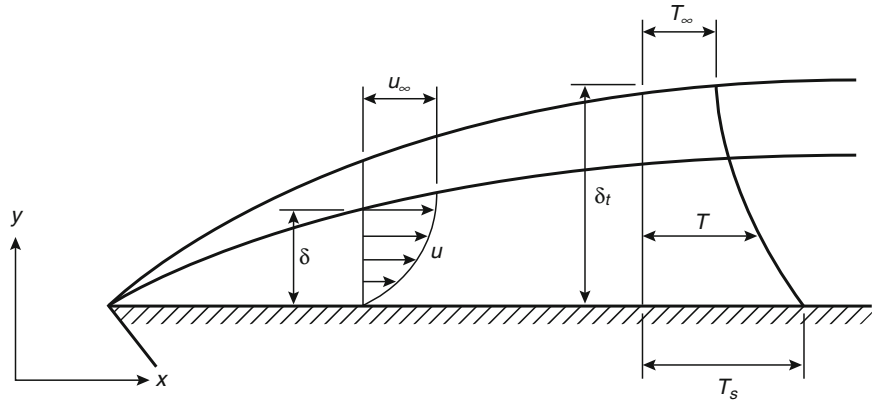

Fig. 3.12 Velocity and thermal boundary layers on a flat plate

Boundary Layer Approximation The governing Equations 3.35 through 3.37 and 3.39 can be further simplified for the case when the Reynolds number is reasonably large ($\mathrm{Re} \sim (L/\delta)^2$; that is, Re is of the order $(L/\delta)^2$) such that $\delta \ll L$. To compare the various terms in the governing equations, first normalize all the variables so that they are of the order of magnitude unity. By defining

$$x^* = \frac{x}{L} \qquad y^* = \frac{y}{\delta} \qquad u^* = \frac{u}{u_\infty}$$

and

$$T^* = \frac{T - T_s}{T_\infty - T_s} \tag{3.40}$$

variables that change from 0 to 1 inside the boundary layer are obtained. Substituting these into Equation 3.35 we find that

$$-\frac{\partial u^*}{\partial x^*} = \left(\frac{L}{\delta u_\infty}\right)\frac{\partial v}{\partial y^*}$$

This suggests that

$$v^* = \frac{Lv}{\delta u_\infty}$$

so that

$$\frac{\partial u^*}{\partial x^*} + \frac{\partial v^*}{\partial y^*} = 0 \tag{3.41}$$

Substituting x^*, y^*, u^*, and v^* into Equation 3.36 and simplifying

$$u^*\frac{\partial u^*}{\partial x^*} + v^*\frac{\partial u^*}{\partial y^*} = -\frac{\partial p^*}{\partial x^*} - g_x^* + \left(\frac{\nu}{Lu_\infty}\right) \times \left[\frac{\partial^2 u^*}{\partial x^{*2}} + \left(\frac{L}{\delta}\right)^2 \frac{\partial^2 u^*}{\partial y^{*2}}\right] \tag{3.42}$$

where $p^* \equiv p/\rho u_\infty^2$ and $g_x^* \equiv g_x L/u_\infty^2$.

In Equation 3.42, the quantity ν/Lu_∞ is recognized as 1/Re which is of the order $(\delta/L)^2$. Thus all terms in Equation 3.42 are of order of magnitude unity except the term $[(\nu/Lu_\infty)\partial^2 u^*/\partial x^{*2}]$, which is much less than 1 and can be ignored. Thus, Equation 3.36 is simplified to

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{dp}{dx} - g_x + \nu\frac{\partial^2 u}{\partial y^2} \tag{3.43}$$

Similarly, Equations 3.37 and 3.39 reduce to

$$\frac{\partial p}{\partial y} \approx 0 \tag{3.44}$$

and

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\frac{\partial^2 T}{\partial y^2} \tag{3.45}$$

Equation 3.44 simply implies that $p = p(x)$, that is, the pressure at any plane where $x =$ constant does not vary with y inside the boundary layer and hence is equal to the free stream pressure. To summarize, the boundary layer approximation yields a simpler set of governing equations that are valid inside the boundary layer. These equations for steady flow of an incompressible fluid with constant properties are

Continuity

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{3.35}$$

x-momentum

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} - g_x + \nu\frac{\partial^2 u}{\partial y^2} \tag{3.43}$$

Energy

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\frac{\partial^2 T}{\partial y^2} \tag{3.45}$$

To illustrate the use of these equations in determining the heat transfer coefficient, consider two classical examples: (1) laminar forced convection over a flat surface, and (2) laminar free convection on a vertical flat surface. Forced convection is chosen as a precursor to free convection because

it is simpler and also allows us to illustrate the difference between them. A flat geometry is also chosen in both cases for simplicity.

Laminar Forced Convection Over a Flat Surface A schematic of this problem is presented in Fig. 3.12, and the objective here is to obtain the gradients of temperature and velocity profile at $y = 0$. By applying the Bernoulli Equation in the potential flow region outside the boundary layer we obtain

$$\frac{u_\infty^2}{2} + \frac{p}{\rho} + gh = \text{constant} \tag{3.46}$$

Since the free stream velocity, u_∞, is constant, for a given height $y = h$ above the flat surface we obtain that $p =$ constant, that is, $p \neq p(x)$ outside the boundary layer in the potential flow region. From Equation 3.44 note that $p \neq p(y)$ inside the boundary layer. Hence, $p =$ constant both inside and outside the boundary layer over a flat surface. This implies that the term $\partial p/\partial x$ equals zero in Equation 3.43. Also, since the flow is forced (i.e., generated by an external agent such as a fan, rather than by buoyancy) the gravitational force, g_x, in Equation 3.43 does not contribute to the increase in momentum represented by the left side of the equation, and $g_x = 0$. Thus Equation 3.43 becomes

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = \nu\frac{\partial^2 u}{\partial y^2} \tag{3.47}$$

Equations 3.35, 3.45, and 3.47 govern the temperature and velocity distributions inside the boundary layer shown in Fig. 3.12. The associated boundary conditions areno-slip

$$u = v = 0 \qquad \text{at} \qquad y = 0$$

and

$$T = T_s \qquad \text{at} \qquad y = 0 \tag{3.48}$$

also

$$u = u_\infty \text{ and } T = T_\infty \text{ as } y \to \infty$$

Nondimensionalizing Equations 3.35, 3.45, 3.47, and 3.48 according to Equation 3.40[1] we obtain

$$\frac{\partial u^*}{\partial x^*} + \frac{\partial v^*}{\partial y^*} = 0 \tag{3.49}$$

$$u^*\frac{\partial u^*}{\partial x^*} + v^*\frac{\partial u^*}{\partial y^*} = \frac{1}{\text{Re}_L}\frac{\partial^2 u^*}{\partial y^{*2}} \tag{3.50}$$

$$u^*\frac{\partial T^*}{\partial x^*} + v^*\frac{\partial T^*}{\partial y^*} = \frac{1}{\text{Re}_L\text{Pr}}\frac{\partial^2 T^*}{\partial y^{*2}} \tag{3.51}$$

along with the boundary conditions

$$u^* = v^* = T^* = 0 \text{ at } y^* = 0$$

and

$$u^* = T^* = 1 \text{ at } y^* \to \infty \tag{3.52}$$

where

$$\text{Re}_L \equiv \frac{u_\infty L}{\nu}$$

is the Reynolds number based on length, L, and $\text{Pr} \equiv \nu/\alpha$ is the Prandtl number. Note that Equations 3.49 and 3.50 are sufficient for determining u^* (x^*, y^*) and v^* (x^*, y^*) and that once these are known, Equation 3.51 can be independently solved for T^* (x^*, y^*) Also note that for $\text{Pr} = 1$, Equations 3.50 and 3.51 as well as their corresponding boundary conditions are identical. Thus for $\text{Pr} = 1$ only Equations 3.49 and 3.50 need to be solved.

A similarity solution of Equations 3.49 and 3.50 along with the boundary conditions (Equation 3.52) was obtained by Blasius [2]. Blasius observed that since the system under consideration has no preferred length, it is reasonable to suppose that the velocity profiles at different

[1] A more convenient definition of $y^* = y/L$ and $v^* = v/u_\infty$ has been used since we are no longer interested in quantities of order of magnitude unity; instead we are simply interested in eliminating units.

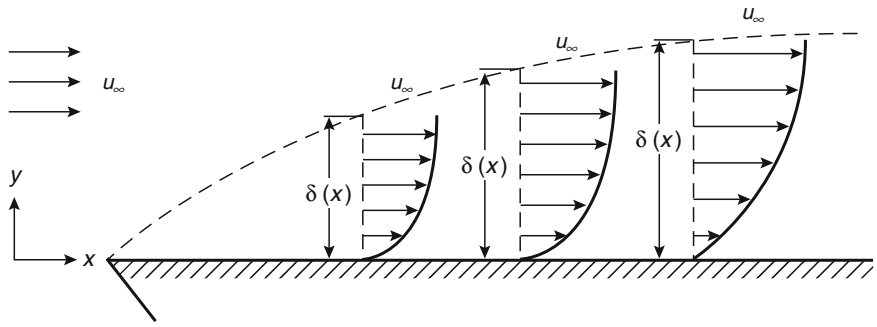

Fig. 3.13 Observed velocity profiles at different values of x

values of x have similar shapes; that is, if u and y are suitably scaled then the velocity profile may be expressed by a single function for all values of x (Fig. 3.13). An obvious choice is

$$\frac{u}{u_\infty} = \phi\left[\frac{y}{\delta(x)}\right]\phi \tag{3.53}$$

This choice, as it stands, is not very useful because $\delta(x)$ is not known. However, in accordance with the boundary layer approximation, $\mathrm{Re}_x \equiv u_\infty x/\nu \sim (x/\delta)^2$. Therefore,

$$\delta \sim \sqrt{\frac{\nu x}{u_\infty}}$$

can be expected. Substituting into Equation 3.53 we obtain

$$u^* = \frac{u}{u_\infty} = \phi\left[\frac{y}{x}\sqrt{\mathrm{Re}_x}\right] = \phi(\eta) \tag{3.54}$$

where

$$\eta \equiv \frac{y}{x}\sqrt{\mathrm{Re}_x} = \left[\left(\frac{y^*}{\sqrt{x^*}}\right)\sqrt{\mathrm{Re}_L}\right]$$

is the similarity variable. By introducing a stream function, ψ, such that

$$u^* = \frac{\partial\psi}{\partial y^*} \quad \text{and} \quad v^* = -\frac{\partial\psi}{\partial x^*} \tag{3.55}$$

Equation 3.49 is identically satisfied. Substituting Equation 3.54 into Equation 3.55 and integrating, we get

$$\psi = \int \phi(\eta)dy^* + f_1(x^*)$$
$$= \frac{\sqrt{x^*}}{\sqrt{\mathrm{Re}_L}}\int \phi(\eta)d\eta + f_1(x^*)$$

Since $v^* = 0$ at $y^* = 0, f_1(x^*)$ is at best an arbitrary constant which is taken as zero. Also, defining a new function $f(\eta) \equiv \int \phi(\eta)d\eta$, we obtain

$$\psi = \sqrt{x^*}\frac{f(\eta)}{\sqrt{\mathrm{Re}_L}} \tag{3.56}$$

therefore,

$$u^* = \left(\frac{\partial\psi}{\partial y^*}\right)_{x^*} = \left(\frac{\partial\psi}{\partial\eta}\right)_{x^*}\left(\frac{\partial\eta}{\partial y^*}\right)_{x^*}$$
$$= f'(\eta) = \frac{df}{d\eta} \tag{3.57}$$

and

$$-v^* = \left(\frac{\partial\psi}{\partial x^*}\right)_{y^*} = \left(\frac{\partial\psi}{\partial x^*}\right)_{\eta} + \left(\frac{\partial\psi}{\partial\eta}\right)_{x^*}\left(\frac{\partial\eta}{\partial x^*}\right)_{y^*}$$
$$= \frac{1}{2}\left(f - \eta f'\right)\sqrt{x^*\mathrm{Re}_L} \tag{3.58}$$

On substituting u^*, v^* into Equation 3.50 and simplifying we obtain

$$2f''' + ff'' = 0 \tag{3.59}$$

where primes represent differentiation with respect to η. Equation 3.59 is a third-order

nonlinear ordinary differential equation. Recall that η was a combination of two independent variables, x^* and y^*, and it was assumed that $u^* = \phi(\eta)$. If this similarity assumption was incorrect, then the partial differential Equation 3.50 would not have reduced to an ordinary differential Equation 3.59—that is, x^* would not have completely disappeared from the governing equation. Note also that even though Equation 3.59 is nonlinear and has to be solved numerically, there are no parameters and therefore it needs to be solved only once. Boundary conditions corresponding to Equation 3.59 become

$$f = f' = 0 \text{ at } \eta = 0, \text{ and } f' = 1 \text{ as } \eta \to \infty \tag{3.60}$$

A numerical solution of Equation 3.59 along with the boundary conditions, Equation 3.60 is shown in Fig. 3.14. Note that for Pr = 1, the solution for T^* is the same as that for u^*. Also, once T^* (x^*, y^*) and u^* (x^*, y^*) are known the heat transfer coefficient and friction factor can easily be obtained from Equations 3.5 and 3.11. Furthermore, from the definition of thermal and velocity boundary layer thickness ($T^* = u^* = 0.99$), we find that η = 5.

Therefore,

$$\eta = \frac{y}{x}\sqrt{\frac{u_\infty x}{\nu}} = 5 \quad \text{for} \quad y = \delta = \delta_t$$

or for Pr = 1,

$$\delta = \delta_t = \frac{5x}{\sqrt{\text{Re}_x}} \tag{3.61}$$

From Equation 3.61 it is clear that δ and δ_t increase with x but decrease with increasing u_∞ (the larger the free stream velocity, the thinner the boundary layer). Now, to determine the heat transfer coefficient and the friction factor we need $\partial T/\partial y\big|_{y=0}$ and $\partial u/\partial y\big|_{y=0}$. From Fig. 3.14, we have

$$\left.\frac{\partial T^*}{\partial \eta}\right|_{\eta=0} = \left.\frac{\partial u^*}{\partial \eta}\right|_{\eta=0} = 0.332$$

Thus,

$$\tau_s = \mu\left.\frac{\partial u}{\partial y}\right|_{y=0} = 0.332 u_\infty \sqrt{\rho\mu u_\infty / x} \tag{3.62}$$

and

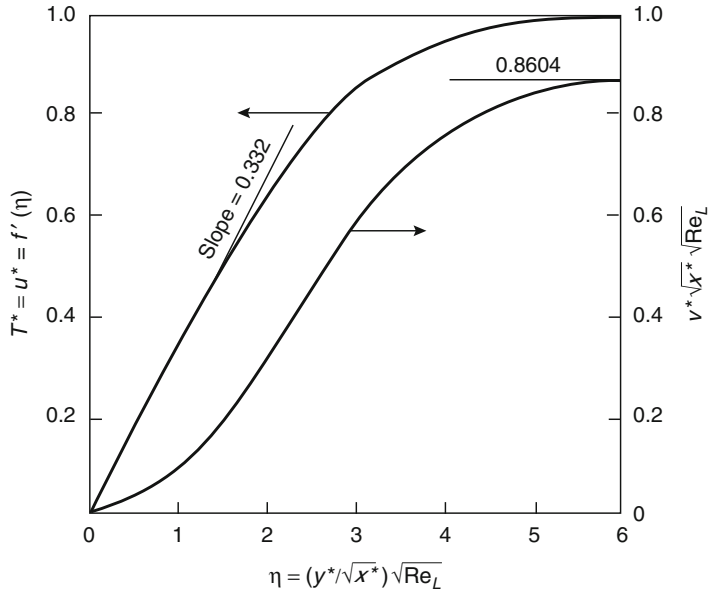

Fig. 3.14 Nondimensional velocity profiles in laminar boundary layer over a flat plate

$$\dot{q}_s'' = -k\frac{\partial T}{\partial y}\bigg|_{y=0} = 0.332(T_s - T_\infty)k\sqrt{\rho u_\infty/\mu x} \tag{3.63}$$

Hence the *local* friction and heat transfer coefficients are

$$C_f = \frac{0.664}{\sqrt{\mathrm{Re}_x}} \tag{3.64}$$

and

$$h = 0.332\frac{k}{x}\sqrt{\mathrm{Re}_x} \tag{3.65}$$

Equation 3.65 is often rewritten in terms of a nondimensional heat transfer coefficient called the Nusselt number, Nu, as

$$\mathrm{Nu} = \frac{hx}{k} = 0.332\sqrt{\mathrm{Re}_x} \tag{3.66}$$

All the above results are for the case when Pr = 1. When Pr ≠ 1, Equation 3.51 must also be solved with the help of the solution just obtained for Equations 3.49 and 3.50. Equation 3.51 becomes

$$\frac{d^2T^*}{d\eta^2} + \frac{\mathrm{Pr}}{2}f\frac{dT^*}{d\eta} = 0$$

with $T^*(0) = 0$ and $T^*(\infty) = 1$. This solution does not change the expressions for δ and C_f given by Equations 3.61 and 3.64. However δ_t and Nu become [2]

$$\delta_t = \frac{5x}{\sqrt{\mathrm{Re}_x}}\mathrm{Pr}^{-1/3} = \delta\mathrm{Pr}^{-1/3} \tag{3.67}$$

and

$$\mathrm{Nu} = 0.332\sqrt{\mathrm{Re}_x}\mathrm{Pr}^{1/3}(\mathrm{Pr}\gtrsim 0.6) \tag{3.68}$$

Note that for Pr < 1 (usually true for gases), δ_t is greater than δ; that is, the thermal boundary layer is thicker than the momentum boundary layer. This is to be expected since Pr < 1 implies that ν is less than α.

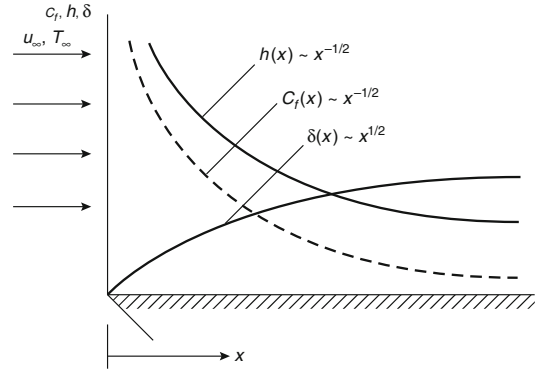

Fig. 3.15 Variation of C_f, h, and δ with x for flow over a flat plate

The results for the friction factor, C_f, and the Nusselt number, Nu, given by Equations 3.64 and 3.68 are for local values; that is, C_f and Nu change with x. This variation is shown in Fig. 3.15. At $x = 0$, both C_f and h tend to infinity. This is physically incorrect and happens because near $x = 0$ the boundary layer approximation breaks down since δ is no longer much less than x.

For many applications, only average values of the heat transfer coefficient, $\overline{h}$, and friction factor, $\overline{C}_f$, are required. These are obtained by using Equations 3.9 and 3.15. In these equations $dA_s = dx \cdot$ (the unit width of the flat plate), and the average can be obtained from $x = 0$ to any length, L (which may be the total length of the plate). Simple integration leads to the following results:

$$\overline{C}_{fL} = 1.328\,\mathrm{Re}_L{}^{-1/2} = 2C_f(\text{Evaluated at } x = L) \tag{3.69}$$

and

$$\overline{\mathrm{Nu}}_L \equiv \frac{\overline{h}_L L}{k} = 0.664\,\mathrm{Re}_L{}^{1/2}\,\mathrm{Pr}^{1/3} = 2\,\mathrm{Nu}(\text{Evaluated at } x = L) \tag{3.70}$$

It is interesting to note that C_f and Nu are closely related. For example, from Equations 3.69 and 3.70 one can easily obtain

$$\overline{\mathrm{Nu}}_L = \frac{C_{fL}\mathrm{Re}_L\mathrm{Pr}^{1/3}}{2}$$

or

$$\mathrm{St} \equiv \frac{\overline{\mathrm{Nu}}_L}{\mathrm{Re}_L \mathrm{Pr}} = \frac{\overline{C}_{fL}}{2} \mathrm{Pr}^{-2/3} \tag{3.71}$$

where St is known as the Stanton number.

This analogy between heat and momentum transfer is called the *Reynolds analogy* which is significant because the heat transfer coefficient can be determined from the knowledge of the friction factor. This analogy is especially useful for cases where mathematical solutions are not available.

Laminar Free Convection In contrast with forced convection, where the fluid motion is externally imposed, for free convection the fluid motion is caused by the buoyancy forces. Buoyancy is due to the combined effect of *density gradients* within the fluid and a *body force* that is proportional to the fluid density. In practice the relevant body force is usually gravitational, although it may be centrifugal, magnetic, or electric. Of the several ways in which a density gradient may arise in a fluid, the two most common situations are due to (1) the presence of temperature gradients, and (2) the presence of concentration gradients in a multicomponent system such as a fire. Here, the focus will be on free convection problems in which the density gradient is due to temperature and the body force is gravitational. Note, however, that the presence of density gradients in a gravitational field does not ensure the existence of free convection currents. For example, the high temperature, lighter fluid may be on top of a low temperature, denser fluid, resulting in a stable situation. It is only when the condition is unstable that convection currents are generated. An example of an unstable situation would be a denser fluid on top of a lighter fluid. In a stable situation there is no fluid motion and, therefore, heat transfer occurs purely by conduction. Here we will only consider the unstable situation that results in convection currents.

Free convection flow may be further classified according to whether or not the flow is bounded by a surface. In the absence of an adjoining surface, free boundary flows may occur in the form of a plume or a buoyant jet. A buoyant plume above a fire is a familiar example. However, here we will focus on free convection flows that are bounded by a surface. A classical example of boundary layer development on a heated vertical flat plate is discussed below.

Heated, Vertical Flat Plate Consider the flat plate shown in Fig. 3.16. The plate is immersed in an extensive, quiescent fluid, with $T_s > T_\infty$. The density of the fluid close to the plate is less than that of the fluid that is farther from the plate. Buoyancy forces therefore induce a free convection boundary layer in which the heated fluid rises vertically, entraining fluid from the quiescent region.

Under steady-state laminar flow conditions, Equations 3.35, 3.43, and 3.45 describe the mass, momentum, and energy balances for the two-dimensional boundary layer shown in Fig. 3.16. Assume that the temperature

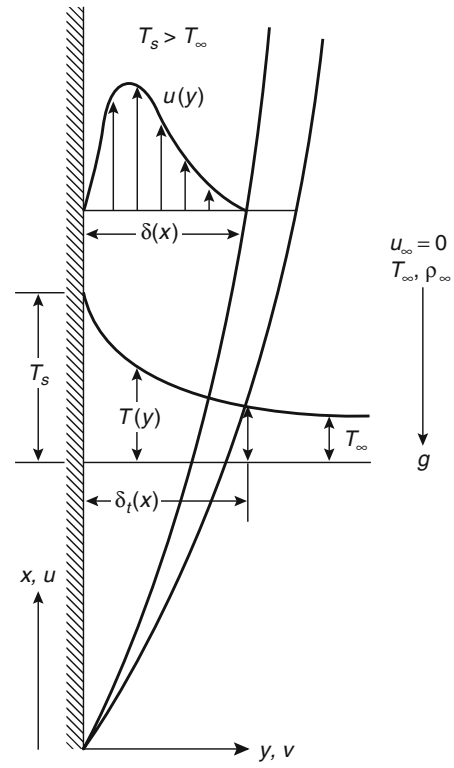

Fig. 3.16 Boundary layer development on a heated vertical plate

differences are moderate, such that the fluid may be treated as having constant properties. Also, with the exception of the buoyancy force term (g_x in Equation 3.43), the fluid can be assumed to be incompressible. Outside the boundary layer, Equation 3.36 is valid, and since $u = v = 0$ outside the boundary layer we obtain: $dp/dx = -\rho_\infty g_x$. Since $\partial p/\partial x = 0$ because of the boundary layer approximation (i.e., $p \neq p(y)$ inside the boundary layer; Equation 3.44), dp/dx inside the boundary layer must be equal to its corresponding value outside, that is, $dp/dx = -\rho_\infty g_x$.

Substituting this into Equation 3.43

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = g_x\frac{(\rho_\infty - \rho)}{\rho} + \nu\frac{\partial^2 u}{\partial y^2} \tag{3.72}$$

The first term on the right side of Equation 3.72 is the buoyancy force, and the flow originates because the density ρ is variable. By introducing the coefficient of volumetric thermal expansion, β,

$$\beta = -\frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_\rho \approx -\frac{1}{\rho}\frac{(\rho_\infty - \rho)}{(T_\infty - T)} \tag{3.73}$$

it follows that

$$\frac{(\rho_\infty - \rho)}{\rho} = \beta(T - T_\infty) \tag{3.74}$$

Substituting Equation 3.74 into Equation 3.72 a useful form of the x-momentum is obtained as

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = g_x\beta(T - T_\infty) + \nu\frac{\partial^2 u}{\partial y^2} \tag{3.75}$$

From Equation 3.75 it is now apparent how buoyancy force is related to temperature difference. Note that the appearance of the buoyancy term in the momentum equation mathematically complicates the situation. The decoupling between the hydrodynamic and the thermal problems achieved in forced convection is no longer possible, since T appears in both Equations 3.45 and 3.75. The boundary conditions associated with the governing equations, Equations 3.35, 3.45, and 3.75, are

$$u = v = 0 \quad T = T_\infty \quad as\ y \to \infty \tag{3.76}$$

Nondimensionalizing Equations 3.35, 3.45, 3.75, and 3.76 with $x^* = x/L$, $y^* \equiv y/L$, $u = u/u0$, $v^* \equiv v/u0$, and $T^* \equiv (T - T_\infty)/(T_s - T_\infty)$, we obtain

$$\frac{\partial u^*}{\partial x^*} + \frac{\partial v^*}{\partial y^*} = 0 \tag{3.77}$$

$$u^*\frac{\partial u^*}{\partial x^*} + v^*\frac{\partial u^*}{\partial y^*} = \frac{g\beta T^*(T_s - T_\infty)L}{u_0^2} + \frac{1}{\mathrm{Re}_L}\frac{\partial^2 u^*}{\partial y^{*2}} \tag{3.78}$$

and

$$u^*\frac{\partial T^*}{\partial x^*} + v^*\frac{\partial T^*}{\partial y^*} = \frac{1}{\mathrm{Re}_L\mathrm{Pr}}\frac{\partial^2 T^*}{\partial y^{*2}} \tag{3.79}$$

Note that u_0 in Equation 3.78 is an unknown reference velocity and not the free stream velocity as in the case of forced convection. Also, the dimensionless parameter

$$\frac{g\beta(T_s - T_\infty)L}{u_0^2}$$

is a direct result of buoyancy forces. To eliminate the unknown reference velocity, u_0 from the dimensionless parameter, we define

$$\text{Grashof number, } \mathrm{Gr}_L \equiv \frac{g\beta(T_s - T_\infty)L}{u_0^2}\left(\frac{Lu_0}{\nu}\right)^2 = \frac{g\beta(T_s - T_\infty)L^3}{\nu^2}$$

Thus, the first term on the right side of Equation 3.78 becomes $\mathrm{Gr}_L/(\mathrm{Re}_L)^2$. The Grashof number plays the same role in free convection as the Reynolds number does in forced convection. Gr is the ratio of buoyancy and viscous forces. The governing equations now contain three parameters—the Grashof number, Reynolds number, and Prandtl number. For the forced convection case it is seen (Equation 3.68) that Nu = Nu (Re, Pr); thus for the free convection case, we expect Nu = Nu (Re, Gr, Pr). If the

buoyancy term in Equation 3.79 is $Gr/(Re)^2 \gg 1$, then we primarily have free convection; that is, $Nu = Nu(Gr, Pr)$. For $Gr/(Re)^2 \ll 1$, the forced convective case exists, where as has already been seen, $Nu = Nu\ (Re, Pr)$. However, when $Gr/(Re)^2 \sim 1$ a mixed (free and forced) convection case is obtained. For the present problem we will assume that $Gr \gg (Re)^2$, thus, Nu must be a function of only Gr and Pr.

Since $Gr \gg Re^2$, it follows that buoyancy forces are much larger than inertia forces; in other words, the primary balance is between the buoyancy and viscous forces. Since the left side of Equation 3.78 represents the inertia forces, the primary balance is between the two terms on the right side, that is,

$$-\frac{g\beta T^*(T_s - T_\infty)L}{u_0^2} \approx \left(\frac{\nu}{u_0 L}\right)\frac{\partial^2 u^*}{\partial y^{*2}}$$

Crudely approximating the various terms, we have in dimensional variables

$$g\beta(T_\infty - T) \approx \nu\frac{u}{\delta^2} \tag{3.a}$$

Similarly approximating Equations 3.77 and 3.79 and expressing the result in dimensional form (it is more convenient to use Equations 3.35 and 3.45), we get from Equation 3.35 or 3.77

$$\frac{u}{x} \approx \frac{v}{\delta} \quad \text{or} \quad v \approx \frac{\delta u}{x} \tag{3.b}$$

and from Equation 3.79 or 3.45 along with relation (3.b)

$$u\frac{(T_\infty - T)}{x} \approx \alpha\frac{(T_\infty - T)}{\delta^2} \quad \text{or} \quad u \approx \frac{\alpha x}{\delta^2} \tag{3.c}$$

Combining (3.a) and (3.c) we obtain an expression for the boundary layer thickness, δ,

$$\delta \approx \left(\frac{\nu\alpha x}{g\beta(T_\infty - T)}\right)^{1/4}$$

Thus, we expect δ to scale with $x^{1/4}$ and u to scale with $x^{1/2}$. (Note that in the forced convective case we found that $\delta \sim x^{1/2}$; Fig. 3.15). Following a reasoning similar to the forced convective case, a similarity variable $\xi \approx y/\delta(x)$ or $\xi = Ay/x^{1/4}$ may be found, where A is an arbitrary constant. Also, motivated by Equation 3.57 for forced convection, it is hoped that $u = Bx^{1/2}f'(\xi)$ where B is an arbitrary constant. Expressing these in nondimensional variables, we get

$$\zeta = Ay^*/x^{*1/4} \tag{3.80}$$

and

$$u^* = Bx^{*1/2}f'(\xi)$$

where $f'(\xi) = df/d\xi$. Note that the definitions of the arbitrary constants A and B have been changed during nondimensionalization. By introducing a stream function, ψ, as in Equation 3.55, Equation 3.77 is identically satisfied.

Thus,

$$\begin{aligned}\psi &= \int Bx^{*1/2}f'(\xi)dy^* + f_1(x^*)\\ &= \int \frac{B}{A}x^{*3/4}f'(\xi)d\xi + f_1(x^*)\\ &= \frac{B}{A}x^{*3/4}f(\xi) + f_1(x^*)\end{aligned} \tag{3.81}$$

Since $v^* = 0$ at $y^* = 0$ (or $\xi = 0$), $f_1(x^*)$ is at best an arbitrary constant which is taken to be zero without any loss of generality. From Equations 3.55 and 3.81 we get

$$v^* = -\frac{B}{4Ax^{*1/4}}\left[3f(\xi) - \xi f'(\xi)\right] \tag{3.82}$$

By using Equations 3.80 and 3.82, Equations 3.78 and 3.79 can be reduced to

$$f''' + 3ff'' - 2\left(f'\right)^2 + T^* = 0 \tag{3.83}$$

and

$$T^{*''} + 3\mathrm{Pr}fT^{*'} = 0 \tag{3.84}$$

where the following definitions of the arbitrary constants A and B have been used:

$$B = \left[\frac{4g\beta(T_s - T_\infty)L}{u_0^2}\right]^{1/2}$$
$$A = \left[\frac{g\beta(T_s - T_\infty)L^3}{4\nu^2}\right]^{1/4} \quad (3.85)$$

Note that in Equation 3.84 it has been assumed that T^* is a function of ξ only. From Equation 3.85 it follows that

$$\xi = \frac{y^*}{x^{*1/4}}\left[\frac{g\beta(T_s - T_\infty)L^3}{4\nu^2}\right]^{1/4}$$
$$= \frac{y^*}{x^{*1/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} \quad (3.86)$$

The associated boundary conditions given by Equation 3.76 become

$$f = f' = 0 \text{ and } T^* = 1 \text{ when } \xi = 0$$

and

$$f' = 0\, T^* = 0 \text{ at } \xi = \infty \quad (3.87)$$

A numerical solution of Equations 3.83 and 3.84 along with the boundary conditions given by Equation 3.87 are shown in Fig. 3.17. Note that the nondimensional x-velocity component, u, may be readily obtained from Fig. 3.17 part (a) through the use of Equations 3.80 and 3.85. Note also that, through the definition of the similarity variable, ξ, Fig. 3.17 may be used to obtain values of u^* and T^* for any value of x^* and y^*. Once $u^*(x^*, y^*)$ and $T^*(x^*, y^*)$ are known, the heat transfer coefficient can easily be obtained from Equation 3.5. Thus, the temperature gradient at $y = 0$ after using Equation 3.86, becomes

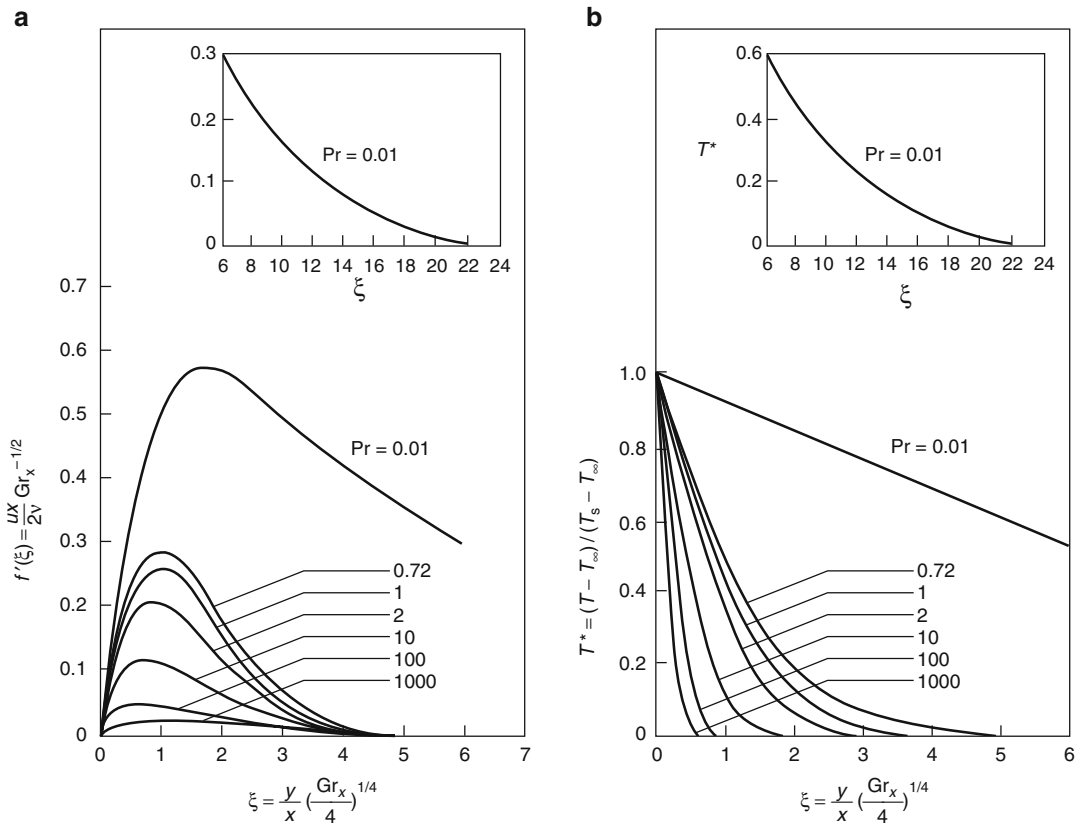

Fig. 3.17 Laminar free convection boundary layer on an isothermal, vertical surface

Table 3.1 Dimensionless temperature gradient for free convection on a vertical flat plate

Pr	0.01	0.72	1	2	10	100	1000
$g(Pr)$	0.081	0.505	0.567	0.716	1.169	2.191	3.966

$$\left.\frac{\partial T}{\partial y}\right|_{y=0} = \frac{(T_s - T_\infty)}{L}\left.\frac{\partial T^*}{\partial y^*}\right|_{y^*=0} = \frac{(T_s - T_\infty)}{Lx^{*1/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4}\left.\frac{dT^*}{d\xi}\right|_{\xi=0}$$

The *local* heat transfer coefficient is

$$h = \frac{-k}{Lx^{*1/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4}\left.\frac{dT^*}{d\xi}\right|_{\xi=0} \tag{3.88}$$

or

$$\mathrm{Nu} = \frac{hx}{k} = -x^{*3/4}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4}\left.\frac{dT^*}{d\xi}\right|_{\xi=0} = \left(\frac{\mathrm{Gr}_x}{4}\right)^{1/4} g(\mathrm{Pr}) \tag{3.89}$$

As is evident from Fig. 3.17, the dimensionless temperature gradient at $\xi = 0$ is a function of the Prandtl number. In Equation 3.89 this function is expressed as $-g(\mathrm{Pr})$. Values of $g(\mathrm{Pr})$ obtained from the numerical solution are listed in Table 3.1.

From Equation 3.88 for the local heat transfer coefficient, the average heat transfer coefficient for a surface of length L is obtained by using Equation 3.9 as follows:

$$\bar{h}_L = \frac{1}{L}\int_0^L h(dx \cdot 1) = \frac{k}{L^{7/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} g(\mathrm{Pr}) \times \int_0^L \frac{dx}{x^{1/4}} = \frac{4k}{3L}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} g(\mathrm{Pr}) \tag{3.90}$$

Thus,

$$\overline{\mathrm{Nu}}_L = \frac{\bar{h}_L L}{k} = \frac{4}{3}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} g(\mathrm{Pr}) \tag{3.91}$$

or from Equation 3.89, with $x = L$ we get

$$\overline{\mathrm{Nu}}_L = \frac{4}{3}\,\mathrm{Nu}\begin{pmatrix}\text{Evaluated}\\ \text{at } x = L\end{pmatrix} \tag{3.92}$$

It should be noted that the foregoing results apply irrespective of whether $T_s > T_\infty$ or $T_s < T_\infty$. If $T_s < T_\infty$, the conditions are inverted from those shown in Fig. 3.16. The loading edge is on the top of the plate, and positive x is defined in the direction of the gravity force.

Integral Solution Methods

For many problems an exact similarity solution is not possible. An alternate approach is to use approximate integral methods originally proposed by von Kárman in 1921 [6]. Intelligent use of integral methods gives good result and it can be very useful for solving difficult fire problems. This method is also very useful for conduction problems.

Forced Flow Laminar Boundary Layer on a Flat Plate

Referring to Fig. 3.12, one can essentially integrate the equations in the y direction across the boundary layer. This eliminates one variable—resulting in ODEs. Integrating the continuity equation:

$$\int_0^\delta \frac{\partial u}{\partial x}dy + \int_0^\delta \frac{\partial V}{\partial y}dy = 0;\ \textit{Since},\ V = 0\ \textit{at}\ \ y = 0,\ V(y = \delta) = -\int_0^\delta \frac{\partial u}{\partial x}dy$$

Integrating the momentum equation:

$$\int_0^\delta u\frac{\partial u}{\partial x}dy + uV|_0^\delta - \int_0^\delta u\frac{\partial V}{\partial y}dy = v\left(\left.\frac{\partial u}{\partial y}\right|_\delta - \left.\frac{\partial u}{\partial y}\right|_0\right)$$

Eliminating V by using continuity and rearranging, the integral form of the boundary layer momentum equation results. It basically states that the decrease in kinetic energy of the fluid in the B.L. occurs because of the wall friction at $y = 0$.

$$\frac{d}{dx}\left[\int_0^\delta (u_\infty - u)u\,dy\right] = v\left.\frac{\partial u}{\partial y}\right|_{y=0}$$

In a similar fashion, the integral form of the boundary layer energy equations may be obtained as:

$$\frac{d}{dx}\left[\int_0^{\delta t} (T_\infty - T)u\,dy\right] = \alpha\left.\frac{\partial T}{\partial y}\right|_{y=0}$$

These equations satisfy the x-momentum and energy conservation requirements in an integral (or average) fashion over the entire boundary layer. In contrast, the original conservation equations satisfy the conservation requirements locally at each point in the boundary layer.

The solution procedure involves:

1. Assuming reasonable functional forms for the unknowns u *and* T in terms of the corresponding (unknown) boundary layer thicknesses.
2. These functional forms must satisfy appropriate boundary conditions.
3. Substituting these forms into the integral equations, expressions for the boundary layer thicknesses are determined and the assumed functional forms are then completely specified.
4. While this method is approximate, it frequently leads to accurate results for the surface parameters that are usually of interest in fire problems.

Now consider the hydrodynamic boundary layer, for which the appropriate boundary conditions are: $u(y=0) = 0;\ u(y=\delta) = u_\infty; (\partial u/\partial y)_{y=\delta} = 0$ Since $u = v = 0\ ; at\ y = 0$, $\partial^2 u/\partial y^2|_{y=0} = 0$.

With these conditions, we could approximate the velocity profile as a third degree polynomial of the form:

$$\frac{u}{u_\infty} = a_1 + a_2\left(\frac{y}{\delta}\right) + a_3\left(\frac{y}{\delta}\right)^2 + a_4\left(\frac{y}{\delta}\right)^3$$

Applying the boundary conditions to determine the coefficients a_1 *to* a_4. It is easily verified that $a_1 = a_3 = 0, a_2 = 3/2$ *and* $a_4 = -1/2$, in which case:

$$\frac{u}{u_\infty} = \frac{3}{2}\left(\frac{y}{\delta}\right) - \frac{1}{2}\left(\frac{y}{\delta}\right)^3$$

This velocity profile is specified in terms of the unknown boundary layer thickness δ which is determined by substituting into the momentum equation and integrating over y to obtain:

$$\frac{13\,u_\infty}{140\,\nu}\frac{d\delta}{dx} = \frac{1}{\delta};\ or\ \ \delta d\delta = \frac{140\,\nu}{13\,u_\infty}dx\ i.e.\ \ \frac{\delta^2}{2} = \frac{140}{13}\frac{\nu x}{u_\infty} + const.$$

Since $\delta = 0$ at the leading edge $(x = 0)$, the integration constant $= 0$. Thus:

$$\delta = 4.641\sqrt{\frac{\nu x}{u_\infty}} = 4.641\,x\,\mathrm{Re}_x^{-1/2}\ ;\ \text{This completely specifies the above velocity profile.}$$

$$\text{Thus } \tau_s = \mu\left.\frac{\partial u}{\partial y}\right|_{y=0};\ \text{differenciating the velocity profile, we get :}\ C_{f,x} \equiv \frac{\tau_s}{\rho u_\infty^2/2} = \frac{0.646}{\mathrm{Re}_x^{1/2}}.$$

The exact solution gave us 0.664 instead of 0.646 as the constant—a minor difference.

Integral Solution for the Thermal Laminar Boundary Layer

Similar to the momentum boundary layer, the temperature profile of the following form is assumed:

$$T^* = \frac{T - T_s}{T_\infty - T_s} = b_1 + b_2\left(\frac{y}{\delta_t}\right) + b_3\left(\frac{y}{\delta_t}\right)^2 + b_4\left(\frac{y}{\delta_t}\right)^3$$

Boundary conditions are:

$$T^*(y=0) = 0; T^*(y=\delta_t) = 1; \left(\partial T^*/\partial y\right)_{y=\delta_t} = 0; \;\&\; \partial^2 T^*/\partial y^2\big|_{y=0} = 0.$$

Applying these conditions: $T^* = \frac{3}{2}\left(\frac{y}{\delta_t}\right) - \frac{1}{2}\left(\frac{y}{\delta_t}\right)^3$.

Substituting both velocity and temperature profiles into the integral energy equation and manipulating for $\mathrm{Pr} \geq 1$:

$\frac{\delta}{\delta_t} = \frac{\mathrm{Pr}^{-1/3}}{1.026}$; This result is in good agreement with the exact solution of 1.0 instead of 1.026. Thus, the heat transfer coefficient may be then computed from:

$$h \equiv \frac{-k_f \partial T/\partial y\big|_{y=0}}{T_s - T_\infty} = \frac{3}{2}\frac{k_f}{\delta_t}\;;$$
$$Nu_x \equiv \frac{hx}{k_f} = 0.332\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3}$$

Same as before within 3 decimal. This analysis proves that good solutions may be obtained using approximate integral methods. These could be very useful in fire problems.

Integral Solution for a Heated Vertical Plate (Laminar Free Convection)

The problem shown in Fig. 3.16, for which the similarity solution was obtained above, can now be solved using integral methods.

Integral Conservation Equations

The integral form of the momentum conservation equation with buoyancy force is derived by using the Archimedes' principle. The buoyancy force per unit volume acting on an element of the warmer fluid in the boundary layer is $g(\rho_\infty - \rho)$ directed vertically upward, where g is the gravitational acceleration, ρ_∞ is the constant fluid density outside the boundary layer, and ρ is the density of the fluid element that varies across the boundary layer. In Fig. 3.18, Newton's second law of motion is applied to the elemental control volume of unit depth Δx and extending to $y = Y$, where Y is greater than the boundary layer thickness. The net momentum outflow from the volume is equal to the buoyancy force minus the viscous drag force exerted by the wall:

$$\int_0^Y \rho u^2 dy\big|_{x+\Delta x} - \int_0^Y \rho u^2 dy\big|_x = \int_0^Y g(\rho_\infty - \rho) dy \Delta x - \mu \frac{\partial u}{\partial y}\Big|_{y=0} \Delta x$$

Notice that there is no momentum flow across the boundary at $y = Y$ since $u(Y) = 0$.

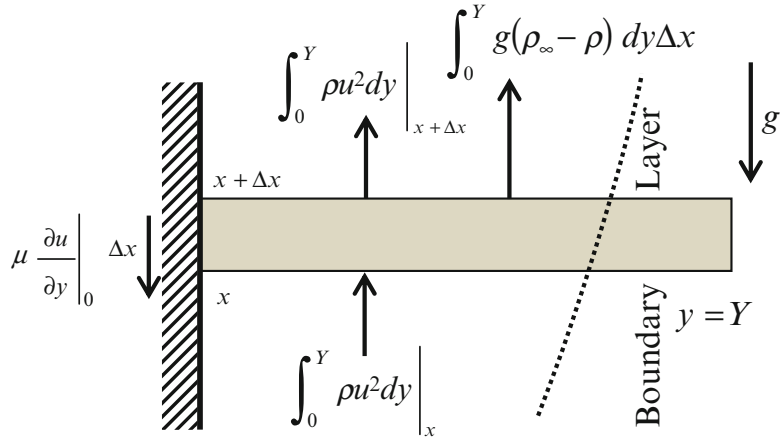

Fig. 3.18 Force balances on an elemental control volume in the boundary layer of a heated vertical plate

Dividing by Δx and letting $\Delta x \to 0$

$$\frac{d}{dx}\int_0^Y \rho u^2 dy = \int_0^Y g(\rho_\infty - \rho)dy - \mu\frac{\partial u}{\partial y}\bigg|_{y=0}$$

The Boussinesq approximation is introduced by taking the density to be constant except in the buoyancy term; dividing by ρ then gives:

$$\frac{d}{dx}\int_0^Y u^2 dy = \int_0^Y g\left(\frac{\rho_\infty - \rho}{\rho}\right)dy - \nu\frac{\partial u}{\partial y}\bigg|_{y=0}$$

Since $\rho = \rho(P, T)$ a Taylor expansion can be written as: $(\rho_\infty - \rho) = (\partial\rho/\partial T)_p(T_\infty - T) + (\partial\rho/\partial T)_T(P_\infty - P) +$ higher order terms. The pressure variation across the boundary layer is negligible; thus, $P = P_\infty$ to obtain:

$$\left(\frac{\rho_\infty - \rho}{\rho}\right) = -\frac{1}{\rho}\left(\frac{\partial\rho}{\partial T}\right)_P (T - T_\infty) = \beta(T - T_\infty),$$

where β is the volumetric coefficient of thermal expansion, as before. For an ideal gas, $\beta = 1/T$. Substituting and letting $Y \to \infty$, since there is no contribution to the integrals for y > Y,

$$\frac{d}{dx}\int_0^\infty u^2 dy = \int_0^\infty g\beta(T - T_\infty)dy - \nu\frac{\partial u}{\partial y}\bigg|_{y=0} \tag{3.93}$$

The integral form of the energy conservation equation is identical to that for forced flow:

$$\frac{d}{dx}\left[\int_0^\infty (T_\infty - T)u\,dy\right] = \alpha\frac{\partial T}{\partial y}\bigg|_{y=0} \tag{3.94}$$

Simultaneous Solution of the Equations

The two ordinary differential equations above, Equations (3.93) and (3.94) are coupled since the variable T appears in both; hence, they must be solved simultaneously. Boundary conditions for the velocity and temperature profiles are:

$$y = 0: \; u = 0, \; T = T_s,$$

a constant for an isothermal wall, and as

$$y \to \infty \; (or \; \delta): \; u = 0, \; T = T_\infty$$

Assuming that the hydrodynamic and thermal boundary layers have the same thickness, *i.e.* $\delta = \delta_t$, which seems reasonable because the momentum is driven by thermal differences. Also assuming the following forms for the velocity and temperature profiles that satisfy the boundary conditions:

$$\frac{u}{u_0} = \frac{y}{\delta}\left(1 - \frac{y}{\delta}\right)^2, \text{ and } \frac{(T - T_\infty)}{T_S - T_\infty} = \left(1 - \frac{y}{\delta}\right)^2$$

Here u_0 is a scaling velocity, which is a function of x only and is yet to be determined. Figure 3.19 shows these profiles; the maximum velocity is $0.148u_0$ at y = δ/3. In the forced-convection problem, the known free-stream velocity was used to scale the velocity profile; here the scaling velocity u_0, as well as the boundary layer - thickness δ, are unknowns. The chosen boundary layer profiles give $\frac{\partial u}{\partial y} = 0$ and $\frac{\partial T}{\partial y} = 0$ at y = δ (i.e., they are smooth at the edge of the boundary layer). However, the velocity profile does not have the correct limiting value of $\frac{\partial^2 u}{\partial y^2}$ at the wall; also, the assumption of $\delta = \delta_t$ is not valid for high-Prandtl-number fluids. But the use of these profiles gives surprisingly good results. Substituting the profiles and performing the indicated operations gives:

$$\frac{d}{dx}\left(\frac{u_0^2\delta}{105}\right) = -\frac{\nu u_0}{\delta} + \frac{g\beta(T_S - T_\infty)\delta}{3}$$

$$\frac{d}{dx}\left(\frac{u_0\delta}{30}\right) = \frac{2\alpha}{\delta}$$

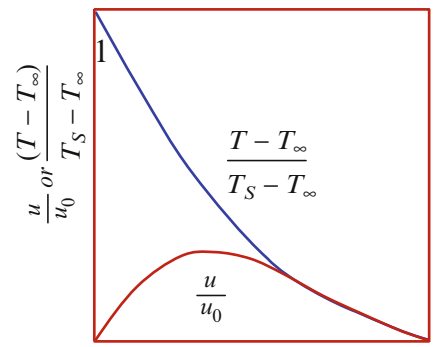

Fig. 3.19 Shape of chosen velocity and temperature profiles

These are two ordinary differential equations for two unknowns: u_0 and δ. Assuming power law variations for δ and U of the form: $\delta = D_1 x^m; u_0 = D_2 x^n$, which give $\delta = 0$ and $u_0 = 0$ at x = 0. Substituting in the above equation gives:

$$\frac{d}{dx}\left(\frac{D_2^2 D_1 x^{2n+m}}{105}\right) = -\frac{\nu D_2^2 x^{n-m}}{D_1} + \frac{g\beta(T_S - T_\infty)D_1 x^m}{3}$$

The x dependence cancels if 2n + m − 1 = n − m = m, which requires m = 1/4, and n = 1/2. The differential equations then reduce to two algebraic equations for D_2 and D_1:

$$\frac{5}{4}\left(\frac{D_2^2 D_1}{105}\right) = -\frac{\nu D_2^2}{D_1} + \frac{g\beta(T_S - T_\infty)D_1}{3}$$

$$\frac{3}{4}\left(\frac{D_2^2 D_1}{30}\right) = \frac{2\alpha}{D_1}$$

Solving gives:

$$D_2 = \frac{80\alpha}{D_1^2}$$

$$D_1 = 3.94\left[\frac{(20/21)\alpha^2 + \nu\alpha}{g\beta(T_S - T_\infty)}\right]^{1/4}$$

The wall heat flux is obtained from the temperature profile as:

$$q_S = -k\left.\frac{\partial T}{\partial y}\right|_{y=0} = \frac{2k}{\delta}(T_S - T_\infty) = h_x(T_S - T_\infty)$$

$$\frac{h_x}{k} = \frac{2}{\delta} = \frac{2}{D_1 x^{1/4}};\ Thus,\ Nu_x = \frac{h_x x}{k} = \frac{2x^{3/4}}{D_1}$$

Substituting for D_1 and rearranging gives:

$$Nu_x = 0.508\left[\frac{\Pr}{0.952 + \Pr}\right]^{1/4} Ra_x^{1/4};\ \text{where } Ra_x = \frac{\beta(T_S - T_\infty)g x^3}{\nu\alpha} \text{ is the Rayleigh number}$$

This result agrees very well with the exact numerical solutions of the differential conservation equations and has been widely used.

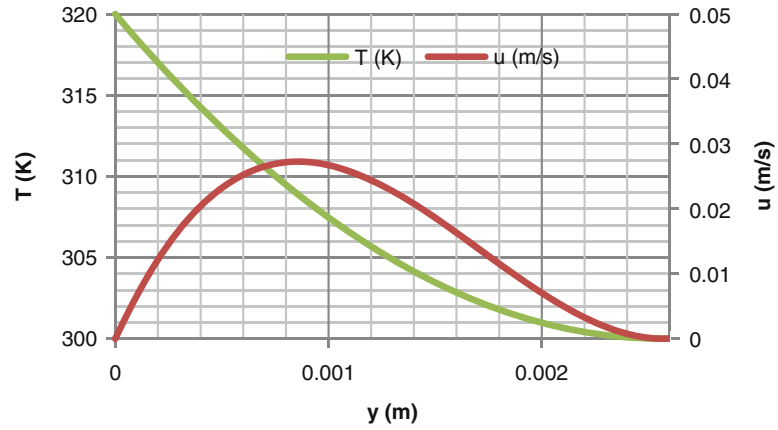
Example: Laminar Natural-Convection Boundary Layer on a Vertical Flat Plate A vertical plate at 320 K is immersed in water at 300 K. At a location 10 cm from the bottom of the plate, determine δ, u_0, Nu_x, h_x, and q_s . Also plot the velocity [u(y)] and temperature [T(y)] profiles.

Solution Properties are evaluated at the mean film temperature of 310 K; k = 0.628 W/m K, ρ = 993 kg/m^3, ν = 0. 70 x 10^{-6} m^2/s, Pr = 4.6. Also, $\boldsymbol{\alpha} = \nu/\Pr = 1.52\times10^{-7}$ m^2/s, $\beta = 3.62 \times 10^{-4}$ K^{-1}. The Rayleigh number is checked to see if the flow is laminar:

$$Ra_x = \frac{\beta(T_S - T_\infty)g x^3}{\nu\alpha} = 6.68 \times 10^8 < 10^9 \text{ (laminar)}$$

The boundary layer thickness is $\delta = Dx^{1/4}$, where D is given by the equation above:

$$\delta = D_1 x^{1/4};\ and\ D_1 = 3.94\left[\frac{(20/21)\alpha^2 + \nu\alpha}{g\beta(T_S - T_\infty)}\right]^{1/4} \text{ or, } \delta = \left(4.57 \cdot 10^{-3}\ m^{\frac{3}{4}}\right)(0.1\ m)^{\frac{1}{4}}$$
$$= 2.57 \cdot 10^{-3} m = 2.57\ mm$$



The scaling velocity is: $u_0 = D_2 x^{1/2}$, where $D_2 = \dfrac{80\alpha}{D_1^2} = 0.582\ m^{1/2}/s$;

Thus, $u_0 = (0.582)(0.1)^{1/2} = 0.184$ m/s.

The local Nusselt number:

$$Nu_x = 0.508\left[\frac{\Pr}{0.952 + \Pr}\right]^{1/4} Ra_x^{1/4} = 77.9;$$

At x = 0.1 m. Hence, the local heat transfer coefficient and heat flux are:

$$h_x = (k/x)Nu_x = (0.628/0.1)(77.9)$$
$$= 489\ W/m^2K$$
$$q_s = h_x(T_S - T_\infty)$$
$$= 489(320 - 300)$$
$$= 9790\ W/m^2$$

The velocity and temperature profiles are obtained from:

$$\frac{u}{u_0} = \frac{y}{\delta}\left(1 - \frac{y}{\delta}\right)^2, \text{ and } \frac{(T - T_\infty)}{T_S - T_\infty} = \left(1 - \frac{y}{\delta}\right)^2; \textit{Substituting}: \ \delta = D_1 x^{1/4};\ u_0 = D_2 x^{1/2}$$

$$u = \frac{y x^{1/4} D_2}{D_1}\left(1 - \frac{y}{D_1 x^{1/4}}\right)^2, \text{ and } T = T_\infty + (T_S - T_\infty)\left(1 - \frac{y}{D_1 x^{1/4}}\right)^2$$

From above : $D_1 = 4.57 \times 10^{-3}\ \mathrm{m}^{3/4}$, $D_2 = 0.582 \mathrm{m}^{1/2}/\mathrm{s}$, and $x = 0.1m$

The plot is shown above.

Complications in Practical Problems

In the previous section, two relatively simple problems of laminar forced and free convection on a flat surface were solved. These solutions illustrate the methodology for determining the heat transfer coefficient and provide the necessary insight regarding the relationship between the various dimensionless parameters. Most practical situations are often more complex, and mathematical solutions, such as those presented in the previous section, are not always possible. Complexities arise due to more complex geometry, onset of turbulence, changes in fluid properties with temperature, and because of simultaneous mass transfer from the surface as illustrated in Fig. 3.17. For such cases, empirical correlations are obtained. These correlations are discussed in the next section and the various complications are individually discussed below.

Effect of Turbulence In both forced and free convective flows, small disturbances may be amplified downstream, leading to transition from laminar to turbulent flow conditions. These disturbances may originate from the free

stream or be induced by surface roughness. Whether these disturbances are amplified or attenuated depends on the ratio of inertia to viscous forces for forced flows (the Reynolds number) and the ratio of buoyancy to viscous forces for free convective flows (the Grashof number). Note that in both Reynolds and Grashof numbers, viscosity appears in the denominator. Thus for relatively large viscous forces or small Reynolds and Grashof numbers, the naturally occurring disturbances are dissipated, and the flow remains laminar. However, for sufficiently large Reynolds and Grashof numbers ($Re > 5 \times 10^5$ and $Gr > 4 \times 10^8$, for flow over a flat plate) disturbances are amplified, and a transition to turbulence occurs.

The onset of turbulence is associated with the existence of *random fluctuations* in the fluid, and on a small scale the flow is *unsteady*. As shown in Fig. 3.20, there are sharp differences between laminar and turbulent flows. In the laminar boundary layer, fluid motion is highly ordered and it is possible to identify streamlines along which fluid particles move. In contrast, fluid motion in the turbulent boundary layer is highly irregular and is characterized by velocity fluctuations. These fluctuations enhance the momentum and energy transfers and hence increase the surface friction and convection heat transfer rate. Also, due to the mixing of fluid resulting from the turbulent fluctuations, the turbulent boundary layer is thicker and the boundary layer profiles (of velocity, temperature, and concentration) are flatter than in laminar flow.

In a fully turbulent flow, the primary mechanism of momentum and heat transfer involves macroscopic lumps of fluid randomly moving about in the flow. Turbulent flow contrasts with the random molecular motion resulting in molecular properties discussed at the beginning of this chapter. In the turbulent region, *eddy viscosity* and *eddy thermal conductivity* are important. These eddy properties may be ten times as large as their molecular counterparts.

If one measures the variation of an arbitrary flow variable, P, as a function of time at some location in a turbulent boundary layer, then the typical behavior observed is shown in Fig. 3.21. The variable P, which may be a velocity component, fluid temperature, pressure, or species concentration, can be represented as the sum of a time-mean value, $\overline{P}$, and a fluctuating

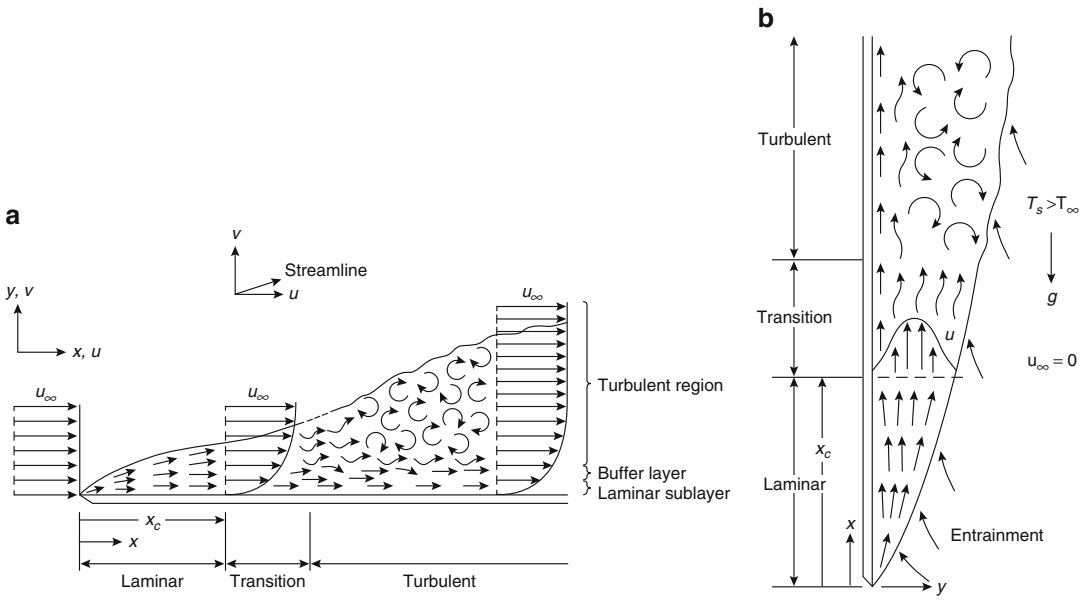


Fig. 3.20 (**a**) Velocity boundary layer development on a flat plate for forced flow; (**b**) velocity boundary layer development on a vertical flat plate for free convective flow

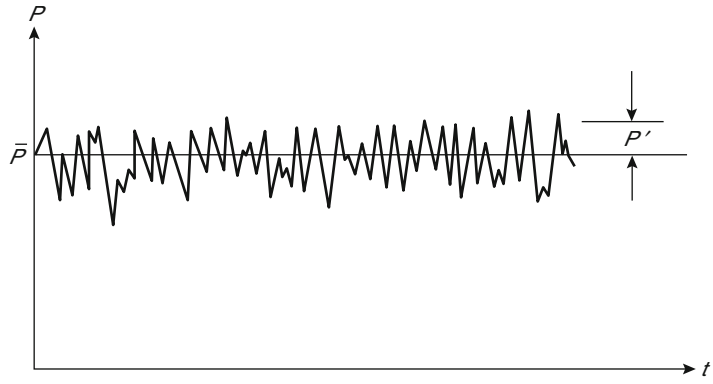

Fig. 3.21 Variation in the variable P with time at some point in a turbulent boundary layer

component, P'. The average is taken over a time interval that is large compared with the period of a typical fluctuation, and if $\overline{P}$ is time independent then the mean flow is steady. Thus, the instantaneous values of each of the velocity components, pressure, and temperature are given by

$$u = \overline{u} + u', \quad v = \overline{v} + v', \quad p = \overline{p} + p'$$
$$T = \overline{T} + T', \quad \text{and} \quad \rho = \overline{\rho} + \rho' \tag{3.95}$$

Substituting these expressions for each of the flow variables into the boundary layer equations (Equations 3.35, 3.43, and 3.45) and assuming the mean flow to be steady, incompressible (ρ = constant) with constant properties, and using the well-established time averaging procedures [1–4], the following governing equations are obtained:

Continuity

$$\frac{\partial \overline{u}}{\partial x} + \frac{\partial \overline{v}}{\partial y} = 0 \tag{3.96}$$

x-momentum

$$\rho\left(\overline{u}\frac{\partial \overline{u}}{\partial z} + \overline{v}\frac{\partial \overline{u}}{\partial y}\right) = \frac{\partial}{\partial y}\left(\mu\frac{\partial \overline{u}}{\partial y} - \rho\overline{u}'\overline{v}'\right) - \frac{\partial \overline{p}}{\partial x} - \rho g_x \tag{3.97}$$

Energy

$$\rho C_p\left(\overline{u}\frac{\partial \overline{T}}{\partial x} + \overline{v}\frac{\partial \overline{T}}{\partial y}\right) = \frac{\partial \overline{T}}{\partial y}\left(k\frac{\partial \overline{T}}{\partial y} - \rho C_p\overline{v}'\overline{T}'\right) \tag{3.98}$$

Equations 3.96 through 3.98 are similar to the laminar boundary layer equations expressed in mean flow variables, except for the presence of additional terms $\rho\overline{u}'\overline{v}'$ and $\rho C_p\overline{v}'\overline{T}'$. Physical arguments [2] show that these terms result from the motion of macroscopic fluid lumps and account for the effect of the turbulent fluctuations on momentum and energy transport.

On the basis of the foregoing result it is customary to speak of total shear stress and total heat flux, which are defined as

$$\tau_{\text{tot}} \equiv \left(\mu\frac{\partial \overline{u}}{\partial y} - \rho\overline{u}'\overline{v}'\right)$$

and

$$\dot{q}_{\text{tot}} \equiv -\left(k\frac{\partial \overline{T}}{\partial y} - \rho C_p\overline{v}'\overline{T}'\right) \tag{3.99}$$

The terms $\rho\overline{u}'\overline{v}'$ and $\rho C_p\overline{v}'\overline{T}'$ are always negative and so result in a positive contribution to total shear stress and heat flux. The term $\rho\overline{u}'\overline{v}'$ represents the transport of momentum flux due to turbulent fluctuations (or eddies), and it is known as the Reynolds stress. The notion of transport of heat and momentum by turbulent eddies has prompted the introduction of transport coefficients, which are defined as the eddy diffusivity for momentum transfer, ε_M, and eddy diffusivity for heat transfer, ε_H, and have the form

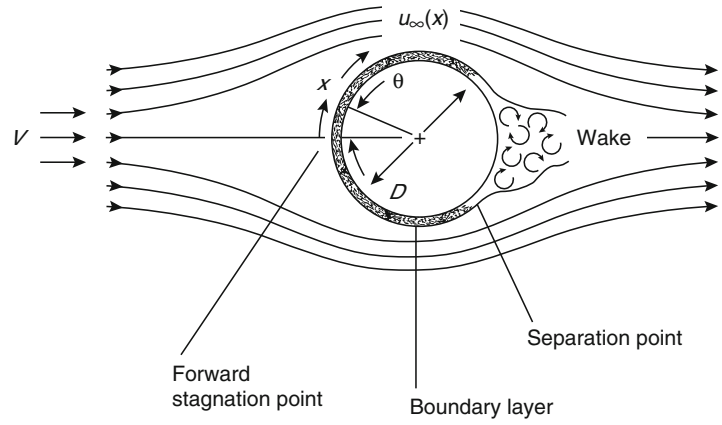

Fig. 3.22 Boundary layer formation and separation on a circular cylinder in cross flow

$$\varepsilon_M \frac{\partial \overline{u}}{\partial y} \equiv -\overline{u}'\overline{v}'$$
$$\varepsilon_H \frac{\partial \overline{T}}{\partial y} \equiv -\overline{v}'\overline{T}' \tag{3.100}$$

Thus Equation 3.99 becomes

$$\tau_{\text{tot}} \equiv \rho(\nu + \varepsilon_M)\frac{\partial \overline{u}}{\partial y}$$

and

$$\dot{q}''_{\text{tot}} \equiv -\rho C_p(\alpha + \varepsilon_H)\frac{\partial \overline{T}}{\partial y} \tag{3.101}$$

As noted earlier, eddy diffusivities are much larger than molecular diffusivities, therefore the heat and momentum transfer rates are much larger for turbulent flow than for laminar flow. A fundamental problem in performing turbulent boundary layer analysis involves determining the eddy diffusivities as a function of the mean properties of the flow. Unlike the molecular diffusivities, which are strictly fluid properties, the eddy diffusivities depend strongly on the nature of the flow. They vary across the boundary layer and the variation can only be determined from experimental data. This is an important point, because all analyses of turbulent flow must eventually rely on experimental data. To date, there is no adequate theory for predicting turbulent flow behavior.

Complex Geometry In a previous section on the boundary layer concept, analysis was limited to the simplest possible geometry, that is, a flat plate. This provided considerable simplification because $dp/dx = 0$ in Equation 3.43 for the forced flow case. However, the situation is not as simple for fluid flow over bodies with a finite radius of curvature.

Consider a common example of flow across a circular cylinder shown in Fig. 3.22. Boundary layer formation is initiated at the forward stagnation point, where the fluid is brought to rest with an accompanying rise in pressure. The pressure is a maximum at this point and decreases with increasing x, the streamline coordinate, and θ, the angular coordinate. (Note: In the boundary layer approximation, the pressure is the same inside and outside the boundary layer. This can be seen from Equation 3.44.) The boundary layer then develops under the influence of a favorable pressure gradient ($dp/dx < 0$). At the top of the cylinder (i.e., at $\theta = 90°$) the pressure eventually reaches a minimum and then begins to increase toward the rear of the cylinder. Thus, for $90° < \theta < 180°$, the boundary layer development occurs in the presence of an adverse pressure gradient ($dp/dx > 0$).

Unlike parallel flow over a flat plate, for curved surfaces the free stream velocity, u_∞, varies with x. (Note that in Fig. 3.22 a distinction has been made between the fluid velocity upstream of the cylinder, V, and the velocity

outside the boundary layer, $u_\infty(x)$.) At the stagnation point, $\theta = 0°$, $u_\infty = 0$. As the pressure decreases for $\theta > 0°$, u_∞ increases according to the Bernoulli equation, Equation 3.46, and becomes maximum at $\theta = 90°$. For $\theta > 90°$, the adverse pressure gradient decelerates the fluid, and conversion of kinetic energy to pressure occurs in accordance with Equation 3.46, which applies only to the inviscid flow outside the boundary layer. The fluid inside the boundary layer has considerably slowed down because of viscous friction and does not have enough momentum to overcome the adverse pressure gradient, eventually leading to boundary layer separation, which is illustrated more clearly in Fig. 3.23. At some location in the fluid, the velocity gradient at the surface becomes zero and the boundary layer detaches or separates from the surface. Farther downstream of the separation point, flow reversal occurs and a wake is formed behind the solid. Flow in this region is characterized by vortex formation and is highly irregular. The separation point is defined as the location at which $(\partial u/\partial y)_{y=0} = 0$. If the boundary layer transition to turbulence occurs prior to separation, the separation is delayed and the separation point moves farther downstream. This happens because the turbulent boundary layer has more momentum than the laminar boundary layer to overcome the adverse pressure gradient.

The foregoing processes strongly influence both the rate of heat transfer from the cylinder surface and the drag force acting on the cylinder. Because of the complexities associated with flow over a cylinder, experimental methods are used to determine the heat transfer coefficient. Such experimental results for the variation of the local Nusselt number with θ are shown in Fig. 3.24 for a cylinder in a cross flow of air. Consider the results for $Re_D \leq 10^5$ (note: Re_D is defined as VD/ν). Starting at the stagnation point, Nu_θ decreases with increasing θ due to the development of the laminar boundary layer. However, a minimum is reached at $\theta \approx 80°$. At this point separation occurs, and Nu_θ increases with θ due to the mixing associated with vortex formation in the wake. For $Re_D \geq 10^5$, the variation of Nu_θ with θ is characterized by two minima. The decline in Nu_θ from the value at the stagnation point is again due to laminar boundary layer development, but the sharp increase that occurs

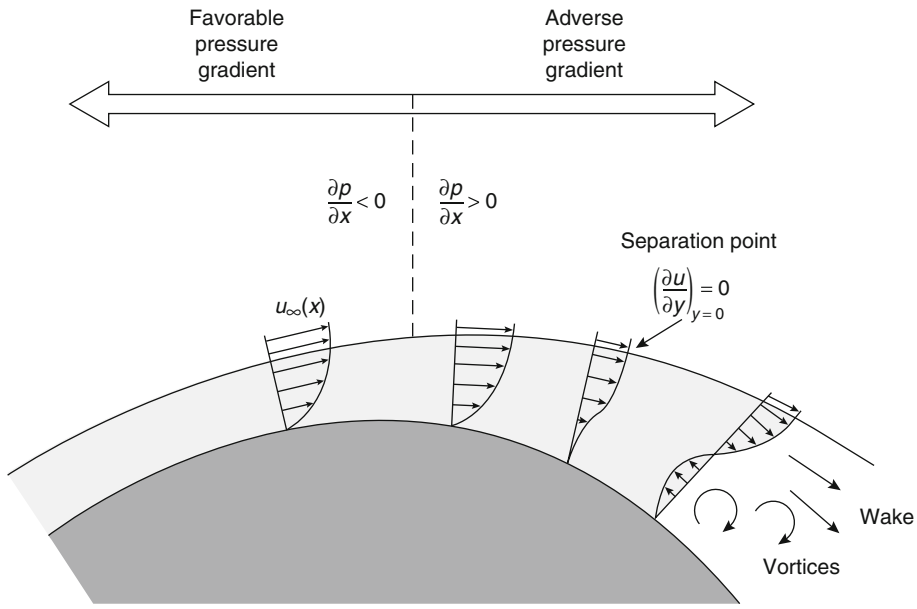

Fig. 3.23 Velocity profiles associated with separation on a circular cylinder in cross flow

between 80° and 100° is now due to boundary layer transition to turbulence. With further development of the turbulent boundary layer, Nu_θ must again begin to decline. However, separation eventually occurs ($\theta \approx 140°$), and Nu_θ increases due to considerable mixing associated with the wake region.

The foregoing example clearly illustrates the complications introduced by nonplanar geometry. Heat transfer correlations for these cases are often based on experimental data. Fortunately, for most engineering calculations the local variation in the heat transfer coefficient such as that presented in Fig. 3.24 is not required; only the overall average conditions are needed. Empirical correlations for average heat transfer coefficients will be presented in the next section.

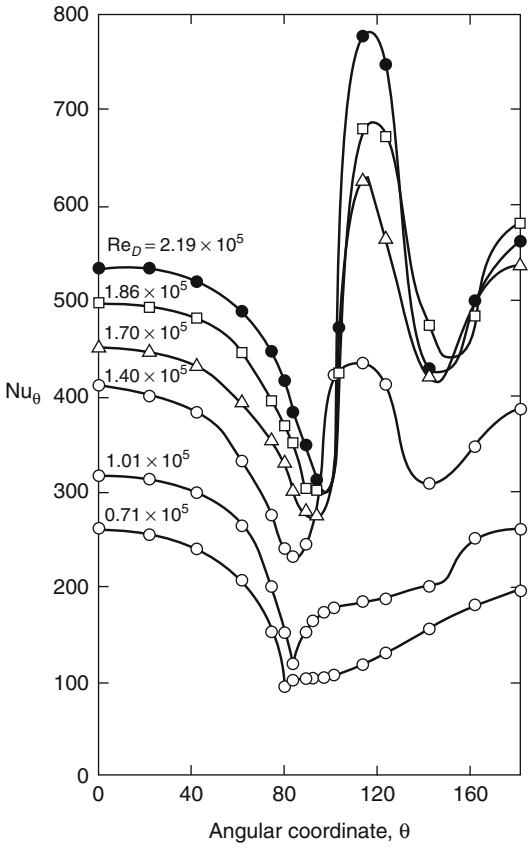

Fig. 3.24 Local Nusselt number for airflow normal to a circular cylinder

Changes in Fluid Properties In the analysis and discussion presented thus far, fluid properties were assumed to be constant. However, fluid properties vary with temperature across the boundary layer and this variation will have a significant impact on the heat transfer rate. In the empirical heat transfer correlations this influence is accounted for in one of two ways: (1) in correlating the experimental data, all properties are evaluated at the mean boundary layer temperature, $T_f = (T_s + T_\infty)/2$, called the film temperature, and (2) alternatively, all properties are evaluated at T_∞ and an additional parameter is used to account for the property variation. This parameter is commonly of the form $(Pr_\infty/Pr_s)^r$ or $(\mu_\infty/\mu_s)^r$, where the subscripts ∞ and s designate evaluation of properties at the free stream and surface temperatures, respectively, and r is an empirically determined constant.

It is important to note that in the empirical correlations to be presented in the next section, the same method that is employed in deriving the correlation should be used when applying the correlation.

Effect of Mass Transfer Special attention needs to be given to the effect that species mass transfer from the surface of the solid has on the velocity and thermal boundary layers. Recall that the velocity boundary layer development is generally characterized by the existence of zero fluid velocity at the surface. This condition applies to the velocity component v normal to the surface, as well as to the velocity component u parallel to the surface. However, if there is simultaneous mass transfer to or from the surface, it is evident that v can no longer be zero at the surface. Nevertheless, for the problems discussed in this chapter, mass transfer is assumed to have a negligible effect, that is, $v \approx 0$. This assumption is reasonable for problems involving some evaporation from gas-liquid or sublimation from gas-solid interfaces. For larger surface mass transfer rates a correction factor (often called the blowing correction) is utilized. This correction factor is simply stated here, and discussed in greater detail by Bird et al. [1]. The correction factor is defined as

$E(\phi) \equiv h^*/h$, where h^* is the corrected heat transfer coefficient and h is the heat transfer coefficient in the absence of mass transfer. According to film theory, $E(\phi)$ is given by

$$E(\phi) = \frac{\phi}{(e^{\phi} - 1)} \tag{3.102}$$

where

$$\phi = \frac{\dot{m}'' C_{pg}}{h}$$

$\dot{m}'' = \rho_s v_s$ is the mass flux coming out of the surface and C_{pg} is the specific heat of the gas.

Empirical Relations of Convection Heat Transfer

The analysis and discussion presented in the section on the boundary layer concept have shown that for simple cases the convection heat transfer coefficient may be determined directly from the conservation equations. In the previous section it was noted that the complications inherent to most practical problems do not always permit analytical solutions, and that it is necessary to resort to experimental methods. Experimental results are usually expressed in the form of either empirical formulas or graphical charts so that they may be utilized with maximum generality. Difficulties are encountered in the process of trying to generalize the experimental results in the form of empirical correlations. The availability of an analytical solution for a simpler but similar problem greatly assists in guessing the functional form of the results. Experimental data is then used to obtain values of constants or exponents for certain significant parameters, such as the Reynolds or Prandtl numbers. If an analytical solution for a similar problem is not available, it is necessary to rely on the physical understanding of the problem and on dimensional or order-of-magnitude analysis. In this section the experimental methods, the dimensionless groups, and the functional form of the relationships expected between them will be discussed; in addition the empirical formulas that will be used in the "Applications" section of this chapter will be summarized.

Functional Form of Solutions The nondimensional Equations 3.49, 3.50, 3.51, and 3.78 are extremely useful from the standpoint of suggesting how important boundary layer results can be generalized. For example, the momentum equation, Equation 3.50, suggests that although conditions in the velocity boundary layer depend on the fluid properties, ρ and μ, the velocity, μ_∞, and the length scale, L, this dependence may be simplified by grouping these variables in a nondimensional form called the Reynolds number. We therefore anticipate that the solution of Equation 3.50 will be of the form

$$u^* = f_1\left(x^*, y^*, \mathrm{Re}_L, \frac{dp^*}{dx^*}\right) \tag{3.103}$$

Note that the pressure distribution, $p^*(x^*)$, depends on the surface geometry and may be obtained independently by considering flow conditions outside the boundary layer in the free stream. Hence, as discussed in the section on complex geometry, the appearance of dp^*/dx^* in Equation 3.103 represents the influence of geometry on the velocity distribution. Note also that in Equation 3.50 the term dp^*/dx^* did not appear because it was equal to zero for a flat plate.

Similarly we anticipate that the solution of Equation 3.78 will be of the form

$$u^* = f_2(x^*, y^*, \mathrm{Gr}_L, \mathrm{Pr}) \tag{3.104}$$

Here, the Prandtl number is included because of the coupling between Equations 3.78 and 3.79. If the flow is mixed, that is, buoyant as well as forced, then the Reynolds number must also be included in the functional relationship expressed by Equation 3.104.

From Equation 3.1, the shear stress at the surface, $y^* = 0$, may be expressed as

$$\tau_s = \mu \left.\frac{\partial u}{\partial y}\right|_{y=0} = \left(\frac{\mu u_\infty}{L}\right) \left.\frac{\partial u^*}{\partial y^*}\right|_{y^*=0}$$

and from Equation 3.10 it follows that the friction coefficient is

$$C_f = \frac{\tau_s}{1/2\rho u_\infty^2} = \frac{2}{\mathrm{Re}_L}\frac{\partial u^*}{\partial y^*}\Big|_{y^*=0} \tag{3.105}$$

From Equation 3.103 it is clear that

$$\left.\frac{\partial u^*}{\partial y^*}\right|_{y^*=0} = f_3\left(x^*, \mathrm{Re}_L, \frac{dp^*}{dx^*}\right) \tag{3.106}$$

Hence, for a prescribed geometry (i.e., dp^*/dx^* is known from the free stream conditions) we have

$$C_f = \frac{2}{\mathrm{Re}_L} f_3(x^*, \mathrm{Re}_L) \tag{3.107}$$

Equation 3.107 is very significant because it states that the friction coefficient may be expressed exclusively in terms of a dimensionless space coordinate and the Reynolds number. For a prescribed geometry, the function that relates C_f to x^* and Re_L can be expected to be *universally* applicable. That is, it can be expected to apply to different fluids and over a wide range of values for u_∞ and L.

Similar results may be obtained for the heat transfer coefficient. Equation 3.51 suggests that the solution may be expressed in the form

$$T^* = f_4\left(x^*, y^*, \mathrm{Re}_L, \frac{dp^*}{dx^*}\right) \tag{3.108}$$

for forced flow, and

$$T^* = f_5(x^*, y^*, \mathrm{Gr}_L, \mathrm{Pr}) \tag{3.109}$$

for free convective flow. Here Re_L, Gr_L, and dp^*/dx^* originate from the influence of fluid motion (u^* and v^*) on Equation 3.51.

From the definition of the convection heat transfer coefficient, Equation 3.5, and Equation 3.40 with $y^* = y/L$ we obtain

$$h = -\frac{k(\partial T/\partial y)\big|_{y=0}}{(T_s - T_\infty)} = +\frac{k}{L}\left.\frac{\partial T^*}{\partial y^*}\right|_{y^*=0} \tag{3.110}$$

Thus

$$\mathrm{Nu} \equiv \frac{hL}{k} = \frac{\partial T^*}{\partial y^*}\Big|_{y^*=0}$$

Note that the Nusselt number, Nu, is equal to the dimensionless temperature gradient at the surface. From Equation 3.108 or Equation 3.107 it follows that for a prescribed geometry, i.e., known dp^*/dx^*

$$\mathrm{Nu} = f_6(x^*, \mathrm{Re}_L, \mathrm{Pr}) \tag{3.111}$$

for forced flow, and

$$\mathrm{Nu} = f_7(x^*, \mathrm{Gr}_L, \mathrm{Pr}) \tag{3.112}$$

for free convective flow. The Nusselt number is to the thermal boundary layer what the friction factor is to the velocity boundary layer. Equations 3.111 and 3.112 imply that for a given geometry, the Nusselt number must be some *universal* function of x^*, Re_L, and Pr. If this function were known, it could be used to compute the value of Nu for different fluids and different values of u_∞, T_∞, and L. Furthermore, since the average heat transfer coefficient is obtained by integrating over the surface of the body, it must be independent of the spatial variable, x^*. Hence, the functional dependence of the average Nusselt number is

$$\overline{\mathrm{Nu}} = \frac{\overline{h}L}{k} = f_8(\mathrm{Re}_L, \mathrm{Pr}) \tag{3.113}$$

for forced flow, and

$$\overline{\mathrm{Nu}} = f_9(\mathrm{Gr}_L, \mathrm{Pr}) \tag{3.114}$$

for free convective flows.

Although it is very helpful to know the functional dependence of Nu, the task is far from complete, because the function may be any of millions of possibilities. It may be a sine, exponential, or a logarithmic function. The exact form of this function can only be determined by an analytical solution of the governing equations, such as Equations 3.70 and 3.91.

Experimental Determination of Heat Transfer Coefficient The manner in which a convection heat transfer correlation may be obtained experimentally is illustrated in Fig. 3.25. If a prescribed geometry, such as the flat plate in parallel flow, is heated electrically to maintain $T_s > T_\infty$, convection heat transfer occurs from the surface to the fluid. It would be a simple matter to measure T_s and T_∞ as well as the electrical power, $E \cdot I$, which is equal to the total heat transfer rate, $\dot{q}$. The average convection coefficient, $\overline{h}_L$, can now easily be computed from Equation 3.7. Also, from the knowledge of the characteristic length, L, and the fluid properties, the values of the various nondimensional numbers—such as the Nusselt, Reynolds, Grashof, and Prandtl numbers—can be easily computed from their definitions.

The foregoing procedure is repeated for a variety of test conditions. We could vary the velocity, u_∞, the plate length, L, and the temperature difference $(T_s - T_\infty)$, as well as the fluid properties, using, for example, fluids such as air, water, and engine oil, which have substantially different Prandtl numbers. Many different values of the Nusselt number would result, corresponding to a wide range of Reynolds and Prandtl numbers. At this stage, an analytical solution to a similar but simpler problem proves very useful in guiding how the various nondimensional numbers should be correlated. For laminar flow over a flat plate it has been seen that in Equation 3.70 the relationship is of the form

$$\overline{\mathrm{Nu}} = C\mathrm{Re}_L^m \mathrm{Pr}^n$$

Thus, we plot the results on a log-log graph as shown in Fig. 3.26 and determine the values of C, m, and n. Because such a relationship is inferred from experimental measurements, it is called an empirical correlation. Along with this empirical correlation it is specified how the temperature-dependent properties were determined for calculating the various nondimensional numbers. When such a correlation is used, it is important that the properties must be calculated in exactly the manner specified. If they are not specified,

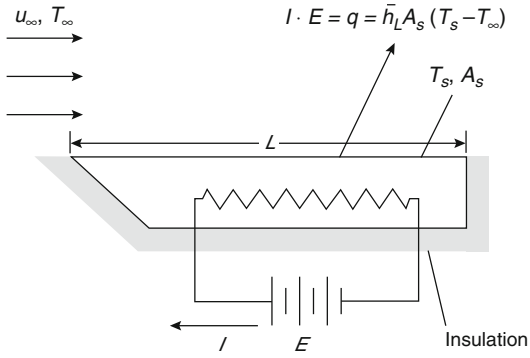

Fig. 3.25 Experiment for measuring the average convection heat transfer coefficient, $\overline{h}_L$

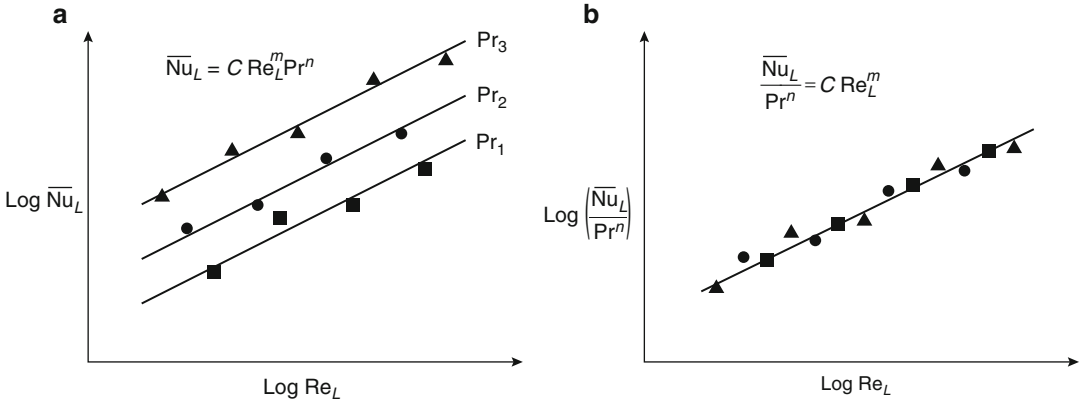

Fig. 3.26 Dimensionless representation of convection heat transfer measurements

then the mean boundary layer temperature, T_f, called the film temperature, must be used.

$$T_f \equiv \frac{T_s + T_\infty}{2} \tag{3.115}$$

A Summary of Empirical and Practical Formulas In this section, selected dimensionless groups (Table 3.2) and a variety of convection correlations (Tables 3.3 and 3.4) for external flow conditions are tabulated. Correlations for both forced and free convection are presented along with their range of applicability. The contents of this section are more or less a collection of "recipes." Proper use of these recipes is essential to solving practical problems. The reader should not view these correlations as sacrosanct; each correlation is reasonable over the range of conditions specified, but for most engineering calculations one should not expect the accuracy to be much better than 20%.

For proper use of the foregoing correlations it is important to note that the flow may not be laminar or turbulent over the entire length of the plate under consideration. Instead, transition to turbulence may occur at a distance x_c ($x_c < L$, where L is the plate length) from the leading edge of the plate. In this mixed boundary layer situation, the average convection heat transfer coefficient for the entire plate is obtained by integrating first over the laminar region ($0 \leq x \leq x_c$) and then over the turbulent region ($x_c < x \leq L$) as follows:

$$\overline{h}_L = \frac{1}{L}\left(\int_0^{x_c} h_{\text{lam}}\,dx + \int_{x_c}^{L} h_{\text{turb}}\,dx\right) \tag{3.116}$$

Table 3.2 Selected dimensionless groups

Group		Definition	Interpretation
Friction coefficient	Local	$C_f = \frac{\tau_2}{\rho u^2 \infty/2}$	Dimensionless surface shear stress
	Average	$\overline{C}_f = \frac{\overline{\tau}_2}{\rho u^2 \infty/2}$	
Reynolds number	Location x	$\text{Re}_x = \frac{u_\infty x}{\nu}$	Ratio of inertia and viscous forces
	Length L	$\text{Re}_L = \frac{u_\infty L}{\nu}$	
	Diameter D	$\text{Re}_D = \frac{u_\infty D}{\nu}$	
Prandtl number		$\text{Pr} = \frac{C p \mu}{k} = \frac{\nu}{\alpha}$	Ratio or molecular momentum and thermal diffusivities
Grashof number	Location x	$\text{Gr}_x = \frac{g\beta(T_s - T_\infty)x^3}{\nu^2}$	Ratio of buoyancy to viscous forces
	Length L	$\text{Gr}_L = \frac{g\beta(T_s - T_\infty)L^3}{\nu^2}$	
	Diameter D	$\text{Gr}_D = \frac{g\beta(T_s - T_\infty)D^3}{\nu^2}$	
Rayleigh number	Location x	$\text{Ra}_x = \text{Gr}_x\text{Pr} = \frac{g\beta(T_s - T_\infty)x^3}{\nu\alpha}$	Product of Grashof and Prandtl numbers
		Replace x by $L$and D to get Ra_L and Ra_D	
Nusselt number	Location x	$\text{Nu}_x = \frac{hx}{k}$	Ratio of convection heat transfer to conduction in a fluid slab of thickness x
		Replace x by L and D to get Nu_L and Nu_D	
Modified Grashof number	Location x	$\text{Gr}_x^* = \text{Gr}_x\text{Nu}_x = \frac{g\beta\dot{q}_s'' x^4}{k\nu^2}$	Product of Grashof and Nusselt numbers
Stanton number		$\text{St} = \frac{h}{\rho u_\infty C_p} = \frac{\text{Nu}}{\text{RePr}}$	Dimensionless heat transfer coefficient

Table 3.3 Summary of forced convection correlations for external flow geometries

Geometry/flow	Type	Equation	Restrictions	Comments
Flat plate/laminar (Ts = constant)	Local	$\mathrm{Nu}_x = 0.332\,\mathrm{Re}_x^{1/2}\,\mathrm{Pr}^{1/3}$	$\mathrm{Re}_x < 5 \times 10^5$	Properties evaluated at $T_t = (T_s + T_\infty)/2$
	Average	$\overline{\mathrm{Nu}}_L = 0.664\,\mathrm{Re}_L^{1/2}\,\mathrm{Pr}^{1/3}$	$0.6 \le \mathrm{Pr} \le 50$	
	Boundary layer thickness	$\frac{\delta}{x} = 5\mathrm{Re}_x^{-1/2}$		
Flat plate/laminar ($\dot{q}_s'' =$ constant)	Local	$\mathrm{Nu}_x = 0.453\,\mathrm{Re}_x^{1/2}\,\mathrm{Pr}^{1/3}$	$\mathrm{Re}_x < 5 \times 10^5$	Properties evaluated at T_f. However, T_s is not known. Instead, q_s'' is known. Thus, $T_f = T_\infty + \left(\overline{T}_s - \overline{T}_\infty\right)/2$ where $\left(\overline{T}_s - \overline{T}_\infty\right) = \frac{q_s L/K}{0.6795\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3}}$
			$0.6 \le \mathrm{Pr} \le 50$	
Flat plate/turbulent (Ts = constant)	Local	$\mathrm{Nu}_x = 0.0296\,\mathrm{Re}_x^{4/5}\,\mathrm{Pr}^{1/3}$	$\mathrm{Re}_x < 10^8$	Properties evaluated at T_f
	Boundary layer thickness	$\frac{\delta}{x} = 0.37\mathrm{Re}_x^{-1/5}$	$0.6 \le \mathrm{Pr} \le 60$	
	Mixed average (laminar turbulent)	$\overline{\mathrm{Nu}}_L = \left(0.037\,\mathrm{Re}_L^{4/5} - 871\right)\mathrm{Pr}^{1/3}$	Transition to turbulence at $\mathrm{Re}_{\mathrm{crit}} = 5 \times 10^5$	
Flow across cylinders circular cylinder	Average	$\overline{\mathrm{Nu}}_D = C\mathrm{Re}_D^m\mathrm{Pr}^{1/3}$	$0.4 < \mathrm{Re}_D < 4 \times 10^5$	Properties evaluated at T_f
		Re_D	C	m

Spheres 	Average: (T_s = const)	$\overline{\text{Nu}}_D = 2 + 0.43\ \text{Ra}_D^{1/4}$ $\overline{\text{Nu}}_D = 2 + 0.5\ \text{Ra}_D^{1/4}$	$1 < \text{Ra}_D < 10^5$ Pr ≈ 1 $3 \times 10^5 < \text{Ra} < 8 \times 10^8$	Properties evaluated at T_f

where x_c may be obtained from the critical Reynolds or Grashof numbers.

Also, several correlations given in Tables 3.3 and 3.4 are for the constant heat flux $\left(\dot{q}_s'' = \text{constant}\right)$ boundary condition. Thus, the surface temperature of the object is unknown and yet the fluid properties are to be determined at $T_f = (T_s + T_\infty)/2$. For such cases an iterative procedure is employed and the average surface temperature can be determined as follows:

$$\dot{q}_s''(\text{Known}) = \overline{h}(T_s - T_\infty) = \frac{\overline{\text{Nu}}_L}{(L/k)}(T_s - T_\infty)$$

thus

$$T_s(\text{Average}) = T_\infty + \frac{\dot{q}_s''(L/k)}{\overline{\text{Nu}}_L} \qquad (3.117)$$

The use of correlations given in Tables 3.3 and 3.4 is illustrated via examples in the next section.

Applications

This section briefly summarizes the methodology for convection calculations and then presents examples to illustrate the use of various correlations.

Methodology for Convection Calculations The application of a convection correlation for any flow situation is facilitated by following a few simple rules:

1. Become immediately cognizant of the flow geometry. Does the problem involve flow over a flat plate, a sphere, a cylinder, and so forth? The specific form of the convection correlation depends, of course, on the geometry.
2. Specify the appropriate reference temperature and then evaluate the pertinent fluid properties at that temperature. For moderate boundary layer temperature differences, it has been found that the film temperature may be used for this purpose. However, there are correlations that require property evaluation at the free stream temperature and include a property ratio to account for the nonconstant property effect.
3. Determine whether the flow is laminar or turbulent. This determination is made by calculating the Reynolds number and comparing the value with the appropriate transition criterion. For example, if a problem involves parallel flow over a flat plate for which the Reynolds number is $\text{Re}_L = 10^6$ and the transition criterion is $\text{Re}_{\text{crit}} = 5 \times 10^5$, it is obvious that a mixed boundary layer condition exists.
4. Decide whether a local or surface average coefficient is required. Recall that the local coefficient is used to determine the flux at a particular point on the surface, whereas the average coefficient determines the transfer rate for the entire surface.

Having complied with the foregoing rules, sufficient information will be available to select the appropriate correlation for the problem.

Example 1 Electrical strip heaters are assembled to construct a flat radiant heater 1 m wide for conducting fire experiments in a wind tunnel. The heater strips are 5 cm wide and are independently controlled to maintain the surface temperature at 500 °C. Construction details are shown in Fig. 3.27. If air at 25 °C and 60 m/s flows over the plate, at which strip is the electrical input maximum? What is the value of this input? The radiative heat loss is ignored.

Solution Assumptions
Steady-state conditions, neglect radiation losses, and no heat loss through the bottom surface.

Properties
$T_f = 535$ K: $\rho = 1$ atm. From air property Table 3.5, $k = 42.9 \times 10^{-3}$ W/m·K; $\nu = 43.5 \times 10^{-6}$ m^2/s; Pr = 0.683.

Analysis
The strip heater requiring the maximum electrical power is that for which the average convection coefficient is the largest. From the knowledge of variation of the local convection

coefficient with distance from the leading edge, the local maximum can be found. Figure 3.15 shows that a possible location is the leading edge on the first plate. A second likely location is where the flow becomes turbulent. To determine the point of boundary layer transition to turbulence assume that the critical Reynolds number is 5×10^5. It follows that transition will occur at x_c, where

$$x_c = \frac{\nu \mathrm{Re}_{crit}}{u_\infty} = \frac{43.5 \times 10^{-6} \times 5 \times 10^5}{60} \mathrm{m}$$
$$= 0.36 \text{ m or on the eighth strip}$$

Thus there are three possibilities:

1. Heater strip 1, since it corresponds to the largest local, laminar convection coefficient
2. Heater strip 8, since it corresponds to the largest local turbulent convection coefficient
3. Heater strip 9, since turbulent conditions exist over the entire heater

For the first heater strip

$$q_{\mathrm{conv},1} = \overline{h}_1 L_1 W (T_s - T_\infty)$$

where $\overline{h}_1$ is determined from the equation below (see also Table 3.3).

$$\overline{\mathrm{Nu}}_1 = 0.664 \mathrm{Re}_1{}^{1/2} \mathrm{Pr}^{1/3}$$
$$= 0.664 \left(\frac{60 \times 0.05}{43.5 \times 10^{-6}} \right)^{1/2} (0.683)^{1/3}$$
$$= 153.6$$

hence,

$$\overline{h}_1 = \frac{\overline{\mathrm{Nu}}_1 k}{L_1} = \frac{153.6 \times 42.9 \times 10^{-3}}{0.05}$$
$$= 131.8 \mathrm{W/m^2 \cdot K}$$

hence,

$$q_{\mathrm{conv},1} = (131.8)(0.05)(1 \text{ m})(500 \ \ 25)$$
$$= 3129 \text{ W}$$

The power requirement for the eighth strip may be obtained by subtracting the total heat loss associated with the first seven heaters from that associated with the first eight heaters. Thus

$$q_{conv,8} = \overline{h}_{1-8} L_8 W (T_s - T_\infty) - \overline{h}_{1-7} L_7 W (T_s - T_\infty)$$

The value of $\overline{h}_{1-7}$ is obtained from the equation applicable to laminar conditions (Table 3.3). Thus

$$\overline{\mathrm{Nu}}_{1-7} = 0.664 \mathrm{Re}_7{}^{1/2} \mathrm{Pr}^{1/3}$$
$$= 0.664 \left(\frac{60 \times 7 \times 0.05}{43.5 \times 10^{-6}} \right)^{1/2} (0.683)^{1/3}$$
$$= 406.3$$
$$\overline{h}_{1-7} = \frac{\overline{\mathrm{Nu}}_{1-7} k}{L_7} = \frac{406.3 \times 42.9 \times 10^{-3}}{7 \times 0.05}$$
$$= 49.8 \mathrm{W/m^2 \cdot K}$$

By contrast, the eighth heater is characterized by mixed boundary layer conditions. Thus use the formula (Table 3.3).

$$\overline{\mathrm{Nu}}_{1-8} = \left(0.037 \mathrm{Re}_8^{4/5} - 871 \right) \mathrm{Pr}^{1/3}$$
$$\mathrm{Re}_8 = 8 \times \mathrm{Re}_1 = 5.52 \times 10^5$$
$$\overline{\mathrm{Nu}}_{1-8} = 510.5$$
$$\overline{h}_{1-8} = \frac{\overline{\mathrm{Nu}}_{1-8} k}{L_8} = 54.7 \mathrm{W/m^2 \cdot K}$$

The rate of heat transfer from the eighth strip is then

$$q_{\mathrm{conv},8} = (54.7 \times 8 \times 0.05 - 49.8 \times 7 \times 0.05) \times (500 - 25) = 2113.8 \text{ W}$$

The power requirement for the ninth heater strip may be obtained by either subtracting the total heat loss associated with the first eight from that associated with the first nine, or by integrating over the local turbulent expression, since the flow is completely turbulent over the entire width of the strip. The latter approach produces

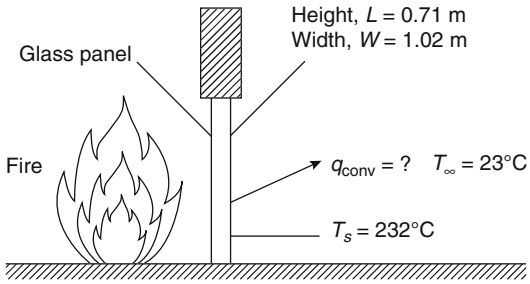

Fig. 3.28 Glass panel fire screen

$$\overline{h}_9 = \left(\frac{k}{L_9 - L_8}\right) 0.0296 \left(\frac{u_\infty}{\nu}\right)^{4/5} \mathrm{Pr}^{1/3} \int_{L_8}^{L_9} \frac{dx}{x^{1/5}}$$

$$\overline{h}_9 = \left(\frac{42.9 \times 10^{-3}}{0.05}\right) 0.0296 \left(\frac{60}{43.5 \times 10^{-6}}\right)^{4/5} \times (0.683)^{1/3} \int_{L_8}^{L_9} \frac{dx}{x^{1/5}}$$

$$= 1825.22\left[(0.45)^{0.8} - (0.4)^{0.8}\right] = 86.7$$

$$q_{conv,9} = 86.7 \times 0.05 \times 1 \times (500 - 25)$$

$$= 2059 \text{ W}$$

hence

$$q_{\mathrm{conv},1} > q_{\mathrm{conv},8} > q_{\mathrm{conv},9}$$

and the first heater strip has the largest power requirement.

Example 2 A glass-door fire screen, shown in Fig. 3.28, is used to reduce exfiltration of room air through a chimney. It has a height of 0.71 m, a width of 1.02 m, and reaches a temperature of 232 °C. If the room temperature is 23 °C, estimate the convection heat transfer rate from the fireplace to the room.

Solution Assumptions
The screen is at a uniform temperature, T_s, and room air is quiescent.

Properties
$T_f = 400$ K, $P = 1$ atm. From air property table (Table 3.5):

$k = 33.8 \times 10^{-3}$ W/m·K; $\nu = 26.41 \times 10^6$ m^2/s;
$\alpha = 38.3 \times 10^{-6}$ m^2/s; Pr = 0.69; $\beta = 1/T_f = 0.0025$ K^{-1}

Analysis
The rate of heat transfer by free convection from the panel to the room is given by

$$q = \overline{h} A_s (T_s - T_\infty)$$

where $\overline{h}$ is obtained from the following equation from Table 3.4.

$$\overline{\mathrm{Nu}}_L = \left\{ 0.825 + \frac{0.387 \mathrm{Ra}_L^{1/6}}{\left[1 + (0.492/\mathrm{Pr})^{9/16}\right]^{8/27}} \right\}^2$$

here

$$\mathrm{Ra}_L = \frac{g\beta(T_s - T_\infty)L^3}{\alpha\nu}$$

$$= \frac{9.8 \times 0.0025 \times (232 - 23) \times (0.71)^3}{38.3 \times 10^{-6} \times 26.4 \times 10^{-6}}$$

$$= 1.813 \times 10^9$$

Since $\mathrm{Ra}_L > 10^9$, transition to turbulence will occur on the glass panel and the appropriate correlation from Table 3.4 has been chosen

$$\overline{\mathrm{Nu}}_L = \left\{ 0.825 + \frac{0.387\left(1.813 \times 10^9\right)^{1/6}}{\left[1 + (0.492/0.69)^{9/16}\right]^{8/27}} \right\}^2$$

$$= 147$$

Hence

$$\overline{h} = \frac{\overline{\mathrm{Nu}}_L \times k}{L} = \frac{147 \times 33.8 \times 10^{-3}}{0.71}$$

$$= 7 \text{ W/m}^2 \cdot \text{K}$$

and

$$q = 7 \frac{W}{\text{m}^2\text{K}} (1.02\text{m} \times 0.71\text{m}) \times (232 - 23)^\circ\text{C}$$

$$= 1060 \text{ W}$$

Note: in this case radiation heat transfer calculations would show that radiant heat transfer is greater than free convection heat transfer.

Example 3 A fire door is constructed as shown in Fig. 3.29. Two thin (but rigid) stainless steel walls are separated by an argon-filled gap of thickness $2b$. The door height, approximately equal to the door width, is much greater than $2b$. All other sides of the door with one dimension $2b$ seal the argon-filled gap and are assumed to be insulated. In the event of a fire, the two vertical walls will be at different temperatures, designated as "hot" and "cold." Assuming that the wall temperatures T_1 and T_2 remain constant and using the *Boussinesq approximation*, derive expressions for velocity and temperature profiles in argon under steady-state conditions. Also determine the heat flux through argon. Does it provide adequate insulation? Note that the gas motion in the y direction is expected to be small; thus it may be neglected along with any edge effects. Viscous dissipation may also be neglected.

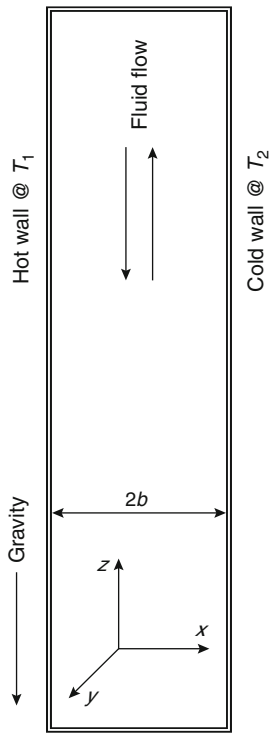

Fig. 3.29 Example 3

Solution We expect the argon near the heated wall to rise, and that near the cold wall to descend. Also, for all practical purposes, the two parallel steel plates are infinite in extent compared with the gap $2b$. Since the gap is sealed, under steady-state conditions any mass going up must be equal to the mass coming down to conserve the total mass of the gas inside the gap.

The velocity vector has three components: V_X, V_Y, and V_Z. Of these, only V_Z is nonzero. Also, based on the assumption made, V_Z varies only with x. The continuity and momentum equations thus become

Continuity

$$\frac{\partial V_Z}{\partial Z} = 0$$

The Z-component of the momentum equation becomes

$$\mu \frac{d^2 V_Z}{dx^2} + \rho_m g \beta (T_m - T) = 0$$

Here T_m is the mean temperature, yet to be defined. The constant value of density ρ_m is also taken at this mean temperature. Any variation above or below this mean temperature will provide the buoyancy force to drive the fluid. Other than in the buoyancy term, throughout the equations ρ_m is taken as constant—this is the *Boussinesq approximation*. Note that with the increase in the mean temperature, the pressure will rise given the rigid walls of the door. Thus, the mean density will remain constant regardless of the temperature. However, the density will vary with temperature.

The boundary conditions are

$$\text{BC1}: x = \pm b,\ V_Z = 0$$

$$\text{BC2}: x = 0,\ V_Z = \text{by symmetry}$$

Temperature can depend on at most three space variables and time. For this problem $T = T(x)$ because T_1 and T_2 are constant and conditions are steady. Thus, the energy equation reduces to

$$k\frac{d^2T}{dx^2} = 0$$

With the boundary conditions

$$\begin{aligned} \text{BC1}: x &= b, T = T_1 \\ \text{BC2}: x &= b, T = T_2 \end{aligned}$$

The energy equation can be integrated directly to give

$$T = \frac{T_1 + T_2}{2} - \frac{x}{2b}(T_1 - T_2)$$

Thus, T_m can be conveniently defined as

$$T_m = \frac{T_1 + T_2}{2}$$

In terms of the mean temperature, the temperature profile becomes

$$\frac{T - T_m}{T_1 - T_2} = -\frac{x}{2b}$$

Thus,

$$q_x'' = -k\frac{dT}{dx} = k\frac{(T_1 - T_2)}{2b}$$

With mean temperature defined, we can now rewrite the momentum equation as

$$\frac{d^2V_Z}{dx^2} = \frac{\rho_m g\beta}{\mu}(T - T_m) = \frac{\rho_m g\beta x(T_2 - T_1)}{2b\mu}$$

This can also be directly integrated as

$$V_Z = \frac{\rho_m g\beta x^3}{12b\mu}(T_2 - T_1) + C_3 x + C_4$$

Applying the boundary conditions, we obtain the velocity distribution as

$$\begin{aligned} V_Z &= \frac{\rho_m g\beta x^3}{12b\mu}(T_2 - T_1) - \frac{\rho_m g\beta bx}{12\mu}(T_2 - T_1) \\ &= \frac{\rho_m g\beta b^2}{12\mu}(T_2 - T_1)\left(\frac{x}{b} - \frac{x^3}{b^3}\right) \end{aligned}$$

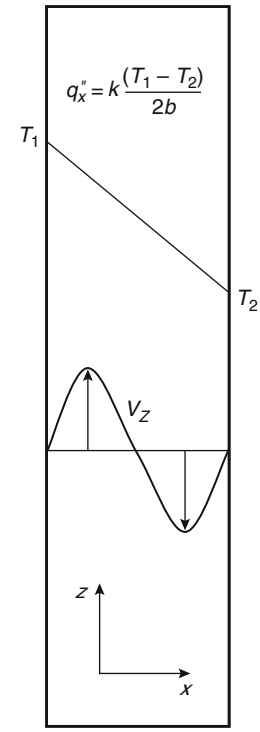

Fig. 3.30 Example 3 solution

As shown in Fig. 3.30, despite the fluid motion inside the door, the temperature profile is linear and effectively heat is conducted through low thermal conductivity argon gas providing excellent insulation. For this condition to hold, door height must be much greater than $2b$.

Nomenclature

$\boldsymbol{A}$	Area (m^2)
$\boldsymbol{A_s}$	Surface area (m^2)
Bi	Biot number
$\boldsymbol{C}$	Molar concentration ($kmol/m^3$)
$\boldsymbol{C_f}$	Friction coefficient
$\boldsymbol{c_p}$	Specific heat at constant pressure (J/kg·K)
$\boldsymbol{c_v}$	Specific heat at constant volume (J/kg·K)
$\boldsymbol{D}$	Diameter (m)
$\boldsymbol{D_{AB}}$	Binary mass diffusion coefficient (m^2/s)

D_h	Hydraulic diameter (m)
E	Specific internal or thermal (sensible) energy (J/kg)
F_{BX}, F_{BY}, F_{BZ}	Components of the body force per unit volume (N/m^3)
F_{SX}, F_{SY}, F_{SZ}	Components of the surface force
F	Friction factor
Gr	Grashof number
G	Gravitational acceleration (m/s^2)
H	Convection heat transfer coefficient (W/m^2 ·K)
$\overline{h}$	Average convection heat transfer coefficient (W/m^2 ·K)
h_m	Convection mass transfer coefficient (m/s)
h_{rad}	Radiation heat transfer coefficient (W/m^2 ·K)
K	Thermal conductivity (W/m·K)
L	Characteristic length (m)
Le	Lewis number
M	Mass (kg)
$\dot{M}$	Mass flow rate (kg/s)
$\dot{m}''$	Mass flux (kg/m^2 · s)
$\dot{m}_i''$	Mass flux of species i (kg/m^2 · s)
Nu	Nusselt number
P	Perimeter (m)
Pe	Peclet number (RePr)
Pr	Prandtl number
P	Pressure (N/m^2)
Q	Energy generation rate per unit volume (W/m^3)
$\dot{q}'$	Heat transfer rate per unit length (W/m)
$\dot{q}''$	Heat flux (W/m^2)
R	Universal gas constant
Ra	Rayleigh number
Re	Reynolds number
r, ϕ, z	Cylindrical coordinates
r, θ, ϕ	Spherical coordinates
Sc	Schmidt number
Sh	Sherwood number
St	Stanton number
T	Temperature (K)
T	Time (s)
U	Overall heat transfer coefficient (W/m^2 ·K)
u, v, w	Mass average fluid velocity components (m/s)
x, y, z	Rectangular coordinates (m)
$x_{fd,h}$	Hydrodynamic entry length (m)
$x_{rd,t}$	Thermal entry length (m)

Greek Letters

α	Thermal diffusivity (m^2/s)
β	Volumetric thermal expansion coefficient (K^{-1})
δ	Hydrodynamic boundary layer thickness (m)
δ_t	Thermal boundary layer thickness (m)
δ_d	Mass transfer boundary layer thickness (m)
η	Similarity variable
θ	Zenith angle (rad)
ϕ	Azimuthal angle (rad)
μ	Viscosity (kg/s·m)
ν	Kinematic viscosity (m^2/s)
ρ	Mass density (kg/m^3)
σ_{ij}	Components of the stress tensor (N/m^2)
ψ	Stream function (m^2/s)
τ	Shear stress (N/m^2)

Subscripts

A,B	Species in a binary mixture
Conv	Convection
D	Diameter; drag
F	Fluid properties
Fd	Fully developed conditions
H	Heat transfer conditions
H	Hydrodynamic; hot fluid
L	Based on characteristic length
Max	Maximum fluid velocity
S	Surface conditions
Sur	Surroundings
T	Thermal
X	Local conditions on a surface
∞	Free stream conditions

Radiation Heat Transfer

4

Revised by C. Lautenberger
Original chapter authored by C.L. Tien, K.Y. Lee, and A.J. Stretton

Introduction

Thermal radiation is the dominant mode of heat transfer in flames with characteristic lengths exceeding approximately 0.2 m. It is for this reason that quantitative analysis of fire dynamics requires a working knowledge of thermal radiation. This chapter will introduce the fundamentals of thermal radiation and offer several methods for calculating radiant heat transfer in fires. Basic thermal radiation concepts are presented with an emphasis on application to fire phenomena; the reader is referred the literature for specialized topics [1–4].

Basic Concepts

The Nature of Thermal Radiation

Whereas conduction and convection require direct contact for objects at different temperatures to exchange heat, thermal radiation is a distinct mechanism of heat transfer that allows spatially separated objects at different temperatures to transfer heat. Although the Earth is separated from its Sun by 1.5×10^{11} m of near perfect vacuum, we have all enjoyed its radiative heat transfer on cool days, and cursed it on hot ones.

All objects with a finite temperature emit thermal radiation through a physical mechanism related to electron oscillations and transitions. As an object's absolute temperature increases, these electron oscillations and transitions become more rapid, resulting in increased radiant emission. Since all objects emit radiation, all objects also have a certain amount of thermal radiation impinging upon them (originating from other emitting objects). It is the net difference between incoming and outgoing thermal radiation that leads to a net rate of radiant heat transfer between objects at different temperatures, and quantification of this rate is usually the ultimate goal of a radiation heat transfer analysis.

The nature of thermal radiation transport can be explained on the basis of quantum mechanics or electromagnetic wave theory. In the general quantum mechanical consideration, electromagnetic radiation is viewed as the propagation of an ensemble of particles (usually called photons or quanta). These particles, being generated by sub-molecular processes that are fed by an object's internal energy, carry different energies. The energy of a photon (e, J) is proportional to its frequency (ν, s^{-1}):

$$e = h\nu \tag{4.1}$$

The constant of proportionality in Equation 4.1 is Planck's constant, $h = 6.6256 \times 10^{-34}$ J · s. It is seen that the higher the frequency, the higher

DOI 10.1007/978-1-4939-2565-0_4, © Society of Fire Protection Engineers 2016

the photon energy. Thus, a radiation field is fully described when the flux of photons (or energy) is known for all points in the field for all directions and for all frequencies.

Due to its wave-particle duality, electromagnetic radiation exhibits properties of both particles and waves. Therefore, thermal radiation can also be explained as the propagation of electromagnetic waves. In this context, wavelength (λ) is related to frequency (ν) and the speed of light (c) as:

$$\lambda = \frac{c}{\nu} \tag{4.2}$$

The speed of light in a particular medium is denoted c, and in a vacuum it is denoted c_0 where $c_0 = 2.998 \times 10^8$ m/s. Wavelength has units of length, and for convenience it is usually given in microns (μm, or micrometers) where 1 μm $= 10^{-6}$ m. Substituting Equation 4.2 into Equation 4.1 shows that a photon's energy increases as wavelength decreases:

$$e = \frac{hc}{\lambda} \tag{4.3}$$

Electromagnetic waves of practical significance have wavelengths ranging from 10^{-5} to 10^4 μm. Figure 4.1 shows the electromagnetic spectrum spanning this range. *Thermal radiation* usually refers to electromagnetic waves with wavelengths between 10^{-1} and 10^2 μm. For comparison, visible light has wavelengths between 0.4 and 0.7 μm. Thermal radiation with wavelengths between 0.7 and 100 μm is *infrared* thermal radiation, whereas *ultraviolet* thermal radiation has wavelengths between 0.1 and 0.4 μm.

Example 1 Calculate the energy of photons (in a vacuum) with a wavelength of 10^{-1} μm (ultraviolet limit of thermal radiation) and 10^2 μm (infrared limit of thermal radiation).

Solution Equation 4.3 can be used to calculate photon energies. For the photon at the ultraviolet limit:

$$\begin{aligned} e &= \frac{hc_0}{\lambda} \\ &= \frac{\left(6.6256 \times 10^{-34}\ \text{J}\cdot\text{s}\right)\left(2.998 \times 10^{8}\ \text{m/s}\right)}{10^{-1}\mu\text{m} \times \left(10^{-6}\text{m}/\mu\text{m}\right)} \\ &= 1.99 \times 10^{-18}\ \text{J} \end{aligned}$$

And for the photon at the infrared limit:

$$\begin{aligned} e &= \frac{hc_0}{\lambda} \\ &= \frac{\left(6.6256 \times 10^{-34}\ \text{J}\cdot\text{s}\right)\left(2.998 \times 10^{8}\ \text{m/s}\right)}{10^{2}\mu\text{m} \times \left(10^{-6}\text{m}/\mu\text{m}\right)} \\ &= 1.99 \times 10^{-21}\ \text{J} \end{aligned}$$

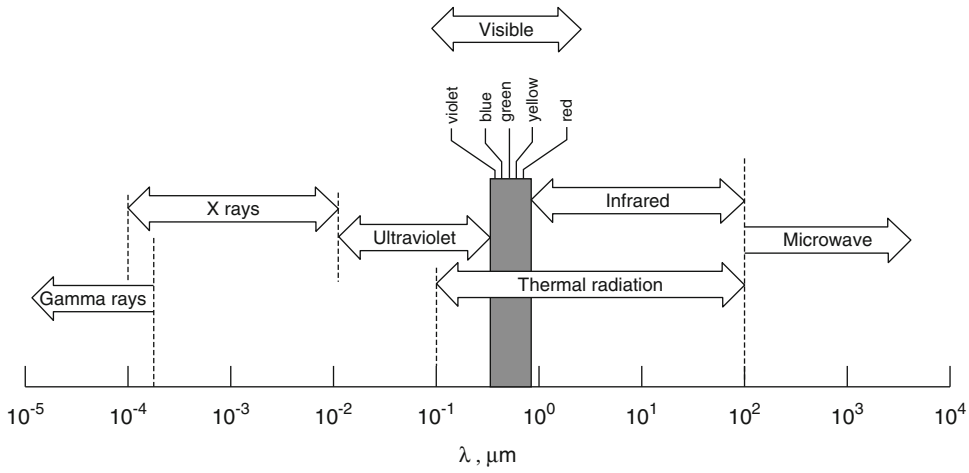

Fig. 4.1 Electromagnetic spectrum. Adapted from Incropera and DeWitt [4]

Spectral Distribution of Radiation from a Perfect Emitter

A *diffuse* surface is an idealized surface that emits thermal radiation equally in all directions, i.e. its emission exhibits no directional dependency. A *perfect emitter* is an idealized surface that emits the maximum possible thermal radiation at every wavelength. A *blackbody* is a diffuse perfect emitter that also absorbs all incident radiation.

The energy spectrum of radiation emitted by a diffuse perfect emitter, or blackbody, can be calculated from Planck's quantum theory. In particular, the spectral (or monochromatic) blackbody emissive power ($E_{\lambda,b}$, W/m^2 · μm) is given by the Planck distribution:

$$E_{\lambda,b}(\lambda,T) = \frac{C_1}{\lambda^5(\exp(C_2/\lambda T)-1)} \qquad (4.4)$$

where $C_1 = 2\pi hc_0^2 = 3.742 \times 10^8$ W · μm^4/m^2 is Planck's first constant (often called the first radiation constant) and $C_2 = hc_0/k = 1.439 \times 10^4$ μm · K is Planck's second constant (or the second radiation constant). Note that k is the Boltzmann constant ($k = 1.3805 \times 10^{-23}$ J/K). In Equation 4.4 and throughout this chapter, a subscript "b" indicates "blackbody" and a subscript λ indicates "wavelength", e.g. $E_{\lambda,b}$ is the blackbody emissive power at a particular wavelength λ.

Spectral emissive power is plotted in Fig. 4.2 as a function of wavelength for several different blackbody temperatures. Also shown in Fig. 4.2 is a line labeled $\lambda_{max} = C_3/T$ (where the third radiation constant is $C_3 = 2897.8$ μm · K) that relates the wavelength corresponding to the peak spectral emissive power (λ_{max}) to the blackbody temperature T. This is Wien's displacement law, which is obtained by differentiating Equation 4.4 with respect to T, setting that result equal to zero, and solving for λT. Wien's displacement law shows that the maximum monochromatic emissive power of a blackbody shifts to shorter wavelengths as its temperature increases. From Equation 4.3, it is also seen that the photons emitted from blackbodies high temperature (shorter wavelengths) carry more energy than photons emitted from blackbodies at lower

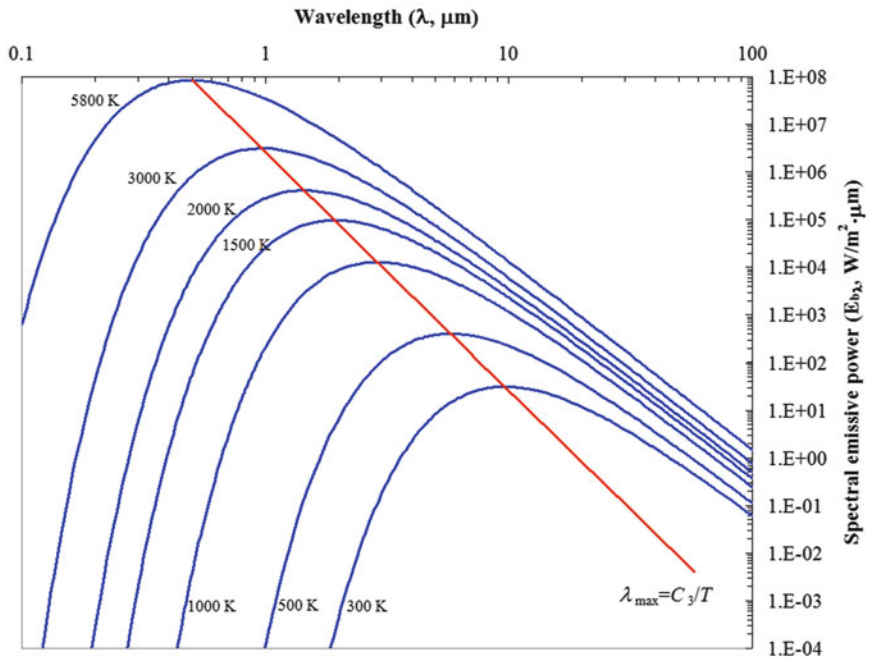

Fig. 4.2 The Planck distribution: blackbody emissive power and Wien's displacement law

temperatures (longer wavelengths), a result that one intuitively expects.

The Stefan-Boltzman Law is obtained by integrating the spectral blackbody emissive power over all wavelengths:

$$E_b = \int_0^\infty E_{\lambda,b}(\lambda)d\lambda = \int_0^\infty \frac{C_1}{\lambda^5(\exp(C_2/\lambda T)-1)}d\lambda = \sigma T^4 \quad (4.5)$$

where σ is the Stefan-Boltzman constant ($\sigma = 5.67 \times 10^{-8}$ W/m$^2 \cdot$ K^4) and E_b is the total (integrated over all wavelengths) blackbody emissive power. It is seen that the oft-cited "fourth power dependency" of thermal radiation on temperature is a direct consequence of integrating the Planck spectral distribution over all wavelengths.

Equations 4.4 and 4.5 can be used to calculate the fraction of a blackbody's radiant emission in a particular wavelength band, i.e. between two wavelengths. Denote $F_{\lambda_1\to\lambda_2}$ as the fraction of a blackbody's radiant emission between wavelengths λ_1 and λ_2. It is then calculated as:

$$F_{\lambda_1\to\lambda_2} = \frac{\int_0^{\lambda_2} E_{\lambda,b}d\lambda - \int_0^{\lambda_1} E_{\lambda,b}d\lambda}{E_b} = F_{0\to\lambda_2} - F_{0\to\lambda_1} \quad (4.6)$$

Thus, $F_{\lambda_1\to\lambda_2}$ can be calculated from two values of $F_{0\to\lambda}$, which is readily tabulated from Equation 4.4 as a function of λT (Table 4.1). This then makes it possible to calculate the fraction of emission between two wavelengths.

Table 4.1 Blackbody radiation fractions

Example 2 Consider an electrically heated surface used as a heater in a flammability test. What fraction of thermal radiation does this surface emit in the visible range at temperatures of 800 and 1429 K?

Solution The visible range is from 0.4 to 0.7 μm. Thus for the 800 K emitter:

$$(\lambda T)_1 = 0.4\,\mu\text{m} \times 800\,\text{K} = 320\,\mu\text{m}\cdot\text{K and } F_{0\to\lambda_1} = 0.000000$$

$$(\lambda T)_2 = 0.7\,\mu\text{m} \times 800\,\text{K} = 560\,\mu\text{m}\cdot\text{K and } F_{0\to\lambda_2} = 0.000000$$

$$F_{\lambda_1\to\lambda_2} = F_{0\to\lambda_2} - F_{0\to\lambda_1} = 0.000000 - 0.000000 = 0.000000$$

Since the fraction of radiant between 0.4 and 0.7 μm is 0 (to six decimal places), the heater would not appear to be "glowing" at 800 K.

For the 1429 K emitter:

$$(\lambda T)_1 = 0.4\,\mu\text{m} \times 1429\,\text{K} = 572\,\mu\text{m}\cdot\text{K} \text{ and } F_{0\to\lambda_1} = 0.000000$$

$$(\lambda T)_2 = 0.7\,\mu\text{m} \times 1429\,\text{K} = 1000\,\mu\text{m}\cdot\text{K} \text{ and } F_{0\to\lambda_2} = 0.000321$$

$$F_{\lambda_1\to\lambda_2} = F_{0\to\lambda_2} - F_{0\to\lambda_1} = 0.000321 - 0.000000 = 0.000321$$

Since the emission fraction in the visible range is nonzero (albeit very small) the heater would appear to be glowing (if it didn't melt first).

Radiant Intensity and Heat Flux

When analyzing fire phenomena, we usually speak in terms of heat fluxes. For example, a radiant heat flux ($\dot{q}''_r$) of 20 kW/m^2 to the floor is often quoted as a rule of thumb for determining the onset of flashover in a compartment. Consider a target located on the floor of a compartment as it approaches flashover: the radiant heat flux "felt" by this target is the sum of all thermal radiation incident on this target, regardless of where the radiation originated. Some of the radiation incident to the target may have been emitted by flames, another part may have been emitted by the ceiling or walls, and another part may have been emitted by soot particles located in the hot gas layer. Thus, incident radiation comes in from all directions and the radiation felt by the target passes through an imaginary hemisphere surrounding the target. The radiant intensity passing through different parts of this hemisphere will, in general, vary spatially. The radiant intensity passing through part of the hemisphere facing the flames is likely greater than the radiant intensity passing through part of the hemisphere facing away from the flames. It is seen that in order properly analyze a radiant heat transfer problem, it is necessary to take into account the directional nature of radiation. The concept of *radiant intensity* is introduced as a tool to analyze the directional nature of thermal radiation.

Radiant intensity is defined on a per unit solid angle (Ω, sr or steradians) basis. The surface area of a sphere having radius r is $4\pi r^2$ and a unit sphere, i.e. a sphere with a radius of 1, has a surface area of 4π. The solid angle subtended by a surface is the area of a unit sphere covered by the surface's projection onto that unit sphere. For example, a hemisphere subtends a solid angle of 2π steradians, and all space subtends a solid angle of 4π steradians. Referring to the spherical coordinate system in Fig. 4.3, the differential solid angle $d\Omega$ is defined as:

$$d\Omega = \frac{dA}{\left|\vec{R}\right|^2} = \sin(\theta) d\theta d\phi \qquad (4.7)$$

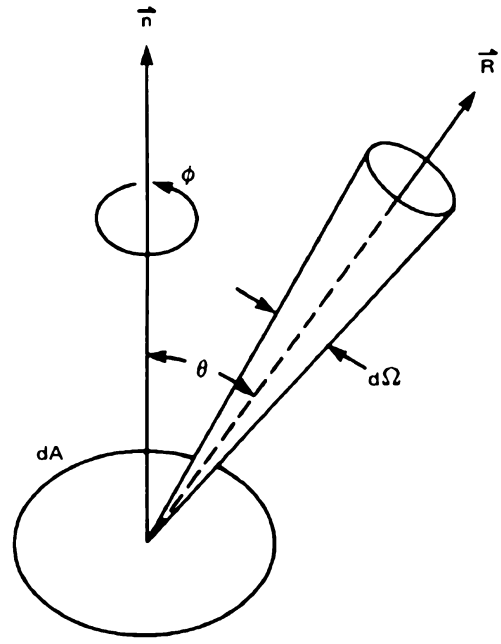

Fig. 4.3 Coordinate system for radiation intensity

where ϕ is azimuthal angle (radians), θ is polar angle (radians), and dA is the differential area normal to the θ and ϕ directions. In simple terms, ϕ can be thought of as degrees longitude and θ can be thought of as degrees latitude on a globe.

Spectral radiant intensity ($W/m^2 \cdot sr \cdot \mu m$) is an inherently directional quantity defined as radiant power per unit area normal to the emitting surface per unit solid angle per unit wavelength:

$$I_\lambda(\lambda, \theta, \phi) = \frac{d\dot{q}}{dA \cdot d\Omega \cdot d\lambda} \tag{4.8}$$

The radiant heat flux at a single wavelength across a surface of an arbitrary orientation is the spectral radiant heat flux [5, 6]:

$$\begin{aligned} \dot{q}''_\lambda(\lambda) &= \int_0^{4\pi} I_\lambda(\lambda, \theta, \phi) \cos(\theta) d\Omega \\ &= \int_0^{2\pi} \int_0^{\pi/2} I_\lambda(\lambda, \theta, \phi) \cos(\theta) \sin(\theta) d\theta d\phi \end{aligned} \tag{4.9}$$

where I_λ is the radiation intensity at wavelength λ per unit solid angle (Fig. 4.3). Intensity is a useful measure for thermal radiation because the intensity of a radiant beam remains constant if it is traveling through a nonparticipating medium. The total radiant heat flux is obtained by integrating Equation 4.9 over all wavelengths:

$$\dot{q}''_r = \int_0^\infty \dot{q}''_\lambda(\lambda) d\lambda \tag{4.10}$$

The salient point here is that radiant intensity is not the same as radiant heat flux. Radiant intensity is a directional (and possibly spectral) quantity. Radiant heat flux is obtained by summing (or integrating) individual contributions over all directions (Equation 4.9) and usually wavelengths (Equation 4.10).

Emission, Irradiation, and Radiosity

Emission

Now define $I_{\lambda,e}(\lambda, \theta, \phi)$ as the spectral intensity of radiation emitted by a surface (subscript "e" means emission or emitted). The emissive power of that surface at wavelength λ is defined in an analogous manner to Equation 4.9, but with $\dot{q}''_\lambda$ replaced by E_λ and I_λ replaced by $I_{\lambda,e}$:

$$\begin{aligned} E_\lambda(\lambda) &= \int_0^{4\pi} I_{\lambda,e}(\lambda, \theta, \phi) \cos(\theta) d\Omega \\ &= \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e}(\lambda, \theta, \phi) \cos(\theta) \sin(\theta) d\theta d\phi \end{aligned} \tag{4.11}$$

It is seen that for a surface at a given temperature, the intensity of emitted radiation depends on wavelength and direction. For engineering applications, this directional dependency of surface emission is usually neglected and we instead (implicitly or explicitly) work with *hemispherical* radiation emission. Hemispherical emission can be envisioned by picturing a small (differential) element located at the center of an imaginary hemispherical enclosure (see Fig. 4.4). Due to the directional dependency of surface emission, the intensity of radiation emitted

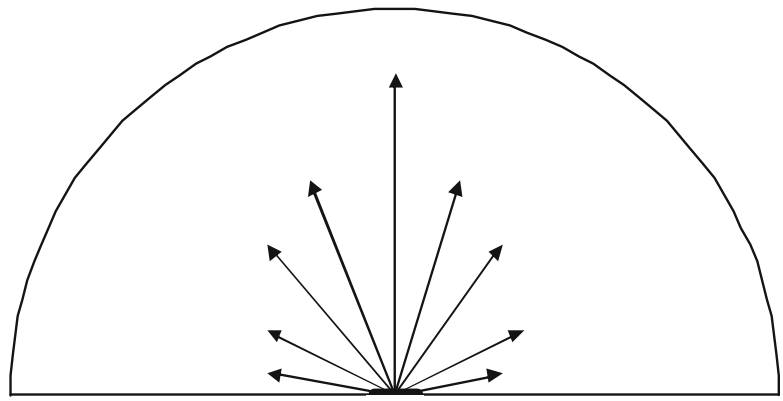

Fig. 4.4 Directional emission from a differential surface. Length of arrows represents spectral directional intensity of emitted thermal radiation

by this surface that impinges on the imaginary hemispherical enclosure may vary with location. However, for engineering purposes, it is usually adequate to neglect the potentially directional character of surface emission and consider only hemispherical emission, meaning the radiant emission that impinges on some part of the imaginary hemispherical enclosure. In practice, this is equivalent to assuming that a surface is a diffuse emitter, meaning the intensity of emitted radiation is independent of direction.

For the reasons described above, in most engineering applications surfaces are approximated as diffuse, which means that $I_{\lambda,e}$ is a constant that does not vary with θ and ϕ, even though emission of thermal radiation from all real surfaces exhibits some directional dependency. Under this diffuse approximation $I_{\lambda,e}$ can be removed from the integrand in Equation 4.11:

$$\begin{aligned} E_\lambda(\lambda) &= \int_0^{2\pi}\int_0^{\pi/2} I_{\lambda,e}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi \\ &= I_{\lambda,e}(\lambda)\int_0^{2\pi}\int_0^{\pi/2}\cos(\theta)\sin(\theta)d\theta d\phi \\ &= \pi I_{\lambda,e}(\lambda) \end{aligned} \tag{4.12}$$

and it is seen that the emissive power of a diffuse surface equals its spectral intensity multiplied by π steradians (for diffuse surfaces $E = \pi I$ and for this reason Equation 4.4 can also be written as $E_{\lambda,b}(\lambda,T) = \pi I_{\lambda,b}(\lambda,T)$). The total emissive power is obtained by integrating over all wavelengths:

$$E = \int_0^\infty E_\lambda(\lambda)d\lambda = \pi I_e \tag{4.13}$$

An important result that is obtained from Equation 4.4 after performing the integration in Equation 4.13 is the Stefan-Boltzman Law, already presented as Equation 4.5.

For a diffuse surface, the fraction of radiation emitted in angle range $\phi_1 \le \phi \le \phi_2$ and $\theta_1 \le \theta \le \theta_2$ can be calculated as:

$$F(\theta_1,\theta_2,\phi_1,\phi_2) = \frac{1}{\pi}\int_{\phi_1}^{\phi_2}\int_{\theta_1}^{\theta_2}\cos(\theta)\sin(\theta)d\theta d\phi \tag{4.14}$$

Example 3 What is the emissive power of a blackbody at 1000 K? What is its emissive power between 1 and 5 μm for all emission angles? What is its emissive power between 1 and 5 μm for $0 \le \phi \le 2\pi$ and $0 \le \theta \le \pi/4$?

Solution Blackbody emissive power is calculated from Equation 4.5:

$$\begin{aligned} E_b &= \sigma T^4 = 5.67\times10^{-8}\times1000^4 \\ &= 56.7\,\mathrm{kW/m^2} \end{aligned}$$

The fraction of this radiation emitted at wavelengths between 1 and 5 μm can be calculated with Equation 4.6 and Table 4.1 as follows:

$$(\lambda T)_1 = 1\,\mu\mathrm{m}\times1000\,\mathrm{K} = 1000\,\mu\mathrm{m}\cdot\mathrm{K} \text{ and } F_{0\to\lambda_1} = 0.000321$$

$$(\lambda T)_2 = 5\,\mu\mathrm{m}\times1000\,\mathrm{K} = 5000\,\mu\mathrm{m}\cdot\mathrm{K} \text{ and } F_{0\to\lambda_2} = 0.633747$$

$$F_{\lambda_1\to\lambda_2} = F_{0\to\lambda_2} - F_{0\to\lambda_1} = 0.633747 - 0.000321 = 0.633426$$

The emissive power between 1 and 5 μm, for all emission angles, is 56.7 $\mathrm{kW/m^2}\times0.633 = 35.9\,\mathrm{kW/m^2}$.

The fraction of radiation emitted in the direction $0 \le \phi \le 2\pi$ and $0 \le \theta \le \pi/4$ can be calculated from Equation 4.14 as:

$$F(\theta_1,\theta_2,\phi_1,\phi_2)=\frac{1}{\pi}\int_0^{2\pi}\int_0^{\pi/4}\cos(\theta)\sin(\theta)d\theta d\phi$$

$$F(\theta_1,\theta_2,\phi_1,\phi_2)=\frac{1}{\pi}\int_0^{2\pi}\left(-\frac{1}{2}\cos^2(\theta)\Big|_{\theta=0}^{\theta=\pi/4}\right)d\phi$$
$$=\frac{1}{4\pi}\int_0^{2\pi}d\phi=\frac{2\pi}{4\pi}=0.5$$

The emissive power between 1 and 5 μm for this angle range is 35.9 kW/m^2 × 0.5 = 18 kW/m^2.

Irradiation

Spectral irradiation $G_\lambda(\lambda)$ (W/m^2 · μm) is the radiant heat flux at wavelength λ to a surface incident from all directions. It is obtained by integrating the incident spectral radiation intensity over all angles in a manner directly analogous to the way that spectral emissive power was defined in Equation 4.11:

$$G_\lambda(\lambda)=\int_0^{2\pi}\int_0^{\pi/2}I_{\lambda,i}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi \tag{4.15}$$

Total irradiation (G, W/m^2) is obtained by integrating G_λ over all wavelengths:

$$G=\int_0^{\infty}G_\lambda(\lambda)d\lambda \tag{4.16}$$

Note that G_λ has no subscript i (for incident) because by definition irradiation is incident on a surface so the "i" would be redundant. G is the total radiant heat flux incident to a target.

Example 4 A surface is uniformly irradiated with a source having the following characteristics:

$G_\lambda = 0\ \text{kW/m}^2\cdot\mu\text{m}$ for $\lambda \le 2\ \mu\text{m}$
$G_\lambda = 5\ \text{kW/m}^2\cdot\mu\text{m}$ for $2 < \lambda \le 8\ \mu\text{m}$
$G_\lambda = 10\ \text{kW/m}^2\cdot\mu\text{m}$ for $8 < \lambda \le 20\ \mu\text{m}$
$G_\lambda = 0\ \text{kW/m}^2\cdot\mu\text{m}$ for $\lambda > 20\ \mu\text{m}$

What is its total irradiation?

Solution Total irradiation can be calculated from Equation 4.16 as:

$$G=\int_0^{\infty}G_\lambda(\lambda)d\lambda=\int_2^8 5d\lambda+\int_8^{20}10d\lambda$$
$$=5\times(8-2)+10\times(20-8)$$
$$=150\ \text{kW/m}^2$$

Radiosity

As will be discussed later, a certain fraction of radiation impinging on a surface may be reflected by that surface. Thus, the total amount of radiation leaving a surface is the sum of the radiation emitted by that surface plus the radiation reflected by that surface. The total radiation leaving a surface, whether emitted or reflected, is called radiosity, J.

Spectral radiosity J_λ is:

$$J_\lambda(\lambda)=\int_0^{2\pi}\int_0^{\pi/2}I_{\lambda,e,r}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi \tag{4.17}$$

Total radiosity (J, W/m^2) is obtained by integrating J_λ over all wavelengths:

$$J=\int_0^{\infty}J_\lambda(\lambda)d\lambda \tag{4.18}$$

Surface Properties

Thermal radiation may be absorbed at, reflected by, or transmitted through a surface. Imprecisely, absorptivity (α) is the fraction absorbed at the surface, reflectivity (ρ) is the fraction reflected by the surface, and transmissivity (τ) is the fraction transmitted through the surface. It follows from a radiation balance:

$$\alpha+\rho+\tau=1 \tag{4.19}$$

where each property in Equation 4.29 may exhibit spectral and directional characteristics

(but such dependency is not explicitly shown). Additionally, emissivity (ε) is the ratio of the actual amount of radiation emitted by a surface to the maximum possible amount of radiation that could be emitted by that surface if it was a blackbody. These properties are defined more precisely in the sections that follow.

Emissivity

Since no surface can emit more thermal radiation than a blackbody, a logical tool for normalizing thermal emission from real surfaces is the blackbody. Spectral surface emissivity is defined as the ratio of the actual spectral intensity of radiation emitted by a surface to the blackbody spectral intensity:

$$\varepsilon_\lambda(\lambda,\theta,\phi,T) = \frac{I_{\lambda,e}(\lambda,\theta,\phi,T)}{I_{\lambda,b}(T)} \tag{4.20}$$

As described earlier, hemispherical radiation quantities are usually applied in engineering applications. The spectral hemispherical emissivity is defined in terms of the blackbody emissive power at wavelength λ and is obtained by integrating Equation 4.20 over all directions with the result:

$$\varepsilon_\lambda(\lambda,T) = \frac{E_\lambda(\lambda,T)}{E_{\lambda,b}(\lambda,T)} \tag{4.21}$$

Spectral normal emissivity (very close to hemispherical emissivity) is shown for several materials in Fig. 4.5 [4].

Total emissivity is obtained by integrating Equation 4.21 over all wavelengths:

$$\varepsilon(T) = \frac{E(T)}{E_b(T)} \tag{4.22}$$

By definition, the emissivity of a blackbody (whether $\varepsilon_\lambda(\lambda, \theta, \phi, T)$, $\varepsilon_\lambda(\lambda, T)$, or $\varepsilon(T)$) is unity. Total normal emissivity (very close to hemispherical emissivity) is shown graphically in Fig. 4.6 for several materials [4]. Representative values of total hemispherical emissivity are tabulated for several materials in Table 4.2 [7] (metals) and Table 4.3 [7] (non-metals).

Absorptivity

In a fire, one of the most important radiative characteristics of a material or surface is its absorptivity, defined loosely as the fraction of the incident radiation that is absorbed by the material. The absorptivity is strongly

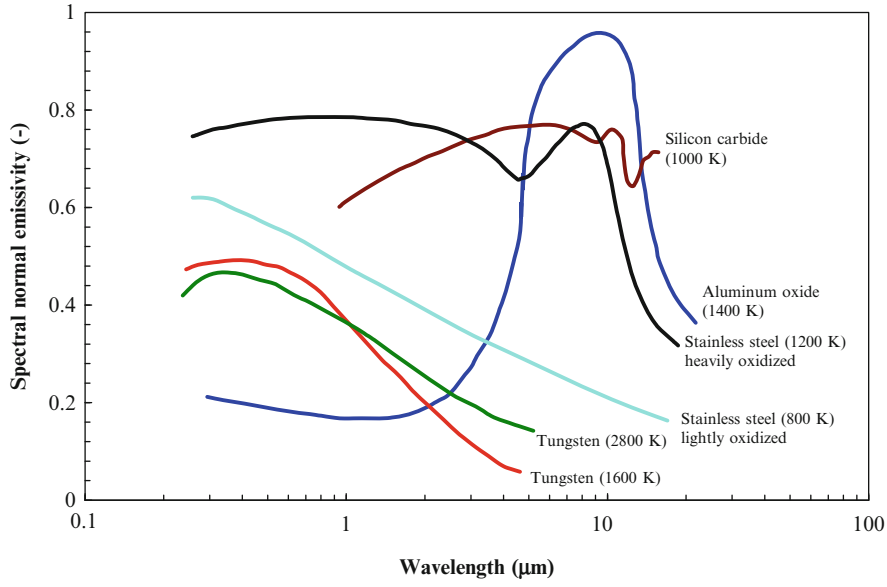

Fig. 4.5 Spectral normal emissivity of several materials [4]

	Tiles, asbestos cement	0.66 (1400 °C)
	Weathered asphalt	0.88 (1400 °C)

(continued)

Table 4.3 (continued)

Material	Description	Emissivity
Rubber	Hard, black, glossy	0.95 (40 °C)
	Soft, gray	0.86 (40 °C)
Snow	Fine	0.82 (−10 °C)
	Frost	0.98 (0 °C)
	Granular	0.89 (−10 °C)
Soils	Black loam	0.66 (20 °C)
	Plowed field	0.38 (20 °C)
Water		0.92–0.96 (0–40 °C)
Wood	Beech	0.91 (70 °C)
	Oak, planed	0.91 (40 °C)
	Sawdust	0.75 (40 °C)
	Spruce, sanded	0.82 (100 °C)

wavelength–dependent. For example, at wavelengths below 1 μm the absorptivity of clear Polymethylmethacrylate is close to zero, but at wavelengths above 3 μm it approaches unity.

A blackbody absorbs all incident radiation with no spectral or directional dependency. As with emissivity, the idealized blackbody behavior is used as a normalization tool to quantify the amount of radiation absorbed by a surface relative to the maximum possible amount the surface may absorb (i.e., if it was a blackbody).

Spectral radiant intensity incident on a surface is denoted $I_{\lambda,i}$; it is, in general, a function of λ, θ, and ϕ. Spectral, directional absorptivity is the ratio if the spectral directional radiant intensity absorbed by a surface $I_{\lambda,i,abs}(\lambda, \theta, \phi)$ to the spectral directional radiant intensity incident on that surface $I_{\lambda,i}(\lambda, \theta, \phi)$ (because the latter is the maximum possible radiation that could be absorbed by that surface, i.e. if it was a blackbody):

$$\alpha_\lambda(\lambda,\theta,\phi) = \frac{I_{\lambda,i,abs}(\lambda,\theta,\phi)}{I_{\lambda,i}(\lambda,\theta,\phi)} \tag{4.23}$$

Spectral hemispherical absorptivity, a directionally-averaged property that is obtained by integrating over all incident angles, is the ratio of the spectral irradiation absorbed by the surface ($G_{\lambda,abs}$) to the spectral irradiation of the surface G_λ:

$$\begin{aligned}\alpha_\lambda(\lambda) &= \frac{\int_0^{2\pi}\int_0^{\pi/2} I_{\lambda,i,abs}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi}{\int_0^{2\pi}\int_0^{\pi/2} I_{\lambda,i}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi} \\ &= \frac{G_{\lambda,abs}(\lambda)}{G_\lambda(\lambda)}\end{aligned} \tag{4.24}$$

Finally, total hemispherical absorptivity is obtained by integrating spectral hemispherical absorptivity over all wavelengths:

$$\begin{aligned}\alpha &= \frac{\int_0^\infty G_{\lambda,abs}(\lambda)d\lambda}{\int_0^\infty G_\lambda(\lambda)d\lambda} = \frac{\int_0^\infty \alpha_\lambda(\lambda)G_\lambda(\lambda)d\lambda}{\int_0^\infty G_\lambda(\lambda)d\lambda} \\ &= \frac{G_{abs}}{G}\end{aligned} \tag{4.25}$$

Example 5 A particular diffuse material is idealized as having a spectral absorptivity of zero for wavelengths less than 3 μm and unity for wavelengths greater than 3 μm. Calculate its total hemispherical absorptivity for a blackbody at 800, 1200, and 2000 K.

Solution Assume $G_\lambda(\lambda) = E_{\lambda,b}(\lambda,\mathrm{T}_e)$ where T_e is the temperature of the emitter (800, 1200, and 2000 K) and use Equation 4.25:

$$\alpha(T_e) = \frac{\int_0^\infty \alpha_\lambda(\lambda)E_{\lambda,b}(\lambda,T_e)d\lambda}{\int_0^\infty E_{\lambda,b}(\lambda,T_e)d\lambda} = \frac{\int_0^3 0\times E_{\lambda,b}(\lambda,T_e)d\lambda + \int_3^\infty 1\times E_{\lambda,b}(\lambda,T_e)d\lambda}{\sigma T_e^4} = \frac{\int_3^\infty E_{\lambda,b}(\lambda,T_e)d\lambda}{\sigma T_e^4}$$

It is possible to put this in a form that allows use of the radiation fraction tabulated in Table 4.1:

$$\alpha = \frac{\int_0^\infty E_{\lambda,b}(\lambda, T_e)d\lambda - \int_0^3 E_{\lambda,b}(\lambda, T_e)d\lambda}{\sigma T_e^4}$$

$$= \frac{\sigma T_e^4 - \int_0^3 E_{\lambda,b}(\lambda, T_e)d\lambda}{\sigma T_e^4}$$

$$= 1 - \frac{\int_0^3 E_{\lambda,b}(\lambda, T_e)d\lambda}{\sigma T_e^4} = 1 - F_{0\to 3}(3T_e)$$

For $T_e = 800$ K, $\lambda T_e = 2400\ \mu$m · K and from Table 4.1 $F_{0\to 3} = 0.14$ so $\alpha = 0.86$.
For $T_e = 1200$ K, $\lambda T_e = 3600\ \mu$m · K and from Table 4.1 $F_{0\to 3} = 0.40$ so $\alpha = 0.60$.
For $T_e = 2000$ K, $\lambda T_e = 6000\ \mu$m · K and from Table 4.1 $F_{0\to 3} = 0.76$ so $\alpha = 0.24$.

It is seen that, for this idealized material, the effective absorptivity is a strong function of emitter temperature.

In a fire we are usually interested in the total hemispherical absorptivity defined in Equation 4.25. However, as demonstrated above, the total hemispherical absorptivity depends on the spectral energy distribution of the radiation source. Therefore, a material technically cannot be assigned a single absorptivity value because the spectral distribution of the incoming radiation depends on the temperature of the emitter. Due to Wien's displacement law and the Planck distribution, this is true even if the emitter behaves as a blackbody. In fires, the temperature of radiation sources ranges from approximately ~600 K (smoke layer, hot surfaces) to ~2000 K (flames). Additionally, certain bench–scale fire tests use tungsten–filament heaters that operate at temperatures near 3000 K. Thus, the effect of source temperature on the integrated (or effective) absorptivity has relevance for both real fires and bench-scale fire testing.

Hallman's 1971 Ph.D. dissertation [8] and subsequent publications [9, 10] remain some of the most comprehensive sources of information on the change of polymers' total hemispherical absorptivity with the temperature of the emitter. Hallman measured the spectral absorptivity of several solids and then determined the integrated surface absorptivity of different solids irradiated by hexane flames, blackbodies between 1000 and 3500 K, and solar energy. His absorptivity data are reproduced in Table 4.4. Note that the total hemispherical absorptivity of some materials is relatively insensitive to the temperature of the radiation source (black PMMA) but others are quite sensitive. For example, the absorptivity of clear PMMA decreases from 0.85 for a 1000 K blackbody to 0.25 for a 3500 K blackbody.

Similar measurements were made by Wesson et al. [11] for undegraded wood. Their results are reproduced in Table 4.5. More recently, Försth and Roos [12] conducted similar measurements for wood products (Table 4.6), carpet (Table 4.7), painted plywood (Table 4.8), and plastics (Table 4.9).

During a fire, a material's radiative characteristics may change. Although the integrated absorptivities from Wesson et al. [11] (reproduced in Table 4.5) are relatively low, the absorptivity of charred wood is generally not the same as that of virgin wood. Janssens [13] suggested that blackening causes the absorptivity of wood to increase from ~0.76 (based on Reference [11]) to approximately unity as the surface temperature approaches the ignition temperature. He therefore used an average value of 0.88 in his ignition analyses, and recommends using an integrated absorptivity of 1.0 during flaming combustion [14]. Interestingly, Försth and Roos [12] noted the opposite trend, i.e. a reduction in effective absorptivity as wood darkens. More research is needed in this area.

Wood is not the only class of materials that exhibits a change in radiative characteristics during a fire. Under nonflaming conditions, low density polyethylene has been observed to change from visually opaque to transparent, eventually followed by a darkening of the surface [15]. This indicates that a change in the material's radiative characteristics occurred (at least in the visible range). Modak and Croce [16] reported that for clear PMMA, 39 % of flame radiation is transmitted through the surface, but for "charred" PMMA (previously exposed to a fire environment and then cooled) no radiation penetrates in depth. Bubbling

Table 4.4 Integrated surface absorptivities for polymers from Hallman [9]

		Blackbody emitter temperature (K)						
Generic name	Trade name	1000	1500	2000	2500	3000	3500	Flame

Redwood	0.77	0.51	0.55
Spruce	0.76	0.45	0.35
White pine	0.76	0.49	0.43
Masonite	0.75	0.52	0.61

occurring near the surface of polymers can change their radiative characteristics, but this effect is has not yet been reliably quantified. In a real fire, materials may become coated in soot from flames or a smoke layer, causing their absorptivities to approach unity.

Reflectivity

A fraction of radiation incident on a surface may be reflected. One complicating factor is that reflection may be diffuse, specular, or (most likely) some combination of these two idealizations. A diffuse reflector is a surface for which, analogous to a diffuse emitter, the intensity of reflected radiation is equal in all directions and does not depend on the angle of incoming

Table 4.6 Effective absorptivities for different grey body temperatures for various wood products (From Försth and Roos [12])

Grey body emitter T (K)	674	852	1025	1153	1300	5777

radiation. This contrasts to a specular emitter which is an idealized surface where the angle of reflected radiation is equal to the angle of incident radiation, like a billiard ball bouncing off the rail. Rough surfaces approximate diffuse emitters, and polished surfaces are close to specular surfaces. It is seen that, in its most general form, surface reflection is a bidirectional process meaning the intensity of reflected radiation depends not only on the angle of incident radiation, but also on the angle of reflected radiation. As a simplification, we look only at hemispherically-integrated reflection. Then the spectral directional reflectivity is defined as the ratio of the reflected spectral radiant intensity to the incident spectral radiant intensity:

$$\rho_\lambda(\lambda,\theta,\phi) = \frac{I_{\lambda,i,ref}(\lambda,\theta,\phi)}{I_{\lambda,i}(\lambda,\theta,\phi)} \tag{4.26}$$

note that in Equation 4.26, θ and ϕ refer to the direction of the incident radiation, not the reflected radiation (since, for simplification, no consideration is given to the direction of reflected radiation). Spectral hemispherical reflectivity is obtained by integrating over all incident angles:

Table 4.8 Effective absorptivities for different grey body temperatures for various paints painted on plywood (From Försth and Roos [12])

Grey body emitter T (K)	674	852	1025	1153	1300	5777

$$\rho_\lambda(\lambda) = \frac{\int_0^{2\pi}\int_0^{\pi/2} I_{\lambda,i,ref}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi}{\int_0^{2\pi}\int_0^{\pi/2} I_{\lambda,i}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi} = \frac{G_{\lambda,ref}(\lambda)}{G_\lambda(\lambda)} \tag{4.27}$$

Final, total hemispherical reflectivity is obtained by integrating over all wavelengths:

$$\rho = \frac{\int_0^\infty G_{\lambda,ref}(\lambda)}{\int_0^\infty G_\lambda(\lambda)} = \frac{G_{ref}}{G} \tag{4.28}$$

Transmissivity

Directional spectral transmissivity is defined in an analogous manner to the other radiation properties discussed here:

$$\tau_\lambda(\lambda,\theta,\phi) = \frac{I_{\lambda,i,trans}(\lambda,\theta,\phi)}{I_{\lambda,i}(\lambda,\theta,\phi)} \tag{4.29}$$

Hemispherical spectral transmissivity is:

$$\tau_\lambda(\lambda) = \frac{\int_0^{2\pi}\int_0^{\pi/2} I_{\lambda,i,trans}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi}{\int_0^{2\pi}\int_0^{\pi/2} I_{\lambda,i}(\lambda,\theta,\phi)\cos(\theta)\sin(\theta)d\theta d\phi} = \frac{G_{\lambda,trans}(\lambda)}{G_\lambda(\lambda)} \tag{4.30}$$

And total transmissivity is then obtained by integrating over all wavelengths:

$$\tau = \frac{\int_0^\infty G_{\lambda,trans}(\lambda)}{\int_0^\infty G_\lambda(\lambda)} = \frac{G_{trans}}{G} \tag{4.31}$$

Kirchhoff's Law: Relation Between Emissivity and Absorptivity

Kirchoff's law is used extensively in radiation heat transfer calculations. In its most general form, Kirchoff's law states that in order to maintain thermal equilibrium, the spectral directional absorptivity must be equal to the spectral directional emissivity:

$$\alpha_\lambda(\lambda,\theta,\phi) = \varepsilon_\lambda(\lambda,\theta,\phi,T) \tag{4.32}$$

Using the relations presented earlier in the chapter, it can be shown that if the irradiation is diffuse *or* the surface is diffuse, then Kirchoff's law has no directional dependency, i.e.:

$$\alpha_\lambda(\lambda) = \varepsilon_\lambda(\lambda,T) \tag{4.33}$$

If Equation 4.33 applies (i.e., the irradiation is diffuse or the surface is diffuse), then if the surface is also *gray* (meaning α_λ and ε_λ are invariant with λ) *or* the surface is irradiated only by radiation emitted from a blackbody at the same temperature as the surface, its total absorptivity is equal to its total emissivity:

$$\alpha = \varepsilon \tag{4.34}$$

For engineering calculations, Equation 4.34 is most commonly applied for the special case of diffuse and gray surfaces. Fortunately, this is a reasonable approximation for many radiation heat transfer engineering models for participating media in fire applications.

Although real surfaces may exhibit an emissivity that varies with wavelength (see Fig. 4.7), an effective emissivity can be selected so that the integrated emissive power of the gray surface matches the integrated emissive power of the real surface at a particular temperature.

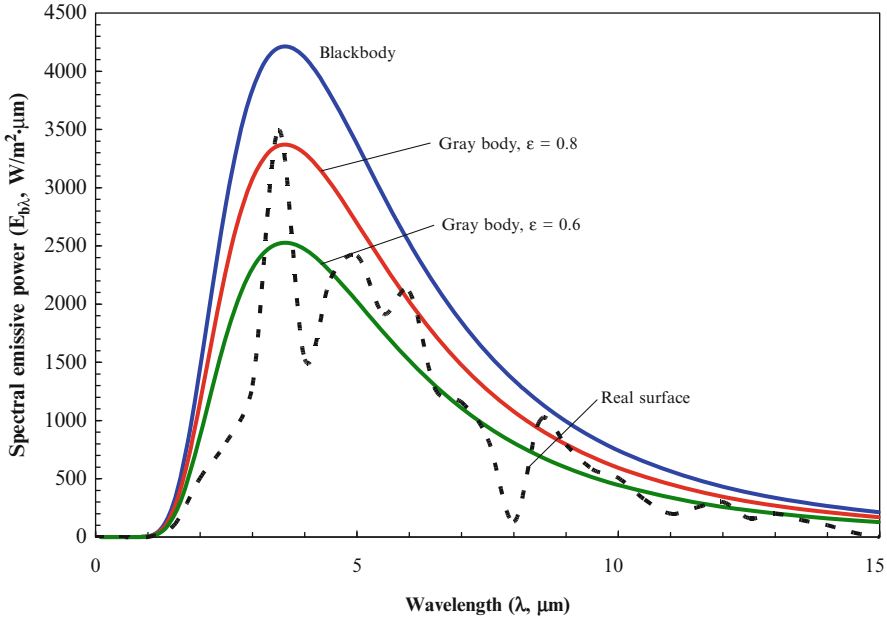

Fig. 4.7 Monochromatic emissive power for black body, two gray bodies, and real surface

Radiant Heat Transfer in Nonparticipating Media

In this section, cases are examined where the surfaces are separated by a medium that does not emit, absorb, or scatter radiation. A vacuum meets this requirement exactly, and common diatomic gases of symmetric molecular structure such as N_2, O_2, and H_2 are very nearly nonparticipating media within the thermal radiation spectrum. The radiative energy transfer between the surfaces depends on the geometry, orientation, temperature, and radiation properties of the surfaces. In practice, surfaces are usually idealized as isothermal, diffuse, and gray to make engineering calculations tractable. The geometry and orientation of each surface is commonly accounted for in calculations by one or more configuration factors, also known as view factors, shape factors, angle factors, and geometric factors [1–7, 17–19].

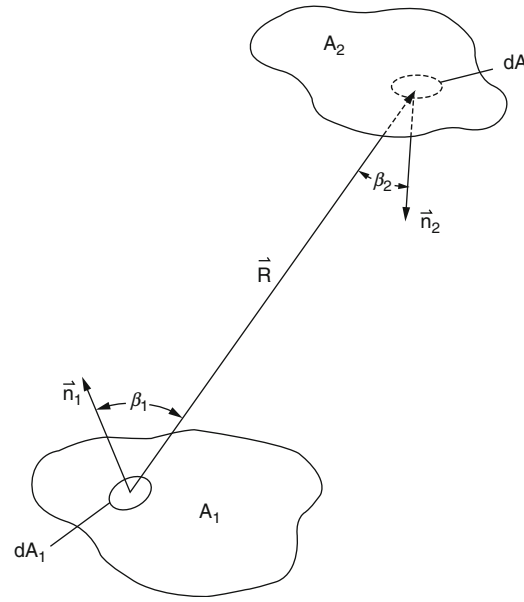

Fig. 4.8 Coordinate system for shape factors

View Factors

A view factor, or configuration factor, is a purely geometrical relation between two surfaces. It is defined as the fraction of radiation leaving one surface which is intercepted by the other surface.

Consider the two arbitrarily oriented surfaces A_1 and A_2 in Fig. 4.8. Assuming that the radiosity from differential area dA_1 is diffuse, the

configuration factor from dA_1 to the finite area A_2, $F_{d1\,-\,2}$, is given by

$$F_{d1-2} = \int_{A_2} \frac{\cos(\beta_1)\cos(\beta_2)}{\pi\left|\vec{R}\right|^2} dA_2 \qquad (4.35)$$

where the separation distance between the two surfaces is $\left|\vec{R}\right|$, β is the angle between the line of sight $\vec{R}$ and the surface normal $\vec{n}$, and A_2 is the area of surface 2. If the radiosity from all of surface A_1 (not just differential are dA_1) is diffuse, then the configuration factor for the finite area A_1 to A_2, $F_{1\,-\,2}$, is calculated as:

$$F_{1-2} = \frac{1}{A_1}\int_{A_1}\int_{A_2} \frac{\cos(\beta_1)\cos(\beta_2)}{\pi\left|\vec{R}\right|^2} dA_1 dA_2 \qquad (4.36)$$

All configuration factors can be derived using the multiple integration of Equations 4.35 and 4.36, but this is generally very tedious except for simple geometries. Several cases have been tabulated with the numerical results or algebraic formulas available in various references [1–7, 17, 18]. Several configuration factors are provided in Appendix D.

The configuration factors in Appendix D can be extended to other geometries by using configuration factor algebra and the method of surface decomposition. In surface decomposition, unknown factors can be determined from known factors for convenient areas or for imaginary surfaces which can extend real surfaces or form an enclosure [1, 6].

When the radiant fluxes from both surfaces are uniformly and diffusely distributed (a common engineering assumption), a reciprocity relation for any given pair of configuration factors in a group of exchanging surfaces is:

$$A_i F_{i-j} = A_j F_{j-i} \qquad (4.37)$$

The summation rule is another useful relation for calculating unknown configuration factors

$$\sum_j F_{i-j} = 1 \qquad (4.38)$$

where F_{i-j} relate to surfaces that subtend a closed system. It is possible for a concave surface to "see" itself, which can make F_{i-i} important in certain situations.

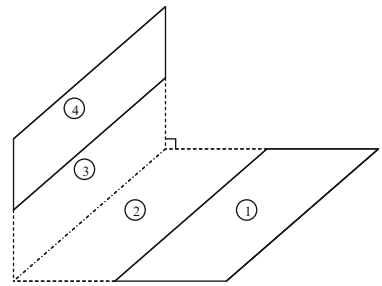
In many cases, it is advantageous to define a single surface (j) as a composite surface consisting of multiple (real or imaginary) surfaces (k), i.e.:

$$A_j = \sum A_k \qquad (4.39)$$

For a composite surface j, made up of multiple surfaces k, since view factors are additive:

$$F_{ij} = \sum A_{ik} \qquad (4.40)$$

Example 6 For the geometry shown below, use shape factor algebra to develop an expression for the view factor between surface 1 and surface 4 that could be evaluated from the shape factor relations provided in Appendix D.



Solution The desired view factor is F_{14}. For simplicity of nomenclature, denote surface A as a composite surface made up of surfaces 1 and 2. Similarly, denote surface B as a composite surface made up of surfaces 3 and 4. Then, from the additive property of shape factors:

$$A_A F_{AB} = A_1 F_{1B} + A_2 F_{2B}$$

Both F_{AB} and F_{2B} can be calculated from the appropriate shape factor in Appendix D. Note that

$$F_{1B} = F_{13} + F_{14}$$

$$F_{13} = F_{A3} - F_{23}$$

Combining these two equations gives an expression for F_{1B}:

$$F_{1B} = F_{A3} - F_{23} + F_{14}$$

Substituting this expression into the first equation above:

$$\begin{aligned} A_A F_{AB} &= A_1(F_{A3} - F_{23} + F_{14}) + A_2 F_{2B} \\ &= A_1 F_{A3} - A_1 F_{23} + A_1 F_{14} + A_2 F_{2B} \end{aligned}$$

Solving for F_{14}:

$$\begin{aligned} F_{14} &= \frac{1}{A_1}(A_A F_{AB} - A_2 F_{2B} - A_1 F_{A3} + A_1 F_{23}) \\ &= \frac{1}{A_1}(A_A F_{AB} - A_2 F_{2B}) + F_{23} - F_{A3} \end{aligned}$$

Note that all of the view factors in the above example can be evaluated from the shape factor relations provided in Appendix D.

Gray Diffuse Surfaces

For engineering applications, thermal emission from most surfaces is treated as having diffuse directional characteristics independent of wavelength and temperature. Real surfaces exhibit radiation properties that are so complex that information about these property measurements for many common materials is not available. The gray diffuse surface is a useful model that alleviates many of the complexities associated with a detailed radiation analysis, while providing reasonably accurate results in many practical situations. The advantage of diffuse surface analysis is that radiation leaving the surface is independent of the direction of the incoming radiation, which greatly reduces the amount of computation required to solve the governing equations. Discussions for specularly reflecting surfaces and nongray surfaces can be found in the literature [1, 6].

A convenient method to analyze radiative energy exchange in a diffuse gray enclosure relies on the concepts of radiosity and irradiation introduced earlier. The irradiation of surface i (G_i) is the radiative flux reaching the i^{th} surface regardless of its origin:

$$G_i = \sum_j F_{i-j} J_j \tag{4.41}$$

where J_j is the surface radiosity, defined as the total radiative flux leaving the j^{th} surface including both emitted and reflected radiation:

$$J_i = E_i + \rho_i G_i = \varepsilon_i E_{bi} + \rho_i G_i \tag{4.42}$$

The net rate at which radiation leaves surface i is given by

$$\begin{aligned} Q_i &= A_i(J_i - G_i) = A_i(E_i + \rho_i G_i - G_i) \\ &= A_i(E_i - G_i(1 - \rho_i)) \\ &= A_i(E_i - \alpha_i G_i) \end{aligned} \tag{4.43}$$

since, for a diffuse gray opaque surface $\rho_i = 1 - \alpha_i$. It must be emphasized that the radiosity-irradiation formulation is based on the assumption that each surface has uniform radiosity and irradiation (or equivalently, uniform temperature and uniform heat flux). Physically unrealistic calculations can result if each surface does not approximately satisfy this condition. Larger surfaces should be subdivided into smaller surfaces if necessary.

The radiosity-irradiation formulation allows a more physical and graphic interpretation using the resistance network analogy. Eliminating the irradiation G_i from Equations 4.41, 4.42 and 4.43, and substituting $\rho_i = 1 - \varepsilon_i$ gives

$$Q_i = \frac{E_{bi} - J_i}{(1 - \varepsilon_i)/(\varepsilon_i A_i)} = \sum_j \frac{J_i - J_j}{\left(A_i F_{i-j}\right)^{-1}} \tag{4.44}$$

Note that the second equality in Equation 4.44 can be written as:

$$Q_i = \sum_j A_i F_{i-j}\left(J_i - J_j\right) = \sum_j Q_{ij} \tag{4.45}$$

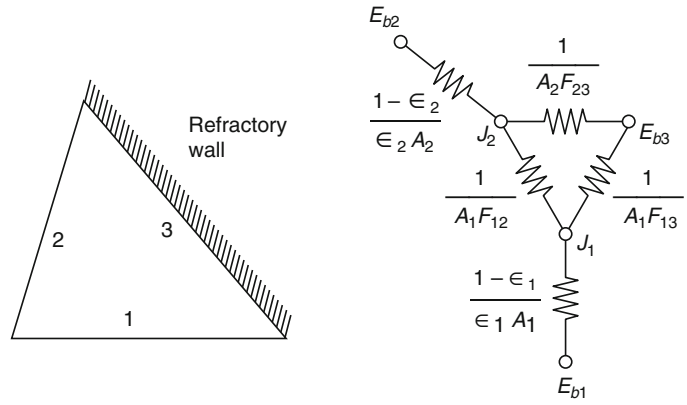


Fig. 4.9 Network analogy for radiative exchange

The denominator in the rightmost term of Equation 4.44 corresponds to resistance in electric circuits. This electrical resistance analogy was first proposed by Oppenheim [20]. As illustrated in Fig. 4.9, the diffuse-gray surface has a radiation potential difference $(E_{bi} - J_i)$ and a resistance $(1 - \varepsilon_i)/\varepsilon_i A_i$. This example also illustrates that an adiabatic surface, such as a reradiating or refractory wall, exhibits a surface temperature that is independent of the surface emissivity or reflectivity.

Thermal Radiation in Participating Media

The Equation of Transfer

The equation of transfer describes the variation in intensity of a radiant beam at any position along its path in an absorbing-emitting-scattering medium. This equation is the foundation upon which detailed radiation analyses are based, and the source of approximate solutions when simplifying assumptions are made. For a given direction line in the medium, the equation of transfer is

$$\frac{1}{\kappa_\lambda(T,S)}\frac{dI_\lambda(S)}{dS} + I_\lambda(S) = I_{\lambda,b}(T) \qquad (4.46)$$

where S represents the physical pathlength and κ_λ represents the spectral extinction coefficient, which includes the effects of both absorption and scattering within the medium. The intensity, $I_\lambda(S)$, is coupled with the spatial distribution of the extinction coefficient and with temperature through conservation of energy in the medium. The contributions of intensity passing through an area must be integrated over all directions to calculate a net radiative energy flux. The integral nature of radiation makes analysis difficult and simplifications necessary for engineering practice.

Spectral Emissivity and Absorptivity

From a microscopic viewpoint, emission and absorption of radiation is attributed to changes in energy levels of atoms and molecules caused by interactions with photons. Tien [21] discusses these effects in gases from an engineering perspective.

Consider a monochromatic beam of radiation passing through a radiating medium of thickness L. For the special case where the temperature and properties of the medium are uniform along this path, the intensity of radiant beam at point x is obtained by integrating Equation 4.46:

$$I_\lambda(x) = I_\lambda(0)\exp(-\kappa_\lambda x) + I_{\lambda,b}(1 - \exp(-\kappa_\lambda x)) \qquad (4.47)$$

which accounts for the loss of intensity by absorption and the gain by emission, and where κ_λ denotes the extinction coefficient. The extinction coefficient is generally the sum of two parts:

the absorption coefficient and the scattering coefficient. In many engineering applications, the effects of scattering are negligible and the extinction coefficient represents only absorption. The spectral emissivity for pathlength S in a uniform gas volume can be readily expressed by considering the case of no incident radiation (or $I_\lambda(0) = 0$):

$$\varepsilon_\lambda = \frac{I_\lambda}{I_{\lambda,b}} = 1 - \exp(-\kappa_\lambda S) \tag{4.48}$$

which compares the fraction of energy emitted to the maximum (blackbody) emission at the same temperature for the pathlength S through the material.

The term $\kappa_\lambda S$ in Equation 4.48 is called optical pathlength or opacity and is denoted τ_λ (not to be confused with transmissivity). It can be defined more generally for nonhomogeneous media as:

$$\tau_\lambda = \int_0^S \kappa_\lambda(x)dx \tag{4.49}$$

If $\tau_\lambda << 1$, the medium is optically thin at wavelength λ and the properties of the participating medium can generally approximated as $\varepsilon_\lambda \approx \tau_\lambda$. The medium is considered optically thick when $\tau_\lambda >> 1$, which implies that the mean penetration distance is much less than the characteristic length of the medium. In optically thick media, as will be described below, the local radiant intensity results only from local emission and the equation of transfer can be approximated by a diffusion equation.

Planck and Rosseland Mean Absorption Coefficients

The mean absorption coefficient is often useful when radiative energy transport theory must be used to describe the local state of a gas at various locations. The mathematical complexity involved in the calculations often dictates a solution based on the gray-gas assumption, where all radiation parameters are considered to be wavelength independent. Thus solutions are given in terms of mean (gray-gas) absorption coefficients representing average properties over the whole spectrum of wavelengths. The appropriate mean absorption coefficients are the Planck mean, κ_P, for optically thin media, and the Rosseland mean, κ_R, for optically thick media [5, 6, 21].

The Planck mean absorption coefficient is defined as

$$\kappa_P \equiv \frac{\int_0^\infty I_{\lambda,b}\kappa_\lambda d\lambda}{\int_0^\infty I_{\lambda,b}d\lambda} = \frac{\pi}{\sigma T^4}\int_0^\infty I_{b\lambda}\kappa_\lambda d\lambda \tag{4.50}$$

This form of the absorption coefficient is a function of temperature alone and is independent of pressure. The effect of the beam source temperature (e.g., a hot or cold wall) in the gas absorptivity is approximated by a ratio correction [21, 22]

$$\kappa_m = \kappa_P(T_s)\frac{T_s}{T_g} \tag{4.51}$$

where T_s is the source temperature and T_g is the gas temperature. When the Planck mean absorption coefficient is used to estimate the emissivity of a gas, the source temperature is set equal to the gas temperature.

The formulation of radiative transfer is simplified when the medium is optically thick. In this case, the radiative transfer can be regarded as a diffusion process (the Rosseland or diffusion approximation), and the governing equation is approximated by:

$$\begin{aligned} q_r'' &\approx -\frac{4}{3}\frac{1}{\kappa_R}\frac{\partial E_{\lambda,b}}{\partial x} = -\frac{4}{3}\frac{1}{\kappa_R}\frac{\partial\left(\sigma T^4\right)}{\partial x} \\ &= -\frac{16\sigma}{3}T^3\frac{1}{\kappa_R}\frac{\partial T}{\partial x} \end{aligned} \tag{4.52}$$

Evaluation of the total heat flux in an optically thick medium is simplified by defining the Rosseland mean absorption coefficient which is independent of wavelength:

$$\frac{1}{\kappa_R} \equiv \int_0^\infty \frac{1}{\kappa_\lambda}\frac{\partial E_{\lambda,b}}{\partial E_b}d\lambda \tag{4.53}$$

In Equation 4.53, $\partial E_{\lambda,b}/\partial E_b$ is evaluated from the Planck distribution after setting $T = (E_b/\sigma)^{1/4}$. The Rosseland mean absorption coefficient is not well defined for gases under ordinary conditions because astronomically long pathlengths are required to make the windows between the bands optically thick. However, the Rosseland limit is useful when dealing with gases in the presence of soot particles, which are characterized by a continuous spectrum. The source temperature effect is accounted for by using Equation 4.51 in the same manner as for the Planck mean absorption coefficient.

The radiating gas in many actual fire systems is neither optically thin nor optically thick, so it may be necessary to use band theory to rigorously calculate a mean absorption coefficient, κ_m. However, with a reasonable estimate of the mean absorption coefficient, radiative transport calculations are much more convenient.

Mean Beam Length for Homogeneous Gas Bodies

The concept of mean beam length is a powerful and convenient tool to calculate the energy flux from a radiating homogeneous gas volume to its boundary surface. It may also be used to approximate radiative energy flux for a nonhomogeneous gas, especially when more elaborate calculations are not feasible. Consider the coordinate system given in Fig. 4.3, where dA is a differential area on the boundary surface of the gas body. The radiative heat flux from the gas body to dA is

$$\dot{q}_r'' = \int_0^\infty \int_\Omega \varepsilon_\lambda(X) I_{\lambda,b} \cos(\theta) d\lambda d\Omega \qquad (4.54)$$

where the spectral emissivity, ε_λ, is a function of pressure pathlength:

$$X \equiv \int_0^S P_a x(\xi) d\xi \qquad (4.55)$$

which in turn varies with solid angle Ω according to the gas body geometry. In practical situations, the calculation of $\dot{q}_r''$ is more convenient in terms of total emissivity, which is often available in chart form. From the definition of total emissivity, Equation 4.54 can be expressed as:

$$\dot{q}_r'' = \frac{\sigma T^4}{\pi} \int_\Omega \varepsilon(X) \cos(\theta) d\Omega \equiv \sigma T^4 \varepsilon(L) \qquad (4.56)$$

which gives the definition of mean beam length, L, for a gas body, where $\varepsilon(L)$ has the same functional form as $\varepsilon(X)$. Physically, the mean beam length represents the equivalent radius of a hemispherical gas body such that it radiates a flux to the center of its base equal to the average flux radiated to the boundary surface by the actual volume of gas. The determination of the mean beam length is simplified when the gas is optically thin and only the geometry of the gas body enters the calculation. In the optically thin limit, it is convenient to define

$$L = L_0 \equiv \frac{1}{\pi} \int_\Omega X \cos(\theta) d\Omega \qquad (4.57)$$

where L_0 is called the geometric mean beam length. In the optically thick limit, a correction factor (C) can be used to obtain reasonable radiative heat flux estimates:

$$L \approx C L_0 \qquad (4.58)$$

In Table 4.10, L_0 and C have been provided for a variety of gas body shapes. For an arbitrarily shaped gas volume, the geometric beam length from the gas volume to the entire boundary surface can be estimated by:

$$L_0 = \frac{4V}{A} \qquad (4.59)$$

where V and A are the volume and the area of the boundary surface of the gas body, respectively. The correction factor C is approximately 0.9.

Table 4.10 Mean beam lengths for various gas body shapes

Thermal Radiation Properties of Combustion Products

Radiation Properties of Gases

The emissivity of any gas is a strong function of wavelength, varying by as much as several orders of magnitude over small changes in wavelength. However, the level of accuracy required in engineering calculations, where many of the parameters are difficult to measure or estimate, seldom requires high resolution emissivity spectra. Where wavelength dependence of radiative heat flux is a concern, gas properties may be calculated using the exponential wide-band model [23]. The uncertainties involved in estimating parameters to calculate radiative heat flux make average properties such as total emissivity a useful tool. The first comprehensive total emissivity charts were formulated by Hottel and coworkers to summarize work performed up to about 1945. Modern formulations for the emissivity of gases have been summarized by Edwards [22].

Total emissivity charts for water vapor and carbon dioxide [22] are provided in Figs. 4.10 and 4.11, respectively. Gas emissivity can be

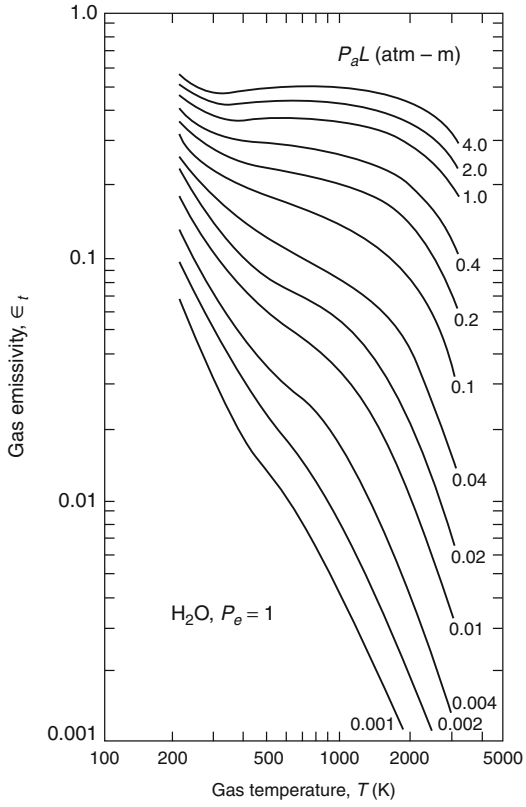

Fig. 4.10 Total emissivity of water vapor

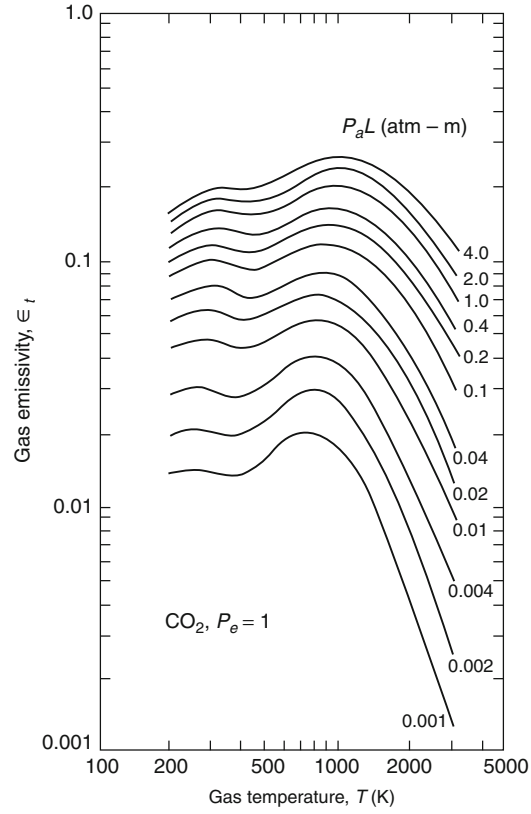

Fig. 4.11 Total emissivity of carbon dioxide

read off these charts from the partial pressure and temperature of each gas and the mean beam length for the gas volume geometry. Correction factors for the chart emissivities are available in the literature for the pressure effect on water vapor emissivity [24], the pressure effect on carbon dioxide emissivity [5, 6], and the band overlap for mixtures of the two gases [25]. For most fire protection engineering applications, the pressure correction factors are 1.0 and the band overlap correction is approximately $\Delta\varepsilon \approx \frac{1}{2}\varepsilon_{CO_2}$ for medium to large fires. Assuming the carrier gas is transparent (e.g., air), the emissivity is:

$$\varepsilon_g = C_{H_2O}\varepsilon_{H_2O} + C_{CO_2}\varepsilon_{CO_2} - \Delta\varepsilon \approx \varepsilon_{H_2O} + \frac{1}{2}\varepsilon_{CO_2} \tag{4.60}$$

At temperatures below 400 K, the older charts by Hottel [5, 6] may be more reliable than the charts in Figs. 4.10 and 4.11, and the use of wide-band models is advised to estimate the band overlap correction instead of using the correction charts at these lower temperatures [26]. For crucial engineering decisions, wide-band model block calculations as detailed by Edwards [22] are recommended over the graphical chart method to determine total emissivity.

Other gases such as sulfur dioxide, ammonia, hydrogen chloride, nitric oxide, and methane have been summarized in chart form [5]. The carbon monoxide chart by Hottel is not recommended for use [27] due to uncertainties most likely introduced by traces of carbon dioxide in the original experiments. Spectral and total properties have been published for some of the important hydrocarbon gases, e.g., methane, acetylene, and propylene [28–30]. Mixtures of several hydrocarbon gases are subject to band

overlapping, and appropriate corrections must be made to avoid overestimating total emissivity of a mixture of fuels.

The total emissivity for a gas in the optically thin limit can be calculated from the Planck mean absorption coefficient. Graphs of the Planck mean absorption coefficient for various gases that are important in fires are shown in Fig. 4.12, which can be used with Equation 4.48 to estimate the total emissivity (by assuming that total properties represent a spectral average value).

Radiation Properties of Soot

In a nonhomogeneous (e.g., with soot) medium, scattering becomes an important radiative mechanism in addition to absorption and emission. The absorption and scattering behavior of a single particle can be described by solving the electromagnetic field equations; however, many physical idealizations and mathematical approximations are necessary. The most common assumptions include perfectly spherical particles, uniformly or randomly distributed particles, and interparticle spacing so large that the radiation for each particle can be treated independently.

Soot particles are produced as a result of incomplete combustion and are usually observed to be in the form of spheres, agglomerated chunks, and long chains. They are generally very small (50–1000 Å where 1 Å $= 10^{-10}$ m $= 10^{-4}$ μm) compared to infrared wavelengths, so that the Rayleigh limit is applicable to the calculation of radiation properties [31, 32]. Soot particles are normally characterized by their optical properties, size, shape, and chemical composition (hydrogen-carbon ratio). From a heat transfer viewpoint, radiation from a soot cloud is predominantly affected by the particle size distribution and can be considered independent of the chemical composition [31]. Soot optical properties are relatively insensitive to temperature changes at elevated temperatures, but as shown in Fig. 4.13, room temperature values representative of soot in smoke do show appreciable deviations.

By choosing appropriate values of optical constants for soot, the solution for the electromagnetic field equations gives [33]

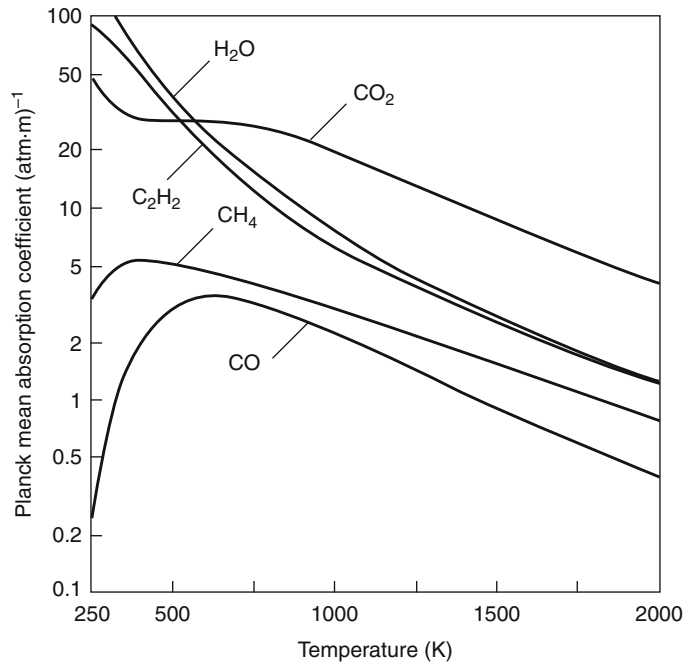

Fig. 4.12 Planck mean absorption coefficient for various gases

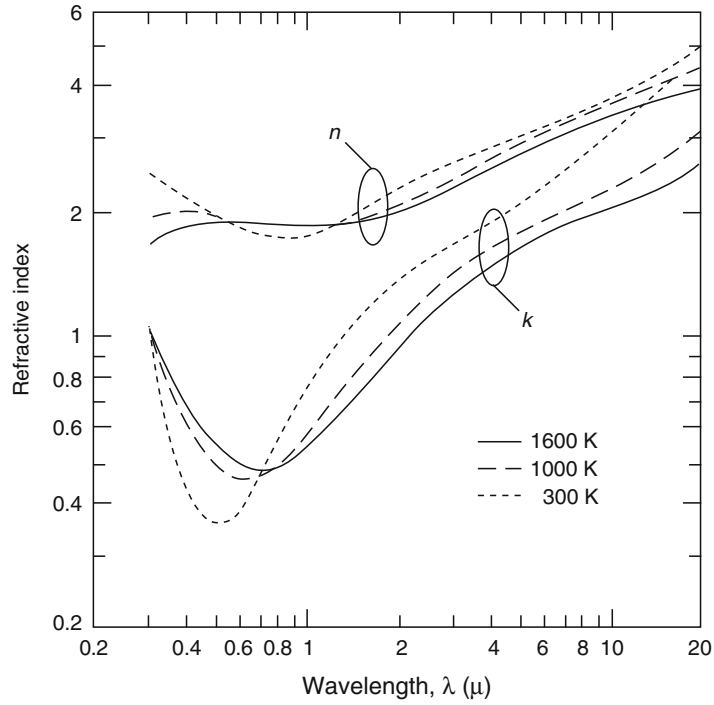

Fig. 4.13 Optical constants for soot

$$k_\lambda = \frac{C_0}{\lambda} f_v \tag{4.61}$$

where f_v is the soot volume fraction (generally about 10^{-6} in flames) and C_0, a constant between 2 and 6 dependent on the complex index of refraction $m = n - ik$, is given by

$$C_0 = \frac{36\pi nk}{\left(n^2 - k^2 + 2\right)^2 + 4n^2k^2} \tag{4.62}$$

Equations 4.61 and 4.62 can be used to evaluate the Planck mean absorption coefficient in the optically thin limit [34], giving:

$$\kappa_P = 3.83 \frac{C_0}{C_2} f_v T \tag{4.63}$$

where C_2 is Planck's second constant (1.4388×10^{-2} m-K). The Rosseland mean absorption coefficient in the optically thick limit is

$$\kappa_R = 3.6 \frac{C_0}{C_2} f_v T \tag{4.64}$$

A mean coefficient that may be used for the entire range of optical thickness is suggested as

$$\kappa_R = 3.72 \frac{C_0}{C_2} f_v T \tag{4.65}$$

to be used in Equation 4.66 for the soot radiation calculations. Typical temperatures, volume fractions, and mean absorption coefficients for soot particles in the luminous flames of various fuels are tabulated in Table 4.11.

Radiation Properties of Gas-Soot Mixtures

The calculation of the total emissivity of a gas-soot mixture requires information on basic flame parameters such as soot volume fraction, soot absorption coefficient, temperature and geometric length of the flame, and partial pressure of the participating gas components [35]. These parameters can be estimated for various types of

Table 4.11 Radiative properties for soot particles

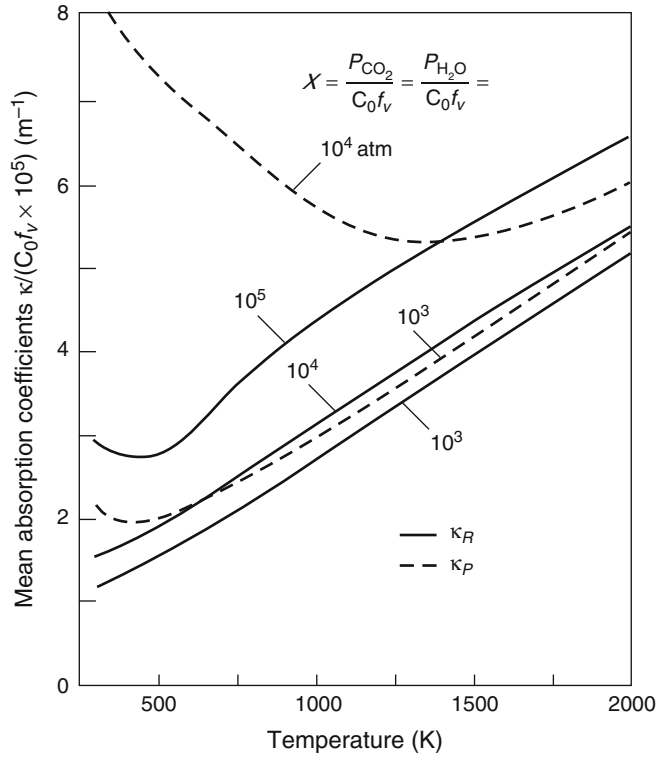

Fig. 4.14 Mean absorption coefficients for luminous flames and smoke

fuel when actual measurements are unavailable for a particular situation. The following equation is a good approximation [36] for total emissivity of homogeneous gas-soot mixtures:

$$\varepsilon_t = (1 - \exp(-\kappa S)) + \varepsilon_g \exp(-\kappa_s S) \quad (4.66)$$

where S is the physical pathlength, ε_g is the total emissivity of the gas alone, and κ_s is the effective absorption coefficient of the soot. The Planck mean absorption coefficients for gas-soot mixtures in luminous flames and smoke are shown in Fig. 4.14.

Application to Flame and Fire

Heat Flux Calculation from a Flame

Prediction of the radiative heat flux from a flame is important in determining ignition and fire spread hazard, and in the development of fire detection devices. The shape of flames under actual conditions is transient, which makes detailed radiation analysis cumbersome. In most calculations, flames are idealized as simple geometric shapes such as plane layers or axisymmetric cylinders and cones. A cylindrical geometry, shown in Fig. 4.15, will be analyzed here and used in a sample calculation.

Assuming κ_λ is independent of pathlength, integration of the transport equation (Equation 4.48) yields [37]

$$I_\lambda = I_{b\lambda}\left(1 - \exp\left(\frac{-2\kappa_\lambda}{\sin(\theta)}\sqrt{r^2 - L^2\cos^2(\phi)}\right)\right) \tag{4.67}$$

where θ, ϕ. r, and L are geometric variables defined in Fig. 4.15. The monochromatic radiative heat flux on the target element is given by

$$\frac{d\dot{q}_r''}{d\lambda} = \int_\Omega \frac{I_\lambda}{\left|\vec{R}\right|}\left(\vec{n}\cdot\vec{R}\right)d\Omega \tag{4.68}$$

Where $\vec{n}$ is a unit vector normal to the target element dA and $\vec{R}$ is the line-of-sight vector extending between dA and the far side of the flame cylinder. Evaluation of Equation 4.68 is quite lengthy, but under the condition of $L/r \geq 3$, it can be simplified to [37]

$$\frac{d\dot{q}_r''}{d\lambda} = \pi I_{\lambda,b}\varepsilon_\lambda(F_1 + F_2 + F_3) \tag{4.69}$$

where the shape factor constants and emittance are defined as

$$F_1 = \frac{u}{4\pi}\left(\frac{r}{L}\right)^2(\pi - 2\theta_0 + \sin(2\theta_0)) \tag{4.70a}$$

$$F_2 = \frac{v}{4\pi}\left(\frac{r}{L}\right)(\pi - 2\theta_0 + \sin(2\theta_0)) \tag{4.70b}$$

$$F_3 = \frac{w}{\pi}\left(\frac{r}{L}\right)\cos^2(\theta_0) \tag{4.70c}$$

$$\varepsilon_\lambda = 1 - \exp(-0.7\mu_\lambda) \tag{4.71}$$

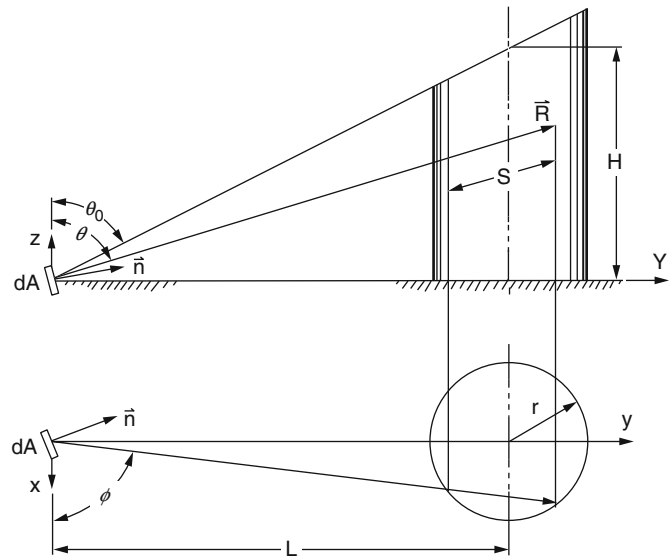

Fig. 4.15 Schematic of a cylindrical flame

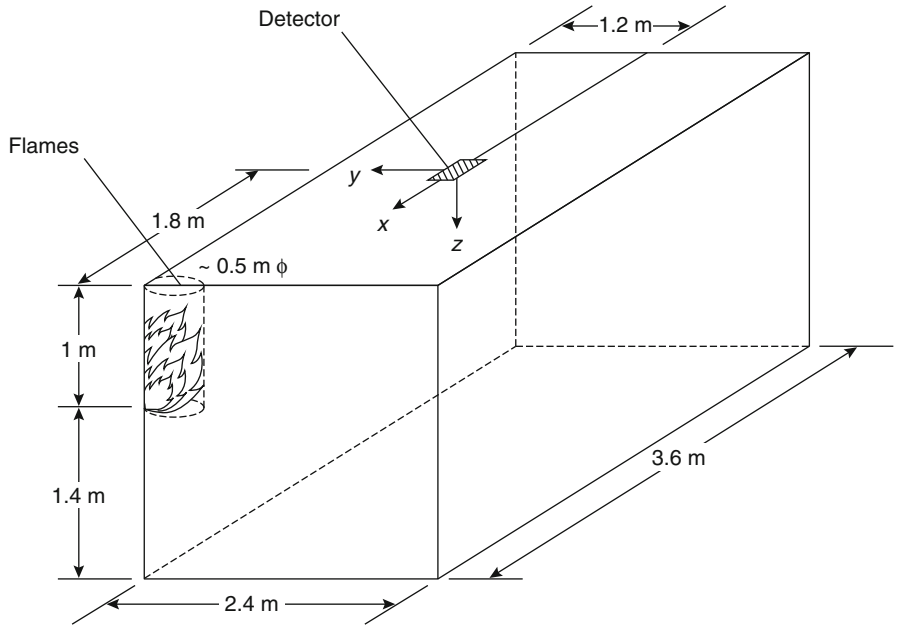

Fig. 4.16 Example calculation for flux to target element from flame

The parameters in the definitions are given by

$$\theta_0 = \tan^{-1}(L/H) \tag{4.72a}$$

$$\mu_\lambda = 2r\frac{\kappa_\lambda}{\sin\left(\frac{\theta_0}{2}+\frac{\pi}{4}\right)} \tag{4.72b}$$

$$\vec{n} = u\vec{i} + v\vec{j} + w\vec{k} \tag{4.72c}$$

If the flame is considered to be homogeneous and Equation 4.69 is integrated over all wavelengths, the total heat flux is:

$$\dot{q}_r'' = \varepsilon_m E_b \sum_{j=1}^{3} F_j \tag{4.73}$$

Example 7 As shown in Fig. 4.16, a fire detector is located at the center of the ceiling in a room (2.4 × 3.6 × 2.4 m) with wood wall linings. The sprinkler system is capable of extinguishing fires smaller than 0.5 m in diameter × 1.0 m high. For this example, determine the appropriate heat flux setting for the detector, using a worst case scenario of ignition in one of the upper ceiling corners.

Solution First, the condition of $L/r \geq 3$ should be checked to verify that the previous analysis is applicable.

$$\frac{L}{r} \approx \frac{\sqrt{1.2^2 + 1.8^2}}{0.25} = 8.65 > 3 \tag{4.74}$$

The unit normal vector to the detector is given by $\vec{n} = \vec{k}$, the polar angle $\theta_0 = \tan^{-1}(1.818) = 1.068$ is determined from Equation 4.72a, and the shape factors are evaluated from Equations 4.70a, 4.70b, and 4.70c:

$$F_1 = 0 \tag{4.75a}$$

$$F_2 = 0 \tag{4.75b}$$

$$F_3 = \frac{1}{\pi}\left(\frac{0.25}{1.818}\right)\cos^2(1.068) = 0.0102 \tag{4.75c}$$

From Equation 4.73, the radiant heat flux can be calculated as:

$$\begin{aligned}\dot{q}_r'' &= (1-\exp(-\kappa_m S))\sigma T_f^4 F_3 \\ &= (1-\exp(-0.8\times 0.5))\times 5.67\times 10^{-8}\times 1732^4\times 0.0102 \\ &= 1.7\ \mathrm{kW/m^2}\end{aligned} \tag{4.76}$$

where wood flame properties were taken from Table 4.11. If the geometry of the example had been $L/r < 3$, it would have been necessary to interpolate between the $L/r = 3$ case and the $L/r = 0$ case, which has been obtained accurately [6, 37]. If the detector is pointed directly at the burning corner in this example (i.e., $\vec{n} = 0.55\vec{i} + 0.83\vec{j}$), the calculated heat flux jumps to 9.0 kW/m^2, showing the strong influence of direction in calculations of radiation heat transfer.

Heat Flux Calculation from a Smoke Layer

Consider the situation shown below in Fig. 4.17 involving radiative heat transfer in a compartment fire with a hot gas layer located below the ceiling.

Hot upper gas layers are composed of strongly participating media such as carbon dioxide, water vapor, and soot particles. Heat flux from the smoke layer is directly related to ignition of remote surface locations such as furniture or floor carpets. The schematic in Fig. 4.17 will be considered in a radiative transport analysis and example calculation. The calculation is based on a considerably simplified formulation which provides reasonable results with only a small penalty in accuracy.

Integration of Equation 4.46 over the pathlength S through the smoke layer yields

$$I(S) = \frac{\sigma T^4}{\pi}\left(1-\left(\frac{T_w}{T}\right)^4\right)\exp(-\kappa S) \tag{4.77}$$

The monochromatic radiative heat flux on a differential target element is again given by Equation 4.68. However, for the present geometry of

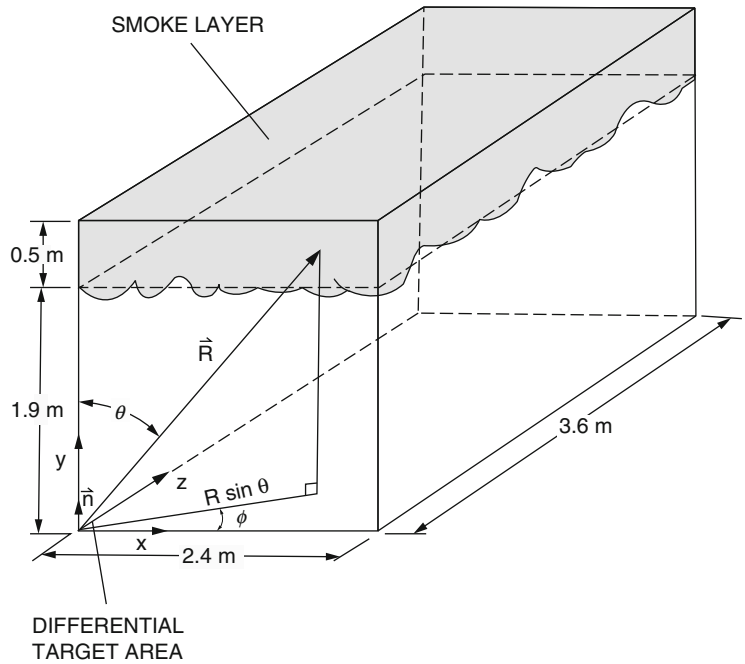

Fig. 4.17 Example calculation for flux to target element from smoke layer

the ceiling layer and enclosure surface, integration of Equation 4.68 is quite time-consuming since the upper and lower bounds of the integral vary with the angle of the pathlength. The calculation can be simplified by assuming as a first order approximation that the lower face of the smoke layer is an isothermal surface. Using this assumption, the problem can be handled using the simple relations of radiative exchange in a nonparticipating medium between gray surfaces (the absorption of the clear air below the smoke layer is negligible). The radiosity and irradiation of each surface in the enclosure is:

$$J_i = \varepsilon_i \sigma T_i^4 + (1 - \varepsilon_i) G_i \tag{4.78a}$$

$$G_i = \sum_j F_{i-j} J_j \tag{4.78b}$$

After solving the simultaneous equations for all J_i and G_i, the net heat flux on any of the surfaces can be calculated from

$$\dot{q}''_{r,i} = J_i - G_i \tag{4.79}$$

This situation is considered in Example 8 below.

Example 8 A smoke layer 0.5 m thick is floating near the ceiling of a room with dimensions of 3.6 × 2.4 × 2.4 m. (See Fig. 4.17.) The floor is made from wood (emissivity = 0.9), and the four side walls are painted concrete (emissivity = 0.94). The calculation will determine the heat flux in a bottom corner of the room, assuming that each surface in the enclosure is kept at constant temperature: the smoke layer at 1400 K, the side walls at 800 K, and the floor at 300 K. Assume there is a differential target area 0.01 m^2 in one of the corners of the floor, and also at the floor temperature of 300 K.

Solution The bottom of the smoke layer will be designated surface 1, the floor will be surface 2, and the differential target area in the bottom corner will be surface 3. Only four surfaces are required since the four side walls can be treated as a single surface 4. Shape factors F_{12} and F_{31} can be found in Appendix D, and from these two factors, the remaining shape factors are determined by shape factor algebra:

$$F_{12} = 0.3242$$

$$F_{31} = 0.1831$$

$$F_{13} = \frac{A_3}{A_1} F_{31} = 0.0002$$

$$F_{14} = 1 - F_{12} - F_{13} = 0.6756$$

Continuing in a similar fashion, the other shape factors are obtained as:

$$\begin{array}{lll} F_{21} = 0.3242 & F_{31} = 0.1831 & F_{41} = 0.2560 \\ F_{22} = 0.0000 & F_{32} = 0.0000 & F_{42} = 0.2561 \\ F_{23} = 0.0000 & F_{33} = 0.0000 & F_{43} = 0.0003 \\ F_{24} = 0.6758 & F_{34} = 0.8169 & F_{44} = 0.4876 \end{array}$$

The emissivity for the smoke layer can be estimated from the mean absorption coefficient for a wood flame (Table 4.11) as:

$$\begin{aligned} \varepsilon_1 &= 1 - \exp(-\kappa_m S) = 1 - \exp(-0.8 \times 0.5) \\ &= 0.33 \end{aligned}$$

The blackbody emissive power of each surface is calculated as σT^4, for example:

$$\begin{aligned} \left(\sigma T^4\right)_1 &= 5.6696 \times 10^{-8} \times 1400^4 \\ &= 217.8 \text{ kW/m}^2 \end{aligned}$$

From Equations 4.78a and 4.78b, the radiative fluxes to and from each surface are determined by solving the eight simultaneous equations:

$$\begin{array}{ll} J_1 = 88.7 \text{ kW/m}^2 & G_1 = 17.7 \text{ kW/m}^2 \\ J_2 = 4.7 \text{ kW/m}^2 & G_2 = 43.3 \text{ kW/m}^2 \\ J_3 = 3.9 \text{ kW/m}^2 & G_3 = 34.8 \text{ kW/m}^2 \\ J_4 = 23.9 \text{ kW/m}^2 & G_4 = 34.3 \text{ kW/m}^2 \end{array}$$

The net radiative heat flux on the target element from Equation 4.79 is

$$\dot{q}''_{r,3} = J_3 - G_3 = -30.9 \text{ kW/m}^2$$

where the negative sign indicates that heat must be removed from the target element so it remains

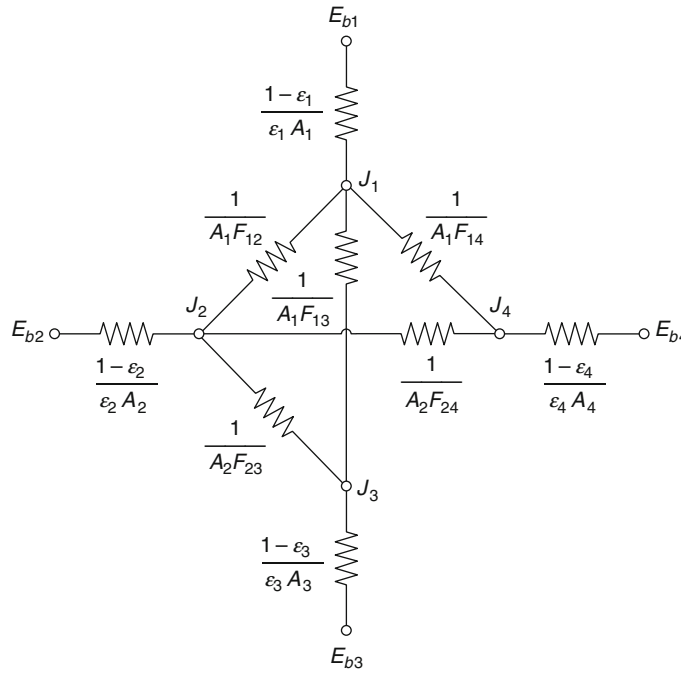

Fig. 4.18 Equivalent resistance network for an enclosure

in equilibrium. This example also could have been solved by the resistance network method shown in Fig. 4.18)

Nomenclature

A	Area (m^2)
C	Correction factor for mean beam length
C_0	Soot concentration parameter
C_2	Planck's second constant (1.4388×10^{-2} m · K)
c	Speed of light in the medium (m/s)
c_0	Speed of light in a vacuum (2.998×10^8 m/s)
E	Radiative emissive power (W/m^2)
F_{i-j}	Configuration factor from surface i to surface j
f_v	Soot volume fraction
G	Irradiation or radiative heat flux received by surface (W/m2)
H	Height (m)
h	Planck's constant (6.6256×10^{-34} J s)
I	Radiation intensity (W/m^2)
$\vec{i}, \vec{j}, \vec{k}$	Cartesian coordinate direction vectors
J	Radiosity or radiative heat flux leaving surface (W/m^2)
k	Boltzmann constant (1.3806×10^{-23} J/K), or infrared optical constant of soot (imaginary component), or thermal conductivity (W/m K)
L	Mean beam length or distance (m)
L_0	Geometrical mean beam length (m)
n	Index of refraction (c_0/c) or infrared optical constant of soot (real component)
$\vec{n}$	Unit normal vector
P_a	Partial pressure of absorbing gas (Pa)
P_e	Effective pressure (Pa)
Q	Energy rate (W)
q''	Heat flux (W/m^2)
$\vec{R}$	Line of sight vector
r	Radius of cylinder (m)
S	Pathlength (m)
T	Temperature (K)
t	Time (s)
u, v, w	Cartesian components of unit vector $\vec{n}$
V	Volume (m^3)

X Pressure pathlength, $\int_0^s P_a x(\xi) d(\xi)$ (atm-m)
x Spatial coordinate (m)

Greek Symbols

α Absorptivity or thermal diffusivity k/pc_p (m^2/s)
β Angle from normal (radians)
ε Emissivity
θ Polar angle (radians)
κ Extinction coefficient or absorption coefficient ($m - l$)
λ Wavelength (m)
μ Micron (10^{-6} m)
μ_λ Defined parameter, Equation 4.73
ν Frequency (s^{-t})
ξ Integration dummy variable
ρ Reflectivity or density (kg/m^3)
Ω Solid angle (steradians)
σ Stefan-Boltzmann constant (5.6696×10^{-B} W/m^2K^4)
τ Transmissivity or optical pathlength
ϕ Azimuthal angle (radians)
χ Fractional measure

Thermochemistry

5

D.D. Drysdale

Introduction

Thermochemistry is the branch of physical chemistry that is concerned with the amounts of energy released or absorbed when a chemical change (reaction) takes place [1–3]. Inasmuch as fire is fundamentally a manifestation of a particular type of chemical reaction, viz., combustion, thermochemistry provides methods by which the energy released during fire processes can be calculated from data available in the scientific and technical literature.

To place it in context, thermochemistry is a major derivative of the first law of thermodynamics, which is a statement of the principle of conservation of energy. However, while concerned with chemical change, thermodynamics does not indicate anything about the rate at which such a change takes place or about the mechanism of conversion; this falls within the topic of chemical kinetics [4]. Consequently, the information it provides is normally used in association with other data, for example, to enable the rate of heat release to be calculated from the rate of burning.

The First Law of Thermodynamics

It is convenient to limit the present discussion to chemical and physical changes involving gases; this is not unreasonable, as flaming combustion takes place in the gas phase. It may also be assumed that the ideal gas law applies, that is,

$$PV = n \cdot RT \tag{5.1}$$

where P and V are the pressure and volume of n moles of gas at a temperature, T (in degrees Kelvin); values of the universal gas constant (R) in various sets of units are summarized in Table 5.1. At ambient temperatures, deviations from "ideal behavior" can be detected with most gases and vapors, while at elevated temperatures such deviations become less significant. In this context, it should be noted that whereas the terms *gas* and *vapor* are sometimes used interchangeably, it is best to make a distinction. Both are in the gaseous state, but as a general rule a vapor at normal temperatures can be made to liquefy if the pressure of the vapor is increased sufficiently. Thus, propane can be stored as a liquid under a relatively low pressure (approximately 8.4 bar at 293 Kelvin) whereas the permanent gases (particularly hydrogen, helium, oxygen, and nitrogen) can only be stored as gases at ambient temperatures, typically in pressure cylinders at 2000 psi (c. 138 bar). Again, as a general rule, vapors tend to deviate more strongly from ideal gas behavior than do the permanent gases.

Internal Energy

As a statement of the principle of conservation of energy, the first law of thermodynamics deals

atm	m^3	m^3·atm/K·mol	8.20575×10^{-5}

with the relationship between work and heat. Confining our attention to a "closed system"—for which there is no exchange of matter with the surroundings—it is known that there will be a change if heat is added or taken away, or if work is done on or by "the system" (e.g., by compression). This change is usually accompanied by an increase or decrease in temperature and can be quantified if we first define a function of state known as the internal energy of the system, E. Any change in the internal energy of the system (ΔE) is then given by

$$\Delta E = q - w \tag{5.2}$$

where q is the heat transferred to the system, and w is the work done by the system. This can be expressed in differential form

$$dE = dq - dw \tag{5.3}$$

Being a function of state, E varies with temperature and pressure, that is, $E = E(T, P)$.

According to the standard definition, work, w, is done when a force, F, moves its point of application through a distance, x, thus, in the limit

$$dw = F \cdot dx \tag{5.4}$$

The work done during the expansion of a gas can be derived by considering a cylinder/piston assembly (Fig. 5.1); thus

$$dw = P \cdot A \cdot dx = P\,dV \tag{5.5}$$

where
P = Pressure of the gas
A = Area of the piston
dx = Distance through which the piston is moved; the increment in volume is therefore $dV = A \cdot dx$

The total work done is obtained by integrating Equation 5.5 from the initial to the final state; that is,

$$w = \int_{\text{initial}}^{\text{final}} P \cdot dV \tag{5.6}$$

Combining Equations 5.3 and 5.5, the differential change in internal energy can be written

$$dE = dq - P \cdot dV \tag{5.7}$$

This shows that if the volume remains constant, as $P \cdot dV = 0$, then $dE = dq$; if this is integrated, we obtain

$$\Delta E = q_v \tag{5.8}$$

where q_v is the heat transferred to the constant volume system; that is, the change in internal energy is equal to the heat absorbed (or lost) at constant volume.

Enthalpy

With the exception of explosions in closed vessels, fires occur under conditions of constant pressure. Consequently, the work done as a result of expansion of the fire gases must be taken into account. At constant pressure, Equation 5.5 may be integrated to give

$$w = P \cdot (V_2 - V_1) \tag{5.9}$$

where V_1 and V_2 are the initial and final volumes, respectively. Equation 5.2 then becomes

$$\Delta E = E_2 - E_1 = q_p + PV_1 - PV_2 \tag{5.10}$$

or, rearranging,

$$\begin{aligned} q_p &= (E_2 + PV_2) - (E_1 + PV_1) \\ &= H_2 - H_1 \end{aligned} \tag{5.11}$$

where q_p is the heat transferred at constant pressure, and H is known as the enthalpy ($H \equiv E + PV$). The change in enthalpy is therefore the heat

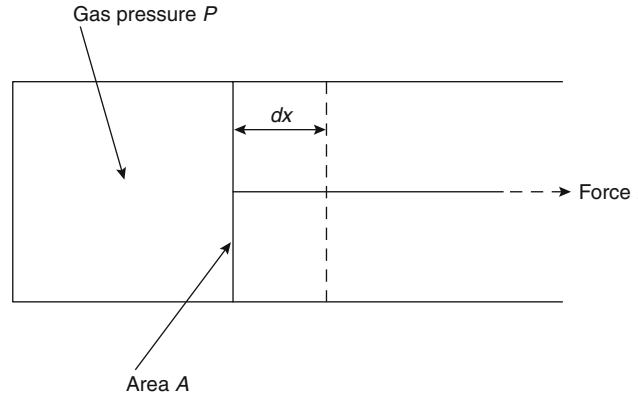

Fig. 5.1 Cylinder/piston assembly

absorbed (or lost) at constant pressure (provided that only $P - V$ work is done), and consequently it is the change in enthalpy that must be considered in fire-related problems.

Specific Heat

Specific heat, or heat capacity, of a body or "system" is defined as the amount of heat required to raise the temperature of unit mass by 1°C; the units are J/kg K, although for most thermochemical problems the units J/mol K are more convenient. The formal definition of the "mole" is the amount of a substance (solid, liquid, or gas) that contains as many elementary units (atoms or molecules) as there are carbon atoms in exactly 0.012 kg of carbon-12 (C^{12}). This number—known as Avogadro's number—is actually 6.023×10^{23}; in its original form, Avogadro's hypothesis was applied to gases and stated that equal numbers of molecules of different gases at the same temperature and pressure occupy the same volume. Thus, the quantity of a substance that corresponds to a mole is simply the gram-molecular weight, but expressed in kilograms to conform with SI units. For example, the following quantities of the gases N_2, O_2, CO_2, and CO represent 1 mole of the respective gas and, according to Avogadro's hypothesis, will each occupy 0.022414 m^3 at 273 K and 760 mmHg (101.1 kPa):

0.028 kg nitrogen (N_2)
0.032 kg oxygen (O_2)
0.044 kg carbon dioxide (CO_2)
0.028 kg carbon monoxide (CO)
0.016 kg methane (CH_4)
0.044 kg propane (C_3H_8)

The concept of specific heat is normally associated with solids and liquids, but it is equally applicable to gases. Such specific heats are required for calculating flame temperatures, as described below. Values for a number of important gases at constant pressure and a range of temperatures are given in Table 5.2.

It is important to note that there are two distinct heat capacities; at constant pressure, C_p, and at constant volume, C_v. Thus, at constant pressure

$$dq_p = dH = C_p \cdot dT \tag{5.12}$$

while at constant volume

$$dq_v = dE = C_v \cdot dT \tag{5.13}$$

For an ideal gas, $C_p = C_v + \mathrm{R}$.

Heats of Combustion

Chemical Reactions and Stoichiometry

When chemical reactions occur, they are normally accompanied by the release or absorption of heat. Thermochemistry deals with the

Table 5.2 Heat capacities of selected gases at constant pressure (101.1 kN/m^2) [5]

Cp (J/mol K)					
Temperature (K)	298	500	1000	1500	2000
Species					
CO	29.14	29.79	33.18	35.22	36.25
CO_2	37.129	44.626	54.308	58.379	60.350
H_2O(g)	33.577	35.208	41.217	46.999	51.103
N_2	29.125	29.577	32.698	34.852	35.987
O_2	29.372	31.091	34.878	36.560	37.777
He	20.786	20.786	20.786	20.786	20.786
CH_4	35.639	46.342	71.797	86.559	94.399

quantification of the associated energy changes. This requires a definition of the initial and final states, normally expressed in terms of an appropriate chemical equation, for example,

$$C_3H_8 + 5O_2 \rightarrow 3CO_2 + 4H_2O \qquad (5.R1)$$

in which the reactants (propane and oxygen) and products (carbon dioxide and water) are specified. This balanced chemical equation defines the *stoichiometry* of the reaction, that is, the exact proportions of the two reactants (propane and oxygen) for complete conversion to products (no reactants remaining). Note that the physical states of the reactants and products should also be specified. In most cases, the initial conditions correspond to ambient (i.e., 25 °C and atmospheric pressure) so that there should be no doubt about the state of the reactants. In this case both are gaseous, but it is more common in fires for the "fuel" to be in a condensed state, either liquid or solid. As an example, the oxidation of *n*-hexane can be written

$$C_6H_{14} + 9.5O_2 \rightarrow 6CO_2 + 7H_2O \qquad (5.R2)$$

but the fuel may be in either the liquid or the vapor state. The consequences of this will be discussed below.

Reaction 5.R1 may be used to calculate the mass of oxygen or air required for the complete oxidation of a given mass of propane. Thus, we deduce that 1 mole of propane (44 g) reacts completely with 5 moles of oxygen ($5 \times 32 = 160$ g); that is, 1 g propane requires 3.64 g oxygen. If the propane is burning in air, then the presence of nitrogen needs to be taken into account, although it does not participate to any significant extent in the chemical change. As the ratio of oxygen to nitrogen in air is approximately 21:79 (or 1:3.76), Reaction 5.R1 can be rewritten

$$C_3H_8 + 5O_2 + 18.8N_2 \rightarrow 3CO_2 + 4H_2O + 18.8N_2 \qquad (5.R3)$$

(where $18.8 = 5 \times 3.76$), showing that 44 g propane requires ($160 + 18.8 \times 28$), or 686.4 g of "air" for complete combustion, that is, 15.6 g air/g propane. Calculations of this type are valuable in assessing the air requirements of fires.

Thus, on the assumption that wood has the empirical formula [5] $CH_{1.5}O_{0.75}$, it can be shown that its stoichiometric air requirement is 5.38 g air for each gram of fuel, assuming complete combustion of wood to CO_2 and H_2O. The relevant stoichiometric equation is

$$CH_{1.5}O_{0.75} + O_2 + 3.76N_2 = CO_2 + 0.75H_2O + 3.76N_2 \qquad (5.R4)$$

In this calculation no distinction is made of the fact that flaming combustion of wood involves oxidation of the volatile gases and vapors produced by the pyrolysis of wood, while the residual char burns much more slowly by surface oxidation.

Measurement of Heats of Combustion

The heat of combustion of a fuel is defined as the amount of heat released when unit quantity is oxidized completely to yield stable end products.

In the present context, the relevant combustion processes occur at constant pressure so that we are concerned with an enthalpy change, ΔH_c. By convention, for exothermic reactions such as oxidation, values of ΔH_c are negative; that is, the reaction produces energy that can then be lost from the system. (By contrast, an endothermic reaction such as the conversion of water to hydrogen and oxygen will take place only if energy is provided in a suitable form.)

Heats of combustion are measured in the combustion bomb calorimeter in which a precise amount of fuel is burned in pure oxygen inside a pressure vessel whose temperature is strictly monitored. The apparatus is designed to reduce heat losses from the calorimeter to a minimum so that the amount of heat released can be calculated from the rise in temperature and the total thermal capacity of the system; corrections can be made for any heat loss. In the past, combustion bomb calorimetry received a great deal of attention within physical chemistry [1, 6] as the technique was able to provide a wealth of data of relevance to thermochemistry. However, the experiment gives the heat released at constant volume; that is, the change in internal energy, ΔE (Equation 5.8). The change in enthalpy is given by

$$\Delta H = \Delta E + \Delta(PV) \tag{5.14}$$

where $\Delta(PV)$ is calculated using the ideal gas law

$$\Delta(PV) = \Delta(nRT) \tag{5.15}$$

The method gives the gross heat of combustion—that is, in which the reactants and products are in their standard states. The net heat of combustion, on the other hand, refers to the situation in which the products are in the sate in which they are formed. For Reaction 5.R1, for example, water is formed in the gaseous phase so that the amount of energy released is less than the gross heat of combustion by an amount equivalent to the latent heat of evaporation of water (2.26 kJ/g). The net heat of combustion is the value that should be used in fire calculations. This is illustrated in the next section: see Reactions 5.R5a and 5.R5b. It should also be remembered that there is a heat of gasification associated with any condensed fuel (liquid or solid); a correction must be made for this if the heat of combustion of the fuel vapor is required.

Table 5.3 contains the heats of combustion (ΔH_c) of a number of combustible gases, liquids, and solids, expressed in various ways, viz., kJ/mole (fuel), kJ/g (fuel), kJ/g (oxygen), and kJ/g (air). The first of these is the form normally encountered in chemistry texts and reference books, whereas the second is more commonly found in sources relating to chemical engineering and fuel technology and is more useful to the fire protection engineer. However, the third and, particularly, the fourth have very specific uses in relation to fire problems. It is immediately apparent from Table 5.3 that ΔH_c (O_2) and ΔH_c (air) are approximately constant for most of the fuels listed, having average values of 13.1 kJ/g and 3 kJ/g, respectively. (See the section on "Rate of Heat Release in Fires".)

The data quoted in Table 5.3 refer to heats of combustion measured at ambient temperature, normally 25 °C. These data will be satisfactory for virtually all relevant fire problems, but occasionally it may be necessary to consider the heat released when combustion takes place at higher temperatures. This requires a simple application of the first law of thermodynamics. If the reaction involves reactants at temperature T_0 reacting to give products at the final temperature T_F, the process can be regarded in two ways:

1. The products are formed at T_0, absorb the heat of combustion, and are heated to the final temperature T_F.
2. The heat of combustion is imagined first to heat the reactants to T_F, then the reaction proceeds to completion, with no further temperature rise.

   By the first law, we can write

$$(\Delta H_c)^{T_0} + C_p^{\mathrm{Pr}} \cdot (T_F - T_0) = (\Delta H_c)^{T_F} + C_p^{\mathrm{R}} \cdot (T_F - T_0) \tag{5.16}$$

where C_p^{Pr} and C_p^{R} are the total heat capacities of the products and reactants, respectively. This may be rearranged to give

Table 5.3 Heats of combustion of selected fuels at 25 °C (298 K) [7]

Fuel	ΔH_c (kJ/mol)	ΔH_c (kJ/g)	ΔH_c[b] (kJ/g[O_2])	ΔH_c (kJ/g[air])
Carbon monoxide (CO)	283	10.10	17.69	4.10
Methane (CH_4)	800	50.00	12.54	2.91

[a]Apart from the solids (D-glucose, et seq.), the initial state of the fuel and of all the products is taken to be gaseous
[b]$\Delta H_c(O_2) = 13.1$ kJ/g is used in the oxygen consumption method for calculating rate of heat release
[c]Cotton and rayon are virtually pure cellulose and can be assumed to have the same heat of combustion

$$\frac{(\Delta H_c)^{T_F} - (\Delta H_c)^{T_0}}{T_F - T_0} = \Delta C_p \qquad (5.17)$$

or, in differential form, we have Kirchoff's equation

$$\frac{d(\Delta H_c)}{dT} = \Delta C_p \qquad (5.18)$$

where $\Delta C_p = C_p^{\mathrm{Pr}} - C_p^{\mathrm{R}}$. This may be used in integrated form to calculate the heat of combustion at temperature T_2 if ΔH_c is known at temperature T_1 and information is available on the heat capacities of the reactants and products, thus

$$(\Delta H_c)^{T_2} = (\Delta H_c)^{T_1} + \int_{T_1}^{T_2} \Delta C_p \cdot dT \qquad (5.19)$$

Where

$$\Delta C_p = \sum C_p(\text{products}) - \sum C_p(\text{reactants}) \tag{5.20}$$

and C_p is a function of temperature, which can normally be expressed as a power series in T, for example,

$$C_p = a + bT + cT^2 + \ldots \tag{5.21}$$

Information on heat capacities of a number of species and their variation with temperature may be found in Stull and Prophet [7] and Strehlow [8]. Some data are summarized in Table 5.2.

Heats of Formation

The first law of thermodynamics implies that the change in internal energy (or enthalpy) of a system depends only on the initial and final states of the system and is thus independent of the intermediate stages. This is embodied in thermochemistry as Hess's law, which applies directly to chemical reactions. From this, we can develop the concept of heat of formation, which provides a means of comparing the relative stabilities of different chemical compounds and may be used to calculate heats of chemical reactions that cannot be measured directly.

The heat of formation of a compound is defined as the enthalpy change when 1 mole of that compound is formed from its constituent elements in their standard state (at 1 atm pressure and 298 K). Thus, the heat of formation of liquid water is the enthalpy change of the reaction (at 298 K)

$$H_2(\text{g}) + 0.5\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})\Delta H_f = -285.8\text{kJ/mol} \tag{5.R5a}$$

so that ΔH_f (H_2O) (l) = −285.8 kJ/mole at 25 °C. This differs from the heat released by the reaction if the product is water vapor rather than liquid ("The heat of formation of water vapor" kJ/mol [ΔH_f {H_2O(g)} = –241.84 kJ/mol]) by the latent heat of evaporation of water at 25 °C (43.96 kJ/mol). Thus

$$H_2(\text{g}) + 0.5\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})\Delta H_f[\text{H}_2\text{O}(\text{g})] = -241.84\ \text{kJ/mol} \tag{5.R5b}$$

By definition, the heats of formation of all the elements are set arbitrarily to zero at all temperatures. This then allows the heats of reaction to be calculated from the heats of formation of the reactants and products, thus

$$\Delta H = \Delta H_f(\text{products}) - \Delta H_f(\text{reactants}) \tag{5.22}$$

where ΔH is the heat (enthalpy) of the relevant reaction. However, most heats of formation cannot be obtained as easily as heats of combustion. The example given in Reaction (5.R5a) is unusual in that the heat of formation of water also happens to be the heat of combustion of hydrogen. Similarly, the heat of combustion of carbon in its most stable form under ambient conditions (graphite) is the heat of formation of carbon dioxide.

Combustion calorimetry can be used indirectly to calculate heats of formation. The heat of formation of ethyne (acetylene), which is the enthalpy change of the reaction

$$2\text{C}(\text{graphite}) + \text{H}_2 \rightarrow \text{C}_2\text{H}_2 \tag{5.R6}$$

can be deduced in the following way: the heat of combustion of ethyne has been determined by bomb calorimetry as −1255.5 kJ/mol at 25 °C (298 K). This is the heat of the reaction

$$\text{C}_2\text{H}_2 + 2.5\text{O}_2 \rightarrow 2\text{CO}_2 + \text{H}_2\text{O} \tag{5.R7}$$

which, by Hess's law (see Equation 5.22), can be equated to

$$(\Delta H_c)^{298}(\text{C}_2\text{H}_2) = 2\left(\Delta H_f\right)^{298}(\text{CO}_2) + \left(\Delta H_f\right)^{298}(\text{H}_2\text{O}) - \left(\Delta H_f\right)^{298}(\text{C}_2\text{H}_2) - 2.5\left(\Delta H_f\right)^{298}(\text{O}_2) \tag{5.23}$$

We know that

$$(\Delta H_c)^{298}(\text{C}_2\text{H}_2) = -1255.5\ \text{kJ/mol}$$
$$(\Delta H_f)^{298}(\text{CO}_2) = -393.5\ \text{kJ/mol}$$

$$(\Delta H_f)^{298}\,(H_2O) = -241.8\ \text{kJ/mol}$$

$$(\Delta H_f)^{298}\,(O_2) = 0.0\ \text{kJ/mol (by definition)}$$

so that by rearrangement, Equation 5.23 yields

$$(\Delta H_f)^{298}\,(C_2H_2) = +226.7\ \text{kJ/mol}$$

This compound has a positive heat of formation, unlike CO_2 and H_2O. This indicates that it is an endothermic compound and is therefore less stable than the parent elements. Under appropriate conditions, ethyne can decompose violently to give more stable species.

The heats of formation of a number of compounds are given in Table 5.4. The most stable compounds (CO_2 and H_2O) have the largest negative values, while positive values tend to indicate an instability with respect to the parent elements. This can indicate a high chemical reactivity, and indeed heats of formation have been used in preliminary hazard assessment to provide an indication of the risks associated with new processes in the chemical industry. It should be noted that the heats of combustion of endothermic compounds do not give any indication of any associated reactivity (compare ethane, ethene, and ethyne in Tables 5.3 and 5.4).

Table 5.4 Heats of formation at 25 °C (298 K)

Compound	$(\Delta H_f)298$ (kJ/mol)
Hydrogen (atomic)	+218.00
Oxygen (atomic)	+249.17
Hydroxyl (OH)	+38.99
Chlorine (atomic)	+121.29
Carbon monoxide	–110.53
Carbon dioxide	–393.52
Water (liquid)	–285.8
Water (vapor)	–241.83
Hydrogen chloride	–92.31
Hydrogen cyanide (gas)	+135.14
Nitric oxide	+90.29
Nitrogen dioxide	+33.85
Ammonia	–45.90
Methane	–74.87
Ethane	–84.5
Ethene	+52.6
Ethyne (acetylene)	+226.9
Propane	–103.6
n-Butane	–124.3
Iso-butane[a]	–131.2
Methanol	–242.1

[a]Heats of formation of other hydrocarbons are tabulated in Weast [9]

Rate of Heat Release in Fires

Although thermochemistry can give information relating to the total amount of energy that can be released when a fuel is burned to completion, it is rarely (if ever) possible to use heats of combustion directly to calculate the heat released in "real" fires. Indeed, it can be argued that the *rate* of heat release is more important than the total available [10]. When a single item is burning in isolation, the rate of burning and the rate of heat release in the flame are coupled. It has been common to express the rate of heat release as the product of the burning rate (i.e., the rate of mass loss $\dot{m}$ [kg/s]) and the net heat of combustion of the fuel (ΔH_c kJ/kg).

$$\dot{Q}_c = \dot{m} \cdot \Delta H_c \qquad (5.24)$$

However, this assumes that combustion is complete, although it is known that this is never so in natural fires, which involve diffusion flames rather than premixed flames. Air and fuel have to mix by the process of diffusion (laminar or turbulent, depending on the size of the fire) before combustion can occur. The mixing process is relatively inefficient, and despite the fact that excess air is drawn (or *entrained*) into the flame, the products of combustion will contain some species that are only partially oxidized, such as carbon monoxide, aldehydes, ketones, and particulate matter in the form of soot or smoke. Their presence indicates that not all the available combustion energy has been released. The "combustion efficiency" is likely to vary from around 0.3–0.4 for heavily fire-retarded materials to 0.9 or higher in the case of oxygen-containing products (e.g., polyoxymethylene) [10, 11]. This is discussed in detail by Tewarson [12].

Fires burning in compartments present a completely different problem. In the first place, there is likely to be a range of different fuels present, each with a different stoichiometric air

requirement. These will burn at different rates, dictated not just by the nature of the fuel but also by the levels of radiant heat existing within the compartment during the fire. The rate of heat release during the fully developed stage of a compartment fire is required for calculating postflashover temperature-time histories for estimating fire exposure of elements of structure, as in the method developed by Pettersson et al. [13]. To calculate the rate of heat release within the compartment, it is assumed that the fire is ventilation controlled and that all combustion takes place within the compartment. The rate of heat release ($\dot{Q}_c$) can be obtained from the expression

$$\dot{Q}_c = \dot{m}_{\text{air}} \cdot \Delta H_c(\text{air}) \tag{5.25}$$

where ΔH_c (air) is the heat of combustion per unit mass of air consumed (3 kJ/g; see Table 5.3), and $\dot{m}_{\text{air}}$ is the mass flow rate of air into the compartment, given approximately by the expression

$$\dot{m}_{\text{air}} = 0.52 A_0 H_0^{1/2} \tag{5.26}$$

where A_0 is the effective area of ventilation (m^2) and H_0 is the height of the ventilation opening (m) [14]. The compartment temperature (as a function of time) is then obtained from heat balance calculations, as described in Drysdale [3], Tewarson [12], and Walton and Thomas [14].

The assumption behind Equation 5.25 is that the burning process is stoichiometric and that all the fuel vapors are burned within the compartment—air is supplied at exactly the rate required to consume the fuel vapors, that is,

$$\frac{\text{Rate of supply of air}}{\text{Rate of supply of fuel}} = r$$

where r is the stoichiometric air-fuel ratio and the maximum possible temperatures will be achieved. However, it is worth noting that this does not take into account the fact that the rate of heat release is not instantaneous. Although (in principle) the ideal stoichiometric mixture is created within the compartment, burning gases will emerge from the opening(s) simply because the reaction takes time to reach completion. Burning gases (i.e., flames) are carried outside the compartment, indicating that not all of the heat of combustion is released within the compartment. For a fully developed (postflashover) fire, it is perhaps more likely that the ratio $\dot{m}_{\text{air}}/\dot{m}_{\text{fuel}}$ (the "equivalence ratio") is less than the stoichiometric ratio r—that is, insufficient air is entering the compartment to burn all the fuel vapors. Under these circumstances, excess fuel vapors will escape from the compartment and burn outside as they mix with external air. The external flame length will depend *inter alia* on the equivalence ratio [15].

Regardless of whether the equivalence ratio is equal to or greater than the stoichiometric ratio, fuel vapor will burn outside the compartment and temperatures based on Equation 5.25 will be high. The method will also overestimate the temperatures achieved if the equivalence ratio is much greater than the stoichiometric ratio. Under these conditions, excess air is drawn into the compartment and will act as a diluent and reduce the average temperatures—if the ventilation is high enough, the rate of heat release will be controlled by the area of the burning surface [3, 16].

Note that the concept of equivalence ratio is used elsewhere in this handbook, specifically by Tewarson [12] and by Gottuk and Lattimer [17] in discussing the yields of products generated in the upper layer during the preflashover fire.

Much useful data on the fire behavior of combustible materials can be obtained by using the technique of "oxygen consumption calorimetry." This is the basis of the "cone calorimeter," in which the rate of heat release from a small sample of material burning under an imposed radiant heat flux is determined by measuring the rate of oxygen consumption [18]. The latter can be converted into a rate of heat release using the conversion factor 13.1 kJ/g of oxygen consumed. (A small correction is required for incomplete combustion, based on the yield of CO.) This technique can be used on a larger scale to measure the rate of heat release from items of furniture, wall lining materials, and so on [19, 20] and is now used routinely in both fire research and fire testing facilities.

Calculation of Adiabatic Flame Temperatures

In the previous sections, no consideration has been given to the fate of the energy released by the combustion reactions. Initially it will be absorbed within the reaction system itself by (1) unreacted reactants, (2) combustion products, and (3) diluents, although it will ultimately be lost from the system by various heat transfer processes. This is particularly true for natural fires in enclosed spaces. However, if we consider a premixed reaction system, such as a flammable vapor-air mixture, and assume it to be adiabatic, that is, there is no transfer of heat (or mass) to or from the system, then we can calculate the maximum theoretical temperature, the adiabatic flame temperature.

Consider a flame propagating through a stoichiometric propane-air mixture of infinite extent (i.e., there are no surfaces to which heat may be transferred) and that is initially at 25 °C. The appropriate equation is given by Reaction 5.R8:

$$C_3H_8 + 5O_2 + 18.8N_2 \rightarrow 3CO_2 + 4H_2O + 18.8N_2 \quad (5.R8)$$

This reaction releases 2044 kJ for every mole of propane consumed. This quantity of energy goes toward heating the reaction products, that is, 3 moles of carbon dioxide, 4 moles of water (vapor), and 18.8 moles of nitrogen for every mole of propane burned. The thermal capacity of this mixture can be calculated from the thermal capacities of the individual gases, which are available in the literature (e.g., JANAF) [7]. The procedure is straightforward, provided that an average value of C_p is taken for each gas in the temperature range involved, giving 942.5 kJ/K as the total thermal capacity of the products per mole of propane consumed (see Table 5.5).

As 2044 kJ are released at the same time as these species are formed, the maximum temperature rise will be

Table 5.5 Thermal capacity of the products of combustion of a stoichiometric propane/air mixture

	No. of moles	Thermal capacity at 1000 K	
		(J/mol·K)	(J/K)
CO_2	3	54.3	162.9
H_2O	4	41.2	164.8
N_2	18.8	32.7	614.8
		Total thermal capacity (per mole of propane)	= 942.5 J/K

$$\Delta T = \frac{2044000}{942.5} = 2169 \text{ K}$$

giving the final (adiabatic) temperature as 2169 + 298 = 2467 K. In fact, this figure is approximate for the following reasons:

1. Thermal capacities change with temperature, and average values over the range of temperatures appropriate to the problem have been used.
2. The system cannot be adiabatic as there will be heat loss by radiation from the hot gases (CO_2 and H_2O).
3. At high temperatures, dissociation of the products will occur; as these are endothermic processes, there will be a reduction in the final temperature.

Of these, (2) and (3) determine that the actual flame temperature will be much lower than predicted. These effects can be taken into account. Thus, with propane burning in air, the final temperature may not exceed 2000 K.

If the propane were burning as a stoichiometric mixture in pure oxygen, then in the absence of nitrogen as a "heat sink," much higher temperatures would be achieved. The total thermal capacity would be (942.5 − 614.8) = 327.7 J/K. However, the amount of heat released remains unchanged (2044 kJ) so that the maximum temperature rise would be

$$\Delta T = \frac{2044000}{327.7} = 6238\text{K}$$

predicting a final temperature of 6263 °C. Because dissociation will be a dominant factor,

this cannot be achieved and the temperature of the flame will not exceed approximately 3500 K.

The occurrence of dissociation at temperatures in the region of 2000 K and above makes it necessary to take dissociation into account. Dissociation is discussed in Chap. 6. However, the simple calculation outlined above can be used to estimate the temperatures of near-limit flames, when the temperature is significantly lower and dissociation can be neglected.

It is known that the lower flammability limit of propane is 2.2 %. The oxidation reaction taking place in this mixture can be described by the following equation:

$$0.022C_3H_8 + 0.978(0.21O_2 + 0.79N_2) \rightarrow \text{products}$$

Dividing through by 0.022 allows this to be written

$$C_3H_8 + 9.34O_2 + 35.12N_2 \rightarrow 3CO_2 + 4H_2O + 4.34O_2 + 35.12N_2 \quad (5.R9)$$

showing that the heat released by the oxidation of 1 mole of propane is now absorbed by excess oxygen (4.34 moles) and an increased amount of nitrogen as well as the combustion products. Carrying out the same calculation as before, it can be shown that the total thermal capacity of the products per mole of propane consumed is 1627.6 kJ/K, which gives the adiabatic flame temperature for this limiting mixture is 1281 °C (1554 K). If the same calculation is carried out for the other hydrocarbon gases, it is found that the adiabatic limiting flame temperature lies in a fairly narrow band, 1600 ± 100 K (Table 5.6). This can be interpreted by assuming that the limit exists because heat losses (by radiation from the flame) exceed the rate of heat production (within the flame). As a consequence, flame cannot sustain itself. This concept can be applied to certain practical problems relating to the lower flammability limit.

Example 1 It is recognized that the leak of propane into a test cell could lead to a flammable atmosphere, and it is decided to keep the atmosphere inert by the addition of nitrogen. Calculate the percentage of nitrogen necessary to prevent ignition of a mixture in which the propane and air are in stoichiometric proportions.

Table 5.6 Adiabatic flame temperature of lower-limiting hydrocarbon/air mixtures

Gas	Adiabatic flame temperature at lower flammability limit (K)
Methane	1446
Ethane	1502
Propane	1554
n-Butane	1612
n-Pentane	1564
n-Heptane	1692
n-Octane	1632

Solution The stoichiometric reaction for propane in air is

$$C_3H_8 + 5O_2 + 18.8N_2 \rightarrow 3CO_2 + 4H_2O + 18.8N_2 \quad (5.R10)$$

and the heat of combustion of propane is 2044 kJ/mole. It is assumed that the heat of combustion is absorbed by the products $3CO_2 + 4H_2O + 18.8\ N_2$. It was shown above that the adiabatic flame temperature (i.e., the temperature of the product gases, assuming no heat losses) will be 2169 K. If the flame temperature can be held below 1600 K (or 1554 K, according to Table 5.6), then flame propagation will not be possible and the introduction of an ignition source will not lead to an explosion. Suppose that the extra quantity of nitrogen required to form an "inert atmosphere" corresponds to X moles per mole of propane. Then

$$C_3H_8 + 5O_2 + 18.8N_2 + XN_2 \rightarrow 3CO_2 + 4H_2O + (18.8 + X)N_2 \quad (5.R11)$$

Following the procedure illustrated in Table 5.5, the thermal capacity of the product gases—$3CO_2 + 4H_2O + (18.8 + X)N_2$—will be $3 \times 54.3 + 4 \times 41.2 + (18.8 + X) \times 32.7 = \Sigma C_p$. If sufficient nitrogen has been added to reduce the adiabatic flame temperature to 1554 K, then the

thermal capacity of the product gases will be given by

$$\sum C_p = \frac{2044000}{1554 - 298} = 1627.4\,\text{kJ/mole of propane}$$

Thus

$$3 \times 54.3 + 4 \times 41.2 + (18.8 + X) \times 32.7 = 1627.4$$

$$X = 20.9$$

Consequently, the amount of nitrogen added to the air in the test cell to render the atmosphere "inert" with respect to a leak of propane corresponds to 20.9 moles of N_2 for every (5 + 18.8) = 23.8 moles of air, that is, the mixture in the cell must be 47 % nitrogen, the balance being air. (Experimentally, a significantly lower figure is obtained—c. 40 %. It should be remembered that in the above calculation it is assumed that the adiabatic temperature assumption is valid and that the reaction will go to completion.)

Example 2 A mechanical engineering research laboratory contains a six-cylinder internal combustion engine that is being used for research into the performance of spark plugs. The fuel being used is methane, CH_4, and the fuel-air mixture can be adjusted at will. The combustion products are extracted from the exhaust manifold through a 30 cm square duct, 20 m long. It is found that the engine will continue to operate with a stoichiometric mixture when only three of the cylinders are firing. If under these conditions the average temperature of the gases entering the duct from the manifold is 700 K, is there a risk of an explosion in the duct?

Solution The stoichiometric reaction for methane in air is

$$CH_4 + 2O_2 + 7.52N_2 \rightarrow CO_2 + 2H_2O + 7.52N_2 \quad (5.R12)$$

If we consider that 1 mole of fuel passes through each of the six cylinders, but of the 6 moles only three are burned, we have overall

$$6CH_4 + 12O_2 + 45.12N_2 \rightarrow 3CH_4 + 3CO_2 + 6H_2O + 6O_2 + 45.12N_2 \quad (5.R13)$$

Dividing through by 3 gives

$$2CH_4 + 4O_2 + 15.04N_2 \rightarrow CH_4 + 2O_2 + CO_2 + 2H_2O + 15.04N_2 \quad (5.R14)$$

The mixture discharged into the exhaust manifold has the composition given by the right-hand side of Reaction 5.R14. If this "burns" at 700 K, the final abiabatic flame temperature may be calculated on the basis of the reaction

$$CH_4 + 2O_2 + CO_2 + 2H_2O + 15.04N_2 \rightarrow 2CO_2 + 4H_2O + 15.04N_2 \quad (5.R15)$$

The total thermal capacity of the product gases ($2CO_2$ + $4H_2O$ + 15.04 N_2) (at 1000 K) can be shown to be 765.3 J per mole of methane burned. Using Kirchoff's equation (Equation 5.19), $\Delta H_c(CH_4)$ at 700 K is calculated as 802.8 kJ/mol, giving $\Delta T = 802800/765.3 =$ 1049 K. This gives a final temperature of 1749 K, which is significantly higher than the limiting flame temperature (1600 K) discussed above. This indicates that there is a risk of explosion, and measures should be applied to prevent this mixture being discharged into the duct.

It should be noted that at 700 K there will be a "slow" reaction between methane and the oxygen present, which could invalidate the tacit assumption that the duct becomes completely filled with the mixture described by the right-hand side of Reaction 5.R13. However, slow oxidation of the methane will tend to make the mixture less flammable, and so the calculation gives a conservative answer.

Nomenclature

A	Area (Equation 5.5)
A_w	Area of ventilation opening
C_p	Specific heat
E	Internal energy
F	Force (Equation 5.4)
H	Height of ventilation opening
H	Enthalpy
ΔH_c	Heat of combustion
ΔH_f	Heat of formation
$\dot{m}$	Mass rate of burning
$\dot{m}_{\text{air}}$	Mass flow rate of air
n	Number of moles
p	Pressure
q	Energy
Q_c	Rate of heat release
R	Universal gas constant
T	Temperature
V	Volume
w	Work

Subscripts

c	Combustion
F	Final
f	Formation
o	Initial
p	Constant pressure
v	Constant volume

Chemical Equilibrium

6

Raymond Friedman

Introduction

The temperature of a flame must be known in order to calculate convective and radiative heat transfer rates, which control pool-fire burning rates, flame spread rates, remote ignitions, damage to exposed items (e.g., structural steel, wiring), and response of thermal fire detectors or automatic sprinklers.

Chapter 5 provides a simple technique for calculating flame temperature, based on ignoring the dissociations that occur at high temperature. Although the error is small for near-limit flames, this technique gives answers that are too high. For example, if propane (C_3H_8) burns in stoichiometric proportions with air at 300 K, and it is assumed that the only products are CO_2, H_2O, and N_2, then the simple thermochemical calculation yields a flame temperature of 2394 K. On the other hand, if chemical equilibrium is considered, so that the species CO, O_2, H_2, OH, H, O, and NO are assumed present in the products, then the flame temperature, calculated by methods described in this section, comes out to be 2268 K. Flame temperature measurements in laminar premixed propane-air flames agree with the latter value. (The discrepancy in flame temperature caused by neglecting dissociation would be even greater for fires in oxygen-enriched atmospheres.)

The chemical equilibrium calculation yields not only the temperature but the equilibrium composition of the products. Thus, the generation rate of certain toxic or corrosive products such as carbon monoxide, nitric oxide, or hydrogen chloride may be calculated, insofar as the assumption of equilibrium is valid.

For a fire in a closed volume, the final pressure as well as the temperature will depend on the dissociations and therefore require a calculation taking chemical equilibrium into account.

From a fire research viewpoint, there is interest in correlating flammability limits, extinguishment, soot formation, toxicity, flame radiation, or other phenomena; and chemical equilibrium calculations in some cases will be a useful tool in such correlations.

In a later part of this chapter, departure of actual fires from chemical equilibrium will be discussed.

The Chemical Equilibrium Constant

Consider a chemical transformation, such as

$$2CO + O_2 \rightarrow 2CO_2 \qquad (6.1)$$

If this process can occur, presumably the reverse process can also occur (principle of microscopic reversibility, or principle of detailed balancing):

$$2CO_2 \rightarrow 2CO + O_2 \qquad (6.2)$$

DOI 10.1007/978-1-4939-2565-0_6, © Society of Fire Protection Engineers 2016

If both processes occur at finite rates in a closed system, then, after a sufficient time, a condition of *chemical equilibrium* will be reached, after which no further change occurs as long as the temperature and pressure remain constant and no additional reactants are introduced. This condition of equilibrium can be expressed as a *mathematical constraint* on the system, which, for the gaseous reaction $2CO + O_2 \rightleftarrows 2CO_2$, can be written

$$K_3 = \frac{p^2_{CO_2}}{p^2_{CO}\, p_{O_2}} \tag{6.3}$$

where the p_i are partial pressures (atm)[1] and K_3 is the equilibrium constant. This expression can be rationalized by the following argument.

According to the chemical "law of mass action," first stated a century ago, the rate of the forward reaction (Equation 6.1) at a given temperature is given by $k_f p^2_{CO} p_{O_2}$ while the rate of the reverse reaction (Equation 6.2) is given by $k_r p^2_{CO_2}$. At equilibrium, the forward rate must be equal to the reverse rate:

$$k_f p^2_{CO} p_{O_2} = k_r p^2_{CO_2} \tag{6.4}$$

which may be rearranged to

$$\frac{p^2_{CO_2}}{p^2_{CO}\, p_{O_2}} = \frac{k_f}{k_r} = K_3 \tag{6.5}$$

Although this appears to be a satisfactory explanation, research over the past hundred years has shown that chemical reactions in fact rarely proceed as suggested by the stoichiometric equation. (This is discussed more fully in Chap. 13.) For example, the three-body collision of two CO molecules and an O_2 molecule, resulting in the formation of two CO_2 molecules, simply does not happen. Rather, the reaction would occur as follows:

$$O_2 + M \rightarrow 2O + M \tag{6.6}$$

(where M is any molecule) followed by

$$O + CO + M \rightarrow CO_2 + M \tag{6.7}$$

Now, observe how Equation 6.3 can be obtained from this reaction sequence.

The reverse of $O_2 + M \rightarrow 2O + M$, namely $2O + M \rightarrow O_2 + M$, can also occur, and the equilibrium constant for this pair of reactions, which actually do occur, is $K6 = p_O{}^2 p_M / p_{O_2} p_M = p_O{}^2 / p_{O_2}$. (The p_M term cancels.)

Similarly the reverse reaction $CO_2 + M \rightarrow O + CO + M$ can occur, and the equilibrium constant is $K_7 = p_{CO_2} / p_{CO}\, p_O$. If we now multiply $K_7{}^2$ by K_6, we obtain

$$K_7^2 K_6 = \left(\frac{p_{CO_2}}{p_{CO}\, p_O}\right)^2 \frac{p_O{}^2}{p_{O_2}} = \frac{p^2_{CO_2}}{p^2_{CO}\, p_{O_2}} = K_3 \tag{6.8}$$

Thus, Equation 6.3 is perfectly valid, even if the "law of mass action" does not correctly describe the reaction process involving CO and O_2.

To get a further understanding of the validity of the equilibrium constant concept, consider the following facts: CO will not react with O_2—even by the above mechanism involving O atoms—unless first heated to quite high temperatures. However, at least a trace of moisture is usually present, and in such cases the reaction occurs by the following process, which can occur at lower temperatures. First, H and OH are formed by dissociation of H_2O. Then, the CO is converted by

$$CO + OH \rightleftarrows CO_2 + H \quad K_9 = \frac{p_{CO_2} p_H}{p_{CO}\, p_{OH}} \tag{6.9}$$

while the O_2 reacts with H:

$$O_2 + H \rightleftarrows OH + O \quad K_{10} = \frac{p_{OH} p_O}{p_{O_2} p_H} \tag{6.10}$$

If the quantity $K_9{}^2 K_{10}$ is now calculated,

$$K_9^2 K_{10} = \frac{p^2_{CO_2}}{p^2_{CO}\, p_{O_2}} \frac{p_H p_O}{p_{OH}} \tag{6.11}$$

[1] In place of partial pressures, the concentrations of the species in moles/liter can be used in these formulae instead (see Chap. 13).

But, the reaction $H + O + M \rightarrow OH + M$ can occur, as well as its reverse, $OH + M \rightarrow H + O + M$. It does not matter if these reactions are actually important in the rate of oxidation of CO in the presence of H_2O. As long as these reactions can occur, then at equilibrium

$$k_f p_H p_O p_M = k_r p_{OH} p_M$$

and

$$\frac{k_f}{k_r} = K_{12} = \frac{p_{OH}}{p_H p_O} \tag{6.12}$$

Substituting this into Equation 6.11

$$\frac{p^2_{CO_2}}{p^2_{CO} p_{O_2}} = K_9^2 K_{10} K_{12} = K_3 \tag{6.13}$$

Thus, the ratio $p^2_{CO_2}/p^2_{CO} p_{O2}$ is a constant at equilibrium (at a given temperature) regardless of the reaction mechanism, even if other (hydrogen-containing) species are involved, because by the principle of microscopic reversibility, these other species (catalysts) affect the reverse reaction as well as the forward reaction.

Let us now consider the mathematical specification of the CO–CO_2–O_2 system at equilibrium. The system, at a given temperature and pressure, may be described by three variables, namely the partial pressures of the three species: p_{CO}, p_{O_2}, and p_{CO_2}. There are already two well-known constraints on the system: (1) The sum of the partial pressures must equal the total pressure, p

$$p_{CO} + p_{O_2} + p_{CO_2} = p \tag{6.14}$$

and (2) the ratio of carbon atoms to oxygen atoms in the system must remain at the original, presumably known, value of C/O:

$$\frac{C}{O} = \frac{p_{CO} + p_{CO_2}}{p_{CO} + 2p_{O_2} + 2p_{CO_2}} \tag{6.15}$$

A third constraint, that of chemical equilibrium, provides a third equation involving p_{CO}, p_{O_2}, and p_{CO_2}:

$$\frac{p^2_{CO_2}}{p^2_{CO} p_{O_2}} = K_3 \tag{6.3}$$

Now the system is completely defined by the simultaneous solution of these three equations. The equilibrium constant varies with temperature but is independent of pressure (except at rather high pressures). It is also independent of the presence of other reactive chemical species.

Generalized Definition of Equilibrium Constant

For a generalized reaction

$$aX_1 + bX_2 \rightleftarrows cY_1 + dY_2$$

K would be given by

$$K = \frac{(pY_1)^c (pY_2)^d}{(pX_1)^a (pX_2)^b}$$

Attention should be paid to the manner in which a chemical reaction is written. For example, instead of writing $2CO + O_2 \rightleftarrows 2CO_2$ one could equally well have written $CO + 1/2O_2 \rightleftarrows CO_2$. The equilibrium constant for the latter formulation is

$$K_{16} = \frac{p_{CO_2}}{p_{CO} p_{O_2}^{1/2}} \tag{6.16}$$

By comparison of Equation 6.16 with Equation 6.3, it is clear that $K_{16} = \sqrt{K_3}$. If the reaction was written as $2CO_2 \rightleftarrows 2CO + O_2$ the equilibrium constant would be equal to $1/K_3$.

Simultaneous Equilibria

In most real chemical systems, one must deal with a number of simultaneous chemical equilibria. For example, air at 2500 K will contain the species N_2, O_2, NO, and O. The following simultaneous equilibria may be considered

$$O_2 = 2O \quad K_{17} = \frac{p_O{}^2}{p_{O_2}} \tag{6.17}$$

$$N_2 + O_2 = 2NO \quad K_{18} = \frac{p^2 NO}{p_{N_2} p_{O_2}} \tag{6.18}$$

$$N_2 + 2O = 2NO \quad K_{19} = \frac{p^2NO}{p_{N_2} {p_O}^2} \tag{6.19}$$

It is easily seen from the above relations that $K_{19} = K_{18}/K_{17}$. Hence, Equations 6.17, 6.18, and 6.19 are not three independent equations, and any *two* of these equations may be used to describe the equilibrium condition; the third would be redundant. To determine the four unknowns, p_{N_2}, p_{O_2}, p_{NO}, and p_O, one would solve the selected two equilibrium relations plus the following two relations:

$$p_{NO} + p_{N_2} + p_{O_2} + p_O = p \tag{6.20}$$

And

$$\frac{p_{NO} + 2p_{N_2}}{p_{NO} + 2p_{O_2} + p_O} = 3.76 \tag{6.21}$$

where 3.76 is the ratio of nitrogen atoms to oxygen atoms in air.

If one knows the temperature, the equilibrium constants may be calculated from the thermodynamic properties of the reactants and products, as discussed in the next section. However, since the various equilibrium reactions release or absorb energy, and accordingly raise or lower the temperature of an adiabatic system respectively, the determination of equilibrium composition of an adiabatic system must proceed simultaneously with the calculation of its temperature; that is, an energy balance must be satisfied as well as the equilibrium equations, the atom-ratio equations, and the $p = \sum p_i$ equation.

As a general rule, a gaseous chemical system *at a given temperature,* containing s kinds of chemical species involving e chemical elements, requires s-e equilibrium relations, e-1 atom-ratio relations, and a $p = \sum p_i$ equation, in order to specify it. If the temperature is unknown, an energy balance equation is also needed. (If the pressure is unknown but the volume is known, then the equation of state must be used in the pressure equation.)

In order to solve an actual problem, one must select the species to be considered. The more species one includes, the more difficult is the calculation. There is no need to include any species that will be present in very small quantity at equilibrium. Some guidelines can be provided.

For combustion of a C–H–O compound in air, it is usually sufficient to include the species CO_2, H_2O, N_2, O_2, CO, H_2, OH, H, O, and NO. These species are adequate if the air-fuel ratio is sufficiently large so that the O/C atomic ratio is greater than one. If the O/C atomic ratio is less than one, then solid carbon must be considered, as well as many additional gaseous species. If chlorine is present, then HCl, Cl_2, and Cl must be added. If sulfur is present, then SO_2 and SO_3 are the primary species, unless there is a deficiency of oxygen.

The Quantification of Equilibrium Constants

While a chemist might establish the numerical value of an equilibrium constant for $A \rightleftarrows B$ by direct measurement of the partial pressures of A and B in a system at equilibrium, this is rarely done because it is difficult to make such measurements in a high-temperature system, and it takes a long time to establish equilibrium in a low-temperature system. Instead, the equilibrium constant is generally determined from the thermodynamic relation first deduced by van't Hoff in 1886 [1]

$$\Delta F^o = -RT \ln K \tag{6.22}$$

If this equation is applied to $A \rightleftarrows 2B$ at absolute temperature T, then $K = p_B^2/p_A$, and ΔF^o is the free energy of two moles (mol) of B at 1 atm and temperature T, minus the free energy of 1 mol of A at 1 atm and temperature T. (The superscript o designates that each substance is in its "standard state," that is, an ideal gas at 1 atm.) By definition

$$\begin{aligned} \Delta F^o &= \Delta H^o - T\Delta S^o \\ &= \Delta E^o + (pV^o) - T\Delta S^o \end{aligned} \tag{6.23}$$

Accordingly, if ΔS^o, the entropy difference, and either ΔH^o, the enthalpy difference, or ΔE^o, the

energy difference, are known for the substances involved in an equilibrium at temperature T, then the equilibrium constant, K, may be calculated. It happens that ΔS^o, ΔH^o, and ΔE^o are well known for almost all substances expected to be present at equilibrium in combustion gases at any temperature up to 4000 K, so the calculation of equilibrium constants is straightforward.

The variation of the equilibrium constant with temperature was shown by van't Hoff [1] to be given by

$$\frac{d \ln K}{dT} = \frac{\Delta H^o}{RT^2} \left(= \frac{\Delta H}{RT^2} \text{ for ideal gases} \right) \tag{6.24}$$

Thus, for an exothermic reaction occurring at temperature T, ΔH is negative and K decreases as T increases. The converse is true for endothermic reactions.

It is appropriate to inquire about the underlying physical reason for the value of K to be governed by ΔF^o (actually ΔH^o and ΔS^o). An explanation is as follows: any chemical system being held at constant temperature will seek to reduce its energy, E, and to increase its entropy, S. The reduction of energy is analogous to a ball rolling downhill. The increase of entropy is analogous to shuffling a sequentially arranged deck of cards, yielding a random arrangement. These two tendencies will often affect the equilibrium constant in opposite directions.

Consider the equation

$$\ln K = \frac{\Delta S^o}{R} - \frac{\Delta E^o}{RT} - \Delta n \tag{6.25}$$

where Δn is the increase in the number of moles of product relative to reactant. Equation 6.25 is obtained by combining Equations 6.22 and 6.23 with the ideal gas law at constant temperature $\Delta(pV^o) = \Delta nRT$. Inspection of Equation 6.25 shows that, if ΔS^o is a large positive quantity and $\Delta S^o/R$ dominates the other terms, K will be large, that is, the reaction is driven by the "urge" to increase entropy. Again, if the reaction is highly endothermic, then $-\Delta E^o/RT$ will be a large negative number and can dominate the other terms to cause K to be small, that is, the reaction prefers to go in the reverse, or exothermic, direction and reduces the energy of the system. (Most spontaneous reactions are exothermic.) The Δn term is generally small compared with the other terms and represents the work done by the expanding system on the surroundings, or the work done on the contracting system by the surroundings.

In summary, Equation 6.25 represents the balance of these various tendencies and determines the relative proportions of reactants and products at equilibrium. Notice that the term $\Delta E^o/RT$ becomes small at sufficiently high temperature, and the entropy term then dominates. In other words, all molecules break down into atoms at sufficiently high temperature, to maximize entropy. The important conclusion from this discussion is that there is no need to consider rates of forward and reverse processes to determine equilibrium.

Table 6.1 provides values of equilibrium constants for 13 reactions involving most species found in fire products at equilibrium, over a temperature range from 600 K to 4000 K. Equilibrium constants for other reactions involving the same species may be obtained by combining these constants, as in Equation 6.13, or as illustrated in the examples below.

Table 6.1 does not include the $\frac{1}{2}\ N_2 = N$ equilibrium, because fire temperatures are generally not high enough for significant N to form. Tables 6.2 and 6.3 present information on the degree to which various gases are dissociated at various temperatures.

In performing calculations, remember that even if a relatively small fraction of dissociation occurs, a rather large amount of energy may be absorbed in the dissociation, with a corresponding large increase in the energy of the system. For example, if water vapor initially at 2800 K is allowed to dissociate adiabatically at 1 atm, only 5.7 % of the H_2O molecules will dissociate, but the temperature will drop from 2800 K to 2491 K; that is, the temperature relative to a 300 K baseline is lower by 12.4 %.

Carbon Formation in Oxygen-Deficient Systems

Solid carbon (soot) may be expected to form in oxygen-deficient combustion products, under some conditions. Since solid carbon does not melt or boil until extremely high temperatures (~4000 K), we only need concern ourselves with solid carbon $C_{(s)}$, not liquid $C_{(l)}$ or gaseous carbon $C_{(g)}$.

Consider pure carbon monoxide at 2000 K. There are three conceivable ways in which it might form solid carbon:

$$\alpha: \mathrm{CO} \rightleftarrows \frac{1}{2}\mathrm{C_{(s)}} + \frac{1}{2}\mathrm{CO_2} \qquad K_\alpha = \frac{\left(p_{\mathrm{CO_2}}\right)^{1/2}}{p_{\mathrm{CO}}}$$

$$\beta: \mathrm{CO} \rightleftarrows \mathrm{C_{(s)}} + \frac{1}{2}\mathrm{O_2} \qquad K_\beta = \frac{\left(p_{\mathrm{O_2}}\right)^{1/2}}{p_{\mathrm{CO}}}$$

$$\gamma: \mathrm{CO} \rightleftarrows \mathrm{C_{(s)}} + \mathrm{O} \qquad K_\gamma = \frac{p_{\mathrm{O}}}{p_{\mathrm{CO}}}$$

Note that solid carbon does not appear in any of the equilibrium expressions. (By convention, a solid in equilibrium with gases is assigned a value of unity.)

From Table 6.1, we see that, at 2000 K,

$$K_\alpha = \frac{K_E^{1/2}}{K_F} = \mathrm{antilog}_{10}\left[\left(\frac{10.353}{2}\right) - 7.469\right] = 5.1 \times 10^{-3}$$

$$K_\beta = \frac{1}{K_F} = \mathrm{antilog}_{10}[0 - 7.469] = 3.4 \times 10^{-8}$$

$$K_\gamma = \frac{K_A}{K_F} = \mathrm{antilog}_{10}[-3.178 - 7.469] = 2.2 \times 10^{-11}$$

We see that K_α, K_β, and K_γ are all small compared with unity, so very little of the CO would decompose by any of these modes. However, K_α is much larger than either K_β or K_γ, so it is the dominant mode for whatever decomposition may occur.

Thus, from the expression $p_{\mathrm{CO_2}} = (\mathrm{K_a}\, p_{\mathrm{CO}})^2$, and taking p_{CO} as 1 atm, we calculate $p_{\mathrm{CO_2}} = \left(5.1 \times 10^{-3}\right)^2 = 2.6 \times 10^{-5}$atm. Since, by process α, 2 mol of CO must decompose for each mole of CO_2 formed, we conclude that $2 \times 2.6 \times 10^{-5}$ or 5.2×10^{-5} mol of CO will decompose to $C_{(s)}$ plus CO_2, per mole of CO originally present, after which we will have reached an equilibrium state. In other words, about 1/20,000 of the CO will decompose.

If the original mixture had consisted of CO at 1 atm plus CO_2 at any pressure greater than 2.6×10^{-5} atm, at 2000 K, then we could conclude that no carbon whatsoever would form.

It can also be shown that addition of a trace of O_2 or H_2O to CO at 2000 K would completely suppress carbon formation. As a general statement, for a chemical system containing fewer carbon atoms than oxygen atoms, the equilibrium condition will favor CO formation rather than that of solid carbon.

For a carbon-containing system with little or no oxygen, carbon may or may not form, depending on the hydrogen partial pressure. For example, carbon may form according to $C_2H_2 \rightleftarrows C_{(s)} + H_2$. The equilibrium expression for this reaction is written

$$\frac{p_{\mathrm{H_2}}}{p_{\mathrm{C_2H_2}}} = K(= 13.9\,\mathrm{at}\,3000\mathrm{K})$$

Again, note that solid carbon does not appear in the expression. If we rewrite the expression in the form $p_{\mathrm{H_2}} > 13.9\, p_{C_2H_2}$, it becomes the criterion for suppression of carbon formation at 3000 K. In other words, as long as $p_{\mathrm{H_2}}$ is more than 13.9 times as large as $p_{\mathrm{C_2H_2}}$, no carbon will form at 3000 K and any carbon present will be converted to C_2H_2. On the other hand, pure C_2H_2 will decompose to $C_{(s)}$ plus H_2 until the H_2/C_2H_2 ratio reaches 13.9, after which no further decomposition will occur at 3000 K.

Another way to view this is to say that H_2, C_2H_2, and solid carbon at 3000 K will be in a state of equilibrium if and only if the ratio $p_{\mathrm{H_2}}/p_{\mathrm{C_2H_2}} = 13.9$, and this is true regardless of the quantity of solid carbon present, and also regardless of the presence of other gases.

For a C–H–O–N system, the threshold conditions for equilibrium carbon formation are

Table 6.4 Threshold atomic C/O ratios for carbon formation (equilibrium at 1 atm, N/O = 3.76)

	Temperature (K)			
Atomic H/C ratio	1600	2000	2400	2800
0	1.00	1.00	1.00	1.00
2	1.00	1.02	1.09	1.30
4	1.00	1.05	1.16	1.56

somewhat more complicated, but the trends are illustrated by the calculated values shown in Table 6.4 for carbon formation thresholds in carbon-hydrogen-air systems at 1 atm.

It must be noted that carbon forms more readily in actual flames than Table 6.4 indicates, because of nonequilibrium effects. In premixed laminar flames, incipient carbon formation occurs at a C/O ratio roughly 60 % of the values shown in Table 6.4. See the next section for further comments on nonequilibrium.

Departure from Equilibrium

This procedure of specifying chemical systems by equilibrium equations will only yield correct results if the system is truly in equilibrium. If one prepares a mixture of H_2 and O_2 at room temperature and then ages the mixture for a year, it will be found that essentially nothing has happened and the system will still be very far from equilibrium. On the other hand, such a system at a high temperature characteristic of combustion will reach equilibrium in a small fraction of a second. For example, a hydrogen atom, H, in the presence of O_2 at partial pressure 0.1 atm will react so fast at 1400 K that its half-life is only about 2 μs. (At room temperature, the half-life of this reaction is about 300 days.)

Since peak flame temperatures are almost always above 1400 K, and sometimes as high as 2400 K, it would appear that equilibrium would always be reached in flames. However, luminous (yellow) flames rapidly lose heat by radiation, turbulent flames may be partially quenched by the action of steep velocity gradients, and flames burning very close to a cold wall may be partially quenched by heat transfer to the wall. Thus, the equilibrium condition is only a limiting case that real flames may approach. The products of a nonluminous laminar flame more than a few millimeters from any cold surface will always be very nearly in equilibrium.

Sample Problems

Example 1 Given a mixture of an equal number of moles of steam and carbon monoxide, what will the equilibrium composition be at 1700 K and 1 atm?

Solution We would expect the species CO, H_2O, CO_2, and H_2 to be present. From Table 6.2, we see that the equilibria $H_2 \rightleftarrows 2H$, $O_2 \rightleftarrows 2O$, and $H_2O \rightleftarrows 1/2H_2 + OH$ can all be neglected at 1700 K, so the species H, O, and OH will not be present in significant quantities.

Since we have four species involving three chemical elements, we will require 4—3 or 1, equilibrium relationship, for the equilibrium $H_2O + CO \rightleftarrows H_2 + CO_2$.

The relationship is

$$\frac{p_{H_2} \cdot p_{CO_2}}{p_{H_2O} \cdot p_{CO}} = K \tag{6.26}$$

In addition, we need 3—1, or 2, atom-ratio relations, which are

$$\frac{H}{C} : \frac{2p_{H_2} + 2p_{H_2O}}{p_{CO} + p_{CO_2}} = 2 \tag{6.27}$$

(because the original mixture of H_2O + CO contains two H atoms per C atom) and

$$\frac{O}{C} : \frac{p_{H_2O} + p_{CO} + 2p_{CO_2}}{p_{CO} + p_{CO_2}} = 2 \tag{6.28}$$

(because the original mixture of H_2O + CO contains two O atoms per C atom). Finally, the sum of the partial pressures equals 1 atm:

$$p_{H_2O} + p_{CO} + p_{H_2} + p_{CO_2} = 1 \tag{6.29}$$

We now have a well-set problem, four equations and four unknowns, which may be solved as soon as K is quantified.

We do not find the equilibrium $H_2O + CO \rightleftarrows H_2 + CO_2$ in Table 6.1. However, if we calculate (K_E/K_FK_C) from Table 6.1, we see that

$$\frac{K_E}{K_FK_C} = \frac{p_{CO_2}}{(1)\cdot p_{O_2}} \cdot \frac{(1)\cdot \left(p_{O_2}\right)^{1/2}}{p_{CO}} \cdot \frac{p_{H_2}\cdot \left(p_{O_2}\right)^{1/2}}{p_{H_2O}} = \frac{p_{CO_2}\cdot p_{H_2}}{p_{CO}\cdot p_{H_2O}} = K$$

From Table 6.1, $\log_{10}(K_EI/K_FK_C)$ at 1700 K = 12.180 – 8.011 – 4.699 = –0.51, and K = antilog$_{10}$ (–0.51) = 0.309.

Upon substituting $K = 0.309$ into Equation 6.26, and then simultaneously solving Equations 6.26, 6.27, 6.28, and 6.29, we obtain

$$p_{CO_2} = p_{H_2} = 0.179 \text{ atm}$$

and

$$p_{H_2O} = p_{CO} = 0.321 \text{ atm}$$

Example 2 One mole of hydrogen is introduced into a 50-L vessel that is maintained at 2500 K. How much dissociation will occur, and what will the pressure be?

Solution Let α be the degree of dissociation of the hydrogen defined by $\left(\alpha = (p_H/2)/\left[p_{H_2} + (p_H/2)\right]\right)$. Thus, α ranges from zero to one. One mole of H_2 partially dissociates to produce 2 α mol of H, leaving 1—α mol of H_2. The total number of moles is then 2 α + 1 – α, or α + 1. In view of the definition of α, the total number of moles present is $\left(\left(p_H + p_{H_2}\right)/\left[p_{H_2} + (p_H/2)\right]\right)$.

By the ideal gas law, $PV = nRT$.

$$\left(p_H + p_{H_2}\right)(50) = \frac{p_H + p_{H_2}}{p_{H_2} + (p_H/2)}(0.08206)(2500) \tag{6.30}$$

which reduces to

$$p_{H_2} + \frac{p_H}{2} = 4.103 \tag{6.31}$$

The equilibrium equation is

$$\frac{p_H}{\left(p_{H_2}\right)^{1/2}} = K_B \tag{6.32}$$

From Table 6.1, $\log_{10}K_B = -1.601$ at 2500 K, and therefore $K_B = 0.0251$. Upon substitution into Equation 6.32 and elimination of p_{H_2} between Equations 6.31 and 6.32, one obtains

$$p_H{}^2 + 0.000316\,p_H - 0.00258 = 0 \tag{6.33}$$

This equation yields a positive and a negative root. The negative root has no physical significance. The positive root is $p_H = 0.0506$ atm. Then, Equation 6.32 yields $p_{H_2} = 4.08$ atm, and the total final pressure is 4.08 + 0.0506 = 4.13 atm. The degree of dissociation, α, comes out to be 0.0062. (This is less dissociation than indicated by Table 6.2 because the pressure is well above 1 atm.)

Example 3 Propane is burned adiabatically at 1 atm with a stoichiometric proportion of air. Calculate the final temperature and composition. The initial temperature is 300 K.

Solution The problem must be solved by a series of iterations. The first step is to assume a final temperature, either based on experience or by selecting a temperature substantially below the value calculated by assuming that CO_2 and H_2O are the only products of combustion. The second step is to solve the set of equations that specify the equilibrium composition at the assumed final temperature. The third step is to consult an overall enthalpy balance equation, which will show that the assumed final temperature was either too high or too low. The fourth step is to assume an appropriate new final temperature. The fifth and sixth steps are repeats of the second and third steps. If the correct final temperature is now found to be bracketed between these two assumed temperatures, then an interpolation should give a fairly accurate value of the true final temperature. Additional iterations may be made to improve the accuracy of the results to the degree desired. As a guess, the final temperature is assumed to be 2300 K.

Now the equilibrium equations at 2300 K are set up. The species to be considered are three principal species: CO_2, H_2O, and N_2, and seven minor species: H_2, O_2, OH, H, O, CO, and NO.

(Based on chemical experience, the following possible species may be neglected at 2300 K when stoichiometric oxygen is present: N, $C_{(g)}$, NH, CN, CH, C_2, HO_2, HCN, O_3, C_3, NO_2, HNO, C_2H, CH_2, C_2O, CHO, and NH_2.) Thus, we consider ten species involving four elements, so 10—4 or 6, equilibrium equations are needed. Any six *independent* equilibria may be selected. We can assure independence by requiring that each successive equilibrium expression we write will introduce at least one new chemical species. Observe that this requirement is met in the following list:

$$CO + \frac{1}{2}O_2 = CO_2 \qquad \frac{p_{CO_2}}{p_{CO} \cdot (p_{O_2})^{1/2}} = K = \frac{K_E}{K_F} \tag{6.34}$$

$$\frac{1}{2}O_2 = O \qquad \frac{p_O}{(p_{O_2})^{1/2}} = K_A \tag{6.35}$$

$$\frac{1}{2}O_2 + \frac{1}{2}N_2 = NO \qquad \frac{p_{NO}}{(p_{O_2} \cdot p_{N_2})^{1/2}} = K_G \tag{6.36}$$

$$H_2 + \frac{1}{2}O_2 = H_2O \qquad \frac{p_{H_2O}}{p_{H_2}(p_{O_2})^{1/2}} = K_C \tag{6.37}$$

$$H_2 + \frac{1}{2}O_2 = H_2O \qquad \frac{p_{OH}}{(p_{H_2} \cdot p_{O_2})^{1/2}} = K_D \tag{6.38}$$

$$\frac{1}{2}H_2 = H \qquad \frac{\overline{p}_H}{(p_{H_2})^{1/2}} = K_B \tag{6.39}$$

Four additional equations are needed to determine the ten unknown partial pressures. These are three atom-ratio equations and a summation of the partial pressures to equal the total pressure. To obtain the atom ratios, we take air to consist of 3.76 parts of N_2 (by volume) per part of O_2, neglecting argon, and other species. Then, from stoichiometry, $C_3H_8 + 5O_2 + (5 \cdot 3.76)N_2 \rightarrow 3CO_2 + 4H_2O + 18.8\ N_2$.

$$\frac{H}{C} : \frac{8}{3} = \frac{p_H + p_{OH} + 2p_{H_2O} + 2p_{H_2}}{p_{CO_2} + p_{CO}} \tag{6.40}$$

$$\frac{H}{N} : \frac{8}{37.6} = \frac{p_H + p_{OH} + 2p_{H_2O} + p_{H_2}}{2p_{N_2} + p_{NO}} \tag{6.41}$$

$$\frac{O}{C} : \frac{10}{3} = \frac{p_O + p_{OH} + p_{NO} + p_{CO} + p_{H_2O} + 2p_{O_2} + 2p_{CO_2}}{p_{CO_2} + p_{CO}} \tag{6.42}$$

Finally,

$$p_{CO_2} + p_{H_2O} + p_{N_2} + p_{H_2} + p_{O_2} + p_{OH} + p_H + p_O + p_{CO} + p_{NO} = 1 \tag{6.43}$$

From Table 6.1 at 2300 K:

	$\log_{10} x$	x
K_E	9.001	–
K_F	7.061	–
K_E/K_F	9.001–7.061	87.1
K_A	–2.307	0.00493
K_G	–1.391	0.0406
K_C	2.682	481
K_D	–0.116	0.766
K_B	–2.016	0.00964

We insert these K values into Equations 6.34, 6.35, 6.36, 6.37, 6.38, and 6.39, and then solve the set of ten equations, Equations 6.34, 6.35, 6.36, 6.37, 6.38, 6.39, 6.40, 6.41, 6.42, and 6.43, for the equilibrium values of the ten partial pressures at 2300 K. This solution may be obtained by a tedious set of successive approximations. The first approximation is obtained by solving for the three principal species N_2, CO_2, and H_2O, assuming the partial pressures of the remaining species are zero. Then, using this trial value of p_{CO_2}, solve for p_{CO} and p_{O_2}, using Equation 6.34 and assuming that $p_{CO} = 2p_{O_2}$. Next, using p_{H_2O} and p_{O_2} as determined, use Equation 6.37 to determine a trial value of p_{H_2}. Then, using all the foregoing partial pressures, determine p_O from Equation 6.35, p_{NO} from Equation 6.36, p_{OH} from Equation 6.38, and p_H from Equation 6.39. Thus, ten trial values of the partial pressures are found. However, upon substitution into Equations 6.40, 6.41, 6.42, and 6.43, none of these equations will be quite satisfied. The partial

pressures of the principal species must then be adjusted so as to satisfy Equations 6.40, 6.41, 6.42, and 6.43, and then a second iteration with the equilibrium equations must be carried out to establish new values for the minor species. After four or five such iterations, the results should converge to a set of partial pressures satisfying all equations.

A faster method is to use a computer program to solve the equations. (See the following section.)

The equilibrium partial pressures at 2300 K will come out to be:

P_{N_2}	0.7195 atm
P_{H_2O}	0.1474 atm
P_{CO_2}	0.1006 atm
P_{CO}	0.0143 atm
P_{O_2}	0.0066 atm
P_{H_2}	0.0038 atm
P_{OH}	0.0037 atm
P_{NO}	0.0028 atm
P_{H}	0.0006 atm
P_{O}	0.0004 atm

Now, we must determine if 2300 K was too high or too low a guess, by writing the enthalpy balance equation (see Chap. 5).

As a basis for the enthalpy balance, we assume that we have exactly 1 mol of products, at 1 atm. Then, if $P_{CO_2} = 0.1006$ atm (see above), we must have 0.1006 mol of CO_2. Similarly, we have 0.0143 mol of CO. Since these are the only two carbon compounds in the products, and since 3 mol of CO_2 + CO must form from each mole of C_3H_8 burned, it follows that $(0.1006 + 0.0143)/3 = 0.0383$ mol of C_3H_8 must have burned. Since the original C_3H_8-air mixture was stoichiometric, it follows that the reactants also consisted of $5 \times 0.0383 = 0.1915$ mol of O_2 and $3.76 \times 0.1915 = 0.7200$ mol of N_2. (Thus, a total of 0.9498 mol of reactant form 1 mol of product, if the product is indeed at equilibrium at 2300 K.)

The enthalpy balance equation is

$$\sum n_i H_{i,T_r} = \sum n_j H_{j,T_p} \qquad (6.44)$$

where n_i and H_i are the number of moles and the enthalpy per mol of each reactant species at reactant temperature T_r, and n_j and H_j are the number of moles and the enthalpy per mol of each product species at product temperature T_p.

The enthalpy of each reactant or product species x at temperature T is given by

$$H_{x,T} = \left(\Delta H_f^\circ\right)_{298.15} + H^\circ - H_{298}^\circ \qquad (6.45)$$

where $(\Delta H_f^\circ,\ _{298.15})_x$ is the enthalpy of formation of a mol of species x from its constituent elements in their standard states at 298 K (see Chap. 5). These constituent elements are H_2, O_2, N_2, and $C_{(s)}$, so $\Delta H_f^\circ,\ _{298.15}$ for each of these four species is zero, by definition.

Values of $(\Delta H_f^\circ)_{298.15}$ and $H^\circ - H_{298}^\circ$ [2] for various species are contained in Table 6.5 on page 1–109. Substitution of numerical values into Equation 6.44 yields:

Reactant species	$(\Delta H_f^\circ)_{298.15}$ (kJ/mol)	$H_{2300}^\circ - H_{298}^\circ$ (kJ/mol)	H_{2300}° (kJ/mol)	n_i (mol)	$n_i H_{i,2300}^\circ$ (kJ)
C_3H_8	–103.85	0.16	–103.69	0.0383	–3.971
O_2	0	0.05	0.05	0.1915	+0.010
N_2	0	0.05	0.05	0.7200	+0.036
				Total =	–3.925

and

Product species	$(H_f^\circ)_{298.15}$ (kJ/mol)	$H_{2300}^\circ - H_{298}^\circ$ (kJ/mol)	H_{2300}° (kJ/mol)	n_i (mol)	$n_i H_{i,2300}^\circ$ (kJ)
N_2	0	66.99	66.99	0.7195	+48.199
H_2O	–241.83	88.29	–153.54	0.1474	–22.632
CO_2	–393.52	109.67	–283.85	0.1006	–28.555
CO	–110.53	67.68	–42.85	0.0143	–0.613
O_2	0	70.60	70.60	0.0066	+0.466
H_2	0	63.39	63.39	0.0038	+0.241
OH	38.99	64.28	103.27	0.0037	+0.382
NO	90.29	68.91	159.20	0.0028	+0.446
H	218.00	41.61	259.61	0.0006	+0.156
O	249.17	41.96	291.13	0.0004	0.116
				Total =	–1.794

The enthalpy of the products (–1.794 kJ) is seen to be 2.131 kJ larger than the enthalpy of the reactants (–3.925 kJ). To put this 2.131 kJ

[2] If $H^\circ - H_{298}^\circ$ is not available from a table, it may be evaluated from the equation $H^\circ - H_{298}^\circ = \int_{298}^{T} C_p\, dT$. For C_3H_8, $Cp = 0.09$ kJ/mol·K at 298 K.

Table 6.5 Enthalpies of selected combustion products[a]

[a]These data are taken from the JANNAF thermochemical tables [2]

difference in perspective, note that the heat of combustion of 0.0383 mol of propane at 298 K, to form 3 mol of CO_2 and 4 mol of H_2O per mole of propane, is 0.0383 (3 × 393.52 + 4 × 241.83 – 103.85) = 78.29 kJ. Thus, the 2.131 kJ discrepancy when compared with 78.29 kJ is rather small, showing that the 2300 K "first guess" was very close. Since the products, at 2300 K, are seen to have a slightly higher enthalpy than the reactants, the correct temperature must be slightly less than 2300 K.

To continue the calculation, the next step is to assume that the final temperature is 2200 K instead of 2300 K. The details will not be presented, but this will yield a new and slightly different set of values of the ten partial pressures of the products. Thus, a new enthalpy balance may be attempted, in the same manner as before. When this is done, the result will be that this time the enthalpy of the reactants will come out to be slightly higher than the enthalpy of the products, showing that the correct temperature is above 2200 K.

An interpolation may be made between the 2200 K enthalpy discrepancy and the 2300 K enthalpy discrepancy, which will show that the correct final temperature is 2268 K. Furthermore, the partial pressures of each product species may be obtained by interpolating between the 2200 K partial pressures and the 2300 K partial pressures, with results as follows:

$T = 2268$ K	P_{N_2}	0.7207 atm
	P_{H_2O}	0.1484 atm
	P_{CO_2}	0.1026 atm
	P_{CO}	0.0125 atm
	P_{O_2}	0.0059 atm
	P_{H_2}	0.0034 atm
	P_{OH}	0.0032 atm
	P_{NO}	0.0025 atm
	P_{H}	0.0005 atm
	P_{O}	0.0003 atm

Computer Programs for Chemical Equilibrium Calculations

In view of the extremely tedious calculations needed for determination of the equilibrium temperature and composition in a combustion process, a computer program for executing these calculations would be desirable. Fortunately, such programs have been developed.

However, the user of a computer program should be warned that thorough understanding of the material in this chapter is needed to avoid misinterpreting the computer output. Further, given such understanding, simple manual calculations can be performed to obtain independent checks of the computer output.

One program, entitled GASEQ, can be used with any computer using Windows. It can be downloaded from http://www.gaseq.co.uk. Alternatively, a program may be obtained from Reaction Design, 6440 Lusk Blvd, Suite D209, San Diego, CA 92121. Their e-mail address is <chemkin@ReactionDesign.com>.

These programs will calculate the final equilibrium conditions for adiabatic combustion at either constant pressure or constant volume, given the initial conditions. For the constant-pressure calculations, one specifies the initial temperature, the pressure, and the identities and relative proportions of the reactants. The computer programs contain the properties of selected reactants including: air, oxygen, nitrogen, hydrogen, graphite, methane, acetylene, ethylene, ethane, propane, butane, 1-butene, heptane, octane, benzene, toluene, JP-4, JP-5, methanol, ethanol, and polyethylene. If the fire only involves reactants from this list, no further input is necessary. If the fire involves a reactant not on this list, the input data must include the elemental composition and the enthalpy of formation of the reactant at 298 K, as well as enthalpy versus temperature data for the reactant over the temperature range from 298 K to the initial temperature. (If the initial temperature is 298 K, the last item is not needed.)

The computer programs can handle reactants containing any of the following elements: A, Al, B, Br, C, Cl, F, Fe, H, He, K, Li, Mg, N, Na, Ne, O, P, S, Si, and Xe. Data are included in the program on all known compounds, including liquids and solids, that can form at elevated temperatures from combinations of these elements. It is not necessary for the user to

specify which product species to consider. The program can consider them all, and will print out all equilibrium species present with mole fractions greater than 5×10^{-6}, unless instructed to print out trace values down to some lower specified level.

The program can calculate Chapman-Jouguet detonation products as well as constant-pressure or constant-volume combustion products, if desired.

An addition to the program permits calculation of viscosity and thermal conductivity of gaseous mixtures, selected from 154 gaseous species, at temperatures from 300 K to 5000 K.

Nomenclature

C_p	Heat capacity at constant pressure (kJ/mol·K)
ΔE^o	Energy of products relative to energy of reactants, all at temperature T and 1 atm (kJ/mol)
ΔF^o	Free energy of products relative to free energy of reactants, all at temperature T and 1 atm (kJ/mol)
ΔH^o	Enthalpy of products relative to enthalpy of reactants, all at temperature T and 1 atm (kJ/mol)
K	Equilibrium constant (based on partial pressures expressed in atmospheres)
K	Degrees Kelvin
n	Number of moles (e.g., a mole of oxygen is 32 g)
p_i	Partial pressure of ith species (atm)
p	Total pressure (atm)
R	Gas constant (kJ/mol · K)
ΔS^o	Entropy of products relative to entropy of reactants, all at temperature T and 1 atm (kJ/mol)
T	Absolute temperature (K)

Thermal Decomposition of Polymeric Materials

7

Artur Witkowski, Anna A. Stec, and T. Richard Hull

Introduction

Polymers are composed of large numbers of repeat units forming very long chain molecules. Most polymers are based on carbon, and hence known as organic polymers. The long-chain structure means that polymers can exist in solid or liquid form, but are too large to be volatile. Polymers fuel the vast majority of unwanted fires, as wood, paper, fabrics, foams and plastics. Flaming combustion is a gas phase process, and it is necessary to understand the stages in the conversion of long molecular chains into volatile fragments. This is often referred to as "pyrolysis" or "gasification", but these terms encompass a complex set of chemical and physical processes, leading to the production of volatile flammable molecules.

Polymeric Materials

A *polymer* is a large molecule constructed from many smaller structural units called *monomers*, covalently bonded together in any conceivable pattern (but often, and most simply in long chains).

If the material is composed of only one type of repeating structural unit, it is known as a *homopolymer*. If the material is composed of more than one type of repeat unit it is known as a *copolymer*.

Thermal decomposition is "a process of extensive chemical species change caused by heat". *Thermal degradation* is "a process whereby the action of heat or elevated temperature on a material, product, or assembly causes a loss of physical, mechanical, or electrical properties" [1]. Used correctly, thermal degradation may describe processes occurring before around 1 % of the mass is lost, while thermal decomposition includes the entire mass loss process.

Polymer Classification

Polymers represent the largest class of combustible materials fuelling unwanted fires. The different ways they can be subdivided provides a useful introduction to this wide and important class of materials.

Natural, Synthetic, Semi-natural and Biobased

Before the widespread use of synthetic polymers in the second half of the twentieth century almost all unwanted fires were fuelled by *natural polymers* such as wood, paper, cotton, wool etc. *Synthetic polymers* are generally derived from oil or coal, and share the flammability of those raw materials. The ease of manufacture and processing of synthetic polymers has driven the increase in their use. As most of the common

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_7, © Society of Fire Protection Engineers 2016

synthetic polymers are more flammable then their natural counterparts, this has also increased the number and severity of unwanted fires, despite significant advances in fire prevention, detection and control.

Semi-natural polymers are typically purified, and chemically modified natural polymers, such as cellulose acetate, cellophane or rayon. Drivers towards greater environmental sustainability have led to increased developments in *biobased polymers*, which includes the semi-natural polymers and a new polymeric materials, using raw materials derived from living, rather than the fossilised carbon sources. It seems likely that these materials, such as polylactic acid (PLA) and styrene-soya oil-divinyl benzene (SSD), will increase their market share in the next decade.

Chemical Composition of the Repeat Units

Most natural polymeric materials involved in fires are cellulose based. Cellulose is a polymer with alternating repeat units of glucose (Fig. 7.1).

Several of the common synthetic polymers, the so-called vinyl polymers made from vinyl monomers ($-CH_2 = CHX-$), have a repeat units of ($-CH_2-CHX-$), such as polyethylene (X is $-H$); polypropylene (X is $-CH_3$); polyvinyl chloride (X is $-Cl$); polystyrene (X is $-C_6H_5$); polyacrylonitrile (X is $-C \equiv N$); polyvinyl acetate (X is $-OCOCH_3$); polyvinyl alcohol (X is $-OH$). Other "polymers" such as polyamides, polyesters, epoxy resins and polyurethanes are actually classes of materials with similar bonding between the repeat units, but different structures within each repeat unit.

Chemistry of Polymerisation

Synthetic polymers are made by chemical reaction of monomers to form long polymer chains. Since the reverse process, the decomposition of polymers into smaller volatile fuel molecules, is often related to their synthesis, this can also provide insight into their decomposition behaviour. Broadly the process occurs either by step-growth, or chain-growth polymerisation. *Step-growth polymerisation* occurs by chemical reaction of two functional groups to form the linkage, with the release of a small molecule (such as water). This is known as step-growth polymerization as it takes place one molecule at a time. Figure 7.2 shows the familiar esterification reaction, in this case used to produce a polyester.

As water is often the molecule released, this process is also known as *condensation* polymerization. The synthetic process is slow, and the lack of water or other secondary product in the polymer prevents decomposition being simply the reverse of polymerisation. The second process, *chain-growth polymerisation*, involves opening of double bonds to form consecutive links in the polymer chain. For example, styrene

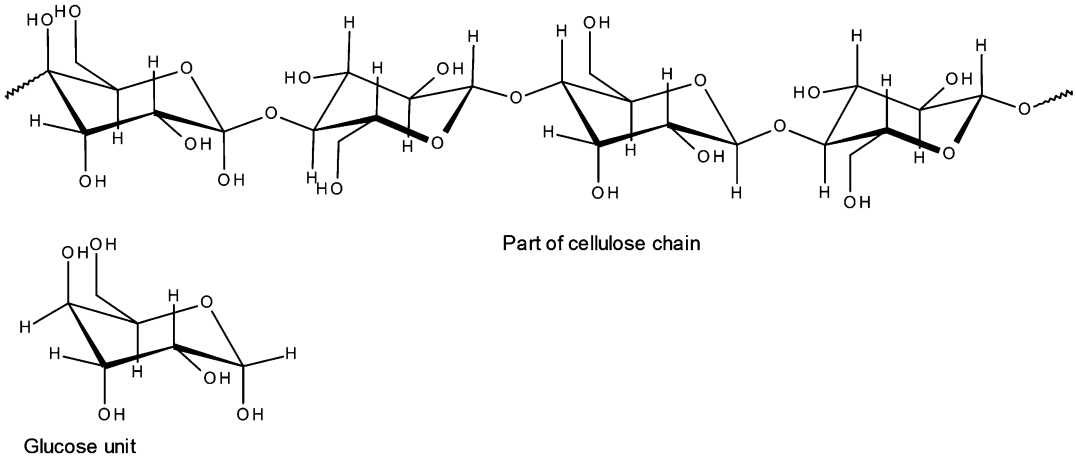

Fig. 7.1 Part of a cellulose polymer chain, and a single glucose unit (monomer)

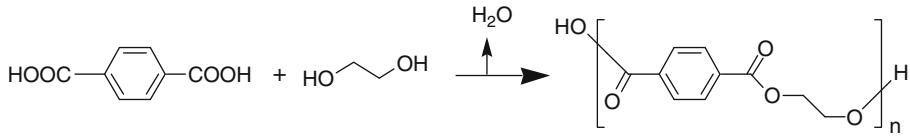

Fig. 7.2 Step-growth polymerisation of polyethylene terephthalate (PET)

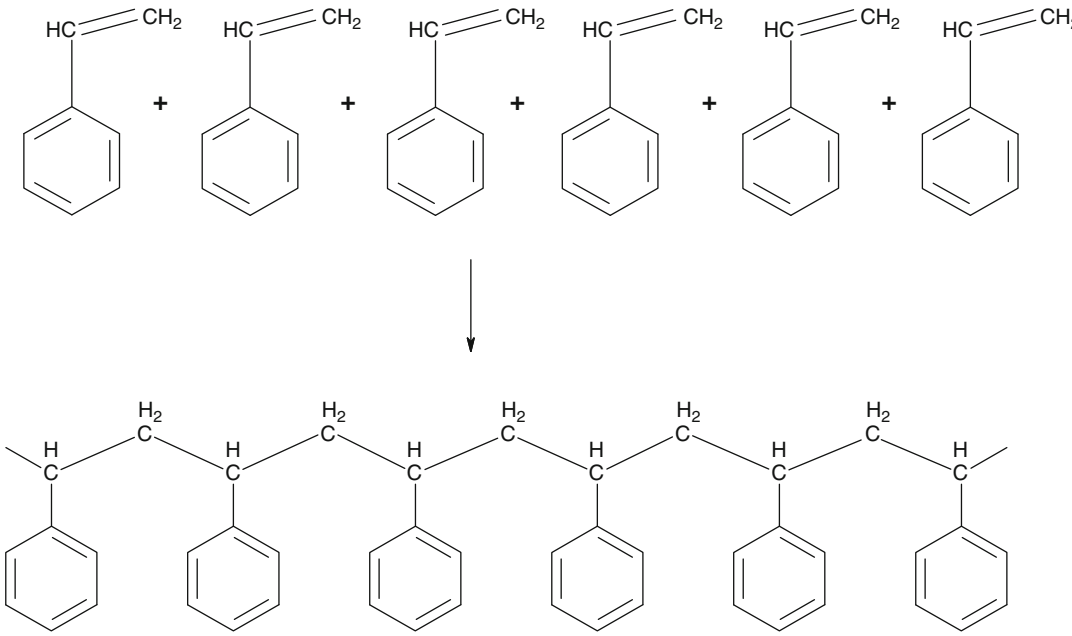

Fig. 7.3 Chain-growth polymerisation of poly(styrene) (PS)

monomers combine to form polystyrene, without release of a secondary product (Fig. 7.3).

The polymerisation reaction is known as *chain-growth* or *addition polymerisation*. Typically, once the monomer becomes activated, the chain grows extremely quickly (less than 1 s), so, during the polymerisation process, only long polymer chains and volatile monomer units will be present. It is highly likely that some monomer will remain at the end of the polymerisation process, since the final material will have very long chains and a high viscosity. During the decomposition of polystyrene, the reverse process occurs, resulting in monomer, dimer and trimer predominating in the vapour phase.

Addition polymerization involves three distinct stages—initiation, propagation and termination. To start the process, an initiator is added to the monomer. The initiator splits to form two free radicals, which attach themselves to a carbon atom of the monomer. When this occurs, the reactive site is transferred to another carbon atom in the monomer, and the chain begins to propagate (Fig. 7.4). Finally the reactivity of the propagating chain end is lost by combination of two reactive sites, or rearrangement, collectively known as termination. In order to maximise the degree of polymerization, the remaining monomers must diffuse towards the reactive chain end, before termination reactions occur.

Addition polymerisation can involve free radical, cationic, anionic, catalytic, or ring opening processes. The means of polymerisation will affect the degree of branching, and the molecular weight and dispersity of the polymer (section "Molecular Mass or Polymer Chain Length"),

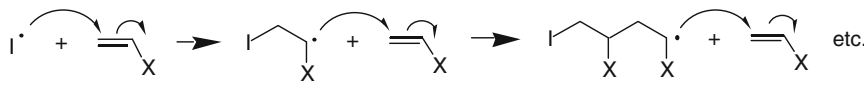

Fig. 7.4 Free radical polymerisation of an alkene ($CH_2 = CHX$)

which will in turn affect its decomposition (section "Decomposition Mechanisms").

Thermoplastics and Thermosets

Synthetic polymers (often referred to as plastics, because of their mouldability) can be subdivided into those which can be repeatedly deformed by heating (*thermoplastics*), so they are melt-processable; and those which once the polymerisation process is complete, cannot be melted or have their shape changed by heating, and decompose directly from solid to vapour (*thermosets* or *thermosetting polymers*). Most thermosets have additional covalent bonds forming crosslinkages between the polymer chains.

Common thermoplastics include polyethylene (PE), polypropylene (PP), polystyrene (PS), polymethylmethacrylate (PMMA), polyvinyl chloride (PVC), polyamides (PA) and some polyesters and polyurethanes.

Thermosets are generally stronger, but more brittle than thermoplastics, have higher thermal stability, higher dimensional stability, higher rigidity, and resistance to creep and deformation under load. Epoxies, vulcanized rubbers, phenolics, unsaturated polyester resins, rigid polyurethanes, urea-formaldehyde and melamine-formaldehyde are examples of thermosets.

Molecular Mass or Polymer Chain Length

The number of repeating units in a synthetic polymer exerts a significant influence on its physical properties. The high molecular weights of polymers increase their viscosity when molten and in solution, decrease their solubility, and of course prevent their volatilisation. Chain length can also be a controlling factor in determining the solubility, elasticity, fibre-forming capacity, tear strength, and impact strength in many polymers. The chain length of commercial polymers is optimised during synthesis for the intended application. For example, PMMA, with an average molecular weight less than 500,000 (around 5000 repeat units) has sufficiently low viscosity to be melt-processable, whereas PMMA with molecular weight of 5,000,000 does not soften sufficiently to allow its shape to be changed on heating, hence it is known as cast PMMA.

The number of repeating units will usually vary as a statistical distribution of chain lengths. This may be classified as a number-average molecular mass $\left(\overline{M}_n\right)$, or a weight-average molecular mass $\left(\overline{M}_w\right)$. Within most synthetic polymers, the most common unit is actually the monomer, although this only represents a tiny proportion by mass. Natural polymers often have narrower molecular mass ranges, or even identical molar masses. The ratio $\overline{M}_n/\overline{M}_w$ is known as the dispersity (or *heterogeneity index*), providing a simple index of the range of chain lengths present. An enzyme, where all the molecules have the same molecular mass is described as monodisperse, a polymer produced by anionic polymerisation will typically have a dispersity around 1.1, a step growth polymer will have a dispersity around 2, while one produced by free radical polymerisation will usually lie between 1.5 and 10.

Consequences of High Molar Mass

Increasing the interaction between polymer molecules leads to increasing cohesive energy per molecule. In polymeric materials this gives rise to certain properties characteristically associated with high molar mass, regardless of their chemical structure:

(i) High crystal melting point (if the polymer is crystalline)
(ii) High viscosity in the melt and in solution
(iii) High mechanical strength
(iv) High flexibility and ductility (unless highly cross-linked)
(v) High resistance to dissolution (especially crystalline polymers)

The average *degree of polymerization*, or D_P, is usually defined as the number of monomeric units in a polymer [2]. For a homopolymer, there is only one type of monomeric unit and the number-average degree of polymerization is given by

$$D_{P_n} = \frac{Number\ average\ molecular\ mass\ of\ polymer}{molecular\ weight\ of\ the\ monomer\ unit} = \frac{\overline{M}_n}{M} \tag{7.1}$$

For most industrial purposes, degrees of polymerization in the thousands or tens of thousands are desired.

Low molecular weight polymeric materials (having short chains) are generally weaker. Although sections may be crystalline, only weak Van der Waals forces hold the crystallites together. This allows the crystalline layers to slip past one another causing a break in the material. Amorphous polymers, with high D_P (such as cast PMMA) have greater strength because the molecules become tangled between layers.

Physical Properties

Polymers can be readily processed by forming or moulding into shapes, either once (thermosets) or repeatedly (thermoplastics). Many are important engineering materials with a wide range of properties, some of which are unattainable from any other material types, and they are generally low in cost. The desirable properties of polymer products include light weight, availability in a wide range of colours, low thermal and electrical conductivity, toughness, and good resistance to acids, bases and moisture.

The applications of a polymer depend most strongly on its mechanical behaviour. The "deformability" of a polymer can be expressed as the ratio of the deformation (strain) resulting from a constant applied stress. The ratio of stress to strain is the elastic modulus.

A large number of synthetic polymers now exist covering a wide range of properties. These can be grouped into three major classes:

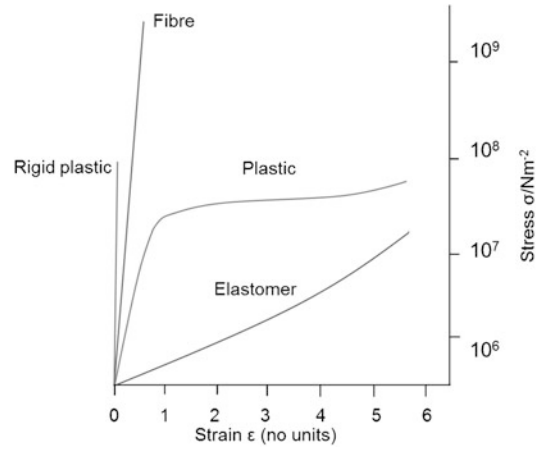

Fig. 7.5 Typical stress—strain plots for a fibre, a flexible plastic, and an elastomer

plastics, fibres, and elastomers. Although there is no firm dividing line between the groups, some distinction between these categories can be obtained from a typical stress—strain plot (Fig. 7.5). Rigid plastics and fibres are resistant to deformation and are characterized by a high elastic modulus and low percentage elongation. Elastomers readily undergo deformation and exhibit large reversible elongations under small applied stresses, i.e., they exhibit elasticity. The flexible plastics are intermediate in behaviour, during the elastic stage of their deformation, and then yield inelastically with typical plastic deformation.

During the final stages of processing, fibres are stretched to three or more times their original length ("drawing") when in a semi-crystalline state, to produce increased chain alignment, crystallinity and strength.

For amorphous materials, the temperature at which the molecules move relative to one another, known as the glass transition temperature (T_g—described in more detail in section "Glass Transition Temperature") exerts a profound influence on the physical properties. In general, elastomers have values of T_g well below room temperature, while rigid, structural polymers have T_g values above room temperature.

Structural Physical and Decomposition Property Data

In order to better understand the range of common polymers, their names, abbreviations, and molecular structures have been listed in Table 7.1. Where available, measurements of their crystallinity, glass transition temperature (T_g) and melting point have also been provided, in order to give the reader an instant guide to the main properties of interest. More detailed tabulations providing citable data have been published [2]. In addition, Lyon et al. [3] have tabulated the decomposition temperatures and Arrhenius parameters E_a and A (section "Kinetics of Polymer Decomposition") for a number of common polymers from literature and the data is reproduced here. Individual polymeric materials will differ according to their method of preparation, thermal history and the definition and method of measurement of the decomposition properties. Therefore individual literature values have been provided to give an indication of the uncertainties in the reported data.

Polymers and Fire

The flammable components of our built and natural environments are almost all based on organic polymers, and the vast majority of unwanted fires are fuelled by these polymers. Smouldering combustion typically occurs by reaction of atmospheric oxygen with a porous, combustible solid matrix, with a reaction zone moving through the solid, releasing gaseous products. Flaming combustion requires the fuel to be present in molecular form in the vapour phase, where it can undergo much more rapid reaction with atmospheric oxygen. Since polymers are much too large to exist in the vapour phase (because the bonding forces holding them in the condensed phase is proportional to their large surface area) they must first break down into volatile fragments. The pyrolysis of a polymer, turning molecular chains of 10,000–100,000 carbon atoms into species small enough to be volatilised, often involves breaking the polymer chain. In some cases, the chain releases groups from its ends most easily, known as *end-chain scission* or unzipping. In others, the chain breaks at random points along its length, known as *random chain scission*. A third process, where groups attached to the backbone as side chains can leave as stable molecules, is known as *chain-stripping*. If the polymer, or the chain resulting from chain stripping, does not undergo chain scission to form volatiles or lose further substituents, it may undergo carbonisation, resulting in *char formation*. Thus the conversion of an organic polymer to volatile organic molecules, and/or a char, may follow one or more of the four general mechanisms. While some polymers fall exclusively into one category, others exhibit mixed behaviour, often dependent on the decomposition conditions.

The temperature of a material is a measure of the kinetic energy of its molecules. At very low temperatures (close to 0 K), molecules are almost stationary, but at all normal temperatures in the solid phase, molecules are in a state of constant vibration. As the temperature increases, the vibrations become stronger, while the strength of the chemical bonds remains constant. For a particular polymer, a critical temperature is reached where there is sufficient kinetic energy to rupture one of the bonds holding the repeat units, or the side chains, of the polymer together. If the resultant molecules are small enough to be volatile, they may escape from the surface of the polymer, or in the case of a thermoplastic, form bubbles within it. When sufficient fuel is present in the vapour phase mixed with air, it can react with oxygen, releasing heat and increasing the free radical concentration. In the presence of a pilot flame or spark, additional free radicals accelerate the ignition process. Ignition and flaming combustion occurs when there is sufficient heat from the flame to replace the gas phase fuel by further pyrolysis. As molecules are released from the decomposing polymer, particularly by chain stripping, this leaves active sites for further reaction. In many cases, such as cellulosic materials, this can result in cross-linking reactions to other polymer chains, leading to char formation. In bulk cellulosic materials such as wood, this can result in the build-up of

the protective layer, shielding the wood from external radiation, slowing the rate of further fuel pyrolysis, and hence the rate of burning.

The burning process can be viewed on either the molecular scale or the macro scale.

The molecular scale

Stage I	Heating	An external source supplies heat causing the temperature of the substance to increase. The extent of temperature change depends on the specific heat of the material. Physical, mechanical, and thermal properties change in the case of polymers. This may include softening, melting and volatilsation
Stage II	Decomposition	At higher temperatures the majority of the bonds reach failure point, causing the release of gaseous molecules which differ depending on the material burning. This can be accelerated by attack of oxygen on the surface of the polymer, producing carbon dioxide and carbon monoxide
Stage III	Oxidation	In the presence of oxygen at high temperatures, oxidation of the gaseous fragments proceeds rapidly, releasing heat, and combustion products (mostly carbon dioxide and water)

The macro scale

Stage I	Heating	Heat causes a temperature rise which will depend on the thermal inertia (kρC) of the material
Stage II	Pyrolysis	Heat causes decomposition of the fuel, followed by pyrolysis of fuel to the gas phase
Stage III	Ignition	Fuel accumulates above the surface, and reacts with oxygen. Once the critical concentration of free radicals is reached, flashing will occur. When the total heat flux to the surface from fuel oxidation is sufficient to pyrolyse enough fuel to replace it, ignition will occur, the rate of reaction will increase and produce carbon dioxide and water
Stage IV	Flame spread	As the radiant heat flux increases it will pyrolyse adjacent materials, leading to a repeated series of ignitions, resulting in fire growth
Stage V	Fire development	As the flame gets larger, it will no longer be able to been entrain sufficient oxygen, and products of incomplete combustion such as carbon monoxide and soot will be produced, increasing the radiative component of heat transfer

Polymer Crystallinity

Although most polymers are solids at room temperature they have more properties in common with glass than with crystalline solids, such as sugar or salt. Glass has an amorphous morphology with properties different to crystalline solids. When heated, it gradually changes, from a brittle solid-like material, softening, and eventually becoming a viscous liquid. In contrast, the application of heat to a crystalline solid turns it sharply to a low viscosity liquid at a particular temperature. The difference lies mainly in the structure of each phase. Crystalline materials have their molecules arranged in repeating patterns. Salt, sugar, ice and most metals are crystalline materials. As such, they all tend to have highly ordered and regular structures. Amorphous materials, by contrast, have their molecules arranged randomly and in long chains which wrap around each other, without any long range order. Both crystalline and amorphous phases exist in polymers.

Polymers can form crystallites either by straightening out the molecules and packing as rods (*extended-chain* crystals), or each chain folds back and forth, so that crystallisation occurs by short segments of the same chain packing together (*folded-chain* crystals) (Fig. 7.6).

Chain-folding is kinetically favoured, as it is a unimolecular process, but orientation of a polymer (such as the "drawing" of a fibre) leads to chain-extension crystal structures. A complete polymer chain is likely pass through many small crystals, tying them together into a strong, coherent mass, surrounded by amorphous sections of polymer. If individual polymer molecules were

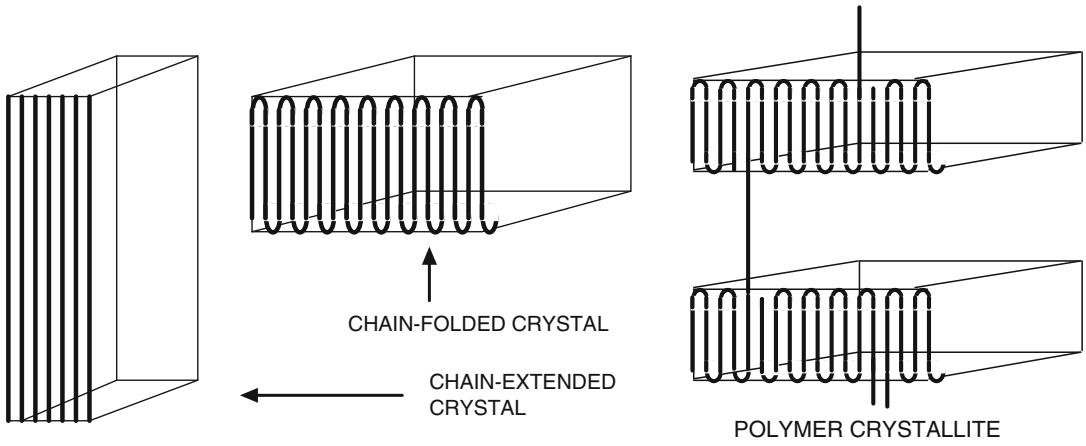

Fig. 7.6 Schematic of chain-folded crystal, chain extended crystal, and polymer crystallite

confined to individual crystals, they would be extremely brittle. The mixtures of small crystals and amorphous material in polymers cause them to melt over a range of temperatures without a sharp melting point. In most polymers, the combination of crystalline and amorphous structures forms a material with advantageous properties of toughness and rigidity.

Some polymers, such as polystyrene and PMMA, are completely amorphous, others have a combination of disordered regions and small crystallites. An amorphous polymer results from polymer chains that lack regular order. If parts of two chains do not pack well together, crystallites do not form. Shorter chains organize themselves into crystalline structures more readily than longer molecules, as those with a high degree of polymerization (D_P) tend to become tangled. The D_P is an important factor in determining the degree of crystallinity of a polymer. The cooling rate also influences the degree of crystallinity (section "Differential Thermal Analysis and Differential Scanning Calorimetry"). Slow cooling provides time for crystallization to occur. Fast cooling yields highly amorphous materials. When characterising the flammability of a material, in order, for example to predict its large scale fire behaviour, it is essential to ensure that all the material has the same thermal history. For example, cone calorimeter plaques prepared from the same semicrystalline polymer may have different decomposition and burning behaviour if they were formed into plaques under different thermal conditions. This can be compensated for by subsequent annealing (heating and holding each specimen at an appropriate temperature below the crystalline melting point, followed by controlled cooling). If the polymer is cooled slowly, this will produce a significant increase in crystallinity, and relieve internal stresses.

The size and shape of the side chains of monomer also influence the polymer morphology. If the monomers are large or irregular, relative to the polymer backbone, as in polystyrene, it is difficult for the polymer chains to arrange themselves in an ordered manner, resulting in a more amorphous material. Likewise, smaller monomers, such as polypropylene, and polymers that have a very regular structure, such as the rod-like structure of PTFE, will form highly crystalline polymers.

Thermal Response Characteristics of Polymers

Physical Transitions

The physical processes occurring during thermal decomposition depend on the material. Thermoplastics can be softened and melted by heating; once polymerisation is complete,

thermosetting polymers are infusible and phase changes such as melting cannot occur. The melting/softening behaviour of thermoplastics on heating depends on the degree of crystallinity. For crystalline materials the intermolecular forces are usually identical, so melting occurs at a well-defined temperature; for amorphous materials a range of intermolecular forces hold the polymer chains to each other, so the polymer will soften over a wider temperature range.

However, many materials cannot undergo the transition to a viscous state without undergoing thermal decomposition. Neither thermosets nor cellulosic materials have a fluid state, so they neither melt or soften. In thermosets, the 3-dimensional network of cross-linking covalent bonds prevents the polymer chains from moving relative to each other. In cellulosic polymers, the extensive hydrogen bonding between the hydroxyl groups and oxygen atoms keeps the polymer chains in place.

Glass Transition Temperature

As the temperature of a polymer rises above a certain critical point, its glass transition temperature, T_g, it becomes more rubber-like. Conversely, as the temperature drops below T_g, it behaves in an increasingly brittle manner. The glass-transition temperature is the point at which the polymer chains in a non-crystalline (amorphous) material acquire sufficient thermal energy to undergo significant translational motion, characteristic of the liquid-like or rubbery state. Below T_g the chains are frozen into a glassy state, where only very localised atomic movement, such as vibration, is possible. If a molten polymer is cooled so quickly that the T_g is reached before the polymer can fully crystallise, then the polymer will remain frozen in its glassy (amorphous) state until its temperature is raised above T_g. The T_g is a transition which is characteristic of non-crystalline phases; it is an important parameter in the selection of materials for particular applications, such as whether rigid or elastomeric properties are required. Above T_g, but well below its melting point, an incompletely crystallised polymer can undergo further crystallisation (section "Differential Thermal Analysis and Differential Scanning Calorimetry").

Melting

The backbone of a typical $(-CH_2CHX-)_n$ polymer is composed of a chain of tetrahedrally bonded carbon atoms covalently bonded to each other so that the molecule can be represented as an extended zigzag chain. The repeating units in a polymer chain are often free to rotate relative to one another. If they are all in a particular position, the polymer molecule will have a linear zigzag shape. If they rotate, this will result in bends in the polymer molecule. While the linear zigzags can stack together easily, each bend will be an obstacle to crystallinity. For polyethylene $(–CH_2CHX–)_n$, a typical value of the molecular weight is 1.6×10^5 g mol^{-1}, so the chain contains 10,000 carbon atoms; thus in the extended zigzag state, the chain would be about 1260 nm long and 0.3 nm diameter. As every group of four atoms in the chain can have three possible stable rotational positions (linear, zigzag or kinking to left or right), a total of $3^{10,000}$ shapes (or additional degrees of freedom) are available to this particular chain, only one of which is the fully extended zigzag. Even though this has the lowest energy, the most probable conformation will be some kind of randomly angled amorphous shape (Fig. 7.7).

The number of different possible states which can exist when leaving the crystalline state (or extended zigzag conformation), known as the entropy change, ΔS, exerts the greatest influence on the melting temperature of a polymer. A large part of this entropy is due to the additional freedom that allows the chain conformational changes to occur in the melt; i.e., the restrictions of the crystalline lattice no longer apply.

In any phase transition, the free energy change involved, ΔG, is zero, since the two phases must be in equilibrium. The free energy is the sum of the chemical bonding forces, or enthalpy ΔH, and the disorder, or number of possible ways the molecule can be arranged. This is the product of the temperature and the entropy change, $-T\Delta S$.

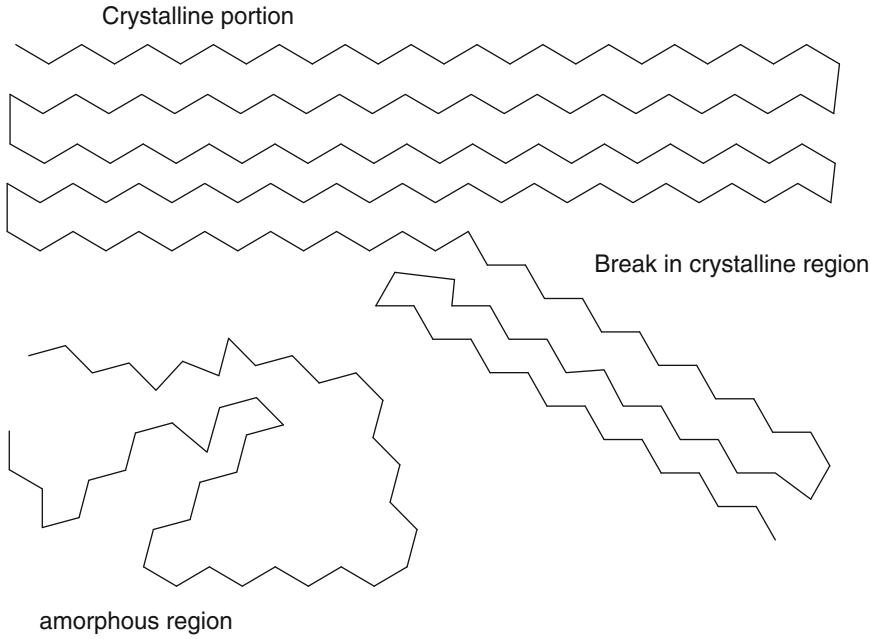

Fig. 7.7 Crystalline and amorphous regions of a polymer

$$\Delta G = \Delta H - T\Delta S = 0 \qquad (7.2)$$

so that during the polymer melting process; the melting temperature T_m is given by

$$T_{\mathrm{m}} = \Delta H_{fusion}/\Delta S_{fusion} \qquad (7.3)$$

The enthalpy of fusion (ΔH_{fusion}) reflects the strength of attractive forces between the molecules. For chemically similar materials (e.g. hydrocarbon polymers) these will not vary greatly. Thus ΔS_{fusion}, the *entropy change on melting*, is the only significant variable.

For polymers, entropy is related to the number of degrees of freedom each polymer molecule has. A molecule in the liquid state has more potential degrees of freedom (bond rotations, bond angle flexions and inversions, translational and rotational motions) than if it is frozen in a crystal. Clearly, the more flexible the polymer chain, the more degrees of freedom it acquires on melting, and the greater is ΔS_{fusion}. A high ΔS_{fusion} leads to a low T_m.

Conversely, the stiffer the polymer chain, the fewer degrees of freedom it acquires on melting, the lower is ΔS_{fusion} and the higher is T_{m}. For completely rigid polymer chains, *only* translational and rotational degrees of freedom are acquired on melting, leading to extremely high values of T_{m}, often well above the decomposition temperature of the polymer.

Table 7.2 Structures and melting temperatures of four polymers

Polymer	T_{m}(°C)
	135
	165
	380
	> 600

Table 7.2 shows the variation in melting point for four polymers. In PE every bond is free to rotate; PP is constrained to a small extent by the coiling of the chain to accommodate the methyl groups in a regular manner. Aromatic rings do not allow any rotation so poly-1,4-phenylene

ethylene $(-Ph-CH_2-CH_2-Ph-)_n$ can only rotate between the two $-CH_2-CH_2-$ carbon atoms. In poly-1,4-phenylene $(-Ph-Ph-)_n$ no rotation is possible (as the conjugated aromatic rings must all lie in the same plane, so the polymer molecule exists as a rigid rod), there is no "entropy advantage" to the polymer on melting. Poly-1,4-phenylene decomposes before melting, so it is not melt-processable, so there is no way of forming it into shapes, and so its practical applications are limited to heat resistant fabrics, electrical insulation etc [4].

Bubble Formation

As a consequence of the chemical processes of polymer decomposition, leading to volatile formation, volatile molecules will start to accumulate within the decomposing polymer. If the polymer is molten when decomposition commences, bubbles will form and migrate upwards, eventually erupting from the surface. This causes physical swelling, reducing the thermal inertia of the material, accelerating the rate of surface heating and the onset of ignition.

Chemical Transformations

In the case of thermosets and cellulosic materials, the polymer molecule starts to decompose before the chains have acquired sufficient energy to overcome the forces holding them in place. These materials tend to produce carbonaceous chars on thermal decomposition. The physical structure of these chars will profoundly affect the heat transfer, volatile release, and access of oxygen, all of which will impact on the thermal decomposition processes. The char can undergo glowing combustion in the presence of oxygen. However, it is unlikely that both glowing combustion of the char and significant flaming can occur simultaneously in the same zone above the surface, since the flame will consume all the available oxygen, and the flow of volatiles through the char will tend to drive oxygen away from the char surface. Therefore, in general, char oxidation will only occur after flaming has subsided.

Influence of Oxygen

The thermal decomposition of polymers may proceed by heat alone, or by the combined action of heat and oxygen. In many polymers, the thermal decomposition processes are accelerated by oxygen, lowering the minimum decomposition temperatures. Prior to ignition, thermo-oxidative decomposition results in pyrolysis of fuel and other species. After ignition, during steady flaming, even in well-ventilated conditions, pyrolysis of the condensed phase (pyrolysis zone) is essentially anaerobic, with all the oxidation taking place in the gas phase (flame zone) [5]. Thus, the mass loss, resulting from pyrolysis, the residue formation etc., of a flaming sample corresponds to a decomposition of the material under an inert atmosphere [6]. Unfortunately, there are several published studies of the development of fire retarded materials which appear oblivious to this fundamental principle of fire science. Only for ignition, non-intense flaming, samples near and after extinction, and non-igniting samples will thermo-oxidative decomposition be relevant to the behaviour in a fire. Indeed the observation of bubbles of volatile fuel in decomposing polymers, around the time to ignition (which have been characterised by immersing the test specimen in liquid nitrogen), showed that for many thermoplastics, even prior to ignition, most volatile formation comes from the bulk of the polymer, not its surface, and hence the critical decomposition condition remains anaerobic [7].

The thermal decomposition of polymers has been broken into for general chemical mechanisms. The first three essentially describe the conversion of an involatile polymer molecule into fragments small enough to be volatile. In many cases the decomposition follows more than one of the mechanisms.

(i) Random-chain scission, in which chain scissions occur at apparently random locations in the polymer chain.
(ii) End-chain scission, in which individual monomer units are successively removed at the chain end.
(iii) Chain-stripping, in which atoms or groups not part of the polymer chain (or backbone) are cleaved.

(iv) Cross-linking, in which bonds are created between polymer chains.

These are discussed further in section "Decomposition Mechanisms".

Influence of Chemical Structure on Thermal Stability

The combustion behaviour of a polymeric material can be interpreted in terms of the properties of the volatiles, particularly their composition, reactivity and rate of formation. Thermal stability can be quantified from the temperature dependence of decomposition.

Detailed studies by Madorsky [8] in the 1960s of the effects of chemical structure on the thermal stability of polymeric materials underpin our understanding of the factors controlling the thermal decomposition of polymers. These experiments investigated the thermal stability by determining the temperature, T_h, at which 50 % of a small polymer sample will volatilise in 30 min in an inert atmosphere. Table 7.3 summarises the effects of chemical structure on the thermal stability of polymers, and provides examples of that behaviour. The individual effects are discussed below.

Chain Branching

With two chain branches on every other carbon atom in the chain, polyisobutylene $(-CH_2-C(CH_3)_2-)_n$ has the lowest thermal stability, followed by polypropylene $(-CH_2-CH(CH_3)-)_n$ with one branching point on every other carbon atom. Commercial polyethylene is not composed only of straight polymer chains. It actually contains a number of branches of its linear chains, either of small groups such as CH_3- or longer side chains, which occur randomly during the polymerisation process. These are the most reactive parts of otherwise unreactive structures. Polymethylene $(-CH_2-)_n$ is the name given to the special, unbranched form of polyethylene. The number of branching points in normal polyethylene also affects its crystallinity. Low density polyethylene (LDPE) has around 60 branching points per 1000 carbon atoms. An intermediate density, linear low density polyethylene (LLDPE) is actually a copolymer of ethane and an alkene such as oct-1-ene, so the regularity of the polymer chain is deliberately disrupted by the presence of side chains, 6 carbon atoms in length. High density polyethylene (HDPE) is closer to the idealised polymethylene with around 7 branching points per 1000 carbon atoms. During thermal decomposition, the

Table 7.3 Factors affecting the thermal stability of polymers (From Madorsky [8])

Factor	Effect on thermal stability	Examples	T_h/K
Chain branching	Weakens	Polymethylene	688
		Polyethylene	679
		Polypropylene	660
		Polyisobutylene	621
Double bonds in polymer backbone	Weakens	Polypropylene	660
		Polyisoprene	596
Aromatic ring in polymer backbone	Strengthens	Poly-1,4-phenylene methylene	703
		Polystyrene	637
High molecular weight	Strengthens	PMMA B (MW = 5.1×10^6)	600
		PMMA A (MW = 1.5×10^5)	556
Cross-linking	Strengthens	Polydivinyl benzene	672
		Polystyrene	637
Oxygen in the polymer backbone	Weakens	Polymethylene	688
		Polyethylene oxide	618
		Polyoxymethylene	<473

branching points are the first to break, initiating chain decomposition reactions.

Double Bonds

In a similar way, the double bonds in the polymer chain of polyisoprene $(-CH_2-CH_2-CH=C(CH_3)-)_n$ also provide reactive sites for the initiation of chain decomposition reactions, reducing its thermal stability compared to polypropylene.

Aromatics in Backbone

Conversely, the presence of an aromatic ring, in the polymer backbone, such as poly-1,4-phenylene methylene $(-CH_2-C_6H_4-)_n$, compared to polystyrene $(-CH_2-CH(C_6H_4)-)_n$, where the aromatic ring is a side chain, increases the rigidity of the chain, lowering the entropy of the liquid state, thus raising the melting point. The higher melting point reduces the rate of pyrolysis, since most of the material is protected by the surface layers.

Molecular Weight

In end-chain scission the reaction starts at the end of a polymer chain, since the end molecule is only held by one bond. PMMA A with 1500 repeat units decomposes 55 K lower than PMMA B with 50,000 repeat units. The rate of the decomposition reaction will then depend on the number of end groups available. The higher the molecular weight, the smaller that number will be.

Cross-Linking

Cross-linking will also prevent melting, inhibiting the transport of molecules to the sample surface for pyrolysis as gas phase fuel. Polydivinylbenzene has two reactive groups per monomer unit, and therefore each monomer can be attached to two chains.

Oxygen in Backbone

Oxygen in a polymer chain, such as in polyoxymethylene $(-CH_2-O-)_n$, will also provide a reactive site for polymer decomposition to start, lowering the thermal stability.

In general, the T_h data indicates the ease of conversion to volatiles, which are likely to act predominantly as fuel. However, the fire behaviour will depend on combustibility of the volatiles as they are produced.

Interaction of Chemical and Physical Processes

The chemical composition of the gas phase fuel, and its production rate, depend both on the chemical structure of the polymer as it breaks down to release fuel, and the physical properties of the material. In particular, the transfer of heat through the solid/liquid and its rheological properties (affecting both heat and gas transport), will influence the decomposition and burning behaviour, under a defined set of external conditions. On the microscale (such as that in TGA, section "Thermogravimetric Analysis", or MCC, section "Microscale Combustion Calorimetry"), a single piece of sample of mass 5 mg, heated at 10 K per minute may be in thermal equilibrium to within a few degrees K, but an escaping monomer would still have to pass over a million repeat units, even if following the shortest straight line trajectory from the centre of the sample to the edge, in order to escape. In actuality, a much more tortuous path around the polymer crystallites would need to be followed in order for fuel to escape. Along this path, the monomer or other volatile fragment could recombine with the polymer; only when bubbles form is the reverse process of repolymerization effectively prevented.

Thermoplastics can melt without chemical reaction to form a viscous state (polymer melt), but they may decompose thermally by random chain scission, reducing their molecular mass, increasing the proportion of short chain polymer molecules in the liquid phase, before melting. In the absence of a flame the fluidity of the polymer will accelerate the access of oxygen, and its release of volatile decomposition products.

Thermal Analysis: Methods for Quantifying the Thermal Response of Polymers

Thermal analysis describes a family of techniques which measure changes in physical and chemical properties during controlled heating. The programme may take many forms:

(i) The sample may be subjected to a constant heating (or cooling) rate ($dT/dt = \beta$), for example 10 K min^{-1}.
(ii) The sample may be held isothermally ($\beta = 0$).
(iii) A "modulated temperature programme" may be used where a sinusoidal or other alteration is superimposed onto the underlying heating rate (section "Differential Thermal Analysis and Differential Scanning Calorimetry").
(iv) To simulate special industrial or other processes, a stepwise or complex programme may be used. For example, the sample might be heated at l0 K min^{-1} to 373 K, and held for 10 min, to drive off any absorbed water, then heated at l0 K min^{-1} to 673 K, then held there for 30 min. In addition, the atmosphere can be changed during a particular part of the heating regime, such as switching from nitrogen to oxygen above 1000 K, to quantify the presence, by oxidation, of carbonaceous residues.
(v) The heating may be controlled by the response of the sample itself (e.g. high resolution TGA).

In order to understand, and alter, the behaviour of a material in a fire, it is necessary to know as much as possible about the processes of decomposition. These processes are often highly dependent on the conditions, particularly the heating rate and atmosphere. Moreover, sensitivity to these parameters can give the vital clues needed to interpret the fire behaviour. Thermal analysis tends to be far more sensitive to instrumental parameters than other branches of chemical analysis. The following summarises the key parameters needed to ensure the validity and reproducibility of results obtained by thermal analysis, conveniently summarised by the acronym SCRAM.

The **Sample**: the chemical composition, the source and pre-treatments, together with the history of the sample, impurities and dilution with inert material can all affect results.

The **Crucible**: the material and shape of the crucible or sample holder is important. Deep crucibles may restrict gas flow more than flat, wide ones, and platinum crucibles catalyse some reactions more than alumina ones. The type of holder or clamping used for thermomechanical methods is equally important. The results are also unlikely to be entirely independent of the make and type of instrument used.

The **Rate of heating**: this has most important effects. A very slow heating rate will allow the reactions to come closer to equilibrium and there will be less thermal lag in the apparatus. Conversely, high heating rates will give a faster experiment, may be more representative of the heating rates in fires (section "Choice of Atmosphere and Heating Rate in Thermal Analysis"), but deviate more from equilibrium and result in greater thermal lag. The parameters of special heating programmes, such as modulated temperature or sample control, will also affect the results.

The **Atmosphere**: both the transfer of heat, the supply and removal of gaseous reactants, and the nature of the reactions which occur, or are prevented, depend on the chemical composition of the atmosphere and its flow. Oxidations will occur quickly in oxygen, more slowly in air, and not at all in nitrogen or other inert gas; product removal by a fairly rapid gas flow may prevent reverse reactions occurring.

The **Mass of the sample**: a large mass of sample will require more energy, and heat transfer will be determined by sample mass and dimensions. These include the volume, packing, and particle size of the sample. Fine powders react rapidly, lumps more slowly. Large samples may allow the detection of small effects. Comparison of runs should preferably be made using similar sample masses, sizes and shapes.

Thermogravimetric Analysis

"Thermogravimetry is a technique in which the mass of a test specimen is measured as a function of temperature or time, while the test specimen is subjected to a controlled temperature program." [9] Thermogravimetric analysis (TGA) is the

most commonly used method for investigating the complex thermal decomposition processes of polymers. In TGA experiments, at heating rates around 10 K min^{-1}, a sample size around 5–10 mg is small enough to ensure that it is in thermal equilibrium with the apparatus.

In isothermal TGA, the sample is brought quickly up to the desired temperature, usually by rapid insertion into a preheated furnace, and the weight of the sample is monitored during the course of thermal decomposition. In practice, the sample does not heat instantaneously, so errors arise where the selected temperature is high enough for significant decomposition to occur within the first few minutes.

In dynamic TGA, the sample is subjected to temperature programmed heating. This varies from a fixed rate, such as 10 K min^{-1}, to a variable rate, designed to highlight particular features (such as 10 K min^{-1} up to 650 K followed by 1 K min^{-1} up to 660 K, in order to focus on a particular step. A further modification is high resolution TGA, in which the changes in sample mass are used to slow the heating programme, to get better resolution of particular thermal events. As isothermal TGA is falling into disuse, it is common to refer to "dynamic TGA" simply as TGA.

The cylindrical furnace is designed to have a long constant temperature zone in its centre. TGA experiments rarely use static air, because of the uncertainty of its composition during a run, and the possibility of reverse reactions occurring with the vapour phase effluent. A flowing purge gas is almost always used, although operation under a vacuum is sometimes possible, and useful for techniques involving evolved gas analysis (although the typically boiling points and gasification temperatures are lowered by 150–250 K). The best crucibles are made of platinum, which is inert, does not melt below 2042 K and may be cleaned in strong acid. To reduce their thermal inertia, they are thin, and hence delicate. They can chemisorb hydrogen, giving rise to a spurious weight gain, although this is unlikely in routine polymer decomposition studies. The alternative, ceramic crucibles, can suffer from fusion with molten samples and be very difficult to clean.

A sample is suspended on a highly sensitive balance over a precisely controlled furnace. Usually heating rates of 5–20 K min^{-1} are used to look for broad decomposition stages, while slower heating rates, around 1 K min^{-1} are better for isolating individual events. Sample sizes are usually kept as small as possible, within the limits of sensitivity of the apparatus this is usually around 5 mg per run. This reduces bulk effects, and at higher heating rates, avoids thermal gradients being set up within the sample.

A typical microbalance has a rotating pivot, and is controlled electronically using a zero detection device, as used in a galvanometer, usually a light and photocell and a magnet and moving coil system to restore balance. The control system varies the current passed through the coil to keep the beam of the balance in the zero position. This is known as a null deflection system and has the advantage that it keeps the sample in the same position in the furnace throughout the run.

The results of TGA experiments may be presented as mass losses, usually as a percentage of total mass as a function of temperature, (or time, for isothermal TGA), or may be presented as the differential, showing the peaks of mass loss (DTG). Both formats have their advantages—the mass *vs* temperature plot gives direct information about sample composition, the percentage of non-volatiles etc., while DTG is much easier to see small differences in peak decomposition temperatures, and allows easy quantification of the maximum rate of mass loss (or fuel production in fire science). Figure 7.8 shows the TGA and DTG curves for polyacrylonitrile (PAN) in nitrogen at a heating rate of 10 K min^{-1}, showing three distinct decomposition stages at 550, 700 and 1100 K.

There are three common designs of TGA instrument, each having advantages and disadvantages (Fig. 7.9). The hangdown thermobalance is probably the simplest and most robust design, and dominated in the early instruments. The top-loading thermobalance has the advantages that, for evolved gas analysis the volatiles may be sampled more directly, and the surrounding atmosphere moves more naturally around the crucible (though this will give different results, for example

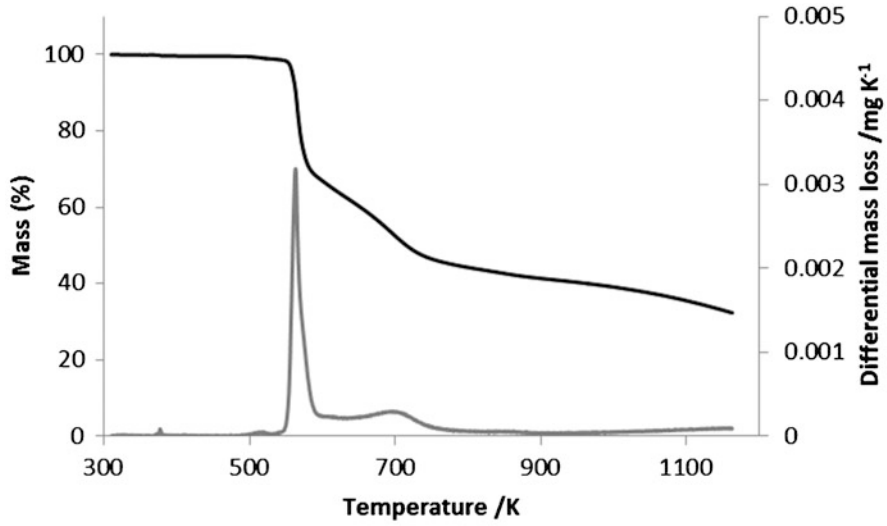

Fig. 7.8 TGA and DTG curves for polyacrylonitrile decomposition in nitrogen at 10 K min^{-1}

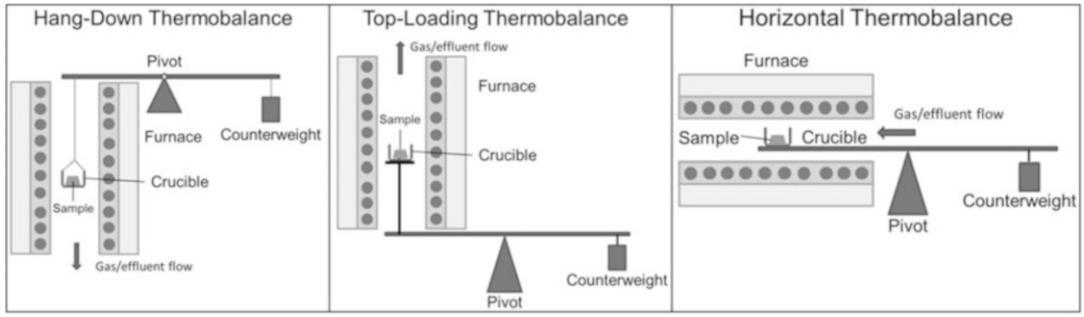

Fig. 7.9 Three common TGA instrument designs

in studies of char oxidation, where the rate is dependent on collisions of oxygen gas with the sample surface). The horizontal thermobalance minimises the effect of gas flow on the recorded mass. In the other two instrument designs this is compensated for by subtracting a blank run from the baseline, with an empty crucible with the same gas and flow rate over the entire temperature range.

Data from thermogravimetric analysis (TGA) is commonly used in the following determinations.

(i) Identification of polymers/materials present in composite materials
(ii) Studies of polymer decomposition
(iii) Generation of evolved products
(iv) Determination of kinetic data
(v) Quantifying thermal stability
(vi) Determination of the content of low volatiles (plasticizer, solvents)
(vii) Quantitative determination of single polymer components
(viii) Filler content (e.g. carbon black, chalk, glass fibre)
(ix) Oxidative stability

Differential Thermal Analysis and Differential Scanning Calorimetry

These two techniques allow quantification of the energy required, or released, during temperature programmed heating. Originally, differential

scanning calorimetry (DSC), invented by Perkin-Elmer, was deemed by the International Conference on Thermal Analysis (ICTA) to describe only the technique where a quantifiable amount of energy, as an electric current, was supplied to the sample (or reference) to maintain the sample and reference temperatures equal, now known as *power compensation DSC*.

In differential thermal analysis (DTA), the temperature of the sample is compared to the temperature of a reference (usually a matching empty crucible) during programmed heating (or cooling). Raw DTA data is a recorded as temperature difference (between the sample and reference pans) as a function of temperature. Prior calibration using materials of known heat capacity, such as sapphire discs, together with software converts the temperature difference into energy units, to make the results comparable to power compensation DSC. Thus, calibrated DTA became known as *heat flux DSC*. Now it is recognized that both techniques provide the same information and are both classed as DSC [10]. Data is reported as a differential, showing endothermic (heat to sample) or exothermic (heat from sample) processes. Unfortunately some manufacturers have the exo-peaks going upward, while others show them going down. Thus there is an established convention to label all DSC plots with an arrow labelled "exo" to show how the results have been reported. DSC provides useful information about polymeric materials and their decomposition. As the most commonly used thermal analysis technique, DSC also provides the following quantitative measurements of physical processes and characteristics.

Thermophysical Properties
- Specific heat capacity

Product Identification and Characterization
- Melting temperatures
- Transition enthalpies
- Phase transformations, phase diagrams
- Crystallization temperatures
- Degree of crystallinity
- Glass transition temperatures

Advanced Material Analysis
- Decomposition and oxidative susceptibility
- Reaction kinetics
- Purity determinations

The basis for obtaining kinetic parameters from DSC is to identify the rate of reaction with the DSC signal, and the extent of reaction with the fractional area of the peak plotted against time. It is possible to obtain the three variables, rate of reaction, extent of reaction and temperature by carrying out a series of isothermal experiments at different temperatures in much the same way as in classic kinetic investigation. The set-up of the experimental procedure is not without difficulty, but the interpretation of the result is less contentious than with the alternative dynamic procedures [10].

Standard protocols have been published covering most of the common DSC measurements [11]. Some of these, such as chemical kinetic parameters, and the enthalpies of these transitions, are of direct value in prediction of thermal decomposition, where others, such as the heat capacity and thermal conductivity, are required when modelling the heat transfer through the condensed phase (such as a $6 \times 100 \times 100$ mm cone calorimeter sample) from microscale thermal analysis data.

Excellent thermal contact is essential between the sample and reference pans and the instrument. Such contact is vulnerable to attack from acids such as hydrogen chloride and carbon rich vapours from the decomposition products of polymers. For these reasons, and the importance of the DSC for characterising the properties of polymers and other materials, DSC is used with some reluctance in polymer decomposition studies.

Prior to thermal decomposition, the enthalpy change of processes occurring in the condensed phase may be quantified using DSC or DTA. The glass transition, T_g is manifested by a *step* rather than a peak in the trace, resulting from an increase in *specific heat capacity* of the sample. On a molecular level, below the T_g, the polymer chains are held in place relative to one another. Above the T_g, movement is possible, as there are

more ways for the polymer to absorb energy, hence the increase in specific heat. For non-crystalline polymers T_g is in fact the *only* observable thermal transition prior to decomposition. For a crystalline polymer, a defined melting point will also be observable. If the polymer has been cooled more quickly than the time required for crystallization, then an exothermic peak known as the cold-crystallization temperature may be observed, when the polymer chains are free to move and become more closely aligned. In some polymers, crystallization is almost instantaneous, for others it can take hours or days. Crystallization can only occur above T_g.

The DSC heating-trace for a crystallisable polymer, which has been cooled so rapidly from the melt that the glassy state was reached before crystallisation occurred, is shown on in Fig. 7.10.

Therefore, when detailed studies are performed on polymeric materials, it is essential to ensure that all samples have the same thermal history (e.g. the same degree of crystallinity) if consistent results are to be obtained.

Crucibles for DSC and DTA

Most commonly, single-use aluminium pans are used for measurements from 120 to 870 K. Although aluminium does not melt until 933 K, there is a risk of irreversible and expensive alloying of the pan and temperature sensors above 870 K. The use of a lid on the pan typically gives an order of magnitude improvement in sensitivity. Crimp-on lids can be used which maintain pressures up to three atmospheres. For measurements in oxidising atmospheres, such as air, of boiling temperatures, or heats of vaporisation, a small hole may be pierced in the lid. Polymer samples which do not decompose, may be pre-melted and pressed onto the base of the pan to optimise thermal conductivity, and enhance the signal. For higher temperatures, platinum, silver, gold, quartz, alumina, or graphite may be suitable.

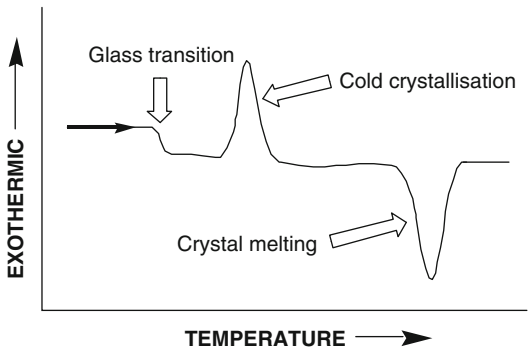

Fig. 7.10 Typical DSC curve obtained during heating of a crystalline polymer that has been subject to fairly rapid cooling

Modulated Temperature DSC (MTDSC)

A minor revolution in thermal analysis occurred with the development by Reading [12] of MTDSC. This allows the two components of enthalpy, such as the heat capacity and a process occurring at a particular temperature, such as T_g or melting, to be separated.

$$\frac{dq}{dt} = C_s\beta + f(t,T) \tag{7.4}$$

Equation 7.4 above separates the two components of the DSC signal, $C_s\beta$, the heat capacity component, and $f(t,T)$ which describes thermal events such as an endothermic transition. The heat capacity of the product of the thermal event will usually differ from that of the reactant, but will be masked by the thermal event. Using a sinusoidally varying heating rate, the reversing (heat capacity), and non-reversing (thermal event) components can be separated. Ideally 4–6 oscillations should occur over the duration of the thermal event.

Simultaneous Thermal Analysis

Simultaneous Thermal Analysis (STA) combines the benefits of TGA and DTA/DSC into a single experiment. The combination has two distinct advantages. It allows unambiguous separation of, or unification of, particular thermal events, such as whether an endothermic process preceded the mass loss stage, or whether the mass loss itself was the endothermic process. The subtle differences in instrumental design of the separate TGA and DSC instruments can make such differentiation problematic. More importantly, during

thermal decomposition mass is often lost. In order to obtain a mass-specific data for a thermal transition (or, for example, the heat capacity of a polymer char), it is necessary to know what mass of material is giving rise to the signal. This can be obtained directly from STA data, since the mass is known across the temperature range.

Thermomechanical Analysis and Dynamic Mechanical Analysis

In thermomechanical analysis (TMA) a probe applies a force to a sample during heating, and the movement of the probe is recorded as a function of temperature. It involves measurement of a specimen's dimensions (length or volume) as a function of temperature whilst it is subjected to a constant mechanical stress. In this way thermal expansion coefficients can be determined and changes in this property with temperature (and/or time) can be monitored. Many materials will deform under the applied stress at a particular temperature which is often connected with the material melting or undergoing a glass transition. Alternatively, the specimen may possess residual stresses which have been "frozen-in" during preparation. On heating, dimensional changes will occur as a consequence of the relaxation of these stresses. Usually the force is static, though modern instruments can offer the facility of an oscillating force. Useful physical data, such as compressive and tensile strength, softening, shrinking, thermal expansion, glass transition, and melting can all be obtained using TMA.

In dynamic mechanical analysis (DMA) a solid sample is held between two moveable clamps and subject to oscillatory forces, and the response measured during temperature programmed heating (or cooling). This allows the measurement of the mechanical properties, such as mechanical modulus or stiffness and damping of a specimen as a function of temperature. DMA is a sensitive probe of molecular mobility within materials and is most commonly used to measure the glass transition temperature and other transitions in macromolecules, or to follow changes in mechanical properties brought about by chemical reactions. For this type of measurement the specimen is subjected to an oscillating stress, usually following a sinusoidal waveform. The applied stress produces a corresponding deformation or strain.

Although TMA and DMA are rarely used for studying the thermal decomposition of polymers, DMA is an essential tool for the development of fire-safe composite materials, such as the carbon-fibre construction of the Airbus A380 or Boeing 787, where maintenance of structural integrity in a fire is at least as important as the suppression of flammability.

Rheology

A decomposing thermoplastic changes from a fluid-like or gel-like solid, to a gel-like or viscous liquid often with no distinct transition from one phase to the other. TMA and DMA are designed for measurement of the fluid or gel-like behaviour of a solid, where rheology is designed to quantify the gel-like or viscous behaviour of a polymer in the liquid state. There is considerable overlap, and many material states can be investigated by both techniques. The term rheology (from *rheo* meaning "to flow") refers to both physical deformation and flow of material under an applied force. Thus, the rheological behaviour of polymers encompasses a wide range of macroscopic phenomena including the flow of viscous liquids, the mechanical properties of elastic solids, and viscoelasticity (the time dependent mechanical properties of a polymer).

The mechanical properties of elastic solids show a region where an applied stress is proportional to the resultant strain (Hooke's law). For liquids, Newton's law describes a region where the applied stress is proportional to the rate of strain. Both are valid only for small strains or rates of strain. In many cases, a polymer will show the characteristics of both a liquid and a solid, and neither of these limiting laws will adequately describe its behaviour. The system is then said to be in a viscoelastic state, where it will respond like an elastic solid to a sudden force, but like a viscous liquid to a slow force.

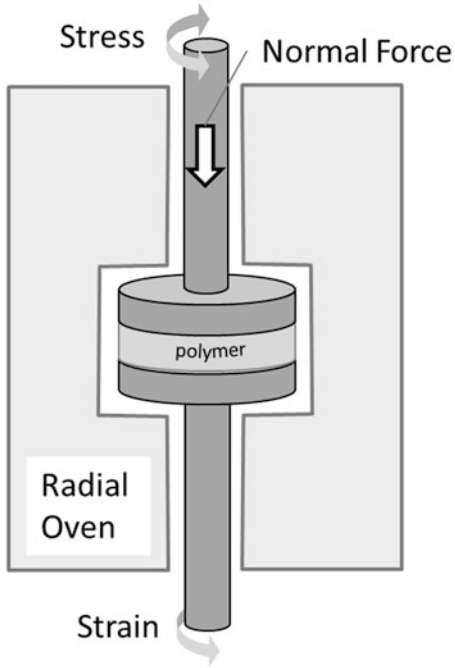

Fig. 7.11 Schematic diagram of a parallel plate rheometer with environmental chamber (oven)

Rheometry provides an essential tool kit for adjusting the conditions in polymer processing. The use of rheometry for studying aspects of the thermal decomposition of polymers is less common. Probably the parallel plate rheometer, with environmental chamber (Fig. 7.11) is most suited to investigating the changing properties of a decomposing polymer. The polymer sample is mounted between two parallel circular metal plates. One plate is driven mechanically with an oscillating motion of fixed angle or torque, and the resistance to the motion is recorded. Various parameters including the elastic and relaxation modulus and the viscosity can be determined. The complex dynamic modulus G* can be separated into two components, the storage modulus G' (representing the solid or gel like behaviour) and the loss modulus G" (representing the viscous or liquid like behaviour).

$$G^* = G' + iG'' \tag{7.5}$$

These are related to the corresponding dynamic viscosities η*.

$$\eta^* = \eta' - i\eta'' \tag{7.6}$$

The release of fuel from a decomposing polymer, as volatiles or bubbles migrating through a viscoelastic medium is a function of its rheological properties.

The Five Regions of Viscoelastic Behaviour

The physical properties of an amorphous polymer are related to its molecular motion, which is governed by the flexibility of the polymer chains and their temperature. For a linear, amorphous polymer, five distinguishable states can be observed if the elastic modulus is measured over a range of temperature. The relaxation modulus E_r (the time dependent change in stress under a constant strain), for polystyrene, plotted as log E_r against temperature, shows these five distinct regions, Fig. 7.12.

(i) **The glassy state**: Below 360 K, even short range motion of one polymer molecule relative to another is frozen, giving the material high rigidity, but with corresponding brittleness.

(ii) **Retarded elastic state**: The glass transition temperature T_g is in this region, and the sharp decrease in modulus with temperature reflects the increase in molecular motion as the temperature rises from T_g to 30 K above T_g. Just above T_g the movement of the chain segments is still rather slow, giving leathery properties to the material.

(iii) **The rubbery state**: At approximately 30 K above T_g the modulus curve begins to flatten out into the plateau region, giving a softer elastic material, since the polymer chains can move relative to each other over a short range, but liquid flow (or long range movement) is still inhibited.

(iv) **Rubbery flow**: After the rubbery plateau, the modulus again decreases as liquid-like flow becomes possible.

(v) **Viscous state**: Above 450 K, there is little evidence of any elastic recovery in the polymer, and all the characteristics of a viscous liquid become evident. Here, there is a steady decrease of the modulus as the temperature increases.

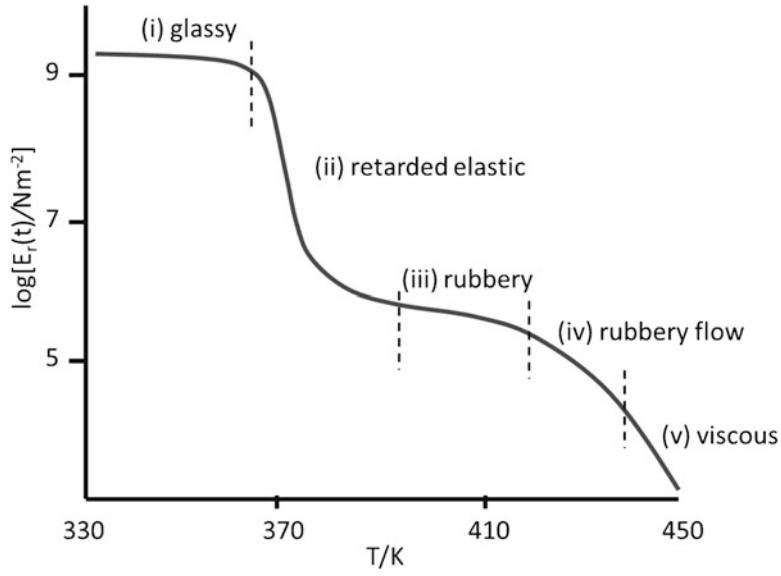

Fig. 7.12 The five regions of viscoelasticity for an amorphous polymer (i) glassy state; (ii) retarded elastic state; (iii) rubbery state; (iv) rubbery flow state; and (v) viscous state

In the glassy, elastic and rubbery states movement of bubbles through the polymer matrix will be inhibited. Sufficient fuel release to support ignition is unlikely in the rubbery flow state. As the polymer moves through the viscous state fuel release will become increasingly easy, allowing a critical concentration to accumulate above the sample to support ignition.

Techniques Involving Chemical Analysis of Decomposition Products

Evolved Gas Analysis (EGA)

Thermogravimetric Analysis (TGA) provides the crucial data with which to interpret the complexities of burning behaviour. For example, ignition can only occur when there is sufficient fuel being released into the gas phase. The temperature at which the first sharp mass loss occurs normally corresponds to the critical surface temperature for ignition, and if, for example, the addition of fire retardants delays this onset, they may also delay ignition. However, if this mass loss is non-combustible (such as the loss of HCl from PVC), it will clearly not result in ignition; it is, therefore, important to know the chemical nature of the products released during mass loss in TGA, as well as the temperature at which they were released. The most widely used fire retardant, aluminium hydroxide releases water vapour as it decomposes; surface oxidation can result in carbon dioxide (CO_2) formation, which tends to delay ignition; evolution of hydrocarbons is indicative of the fuel release step leading to ignition.

In the simplest form of evolved gas analysis (EGA) a non-dispersive infrared analyser (NDIR) may be attached to the exhaust line of a TGA, DSC or STA, in order to provide a time resolved profile of CO_2, carbon monoxide (CO), hydrocarbons and oxygen concentrations as a function of time, during the TGA run [13]. This technique allows the major decomposition products to be distinguished during thermal decomposition, particularly in relation to fuel gases and non-combustible products. The evolution of CO_2 formed on the surface of the decomposing polymer is indicative of the consumption of oxygen and fuel, but accompanied by self-heating. CO_2 is not formed in the gas phase below 500 °C.

Thermal Analysis with Fourier Transform Infrared Analysis

Fourier Transform Infrared (FTIR) has revolutionised infrared analysis, producing spectra of higher resolution in a much shorter time. For polymer decomposition studies this allows the

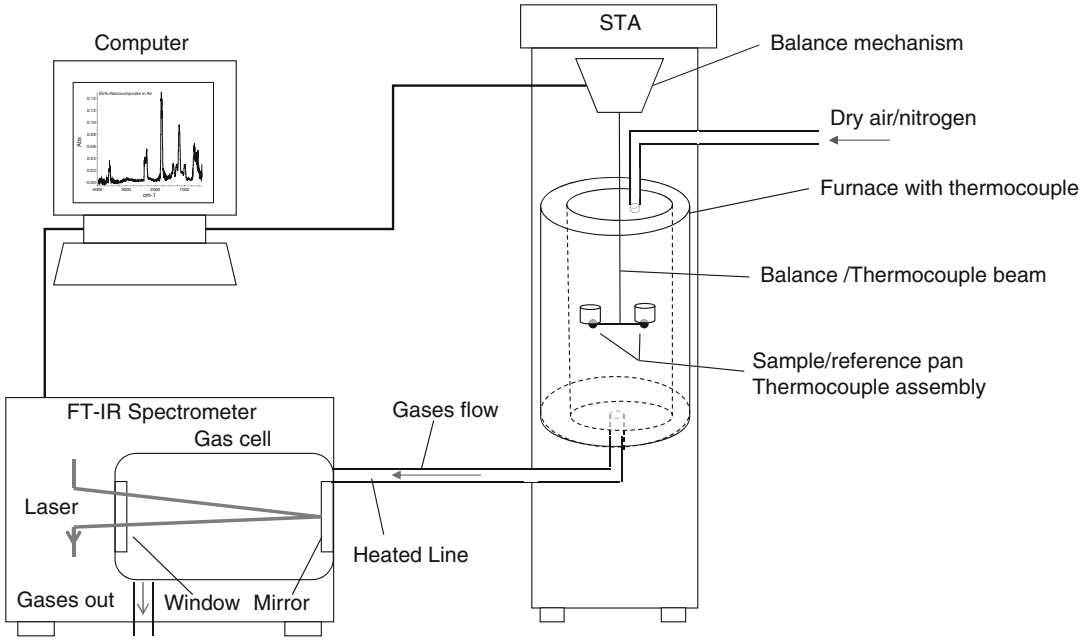

Fig. 7.13 Schematic of a typical STA-FTIR instrument set-up

spectra of gas phase products to be collected continuously as a function of temperature. Gas phase infrared spectra are much sharper than condensed phase spectra, and generally identification of individual molecules is possible in the gas phase, whereas only the presence of functional groups may be obtained from condensed phase spectra. However, when a large number of similar molecules are present, each with their distinctive spectra superimposed, deconvolution software may be necessary in order to identify and quantify the individual components. Figure 7.13 shows a schematic of a typical STA FTIR set up [14].

TGA, DSC or STA, combined with FTIR analysis of the vapour phase provides a very rich profile of polymer decomposition through the spectra of the evolved products. This is shown in Fig. 7.14 for ethylene-vinyl acetate copolymer in nitrogen, and can be deconvoluted to provide profiles with respect to temperature of the evolution of individual species. The technique is gaining popularity amongst the fire retardant community, but the deconvolution of spectra, particularly where compounds are present for which no calibration data has been recorded, limits the applications of the technique.

Pyrolysis-Gas Chromatography Mass Spectrometry

Pyrolysis-gas chromatography–mass spectrometry (py-GCMS) is a three stage process consisting of pyrolysing about 1 mg of sample, separating the mixture of volatile products by gas chromatography, and analysing each of the components by mass spectrometry. From its esoteric origins, gas chromatography–mass spectrometry instruments are now standard, low cost and do not depend on specialist technical support (Fig. 7.15).

Given the large numbers of different products that can result from a single stage in the decomposition of a polymer, separation of the products is often required, before they can be identified. Controlled temperature and heating rate pyrolysis may be followed first by sample collection on a sorption tube, or for rapid pyrolysis, direct injection into a gas chromatography column (py-GC). In its simplest form, a gas chromatograph consists of several metres of capillary tube with a well-controlled flow of a carrier gas through it. The tube or "column" is lined with an absorbent solid coated with an involatile liquid that will adsorb and desorb constituents in the

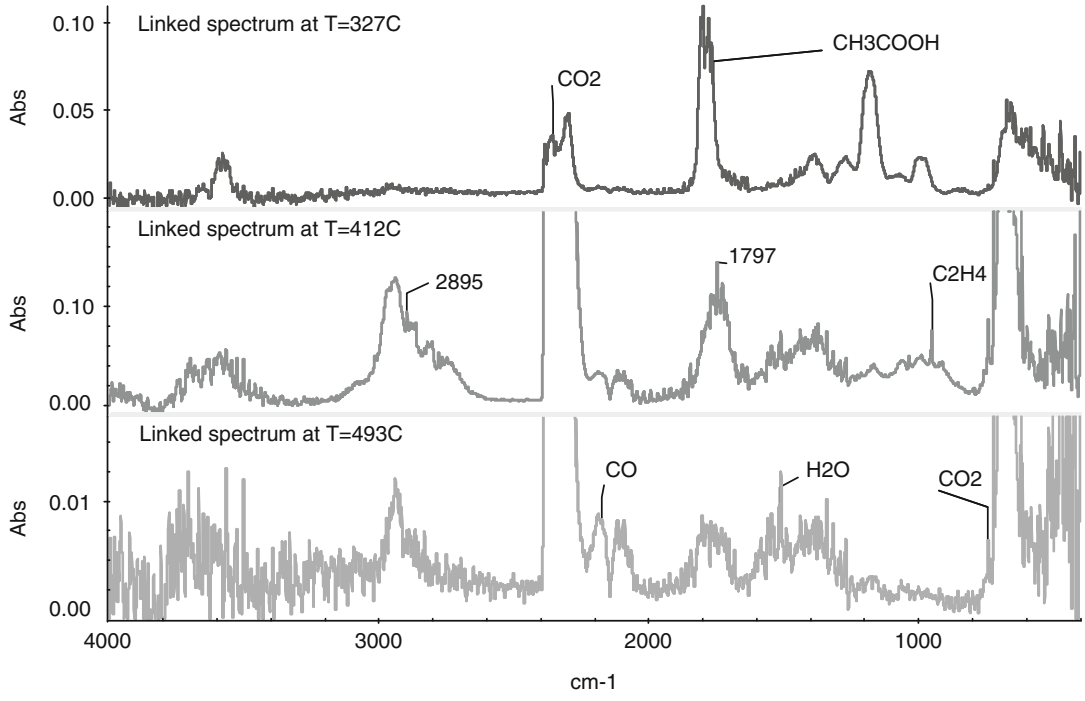

Fig. 7.14 FTIR spectra recorded during decomposition of ethylene vinyl acetate at a heating rate of 10 K min^{-1}

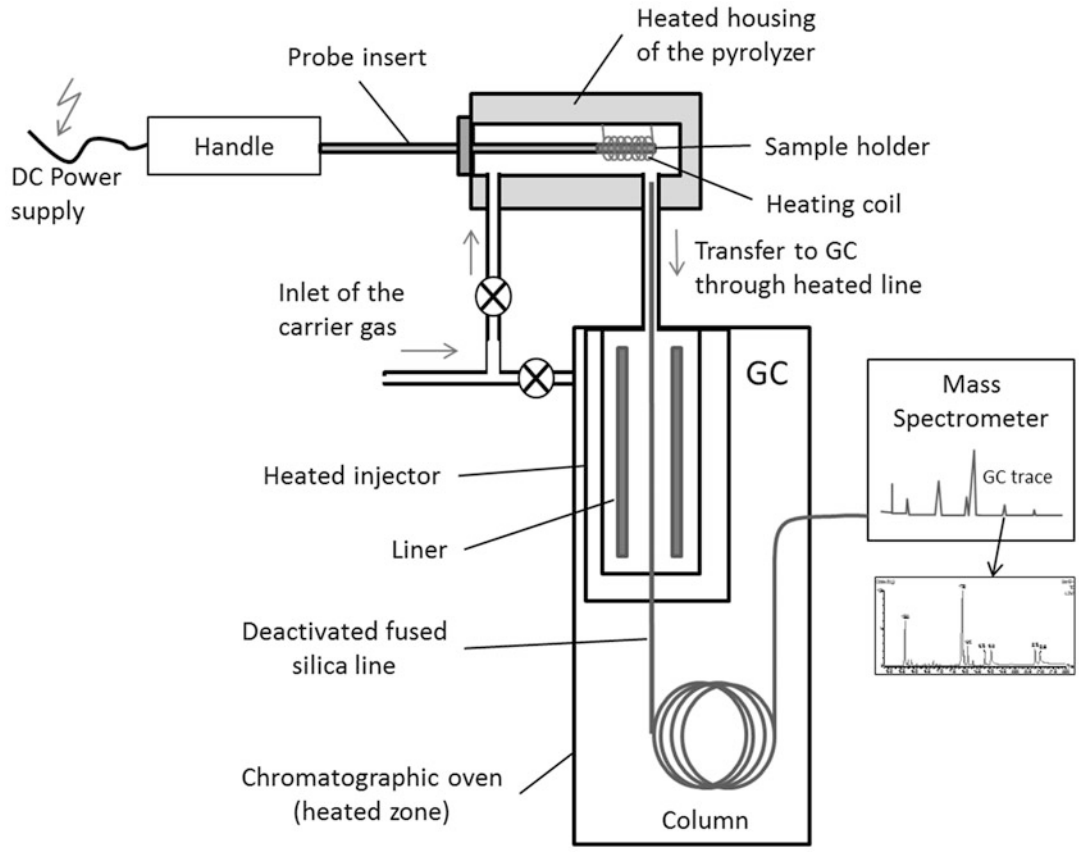

Fig. 7.15 Typical pyrolysis GC-MS apparatus

sample, depending on their affinity for the liquid, and their volatility. The column is located in a temperature programmable oven. Molecules with different adsorption properties relative to the column packing will reach the end of the column at different times, and hundreds of compounds may be separated in a single run. A detector placed at the exit of the gas chromatograph will respond to the concentration of molecules, other than the carrier gas, giving a series of peaks. For a single peak, the time from injection is characteristic of the molecule, and the area under the peak is proportional to its concentration. Column lining, column temperature programming, carrier gas flow rate, sample size, and detector type can be adjusted to achieve optimal separation of the decomposition products.

Simple detectors include the flame ionization detector (FID) which gives a signal roughly proportional to the carbon content of the molecule, and hence its calorific potential. They have a dynamic range spanning several orders of magnitude. However the reduction in cost of the mass spectral analysers, which provide a chemical fingerprint for each separated molecule, which can then be compared to databases such as the NIST mass spectral library, provide the rapid and powerful tool for investigating the true complexity of polymer decomposition. Figure 7.16 shows py-GC/MS chromatograph of the decomposition products of soy-styrene-divinyl benzene (SSD) polymer [15] collected from 323–873 K at 10 K min^{-1}.

Pyrolysis GC-MS complements TGA-FTIR as it provides snapshot identifying all evolved species over a particular temperature range. TGA FTIR shows the variation of the spectrum as a function of temperature, once identified, the temperature evolution profile of a species may be monitored.

Thermal Volatilization Analysis

Another useful method for quantitatively collecting and separating polymer decomposition products is thermal volatilization analysis (TVA) based upon the apparatus and techniques described by McNeill et al. [16]. The apparatus consists of a sample chamber (heated by a programmable tube furnace) connected in series to a primary liquid nitrogen-cooled sub-ambient trap and a set of four secondary liquid nitrogen-cooled cold traps. The whole system is continuously pumped to a vacuum of 1×10^{-7} atm. Volatile condensable products from a ~25 mg sample are initially trapped at two stages: the 'cold-ring' ($T \sim 285$ K) immediately above the heated area of sample tube (for high boiling point materials) and the primary liquid nitrogen cooled sub-ambient trap ($T \sim 77$ K) for lower boiling point species. The pressure increase is proportional to the evolution of both condensable and non-condensable volatiles from the sample [17]. These separated fractions may be subsequently analysed by gas-phase FTIR (section "Thermal Analysis with Fourier Transform Infrared Analysis") and GC–MS (section "Pyrolysis-Gas Chromatography Mass Spectrometry").

Microscale Combustion Calorimetry

A relatively recent innovation in fire calorimetry has been the development of the microscale combustion calorimeter (MCC) [18]. The apparatus was developed by Lyon and Walters at the U.S. Federal Aviation Administration (FAA) [19]. A schematic of the apparatus is shown in Fig. 7.17. It thermally decomposes 1–3 mg of

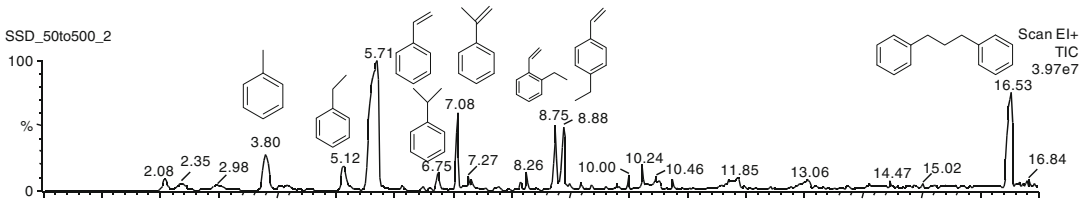

Fig. 7.16 Py-GC/MS chromatographs of the decomposition products of soy-styrene-divinyl benzene (SSD) polymer collected from 323 K to 873 K at 10 K min^{-1}

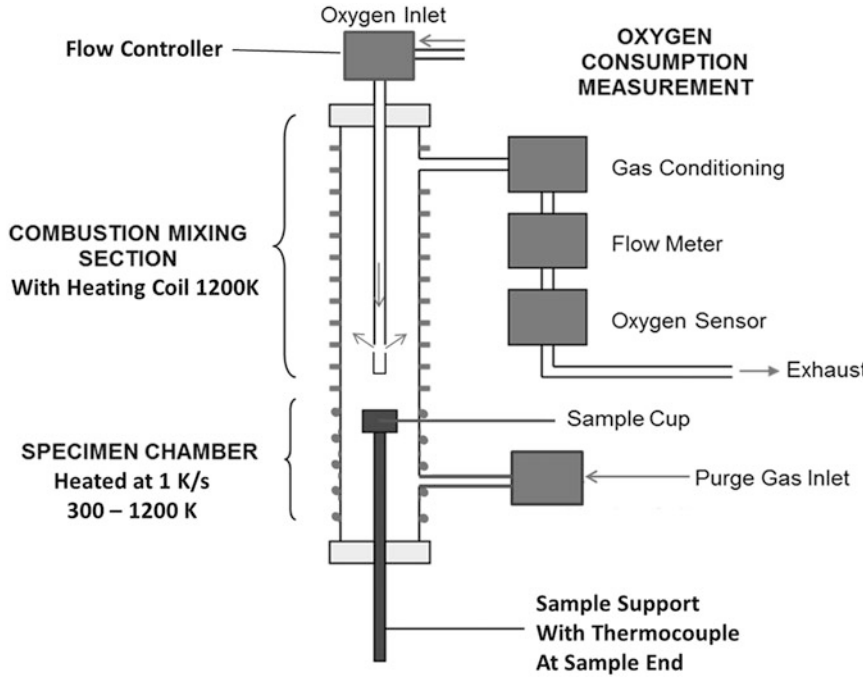

Fig. 7.17 Schematic diagram of MCC

sample in an alumina crucible at a heating rate of 1 K s^{-1} in an atmosphere of nitrogen (or synthetic air). The pyrolysis gases are then passed into the combustor at 1173 K and mixed with oxygen. The oxygen depletion of the dry gas is measured, and a computer algorithm converts the oxygen depletion and mass flow rate data into specific heat release rate (W/g), as a function of temperature. For polymers that decompose to release only fuel, the information obtained is similar to that for DTG in nitrogen. For materials showing gas phase inhibition, the severe oxidising condition of 1173 K will usually suppress any reduction in oxidation. For materials producing char in nitrogen, the mass of residue will increase, though if the experiment is repeated using synthetic air as the pyrolysis gas, the char yield can be separated from the formation of an inorganic residue.

The apparatus has grown in popularity due to its excellent design, relatively low cost and ease of use. It is particularly popular with the aircraft manufacturer, Boeing, who uses it for both materials screening and quality control. However, its popularity has led, for example, to a number of fire retardant development laboratories publishing articles describing their latest fire retardant formulations, based solely on MCC data, paying less regard to what that data actually means.

Figure 7.18 shows the heat release curves for five common polymers measured using the microscale combustion calorimeter. In particular, the pyrolysis temperature and the peak of specific heat release rate of the most useful indicators of fire performance.

Choice of Atmosphere and Heating Rate in Thermal Analysis

Thermal analysis is generally conducted in nitrogen or in dry air. Studies of thermal stability (for example to ensure that a material does not degrade at its normal operating temperature) would normally be carried out in air, or for accelerated ageing, in elevated oxygen atmospheres. The decomposition of a polymer is known to be dependent on the atmosphere in

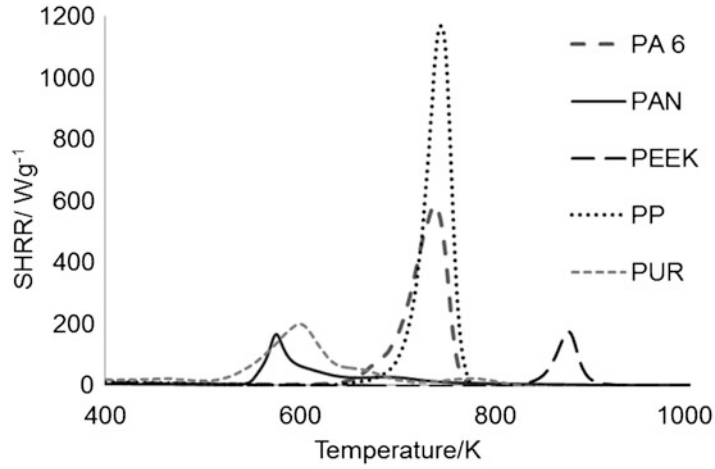

Fig. 7.18 MCC heat release rate curves for common polymers

which the decomposition occurs. For some polymers the decomposition occurs 200 K lower in air than in nitrogen, while for a few others it makes little difference. In other cases, certain decomposition stages are delayed by the presence of oxygen, perhaps through the formation of a more thermally stable char. The decomposition of polypropylene has been widely studied (section "Polypropylene") and it has been shown that the process is accelerated by oxygen, and that the oxygen permeates the decomposing polymer, not only affecting the surface layers.

In contrast, in order to understand the reaction-to-fire behaviour of a material, it should be recognized that

(i) Heating rates in fires are probably closer to 100 K min^{-1} than the 10 K min^{-1} typical of thermal analysis, causing faster fuel production flows and preventing the diffusion of oxygen into the polymer.
(ii) The atmosphere under a flame is practically free of oxygen.
(iii) Fuel is generally released from a decomposing polymer as bubbles of vapour, forcing their way out through a molten or porous condensed phase, and released from the polymer under anaerobic conditions.

These factors all indicate that fire behaviour, both before and after ignition, is better represented by decomposition in nitrogen, than by decomposition in air. However, given the ease with which TGA can be run in flowing air, and the potential for added insight (such as the formation of a more stable char in an oxidising atmosphere) it is often also worthwhile obtaining the TGA in air.

The choice of heating rate during thermal decomposition of polymers has been the subject of much controversy. Low heating rates (around 1 K min^{-1}) produce better quality data and better defined and separated chemical events. High heating rates (around 100 K min^{-1}) are more representative of those found in a fire. However, when analysing the products during the thermal decomposition of a polymer, for example in TGA-FTIR, it is often necessary to use larger amounts of sample (~15 mg) in order to obtain representative spectra. With such larger samples, it is more difficult to maintain thermal equilibrium across the sample bulk, and therefore lower heating rates (around 10 K min^{-1}) are preferable. Conversely, a faster heating rate will produce a higher concentration of volatiles in a shorter time, although these may become mixed in the sampling line before analysis.

Char and Residue Analysis

The complexities of the thermal decomposition of polymeric materials can be investigated by a combination of analysing the volatile components as described above, and by analysing the

chemical composition of the char or residue. In terms of improved fire retardancy, enhancement of the char layer normally provides the best route for improving the fire safety. Chars may show the chemistry of the solid phase processes prior to carbonisation. For example, polyacrylonitrile fibre decomposes to produce materials which ultimately become carbon fibre (a modern, heterocyclic material composed of graphite layers with nitrogen heterocycles along their perimeters).

Unfortunately, chars are predominantly carbon, and can be difficult to analyse. In addition to the chemical composition of chars, the three dimensional and microscopic structure is also important. If the char provides a coherent, uninterrupted layer which seals the underlying polymer from the attack of radiant heat and oxygen, while preventing the escape of fuel, it will be much more effective in reducing the attack of fire. Scanning electron microscopy (SEM) is the most effective tool surveying the permeability of the char or residue layer. With the addition of elemental analysis, more information about the chemistry of the formation of the protective layer can be obtained. For example, some inorganic materials migrate to the surface of the decomposing polymer and form low melting inorganic glasses.

Analysis of the chemical composition of char and residue layers is complicated by the high absorptivity of carbonaceous carbon. If spectroscopic techniques such as Fourier transform infrared (FTIR) are used for the analysis of the carbonaceous layer, very low signals are often found because the infrared radiation is generally absorbed by the black solid, rather than specifically by the organic functional groups of interest. In addition, a high proportion of carbon-carbon bonds will be non-polar, and so will have no dipole moment, and therefore no ability to absorb infrared radiation, so that relatively little useful information can be obtained. Surface analysis techniques such as diamond-attenuated total reflectance FTIR (d-ATR FTIR) can identify the presence of functional groups within the surface layers of the char. Sample preparation is trivial and results can be obtained rapidly. In addition Raman spectroscopy, which uses visible frequency laser light of high intensity and detects scattered wavelengths of lower energy infrared radiation emitted from the sample can be used very effectively to quantify the presence of carbon-carbon single bonds, carbon-carbon double bonds and carbon-carbon aromatic bonds in a carbonaceous char layer, although care must be taken to avoid using a laser wavelength that causes fluorescence. More sophisticated analysis has been undertaken using nuclear magnetic resonance (nmr) with a solids probe (magic angle spinning) to examine the chemical environment of any atomic nuclei with uneven numbers of nucleons, such as C-13, F-19, P-31 etc. [20].

Decomposition of Polymers

Different polymers decompose in different ways. When a polymer is heated its chains will start to break down, which eventually results in the formation of volatile fuel molecules. The pyrolysis of a polymer, which turns polymer chains of 10,000–500,000 carbon atoms into species small enough to be volatilized, often involves breaking the polymer chain. In some cases, the chain releases groups from its ends most easily, known as *end-chain scission* or unzipping. In others, the chain breaks at random points along its length, known as *random chain scission*. A third process, in which groups attached to the backbone as side chains are released, is known as *chain stripping*. If the resulting chain may be prevented from undergoing chain scission to form volatiles or lose further substituents, it may instead undergo carbonization that results in *char formation*. Thus, the conversion of organic polymer into volatile organic molecules may follow four general mechanisms. While some polymers fall exclusively into one category, others exhibit mixed behaviour (Table 7.4).

Decomposition Mechanisms

Random chain scission usually takes place when the bonding energies are similar along the chain. The distinction between random chain and end

Table 7.4 Generalised mechanisms of polymer decomposition

Mechanism	Examples of polymer	Typical products
Random chain scission	Polyethylene	Alkanes, alkenes, very little monomer
	Polypropylene	Alkanes, alkenes, very little monomer
	Polystyrene	Styrene monomer, dimer and trimer
	. . .more generally	Monomers and oligomers
End chain scission	Polymethylmethacrylate	90–100 % monomer
	Polytetrafluoroethylene	90–100 % monomer
	. . ..more generally	monomer
Chain stripping	Polyvinyl chloride	Hydrogen chloride, aromatic hydrocarbons and char
	Polyvinyl alcohol	Water and char
	Generally	Small molecules and char
Cross-linking	Polyacrylonitrile	Hydrogen cyanide and char
	Polyetheretherketone	Volatile aromatics and char
	Generally	Char and volatile products

chain scission is generally based on the extent of monomer evolution, and on the measurement of the polymer's average molecular mass when heating the polymer below its typical pyrolysis temperature. The slow evolution of monomer and rapid decrease of the molecular mass is an indication of random chain scission.

Both end and random chain scission are dominated by free radical processes. The decomposition of a polymer by a free radical mechanism can be divided into three processes.

Initiation—the time taken and for the first bond to rupture, generating two free radicals. In random chain scission each radical will be at the end of a polymer chain, in end chain scission the $H\cdot$ or $\cdot CH_3$ radical released will attach itself to another polymer chain. This is likely to occur at the weakest link in the polymer chain, such as a C–C single bond one bond away from a double bond, triple bond or an aromatic ring $\left(-C^{\gamma}-C^{\beta}-C^{\alpha}=C-\right)$, the β-carbon shown here. These bonds are generally weaker than other C–C or C–H bonds, and significantly weaker than aromatic, double, or triple bonds. Bond breaking can take place as a random or end chain scission. Since larger free radicals are more stable than those on small molecules, the fragmentation in the middle of the polymeric chain is favoured thermodynamically compared to the formation of smaller molecules. However, kinetic factors may also play a role in determining the abundance of a specific compound. The formation of small radicals from the end of a polymeric chain can be kinetically favoured, and, as a result, formation of small radicals in the initiation step is more common than predicted by thermodynamic criteria. In polystyrene, end chain scission produces styrene monomer in competition with random chain scission, which ultimately produces the dimer, trimer, tetramer etc.

Propagation—once a polymer chain has a free radical, the reactivity will propagate along the polymer macromolecule very quickly, releasing monomers or other small volatile molecules.

Termination—at some point the rapid propagation step must end. This may be at the end of the polymer chain, at the branching point, or some other structural irregularity where two radicals can combine.

Thermodynamics of Polymer Decomposition

At every propagation step in the depolymerisation of a vinyl polymer $-(CH_2-CHX)_n-$ a C–C σ-bond is broken, and a $C=C$ π-bond is formed (Fig. 7.19).

The enthalpy on breaking a σ-bond is around 320 kJ mol^{-1}, and that of forming the π-bond in the volatile fragment is around 260 kJ mol^{-1}.

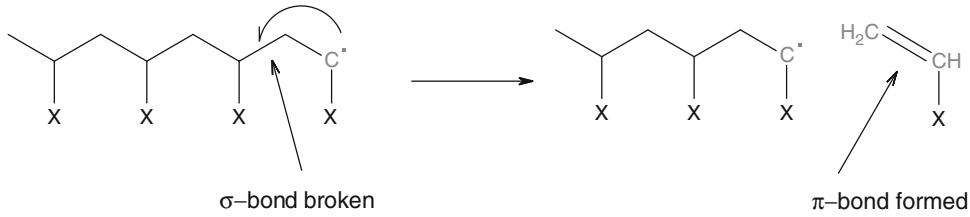

Fig. 7.19 Generalised mechanism for free radical depolymerisation of a vinyl polymer

Thus, in purely enthalpic terms, depolymerisation requires about 60 kJ per mole of volatile alkene formed, i.e. $\Delta H = +60$ kJ mol^{-1}. However, a reaction can only proceed when the *free energy change* ΔG is negative, and since:

$$\Delta G = \Delta H - T\Delta S \tag{7.7}$$

the entropy change involved must also be considered. The entropy (or disorder) of a decomposing polymer is obviously *increasing*, since the number gas molecules is increasing. Thus ΔS is positive, and is typically around +120 J mol^{-1} K^{-1}. At room temperature, 300 K, the free energy change on depolymerisation is thus:

$$\Delta G = +60\,000 - (+300 \times 120)\,\mathrm{J\,mol^{-1}}$$
$$\Delta G = +24\,000\,\mathrm{J\,mol^{-1}} = +24\,\mathrm{kJ\,mol^{-1}}$$

This demonstrates the obvious fact that at room temperature depolymerisation is unfavourable, and hence polymers are thermodynamically stable. However, at a much higher temperature of 570 K, the $T\Delta S$ term is greatly increased:

$$\Delta G = +60\,000 - (+570 \times 120)\,\mathrm{J\,mol^{-1}}$$
$$\Delta G = +8\,400\,\mathrm{J\,mol^{-1}} = -8.4\,\mathrm{kJ\,mol^{-1}}$$

From this it can be concluded that, above a certain temperature, sometimes known as the *ceiling temperature*, depolymerisation will prevail, as polymer chains (formed at lower temperatures) "unzip" to regenerate monomers. The ceiling temperature for polymethylmethacrylate is about 500 K, and for polystyrene 580 K.

In addition to this simplified view of depolymerisation, a burning polymer is a complex situation, where chemical reactions can take place in the condensed phase, between the condensed phase and the gas phase and, for sustained burning, in the gas phase. The applied heat and exothermic release of energy by chemical reactions such as combustion must exceed the energy required for endothermic process such as heating, melting, depolymerisation and volatilisation.

Kinetics of Polymer Decomposition

Chemical kinetics is the study of reaction rates. Theoretically, the rate of a chemical reaction, as a function of state variables such as temperature, pressure, and concentration, can be predicted for any set of conditions. However, since many chemical reactions are the sum of a number of competing processes, such predictions do not often agree with the experimental data. The most common reason for carrying out kinetic studies is to investigate reaction mechanisms, although empirical estimates of gasification rates provide essential data for fire models that include condensed phase fuel. Kinetic data provides insight into the mechanism, although this generally needs to be corroborated with chemical evidence. The simplest media for investigating the kinetics of chemical reactions are gas and solution phases, which are described briefly below.

Gas and Solution Phase Kinetics

For a reaction of A → Products, simple gas or solution phase kinetics classifies reactions in terms of order (Table 7.5).

In gas and solution phases, most reaction rates lie between zero and second order—genuine third order reactions, where three molecules collide simultaneously, and possess sufficient

Table 7.5 Orders of chemical reactions, and their corresponding rate equations

Reaction order	Description	Differential rate equation	Integrated rate equation	Examples
Zero	Reactant concentration does not affect rate	$-\frac{\mathrm{d[A]}}{\mathrm{d}t} = \mathrm{k}$	$\mathrm{k}t = [\mathrm{A}]$	e.g. vaporisation, where the reactants have to pass through a narrow orifice, or when heat is supplied at a fixed rate.
First	Rate of reaction depends on amount of reactant	$-\frac{\mathrm{d[A]}}{\mathrm{dt}} = \mathrm{k}\,[\mathrm{A}]$	$\ln\left(\frac{[\mathrm{A}]_0}{[\mathrm{A}]}\right) = \mathrm{k}t$	Typical of a simple decomposition reaction, or radioactive decay.
Second	Rate of reaction depends on amount present of two reactants (which may both be A)	$-\frac{d[\mathrm{A}]}{dt} = \mathrm{k}[\mathrm{A}]^2$	$\frac{1}{[\mathrm{A}]} - \frac{1}{[\mathrm{A}]_0} = \mathrm{k}\,t$	Common for gas phase processes such as 2A → Products. Kinetics more complex for A + B → Products
nth	Rate is not a simple function of reactant concentration	$\mathrm{Rate} = -\frac{\mathrm{d[A]}}{\mathrm{d}t} = \mathrm{k}\,[\mathrm{A}]^n$	$\mathrm{k}t = \frac{1}{n-1}\left(\frac{1}{[\mathrm{A}]^{n-1}} - \frac{1}{[\mathrm{A}]_0^{n-1}}\right)$	May be a simple fraction (based on kinetic analysis) or an experimental value (for a complex processes)

energy to react, are very unlikely. Where complex reaction pathways occur, particularly with multiple competing processes, precise fractional order processes are also observed.

Solid Phase Kinetics

In the solid phase the reacting molecules do not move freely and collide at a rate controlled by the thermal energy of the system in contrast to gases and liquids. The reacting species cannot move through the solid and so the rate will not depend on concentration within the solid. If a diffusion process controls the mechanism, the rate will be dependent on concentration gradients within the solid. Alternatively, a reaction interface may move through the bulk with pure reactant ahead of it and pure product behind. Here concentration is meaningless and is replaced by fraction reacted, α.

Experimentally, the rate constant (k) has been found to vary as a function of two variables, A and E_a, defined by the Arrhenius equation.

$$k = A\,e^{\frac{-E_a}{\mathrm{RT}}}. \tag{7.8}$$

This is a very flexible mathematical function, allowing the influence of the underlying rate to be described by the pre-exponential factor A, (including the number of collisions, the molecular orientation, and factors intrinsic to the reaction mechanism) and the temperature dependence of the reaction, E_a (the proportion of molecules with sufficient energy to overcome the barriers to reaction, E_a) to be quantified. Unfortunately, even in the gas and solution phases, all theoretical attempts to make general predictions of the value of the pre-exponential factor have been unsuccessful.

The thermal decomposition of a polymer involves many competing chemical processes. The goal of chemical kinetics is to parameterise all the competing processes, so they switch in or out under different conditions. The reality is that such universal mechanisms have so far only been applied to simple gas phase systems such as the combustion methane (which itself involves over 50 reactions) [21].

Generally, solid-phase pyrolysis is assumed to follow the Arrhenius equation with three parameters defining the reaction kinetics. These kinetic parameters are reaction order, activation energy (E_a) and pre-exponential factor (A). Figure 7.20 shows how the pairs of values of A and E_a affect the mass loss rate, for a particular peak pyrolysis temperature (T_p), based on the analysis of Lyon [22]. Rearranging the Arrhenius equation gives

$$T_p = \frac{E_a}{R\ln\left(\frac{A}{k_p}\right)} \tag{7.9}$$

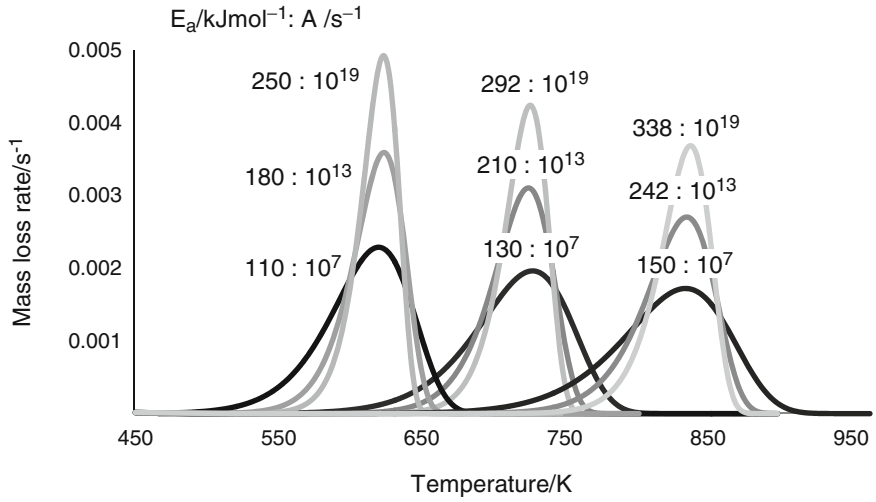

Fig. 7.20 Relationship of Arrhenius parameters A and E_a, shown as E_a in kJmol^{-1}: A in s^{-1} by the peak (T_p) of each mass loss curve, to the pyrolysis temperature and mass loss rate

Polymer decompositions are frequently free radical process, where first a bond is broken resulting in two free radicals (initiation), then the reactive free radical causes a rapid sequence of similar reactions (propagation), until a process occurs which removes the activity of the free radical (termination).

The initiation mechanism in decomposition kinetics can be considered as random- or end-chain initiation with propagation by unzipping or random chain scission, without termination reactions other than exhaustion of the polymer chain by unzipping. The rate of mass loss, $\frac{dm}{dt}$, for random-chain initiation can be considered as

$$\frac{dm}{dt} = D_p k_{ri} m \tag{7.10}$$

Where D_p is the degree of polymerisation, (or number of monomer units per polymer chain); and k_{ri} is the rate constant for the random-chain initiation reaction. Here, the rate constant of the propagation reaction is ignored in the expression because it is very rapid relative to the initiation step. The degree of polymerisation is included in the equation because, for each initiation, D_p monomer units will be released; the remaining mass, m, corresponds to the reactant concentration; and the process is assumed to follow first order kinetics. The polymer unzips completely so the molecular weight of all remaining polymer chains is the same as the initial average molecular weight.

For end-chain initiation, the rate of mass loss, $\frac{dm}{dt}$, is described by

$$\frac{dm}{dt} = D_p k_{ei} 2n \tag{7.11}$$

n the number of the polymer chains, so $2n$ is the number of chain ends, and k_{ei} is the rate constant for end-chain initiation. The number of polymer chains is simply the mass of the sample divided by the molecular weight of each chain, or

$$n = \frac{m}{D_p W_m} \tag{7.12}$$

where W_m is the molecular weight of the monomer, which allows the expression to be rearranged, to give

$$\frac{dm}{dt} = \frac{2k_{ei} m}{W_m} \tag{7.13}$$

It is apparent that for random initiation the rate is dependent on the chain length of the polymer, or "dispersity" of the sample; whereas for end-chain initiation the rate is dependent on the number of chain ends, or initiation sites. However, in both cases, the rate is assumed first order with respect to the mass of the sample and it is assumed that the average value used for D_p

adequately represents the effect of chain length on the kinetic process.

In the random-chain initiation expression, the longer chains are more likely to decompose first because they have more initiation sites, and therefore the longer chains would decompose more quickly than the shorter chains. If the initial sample had a range of molecular weights, the distribution of the molecular weight would change with time. In this case, the rate equation would be,

$$\frac{dm}{dt} = \frac{2k_{ei}m^n}{W_m} \tag{7.14}$$

with $1 < n < 2$.

Depending on the molecular weight distribution the reaction order normally lies between one and two for random-chain initiation leading to complete unzipping of a polydisperse system [23].

This comparison shows how the decomposition process can be influenced by the polymerisation process, and its influence on the molecular weight distribution. The same polymer may be polymerised using free radical, cationic, anionic or catalytic reactions, which result in different molecular weight distribution curves for polymers of the same average molecular weight. For a particular polymer sample, both end and random chain initiation reactions may be important. The activation energies for the different initiation steps may be quite different, leading to large variations in the relative rates with temperature. For instance, in PMMA, at low temperatures (around 570 K), end-chain initiation predominates. At higher temperatures (around 770 K), the random-chain initiation step dominates.

Modelling Polymer Decomposition and Pyrolysis

Historically (from 1950–1990), determination of kinetic parameters for polymer decomposition involved analysis of paper traces from thermal analysis output and numerical calculation, without the aid of computers. Only in the last 25 years has thermal analysis data been readily available in digital form. A great deal of painstaking experimental work and analysis relied on these manual techniques, and the parameters obtained are still valid, and in use today. A compilation of kinetic parameters for several common polymers, prepared by Lyon et al. [3], is included in Table 7.1. In order to set the different methods into context the brief description of the approaches is provided below.

Kinetics describing condensed phase decomposition processes often involves physical and chemical mechanisms. In pyrolysis modelling, the overall kinetic expressions are highly simplified, if considered at all. The most common assumption is that the reaction rate is described by first order or sometimes zero order kinetics.

Since the kinetic parameters cannot be measured directly, they have to be extracted by estimation methods based on microscale data. Generally there are two approaches to property estimation: direct, analytical methods [32, 24–26], and curve-fitting sometimes with the use of evolutionary algorithms [27–32]. Recently, methods based on optimisation algorithms and curve fitting have gained popularity. These methods use specific software for performing the simulation, and can analyse complicated, overlapping reactions and noisy data but still may require significant computational time for the iteration process to converge. Due to the kinetic compensation effect (where a change in the activation energy (E_a) can be partially or completely compensated for by a change in the frequency factor (A) [33], described in section "Solid Phase Kinetics" and Fig. 7.20), and other factors, the solution is not unique. Furthermore, the process is stochastic, so if it is repeated, it may not produce exactly the same parameters. Much simpler and faster are analytic methods, which give unique solutions based on reference points (such as the peak reaction rate) without requiring lengthy iterations, but often have more restrictions and limited accuracy. They only operate well on simple, non-noisy and

non-overlapping, well-separated reactions, and are often limited to a specific reaction path.

If the reaction chemistry is known it can be used to identify the reaction path. For an engineering solution of polymer pyrolysis rates, this is usually too complicated and ambitious. In polymer pyrolysis, several competing reactions occur simultaneously, which may overlap in time and temperature. This leaves pyrolysis and fire modellers with the choice of describing each reaction, with the resultant complex computations, or to mathematically mimic the mass loss rate data in its simplest form, and establish model-specific kinetics that can reproduce the experimental curve. It has been established that the model parameters can compensate for other shortcomings and simplifications [34, 35]. As approximations are inherent in a simplified reaction mechanism, and the "components" included in the mechanism may have no fundamental physical significance, choosing their values freely provides the best possible approximation to fit the experimental data. Within the two broad categories of curve-fitting and analytical methods, a number of different approaches have been developed for estimating the kinetic parameters for the thermal decomposition of polymers.

Experimental Determination of Kinetic Parameters

Solid state kinetic data are of practical interest for both thermal decomposition and combustion of polymeric materials [36]. The most popular experimental techniques used to study kinetics of thermally stimulated reactions are thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) (sections "Thermogravimetric Analysis and "Differential Thermal Analysis and Differential Scanning Calorimetry"). These techniques are capable of measuring the global kinetics of many types of thermally activated reactions but are not themselves able to give any evidence about the nature of these reactions. Techniques that can provide additional information on the mechanisms of solid state reactions are based on evolved gas analysis (section "Techniques Involving Chemical Analysis of Decomposition Products"). The most detailed detection methods for volatiles produced by thermal analysis techniques are Fourier transform infrared (FTIR) spectroscopy, and mass-spectrometry (MS), particularly when gas chromatography (GC) is used for prior separation of the individual components.

The kinetics of thermal decomposition reactions were traditionally determined under isothermal conditions. Dynamic, linear heating rates are now more common as computers are able to tackle the greater mathematical complexity of the data analyses. Various approaches to kinetic data analysis aim to provide consistent, predictive methods of reaction rate parameterisation, and contribute to a better understanding of the physical and chemical characteristics of solid state decomposition.

Mathematical Models of Polymer Decomposition Kinetics

The pyrolysis process of many polymers may be described by a simple reaction scheme:

$$A_{solid} \rightarrow B_{solid} + C_{volatile}$$

In the kinetic analysis of depolymerisation (section "Kinetics of Polymer Decomposition") it was assumed all the products were volatile, so the sample mass represented the amount of reactants. Here, both reactant and product contribute to the mass, so the rate of reaction must be expressed in terms of the degree of conversion. Kinetic models are usually based on a single-step rate Equation 7.15.

$$\frac{d\alpha}{dt} = k(T)f(\alpha) \qquad (7.15)$$

Where t is time, T is temperature, α is the degree of conversion of reactants to products, and $f(\alpha)$ is the reaction model. The rate constant, k, has the usual Arrhenius form. The kinetic parameters can be decoupled by specifying $f(\alpha)$. A reaction model that is widely used in thermal analysis [37–44], but less in pyrolysis models for fire simulation [44, 45], is the n^{th} order reaction model in which the residual conversion $1-\alpha$ is raised to the power n, so $f(\alpha) = (1-\alpha)^n$.

Solid Phase Mechanisms

Historically, several physical mechanisms of solid phase thermal decomposition kinetics were proposed [46], typically for simple inorganic systems, in order to explain experimentally derived thermal analysis data. The mechanisms have a common starting point of nucleation, where initial bond breaking leads to rearrangement, followed by the formation of gaseous and solid products. This may be repeated randomly, putting strain on the bonds around the product nucleus, and may be geometrically spherical, cylindrical or linear, often dependent upon the structure. Alternatively, a two-dimensional interface sweeps through the reactant from one end to the other. A large number of mechanisms based on diffusion of product have been proposed, which assume the rate depends on movement of gaseous reactants or products through the solid. The most commonly used are shown in Table 7.6 [47, 48, 59, 64, 65], but there is no consensus as to which ones are valid. Most of these models were devised in an attempt to interpret the simpler solid-state decompositions of inorganic solids such as calcium oxalate and calcium carbonate, involving transport processes of less complexity than those of a decomposing polymer.

The first difficulty in studying solid-state kinetics is in deciding which of such a large number of equations is being obeyed. Several equations may give very similar curves and thus appear to give equally good fits to some experimental data. The range of tools and approaches for kinetic parameter determination of solid state decomposition reactions are shown in Fig. 7.21.

For many years the different methods of obtaining the kinetic parameters for pyrolysis reactions were surrounded by controversy, as to which method was the most reliable and efficient. Each method had its limitations, frequently ignoring many factors in order to simplify the model. For example, the limitations of nonisothermal methods include the need to choose a particular reaction model, the error associated with predicting rates outside the range of experimentally determined heating rates, and if the reaction order is used as an adjustable parameter the inability to derive

Table 7.6 Reaction models used to describe the diffusional processes of solid state thermal decomposition

Reaction model		$f(\alpha)$	$g(\alpha)$
1	Power law	$\frac{2}{3}\alpha^{-1/2}$	$\alpha^{3/2}$
2	Power law	$2\alpha^{1/2}$	$\alpha^{1/2}$
3	Power law	$3\alpha^{2/3}$	$\alpha^{1/3}$
4	Power law	$4\alpha^{3/4}$	$\alpha^{1/4}$
5	One-dimensional diffusion	$\frac{1}{2}\alpha^{-1}$	α^2
6	Exponential law	α	$\ln(\alpha)$
7	Mampel (first order)	$\alpha - 1$	$-\ln(1-\alpha)$
8	Second order	$(1-\alpha)^2$	$(1-\alpha)^{-1} - 1$
9	Third-order	$(1-\alpha)^3$	$\frac{1}{2}\left[(1-\alpha)^{-2} - 1\right]$
10	Avrami-Erofe'ev[a]	$4(1-\alpha)[-\ln(1-\alpha)]^{3/4}$	$[-\ln(1-\alpha)]^{1/4}$
11	Avrami-Erofe'ev[a]	$3(1-\alpha)[-\ln(1-\alpha)]^{2/3}$	$[-\ln(1-\alpha)]^{1/3}$
12	Avrami-Erofe'ev[a]	$2(1-\alpha)[-\ln(1-\alpha)]^{1/2}$	$[-\ln(1-\alpha)]^{1/2}$
13	Three-dimensional diffusion	$2(1-\alpha)^{2/3}\left(1-(1-\alpha)^{1/3}\right)^{-1}$	$\left[1-(1-\alpha)^{1/3}\right]^2$
14	Two-dimensional diffusion	$[-ln(1-\alpha)]^{-1}$	$[(1-\alpha)ln(1-\alpha)] + \alpha$
15	Contracting sphere	$3(1-\alpha)^{2/3}$	$1-(1-\alpha)^{1/3}$
16	Contracting cylinder	$2(1-\alpha)^{1/2}$	$1-(1-\alpha)^{1/2}$

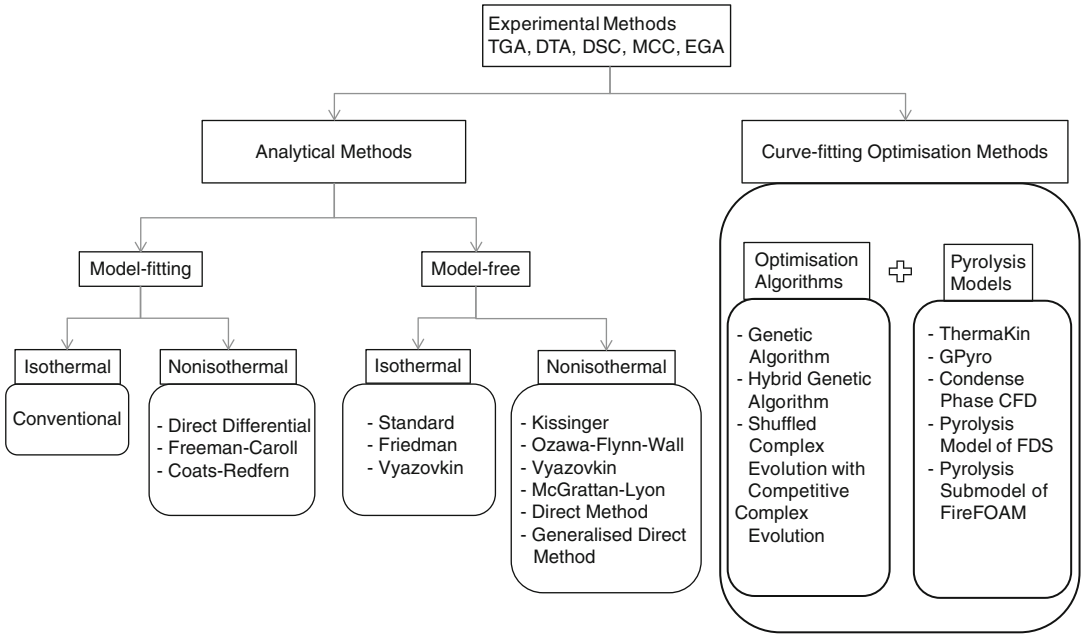

Fig. 7.21 Grouping of methods developed to study solid-phase chemical kinetics

mechanistic information from it. This could be described as curve-fitting where the physical significance of the parameter is (conveniently) ignored. The kinetic parameters that are required to calculate the reaction rates can be obtained from nonisothermal analyses by direct (inspection) and indirect (numerical regression) methods. Direct methods are fast, simple and sufficiently accurate for certain applications. Indirect methods are more flexible but require sophisticated software, and the resulting kinetic parameters may not be unique.

Very often the accuracy of a particular kinetic method and reaction model is not perfect; however such results are sufficient for predicting the time to ignition and surface temperature of a burning solid in fire simulations using a numerical pyrolysis model. Analytical methods can substitute the computationally expensive optimization methods when estimating the parameters of pyrolysis kinetics. The choice of method depends on the accuracy required, and the complexity of the experimental data. Methods with fewer reference values work better in the case of noisy data and overlapping reactions, while more complicated methods yield more accurate results for clean, simple data.

Isothermal Model-Fitting Method (Conventional Method)

This method is identical to that in the kinetics of a simple gas or solution phase reaction. It involves determination of the rate constant (k), for isothermal decomposition at a number of different temperatures.

$$g(\alpha) = kt \tag{7.16}$$

From which specific kinetic parameters such as the activation energy (E_a) and frequency factor (A) of the Arrhenius Equation 7.17 can be determined.

$$k = A\ exp\left(-\frac{E_a}{RT}\right) \tag{7.17}$$

First $g(\alpha)$ is calculated using models, such as zero or first order, or the diffusion models in Table 7.6. Once the best fit model is found, the

slope of $g(\alpha)$ *vs* time provides k for each temperature. Ln k may be plotted against $1/T$ to obtain E_a (slope) and A (intercept).

Non-isothermal Model Fitting Analytical Methods

Direct Differential Method

This method [49, 50] uses the differential form of the non-isothermal rate law

$$\frac{d\alpha}{dT} = \frac{A}{\beta} exp\left(-\frac{E_a}{RT}\right) f(\alpha) \tag{7.18}$$

Taking the logarithm of the non-isothermal rate law, gives:

$$\ln\frac{d\alpha/dT}{f(\alpha)} = \ln\frac{A}{\beta} - \frac{E_a}{RT} \tag{7.19}$$

Plotting the left-hand side versus $1/T$ gives the activation energy E_a and frequency factor A from the slope and intercept, respectively. The model that gives the best linear fit is usually chosen.

Freeman–Carroll Method

The Freeman and Carroll method [51, 52] is a differential method originally developed with a reaction model $f(\alpha) = (1-\alpha)^n$. Taking the natural logarithm of the differential form of the non-isothermal rate law gives,

$$\ln\frac{d\alpha}{dT} = \ln\frac{A}{\beta} - \frac{E_a}{RT} + \ln f(\alpha) \tag{7.20}$$

$$\Delta\ln\frac{d\alpha}{dT} = \Delta\ln f(\alpha) - \frac{E_a}{R}\Delta\frac{1}{T} \tag{7.21}$$

$$\frac{\Delta\ln\frac{d\alpha}{dT}}{\Delta\frac{1}{T}} = \frac{\Delta\ln f(\alpha)}{\Delta\frac{1}{T}} - \frac{E_a}{R} \tag{7.22}$$

$$\frac{\Delta\ln\frac{d\alpha}{dT}}{\Delta\ln f(\alpha)} = -\frac{E_a}{R}\frac{\Delta\frac{1}{T}}{\Delta\ln f(\alpha)} \tag{7.23}$$

The activation energy can be obtained from intercept $-E_a/R$ of Equation 7.22, or from the $-E_a/R$ slope of Equation 7.23.

Coats-Redfern Method

This method [53, 54] uses the integral form of the non-isothermal rate law

$$g(\alpha) = \frac{A}{\beta}\int_0^T exp\left(-\frac{E_a}{RT}\right) dT \tag{7.24}$$

Coats and Redfern utilized the asymptotic series expansion for approximating the temperature integral, producing:

$$\ln\frac{g(\alpha)}{T^2} = \ln\left(\frac{AR}{\beta E_a}\left[1 - \left(\frac{2RT_{exp}}{E_a}\right)\right]\right) - \frac{E_a}{RT} \tag{7.25}$$

Where, T_{exp} is the mean experimental temperature.

Plotting the left-hand side of Equation 7.25 versus $1/T$ gives the activation energy (E_a) and frequency factor (A) from the slope and intercept, respectively. The model with the best linear fit is chosen as the final solution. The Coats-Redfern equation was originally used with a first-order model $g(\alpha) = -\ln(1\text{-}\alpha)$ but later has been generalized to other reaction models as well.

Kissinger Method

Kissinger [41, 42] proposed a kinetic analysis method for reaction-order models ($f(\alpha) = (1-\alpha)^n$) based on taking the derivative of Equation 7.18 giving $d^2\alpha/dT^2$. Accordingly, the maximum reaction rate occurs when the second derivative is zero, from which the following equation can be obtained:

$$\frac{\beta E_a}{RT_{max}^2} = A\left(n(1-\alpha_{max})^{n-1}\right)\exp\left(-\frac{E_a}{RT_{max}}\right) \tag{7.26}$$

Where, T_{max} is the temperature of the maximum rate, β is the heating rate and α_{max} is the conversion value at that maximum rate. The maximum reaction rate represents the peak DTG curve. Taking the natural logarithm of equation above and rearranging gives,

$$\ln\frac{\beta}{T_{max}^2} = \ln\left(\frac{AR\left(n(1-\alpha_{max})^{n-1}\right)}{E_a}\right) - \frac{E_a}{RT_{max}} \tag{7.27}$$

The activation energy (E_a) is obtained by plotting the left-hand side of Equation 7.27 versus $1/T_{max}$ for a series of runs at different heating rates. Equation above has been generalized to any reaction model $f(\alpha)$ [55].

As the Kissinger method is a model-free method it does not require any modelistic assumptions to calculate E_a. However, it is not an isoconversional method because it does not calculate E_a values at progressive values of α but rather assumes a constant E_a [38].

Model-Free/Isoconversional Methods

Isoconversional methods do not rely on mathematical models such as those in Table 7.6, instead they evaluate kinetic parameters at progressive conversion values of α [56]. These methods require several kinetic curves to perform the analysis and have therefore been called, "multi-curve" methods [57, 58]. The term isoconversional derives from the analysis of several curves at different heating rates at the same degree of conversion, α. They determine the activation energy for each conversion point (E_a, α), drawing an isoconversional plot (E_a vs. α). The terms, "isoconversional" and "model-free" are sometimes used interchangeably, but not all model-free methods are isoconversional.

Model-free methods usually only calculate activation energies (E_a) from the slope of a linear equation while terms such as the frequency factor (A) and model are grouped into the intercept, and cannot be determined without assuming a particular model. Isoconversional methodologies can be used to analyse both isothermal and non-isothermal data, as described below.

Standard Isoconversional Method

This method [59, 60] can be derived by taking the logarithm of the isothermal rate law

$$g(\alpha) = Ae^{-\frac{E_a}{RT}}t \tag{7.28}$$

to give:

$$\ln g(\alpha) = \ln A - \frac{E_a}{RT} + \ln t \tag{7.29}$$

This can be rearranged to give:

$$-\ln t = \ln\left(\frac{A}{g(\alpha)}\right) - \frac{E_a}{RT} \tag{7.30}$$

A plot of –ln t versus $1/T$ for each degree of conversion, α, gives E_a from the slope for that α regardless of the model.

Ozawa, Flynn and Wall (OFW) Method

Ozawa [61], and Flynn and Wall [62] independently developed an isoconversional calculation method for nonisothermal data which is commonly referred to as the OFW method. Taking the natural logarithm of the nonisothermal rate law (Equation 7.24) and using Doyle's approximation [63] for the temperature integral gives the following,

$$\ln\beta = \ln\frac{AE_a}{Rg(\alpha)} - 5.331 - 1.052\frac{E_a}{RT} \tag{7.31}$$

For a fixed degree of conversion, α, the plot of ln β vs. $1/T$, obtained from thermograms recorded at several heating rates, should be a straight line whose slope can be used to evaluate the activation energy.

Vyazovkin's Methods

The non-isothermal rate law (Equation 7.24) can be transformed by substituting $x = E_a/RT$ to give

$$g(\alpha) = \frac{AE_a}{\beta R}\int_x^\infty \frac{e^{-x}}{x^2}dx \tag{7.32}$$

or more simply $g(\alpha) = \frac{AE_a}{\beta R}p(x)$ where $p(x) = \int_x^\infty \frac{e^{-x}}{x^2}dx$. The temperature integral $p(x)$ is a function of E_a and temperature, so can also be represented as $p(x) = I(E_a, T)$.

The first Vyazovkin method [64] is based on the assumption that the reaction model is independent of heating rate. Therefore

$$g(\alpha) = \frac{AE_a}{\beta_1 R} I(E_a, T_1) = \frac{AE_a}{\beta_2 R} I(E_a, T_2) = \cdots = \frac{AE_a}{\beta_n R} I(E_a, T_n) \tag{7.33}$$

where β_1, β_2,..., β_n, T_1, T_2, ..., T_n are different heating rates and temperatures respectively, and together with E_a and A they correspond to the same degree of conversion α.

Equation 7.33 can be reduced to:

$$\frac{I(E_a, T_1)}{\beta_1} = \frac{I(E_a, T_2)}{\beta_2} = \cdots = \frac{I(E_a, T_n)}{\beta_n} = \sigma \tag{7.34}$$

where, is a constant.

Therefore:

$$\frac{\beta_1 I(E_a, T_2)}{\beta_2 I(E_a, T_1)} = \frac{\sigma}{\sigma} = 1 \tag{7.35}$$

For n heating rates, the summation of pairs of such inverse ratios can be generalised to:

$$\sum_{i=1}^{n} \sum_{j \neq i}^{n} \frac{\beta_i I(E_a, T_j)}{\beta_j I(E_a, T_i)} = n(n-1) \tag{7.36}$$

or

$$\left(\sum_{i=1}^{n} \sum_{j \neq i}^{n} \frac{\beta_i I(E_a, T_j)}{\beta_j I(E_a, T_i)} \right) - n(n-1) = 0 \tag{7.37}$$

However for experimental data such a difference might not converge to zero, so separate values of E_a could be found for each degree of conversion, α, to find the minimum value of the following equation:

$$\left| \sum_{i=1}^{n} \sum_{j \neq i}^{n} \frac{\beta_i I(E_a, T_j)}{\beta_j I(E_a, T_i)} \right| = \Omega \tag{7.38}$$

where Ω is non-zero constant.

It is known that exponential temperature integral of the non-isothermal rate law, Equation 7.24 has no analytical solution [65, 66] but its approximation can be found in mathematical tables [67].

Later, Vyazovkin [68] modified his isoconversional method to analyse kinetics from isothermal and nonlinear heating rate experiments. In this version, the heating rate β in the nonisothermal rate law (Equation 7.24) represents the heating function with respect to time. Therefore, the temperature integral in Equation 7.24 becomes a time integral, as shown below:

$$g(\alpha) = A \int_0^t exp\left(-\frac{E_a}{RT(t)} \right) dt \tag{7.39}$$

where $T(t)$ is the heating program.

This method allows for use of linear and nonlinear heating rates and also is suitable for isothermal analysis.

Before analogical procedures should be employed as used to get to Equation 7.38 the temperature integral $I(E_a, T)$ needs to be replaced by time integral $J(E_a, T(t))$.

Vyazovkin [69] presented further modification as the advanced isoconversional method (AIC). The principle enhancement in the AIC is the integration over smaller time intervals, to better account for variations in E_a.

Therefore, Equation 7.39 was modified to give:

$$g(\alpha) = A \int_{t-\Delta\alpha}^{t} exp\left(-\frac{E_a}{RT(t)} \right) dt \tag{7.40}$$

where $\Delta\alpha = 1/m$ and m is the number of segments into which the integration is divided, typically m = 10–50.

As in the previous Vyazovkin methods, the activation energy E_a at each α is the value that minimises Ω, as shown in Equation 7.38.

Some other analytical methods for obtaining the kinetic parameters are listed in Table 7.7. These methods are fast and easy to use and they provide relatively unique and efficient solutions for most engineering applications. The direct method (DM) and generalized direct method (GDM) proposed by Matala et al. [70] consider a multiple step of n^{th} order reaction. They both describe reactions being well separated, where the DM, generally, is based on the same approach as Friedman's [26] single-step reaction model

Table 7.7 Analytical methods for obtaining kinetic parameters

Method	Kinetic parameters	
Direct method	E_a	$E_k = N_k R \frac{r_{pk}}{\alpha_k - \alpha_{pk}} T_{pk}^2$
	A	$A_k = r_{pk} \beta \frac{(\alpha_k - \alpha_{k-1})^{N_{k-1}}}{(\alpha_k - \alpha_{pk})^{N_k}} \exp\left(\frac{E_k}{RT_{pk}}\right)$
Generalized direct method	E_a	$E = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$
		Where
		$a = \frac{(\alpha_k - \alpha_{pp})^2}{R^2 T_{pp}^4}$
		$b = -\frac{2 r_{pp} N_k (\alpha_k - \alpha_{pp})}{R T_{pp}^2} - \frac{2(\alpha_k - \alpha_{pp})^2}{R T_{pp}^3}$
		$c = r_{pp}^2 (N_k - 1) N_k - r_{T_{pp}} N_k (\alpha_k - \alpha_{pp})$
	A	$A_k = r_{p\,pk} \beta \frac{(\alpha_k - \alpha_{k-1})^{N_{k-1}}}{(\alpha_k - \alpha_{p\,pk})^{N_k}} \exp\left(\frac{E_k}{RT_{pp}}\right)$
Friedman	E_a	$E_k = -R \frac{\ln\left(\frac{r_{2k}}{r_{1k}}\right) + N_k \ln\left(\frac{\alpha_k - \alpha_{1k}}{\alpha_k - \alpha_{2k}}\right)}{\frac{1}{T_{2k}} - \frac{1}{T_{1k}}}$
	A	$A_k = \beta \frac{r_{1k} (\alpha_k - \alpha_{k-1})^{N_{k-1}}}{\exp\left(-\frac{E}{RT_{1k}}\right) (\alpha_k - \alpha_{k-1})^{N_k}}$
McGrattan et al. and Lyon et al.	E_a	$E_k = \frac{e R T_{pk}^2 r_{pk}}{\alpha_k - \alpha_{k-1}}$
	A	$A_k = \frac{e \beta r_{pk}}{\alpha_k - \alpha_{k-1}} \exp\left(\frac{E_k}{RT_{pk}}\right)$

Adapted from Ref. [70]
Note:
Reference points from first derivative of mass data (MLR curve) are: $r_p, r_{1T}, r_{2T}, T_p, T_{pk}, T_{1k}, T_{2k}, \alpha_p, \alpha_k, \alpha_{k-1}, \alpha_{1k}, \alpha_{2k}$
Values to specify from second derivative of mass data are: $r_{pp}, r_{p\,pk}, r_{T_{pp}}, T_{pp}, \alpha_{pp}, \alpha_{p\,pk}$

and the GDM relies on a higher-order derivative of the mass data. McGrattan et al. [24] and Lyon et al. [25] presented equations with slightly different derivations but essentially based on the same idea. They both analysed first-order reaction kinetics. Lyon et al. worked on a single-step reaction path but additionally offered an alternative method for extracting the reaction parameters using the heat release rate from micro-scale combustion calorimeter (MCC) data [71].

Computational Models of Polymer Decomposition

Computer simulation has become an integral part of fire safety engineering and this tendency is expected to increase with the evolution of performance based design. A broad spectrum of options for simulation is currently available, from simple programmes to various high-level packages implementing advanced methods. Despite the continuous development of tools for fire modelling, most of the development has focused on gas phase processes, particularly zone and CFD models. The current state of the art is still not capable of reliable prediction of the time to ignition of a solid polymer exposed to a constant applied heat flux. This leaves predictions of flammability, flame spread, fire growth rate, and fire suppression even further behind. Condensed phase fuel production, which plays a pivotal role in fire growth, has become an increasingly large research area in the last decade, resulting in the development of numerical models of pyrolysis incorporating

complex arrays of physical and chemical processes.

Generally, one of the first modelling tasks is to select the appropriate mechanism to represent the physical phenomena. A computer simulation environment attempts to translate real-world physical laws into their virtual form. How much simplification takes place in the translation process will determine the accuracy of the resulting model. However, this process is often subjective, and detailed justifications of the inclusion or exclusion of the different mechanisms are often lacking.

First, a new multistep decomposition method was proposed by Ohlemiller [72] where the kinetic parameters are calculated by numerical iteration from TGA mass loss (ML) and mass loss rate (MLR) measurements. This method was used by Rein et al. [28] to simulate the decomposition of polyurethane foam and by Matala [73], Lautenberger [74], Lyon and Stoliarov [75, 76] to simulate numerically the decomposition of various materials. A substantial number of studies [29, 32, 77–80] have demonstrated that numerical pyrolysis modelling (using e.g. GPyro [30, 81–83], the general pyrolysis model of FDS [84], pyrolysis submodel of FireFOAM CFD code [85] or ThermaKin [86, 87]) can describe degradation of solid materials exposed to external heat flux, and determine the relationships between the fundamental physical and chemical properties of polymeric materials and their gasification behaviour. Most of the models calculate the ML and MLR of a sample exposed to a heat source in one-dimension. Models with a controlled volume approach combine the transfer of thermal energy with Arrhenius kinetics for the decomposition of the polymer. They can predict the overall behaviour of a pyrolysing polymer by solving a set of mass and energy conservation equations using a fully implicit scheme. In many cases only three species are considered, virgin solid, char (where applicable), and pyrolysis products, and it is assumed that the virgin solid decomposes to char and/or gas phase products through a single heterogeneous *n*th order Arrhenius-type reaction. Material properties for the condensed phase species (i.e. char and/or virgin solid) may also be temperature dependent. Pyrolysis gases are assumed to be in thermal equilibrium with the solid.

Very often it is difficult to establish and quantify the kinetic mechanism of solid phase decomposition with certainty, especially for materials with complex kinetics (multistep decomposition, sequential and parallel reactions etc.) such as most polymers. Usually, condensed and gas phase species in the reactions are not characterised experimentally. However, Bustamante [88] showed that numerical approaches can be used to derive a multiple hypothetical decomposition mechanism for polyurethane foam. Additional parameters, such as chemical analysis of gas and condensed phases support the assignment of the actual decomposition mechanisms better than merely obtaining agreement with the MLR curves. The kinetic parameters in multiple reaction mechanisms, due to their complexity, must be often determined by several curve-fitting algorithms. Evolutionary algorithms are most commonly used, including genetic algorithms (GA) [27–31, 89] or shuffled complex evolution (SCE) [90, 91] algorithms. They operate on a "survival of the fittest" principle. The algorithm uses a mathematical formulation of the experimental pyrolysis data, and the optimisation process starts from a random set of automated trial solutions and tests their fitness against the experimental (TGA) curve. The suitability of the stochastic processes is assessed by its fitness value; the better the fitness value, the greater the probability of the trial solution surviving to the next iteration round. The method has a stochastic component in the mutation (one or more parameters are replaced by a random number), crossover (creating new trial solution by uniting two older solutions) and selection operations to ensure wide exploration and to avoid becoming trapped in local minima or maxima. These algorithms are very efficient for high-dimensional problems with many parameters, resistant to becoming trapped in local optima caused by overlapping reactions or even noisy data. However, they are a bit more complicated to use than the analytical methods; they are heuristic in nature; inefficient for small problems, and they require significant amount of computer resources.

Recently, modelling tools have created a more flexible simulation environment with the possibility of adding any physical effect to the model. All the relevant physical aspects of particular design may be included. Adaptability of modelling platform allows customised solutions to be developed, applicable to unique circumstances. This is very often required for the complicated process of polymer decomposition. Using tools like parameterized geometry, interactive meshing, and custom solver sequences, they can quickly adapt to different, complex requirements. With this kind of all-inclusive modelling environment, increasing the prospect of building models with real-world precision. The growth of complexity in the models has been justified by the implicit assumption that models with a higher number of mechanisms should be more accurate. However, as direct consequence, the number of parameters required to perform a simulation has also increased significantly. It is important to control the accumulation of uncertainty in the input parameters in order to prevent the model's output to extend beyond the limits of reliable prediction [92]. The global error induced by the uncertainty of a large number of parameters may exceed the improvements obtained with the incorporation of complex mechanisms; thus there remains an optimum level of model complexity.

Computational Modelling of Polymer Combustion

The same pyrolysis models may also be used to calculate the mass loss rate of a one-dimensional sample of solid fuel exposed to a uniform heat flux. ThermaKin is an example of such a model, which has been effectively utilised as a practical tool for the prediction and/or extrapolation of the results of fire calorimetry experiments [3, 93–96]. The model, which combines the absorption and transfer of thermal energy with Arrhenius kinetics for the decomposition of the polymer, predicts the overall behaviour of a pyrolysing object through mass and energy conservation equations. These equations are formulated in terms of rectangular finite elements, each element being characterised by component mass and temperature. Additionally, the model describes the transport of gaseous products through the condensed phase and follows changes in the volume of the bulk material.

For thermally thick solids (typically, thicknesses above 15 mm [97]) the thermal inertia, $k\rho c$, the product of thermal conductivity (k), density (ρ), and specific heat (c), of a material governs its ignition and flame spread properties. This determines the rate of rise in surface temperature and consequently, the time to ignition [98]. The time to ignition (t_{ig}) of a thermally thick solid exposed to a constant net heat flux $Q_{\mathrm{R}} = Q_{\mathrm{ext}} - \mathrm{CHF}$, where Q_{ext} is the external heat flux from fire or radiant heater and CHF is the critical heat flux for ignition, has been expressed in Equation 7.41.

$$t_{ig} = \frac{\pi}{4} k\rho c \frac{\left(T_{ig} - T_0\right)^2}{\dot{Q}\dot{R}^2} \tag{7.41}$$

where T_{ig} and T_0 are the ignition and ambient temperatures, respectively. The time to ignition of a thermally thin solid exposed to a constant net heat flux has also been expressed in Equation 7.42.

$$t_{ig} = \rho c \tau \frac{\left(T_{ig} - T_0\right)}{\dot{Q}_{\dot{R}}} \tag{7.42}$$

Where τ refers to material thickness. Equations 7.41 and 7.42 follow from the concept of a constant ignition temperature T_{ign} and temperature-independent thermal inertia. Once ignition has occurred and a flame is established on the surface, the net heat flux becomes $Q_{\mathrm{R}} = Q_{\mathrm{ext}} + Q_{\mathrm{flame}} - \mathrm{CHF_b}$, where Q_{flame} is the additional heat flux supplied by the flame and $\mathrm{CHF_b} \approx \sigma T_b^4$ is the critical heat flux for burning in terms of the surface burning temperature T_{b} and the Boltzmann radiation consant σ. It has been shown that $T_{\mathrm{b}} \approx T_{\mathrm{p}}$ where T_{p} is the pyrolysis temperature measured in laboratory thermal analysis experiments using small samples and constant heating rates [22]. Thus, polymers with high pyrolysis temperatures reradiate more of the incident heat flux from the heater and flame back to the surroundings, and the net heat flux that drives the burning process is reduced accordingly.

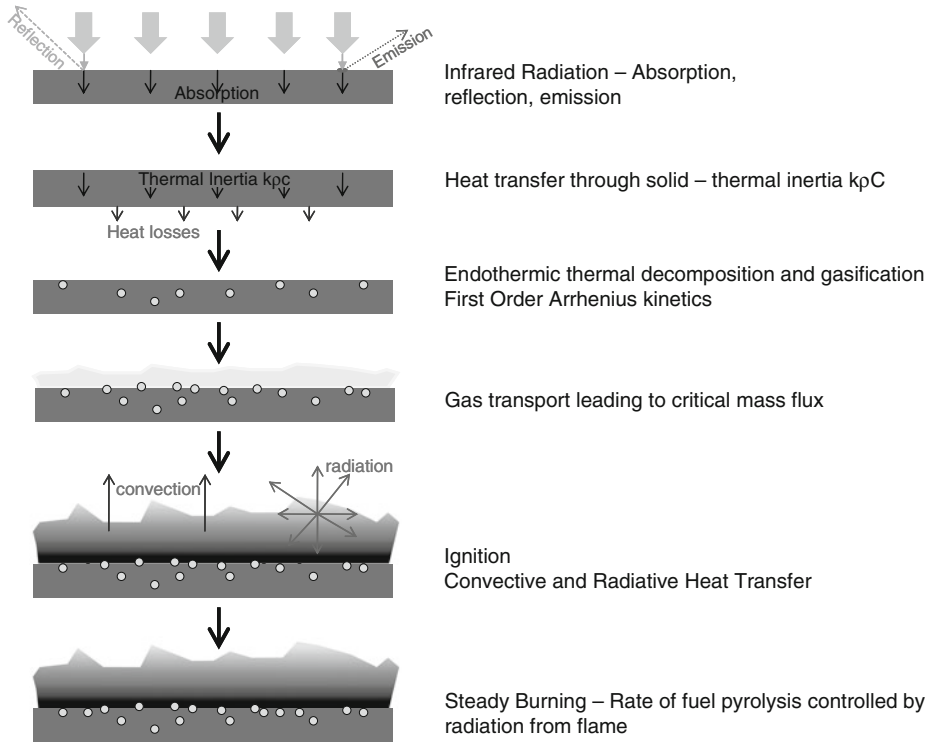

Fig. 7.22 Schematic of processes occurring in the cone calorimeter, as modelled by ThermaKin

The processes modelled by ThermaKin have been summarised in Fig. 7.22. For this study, radiant heat from above the sample is absorbed, emitted or reflected, and the condensed phase heat transfer process is modelled through the solid. The resulting temperature increases drives endothermic decomposition processes, leading to the gasification of volatile fuel components. When a critical mass flux for ignition is reached, ignition will occur, and the incident radiant flux is augmented by radiation from the flame. Thereafter, quasi-steady state conditions pertain, until the sample is so thin that it has no more capacity to absorb heat, and the rate of pyrolysis increases.

Behaviour of Individual Polymers

In general, each polymer decomposes in an individual way, and most generalisations are of limited value. A brief description of the distinctive features of selected individual polymers, their applications and thermal decomposition is provided below.

Thermoplastics

Polyethylene

Three types of polyethylene are generally available, high density polyethylene (HDPE), linear low density polyethylene (LLDPE), and low density polyethylene (LDPE). HDPE is composed of structurally regular chains with very few branch points (less than 1 % of carbon atoms) which pack efficiently, resulting in a highly crystalline material with a correspondingly higher density. The polymer is used to manufacture bottles, crates and pipes. LDPE is approximately 6 % branched with a much lower crystallinity and lower density, with good film forming properties, so that its largest application is as film for packaging, and cable coverings. LLDPE fills the gap between the two materials and is generally prepared as a

copolymer of ethylene with 8–10 % of an α-olefin such as but-1-ene, or oct-1-ene. This produces a chain with a controlled number of similar short chain branches, with densities intermediate between HDPE and LDPE. Initiation of decomposition of each of the different types of polyethylene occurs at the branching points, as observed by Madorsky (section "Chain Branching"). Thus LDPE, having a greater number of branching points and other abnormalities in its structure, decomposes at a slightly lower temperature than HDPE, although the general mechanism is the same for each type of PE. The mechanism of thermal decomposition of polyethylene follows random chain scission, resulting in a mixture of alkanes, alkenes, and dienes. The elimination of ethylene (the monomer) is not favoured energetically and pyrolysis of polyethylene does not occur by end chain scission.

The kinetics of polyethylene pyrolysis has been studied frequently [99]. It has been shown that random chain scission decomposition of polyethylene does not rigorously follow first order kinetics. The reaction order, in both dynamic and isothermal decomposition of a high density polyethylene, was determined [100] to be 0.55. The thermal decomposition of polyethylene with different characteristics, such as density or melt flow index, showed no significant differences, except in the presence of an added catalyst [101].

The thermal decomposition of polyethylene comprises several steps, presented schematically in Fig. 7.23. The temperature increase causes random scission of the polymer backbone resulting in the formation and release of a large amount of small molecules and radicals. Formation of cyclic hydrocarbons and aromatic

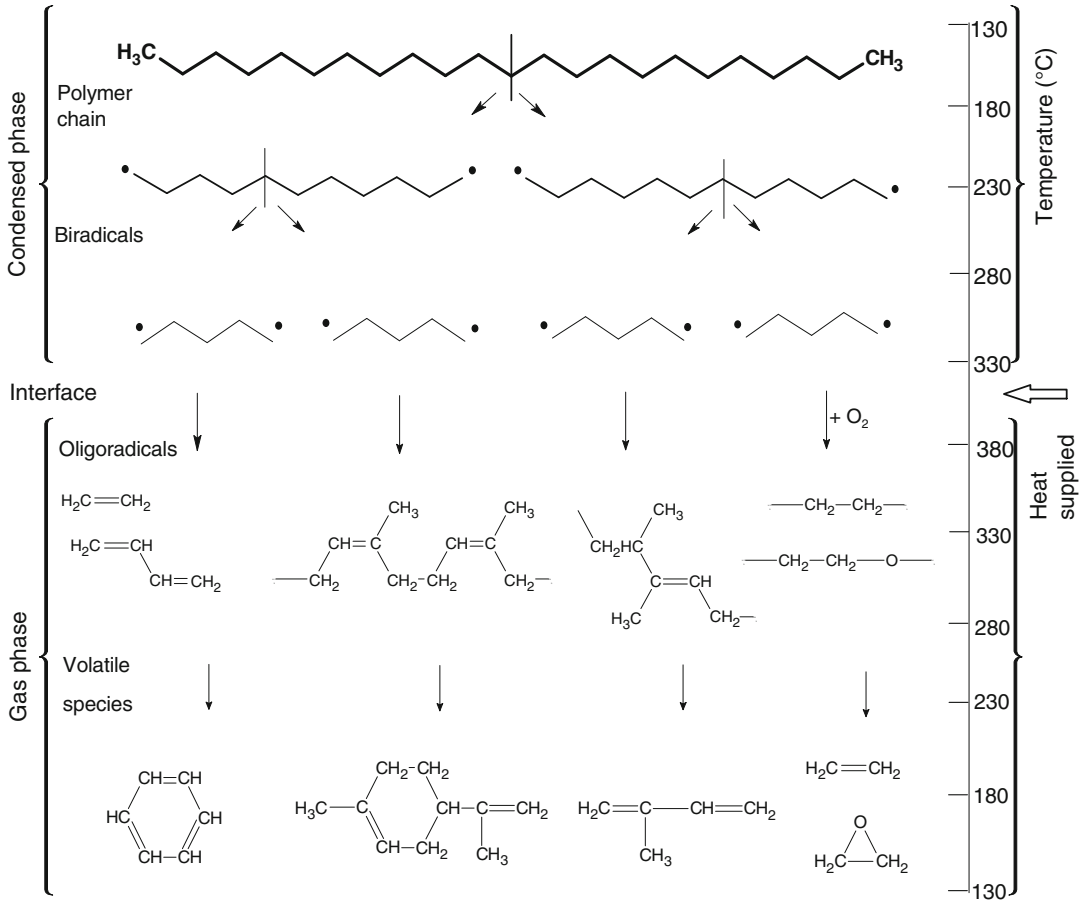

Fig. 7.23 LDPE decomposition processes [103]

rings occurs at higher temperature by Diels-Alder cyclisation reactions of alkenes. The aromatic content of the pyrolysate increases with temperature. The thermal decomposition in air (shown on the right hand side of Fig. 7.23) also produces partially oxygenated products such as aldehydes, ketones and major combustion products such as carbon monoxide, carbon dioxide, water etc.) [102].

Polypropylene

Three types of polypropylene (PP) can be synthesised; isotactic, syndiotactic and atactic, although only the isotactic form is used commercially (the difference lies in the stereochemical positioning of the methyl group relative to the main chain). Isotactic PP is highly crystalline, with a sharp melting point at 443 K. The thermal decomposition of polypropylene in an inert atmosphere also proceeds via random chain scission, to generate between 10 % and 25 % propene, in addition to other fragments, typically containing multiples of three carbon atoms (e.g. 6, 9, 12 up to 18 carbon atoms). The thermal decomposition of PP is particularly sensitive to the presence of even small (<1 %) quantities of oxygen, causing earlier fuel release, and this aspect has been studied extensively. In a detailed study [104] using a set of three isotactic polypropylene samples that had been individually labelled with carbon-13 at each of the three positions in the monomer unit (Fig. 7.24), experiments were conducted to determine the original position of the carbon forming carbon monoxide and carbon dioxide during thermal decomposition. By GC-MS analysis, it was found that 2/3 of the CO_2 was derived from the C(1) [methylene] carbon, while the remaining 1/3 comes from the C(2) [tertiary] carbon, with none coming from the C(3) [methyl group] carbon. The CO also comes mainly from the C (1) [methylene] carbon (~80 %). This is in contrast to the solid-phase oxidation products, which have been found (by C-13 NMR on these same labelled PP materials) to originate predominantly (80–85 %) from oxidation at the C(2) [tertiary] carbon. Thus oxygen preferentially attacks the main carbon backbone, resulting in release of volatile fuel at lower temperatures than from anaerobic decomposition.

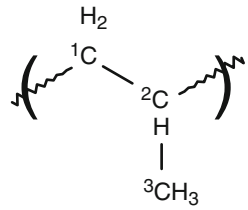

Fig. 7.24 Polypropylene repeat unit showing C (1) methylene, C(2) tertiary and C(3) methyl group carbon positions

A further investigation [105] of the volatile products provided a detailed description of the organic carbon compounds found in the vapour phase above the decomposing polypropylene. Approximately half of the volatile products identified have a methyl ketone at one end of the molecule. In all of the methyl ketones, the carbonyl carbon originates from the C(2) [tertiary] position within the PP molecule, and the terminal methyl group originates from the C (3) [methyl] position. This demonstrates the susceptibility to thermal decomposition of the C (2) branching point (c.f. LDPE and HDPE).

Polystyrene PS

Polystyrene and has good physical properties allowing for easy processing by injection moulding, transparency, good electrical insulating characteristics etc. It is typically found in atactic and amorphous forms, for example in a CD or DVD "jewel case", as well as in expanded form as EPS packaging, or EPS and extruded PS (XPS), for thermal insulation. It is entirely amorphous, with no defined melting point, above T_g it shows the classic five regions of viscoelastic behaviour. The rate of decomposition is influenced by the method of synthesis of polystyrene—anionically initiated polystyrene is more thermally stable than that produced by thermal initiation or with free radical initiators [106], presumably because it has less structural irregularities in its backbone.

Thermal analysis shows that polystyrene degrades thermally in a single step, and that monomeric styrene (~40 %) is the principal volatile, together with a much smaller amount of benzene and toluene. However there is also a significant amount of dimer, trimer, tetramer and

pentamer. These oligomers are formed in intramolecular transfer reactions, in direct competition with the monomer-producing depolymerisation process. A significant feature of the thermal degradation of polystyrene is the rapid initial decrease in molecular weight, which is followed by a more gradual fall as volatilisation exceeds 10 % [107].

Oxygen plays a very important role in the degradation of PS. The degradation mechanism involves depropagation, thermo-oxidative products include benzaldehyde, benzoic acid, phenol, and benzyl alcohol.

Polymethylmethacrylate (PMMA)

PMMA is probably the polymer with most widely studied the thermal decomposition, and the clear favourite amongst fire scientists as a model fuel. Like polystyrene, PMMA is an amorphous polymer with no defined crystalline melting point. Low molecular mass "extrudable" PMMA softens on heating to form a viscous liquid, while higher molecular mass "cast" PMMA decomposes prior to softening. Almost uniquely amongst the common polymers, lower molecular weight PMMA decomposes by end chain scission (Fig. 7.25), while higher molecular weight PMMA decomposes by a combination of end and random chain scission (Fig. 7.26) [108].

In both cases, the decomposition follows a free radical mechanism, stabilised by the four substituents on the α-carbon atom. This allows the unpaired electron to reside on the α-carbon atom long enough for the double bond to reform, releasing methyl methacrylate monomer. The monomer the yield has been quantified as 59–95 % depending on the decomposition conditions [4]. During the decomposition of high molecular weight PMMA, the monomer is evolved from the decomposing solid, avoiding the complexity of sample dripping. The combination of a single gas phase fuel molecule, and avoiding dripping, are possible reasons for this polymer's popularity in fire science. Its atypical decomposition may be one of the reasons fire scientists have not made the necessary progress on condensed phase decomposition and pyrolysis of polymers.

Polycarbonates

Polycarbonates are a class of polymers with good mechanical properties, containing the repeat group $(-O-C(O)-O-)_n$ in their backbone. They are crystal clear, highly impact resistant, amorphous engineering plastics. In addition to CD and DVD discs, they are used in the construction industry and car headlights for tough plastic

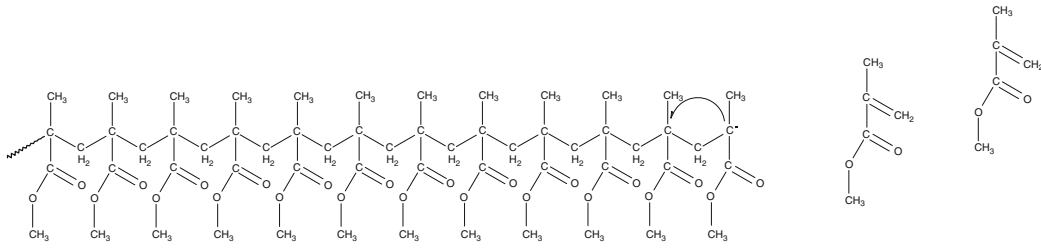

Fig. 7.25 End chain scission of PMMA

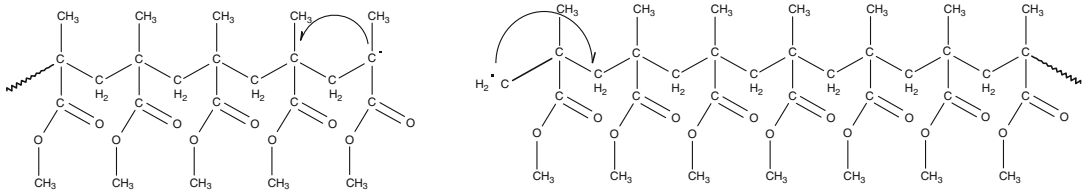

Fig. 7.26 Random chain scission of PMMA

glazing. Polycarbonates are relatively resistant to thermal decomposition, which may take place either by an anionic ester interchange route, or by free radical chain scission [109]. In either case, carbon dioxide is the main decomposition product (~35 %) and the resultant organic material forms a char. Below 675 K the decomposition products also include cyclic dimers and cross-linked species. The decomposition mechanism depends on the temperature and heating rate. Above 775 K most functionality of the original polymer is lost with the formation of aromatic compounds, leading to extensive char formation above 800 K. The maximum rate of decomposition of polycarbonate in nitrogen is around 745 K. The formation of carbon dioxide in the thermal decomposition of polycarbonate [110] can be explained by reactions of the type shown in Fig. 7.27.

The ether typically continues the decomposition process and for this reason there are similarities between the pyrolysis products of aromatic ethers and aromatic carbonates (see section "Polyetheretherketone (PEEK)")

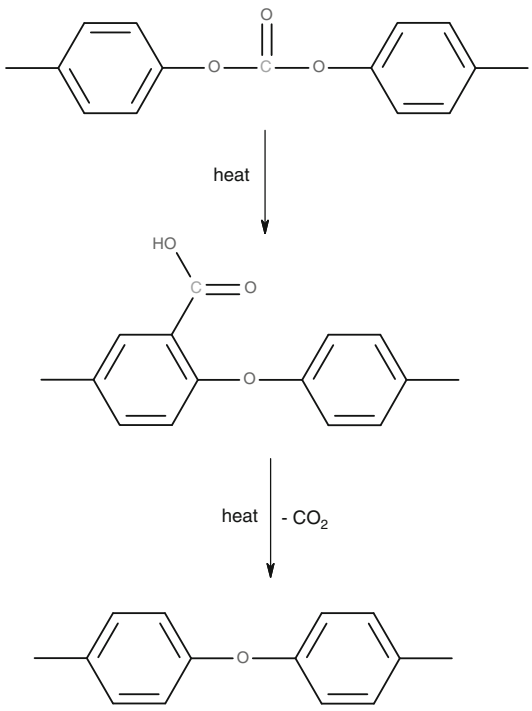

Fig. 7.27 Loss of CO_2 and ether formation in polycarbonate decomposition

Aliphatic Polyamides

Polyamides are the most widely used engineering plastics. In addition to fabrics and fibres, polyamides are widely used in motor vehicles. They are semicrystalline polymers with reasonable thermal stability but high water absorption, frequently used with glass fibre reinforcement for increased stiffness at elevated temperatures. The C—N bonds are the weakest in any polyamide, and these tend to break first, followed by the C(O)—CH_2 bonds. In an inert atmosphere, the decomposition products of polyamide 6 (−NH$(CH_2)_5$CO−)$_n$ at 875 K is predominantly the cyclic monomer (caprolactam) 73 %, with small amounts of CO_2, water and other minor decomposition products. The decomposition products from polyamides made from a diamine and a dicarboxylic acid, such as polyamide 6.6, the most widely used polyamide, include a mixture of hydrocarbons, nitriles, amides and acids [111]. Decomposition at 875 K in an inert atmosphere produced cyclopentane, 39 %, carbon dioxide, 26 %, water, 6 %, and surprisingly caprolactam, 6 % (believed to be formed by the radical bite-back mechanism [112]) and hexane dinitrile 2 %.

Polyesters, Polyethylene Terephthalate and Polybutylene Terephthalate

Polyesters are commonly used both as thermoplastics in various high volume automotive, electrical, and other engineering applications and as textile fibres. They are widely used as structural composites in glass reinforced polyesters (GRP) or "fibreglass". Commercially the most important are polyethylene terephthalate (PET) and polybutylene terephthalate (PBT), although recent demands for sustainability have favoured the development of polylactic acid (PLA), derived from biologically sourced lactic acid.

Thermal decomposition of polyesters usually starts with the scission of the polymer chain through a six-membered ring transition stage [113] (Fig. 7.28). It is believed that this scission is mostly heterolytic and not a free-radical process, although this is still under discussion in the literature. Secondary reactions mostly involve

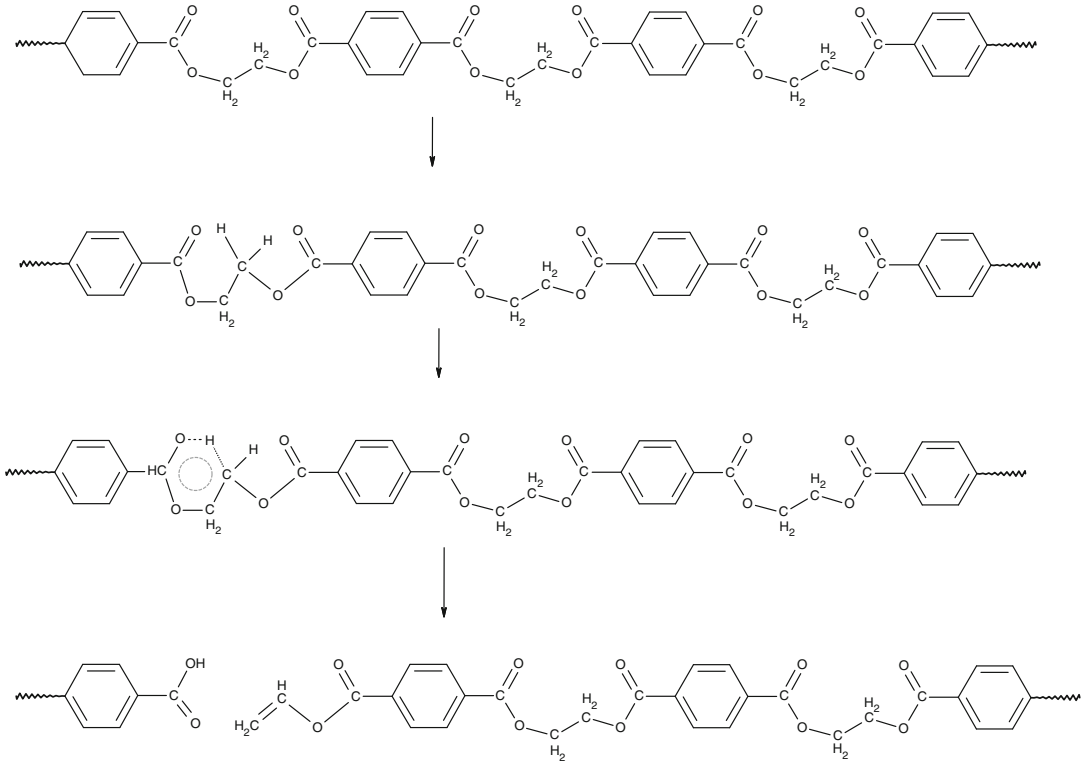

Fig. 7.28 Ring formation in the decomposition of PET

the formation of vinyl ester chain ends (CH_2 = CH-O-C(O)-Ar-) which lead to polyene structures, and crosslinking, but also evolution of light volatile products. In air, polyesters undergo crosslinking, a relatively minor process in an inert atmosphere.

Pyrolysis of PET showed evolution of benzoic acid (43 %), acetaldehyde (16 %), CO_2 (10 %), and the vinyl and divinyl esters of benzoic acid (7 and 4 % respectively). Rapid volatilization of light fragments makes polyesters easily ignitable polymers. Despite the presence of benzene groups in the main polymer chain, thermoplastic polyesters show very limited tendency to char, but instead, aromatic-containing polymer fragments volatilize and feed the flame [114].

Polyacrylonitrile (PAN)

Polacrylonitrile (PAN) is a significant bulk polymer, extensively employed in the textile industry in fibre form, which is significantly more flammable than its natural counterparts, such as wool or cotton. It is also used extensively as a copolymer, for example in acrylonitrile-butadiene-styrene (ABS) formulations. Depending on conditions, polyacrylonitrile either decomposes by cyclisation, or chain scission resulting in volatile formation, or chain stripping with the release of hydrogen cyanide [115]. The resulting structure may either decompose further producing volatiles, such as ethyne by random chain scission, and rearrangements such as cyclisation, resulting in ethyne, ethane, benzene and higher aromatics, or, under different (usually slower) conditions undergo rearrangements such that the polyene may cross-link, ultimately resulting in the formation of a protective char. This may shield the remaining polymer from radiative heating, while acting as a barrier to fuel and oxygen. Indeed, under controlled conditions of slow heating this process is used to manufacture carbon fibre from polyacrylonitrile fibre, and has been studied extensively [116].

Horrocks [117] identified three pairs of competing volatilisation and cyclisation/carbonisation decomposition reactions in pure PAN which depended on atmosphere and heating rate. At the slowest heating rates in air, cyclisation (~625 K) was followed by the first carbonisation processes, around 725 K, followed by volatilisation at around 825 K. At higher heating rates, chain scission leading to volatilisation, at around 625 K competes with cyclisation or carbonisation processes. The residue then undergoes the first carbonisation stage, and the final volatilisation stage. It is this volatilisation stage which is responsible for the high flammability of acrylonitrile polymers in general.

In the production of carbon fibres from PAN, the initial stabilisation stage is conducted under carefully controlled conditions in the presence of oxygen, where a strongly exothermic process occurs around 473 K. In DSC studies, a sharp, narrow exothermic peak is observed under inert conditions in contrast to a broad exotherm, some 50 K higher, associated with oxidising atmospheres [118, 119]. The atmosphere is then changed for nitrogen in the subsequent thermal decomposition stages, in order not to oxidise the carbon fibres.

During the stabilisation stage, the following processes, shown in Fig. 7.29 are believed to occur [120]. Polyacrylonitrile (A), particularly as a result of nucleophilic attack (X), undergoes cyclisation of nitrile groups leading to the formation of hydronaphthiridine rings [121] (B). The hydronaphthiridine rings may undergo oxidative dehydrogenation leading to acridone and other structures [122] (C) increasing the aromaticity [123].

The result is a ladder polymer containing a mixture of acridone, pyridine, hydronaphiridine and other structures. In the early stages of decomposition this ladder polymer alternates with unchanged PAN [124]. Figure 7.30 shows typical ratios of these different components obtained under certain conditions, which started to form the ladder polymer at 180 °C, as shown by FTIR [121].

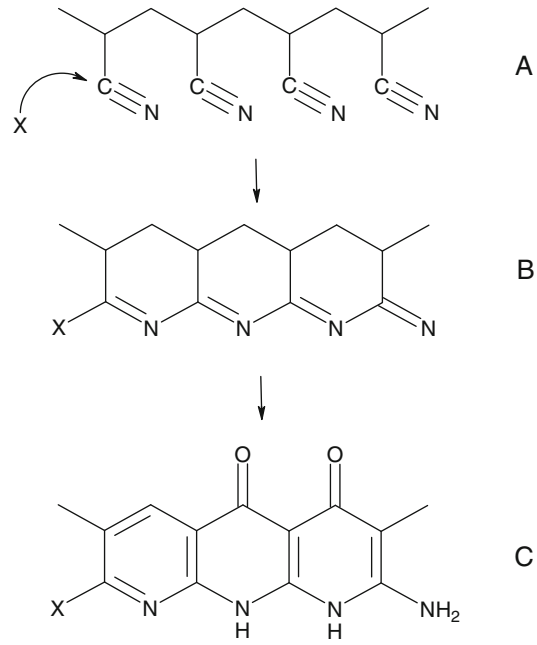

Fig. 7.29 Stages in the decomposition of PAN

Halogenated Polymers

Polyvinyl Chloride (PVC)

PVC is ranked third behind polyethylene and polypropylene in terms of worldwide polymer consumption because it has a good chemical resistance and can be used in many different applications, such as cables, pipes, furniture, etc. As the pure polymer is rather brittle it does not enjoy widespread use. The popularity of PVC lies in its unmatched ability to form a stable, dry, flexible and easily processed material when plasticized. However, this involves adding a significant amount, typically 30 %, of flammable organic liquid such as di-iso-octyl phthalate as a plasticiser, to an otherwise low flammability polymer.

At elevated temperatures PVC undergoes a dehydrochlorination reaction to release hydrogen chloride by β-elimination to form a conjugated polyene [125]. β-elimination is catalysed by acids, such as HCl, and hence the decomposition is auto catalytic and very rapid. As a consequence PVC materials usually contain stabilisers which absorb hydrogen chloride to allow the

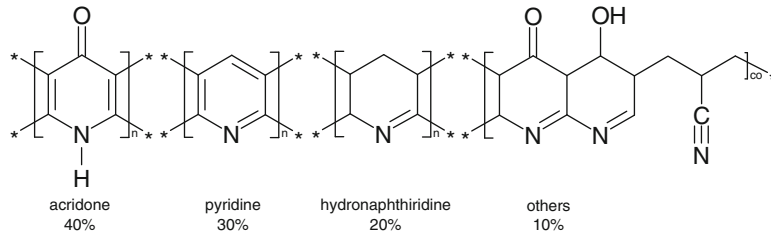

Fig. 7.30 Typical ladder polymer structure [116]

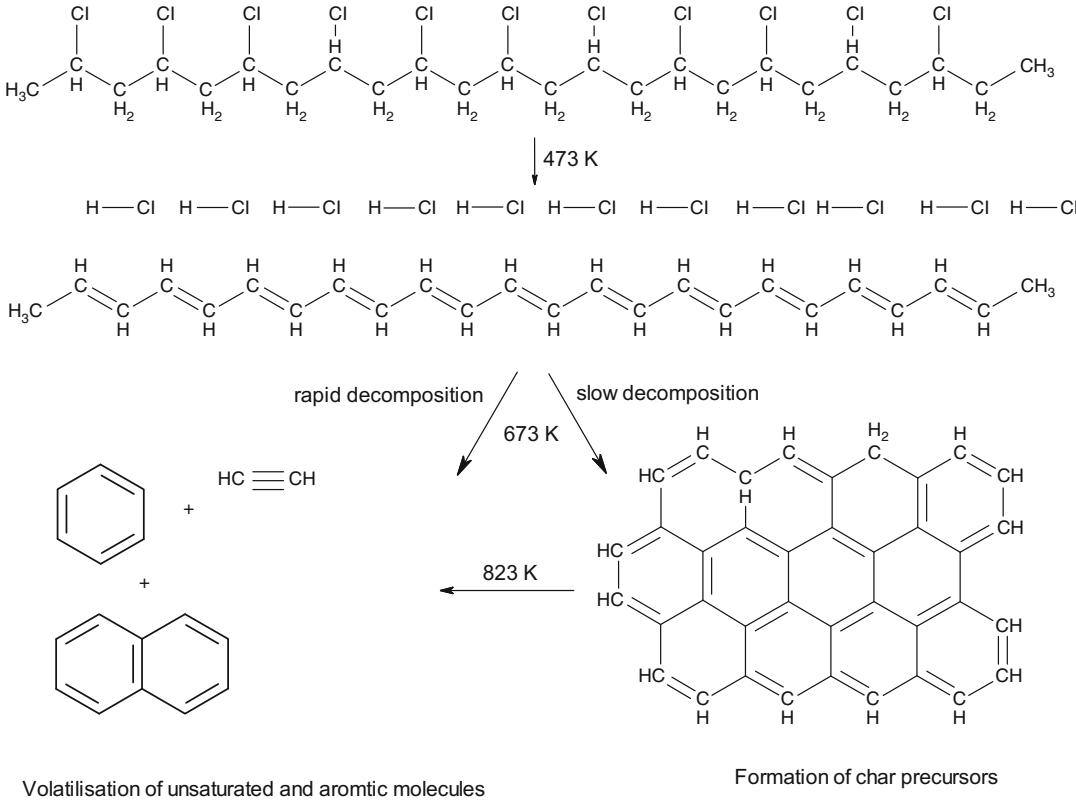

Fig. 7.31 PVC decomposition

extrusion and processing without decomposition. At higher temperatures the polyene undergoes further rearrangements and product elimination to produce a complex pattern of hydrocarbons with aromatic materials predominating (Fig. 7.31). At temperatures between 475 and 575 K, 80–95 % of the chlorine content of rigid PVC is released as HCl, 70 % within one minute at 575 K [126]. Under combustion conditions at 925 K, 75–90 % of chlorine has been recovered as HCl. As HCl is a reasonably efficient free radical trap, it removes high energy H·, ·O · and · OH radicals from the flame zone, which can quench gas phase flaming. In some formulations, some chlorine may remain in the residue. For example calcium carbonate, a common filler in PVC, will react with HCl to produce non-volatile calcium chloride, while releasing non-fuel CO_2

from the carbonate. The chorine content of the residue depends on the decomposition conditions. When a plasticised PVC containing calcium carbonate was decomposed under non-flaming conditions 58 % of chlorine was released as HCl. Under combustion conditions at 925 K, the recovery decreased to 34 %, but at 1275 K, calcium carbonate decomposes to calcium oxide and gas phase chloride recovery increased to 43 % [127].

A small proportion of the chlorine is released as other chorine containing gas or vapour species and a number of chlorine containing species have been identified from large-scale PVC fires, including mono- and dichlorobenzenes and other chloro-aromatic and chloro-aliphatic hydrocarbons [128]. Evidence exists to show that, depending on the fire situation, as much as 20 % of the chlorine may exist in an organic form [129].

PVC has a low heat of combustion, and burns with a low heat release rate, because the halogen atoms in the structure release HCl, almost 60 % of its mass, which then inhibits the conversion of CO to CO_2. This is the major heat release step in polymer combustion. When hydrogen chloride gas (HCl) comes off on heating, this causes a double bond to form between alternate carbons, strengthening the chain. As this residue gets hotter, the chain either cross-links, as double bonds open and attachments to neighbouring chains occur, eventually leading to char formation, or they break down and cyclise to form volatile aromatic hydrocarbons. If the aromatic hydrocarbons only contain a few rings, they may form into soot particles, if they are large or cross-linked the residue may form a stable protective char layer [130].

Polytetrafluoroethylene (PTFE)

PTFE has many applications due to its excellent resistant to thermal decomposition, electrical insulation and mechanical toughness. Despite being polymerised by a free radical process, the polymer has very little chain branching, and is highly crystalline. The thermal decomposition, by end chain scission, starts at 713 K, reaching a maximum at 813 K [131]. The predominant species in the vapour phase is the monomer ($CF_2 = CF_2$) at 800 K, although at 873–973 K larger fragments predominate (C_2F_4, 16 %; C_3F_6, 26 %; C_4H_8 58 %) [132]. In fires PTFE can evolve carbonyl fluoride (COF_2), which hydrolyses to produce toxic carbon monoxide and hydrogen fluoride. Under certain conditions, PTFE was found to produce supertoxic particulates on thermal decomposition [133].

Elastomers

Silicone Polymers

Silicone polymers are typically heat resistant elastomers, used as sealants, adhesives, lubricants, and for electrical insulation. Somewhat surprisingly, in North America and in aircraft, silicone foams have also been used, with some controversy, as firestops [134]. Polysiloxanes are inorganic–organic polymers that have a backbone formed from alternating oxygen and silicon atoms of the form $(-O-Si(R_2)-)_n$. Various substituents (as R) are added to the silicon atom. Polydimethyl siloxane, for example, has two methyl groups attached to the silicon atom. In addition to the linear backbone, polysiloxanes can undergo crosslinking of the macromolecular chains through oxygen bridges, giving them rubber-like properties. Low molecular weight polysiloxanes are sold as silicone fluids with many practical applications. Higher molecular weight siloxanes are cross-linked to make silicone rubbers.

The pyrolysate of polydimethyl siloxane consists of various cyclic siloxanes, such as hexamethylcyclotrisiloxane, octamethylcyclotrisiloxane, decamethylcyclotrisiloxane etc. The formation of these compounds is exemplified below in Fig. 7.32 for the formation of hexamethylcyclotrisiloxane [4].

Polyisoprenes and Other Rubbers

An elastomer is a polymer with elastic properties (section "Physical Properties") whereas a rubber generally refers to a cross-linked compound comprising elastomer and additives (Fig. 7.33).

Polyisoprene was the world's first commercially produced elastomer, originally derived from the latex of the rubber tree *Hevea*

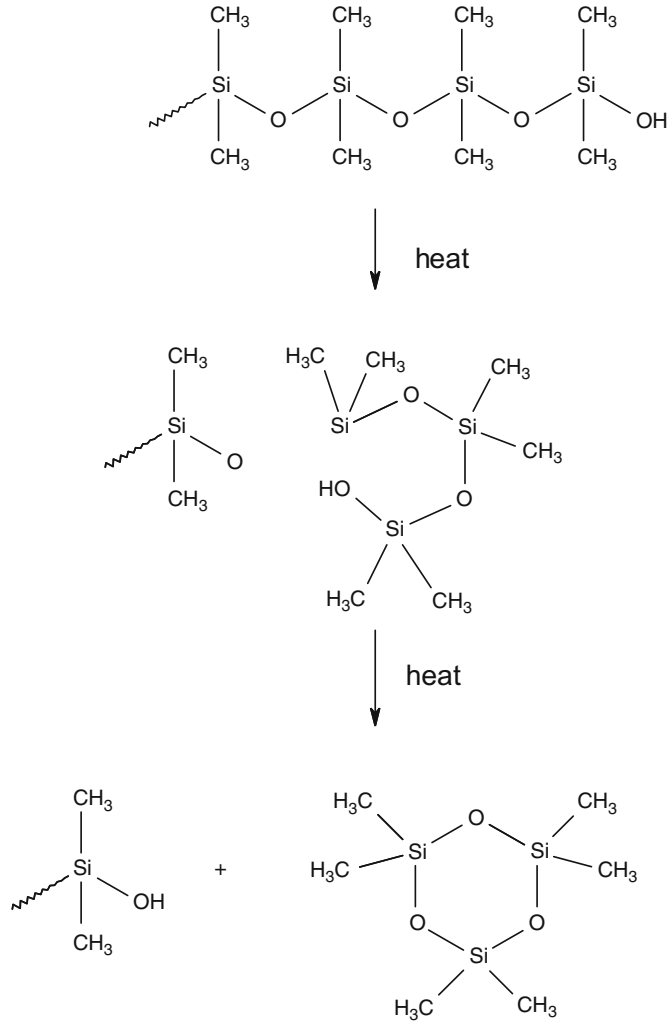

Fig. 7.32 Example decomposition of polydimethyl siloxane to hexamethylcyclotrisiloxane

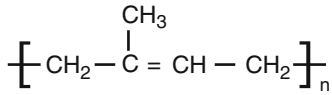

Fig. 7.33 Repeat unit polyisoprene

Brasilienis, although a synthetic equivalent was developed on an industrial scale during World War 2. The main disadvantages of natural (NR) and synthetic isoprene (IR) rubbers are their limited resistance to high temperatures and oils, which has led to the use of other elastomers such as chloroprene (CR), acrylonitrile butadiene rubber (NBR) and ethylene propylene diene modified rubber (EPDM). Nearly all of these alternative polymers have higher damping and dynamic stiffness [135], typically leading to higher noise and greater transmission of vibration.

The thermal decomposition of polyisoprenes has been reviewed elsewhere [136]. NR and IR raw polymer have identical TGA curves with a single large maximum mass loss peak [137] at 646 K in N_2 with less than 0.5 % residue at 773 K. When compounded with carbon black and sulphur into a typical commercial formulation a difference is noted; the NR mix retains a single peak temperature for mass loss, but the IR compound gains a second mass loss peak [138] at around 700 K. It is believed that IR polymer may undergo cyclisation, catalysed by small

quantities of residual titanium tetrachloride used in polymerisation.

Polyisoprene decomposes predominantly by random chain scission, initiated at a 'weak link' due to a chain defect. This defect may be due to residues from polymerisation such as initiator, or some head to head linkages. Common chemical species detected from decomposition include isoprene (2-methylbutadiene) and dipentene (1-methyl-4-(1-methylethenyl)cyclohexene), for which the yield quantities vary considerably, depending on the temperature and conditions of thermal decomposition. Typically, at temperatures below 573 K, the yields of isoprene and dipentene may be in the region of 5 and 15 % [139]. At higher temperatures, however, the isoprene yield may be significantly higher. A simplified process of depolymerisation at lower temperatures has been summarised by Cataldo [140], although at higher temperatures more species are generated, including 2,4-dimethyl-2-ethenylcyclohexene (Fig. 7.34).

Overall, polyisoprene decomposes dramatically to low molecular weight fragments which vaporise into fuel for combustion, with almost no char to slow down decomposition. This is consistent with the observation that polyisoprenes burn readily with high heat release and with high yields of small aromatic species that will create high levels of smoke.

Thermosetting Polymers

Epoxy Resins

Epoxy resins are tough, thermally stable and an important class of thermosetting polymeric material. They are widely used in electronic applications, binding carbon fibres together in metal replacement composites enjoying wide use in aerospace, automotive and even bicycle engineering applications, and find use as excellent adhesives. Typically synthesised from epichlorohydrin and *bis*-phenol A, the pre-polymer contains reactive epoxide groups as part of a polymeric diglycidylether (Fig. 7.35), terminated with epoxy groups. On the addition of an initiator or hardener, the epoxy groups react by crosslinking, resulting in a three dimensional network of polymer chains.

The thermal stability of epoxy resins, as well as their flammability, depends on the structure of the monomer, the structure of the curing agent and the crosslink density [141]. In general, the thermal stabilities of aromatic epoxy resins are higher than those of aliphatic ones, even though the crosslink densities of the aromatic networks may be lower. Usually, thermal decomposition of any epoxy resin starts from the dehydration of the secondary alcohol ($R^1C(R^2)$–OH), leading to the formation of vinylene ethers (the first step in Fig. 7.36). Upon further decomposition, aliphatic

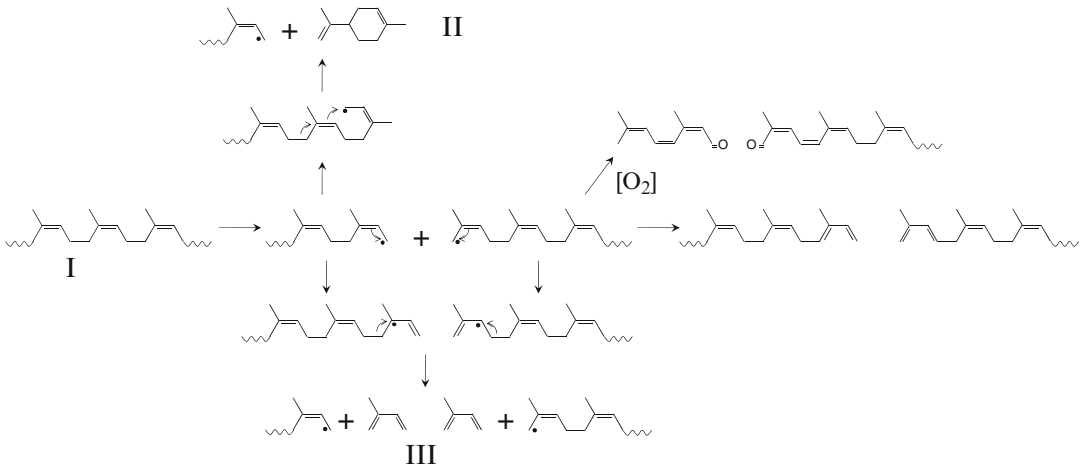

Fig. 7.34 Decomposition scheme for polyisoprene (I—polyisoprene; II—dipentene; III—isoprene) (After Ref. [142])

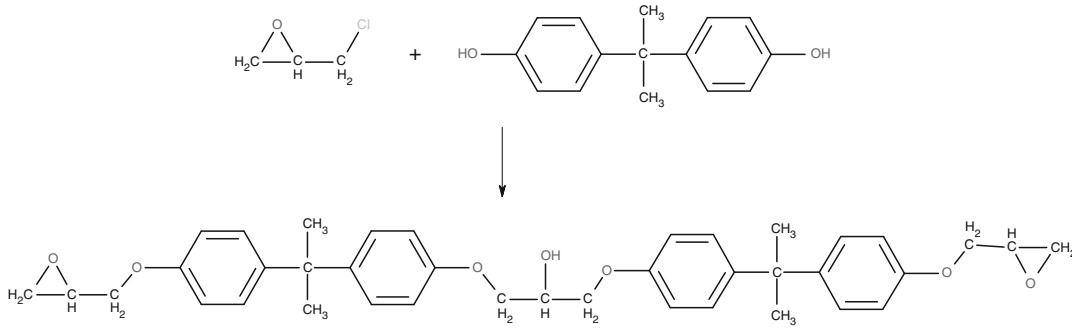

Fig. 7.35 Synthesis of an epoxy resin, showing basic repeat unit, before reaction of terminal epoxy groups

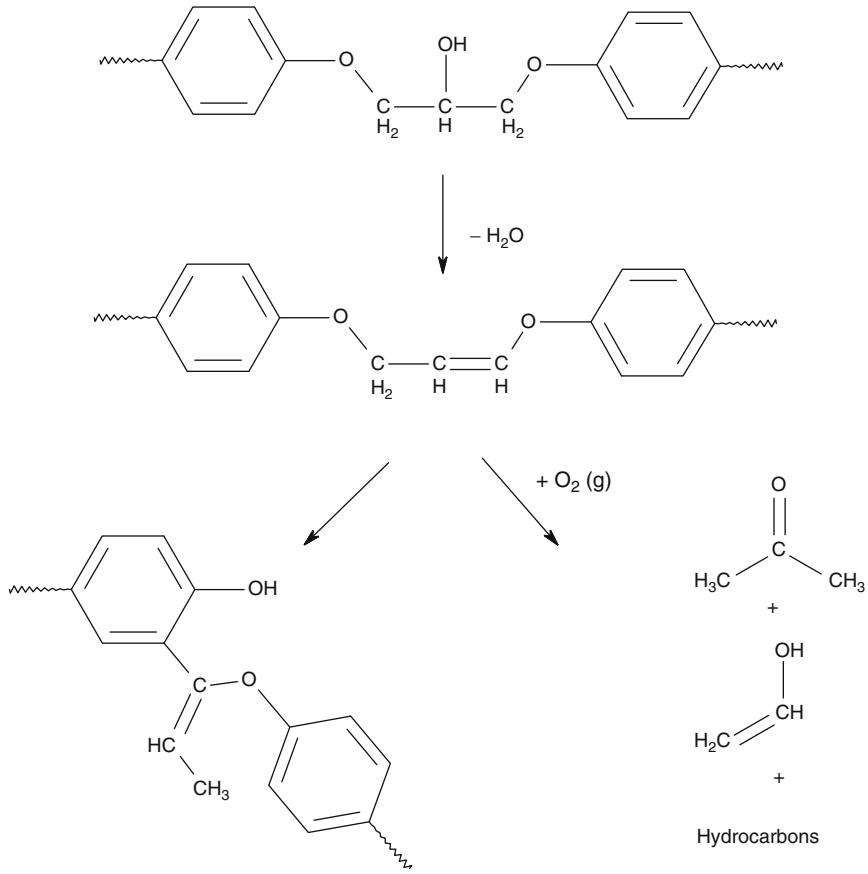

Fig. 7.36 Decomposition of epoxy resins, showing loss of water, to form a vinylene ether, followed by Claisen rearrangement to form a tri-substituted benzene char precursor

chain ends produce light combustible gases, allyl alcohol, acetone and various hydrocarbons. Alternatively, the allylic ethers or amides, formed after losing water, can undergo the Claisen rearrangement (the second step in Fig. 7.36) which changes the paraphenylene group to a 1,2,4-trisubstituted benzene with increased thermal stability [142]. This structure is partially responsible for further crosslinking and charring of epoxy resins.

Polyurethanes

Polyurethanes (PU) represent an important class of polymers and elastomers with a wide variety of structures and properties. As solids, they are used for elastomeric wheels (revolutionising skateboards and rollerblades in the 1980s), suspension components, electrical potting compounds, hoses, high performance adhesives, surface coatings and sealants. As flexible foams (PUF) they are very widely used in upholstered furnishing and carpet underlay. As rigid foams (PUR), they are widely used in thermal insulation products in buildings etc. Although included in the section on thermosets, a class of thermoplastic polyurethanes (TPU) also exist.

Polyurethanes are formed by reaction of an isocyanate ($O = C = N{-}R^1{-}N = C = O$) with a polyol ($HO{-}R^2{-}OH$) to form a polyurethane $(-C(O){-}NH{-}R^1{-}NH{-}C(O){-}R^2{-}O-)_n$. However use of isocyantes or polyols with more than two functional groups, such as $R^1(-N = C = O)_3$ or $R^2(-OH)_3$ will lead to a complex cross-linked structure. For example, in such formulations, the presence of traces of water is one way to promote cross-linking between two unreacted isocyanate groups.

$$2R - N = C = O + H_2O \rightarrow R - NH - C(O) - NH - R + CO_2$$

The reaction can continue between further isocyanate groups, and -NH groups by the formation of biuret linkages (Fig. 7.37).

The decomposition of polyurethanes is dependent on the chemistry of both the polyol and the isocyanate and the polymerisation process. Variation of R1, R2 and the number of functional groups in the polyol and isocyante leads to a large variety of PU polymers. In flexible PU foams, the polymer decomposes to form a pool, isocyanate tends to be released first from the pool, followed by the polyol. In rigid PU foams the greater cross-linking can lead to charring of the foam.

During combustion, particularly in under ventilated conditions, polyurethanes produce toxicologically significant quantities of hydrogen cyanide [143]. This is believed to be a major contributor to fire deaths [144]. The low thermal inertia of PU foams, their resultant flammability and their widespread use, means that that they make a particularly important contribution to fire risk and hazard.

Phenolic Resins

Some of the oldest synthetic polymers were phenolic resins, originally sold as Bakelite. Today their applications include low flammability rigid components of railway seats, snooker balls, circuit boards, adhesives (particularly for plywood and other wood-based composites) and as foam thermal insulation of lower flammability than XPS, EPS or PUR. Phenolic resins are formed by reaction of a phenol with formaldehyde. They contain both aromatic rings and aliphatic carbon in the polymer backbone, and are fully cross-linked thermosetting polymers.

Ten percent of mass loss is observed between 373 and 423 K, and a further 30 % between 673 K and 1173 K in nitrogen (Fig. 7.38), through loss of water. The main volatile products of the thermal decomposition of phenolic resins found in a study using thermogravimetric

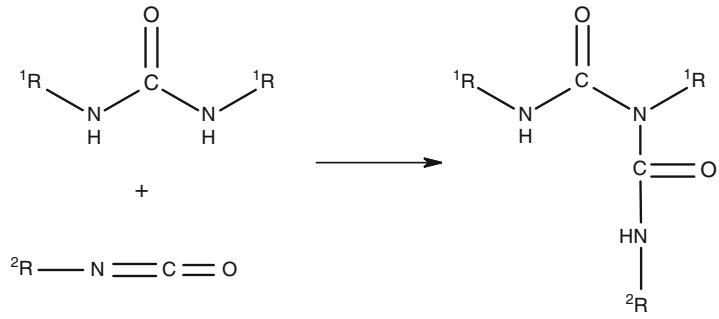

Fig. 7.37 Formation of a biuret linkage in polyurethanes

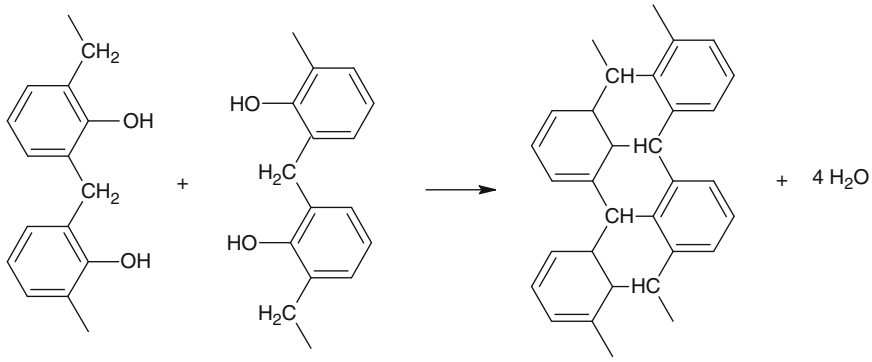

Fig. 7.38 Cross linking of phenolic resins between 373 K and 423 K accounting for 10 % mass loss

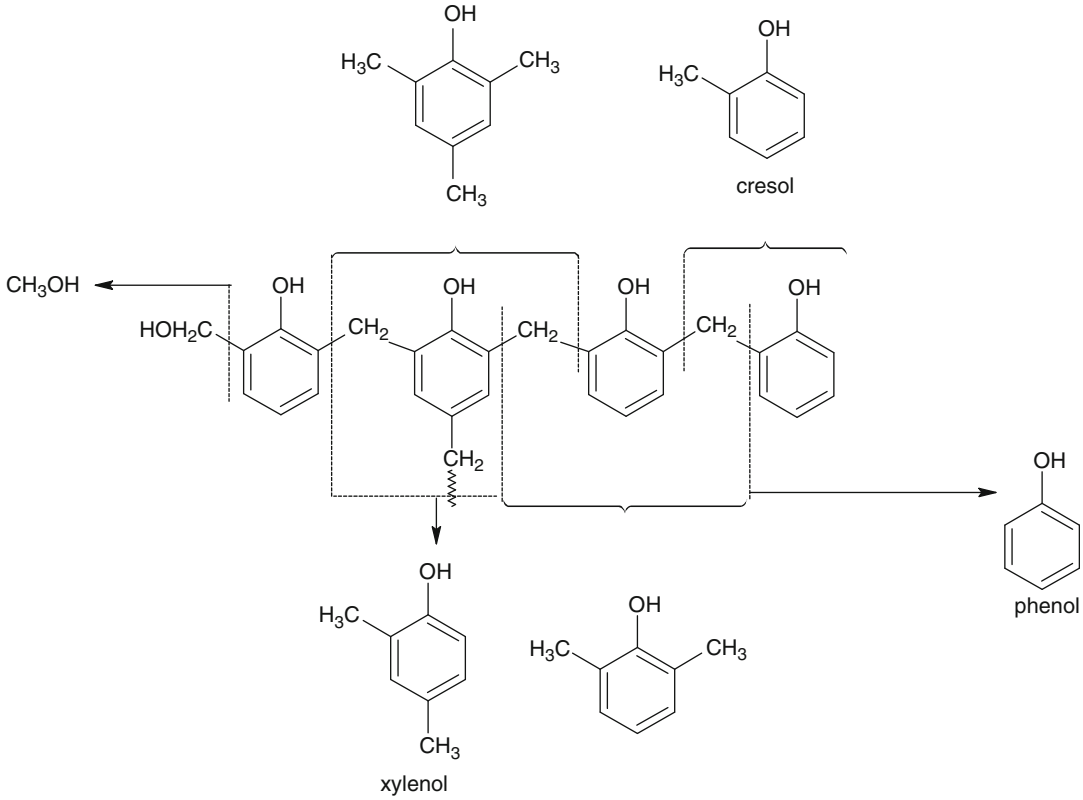

Fig. 7.39 Formation of phenol and its methyl derivatives

analysis and Fourier transform infrared spectroscopy (TGA-FTIR) at 30 K per minute include tars, various phenols and cresols, water, carbon dioxide, methane and carbon monoxide [145] (Fig. 7.39). The char residue was measured as 63 % at 975 K and 60 % at 1275 K.

Polymers with High Thermal Stability

Polyetheretherketone (PEEK)

Poly(oxy-1,4-phenyleneoxy-1,4-phenylenecarbonyl-1,4-phenylene), (PEEK), is a semi-crystalline polymer with excellent mechanical,

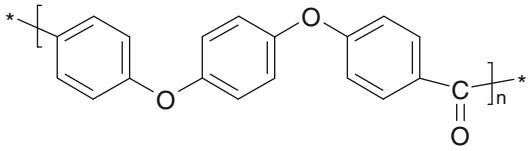

Fig. 7.40 Repeat unit of polyetheretherketone

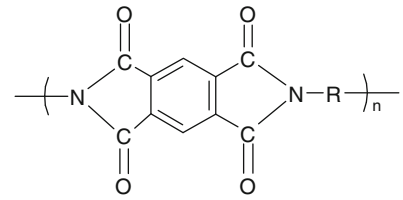

Fig. 7.41 Structure of a repeat unit of polyimide (PI)

chemical and thermal properties which permits for its use in a variety of industries and particularly as an ideal metal replacement with exceptionally high thermal stability [146].

The structure of PEEK is shown in Fig. 7.40. The stable aromatic backbone, which makes up the bulk of the monomer unit, is attributed to giving the polymer its excellent thermal properties [147, 148]. PEEK has a continuous use temperature of 533 K and a melting point of 616 K [149]. The onset of thermal decomposition occurs between 848 and 853 K. The thermal decomposition of PEEK is different in both oxygen and nitrogen environments, however, both show a two step decomposition process. In the first step around 50 % of the mass is lost, (~873 K in nitrogen and ~823 K in air), random chain scission of the ketone and to a lesser extent, the ether bonds is believed to be the main mechanism [150]. The second step is slower, with over 35 % of the residue remaining at 1273 K in nitrogen; in air mass loss is complete at 1000 K.

The main decomposition products contain lower molecular weight volatiles as well as benzene and methylbenzene. As the randomness of the main chain scission increases, other volatile products are formed such as diphenylether and CO and CO_2 at 923 K and dibenzofuran, biphenyl and naphthalene at and above 1023 K [151].

The high char yield suggests that random chain scission is accompanied by carbonisation and pyGC/MS data indicates that carbonisation might be the dominant pyrolysis pathway at temperatures above 1023 K [153].

Polyimide (PI)

Polyimide (PI) is a high-temperature, linear thermoplastic. Similar to PEEK, PI is used in high performance applications as a replacement for glass and metal products. PI contains the sequence CO – NR – CO as part of a ring structure along the backbone, shown in Fig. 7.41, the presence of which gives the polymer its high temperature properties [152].

PI has high oxidative stability and therefore can withstand temperatures of up to 533 K [154]. They are resistant to weak acids and organic solvents but not bases. PI also resists ionising radiation and has good electrical properties, however, exposure to water or steam above 100 °C may cause parts to crack rendering poor hydrolysis resistance [154]. Common uses for PI are appliance bearings, seals and electronic components and products.

Polyetherimide (PEI)

Polyetherimide (PEI) is an amorphous thermoplastic with high temperature resistance, rigidity and impact strength. PEI has similar properties to PI and although it will burn, both have self-extinguishing properties [154]. PEI also has aromatic rings in its backbone (Fig. 7.42)

PEI has low smoke emission and is resistant to alcohols, acids and hydrocarbon solvents however, dissolves in partially halogenated solvents. PEI is sold under the trade name of Ultem™ and similar to PI, the polymer is used widely thorough out the electronics industry. PEI is also used in the automotive industry for temperature sensors and lamp sockets and due to its dimensional stability is used for large, flat parts such as computer hard disks [154].

Polyphenylene Sulphide (PPS)

Polyphenylene Sulphide (PPS) is a high temperature, high strength and highly chemically resistant thermoplastic. This is indicated by the presence of an aromatic benzene ring on the

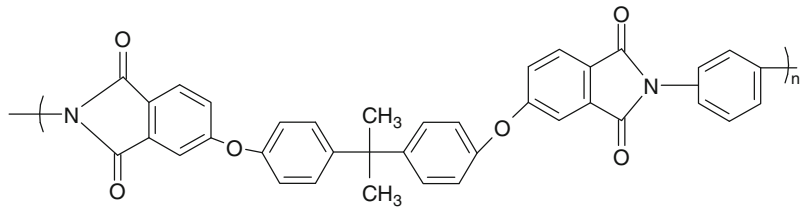

Fig. 7.42 Structure of a repeat unit of polyether imide (PEI)

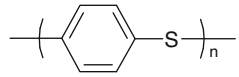

Fig. 7.43 Structure of a repeat unit of Polyphenylene Sulphide (PPS)

Table 7.8 Onset decomposition (T_d), peak mass loss temperature (T_p), and ignition (T_{ig}) temperatures of PEEK, PEI and PPS [155]

Polymer	T_d/K	T_p/K	T_{ig}/K
PEEK	843	873	843
PEI	800	828	801
PPS	777	818	848

backbone of the structure linked with an electronegative sulphur atom [154] shown in Fig. 7.43.

Due to its highly crystalline nature, PPS is brittle and is often reinforced with glass fibre. PPS has similar mechanical properties to other engineering thermoplastics and its intrinsic flame resistance allows for applications in the electronic industry and instances where the material's mechanical properties need to remain constant at elevated temperatures. As such, PPS is used for impellers and pump housings [154].

The onset of decomposition (T_d) in PEEK occurs at a higher temperature (843 K) than in PEI and PPS as is shown in Table 7.8 [153]. In both PEEK and PEI, the peak mass loss temperature (T_p) occurs after ignition, in PPS this occurs before. PPS also ignites at a higher temperature than PEI and PEEK.

Natural Polymers

Polysaccharides

Cellulosic materials contain both bound and unbound water. Unbound water is lost below its normal boiling point of 373 K. Bound water is released above 373 K in a reversible process. At higher temperatures irreversible water loss is also observed, through chemical dehydration leading to crosslinking and char formation (Fig. 7.44).

Wood based products are primarily composed of three components; hemicellulose, cellulose and lignin. Breakdown of these components, however, is not entirely simultaneous. The hemicellulose, particularly its pentosans, decompose first, largely between 473 and 533 K, followed by cellulose at 513 K to 623 K, and finally by the lignin at 653–773 K.

Cellulose evolves water in the first stage of thermal decomposition, before any other significant changes are observable. Early in the pyrolysis of cellulose some of the carbon-oxygen bonds in the links between the glucose units may be expected to undergo random chain scission (Fig. 7.44). During pyrolysis the water present from the first decomposition stage, and if hemicellulose is also present, the acids resulting from its decomposition will also be present; both serve to promote hydrolysis. The decomposition continues until molecules are small enough to be volatile are produced. These include formaldehyde, acetone, glyoxal, glycolic aldehyde, glycolic acid, lactic and dilactic acid, formic and acetic acid, as well as water, carbon monoxide and carbon dioxide.

Proteins

Proteins (poly α-amino acids) $(-NHCHRC(O)-)_n$ are linked in the same way as polyamides, but as the R substituent is different for each of over 20 amino acids, these affect their decomposition. Thermal decomposition of proteins has probably been more extensively studied than the sum of all other polymers, and is more usually described as cooking. The most important protein polymers from a fire safety perspective are silk and wool and others associated with textiles. When heated,

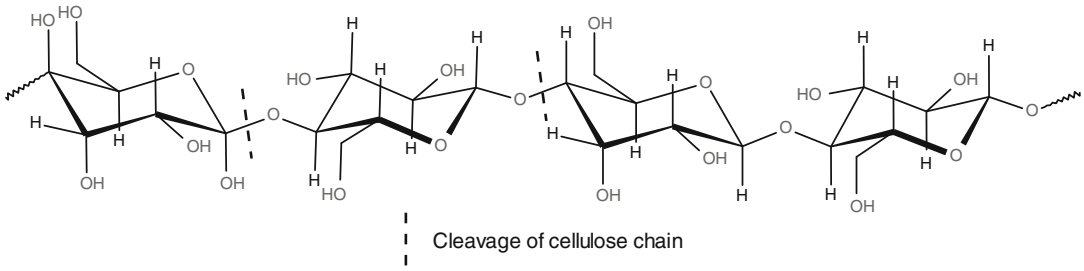

Fig. 7.44 Part of a cellulose chain showing cleavage between two glucose units

silk starts to decompose above 250 °C and forms a char. This charring characteristic is probably largely influenced by the dehydrating and cross-linking tendency of the hydroxyl group within the serine-CH_2OH substituent. Wool fibres and fabrics have significantly greater commercial applications in products such as protective clothing and contract upholstery, where high levels of fire-resistant performance are required. Wool comprises 18 α-amino acids, including nearly 10 % by mass cysteine, (−NHCH(CH_2SH)C(O)−) which dimerises forming cystine linkages (two R groups from different parts of the chain form linkages −CH_2−S−S−CH_2−) providing cross-links between adjacent chains. The high sulphur content (3–4 wt%) coupled with the high nitrogen content (15–16 wt%) contributes to the inherently low flammability of wool. The fibre also contains about 15 wt% of adsorbed moisture under normal atmospheric conditions. When wool is heated, it starts to give off its adsorbed moisture at 100 °C and above, and then starts to thermally degrade rapidly above 200 °C, with the notable evolution of hydrogen sulphide (H_2S) from cleavage of cysteine linkages above 230 °C alongside char formation. The low flammability of the volatiles, coupled with char formation, from cross-linking and dehydration of many α-substituents gives a relatively high ignition temperature of 840–870 K.

Biopolymers

Cellulose Based

Cellulose derived from wood pulp has an average of 3000 repeat units, while cellulose derived from cotton has around 15,000 repeat units. The large

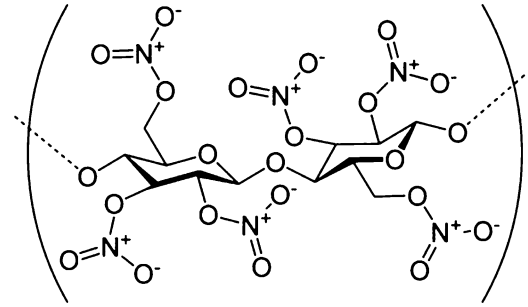

Fig. 7.45 Structure of cellulose nitrate

number of hydroxyl groups on the sugar molecule, which leave the polymer as water molecules during decomposition, result in char formation. Numerous derivates of cellulose have been prepared, including cellulose acetate ("acetate") and cellulose nitrate (once used as a medium for photographic films, now presenting a problem for safe storage of archive film), which is also used as a paint. Cellulose nitrate (or nitrocellulose) deserves special mention as it contains enough oxygen to fuel its own decomposition, and therefore can burn under water, and its heat release is not measurable by oxygen depletion calorimetry. Fortunately, its only other common use is for table-tennis balls (Fig. 7.45).

Polyesters Polylactic Acid (PLA), Polyhydroxybutyrate (PHB)

These materials have an aliphatic backbone, and are therefore more flammable than their aromatic counterparts. As the monomer may be derived from living sources, rather than fossilised material, they are favoured as being part of a cycle which does not contribute to the global increase

in carbon dioxide. They are, however, flammable and this is one of the limitations on their wider use. They are used for packaging, films etc.

Polylactic acid decomposes to produce water, carbon dioxide, acetaldehyde, acetone, acrylic acid, acetic acid and cyclic oligomers [154]. Polyhydroxybutyrate decomposes to give dimer (41 %) crotonic acid (35 %) trimer (12 %) and tetramer (3 %) below 611 K, with crotonic acid predominating at higher temperatures [155].

Fire Retardants

In general, fire retardants are more expensive than their host polymers, and are only added in order to meet regulatory requirements. If a particular polymer is used in a high risk situation (mass transport, electrical and electronic, upholstered furniture, or certain construction applications) and it is too flammable, fire retardants may be incorporated to ensure that it meets regulatory criteria. Understandably, manufacturers will optimise their materials in order to pass regulatory tests, and it is incumbent on the regulators to ensure that their tests continue to be appropriate to the types of fire retardant technologies being deployed.

Drivers in Fire Retardant Development

The history of fire retardants goes back to Egyptian times when solutions of alum (hydrated potassium aluminium sulphate ($KAl(SO_4)_2 .12H_2O$)) were used to treat timber. Gay-Lussac protected theatre fabrics from fire by treatment with mixtures of ammonium phosphate, ammonium chloride and borax which formed a glassy layer on heating [156]. However, the main driver for development came with the growth of the plastics industries and the resultant widespread use of synthetic polymers. During the 1960s and 1970s fires became more common and more severe. Anecdotally, fire fighters reported a change from fires with limited visibility, to those with almost no visibility due to dense smoke, primarily resulting from newly available low-cost polyurethane foam furniture. The increasing severity of the fire problem led to the development from empirical tests for flammability to engineering models capable of providing data on burning behaviour. This was accompanied by a shift in emphasis from ignitability to peak heat release rate. The cone calorimeter provided a reproducible means of quantifying penetrative burning into a sample, but not surface spread of flame. The main drivers in fire retardant development have been summarised in Table 7.9.

According to a survey carried out by SRI Consulting [157], the total market for flame retardants in the United States, Europe and Asia in 2007 amounted to about 1.8 million metric tons (Fig. 7.46). This market was expected to grow at an average annual rate of about 3.7 % per year on a volume basis over the period 2007–2012. It is split roughly equally between Europe, America and Asia, with halogenated flame retardants and antimony oxide comprising around 37.5 %.

Fire Retardant Strategies

The wealth of different fire retardant strategies is a testament to the ingenuity of the chemists who developed them. Fire retardant agents have been

Table 7.9 The main drivers in fire retardant development

Decade	Event	Demand
1960s	Widespread availability of cheap polymer products—more serious fires	Reduced ignitability
1970s	Smoke much worse	Reduced smoke
1980–1990s	Development of Cone Calorimeter (and emphasis on peak heat release rate, rather than ignitability)	Reduced Peak Heat Release
	Increase in deaths from smoke inhalation	Reduced Fire Toxicity
2000s	Halogen FRs found across the ecosystem	Halogen-free FRs
2010s	Climate change and other environmental concerns become mainstream	Sustainable FRs

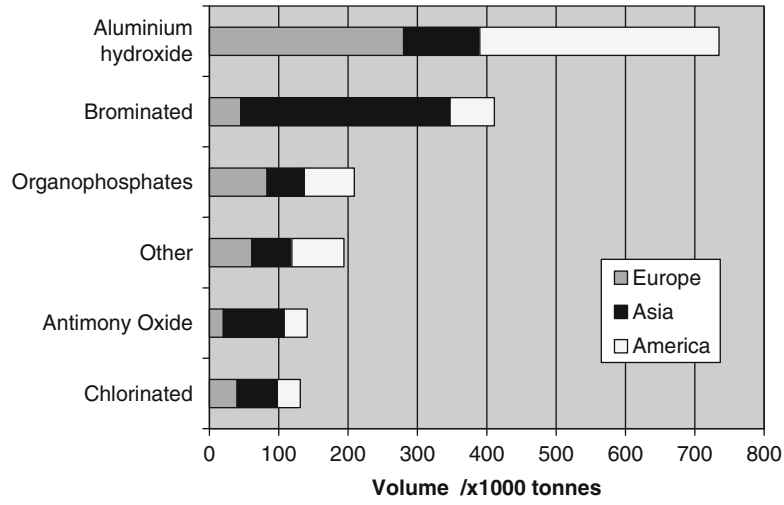

Fig. 7.46 Volume consumption of flame retardants in the USA, Europe and Asia [159]

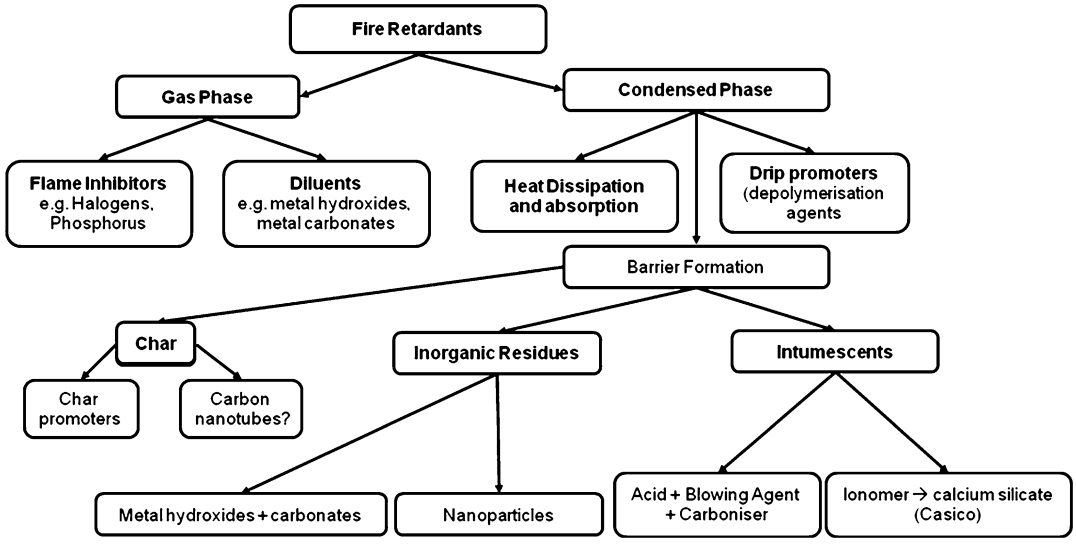

Fig. 7.47 Classification of fire retardant strategies

classified in many ways: place of action—gas or condensed phase; mode of action—physical or chemical; chemical nature of agent—halogen, phosphorus, metal hydroxide or carbonate, etc.; means of incorporation of agent—additive or reactive (i.e. bound onto the polymer chain etc.). Unfortunately, these classifications cannot be unambiguously applied to particular fire retardants—for example, the most widely used fire retardant, aluminium hydroxide releases water, so acting in the gas phase, but in doing so absorbs heat and leaves a protective residue in the condensed phase [158]. It is useful to distinguish within the broadest category: *fire* retardants include any material which reduces the flammability of the polymer; *flame* retardants inhibit the gas phase free radical reactions responsible for flaming combustion. Figure 7.47 illustrates how the major fire retardant strategies could be subdivided. Fire retardants have evolved over the last four decades in order to meet the demands of industry and regulators, from halogen based flame inhibitors to cleaner, char promoters, resulting in less smoke and toxic gas emissions.

While halogenated flame retardants continue to be used in a wide range of existing products, very little new work has been published on them. Instead, research has been heavily focussed on finding suitable halogen-free replacement fire retardants, indicating that the industry has indeed recognised the need for change, in the face of increasing pressure, predominantly resulting from environmental concerns.

A fire retardant should inhibit ignition, and may also suppress the combustion process. Most fire retardants interfere with a particular stage of combustion, e.g. during heating, decomposition, pyrolysis, ignition or sustained burning.

Physical Action

There are several ways in which the combustion process can be retarded by physical action:

- ***By cooling:*** Endothermic processes such as decomposition of additives, cool the substrate to a temperature below that required for sustaining the combustion process.
- ***By formation of a protective layer:*** The combustible components of the condensed phase can be shielded from the gaseous phase with a protective solid layer. The condensed phase is thus protected from radiation, and oxidative attack, while pyrolysis gas evolved is inhibited.
- ***By dilution:*** The incorporation of inert substances (e.g. fillers) and additives which evolve inert gases on decomposition dilutes the fuel in the condensed and gaseous phases so that the lower ignition limit of the gas mixture is not exceeded, and heat to the condensed phase is dissipated.

Chemical Action

Chemical reactions in the condensed and gas phases may interfere with the combustion process.

- ***Reaction in the gas phase:*** The radical mechanism of the combustion process which takes place in the gas phase is interrupted by the flame retardant. The radical concentration falls below a critical value, and flaming cannot occur. The exothermic processes are thus stopped, the thermal feedback to the condensed phase is reduced, so the supply of flammable volatiles is reduced.
- ***Reaction in the solid phase:*** Here two types of reaction can take place. Firstly, breakdown of the polymer can be accelerated by the fire retardant, causing pronounced flow of the polymer allowing it to recede from the flame, usually by dripping. Secondly, the fire retardant can promote the formation of a layer of carbonaceous char on the polymer surface. This can occur, for example, through the dehydrating action of the fire retardant generating double bonds in the polymer. Ultimately, these form the carbonaceous layer by cyclizing and cross-linking.

Additive vs Reactive Fire Retardants

Additive fire retardants are incorporated in the plastic either prior to, during, or, more frequently, following polymerisation. They are used especially in thermoplastics. If they are compatible with the plastic they may act as plasticisers, otherwise they are considered as fillers. They are sometimes volatile or tend to leach out of the polymer, so fire retardance may be gradually lost. The development of high molecular weight products (oligomeric and polymeric fire retardants) can eliminate this problem.

Reactive fire retardants are built into the polymer molecule, for example by attaching a fire retarding group to a monomer group. This prevents them from bleeding out of the polymer and volatilising and their fire retardance is thus retained. In addition, they have no plasticising effect and do not affect the thermal stability of the polymer. They are used mainly in thermosets (especially polyesters, epoxy resins and polyurethanes) in which they can be easily incorporated. They are, however, normally a more expensive solution than additive fire retardants. In crystalline polymers, where the structural integrity, strength and other physical properties depends on the microcrystalline structure, the presence of foreign groups on the polymer

chain is likely to have a detrimental effect on the physical properties.

Combinations of additive or reactive fire retardants with further additives can produce an *additive*, *synergistic* or *antagonistic* effect. While the *additive* effect is the sum of the individual actions, *synergism* is a greater than additive effect, and *antagonism* a less than additive effect. When used alone, some additives show no or only negligible effectiveness. The synergistic effect occurs when they are used together with other specific fire retardants. Such synergists have achieved great importance in practical use because they are often more effective or less expensive than the single fire retardants.

Halogenated Flame Retardants

There are more than 40 brominated flame retardants in current use and an additional number of chlorinated FRs [159]. These are used by simple melt blending with the polymer (additive FRs) or by incorporation into the polymer chain during polymerisation, (reactive FRs). Some additive FRs are small molecules while others are oligomers or polymers. From a health and environmental perspective, small molecules will be easiest to release from the polymer matrix (by evaporation, leaching, end-of-life processing etc.) Oligomeric or polymeric additives may be released during end-of-life processes, while reactive FRs, which have been successfully incorporated into the polymer are only likely to be problematic during burning or incineration or other end-of-life processes.

Mode of Action of Halogenated Flame Retardants

Halogenated flame retardants act by releasing hydrogen halides (HX) during thermal decomposition. If the hydrogen halide release coincides with fuel gasification, then HX can interfere with the gas phase combustion processes. Flaming combustion involves a very small number of highly reactive free radicals to propagate the gas phase oxidation processes. For ignition to occur, the number of radicals must increase. This occurs in reaction 1 and 2 where each "·"represents an unpaired electron.

$$H\cdot + O_2 \rightarrow OH\cdot + \cdot O\cdot \tag{7.43}$$

$$\cdot O\cdot + H_2 \rightarrow OH\cdot + H\cdot \tag{7.44}$$

Halogen-containing flame retardants act by interfering with the radical chain mechanism taking place in the gas phase. The high-energy OH · and H · radicals formed by chain branching are removed by the halogen-containing flame retardant.

At first the flame retardant breaks down to

$$RX \rightarrow R\cdot + X\cdot \tag{7.45}$$

where X · is either Cl · or Br · .

The halogen radical reacts to form the hydrogen halide:

$$X\cdot + RH \rightarrow R\cdot + HX \tag{7.46}$$

which in turn interferes with the radical chain mechanism:

$$HX + H\cdot \rightarrow H_2 + X\cdot \tag{7.47}$$

The removal of H · is key to elimination of the main chain branching step (when 1 unpaired electron becomes 3).

$$HX + OH\cdot \rightarrow H_2O + X\cdot \tag{7.48}$$

The removal of OH · blocks the main heat release step of hydrocarbon combustion, the conversion of CO to CO_2, by replacement with less reactive halogen free radicals in the gas phase [160]. The H· and OH· radicals are essential for many flame reactions and are involved in the main heat release in reaction 7.49.

$$CO + OH\cdot \rightarrow CO_2 + H\cdot \tag{7.49}$$

Loss of H· and OH· will increase the yield of toxic carbon monoxide and other products of incomplete combustion (hydrogen cyanide (HCN), organoirritants and soot).

The high-energy H · and OH · radicals are removed by reaction with HX and replaced with lower-energy X · radicals. The actual flame retardant effect is thus produced by HX. Kinetic reaction

schemes predict that HBr is recycled around seven times in order to account for the observed flame inhibition [161], while the HCl is not recycled.

In the condensed phase, the resulting unsaturated polyenes may act as char precursors, forming products with a tendency to cyclize and condense to yield carbonaceous products, which protect the condensed phase below the flame zone against attack by oxygen and radiant heat. In PVC, after loss of 60 % mass as hydrogen chloride from the surface layers, char formation is a significant fire retardant mechanism protecting the underlying polymer.

The halogen content in the polymer compound, and its chemical binding, will dictate the flame retardant behaviour. In the presence of antimony oxide (Sb_2O_3), the efficiency of halogenated flame retardants is improved, although antimony has no flame retardant effect on its own. This is believed to result from the formation of volatile SbX_3 and other species which are more effective halogen carriers than HX.

Metal Hydroxide and Carbonate Fillers

These involve incorporation of a material that evolves an inert gas on heating. This is often achieved with a filler material such as a metal hydroxide. For example, aluminium hydroxide not only evolves water vapour, but also absorbs a vast amount of heat as it is dehydrated.

$$2\,Al(OH)_3(s) \overset{180-200^\circ C}{\rightarrow} Al_2O_3(s) + 3\,H_2O(g)$$
$$\Delta H = +1.3\,kJ\,g^{-1}$$

This is about the same amount of energy that would heat 1.6 g of polythene to 673 K (its decomposition temperature).

In addition, aluminium hydroxide is a good conductor of heat, reducing the local hot spots, which are responsible for starting fires. Aluminium hydroxide (incorrectly referred to in industry as alumina trihydrate or ATH), accounts for half of all the fire retardant additives used by weight. However, this is partly due to its low price and the requirement for it to be present in a polymer at a 50–70 % loading to be effective.

Alternatives to aluminium hydroxide have also been investigated (Table 7.10).

The absolute contributions of these fillers to fire retardancy have been estimated [160] as shown in Table 7.11 and Fig. 7.48.

Table 7.10 Mineral filler fire retardants

Filler	Formula	T_{decomp}/°C	ΔH_{decomp}/kJ g^{-1}
Aluminium hydroxide	$Al(OH)_3$	180–200	1300
Magnesium hydroxide	$Mg(OH)_2$	300–320	1450
Calcium hydroxide	$Ca(OH)_2$	430–450	1150
Nesquehonite	$MgCO_3.3H_2O$	70–100	1750
Hydromagnesite	$Mg_5(CO_3)_4(OH)_2.4H_2O$	220–240	1300
Huntite	$Mg_3Ca(CO_3)_4$	400	980
Ultracarb	Hydromagnesite/Huntite	220–400	1172
Boehmite	AlO(OH)	340–350	560

Table 7.11 Assumptions for quantification of the magnitude of physical fire retardant effects of mineral fillers

Effect	How quantified
Diluting polymer in condensed phase	Heat capacity of the filler prior to decomposition
Endothermic decomposition of filler	Heat of decomposition
Presence of inert residue	Heat capacity of the residue after decomposition
Presence of diluent gases	Heat capacity of the diluent gases

Burning Behaviour of Polymeric Materials

Quantifying Fire Behaviour

Polymer flammability has no specific meaning; the flammability of a polymer is often defined by the method used to measure it [162]; flammability has been described as the ease at which a substance will ignite [163] but is also used to indicate the rate of fire growth after ignition: flammability is a function of both gas and solid phase chemistry [164]. Fire tests are crucial to the development, screening and evaluation of materials with improved fire safety. Techniques employed to measure the ignition and burning behaviour of a polymer are numerous. Some examples of fire tests are shown in

Table 7.12 together with the individual fire properties they can quantify [165].

It can be seen from Table 7.12 that no one test covers all the parameters describing fire safety behaviour, but many address more than one parameter. When selecting a test method, it is necessary to determine the end use of the product, and the likely fire scenarios. Aside from materials' development, in fire testing, there are generally two end purposes:

- To meet a regulatory requirement; and
- To demonstrate that the material being tested will perform adequately in a specific fire scenario [166].

A wide range of industry standard tests are used to demonstrate a product's suitability for a particular application, and ultimately all products with specified fire performance must meet these criteria. However, the specification of materials, or the design of fire retardant materials requires simple quantifications of a material's fire behaviour. A relatively small number of fire tests are employed in order to quantify the fire behaviour of a material. The most common of these are the limiting oxygen index (LOI) and the Underwriters' Laboratory UL 94 test, both ease of extinction tests, and the cone calorimeter, which measures time to ignition and rate of heat release.

Ignitability

Ignition is a very important parameter controlling flame spread and fire growth. However, the source of ignition necessarily impacts on the result, and therefore ignition temperature is found to depend on the design of the test used to measure it. The characteristics of several common ignition sources have been reported [167] and are shown in Table 7.13. Tests which use

Table 7.12 Common fire tests and parameters assessed

sparks, electric arcs, hot surfaces or open flames for less than 30 s will not deliver more than 100 kJ, and represent low severity tests. Crumpled or folded paper can deliver between 200 and 4000 kJ in 1–8 min, representing a medium severity exposure, while burning bedding can deliver 130,000 kJ in 20 min, representing a high severity exposure. Many standard tests use a gas or liquid fuel ignition source, of specified energy or power, corresponding to one of the "unwanted fire" ignition sources.

Ignition is a complex subject, which has been addressed by several authors [168–172] and comprehensively described and summarized elsewhere [173]. Ignition occurs when the oxidising volatiles feed enough heat back to the polymer to volatilise a similar concentration under the conditions of the test. Thus, the fraction of the heat of combustion passed back to the polymer for a given mass of fuel must be greater than its heat of gasification. This critical condition can be described by the mass loss rate at ignition. For the cone calorimeter the critical mass loss rate is around 1–6 g s^{-1} m^{-2}, and the resulting heat release rate at ignition (HRR_{ig}) is around 20–100 kW m^{-2} [174–176]. Ignition does not directly or necessarily correspond to "flammability" measured by LOI or UL 94, since both of these are ease of extinction tests, and correspond better to the minimum mass loss rate needed for sustained burning or fire propagation [177]. Ignitability can be determined by measurement of the ignition delay time, an important fire parameter, for example using a cone calorimeter.

Ease of Extinction Tests

UL-94 'Bunsen Burner' Test IEC 60695-11-10

This is a small-scale laboratory screening procedure for comparing the relative burning behaviour of vertically or horizontally oriented specimens made from plastic and other non-metallic materials, exposed to a small-flame ignition source of nominal 50 W power [178].

The method determines the linear burning rate and the afterflame/afterglow times, as well as the damaged length of specimens, and is applicable to solid and cellular materials with density of at least 0.25 g cm^{-3}, provided they do not shrink away from the applied flame without igniting. The test method described provides a classification system, which may be used for quality assurance, or the pre-selection of component materials of products, provided that the test sample thickness is the thinnest to be used in the application. The Underwriter's Laboratory designed this standard to indicate a plastic's flammability for use as part of an electrical appliance, rather than the hazards of a material under actual fire conditions. UL 94 flammability testing is the first step toward obtaining a plastic recognition and subsequent listing in the "Plastics Recognized Component Directory" (formerly known as "Yellow Cards").

The 94 V test describes the Vertical Burn test (Fig. 7.10), which is a more stringent test than the Horizontal Burn method 94HB. The set up uses a very small Bunsen flame with a manometer and needle valve to control the gas flow. The criteria for each classification are shown below (Table 7.3). While the test is crude, it is a realistic ignition scenario, and lets the user see what is happening during the test. It is easy to set up a small test burner with a 15 mm blue flame in order to provide an instant simulation of the test (Table 7.14).

For the UL-94 vertical burning test, the conditions and measures are depicted in Fig. 7.49.

Table 7.14 UL94 classifications

V-0 Vertical burn	Burning stops within 10 s after two applications of ten seconds each of a flame to a test bar. NO flaming drips are allowed
V-1 Vertical burn	Burning stops within 60 s after two applications of ten seconds each of a flame to a test bar. NO flaming drips are allowed
V-2 Vertical burn	Burning stops within 60 s after two applications of ten seconds each of a flame to a test bar. Flaming drips ARE allowed
H-B Horizontal burn	Slow horizontal burning on a 3 mm thick specimen, with a burning rate less than 3" per minute or stops burning before the 5" mark. H-B rated materials are considered "self-extinguishing"
	This is the lowest (least flame retardant) UL94 rating

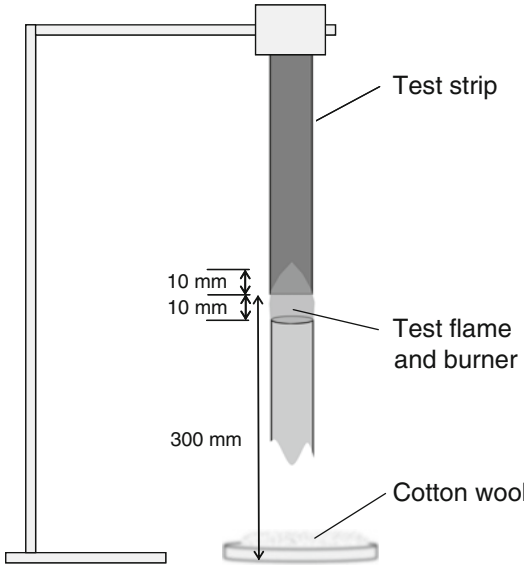

Fig. 7.49 The UL-94 vertical test arrangement

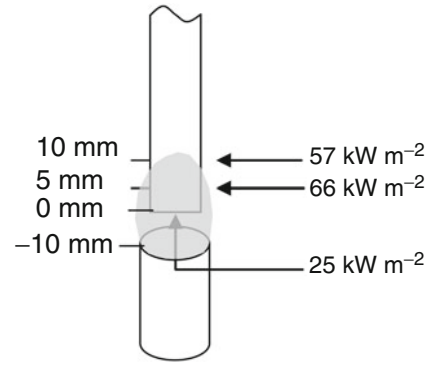

Fig. 7.50 The time-average incident burner flux in the UL-94 V test showing the heat flux at the top of the flame, 5 mm below the top, and at the base of the sample strip [189]

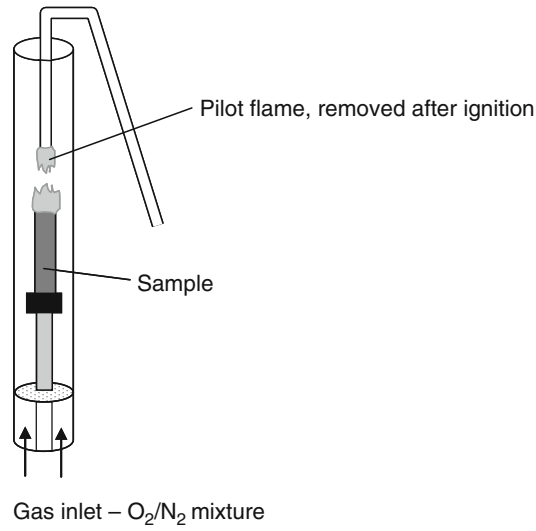

Fig. 7.51 Limiting oxygen index test

Attempts at explaining the phenomena occurring during the test have been made, however understanding the relationship between ignition and small flames has been described as 'poor or lacking' [179]. Several studies have endeavoured to correlate the results of the UL-94 test to other flammability measures, most commonly the cone calorimeter (ISO 5660 [180–185] although correlation to data, where little consensus exists on its interpretation, is ambiguous [96, 186]. The heat flux generated by the Bunsen burner, due to its partially premixed, blue diffusion flame is responsible for the ignition of the polymer and as a result, research has been conducted on determining the values for this parameter [187]. The time-average incident heat flux at height of 0.5 cm and 1 cm for the burner are shown in Fig. 7.50.

Limiting Oxygen Index

This test relates to the minimum concentration of oxygen that will just support flaming combustion in a flowing mixture of oxygen and nitrogen (Fig. 7.51) [188]. A specimen is positioned vertically in a transparent borosilicate glass test column and a mixture of oxygen and nitrogen is forced upwards through the column. The specimen is ignited at the top. If the flame remains for 3 min, or propagates down the length of the sample, the test is repeated at lower oxygen concentrations. If it self-extinguishes the test is repeated at higher oxygen concentration. The oxygen concentration is adjusted in this manner until the specimen just supports combustion. The oxygen concentration reported is the volume percent, with repeatability often as good as $\pm$ 0.1 % O_2.

Downward flame spread may be regarded as a best case scenario, and while a material with limiting oxygen index (LOI) $<$ 21 % should be considered to support downward flame spread,

materials with LOI $>>$ 21 % should still be considered flammable. Particular problems arise with materials with a high dripping propensity, since ignition will only occur under extreme circumstances. Very thin materials often have insufficient heat release per unit area to support combustion, while thicker materials conduct too much heat away from the flame zone. Thus there is a "most flammable thickness" for many materials around 1.6 mm. For non-charring materials, the criteria for ignition (heat transfer from the flame > heat of gasification per unit mass) are replicated in the criteria for extinction. However, while ignition requires a source (whose energy input will affect the result), extinction has no such dependence. The dilution of the flame by nitrogen causes the flame to swell, reducing the amount of heat fed back to the sample below the flame. As a rule of thumb, there is generally some correlation between the time to ignition in the cone calorimeter and the LOI, but none between LOI and heat release rate.

Bench-Scale Measurement of Heat Release

The Cone Calorimeter

The Cone Calorimeter [180, 189] (Fig. 7.52) was developed specifically to determine the rate of heat release and effective heat of combustion of building materials (ISO 5660–1). It was subsequently modified to determine smoke generation (ISO 5660–2) and later applied to furniture.

A horizontal specimen, 100 mm square, typically 3–6 mm, but up to 50 mm, thick is mounted under a steel frame, such that only the surfaces, but not the edges are exposed to a conical radiator pre-set to between 10 and 100 kW m^{-2} mounted beneath an instrumented hood and duct. A spark ignition is used and the specimen is mounted on a load cell. Heat release is quantified by oxygen depletion calorimetry. Measurement of heat release from real fires by oxygen depletion calorimetry is well established, and gives sensible values which relate to the

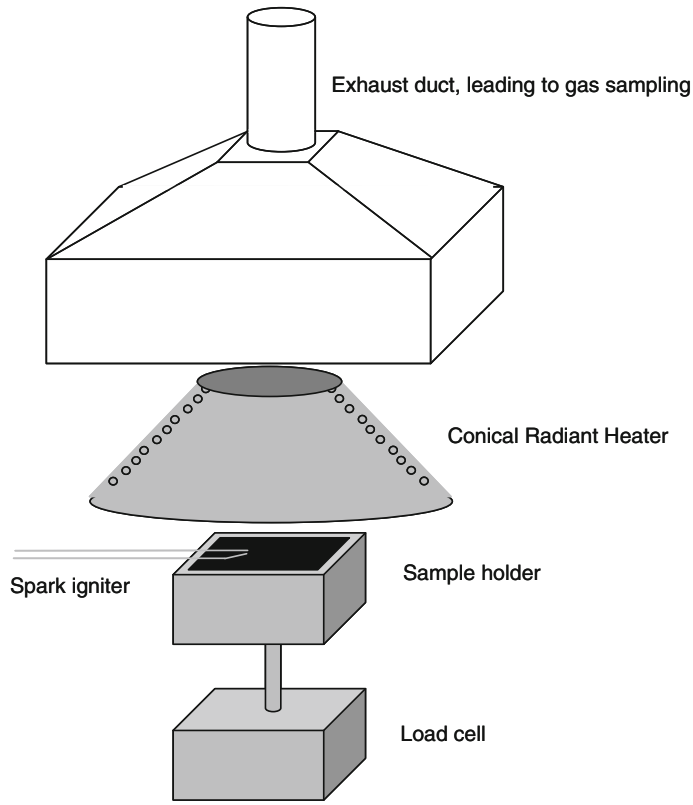

Fig. 7.52 Diagram of cone calorimeter

extent of burning. Provided the effluent flow through the exhaust is carefully controlled, the heat release will be proportional to the oxygen depletion. A sample of the effluent is cooled to remove water and analysed using a paramagnetic analyser and non-dispersive infrared CO and CO_2 analysers. It will not take into account the reduction in heat release due to the endothermic decomposition of metal hydroxide fire retardants, such as aluminium hydroxide (ATH), although this can be compensated for separately. (For PMMA containing 60 % ATH this would result in an overestimation of total heat release by ~8 %). A detailed description of the use and interpretation of data from the cone calorimeter for fire retardant materials development has been published [193]. The cone calorimeter monitors a comprehensive set of fire properties in a well defined fire scenario. The results can be used to evaluate material specific properties, setting it apart from many of the established fire tests which are designed to monitor the fire response of a certain specimen.

The cone calorimeter covers ignition followed by essentially penetrative flaming combustion, where the flame front moves through the bulk of the sample. The ignition parameter measured in the cone calorimeter is the time to ignition, which depends on the thermal inertia, critical heat flux and critical mass loss for ignition, or alternatively the critical surface temperature for ignition. Fire response parameters measured in the cone calorimeter include mass loss, heat release rate (HRR), total heat release (THR), smoke production and CO production. Fire response properties more typical of fully developed or post flashover fire scenarios are not replicated in the cone calorimeter.

There are three distinct uses of cone calorimeter data:

- To compare the fire response of materials: to assess their fire performance; to perform screening for materials development; or to develop pyrolysis and burning models.
- To determine data for input to simulations or predictions of full-scale fire behaviour.
- To determine characteristic parameters such as the maximum HRR (peak heat release rate, pHRR), fire growth rate index (FIGRA), THR etc., for regulatory purposes.

These applications of the cone calorimeter define different techniques and data evaluation. For regulatory purposes, its strengths are its well-defined conditions, reproducibility and unambiguous data evaluation of one or two characteristic values. The use of defined, and in some way ideal, burning behaviour is suitable for developing pyrolysis and burning models and for obtaining reasonable input values for the simulation of fires. However, as a fire scenario, it is not representative of most real fires. Small fires are not usually initiated with radiation from above, piloted by a spark ignition source, and surrounded by a frame which acts as a large heat sink, producing an unusual gas flow field around the flame zone, and where the effects of sample dripping are negligible.

Heat Release Curves from Cone Calorimetry

The heat release rate (HRR) during the cone calorimeter experiment gives rise to a characteristic heat release rate curves versus the time (Fig. 7.53) [174, 190].

Microscale Measurement of Heat Release

Microscale Combustion Calorimetry [192] (MCC) (section "Microscale Combustion Calorimetry") evaluates the combustibility of milligram samples by separately reproducing the solid state and gas phase processes of flaming combustion by controlled pyrolysis of the sample in an inert gas stream, followed by high temperature oxidation of the volatile pyrolysis products. Oxygen consumption calorimetry is used to measure the heat of combustion of the pyrolysis products. The maximum amount of heat released per unit mass per degree of temperature ($J\ g^{-1}\ K^{-1}$) is a material property that appears to be a good predictor of "flammability". The heat release capacity (HRC) and total heat release (THR), obtained by MCC, are related to the char yield and the heat of complete combustion of the volatiles. It takes no account of physical effects, such as dripping, wicking, and sample thickness; or chemical effects such as flame inhibition, because the conditions force

	Thermally thick non-charring (or non-residue forming) samples show a strong initial increase after ignition up to a steady HRR[191]. This plateau remains until near the end of the test, when an additional pHRR occurs. This peak is caused by reduction in heat transfer by conductivity through the increasingly thin sample, since the glass wool supporting the sample prevents heat transfer to the sample holder as the pyrolysis zone approaches it.
	For intermediate thermally-thick, non-charring samples the plateau vanishes. The averaged or steady HRR is only marked by a shoulder. The pHRR increases in comparison with thermally thick non-charring samples since its origin is half way between the thermally-thick non-charring and thermally-thin behaviour.
	Thermally-thick charring (residue forming) samples show an initial increase in HRR until an effective char layer is formed. As the char layer thickens, this results in a decrease in HRR. The maximum reached at the beginning is the steady HRR and the pHRR. Some thermally thick charring materials, such as wood, show a pHRR at the beginning, typical for charring, and a second pHRR at the end. The second peak may be caused by cracking char or increase in effective pyrolysis temperature, as observed with the thick non-charring materials.
	Thermally-thin samples are characterized by a sharp peak in HRR, since the whole sample is pyrolysed at the same time. In this case, the pHRR is determined by their total fire load.

Fig. 7.53 Types of heat release curves from cone calorimetry [191]

pyrolysis and combustion to completion [193]. However, varying the combustion temperature or oxygen concentration results in incomplete combustion as occurring in real fires. The THR results have been correlated to LOI; HRC and char residue to LOI; and HRC and THR with peak heat release rate (pHRR) in the cone calorimeter. It has been used as a screening test for efficacy of flame retardant additives [194].

Influence of Physical Properties on Flammability

The following factors affect polymer combustion in real fires, and should therefore influence the outcome of a suitably designed test.

Fuel production—when the fuel in the gas phase reaches a critical concentration, ignition and flaming can occur. While the fuel production rate during heating is essentially a

material property, the air flow around the sample may profoundly alter the ignition temperature.

Presence of inhibitors or diluents—Cl · or Br · or PO · are stable radicals which will reduce the critical concentration of active radicals such as H · and OH·, in the flame zone. The effect is most pronounced at ignition, and least evident under developed fire conditions.

Rheology of decomposing polymer—Some polymers depolymerise during decomposition reducing their viscosity. This allows better dispersion of heat, and material flow away from the source of heat. This can result in harmless dripping away from the flame zone, or flaming drips allowing flaming to spread downwards. Some additives (e.g. high surface area fillers, such as nanofillers) will increase the viscosity reducing dripping resulting in a more rapid increase in the surface temperature. This will reduce the time to ignition. In some cases free radical initiators are added purely to promote dripping to remove the fuel from the source of heat.

Char formation—the formation of a char on the surface of the polymer will reduce the flow of heat to and fuel from the sample. Intumescent chars bubble up and provide a more effective barrier. However, in a typical fire test, the direction of swelling is often towards the heat source, increasing the radiant flux to the sample.

Orientation of sample—as flames rise, flame spread is easiest from below (going upwards) and hardest from above (going downwards). Because of flow of molten material and ultimately dripping, it is very difficult to correlate vertical burning behaviour with horizontal burning behaviour.

Absorption of radiation—radiation from flames or a radiant panel must be absorbed by the polymer. The presence of absorbing centres (conjugated double bonds, or black pigments) can increase the localisation of the heating. Conversely, a highly reflective surface can significantly lengthen the time to ignition in certain tests.

Smoke Formation—Smoke can act as both the source of radiation (a sooty yellow diffusion flame radiates much more than a blue premixed flame) or block radiation from the flame back to the polymer.

Char Formation

Classifying polymers by the structural units they contain has been used to calculate various flammability parameters and predict burning behaviour [195, 196]. The char-forming tendency (C_{FT}) of polymers may be estimated from the contributions from each structural group, referred to as "molar group contributions". Van Krevelen has taken the char-forming tendency of the individual structural units of polymers as an additive quantity, and based on this, the following relationship has been created:

$$\mathrm{CR} \approx \frac{\sum (C_{FT})_i}{\mathrm{M}} \times 1200 \qquad (7.50)$$

Where

$$\mathrm{CR} = \mathrm{Char\,Residue}\,(\%)$$
$$\mathrm{C_{FT}} = \mathrm{Char-Forming\,Tendency\,(no\,units)}$$
$$\mathrm{M} = \mathrm{Molecular\,Weight\,of\,repeat\,unit}\left(\mathrm{g\,mol^{-1}}\right)$$

Each structural group is assigned a value. This is known as the char-forming tendency (C_{FT}) shown in Table 7.15. Aliphatic groups are generally assigned a value of zero, although if they are connected to aromatic nuclei they can have negative values (Table 7.16). Char forming tendency cannot be calculated for polymers which contain halogenated species as their soot-forming tendencies would significantly affect the char formation.

The char-forming tendency is a statistical concept. For example the phenyl group has a C_{FT} value of 1 C equivalent, which means that on average only 1 in 6 phenyl groups in the polymer forms a char, where the other 5 contribute to tar and gas formation. If the benzene ring contains 4 non-hydrogen, non-aliphatic substituents, all the rings will contribute to the char.

Table 7.15 Molar group contributions for char formation

Example: Calculation of Char Forming Tendency (C_{FT})

Figure 7.54 shows the values assigned to the structural groups which make up the monomer unit in polyetheretherketone (PEEK) [197]:

These values are summarised in Table 7.17.

The C_{FT} of PEEK has been determined as 12 and therefore the char residue will amount to 144 g per structural unit of PEEK. The molecular weight of the PEEK monomer unit is 288.3 g mol^{-1}. These can be used to estimate the mass of the char residue (CR) to give:

$$CR \approx \frac{12}{288} \times 1200 = 50\%$$

The calculated char residue (CR) is 50 %. This is slightly greater than char yields determined by experimental methods which give values ranging from 41 % [198] to 47 % [199, 200].

Calculating Polymer Flammability from Molar Group Contributions

Recently, another useful method has been developed to calculate the heat release capacity (HRC) from additive molar group contributions. As a material flammability parameter [201–203] the

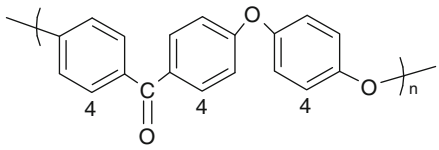

Fig. 7.54 PEEK assigned with structural group contributions for char

Table 7.17 Summary of structural group contributions and their char-forming tendencies

Chemical group	Value	N	C_{FT}
	4	3	12
	0	2	0
	0	1	0
		Total	12

HRC has been recognized as a tool for analysing fire response and flammability of polymers. A quantitative laboratory pyrolysis-combustion method for directly measuring the heat release capacity has been established [204–206], and experimental data are presented which indicate that HRC can be used to correlate polymer structure with fire behaviour.

The contribution of over 40 M groups has been correlated to HRC [207, 208] as shown in Table 7.18. The measured and estimated heat release capacities for over 80 polymers agree to within ±15 %, demonstrating a capability for prediction of polymer flammability from chemical structure.

Specific heat release rate is a molecular-level fire response parameter of a burning polymer. Lyon et al. determined the specific heat release rate using the MCC (section "Microscale Combustion Calorimetry"). Dividing the specific heat release rate (W g^{-1}) by the rate of temperature rise (K s^{-1}) gives a material fire parameter with the units (J g^{-1} K^{-1}) representing the HRC. They argue that the HRC is a true material property that is rooted in the chemical structure of the polymer, and is calculable from additive molar group contributions [199].

Example: Calculating Heat Release Capacity (HRC)

The calculation of heat release capacity is illustrated by example of molar group contributions for a diglycidylether of bisphenol-A (BPA epoxy) cured by anionic ring opening polymerization. The chemical structure of the repeat unit of the polymer is shown in Fig. 7.55.

The polymer repeat unit is comprised of six basic chemical groups, and the heat release capacity is calculated from the associated N_i, M_i, and ψ_i for these groups, which are listed in Table 7.19.

The molar heat release capacity (η_c) is obtained by summing the group contributions according to their mole fraction in the repeat unit, then dividing by the molar mass of the repeat unit to give the heat release capacity on a mass basis in units of J g^{-1} K^{-1}.

$$\eta_c = \frac{\Psi}{M} = \frac{\sum_i n_i \Psi_i}{\sum_i n_i M_i} = \frac{\sum_i N_i \Psi_i}{\sum_i N_i M_i}$$

$$= \frac{204.5\ kJ/mole - K}{340 g/mole} = 601\,\mathrm{J\,g^{-1}\,K^{-1}}$$

The predicted value of 601 J g^{-1} K^{-1} compares favourably with the measured value of 657 J g^{-1} K^{-1} for this polymer.

Conclusions

Polymeric materials fuel nearly all unwanted fires. All polymeric materials contain large molecular chains, giving them greater strength and resilience, than either small molecules or metallic structures. However, as almost all contain carbon and hydrogen they are easily oxidised and burn readily.

The diversity in the range of polymeric materials is huge and polymers may be classified in several ways: natural, biobased or synthetic; means of polymerization; thermoplastics or thermosets; molecular mass distribution; or physical properties. Each has impacts on their burning behaviour. Some polymers, such as polyamide 6, polyvinyl chloride and polyacrylonitrile differ

only in their average molecular mass, its distribution and any impurities arising from manufacture. Others such as polyethylene, differ as a result of the polymerization process, so free radical polymerised low-density polyethylene (LDPE) has the most branching points (or starting points for decomposition), catalytically polymerised linear low-density polyethylene (LLDPE) has a smaller number of identical branching points, and high density polyethylene (HDPE) has the least of branching points and hence the highest decomposition temperature. Many polymers, such as polyamides, polyesters, polyurethanes and epoxies represent diverse classes, having only the chemistry of the linkages (e.g. esters or urethanes) between repeat units in common.

Both the physics and chemistry of polymers affect their thermal decomposition and burning behaviour. Depending on their thermal history, most polymers exert a degree of crystallinity, increasing with the duration of cooling, giving a sharper transition between solid and liquid phases. The chemical composition of the molecular chains exerts a profound influence on the thermal decomposition of the polymers, with chain branching, double bonds, or oxygen in the polymer backbone reducing the thermal stability, and aromatic rings and crosslinking of the polymer backbone increasing the thermal stability.

Polymer decomposition can best be studied on a microscale by thermogravimetric analysis, which provides fundamental information about gaseous fuel production rates, quantified by the Arrhenius parameters A and E_a. Other techniques, such as DSC, DTA, DMTA, and rheology provide additional information on the physical transformations occurring, while evolved gas analysis, using FTIR or GCMS, or

oxygen depletion calorimetry, and char analysis, illuminate the chemical processes.

The thermal decomposition of polymers is thermodynamically driven, as higher temperatures favour the formation of gaseous molecules, and is controlled by a frequently complex array of competing kinetic processes. Attempts to identify individual reactions have generally failed, and there is a broad consensus that predicting the rate of fuel gasification will suffice as input to pyrolysis models, and fire models that include condensed phase processes.

The breakdown of individual polymers can follow up to four competing pathways: end chain scission (PMMA, PTFE, PS); random chain scission (PE, PP, PS, PA, polyisoprene etc.); chain-stripping (PVC, PAN, PVA, cellulose etc.); and char formation (PAN, PEEK, cellulose etc.), with a significant variation from individual polymers.

Fire retardants are added to our around a third of plastic materials in order to meet regulatory requirements. In general, these apply to high risk applications, such as construction products, upholstered furnishings, electrical and electronic goods, and materials for mass transport applications. There is considerable diversity in the different fire retardant mechanisms, from the gas phase flame inhibitors, using halogens or organophosphorus compounds, to condensed phase processes ranging from intumescents and char formation, to endothermic dehydration and formation of a refractory shield.

Fire behaviour may be quantified on a bench scale using ease of ignition tests such as the UL 94, or the much criticised limiting oxygen index, or using more sophisticated apparatus such as the cone calorimeter or microscale combustion calorimeter. The physical properties of polymers exert an influence on this process, with perhaps the greatest benefit being conferred by char formation, reducing the rate of thermal attack.

Dr Witkowski is a Lecturer at the University of Central Lancashire (UCLan), UK. His work focuses on thermal decomposition of solids and pyrolysis mechanisms, and numerical modelling.

Dr Stec is an Associate Professor in Fire Chemistry and Toxicity at UCLan. Her work focuses on quantification of combustion products and the factors affecting fire toxicity from bench- and largescale tests.

Prof Hull is a Professor of Chemistry and Fire Science at the University of Central Lancashire (UCLan). He obtained his PhD in 1987 in Fire Retardant Mechanisms from the University of Salford, UK. His current research interests include the development of fire retardant materials and the assessment of fire toxicity.

Structural Mechanics

8

Luke A. Bisby

Introduction

Structural mechanics, sometimes called 'solid mechanics' or 'mechanics of materials' is concerned with describing the behavior of structural members under loading, as occurs in all buildings and other structures due to the effects of gravity and other forces (e.g. wind, earthquake, etc.). A detailed understanding of structural mechanics is essential for anyone seeking to perform structural fire engineering analysis or design.

It is not possible within this brief chapter to provide a complete treatment of the topic; however when reviewed in conjunction with Chap. 9 of this handbook, the current chapter provides a basic description of structural mechanics as is required for an initial understanding of the means by which structural stability, and to a certain extent integrity, against fire spread and insulation during fire, are engineered through careful selection and design of building materials.

Philosophy of Structural Design

Structural design is both a creative art and a science, and structural engineers may use considerable creativity in determining the load bearing system for a particular building. In general, the process of structural design under normal (ambient) temperature conditions takes little (if any) explicit account of the possible effects of fire; it typically consists of the following steps:

1. The architect and the engineer establish the aesthetic, general structural layout, and functional requirements for the building.
2. The overall structural framing system and building materials are selected and a structural concept is proposed, based on the competing interests of architectural, functional, economic, and sustainability considerations. At this stage only approximate sizes of structural elements are known.
3. The likely loads which will act on the structure are estimated in accordance with structural engineering principles (discussed below), with due consideration given to all possible loads and their likelihood of acting (on their own or in combination with other loads).
4. A structural analysis is performed to determine the *load path* by which all loads are transferred through the structure from the location where they act and into the structure's foundations. The internal forces and stresses acting within the various structural elements are subsequently determined.
5. The likely *stresses* and *forces* acting in each structural element (the design *loads*) are checked against the capacities of the respective structural elements (the design *resistances*) to ensure that the structural elements have sufficient strength and stiffness to (a) resist the applied loads without collapse

(called *ultimate design* considerations), and (b) provide a suitable level of in-service performance of the structure (called *serviceability* considerations; for instance deflections, vibrations, durability, etc.).

6. Steps 3–5 are repeated as necessary, until the structural elements satisfy both ultimate and serviceability design requirements and the building is deemed to satisfactorily achieve the functional requirements set out in the early stages of the design process.

It is clear from the above steps that the structural design process fundamentally involves a comparison between the *loads* acting on and within the structure, and the *resistances* or capacities of the structural elements from which the structure is made. This chapter focuses on how a structural element's resistance to load can be determined using basic structural mechanics; however a description of the means by which the loads acting on a structure are typically estimated by structural engineers is instructive and is briefly treated first.

Structural Design at Ambient Temperature

To understand the goals of structural fire engineering and the means by which these goals are met during design it is first necessary to understand the general framework through which structures are designed to resist the full suite of potential loads to which they might be subjected during their lifetime, as well as the probabilistic basis of this framework which is intended to provide a suitably low probability of failure.

Loads and Load Combinations

Throughout a structure's lifetime it will be subjected to a wide variety of loads. During the structural design process it is essential that all credible loading scenarios be considered and addressed. Loads to be used in structural design are typically specified in design *codes*, which provide empirically determined and statistically characterized worst case credible loads to be assumed in the particular jurisdiction in which the design code is in force. The most common loads for which typical structures are designed are given below.

1. *Dead Loads*: These are loads which are always present, and include the self weight of the structure as well as loads arising from permanent fixtures and equipment. Dead loads may include the weight of floor coverings, walls, doors, suspended ceilings, etc., and are usually estimated based on the dimensions and construction materials of the trial structure under analysis.
2. *Live Loads*: Sometimes called *Imposed Loads*, these are typically specified by design codes on the basis of data obtained from surveys of real buildings and account for the weight of people and moveable fixtures and equipment. It is important to recognize that live loads are likely to be variable throughout the life of a structure, and thus the specified values of live loads given in codes may be considerably higher than those which are actually experienced on a day-to-day basis.
3. *Snow Loads*: As the name implies, these are loads due to the weight of snow and ice which can accumulate on structures in cold climates. Snow loads are estimated based on geographic and climatic data which has been collected and calibrated over many decades. In some design codes loads due to snow may be treated as live loads.
4. *Wind Loads*: Wind loads may cause lateral forces which act on the vertical surfaces of a building, but may also cause uplift on horizontal surfaces such as roofs and slabs. Wind loads are highly variable and again are treated in design codes using empirical correlations based on geography, topography, and the form of the building. Wind loads are particularly important during the design of tall buildings, for which lateral load resistance often governs the design of the overall structural system. Modern tall building design typically includes complex wind tunnel tests to determine the possible distributions of wind pressures over the building's surface given its

geometry and the surrounding climate and topography.

5. *Seismic Loads*: In many parts of the world, loads arising form both vertical and horizontal ground acceleration during earthquake must be considered during design. Design earthquake loads are given in design codes and account for geography, probability and magnitude of possible earthquakes, soil conditions, etc. It is worth noting that the statistical likelihood of a fire and earthquake occurring simultaneously is very low.

It is clear that there is uncertainty associated with the likely magnitude of each of the different loads, and also with the likelihood that each of the loads might be acting at its full (or some lesser) value at any given point in time during the life of a structure. For instance, the self weight of a structure, once designed, is reasonably well known and can be assumed to always be acting, whereas the weight of the people in a structure has large variability and may not ever be known with any degree of certainty either spatially or temporally. Furthermore, it is highly unlikely that all of the noted loads will be acting at their full value at any given time (i.e. the chances are low that a building will be completely full of people, in the middle of winter, with the wind blowing a gale, and during an earthquake).

Most modern building codes deal with the uncertainty around loading using a series of *load combinations* which seek to statistically account for the variability in magnitude and occurrence of the respective loads when acting in combination. These load combinations help engineers to decide which combinations of loads they must consider in designing a structure; any given structure may need to be checked under a variety of potential load combinations to determine the worst possible case which must be used in designing the individual structural elements.

As an illustrative example, some of the loading combinations required by The American Society of Civil Engineers' *Minimum Design Loads for Buildings and Other Structures* (ASCE-7-05) [1], assuming that only those loads noted previously might be acting, include:

$$\begin{gathered} 1.4D \\ 1.2D + 1.6L + 0.5S \\ 1.2D + 1.6S + (L \text{ or } 0.8W) \\ 1.2D + 1.6W + L + 0.5S \\ 1.2D + E + L + 0.2S \end{gathered} \tag{8.1}$$

and so on, where:
D = dead load;
L = live load;
S = snow load;
W = wind load; and
E = earthquake load.

The various load combinations are based on the philosophy that, under any given set of circumstances, the worst case loads on a structure will be described by one of these combinations of loads—with a selected level of statistical confidence as described in the following sections.

Working Stress Design

Once the worst case load acting on a structural element at any given instant is determined using the procedures described above, the structural engineer must assess whether or not the performance of the candidate structural element design is satisfactory under that load. There are a number of means by which this can be accomplished so as to ensure a reasonable level of confidence that the design will not fail. Most modern structural design codes use a procedure which is called *Load and Resistance Factor Design (LRFD)*, or in some codes *Limit States Design* (described in detail in the next section). However, some older codes still use an approach called *Working Stress* or *Allowable Stress Design*.

It is important to recognize that all building materials have their own distinct response under loading (refer to Chap. 9), and that this specific response under loading profoundly influences

their ability to resist deformation and eventual failure. The key parameters of interest are a material's strength (usually described in terms of its failure *stress*) and its resistance to deformation (usually referred to as its *stiffness*). Strength and stiffness are described in the following sections, but it should be noted that there are differing amounts of uncertainty associated with both of these properties—for all building materials. For instance, timber, which is a naturally occurring material with associated defects, has a relatively high level uncertainty associated with its mechanical properties, since these depend on numerous factors including the species of tree, the climate in which the tree was grown, the grade of lumber, the in-service humidity condition, etc., whereas structural steel has relatively little uncertainty since it is manufactured under well controlled factory conditions and is relatively insensitive to humidity, etc. LRFD and Working Stress design provide alternative means by which this variability and uncertainty in material response to loading can be accounted for during design.

In Working Stress Design, the loads expected to be acting on the structure during service are compared against the permissible stress levels which are considered safe for the structural elements under long term loads. The loads to be considered in Working Stress design are determined based on guidance given in building codes, and are intended to represent a conservative estimate of the most likely in-service loading on the structure. The analysis of the structure is subsequently performed under these loads, and the stresses in the structural elements are calculated (using principles presented later). The resulting stresses are compared against the allowable stresses for the materials in question; these are also specified in building codes.

Working stress design loads and allowable stresses have been calibrated over time to provide safe designs by implicitly building a relatively large safety factor into the allowable stress values specified in codes. These methods have now fallen out of favour in most jurisdictions, and all modern building codes are moving towards a Limit States design approach.

Limit States Design

Limit States Design is now the preferred method of design in most national building codes, largely because it (1) removes some of the unnecessary conservatism which is inherent in Working Stress Design and (2) attempts to rationally assess and account for the statistical variability of both the loads acting on a structure and the resistance of the structural elements, including variability associated with material response. Limit States Design accomplishes this by applying reliability concepts to both loads and resistances such that a consistent level of safety or *safety index* is achieved for all designs.

As the name implies, Limit States Design uses a variety of so-called 'limit states' which represent the functional requirements for a structure. *Ultimate Limit States* (ULS) are those associated with structural failure or collapse, and are addressed by checking the capacity of the structural element, with material and member strengths artificially (statistically) *reduced* to account for known variability in material properties, errors and uncertainties in construction, etc., against the credible worst case loads which might act on the structure. The most likely (mean) loads are artificially *increased* to account for their spatial and temporal variability. *Serviceability Limit States* (SLS) are those associated with the in-service performance of the structure and are checked against the loads assumed to be acting in service. Since serviceability limit states are not associated with life safety, the service loads need not be unduly increased during design.

The design checks which are made in Limit States Design can be expressed in general as:

$$\alpha E \leq \phi R \tag{8.2}$$

where:

E = the specified effect of loads acting on the structure;

α = load factors applied to the specified loads which take into account the variability of the load and load patterns and, to some extent, inaccuracy in the structural analysis;

R = the calculated resistance of a member based on specified material properties and cross-sectional dimensions; and

ϕ = the resistance factor applied to the calculated resistance or to specified properties and dimensions, workmanship, type of failure (e.g. brittle versus ductile) and uncertainty in the prediction of resistance.

Serviceability Limit States

For the serviceability limit states, the factored resistance on the right side of Equation 8.1 is replaced with a serviceability criterion such as an allowable deflection, acceleration, etc. The load factors, α, are assigned different values, as described for example in ASCE-7-05 (ASCE 2005); typically close to or less than 1.0.

Material or Member Resistance Factors

As indicated in the definitions of ϕ and R, for ultimate strength design the resistance, R, is scaled by a resistance factor, ϕ, which is typically less than 1.0 to reflect the probability that the full theoretical value of R may not be achieved at all times (i.e., in some cases the structural members and materials may not be as strong as we calculate them to be based on nominal material properties, dimensions, tolerances, and construction qualities). This results from a statistical consideration of the likely ability of a structural member to resist load. In some jurisdictions these resistance factors are applied to structural elements of different types based on the member type (e.g. beam, column, wall, etc.) and materials of construction (e.g. steel, concrete, timber, etc.). Values may vary between about 0.60 and about 0.95. In other jurisdictions resistance factors may be applied to materials rather than to structural elements. Values of resistance factors for structural materials also vary depending on the particular building code and jurisdiction. For structural steel, the value of ϕ is typically in the range of 0.85–0.95. Interestingly, for connections (i.e., bolts, welds, etc.) build from steel, the resistance factor is typically reduced somewhat to ensure that member failure occurs before connection failure; this is preferred because connection failures can occur with little warning whereas member failures generally give some warning prior to failure. Concrete tends to have lower specified material resistance factors in the range of 0.60–0.65 to reflect its higher variability; designers and codes are statistically less confident of its nominal strength.

Safety Index

In Limit States Design, the values of both the load factors, α, and the material or member resistance factors, ϕ, in a given building code have been calibrated to provide the desired level of safety (or rather to give an acceptable probability of failure). This is generally accomplished using the concept of a *safety index, β*.

In reality, both E and R in Equation 8.1 are random statistical variables with an associated probability distribution about a mean value. This is shown schematically in Fig. 8.1, where the probability that either the load, E, or the resistance, R, take on given values is plotted. Clearly, the mean resistance must be greater than the mean load effect to prevent failure; however, because both load and resistance are probabilistic in nature there is always a small chance of failure (occurring when then resistance is less than the applied load). The probability of failure is represented by the shaded overlapping area in Fig. 8.1.

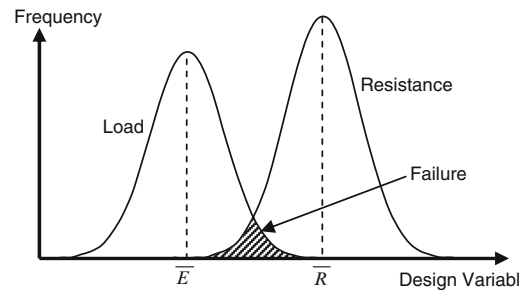

Fig. 8.1 Probabilistic nature of load effect, E, and structural resistance, R

It is clear that the probability of failure can be reduced by artificially increasing the true (nominal) resistance, R, of a structure by imposing smaller values of ϕ (i.e. by shifting the R-curve to the right in Fig. 8.1) or by artificially decreasing the true loads by imposing larger values of α (i.e. by shifting the E-curve to the left). The target *safety index*, β, allows building code developers to determine what these values should be based on known (or approximated) probability distributions for both the loads and the material or member resistances.

Since failure will occur if $R < E$, the probability of failure can be represented by the distribution of $Z = R - E$. This is shown schematically in Fig. 8.2, where failure is again represented by the shaded region. This failure probability distribution also has a mean value and an associated standard deviation. The goal of Limit States Design is to ensure that the mean value is sufficiently above zero.

As shown in Fig. 8.2, the Safety Index is simply the number of standard deviations that the mean value of the Z curve is greater than zero. In most international codes this value is set between 2 and 3. The safety Index can be quantified, provided that the mean and standard deviations of the load and resistance distributions are known, using:

$$\beta = \frac{\overline{Z}}{\sigma_z} = \frac{\overline{R} - \overline{E}}{\sqrt{\sigma_R{}^2 + \sigma_E{}^2}} \tag{8.3}$$

Clearly, to be able to quantify the safety index, it is necessary to have good statistical data for both the applied loads on a structural member and its resistance; in many cases these data are not very well known—particularly during fire.

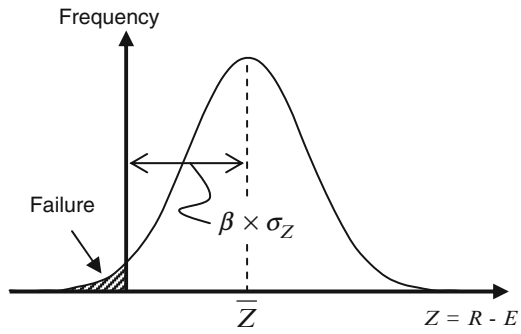

Fig. 8.2 Probabilistic nature of $Z = R–E$, and definition of the Safety Index, β

Structural Design Under Fire Conditions

Structural design for fire conditions generally follows the same approach as for structural design under ambient conditions, however because a severe fire in most buildings is a statistically 'rare' event, the load and resistance factors specified in building codes for the fire limit state change to reflect this fact.

Philosophy and Goals

The design equation during fire is similar to Equation 8.2, and can be expressed in general as:

$$\alpha_\theta E_\theta \leq \phi_\theta R_\theta \tag{8.4}$$

where the subscript θ is added to denote the effects of elevated temperature. Elevated temperature may have an effect on each of the terms in Equation 8.4. For instance:

E_θ = the specified effect of loads acting on the structure at elevated temperature. It should be noted that thermal expansion of structural elements may introduce new loads into the structure due to restraint to thermal expansion, and these should be considered;

α_θ = load factors applied to the specified loads for the elevated temperature condition. These are typically reduced as compared with the ambient temperature values to reflect the most likely load condition at the time of a fire (service loading condition). Typical load combinations for fire are given later in this chapter;

R_θ = the calculated resistance of a member at elevated temperature, based on material properties (and in some cases reduced cross-sectional dimensions) which have been reduced due to the damaging effects of heating. The resistance of a structural element will reduce during the course of a fire as it heats up; and

ϕ_θ = the resistance factor applied to the calculated resistance or to specified properties and dimensions, workmanship, type of failure, and uncertainty in the prediction of resistance at high temperature. These factors are typically set to 1.0 such that the nominal member or material strength at elevated temperature is used in calculations.

It is also important to recognize that structural design for fire typically considers three distinct modes of failure which must be prevented when satisfying Equation 8.4. Recognizing that ensuring that fire does not spread beyond the compartment of origin for the requisite period of time is a fundamental goal of fire safety engineering, these failure modes are:

1. loss of load bearing capacity (i.e. structural collapse);
2. passage of flame or hot gas through a building element (e.g. wall or floor), which would represent a breach of fire compartmentation; and
3. excessive temperature rise at the exposed face of the structural element, which may also represent a breach of fire compartmentation.

Structural Fire Design Loads and Load Combinations

Load combinations for use in Limit States Design for ultimate capacity at ambient conditions were given previously. In the case of structural fire analysis, the load combinations are altered to reflect the statistical unlikelihood of a severe fire occurring in the first place, as well as the fact that the actual likely loads acting on a structure on a day-to-day basis are typically much less than those used for ultimate strength design. Various countries apply slightly different load combinations for fire. As one example, ASCE-7-05 [1] suggests the following load combination for fire:

$$1.2D + A_k + (0.5L \text{ or } 0.25) \tag{8.5}$$

It should be noted that other codes may also include the effects of snow and wind loads during fire, however again at reduced levels as compared with ambient temperature design. The most important outcome of assuming these reduced loads during fire is the realization that, und er day-to-day conditions which are typically used to assess structural performance in fire, most structures are subjected to loads of 50 % or less of their ultimate design capacities [2].

It should be noted that the value of the load or load effect resulting from the extraordinary event (fire) should be included and is denoted by A_k in Equation 8.5.

Structural Mechanics

Thus far, this chapter has concerned itself with the method that structural engineers use to quantify the likelihood of failure of, and hence design, structural members under the influence of the various combinations of loads to which they might be subjected. Structural mechanics is the branch of physics which allows structural engineers to determine the strength, or load bearing capacity, and deformation of structural elements of various types (e.g. beams, columns, slabs) under load. To provide a basic overview of the procedures used, the following sections give a brief summary of the necessary concepts; the steps in any analysis typically include:

1. Calculation of external reaction (support) forces;
2. Determination of internal forces (axial, bending, shear, and torsion); and
3. Prediction of failure modes depending on the materials of construction, the geometry, the support conditions, and the loads.

Statics

With the previous issues in mind, we now move to a discussion of the physics which are used to evaluate the capacities of various types of structural elements. The first of these topics is *statics*. Statics provides the means by which both the *external reactions* and *internal forces* within a structural element can be determined. If a structure is in *equilibrium* (i.e. it is not moving but 'static') then the algebraic sum of all of the *forces*

and *moments* acting on that structure is equal to zero. Otherwise the structure would be accelerating.

Static Equilibrium and Reaction Forces

The first step in the analysis of structural element under load is the determination of its support reactions. For simple two-dimensional (i.e. planar) structures, static equilibrium can be applied using an orthogonal coordinate system, such that the algebraic sum of the forces in the x (horizontal) and y (vertical) directions must be zero, and also the sum of the moments acting on the structure must be zero. These equations can be expressed as follows:

$$\sum F_x = 0, \quad \sum F_y = 0, \quad \sum M_z = 0 \qquad (8.6)$$

In reality structures are three-dimensional, and in this case there would be six equations governing static equilibrium; three translations along x, y and z-axes and moments about all three axes. As is typical in elementary structural mechanics this chapter considers only planar structures for simplicity.

To illustrate the use of these equations consider the planar beam structure shown in Fig. 8.3; this is similar to the example structure used in the previous edition of this handbook [3, 4]. The structure is a solid beam of constant cross-sectional area and materials of construction along its length. The beam is supported on an idealized pin support at Location B and an idealized roller support at Location C. It is loaded by a diagonal tension force at Location A, as well as a distributed load of varying magnitude along its length.

Figure 8.3b shows a free body diagram of the beam, where the supports have been replaced by the unknown reaction forces which they would generate (in the directions in which they *prevent* motion). Note that there are three unknown reaction forces in this case, and since three equations of equilibrium are available in two dimensions, the unknowns can be determined. Such structures are referred to as *statically determinate*. The equations are applied as follows (with units of kN and m):

$$\sum F_y = 0: \quad -6 + R_{By} + R_{Cy} - 1(24) - 2(18)/2 = 0$$

$$\sum M_z = 0: \quad -6(6) + 1(24)(6) - R_{Cy}(18) + 2(18)(9)/2 = 0$$

$$\therefore R_{Cy} = 18, \; R_{By} = 30$$

Note that if this structure had one or more additional supports there would not have been sufficient equilibrium equations to solve for all of the unknown reactions, and the structure would have been referred to as *statically indeterminate*. Unknown support reactions for statically indeterminate structures can only be obtained by considering compatibility of their deformation under load in addition to equilibrium; such methods are beyond the scope of this introductory discussion.

Internal Forces

Once the support reactions for a statically determinate structure are known the internal forces can be determined at any desired location. Again, for a two-dimensional planar structure there are three internal forces which must be considered: Axial force, $N(x)$, shear force, $V(x)$, and moment, $M(x)$. The internal forces are found by taking a section through the structure, which leads to the development of three unknown internal forces. Again the three equations of equilibrium can be applied to solve for the unknowns.

As an example, for the two-dimensional planar structure shown in Fig. 8.3c, the internal forces at any location between B and C can be determined from the following equilibrium equations (again with units of kN and m):

$$\sum F_x = 0: \quad -8 + 8 + N = 0 \rightarrow \quad N = 0$$

$$\sum F_y = 0: \quad -6 - 1(6 + x) + 30 - (2x/18)(x)/2 + V = 0$$
$$\therefore V(x) = -x^2/18 - x + 18$$

$$\sum M_z = 0: \quad M + 6(6 + x) + 1(6 + x)(6 + x)/2 - 30(x) + (2x/18)(x)(x/3)/2 = 0$$
$$\therefore M(x) = -x^3/3 - x^2/2 + 18x - 54$$

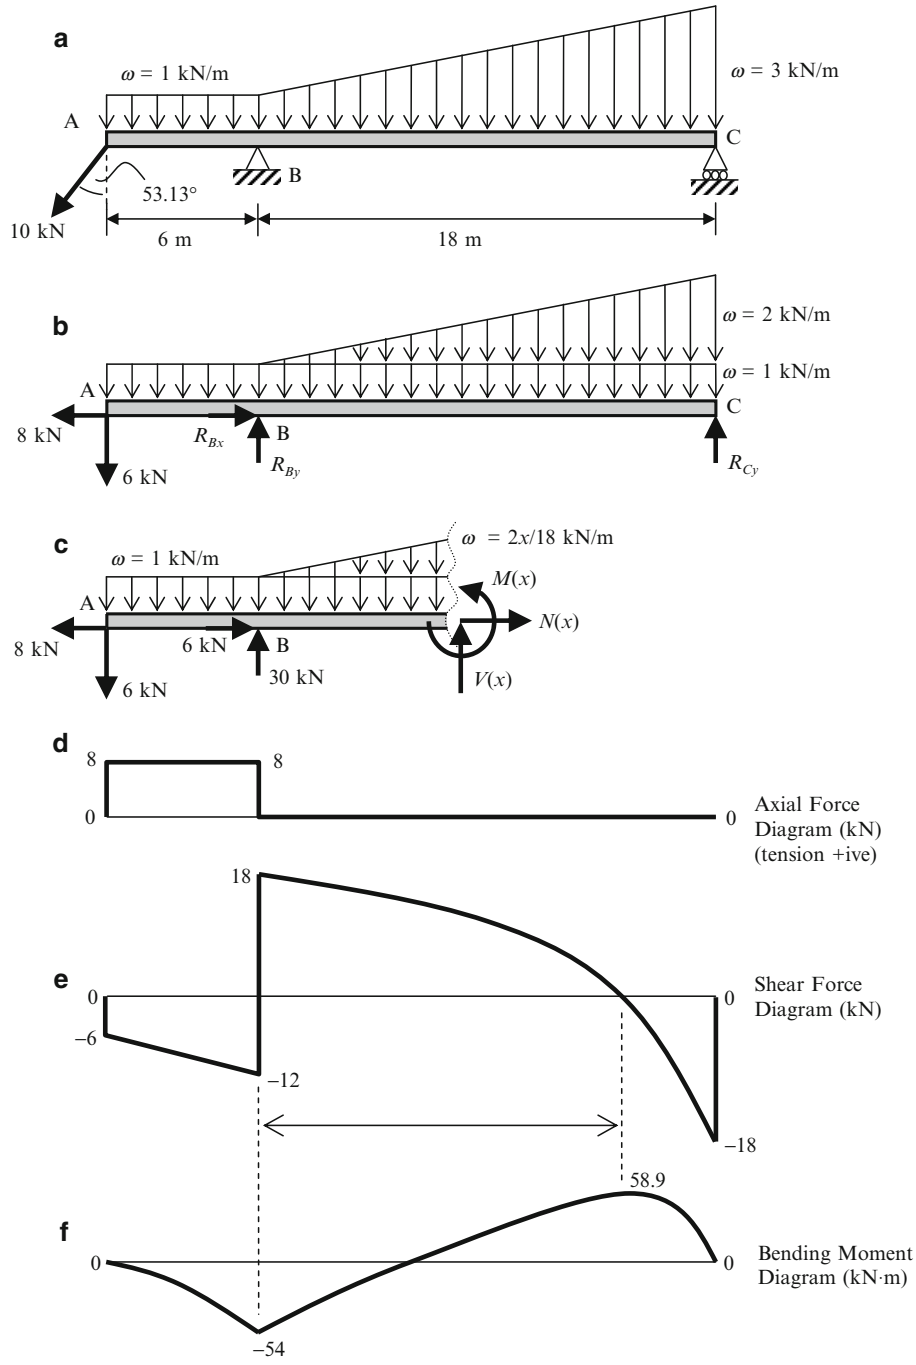

Fig. 8.3 (**a**) Example structure, (**b**) free body diagram, (**c**) section to the left of location x, (**d**) axial force diagram, (**e**) shear force diagram, and (**f**) bending moment diagram

By taking sections at successive locations along the length of the beam and calculating the internal forces it is possible to develop diagrams which plot the variation of the respective internal forces along the length of the structure; these are called the axial force, shear force, and bending moment diagrams, respectively, and are shown in Fig. 8.3d–f for the structure in question.

Strength of Simple Structural Elements

Once the internal forces within a structural element are known using the principles briefly presented above (or using more advanced techniques for statically indeterminate structures) the effects of these forces must be determined so as to check the capacity of the structural element in question against the loading demand. To do this the likely failure mode for the structural element must be determined.

There are a variety of failure modes which must be considered, depending on the type of structural element (i.e. beam, column, etc.) and the material from which it is constructed (some materials are more prone to certain types of failures than other materials). The most important failure modes in buildings are typically tension failure, compression failure, and bending failure. For some structures or structural elements under certain conditions shear failure may also be important; however shear is not treated in this introductory discussion.

Tension Members (Cables and Ties)

Tension members are much less common in buildings that compression elements (columns) or flexural (bending) elements (beams and slabs), however tension members are the simplest structural element because their failure mode can be described in relatively simple terms. Tension elements in real buildings include diagonal bracing, cable-supports and ties, and hangar bars.

Consider a cylindrical steel bar of a given material and length L and cross-sectional area A which is subjected to a tensile axial load, P, in the direction of its longitudinal axis (Fig. 8.4). Using the principles of the preceding section, if the bar is sectioned at any internal location, a tension force, P, will be acting internally (Fig. 8.5).

The force is tensile as it acts to elongate the bar. The average tensile *stress* in the bar, which is a measure of the intensity of force in a material, can be determined from:

$$\sigma = \frac{P}{A} \tag{8.7}$$

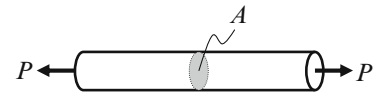

Fig. 8.4 Tensile loading of cylindrical bar of cross-sectional area, A

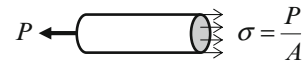

Fig. 8.5 Determination of average axial stress, σ, of cylindrical bar of cross-sectional area, A, under tensile load, P

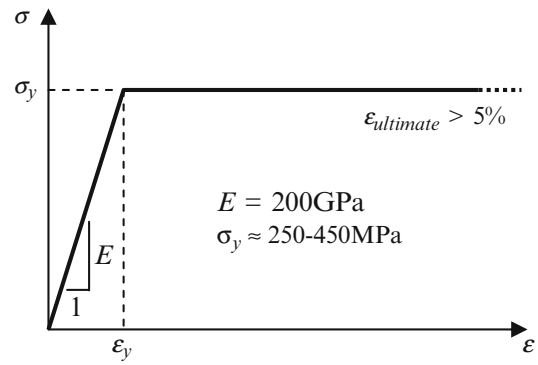

Fig. 8.6 Idealized axial stress, σ, versus axial strain, ε, for typical structural steel

This shows that stress in the bar is proportional to the internal force and is given in units of force per unit area (in this case N/mm^2 or MPa). Using *Hooke's Law* the strain, ε, and hence elongation, δ, of the bar can be determined from the following expressions (within the *linear-elastic* range of material response) from:

$$\begin{aligned} \sigma &= \varepsilon E \\ \varepsilon &= \frac{\delta}{L} \end{aligned} \tag{8.8}$$

In the above expressions, E is the modulus of elasticity of the material from which the bar is made (a material characteristic, see below and Fig. 8.6), and the strain, ε, represents the intensity of deformation.

To determine if the bar will fail under this load (and hence stress) the stress versus strain response of the material from which the bar is

made must be known. As an example, for structural steel a typical idealized plot of stress versus strain is given in Fig. 8.6. Note that in practice this curve would be determined experimentally.

Figure 8.6 shows that the loading response of steel is characterized by a linear increase in stress with increasing strain, with slope E providing the definition of Hooke's Law used previously, up to a given stress, σ_y, which is called the *yield stress*. Beyond the yield stress the strain increases linearly with no further increase in stress. Hence, the steel can be assumed to fail in tension when it reaches its yield stress, and its load carrying capacity (resistance), R, can be easily determined under this condition from:

$$R = \sigma_y A \tag{8.9}$$

Calculation of tensile strength at elevated temperature can be performed in a similar manner provided that the temperature of the structural element and the effect of this temperature on the stress versus strain response of the material are known. Chapter 9 provides information on the probable reductions in mechanical properties of various structural materials at elevated temperature.

For the purposes of illustration, if it is assumed that the yield strength of steel is reduced from σ_y at ambient temperature to $\sigma_{y\theta}$ at elevated temperature, then the tensile strength at elevated temperature, R_θ, can be determined from:

$$R_\theta = \sigma_{y\theta} A_\theta \tag{8.10}$$

It should be noted that the cross-sectional area at elevated temperature, A_θ, may also be reduced in applying Equation 8.10 to reflect a reduction in cross-sectional area due to heating, as would occur for example due to charring of wood for timber elements in fire.

It must be recognized that all structural materials display distinct differences in mechanical response to loading and widely varying strength and stiffness. For example, a typical stress versus strain response for 'normal' strength concrete is shown in Fig. 8.7, where drastic differences in both the qualitative and quantitative aspects as compared with steel are obvious.

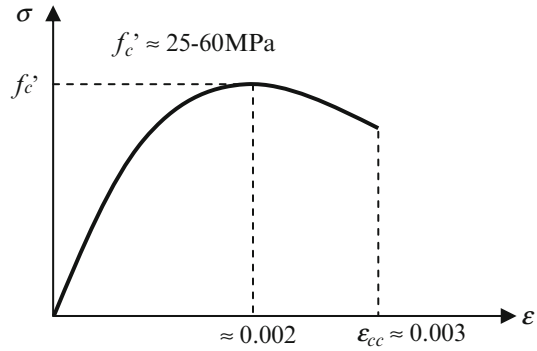

Fig. 8.7 Idealized axial stress, σ, versus axial strain, ε, for typical 'normal' strength concrete

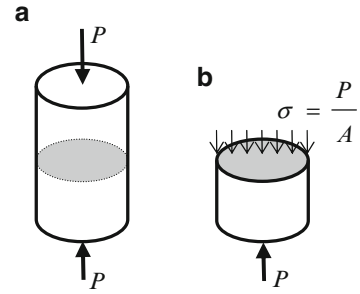

Fig. 8.8 (**a**) Compressive loading of short (stocky) cylindrical bar of cross-sectional area, A, and (**b**) determination of average axial stress, σ

Compression Members (Columns and Struts)

Compression elements are common in buildings and include columns and struts. The strength of these elements can be determined in a similar manner as for tension elements, with the exception that compression elements may also be susceptible to *buckling* failure.

Consider the short, stocky compression element shown in Fig. 8.8. As for the tension element discussed previously, the column has height L, cross-sectional area A, and is subjected to an axial load P (in this case compressive).

Provided that the element is not prone to buckling failure, its compressive (crushing) strength at ambient or elevated temperature can be approximated using Equations 8.9 and 8.10, respectively. However, in reality all compression elements in buildings are susceptible to buckling

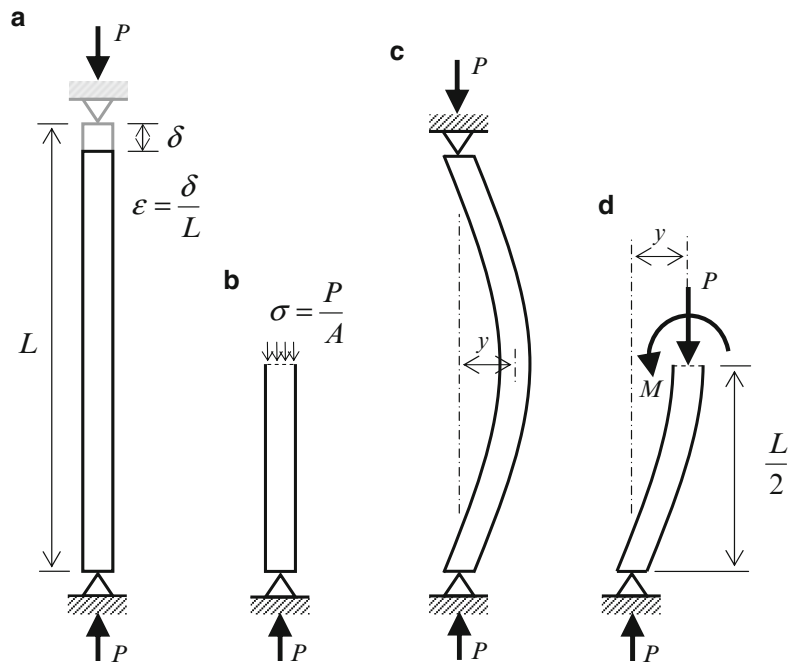

Fig. 8.9 (**a**) Compressive loading of long (slender) bar of cross-sectional area, A, (**b**) determination of average axial stress, σ, of the bar under compressive load, P, (**c**) buckling failure of the bar under load, P, and (**d**) equilibrium of half the bar under buckling failure

failure and to the combined effect of axial load and the inevitable bending which also occurs; failure by buckling must therefore also be checked.

To illustrate the alternative compressive failure mode by buckling, Fig. 8.9 shows a vertical column of height L, cross-sectional area A, and applied load P. The column is assumed to be pin-supported at both ends, such that there is no rotational restraint of its extremities (note that this is not the case for most real columns in buildings). When the load is applied to the column (Fig. 8.9a) the column experiences an axial compressive stress of σ (Fig. 8.9b), and the column's length will reduce by an amount δ (Fig. 8.9a). However, because in reality it is impossible to apply a perfectly concentric compressive load, and because all structural elements contain small imperfections and irregularities, the column will inevitably also experience a small amount of bending (Fig. 8.9c); the result is a lateral deflection, y.

Figure 8.9d shows the bottom half of the column when it is sectioned at its mid-height. If we consider the section's equilibrium under this condition, taking moments at the section the following moment equilibrium equation is obtained:

$$\sum M_z = 0: \quad M - Py = 0 \rightarrow \quad M = Py \tag{8.11}$$

The elastic deformation of an element in bending can be described by the following equation:

$$\frac{M}{EI} = \frac{d^2y}{dx^2} \tag{8.12}$$

where y is the displacement perpendicular to the axis of the element, x is the distance along the element, and M is the internal moment which is acting at the section. I is the *moment of inertia* of the element and is a measure of its resistance to flexural deformation. The moment of inertia it is a function of the element's cross-sectional geometry and can be considered as a flexural analogue of area, A, for calculating tensile strength.

Substituting Equation 8.12 into Equation 8.11 and rearranging gives:

$$\frac{d^2y}{dx^2} - \frac{P}{EI}y = 0 \tag{8.13}$$

This is a second order differential equation which has the following solution:

$$v = C_1 \sin\left(\sqrt{\frac{P}{EI}}x\right) + C_2 \cos\left(\sqrt{\frac{P}{EI}}x\right) \tag{8.14}$$

If the ends of the column are pinned (as in this case), then Equation 8.14 is only satisfied when:

$$\sin\left(\sqrt{\frac{P}{EI}}L\right) = 0 \quad \text{or} \quad \sqrt{\frac{P}{EI}}L = n\pi \tag{8.15}$$

Rearranging for P, the critical buckling load, $P_{critical}$, is obtained; this is the theoretical load which will cause global buckling failure:

$$R = P_{critical} = \frac{n^2\pi^2 EI}{L^2} \quad \text{where :} \quad n = 1, 2, 3\ldots \tag{8.16}$$

It is clear that the lowest value of $P_{critical}$ will govern and that this occurs for $n = 1$. Whilst this equation is only valid for linear elastic materials, as it depends on the assumptions of elastic beam theory (i.e. Equation 8.12), it is instructive for studying the propensity of elements to buckling failure under compressive loads.

An interesting feature of Equation 8.16 is that it shows buckling strength to be proportional to the inverse of the square of the buckling length. Thus, if the length of a column is doubled then its buckling strength decreases by a factor of four, and so on. This can be important for the response of columns in fire in cases where lateral support from beams and slabs is removed by heating of the floorplate.

The preceding section has given two means of calculating the strength of a structural element subjected to compressive axial load. Figure 8.10 plots these two methods versus column length. For very short columns, the crushing strength given by Equation 8.9 will govern, whereas for slender columns buckling (Equation 8.16) will govern. In reality, the transition between the two failure modes is more gradual due to column imperfections and inadvertent load eccentricities, and for intermediate column lengths a combined buckling crushing failure mode will be observed in reality. Building codes contain structural

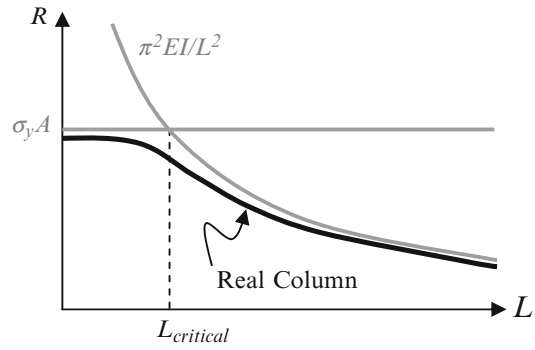

Fig. 8.10 Column compressive strength versus buckling length

design procedures which have been calibrated to take account of the necessary factors.

Calculation of compressive strength at elevated temperature is similar to at ambient temperature, however several additional important considerations are required; these are that:

1. the strength of materials is reduced at elevated temperature, such that the crushing strength will be less than at ambient temperature (see Chap. 9), according to Equation 8.10;
2. the stiffness (i.e. elastic modulus, E) is reduced at elevated temperature (possibly more or less severely than the material's strength), thus reducing the critical buckling load, $P_{critical}$ to:

$$R_\theta = P_{critical,\ \theta} = \frac{n^2\pi^2 E_\theta I_\theta}{{L_\theta}^2} \quad \text{where :} \quad n = 1, 2, 3; \tag{8.17}$$

3. the effective size of the column's cross section may be reduced, thus reducing the moment of inertia of the section from I to I_θ;
4. local increases in temperature may result in additional loads and moments due to interactions with the rest of the structure during fire; for instance thermal restraint to expansion of columns by the cool surrounding structure can increase the compressive loads on a column by 20–30 % in some cases; and
5. thermal expansion of the floorplate may result in lateral forces and displacements being imposed on columns, resulting in unexpected shear forces and so-called second-order bending moments.

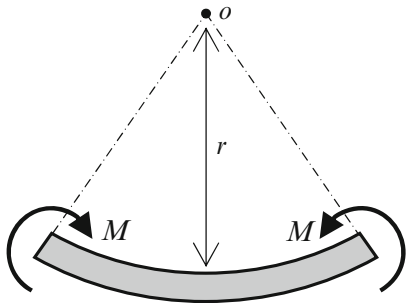

Fig. 8.11 Segment of a beam in bending

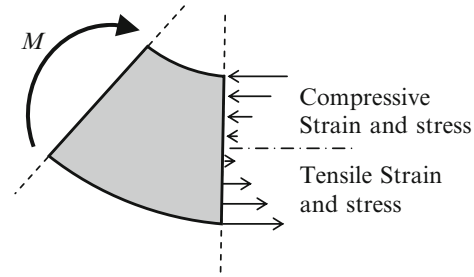

Fig. 8.12 Segment of a beam in bending

Flexural Elements (Joists, Beams and Girders)

Flexural elements in buildings are those which resist the applied loads primarily by bending; these include joists, beams, girders, and slabs. The variation of internal moment in a structural element under a set of loads, E, can be determined using the techniques discussed previously with reference to Fig. 8.3. The resistance of an element to bending, R, must be determined using structural mechanics.

When a structural element is subjected to bending it experiences *curvature*. This is shown in Fig. 8.11, where a short segment of beam is subjected to a moment couple (i.e. an internal bending moment) which causes the segment to bend in a concave-up direction. Lines which were previously vertical drawn on the side of the beam would now both point towards a distant origin called the *center of curvature* (denoted by O in Fig. 8.11). The distance to the center of curvature is called the *radius of curvature*, r.

This concave up condition is typically referred to as a positive or sagging moment. When an internal moment causes bending in a concave down direction it is referred to as a negative or hogging moment.

When the segment is subjected to a sagging moment, material at the top of the beam's cross section is compressed whereas material at the bottom of the beam is elongated, as shown in Fig. 8.12.

At one specific location on the beam's cross section it is neither being compressed nor stretched; this location is called the *neutral plane*, and occurs at the mid-height for sections which are symmetric about a horizontal axis of bending (such as the I-shaped cross section shown in Fig. 8.13).

If it is assumed that the beam is homogenous and fabricated from a linear elastic material (a helpful simplification for illustrative purposes), the distribution of strains over the cross section is linear as shown in Fig. 8.13. Applying Hooke's Law the stress distribution over the cross section is therefore also linear, with maximum compressive stress at the top fibre of the cross section and maximum tensile stress at the bottom fibre. These assumptions can be expressed as:

$$\varepsilon_y = \frac{\varepsilon_{top}}{y_{top}} y = \frac{\varepsilon_{bottom}}{y_{bottom}} y \tag{8.18}$$

$$\sigma_y = \frac{\sigma_{top}}{y_{top}} y = \frac{\varepsilon_{top} E}{y_{top}} y \tag{8.19}$$

If the beam is in equilibrium, then at any section to the total compressive forces must be equal to the total tensile forces. For any small area, dA, located anywhere on the cross section, the resultant force is determined as the stress multiplied by its area:

$$dF = \sigma dA \tag{8.20}$$

Applying equilibrium in the horizontal direction and integrating over the cross section:

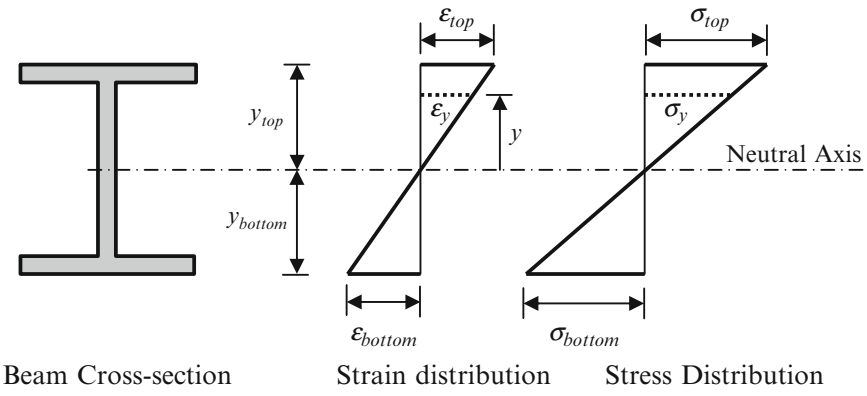

Fig. 8.13 Beam cross-section, strain distribution, and stress distribution for a homogenous, linear elastic beam in bending

$$\sum F_x = 0: \; 0 = \int_A dF = \int_A \sigma dA = \int_A \frac{y}{y_{top}} \sigma_{top} dA = \frac{\sigma_{top}}{y_{top}} \int_A y dA \tag{8.21}$$

Since the term in front of the integrand is non-zero, then for equilibrium it is required that:

$$0 = \int_A y dA \tag{8.22}$$

This is equivalent to stating that the axis of zero strain, called the *neutral axis*, must pass through the *centroid* of the cross section.

Stresses in the beam can also be determined using equilibrium, which requires that the internal moment, M, be equal to the moment produced by integrating the moment contributions of the individual areas over the cross section. This can be expressed as:

$$\sum M = M: \; M = \int_A y dF = \int_A y(\sigma dA) = \int_A y\left(\frac{y}{y_{top}}\sigma_{top}\right) dA = \frac{\sigma_{top}}{y_{top}} \int_A y^2 \, dA \tag{8.23}$$

The term inside the integrand represents the *moment of inertia* (or second moment of area), I, of the cross section, and can be found using simple techniques or tables given in solid mechanics textbooks. Rearranging and incorporating Equation 8.19, an equation for the stress at any location in a cross section is obtained:

$$\sigma_y = \frac{My}{I} \tag{8.24}$$

This is referred to as *The Flexure Formula*, and can be used (for linear elastic materials) to check that the stress in a cross section is less than the failure stress for the material from which a beam is made; and hence to define the resistance of an element, R, with respect to bending failure. This approach works for most statically determinate structures, because for these types of structures the formation of a single flexural failure point (called a *plastic hinge*) is sufficient to cause failure. Statically indeterminate structures are more complicated as they require the formation of more than one location of flexural failure, as discussed below.

The above approach to flexural analysis can also be used for elevated temperature analysis provided that the likely reductions in mechanical properties of a structural member's constituent materials are known, and also provided that reductions in cross sectional area are accounted for.

Similar mechanics can be used to develop equations for stress in sections made from

inelastic or non-linear materials, however these are considerably more involved and are not discussed here. For beams made from steel, which is often considered to be elastic-plastic, as previously shown in Fig. 8.6, or for reinforced concrete which is built up from a combination of steel and concrete (refer to Fig. 8.7), specialist texts should be consulted for information in this area.

Lateral Instability of Beams

The above equations assume failure of a beam by excessive bending stresses. This is analogous to crushing failure of a column in compression. However, in certain cases beams may fail due to instability failures which are akin to buckling failures in compressively loaded columns. Lateral instability failures result when a beam's compression fibre has insufficient lateral support, allowing it to buckle in a direction perpendicular to its longitudinal axis. Obviously, this is more of a problem for slender beams or beams built up from thin plates. In design the propensity of an element to lateral instability is accounted for by limiting the maximum stresses which are permitted in the cross section; this is particularly an issue for structural steel beams (and columns).

In structural fire design it is important to recognize that any members which provide lateral bracing to beams must have sufficient fire resistance to be able to continue to provide this bracing in the event of a fire. This is an important consideration for both beams and, as already noted, for columns. Specialist texts should be consulted for additional information on lateral instability of beams in bending.

Continuity and Full Structure Response

As already noted, most real structures are too complicated to use equilibrium alone to determine all of the external and internal forces which may be acting. In these case more advanced methods of analysis must be used which generally account also for the deformations of structures under loading (in addition to static equilibrium). Such methods are beyond the scope of the current chapter, however the implications of static indeterminacy for real structural response, both at ambient and at elevated temperature, are worthy of brief discussion.

Continuous Beams

Continuous beams are statically indeterminate due to their being, as the name implies, continuous over multiple supports. An example of a relatively simple continuous beam is given in Fig. 8.14. This figure shows that unlike simply-supported beams, which require only a single location of flexural failure for collapse to occur, continuous beams require multiple failure locations before a failure mechanism can form; three failure locations in the case of the beam shown. Continuous beams are therefore *redundant* structures, and they can benefit from beneficial structural actions such as *moment redistribution*, both at ambient temperature and during fire. Techniques to account for moment redistribution during fire are described in detail elsewhere (e.g. [2]).

Frames

The structural response of building frames, for instance the idealized two-dimensional portal frame and moment resisting frame shown in Figs. 8.15 and 8.16, respectively, under gravity loads is complex, and for most real structures requires the use of detailed computer analysis techniques to determine the internal forces and moments. In fire the response of frames is even further complicated; for instance by the effects of thermal expansion and thermal restraint at elevated temperature.

To illustrate some of the important behaviors which may occur in statically indeterminate frame structures during fire, Fig. 8.15 shows a possible sequence of deformation that is likely to occur in a simple planar portal frame structure subjected to a fire in its interior.

The initial geometry of the structure is shown in Fig. 8.15a, where the well-known shape of an industrial building such as a warehouse is evident. Under ambient conditions the stability of the structure is assured by moment

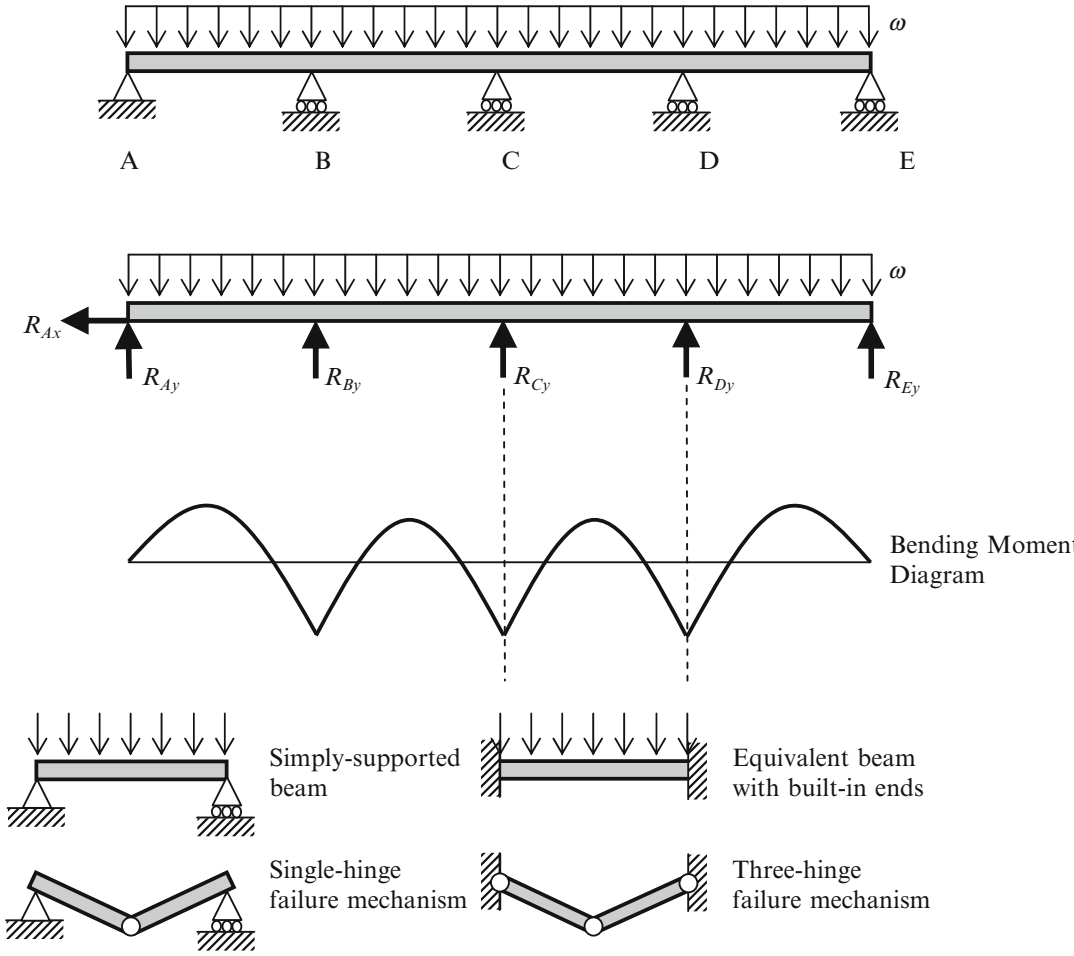

Fig. 8.14 Bending moment diagram and failure mechanism for a continuous beam as compared with a simply-supported beam under a uniformly distributed load

resisting connections at locations B, C, and D (i.e. these connections resist relative rotational displacements between the structural elements framing into the joints). Without moment resisting connections at these locations the structure would be a mechanism and would immediately collapse. The connections to the foundations at A and E are not strictly required to be moment resisting for stability under ambient conditions. Under ambient conditions this structure resists loads by a combination of bending and axial compression in its structural elements.

Figure 8.15b shows how this portal frame might react during the early stages of a fire. The roof elements (B-C and C-D) would initially be heated by the fire, and two important actions would occur:

1. The beams would experience an overall longitudinal thermal expansion, which would tend to increase the length of the beams under heating by amount ΔT, as a function of the constituent materials' coefficient of thermal expansion, α_T. This thermal expansion, if occurring without any axial restraint, would be described by the following expressions:

$$\varepsilon_T = \alpha_T \Delta T \quad \text{or} \quad \Delta L_T = \alpha_T \Delta T L \tag{8.25}$$

The result of this thermal expansion would be to push the columns outwards, and hence to

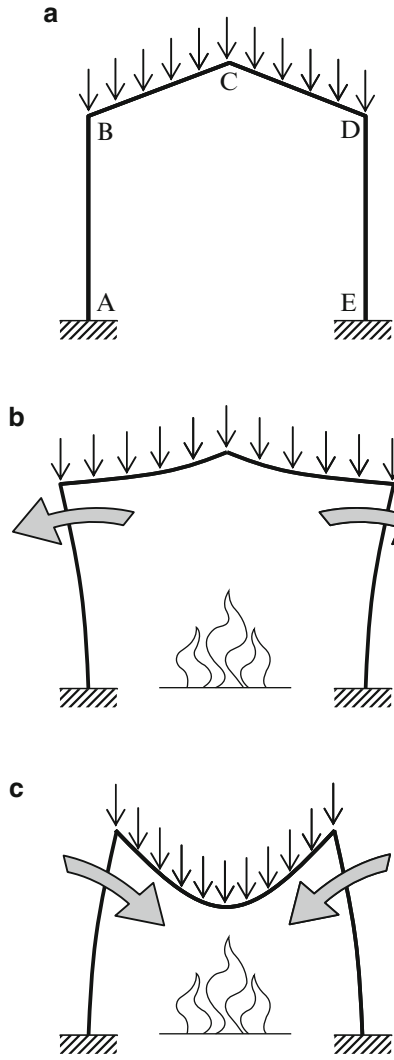

Fig. 8.15 Schematic showing complexities of structural response and possible failure mode of a statically indeterminate portal frame in fire

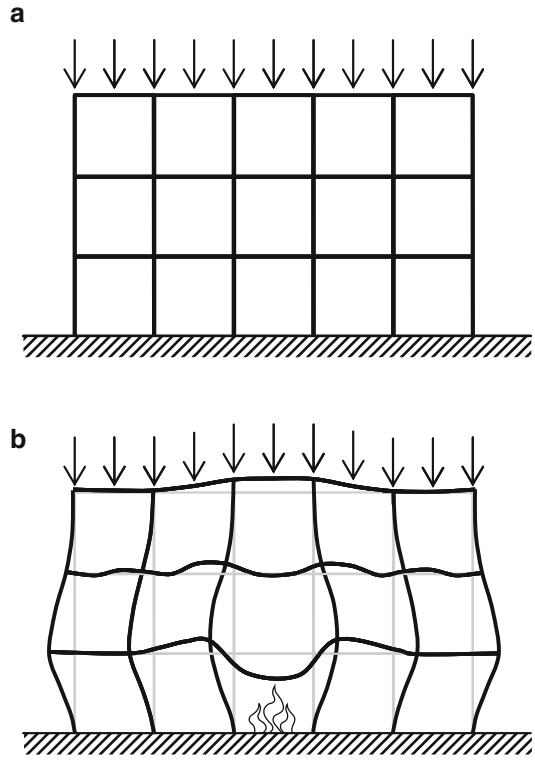

Fig. 8.16 Schematic showing complexities of structural response of a statically indeterminate multi-floor moment resisting frame in fire (Reproduced after Buchanan [2])

increase the moments in the columns and in the connections to the foundation. In reality there would be some restraint to axial thermal expansion, which would also tend to increase the mechanical compressive loads in the beams on heating.

2. The beams, which when heated from below would experience greater heating at their bottom fibre than at their top, would undergo thermal curvature and thermal bowing, to various degrees depending on the materials of construction, the roofing system, etc. The result of this is that the roof beams would bow toward the fire and begin to sag purely as a consequence of the thermal gradient.

As a consequence of the thermal elongation and thermal bowing, combined with reductions in the mechanical properties of the beam on further heating, the peak in the roof would gradually displace downwards under the influence of gravity loads. At some point the peak of the roof, Point C, may displace below the height of points B and D, and the roof would snap-through forming a *catenary*.

Figure 8.15c shows the structure once the roof has snapped through. Under this condition the roof acts in tension (rather than bending and compression) to support the load under a severely deformed geometry. In addition, the moments on the column bases would be reversed and stability of the structure would be assured

only by the moment capacity of the columns and their base connections to the foundations. Eventual failure of the structure would occur with the columns pulled inward leading to collapse.

This relatively simple example clearly illustrates that thermal expansion, thermal bowing, large deflections, and alternative load carrying mechanisms can all be expected to play pivotal roles in the structural mechanics of a real, however simplified, structure during fire.

A more complicated, yet still highly idealized structure is shown in Fig. 8.16; this is a two-dimensional moment resisting frame. Again, Fig. 8.16a shows the frame supporting gravity loads under ambient conditions. Again, the structure resists both vertical (e.g. gravity) and possibly lateral (e.g. wind) loads through a combination of bending and compressive loading.

Figure 8.16b shows a highly exaggerated idealization of the possible deformation of this moment resisting frame under exposure to a fire which is localized to a single internal bay at the ground floor level. This suggests that the response of the structure is far more complex than the response of a single isolated beam presented earlier, and that the effects of continuity, axial restraint, thermal elongations and rotations, and reductions in mechanical properties of the constituent materials will all profoundly affect the forces, stresses, deformations, and ultimately the failure mode of the structure during fire. As a result of the heating during a fire, elements are subjected to loads which may never have been considered during ambient design (for example shearing or unexpected bending of the perimeter columns due to being pushed laterally by the expanding floor plate). Such factors must be considered during design in order for structures to be rationally engineered to resist the effects of fire. Such analysis is extremely complex and requires the use of specialized computer analysis software.

Slabs and Shells (Membrane Actions)

An additional structural action which often plays an important role in the response of real structures during fire is *membrane* action.

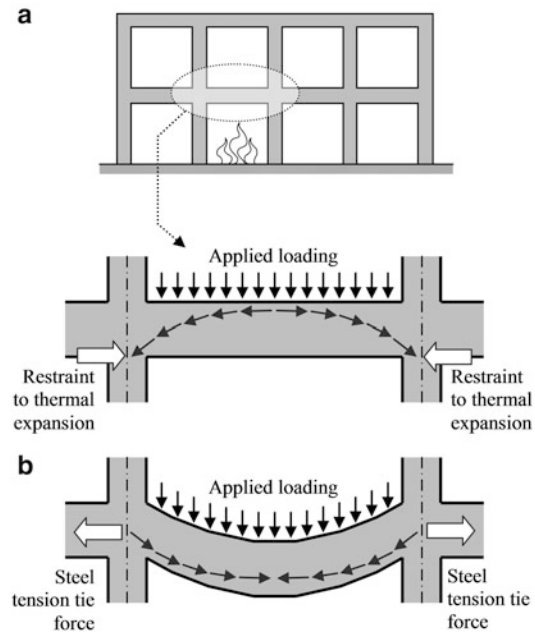

Fig. 8.17 Schematic representation of compressive and tensile membrane actions in a reinforced concrete slab

Membrane action, which can be either compressive or tensile, manifests itself in planar structures such as reinforced concrete floor slabs or steel-concrete composite deck slabs.

Figure 8.17 shows two-dimensional idealizations of both tensile and compressive membrane actions, where compressive membrane action can be though of as *arching* action, and tensile membrane action can be thought of as *catenary* action. In reality these actions normally manifest themselves in three dimensions; think of a dome (compressive membrane) or a net (tensile membrane).

Compressive membrane action is particularly important in continuous reinforced concrete structures during the early stages of a fire, where restrained thermal expansion of concrete slabs can lead to the development significant lateral restraint forces resulting in arching action during fire (provided of course that the thrust forces have a line of action *below* the neutral axis of bending of the slabs).

Tensile membrane action is particularly important during the late stages of fires for structures with relatively thin concrete or

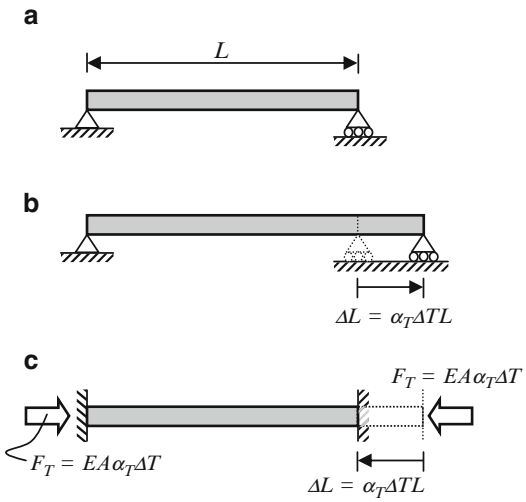

Fig. 8.18 Schematic representation of the possible effects of restraint to thermal expansion of a cylindrical steel bar

steel-concrete composite slabs. In these cases tensile membrane action can prevent structural collapse (however under large vertical deflections) for durations of fire exposure much greater than would be expected on the basis of single element analysis.

Membrane actions are discussed in considerable detail in specialized structural fire engineering references (e.g. [2, 5, 6]).

Thermally-Induced Loading

As discussed previously, thermal expansion (and more importantly restraint to thermal expansion) may significantly affect the deformation and eventual failure of real structures in real fires. To illustrate the possible importance of thermal expansion, consider a simple cylindrical steel bar of length L which is uniformly heated an amount ΔT (Fig. 8.18).

If the bar is free to expand as in Fig. 8.18a then the change in length during heating is described by Equation 8.25 given previously. If however, the bar is rigidly supported between two immovable walls (i.e. a case of perfect axial restraint as in Fig. 8.18b) then the bar is prevented from expanding and as a result it experiences zero thermal strain (i.e. zero elongation) but an increase of thermal stress. By invoking Hooke's Law (Equation 8.8 presented previously) the thermal stress, σ_T (or thermal force F_T), in the bar will be:

$$\begin{aligned} \sigma_T &= E\varepsilon_T = E\alpha_T\Delta T \\ F_T &= \sigma_T A = EA\alpha_T\Delta T \end{aligned} \tag{8.26}$$

If it is assumed that the bar is made from structural steel, with a typical yield strength, σ_y, of 350 MPa and modulus of elasticity E of 200,000 MPa (refer to Fig. 8.6), and if it is further assumed that the coefficient of thermal expansion of steel, α_T, is 13×10^{-6}/K then the increase of temperature required to cause the bar to yield can be determined as follows:

$$\begin{aligned} \varepsilon &= -\varepsilon_T = \alpha_T\Delta T \\ \sigma_y &= -E\varepsilon_T = E\alpha_T\Delta T \\ \therefore \Delta T &= \frac{\sigma_y}{E\alpha_T} = \frac{350}{200{,}000 \cdot 13 \times 10^{-6}} = 134^{\circ}\text{C} \end{aligned} \tag{8.27}$$

In other words, a change in temperature of the perfectly restrained steel bar of +134 °C can cause the bar to reach its failure stress. This simple example, whilst clearly not representative of a real structure, shows that a relatively mild increase of temperature can have a profound influence on the forces and deformations within a structure during heating. Only recently has the significance of thermal interaction within a structure been widely acknowledged within the structural fire engineering community in terms of its possible influences on the overall stability, and likely failure modes, of a building during fire (e.g. [6]).

Other Considerations

There are a host of other important structural mechanics issues which must be considered in the analysis and design of structures to resist the

damaging effects of fire and elevated temperature; it is not possible to discuss all of these here. There are many failure modes and structural interactions which could occur in any given structure, and hence structural fire analysis and design should only be undertaken by individuals with specialist knowledge in this area.

Connections

One area which has not traditionally been explicitly considered within mainstream structural design for fire is the specific performance of connections at elevated temperature. Under ambient conditions structures are generally designed under the assumption that structural members will fail before their connections. Indeed, as already noted more onerous strength reduction factors are typically applied during connection design to ensure that this is the case. The performance in fire of connections of various types is currently a topic of considerable research interest; however a detailed discussion of this topic is avoided here. It is sufficient for the reader to be aware that connection performance in fire should be considered during the fire safe structural design of a building.

Disproportionate Collapse

Disproportionate collapse refers to a situation where localized failure of a single structural element can lead to major or global collapse of a large, or disproportionate, portion of a structure [2]. There have been numerous real examples of disproportionate structural failure due to extreme loading events such as blast, earthquake, and even fire. The most notable case of a disproportionate structural collapse resulting from fire is probably the collapse of Building 7 of the World Trade Center complex in New York on September 11th, 2001.

Design to avoid disproportionate collapse, termed design for redundancy or *resilient design*, requires the provision of structural redundancy and alternative load paths. Again, this topic is beyond the scope of this introductory discussion; additional guidance is available elsewhere (e.g. [7]).

Summary

This chapter has provided a brief, introductory summary of basic structural mechanics, as is relevant to a surface level understanding of the response of structural elements and structures to fire. In conjunction with Chap. 9 of this handbook, it provides a basic understanding of the means by which structural stability, and to a certain extent integrity and insulation during fire, can be engineered through careful selection and design of building materials.

Acknowledgements The overall structure and format of this chapter of the SFPE Handbook has been based on the previous (4/e) version, which was authored by Robert W. Fitzgerald. The significant contribution of Prof. Fitzgerald to the development of this handbook must therefore be gratefully acknowledged.

Nomenclature

A	Area (nm^2)
A_k	Load or load effect resulting from an extraordinary event (e.g. fire)
C_1	Integration constant
C_2	Integration constant
c	Distance from the extreme compression fiber to the neutral axis of bending (mm)
$\mathbf{D}$	Dead load
$\mathbf{E}$	Earthquake load
E	Load effect, or modulus of elasticity (Young's modulus) (GPa)
F	Force (kN)
f_c'	Compressive strength of concrete (MPa)
I	Moment of inertia (mm^4)
$\mathbf{L}$	Live load
L	Length (mm)
M	Moment (kN·m)
n	0, 1, 2. . .
O	Center of curvature
P	Load (kN)
R	Member resistance, or reaction force (kN)

r Radius of gyration (mm)
$\mathbf{S}$ Snow load
V Shear force (kN)
$\mathbf{W}$ Wind load
x Coordinate parallel to the axis of the structural element (mm)
y Coordinate normal to the axis of the structural element (mm), or lateral deflection (mm)
Z Difference between resistance and load demand
α Load factor
α_T Coefficient of thermal expansion (K^{-1})
β Safety index
ε Strain (no units)
ε_{cc} Compressive failure strain of concrete (no units)
ε_y Yield strain (no units)
ΔL Change in length (mm)
ΔT Change in temperature (K)
δ Deformation (mm)
σ Stress (MPa)
σ_y Yield stress (MPa)
ϕ Resistance factor
π Pi
θ Subscript denoting elevated temperature
ω Uniformly distributed loading (kN/m)

Professor Luke Bisby is Arup Chair of Fire and Structures, and Royal Academy of Engineering Research Chair, within the BRE Centre for Fire Safety Engineering at the University of Edinburgh. Educated in Canada as a structural engineer, his research and teaching are focused predominantly in the area of Fire Safety Engineering. His reasearch is broadly in the areas of structural engineering and the provision of fire safety across the built environment, with an emphasis on the mechanical response of buildings and construction materials during fire. He has published widely in areas related to the fire behaviour of reinforced concrete structures, and on fibre-reinforced polymers in structural engineering applications. His current reasearch is interested in the response of novel structural materials to heating, including high performance and high strength concretes, polymers and polymer composites for construction, fire protection materials (including reactive fire protection coatings), and structural cross-laminated timber. He is also involved in research projects seeking to better understand and unpick sociological and psychological issues in fire safety engineering and regulation.

Properties of Building Materials

9

V.K.R. Kodur and T.Z. Harmathy

Introduction

Building components are to be designed to satisfy the requirements of serviceability and safety limit states. One of the major safety requirements in building design is the provision of appropriate fire resistance to various building components. The basis for this requirement can be attributed to the fact that, when other measures of containing the fire fail, structural integrity is the last line of defense. In this chapter, the term *structural member* is used to refer to both load-bearing (e.g., columns, beams, slabs) and non-load-bearing (e.g., partition walls, floors) building components.

Fire resistance is the duration during which a structural member exhibits resistance with respect to structural integrity, stability, and temperature transmission. Typical fire resistance rating requirements for different building components are specified in building codes.

In the past, the fire resistance of structural members could be determined only by testing. In recent years however, the use of numerical methods for the calculation of the fire resistance of various structural members is gaining acceptance because these calculation methods are far less costly and time consuming. The fire performance of a structural member depends, in part, on the properties of the materials the building component is composed of. The availability of material properties at high temperature and temperature distributions permits a mathematical approach to predicting the performance of building components exposed to fire. When a structural member is subjected to a defined temperature-time exposure during a fire, this exposure will cause a predictable temperature distribution in the member. Increased temperatures cause deformations and property changes in the materials. With knowledge of the deformations and property changes, the usual methods of structural mechanics can be applied to predict fire resistance performance.

In recent years, significant effort has been undertaken to develop material properties of various construction materials at elevated temperatures. In this chapter, the characteristics of materials are outlined. The various properties that influence fire resistance performance, together with the methods used to develop these properties, is discussed. The trends on the variation of thermal, mechanical, and other material-specific properties with temperature of commonly used construction materials are presented.

Material Characteristics

Classification

Materials, based on composition, can be classified as either a homogeneous or heterogeneous type.

T.Z. Harmathy

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_9, © Society of Fire Protection Engineers 2016

Homogeneous materials have the same composition and properties throughout their volume and are rarely found in nature. *Heterogeneous* materials have different composition and properties. Most construction materials are heterogeneous, yet their heterogeneity is often glossed over when dealing with practical problems.

The heterogeneity of concrete is easily noticeable. Other heterogeneities related to the microstructure of materials, that is, their grain and pore structures, are rarely detectable by the naked eye. The microstructure depends greatly on the way the materials are formed. In general, materials formed by solidification from a melt show the highest degree of homogeneity. The result of the solidification is normally a *polycrystalline* material, comprising polyhedral grains of crystals, which, in general, are equiaxial and randomly oriented. Severe cold working in metals may produce an elongated grain structure and crystals with preferred orientations.

Noncrystalline solids are called *amorphous* materials. Gels and glasses are amorphous materials. Gels are formed by the coagulation of a colloidal solution. Glasses (vitreous materials) are solids with a liquid-like, grainless submicroscopic structure with low crystalline order. On heating, they will go through a series of phases of decreasing viscosity.

Synthetic polymers (plastics) are made up of long macromolecules created by polymerization from smaller repeating units (monomers). In the case of *thermoplastic* materials, the mobility of the molecular chains increases on heating. Such materials soften, much like glass. In some other types of plastics, called *thermosetting* materials, polymerization also produces cross-bonds between the molecular chains. These cross-bonds prevent the loosening of the molecular structure and the transition of the material into a liquid-like state.

Some building materials (e.g., gypsum, brick) are formed from a wet, plastic mass or from compacted powders by firing. The resulting product is a polycrystalline solid with a well-developed pore structure. Two important building materials, concrete and gypsum, are formed by mixing finely ground powders (and aggregates) with water. The mixture solidifies by hydration. The cement paste in a concrete has a highly complex microstructure, interspersed with very fine, elaborate pores.

Most building materials can be treated as *isotropic* materials, that is, as though they possessed the same properties in all directions. An exception to this is some of the advanced composite materials, such as fiber-reinforced polymers (FRP), which might possess varying properties in different directions and are classified as *anisotropic* materials.

Among the material properties, those that are unambiguously defined by the current composition and phase are referred to as *structure-insensitive*. Some others depend on the microstructure of the solid or on its previous history. These properties are *structure-sensitive*.

Porosity and Moisture Sorption

The fire performance of a material is dependent on the chemical composition and molecular structure of the material. The presence of water in the material composition influences the properties of materials at elevated temperatures. The two commonly associated terms to describe the composition and the extent of water present in a material are porosity and moisture sorption.

What is commonly referred to as a solid object is actually all the material within its visible boundaries. Clearly, if the solid is porous—and most building materials are—the so-called solid consists of at least two phases: (1) a solid-phase matrix and (2) a gaseous phase (namely, air) in the pores within the matrix. Usually, however, there is also a liquid or liquid-like phase present: moisture either absorbed from the atmosphere to the pore surfaces or held in the pores by capillary condensation. This third phase is always present if the pore structure is continuous; discontinuous pores (like the pores of some foamed plastics) are not readily accessible to atmospheric moisture.

The pore structure of materials is characterized by two properties: *porosity, P* ($m^3 \cdot m^{-3}$), the volume fraction of pores within the visible boundaries of the solid; and *specific surface, S* ($m^2 \cdot m^{-3}$), the surface area of the pores per unit volume of the material. For a solid with

continuous pore structure, the porosity is a measure of the maximum amount of water the solid can hold when saturated. The specific surface and (to a lesser degree) porosity together determine the moisture content the solid holds in equilibrium with given atmospheric conditions.

The *sorption isotherm* shows the relationship at constant temperature between the equilibrium moisture content of a porous material and the relative humidity of the atmosphere. A sorption isotherm usually has two branches: (1) an *adsorption branch,* obtained by monotonically increasing the relative humidity of the atmosphere from 0 to 100 % through very small equilibrium steps; and (2) a *desorption branch,* obtained by monotonically lowering the relative humidity from 100 to 0 %. Derived experimentally, the sorption isotherms offer some insight into the nature of the material's pore structure [1, 2].

For heterogeneous materials consisting of solids of different sorption characteristics (e.g., concrete, consisting of cement paste and aggregates), the sorption isotherms can be estimated using the simple mixture rule (with $m = 1$; see Equation 9.1).

Building materials, such as concrete (or more accurately, the cement paste in the concrete) and wood, because of their large specific surfaces, can hold water in amounts substantial enough to be taken into consideration in fire performance assessments.

Mixture Rules

Some properties of materials of mixed composition or mixed phase can be calculated by simple rules if the material properties for the constituents are known. The simplest mixture rule is [3]

$$\pi^m = \sum_i v_i \pi_i^m \tag{9.1}$$

where

π = Material property for the composite

π_i = Material property for the composite's ith constituent

v_i ($m^3 \cdot m^{-3}$) = Volume fraction of the ith constituent

m (dimensionless) = Constant that has a value between −1 and +1

Hamilton and Crosser recommended the following rather versatile formula for two-phase solids [4]:

$$\pi = \frac{v_1 \pi_1 + \gamma v_2 \pi_2}{v_1 + \gamma v_2} \tag{9.2}$$

where

$$\gamma = \frac{n \pi_1}{(n-1)\pi_1 + \pi_2} \tag{9.3}$$

Here phase 1 must always be the principal continuous phase. n (dimensionless) is a function of the geometry of phase distribution. With $n \to \infty$ and $n = 1$, Equations 9.2 and 9.3 convert into Equation 9.1 with $m = 1$ and $m = -1$, respectively. With $n = 3$, a relation is obtained for a two-phase system where the discontinuous phase consists of spherical inclusions [5].

By repeated application, Equations 9.2 and 9.3 can be extended to a three-phase system [6], for example, to a moist, porous solid that consists of three essentially continuous phases (the solid matrix, with moisture and air in its pores).

Survey of Building Materials

There are burnable (combustible) and nonburnable (noncombustible) building materials. The reason for preferring the use of the words *burnable* and *nonburnable* has been discussed by Harmathy [2]. To a designer concerned with the structural performance of a building during a fire, the mechanical and thermal properties of these materials are of principal interest. Yet burnable building materials may become ignited, and thereby the positive role assigned to these materials by design (i.e., functioning as structural elements of the building) may change into a negative role—that is, becoming fuel and adding to the severity of fire. Those properties of burnable building materials that are related to the latter role are discussed in other chapters of this handbook.

From the point of view of their performance in fire, building materials can be divided into the following groups:

1. *Group L (load-bearing) materials*. Materials capable of carrying high stresses, usually in tension or compression. With these materials, the mechanical properties related to behavior in tension and/or compression are of principal interest.
2. *Group L/I (load-bearing/insulating) materials*. Materials capable of carrying moderate stresses and, in fire, providing thermal protection to Group L materials. With Group L/I materials, the mechanical properties (related mainly to behavior in compression) and the thermal properties are of equal interest.
3. *Group I (insulating) materials*. Materials not designed to carry load. Their role in fire is to resist the transmission of heat through building elements and/or to provide insulation to Group L or Group L/I materials. With Group I materials, only the thermal properties are of interest.
4. *Group L/I/F (load-bearing/insulating/fuel) materials*. Group L/I materials that may become fuel in fire.
5. *Group I/F (insulating/fuel) materials*. Group I materials that may become fuel in fire.

The number of building materials has been increasing dramatically during the past few decades. In the last decade or so, a number of high-performing materials, such as FRP and high-strength concrete (HSC), have been developed to achieve cost-effectiveness in construction. Although many of these high-performing materials possess superior properties at ambient temperatures, the same cannot be said of their performance at elevated temperatures. In materials such as HSC, additional complexities such as spalling arise, which may severely impact the fire performance of a structural member.

By necessity, only a few of those materials that are commonly used will be discussed in this chapter in some detail. These materials are as follows: in Group L—structural steel, light-gauge steel, and reinforcing/prestressing steel; Group L/I—concrete and brick (including fiber-reinforced concrete); Group L/I/F (or Group I/F and L/F)—wood and FRP; and Group I—gypsum and insulation.

Material Properties at Elevated Temperatures

The behavior of a structural member exposed to fire is dependent, in part, on the thermal and mechanical properties of the material of which the member is composed. While calculation techniques for predicting the process of deterioration of building components in fire have developed rapidly in recent years, research related to supplying input information into these calculations has not kept pace. The designer of the fire safety features of buildings will find that information on the properties of building materials in the temperature range of interest, 20–800 °C is not easy to come by. Most building materials are not stable throughout this temperature range. On heating, they undergo physicochemical changes ("reactions" in a generalized sense), accompanied by transformations in their microstructure and changes in their properties. For example, concrete at 500 °C is completely different from the material at room temperature.

The thermophysical and mechanical properties of most materials change substantially within the temperature range associated with building fires. In the field of fire science, applied materials research faces numerous difficulties. At elevated temperatures, many building materials undergo physicochemical changes. Most of the properties are temperature dependent and sensitive to testing method parameters such as heating rate, strain rate, temperature gradient, and so on. Harmathy [7] cited the lack of adequate knowledge of the behavior of building materials at elevated temperatures as the most disturbing trend in fire safety engineering. There has been a tendency to use "notional" (also called "typical," "proprietary," "empirical," etc.) values for material properties in numerical computations—in other words, values that ensure agreement between experimental and analytical results. Harmathy warned that this practice might lead

to a proliferation of theories that lack general validity.

Clearly, the generic information available on the properties of building materials at room temperature is seldom applicable in fire safety design. It is imperative, therefore, that the fire safety practitioner knows how to extend, based on a priori considerations, the utility of the scanty data that can be gathered from the technical literature. Also, knowledge of unique material-specific characteristics at elevated temperatures, such as spalling in concrete or charring in wood, is critical to determine the fire performance of a structural member. These properties are discussed in the following sections.

Reference Condition

Most building materials are porous and therefore capable of holding moisture, the amount of which depends on the atmospheric conditions. Because the presence of moisture may have a significant and often unpredictable effect on the properties of materials at any temperature below 100 °C, it is imperative to conduct all property tests on specimens brought into a moistureless "reference condition" by some drying technique prior to the test. The reference condition is normally interpreted as that attained by heating the test specimen in an oven at 105 °C until its weight shows no change. A few building materials however, among them all gypsum products, may undergo irreversible physicochemical changes when held at that temperature for an extended period. To bring them to a reference condition, specimens of these materials should be heated in a vacuum oven at some lower temperature level (e.g., at 40 °C in the case of gypsum products).

Mechanical Properties

The mechanical properties that determine the fire performance of structural members are strength, modulus of elasticity, and creep of the component materials at elevated temperatures.

Stress-Strain Relationships

The mechanical properties of solids are usually derived from conventional tensile or compressive tests. The strength properties are usually expressed in stress-strain relations, which are often used as input data in mathematical models calculating the fire resistance. Figure 9.1 shows, for a metallic material, the variation of stress, σ (Pa), with increasing strain (deformation), ε ($m \cdot m^{-1}$), while the material is strained (deformed) in a tensile test at a more or less constant rate (i.e., constant crosshead speed), usually of the order of 1 $mm \cdot min^{-1}$. Generally, because of a decrease in the strength and ductility of the material, the slope of the stress-strain curve decreases with increasing temperature.

Modulus of Elasticity, Yield Strength, Ultimate Strength

The modulus of elasticity is a measure of the ability of the material to resist deformation and is expressed as the ratio of the deforming stress to the strain in the material. Generally, the modulus of elasticity of a material decreases gradually with increasing temperature.

The tensile or compressive strength of the material is generally expressed by means of yield strength and ultimate strength. Often the

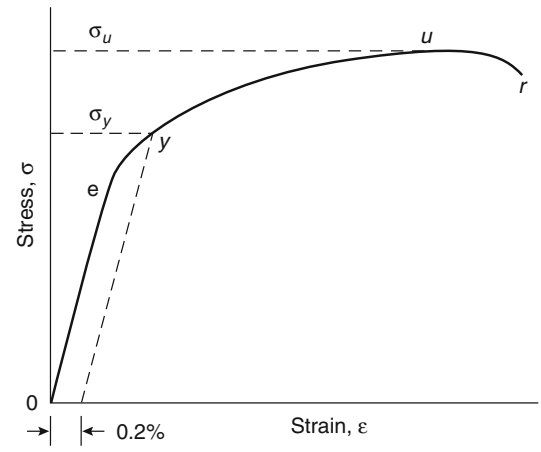

Fig. 9.1 Stress-strain curve (strain rate is roughly constant)

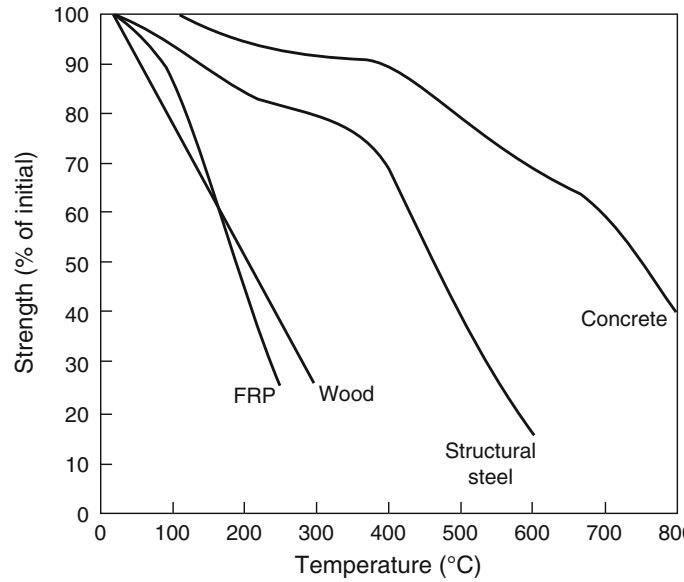

Fig. 9.2 Variation of strength with temperature for different materials

strength at elevated temperature is expressed as a percentage of the compressive (tensile) strength at room temperature. Figure 9.2 shows the variation of strength with temperature (ratio of strength at elevated temperature to that at room temperature) for concrete, steel, wood, and FRP. For all four materials, the strength decreases with increasing temperature; however, the rate of strength loss is different.

For materials such as concrete, compressive strength is of main interest because it has very limited tensile strength at higher temperatures. However, for materials such as steel, both compressive and tensile strengths are of equal interest.

Section 0-*e* of the curve in Fig. 9.1 represents the elastic deformation of the material, which is instantaneous and reversible. The modulus of elasticity, E (Pa), is the slope of that section. Between points *e* and *u* the deformation is plastic, nonrecoverable, and quasi-instantaneous. The plastic behavior of the material is characterized by the yield strength at 0.2 % offset, σ_y (Pa), and the ultimate strength, σ_u (Pa). After some localized necking (i.e., reduction of cross-sectional area), the test specimen ruptures at point *r*. The modulus of elasticity is more or less a structure-insensitive property.

For metals of similar metallurgical characteristics, the stress-strain curve can be reproduced at room temperature at a reasonable tolerance, and the shape of the curve does not depend significantly on the crosshead speed. At sufficiently high temperatures, however, the material undergoes plastic deformation even at constant stress, and the *e*-*r* section of the stress-strain curve will depend markedly on the crosshead speed.

Creep

Creep, often referred to as creep strain, is defined as the time-dependent plastic deformation of the material and is denoted by ε_t ($\mathrm{m \cdot m^{-1}}$). At normal stresses and ambient temperatures, the deformation due to creep is not significant. At higher stress levels and at elevated temperatures, however, the rate of deformation caused by creep can be substantial [8]. Hence, the main factors that influence creep are the temperatures, the stress level, and their duration.

In a creep test the variation of ε_t is recorded against time, t (h), at constant stress (more accurately, at constant load) and at constant (elevated) temperature T (K). A typical strain-time

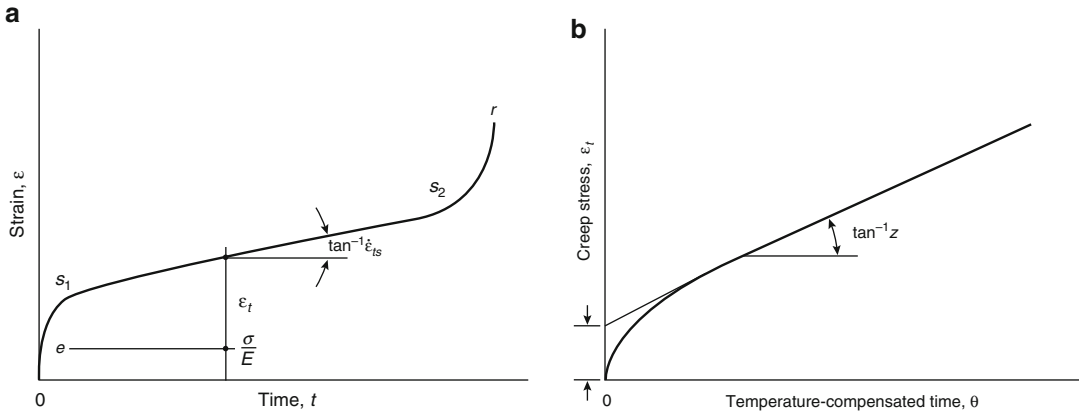

Fig. 9.3 (**a**) Creep strain vs. time curve (T = constant; σ ≈ constant); (**b**) creep strain vs. temperature-compensated time curve (σ ≈ constant)

curve is shown in Fig. 9.3a. The total strain, ε (m·m^{-1}), is

$$\varepsilon = \frac{\sigma}{E} + \varepsilon_t \tag{9.4}$$

The 0-*e* section of the strain-time curve represents the instantaneous elastic (and reversible) part of the curve; the rest is creep, which is essentially nonrecoverable. The creep is fast at first (primary creep, section *e*-s_1 in Fig. 9.3a, then proceeds for a long time at an approximately constant rate (secondary creep, section s_1-s_2), and finally accelerates until rupture occurs (tertiary creep, section s_2-*r*). The curve becomes steeper if the test is conducted either at a higher load (stress) or at a higher temperature.

Dorn's concept is particularly suitable for dealing with deformation processes developing at varying temperatures [9]. Dorn eliminated the temperature as a separate variable by the introduction of a new variable: the "temperature-compensated time," θ (h), defined as

$$\theta = \int_0^t e^{-\Delta H_c/RT} dt \tag{9.5}$$

where ΔHc (J·kmol^{-1}) is the activation energy of creep, and R (J·kmol^1·K^{-1}) is the gas constant.

From a practical point of view, only the primary and the secondary creeps are of importance. It has been shown that the creep strain in these two regimes can be satisfactorily described by the following equation [10]

$$\varepsilon_t = \frac{\varepsilon_{t0}}{\ln 2} \cosh^{-1}\left(2^{Z\theta/\varepsilon_{t0}}\right) \quad (\sigma \simeq \text{constant}) \tag{9.6}$$

or approximated by the simple formula [11]

$$\varepsilon_t \approx \varepsilon_{t0} + Z\theta \quad (\sigma \simeq \text{constant}) \tag{9.7}$$

where Z (h^{-1}) is the Zener-Hollomon parameter, and ε_{t0} (mm^{-1}) is another creep parameter, the meaning of which is explained in Fig. 9.3b. The Zener-Hollomon parameter is defined as [12]

$$Z = \dot{\varepsilon}_{ts} e^{\Delta H/RT} \tag{9.8}$$

where $\dot{\varepsilon}_{ts}$ (mm^{-1}·h^{-1}) is the rate of secondary creep at a temperature, T. The two creep parameters, Z and ε_{t0}, are functions of the applied stress only (i.e., they are independent of the temperature).

For most materials, creep becomes noticeable only if the temperature is higher than about one-third of the melting temperature (on the absolute scale).

The creep of concrete is due to the presence of water in its microstructure [13]. There is no satisfactory explanation for the creep of concrete at elevated temperatures. Anderberg and Thelandersson [14], and Schneider [15] suggested techniques for the calculation of the deformation of concrete under conditions characteristic of fire exposure.

Thermal Properties

The material properties that influence the temperature rise and distribution in a member are its thermal conductivity, thermal expansion, specific heat, thermal diffusivity, and mass loss. These properties depend on the composition and characteristics of the constituent materials.

Thermal Expansion

The thermal expansion characterizes the expansion (or shrinkage) of a material caused by heating and is defined as the expansion (shrinkage) of unit length of a material when it is raised 1° in temperature. The expansion is considered to be positive when the material elongates and is considered negative when it shortens. In general, the thermal expansion of a material is dependent on the temperature. The dilatometric curve is a record of the fractional change of a linear dimension of a solid at a steadily increasing or decreasing temperature. With mathematical symbolism, the dilatometric curve is a plot of

$$\frac{\Delta \ell}{\ell_0} \text{ against T}$$

where $\Delta \ell = \ell - \ell_0$ and ℓ_0 (m) and ℓ (m) are the changed and original dimensions of the solid, respectively, the latter usually taken at room temperature. $\Delta \ell$ reflects not only the linear expansion or shrinkage of the material, but also the dimensional effects brought on by possible physicochemical changes (i.e., "reactions").

The heating of the solid usually takes place at a predetermined rate, 5 °C·min^{-1} as a rule. Because the physicochemical changes proceed at a finite rate and some of them are irreversible, a dilatometric curve obtained by heating rarely coincides with that obtained during the cooling cycle. Sluggish reactions may bring about a steady rise or decline in the slope of the dilatometric curve. Discontinuities in the slope indicate very fast reactions. Heating the material at a rate higher than 5 °C·min^{-1} usually causes the reactions to shift to higher temperatures and to develop faster.

The coefficient of linear thermal expansion, β (m·m^{-1}·K^{-1}), is defined as

$$\beta = \frac{1}{\ell} \frac{d\ell}{dT} \tag{9.9}$$

Since $\ell = \ell_0$ the coefficient of linear thermal expansion is, for all intents, the tangent to the dilatometric curve. For solids that are isotropic in a macroscopic sense, the coefficient of volume expansion is approximately equal to 3β.

The thermal expansion is measured with a dilatometric apparatus, capable of producing curves that show the expansion of the materials with temperature in the range from 20 to 1000 °C. Harmathy [7, 16], using a horizontal dilatometric apparatus, recorded dilametric curves for various types of concrete and brick, some of which are presented in later sections. The sample was 76.2 mm long and about 13 by 13 mm in cross section. It was subjected to a small spring load that varied during the test. Unfortunately, even this small load caused creep shrinkage with those materials that tended to soften at higher temperatures. Furthermore, because the apparatus did not provide a means for placing the sample in a nitrogen atmosphere, in certain cases oxidation may also have had some effect on the shape of the curves.

Mass Loss

The mass loss is often used to express the loss of mass at elevated temperatures. The thermogravimetric curve is a record of the fractional variation of the mass of a solid at steadily increasing or decreasing temperature. Again, with mathematical symbolism, a thermogravimetric curve is a plot of

$$\frac{M}{M_0} \text{ against } T$$

where M and M_0 (kg) are the changed and original masses of the solid, respectively, the latter usually taken at room temperature.

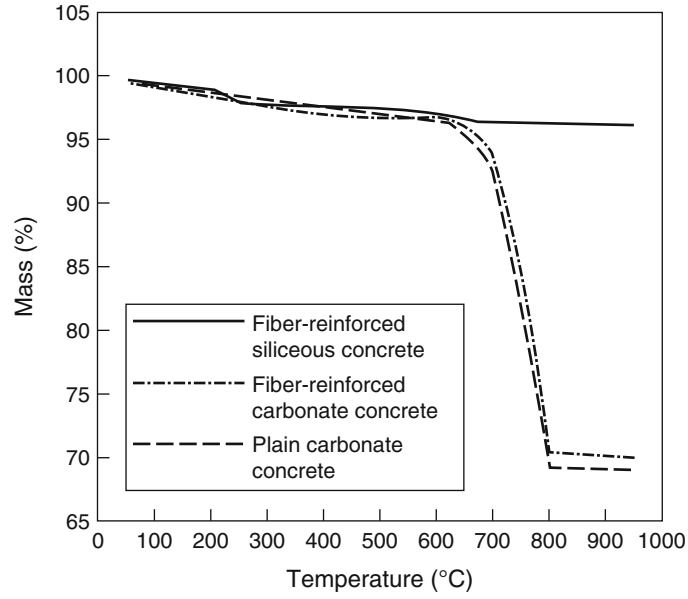

Fig. 9.4 Mass loss of various concrete types as a function of temperature [18]

Generally a heating rate of 5 °C·min^{-1} is used in the measurements.

A thermogravimetric curve reflects reactions accompanied by loss or gain of mass but, naturally, it does not reflect changes in the materials' microstructure or crystalline order. $M/M_0 = 1$ is the thermogravimetric curve for a chemically inert material. Again, an increase in the rate of heating usually causes those features of the curve that are related to chemical reactions to shift to higher temperatures and to develop faster.

The thermogravimetric curves to be shown were obtained by a DuPont 951 thermogravimetric analyzer [17], using specimens of 10–30 mg in mass, placed in a nitrogen atmosphere [7]. The rate of temperature rise was 5 °C·min^{-1}. Figure 9.4 shows the variation of mass loss for concrete in the temperature range from 20 to 1000 °C.

Density, Porosity

The density, ρ (kg·m^{-3}), in an oven-dry condition, is the mass of a unit volume of the material, comprising the solid itself and the air-filled pores. Assuming that the material is isotropic with respect to its dilatometric behavior, its density at any temperature can be calculated from the thermogravimetric and dilatometric curves.

$$\rho = \rho_0 \frac{(M/M_0)_T}{\left[1 + ((\Delta \ell)/(\ell_0))_T\right]} \tag{9.10}$$

where ρ_0 (kg·m^{-3}) is the density of the solid at the reference temperature (usually room temperature), and the T subscript indicates values pertaining to temperature T in the thermogravimetric and dilatometric records.

The density of composite solids at room temperature can be calculated by means of the mixture rule in its simplest form (Equation 9.1 with $m = 1$).

$$p = \sum_i v_i p_i \tag{9.11}$$

where the i subscript relates to information on the ith component. At elevated temperatures, the expansion of the components is subject to constraints, and therefore the mixture rule can yield only a crude approximation.

If, as usual, the composition is given in mass fractions rather than in volume fractions, the volume fractions can be obtained as

$$v_i = \frac{w_i / p_i}{\sum_i w_i / p_i} \tag{9.12}$$

where w_i is the mass fraction of the ith component (kg·kg^{-1}).

True density, ρ_t (kg·m^{-3}), is the density of the solid in a poreless condition. Such a condition is nonexistent for many building materials and, therefore, may be a theoretical value derived on crystallographic considerations, or determined by some standard technique, for example, ASTM C135 [19]. The relationship between the porosity and density is

$$P = \frac{\rho_t - \rho}{\rho_t} \tag{9.13}$$

The overall porosity of a composite material consisting of porous components is

$$P = \sum_i v_i P_i \tag{9.14}$$

where, again, the i subscript relates to the ith component of the material.

Specific Heat

The specific heat of a material is the characteristic that describes the amount of heat required to raise a unit mass of the material at unit temperature. A calorimetric curve describes the variation with temperature of the apparent specific heat of a material at constant pressure, cp (J·kg^{-1}·K^{-1}). The apparent specific heat is defined as

$$c_p = \frac{\delta h}{\delta T_p} \tag{9.15}$$

where h is enthalpy (J·kg^{-1}), and the p subscripts indicate the constancy of pressure. If the heating of the solid is accompanied by physicochemical changes (i.e., "reactions"), the enthalpy becomes a function of the reaction progress variable, ξ (dimensionless), that is, the degree of conversion at a particular temperature from reactant(s) into product(s). For any temperature interval where physicochemical change takes place [2, 6, 20], $0 \leq \xi \leq 1$, and

$$c_p = \overline{c}_p + \Delta h \frac{d\xi}{dT} \tag{9.16}$$

where cp (J·kg^{-1}·K^{-1}) is the specific heat for that mixture of reactants and (solid) products that the material consists of at a given stage of the conversion (as characterized by ξ), and $\Delta\, hp$ (J·kg^{-1}) is the latent heat associated with the physicochemical change.

As Equation 9.16 and Fig. 9.5 show, in temperature intervals of physicochemical instability, the apparent specific heat consists of sensible heat and latent heat contributions. The latter contribution will result in extremities in the calorimetric curve: a maximum if the reaction is endothermic, a minimum if it is exothermic.

In heat flow studies, it is usually the ρcp product (J·m^{-3}·K^{-1}) rather than cp that is needed as input information. This product is referred to as volume specific heat.

Until the 1980s, adiabatic calorimetry was the principal method to study the shape of the cp versus T relationship. Since the 1980s, differential scanning calorimetry (DSC) has been the most commonly used technique for mapping the curve in a single temperature sweep at a desired rate of heating. Unfortunately, the accuracy of the DSC technique in determining the sensible heat contribution to the apparent specific heat may not be particularly good (sometimes it may be as low as ±20 %). The rate of temperature rise was usually 5 °C·min^{-1}. At higher heating rates, the peaks in the DSC curves tend to shift to higher

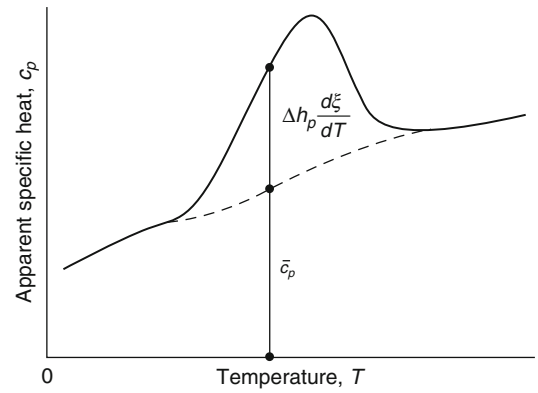

Fig. 9.5 The apparent specific heat

temperatures and become sharper. For temperatures above 600 °C, a high-temperature differential thermal analyzer (DTA) is also used. Harmathy, with the aid of a DuPont 910 differential scanning calorimeter, developed calorimetric curves for a number of materials by placing the samples, 10–30 mg in mass, in a nitrogen atmosphere [7, 21].

Materials that undergo exothermic reactions may yield negative values in the calorimetric curve. A negative value for *cp* indicates that, at the applied (and enforced) rate of heating, the rate of evolution of reaction heat exceeds the rate of absorption of sensible heat by the material. In natural processes, the apparent specific heat can never be negative, because the heat evolving from the reaction is either scattered to the surroundings or, if absorbed by the material, causes a very fast temperature rise. If the heat of reaction is not very high, obtaining nonnegative values for *cp* can be achieved by suitably raising the scanning rate. For this reason, some materials undergoing exothermic reactions must be tested at rates of heating higher than 5 °C·min^{-1}, often as high as 50 °C·min^{-1}.

If experimental information is not available, the *cp* versus *T* relationship can be calculated from data on heat capacity and heat of formation for all the components of the material (including reactants and products), tabulated in a number of handbooks [22, 23]. Examples of calculations are presented in Harmathy [2, 6], where information is developed for the apparent specific heat versus temperature relation for a cement paste and four kinds of concrete.

Thermal Conductivity

The temperature rise in a member, as a result of heat flow, is a function of the thermal conductivity of the material. Heat transmission solely by conduction can occur only in poreless, nontransparent solids. In porous solids (most building materials), the mechanism of heat transmission is a combination of conduction, radiation, and convection. (If pore size is less than that about 5 mm, the contribution of pores to convective heat transmission is negligible.) The thermal conductivity of porous materials is, in a strict sense, merely a convenient empirical factor that makes it possible to describe the heat transmission process with the aid of the Fourier law. That empirical factor will depend not only on the conductivity of the solid matrix but also on the porosity of the solid and the size and shape of the pores. At elevated temperatures, because of the increasing importance of radiant heat transmission through the pores, conductivity becomes sensitive to the temperature gradient.

Because measured values of the thermal conductivity depend to some extent on the temperature gradient employed in the test, great discrepancies may be found in thermal conductivity data reported by various laboratories. A thermal conductivity value yielded by a particular technique is, in a strict sense, applicable only to heat flow patterns similar to that characteristic of the technique employed.

Experimental data indicate that porosity is not a greatly complicating factor as long as it is not larger than about 0.1. With insulating materials, however, the porosity may be 0.8 or higher. Conduction through the solid matrix may be an insignificant part of the overall heat transmission process; therefore, using the Fourier law of heat conduction in analyzing heat transmission may lead to deceptive conclusions. If the solid is not oven-dry, a temperature gradient will induce migration of moisture, mainly by an evaporation condensation mechanism [24]. The migration of moisture is usually, but not necessarily, in the direction of heat flow and manifests itself as an increase in the apparent thermal conductivity of the solid. Furthermore, even oven-dry solids may undergo decomposition (mainly dehydration) reactions at elevated temperatures. The sensible heat carried by the gaseous decomposition products as they move in the pores adds to the complexity of the heat flow process. At present there is no way of satisfactorily accounting for the effect of simultaneous mass transfer on heat flow processes occurring under fire conditions.

The thermal conductivity of layered, multiphase solid mixtures depends on whether the phases lie in the direction of, or normal to, the direction of heat flow and is determined

using the simple mixture rule [4, 25]. At higher temperatures, because of radiative heat transfer through the pores, the contribution of the pores to the thermal conductivity of the solid must not be disregarded [26].

The thermal conductivity of solids is a structure-sensitive property. For crystalline solids, the thermal conductivity is relatively high at room temperature and gradually decreases as the temperature rises. For predominantly amorphous solids, on the other hand, the conductivity is low at room temperature and increases slightly with the rise of temperature. The conductivity of porous crystalline materials may also increase at very high temperatures because of the radiant conductivity of the pores.

The thermal conductivity of materials such as concrete or brick can be measured, in the temperature range between 20 and 800 °C, using a non-steady-state hot wire method [27, 28]. The thermal conductivity values at discrete temperature levels can be plotted to obtain a curve. Unfortunately, no scanning technique exists for acquiring a continuous thermal conductivity versus temperature curve from a single temperature sweep. Special problems arise with the estimation of the thermal conductivity for temperature intervals of physicochemical instability. Both the steady-state and variable-state techniques of measuring thermal conductivity require the stabilization of a pattern of temperature distribution (and thereby a certain microstructural pattern) in the test sample prior to the test. The test results can be viewed as points on a continuous thermal conductivity versus temperature curve obtained by an imaginary scanning technique performed at an extremely slow scanning rate. Because each point pertains to a more or less stabilized microstructural pattern, there is no way of knowing how the thermal conductivity would vary in the course of a physicochemical process developing at a finite rate and varying microstructure.

On account of the nonreversible microstructural changes brought about by heating, the thermal conductivity of building materials (and perhaps most other materials) is usually different in the heating and cooling cycles. Open and solid circles are used in the figures to identify thermal conductivity values obtained by stepwise increasing and stepwise decreasing the temperature of the sample, respectively. Also, often the thermal conductivity of a material is taken as invariant with respect to the direction of heat flow.

Thermal Diffusivity

The thermal diffusivity of a material is defined as the ratio of thermal conductivity to the volumetric specific heat of the material. It measures the rate of heat transfer from an exposed surface of a material to the inside. The larger the diffusivity, the faster the temperature rise at a certain depth in the material. Similar to thermal conductivity and specific heat, thermal diffusivity varies with temperature rise in the material. Thermal diffusivity, α, can be calculated using the relation

$$\alpha = \frac{k}{\rho c_p} \tag{9.17}$$

where
k = Thermal conductivity
ρ = Density
c_p = Specific heat of the material

Special (Material-Specific) Properties

In addition to thermal and mechanical properties, certain other properties, such as spalling in concrete and charring in wood, influence the performance of a material at elevated temperature. These properties are unique to specific materials and are critical for predicting the fire performance of a structural member.

Critical Temperature

In building materials, such as steel and FRP, the determination of failure in a structural member exposed to fire is simplified to the calculation of critical temperature. The critical temperature is defined as the temperature at which the material

loses much of its strength and can no longer support the applied load. When this temperature is reached, the safety factor against failure becomes less than 1.

North American standards (ASTM E119) assume a critical or failure temperature of 538 °C (1000 °F) for structural steel. It is a typical failure temperature for columns under full design load. This temperature is also regarded as the failure temperature in the calculation of fire resistance of steel members. If a load is applied to the member, the test is continued until the member actually fails, which, depending on the load intensity, may occur at a higher or lower steel temperature.

This concept of critical temperature is also used for reinforced and prestressed steel in concrete structural members for evaluating the fire resistance ratings. These ratings are generally obtained through the provision of minimum member dimensions and minimum thickness of concrete cover. The minimum concrete cover thickness requirements are intended to ensure that the temperature in the reinforcement does not reach its critical temperature for the required duration. For reinforcing steel, the critical temperature is 593 °C, whereas for prestressing steel the critical temperature is 426 °C [29].

Spalling

Spalling is defined as the breaking of layers (pieces) of concrete from the surface of the concrete elements when the concrete elements are exposed to high and rapidly rising temperatures, such as those experienced in fires. Spalling can occur soon after exposure to heat and can be accompanied by violent explosions, or it may happen when concrete has become so weak after heating that, when cracking develops, pieces fall off the surface. The consequences may be limited as long as the extent of the damage is small, but extensive spalling may lead to early loss of stability and integrity due to exposed reinforcement and penetration of partitions.

Although spalling might occur in all concretes, high-strength concrete (HSC) is believed to be more susceptible than normal-strength concrete (NSC) because of its low permeability and low water-cement ratio. In a number of test observations on HSC specimens, it has been found that spalling is often of an explosive nature [30, 31]. Hence, spalling is one of the major concerns in the use of HSC and should be properly accounted for in evaluating fire performance. Spalling in NSC and HSC columns is compared in Fig. 9.6 using the data

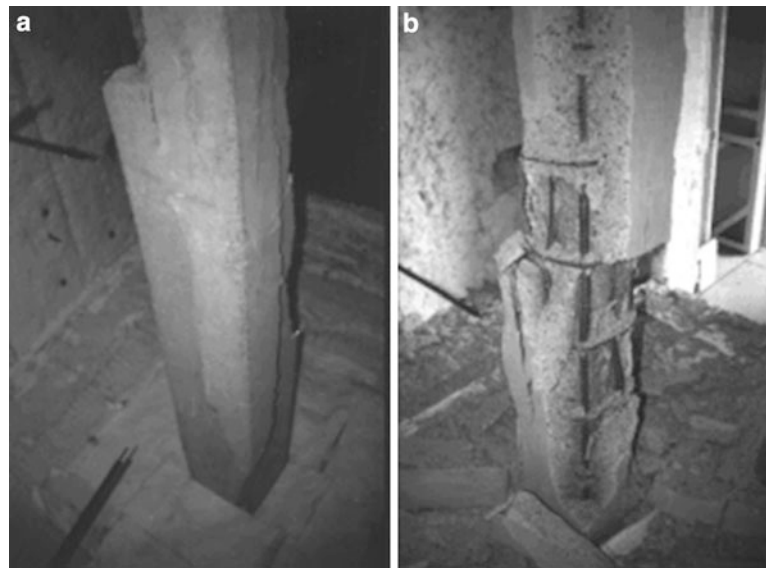

Fig. 9.6 Spalling in NSC and HSC columns after exposure to fire [32]: (**a**) normal-strength concrete column and (**b**) high-strength concrete column

obtained from full-scale fire tests on loaded columns [32]. It can be seen that the spalling is quite significant in the HSC column.

Spalling is believed to be caused by the buildup of pore pressure during heating. The extremely high water vapor pressure, generated during exposure to fire, cannot escape due to the high density (and low permeability) of HSC, and this pressure buildup often reaches the saturation vapor pressure. At 300 °C, the pressure reaches approximately 8 MPa; such internal pressures are often too high to be resisted by the HSC mix having a tensile strength of approximately 5 MPa [33]. The drained conditions at the heated surface, and the low permeability of concrete, lead to strong pressure gradients close to the surface in the form of the so-called "moisture clog." [2, 34] When the vapor pressure exceeds the tensile strength of concrete, chunks of concrete fall off from the structural member. The pore pressure is considered to drive progressive failure; that is, the lower the permeability of concrete, the greater the spalling. This falling off can often be explosive in nature, depending on the fire and concrete characteristics.

However, other researchers explain the occurrence of spalling on the basis of fracture mechanics and state that the spalling results from restrained thermal dilatation close to the heated surface [35]. This leads to compressive stresses parallel to the heated surface, which are released by brittle fractures of concrete, in other words, spalling.

Spalling, which often results in the rapid loss of concrete during a fire, exposes deeper layers of concrete to fire temperatures, thereby increasing the rate of transmission of heat to the inner layers of the member, including the reinforcement. When the reinforcement is directly exposed to fire, the temperatures in the reinforcement rise at a very high rate, leading to a faster decrease in strength of the structural member. The loss of strength in the reinforcement, added to the loss of concrete due to spalling, significantly decreases the fire resistance of a structural member.

In addition to strength and porosity of concrete mix, density, load intensity, fire intensity, aggregate type, and relative humidity are the primary parameters that influence spalling in HSC. The variation of porosity with temperature is an important property needed for predicting spalling performance of HSC. Noumowe et al. carried out porosity measurements on NSC and HSC specimens, using a mercury porosimeter, at various temperatures [36].

Charring

Charring is the process of formation of a layer of char at the exposed surface of wood members during exposure to fire. The charring process also occurs in other members, such as FRP and some types of plastics. When exposed to heat, wood undergoes thermal degradation (pyrolysis), the conversion of wood to char and gas, resulting in a reduction of the density of the wood. Studies have shown that the charring temperature for wood lies in the range of 280–300 °C [29].

The charred layer is considered to have practically no strength. The fire resistance of the member depends on the extent of charring and the remaining strength of the uncharred portion.

The charring rate, a critical parameter in determining the fire resistance of a structural wood member, is defined as the rate at which wood is converted to char. In the standard fire resistance test, it has been noted that the average rate of charring transverse to the grain is approximately 0.6 mm/min [29]. The charring rate parallel to the grain of wood is approximately twice the rate when it is transverse to the grain. Detailed studies on the charring rates for several specimen and timber types are reported by various researchers [37–39] and are summarized in a report [40]. These charring rates were constant (in each study) and ranged from 0.137 to 0.85 mm/min. The assumption of a constant rate of charring is reasonable for thick wood members.

Charring is influenced by a number of parameters, the most important ones being density, moisture content, and contraction of wood. The influence of the moisture content and density of the wood on the charring rate is illustrated in Fig. 9.7 for Douglas fir exposed to the standard

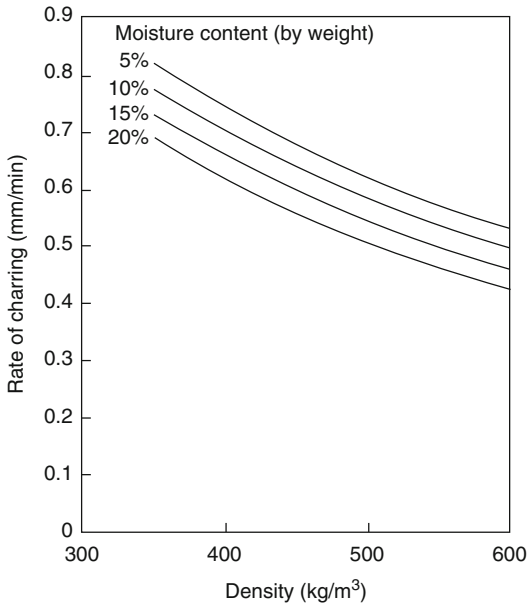

Fig. 9.7 Rate of charring in Douglas fir as a function of its density (dry condition) for various moisture contents when exposed to ASTM standard fire [29]

fire [29]. It can be seen that the charring rate decreases with increasing density of the wood and also with increasing moisture content.

It is important to recognize that the charring rate in real fires depends on the severity of fire to which the wood is exposed. It should be noted that the charring rate is a function of the imposed radiant heat flux. This depends on the fuel load and the ventilation factor of the compartment (for full details see Chap. 30, in this book). Detailed information on the charring of untreated wood—with expressions for charring rate in terms of the influencing factors of density, moisture content, external heat flux, and oxygen concentration—when exposed to real fires is given by Hadvig [41] and Mikkola [42].

Sources of Information

Information on the properties of building materials at elevated temperatures is scattered throughout the literature. There are a few publications, however, that may be particularly valuable for fire safety practitioners. A book by Harmathy [2] and the ASCE manual on structural fire protection [29] present a wealth of information on concrete, steel, wood, brick, gypsum, and various plastics. The thermal properties of 31 building materials are surveyed in an NRCC report [7]. The mechanical and thermal properties of concrete are discussed in an ACI guide [43], and in reports by Bennetts [44] and Schneider [45]. Those of steel are surveyed in the ACI guide, in Bennetts's report, and in a report by Anderberg [46]. Information on the thermal conductivity of more than 50 rocks (potential concrete aggregates) is presented in a paper by Birch and Clark [47]. The relationships for thermal and mechanical properties, at elevated temperatures, for some building materials are listed in the ASCE structural fire protection manual [29]. In most cases these properties are expressed, in the temperature range of 0–1000 °C, as a function of temperature and other properties at ambient temperature. These values can be used as input data in mathematical models for predicting cross sectional temperatures and fire performance of structural members.

Steel

Steel is a Group L material. The steels most often used in the building industry are either hot-rolled or cold-drawn. The structural steels and concrete reinforcing bars are hot-rolled, low-carbon, ferrite-pearlite steels. They have a randomly oriented grain structure, and their strength depends mainly on their carbon content. The prestressing steel wires and strands for concrete are usually made from cold-drawn, high-carbon, pearlitic steels with an elongated grain structure, oriented in the direction of the cold work. In addition, light-gauge steel, made from cold-formed steel, finds wide applications in lightweight framing, such as walls and floors.

Information on the mechanical properties of two typical steels (a structural steel [ASTM A36] and a prestressing wire [ASTM A421]) is presented in Figs. 9.8, 9.9, and 9.10 and in Table 9.1 [48]. Figures 9.8 and 9.9 are stress-strain curves at room temperature (24 °C and

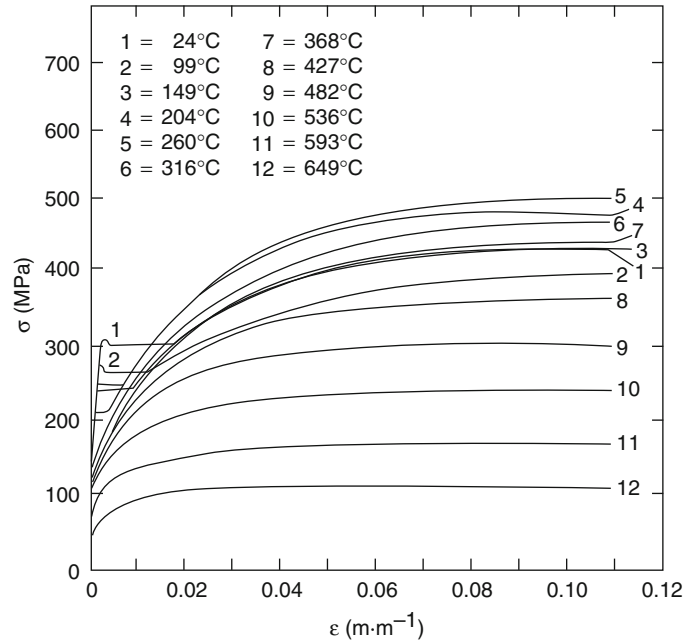

Fig. 9.8 Stress-strain curves for a structural steel (ASTM A36) at room temperature and elevated temperatures [48]

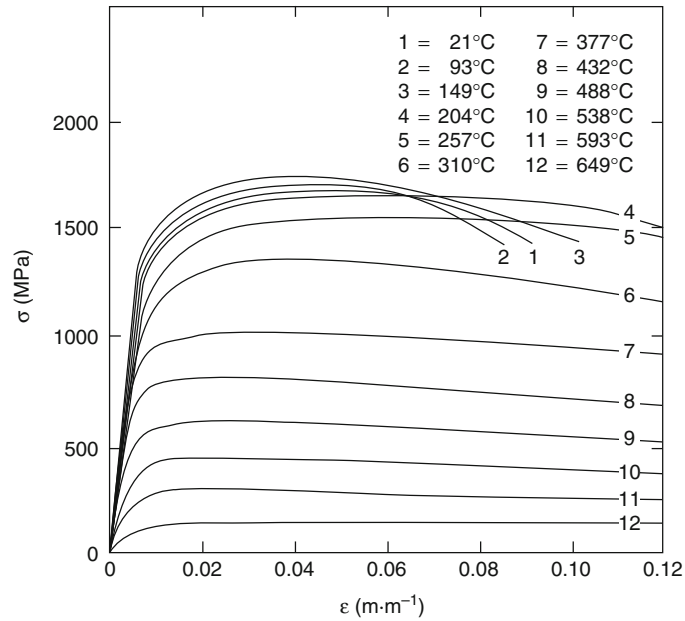

Fig. 9.9 Stress-strain curves for prestressing steel (ASTM A421) at room temperature and elevated temperatures [48]

21 °C, respectively) and at a number of elevated temperature levels. Figure 9.10 shows the effect of temperature on the yield and ultimate strengths of the two steels.

Table 9.1 presents information on the effect of stress on the two creep parameters, Z and ε_{t0} (see Equation 9.7). Because creep is a very structure-sensitive property, the creep parameters may show a substantial spread, even for steels with similar characteristics at room temperature. The application of the creep parameters to the calculation of the time of structural failure in fire is discussed in Hamilton and Crosser [4, 8].

The modulus of elasticity (E) is about 210×10^3 MPa for a variety of common steels at room temperature. Figure 9.11 shows its variation with temperature for structural steels [50] and steel reinforcing bars [49]. (E_0 in Fig. 9.11 is the modulus of elasticity at room temperature.)

The density (ρ) of steel is about 7850 kg·m^{-3}. Its coefficient of thermal expansion (β) is a structure-insensitive property. For an average carbon steel, β is 11.4×10^{-6} m·m^{-1}·K^{-1} at room temperature. The dilatometric curve shown in Fig. 9.12 is applicable to most of the common steels. The curve reveals substantial contraction of the material at about 700 °C, which is associated with the transformation (phase change of steel) of the ferrite-pearlite structure into austenite.

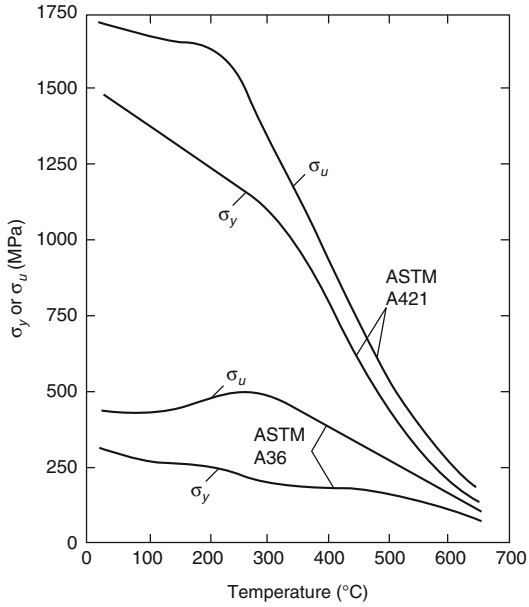

Fig. 9.10 The ultimate and yield strengths for a structural steel (ASTM A36) and a prestressing steel (ASTM A421) at elevated temperatures [48]

Being a structure-sensitive property, the thermal conductivity of steel is not easy to define. For carbon steels it usually varies within the range of 46–65 W·m^{-1}·K^{-1}.

Equations for various properties of steel, as functions of temperature, are available in the ASCE structural fire protection manual [29] and in Eurocode 3 [51, 52]. In the ASCE manual, the same set of relationships is applicable for thermal properties of both structural and reinforcing steel. However, separate relationships for stress-strain and elasticity are given for the two steels with slightly conservative values for structural steel. Recently, Poh proposed a general stress-strain equation that expresses stress explicitly in terms of strain in a single continuous curve [53, 54].

The critical temperature of steel is often used as a benchmark for determining the failure of structural members exposed to fire. This ensures that the yield strength is not reduced to less than that of 50 % of ambient value. The critical temperature for various types of steels is given in Table 9.2.

The above discussed high temperature properties are generally applicable to conventional carbon (mild) steel whose chemical composition consist of iron, carbon, manganese, sulfur and phosphorous. In recent years, a number of new steels are available and these steel are made by adding alloys, such as nickel, titanium, boron and chromium. These alloys influence durability characteristics, as well mechanical properties of steel. For example, molybdenum, chromium and niobium can increase the fire resistance property of steel, while chrome and nickel can enhance the corrosion resistance of steel [56]. Current design rules on fire resistance of steel structures (EC3 2005b [51], BS:5950

Table 9.1 Creep parameters for a structural steel and a prestressing steel [48]

Steel	$\Delta H_c/R$ (k)	$\varepsilon_{t0}(\sigma)$ (m · m^{-1})	$Z(\sigma)$ (h^{-1})
ASTM A36	38,890	$3.258 \times 10^{-17\sigma 1.75}$	$2.365 \times 10^{-20\sigma 4.7}$ if $\sigma \leq 103.4 \times 106$
			$1.23 \times 10^{16} \exp(4.35 \times 10^{-8\sigma})$ if $103.4 \times 10^6 \leq \sigma \leq 310 \times 10^6$
ASTM A421	30,560	$8.845 \times 10^{-9\sigma 0.67}$	$1.952 \times 10^{-10\sigma 3}$ if $\sigma \leq 172.4 \times 10^6$
			$8.21 \times 10^{13} \exp(1.45 \times 10^{-8\sigma})$ if $172.4 \times 10^6 \leq \sigma \leq 690 \times 10^6$

σ is measured in Pa

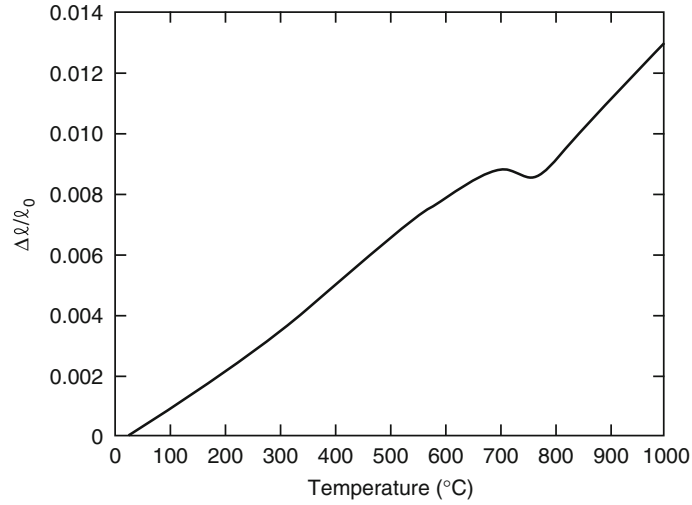

Fig. 9.12 Dilatometric curve for steel

Table 9.2 Critical temperature for various types of steel

Steel	Standard/reference	Temperature (°C)
Structural steel	ASTM	538
Reinforcing steel	ASTM	593
Prestressing steel	ASTM	426
Light-gauge steel	EC 3 [51]	350
	Gerlich et al. [55]	400

2003 [57]) are mainly based on experimental data on mild steel and do not account for specific property variations in new types of alloy steels.

Recent research by Wang et al. [58] clearly show that high strength (Q460) steel exhibits slower loss of strength and modulus throughout 20–800 °C temperature range as compared to mild steel. This is mainly due to the presence of chromium and niobium, which improves fire resistance properties of steel.

Furthermore, tests by Kodur et al. [59] have shown that type of heat treatment has significant influence on strength properties of steel e.g. annealing and normalizing produces normal strength steel, whereas quenching and tempering produces high strength steel. High strength steel, produced using quenching and tempering process, and that is used in bolts (A490 bolts) possesses slightly lower thermal conductivity than that of conventional mild steel.

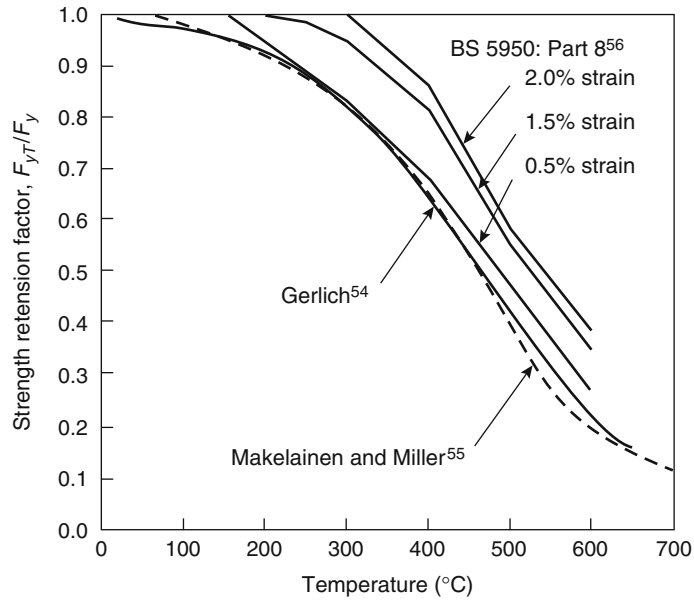

Fig. 9.13 Reduction of the yield strength of cold-formed light-gauge steel at elevated temperatures [57–61]

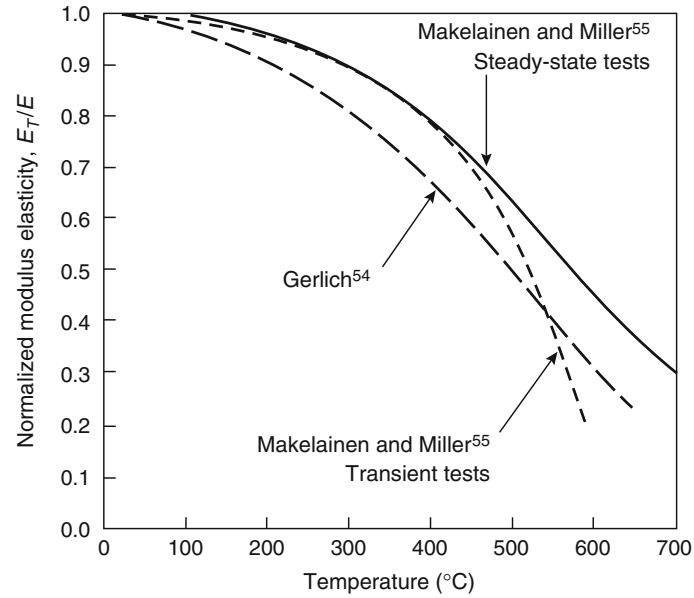

Fig. 9.14 Modulus of elasticity of cold-formed light-gauge steel at elevated temperatures [57–61]

The properties of cold-formed light-gauge steel are slightly different from those of hot-rolled structural steel. Gerlich [60] and Makelainen and Miller [61], based on steady-state and transient tests on cold-formed steel tension coupons (cut from studs) and galvanized sheets, proposed relationships for yield strength and modulus of elasticity. Figure 9.13 shows the variation of yield strength of light-gauge steel at elevated temperatures, corresponding to 0.5 %, 1.5 %, and 2 % strains based on the proposed relationships and on the relationship in BS 5950 [57]. The BS 5950 curves represent a conservative 95 % confidence limit (i.e., a 5 % chance that strength would fall below the curve), whereas the other two curves are representative of mean test data. Figure 9.14 shows the variation of modulus of elasticity of light-gauge steel at elevated

temperatures. The modulus E_T represents the tangent modulus at low stress levels (or initial tangent modulus), because steel stress-strain relationships become increasingly nonlinear at elevated temperatures. The effect of zinc coating on the mechanical properties of steel is of little significance.

The light-gauge steel has somewhat lower thermal expansion when compared to similar expressions for other steels [61]. The other thermal properties of steel, such as specific heat and thermal conductivity, are of little importance for the thermal modeling of light-gauge steel because steel framing plays a minor role in the heat transfer mechanism. A review of some of these properties is presented in a review paper [62].

The critical temperature of light-gauge steel is much lower than for other types of steels. Although Eurocode 3 limits this to a conservative value of 350 °C, in other cases a critical temperature of 400 °C is used (see Table 9.2).

Concrete

Concrete is a Group L/I material. The word *concrete* covers a large number of different materials, with the single common feature that they are formed by the hydration of cement. Because the hydrated cement paste amounts to only 24–43 volume percent of the materials present, the properties of concrete may vary widely with the aggregates used.

Traditionally, the compressive strength of concrete used to be around 20–50 MPa, which is referred to as normal-strength concrete (NSC). In recent years, concrete with a compressive strength in the range 50–100 MPa has become widely used and is referred to as high-strength concrete (HSC). Depending on the density, concretes are usually subdivided into two major groups: (1) normal-weight concretes with densities in the 2150- to 2450-kg·m^{-3} range and (2) lightweight concretes with densities between 1350 and 1850 kg·m^{-3}. Fire safety practitioners again subdivide the normal-weight concretes into silicate (siliceous) and carbonate aggregate concrete, according to the composition of the principal aggregate. Also, a small amount of discontinuous fibers (steel or polypropylene fibers) is often added to the concrete mix to achieve superior performance; this concrete is referred to as fiber-reinforced concrete (FRC). In this section, the properties of concrete are discussed under three groups: namely, NSC, FRC, and HSC.

Normal-Strength Concrete

A great deal of information is available in the literature on the mechanical properties of various types of normal-strength concrete. This information is summarized in reports by Bennetts [44] and Schneider [45], the ACI guide [43], the ASCE fire protection manual [29], and in Harmathy's book [2]. Figure 9.15 shows the stress-strain curves for a lightweight concrete with expanded shale aggregate at room temperature (24 °C) and a few elevated temperature levels [63]. The shape of the curves may depend on the time of holding the test specimen at the target temperature level before the compression test.

The modulus of elasticity (E) of various concretes at room temperature may fall within a very wide range, 5.0×10^3–35.0×10^3 MPa,

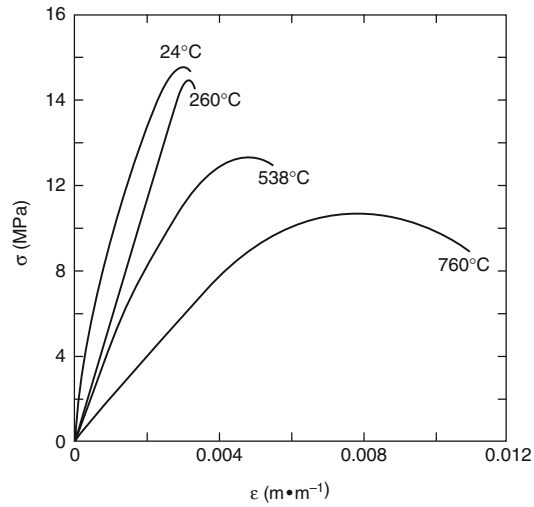

Fig. 9.15 Stress-strain curves for a lightweight masonry concrete at room and elevated temperatures [63]

dependent mainly on the water-cement ratio in the mixture, the age of concrete, the method of conditioning, and the amount and nature of the aggregates. Cruz found that the modulus of elasticity decreases rapidly with the rise of temperature, and the fractional decline does not depend significantly on the type of aggregate [64] (in Fig. 9.16, E_0 is the modulus of elasticity at room temperature). From other surveys [2, 44], it appears, however, that the modulus of elasticity of normal-weight concretes decreases faster with the rise of temperature than that of lightweight concretes.

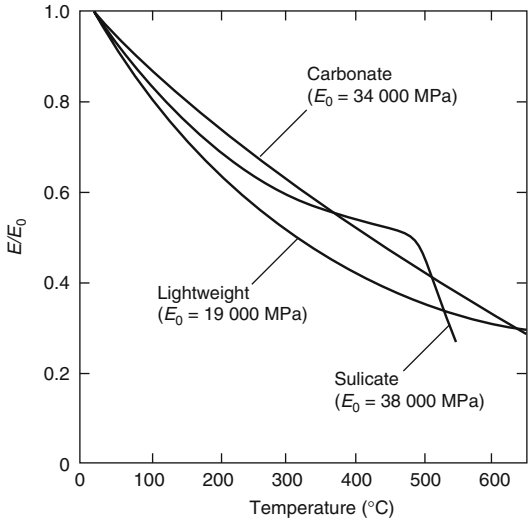

Fig. 9.16 The effect of temperature on the modulus of elasticity of concretes with various aggregates [61]

The compressive strength (σ_u) of NSC may also vary within a wide range. Compressive strength is influenced by the same factors as the modulus of elasticity. For conventionally produced normal-weight concretes, the strength at room temperature is usually between 20 and 50 MPa. For lightweight concretes, the strength is usually between 20 and 40 MPa.

Information on the variation of the compressive strength with temperature is presented in Fig. 9.17 (for a silicate aggregate concrete), Fig. 9.18 (for a carbonate aggregate concrete), and Fig. 9.19 (for two lightweight aggregate concretes, one made with the addition of natural sand) [65]. ($[\sigma_u]_0$ in the figures stands for the compressive strengths of concrete at room temperature.) In some experiments, the specimens were heated to the test temperature without load (see curves labeled "unstressed"). In others they were heated under a load amounting to 40 % of the ultimate strength (see curves labeled "stressed"). Again, in others they were heated to the target temperature without load, then cooled to room temperature and stored at 75 % relative humidity for six days, and finally tested at room temperature (see curves labeled "unstressed residual").

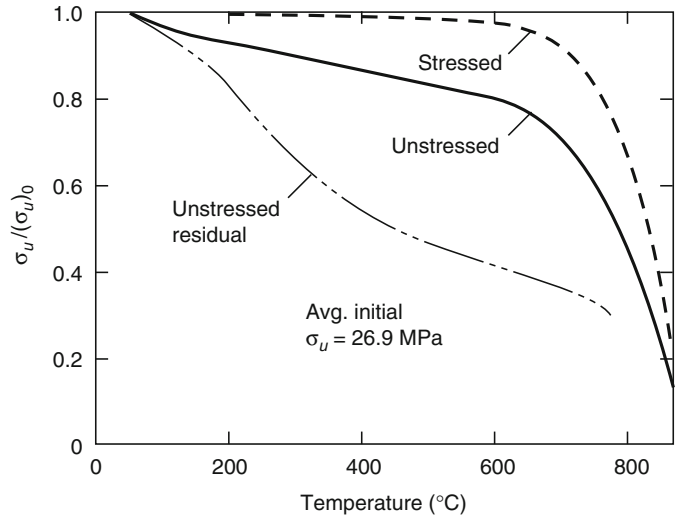

Fig. 9.17 The effect of temperature on the compressive strength of a normal-weight concrete with silicate aggregate [65]

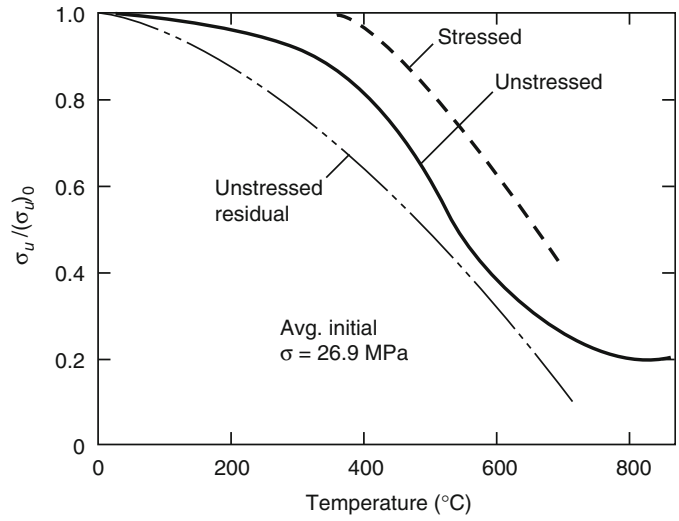

Fig. 9.18 The effect of temperature on the compressive strength of a normal-weight concrete with carbonate aggregate [65]

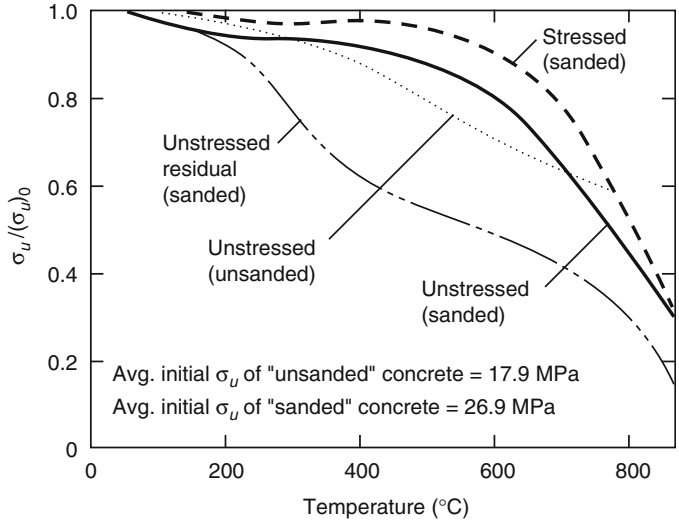

Fig 9.19 The effect of temperature on the compressive strength of two lightweight concretes (one with natural sand) [65]

Some information on the creep of concrete at elevated temperatures is available from the work of Cruz [66], MareÂchal [67], Gross [68], and Schneider et al. [69] The creep curves shown in Fig. 9.20 are those recorded by Cruz for a normal-weight concrete with carbonate aggregates.

Because the aggregates amount to 60–75 % of the volume of concrete, the dilatometric curve usually resembles that of the principal aggregate. However, some lightweight aggregates, for example, pearlite and vermiculite, are unable to resist the almost continuous shrinkage of the cement paste on heating, and therefore their dilatometric curves bear the characteristic features of the curve for the paste.

The dilatometric curves of two normal-weight concretes (with silicate and carbonate aggregates) and two lightweight concretes (with expanded shale and pumice aggregates) are shown in Fig. 9.21 [20]. These curves were obtained in the course of a comprehensive study performed on 16 concretes.

The results of dilatometric and thermogravimetric tests were combined to calculate the volumetric heat capacity (ρcp) versus temperature relation for these four concretes, as shown in

Fig. 9.22. The partial decomposition of the aggregate is responsible for a substantial drop (above 700 °C) in the density of concretes made with carbonate aggregate.

The aggregate type and moisture content have significant influence on the specific heat of concrete. The usual ranges of variation of the volume-specific heat (i.e., the product ρcp) for normal-weight and lightweight concretes are shown in Fig. 9.23. This information, derived by combining thermodynamic data with thermogravimetric observations [2, 6], has since been confirmed by differential scanning calorimetry [7]. Experimental data are also available on a few concretes and some of their constituents [2, 7].

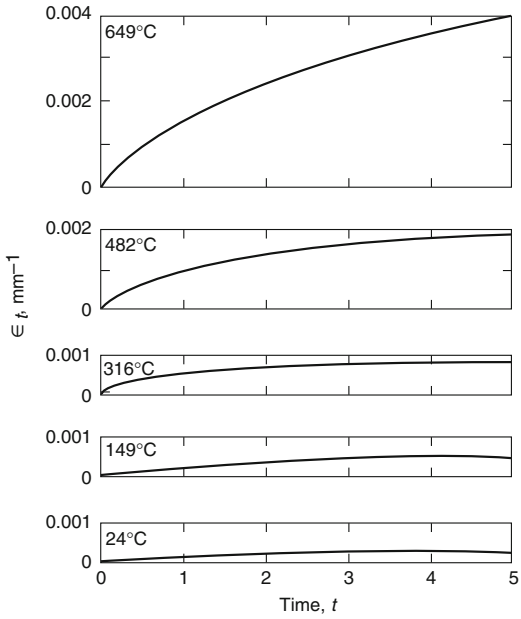

Fig. 9.20 Creep of a carbonate aggregate concrete at various temperature levels (applied stress: 12.4 MPa; compressive strength of the material at room temperature: 27.6 MPa) [66]

The thermal conductivity (k) of concrete depends mainly on the nature of its aggregates. In general, concretes made with dense, crystalline aggregates show higher conductivities than those made with amorphous or porous aggregates. Among common aggregates, quartz has the highest conductivity; therefore, concretes made with siliceous aggregates are on the whole more conductive than those made with other silicate and carbonate aggregates.

Derived from theoretical considerations [6], the solid curves in Fig. 9.24 describe the variation with temperature of the thermal conductivity of four concretes. In deriving these curves, two concretes (see curves 1 and 2) were visualized to represent limiting cases among normal-weight concretes, and the other two (see curves 3 and 4), limiting cases among lightweight concretes. The points in Fig. 9.24 stand for experimental data. They reveal that the upper limiting case is probably never reached with aggregates in common use and that the thermal conductivity of lightweight concretes may be somewhat higher than predicted on theoretical considerations.

Further experimental information on the thermal conductivity of some normal-weight and many lightweight concretes is available from the literature [6, 7, 20].

In reinforced concrete structures, the bond between rebars and concrete (at elevated temperatures) plays a major role in determining the fire endurance of structural members. Diederichs and Schneider investigated the variation of bond strength between deformed and plain rebars and concrete as a function of temperature [70]. They found that the bond strength reduction follows the same pattern as compressive strength for deformed and rusted plain bars. However, higher reduction in bond strength was observed for new plain bars. They also found that the bond strength at elevated temperature increases with decreasing coefficient of thermal expansion of concrete, which is significantly influenced by the type of aggregate. Diederichs and Schneider also concluded that the water-cement ratio and the bar diameter have a minor effect on the bond strength between steel and concrete [70]. Figure 9.25 illustrates the variation of bond strength as a function of temperature for reinforced and prestressed concrete.

Fiber-Reinforced Concrete

Steel and polypropylene discontinuous fibers are the two most common fibers used in the concrete mix to improve structural properties of concrete. Studies have shown that polypropylene fibers in a concrete mix are quite effective in minimizing spalling in concrete under fire conditions [71, 72]. The polypropylene fibers melt at a relatively low temperature of about 170 °C and create channels for the steam pressure in concrete to escape. This prevents the small explosions that cause the spalling of the concrete. Based on these studies, the amount of polypropylene fibers needed to minimize spalling is about 0.1–0.25 % (by volume). The polypropylene fibers were found to be most effective for HSC made with normal-weight aggregate.

The addition of fibers improves certain mechanical properties, such as tensile strength, ductility, and ultimate strain, at room temperature. However, there is very little information on the high-temperature properties of this type of concrete [73].

Steel fiber–reinforced concrete (SFRC) exhibits, at elevated temperatures, mechanical properties that are more beneficial to fire resistance than those of plain concrete. There is some information available on SFRC's material properties at elevated temperatures. The effect of temperature on the compressive strength for two types of SFRC is shown in Fig. 9.26. The strength of both types of SFRC exceeds the initial strength of the concretes up to about 400 °C. This is in contrast to the strength of plain concrete, which decreases slightly with temperatures up to 400 °C. Above approximately

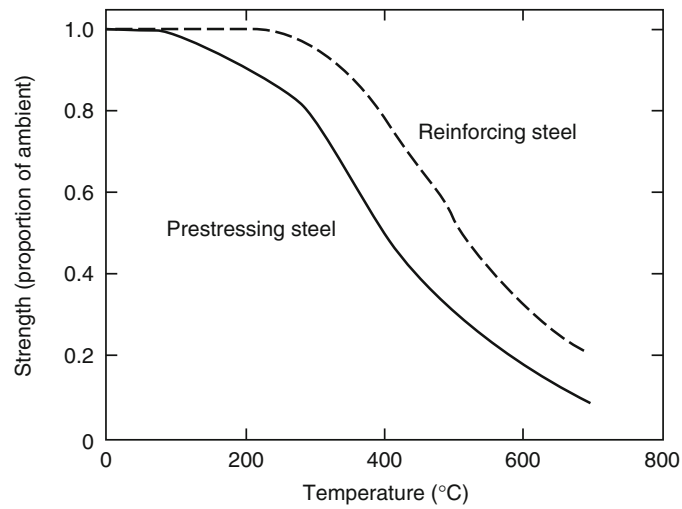

Fig. 9.25 Variation of bond strength as a function of temperature for reinforced and prestressed concrete [70]

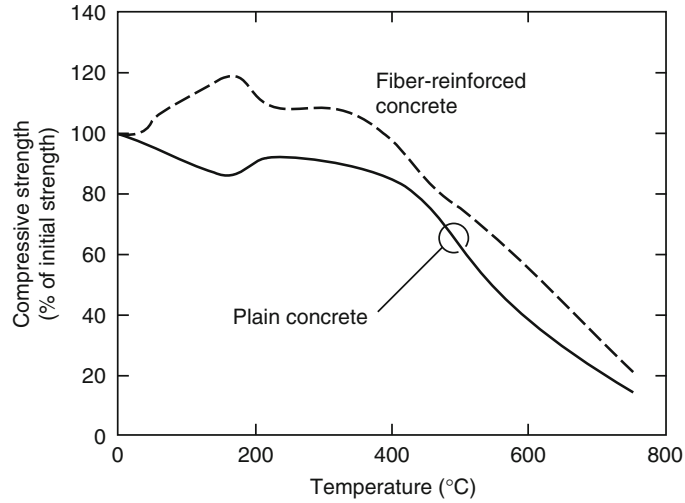

Fig. 9.26 Effect of temperature on compressive strength of steel fiber–reinforced concrete

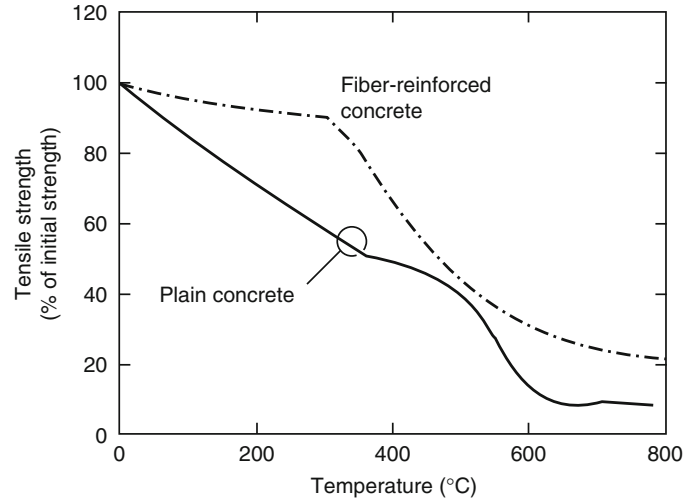

Fig. 9.27 Effect of temperature on tensile strength of steel fiber–reinforced concrete

400 °C, the strength of SFRC decreases at an accelerated rate [74].

The effect of temperature on the tensile strength of steel fiber–reinforced carbonate concretes is compared to that of plain concrete in Fig. 9.27 [75]. The strength of SFRC decreases at a lower rate than that of plain concrete throughout the temperature range, with the strength being significantly higher than that of plain concrete up to about 350 °C. The increased tensile strength delays the propagation of cracks in fiber-reinforced concrete structural members and is highly beneficial when the member is subjected to bending stresses.

The type of aggregate has a significant influence on the tensile strength of steel fiber–reinforced concrete. The decrease in tensile strength for carbonate aggregate concrete is higher than that for siliceous aggregate concrete [75].

The thermal properties of SFRC, at elevated temperatures, are similar to those of plain concrete. Kodur and Lie [27, 73] have carried out detailed experimental studies and developed dilatometric and thermogravimetric curves for various types of SFRC. Based on these studies, they have also developed expressions for thermal and mechanical properties of steel fiber–reinforced concrete in the temperature range 0–1000 °C [18, 76].

High-Strength Concrete

The strength of concrete has significant influence on the properties of HSC. The material properties of HSC vary differently with temperature than those of NSC. This variation is more pronounced for mechanical properties, which are affected by these factors: compressive strength, moisture content, density, heating rate, percentage of silica fume, and porosity [77]. The available information on the mechanical properties of HSC at elevated temperatures is presented in a review report by Phan [30].

The loss in compressive strength with temperature is higher for HSC than that for NSC up to about 450 °C. Figure 9.28 shows the comparison of strengths for NSC and HSC types, together with CEB and European design curves for NSC. The difference between compressive strength versus temperature relationships of normal-weight and lightweight aggregate concrete is not significant. However, HSC mixture with silica fume have higher compressive strength loss with increasing temperature than HSC mixture without silica fume. Based on a series of high-temperature material property tests, Kodur et al. have proposed a set of stress-strain relationships for HSC as a function of temperature [78, 79]. The variation, with temperature, of modulus of elasticity and tensile strength of HSC is similar to that of NSC.

Kodur and Sultan have presented detailed experimental data on the thermal properties of HSC (for both plain and steel fiber–reinforced concrete types) [80]. The type of aggregate has significant influence on the thermal properties of HSC at elevated temperatures. Figure 9.29 shows the thermal conductivity and specific heat of HSC, with siliceous and carbonate aggregates, as a function of temperature. Based on the test data, Kodur and Sultan have proposed relationships for thermal conductivity, specific heat, thermal expansion, and mass loss of HSC as a function of temperature [81].

The variation of thermal expansion with concrete temperature for siliceous and carbonate aggregate HSC is similar to that of NSC, with the aggregate having a strong influence. Overall, the thermal properties of HSC, at elevated temperatures, are similar to those of NSC [82].

HSC, due to low porosity, is more susceptible to spalling than NSC, and explosive spalling may occur when HSC is exposed to severe fire conditions. Hence, one of the major concerns for the use of HSC is regarding its behavior in fire, in particular, the occurrence of spalling at elevated temperatures. For predicting spalling performance, knowledge of the variation of porosity with temperature is essential. Figure 9.30 shows the variation of porosity with temperature for NSC and HSC. The data in this figure are taken from the measurements

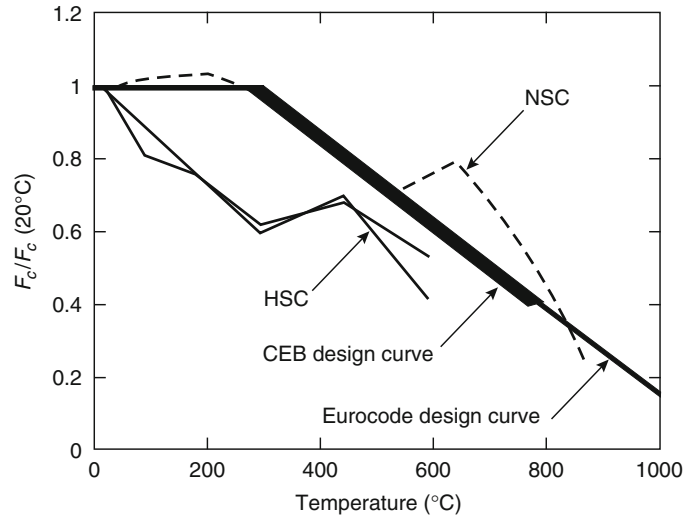

Fig. 9.28 Comparison of design compressive strength and results of unstressed tests of lightweight aggregate concrete [30]

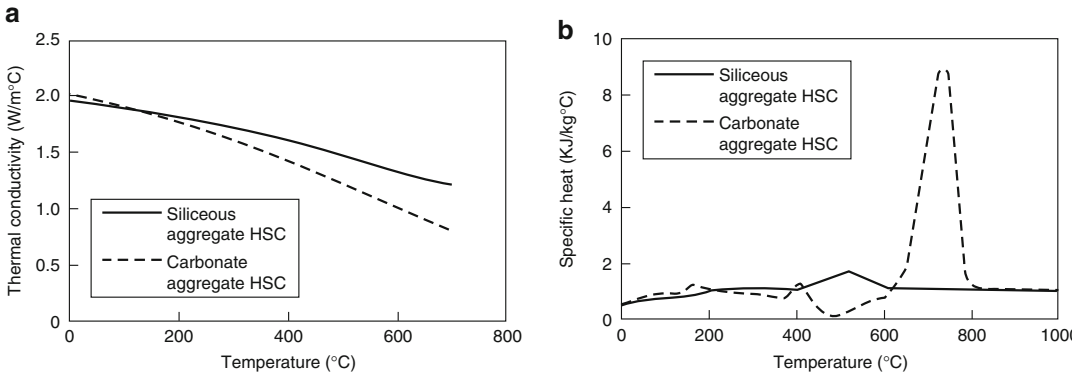

Fig. 9.29 Thermal conductivity and specific heat capacity of HSC as a function of temperature: [80] (**a**) thermal conductivity of high-strength concrete and (**b**) specific heat of high-strength concrete

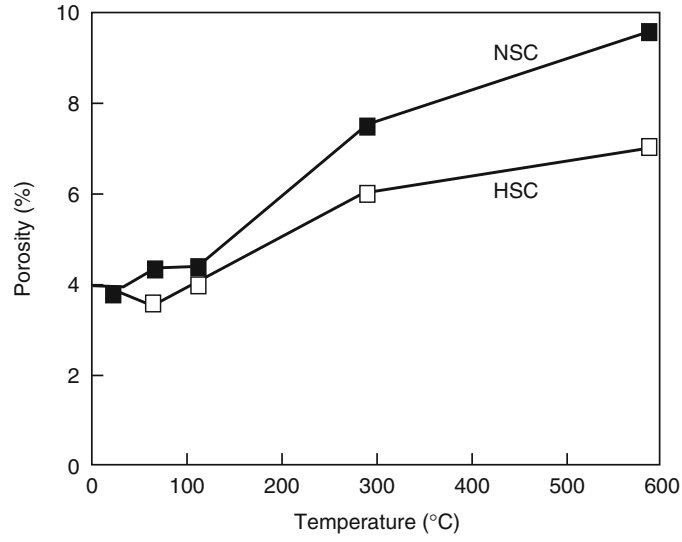

Fig. 9.30 Porosity of HSC and NSC as a function of temperature [36]

of porosity after exposure to different temperatures [36].

The spalling in HSC can be minimized by creating pores through which water vapor can be relieved before vapor pressure reaches critical values. This is usually done by adding polypropylene fibers to the HSC [71, 72, 83]. Also, Kodur et al. have reported that spalling in HSC columns can be minimized to a significant extent by providing bent ties as lateral confinement [77, 84]. Figure 9.31 illustrates conventional and improved tie configuration for minimizing spalling in HSC columns [84].

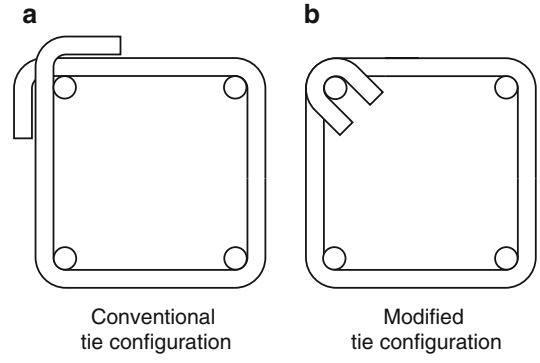

Fig. 9.31 Tie configuration for achieving higher fire resistance in concrete structures [79]

Brick

Building brick belongs in the L/I group of materials. The density (ρ) of bricks ranges from 1660 to 2270 kg·m^{-3}, depending on the raw materials used in the manufacture, and on the molding and firing technique. The true density of the material (ρt) is somewhere between 2600 and 2800 kg·m^{-3}.

The modulus of elasticity of brick (E) is usually between 10×10^3 and 20×10^3 MPa. Its compressive strength (σ_u) varies in a very wide range, from 9 to 110 MPa—50 MPa may be regarded as average [85]. This value is an order of magnitude greater than the stresses allowed in the design of grouted brickwork. Because brick is rarely considered for important load-bearing roles in buildings, there has been little interest in the mechanical properties of bricks at elevated temperatures.

At room temperature, the coefficient of thermal expansion (α) for clay bricks is about 5.5×10^{-6} m·m^{-1} K^{-1}. The dilatometric and thermogravimetric curves for a clay brick of 2180 kg·m^{-3} density are shown in Fig. 9.32 [7]. The variation with temperature of the specific heat and the thermal conductivity of this brick is shown in Figs 9.33 and 9.34, respectively [7].

Wood

Wood is a Group L/I/F or I/F material. As structural members, wood is widely used in residential and low-rise constructions. Although about 180 wood species are commercially grown in the United States, only about 25 species have been assigned working stresses. The two groups most extensively used as structural lumber are the Douglas firs and the southern pines.

The oven-dry density (ρ) of commercially important woods ranges from 300 kg·m^{-3} (white cedar) to 700 kg·m^{-3} (hickory, black locust). The density of Douglas firs varies from 430 to 480 kg·m^{-3} and that of southern pines from 510 to 580 kg·m^{-3}. The true density of the solid material that forms the walls of wood cells (αt) is about 1500 kg·m^{-3} for all kinds of wood. The density of wood decreases with temperature; the density ratio (ratio of density at elevated temperature to that at room temperature) drops to about 0.9 at 200 °C and then declines sharply to about 0.2 at about 350 °C [40].

Wood is an orthotropic material, so the strength and stiffness in longitudinal and transverse directions are influenced by grain orientation. The mechanical properties of wood are

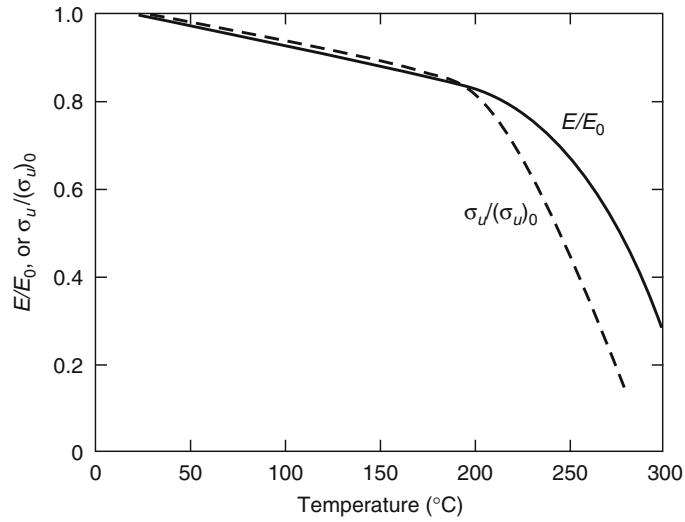

Fig. 9.35 The effect of temperature on the modulus of elasticity and compressive strength of wood [87–89]

affected by temperature and are influenced by moisture content, rate of charring, and grain orientation. The modulus of elasticity (E) of air-dry, clear wood along the grain varies from 5.5×10^3 to 15.0×10^3 MPa, and its crushing strength (σ_u) varies from 13 to 70 MPa. These properties are related and roughly proportional to the density, regardless of the species [86].

Figure 9.35 shows the variation of the modulus of elasticity and compressive strength of oven-dry, clear wood with temperature [87–89]. (E_0 and $[\sigma_u]_0$ in the figure are modulus of elasticity and compressive strength at room temperature, respectively.) The modulus of elasticity decreases slowly with temperature up to about 200 °C, when it reaches about 80 %, and then the decline is more rapid. The compressive strength also drops linearly to about 80 % at about 200 °C, and then the drop is more rapid—to about 20 % around 280 °C.

The tensile strength exhibits behavior similar to that of compressive strength, but the decline in tensile strength with temperature is less rapid. The moisture content plays a significant role in determining the strength and stiffness, with increased moisture content leading to higher reduction. There is very little information on stress-strain relationships for wood. The formulas for reduced stiffness and design strength can be found in Eurocode 5 [90] (Part 1.2).

The coefficient of linear thermal expansion (β) ranges from 3.2×10^{-6} to 4.6×10^{-6} $m \cdot m^{-1} \cdot K^{-1}$ along the grain and from 21.6×10^{-6} to 39.4×10^{-6} $m \cdot m^{-1} \cdot K^{-1}$ across the grain [91]. Wood shrinks at temperatures above 100 °C, because of the reduction in moisture content. Lie [29] reported that the amount of shrinkage can be estimated as 8 % in the radial direction, 12 % in the tangential direction, and an average of 0.1–0.2 % in the longitudinal direction. The dilatometric and thermogravimetric curves of a pine with a 400 $kg \cdot m^{-3}$ oven-dry density are shown in Fig. 9.36 [7].

The thermal conductivity (k) across the grain of this pine was measured as 0.86–1.07 $W \cdot m^{-1} \cdot K^{-1}$ between room temperature and 140 °C [14]. The thermal conductivity increases initially up to a temperature range of 150–200 °C, then decreases linearly up to 350 °C, and finally increases again beyond 350 °C.

Figure 9.37 shows the apparent specific heat for the same pine, as a function of temperature [7]. The accuracy of the curve (developed by differential scanning calorimeter [DSC]) is somewhat questionable. However, it provides useful information on the nature of decomposition reactions that take place between 150 and 370 °C.

Charring is one of the main high-temperature properties associated with wood and should be considered in predicting performance under fire

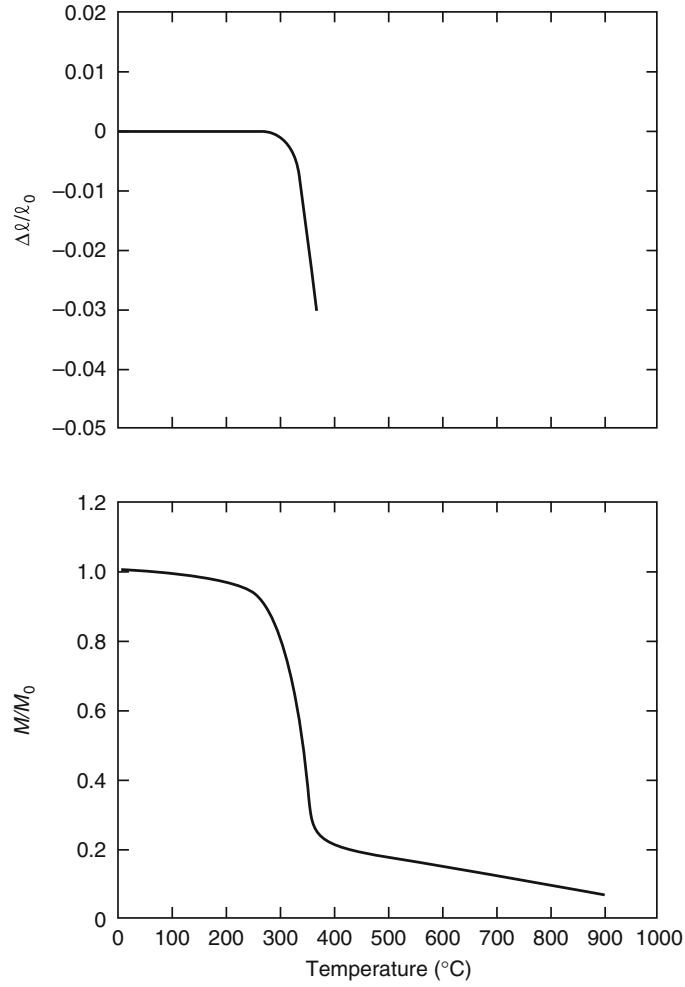

Fig. 9.36 Dilatometric and thermogravimetric curves for a pine of 400 kg·m^{-3} density [7]

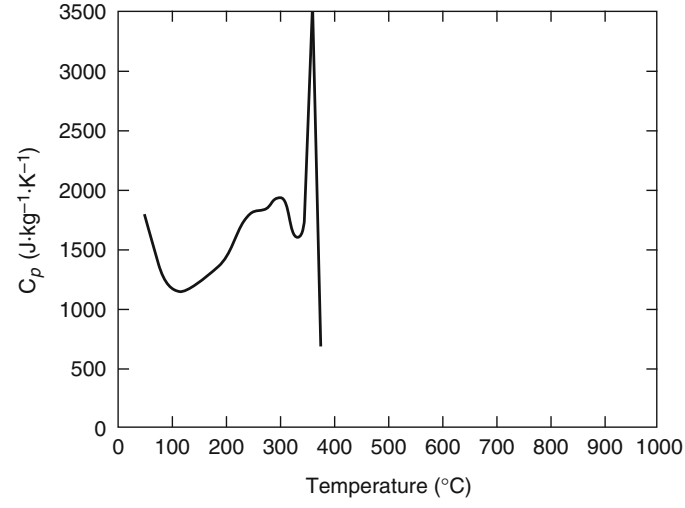

Fig. 9.37 Apparent specific heat for a pine of 400 °C density [7]

conditions. The rate of charring is influenced by the radiant heat flux or, alternatively, the fire severity. Generally, a constant transverse-to-grain char rate of 0.6 mm/min can be used for woods subjected to standard fire exposure [29]. The charring rate parallel to the grain of wood is approximately twice the rate when it is transverse to the grain. These charring rates should be used only when attempting to model the performance of wood sections in the fire resistance furnace.

Charring is influenced by a number of parameters, the most important ones being density, moisture content, and contraction of wood. It is reasonable to modify the 0.6 mm/min to approximately 0.4 mm/min for moist dense wood or to 0.8 mm/min for dry and light wood. The fire retardants often used to reduce flame spread in wood may only slightly increase the time until ignition of wood.

Specific charring rates for different types of wood can be found in "Structural Fire Protection" [29] and Bénichou and Sultan [40]. Eurocode [90] gives an expression for charring depth in a wood member exposed to standard fire. The dependence of charring rate on the radiant heat flux is discussed in *Wood Handbook* [87].

In recent years different types of engineered wood is widely used in residential construction. These engineered wood products (ex: joists and studs) capitalize on the strength of wood and the efficiency of the sectional shapes (ex: I-shaped joists) to enhance load bearing capacity at ambient conditions, while at the same time reducing the mass and cost of the structural member. However, there is very limited data on high temperature thermo-mechanical properties of engineered lumber and fire resistance of engineered joists and studs. Limited research has clearly shown that fire resistance of engineered joists to be significantly lower than that of conventional wood joists [92]. This was mainly attributed to poor thermal, mechanical and charring properties of engineered lumber as compared to conventional wood products. Typically, room temperature thermal conductivity and modulus of elasticity of engineered lumber is higher than other types of wood due to the presence of compressed plies [92]. Comparison of charring rates indicate that engineered lumber has higher rate of charring rate as compared to conventional wood [92].

Fiber-Reinforced Polymers

In recent years, there has been a growing interest in the use of fiber-reinforced polymers (FRPs) in civil engineering applications due to the advantages, such as high strength and durability (resistance to corrosion), that FRP offers over traditional materials. FRP composites consist of two key elements, namely the fibers (glass, carbon, or aramid) and a thermosetting polymer matrix such as epoxy, vinyl ester, phenolic, or polyester resin. The commonly used types of FRP composite materials are glass fiber–reinforced plastic (GFRP), carbon fiber–reinforced plastic (CFRP), and aramid fiber–reinforced plastic (AFRP) composites. FRPs are similar to wood in that they will burn when exposed to fire and can be classified as an L/I/F type material.

FRP is used as an internal reinforcement (reinforcing bars as an alternative to traditional steel reinforcement) and as external reinforcement in forms, such as wrapping and sheeting for the rehabilitation and strengthening of concrete members. One of the main impediments to using FRPs in buildings is the lack of knowledge about the fire resistance of FRP [93, 94].

There are some major differences associated with FRP as a material. The properties depend on the type and composition of FRP, and the availability of various types of FRP makes it difficult to establish the properties at elevated temperatures. The material properties are controlled by the fibers in the longitudinal direction and by the matrix in the transverse direction. In addition to thermal and mechanical properties, factors such as burning, charring, evolution of smoke, and toxicity in fire also play a significant role in determining the fire performance. A summary of typical mechanical properties for various types of FRPs, in comparison to other commonly used construction materials, at room temperature, is presented in Table 9.3.

Table 9.3 Properties of various FRP composites and other materials

Material	Modulus of elasticity E_1 (MPa)	Modulus of elasticity E_2 (MPa)	Tensile strength σ_{t1} (MPa)	Comp. strength σ_{c1} (MPa)	Shear modulus G (MPa)	Shear strength S (MPa)	Poisson's ratio ν	Tensile strength σ_2 (MPa)	Comp. strength σ_{c2} (MPa)
GFRP (glass/epoxy)	55,000	18,000	1050	1050	9000	42	0.25	28	140

E_1 = modulus of elasticity in longitudinal direction
E_2 = modulus of elasticity in transverse direction

There is very little information on the material properties of FRPs at elevated temperatures [93]. The impact of high temperatures on the behavior of FRP composites is severe degradation of their properties: reduction of strength and stiffness, and increase in deformability, thermal expansion, and creep. Above 100 °C temperature, the degradation can be quite rapid as the glass transition temperature of the matrix is reached.

The glass transition temperature, which is often considered the upper use temperature, varies with the type of resin used and was found to be as low as 100 °C in some resins and as high as 220 °C in others. From the limited studies, it appears that as much as 75 % of the GFRP strength and stiffness is lost by the time the temperature reaches 250 °C [93, 95].

The stress-strain relationships, from the studies conducted by Gates [95], for a CFRP composite (IM7/5260) are shown in Fig. 9.38 for various temperatures. It can be seen that the tensile strength of IM7/5260 composite reduces to approximately 50 % at about 125 °C and to about 75 % at a temperature of 200 °C. The strain level, for a given stress, is also higher with the increase in temperature. Recently, Wang and Kodur reported high temperature strength and stiffness properties of glass and carbon FRP rebars; full details of the tests are reported in Wang and Kodur [96].

The variation of strength with temperature (ratio of strength at elevated temperature to that at room temperature) for FRP along with that of other traditional construction materials is shown in Fig. 9.2. The curve showing the strength degradation of FRP is based on the limited information reported in the literature [93, 95]. The rate of strength loss is much greater for FRP than for concrete and steel, resulting in a 50 % strength loss by about 200 °C.

The bond between FRPs and concrete (or between FRP layers or lap splices in multiply layup applications) is essential to transfer loads. This load transfer occurs through the polymer resin matrix and thus relies heavily on the mechanical properties of the polymer.

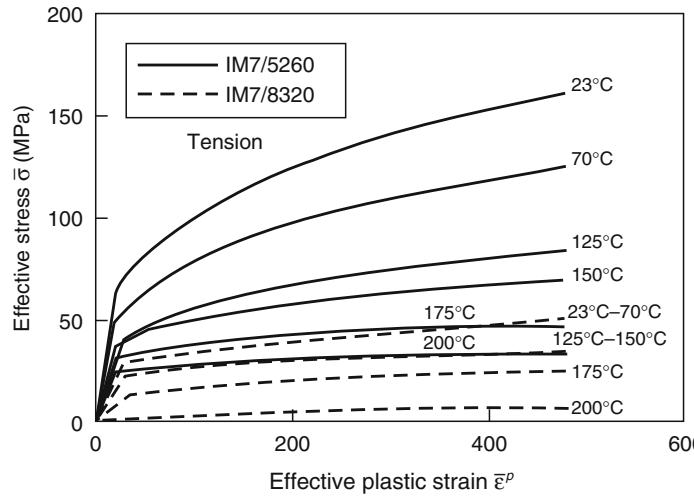

Fig. 9.38 Tensile stress-strain curves for CFRP at various temperatures [95]

Deterioration of the mechanical properties of the matrix material at temperatures above the specific polymer's glass transition temperature, T_g, have the potential to cause loss of bond at only modestly increased temperatures, resulting in loss of interaction between FRP and concrete. The glass transition temperature of commonly used polymer matrix materials is typically in the range of 65–140 °C.

No specific research has yet been reported on the bond between concrete and externally bonded FRP strengthening systems at high temperature, although limited data on the high-temperature residual performance of the FRP concrete bond has recently been presented [97].

Research on the bond properties of FRP bars for concrete reinforcement applications (internal reinforcement) at elevated temperature has been reported in the literature [98–101]. This work has indicated that dramatic decreases in bond strength can be expected, to values of about 10 % of room temperature strength, at temperatures between 100 and 200 °C (i.e., at temperatures close to or above T_g). The observed bond strength reductions have been attributed to changes in the properties of the polymer matrix at the surface of the FRP bars.

It seems clear that temperature effects on the FRP–FRP and FRP–concrete bond are critical, both in FRP internal reinforcement and in externally bonded FRP applications, and a great deal of additional research is required in this area. Thus, bond degradation at elevated temperature is a critical factor to be considered in the design of FRP-reinforced or -strengthened concrete members. This was observed in full-scale fire tests on FRP-strengthened reinforced concrete columns [102].

The critical temperature of FRP is much lower than that for steel and depends on the composition of fibers and matrix. Kodur and Baingo have assumed a critical temperature of 250 °C in modeling the behavior of FRP-reinforced concrete slabs [93]. Recently, Wang and Kodur have developed critical temperature information for glass and carbon FRP reinforcing rebars [103, 104].

They carried out a series of tensile strength tests at high temperatures on two types of commercially available FRP rebars. This included both carbon FRP and glass FRP bars of different diameters. Conventional steel rebars were also tested for comparison. The data were used to determine the variation of average failure strength and elastic modulus for each type of reinforcement with increasing temperature. Full details of experimental studies, including specimen preparation, test setup, test procedure, and observations as well as test data, are described elsewhere [96, 104].

A summary of the results of these studies are shown in Fig. 9.39. For the GFRP and CFRP bars, observed failure strengths were used, whereas for the steel bars, the 0.2 % proof stress was used. The elastic modulus was taken as the

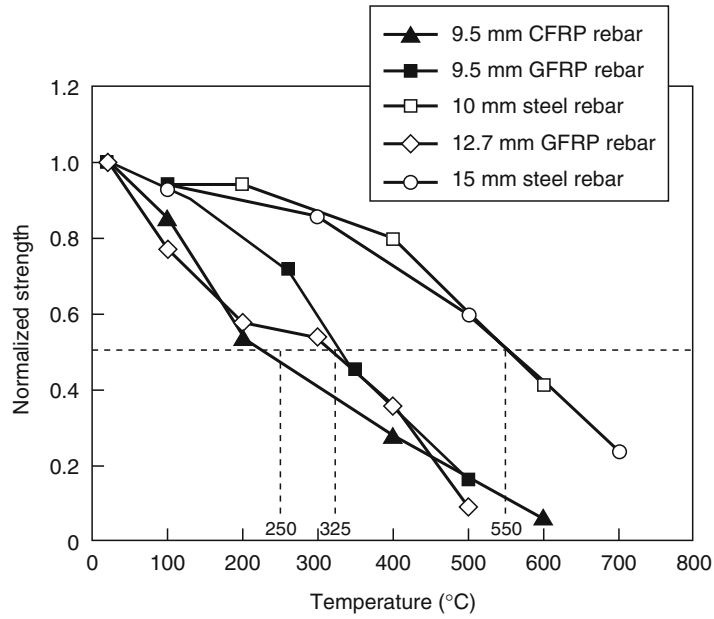

Fig. 9.39 Effect of strength degradation as a function of temperature for FRP [96]

Table 9.4 Thermal properties of various FRPs and other materials at room temperature

	Coefficient of thermal expansion (unidirectional) (β: 10^{-6} m · m^{-1}·°C)		Thermal conductivity k (W · m^{-1} ° C^{-1})	
Material	Longitudinal α_L	Transverse α_T	Longitudinal k_L	Transverse k_T
Glass/epoxy (S-glass)	6.3	19.8	3.46	0.35

Steel	10.8–18		15.6–46.7	
Epoxy	—	54–90	—	0.346

slope of a straight line fitted to the initial linear portion of the recorded stress-strain relationship for each specimen. The critical temperature for the FRP reinforcement was derived based on a 50 % tensile strength reduction, as is the case for steel reinforcement. This resulted in critical temperatures of about 325 °C and 250 °C for GFRP and CFRP reinforcing bars, respectively. These critical temperatures are significantly less than 593 °C, the critical temperature for steel reinforcement, thus highlighting the presumed susceptibility of FRP reinforcement to fire. Figure 9.39 also shows that the steel reinforcing bars in these tests lost about 50 % of their room-temperature yield strength at about 550 °C, a result that agrees well with published data available in the literature.

The variation of elastic moduli of FRP with temperature is different in each direction. Typical values for various types of FRP are given in Table 9.3 [93]. The three values represent the longitudinal, transverse, and shear moduli, respectively, of different unidirectional FRPs. At high temperature, the elastic moduli of FRPs decreases at a faster rate than that for concrete or steel.

Similar to mechanical properties, the thermal properties of FRP are also dependent on direction, fiber type, fiber orientation, fiber volume fraction, and laminate configuration. Table 9.4 shows thermal properties for various types of

FRP at room temperature. In the longitudinal direction, the thermal expansion of FRPs is lower than that of steel. However, in the transverse direction, it is much higher than that of steel. Some of the information available in the literature can be found in a review report by Kodur and Baingo [93]. At room temperatures, FRPs in general have low thermal conductivity, which makes them useful as insulation materials. With the exception of carbon fibers, FRPs have a low thermal conductivity.

Information on the thermal properties of FRP at elevated temperatures is very scarce, which is likely due to the fact that such information is proprietary to the composite materials' manufacturers. Also, there is not much information on evolution of smoke and toxins in FRP composites exposed to fire.

Thermal expansion of FRP reinforcement varies in longitudinal and transverse directions, and the coefficient of thermal expansion highly depends on type of fiber, resin, and volume fraction of fiber. The longitudinal coefficient of thermal expansion is dominated by properties of the fiber, while the transverse coefficient is dominated by properties of the resin. Figure 9.40

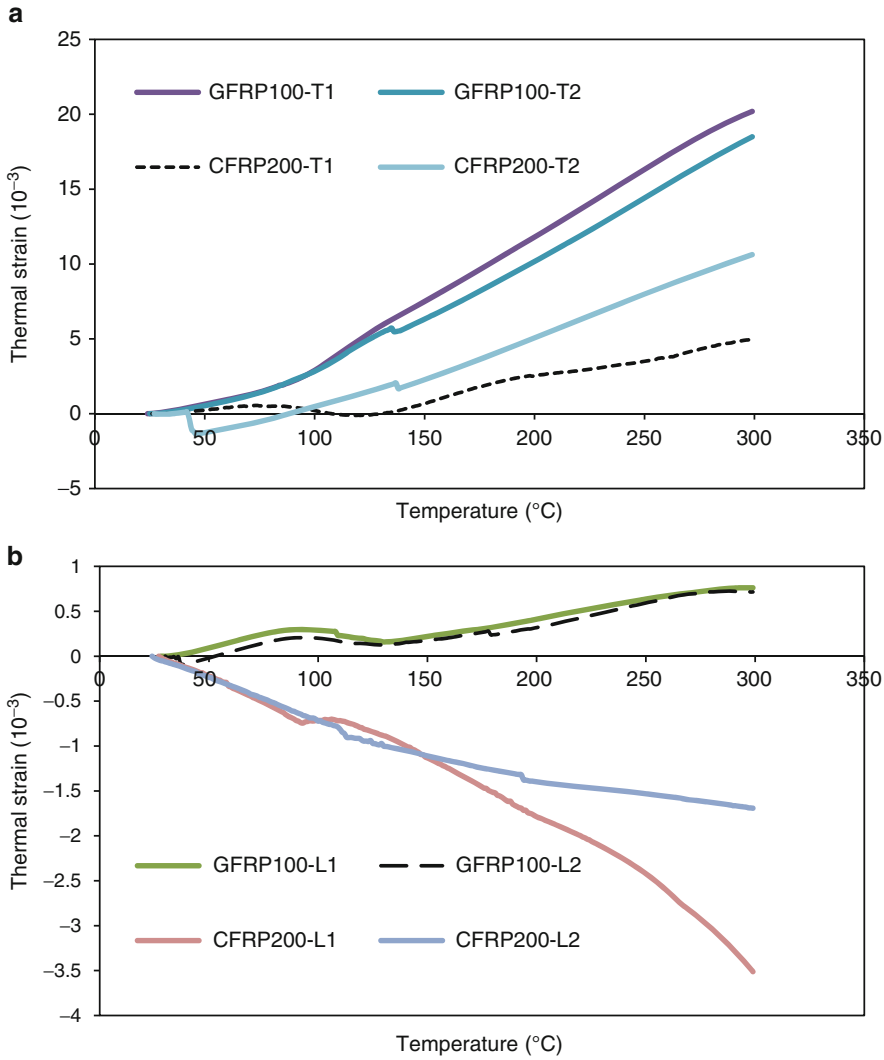

Fig. 9.40 Variation of thermal strain in GFRP and CFRP in (**a**) longitudinal and (**b**) transverse directions as a function of temperature

(a and b) shows longitudinal and transverse coefficients of thermal expansion for typical GFRP and CFRP bars. It can be noted that usually there is a change in expansion rate at around glass transition temperature (Tg), indicating FRP reinforcement experiences different coefficients of thermal expansion before and after phase change (Tg). In transverse direction, the dimension of GFRP and CFRP rebars increase with temperature, and GFRP undergoes higher thermal expansion than that of CFRP. However, in longitudinal direction, GFRP rebar slightly expands with temperature, but CFRP rebar contracts with increase in temperature. The coefficients of thermal expansion in transverse direction for GFRP and CFRP rebars can be taken to be 64.5 and 7.79 $\times$ 10^{-6}/°C, respectively, while the corresponding coefficients of thermal expansion in longitudinal direction are 2.48 and -7.6×10^{-6}/°C, respectively [105]

Gypsum

Gypsum (calcium sulfate dihydrate: $CaSO_4 \cdot 2H_2O$) is a Group I material. Gypsum board is produced by mixing water with plaster of paris (calcium sulfate hemihydrate: $CaSO_4 \cdot {}^1/_2H_2O$) or with Keene's cement (calcium sulfate anhydrite: $CaSO_4$). The interlocking crystals of $CaSO_4 \cdot 2H_2O$ are responsible for the hardening of the material.

Gypsum products are used extensively in the building industry in the form of boards, including wallboard, formboard, and sheathing. The core of the boards is fabricated with plaster of paris, into which weight- and set-controlling additives are mixed. Furthermore, plaster of paris, with the addition of aggregates (such as sand, pearlite, vermiculite, or wood fiber) is used in wall plaster as base coat, and Keene's cement (neat or mixed with lime putty) is used as finishing coat.

Gypsum board, based on composition and performance, is classified into various types, such as regular gypsum board, type X gypsum board, and improved type X gypsum board. A gypsum board with naturally occurring fire resistance from the gypsum in the core is defined as regular gypsum. When the core of the gypsum board is modified with special core additives or with enhanced additional properties, to improve the natural fire resistance from regular gypsum board, it is classified as type X or improved type X gypsum board. There might be significant variation in fire performance of the gypsum board based on the type and the formulation of the core, which varies from one manufacturer to another.

Gypsum is an ideal fire protection material. The water inside the gypsum plays a major role in defining its thermal properties and response to fire. On heating, it will lose the two H_2O molecules at temperatures between 125 and 200 °C. The heat of complete dehydration is 0.61×10^6 J/kg gypsum. Due to the substantial absorption of energy in the dehydration process, a gypsum layer applied to the surface of a building element is capable of markedly delaying the penetration of heat into the underlying load-bearing construction.

The thermal properties of the gypsum board vary depending on the composition of the core. The variation with temperature of the volume specific heat (ρcp) of pure gypsum has been illustrated in Harmathy [106], based on information reported in the literature [107, 108]. The thermal conductivity of gypsum products is difficult to assess, owing to large variations in their porosities and the nature of the aggregates. A typical value for plaster boards of about 700 $kg \cdot m^{-3}$ density is 0.25 $W \cdot m^{-1} \cdot K^{-1}$. Figures 9.41 and 9.42 illustrate the typical variation of the thermal conductivity and the specific heat, respectively, of the gypsum board core with temperature. The plots reflect the expressions proposed recently by Sultan [109], based on tests conducted on type X gypsum board specimens. The specific heat measurements were carried out at a heating rate of 2 °C/min. The dehydration of gypsum resulted in the two peaks that appear in the specific heat curve at temperatures around 100 °C and 650 °C. The peak values are slightly variant to those reported earlier by Harmathy [16]; this may be due to the differences in gypsum composition.

The coefficient of thermal expansion (β) of gypsum products may vary between

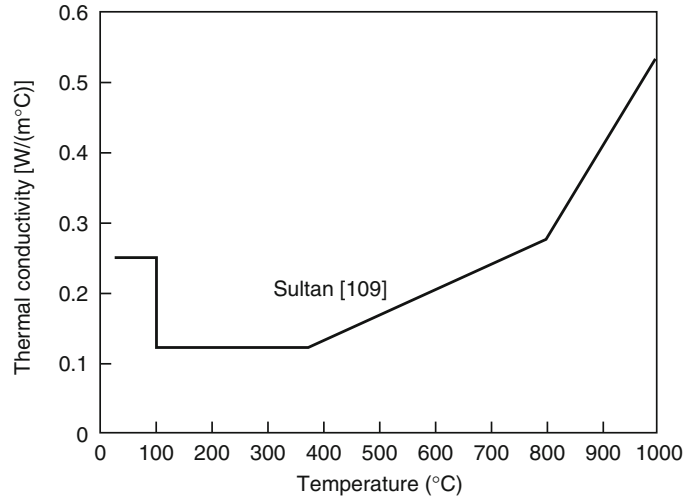

Fig. 9.41 Thermal conductivity of type X gypsum board core as a function of temperature [109]

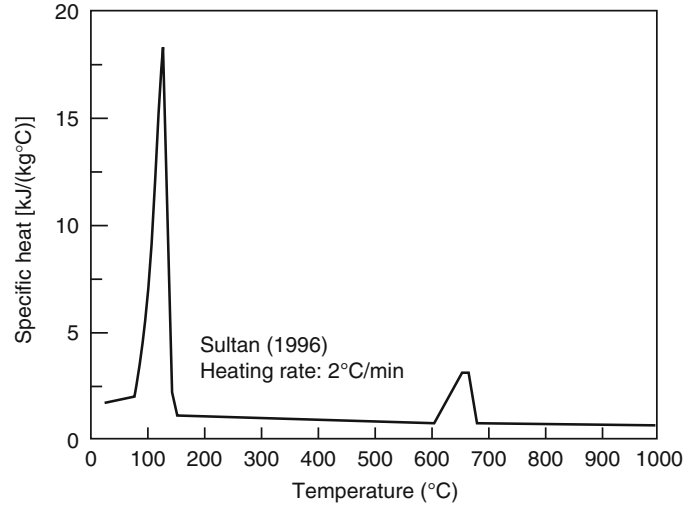

Fig. 9.42 Specific heat of type X gypsum board core as a function of temperature [109]

11.0×10^{-6} and 17×10^{-6} $m \cdot m^{-1} \cdot K^{-1}$ at room temperature, depending on the nature and amount of aggregates used. The dilatometric and thermogravimetric curves of a so-called fire-resistant gypsum board of 678 $kg \cdot m^{-3}$ density are shown in Fig. 9.43.

There is not much information about the mechanical properties of the gypsum board at elevated temperatures because these properties are difficult to obtain experimentally. The strength of gypsum board at an elevated temperature is very small and can be neglected. The Gypsum Association [110] lists typical mechanical properties, at room temperature, for some North American gypsum board products. The attachment details (screw spacing, orientation of gypsum board joints, stud spacing, etc.) may have a noticeable effect on the fire performance of the gypsum board.

Insulation

Insulation is a Group I material and is often used as a fire protection material both for heavy structural members such as columns and beams and for lightweight framing assemblies such as floors and walls. The insulation helps delay the

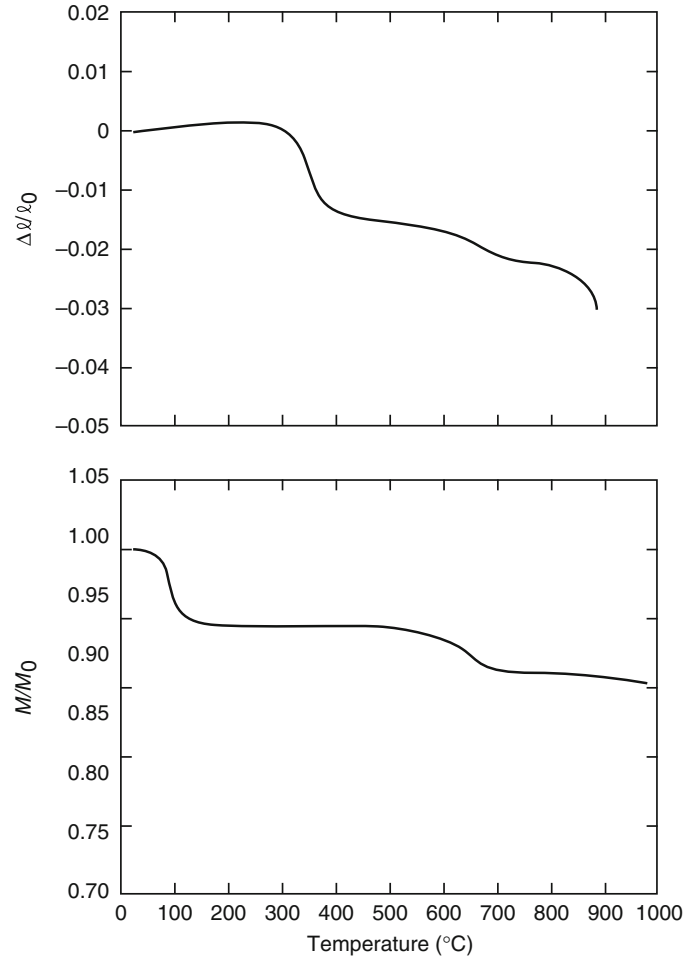

Fig. 9.43 Dilatometric and thermogravimetric curves for a gypsum board of 678 kgm^{-3} density [7]

temperature rise of structural members, thereby enhancing fire resistance. There are a number of insulation materials available in the market. Mineral wool and glass fiber are the two most widely used insulation materials in walls and floors. Other insulation materials used for fire protection include intumescent paints, spray mineral fibers, insulation boards, and compressed fiber board.

The thermal properties of insulation play an important role in determining the fire resistance. However, there is not much information available on the thermal properties of various types of insulation. Figure 9.44 shows the variation of thermal conductivity with temperature for glass and rock fiber insulation types. The differences in thermal conductivity values at higher temperatures are mainly due to variation in the chemical composition of fiber.

Full-scale fire resistance tests on walls and floors have shown that the mineral fiber insulation performs better than glass fiber insulation. This is mainly because glass fiber melts in the temperature range of 700–800 °C and cannot withstand direct fire exposure. The melting point for mineral fiber insulation is higher. The density of glass fiber is about 10 kg/m^3 and is much lower than that of rock fiber, which is about 33 kg/m^3.

The mineral wool insulation, when installed tightly between the studs, can be beneficial for the fire resistance of non-load-bearing steel stud walls because it acts as an additional fire barrier

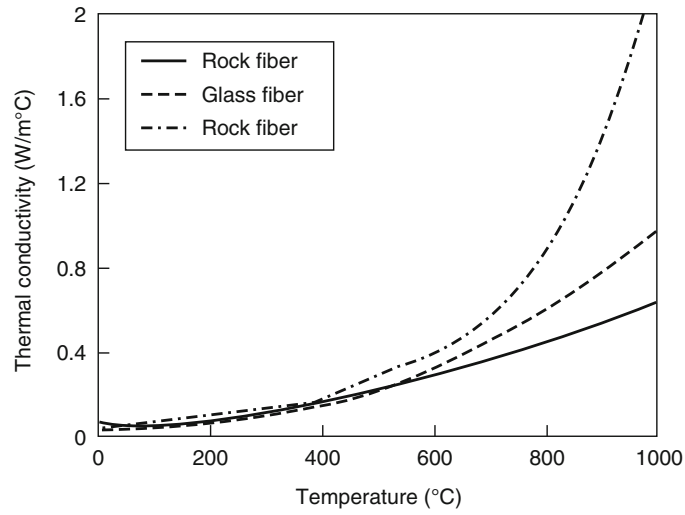

Fig. 9.44 Thermal conductivity of insulation as a function of temperature [40]

Table 9.5 Properties of some commonly used insulation materials [105]

Material	Density ρ (kg/m3)	Thermal conductivity k (W/m·K)	Specific heat c (J/kg·K)	Equilibrium moisture content %
Spray				
Sprayed mineral fibers	300	0.12	1200	1
Perlite or vermiculite plaster	350	0.12	1200	15
High-density perlite or vermiculite plaster	550	0.12	1200	15
Boards				
Fiber silicate or fiber calcium silicate	600	0.15	1200	3
Gypsum plaster	800	0.2	1700	20
Compressed fiber boards				
Mineral wool, fiber silicate	150	0.2	1200	2

after the fire-exposed gypsum board falls off [111]. On the other hand, cavity insulation slows down the flow of heat through the wall assembly and can cause an accelerated temperature rise in the fire-exposed gypsum board.

Another common form of fire insulation applied on steel structural members to achieve required fire resistance is spray applied fire resistive materials (SFRM), which work by delaying temperature rise in steel. SFRM, available under different trade names, offers several advantages over other types of fire insulation such as cost effectiveness, ease of application, and light weight, and therefore is widely used as fire proofing material for steel structures. SFRM is mainly composed of base materials such as gypsum, cementitious and mineral fiber and other additives such as vermiculite.

The thermal properties of some of the commonly used insulation systems are given in Table 9.5 [112]. It should be noted that these values are average property values and can vary depending on the manufacturer and on the proportions of different constituent materials. Also the moisture content of the insulation material has an effect on the thermal properties.

The above listed thermal properties for fire insulation are at room temperature and they can vary significantly with temperature and also with insulation composition, which can vary for different trade names (from different commercial manufactures) among the same type of insulation

(ex: SFRM). However, in practice fire resistance of insulated structural (steel) members is evaluated by considering only room temperature thermal properties of fire insulation [113]. This is mainly due to lack of reliable data on the effect of temperature on thermal properties of fire insulation. Further, there is no data on relative thermal performance of similar fire insulation products (ex: SFRM) produced from different commercial manufactures.

Figure 9.45a shows variation of thermal conductivity with temperature for three types of commercially available SFRM (A, B, and C) generated in a recent research study [114]. The thermal conductivity of three SFRM types at room temperature is in the range of 0.07 and 0.2 W/m.K. This variation of thermal conductivity among three types of SFRM well pertains to the variation in their densities and also to composition of ingredients in each type. The trends in the figure further indicate that temperature has significant effect on thermal conductivity of SFRM. This variation in thermal conductivity at higher temperatures is primarily governed by changes in moisture content and density of different SFRM types.

Insulation materials such as SFRM experience shrinkage at higher temperatures, as opposed to expansion phenomenon in materials such as steel, concrete and wood. The variation of thermal strain for three types of SFRM is plotted as a function of temperature in Fig. 9.45b [114]. This variation of thermal strain with temperature is also linked to changes in moisture content.

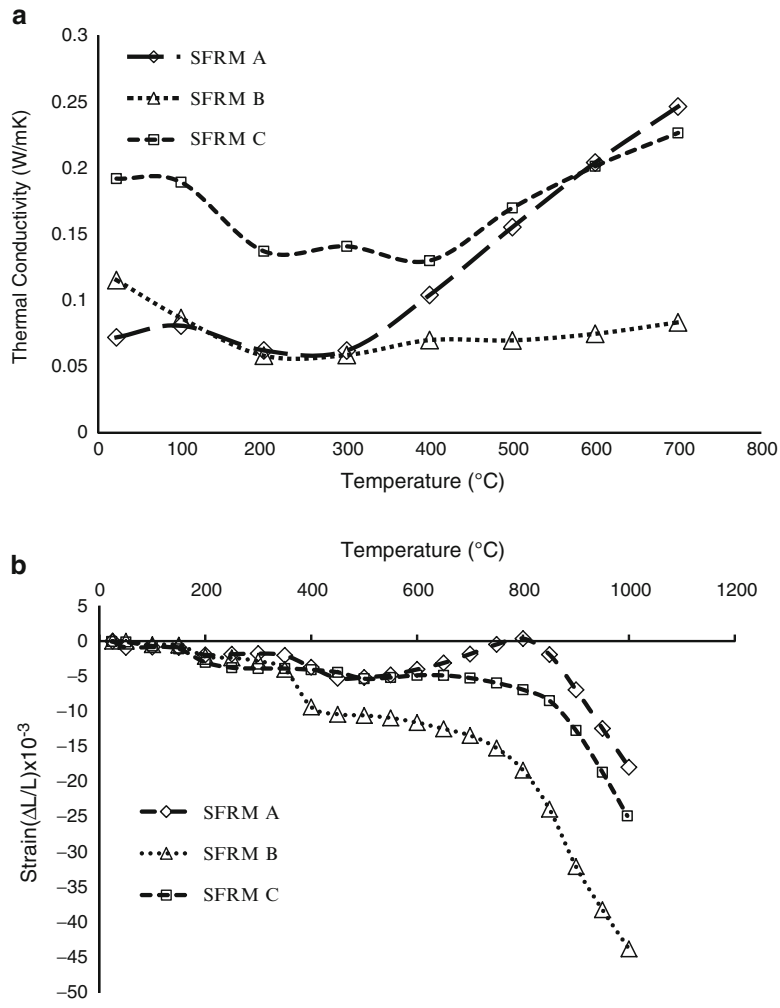

Fig. 9.45 Effect of temperature on (**a**) thermal conductivity and (**b**) thermal contraction, of different SFRMs

Table 9.6 Density of SFRM at room temperature and after exposure to 700 °C

Insulation type	Density (Kg/m^3)		Decrease in density (%)
	Room temp. (20 °C)	700 °C	
SFRM A	298	241.3	19.0
SFRM B	423.2	349.8	17.3
SFRM C	451.8	381.2	15.6

However, the loss of moisture content only account for the shrinkage phenomenon that occurs in 100–400 °C range. The intermediate expansion resulting in increase in thermal strains in 400–800 °C range is dictated by the expansion of intumescent material, such as, vermulite, which is added to SFRM to counteract shrinkage and the percentage of Vermiculite in SFRM has major influence on the level of contraction.

The change in density for three types of SFRM at ambient conditions and after exposure to 700 °C is presented in Table 9.6 [114]. There is a decrease in density in all three types of SFRM at 700 °C, which is predominantly due to the loss of moisture. This decrease in density in SFRM is comparable to that in gypsum, and attributed to dehydration reactions, which takes place with increase in temperature [115].

Other Miscellaneous Materials

Further information is available from the literature on the dilatometric and thermogravimetric behavior, apparent specific heat, and thermal conductivity of a number of materials in Group I, including asbestos cement board, expanded plastic insulating boards, mineral fiber fireproofing, arborite, and glass-reinforced cement board [7]. The properties of plastics and their behavior in fire are discussed in other chapters of this handbook and in Harmathy [2].

Summary

The use of numerical methods for the calculation of the fire resistance of various structural members is gaining acceptance. One of the main inputs needed in these models is the material properties at elevated temperatures. The thermal and mechanical properties of most materials change substantially within the temperature range associated with building fires.

Even to date, there is lack of adequate knowledge of the behavior of many building materials at elevated temperatures. Although there is sufficient information available for some materials, such as normal-strength concrete and steel, there is a complete lack of information on certain properties for widely used materials, such as wood, insulation, and so on. Often, traditional materials are being modified (e.g., high-strength concrete) to enhance their properties at room temperatures without giving due consideration to elevated temperatures. In many cases, these modifications will cause the properties to deteriorate at elevated temperatures and introduce additional complexities, such as spalling in HSC.

In the field of fire science, applied materials research faces numerous difficulties. At elevated temperatures, many building materials undergo physicochemical changes. Most of the properties are temperature dependent and sensitive to testing method parameters such as heating rate, strain rate, temperature gradient, and so on. One positive note is that in the last two decades, there has been significant progress in developing measurement techniques and commercial instruments for measuring the properties. This will likely lead to further research in establishing material properties.

The review on material properties provided in this chapter is a broad outline of the available information. Additional details related to specific conditions on which these properties are developed can be found in cited references. Also, when using the material properties presented in this chapter, due consideration should be given to the material composition and other characteristics, such as fire and loading, because the properties at elevated temperatures depend on a number of factors.

Disclaimer Certain commercial products are identified in this paper in order to adequately specify the experimental procedure. In no case does such identification imply

recommendations or endorsement by the authors, nor does it imply that the product or material identified is the best available for the purpose.

Nomenclature

a	Material constant, dimensionless
b	Constant, characteristic of pore geometry, dimensionless
c	Specific heat ($J \cdot kg^{-1} \cdot K^{-1}$)
$\overline{c}$	Specific heat for a mixture of reactants and solid products ($J \cdot kg^{-1} \cdot K^{-1}$)
E	Modulus of elasticity (Pa)
h	Enthalpy ($J \cdot kg^{-1}$)
Δh	Latent heat associated with a "reaction" ($J \cdot kg^{-1}$)
ΔH_c	Activation energy for creep ($J \cdot kmol^{-1}$)
k	Thermal conductivity ($W \cdot m^{-1} \cdot K^{-1}$)
L_v	Heat of gasification of wood
ℓ	Dimension (m)
$\Delta \ell$	$\ell - \ell_0$
m	Exponent, dimensionless
M	Mass (kg)
n	Material constant, dimensionless
P	Porosity ($m^3 \cdot m^{-3}$)
q_n	Net heat flux to char front
R	Gas constant (8315 $J \cdot kmol^{-1} \cdot K^{-1}$)
S	Specific surface area ($m^2.m^{-3}$)
t	Time (h)
T	Temperature (K or °C)
v	Volume fraction ($m^{-3}.m^3$)
w	Mass fraction ($kg \cdot kg^{-1}$)
Z	Zener-Hollomon parameter (h^{-1})

Greek Letters

α	Thermal diffusivity
β	Coefficient of linear thermal expansion ($m \cdot m^{-1}$)
γ	Expression defined by Equation 9.3, dimensionless
β_0	Charring rate (mm/min)
δ	Characteristic pore size (m)
ε	Emissivity of pores, dimensionless
ε	Strain (deformation) ($m \cdot m^{-1}$)
ε_{t0}	Creep parameter ($m \cdot m^{-1}$)
$\dot{\varepsilon}_{ts}$	Rate of secondary creep ($m.m^{-1} \cdot h^{-1}$)
θ	Temperature-compensated time (h)
ξ	Reaction progress variable, dimensionless
π	Material property (any)
ρ	Density ($kg \cdot m^{-3}$)
σ	Stress; strength (Pa)
σ	Stefan-Boltzmann constant (5.67×10^{-8} $W \cdot m^{-2} \cdot K^{-4}$)

Subscripts

g	Glass transient (temperature)
a	Of air
I	Of the ith constituent
p	At constant pressure
s	Of the solid matrix
t	True
t	Time-dependent (creep)
T	At temperature T
u	Ultimate
y	Yield
0	Original value, at reference temperature

V.K.R. Kodur is a Professor in the department of Civil and Environmental Engineering and also serves as Director of the Center on Structural Fire Safety and Diagnostics at the Michigan State University (MSU). Dr. Kodur's research has focused on the evaluation of fire resistance of structural systems through large scale fire experiments and numerical modelling; characterization of materials under high temperature; and non-linear design and analysis of structural systems. He is a Fellow of the Canadian Academy of Engineering, a Foreign Fellow of Indian National Academy of Engineering and Fellow of ASCE, ACI and SEI. He is an Associate Editor of Journal of Structural Engineering, Chairman of ACI Fire Protection Committee, and Chairman of ASCE-29 (Fire) Standards Committee.

T.Z. Harmathy was head of the Fire Research Section, Institute of Research in Construction, National Research Council of Canada, until his retirement in 1988. His research centered on materials science and the spread potential of compartment fires.

Chemical Kinetics and Fire

10

Gregory T. Linteris and John F. Griffiths

Introduction

The purpose of this chapter is to set out the principles of chemical kinetics as they apply to combustion in flames and fires. Chemical equilibrium, which was discussed in a previous chapter, deals with the final preferred state of a given set of reactants after an infinite time has passed. In contrast, chemical kinetics deals with the rate at which the system proceeds to the equilibrium state, i.e., the specific participating chemical reactions and their rates. Chemical equilibrium and chemical kinetics are related in that the thermodynamic, equilibrium state provides the driving force for chemical reaction. The material in this chapter is covered briefly; more detailed descriptions can be found in chemistry [1] and combustion [2–4] text books, upon which much of the material is based.

The foundations of chemical kinetics have validity in gas, liquid or solid phases, but for fires, the gas phase has the greatest relevance because the main heat release normally occurs during flaming combustion. The role of solid- and liquid-phase chemical kinetics in fires is discussed in Chap. 7. Similarly, smoldering combustion is a surface combustion process and the chemical kinetic description is closely related to that of pyrolyzing materials. The specialized fields of propellants, explosives, and material synthesis also require solid-phase chemical kinetic descriptions, but these are beyond the scope of the present chapter. Nonetheless, many of the fundamental principles of chemical kinetics discussed here are relevant regardless of the phase of the reacting system.

Gas-phase chemical kinetics is of interest in fires for many reasons. The heat release in a fire typically occurs in the gas phase, and is responsible for the gas-phase temperature field, and hence the heat flux to the burning materials (a feedback loop which controls the fuel supply rate in the fire, and hence the geometric growth in fire size with time). Some fundamental fire phenomena, such as ignition and extinction, are clearly controlled by the gas-phase chemical kinetics. Fire suppression is controlled by the rates of chemical reaction, both for the relatively inert agents (e.g., CO_2, water) which reduce the temperature (and hence overall reaction rate) to the point of extinction, and for chemically acting agents (e.g., CF_3Br and hydrofluorocarbons) which interfere with the normal chemistry of the fuels with air. Similarly, the action of the most commonly used fire retardants in polymers is controlled by their gas-phase chemical behavior. In general, chemical reaction rates must be fast enough to match the local residence time for transport (either convective or diffusive); if not, the flame will extinguish.

The formation of soot, the major radiating species from fire plumes, is controlled by gas-phase chemical kinetics, as is the formation

of CO, which is the major toxic compound responsible for fire deaths. In fires, the formation of other toxic compounds, for example of HCN, as well as environmental pollutants (polycyclic aromatic hydrocarbons, dioxins, etc.) is controlled by the chemical kinetics of reactions occurring in the gas-phase. Clearly, understanding chemical kinetics is central to controlling unwanted fires and their deleterious effects. It is of great value if the Fire Scientist can answer the question: "Is the process at hand controlled by the rate of chemical reactions or by some other physical process?" The goal of the present chapter is to provide some fundament materials for approaching such a question.

The reaction of a fuel (for example methane) with air to products can be represented by an expression such as:

$$CH_4 + 2O_2 \rightarrow CO_2 + H_2O \qquad (10.1)$$

which is an example of a global (or overall) reaction. While reaction (10.1) shows the reactants and products, it does not represent the detailed chemical interactions which actually occur. Rather, the conversion of CH_4 to CO_2 and H_2O is a multi-step process involving many species and many reactions. A more complete representation might include some intermediate species along the path:

$$CH_4 \rightarrow \bullet CH_3 \rightarrow CH_2O \rightarrow \bullet CHO \rightarrow CO \rightarrow CO_2, \qquad (10.2)$$

but again, the details are missing.

Figure 10.1 shows reaction pathways for a premixed methane-air flame (initial pressure P_0 and temperature T_0 of 1 bar and 298 K). The

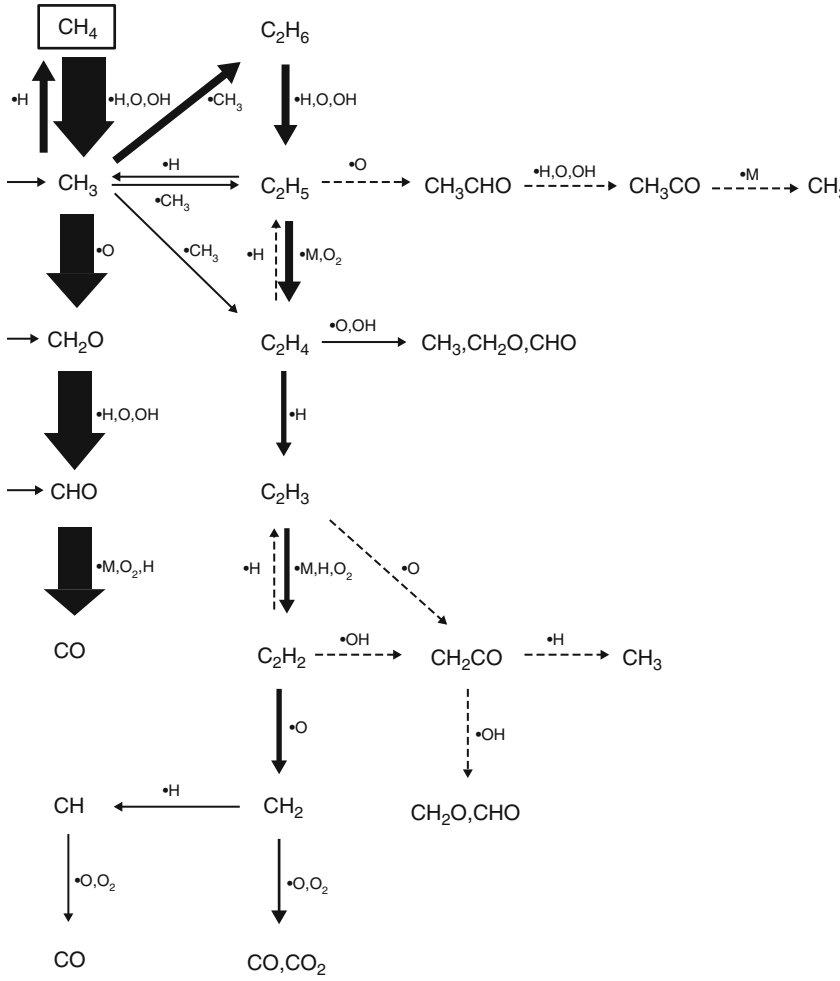

Fig. 10.1 Reaction pathway analysis for premixed stoichiometric methane-air flame (From [5])

arrows connect the initial, intermediate, and product species for the major reaction steps involved in the consumption of methane. For each species in the figure, the major reactants and products are at the ends of the arrows, while participating reaction partners are listed next to the arrow. The thickness of the arrows indicates the fraction of the total reaction flux which proceeds through that particular reaction path (normalized, in this case, by the total reaction rate of CH_4.) The purpose of such a figure is to provide not only detailed knowledge of the important steps in the consumption of a reactant, but also to provide a heuristic understanding of the general features of the chemical system. For example, Fig. 10.2 shows the chemical reaction pathways for methane in the same configuration (a premixed laminar flame), but at a different fuel-air ratio, in this case, fuel rich. In Fig. 10.1, the decomposition of methane proceeds mostly through the sequence shown in Equation 10.2, with the molecule oxidized to smaller and smaller fragments. In contrast, Fig. 10.2 shows that under rich conditions, reaction of CH_3 proceeds largely through its reaction with other CH_3 molecules, in pyrolysis reactions which tend to form larger molecules, and finally, acetylene C_2H_2, which is a precursor for soot.

Pictures such as those in Figs. 10.1 and 10.2 are very useful tools for understanding the role of chemistry in the physical behavior of combustion systems. Indeed, the widespread availability of numerical codes for performing the simulations, chemical databases for the mechanisms, and fast computers have made such simulations integral design tools in many chemical and engineering fields. These include the design of propulsion devices (gas turbines, diesel and spark ignition

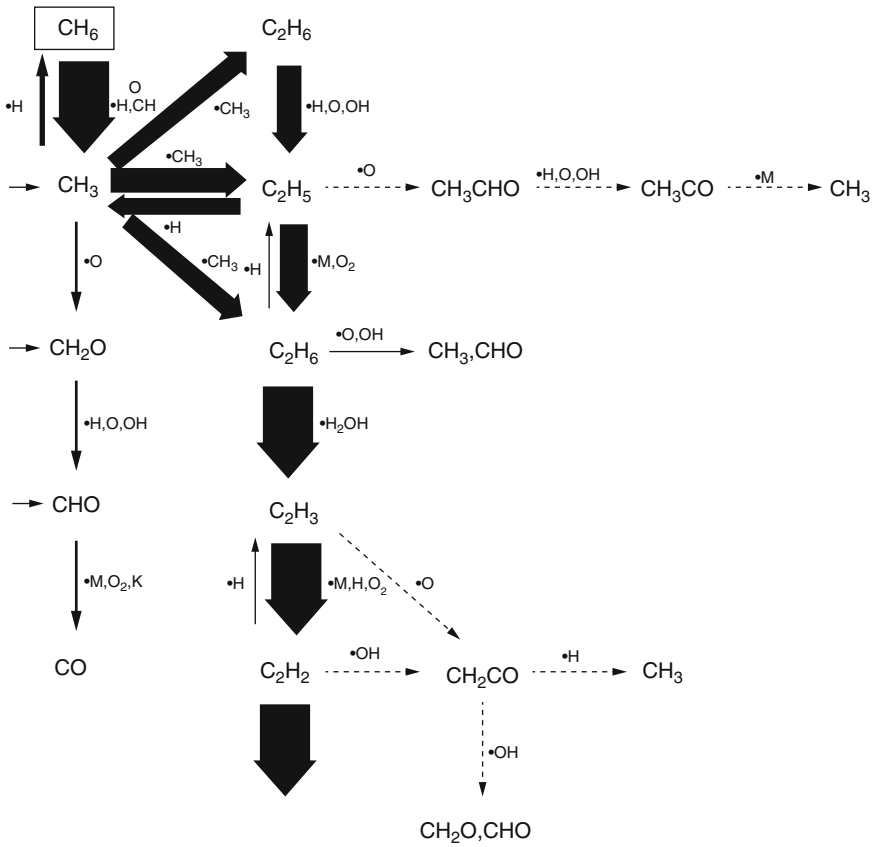

Fig. 10.2 Reaction pathway analysis for premixed fuel-rich methane-air flame (From [5])

engines, etc.) and new power plants and incinerators, particularly in regard to understanding the efficiency and pollutant formation. In fire safety, detailed chemical kinetic descriptions are primarily used in research. As computer models, kinetic mechanisms, and computer speed all improve, however, the contributions of chemical kinetics to the understanding of fire safety will increase, as it has in other fields.

A reaction mechanism (such as that used to produce the reaction pathway analyses in Figs. 10.1 and 10.2) starts with a list of species believed to be participating in chemical reactions for the physical system and conditions of interest. Thermodynamic properties of the species are required, as are the rates of the reaction of each species with all others in the list, and the temperature and pressure dependence on the rates of reaction. The development of such mechanism, and validation of the mechanisms, is a time-consuming and arduous task. Fortunately, there are many combustion and chemical kinetics researchers worldwide working in this area [6–9]. The databases are constantly in development, and versions are freely available, as discussed below. The remainder of this chapter describes the fundamental concepts used in developing chemical mechanisms, and some examples of their application.

Fundamentals

Radical Reactions

In a combustion system, the consumption of a fuel molecule (and its decomposition products) is driven largely by attack from radicals. A radical (or free radical) is an atom, molecule, or ion with one or more unpaired electron or an open shell configuration. A radical can be formed by breaking the bond of a stable molecule, for example due to a high-energy collision: $CH_4 + M => \cdot CH_3 + \cdot H + M$. In this reaction, M (discussed further below) represents any other molecule in the system which can act as a collision partner with CH_4, and thereby supply the energy to break the C-H bond. In this case, the fragments, ·H and $\cdot CH_3$, are radicals. The unpaired electron is typically shown by "·". Radicals tend to be highly reactive, and are responsible for promoting the chemistry occurring in combustion systems. The unpaired electron in a radical attacks bonds in stable molecules, leading to their decomposition. The energy barrier in radical reactions tends to be very low, which is why their reactions are so fast.

In high-temperature gaseous combustion systems, the equilibrium concentration of radicals increases with temperature, and peak radical concentrations can be quite high, with a volume fraction on the order of 1 % in the primary reaction zone of premixed flames. While this number may appear low, recall that radicals are highly reactive: their concentrations do not build up higher because they are consumed so fast.

Typical radicals in combustion are: ·H, ·O·, ·OH, ·CH, $\cdot C_2$, $\cdot CH_2$, ·CHO, $\cdot CH_3$, ·R, etc. Here, ·R denotes any hydrocarbon molecule with an unpaired electron at one site. For example, ·R can be $\cdot CH_3$, $\cdot C_2H_5$, $\cdot C_3H_7$, for the methyl, ethyl, and propyl radicals, formed by the abstraction (removal) of H atom from CH_4, C_2H_6, and C_3H_8. In these cases, the stable molecules can also be represented generically as RH; for example: $C_2H_6 + OH \rightarrow C_2H_5\cdot + H_2O$, which can be written as $RH + OH \rightarrow R\cdot + H_2O$.

In the context of combustion kinetics, explosive behavior corresponds to extremely rapid reaction. There are two types of explosive behavior: thermal explosions, and chain branched explosions. The former is due to temperature rise, while the latter is due to an exponential build-up in radical concentrations. In combustion, the radical pool refers to the chain-carrying radicals which are involved in the branching reactions, for example H, OH, O, and HO_2. It often takes time for this pool to develop, which leads to an induction time for ignition (also called the ignition delay). The buildup, maintenance, and decay of the radical pool in combustion is determined by the relative rates of the production and destruction of radicals, and relies upon certain key branching steps in the reactions scheme, as described below.

The typical steps of radical chain reactions, *initiation*, *propagation*, *branching*, and *termination*, are described here in the context of ignition of H_2/O_2 systems (following Ref. [2]). The initial radicals required to start the process come from the breaking of a bond of a stable molecule (either thermally through collisional energy transfer, or through photolytic interactions, for example in the presence of UV light). Since the bond strengths of most stable molecules relevant to combustion systems tend to be high, the process is slow (photolytic bond breaking is typically unimportant in combustion).

Initiation steps, for example reaction 10.3 in Table 10.1, are those in which two reactive radicals are formed from stable species. *Propagation steps* (reaction 10.4) involve radicals, changing the type, but not the total number of radicals. These reactions tend to have very low activation energies, and hence are very fast. Propagation steps are mostly responsible for the consumption of the fuel and its decomposition products in combustion system. Chain *branching* steps (e.g., reaction 10.6) increase the number of radicals, and hence are responsible for the explosive growth in the radical concentration, which leads to rapid reaction in the system as a whole. *Termination* steps reduce the number of radicals, and thereby shut down the overall combustion. Reaction 10.7, while it technically is a propagation step, is usually thought of as a termination step because at low temperatures the radical HO_2• is relatively unreactive, and its fate is often to be destroyed at walls (as in the reconciling of the explosion limits of the H_2–O_2 system [2–4]). In reaction 10.7, a non-reacting third body (M) takes away energy from the radical-radical combination. In this example, after the reaction of H• + O_2, HO_2• would have too much energy stay together (since it is a relatively small molecule and cannot absorb the energy in vibrational or rotational modes of energy storage). Another example of such a three-body termination reaction is: H + H + M → H_2 + M, which is important in flames. Reaction 10.8 represents the destruction of a radical without another interacting gas molecule (for example through radical quenching at a wall), which can be very important in many situations where solid surfaces are available to the gas-phase reactants. Although it looks as if reaction 10.5 is a propagation step (because there is no increase in the number of unpaired electrons) this is classified as a chain branching reaction since the number of active reaction chains has been multiplied.

There is another class of overall termination steps: the gas-phase catalytic cycles involving flame inhibitors such as FeO, HBr, and HOPO. These catalytic cycles serve to reduce radical concentrations in flames, and are discussed in more detail below.

Table 10.1 Radical reactions important in H_2/O_2 ignition

Initiation	$H_2 + O_2 \rightarrow 2OH\bullet$	(10.3)
Propagation	$OH\bullet + H_2 \rightarrow H_2O + H\bullet$	(10.4)
Branching	$\bullet O\bullet + H_2 \rightarrow OH\bullet + H\bullet$	(10.5)
	$H\bullet + O_2 \rightarrow OH\bullet + O\bullet$	(10.6)
Termination	$H\bullet + O_2 + M \rightarrow \bullet HO_2 + M$	(10.7)
	$H\bullet \rightarrow \frac{1}{2}H_2$	(10.8)

Law of Mass Action

The rate of disappearance of a reactant is generally proportional to the concentrations of participating reactants. For an arbitrary chemical reaction:

$$A + B \rightarrow \text{products}, \tag{10.9}$$

the proportionality is represented by the Law of Mass Action:

$$\frac{d[A]}{dt} = \dot{\omega}_A = -k[A]^1[B]^1 \tag{10.10}$$

Here, the brackets denote concentration (for example with units of mol cm^{-3}), $d[A]/dt$ is the rate of change in the concentration of A with time (t), and k is a proportionality constant. This expression was phenomenologically developed, based on empirical results, but there is a theoretical basis for it. Molecules of A and B must collide to react. Their collision rate depends upon their concentrations (which depend upon the total concentration via the ideal gas law and their volume fraction). Today, k is known as the

specific reaction rate constant (or often just the rate constant). The magnitude of k is usually a function only of temperature, and that dependence is often significant.

Note that the concentration C of species i, C_i, or $[i]$ can be expressed as $C_i = X_i \cdot C_T$, where the total concentration is given by the ideal gas law

$$C_T = \frac{N_T}{V} = \frac{P}{RT} \tag{10.11}$$

in which N_T is the total number of moles in the volume, V, at the given pressure P and temperature T, and R is the universal gas constant (8.314 J mol^{-1} K^{-1}) The mole fraction X_i (known also as the volume fraction), is

$$X_i = \frac{N_i}{N_T} = \frac{N_i}{\sum_i N_i} \tag{10.12}$$

in which N_i is the number of moles of species i, and the summation is over all species in the system.

Global vs. Elementary Rates

The Law of Mass Action can be written for either *global* or *elementary* reactions. An example of a *global reaction* (also called a *net reaction* or *overall reaction*) is

$$2H_2 + O_2 \rightarrow 2H_2O \tag{10.13}$$

in which 2 moles of hydrogen reacts with 1 mole of oxygen to form 2 moles of water; the Law of Mass Action would be:

$$-\frac{d[O_2]}{dt} = -\frac{\frac{1}{2}d[H_2]}{dt} = \frac{d[H_2O]}{dt} = k_G[H_2]^n[O_2]^m \tag{10.14}$$

where k_G is the global rate coefficient, n is the reaction order with respect to H_2, m is the order with respect to O_2, and $m + n$ is the overall order. Note that a distinction is made on the left hand side of the equation between reactant removal and product formation. Reaction 10.13 with 10.14 describe what happens to the reactants globally. Relations such as these are typically obtained experimentally, and are valid only for that experiment and the range of conditions from which it was developed. The expressions are usually complex; the empirical reactions orders are typically not integers, can be negative, and depend upon time and the reaction conditions. Extrapolation to other experimental conditions can be unreliable or incorrect.

Note that reaction 10.13 is not believed to actually occur; detailed experiments have shown that on the molecular level, two molecules of hydrogen do not collide with one molecule of oxygen to form two molecules of water. In contrast, elementary reactions, such as

$$OH + H_2 \rightarrow H_2O + H \tag{10.15}$$

are believed to represent an actual interaction between molecules: an OH molecule collides with an H_2 molecule, and (if there is sufficient energy involved in the collision) they react to form one H_2O molecule and an H atom. The Law of Mass Action for this elementary reaction would be:

$$\frac{d[H_2]}{dt} = -k_{15}[OH]^1[H_2]^1 \tag{10.16}$$

and the specific reaction rate constant k_{15} describes the probability of reaction. The dependence (i.e. reaction order) on the concentrations of H and OH (1 in this example) are the molecularity with respect to that reactant, and the overall molecularity is the sum of individual molecularities of the reactants. Generally, for elementary reactions, the determination of reaction orders is easy: they correspond to the molecularities.

An overall reaction such as reaction 10.13 is the result of a large number of elementary reactions. For example the reaction of hydrogen and oxygen, in a simple but satisfactory form, can be described through a sequence of reactions involving about 8 species and 40 reactions; that for methane 30 species and 400 reactions, and hexane, 450 species 1500 reactions.

Comprehensive representations of mechanisms for the combustion of hydrocarbon fuels run into many hundreds of species involved in many

thousands of reactions, the complexity increasing with their size or the number of compounds in the fuel mixture [6]. Describing a chemical system in terms of elementary reactions is a difficult and time consuming task, but has many advantages. The reaction order of elementary reactions is constant (does not change with system or conditions, as the global orders might), and the specific reaction rate constant varies only with temperature; hence, the rate expressions should be valid over a wider range of conditions than those of one-step global reactions.

Type of Reactions

There are three types of elementary reactions actually observed in gaseous combustion systems: *unimolecular*, *bimolecular*, and *termolecular* (depending upon the number of species involved).

Bimolecular Reactions

Bimolecular reactions are those given by

$$A + B \rightarrow C \tag{10.17}$$

or

$$A + B \rightarrow C + D \tag{10.18}$$

with

$$\frac{d[A]}{dt} = \dot{\omega}_A = -k[A]^1[B]^1 \tag{10.19}$$

These are the most common types of reactions; the molecularity is one for each reactant and two overall (a so-called *second-order reaction*). Common examples would be $H + H_2O \rightarrow OH + H_2$, $CO + OH \rightarrow CO_2 + H$, or $C_4H_{10} + \cdot OH \rightarrow \cdot C_4H_9 + H_2O$. This last reaction is called an *abstraction reaction* because the ·OH radical abstracts a hydrogen atom from the butane molecule.

Unimolecular Reactions

Unimolecular reactions are given by

$$A \rightarrow B \text{ or } A \rightarrow B + C \tag{10.20}$$

with

$$\frac{d[A]}{dt} = -k_{uni}[A]^1 \tag{10.21}$$

Some bimolecular reactions behave as though they were unimolecular. For example, in the bimolecular reaction 10.17 above, $A + B \rightarrow$ products, if the concentration of B is present in large excess as compared to A, its concentration will not change appreciably, so the rate expression Equation 10.19 would be:

$$\frac{d[A]}{dt} = -k_{eff}[A]^1 \tag{10.22}$$

in which the effective rate constant is determined by $k_{eff} = k[B]^1$. Hence, this second-order reaction is pseudo-first order in A.

A special example of a pseudo first-order reaction is the decomposition of the butyl radical $\cdot C_4H_9$ (formed after abstraction of a hydrogen atom from C_4H_{10}) after a collision with another molecule M:

$$\cdot C_4H_9 + M \rightarrow C_3H_6 + CH_3 + M \tag{10.23}$$

The collision partner M, represents any other molecule in the system. It is called a chaperone molecule or a third body (as in reaction 10.7). Conceptually, its role is to provide the energy needed (via a collision) to break the necessary bonds in reactions 10.23, but it does not otherwise participate in the reaction. In reaction 10.7, it serves the opposite role: to carry away the excess energy resulting from the joining of two free radicals.

The role of M can be recognized in the following way. Reaction 10.23 constitutes the breaking of a C–C bond. In order for this to happen it is necessary for sufficient energy to be accumulated at the appropriate part of the $C_4H_9\cdot$ radical. The energy required is approximately equal to the bond dissociation energy (see Chap. 5). $C_4H_9\cdot$ is able to gain the necessary thermal energy via kinetic energy transfer from another species during a collision. So M can be any molecule in the system and the concentration [M] represents the total concentration of species in the system.

As a result of this special function of "M" the order of reaction 10.23 can vary, with k_{eff} showing a complex experimental dependence

on concentration. The reaction is second order overall at low concentrations of species in the system (signifying low pressures), which arises from a first order dependence with respect to both the reactant, $C_4H_9\cdot$ and M, e.g.

$$\frac{d[C_4H_9\cdot]}{dt} = -k_0[C_4H_9\cdot][M] \qquad (10.24)$$

where the subscript o signifies the rate constant at the low pressure limit, and represents the second order case. However, as the concentration (or pressure) of the system is raised the reaction changes to eventually achieve a first order dependence on the principal reactant and with no dependence on M, e.g.

$$\frac{d[C_4H_9\cdot]}{dt} = -k_\infty[C_4H_9\cdot], \qquad (10.25)$$

where the subscript ∞ signifies the rate constant at the high (infinite) pressure limit, and is strictly a first order rate constant. There is a complex dependence of the rate constant on concentration between the two limits, and the overall reaction order varies between 2 and 1. There are sophisticated theories applied in combustion chemistry to interpret these data, but the two limiting conditions can be derived on the basis of simple algebraic analysis as is found in chemical kinetic texts (e.g. [1]).

Termolecular Reactions

Termolecular reactions are described by

$$A + B + M \rightarrow C + M \qquad (10.26)$$

with

$$\frac{d[A]}{dt} = -k_{ter}[A]\,[B]^1[M]^1 \qquad (10.27)$$

Examples of such reactions are the radical recombination reactions $OH + H + M \rightarrow H_2O + M$ and $H + H + M \rightarrow H_2 + M$. (Note that for the latter of these reactions, a factor of two would have to be added to Equation 10.27 for the change in [H] with time, since both A and B (i.e. H) are the same. The rates of these third-order reactions are pressure dependent (each concentration in Equation 10.27 is proportional to P via Equation 10.11). Also, via Le Châtelier's principle, the equilibrium is affect by pressure since there is a change in the number of moles in reaction 10.26. Finally, the efficiency of different species as third bodies can vary substantially. For example, in the reaction $OH + H + M \rightarrow H_2O + M$, the efficiency of N_2, CO, H_2, CO_2, and H_2O, as a third body is enhanced by a factor or 1, 1.8, 2, 3.6, and 6.3 relative to N_2. These different third-body efficiencies are usually accounted for in detailed reaction mechanisms.

Units of Reaction Rate Constant

Since the derivative of the concentration with time d[A]/dt always has the units (concentration/time), but since the number of terms on the right hand side of a rate equation varies with the reaction order n (c.f. Equations 10.19, 10.21, 10.27), the units of the specific reaction rate constant k must change accordingly. The units of k are: $(\text{concentration})^{-(n-1)}\cdot s^{-1}$ (or, for example, $(\text{mol cm}^{-3})^{-(n-1)}\ s^{-1}$) which yields the units shown in Table 10.2 for reaction orders of 0 to 3.

Arrhenius Rate Expression

Specific reaction rate constants can be a strong function of temperature (and show no pressure dependence, except in the situations described above). In the late 1800s, Svante Arrhenius discovered empirically that the rate of chemical reactions is described well by an exponential

Table 10.2 Units of the rate constant for various reaction orders

Reaction order	Rate expression, single component, A	Units of k	(in cgs)
0	$d[A]/dt = k_o$	conc time^{-1}	mol cm^{-3} s^{-1}
1	$d[A]/dt = k_1[A]$	time^{-1}	s^{-1}
2	$d[A]/dt = k_2[A]^2$	conc^{-1} time^{-1}	cm^3 mol^{-1} s^{-1}
3	$d[A]/dt = k_3[A]^2[M]$	conc^{-2} time^{-1}	cm^6 mol^{-2} s^{-1}

function of temperature. The equation which bears his name is

$$k(T) = A' e^{(-E_a/RT)} \tag{10.28}$$

in which A' is the pre-exponential factor and E_a is the activation energy. Later, the pre-exponential factor A' was found, for many reactions, to have some temperature dependence, and today, a modified version of the Arrhenius equation is more commonly used:

$$k(T) = AT^b e^{(-E_a/RT)} \tag{10.29}$$

In combustion, E_a is typically given in units of kcal mol^{-1} or kJ mol^{-1}; alternatively, E_a is divided by R to give an activation temperature T_a ($= E_a/R$), with units of K.

The kinetic theory of gases has provided a theoretical basis for the modified Arrhenius equation. For a bimolecular reaction (10.18, 10.19), the reaction rate is proportional to the concentrations of reactants present. The rate constant k represents the probability of reaction, which in turn depends upon the rate of molecular collisions (embodied in the pre-exponential term AT^b). Not all collisions will have sufficient energy for reaction, however, and the exponential term describes the fraction of molecules in the gas with sufficient energy to overcome a barrier to reaction. Figure 10.3 shows the chemical potential energy diagram for a hypothetical reaction. For the forward reaction, the activation energy is $E_{a,f}$, while for the reverse reaction, it is $E_{a,r}$. For this exothermic reaction, the products have less chemical energy than the reactants (and for an adiabatic system, this difference is typically manifested as an increase in temperature of the products). The reverse reaction has a higher activation energy by an amount corresponding to the exothermicity of the forward reaction. Note that potential energy curves are shown for un-catalyzed (solid line) and catalyzed (dashed line) reactions. A catalyst does not change the energy states of the products or reactants, but lowers the effective activation energy (for both forward and reverse reaction), so the system can more rapidly achieve the equilibrium state.

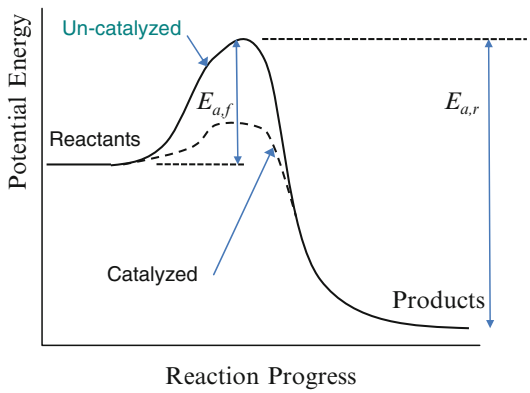

Fig. 10.3 Energy diagram for a chemical reaction

The collision term AT^b in the modified Arrhenius expression represents the frequency of collisions, times the probability of collision—the so-called steric factor, with a typical upper limit of 10^{13}–10^{14} cm^3 mol^{-1} s^{-1}. (Note that the units of AT^b are the same as those of k). Nonetheless, steric factors are often quite low, representing the need for the molecules to have the correct orientation, and have the energy in the molecule (vibrational, rotational, translational) to be distributed optimally for reaction to occur. For unimolecular reactions, A represents the vibrational energy in the molecule which leads to its decomposition. Termolecular reactions are actually two bimolecular reactions in rapid sequence; grouping them together can lead to unusual values for the A and E_a.

Effect of Temperature on Reaction Rates

The parameters for the reaction rate expression are mostly determined through, or validated in, experimental measurements in devices such as shock-tubes, static reactors, flow reactors, premixed and diffusion flames, rapid combustion machines, and combustion bombs. In determining the Arrhenius parameters experimentally, one approach, adopted very early, is to measure the reaction progress for a given set of initial reactant concentrations. By performing experiments over a range of temperatures, it is possible to construct the plot of as ln(k) vs. 1/T as in Fig. 10.4. The activation energy E_a is obtained from the negative slope of the line, while the pre-exponential (as ln (A')) is obtained from the intercept. The results

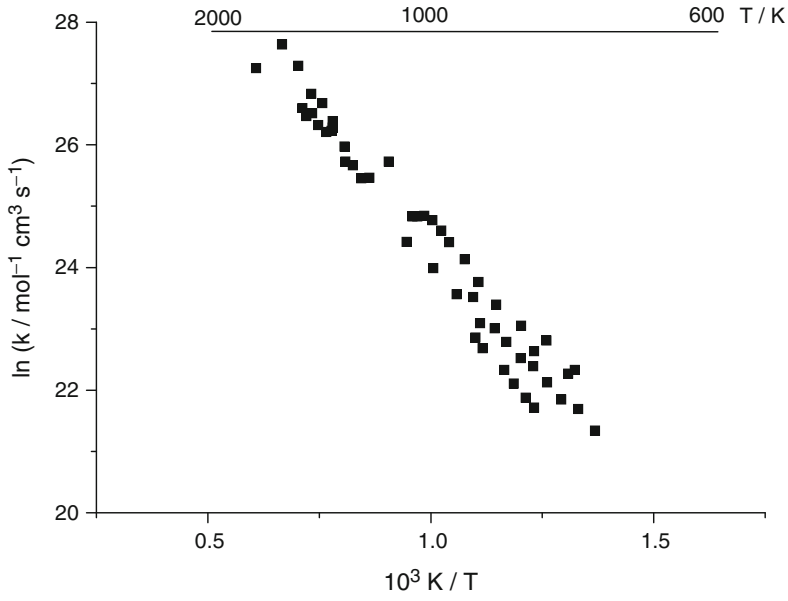

Fig. 10.4 Arrhenius plot from the experimentally determined rate constant for the reaction H + O_2

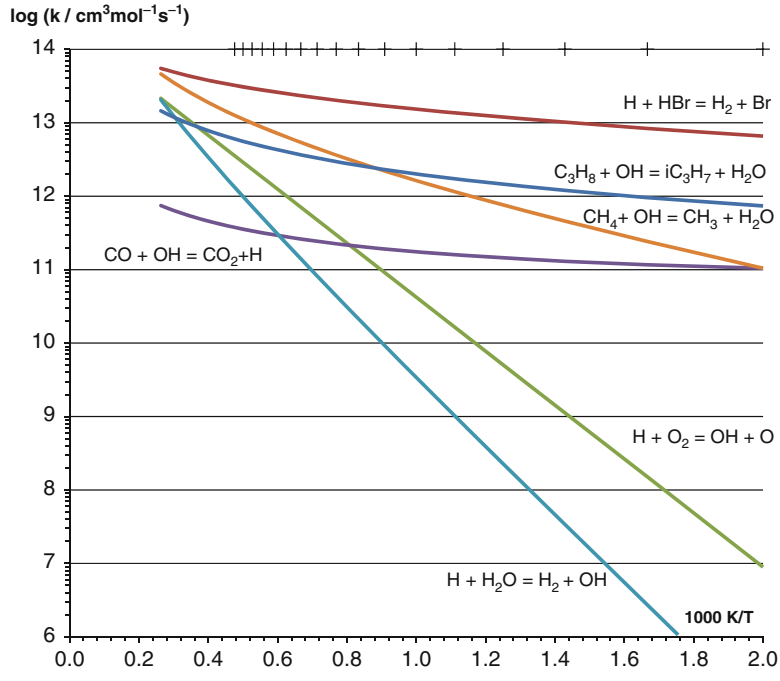

Fig. 10.5 Dependence of reaction rate constant *k* on temperature for various reactions important in combustion

presented in the figure were obtained over a very wide temperature range by many different research groups using a number of different experimental techniques.

Figure 10.5 shows the rate constant for various important reactions in combustion with data from Ref. [10]. As indicated, the reactions CO + OH → CO_2 + H and H + HBr = H_2 + Br have

very low activation energies (E/R =120 K and 290 K respectively), and show very little temperature sensitivity, typical of a radical propagation reactions. The chain-branching reaction $H + O_2 = OH + O$ has a somewhat higher temperature sensitivity (E_a/R = 9,860 K) as does the propagation reaction $H + H_2O \rightarrow H_2 + OH$ (for which the activation energy, $E_a = 82$ kJ mol^{-1}), both of which are endothermic. The lines in Fig. 10.5 that exhibit curvature require the rate constant to be interpreted over the full temperature range using the three parameter representation (Equation 10.29). Otherwise, a different activation energy would have to be applied within more restricted sections of the temperature range, as is reflected in the varying gradient.

Effect of Pressure on Reaction Rates

Pressure manifests itself primarily through its effect on concentration via the Law of Mass Action (Equation 10.10) with the ideal gas law (Equation. 10.11), and in three-body reactions (Equations. 10.26 and 10.27) which are very pressure dependent. In the context of fire, these considerations are most important with regard to the laboratory experiments used to: measure elementary rates, understand a phenomenon, or validate a chemical mechanism. For example, many reaction rates for three-body reactions are in the fall-off regime at ambient pressure. Hence, in specifying the relevant rate, pressure plays a role.

Nonetheless, in actual fires, while small pressure differences have a major effect on the flow of gases, the magnitude of pressure changes typically has little effect on combustion kinetics. Some effect of pressure may be relevant at high altitude, or in aircraft fire safety considerations. Of course, pressure rise in explosions can influence the kinetics. For typical atmospheric pressure fires, however, the limited changes in pressure have little effect on the combustion kinetics.

Important Concepts in Hydrocarbon Combustion Kinetics

Applications of combustion kinetics to fire will be illustrated in examples below.

Ignition

Ignition is defined as the initiation of combustion. Generally, this involves bringing the gas-phase reactants to the point of rapid, exothermic reaction (i.e., explosive behavior). As described above, this high rate of reaction can be induced via thermal or radical chain branching mechanisms. And these, in turn, can be induced by a spark, a local hot spot (due to a hot wire or surface), or a pilot flame. Alternatively, *spontaneous (or auto-)* ignition occurs when a fuel and air mixture, for example in a uniformly heated chamber or next to a hot surface, by itself reaches the explosive reaction conditions. Gas-phase reactions lead to increasing radical concentrations (either due to thermal or chain branching mechanisms), which eventually are high enough for sustained gas-phase flame propagation. A special category of spontaneous ignition takes place when a uniformly mixed gas mixture, at constant initial temperature, is raised instantaneously to a uniformly high temperature after passage of a shock wave, as in a shock tube experiment. This configuration, while not experienced often in fire research, is of significance since most of the experimental and calculated data on ignition delay are obtained using this technique.

In fire research however, the term "ignition" is often used in the context of the initiation of flaming combustion over a solid or liquid material. This process, while also dependent upon the behavior of the gas-phase reactants, largely involves the thermodynamic behavior of the solid material as it heats and decomposes (typically when exposed to an external infrared heat flux, for example from the hot upper layer in a

room fire). Of course, gas-phase reaction and solid material ignition are related in that the solid material ignites when: (1) it is producing gas-phase reactants fast enough, (2) the fuel molecules mix with the oxidizer gas in proportions which are within the flammability limits, and (3) the radical concentrations build up sufficiently, due to heat release, chain-branching, etc. Nonetheless, this last part of the process (ignition, by an externally imposed source, of the gas-phase reactants which are within the flammability limits) is distinctly different from the spontaneous ignition of gas-phase reactants described in the previous paragraph. For the purposes of the discussion below, when discussing "ignition", it is gas-phase spontaneous ignition (not material ignition) with which we are concerned.

Spontaneous ignition is a gas-phase chemical process well described by the detailed kinetic models described above (and below)—provided that the reaction mechanism embraces processes that are relevant to an appropriately wide range of temperatures. For example, if a reactive gas mixture is exposed to a hot surface (or container), and (for the purposes of discussion) uniformly heated, it will reach an explosive condition (i.e., rapid reaction) after some length of exposure time to the heated condition. The parameter of interest is the ignition time or ignition delay τ_{ign}, which is the time it takes for a mixture at a given temperature, to reach the state of rapid reaction. To define the ignition delay, a criterion for the condition of rapid reaction is required. Often, a characteristic temperature rise, the maximum rate of temperature (or pressure) rise, or some minimum radical concentration is used (e.g., $X_{OH} >= 10^{-4}$) is used. Figure 10.6 shows the calculated ignition delay of a stoichiometric H_2/air mixture. As indicated, the ignition delay is a strong function of the initial temperature: it drops by about three orders of magnitude as the initial temperature rises from 925 to 1025 K.

Given a comprehensive kinetic mechanism, ignition delay is readily calculated. The chemistry of homogeneous ignition is often different from that in a flame. Ignition delays are a strong function of the reactants, stoichiometry, initial

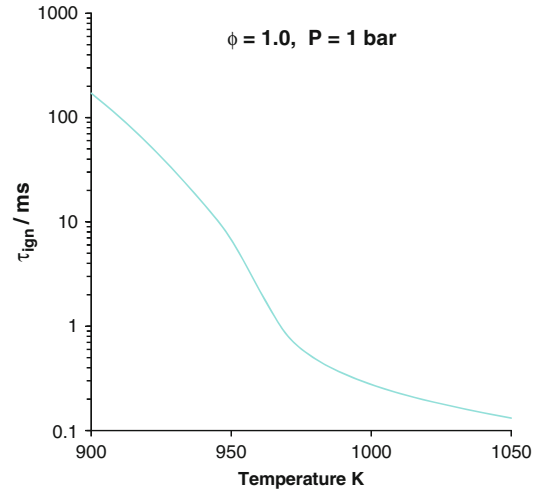

Fig. 10.6 Ignition delay of a stoichiometric H_2/air mixture as a function of initial gas temperature

temperature and pressure, and the presence of trace species. Figure 10.7 shows the H-atom volume fraction and temperature as a function of time for an H_2.air system at an initial temperature of 1000 K. As indicated, the ignition delay is about 1.6×10^{-4} s. The build-up in H radical concentration is exponential in time, and increases drastically for times greater than about 10^{-5} s. Hence, the explosive behavior is predominantly due to a chain-branching mechanism rather than thermal initiation. Some fuels decompose forming H-atoms more readily, and these promote a short ignition delay. Additives which consume H-atoms retard ignition, while those that create H-atoms accelerate ignition.

Competition Between Reactions

The macroscopic behavior in combustion systems is often determined by which of two (or more) possible reaction paths dominate. Reactions proceed in parallel, and which reaction dominates depends upon the temperature and the concentrations of reactants (which can change with time and location in the system), and the pressure. Some examples of combustion reactions in which the competition between alternate reactions are given below.

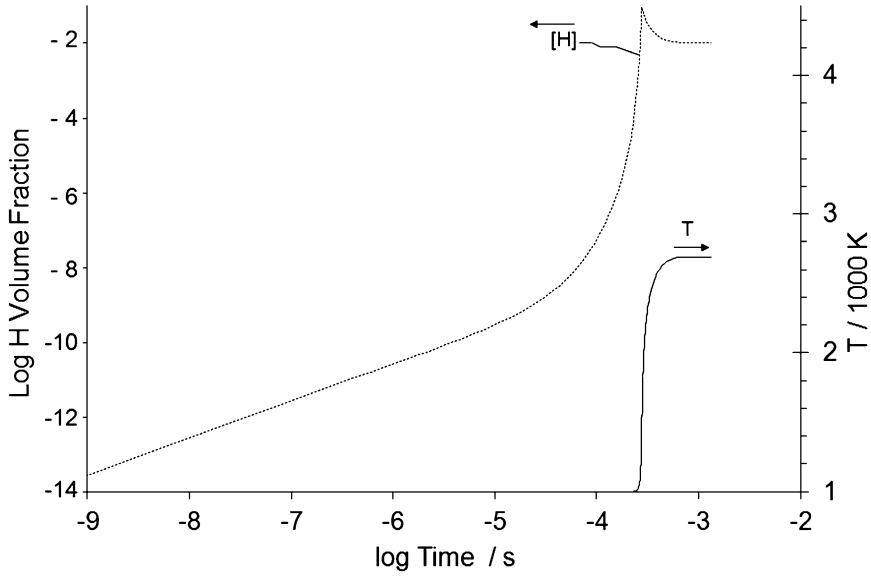

Fig. 10.7 H-atom and temperature increase with time for stoichiometric H_2/air mixture at 1000 K

Initiation Reactions: Thermal Decomposition vs. Oxidation

The homogeneous ignition above requires the buildup in radical concentrations. To get this process started, there must be radical initiation reactions. Two possible initiation routes are the dissociation reaction of H_2, reaction (10.30) and the molecular reaction between H_2 and O_2. reaction (10.31). Figure 10.8 shows the rate constants and the ratio of the rate constants for these two competing reactions. As indicated, reaction (10.31) is 4 and 9 orders of magnitude higher at 2000 K and 1000 K, respectively. Hence, for any reasonable concentration of O_2, the *rate* of the molecular reaction (10.31) (i.e., the rate constant times the relevant concentrations as in Equation 10.19) will be much higher, making it the favored initiation route.

$$H_2 + M \rightarrow H\cdot + H\cdot + M \qquad k = 6.7 \times 10^{14} e^{(-51000/T)} s^{-1} \qquad (10.30)$$

$$H_2 + O_2 \rightarrow HO_2\cdot + H\cdot \qquad k = 1.5 \times 10^{14} e^{(-28{,}500/T)} s^{-1} \qquad (10.31)$$

Relative Rates of Oxidation and Degradation of the Primary Fuel Radical

As described above, the propagation reactions are the principal means of reactant consumption through, for example,

$$RH + \cdot OH \rightarrow R\cdot + H_2O \qquad (10.32)$$

where R· represents an alkyl radical generated from an alkane (e.g. an ethyl radical (C_2H_5) from ethane (C_2H_6)). Whether or not the alkyl radical then decomposes or oxidizes depends upon the temperature and the concentration of oxygen. Consider normal undecane (n-$C_{11}H_{24}$), a component of kerosene. The undecyl radical formed from it in a reaction such as (10.32) may undergo the competitive reactions

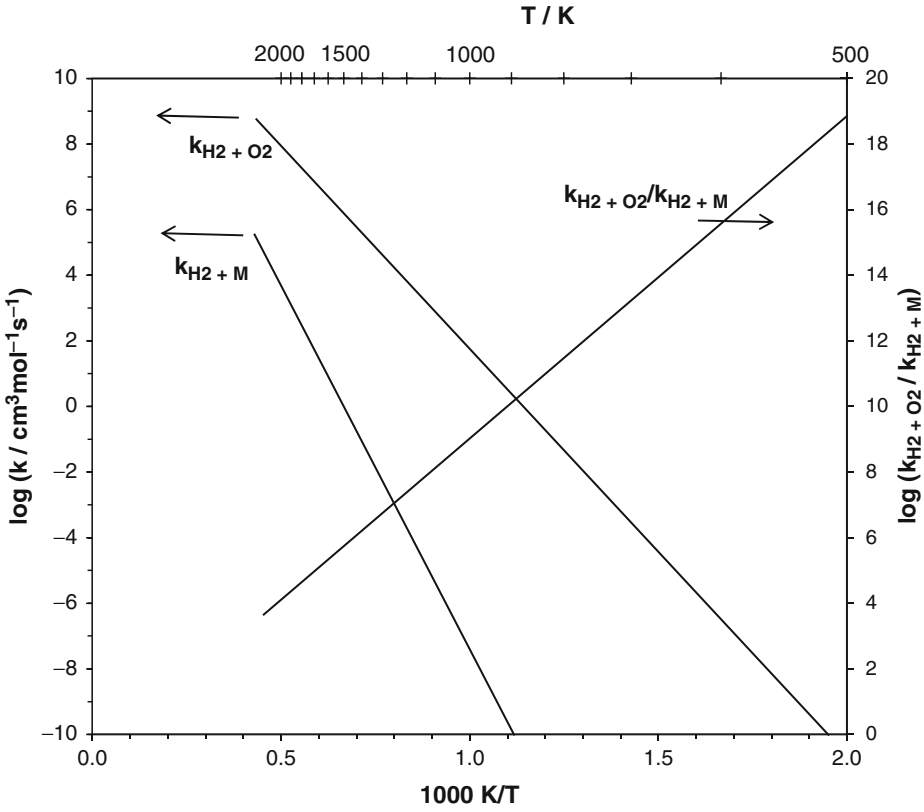

Fig. 10.8 Rate constant (*left scale*) and ratio of the rate constants (*right scale*) for $H_2 + O_2$ abstraction reaction and H_2 + M dissociation reaction, as a function of temperature (*top scale*) and inverse temperature (*bottom scale*)

$$\underset{\text{alkyl radical}}{n-C_{11}H_{23}\cdot} \rightarrow \underset{\text{alkene}}{n-C_6H_{12}} + \underset{\text{lower alkyl radical}}{n-C_5H_{11}\cdot} \qquad k = 2.5\times10^{13}e^{(-14433/T)}s^{-1} \tag{10.33}$$

$$\underset{\text{alkyl radical}}{n-C_{11}H_{23}\cdot} + O_2 \rightarrow \underset{\text{alkene}}{n-C_{11}H_{22}} + \underset{\text{hydroperoxy radical}}{HO_2\cdot} \qquad k = 1.0\times10^{12}e^{(-1000/T)}mol^{-1}cm^3s^{-1} \tag{10.34}$$

Examining the activation energy for the two competing reactions reveals that the first, the thermal decomposition route (E_a/R = 14,443 K), is very temperature sensitive, whereas the second route (E_a/R = 1,000 K), H-atom abstraction by O_2 (a radical propagation reaction), is less temperature sensitive. Figure 10.9 shows the ratio of the rate constant for the two reactions. As indicated, the relative importance of the decomposition reaction to the consumption of n-$C_{11}H_{23}$· increases at higher temperature by many orders of magnitude. To compare the rates of disappearance of the fuel radical d[n-$C_{11}H_{23}$·]/dt by the two routes, it is necessary to use Equation 10.21 and Equation 10.19 for unimolecular and bimolecular reactions, so that the ratio of rates is $\omega_{dec}/\omega_{+O2} = k_{dec}/(k_{+O2}[O_2])$ in which the concentration of [O_2] is determined

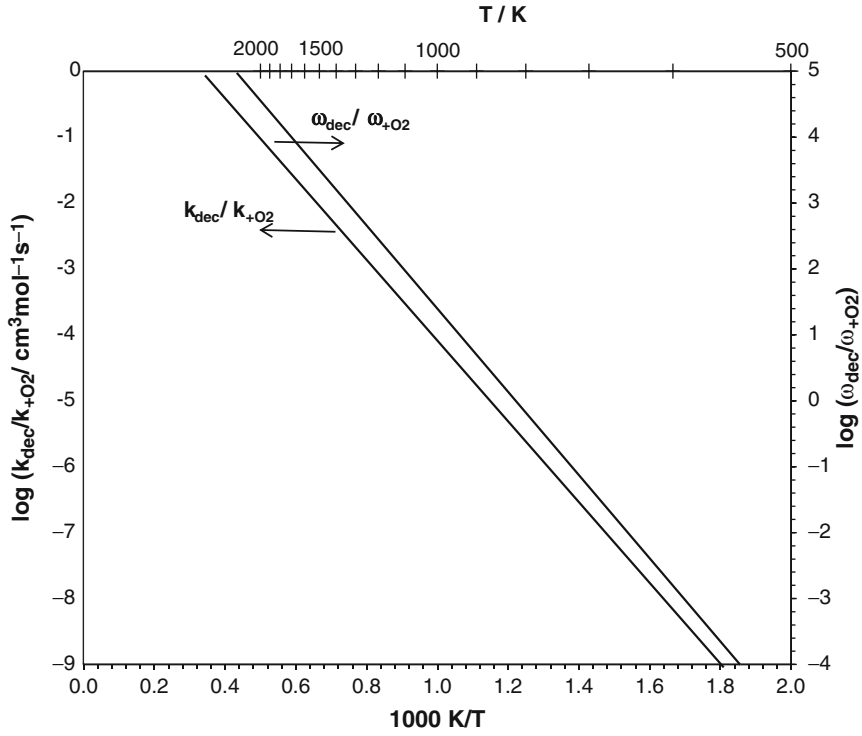

Fig. 10.9 Ratio of the rate constant (*left scale*) and reaction rate (*right scale*) for decomposition (dec) vs. H abstraction by O_2 ($+O_2$) reactions for n-$C_{11}H_{23}{}^{\circ}$, as a function of temperature (*top scale*) and inverse temperature (*bottom scale*)

at each temperature via Equations 10.11 and 10.12, with $X_{O2} = 0.21$ in air. As shown in the figure, the reaction rates are about equal at 850 K; whereas the decomposition rate is 1000 times slower at 600 K, and 1000 times faster at 1500 K, then the abstraction route.

The competition between radical abstraction and thermal decomposition reactions has several consequences. The relative rate of reaction is dependent upon the oxygen concentration, so in fuel rich conditions, thermal decomposition will be favored, leading to the build-up of small fuel radicals, and ultimately acetylene, which is a precursor for soot. Also, at temperatures below 1000 K, the combustion chemistry tends to be specific to the primary fuel structure; whereas at higher temperatures the large fuels will tend to decompose to smaller hydrocarbon fragments, so that ultimately, the important reactions for heat release all involve combustion of the same, much smaller (e.g., one- and two-carbon) hydrocarbon species. This explains why the macroscopic combustion behavior of different hydrocarbons can be very similar in flames.

Relative Rates of Reaction of OH with CO vs. Hydrocarbon

The reaction of carbon monoxide, an intermediate species in hydrocarbon-air flames, controls two of the most important features of fires. (1) Most of the heat release in a flame occurs via conversion of CO to CO_2, and (2) residual CO, the most important toxic by-product of flames (and the species responsible for most fire deaths) is often controlled by its reaction rate. As described below, the consumption of CO in flames occurs almost entirely by its reaction with OH. Hence, it is of interest to compare the rate of OH reaction with CO to that of OH reaction with other hydrocarbon species (for example, the fuel itself).

Figure 10.10 shows the reaction rate constant for OH reaction with n-C_4H_{10} or CO. As the figure indicates, the reaction of OH with n-C_4H_{10} is on the order of 140 times faster than

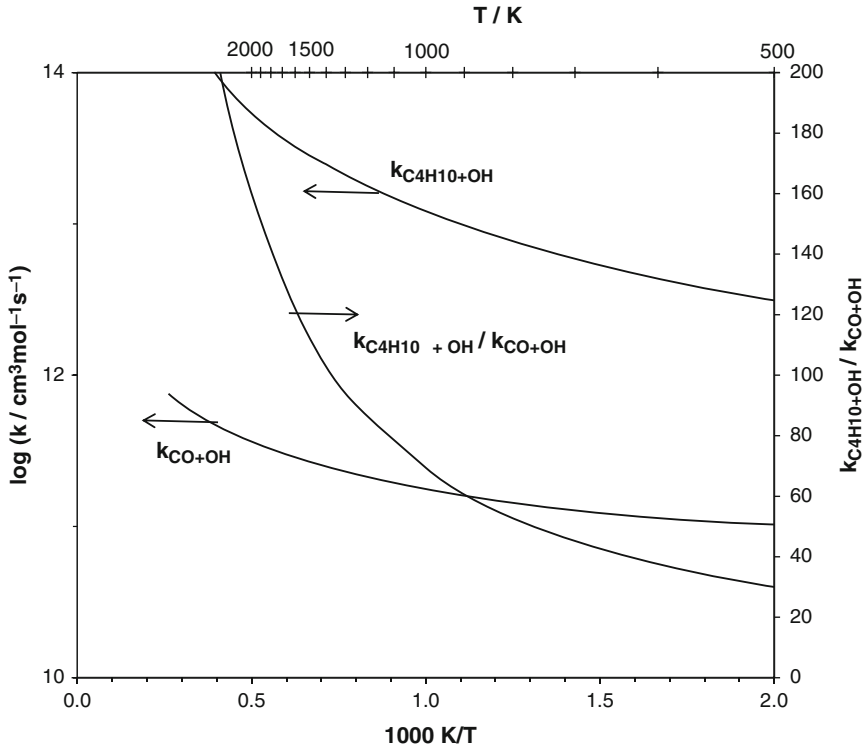

Fig. 10.10 Rate constant k (*left scale*) and ratio of rate constants (*right scale*) for reaction of OH with CO or n-C_4H_{10}, as a function of temperature (*top scale*) and inverse temperature (*bottom scale*)

its reaction with CO at 1800 K. This illustrates that in many flames, the burnout of CO will be kinetically limited until the hydrocarbon content is much lower than the CO concentration; i.e., for n-C_4H_{10} (and many other hydrocarbons) concentrations of 1/140 that of CO, the rate of consumption will be about equal. The burnout of the CO is typically the last stage of reaction sequence and occurs after the hydrocarbon is essentially gone.

H-Atom Reaction with O_2 vs. Reaction with Fuel

The reaction of $H + O_2 \rightarrow OH + O$ (reaction 10.6) is the most important chain branching reaction in combustion, and greatly increases radical concentrations in the flame. Nonetheless, as described above, reactions of hydrocarbon species with radicals (chain propagation processes such as reaction 10.32) are largely responsible for the consumption of the fuel species and its decomposition products. Hence, it is of interest to compare the rates of these two processes.

Figure 10.11 shows the rate constant (left scale) for the H-atom abstraction reaction n-$C_4H_{10} + H \rightarrow C_4H_9 + H_2$ and for the reaction the $H + O_2 \rightarrow OH + O$ (using the rate expressions: $k = 3.1 \times 10^{14}\, exp^{(-4320/T)}$ / mol^{-1}-$cm^3\ s^{-1}$; and $k = 1.99 \times 10^{14}\ exp^{(-8460/T)}$/ $mol^{-1}\ cm^3\ s^{-1}$, respectively). The ratio of the rate constants is also shown (right scale). As indicated, both reactions have a comparatively high temperature sensitivity, so they become increasingly important at high temperatures. Furthermore, the abstraction reaction is roughly 20 times faster at typical flame temperatures (1200–2000 K) and in the range of 50–1000 times faster at temperatures between 650 and 1000 K. Hence, the chain branching reaction is most influential after the hydrocarbon is consumed. This property of the kinetics has a large influence on flame structure. The regime of the

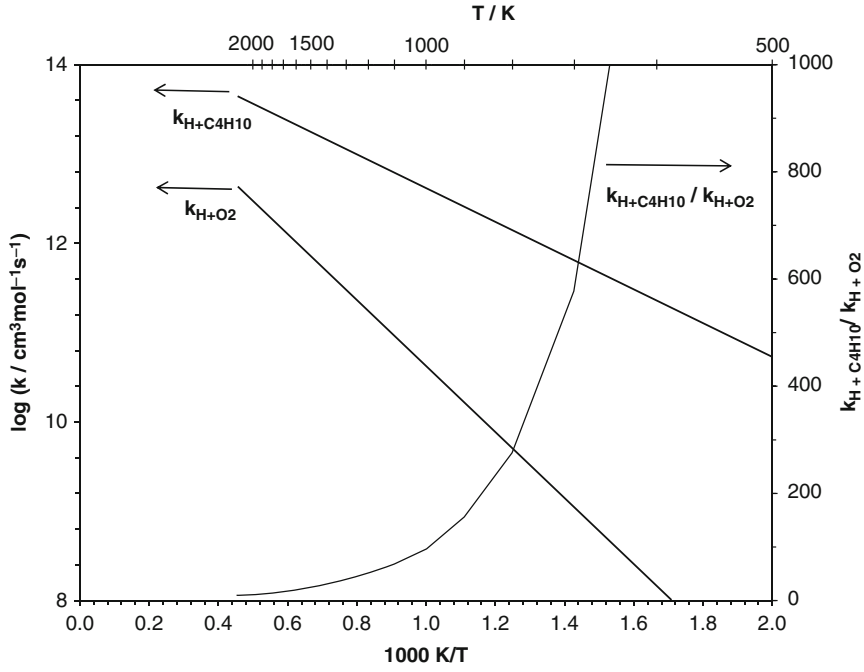

Fig. 10.11 Rate constant k (*left scale*) and ratio of rate constants (*right scale*) for reaction of H with O_2 or n-C_4H_{10}, as a function of temperature (*top scale*) and inverse temperature (*bottom scale*)

chain-branching reactions is separated, either physically or temporally, from the regime of fuel consumption, and one cannot have a large build-up in radical concentrations until the fuel species are significantly depleted. Nonetheless, in the context of spatial structure of a flame, the effect is mitigated somewhat by the diffusion of radicals (especially H atoms) which are transported to regions where they are needed for propagation reactions.

Flame Configuration/Structure Effects on Chemistry

As described above, there often exists competition between possible reaction paths in combustion systems, controlled largely by the temperature and chemical environment. The chemical environment can vary due to different initial conditions, changes with time, or the structure of the flame itself. ("Flame structure" constitutes the profile of concentrations of species, temperature, and flow velocities over space and time.) For example, in a co-flow laminar diffusion flame burner, the high-temperature reaction zone (i.e., the flame sheet) forms a conical shape around the fuel stream above the exit jet of the burner. Figure 10.12 shows of the volume fraction profiles for some of the species as a function of radial position across the high-temperature reaction zone in a cup-burner flame. The peak temperature occurs at $r = 8.5$ mm, and the concentration of O_2 and CH_4 decrease near that location. On the fuel side of the reaction zone (i.e., $r < 8.5$ mm), the species consist mostly of the fuel (CH_4) and its decomposition products (e.g., CH_3); while on the oxidizer side, the major species present are O_2 and the products of combustion (e.g., H_2O, CO_2) which are diffusing radially out from the flame. Due to diffusion, there is some mixing of species from each side. One notable feature is that the peak of the radical pool occurs on the oxidant side of the reaction zone, nearly coincident with the peak temperature.

These results can be explained as follows. First, the major chain branching reaction $H + O_2 \rightarrow OH + O$ (reaction 10.6) has a relatively high

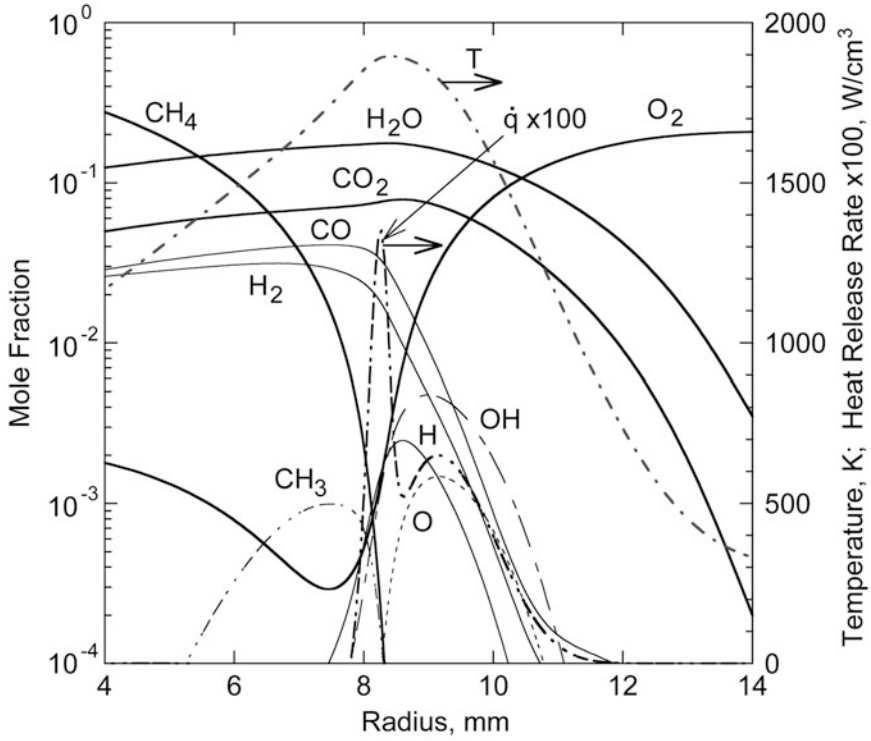

Fig. 10.12 Calculated species volume fraction, temperature, and heat release rate at a height of 11 mm above a cup-burner flame of CH_4 and air

activation energy ($E \sim 70$ kJ mol^{-1}), so its occurrence requires high temperature; but more importantly, it requires O_2, so that reaction must occur primarily on the air side of the flame. Secondly, the rate of reaction of H with CH_4 is much faster than with O_2, so reaction 10.6 cannot dominate on the fuel side. Similarly, the reaction CO + OH $\rightarrow$ CO_2 + H, which is responsible for CO consumption (as discussed above), must also be on the oxidant (air) side of the reaction zone: it needs OH, which would be consumed preferentially by the hydrocarbons on the fuel side. Since the CO + OH reaction, forming CO_2, is also responsible for a large fraction of the heat release, its location also dominates the location of the heat release and peak temperature.

The structure of a premixed flame (Fig. 10.13) also results from the hydrocarbon kinetics described above. As illustrated, the CO consumption and the peak of the chain-branching reaction 10.6 are both retarded until the CH_4 is nearly gone (since, as described above, the radicals required in both reactions react faster with CH_4). The consumption flux of CH_4 creates a dilemma: it needs both CH_4 and H, but they cannot both co-exist at high concentration because the chain-branching reactions producing H will not occur until hydrocarbons are considerably depleted. This is solved by species transport: H atoms are produced at a high rate near the peak temperature, but diffuse rapidly upstream where they are consumed by reaction with CH_4.

Super Equilibrium

Chemical equilibrium is an idealized state, which is sometimes achieved for select conditions in fires, but often is not realized in practice. In premixed and diffusion flames of hydrocarbons with air, for example, the radical pool species H, OH, and O, can achieve concentrations several orders of magnitude higher than those calculated at thermodynamic equilibrium. For example,

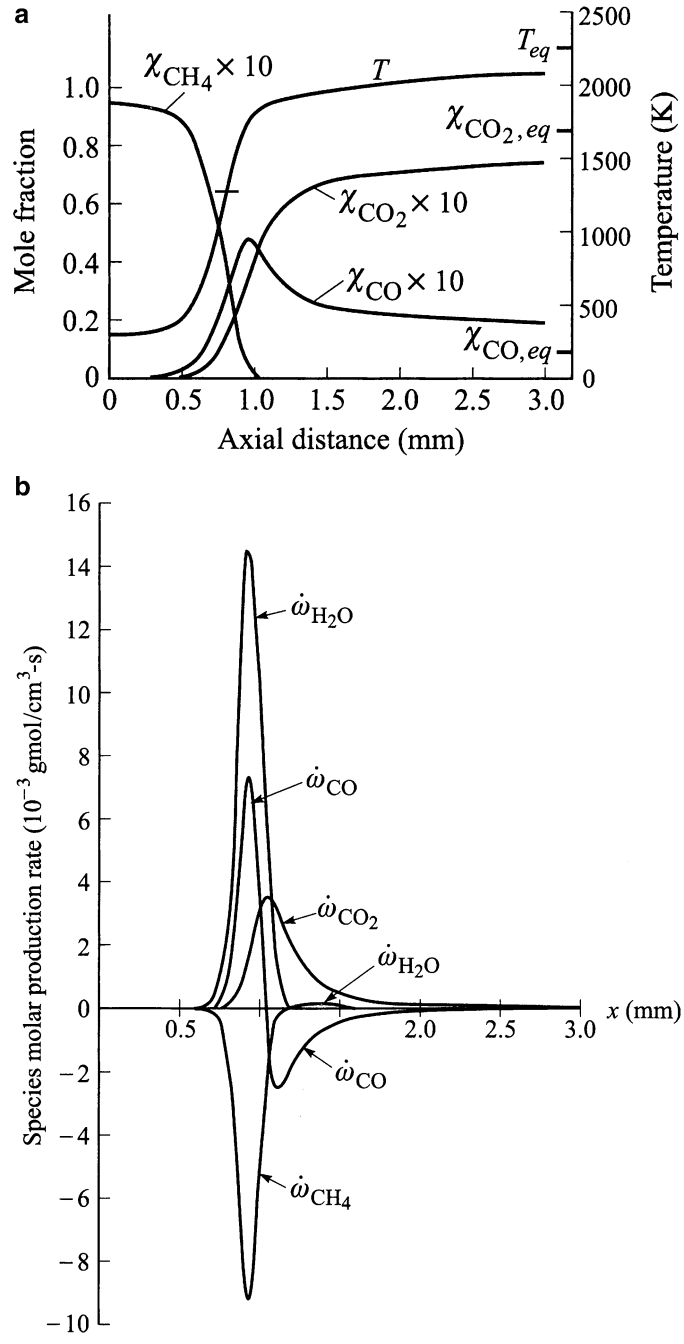

Fig. 10.13 Major species profiles and reaction fluxes for laminar premixed methane-air flame (From [3])

Fig. 10.14 shows the ratio of peak to equilibrium H-atom volume fraction in a methane-air counterflow diffusion flame; the results are plotted as a function of strain rate, which is proportional to the jet velocities of the methane and air streams forming the opposing flows in the burner. As indicated, super-equilibrium ratios range from 1 at zero strain, to 400 at a strain rate of 190 s^{-1}. The super-equilibrium concentrations occur because the reactions which form the radicals

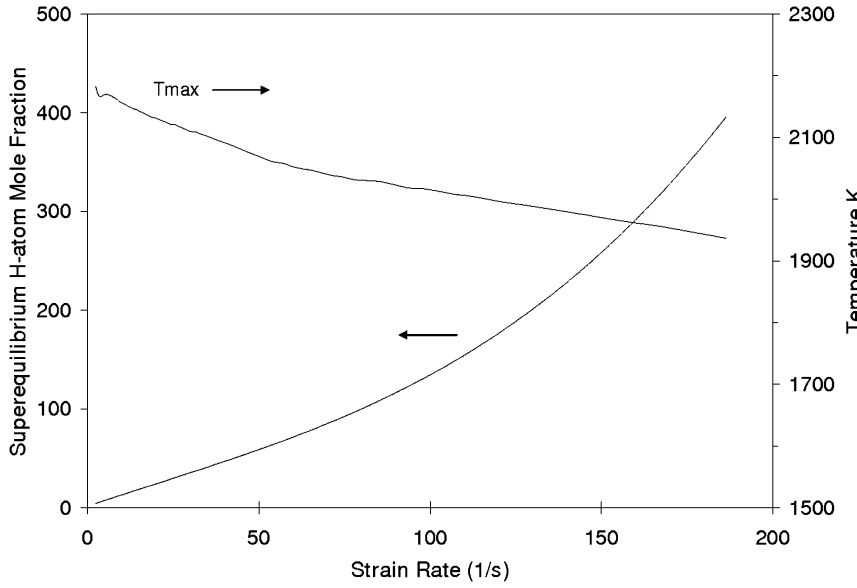

Fig. 10.14 Ratio of peak to final equilibrium H-atom volume fraction as a function of strain rate in a methane-air counterflow diffusion flame

(typically, the chain-branching reactions such as $H + O_2$ and $O + H_2$) are much faster than the reactions which recombine radicals (typically, the three-body recombination reactions such as H + OH + M). The species do not reside long enough in the main reaction zone for the recombination reaction to establish thermodynamic equilibrium at the prevailing temperature. The result is that radical pool species are present in very high concentration, leading to the rapid attack on the fuel species, and fast overall reaction. If the radicals are controlled to be closer to equilibrium levels (even at the elevated temperatures of the flames), the overall reaction rate is greatly reduced.

Premixed flames also have large superequilibrium of radicals. For example, in a stoichiometric methane-air flame, the peak volume fraction of H, O, and OH (which occur near the location of the peak of the $H + O_2$ reaction flux) are 17, 14, and 2.6 times the final equilibrium value, respectively. Note that it is generally accepted that the chemical action of fire suppressants is to decrease the peak radical concentration towards the final equilibrium level.

Role of Trace Species

There are several classic examples in combustion in which very low concentrations of reactants completely change both the route for fuel decomposition, as well as the overall rate of reaction. While they are sometime esoteric, they demonstrate the principles which are important for more practical situations.

Moisture in CO Oxidation

In early research, it was found that the oxidation rate of CO to CO_2 is highly dependent on the presence of trace quantities of water in the system. In fact, many hydrogen containing compounds (e.g., H_2, or a hydrocarbon) can supply the trace hydrogen atom necessary for the faster reaction. In the bone-dry system, the reaction of CO proceeds as follows. The initiation step

$$CO + O_2 \rightarrow CO_2 + \bullet O \bullet \qquad (10.35)$$

is slow. It is believed to be followed by

$$\bullet O \bullet + O_2 + M \rightarrow O_3 + M$$

$$O_3 + CO \rightarrow CO_2 + 2 \bullet O \bullet \quad (10.36)$$

$$CO + \bullet O \bullet + M \rightarrow CO_2 + M \quad (10.37)$$

which are all slow at combustion temperatures.

In contrast, in the presence of water, the reaction proceeds via:

$$CO + O_2 \rightarrow CO_2 + \bullet O \bullet \quad (10.38)$$

$$\bullet O \bullet + H_2O \rightarrow 2OH \bullet$$

$$CO + OH \bullet \rightarrow CO_2 + H \bullet \quad (10.39)$$

$$H \bullet + O_2 \rightarrow OH + \bullet O \bullet \quad (10.40)$$

with the subsequent build-up of the radical pool, followed by fast reaction in the system. A similar mechanism exists if H_2 is present rather than H_2O. At an H_2 content of 0.1 %, the moist reaction route accounts for about 70 % of the CO reaction. Indeed, for a premixed CO-air flame, the presence of only 2000 μL/L (ppmv) of H_2 can increase the burning velocity by factor of two.

Flame Inhibition by Iron-Containing Compounds

In early work with premixed CO-air flames, it was also found that trace contamination of the CO with iron pentacarbonyl strongly affected the reaction mechanism. It was found that iron in the high-pressure steel bottle containing the CO reacted with the CO to form $Fe(CO)_5$, which had high enough vapor pressure to enter the reactant stream (at trace quantities) with the CO. Later work showed that the iron enters into catalytic gas-phase reactions which have a very strong inhibiting effect on the build-up in the radical pool. The inhibiting effect acts similarly for all hydrocarbon flames. Indeed, it has been found that iron compound concentrations as low as 1 μL/L can reduce the burning velocity of premixed hydrocarbon-air flames by 1 %. The mechanism is as follows. The $Fe(CO)_5$ readily decomposes, via a sequence of steps, to form Fe and 5 CO:

$$Fe(CO)_5 \rightarrow Fe + 5CO. \quad (10.41)$$

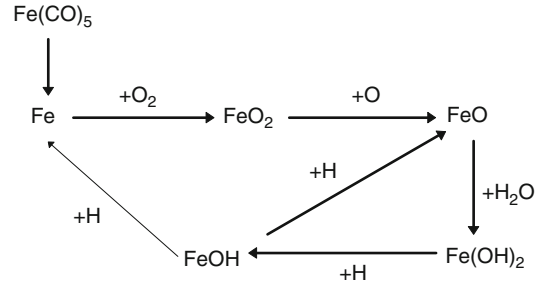

Fig. 10.15 Schematic diagram of reaction pathways of $Fe(CO)_5$ in premixed methane-air flames

This is followed by the formation of the inhibiting species FeO, $Fe(OH)_2$, and FeOH via the sequence shown in Fig. 10.15:

Once formed, the three reactions (forming a triangle on the right side of Fig. 10.15) enter into a gas-phase catalytic cycle:

$$FeO + H_2O \rightarrow Fe(OH)_2 \quad (10.42)$$
$$Fe(OH)_2 + H \bullet \rightarrow FeOH + H_2O \quad (10.43)$$
$$FeOH + H \bullet \rightarrow FeO + H_2 \quad (10.44)$$
$$\text{Net: } H \bullet + H \bullet \rightarrow H_2$$

which effectively recombines H atoms into H_2, thereby greatly reducing the radical concentrations and essentially suppressing the flame propagation chemistry. (Recall that the radicals are typically present at super-equilibrium quantities, so the effect of reactions 10.42 to 10.44 is to drive the system to equilibrium more rapidly.) In the rate constant expression Equation 10.28, the activation energy (E_a/R) for these reactions is low (0 K, 302 K, and 604) K, and the pre-exponential factor A' is high ($10^{13.2}$ s^{-1}, $10^{14.3}$ s^{-1}, and $10^{12.1}$ s^{-1}), so these reactions proceed at nearly gas-kinetic rates: that is, as fast as the molecules can collide, they react. In fact, further analysis has shown that these reactions of iron in flames approach the ideal gas-phase catalytic radical recombination rate [11].

Flame Inhibition by Bromine-Containing Compounds

Similar catalytic cycles are present for bromine added to hydrocarbon flames. For example, the

catalytic cycle of HBr in a methane-air flame can be represented by:

$$H\bullet + HBr = H_2 + Br\bullet \quad (10.45)$$
$$H\bullet + Br_2 = HBr + Br\bullet \quad (10.46)$$
$$Br\bullet + Br\bullet + M = Br_2 + M \quad (10.47)$$
$$\text{Net}: H\bullet + H\bullet \rightarrow H_2$$

The net effect of adding HBr to a flame typically is to recombine H atoms into H_2 (as in the iron mechanism above), and thereby reduce the overall reaction rate. It should be noted that in actual methane-flames, several regeneration steps for the inhibiting molecule HBr are also important, such as $CH_2O + Br\cdot = \cdot HCO + HBr$, and $CH_4 + Br\cdot = \cdot CH_3 + HBr$. These reactions contribute to cycles like reactions 10.45 to 10.47; however, they are not so easy to outline in a concise list because there are many reactions involved in the consumption of other radicals, such as $\cdot CH_3$ and ·HCO. This basic mechanism is believed to occur also during the action of other bromine-containing additives such as CF_3Br (halon 1301).

Chemical Kinetic Models

Overview

A chemical kinetic model starts with a list of species and the reactions between them. The thermodynamic data for the species are required, as are the parameters for the specific reaction rate constants of all reactions. Either the forward or reverse reaction data are required, with the equilibrium relationship usually then providing the rate parameters for the counterpart reaction.

The relevant reactions necessary for inclusion depend upon the environment, and the desired information. For example, a mixture of hydrocarbons and air would have a different chemical mechanism for understanding the atmospheric chemistry at 298 K as opposed to flame chemistry at 2000 K. In the former, only reactions prevalent at low temperature are important, whereas in the latter, high-temperature process are considered; the participating species can be different. Of course, since the reactions are elementary, they should apply to both situations, and the two mechanisms could be combined into a larger, comprehensive unit. Nonetheless, the run time of a simulation depends on the size of the chemical mechanism, so it is usually desirable to minimize the number of species (i.e., the number of variables) and reactions in a model. Selecting the right chemical model, and its complexity, are an essential first step for understanding the chemical behavior of a system. Often, one will eliminate chemistry that is not important for the present problem. For example, while the chemistry for the formation of NO_x is always occurring in high-temperature flames of hydrocarbons with air, the NO_x species are relatively trace compounds, and have a minor effect on the development and overall energetics of flames. Hence, those reactions can be eliminated if the goal of a study is to understand a feature such as the rate of heat release, rather than pollutant (i.e., NO_x) formation.

In combustion, detailed chemical kinetic models are hierarchical: a mechanism for a larger reactant will contain the entire kinetic model of each of the smaller species which are present in the larger model. The simplest kinetic model is that of the H_2/O_2 system, and this is contained in all larger mechanisms; the H_2/O_2 kinetic model is followed in complexity by those for CO, CH_2O, CH_4, and C_2H_6. As a result, a mechanism for cetane ($C_{16}H_{34}$) can have 1200 species and more than 7000 reactions [6]. Usually, each of the smaller, simpler mechanisms is experimentally validated prior to development of the next most complex model, so the reaction sets are internally consistent. Because all the mechanisms are based on elementary rates, the mechanisms should be widely applicable. Unlike the example of NO_x chemistry, the chemistry of smaller hydrocarbon species cannot be eliminated from kinetic models of larger species; rather, they are essential.

Even for a kinetic model based on elementary rates, one still needs to exercise caution in its application. The species and reaction set of a mechanism are developed for a specific range of conditions (e.g., reactant composition and

stoichiometry, flame type, temperature range, etc.). It is incumbent upon the user to understand the conditions for which the mechanism was developed, and interpret if those conditions are close enough to the condition of interest for the mechanism to be useful. An example of this is the NIST chemical kinetic mechanism for hydrofluorocarbon (HFC) inhibition of hydrocarbon flames. The mechanism was developed based on the assumption that the flame inhibitors (for example C_2HF_5) would be added in small amounts (a few percent) to hydrocarbon-air flames. Recently, it has become of interest to understand the flammability of pure refrigerants with air, as well as the reaction of flame inhibitors at very high loading. For these conditions, additional species are likely to participate, and the mechanism will need to be extended.

The important reaction pathways can sometimes be very similar for different fuels. As outlined by Warnatz [12], in combustion at high temperatures (i.e., near 2000 K), larger fuel molecules quickly break down to C_1 and C_2 species, and once these form, their decomposition pathways are similar for all hydrocarbon flames. Similarly, as outlined by Babushok and Tsang [13], the burning velocity of hydrocarbons tends to be controlled by a small set of reactions involving small decomposition products of the larger fuel molecules (and other common species such as O_2). Also, the mechanism of flame inhibition of halogenated compounds also tends to be very similar for different hydrocarbon fuels [13]. The reactions which form and destroy the radical pool are similar, so the effect of the flame inhibitors (which act to reduce radical concentrations) are also related.

Databases

There are many sources, both in publications and online, for thermodynamic data, elementary reaction rates, and comprehensive kinetic models. Some thermodynamic data can be found in [14] and [15], and reaction rate (and other) data in [6–8, 10].

Role of Gas-Phase Kinetics in Some Fire Problems

Understanding Standard Fire Tests Through Kinetic Modeling: The Cup Burner Test

The cup burner method is a standard test [16] used for specifying the amount of fire suppressant to be used in full-scale applications. In this test, a small cup (28 mm dia) holds the liquid fuel, which is supplied to the burner so as to maintain the level of the fuel to the top edge of the cup. For gaseous fuels, a fine screen distributes the low velocity gas evenly over the exit nozzle of the burner. A chimney (10 cm diameter) holds the gaseous oxidizer, which is usually air mixed with fire suppressant. By increasing the volume fraction of the fire suppressant, its extinguishing concentration is determined as the volume fraction in air at which the flame is extinguished.

As with any standard test method, there is always the question as to how the results obtained in small laboratory experiments corresponds to full-scale fires. Insight into this question can be gained by numerically modeling the test method, interpreting the controlling physics, and then comparing those with the parameters believed to be controlling at full scale. Since flame extinction is intimately connected with flame chemistry (and overall reaction rate) a good chemical kinetic description of the flame is necessary. It is possible to model cup-burner flames using direct numerical simulation, in which the momentum, energy, and species conservation equations are solved directly. Using available chemical kinetic mechanisms, the numerical calculation (2-D axi-symmetric) produces detailed information on the flame structure: i.e., the species concentrations, gas velocity and temperature, at all locations in the calculation domain, as a function of time. Using post-processing techniques on the data to generate the reactive and diffusive flux of species, and heat transfer properties of the flame, great insight can be gained (for example, Ref. [17]).

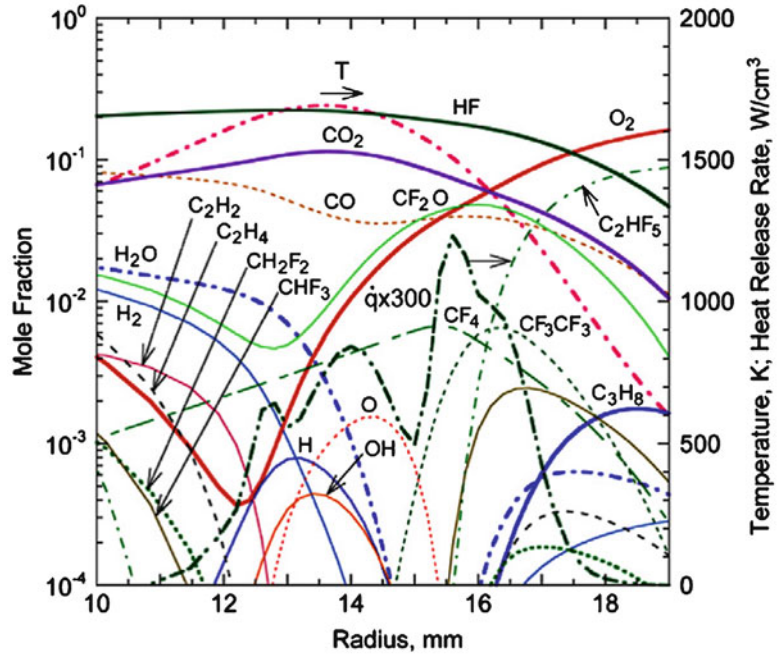

Fig. 10.16 Calculated species profiles at a height of 16 mm above a cup-burner flame of CH_4 and air, with C_2HF_5 added to the air stream at a volume fraction of 9.3 % (From [17])

Figure 10.16 show the calculated flame structure for a cup-burner flame of methane, with C_2HF_5 added to the air stream at a volume fraction just below extinguishment (0.093). Results such as these have been used to answer such questions as:

1. Why do cup-burner flames always extinguish due to flame lift-off, rather than extinction elsewhere?
2. Does a particular fires suppressant work by thermal or chemical kinetic mechanisms?
3. Does a fire suppressant in the air stream add to the heat release in cup-burner flame?
4. Why are cup-burner flames in low gravity harder to extinguish than those in normal gravity?

Analysis of cup-burner flames has shown that:

1. The flame is stabilized at the base, by a partially-premixed region which has a much higher reactivity than the rest of the flame. Addition of the fire suppressant to the air stream lowers the reactivity (either thermally or kinetically) at the flame base. The base can find a new stabilization point if it lifts off further: higher lift-off allows more time for mixing of the fuel and air streams, which leads to more premixed character and a higher reactivity. At the extinguishment agent volume fraction, further lift-off does not sufficiently increase the reactivity to overcome the loss of reactivity caused by agent addition, and the premixed flame base cannot stabilize in the flow field.
2. Simulations have shown that essentially inert agents (such as CO_2, N_2, Ar, He, etc.) act by lowering the temperature at the flame base, reduce reaction rates there, and cause lift off (as described above). For other agents (such as CF_3Br, Br_2, CF_3H, C_2HF_5, etc.) the peak temperature (as well as the temperature in the stabilization region) is actually increased with agent addition; hence, the mechanism cannot be thermal in origin. Further analysis has shown that chemical reactions at the flame base reduce radical concentrations more there than further up in the flame, causing flame extinguishment preferentially at the base.
3. By integrating the heat of reaction for all reactions over the entire calculation domain, it has been demonstrated that, for agent volume fractions just above that for extinguishment, CF_3Br reduces the total heat release, whereas C_2HF_5 increases (i.e. nearly doubles) it.

4. Fire safety in spacecraft requires an understanding of the behavior of flames in zero gravity (0-g_n). Experiments and simulations have shown that despite 0-g_n flames being much weaker, they require more fire suppressant for extinguishment. Simulations have explained this unexpected behavior. The normal-gravity (1-g_n) flames have buoyancy-induced flicker, which causes the flame base to oscillate strongly. This creates a more difficult flow field for flame base stabilization, and causes the flame to blow off earlier than it would without the flame flicker. Hence, the better-stabilized 0-g_n flames require more suppressant to lower the reaction rate at the base and cause blow-off.

The significance of the work to understand the chemical kinetic behavior of laboratory flames goes beyond the goal of understanding standard test methods. Twenty years ago, such 2-D time-dependent simulations with full chemistry were not possible, even for cup-burner flames; but today they are common. As computer speed, numerical methods, and chemical kinetic models all improve, it will not be long before such simulations with detailed chemistry are possible for the larger domains typical of fires. When that happens, the full potential of chemical kinetics for understanding fire problems will start to be realized—as has occurred in other areas of combustion.

Gregory T. Linteris is a mechanical engineer in the Flammability Reduction Group of the Fire Research Division of the Engineering Laboratory at the National Institute of Standards and Technology. Dr. Linteris is a project leader for research on material flammability in the Flammability Reduction Group. He also conducts research to understand the detailed mechanisms of chemically acting fire suppressants. In 1997, Dr. Linteris served as a payload specialist astronaut on two NASA space shuttle missions, conducting microgravity combustion, fluid mechanics and material science experiments while in earth orbit for 20 days.

John F. Griffiths is emeritus professor of combustion chemistry at the University of Leeds in the United Kingdom. His main research interest is the gas-phase combustion of hydrocarbons, which is related both to combustion hazards which may arise from spontaneous ignition processes in the chemical industry and to the efficiency of reciprocating engines.

Diffusion Flames

11

Ali S. Rangwala

Fires involve reactants, usually fuel and air, not intimately mixed at a molecular level before combustion. Usually, the fuel is in the solid or liquid state so transfer of material across a phase boundary (phase change) must also occur. The vaporized fuel must combine with oxygen from air to form a flammable mixture, which when ignited forms the flame zone. In most fire problems, this mixing of fuel vapor and oxygen takes place mostly by diffusion and takes orders of magnitude longer time compared with that of a chemical reaction. Therefore, diffusion of species is the primary controlling process during such burning behavior. A fundamental understanding of diffusion flames then involves exploring the *mechanisms* associated with the transport of the reactants and the resulting flame structure.

In Fire Protection Engineering, diffusion flame theory is used in calculating flame-length, flame-location, and rates of burning. The flame-length, is used for hazard analysis as it provides information to estimate the heat transfer to surrounding surfaces. Knowledge of flame location is necessary for suppression, and finally, the rate of burning provides an estimate of the "size" of the fire and in combination with the heat of combustion is used to calculate the heat release rate.

The Diffusion Coefficient

Diffusion is the phenomena of migration of mass. The mass can be in the form of atoms, molecules, ions, or other particles because of spatial gradient of some quantity (concentration, temperature, pressure etc.). Similar to conduction heat transfer (Fourier's law) and momentum transfer (Newton's law), mass transfer is governed by a law called as Fick's law of diffusion. In a simplified context, Fick's law of diffusion describes the movement of one chemical species A through a binary mixture of A and B because of concentration gradient of A. In most fire problems A is usually fuel vapor, oxidizer or products of combustion, while B represents air. To explain this further, let us consider the example of a candle flame shown in Fig. 11.1. The paraffin of the candle melts because of heat from the flame; it travels by capillary forces through the wick where it then evaporates to become paraffin vapor, a gaseous fuel.

Let F represent fuel vapor, O represent oxygen and P represent products. Fuel vapor will issue out of the wick because of the heat received from the flame. If one traverses along the path X-X' (shown by dashed red line in Fig. 11.1) the concentration of fuel vapor is highest at the wick and reduces until it reaches a concentration most suitable for chemical reaction with oxygen at X'. The concentrations of the various species involved, can be given by the mass fractions, Y_F, Y_O and Y_P, where Y_F denotes the mass of fuel vapor divided by the total mass of

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_11, © Society of Fire Protection Engineers 2016

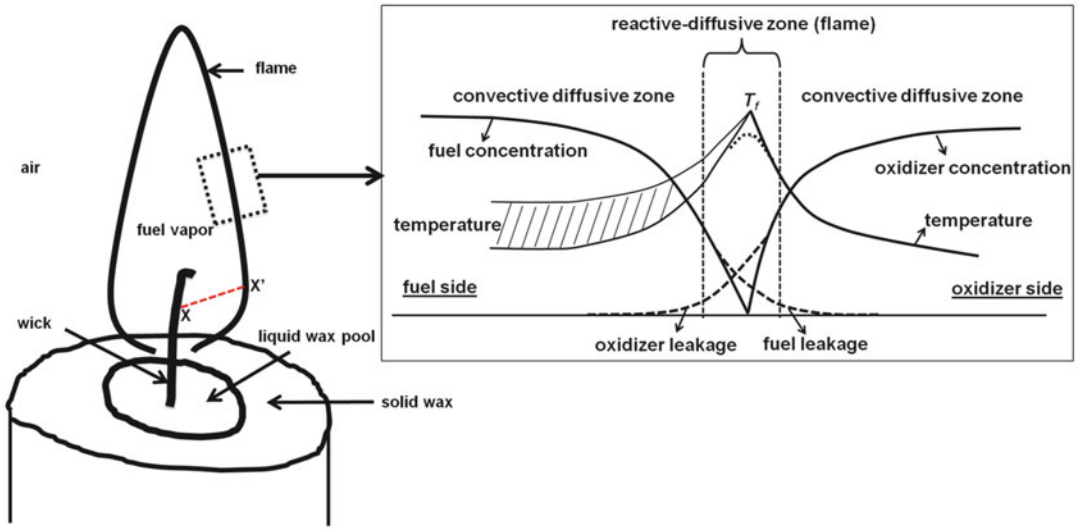

Fig. 11.1 The candle flame

gas-mixture in a given volume and the subscripts O and P denote oxidizer and products, respectively. Initially the mass fraction of F at the wick is 1 at the wick and zero just outside the wick, and this gradient drives the fuel vapor out of the wick. On approaching the flame zone, the mass fractions of the fuel and oxidizer should be such that a stoichiometric mixture should be formed. Now, Fick's law states that the mass transport of fuel vapor along XX' due to mass diffusion can be described by:

$$J_F = \rho D_{FA} \frac{Y_{F,X} - Y_{F,X'}}{XX'}. \tag{11.1}$$

J_F is the mass flow rate of fuel vapor per unit area (or mass flux) and is proportional to the mass fraction difference divided by the distance from the wick to the flame (*XX'*). ρ is the density of the gas-mixture system and D_{FA} is a proportionality factor called as the binary mass diffusivity of fuel vapor with respect to air. In differential form, Equation 11.1 can be written as:

$$J_F = -\rho D_{FA} \frac{dY_F}{dx}. \tag{11.2}$$

The negative sign denotes that the mass fraction of fuel vapor will decrease as one moves along XX', represented as x-direction. This is logical because the fuel vapor originates at the wick (location X). Equation 11.2 is also called the *Ficks law of diffusion* and forms the starting point of our discussion on diffusion flames. Note that similar relationships can be written for oxygen (diffusing towards the flame) and products of combustion (diffusing on either side of the flame).

Table 11.1 gives the binary diffusion coefficients *D* for many common gases. Values refer to atmospheric pressure. The first part of the table gives data for several gases in the presence of a large excess of air. The mass diffusivity *D*, is an important transport property such as thermal diffusivity α and momentum diffusivity (kinematic viscosity) υ, and all three have dimensions of $(\text{length})^2/\text{time}$. The ratios of these quantities, taken as a pair, form three important nondimensional numbers that play a prominent role in analyzing most fire problems. They are Prandtl number, $\text{Pr} = \upsilon/\alpha$, Schmidt number, $\text{Sc} = \upsilon/\text{D}$ and Lewis number, $\text{Le} = \alpha/\text{D}$. Equation 11.2 assumes that the driving force for diffusion is concentration gradient. However, it has been observed, as well as predicted by the kinetic theory of gases, that mass diffusion can occur in the presence of a temperature gradient and pressure gradient. Further, the value of the binary

Table 11.1 Diffusion coefficients of common gases at 0 °C, 760 mmHg. Assuming ideal gas behavior, D can be calculated for other pressures and temperatures using the relation $D \propto P^{-1}T^{3/2}$

Gas-pair	D (cm^2/s)
O_2—air	0.178
CO_2—air	0.138
H_2—air	0.611
H_2O—air	0.220
Methane (CH_4)—air	0.196
Ethane (C_2H_6)—air	0.108
Propane (C_4H_{10})—air	0.0878
Butane (C_3H_8)—air	0.0750
Pentane (C_5H_{12})—air	0.0671
n-Octane (C_8H_{18})—air	0.0505
Benzene (C_6H_6)—air	0.077
Toluene (C_7H_8)—air	0.051
Napthalene ($C_{10}H_8$)—air	0.0513
Anthracen ($C_{14}H_{10}$)—air	0.0421
Methyl alcohol (CH_3OH)—air	0.1325
Ethyl alcohol (C_2H_5OH)—air	0.102

mass diffusivity itself depends on temperature and pressure ($D \sim P^{-1}T^{3/2}$). The diffusion coefficient of common gas-mixtures at various temperatures and pressures can be obtained using this equation in combination with values listed in Table 11.1. However, this effect is usually neglected in fire problems. Further details on the subject can be found in Ref. [1].

Structure of Diffusion Flame

The zoomed inset of the part of the flame zone in Fig. 11.1 shows an illustrative sketch of the structure of a diffusion flame. It consists of a flame separating a fuel-rich zone and an oxidizer-rich zone. The flame or reaction zone incorporates the location of the maximum temperature. For example, for a methane-air flame, this temperature is experimentally observed to be around 1950 K [2]. As shown in Fig. 11.1, fuel and oxidizer both almost disappear in the flame zone, although there is some fuel and oxidizer leakage outside the designated flame zone as shown by the dashed lines. Products of combustion and heat diffuse outwards from the flame zone to both the sides. One of the characteristics of typical hydrocarbon diffusion flames is their yellowness, especially when the fuel can emit soot, and it's appearance can be explained using Fig. 11.2 [3].

The reaction zone usually has a blue emission, especially when the fuel and oxidizer have been mixed in proper proportions. This is mainly due to radiation due to excited CH radicals. The reddish glow arises from radiation from CO_2 and water vapor radiation. Most importantly, the intense yellow radiation which is a characteristic of most fires is due to the presence of carbon particles or soot. Figure 11.2a illustrates a simplified illustrative sketch of three prominent zones in a diffusion flame. Note that emphasis is given to the fuel side. The cracking zone is a region on the fuel side of the reaction zone before the soot formation zone. This where the molecules crack and polymerize forming lighter fuel molecules which chemically react with the oxygen in the reaction zone and rest convert to carbonaceous and tarry substances in a soot formation zone that exists just before the reaction zone. Soot generally forms as particles with diameters of the order of several nanometers by a process called as inception or nucleation. These particles then undergo surface growth. One mechanisms attributed to the surface growth is called as the Hydrogen Abstraction by C2H2 Addition (HACA) mechanism [6] where H-atoms impacting on the soot surface activate acetylene addition thereby increasing the mass of soot particles. The process of nucleation occurs concurrently with coagulation, where small particles coalesce to form larger primary particles, and agglomerations where multiple primary particles line up end-to-end to form larger structures resembling a string of pearls as shown in Fig. 11.2b [5]. When the soot particles pass through the flame front they oxidize whereby the mass of soot is decreased by heterogeneous surface reactions between soot particles and oxidizing species. Incandescent soot results in the

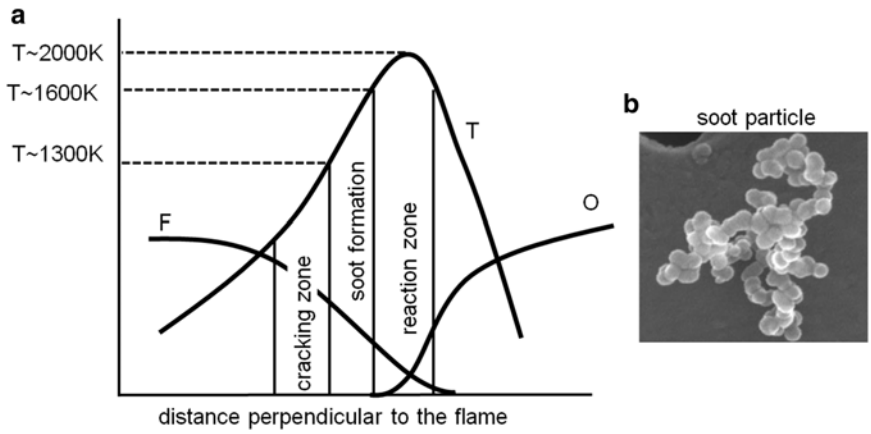

Fig. 11.2 (**a**) Zones in a diffusion flame [4] (**b**) soot particle observed under a scanning electron microscope—resemblance to string of pearls [5]

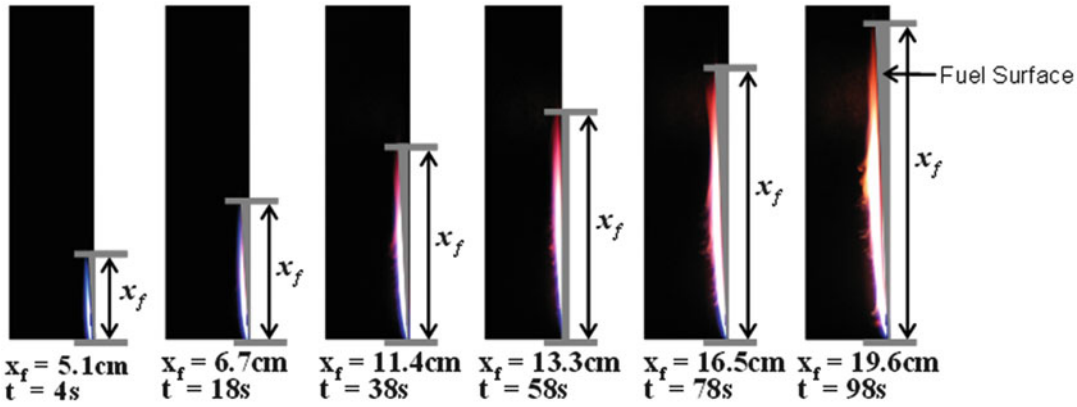

Fig. 11.3 Upward propagating flame on a PMMA surface

characteristic yellow-color of most hydrocarbon diffusion flames. The processes leading to cracking and soot formation are dependent on fuel type and ambient conditions and form an important research topic in fire safety [7–9]. This is mainly because most of the flame radiation from fires originates from soot particles. The luminous radiation from soot often makes it difficult to observe the blue emission from the reaction zone. The blue radiation is observable for small flames (less than 15 cm) as shown in Fig. 11.3 where the initial stages of a wall fire (PMMA, 1.2 cm thick, 5 cm wide, 50 cm long) are shown. The size of the soot particles depends on the time allowed for their growth, the fuel composition and temperature of the flame zone. Since time increases with linear dimensions longer flames are usually yellower, smokier than shorter flames, indicating the escaping of the soot particles out of the flame zone. Large carbon particles will radiate more heat as shown in Fig. 11.3 [10]. A laminar natural convection flame is blue at the base, yellow in the center and red/orange at the tip. The latter condition means that so much heat has been lost by radiation from the carbon particles, that when it does cross the reaction zone into a region where oxygen is available for combustion, it is too cold to burn. The result is emission of smoke.

A useful material-property called **smoke-point** of a fuel can be defined based on this radiative heat loss mechanism by soot. A fuels smoke point is the maximum height of its laminar flame (or fuel mass flow rate) burning in air at which soot is just released from the flame tip. Another definition (and more applicable to fire safety) is the heat release rate at which smoke just begins to be released from the flame tip. Smoke point is a simplified ranking scheme for soot production and was first introduced by Kent and Wagner [11]. Smoke-point can be easily determined for gases and vapors by adjusting the flow rate of the fuel from a simple burner. For liquid fuels a wick-fed lamp (ASTM D1322) is used. Determining the smoke point for solid fuels is difficult, although some progress has been made in this direction by de Ris and Cheng [12]. It has been shown [12–14] that smoke point can provide a convenient measure of the flame radiant fraction. A comprehensive review on the development of an engineering model capable of predicting the release of soot and radiation given the smoke point of the fuel, stoichiometric mass ratio of the reactants and the adiabatic stoichiometric flame temperature is discussed by Lautenberger [15].

Diffusion Flame Theory

The theory of diffusion flames consists of an analysis of factors controlling the mixing of fuel and oxidizer. Main factors controlling the mixing are mass diffusivity (D), gradient of species mass fraction (dY/dn) normal to the condensed fuel surface and the flow field. Unlike premixed flame analysis, the rates of the reaction mechanisms do not dominate the burning behavior in diffusion flames. As discussed earlier, in diffusion flames, fuel and oxidizer come together in a reaction zone through diffusion. This diffusion can be just molecular transport (candle flame, laboratory flames) or be enhanced several times by convection, which may be even turbulent (most large-scale fires such as pool, building, forest etc.) The theoretical solution of the diffusion flame is best approached by considering a candle flame once again. Focus on a control volume in the gas phase as shown by the dashed boxed. The fuel vapor and oxidizer diffuse from opposite directions and approach the flame in a normal direction (Fig. 11.1, LHS). The concentrations of fuel and oxidizer at the flame are in stoichiometric proportion. In other words, the diffusion flame surface is defined as the locus of all points in space where the fuel and oxygen meet at stoichiometric proportions. **A one-step** chemical reaction given by Equation 11.3 can be used to represent the overall chemical process.

$$1\ \mathrm{g}[FUEL] + s\ \mathrm{g}[OXIDIZER] \rightarrow (1+s)\ \mathrm{g}[PRODUCTS] + Heat \quad (11.3)$$

The assumption made here is that the net disappearance rate of the reactants (fuel and oxidizer) is infinitely fast. This is represented by the zoomed inset in Fig. 11.1, where solid lines are used to indicate the profiles of temperature and mass fractions of the reactants. The flame zone is infinitesimally thin, and both fuel and oxygen are consumed at this "zero-thickness" flame sheet. However, in the actual scenario, the assumption of infinitely fast reaction is not true as indicated by the profiles in dashed lines in the flame structure inset in Fig. 11.1, where the flame zone has finite thickness and both the oxygen and the fuel leak through this flame zone. The details of flame broadening are beyond the scope of this chapter. However, an interested reader may refer to a book related to the topic [16]. For our purposes, the infinite rate chemistry assumption is sufficient in predicting parameters such as the mean flame zone location and mass burning rate.

The **one-step** and **infinitely fast** reaction assumptions also imply that $\dot{\omega}_F''' = \frac{\dot{\omega}_O'''}{s} = \frac{-\dot{\omega}_P'''}{1+s}$, where $\dot{\omega}'''$ denotes the nonlinear rate term representing the rate of formation or destruction of a species per unit volume. Subscripts F, O and P, denote fuel, oxidizer and products, respectively. The conservation equations for the control volume are given by:

Species Conservation

Assumption: binary diffusion coefficients are equal for all species.

$$\rho\frac{\partial Y_O}{\partial t}+\rho u_i\frac{\partial Y_O}{\partial x_i}=\frac{\partial}{\partial x_i}\rho D\frac{\partial Y_O}{\partial x_i}-\dot{\omega}_O''', \quad (11.4)$$

$$\rho\frac{\partial Y_F}{\partial t}+\rho u_i\frac{\partial Y_F}{\partial x_i}=\frac{\partial}{\partial x_i}\rho D\frac{\partial Y_F}{\partial x_i}-\dot{\omega}_F''', \quad (11.5)$$

$$\rho\frac{\partial Y_P}{\partial t}+\rho u_i\frac{\partial Y_P}{\partial x_i}=\frac{\partial}{\partial x_i}\rho D\frac{\partial Y_P}{\partial x_i}+\dot{\omega}_P'''. \quad (11.6)$$

Energy Conservation

$$\rho c_p\frac{\partial T}{\partial t}+\rho u_i c_p\frac{\partial T}{\partial x_i}=\frac{\partial}{\partial x_i}\lambda\frac{\partial T}{\partial x_i}+\dot{\omega}_F'''\Delta H_c\left[\text{or }\frac{\dot{\omega}_O'''\Delta H_c}{s}\text{ or }\frac{\dot{\omega}_P'''\Delta H_c}{1+s}\right]. \quad (11.7)$$

In the above equations, ρ represents the gas phase density, c_p represents the specific heat and λ equals the thermal conductivity. ΔH_c represents the heat of combustion of the fuel and D equals the diffusion coefficient which is assumed to be the same for oxygen—air, fuel—air and product—air The nonlinear rate terms ($\dot{\omega}'''$) can be eliminated from the equations by suitable subtractions and assuming that the Lewis number is unity $\left(Le=\frac{\lambda}{\rho c_p D}=1\right)$. Multiply Equation 11.4 by $\frac{1}{s}$, Equation 11.6 by $\frac{1}{1+s}$ and Equation 11.7 by $\frac{c_p}{\Delta H_c}$ to get the modified conservation equations.

Modified Species Conservation Equations

$$\rho\frac{\partial(Y_O/s)}{\partial t}+\rho u_i\frac{\partial(Y_O/s)}{\partial x_i}=\frac{\partial}{\partial x_i}\rho D\frac{\partial(Y_O/s)}{\partial x_i}-\frac{\dot{\omega}_O'''}{s}, \quad (11.8)$$

$$\rho\frac{\partial Y_F}{\partial t}+\rho u_i\frac{\partial Y_F}{\partial x_i}=\frac{\partial}{\partial x_i}\rho D\frac{\partial Y_F}{\partial x_i}-\dot{\omega}_F''', \quad (11.9)$$

$$\rho\frac{\partial[Y_P/(1+s)]}{\partial t}+\rho u_i\frac{\partial[Y_P/(1+s)]}{\partial x_i}=\frac{\partial}{\partial x_i}\rho D\frac{\partial[Y_P/(1+s)]}{\partial x_i}+\frac{\dot{\omega}_P'''}{1+s}. \quad (11.10)$$

Modified Energy Conservation Equation

$$\rho\frac{\partial\left(Tc_p/\Delta H_c\right)}{\partial t}+\rho u_i\frac{\partial\left(Tc_p/\Delta H_c\right)}{\partial x_i}=\frac{\partial}{\partial x_i}\frac{\lambda}{c_p}\frac{\partial\left(Tc_p/\Delta H_c\right)}{\partial x_i}+\dot{\omega}_F'''. \quad (11.11)$$

Equations 11.8, 11.9, 11.10, and 11.11 can be combined into a single equation given by

$$L(\beta)=0, \quad (11.12)$$

where β can take several values as shown in Table 11.2 and the operator L is expressed as,

$$L(\beta)\equiv\rho\frac{\partial\beta}{\partial t}+\rho u_i\frac{\partial\beta}{\partial x_i}-\frac{\partial}{\partial x_i}\rho D\frac{\partial\beta}{\partial x_i}. \quad (11.13)$$

In the operator L, the first term represents the accumulation of thermal energy or chemical species, the second term represents the convection efflux thorough the control surfaces and the third represents the diffusion efflux. The non-linear volumetric reactive effects are eliminated using

Table 11.2 Different forms of the coupling function β introduced in Equation 11.12

β	Value
β_{FO}	$Y_F-\frac{Y_O}{s}$
β_{FP}	$Y_F+\frac{Y_P}{1+s}$
β_{FT}	$Y_F+\frac{Tc_p}{\Delta H_c}$
β_{OP}	$Y_O+\frac{Y_P}{1+s}$
β_{OT}	$Y_O+\frac{Tc_p}{\Delta H_c}$
β_{PT}	$Y_P+\frac{Tc_p}{\Delta H_c}$

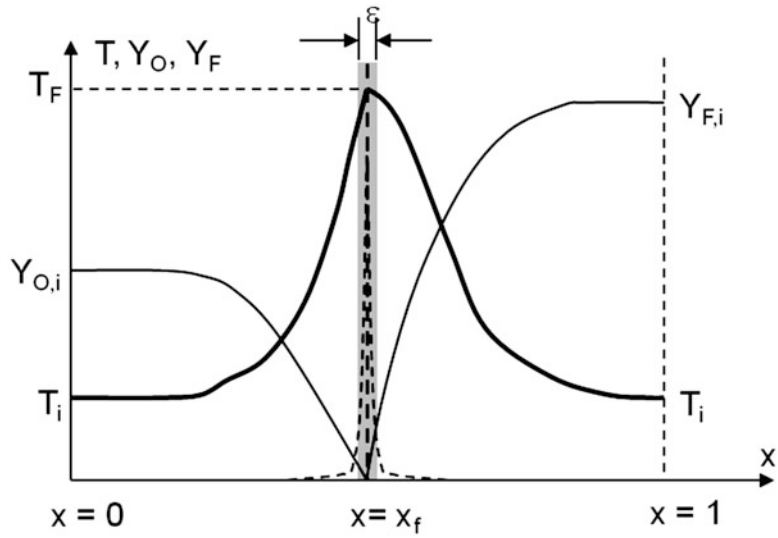

Fig. 11.4 The onedimensional diffusion flame mathematical model

the coupling function β, which can take 6 forms as shown in Table 11.2. This methodology is referred to as the Shvab-Zeldovich transformation after two classical papers by Shvab [17] and Zeldovich [18] that first used the coupling function. Note that although Shvab-Zeldovich proposed a general solution, the original idea was first proposed by Burke-Schumann [19] in 1928.

Equation 11.12 can be solved with knowledge of initial and boundary conditions. However, this is not an easy task! For example, the convective term is also non-linear unless the velocity is constant. Further, many added assumptions such as constant, ρD, steady state ($\frac{\partial \beta}{\partial t} = 0$), one-dimensional system, constant pressure and low speed flow are required before analytical solutions to some problems can be obtained. Nevertheless the coupling function β is a powerful tool that is used extensively in diffusion flame problems. One example is considered below.

Diffusion Flame Location

The diffusion flame surface is defined as the locus of all points in space where the fuel and oxygen meet at stoichiometric proportions. The position of the flame front of a diffusion flame is dependent on the surrounding geometry and the flow rates of the various gas streams. It is apparent, then, that each accidental flame is dependent on the details of the environment in which it burns. Thus the possible variations in behavior are endless. The one-dimensional flame structure discussed earlier will be used once again to describe the problem. A further set of assumptions will be imposed to simplify the math and facilitate physical understanding.

Assumptions

1. The oxidizer enters the system at $x = 0$ with a temperature T_i, a concentration of $Y_{O,i}$ and a velocity of $u = U$ which is a constant.
2. The fuel enters the system at $x = 1$ with a temperature T_i, a concentration of $Y_{F,i}$ and a velocity of $u = U$ Fig. 11.4.
3. The reaction occurs at $x = x_f$ in a zone with thickness, $\varepsilon \to 0$.
4. All reactants are consumed at the reaction zone so for: $\begin{matrix} x < x_f & Y_F = 0 \\ x > x_f & Y_O = 0 \end{matrix}$

Conservation Equations

Since the flow field is assumed to be known and constant ($u = U$), there is no need to solve the overall mass and momentum conservation equations. Thus,

Species Conservation

$$\left(U\frac{d(Y_O/s)}{dx}\right)=-\frac{\dot{\omega}_F'''}{s\rho}+D\left(\frac{d^2(Y_O/s)}{dx^2}\right) \quad (11.14)$$

$$\left(U\frac{dY_F}{dx}\right)=-\frac{\dot{\omega}_F'''}{\rho}+D\left(\frac{d^2Y_F}{dx^2}\right) \quad (11.15)$$

Energy conservation

$$\left(u\frac{d\left(T/\left(\Delta H_c/c_p\right)\right)}{dx}\right)=\frac{\dot{\omega}_F'''}{\rho}+\alpha\left(\frac{d^2\left(T/\left(\Delta H_c/c_p\right)\right)}{dx^2}\right), \quad (11.16)$$

where $\alpha=\frac{\lambda}{\rho c_p}$ represents the thermal diffusivity.

Boundary Conditions

$$\begin{array}{llll} x=0 & T=T_i & Y_O=Y_{O,i} & Y_F=0 \\ x=1 & T=T_i & Y_O=0 & Y_F=Y_{F,i} \end{array} \quad (11.17)$$

The conservation equations are coupled using Equation 11.12. Note that with the steady, 1-D system discussed in the example, the L operator reduces to $L(\beta)\equiv\rho U\frac{d\beta}{dx}-\rho D\frac{d^2\beta}{dx^2}$. This gives,

$$\left(U\frac{d\beta}{dx}\right)=\alpha\left(\frac{d^2\beta}{dx^2}\right). \quad (11.18)$$

Three β-variables will be selected such that the values of temperature and mass fractions of fuel and oxygen (three variables obtained by solving three equations) can be evaluated later. The choices are β_{OF}, β_{OT} and β_{FT}. The variables and the boundary conditions are listed below:

$$\begin{array}{lll} \beta_{OF}=\dfrac{Y_O}{s}-Y_F & and & \begin{array}{ll} x=0, & \beta_{OF}=\dfrac{Y_{O,i}}{s} \\ x=1, & \beta_{OF}=-Y_{F,i} \end{array} \\ \beta_{OT}=\dfrac{Y_O}{s}+\dfrac{Tc_p}{\Delta H_c} & and & \begin{array}{ll} x=0, & \beta_{OT}=\dfrac{Y_{O,i}}{s}+\dfrac{Tc_p}{\Delta H_c} \\ x=1, & \beta_{OT}=\dfrac{Tc_p}{\Delta H_c} \end{array} \\ \beta_{FT}=Y_F+\dfrac{Tc_p}{\Delta H_c} & and & \begin{array}{ll} x=0, & \beta_{FT}=\dfrac{Tc_p}{\Delta H_c} \\ x=1, & \beta_{FT}=Y_{F,i}+\dfrac{Tc_p}{\Delta H_c} \end{array} \end{array} \quad (11.19)$$

As shown above, the coupling function or the Shvab-Zedovich transformation eliminates the nonlinear reaction rate terms from the conservation equations. We are still left with 6 boundary conditions for the three linear equations that can be obtained with β_{OF}, β_{OT} and β_{FT}. We can further decrease the difficulty in the solution procedure without altering the nature of the solution by replacing β with a new normalized variable, $Z=\frac{\beta(x)-\beta(0)}{\beta(1)-\beta(0)}$, which is called as a mixture fraction. Note that β (0) and β (1) are constants obtained from the boundary conditions. Since the boundary conditions for the variable Z at the boundaries $x=0$ and $x=1$ are $Z=0$ and $Z=1$, respectively, irrespective of the β-variable that defines Z, the solution is unique and we need to obtain the solution to one mixture fraction equation only. This simple algebraic manipulation allows us to obtain a single differential equation with normalized boundary conditions given by:

$$\left(U\frac{dZ}{dx}\right)=\alpha\left(\frac{d^2Z}{dx^2}\right) \quad where \quad \begin{array}{l} x=0\rightarrow Z=0 \\ x=1\rightarrow Z=1 \end{array} \quad (11.20)$$

The solution to this differential equation is

$$Z=\frac{\left(e^{x/\delta}-1\right)}{\left(e^{1/\delta}-1\right)} \qquad where \qquad \delta=\frac{\alpha}{U} \quad (11.21)$$

Going back to the dimensional values (oxygen concentration, fuel concentration and temperature) requires the determination of the flame location. Based on the assumption that the flame will place itself where fuel and oxidizer arrive in stoichiometric proportions, the flame location can be expressed by: $\beta\left(x_f\right)=\frac{Y_O}{s}-Y_F=0$. Substituting the appropriate expression for Z(x) in terms of β and evaluating

$$\beta_{OF}(x)=\frac{Y_{O,i}}{s}-\left(\frac{Y_{O,i}}{s}+Y_{F,i}\right)\left[\frac{e^{x/\delta}-1}{e^{1/\delta}-1}\right], \quad (11.22)$$

the flame location, x_f, is obtained as

$$x_f = \delta \; Ln\left[\frac{Y_{O,i}}{s}\frac{\left(e^{1/\delta}-1\right)}{\left(\frac{Y_{O,i}}{s}+Y_{F,i}\right)}+1\right]. \quad (11.23)$$

Finally, assuming there is no oxidizer in the fuel zone and no fuel in the oxidizer zone the fuel and oxygen concentrations can be defined as:

$$\begin{array}{llll} x<x_f & Y_O = s\beta_{OF}(x) & and & Y_F = 0 \\ x>x_f & Y_O = 0 & and & Y_F = -\beta_{OF}(x) \end{array} \quad (11.24)$$

A similar method can be followed when determining the temperature distribution, from f_2 for $x < x_f$ and f_3 for $x > x_f$. This is explained in the worked example.

There are several advantages in introducing the mixture fraction. The mixture fraction (Z) should satisfy the balance equation

$$L(Z) \equiv \rho\frac{\partial Z}{\partial t} + \rho u_i \frac{\partial Z}{\partial x_i} - \frac{\partial}{\partial x_i}\rho D\frac{\partial Z}{\partial x_i} = 0, \quad (11.25)$$

based on the definition of the operator L of Equation 11.10. The boundary condition equation is $Z = 1$ in the fuel stream and $Z = 0$ in the oxidizer stream. This equation converts all the Shvab-Zeldovich variables (β) into a single parameter. Equation 11.25 greatly simplifies the modeling of diffusion flames. Note that there is no source term in Equation 11.25.

Comments on the Formulation and Analysis

It is important to reiterate the assumptions used in working out the solution discussed earlier. 1. **One-step** and **infinitely fast** reaction, 2. Lewis number = 1, 3. Binary diffusion coefficients are equal for all species, 4. ρD = constant, 5. Velocity (U) is constant, 6. Steady state, 7. One-dimensional, and 8. Constant specific heat, thermal diffusivity and density. Assumptions 1, 2 and 3 are necessary for implementing the Shvab-Zeldovich transformation. This is because Z couples the transport of heat and species into a single variable. In some cases, heat and different species may have different diffusivities and therefore can be transported at different rates. Consequently, β and Z are no longer conserved. However, by making the equal diffusivity and Le = 1 assumption, we are requiring that these diffusive fluxes are transported at the same rate and hence preserving the conserved nature of Z. Assumption 4 is used in most fire problems, however, can be relaxed. Assumptions 5–8 were used to solve our specific example of a one-dimensional flame. Of these 5 can be most questionable. This is because the flow-field plays a significant role in diffusion problems. An exact representation of the flow-field can be obtained by solving the overall mass and momentum conservation or the Navier–Stokes equations, which require proper pressure–velocity coupling since most fires are incompressible in nature. Assumption 6 is reasonable mainly because of the slow regression rates observed for most condensed fuels. Assumption 7 facilitated an analytical solution. Assumption 8 is reasonable so long as the properties are chosen correctly. The correct choice of properties is hugely important in all problems of this nature. This is further discussed below.

Property Estimation

Most theoretical and empirical expressions to solve fire problems usually rely on the assumption of constant thermophysical properties. An important issue in using these expressions in practice therefore necessitates a proper method to evaluate the thermophysical properties such that results obtained through them match with experimental data. A first step in property estimation is obtaining certain average temperature.

For a diffusion flame, the temperature can vary from a few hundred degrees at the fuel side to around 1500–2000 K at the flame zone. Surrounding temperature can also be of the order of a few tens to a few hundred degrees based on the problem. Composition of the gas mixture within this range varies from a pure fuel vapor near the interface to pure air in the far field.

Within this range, there exists many gas species formed because of thermal cracking of the fuel vapor as well as combustion products such as CO_2, CO and H_2O. Therefore the process of arriving at an "average" mixture property based on specific mixture composition and average temperature is a nontrivial issue.

This problem of an average gas-composition at an average temperature whose properties can be used for correlations with constant property assumptions has been investigated by several researchers (c.f. Rangwala et al. [20] for a list of references related to the topic). The main method reported in most combustion textbooks is by Law and Williams [21] and employs flame, ambient (or surrounding) and interface temperature to arrive at an average temperature. The average mixture composition is calculated using some proportions of fuel and air. The disadvantage of using the Law and Williams [21] scheme in fire problems is the need to know the fuel-vapor composition which is difficult to evaluate for complex materials usually involved. A much simpler scheme using only properties of air was recently developed by Rangwala et al. [20]. The scheme has been tested in several diffusion controlled problems involving burning behavior of both gaseous liquid and solid fuels. The scheme considers forced convection and variable oxygen concentration. This scheme is simpler to use and recommended for fire problems. In this scheme, the average thermal conductivity is estimated as the thermal conductivity of air calculated at a temperature given as one third the sum of ambient and the adiabatic flame temperature. The gas phase specific heat is estimated as the specific heat of air at adiabatic flame temperature. Adiabatic flame temperatures for several fuels are tabulated in standard fire dynamics textbooks [22, 23].

Solved Example

On a geometrical configuration identical to that of the one-dimensional non-viscous problem presented earlier, a mixture of 22 % oxygen and 78 % nitrogen as oxidizer and a mixture 80 % Ethane and 20 % nitrogen as fuel (all percentages are in volume) do the following: (1) Plot the mixture fraction as a function of "x". (2) Find the flame location (x_F). (3) Plot the fuel and oxygen concentrations as a function of "x". (4) Plot the temperature as a function of "x". Solve for two situations of U = 1 mm/s and U = 0.1 mm/s and U = 1 mm/s. Comment on what is the meaning of the "characteristic length scale δ" and what is the effect of U on δ, the flame location and the flame temperature. Assume thermal properties as those of air at 1000 K.

Part 1: Mixture Fraction

A plot of $Z(x) = \frac{e^{\frac{x}{\delta}}-1}{e^{\frac{1}{\delta}}-1}$ is shown in Fig. 11.5. The value for delta ($\delta = \frac{\alpha}{U}$) based on U of 1 mm/s equals 0.168 m. It is assumed that the thermal diffusivity is that of air at 1000 K ($\alpha = 168 \times 10^{-6}\, m^2/s$).

Part 2: Flame Location

The flame is located at the position where $\beta_{OF} = \frac{Y_O}{s} - Y_F = 0$. This corresponds to a stoichiometric mixture. The flame location can be found using Equation 11.23. Based on the problem statement, $Y_{O,i} = \frac{0.22\times30}{0.22\times32+0.78\times28} = 0.244$ and $Y_{F,i} = \frac{0.8\times30}{0.8\times30+0.2\times28} = 0.811$, where, the molecular weight of ethane is 30 g/mol. $s = \left(\frac{Y_o}{Y_F}\right)_{stoic}$ is

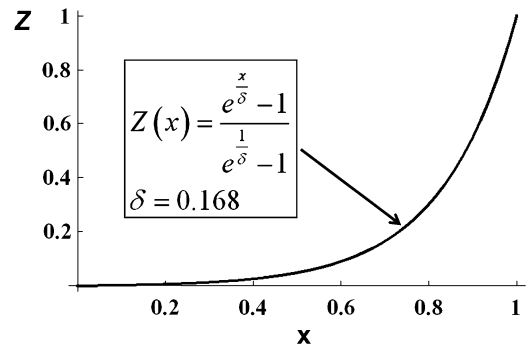

Fig. 11.5 Mixture fraction (Z) vs. x

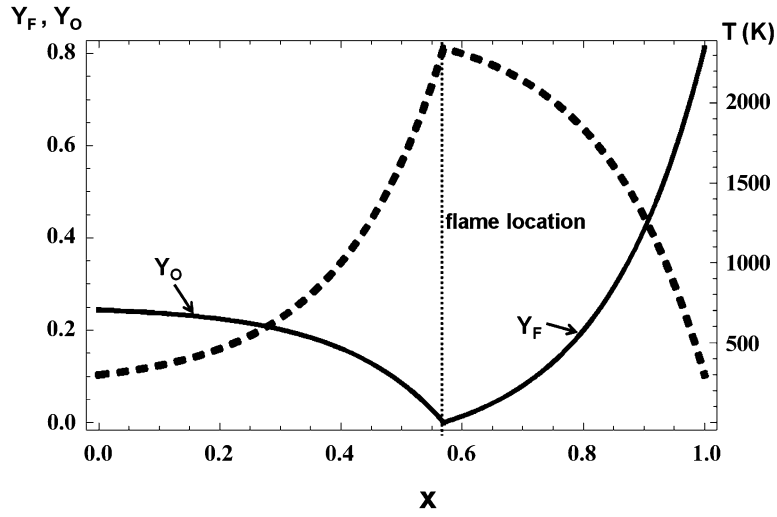

Fig. 11.6 Profiles of oxygen, fuel and temperature

obtained assuming a one step overall reaction of ethane reacting with oxygen $C_2H_6 + \frac{7}{2}O_2 \rightarrow 2CO_2 + 3H_2O$ and equals $s = \frac{112}{30} = 3.73$. Substituting these values in Equation 11.23 gives,

$$x_f = 0.168 \ln\left(\frac{\left(\frac{0.244}{3.73}\right)\left(e^{\frac{1}{0.168}} - 1\right)}{\left(0.811 + \frac{0.244}{3.73}\right)} + 1\right) = 0.57.$$

The location of the flame is shown in Fig. 11.6. It occurs at a location where the concentration of fuel (Y_F) and oxidizer (Y_O) are zero. Note that since the chemical reaction is assumed to be infinitely fast, there is no fuel or oxidizer leakage on either side of the flame. Further, the flame location occurs at the location of maximum temperature. Profiles of fuel, oxidizer and temperature are evaluated in Part 3 and 4 discussed next.

Part 3 and 4: Profiles of Oxygen, Fuel and Temperature

First assume that there is no oxygen in the fuel zone and no fuel in the oxidizer zone. Use f_1 to find the fuel and oxygen mass fractions.

$$\begin{aligned} x < x_f \quad & Y_o = \phi f_1(x) \ \ and \ Y_f = 0 \\ x > x_f \quad & Y_o = 0 \quad\ \ and \ Y_f = -f_1(x) \end{aligned}$$

Since the oxygen and fuel mass fractions are known, the temperature can be plotted using f_2 or f_3.

$$f_3(x) = \Psi(x)(f_3(1) - f_3(0)) + f_3(0) = \left(\frac{e^{\frac{x}{\delta}} - 1}{e^{\frac{1}{\delta}} - 1}\right)\left(Y_{f,i} + \frac{T_i}{(\Delta H_c/c_p)} - \frac{T_i}{(\Delta H_c/c_p)}\right) + \frac{T_i}{(\Delta H_c/c_p)}$$

$$T(x) = (\Delta H_c/c_p)\left(\left(\frac{e^{\frac{x}{\delta}} - 1}{e^{\frac{1}{\delta}} - 1}\right)\left(Y_{f,i} + \frac{T_i}{(\Delta H_c/c_p)} - \frac{T_i}{(\Delta H_c/c_p)}\right) + \frac{T_i}{(\Delta H_c/c_p)} - Y_f(x)\right)$$

The specific heat, $c_p = 1.14\frac{J}{g}$ @ $1000K$ and the heat of combustion is equal to $\Delta H_c = 47500\frac{J}{g}$. The temperature profile is shown in Fig. 11.6.

The characteristic length scale δ represents the ratio of the mass diffusion to the velocity of the gas stream. This characteristic distance

represents the extent that heat mass is diffusing against the gas flow into the gas stream.

Final Note

The example discussed uses constant surface boundary conditions at fuel and oxidizer side. For the case of condensed fuels at the interface between fuel and air, specifying a constant mass fraction for the species as the boundary condition at the interface provides great simplicity in formulating an analytical solution. However, determining an approximate value of $Y_{F,x\,=\,\text{surface}}$, the fuel mass fraction at the interface, is complicated as it involves solving a heat and mass balance at the fuel surface [24]. Further complication is that typically the species concentrations are discontinuous at the interface between two materials, whereas temperature is continuous. To take an example, consider a heptane pool fire. If we are interested in determining the rate at which heptane vapor is transferred to the gas-phase, we would need to specify the vapor concentration of heptane in the gas-phase side of the heptane-air interface. The mass fraction of heptane inside the pool is unity (neglecting the small amount of oxygen or nitrogen dissolved in heptane). However, it would be incorrect to assume $Y_{F,x\,=\,\text{surface}} = 1$ for the gas-phase mass fraction of heptane vapor at the interface. This value primarily depends on the interface temperature besides the pressure. Interface temperature is determined by the heat balance analysis between gas-phase to interface. The conditions at the interface are based on relationships that are theory-based or deduced from experiments. An additional nondimensional number called as B-number arises during the solution of establishing the mass fraction of fuel vapor at the interface. The B-number is an important derived property, which is dependent on the thermo-physical properties of the system, that provides an expression for the mass burning rate eventually. This leads us to the next section which discusses an important parameter usually used to quantifying the fire-hazard associated with a given material—its mass burning rate as a function of time.

Mass Burning Rate

The mass burning rate per unit area ($\dot{m}''$) or mass burning flux is an important parameter to quantify the hazard associated with fire. As mentioned earlier, this mass flux varies with B-number [3], which accounts for the thermodynamic effects, and the Nusselt number to account for the gas-phase convective effects. A general relationship will be derived in this section to account for a variety of physical flow conditions. In fire problems, the fuel is usually a solid or liquid burning in free convective conditions. The fuel vaporizes first, then diffuses toward the oxygen from the ambient. To solve such problems one needs to have information on the velocity, temperature and mass fraction profiles. The solution can be initiated by writing down a heat balance at the surface of the burning fuel,

$$\dot{m}'' L = \dot{q}'', \tag{11.26}$$

where L represents the latent heat of vaporization (for a liquid) or the heat of gasification (for a solid). $\dot{q}''$ is the net heat flux to the surface and depends on the nature of the flow field and boundary conditions (free stream temperature, ambient oxygen concentration etc.). It also depends on $\dot{m}''$, an effect called as the "blocking effect [22]." If the net heat flux to the surface increases, then logically mass flux or mass loss rate per unit area will also increase. This causes the boundary layer to thicken causing reduction in gradients. The burning rate therefore does not increase linearly with external heat flux and to develop a general solution requires generalization of the heat flux to the fuel. It can be assumed that the heat flux to the surface is a product of the heat transfer coefficient (h) and temperature difference between the flame and the surface. If the flame temperature is denoted by T_f and surface temperature by T_s the mass loss rate per unit area can be represented as:

$$\dot{m}'' = \frac{\dot{q}''}{L} = \frac{h\left(T_f - T_s\right)}{L} = B\frac{h}{c_p}, \tag{11.27}$$

Table 11.3 B-number values for different fuels [25]

Solids	Formula	B-number	Liquids	Formula	B-number
Polypropylene	C_3H_6	1.29	Methanol	CH_3OH	2.53
Polyethylene	C_2H_4	1.16	Ethanol	C_2H_5OH	2.89
Polystyrene	C_8H_8	1.55	Propanol	C_3H_7OH	3.29
Nylon 6/6	$C_{12}H_{22}N_2O_2$	1.27	Butanol	C_4H_8OH	3.35
Polycarbonate	$C_6H_{14}O_3$	1.41	n-pentane	C_5H_{12}	7.63
PMMA	$C_5H_8O_2$	1.78	n-hexane	C_6H_{14}	6.67
PVC	C_2H_3Cl	1.15	n-heptane	C_7H_{16}	5.92
Fir wood	$C_{4.8}H_8O_4$	1.75	n-octane (gasoline)	C_8H_{18}	5.42
α-cellulose	$C_6H_{10}O_5$	6.96	iso octane	C_8H_{18}	6.59
Polyoxymethylene	CH_2O	1.47	n-nonane	C_9H_{20}	4.89
			n-decane	$C_{10}H_{22}$	4.61
			n-undecane	$C_{11}H_{24}$	4.43
			n-dodecane (kerosene)	$C_{12}H_{26}$	4.13
			Acetone	C_3H_2O	7.28

where $B = \frac{c_p(T_f - T_s)}{L}$ is nondimensional and represents the mass transfer number. L in Equation 11.27 denotes the latent heat of gasification, h represents the convective heat transfer coefficient, T_f and T_s denote an average flame temperature and temperature of the fuel surface and c_p denotes the specific heat of the gas. The B-number (also called the Spalding mass transfer number) was first introduced by Spalding [3] in 1950 to characterize liquid fuel droplet burning and physically relates the heat release related to combustion (the numerator) to the losses associated with combustion (the denominator). The heat transfer coefficient (h) is expressed in terms of a nondimensional Nusselt number, defined as $Nu = \frac{hx}{\lambda}$, where λ denotes the thermal conductivity of the gas-mixture at the interface between the condensed fuel and air and x is a characteristic length scale. In case of a flat fuel surface x can be defined as the distance from the leading edge and in the case of a sphere or cylinder refers to the diameter. The earlier expression is now equal to:

$$\dot{m}'' = B\frac{\lambda}{xc_p}Nu \tag{11.28}$$

In order to account for the blocking effect, the Nusselt number is first evaluated without the blocking effect and then corrected for this effect through the ratio Nu/Nu_o

$$\dot{m}'' = B\frac{\lambda}{xc_p}\frac{Nu}{Nu_o}Nu_o \tag{11.29}$$

Nondimensionalizing both sides by ρU_∞, where U_∞ is a characteristic velocity representing the flow-field subjected to or induced by the diffusion flame, the above expression can be re-written as:

$$\frac{\dot{m}''}{\rho U_\infty} = B\frac{\lambda}{c_p\mu}\frac{\mu}{\rho U_\infty x}Nu_o\frac{Nu}{Nu_o} \tag{11.30}$$

$$= B(\mathrm{PrRe})^{-1}Nu_o\frac{Nu}{Nu_o} \tag{11.31}$$

The quantity $\frac{\lambda}{c_p\mu}$ equals $1/Pr$ where Pr = Prandtl number. The ratio $\frac{Nu}{Nu_o}$, the blocking effect can be calculated for several laminar flows and equals $\frac{\ln(1+B)}{B}$ for small B. For turbulent flows it can be calculated empirically only. Typical values of B for many fuels are listed in Table 11.3.

Expressions for Nu_o for many geometrical configurations are available in standard heat and mass transfer textbooks and shown in Table 11.4. For example, using Table 11.4, an expression for

Table 11.4 Nu_o values for some standard geometries and flow conditions. $\mathrm{Re} = \frac{U_\infty X}{\upsilon}$, and $Gr = \frac{gX^3\left(T_f - T_o\right)}{T_o \upsilon^2}$

Flow field type	Illustration	Nu_o

mass loss rate of a vertical plate in a laminar free convective flow can be calculated as:

$$\dot{m}'' = C_o B^m \frac{\lambda}{c_p x}(Gr\,\mathrm{Pr})^{1/4} \tag{11.32}$$

A mass burning rate for the same plate in a turbulent natural convective flow-field is:

$$\dot{m}'' = C_o B^m \frac{\lambda}{c_p x}(Gr\,\mathrm{Pr})^{1/3} \tag{11.33}$$

The constant C_o can take different values and usually lies between 0.5 and 1.5. The value of the exponent m on B is ~ 0.5. Recently Ali et al. [26] have extended the correlation (laminar case) to include several orientation angles. The mass burning rate of a plate oriented at an angle θ with respect to the vertical for a plate in a free convective flow-field is given by [26]:

$$\dot{m}'' = 0.737(Gr_x\,\mathrm{Pr}_x)^{0.25}\frac{\ln(1+B)}{B^{0.15}}, \tag{11.34}$$

where $Gr_x = \frac{g_{\mathrm{eff}}\beta\Delta T x^3}{\upsilon^2}$ and $g_{\mathrm{eff}} = g\cos\theta$ for $0 < \theta < 90°$ and $g_{\mathrm{eff}} = g(\cos\theta - \sin\theta)$ for $-90° < \theta \leq 0°$. Note that 0° represents the vertical case, −90° denotes a pool fire and 90° denotes a ceiling configuration. The mass loss rate per unit area $\dot{m}''$ can also be expressed as a regression rate $\dot{m}''/\rho_s$ where ρ_s is the density of the fuel (condensed phase). Typical regression rates of most fuels (solids/liquids shown in Table 11.3) vary between 0.02 and 0.4 mm/s. The regression rates are very small and are essentially due to the diffusion controlled nature of the problem.

Diffusion Flame Height

When gaseous fuel issues out of a tube into ambient atmosphere of air and the gas is ignited a flame is established as shown in Fig. 11.7. The question we will try to answer is how high is the resulting diffusion flame? The problem can be solved using conservation equations with certain approximations as was first shown by Burke and Schuman [19]. However, for practical purposes a simple physical reasoning exercise will be adopted here. It will be shown later that the relationship obtained is similar to that obtained using the more rigorous approach.

Imagine a fuel molecule, shown in Fig. 11.7 by the red circle, initially located at the center of the burner tube. The molecule can traverse two extreme paths (depicted by o-x and o-y) to meet with oxygen at the flame surface. The time taken to traverse horizontally along o-x is given by $d^2/4D$, where D is the diffusion coefficient between methane and air. The relationship is obtained by a dimensional analysis of the two parameters: distance over which diffusion must occur (m) and diffusion coefficient (m^2/s).

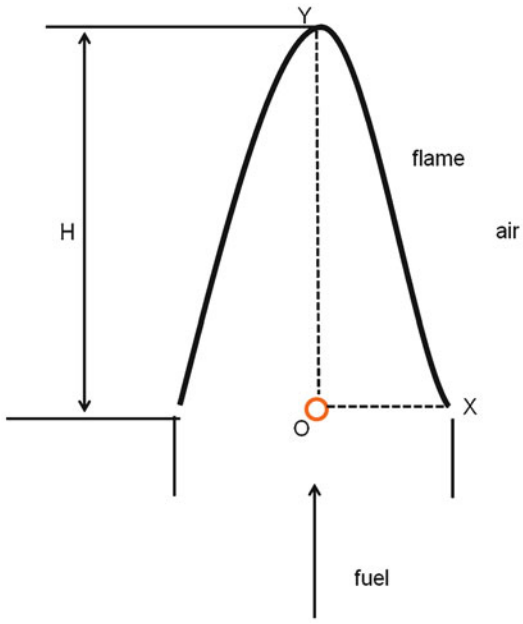

Fig. 11.7 The diffusion jet-flame

The only way of obtaining a time scale from these two quantities is to divide the square of the distance by the diffusion coefficient. The length of the flame will correspond to the condition that a point on the stream axis where combustion is complete, the average depth of penetration of air into gas must equal to the radius of the burner tube.

Similarly, the time taken to traverse vertically along O-Y is given by H_f/V, where H_f is the flame height and V is the velocity of the gas issuing of the burner. Equating the two times gives, $H_f/V \sim d^2/4D$ or $H_f \sim d^2V/4D$. This simple result is reflected in all the correlations (developed by Roper [27, 28]) related to diffusion flame height shown in Table 11.5. An important element in the expression developed is the influence of fuel properties, geometry (of the duct). The influence of fuel properties is usually incorporated in the flame temperature and stoichiometric coefficient (s) shown in Table 11.5.

The inverse error function is generated in the same way as inverse trigonometric functions and is tabulated in standard textbooks (For example see Table 9.4 in Turns [29]). The parameter, I typically takes values between 1 and 1.5. $I = 1$ for uniform flow and $I = 1.5$ for fully developed parabolic exit velocity profile. The subscript "m" denotes that the flow-field is momentum controlled and subscript "b" denotes buoyancy controlled. To determine if the flame is momentum or buoyancy controlled the flame Froude number Fr must be calculated as

Table 11.5 Flame height correlations (all quantities in SI m, m^3/s etc.)

Geometry	Flame height (H_f)
Circular	$H_f = \frac{Q_F(T_\infty/T_F)}{4\pi D \ln\left(1+\frac{1}{s}\right)}\left(\frac{T_\infty}{T_f}\right)^{0.67}$
Square	$H_f = \frac{Q_F(T_\infty/T_F)}{16D\left[\text{inverf}(1+s)^{-0.5}\right]^2}\left(\frac{T_\infty}{T_f}\right)^{0.67}$
Slot	$H_{f_m} = \frac{b\beta^2 Q_F}{hlDY_{F_{stoic}}}\left(\frac{T_\infty}{T_F}\right)^2\left(\frac{T_f}{T_\infty}\right)^{0.33}$ $H_{f_B} = \left[\frac{9\beta^4 Q_F{}^4 T_\infty{}^4}{8D^2 ah^4 T_F{}^4}\right]^{1/3}\left[\frac{T_f}{T_\infty}\right]^{2/9}$ $\beta = \frac{1}{4\text{inverf}\left(1+\frac{1}{s}\right)}$

Q_F volumetric fuel flow rate (m^3/s), D diffusivity (m^2/s), T_∞ ambient temperature (K), T_f mean flame temperature (K), T_F fuel temperature (K), s molar stoichiometric oxidizer-fuel ratio, *inverf* inverse error function, $\omega = inverf[erf(\omega)]$, a = mean buoyant acceleration $\approx 0.6g\left(\frac{T_f}{T_\infty} - 1\right)$ (m^2/s)

$$Fr_f = \frac{(V_e I Y_{F,stoic})^2}{aH_f}. \tag{11.35}$$

If $Fr_f \gg 1$ then flame is momentum controlled and if $Fr_f \ll 1$ then the flame is buoyancy controlled. If $Fr_f \approx 1$, then the flame lies in a transitional zone which is both momentum and buoyancy controlled. In this case,

$$H_{f_T} = \frac{4}{9}H_{f_m}\left(\frac{H_{f_B}}{H_{f_m}}\right)^3\left\{\left[1 + 3.38\left(\frac{H_{f_B}}{H_{f_m}}\right)^3\right]^{2/3} - 1\right\}, \tag{11.36}$$

where H_{f_m} and H_{f_B} represent the momentum and buoyancy controlled flame heights and can be obtained using the correlation presented in Table 11.3. Note that for a circular and square port geometry the equations are applicable for both momentum and buoyancy controlled.

The equations shown in Table 11.5 demonstrate that some of the primary controlling parameters influencing the flame height of a diffusion flame are flow rate, geometry, and stoichiometry. The

flow rate and geometry influence can be characterized by the nondimensional Froude number. The molar stoichiometric ratio (s) is mainly a function of fuel type. For a generic hydrocarbon C_xH_y burning in air the chemical balance equation assuming complete combustion can be written as:

$$C_xH_y + \grave{a}(O_2 + 3.76N_2) \rightarrow xCO_2 + \frac{y}{2}H_2O + 3.76aN_2, \qquad (11.37)$$

where, $a = x + \frac{y}{4}$ and $s = \left(\frac{\text{moles air}}{\text{moles fuel}}\right)_{stoic} = \frac{\left(x+\frac{y}{4}\right)}{X_{O_2}}$. X_{O_2} is the mole fraction of oxygen in air and equals 1/4.76. As the carbon content in the fuel increases (y/x increases) the flame length increases. For example a propane flame (C_3H_8) is nearly 2.5 times longer than a methane flame (CH_4). Fuels which have oxygen in their molecule (e.g. CO) show an even smaller flame length. If the fuel is diluted with an inert gas, the flame height reduces. The molar stoichiometric ratio in this case, is $s = \frac{x+y/4}{\left(\frac{1}{1-X_{dil}}\right)X_{O_2}}$, where X_{dil} is the mole fraction of the inert in the fuel stream.

The discussion so far pertains to gaseous jet flames. Roper's correlations can be extended to predicting flame height of condensed fuels as well. For example, an approximate fuel flow velocity in a candle flame can be obtained by assuming the candle wick to be a vertical cylinder. Using Roper's correlation for a circular burner (Table 11.3) and substituting $Q_F = \frac{\dot{m}_F}{\rho_F}$ and using heat transfer coefficients for a finite vertical cylinder (represents candle wick) and a hot surface facing up (which represents the top face of candle wick) it can be shown that [30]

$$H_f \sim 0.5D\left(\frac{L}{D}Ra^{1/4} - 2\right)^n, \qquad (11.38)$$

where, D equals the diameter of the wick, L is equal to the length of the wick from the base, Ra is the Rayleigh number defined using the wick diameter, and n is a constant approximately equal to 0.7. Sunderland et al. [30] have shown the above relationship to provide a good match with experimental data using candle wicks of different thicknesses.

Turbulent Diffusion Flames

Most fires can be classified as turbulent diffusion flames, and extensive studies related to the basic understanding of the problem can be found in literature [31–38]. Besides the important aspects of height of a diffusion flame and rate of burning, which were discussed in the previous sections, an important fire safety concern with the advent of turbulence is the enhancement in the transport processes, changes in the flame structure, extent and shape, and the radiant energy flux emitted by the flame [39, 40]. In large fires, a solid fuel is normally gasified by radiative heat flux from the fire (and hot zones) and the evolved gases mix with surrounding air. The mixing process is determined by buoyancy induced flow rather than by the forced convection as in jets and sprays usually studied in the field of combustion in engines and furnaces, for example. The advent of turbulence, which is a random process, necessitates the use of statistical methods, thus making the solution probabilistic in nature. Thus an exact solution is seldom possible. Given our current state of understanding a solution that falls in a reasonable range is acceptable. The coupling function described as the mixture fraction (Equation 11.25) plays a central role in reducing problems in the analysis of turbulent diffusion flames to problems associated with non-reacting turbulent flows.

The turbulent flow field can be visualized as being comprised of eddies having wide range of length scales, the larger of which extract energy from the mean flow. The large eddies break up into smaller eddies, which in turn break up into even smaller ones, until the smallest eddies, called Kolmogorov eddies form, and dissipate the energy back to the main flow as viscous dissipation. This concept was first proposed by Kolmogorov is described as the eddy/energy cascade hypothesis in turbulent literature [33]. Note that the size of the smallest eddies are several orders of magnitude larger than the mean free path of the molecules of the gas or fluid. Due to this reason, the turbulent flow field can be considered as continuum and the conservation equations of mass (species), momentum

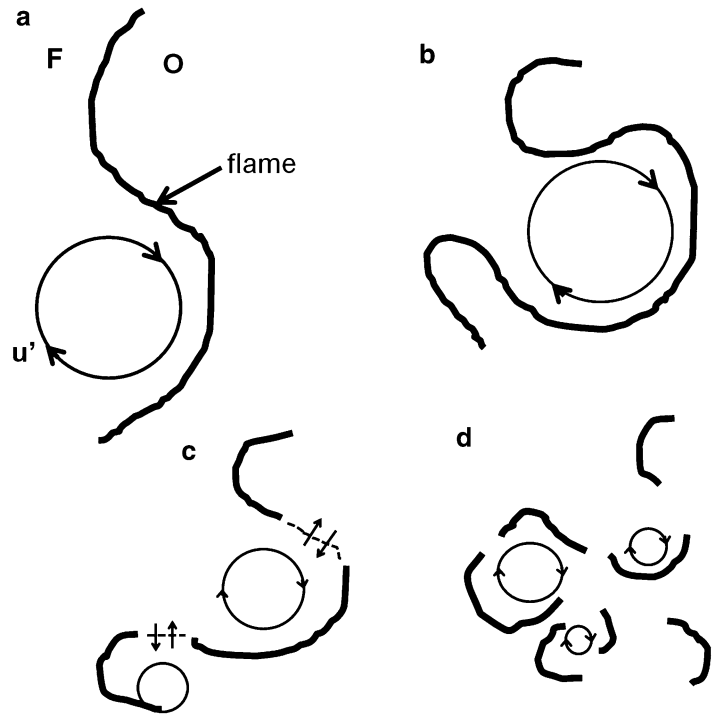

Fig. 11.8 Illustrative sketch of laminar flamelet concept of turbulent diffusion flames. The turbulent intensity increases from (**a**) to (**d**). Local extinction is observed in (**c**) due to flame stretching

and energy are still applicable. The question then arises that how does this flow pattern influence a diffusion flame? For this, the general theory proposed by Williams [41] and models by Peters [38] and Kuznetsov [42] will be discussed. The general model is named as the flamelet model mainly because of the tendency of turbulence to break the flame into several tiny flames or flamelets. Both strain and shear at the interface of eddies increase the concentration gradient between the reactants thereby enhancing the mixing. Going back to Equation 11.1 (Ficks law) as the *gradient* $\frac{\partial Y}{\partial x_i}$, increases, the rate of mixing should also increase eventually. However, this increase is not due to a change in the molecular diffusivity D_{AB}. Thus, in order to model this increase in the overall mixing process, an improvised *turbulent diffusivity* is defined. Note that the turbulent diffusivity is an empirical concept and incorporates both the molecular diffusivity as well as some function which can represent the influence of intensity and scale of turbulence on the mixing at the flamelet level. The flamelets are considered as thin reactive-diffusive layers, considered in general as laminar, embedded within an otherwise non-reacting turbulent flow field. This allows us to use the mixture fraction to describe turbulent flames as well.

If we assume that the turbulent transport of momentum, species and thermal energy are all equal (Sc = Pr = Le) we can substitute existing correlations from the fluid mechanics literature related to turbulent momentum diffusivity (eddy viscosity) to apply for turbulent mass diffusivity and thermal diffusivity as well.

Figure 11.8 shows the influence of increased turbulent intensity on a turbulent flame. As we move from Fig. 11.8a to d, eddies are capable of corrugating a flame and eventually breaking the corrugations and distributing the flame sheet into smaller flamelets. Thus at sufficiently high strain, there is also local extinction achieved. Another aspect, and most important from an aspect of fire safety is an understanding of flame radiation due to large turbulent hydrocarbon diffusion flames. For example flame radiation is an important parameter in design of safe separation distances. The primary factors influencing the problem are the

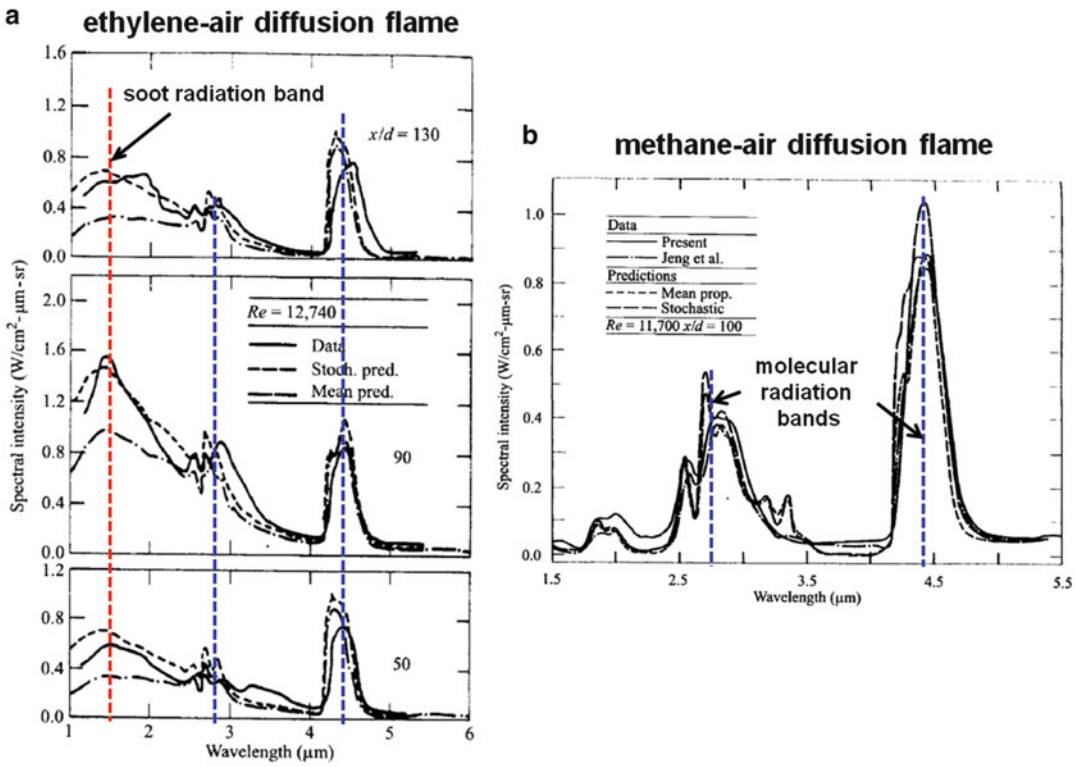

Fig. 11.9 Spectral measurements of thermal radiation from a turbulent (**a**) ethylene-air flame [43] and (**b**) methane-air flame [44]

concentration of soot, CO_2, H_2O, temperature profiles (at different locations in the flame) and geometry of the problem. Incandescent soot formed within the flame is the primary source of flame radiation in large-scale fires, although gaseous products of combustion (CO_2, H_2O) can also emit heat. The radiation emitted from CO_2 and H_2O is usually called molecular radiation. The easiest way to understand (and explore) the difference between the radiation from soot and gaseous products (CO_2, H_2O) is by comparing two diffusion flames.

Figure 11.9a [43] and Fig. 11.9b [44] depict spectral radiation intensities for an ethylene-air and methane-air diffusion flame respectively. The ethylene-air flame produces more soot when compared with the methane-air flame. Correspondingly, it exhibits intensity peaks at 1.5 μm corresponding to the in-flame soot. In comparison, the methane-air flame shows significant intensity peaks at 2.5–3 μm and 4–5 μm corresponding to the molecular radiation from CO_2 and H_2O.

Prediction of flame radiation necessitates knowledge of formation and oxidation of soot in the flame, its concentration profiles, as well as concentration and temperature of sources of molecular radiation such as CO_2 and H_2O, besides the type of fuel and the residence time available. A common approach used in fire problems, is identifying a radiant fraction which represents the ratio of radiant heat transfer rate from the flame to the surroundings to the total heat released by the flame. The radiant fraction is denoted as χ_R, and is expressed as:

$$\chi_R = \frac{\dot{Q}_{rad}}{\dot{m}_F \Delta H_c}, \tag{11.39}$$

where $\dot{Q}_{rad}$ denotes the radiant energy transferred from the flame in the form of radiation. Based on

our current understanding and knowledge-base, χ_R is estimated using empirical correlations. χ_R depends on both flame size and heat release rate and the general trend is for χ_R to increase with flame size. Depending on the fuel type and flow conditions, the radiant fraction can range from a few percent to more than 50 % [45–47].

Flame Extinction

General strategies for extinguishing diffusion flames are cooling, reactant removal, chemical inhibition, and flame removal. These strategies are achieved for example, by adding sufficiently large quantities of a material (such as water) that cools the condensed fuel thereby slowing combustion, removing an essential reactant from the system, adding a chemical suppressant (such as Halon) that inhibits the reactions taking place in the flame zone, or physically removing the flame from the reactant mixture by inducing high gas velocities (for example by explosives in large production-well fires).

The rate of gas-phase chemical reaction that was denoted by $\dot{\omega}_i'''$ in Equations 11.4, 11.5, and 11.6 was thus far ignored. However, it plays an important role in flame extinction (as well as ignition). It is therefore necessary to formulate an expression to quantify $\dot{\omega}_i'''$ in order to establish critical extinction criteria. This is usually done by employing a one-step Arhenius approximations to the rates. The analysis can be generalized using a non-dimensional Damkohler number [48]. To better understand the concept, let us perform an exercise of nondimensionalizing the energy conservation equation (gas-phase) using nondimensional variables: $\widehat{u} = u/u_c$, $\widehat{v} = v/u_c$, $\widehat{x} = x/L_c$, $\widehat{y} = y/L_c$, $\widehat{T} = T/T_c$, where $u_c =$ some characteristic velocity, which we will denote as u_∞ and $L_c =$ L is some characteristic length scale. The definition of u_∞ and L, depends on the nature of the problem. For example, if the flowfield is natural convective mostly (large open pool fires, wall fire etc.) $u_\infty \sim \sqrt{gL}$ where L is for example the diameter of the pool fire or the length of the wall in the case of a wall fire. T_c which is a characteristic temperature can be represented as $\Delta H_c/c_p$. Substituting the nondimensional variables in the energy equation gives,

$$\rho c_p u_\infty \left(\widehat{u}\frac{\partial \widehat{T}}{\partial \widehat{x}} + \widehat{v}\frac{\partial \widehat{T}}{\partial \widehat{y}}\right) = \Delta H_c \frac{A Y_o^{n-j} Y_f^{j} e^{-E/RT}}{s} + \lambda \frac{\Delta H_c}{L^2 c_p}\left(\frac{\partial^2 \widehat{T}}{\partial \widehat{x}^2} + \frac{\partial^2 \widehat{T}}{\partial \widehat{y}^2}\right). \tag{11.40}$$

The term $\frac{\dot{\omega}_O''' \Delta H_c}{s}$, representing the energy released due to the chemical reaction between fuel and oxidizer is expressed using an *empirical* Arhenius expression $\Delta H_c \frac{A Y_o^{n-j} Y_f^{j} e^{-E/RT}}{s}$, or specifically, the rate at which fuel is lost per unit volume is given by $A Y_o^{n-j} Y_f^{j} e^{-E/RT}$. In the expression, A is a constant called as the pre-exponential constant or the frequency factor. The terms, $Y_o^{n-j} Y_f^{j}$ represent the mass fraction of oxidizer and fuel (n and j are empirical constants) to emphasize the fact that the rate of loss of fuel is dependent on the initial concentration of fuel and oxidizer. To simplify the mathematical analysis and gain physical insight into the problem, we will assume a simpler expression of the form $K e^{-E/RT}$, where K is a constant. Note that so far we have been able to neglect this term by assuming the infinitely fast reaction assumption and the resulting Shvab-Zeldovich transformation. We therefore never worried about defining this term. However, for both ignition and extinction analysis, the nonlinear source term cannot be ignored. Rearranging terms gives

$$\left(\widehat{u}\frac{\partial \widehat{T}}{\partial \widehat{x}} + \widehat{v}\frac{\partial \widehat{T}}{\partial \widehat{y}}\right) = \Delta H_c \frac{K e^{-E/RT}}{s} \times \frac{L c_p}{\rho c_p u_\infty \Delta H_c} + \lambda \frac{\Delta H_c}{L^2 c_p} \times \frac{L c_p}{\Delta H_c \rho c_p u_\infty}\left(\frac{\partial^2 \widehat{T}}{\partial \widehat{x}^2} + \frac{\partial^2 \widehat{T}}{\partial \widehat{y}^2}\right) \tag{11.41}$$

or

$$\left(\widehat{u}\frac{\partial\widehat{T}}{\partial\widehat{x}}+\widehat{v}\frac{\partial\widehat{T}}{\partial\widehat{y}}\right)=\frac{e^{-E/RT}}{s}\left[\frac{L/u_\infty}{\rho/K}\right]+\left[\frac{L/u_\infty}{L^2/\alpha}\right]\left(\frac{\partial^2\widehat{T}}{\partial\widehat{x}^2}+\frac{\partial^2\widehat{T}}{\partial\widehat{y}^2}\right) \quad (11.42)$$

The rearrangement of the terms as shown in Equation 11.42 provides some interesting nondimensional numbers. Firstly, we can define some time scales such that:

$\tau_{residence}=\frac{L}{u_\infty}=$ Time the reactants are present in the CV

$\tau_{chemical}=\frac{\rho}{K}=$ Time it take s for a chemical reaction to occur.

$\tau_{conduction}=\frac{L^2}{\alpha},\quad \alpha=\frac{\rho c_p}{\lambda}=$ Pre-heat time

We can now express, the terms on the right hand side of Equation 11.42, in square brackets as two nondimensional numbers which are denoted as:

$$\mathrm{Da}_1=\frac{\tau_{residence}}{\tau_{chemical}}=\frac{L/u_\infty}{\rho/K}, \quad (11.43)$$

and

$$\mathrm{Da}_2=\frac{\tau_{residence}}{\tau_{conduction}}=\frac{L/u_\infty}{L^2/\alpha}. \quad (11.44)$$

"Da" stands for Damkohler number, after Damkohler [49]. As Da_1 (or Da_2) decrease, suppression is obtained. This is explained using the residence and chemical times defined. $\tau_{residence}$ is the residence time which refers to the length of time the fuel vapors remain in the reaction zone. The residence time will depend on the fluid dynamics of the flame. A diffusion flame can be extinguished by the mechanism of blowout, familiar with the small flames of matches and candles. The mechanism involves the distortion of the reaction zone, within the flame in such a way as to reduce the time that the fuel vapors have to react. Blowout can occur if sufficient airflow can be achieved to reduce $\tau_{residence}$ and consequently T_f, thus reducing the Da_1 number below a critical value. This behavior is also observed in turbulent flames where with sufficiently high intensity, the laminar flamelets are distorted to an extent such that the fuel vapor does not have sufficient time to react with the oxygen. This results in further distortion of the corrugated flame illustratively shown in the transition from Fig. 11.8c, d. $\tau_{chemical}$ is the chemical reaction time, i.e. the time taken for the chemical reaction of combustion to occur. $\tau_{chemical}$ can be reduced by influencing the chemical reaction taking place at the flame. For example chemical suppressants such as Halon are effective reduce the rate of gas phase reaction.

If the conduction losses are increased (denominator of Da_2) extinction can be achieved by quenching due to heat losses (in-depth conduction, re-radiation, and radiative feedback from the flame). For example, if the fuel supply can be decreased by say lowering the vaporization rate of a condensed fuel by adding water, the flame approaches the surface and thus looses more heat which may ultimately result in quenching due to increase in heat losses. The quenching due to lack of fuel supply has not been studied extensively with condensed fuels and works by Roberts and Quince [50] and Torero et al. [51] represent the few studies that define a minimum fuel supply stability limit for diffusion flames established over a condensed fuel. Torero et al. [51] show that for diffusion flames spreading on condensed fuel surfaces, such as upward spread along walls, or horizontal spread or lateral spread on floors, the mechanism of gas-phase flame quenching is dependent on blow-out mechanisms (reduction of Da_1) for the leading edge (location of flame anchored to the surface) and quenching (reduction of Da_2) for the trailing edge (location of the flame tip).

Extinction of diffusion flames can also be physically explained using a critical flame temperature concept. The "S-curve" first studied by Fendell [52] and Linan [53] is usually used to represent the response of temperature to the system Damkohler number. For most fire problems the critical flame temperature at which a diffusion flame ceases to exist is approximately 1300 °C [54, 55]. However, this value should be used with caution. A recent study by Tien and Endo [56] show that there is no unique critical extinction temperature for different materials and the flame temperature at extinction is a strong function of flow parameters.

Final Comments and Conclusions

This chapter discussed the problem of diffusion flames also called as non-premixed flames. The discussion illustrates two important aspects. Analysis of diffusion flames involves knowledge of transport properties such as diffusivity, specific heat of species involved in the process and a thorough understanding of the flow system. Both are limited by the postulates that are made in setting up the simple examples discussed in this chapter. It is therefore absolutely necessary to do experiments in order to establish the flow regime and quantify material and gas-phase properties. The inherent non-linear nature of the governing equations makes the subject difficult and solution to simplified geometries is only possible at this stage. Other aspects such as onset of instabilities and turbulent transport are not clearly understood. This leaves the topic with several fascinating areas of research that need further work.

Ali S. Rangwala is an associate professor at the department of Fire Protection Engineering at Worcester Polytechnic Institute (WPI) (2006 – present). He has a BS in Electrical Engineering, from the Government College of Engineering, Pune, India (2000), an MS in Fire Protection Engineering from the University of Maryland, College Park (2002), and a PhD in Mechanical and Aerospace Engineering from the University of California, San Diego (2006).

Professor Rangwala's research interests are in the area of industrial fire and explosion safety, specifically deflagration of combustible dust clouds, ignition behavior of combustible dust layers, in-situ burning of oil, spread of oil slicks, measuring techniques in fire induced flows, and flame propagation and burning rate behavior of condensed fuel surfaces. He teaches three graduate courses: Explosion Protection, Industrial Fire Protection, and Combustion at Worcester Polytechnic Institute, Department of Fire Protection Engineering

Fundamentals of Premixed Flames

12

Grunde Jomaas

Lavoisier, Berthollet and Dalton were pioneers in the understanding of the mixture composition needed for a flame existence, and in the early 1800s, Sir Humphry Davy created a miner's lamp with a fine meshed net that improved the safety for mine workers, as the mesh was finer than the quenching distance and hence reduced the number of accidental explosions. When Bunsen created the burner associated with his name in 1855 [1], the premixed flame was considered to be However, as the following will show, there was, in the words of Richard Feynman, plenty of room at the bottom [126].

There are two main types of flames, namely the non-premixed flame, which is often referred to as a diffusion flame, and the premixed flame. The former is the more common type of flame in fire situations, where the atmospheric oxidizer and the vaporized (liquids) or pyrolyzed (solids) fuel and oxidizer are not mixed until they react in the flame sheet. In the premixed flame, the fuel and the oxidizer are mixed before reaching the reaction zone, where chemical energy is converted to heat and light. This type of flame is seen in petrol (gasoline) engines, gas turbines, some explosions and elsewhere.

In both flame configurations, chemical reactions must convert the fuel and oxidizer into products and they typically release heat in the process. The rate at which the products and concomitant heat are generated is governed by the Arrhenius reaction rate, $\dot{m} \sim Y_F Y_O e^{-E/RT}$, which states that the fuel and oxidizer must have the proper concentrations in order to react and the molecules must have sufficient energy in order to begin to chemically react. In a premixed flame, the fuel and oxidizer are mixed before the heat required to overcome the activation energy, E, and to initiate the chemical chain reactions is added. The added heat is often in the form of a spark, increased temperature or an open flame. The ratio of the fuel and oxidizer must be within the flammability limits (see Chap. 17), which have both lower and upper bounds, and the heat applied must be sufficient to get the chain reactions going, and this is typically referred to as the minimum ignition energy (MIE) (see Chaps. 17 and 69) if it is not a purely thermal explosion (for Auto-Ignition Temperatures, AIT, see Chap. 17). Although premixed flames can be formed directly or indirectly from solids and liquids (e.g. grain elevator explosion), the current discourse will focus on gaseous fuels.

A premixed flame is a wave phenomenon and it will propagate into the unburned mixture if not forced to do otherwise. The wave can either be propagated at subsonic speeds by the heat release from chemical chain reactions (deflagration) or at supersonic speeds with a leading shock initiating combustion (detonation). This contrasts a premixed flame to the non-premixed

(diffusion) flame, which will try to situate itself at the stoichiometric location of the incoming streams of fuel and oxidizer.

It is quite common to refer to a premixed flame as an explosion because the reactions and the wave-front created by the expansion of the gases are occurring very quickly. However, the word explosion should technically be reserved for the case of a purely thermal explosion, which is a fast rate of reaction in a premixture without a wave [2–6]. The classic theories by Semenov and Frank-Kamenetskii [7, 8] use different approaches to show that the chemical gain from exothermic reactions has to exceed the conduction losses in the system for a thermal runaway to occur.

As the reaction rate is proportional to the energy release, and the reaction rate is exponential with respect to temperature, the result of increasing the temperature is typically a thermal runaway (explosion). This requires that the number of chain branching reactions is larger than the number of chain terminating reactions. In the classic example with H_2-O_2, the detailed chemical reaction scheme along with the reaction rates of the reaction steps will reveal the chain initiating reactions (creation of the first free radicals), the chain branching reactions (more free radicals in the products than in the reactants), the chain carrying reactions (equal number of free radicals in the reactants and the products) and the chain terminating reactions (fewer free radicals in the products than in the reactants), and thus reveal the bottle necks of the explosive process [9]. As such, a detailed study of the chemistry can help us understand how to prevent such a runaway, for example by introducing competing radicals that will inhibit the chain branching, which is the fundamental operational aspect of several fire extinguishment agents, such as halons and their more environmentally friendly replacements.

The laminar flame speed is a thermo-chemical property embodying information about the diffusive and reactive aspects of a combustible mixture, and is thus a central link to understanding of premixed flames. Furthermore, high fidelity laminar flame speed data enables precise and accurate studies of other premixed flame phenomena. In order to computationally simulate a flame phenomenon such as the laminar flame speed, reliable and accurate data on the chemical, thermodynamic, and transport properties must be available over a wide range of experimental conditions, and as such this presents a major challenge. These modeling obstacles can be circumvented to some degree by optimizing the kinetic mechanisms based on experimental observations of fundamental properties such as ignition delay times in shock tubes, extinction limits, flame structures, and laminar flame speeds. The following will therefore focus on the theoretical, numerical and experimental work that has enabled the current understanding of premixed flames. Most combustion textbooks contain chapters on Premixed Flames that have discourses ranging from more practical applications to advanced mathematical formulations and derivations, and the reader is encouraged to consult these for further information on the topic [10–24].

Rankine-Hugoniot Relations – Infinitely Thin Flames

In order to analyze the propagation of a premixed flame, the one-dimensional equations for a reacting flow have to be discussed. Figure 12.1 shows the configuration and the relevant parameters in the unburned (left) and the burned (right) region of the infinitely thin flame. In this frame of reference, the flame is stationary such that the unburned gas velocity

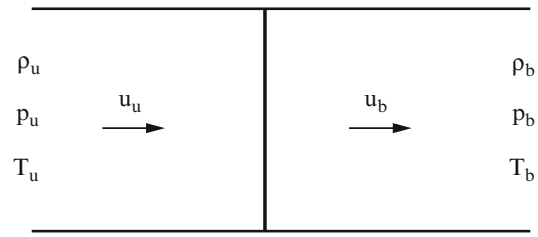

Fig. 12.1 Schematic of the one-dimensional premixed flame, with unburned gases (reactants) to the left and burned gases (products) to the right of the infinitely thin flame

and density match the mass consumption rate of the flame.

The one-dimensional governing equations for conservation of mass, momentum and energy (the energy release, q_c, equals zero for a shock wave) are:

$$\rho_u u_u = \rho_b u_b$$
$$p_u + \rho_u u_u^2 = p_b + \rho_b u_b^2$$
$$h_u + \frac{1}{2}u_u^2 + q = h_b + \frac{1}{2}u_b^2$$

The subscripts refer to the unburned (u) and the burned (b) regions, respectively. The total enthalpy, h, equals the sensible plus the chemical enthalpy (see Chap. 5.)

$$h = c_p T + h^0$$

In addition, we have the equation of state

$$p_u = \rho_u R T_u$$

After some algebraic manipulation of the four equations with five unknowns [13, 15, 16, 19, 24], we can produce the Rankine-Hugoniot [25, 26] diagram, see Fig. 12.2, which enables us to plot the solutions of the underdetermined problem. A key point in this plot is the Chapman-Jouguet point, which is named after Chapman [27] and Jouguet [28].

The diagram offers numerous solutions, but not all the mathematically possible solutions for the burned state are physically possible. The velocity u_u is real and positive in the upper left region. However, it does not exist (imaginary) in the upper right region, as it would require a compression wave to move in the negative direction, which is impossible. The lower left corner is inaccessible because it is impossible to decrease the pressure and the specific volume simultaneously. Similarly, the upper right corner is inaccessible because it is impossible to increase the pressure and the specific volume at the same time.

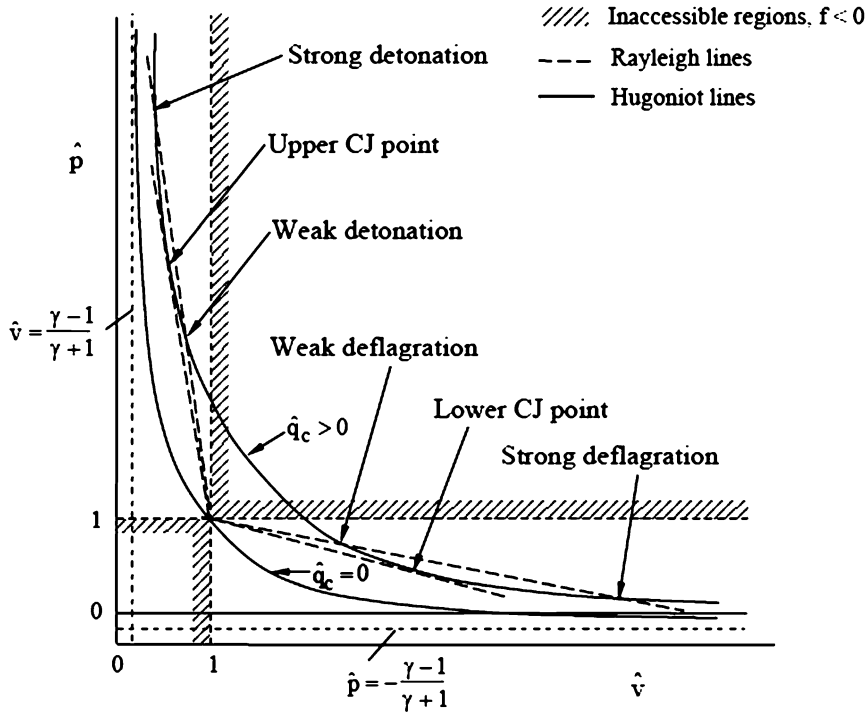

Fig. 12.2 Rankine-Hugoniot plot for the one-dimensional premixed flame. Two lines are shown, one associated with a shockwave ($q = 0$) and one for a wave with a given heat release [13]

The plot is then left with four solution regions, where two are for compression waves and two are for expansion waves [13, 19].

Compression waves (high velocity, the specific volume decreases, the pressure and the density increase when moving from the initial state to the final state)

1. Strong detonation, $p_b > p_{CJ}$, supersonic to subsonic (p_{CJ} is the pressure at the CJ point)
   - Rarefaction waves in the post-combustion gases cause this region to be unstable and waves that occur here will always slow down and end up with a velocity corresponding to that of the upper CJ point. Note that there are theoretical solutions for situations with steady, overdriven detonation waves [127].
2. Weak detonation, $p_b < p_{CJ}$, subsonic to supersonic
   - Does not exist (based on structure analysis)

   Expansion waves (low velocity, the specific volume increases, the pressure and the density decrease when moving from the initial state to the final state)
3. Weak deflagration, $p_b > p_{CJ,\,L}$ ($p_{CJ,\,L}$, pressure at lower CJ point), subsonic to subsonic
   - Deflagration (expansion waves), which requires the structure to be analyzed
4. Strong deflagration, $p_b < p_{jb}$, subsonic to supersonic
   - Does not exist, as it is impossible to have heat addition and proceed past the sonic condition in a constant area duct (Rayleigh flow).

Thus, only region 3 and the upper CJ point exist.

In summary, a Rankine-Hugoniot plot arises from the conservation equations for steady, 1-D flow. The plot shows that combustion waves can either be deflagration or detonation waves, that is, they can, respectively, either be slower or faster than the speed of sound in the medium they traverse. In order to study the deflagration solution, a flame structure is needed, which means that studies of the species concentrations, the flame thickness, diffusion rates, and the temperature become relevant. For the deflagration scenario, one more equation is needed for the underdetermined set of equations, and the flame structure provides this information through the introduction of the heat release rate.

Flame Structure and the Flame Speed

The fact that the flame has a structure is essential, as this means that it has a finite thickness, which is needed in order to move away from the Landau limit (flame sheet, no thickness) in which the flames are intrinsically unstable to all wavelengths [29]. The flame thickness therefore introduces stability.

The detailed structure of a premixed flame contains a preheat zone and a reaction zone, see Fig. 12.3. The laminar flame speed depends on the chemical kinetics and the thermal and mass diffusion.

Although many other methods with more mathematical rigor and more refined physical assumptions [13, 15, 16, 19, 24] exist, the considerations of Mallard and Le Chatelier [30] provide a good starting point for the introductory discussion herein. Also, the main outcome is the same of all the theories, namely that the laminar burning velocity and the flame thickness have a physical dependency on the fuel-air mixture and the ambient conditions. This knowledge can be used for safety design through stabilization and control of the flames.

The following will introduce more details and results associated with the laminar flame speed, which is a steady, self-sustained propagation of an 'exothermic reaction wave' at a low

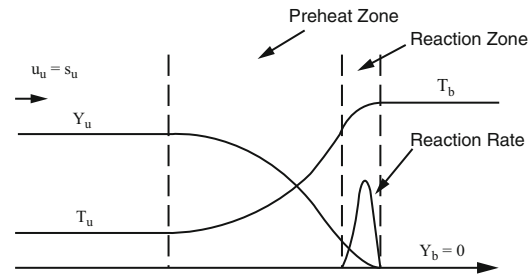

Fig. 12.3 The structure of a premixed flame [13]

subsonic velocity in a direction normal to itself. For the most part, radiative heat transfer and second-order (coupled) transport effects, such as thermal diffusion, are neglected, and the focus is placed on heat conduction, diffusion and the rapid exothermic chemical reactions. Due to the small pressure difference, it can be considered isobaric, and the momentum equation is not needed. As a result, only the mass balance (of each species) and the energy balance are considered.

As the analysis focuses on conservation of mass and energy across the flame (1-D, adiabatic, steady and planar flame propagation into stationary, combustible mixture in a doubly infinite domain), transport and reaction parameters are key. The problem therefore calls for two parameters, which are the laminar flame velocity and the flame thickness.

Mallard and Le Chatelier

The basis for the theoretical development by Mallard and Le Chatelier [30] requires the concept of an ignition temperature, but an actual ignition temperature does not exist in a flame (and hence cannot be determined). The ignition temperature in approach is also not to be confused with the adiabatic flame temperature (See Chaps. 5, 17, and 18). Still, the matching of the timescales and the length scales in a preheat zone and a reaction zone provides useful insight to the physical problem. The governing equations indicate that convection, diffusion and reaction are the relevant transport and reaction processes that should be considered, see Fig. 12.4. The first assumption is that there is no reaction in the far upstream and the far downstream domains, so the reaction timescales go to infinity there. In the preheat zone, the reaction timescale is long due to the low temperature, so convection and diffusion dominate, and have to have matching timescales for the physical problem to be balanced. In the reaction zone, the reaction timescale is small due to the high temperature, so the length scale has to be small so that the thermal and mass gradients, which govern the rate of diffusion, are large. Because convection is a first order differential and diffusion a second order differential, we can deduce that diffusion will be dominating over convection for the small length scales present in the reaction zone. Consequently, we have that diffusion and reaction balance each other in the reaction zone. Finally, at the ignition temperature, all three timescales have to be of approximately the same order.

This approach also allows us to obtain the key parameter for studies on laminar premixed flames, namely the laminar burning velocity, without getting into discussions on the reaction progress variable and details about the reaction rate and the mathematical challenges it causes through its non-linearity.

The assumptions in this approach are that the gases are heated by conduction in the preheat

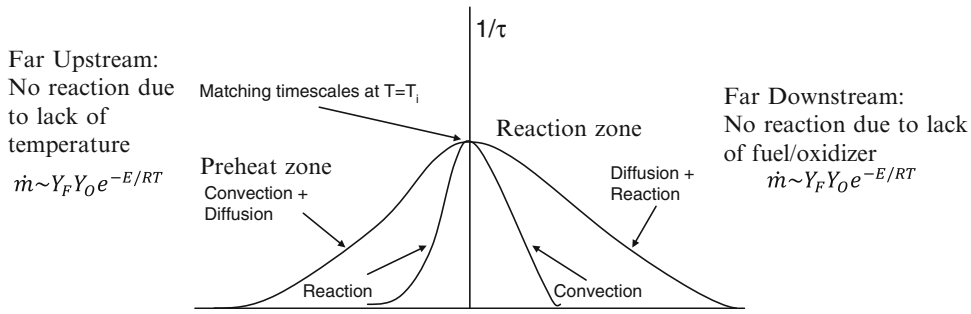

Fig. 12.4 Overview of the laminar premixed flame problem. See also Figs. 12.1 and 12.3

zone and reach ignition at the ignition boundary, that the chemical enthalpy is converted into sensible enthalpy in the chemical reaction zone, and that the temperature curve is linear. The enthalpy balance gives

$$q_{preheat} = q_{conduction}$$
$$\dot{m} c_p (T_i - T_u) = \lambda A \frac{T_b - T_i}{\delta}$$

where $\dot{m}$ is the mass burning rate, c_p is the heat capacity, λ is the thermal conductivity (often estimated to be the average of the unburned and the burned values), A is the surface area, and δ is the flame thickness. The left hand side represents the amount of energy that is absorbed as the unburned mixture flows into the entrance of the preheat zone, raising it to the ignition temperature, T_i. The right hand side represents the heat flux (conduction) to the interface. As such, the heat needed to raise the unburned gas from T_u to T_i equals the heat conducted from the reaction zone.

By using the definition of the mass burning rate, the area cancels out from the equation, and the laminar burning speed is introduced and can be isolated for, as follows.

$$\dot{m} = \rho_u u_u A = \rho_u S_L A$$
$$c_p \rho_u S_L (T_i - T_u) = \lambda \frac{T_b - T_i}{\delta}$$
$$S_L = \frac{\lambda / c_p}{\rho_u \delta} \left(\frac{T_b - T_i}{T_i - T_u} \right)$$

We thereby have that the laminar flame speed depends on the thermal diffusivity of the mixture, $\alpha = \frac{\lambda / c_p}{\rho}$, is inversely proportional to the flame thickness, and is dependent on the reactivity of the mixture, as represented by the ratio of the temperature gradients.

If we then estimate the flame thickness as $\rho_u S_L = \dot{\omega} \delta$, where $\dot{\omega}$ is the volumetric reaction rate, the expression for the flame speed becomes

$$S_L = \sqrt{\frac{\lambda / c_p}{\rho} \left(\frac{T_b - T_i}{T_i - T_u} \right) \frac{\dot{\omega}}{\rho}} \sim \left(\alpha \frac{\dot{\omega}}{\rho} \right)^{1/2}$$

The theoretical results for the laminar flame speed have been compared with experimental results for more than 100 years, with varying success, precision and accuracy. In the following, a series of important experimental findings will be presented.

Flame Speed Measurements

There are numerous methods that enable the measurement of the laminar flame speed. One of the most basic methods is the use of a Bunsen-type burner, see Fig. 12.5, which establishes the flame speed, $S_L = u_u \sin(\alpha)$, based on geometrical considerations. Here, α is the half angle at the top of the flame. Another classic method is the use of flat flame burner and

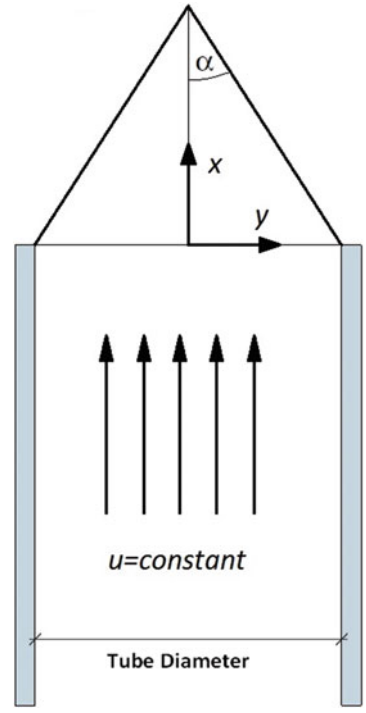

Fig. 12.5 Burner for measuring flame speed

after Spalding [31] introduced the concept of correction for heat losses, see Fig. 12.6, much improved results were obtained. This method is still very relevant today, and substantial research efforts have been undertaken to further develop the fidelity of the measurements [32, 33].

A third method that has been used for more than half a century is the outwardly propagating flame method, which requires that the premixture is contained upon ignition by a spark [10]. This containment can be a soap bubble, a balloon or a chamber. As mentioned, this method requires correction for the expansion that is caused by the hot combustion products, and if the experiments are conducted in a fixed volume chamber, then there is also a need for correction due to the pressure increase in the chamber as the flame propagates.

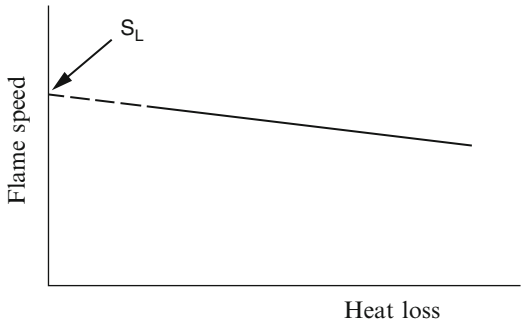

Fig. 12.6 The flame speeds obtained on a flat flame burner have to be corrected for the losses to the burner, as pointed out by Spalding [31]

However, in 1972 Andrews and Bradley [34] pointed out that something was not well understood when it came to the laminar flame speed measurements, despite the fact that more than 100 years had passed since Bunsen's breakthrough experiment for premixed flames and numerous researchers had worked on establishing the flame speed for half a century using all the methods described above. They created a plot of the type shown in Fig. 12.7, which displays the majority of the reported laminar flame speeds for stoichiometric (equivalence ratio, ϕ, equals 1) methane-air flames at normal ambient initial conditions (1 atm, 298 K) as a function of the year the result was published. It can be seen that there was a major discrepancy between the reported results for what should have yielded one data point. It is important to recognize that moderate extents of

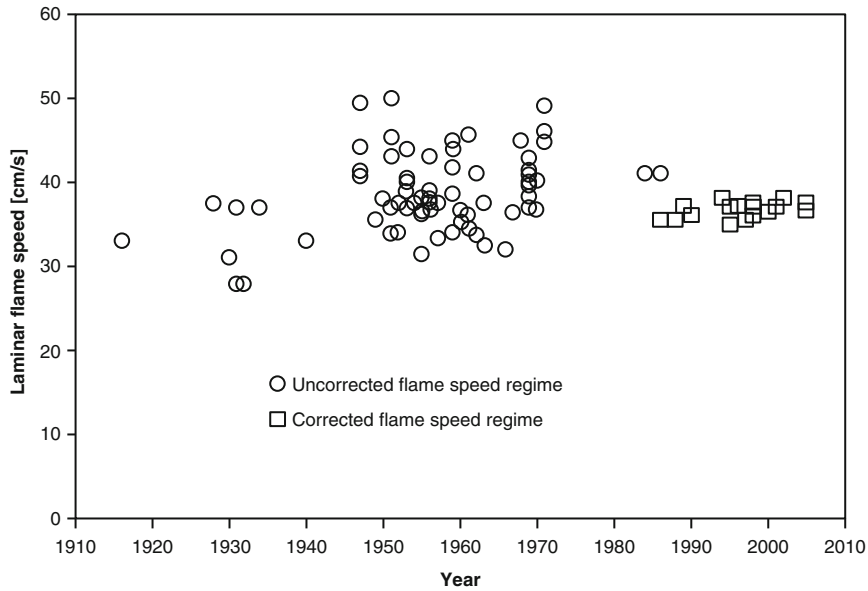

Fig. 12.7 The reported laminar flame speed for stoichiometric methane-air flames at ambient conditions (1 atm, 298 K) versus the year the results were published

error in the laminar flame speed could result in noticeable differences in the chemical mechanisms developed, as the accuracy of the developed mechanism must necessarily depend on the corresponding accuracy of its target points. Such mechanisms, which are developed and validated against incorrect experimental results, will yield poor predictive capabilities and this could lead to dangerous engine designs. Furthermore, it is to be noted that this was for conditions perceived to be simple, as compared to situations with other fuels, fuel mixtures, leaner or richer conditions, higher pressures, other inerts, etc., which will be discussed later.

Wu and Law [35] suggested that the observed scatter in existing experimental methane flame speed data in Fig. 12.7 was caused by the lack of correction for flame stretch (aerodynamic non-uniformity and/or unsteady effects that lead to changes in the flame surface area, which results in a modified reaction rate change, and therefore also in the propagation rate) and diffusion effects, and proposed a methodology to systematically subtract the effects of stretch from flame speed measurements. In particular, they designed a stagnation flow experiment in which flame stretch (aerodynamic non-uniformity and/or unsteady effects) could be measured, and then obtained the unstretched, fundamental flame speed through a linear extrapolation to zero stretch, see Fig. 12.8. Utilizing this technique and applying the stretch correction to other available experimental data, they were able to significantly reduce the discrepancies between measured flame speeds and narrow the discrepancies in the determined fundamental flame speeds of methane and hydrogen, respectively. The impact that this correction method had is obvious from the increased uniformity of the results published thereafter, see 'Corrected flame speed regime' data in Fig. 12.7.

Figure 12.9 is a plot of recent results for the laminar flame speed for methane-air flames at

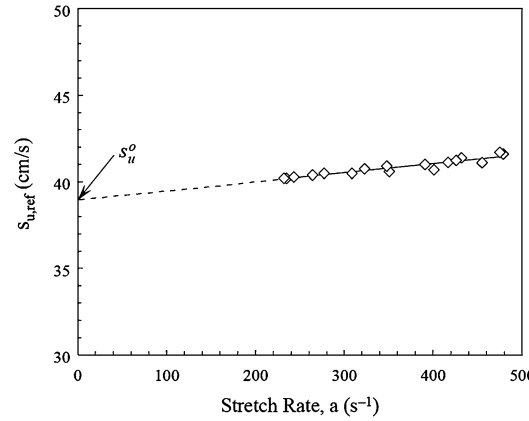

Fig. 12.8 The flame speeds obtained in a burner should be corrected for the stretch rate, as pointed out by Law [35]

atmospheric conditions from various methods that have utilized the abovementioned correction methods [36–39]. The good comparison, also with the numerical results (Wang-mechanism [40]), indicates that the problem of the laminar flame speed is now well-understood. These results have then enabled increased accuracy of the numerical results obtained using detailed chemical reaction schemes, a result that also validates the mechanism due to the fact that the laminar flame speed is the eigenvalue of the initial problem. As such, the theoretical (mathematics, physics and chemistry), numerical and experimental development combined with the utilization of technological developments (computers, cameras, measuring devices) have enabled us to understand the challenging physical problem through a structured effort. Often, the error bars posed in practical, real-life fire problems and in fundamental research problems in the field of fire safety are of the order that the laminar flame speed problem used to have, and the structured effort undertaken to solve the flame speed problem should be of inspiration for other fields of fire and combustion safety [41].

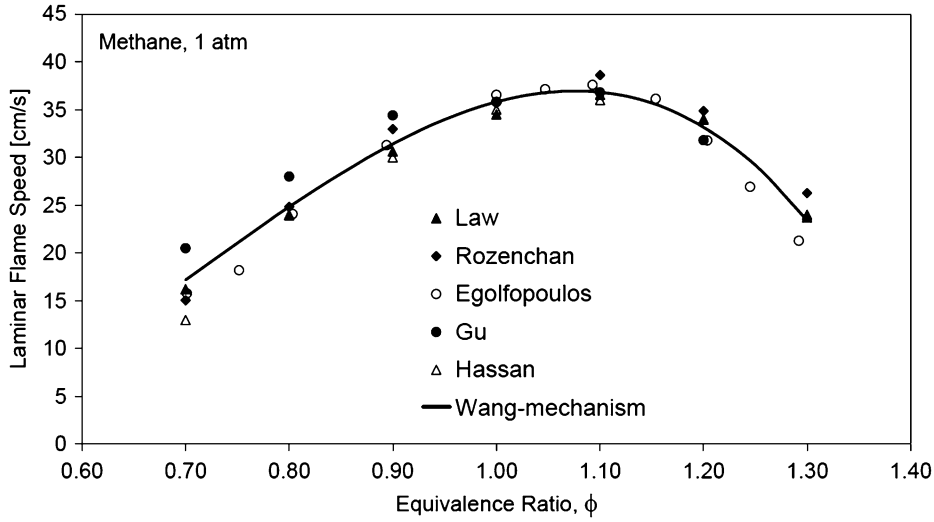

Fig. 12.9 The laminar flame speed as a function of the equivalence ratio for methane-air flames at atmospheric conditions from different experiments [36–39]. The *solid line* represents numerical results from a detailed chemical mechanism [40]

Parameters Affecting the Laminar Flame Speed

The laminar flame speed is a function of a range of practical parameters that will be described in the following.

Fuel Type and Equivalence Ratio

As discussed, the laminar flame speed primarily depends on the thermal diffusivity of the mixture and the reaction rate, and hence on the flame temperature. Given the fact that the flame temperature is dominated by the chemical potential energy stored in the fuel, we therefore expect different fuels to have different laminar flame speeds. The enthalpy of different fuels can be found in Chap. 5. Figure 12.10 shows the calculated adiabatic flame temperatures for a range of hydrocarbon-air mixtures, and the results suggest that acetylene should have the highest flame speed among the hydrocarbons, followed by ethylene. As expected, the reactivity decreases as the mixture is moved from stoichiometric conditions (apart from for acetylene), both towards leaner and richer conditions. As such, most of the fuels have a temperature maximum around stoichiometric conditions, and research has shown that the peak lies slightly on the rich side [42].

The expectations for the flame speed based on the temperature results are confirmed in Fig. 12.11, which shows the experimentally obtained laminar flame speeds of numerous hydrocarbons at standard initial ambient conditions (1 atm, 298 K) using the constant-pressure spherical flame technique [44, 45]. Results from the outwardly propagating spherical flame configuration are chosen, as this configuration is known to yield high accuracy results and has been central in the increased accuracy of the measurements and results that has taken place over the last three decades, as shown in Fig. 12.7 [38, 46–51]. This type of apparatus also easily allows for variations of the initial pressure, for which results will be presented and discussed below. Still, current research is carried out in order to further improve the understanding of the accuracy of various flame speed measurement techniques [137].

Acetylene (C_2H_2) vs. Ethylene (C_2H_4) vs. Ethane (C_2H_6) is one interesting comparison, as the results indicate that the molecular structure

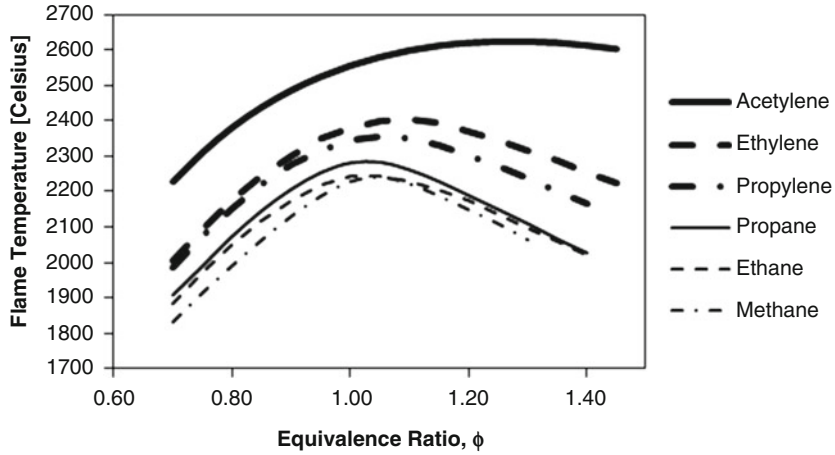

Fig. 12.10 The adiabatic flame temperature as a function of equivalence ratio for a range of hydrocarbons in air. The calculations are based on equilibrium considerations [43]

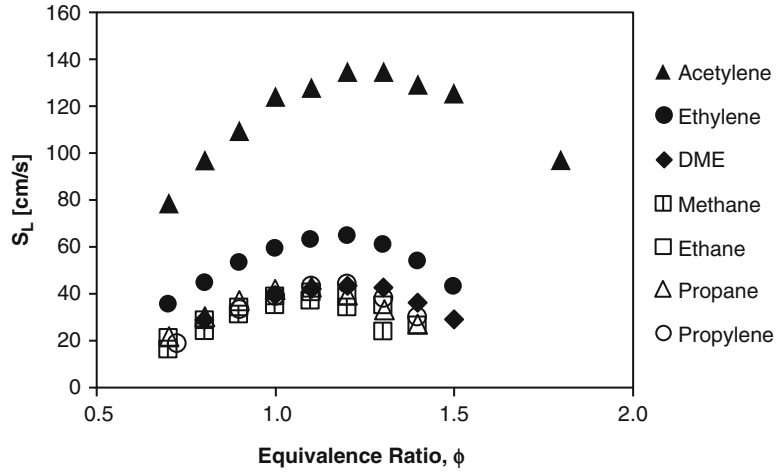

Fig. 12.11 Laminar flame speeds as a function of the equivalence ratio for various hydrocarbons in air at standard conditions

has an effect on the laminar burning velocity. However, as Fig. 12.10 showed that the temperature also was significantly different for the three fuels, further studies were needed to confirm that the molecular structure played a role. Law diluted mixtures of the three fuels with nitrogen so that they all had the same adiabatic flame temperature, and the results were conclusive, in that the ranking from highest to lowest flame speed still was acetylene, ethylene and ethane [13]. Therefore, the flame temperature dominates the laminar flame speed with a second order effect arising from the transport properties of the fuel.

Another point worth noting is that the flame speed for many alkanes is about 40 cm/s for stoichiometric conditions and this has been shown to be the case for numerous fuels in the entire range from methane to octane [52]. However, isomers, alcohols and aromatics display a larger variation in the flame speed at this condition. Just as the flame temperature did, the laminar flame speed decreases as the mixtures move

away from the stoichiometric condition, both towards leaner and richer conditions. Thus, as the flames become leaner/richer, the flame temperature is reduced, the flame speed is reduced and the flame becomes thicker (inversely proportional to the flame speed). The plot for the flame thickness as a function of the equivalence ratio is actually not very unlike the plot for the Minimum Ignition Energy in form (for more on MIE, see Chaps. 17 and 69) and the plot for quenching distance, which also scales with the flame thickness (see Chap. 17). Furthermore, the flammability limits (see Chap. 17) create a sort of asymptote for the characteristic parabolic shape that the flame speed, the flame temperature and the flame thickness have, and estimates on the needed flame temperature for sustained reaction are made in Chap. 5.

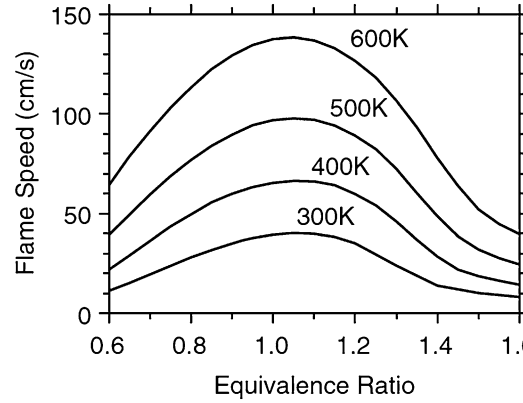

Fig. 12.12 Laminar flame speeds as a function of the upstream mixture temperature for methane at different equivalence ratios at atmospheric pressure [24]

Upstream Temperature

Given the importance that the temperature has on the flame speed, it is also expected that increasing the upstream (unburned) temperature should have an effect on the flame speed. First, it is envisioned that this increase could influence the adiabatic flame temperature. However, as seen in Chap. 5, the adiabatic flame temperature can be estimated as $T_{ad} = T_u + Y_u\, q_c/c_p$, and this effect is therefore small, because T_u is small compared to $Y_u q_c/c_p$. As such, from this perspective, the main effect of the increase in the upstream temperature is to facilitate the reaction by increasing the reaction rate, which has a weak dependence on the temperature for small increases in the upstream temperature. In the more rare cases where the upstream temperature is significantly increased, the effect of the enhanced reaction rate must be given greater attention than in the current string of arguments. Second, there is a small effect due to change in transport properties, because $\left(\lambda/c_p\right) \sim T^{\gamma}$, but this is a mild dependence, as γ is smaller than unity. Finally, there are changes associated with the density change. For a given fixed burning flux, $\dot{m} \sim \rho_u S_L$, the laminar burning speed will increase with an increase in the upstream temperature: $T_u \uparrow \Rightarrow \rho_u \downarrow \Rightarrow S_L \uparrow$. Thus, for an increase in upstream temperature, it is the changes in the density that lead to the only significant increase in the laminar flame speed.

Experimental and numerical results confirm that the laminar flame speed increases as the upstream temperature is increased, as seen in Fig. 12.12. In summary, the reason for this increase is that the laminar flame speed is proportional to the thermal diffusivity, α, which in turn scales as $\alpha \sim T^{3/2} p^{-1}$. Thus, the laminar burning velocity goes up as the temperature is increased.

Inert Type and Oxygen Percentage

As the creation of an inert or partially inert atmosphere is a common fire safety strategy, it is of interest to understand how this influences the flame speed. The type of inert will affect the laminar burning velocity in different ways. Experiments and calculations with detailed chemistry support this, and the most typical comparison is one between nitrogen, argon and helium as inerts for a fuel/oxygen/inert mixture with molar ratio of oxygen to inert equal to 0.21/0.79. In the following, the burning flux, $\dot{m} \sim \rho_u S_L$, is considered, as this parameter is the true eigenvalue of the problem, and thus isolates the

effects of inert addition better than the flame speed does.

The specific heat depends on the degrees of freedom for the respective inert, with increasing c_p for increasing freedom. Monatomic gases have smaller c_p than diatomic gases, so $c_{p,He} = c_{p,Ar} < c_{p,N_2}$. The thermal conductivity is inversely related to the mass of the inert, thus $\lambda_{Ar} \approx \lambda_{N_2} < \lambda_{\mathrm{He}}$ (somewhat larger for N_2 than for Ar). As the burning flux is a function of the ratio of these two parameters, $\dot{m} \sim (\lambda / c_p)$, and as a result, we have that $\dot{m}_{He} > \dot{m}_{Ar} > \dot{m}_{N_2}$, which is shown to hold for methane in Fig. 12.13 and similar results have been reported for other fuels [11, 53].

Figure 12.14 shows that the laminar flame velocity is a strong function of the oxygen concentration in the premixture, which is consistent with the fact that the flame temperature is a strong function of the oxygen concentration. Only a few experimental data points (solid markers) are presented along with the numerical results, as the flames are more and more affected by cellular flame front instabilities (see below) as the flame becomes thinner (flame velocity increases). Also, some of the very rich flames were clearly sooty, and such conditions tend to slow the flame due to increased radiative heat transfer and thus decreased flame temperature. Finally, it is worth noting that the chemical kinetic scheme used to obtain the numerical results is not validated for reduced oxygen concentrations and the results should therefore be used with caution.

It is important to note that these experiments with reduced oxygen concentration reveal that the flames can still propagate in such an environment. This is of interest, as a commonly used safety measure is to reduce the oxygen concentration in a room to around 15 % oxygen in air, as this typically prevents ignition of a non-premixed flame or extinguishes the same type of flame rapidly. However, if a premixture is created in such an environment, ignition and propagation are still possible.

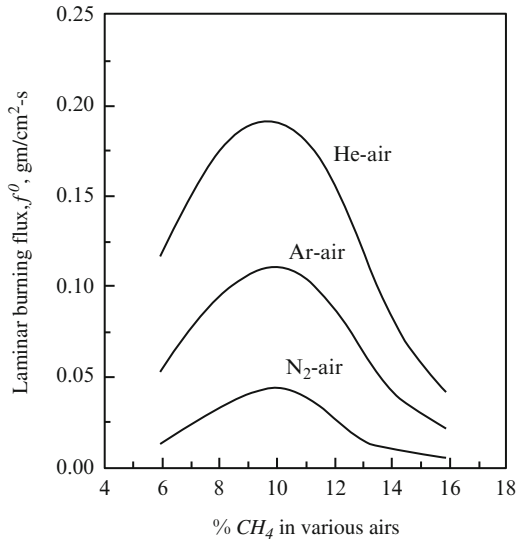

Fig. 12.13 Laminar burning flux for methane-oxygen-inert at different methane concentrations ($\phi = 1$ at 9.5 %) at atmospheric pressure [13]. The molar ratio of oxygen-inert was 0.21–0.79 for all mixtures

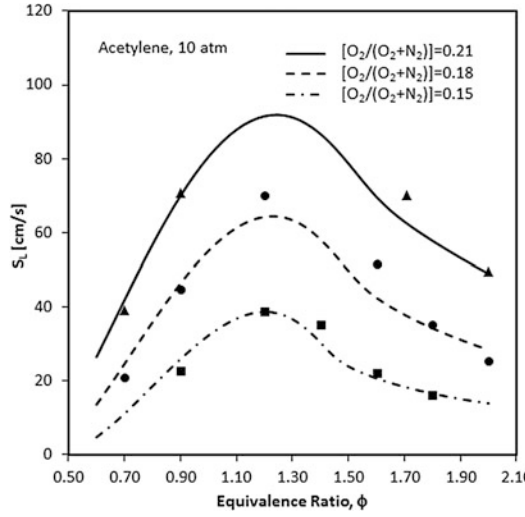

Fig. 12.14 Numerical and experimental laminar flame speeds as a function of the oxygen concentration in the initial environment for acetylene at different equivalence ratios at an initial pressure of 10 atm

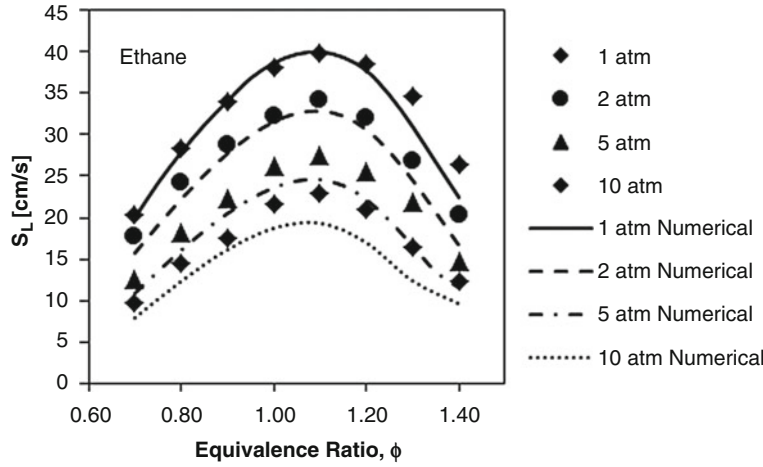

Fig. 12.15 Numerical and experimental laminar flame speeds as a function of pressure for ethane-air at different equivalence ratios

Pressure

The functionality of the laminar flame speed with respect to pressure is $S_L \sim p^{(n/2)-1}$, where n is the reaction order (sometimes referred to as the pressure exponent), which indicates the influence of pressure on the concentrations of the reactants and thus on the reaction rate. For elementary reactions, n can be 1, 2, or 3, and if the reaction order is 2, then it is predicted that the laminar flame velocity should be insensitive to pressure variations [54]. However, the reaction order is smaller than 2 for most hydrocarbons, so the laminar flame speed typically decreases as the pressure is increased. Experiments have validated this, as shown in Fig. 12.15.

However, as mentioned, the true eigenvalue of the problem is the mass burning flux, which is the product of the laminar burning velocity and the density, and this parameter should increase as the pressure is increased. Figure 12.16 shows that the mass burning flux indeed increases as the pressure increases. High-pressure accidents are therefore more severe than low pressure accidents, because the momentum is much higher.

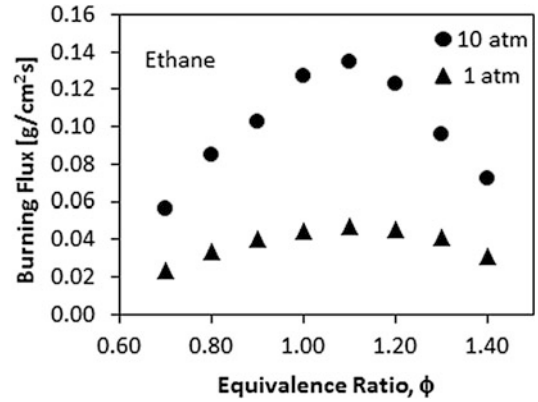

Fig. 12.16 The burning flux of ethane-air (and other fuel-air mixtures) increases as the pressure increases. The results are obtained by multiplying the density obtained from equilibrium calculations with the experimentally obtained flame velocity

Fuel Mixture

Based on the knowledge of the properties of the gases, custom-made compositions can be made to meet the desired design or safety criteria, both for the propagation velocity and for the stability (see below) [55–57]. This becomes very relevant for all the new fuel types, such as syngas and biofuels, as one can either change the burners, or create the mixture (through use of inerts or other fuels) such that it will perform as desired in the existing design. Results for a range of syngas mixtures are shown in Fig. 12.17, and similar results for a range of pressures are shown in the paper by Sun et al. [55].

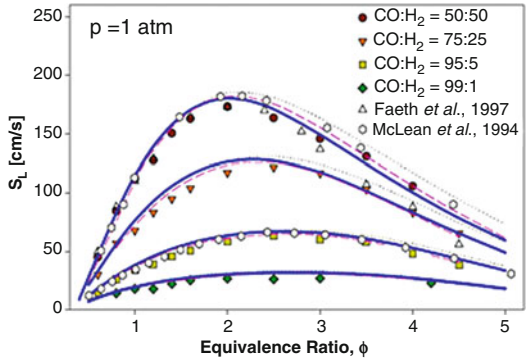

Fig. 12.17 The laminar flame speed of various mixtures of hydrogen and carbon monoxide (syngas) in air at standard conditions [48, 55, 58]. The symbols represents experimental results, whereas the lines represents calculated values

Flame Instabilities and Acceleration

Due to the practical importance of cellular flames in combustion at elevated pressures, and also for safety considerations at atmospheric conditions, the last decade has seen significant experimental efforts pursuing a more thorough understanding of the fundamentals of the phenomenon. An outwardly propagating flame will typically not have instabilities initially, but the flame front will eventually become filled with cellular instabilities, which can either be hydrodynamic or thermal-diffusive in nature, something which has been shown extensively both in experiments and theory [29, 57, 59–68]. Figure 12.18 shows the evolution of a hydrogen flame from a point-source ignition (e.g. accidental explosion) for three different initial conditions. Research has shown that although these cellular instabilities accelerate the propagation velocity [69–74], there is no transition from a laminar to a turbulent flame in an unconfined environment [75]. Bradley has also shown that large scale experiments correlate well with small scale experiments [76, 77]. Under confinement in tubes with or without obstacles [78, 112, 128–131], which is common in places where accidental gas leaks are ignited, initially slow flames may accelerate spontaneously up to supersonic speed, and deflagration to detonation transition (DDT) is possible. These large scale phenomena are challenging to model, given the vast span of the scales, but there are validated models that can handle the problem reasonably well [79].

Flame Structure and Detailed Chemistry of Premixed Flames

Standard tools exist to calculate the flame propagation with detailed chemistry, and one can extract details about all the relevant parameters from such calculations. It is important that such calculations are done in an 'infinite' domain so that boundary conditions do not influence the calculations. This is easily achieved over a small domain, given the fact that premixed flames are very thin. The calculation results presented herein were obtained using the Sandia PREMIX code [80], which simulates the propagation of a planar flame through a premixture under adiabatic conditions. The C_2–C_3 flames were simulated using the detailed reaction mechanism of Qin et al. [40], which includes 70 species and 463 reactions. Other mechanisms exist, either for specific fuels, or for ranges of fuels, with the smallest being that for hydrogen with 9 species and 21 reactions to larger mechanisms with hundreds of species and several thousand reactions [81–89]. As this is a field in rapid development, newer mechanisms and improvements to existing ones are published continuously, and lately there has been a great focus on obtaining results and understanding for biofuels and other alternative fuels [90].

In addition to providing global results such as the propagation velocity of the flames, these detailed mechanisms provide insight into the intermediate steps that take place as reactants are turned into products. For example, calculations with hydrocarbons have shown (in the reaction coordinate, see Fig. 12.19) that the CO is formed before the CO_2 and that temperature goes up as the hydrocarbon is

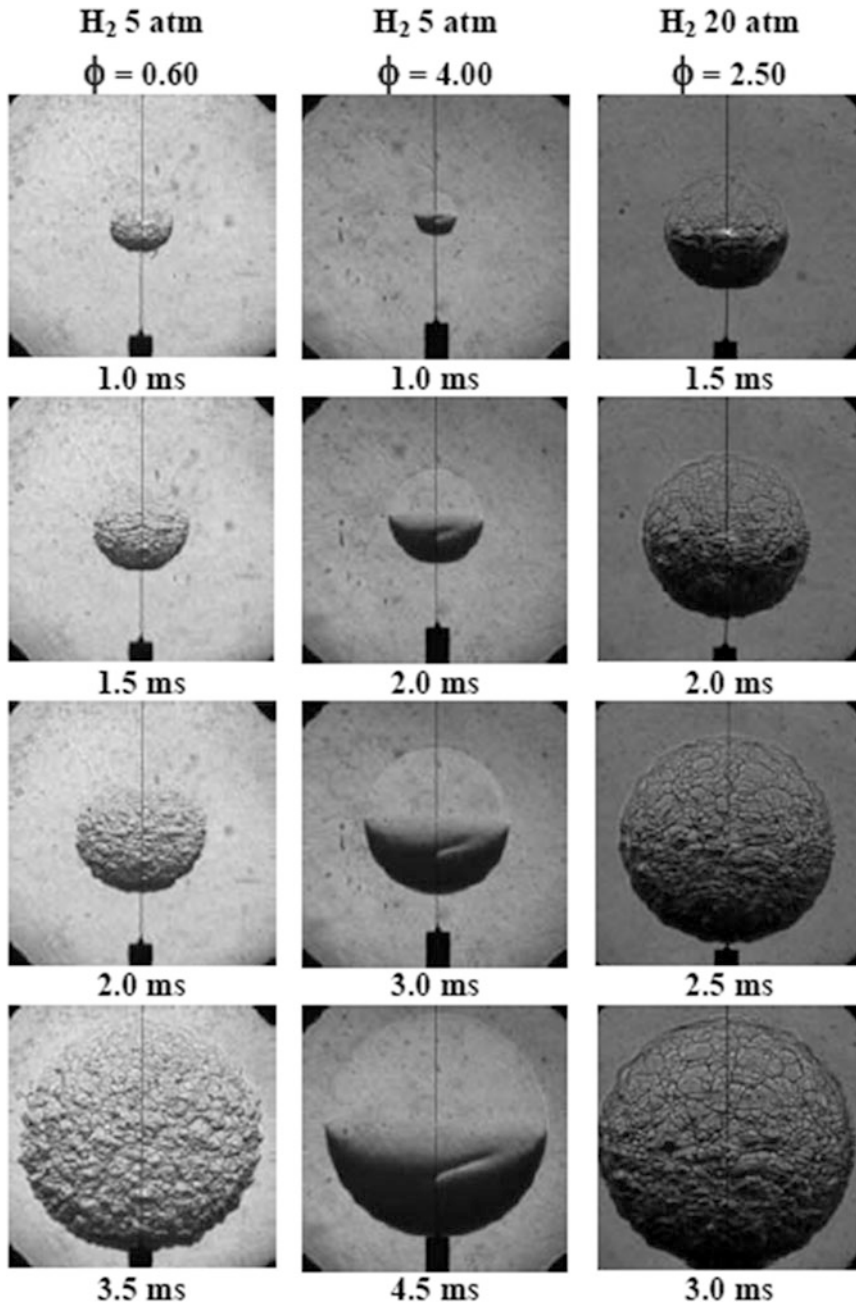

Fig. 12.18 Evolution of an outwardly propagating spherical flame from a point-source ignition in a premixture of hydrogen and air at three different pressures [13]. The lean flame (*left*) has a cellular structure due to thermal-diffusive instabilities, whereas the rich flame at the same pressure (*middle*) is smooth. The rich flame to the right has hydrodynamic cellular instabilities over the flame front as a result of the decrease in flame thickness with the increase in pressure (the flame thickness scales inversely with the laminar flame speed). The increased surface area leads to an increase in the propagation velocity, and the flame no longer traverses into the unburned mixture with the laminar flame velocity

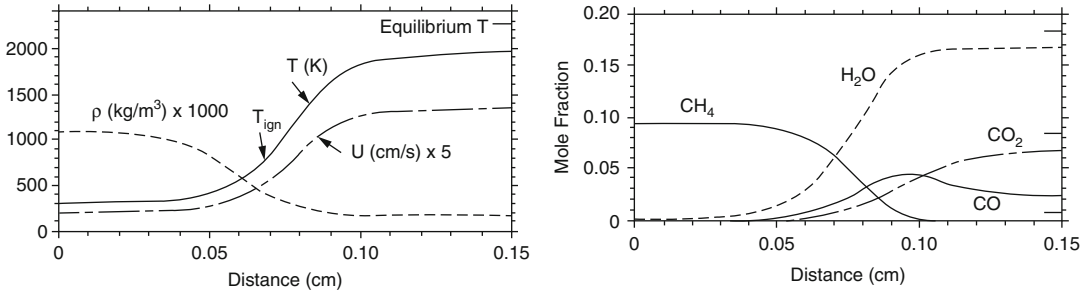

Fig. 12.19 Reaction coordinate view of the physical properties (*left*) and species (*right*) for a methane-air flame [24]

consumed. Further, as the concentration of the hydrocarbon diminishes, the CO concentration is at its max, before decaying as it is converted into CO_2. The intermediate carbon-containing species of the reaction, such as CH_3, CH_2O, HCO and CH exist in a very small zone, whereas HO_2 and H_2O_2 exist over a somewhat broader zone. As such, the reaction zone is very narrow, whereas the equilibrium temperature is reached relatively slowly. The increase in the reaction rate comes with the activation of the reaction, whereas the decrease is caused by depletion of the reactants. The fact that the temperature and fuel depletion profiles are not completely symmetric, indicates that the thermal and the mass diffusion are not equal throughout the flame, which means that the Lewis number (ratio of thermal and mass diffusion) is not equal to unity, as opposed what is typically assumed in a basic flame analysis. Very detailed information and in-depth understanding of flame chemistry and flame structures can be found in numerous classic textbooks [18–22].

Numerical Simulations of Premixed Flames

A proper discussion of Direct Numerical Simulations (DNS), Large Eddy Simulations (LES) and Computational Fluid Dynamics (CFD) modeling requires a book of its own, and excellent ones do exist [89, 90]. In addition, numerous new methods have been developed to deal with the complexity and large computational times that are introduced when detailed chemistry is included in reacting flow scenarios and these methods should be consulted to obtain high fidelity results at reasonable calculation cost [93–96].

Other Aspects Related to Premixed Flames

There are numerous other aspects to the study of premixed flames than the laminar flame speed, but they are all, to some extent, variations or different phases of the main propagation mode. Some of these aspects are briefly mentioned in the following.

Adiabatic Flame Temperature for Constant Pressure Versus Constant Volume Combustion

Another parameter of interest in the study of premixed flames is the adiabatic flame temperature, which is based on thermochemistry (see Chap. 5). The flame temperature of a premixed flame can be estimated as

$$T_b = T_u + \frac{Y_{F,u} q_c}{c_p}$$

where q_c is the chemical heat release.

The adiabatic flame temperature, T_{ad}, is estimated from the total enthalpy, which is the sum of the chemical and the sensible energy (see Chap. 5 for further details). For a constant pressure process, we have that the enthalpy of the reactants should equal the enthalpy of the products, so that

$$H_{react} = H_{prod}$$

$$\sum_{react} N_i h_i = \sum_{prod} N_i h_i = \sum_{prod} N_i \left[h^0_{f,i} + c_{p,i} (T_{ad} - T_u) \right].$$

For a constant volume process, on the other hand, we have the internal energy of the reactants match the internal energy of the products, so that

$$U_{react} = U_{prod}$$

$$H_{react} = H_{prod} + R_u \left(N_{react} T_u - N_{prod} T_{ad} \right).$$

Thus, for the same initial conditions, a constant volume combustion process results in much higher temperatures than a constant pressure combustion process does. This is a consequence of the pressure forces not doing any work when the volume is fixed.

Ignition

In comparison to other premixed phenomena, ignition can be considered a low temperature phenomenon. As for studies of chemical kinetics, both low and high temperature and homogenous and non-homogenous phenomena have to be understood. In the piloted ignition scenario, a local energy is supplied, which will provide situation where the Damköhler number (the ratio of characteristic fluid time and the characteristic chemical time) has to be larger than a critical Damköhler number for ignition to occur. Typical ignition sources for fire scenarios are very large compared to the MIE. Sparks are used for establishing the MIE, and a small spark with short duration is enough. The only requirement is that the duration is long enough compared to the chemical time scale, which typically is so short that it is very unlikely for any spark not to exist for a sufficient time to ignite a premixture within the flammability limits. As such, a non-ignition scenario from a spark means that the energy density (a larger spark will have to heat a larger mass) was not sufficient. Again, several levels of mathematical complexity can be offered for the analysis, which reveals that ignition parameters are a function of the laminar flame speed (and the flame thickness). The critical ignition radius is proportional to the flame thickness (and thus inversely proportional to the laminar burning velocity). Given the fact that the laminar burning velocity is decreasing as the pressure is increased, we have that ignition of most premixtures is facilitated as the pressure is increased.

Turbulence

As reaction is a flame surface phenomenon, it is predicted that the turbulent burning velocity is higher than the laminar burning velocity due to the increased area of a turbulent flame and the increase in the transport at the flame surface, which will lead to increased reaction rate and consequently larger velocity. The reader can consult several resources to learn more on the effect of turbulence on premixed flames [67, 97–110].

Tube Flames

Reacting flow and premixed flames in tubes are of great importance for efficient and safe engine and burner design [11, 111–114]. The pressure dependence in a closed tube creates acoustic excitation (spherical configuration has acoustic decay). The Rayleigh criterion (oscillations) shows that heat must be added in phase with pressure if energy is to be transferred into acoustic waves [115]. The classical demonstration consisted of a hydrogen flame burning

inside an open tube. Pressure variations in the tube cause the flow of gas, and therefore the heat release, volume expansion, and backpressure on the nozzle to vary during the vibration. In Rijke's tube, which is open at both ends, energy from heat is turned into sound from a standing wave [116]. If the product of the fluctuating parts of the heat release and the backpressure, integrated over a cycle of the vibration, is positive, in the absence of damping the vibration will be maintained. In other words, if the fluctuating heat release is more in phase than out of phase with the vibration in the resonator, conditions are right for feeding energy into the vibration.

Experiments [132, 133] and theory [134] have demonstrated a variety of possible outcomes of flame-acoustic interaction, such as flame stabilization by sound waves, a parametric instability and spontaneous turbulization of the flame front. In particular, the spontaneous turbulization may develop as a result of a flame-acoustic resonance with strong increase of pressure and burning rate in the process [135, 136].

Detonation

The main motion of this chapter has been the subsonic propagation of premixed flames, but as shown in Fig. 12.2, the solutions to the equations also predict a regime that is supersonic, and this propagation is referred to as detonation. Whereas the propagation velocity of the laminar premixed flames in the deflagration regime moved with a velocity of the order of 1 m/s, detonation velocities are of the order of 1 km/s. As opposed to what is the case for laminar premixed flames, heat conduction and radical diffusion do not control the velocity for detonations, and the hot gases follow the wave for detonations. The shock wave structure and the developed supersonic wave raise the temperature and pressure substantially and cause explosive reaction and the energy release that sustains the wave propagation. As such, the detonation velocity is the velocity of the unburned gases moving into the wave, and at the Chapman-Jouguet point, the detonation velocity equals the velocity of sound in the gases behind the detonation wave plus the mass velocity of these gases.

From a practical point, it could be of interest to know if the detonation velocity of fuel-oxygen-argon is faster than that of fuel-oxygen-helium. As both have a unity Mach number behind the detonation, and assuming that the flame temperature is not too different (it is different, but not 10 times), the following shows that it all comes down to the molecular weight dependence of the speed of sound, and that the detonation velocity in helium is significantly higher.

$$\frac{u_{He}}{u_{Ar}} = \sqrt{\frac{(\gamma RT)_{He}}{(\gamma RT)_{Ar}}} \approx \sqrt{\frac{R_{He}}{R_{Ar}}} = \sqrt{\frac{R^0/MW_{He}}{R^0/MW_{Ar}}} = \sqrt{\frac{MW_{Ar}}{MW_{He}}} = \sqrt{10}$$

As with the other smaller topics in this subchapter, there is significant knowledge to be found in the literature on detonations [99, 117–125], as well as in Chaps. 69 and 70.

The Role of Premixed Flames in Fire Safety Engineering

As fire safety engineers, our main objective is to avoid ignition. This can be achieved by creating an environment with no or small energy sources, by keeping the atmosphere outside of the flammability limits through design or by use of detection systems, through flame arrestors that will lead to quenching, through creating an overall inert atmosphere (remove oxygen, increase nitrogen). However, if ignition does occur, we want to have appropriately scaled and positioned pressure vents for explosions, or introduce heat losses or energy absorption for flames, which can be

done either chemically or physically. Further information can be found in Chaps. 69 and 70.

Igniting a premixture in a tube that is open at both ends will lead to a combustion wave with transport processes involving heat conduction and diffusion of radicals, which therefore will result in a speed that is lower than the speed of sound in the unburned mixture (deflagration). If, on the other hand, the tube filled with the same premixture is closed at one end, then there is a possibility of a transition from deflagration to detonation (supersonic). This can for example happen in mine explosions. Thus, it is clear that the environment plays a significant role for what happens with the 'explosive' mixture.

The main lesson to be learned for a fire safety engineer from this chapter is that detailed and accurate knowledge of a complex problem like that of premixed burning is achievable, as shown in Fig. 12.7. With structured efforts over time, the field of fire safety can grow into a science in its true form. The challenge lies in scaling up fire [41].

Fire Plumes, Flame Height, and Air Entrainment

13

Gunnar Heskestad

Introduction

Practically all fires go through an important, initial stage in which a coherent, buoyant gas stream rises above a localized volume undergoing combustion into surrounding space of essentially uncontaminated air. This stage begins at ignition, continues through a possible smoldering interval, into a flaming interval, and may be said to end prior to flashover. The buoyant gas stream is generally turbulent, except when the fire source is very small. The buoyant flow, including any flames, is referred to as a fire plume.

Combustion may be the result of pyrolysis of solid materials or evaporation of liquids because of heat feedback from the combustion volume or of pressurized release of flammable gas. Other combustion situations may involve discharge of liquid sprays and aerosols, both liquid and solid, but these will not be discussed here. In the case of high-pressure releases, the momentum of the release may be important. Flames in these situations are usually referred to as *diffusion flames*, being the result of combustible vapor or gas mixing or diffusing into an ambient oxidant, usually air, as opposed to being premixed with an oxidant.

Properties of fire plumes are important in dealing with problems related to fire detection, fire heating of building structures, smoke filling rates, fire venting, and so forth. They can also be important in fire suppression system design.

This chapter deals primarily with axisymmetric, turbulent fire plumes and reviews a number of relations for predicting the properties of such plumes. It is assumed throughout the chapter that the surrounding air is uncontaminated by fire products and that it is uniform in temperature, except where specifically treated as temperature stratified. Release of gas from a pressurized source is assumed to be vertical unless noted otherwise (subsection on "Jet Flames in Horizontal Discharge"). The relations cease to be valid at elevations where the plume enters a smoke layer.

Main topics are flame heights, plume temperatures and velocities, virtual origin, air entrainment, and effects of ambient temperature stratifications. At the end of the chapter, a few additional aspects of fire plumes are discussed, including flame pulsations, rise times of plume fronts propagating upward from suddenly initiated fires, and nonaxisymmetric plume situations including wall/corner effects, wind effects, and jet diffusion flames from horizontal gas discharge. Knowledge of the behavior of fire plumes presented in this chapter is based mostly on observations and dimensional analysis, complemented by analytical models.

Note on Numerical Modeling

Methods of numerical analysis are now showing promise in modeling turbulent fires, e.g., the Fire Dynamics Simulator (FDS). FDS is based on large eddy simulation (LES) of the turbulent convective motion [1, 2] and requires a combustion model. Recent FDS contributions for fire plumes incorporate subgrid mixture-fraction based combustion models and include Ma and Quintiere [3], who compared general predictive capabilities to selected literature data characterized as "the best", and Xin et al. (two separate studies) who compared detailed predictions to careful measurements in the base regions up to an estimated one fourth of the flame height of a 7.1-cm diameter methane burner [4] and a 1-m diameter methane fire [5] (measurements by Tieszen et al. [6]). The challenge is to reproduce experimental results to a high degree of accuracy, which was achieved to a considerable extent in the base-region calculations by Xin et al. [4, 5], although the temperature calculations required an assumption about radiant heat loss.

Another approach is the LES solver, FireFOAM [7], which is based on the open source code OpenFOAM [8] and also incorporates a subgrid mixture-fraction based combustion model. The code has been applied by Wang et al. [9] to model fire plumes on a 0.3-m square burner for comparison with existing data. With an assumption of a constant radiant fraction of 20 % (although the code allows for a more fundamental treatment of thermal radiation), results of axial plume temperatures and velocities are in approximate agreement with the experiments. Flame heights and air entrainment compare favorably with experimental values. Fluctuating velocities are comparable to reported experimental values, whereas fluctuating temperatures are excessive. (The long-term goal is stated to be predictive capability for large scale industrial fires and water-based suppression on the OpenFOAM platform, incorporating pyrolysis and soot models, already available capabilities in FireFOAM.)

Earlier methods were based on Reynolds-Averaged Navier Stokes (RANS) models and are included in a survey of fire models prepared by Olenick and Carpenter [10].

The ultimate approach is to solve the governing equations more fundamentally with Direct Numerical Simulation (DNS), which is becoming gradually more feasible for fire problems with the availability of increasing computing power. At this writing, DNS still remains a great challenge and is not likely to become a viable tool in fire applications for some time because of its demand on resources. Numerical modeling may eventually reproduce actual experiments, with a bonus of numerous variables of the mean and turbulent flow fields hardly accessible by physical experiments.

Fire Plume Features

Figure 13.1 shows a schematic representation of a turbulent fire plume originating at a flaming source, which may be solid or liquid. Volatiles driven off from the combustible by heat feedback from the fire mix with the surrounding air and form a diffusion flame. Laboratory simulations often employ controlled release of flammable gas through a horizontal, porous surface. The mean height of the flame is L. Surrounding the flame and extending upward is a boundary (broken lines) that confines the entire buoyant flow of combustion products and entrained air. The air is entrained across this boundary, which instantaneously is very sharp, highly convoluted, and easily discernible in smoky fires. The flow profile could be the time-averaged temperature rise above the ambient temperature, the concentration of a gas (such as CO_2) generated by the fire, or the axial velocity in the fire plume.

Figure 13.1 suggests qualitatively, based on experimental observations [12–16], how the temperature rise on the centerline, ΔT_0, and the velocity on the centerline, u_0, might behave along the plume axis. In this example of a relatively tall flame, the temperatures are

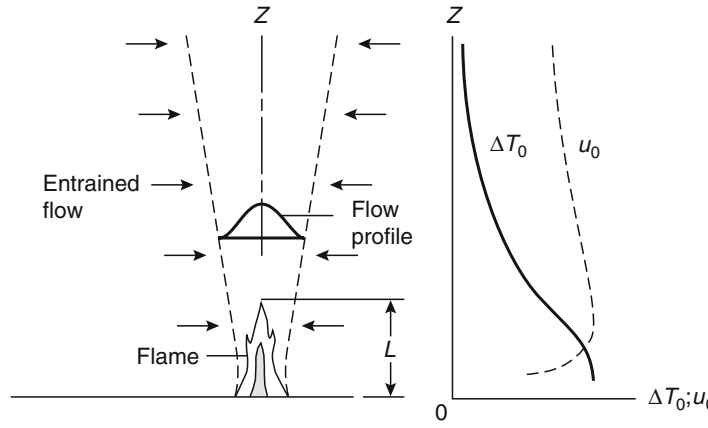

Fig. 13.1 Features of a turbulent fire plume, including axial variations on the centerline of mean excess temperature, ΔT_0, and mean velocity, u_0 [11]

nearly constant in the lower portion of the flame. Temperatures begin to decay in the intermittent, upper portion of the flame as the combustion reactions trail off and air entrained from the surroundings cools the flow. The centerline velocities, u_0, tend to have their maxima slightly below the mean flame height and always decay toward higher elevations. If the combustible is porous and supports internal combustion, there may not be as pronounced a falloff in the gas velocity toward the top of the combustible as suggested in Fig. 13.1 [14].

The total (or chemical) heat release rate of a fire source, $\dot{Q}$, is either convected, $\dot{Q}_c$, or radiated, $\dot{Q}_r$, away from the combustion region. In a fire deep in a porous combustible pile (e.g., a stack of wood pallets), some of the total heat generated is trapped by and stored in the not yet burning material; the rest escapes from the combustible array as either convective or radiative energy flux. If most of the volatiles released undergo combustion above the fuel array, as in pool fires of liquids and other horizontal-surface fires, and even in well-developed porous pile fires, then the convective fraction of the total heat release rate is rarely measured at less than 60–70 % of the total heat release rate [17, 18]. The convective flux, $\dot{Q}_c$, is carried away by the plume above the flames, while the remainder of the total heat liberated, $\dot{Q}_r$, is radiated away in all directions.

For large fires, the radiative fraction tends to decrease with increasing fire size [19] and the convective fraction tends to increase. This result is especially striking in smoky hydrocarbon fires [20] where radiation is increasingly absorbed in the mantle of combustion products surrounding the flames (dashed lines in Fig. 13.1) as the fire increases in size, although the smoke itself will emit some radiation. However, even mantles of combustion products from sufficiently large fires of a clean burning fuel, such as liquefied natural gas (LNG), will absorb significant and increasing amounts of radiation as the fires become larger because of water vapor and carbon dioxide, both major combustion products and radiation-absorbing gases. Another reason for decreasing radiative fraction with increasing size of larger fires is that the flames are optically thick and the radiation-emitting area (flame area) per unit fire power (kW) decreases with increasing fire size (based on Equation 13.8 and constant heat release rate per unit fire area).

The total heat release rate, $\dot{Q}$, is often assumed to be equal to the *theoretical* heat release rate, which is based on complete combustion of the burning material. The theoretical heat release rate in kW is evaluated as the mass burning rate in kg/s multiplied by the lower heat of complete combustion in kJ/kg. The ratio of the total heat release rate to the theoretical heat release rate, which is the combustion efficiency,

is indeed close to unity for some fire sources (e.g., methanol and heptane pools) [17], but may deviate significantly from unity for others (e.g., a polystyrene fire, for which a combustion efficiency of about 45 % [18] has been measured, and a fully involved stack of wood pallets, for which a combustion efficiency has been measured at 63 % [17]).

Calculation Methods

This section presents calculation methods for flame height; plume temperature and velocity; effects of ambient temperature stratification on plume temperature, velocity, and other plume variables; virtual origin of a fire plume, a point source from which the plume appears to originate; and entrainment of air from the surroundings into a fire plume. The calculation methods are illustrated by examples.

Flame Heights

The visible flames above a fire source contain the combustion reactions. Tamanini [21] has investigated the manner in which combustion approaches completion with respect to height in diffusion flames.

Typically, the luminosity of the lower part of the flaming region appears fairly steady, while the upper part appears to be intermittent. Sometimes vortex structures, more or less pronounced, can be observed to form near the base of the flame and shed upward. [22, 23].

Figure 13.2 helps to define the mean flame height, L [23]. It shows schematically the variation of flame intermittency, I, versus distance above the fire source, z, where $I(z)$ is defined as the fraction of time that at least part of the flame lies above the elevation, z. The intermittency decreases from unity deep in the flame to smaller values in the intermittent flame region, eventually reaching zero. The mean flame height, L, is the distance above the fire source where the intermittency has declined to 0.5. Objective determinations of mean flame height according to intermittency measurements are fairly consistent with (although tending to be slightly lower than) flame heights that are averaged by the human eye [23].

The mean flame height is an important quantity that marks the level where the combustion reactions are essentially complete and the inert plume can be considered to begin. Several expressions for mean flame height have been proposed. Figure 13.3, taken from McCaffrey [24], shows normalized flame heights, L/D, as a function of a Froude number, $\dot{Q}^*$ (represented as $\dot{Q}^{*2/5}$ to compress the horizontal scale), from

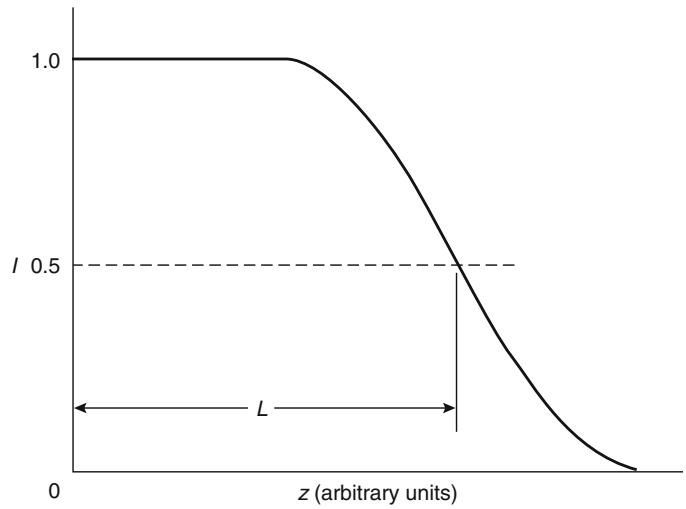

Fig. 13.2 Definition by Zukoski et al. [23] of mean flame height, L, from measurements of intermittency, I

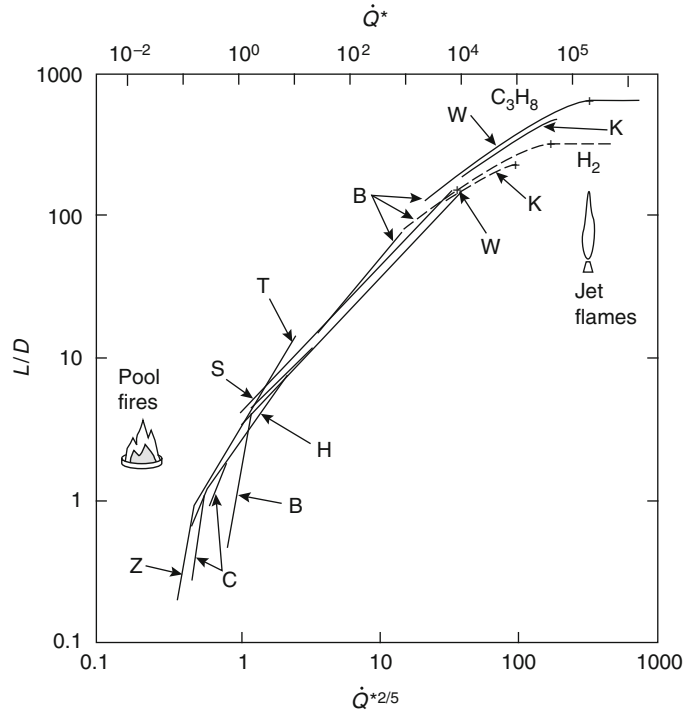

Fig. 13.3 Flame height correlations compiled by McCaffrey [24]. Capital letters without subscripts correspond to various researchers as follows: *B* Becker and Liang [25], *C* Cox and Chitty [26], *H* Heskestad [27], *K* Kalghatgi [28], *S* Steward [29], *T* Thomas [30], *W* Hawthorne et al. [31], and *Z* Zukoski [32]. Capital letters with subscripts represent chemical formulae

data correlations available in the literature. This Froude number is defined as

$$\dot{Q}^* = \frac{\dot{Q}}{\rho_\infty c_p T_\infty \sqrt{gD}D^2} \tag{13.1}$$

where

$\dot{Q}$ = Total heat release rate (given in terms of the mass burning rate, $\dot{m}_f$, as $\dot{m}_f H_c$)
ρ_∞ and T_∞ = Ambient density and temperature, respectively
c_p = Specific heat of air at constant pressure
g = Acceleration of gravity
D = Diameter of the fire source

Quoting McCaffrey with respect to this figure: "On the left are pool-configured fires with flame heights of the same order of magnitude as the base dimension D. In the middle is the intermediate regime where all flames are similar and the $\dot{Q}^{*2/5}$ is seen as a 45 degree line in the figure. Finally, in the upper right is the high Froude number, high-momentum jet flame regime where flame height ceases to vary with fuel flow rate and is several hundred times the size of the source diameter."

Buoyancy Regime The correlation by Heskestad (*H*) represented in Fig. 13.3 covers the entire $\dot{Q}^*$ range except the momentum regime and has the following form given by McCaffrey [24]:

$$\frac{L}{D} = -1.02 + 3.7\dot{Q}^{*2/5} \tag{13.2}$$

Actually, this correlation was originally presented in the form [27]

$$\frac{L}{D} = -1.02 + 15.6N^{1/5} \tag{13.3}$$

As before, D is the diameter of the fire source (or effective diameter for noncircular fire sources such that $\pi D^2/4$ = area of fire source) and N is the nondimensional parameter defined by

$$N = \left[\frac{c_p T_\infty}{g\rho_\infty^2 (H_c/r)^3}\right]\frac{\dot{Q}^2}{D^5} \tag{13.4}$$

where H_c is the actual lower heat of combustion and r is the actual mass stoichiometric ratio of air to volatiles.

It is readily shown that N and $\dot{Q}^*$ are related as follows:

$$N = \left(\frac{c_p T_\infty}{H_c/r}\right)^3 \dot{Q}^{*2} \tag{13.5}$$

This equation, combined with Equation 13.3, leads to Equation 13.2 when typical values are substituted for the environmental and fuel variables.

The parameter N was derived specifically by consideration of the flaming region [27], whereas $\dot{Q}^*$ was originally derived by Zukoski [33] from analysis of the nonreacting turbulent plume. Subsequently, Heskestad [34] presented results of flame height measurements at widely varying ambient temperatures. The parameter $\dot{Q}^*$ did not account correctly for the observed variations in flame height (increasing flame height with increasing ambient temperature), while the parameter N did. For that reason, N is considered the more appropriate scaling parameter.

Equation 13.3 [27] is anchored in the 50 % intermittency flame heights measured by Zukoski et al. [23] for 81 experimental fires of natural gas (essentially methane), burned on circular porous beds of three diameters, 0.10, 0.19, and 0.50 m. The author extended this body of data into the low-N region based on propane fires on a 0.76-m diameter sand bed [35]. Other contributing data [27, 35] were based on time-averaged flame heights, mostly by eye, including (but not limited to) 51 and 102 mm- diameter gas jets of various fuels [36]; 102 and 279 mm-diameter natural-gas sandbox burners [37]; pool fires of gasoline varying from 0.3 to 23 m in diameter [38]; pool fires of JP-4 fuel varying from 1× 1 m to 10× 10 m [39] (treated as circular pools of diameters corresponding to their burn areas); sand filled, 1.52 m-diameter pans initially saturated with acetone or methanol [40]; and pool fires of diameters 1.22, 1.74, and 2.44 m of methanol, heptane, a silicone transformer fluid and a hydrocarbon transformer fluid [15]. Deviations of observed values from values calculated according to Equation 13.3 may be associated with subjective flame-height averaging by eye or photography (including assigning a value for the instantaneous flame height when detached flame fragments appear), departure of fire area from circular, nonuniform volatilization rates across a burning surface (as observed in Wood et al. [40]), density of volatiles, effects of the surrounding topography and wind, and effects of flame Reynolds number (increases with fire size).

Some large scale pool fires of LNG on water as well as on land, reviewed by Mudan [41], appear to have produced flame heights generally a little lower than, but still quite consistent with Equation 13.3 for both water and land sites and from two different investigations. Flame heights from land measurements of a third investigation had great scatter, with a smallest flame height value about one third as large as calculated from Equation 13.3.

Subsequent to its derivation, the Equation 13.3 was found also to represent large, deep storages when the flames extended above the storage and flame heights were measured above the base of the fire (bottom of storage in the experiments) [42]. The storages investigated included 4.5-m-high palletized storage of different commodities, 3- to 6-m-high rack storage of two different commodities, and wood pallets stacked 0.3–3.3 m high. In these cases the fire diameter was calculated as the diameter of a fire area equal to the ratio of heat release rate to heat release rate per unit area.

A convenient form of Equation 13.3 can be developed. Let

$$A = 15.6\left[\frac{c_p T_\infty}{g\rho_\infty^2 (H_c/r)^3}\right]^{1/5} \tag{13.6}$$

Then Equation 13.3 can be written in the dimensional form

$$L = -1.02D + A\dot{Q}^{2/5} \tag{13.7}$$

The coefficient, A, varies over a rather narrow range, associated with the fact that H_c/r, the heat liberated per unit mass of air entering the combustion reactions, does not vary appreciably

among various combustibles. For a large number of gaseous and liquid fuels, H_c/r remains within the range of 2900–3200 kJ/kg, for which the associated range of A under normal atmospheric conditions (293 K, 760 mmHg) is 0.240–0.226 (m $kW^{-2/5}$), with a typical value of $A = 0.235$. Hence, under normal atmospheric conditions

$$L = -1.02D + 0.235\dot{Q}^{2/5} \tag{13.8}$$

(L and D in m; $\dot{Q}$ in kW).

Fairly common fuels that deviate significantly from the cited range 0.240–0.226 for A include acetylene and hydrogen (0.211). In general, the coefficient $A = 0.235$ in Equation 13.8 may be considered adequate unless actual values of H_c and r are known that indicate otherwise and/or atmospheric conditions deviate significantly from normal. While values of H_c/r for complete combustion have been used to calculate the coefficients A, Huggett [43] found a number of years ago that the heat of combustion per unit mass of oxygen consumed, and hence H_c/r for a standard atmospheric composition, was little affected by incompleteness of combustion in a number of test calculations.[1]

Referring to any of the flame-height relations in Equations 13.3, 13.7, and 13.8, it can be seen that negative flame heights are calculated for sufficiently small values of the heat release rate. Of course, this situation is unphysical and the correlation is not valid here. For pool fires, there are indications that a single flaming area breaks down into several zones when heat release rates decrease to the point where negative flame height (L) is calculated [35].

Grove and Quintiere [45] have developed new correlations for flame height, including linear sources (not considered here). They present their results in terms of $\dot{Q}^*$ rather than N.

Newman and Wieczorek [46] have examined "chemical flame heights", defined by the ratio of CO to CO_2 yields decaying to the limit for well-ventilated fires of the combustible material. They found good agreement with determinations of flame height based on flame luminosity. They claim certain attributes for this method, such as the results not being subject to visual bias and available in cases where visual observations are not feasible (presumably as in cases of obscuring smoke, where infrared imaging may also work).

EXAMPLE 1 Consider a 1.5-m-diameter pan fire of methyl alcohol with a heat release intensity of 500 kW/m^2 of surface area. Normal atmospheric conditions prevail (760 mmHg, 293 K). Calculate the mean flame height.

SOLUTION Available values of the lower heat of combustion ($H_c = 21{,}100$ kJ/kg) and stoichiometric ratio ($r = 6.48$) give $H_c/r = 3260$ kJ/kg. With this value for H_c/r substituted in Equation 13.6, together with $c_p = 1.00$ kJ/kg K, $T_\infty = 293$ K, $g = 9.81$ m/s^2, and $\rho_\infty = 1.20$ kg/m^3, the coefficient A is calculated as 0.223 (m $kW^{-2/5}$). The total heat release rate is $\dot{Q} = 500\pi 1.5^2/4 = 884$ kW. Equation 13.7 gives a mean flame height of $L = -1.02 \cdot 1.5 + 0.223 \cdot 884^{2/5} = 1.83$ m.

EXAMPLE 2 This example is similar to Example 1, except for new atmospheric conditions representative of Denver, Colorado, on a hot day: 630 mmHg pressure and 310 K temperature.

SOLUTION Using Equation 13.6, the new coefficient, A, increases from 0.223 to 0.249 [most readily calculated from $(310/293)^{3/5}$ $(760/630)^{2/5}$ $0.223 = 0.249$, where the equation of state for a perfect gas has been used]. Using Equation 13.7, the new flame height is $L = 2.23$ m, increased from 1.83 m for normal atmospheric conditions.

Note Assuming that gas radiation is dominant in heat transfer to the pool surface in the example, that the absorption coefficient varies linearly with atmospheric pressure [47] and using the methanol pool fire data of Burgess et al. [102],

[1] As a further aid in assessing variations in A, Tewarson [44], in his Table 3–4.12, lists values of ΔH_O for complete combustion of many fuels, the lower heat of combustion per unit mass of oxygen consumed. From these values, H_c/r (kJ/kg) can be easily calculated, the lower heat of combustion per unit mass of air (of standard composition) consumed and, hence, the coefficient A.

the burning rate associated with the reduced atmospheric pressure is estimated to decrease by a negligible amount.

EXAMPLE 3 One 1.2-m-high stack of wood pallets (1.07 × 1.07 m) burns at a total heat release rate of 2600 kW under normal atmospheric conditions. Calculate the mean flame height above the base of the pallet stack.

SOLUTION The square flaming area can be converted to an equivalent diameter: $\pi D^2/4 = 1.07^2$, which gives the equivalent diameter, D, of 1.21 m. Since the combustion efficiency of wood is considerably less than 100 %, it is difficult to select reliable and consistent values for H_c and r to form the ratio H_c/r. Instead, it can be assumed that $A = 0.235$, the typical value. Using Equation 13.7, the mean flame height above the base of the pallet stack is calculated as $L = -1.02 \cdot 1.21 + 0.235 \cdot 2600^{2/5} = 4.22$ m.

Momentum Regime In Fig. 13.3 it is seen that at high values of $\dot{Q}^*$ the normalized flame heights begin to level off and eventually attain constant values, but not at the same value of $\dot{Q}^*$ and not at the same normalized flame height.

Flame heights of vertical turbulent jet flames have been studied by a number of investigators reviewed by Blake and McDonald [48, 49], who proposed a new correlation of normalized flame heights versus a "density-weighted Froude number." Although an improvement over previous work, the correlation still exhibits significant scatter. At about the same time, Delichatsios [50] proposed an alternative approach. Previously, other authors had proposed flame height relations, including Becker and coworkers [25, 51], and Peters and Göttgens [52]. Subsequent to these publications, Heskestad [53] also considered the high-momentum regime, especially with respect to defining an unambiguous transition to momentum control and flame heights in this regime.

Heskestad's work [53] was based on an extension of the author's correlation for buoyancy-controlled turbulent diffusion flames. A momentum parameter is defined, which is the ratio of gas release momentum to the momentum generated by a purely buoyant diffusion flame:

$$R_M = 1.36\left[\left(\frac{T_\infty}{T_L}\right)\left(\frac{c_p \Delta T_L}{(H_c/r)}\right)^{4/5}\right]\left(\frac{\rho_\infty/\rho_s}{r^2}\right)N^{2/5} \tag{13.9}$$

Here, T_L and ΔT_L are the plume centerline temperature and excess temperature (above ambient), respectively, at the mean flame height of purely buoyant diffusion flames, and ρ_s is the density of the source gas in the discharge stream. A value of 500 K is assigned [53] to ΔT_L. Note that the first two sets of parentheses are nearly constant for normal ambient temperatures and fuels with comparable values of (H_c/r). Under these circumstances, the momentum parameter is closely linked to the parameter N but is affected quite significantly by the source gas density at the discharge conditions as well as the mass stoichiometric ratio. If the gas discharge is sonic or choked, the density of the source gas can be considerably higher than is the case at atmospheric pressure.

Figure 13.4 presents flame heights of jet diffusion flames in the form L/L_B versus R_M, where L is the flame height reported by various investigators and L_B is the buoyancy-controlled flame height according to Equation 13.3. The data scatter about a value $L/L_B = 1.2$, approximately, for $R_M < 0.1$. At higher values of R_M, the flame height ratio approaches an asymptotic slope of $-1/2$, indicated by a dashed line. The associated values of N are so large that we can take $L_B/D \propto N^{1/5}$ (see Equation 13.3), which together with Equation 13.9 imply that L/D is constant when the slope is equal to $-1/2$ (for constant source gas and discharge density). Constant slope and constant L/D (for a given gas and density) appear to be achieved reasonably quickly above $R_M = 0.1$.

The fact that the low-R_M flame height ratios in Fig. 13.4 tend to scatter about a level higher than

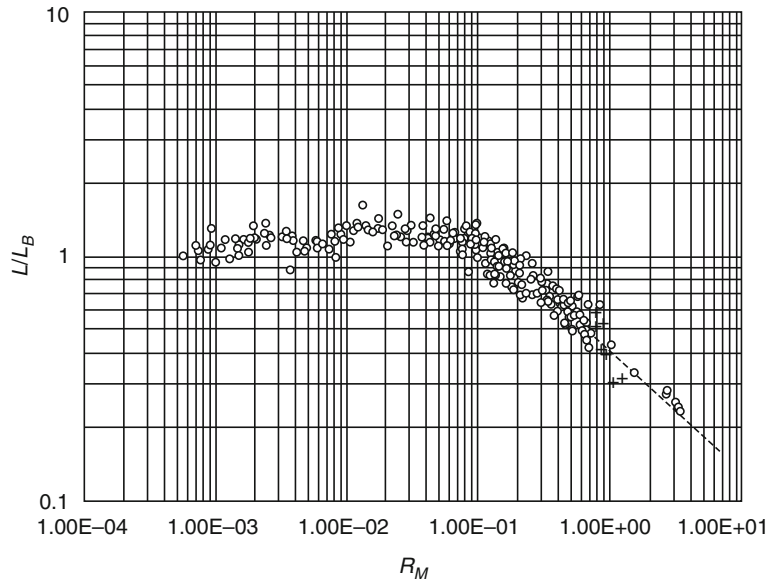

Fig. 13.4 Data on flame heights of turbulent jet diffusion flames in ratio to the corresponding buoyancy-controlled flame heights, plotted versus the ratio of gas release momentum to buoyancy momentum (from Heskestad [53]). Data plotted as + pertain to choked discharge of hydrogen

unity has been attributed to several possible factors [53]. One of the two most important may be the working definition of mean flame height employed by some investigators, producing greater values than the 50 % flame-intermittency height. Another may be retinal retention of flame images in visual averaging of rapidly pulsating flames (typical of the scales of the experiments), tending to make an observer exaggerate the mean flame height.

Above $R_M = 0.1$, adopting the dashed line in Fig. 13.4 as representative of the momentum regime, the normalized flame height is

$$\frac{L_M}{D} = \left[5.42\left(\frac{T_L}{T_\infty}\right)^{1/2}\left(\frac{H_c/r}{c_p \Delta T_L}\right)^{2/5}\right]\left(\frac{\rho_s}{\rho_\infty}\right)^{1/2} r \tag{13.10}$$

where L_M is the flame height in the momentum regime. For $H_c/r = 3100$ kJ/kg (many common gases), $\Delta T_L = 500$ K, and $T_\infty = 293$ K, Equation 13.10 becomes

$$\frac{L_M}{D} = 18.5\left(\frac{\rho_s}{\rho_\infty}\right)^{1/2} r \tag{13.11}$$

In this case the nondimensional flame height in the momentum regime depends in a simple manner on the mass stoichiometric ratio and the source gas density at discharge.

It should be pointed out that the transition to the momentum regime, $R_M = 0.1$, and the flame height in the momentum regime, Equations 13.10 and 13.11, differ significantly from previously proposed relations, as discussed in Heskestad [53].

EXAMPLE 4 Calculate the normalized height of a hydrogen jet flame from a 5-mm-diameter nozzle connected to a reservoir (tank, pipe, etc.) at ambient temperature of 293 K and a pressure of either (a) 150 kPa or (b) 300 kPa.

SOLUTION

(a) The ratio of ambient pressure (101 kPa) to the reservoir pressure (150 kPa) is 0.673, corresponding to subsonic discharge (sonic discharge occurs at a pressure ratio of 0.528, as for air). The mass flow of hydrogen from the nozzle is calculated with the aid of a compressible flow formula (e.g., Shapiro [54]) as 1.74 g/s, using a ratio of specific heats $k = 1.4$ (as for air). Based on a heat of combustion of 120,000 kJ/kg, the heat release rate is $\dot{Q} = 209$ kW. The source

gas density in the discharge stream, ρ_s, is calculated from the source gas density at ambient temperature and pressure, $\rho_{s\infty}$, as follows:
$\rho_s = (\rho_s/\rho_{s\infty})\rho_{s\infty} = (\rho_s/\rho_{s0})(\rho_{s0}/\rho_{s\infty})\rho_{s\infty}$, where ρ_{s0} is the source gas density in the gas reservoir. The density ratios can be expressed in terms of pressure ratios with the result $\rho_s = (p_s/p_{s0})^{1/k}(p_{s0}/p^{\infty})\rho_{s\infty}$, where p_s is the pressure in the discharge stream (ambient pressure for subsonic discharge) and p_{s0} is the pressure of the gas reservoir. Finally, we obtain $\rho_s = (101/150)^{1/1.4}$ (150/101) $\rho_{s\infty} = 1.12\times\ 0.083 = 0.093$ kg/m^3, where 0.083 (kg/m^3) is the density of hydrogen at ambient temperature and pressure. Now the momentum parameter can be calculated from Equation 13.9, taking $\Delta T_L = 500$ K, $H_c = 120{,}000$ kJ/kg, $r = 34.3$, and $\rho_s = 0.093$ kg/m^3, yielding $R_M = 1.16 \times 10^{-3}\ N^{2/5}$. The parameter N is calculated from Equation 13.4 with the result $N = 6.76 \times 10^6$, which results in $R_M = 0.62$ and places the flame in the momentum regime. The normalized flame height is calculated from Equation 13.10 as $L_M/D = 185$. NOTE: The calculated height may include the visual-averaging bias toward somewhat higher than actual values built into the database.

(b) The ratio of ambient pressure (101 kPa) to reservoir pressure (300 kPa) is 0.337, corresponding to sonic, or choked, discharge. The mass flow of hydrogen from the nozzle is calculated with the aid of an appropriate compressible flow formula for choked discharge (e.g., Shapiro [54]) as 3.65 g/s, corresponding to a heat release rate of 436 kW. The source gas density for choked flow is calculated as in (a), except the ratio (p_s/p_{s0}) is set equal to the value for a Mach number of unity, 0.528; that is, $\rho_s = 0.528^{1/k}(\rho_{s0}/\rho_{s\infty}) \times 0.083 = 0.634(300/101) \times 0.083 = 0.156$ kg/m^3. The parameter N is calculated from Equation 13.4 as 294×10^7 and the momentum parameter from Equation 13.9 as $R_M = 6.93 \times 10^{-4}\ N^{2/5} = 0.67$, indicating the flame is in the momentum regime as in (a). The normalized flame height is calculated from Equation 13.10 as $L_M/D = 239$, somewhat higher than for the lower discharge pressure in (a).

Note If the nozzles of cases (a) and (b) are sharp-edged holes or openings instead, it is recommended that the source diameter be multiplied by (discharge coefficient)$^{1/2}$; see, for example, Shapiro [54] for values of the discharge coefficient of sharp-edged orifices in compressible flow (varying from 0.60 near incompressible flow conditions to 0.77 for choked flow).

Plume Temperatures and Velocities

The first plume theories (Schmidt [55], Rouse et al. [56], Morton et al. [57]) assumed the following:

1. Turbulent flow
2. Point source of buoyancy
3. Variations of density in field of motion small compared to ambient density
4. Air entrainment velocity at the edge of the plume proportional to the local vertical plume velocity
5. Profiles of vertical velocity and buoyancy force in horizontal sections of similar form at all heights

Morton et al. [57] developed an integral formulation on the further assumption that the profiles are uniform "top hat" profiles. The mean motion is then governed by the following three conservation equations for continuity, momentum, and buoyancy:

$$\text{Continuity}: \quad \frac{d}{dz}\left(b^2 u\right) = 2\alpha b u \tag{13.12}$$

$$\text{Momentum}: \quad \frac{d}{dz}\left(b^2 u^2\right) = b^2 g \frac{\rho_\infty - \rho}{\rho_\infty} \tag{13.13}$$

$$\text{Buoyancy}: \quad \frac{d}{dz}\left(b^2 u g \frac{\rho_\infty - \rho}{\rho_\infty}\right) = 0 \tag{13.14}$$

In these equations, z is the elevation above the point source of buoyancy; b is the radius to the edge of the plume; u is the vertical velocity in the plume; α is the entrainment coefficient (the proportionality constant relating the inflow velocity due to entrainment at the edge of the plume to u); ρ is the density in the plume; and ρ_∞ is the ambient density. Equation 13.14 can be integrated immediately to

$$b^2 u g \frac{\rho_\infty - \rho}{\rho_\infty} = B = \text{constant} \tag{13.15}$$

Here, B is the buoyancy flux in the plume which remains constant at all heights. The flux can be related to the convective heat in the plume, $\dot{Q}_c$, by noting

$$\begin{aligned} \dot{Q}_c &= \rho u \pi b^2 c_p (T - T_\infty) \\ &= \pi u b^2 c_p (\rho_\infty - \rho) T_\infty \end{aligned} \tag{13.16}$$

where the ideal gas law has been used. In this equation, T is the plume temperature and T_∞ is the ambient temperature. Combining Equations 13.15 and 13.16 gives

$$B = g\left(\pi c_p T_\infty \rho_\infty\right)^{-1} \dot{Q}_c \tag{13.17}$$

Solutions to Equations 13.12, 13.13, and 13.15 can be determined [57] in the form (expressing B in terms of $\dot{Q}_c$ using Equation 13.17)

$$b = \frac{6\alpha}{5} z \tag{13.18}$$

$$u = \frac{5}{6}\left(\frac{9}{10\pi\alpha^2}\right)^{1/3} g^{1/3} \left(c_p \rho_\infty T_\infty\right)^{-1/3} \dot{Q}_c{}^{1/3} z^{-1/3} \tag{13.19}$$

$$\frac{\Delta\rho}{\rho_\infty} = \frac{5}{6}\left(\frac{9\pi^2\alpha^4}{10}\right)^{-1/3} g^{-1/3} \left(c_p \rho_\infty T_\infty\right)^{-2/3} \dot{Q}_c{}^{2/3} z^{-5/3} \tag{13.20}$$

Equations 13.18, 13.19, and 13.20 are the weak plume (small density deficiency) relations for point sources. To account for area sources, a virtual source location or virtual origin, z_0, is introduced [57, 58] and z in Equations 13.18, 13.19, and 13.20 is replaced by $z - z_0$. In addition, to accommodate large density deficiencies as are present in fire plumes, Morton's extension of the weak-plume theory [59] leads to the result that $\Delta\rho/\rho_\infty$ in Equation 13.20 should be replaced by $\Delta\rho/\rho$ ($= \Delta T/T_\infty$ using the ideal gas law). Also, Equation 13.18 for growth in plume radius should incorporate the additional factor $(\rho_\infty/\rho)^{1/2}\left[= (T/T_\infty)^{1/2}\right.$ using the ideal gas law] on the right side of the equation. Relaxing the assumption that the flow profiles are uniform renders the numerical coefficients in the resulting equations in doubt.

Measurements in fire plumes above the flames have to a large extent supported the theory. The plume radius and centerline values of mean excess temperature and mean velocity have been found [11] to obey the following relations:

$$b_{\Delta T} = 0.12\left(\frac{T_0}{T_\infty}\right)^{1/2} (z - z_0) \tag{13.21}$$

$$\Delta T_0 = 9.1\left(\frac{T_\infty}{g c_\rho^2 \rho_\infty^2}\right)^{1/3} \dot{Q}_c^{2/3} (z - z_0)^{-5/3} \tag{13.22}$$

$$u_0 = 3.4\left(\frac{g}{c_p \rho_\infty T_\infty}\right)^{1/3} \dot{Q}_c^{1/3} (z - z_0)^{-1/3} \tag{13.23}$$

Here, $b_{\Delta T}$ is the plume radius to the point where the temperature rise has declined to $0.5\Delta T_0$; T_0 is the centerline temperature, $\dot{Q}_c$ is the convective heat release rate, z is the elevation above the fire source, and z_0 is the elevation of the virtual origin above the fire source.[2] (If z_0 is negative, the virtual origin lies below the top of the fire source).

The virtual origin is the equivalent point source height of a finite area fire. This origin is

[2] For normal atmospheric conditions ($T_\infty = 293$ K, $g = 9.81$ m/s^2, $c_p = 1.00$ kJ/kg K, $\rho_\infty = 1.2$ kg/m^3), the factor $9.1\left[T_\infty/\left(\left(g c_p^2 p_\infty^2\right)\right]^{1/3}\right.$ has the numerical value 25.0 K m$^{5/3}$ kW$^{-2/3}$, and the factor $3.4[g/(c_p \rho_\infty T_\infty)]^{1/3}$ has the numerical value 1.03 m$^{4/3}$ s^{-1} kW$^{-1/3}$.

usually located near the fuel surface for pool fires and may be assumed coincident with the fuel surface when the plume flow is predicted at high elevations. Near the fire source, however, it is important to know the location of the virtual origin for accurate predictions. Calculation of the virtual origin is discussed in the following section for both pool fires and three-dimensional storage arrays.

Equations 13.21, 13.22, and 13.23 are known as the *strong plume relations*. The numerical coefficients for the relations have been determined from data sets for which the locations of the virtual origin, z_0, have been established and the convective heat release rates, $\dot{Q}_c$, are known [15, 60].

We may compare the experimentally derived numerical coefficients in Equations 13.21, 13.22, and 13.23 to the theoretical coefficients indicated in Equations 13.18, 13.19, and 13.20, which are based on the integral theory of Morton et al. [57] for weak plumes, point sources, and top hat profiles. Forcing equality between the predictions of Equations 13.22 and 13.20 (interpreting $\Delta\rho/\rho_\infty$ as $\Delta T/T_\infty$), we obtain a value for the entrainment coefficient of $\alpha = 0.0964$. With this value for α, the theoretical coefficient for centerline velocity in Equation 13.19 becomes 2.61, compared to the experimental value 3.4 in Equation 13.23. The theoretical coefficient for plume radius in Equation 13.18 becomes 0.116, compared to the experimental value 0.12 in Equation 13.21. There is good consistency between the theoretical and experimental coefficients. However, the theoretical expression for mass flow rate in a weak plume, generated from the product $\rho_\infty u(\pi b^2)$ (using Equations 13.18 and 13.19) and the value for α above, produces a numerical coefficient that is only 56 % of the coefficient based on experiments (see discussion of Equation 13.40 later in the chapter).

In addition to the temperature radius of a plume, $b_{\Delta T}$, a velocity radius, b_u, can also be defined. The velocity radius is the plume radius to the point where the gas velocity has declined to 0.5 u_0. The most reliable measurements [60] indicate that b_u is perhaps 10 % larger than $b_{\Delta T}$. Other measurements indicate ratios $b_u/b_{\Delta T}$ of 0.86 [56], 1.00 [61], 1.08 and 1.24 [62], 1.31 [16], 1.05 [12], and 1.5 [13]. The widely differing results can probably be attributed to the difficulty of positioning the measuring probes accurately with respect to the plume centerline and to different, intrinsic errors associated with the diverse types of anemometers used (pitot tube, bidirectional flow probe, hot wire, vane anemometer, cross-correlation techniques, laser Doppler anemometer).

Often profiles of temperature rise and velocity are represented as Gaussian in shape, although there is no theoretical foundation for this distribution.

$$\Delta T = \Delta T_0 \exp\left[-\left(\frac{R}{\sigma_{\Delta T}}\right)^2\right] \tag{13.24}$$

$$u = u_0 \exp\left[-\left(\frac{R}{\sigma_u}\right)^2\right] \tag{13.25}$$

Here, ΔT and u are the local values, at the radius, R, in the plume of temperature rise and gas velocity. The quantities $\sigma_{\Delta T}$ and σ_u are measures of the plume width, corresponding to the radii where local values of temperature rise and velocity are $e^{-1} = 0.368$ multiplied by the centerline values. For Gaussian profiles, the plume radii $\sigma_{\Delta T}$ and σ_u are 1.201 multiplied by the plume radii, $b_{\Delta T}$ and b_u, discussed previously.

Equations 13.21, 13.22, and 13.23 cease to be valid at and below the mean flame height. However, it is possible to represent ΔT_0 such that a general plot of experimental temperature variations is produced throughout the length of the plume, including the flames. The method is based on the observation that $\dot{Q}_c^{2/3}(z - z_0)^{-5/3}$ in Equation 13.22 can be written as $\left[(z - z_0)/\dot{Q}_c^{2/5}\right]^{-5/3}$. This result suggests plotting ΔT_0 versus $(z - z_0)/\dot{Q}_c^{2/5}$. Figure 13.5 shows the result in logarithmic coordinates for normal atmospheric conditions. For values of the abscissa greater than 0.15–0.20 (m/kW$^{2/5}$), the centerline temperature rise falls off with the $-\frac{5}{3}$ power of the abscissa, in accordance with the

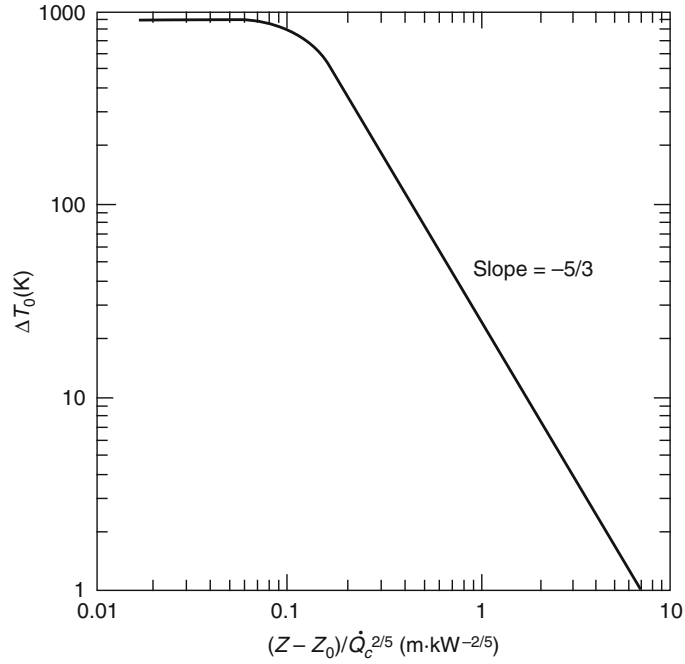

Fig. 13.5 Temperature rise on the plume centerline of pool fires for normal atmospheric conditions [11] in a form attributable to McCaffrey [12], and Kung and Stavrianidis [15]

plume law for temperature (Equation 13.22). Abscissa values in the 0.15–0.20 range correspond to the mean flame height (see Equation 13.37); an associated temperature rise of about 500 K is indicated in Fig. 13.5. At smaller abscissa values, the experimentally observed temperature rise increases more slowly, approaching a value deep in the flame of approximately $\Delta T_0 = 900$ K. When closer to the fuel surface than represented in Fig. 13.5, the temperatures on the plume axis tend to decrease again [12, 13, 16].

Figure 13.5 is based on the pool fire data of Kung and Stavrianidis [15] of methanol, heptane, a silicone transformer fluid, and a hydrocarbon transformer fluid, for the three pool diameters 1.22, 1.74 and 2.44 m and using 1-mm diameter bare bead thermocouples. For the fires that produced the highest values of temperature rise in the deep-flame region, near 900 K, which include all the fluids except the silicone fluid, the data from the various combinations of fluid and pool diameter were in good agreement.

The plume law for velocity, Equation 13.23, may be combined with the plume law for temperature, Equation 13.22, to produce the following useful nondimensional parameter: [14]

$$\xi = \left[\frac{T_\infty^{2/5}\left(c_p\rho_\infty\right)^{1/5}}{g^{2/5}}\right]\frac{u_0}{\left(\Delta T_0\dot{Q}_c\right)^{1/5}} \qquad (13.26)$$

In the plume region where Equations 13.22 and 13.23 are valid, their numerical coefficients correspond to a constant value $\xi = 2.2$. This value has been confirmed for a number of test fires [14], at heights as low as the mean flame height and even somewhat lower. Equation 13.26 with $\xi = 2.2$ is a useful relation for determining the maximum velocity in the plume, which occurs slightly below the mean flame height where the temperature rise may be taken at approximately $\Delta T_0 = 650$ K. For normal atmospheric conditions and the value $\xi = 2.2$, Equation 13.26 becomes

$$\frac{u_0}{\left(\Delta T_0\dot{Q}_c\right)^{1/5}} = 0.54 \qquad (13.27)$$

The maximum velocity just under the mean flame height, u_{0m}, is obtained by setting $\Delta T_0 = 650$ K

$$u_{0m} = 1.97\dot{Q}_c^{1/5} \tag{13.28}$$

Fires with low flame height-to-diameter ratios have not been investigated extensively and may require special consideration. For one particular fire with very low flame height [15] in which a proprietary silicone transformer fluid was burned in a 2.44-m-diameter pool, a flame height ratio of $L/D = 0.14$ was measured[3] at a convective heat release rate of $\dot{Q}_c = 327$ kW. Using the results in the next section, the virtual origin is calculated at $z_0 = -1.5$ m, assuming $\dot{Q}_c/\dot{Q} = 0.7$. With respect to the abscissa in Fig. 13.5, the lowest possible value is $-z_0/\dot{Q}_c^{2/5}$ corresponding to the fuel surface, $z = 0$. For the present case, $-z_0/\dot{Q}_c^{2/5} = 1.5/327^{2/5} = 0.15\left(\text{m kW}^{-2/5}\right)$. At this abscissa value, a centerline temperature rise of 580 K is indicated in Fig. 13.5. From the experiment [15], a near surface ΔT_0 of 440 K can be determined by slight extrapolation, fairly close to the prediction from Fig. 13.5. Fires with very low flame height-to-diameter ratios may generally be expected to produce lower maximum mean temperatures than other fires. However, it is not yet clear whether the type of prediction attempted here for a particular low L/D fire is generally valid.

There is also uncertainty associated with assuming that ξ in Equation 13.26 remains completely constant down to the flame level in low L/D fires. It may be found that ξ still remains approximately constant down to the height where the maximum gas velocity occurs, although this maximum will probably occur above the flames. The associated temperatures at this height cannot as yet be predicted. Consequently, the relation in Equation 13.28 becomes somewhat uncertain as L/D decreases (ΔT_0 is overestimated, resulting in u_{0m} being overestimated, although the effect is probably not very large because of the slow, ⅕th power dependence on ΔT_0).

The turbulence intensities in a fire plume are quite high. On the axis, George et al. [60] report an intensity of temperature fluctuations of approximately $T'/\Delta T_0 = 0.38$, where T' is the root mean square (rms) temperature fluctuation. Centerline values of the intensity of axial velocity fluctuations were measured near $u'/u_0 = 0.27$ by George et al. [60] and near $u'/u_0 = 0.33$ by Gengembre et al. [16], where u' is the rms velocity fluctuation in the axial direction.

EXAMPLE 5 Example *1* concerned a 1.5-m-diameter methyl alcohol fire burning under normal atmospheric conditions, generating $\dot{Q} = 884$ kW with a calculated mean flame height of 1.83 m. For an elevation of 5 m and given a virtual origin $z_0 = -0.3$ m (from Example 8), calculate the temperature radius, $b_{\Delta T}$, as well as the centerline value of temperature rise, ΔT_0, and gas velocity, u_0. Also calculate the maximum gas velocity in the flame.

SOLUTION Assume[4] $\dot{Q}_c = 0.8\ \dot{Q}$ and first calculate the temperature rise, using Equation 13.22 and properties for normal atmospheric conditions ($T_\infty = 293$ K, $g = 9.81$ m/s^2, $c_p = 1.00$ kJ/kg K, $\rho_\infty = 1.20$ kg/m^3)

$$\Delta T_0 = 9.1\left(\frac{293}{9.81 \cdot 1.00^2 \cdot 1.20^2}\right)^{1/3}(0.8 \cdot 884)^{2/3} \times (5+0.3)^{-5/3} = 123\,\text{K}$$

The temperature radius can now be calculated from Equation 13.21 as

$$b_{\Delta T} = 0.12\left(\frac{123+293}{293}\right)^{1/2}(5+0.3) = 0.76\ \text{m}$$

[3] A ratio $L/D = 0.02$ can be calculated from Equation 13.7 assuming $H_c/r = 3470$ kJ/kg, an average for silicone oils from values reported by Tewarson [63] and assuming a convective heat fraction $\dot{Q}_c/\dot{Q} = 0.7$. If a value of H_c/r near the bottom of the reported range [63] is selected, 3230 kJ/kg, the observed value $L/D = 0.14$ is reproduced; slight changes in the assumed convective fraction will also reproduce the measured value.

[4] Without specific knowledge, $\dot{Q}_c/\dot{Q}$ may usually be assumed at 0.7. However, methyl alcohol produces a fire of low luminosity and radiation, for which $\dot{Q}_c/\dot{Q} = 0.8$ is a good estimate.

The velocity is calculated from Equation 13.23 as

$$u_0 = 3.4\left(\frac{9.81}{1.00 \cdot 1.20 \cdot 293}\right)^{1/3}(0.8 \cdot 884)^{1/3} \times (5 + 0.3)^{-1/3} = 5.3 \text{ m/s}$$

Instead of Equation 13.23, the velocity can also be calculated from Equation 13.26 in this case, since ΔT_0 is already known. Actually, because normal ambient conditions prevail, Equation 13.27 can be used as follows:

$$u_0 = 0.54(123 \cdot 0.8 \cdot 884)^{1/5} = 5.3 \text{ m/s}$$

Finally, the maximum velocity in the flame is given by Equation 13.28 as

$$u_{0m} = 1.97(0.8 \cdot 884)^{1/5} = 7.3 \text{ m/s}$$

EXAMPLE 6 Recalculate the quantities called for in Example 5 using ambient conditions representative of Denver, Colorado, on a hot day: 630 mmHg pressure and 310 K temperature. (See Note on heat release rate for EXAMPLE 2.)

SOLUTION Changed ambient variables entering the equations include $T_\infty = 310$ K and $\rho_\infty = 0.78$ kg/m^3. From Equation 13.22, the new temperature rise is

$$\Delta T_0 = 167 \text{ K} (\text{versus } 123 \text{ K in Example 5})$$

The new velocity from Equation 13.23 is

$$u_0 = 6.0 \text{ m/s} (\text{versus } 5.3 \text{ m/s})$$

For the new ambient conditions, the relation analogous to Equation 13.28 is calculated as

$$u_{0m} = 2.10\dot{Q}_c^{1/5}$$

from which the new maximum velocity in the flame is

$$u_{0m} = 7.8 \text{ m/s} \text{ (versus } 7.3 \text{ m/s)}$$

Plumes in Temperature-Stratified Ambients

When a buoyant, turbulent plume rises, it cools by entrainment of ambient air. If the ambient air increases in temperature with height, which is normal in buildings, and the fire source is weak, the temperature difference between the plume and the ambient, which gives the plume buoyancy, may vanish and actually reverse in sign. Eventually the plume ceases to rise.

The maximum height achieved by plumes in temperature-stratified space has been given by Heskestad [64], based on pioneering theoretical and experimental work by Morton et al. [57]

$$z_m = 3.79\left[\frac{T_{a1}}{g\left(\rho_{a1}c_p\right)^2}\right]^{1/8}\dot{Q}_c^{1/4}\left(\frac{dT_a}{dz}\right)^{-3/8} \tag{13.29}$$

Here, dT_a/dz is the ambient temperature gradient, T_{a1} and ρ_{a1} are the ambient temperature and density, respectively, at the level of the fire source, and the constant 3.79 traces to experiments using dyed light liquid injected into a density stratified salt solution [57]. Other results are presented in Fig. 13.6, which shows the ratio on the plume centerline of stratified value versus unstratified value for various plume variables: temperature rise relative to the pre-existing value at each level (curve A), axial velocity (curve B), plume radius (curve C), and volume concentration of a combustion species (curve D). The ratios are plotted against the fraction of maximum elevation achieved by the plume, z/z_m. By definition, the stratified velocity (B) decreases to zero at $z/z_m = 1$. The stratified temperature rise (A) becomes negative below the maximum reach. The stratified plume radius (C) grows rapidly in approach to the maximum plume reach. However, there is little effect of the stratification on the centerline variation of concentration of a combustion species.

Fire experiments in temperature stratified space [66] have largely supported the validity of Fig. 13.6 for temperature rise (A) and volume concentrations (D), except that the experimental values needed an incremental height, roughly equal to 25 % of the theoretical plume reach, to return to zero.

The maximum plume reach can be interpreted in terms of a critical ambient temperature rise

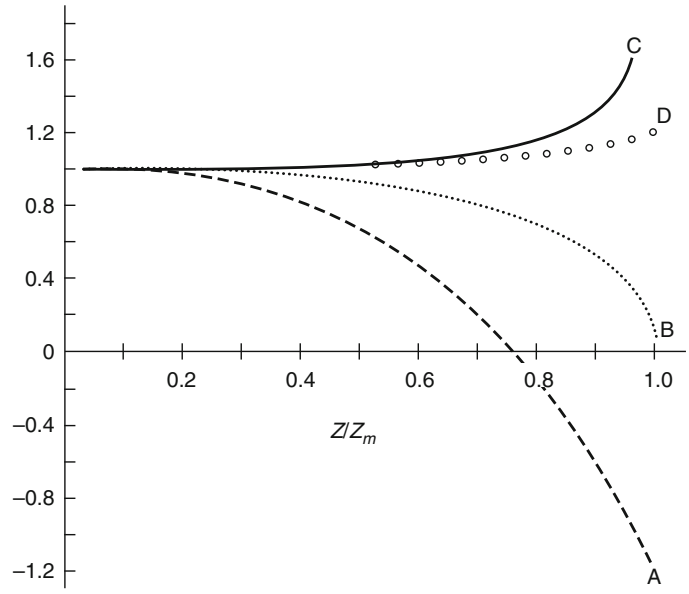

Fig. 13.6 Theoretical behavior of centerline plume variables in linearly temperature-stratified ambients. From Heskestad [64, 65], traceable to Morton et al. [57] *Curve A*: ratio of temperature rises (stratified versus unstratified). *Curve B*: ratio of axial velocities. *Curve C*: ratio of plume radii. *Curve D*: ratio of volumetric species concentrations

from the source level to an elevated observation plane, just strong enough to prevent plume fluid from penetrating the plane. Experiments [66] show that the critical ambient temperature rise for a linear profile is *7.4 times the centerline temperature rise at the level of the observation plane that results from a fire source in a uniform environment*. Furthermore, the critical temperature rise is surprisingly insensitive to the shape of the stratification profile. For a profile where one-half of the ambient temperature rise to the observation plane occurred higher than 75 % of the elevation of the observation plane above the source, the critical ambient temperature rise was only 12 % greater than that for the linear profile.

Effects of ambient temperature stratifications have been considered anew by Watanabe and Tanaka [67]. They developed their own model and tested it against experiments using a smoldering fire source.

EXAMPLE 7 Consider a 20-m-high atrium where the temperature rise, floor to ceiling, is 5 K. What heat release rate is required of a floor-level fire to drive the plume to the ceiling? What would be the effect of doubling the ceiling height?

SOLUTION The temperature rise in unstratified space is required as a reference and is calculated from Equation 13.22, taking $z_0 = 0$ for simplicity since deviations of the virtual origin from the level of the fire can be assumed to be inconsequential in this case. We have

$$\Delta T_0 = 25.0 \dot{Q}_c^{2/3} z^{-5/3} \tag{13.30}$$

The temperature rise of the stratification, 5 K, is 7.4 times the value of ΔT_0 for this associated unstratified-space fire, which will just drive the plume to the ceiling. Solving Equation 13.30 for $\dot{Q}_c$, setting $\Delta T_0 = 5/7.4$ K and $z = 20$ m, we get $\dot{Q}_c = 7.9$ kW. Assuming a ratio of 0.7 for convective in ratio to the total heat release rate, the latter is $\dot{Q} = 11.4$ kW. If the ceiling height is doubled to 40 m, the new result is $\dot{Q} = 64$ kW.

Virtual Origin

Pool Fires As pointed out earlier in this chapter, knowledge of the virtual origin of fire plumes is important for predicting the near-source plume behavior. The virtual origin is a point source

from which the plume above the flames appears to originate.

The virtual origin of a test fire is most conveniently determined from temperature data above the flames along the plume axis. According to Equation 13.22, a plot of $\Delta T_0^{-3/5}$ versus z should produce a straight line that intercepts the z-axis at z_0. Despite this apparent simplicity of obtaining z_0, the task is very difficult in practice. Slight inaccuracies in the determinations of centerline temperatures have large effects on the intercept, z_0; such inaccuracies may be associated with off-axis placement of sensors, radiation-induced errors in the temperature signal, or inadequate averaging of the signal.

Data obtained in this manner on the virtual origin for pool fires varying in diameter from 0.16 to 2.4 m [12, 14, 15], were examined for consistency with a theoretical model by Heskestad [68]. The model relied heavily on the flame-height correlation represented by Equation 13.3 and led to the prediction

$$\frac{z_0}{D} = -1.02 + F\frac{\dot{Q}^{2/5}}{D} \tag{13.31}$$

where F is a rather complex dimensional function of environmental variables c_p, T_∞, ρ_∞, g; H_c/r for the combustible, the fraction of the total heat release carried away by convection, and the mean centerline temperature at the mean flame height, T_L. It appeared that F could be considered a constant for wide variations in ambient temperature and pressure but might be affected by wide swings in the fuel variables, H_c/r, and convective fraction. The available data did not reflect any sensitivity to fuel identity within their scatter and led to the determination $F = 0.083$ m kW$^{-2/5}$, with Equation 13.31 becoming

$$\frac{z_0}{D} = -1.02 + 0.083\frac{\dot{Q}^{2/5}}{D} \quad (\dot{Q} \text{ in kW},\ D \text{ in m}) \tag{13.32}$$

Later, Hasemi and Tokunaga [69] analyzed their temperature measurements in plumes from gas burners of diameters in the 0.2–0.5 m range and established alternative correlations for the virtual origin. In terms of the nondimensional parameter $\dot{Q}^*$ defined in Equation 13.1, their correlations are

$$\begin{aligned} \frac{z_0}{D} &= 2.4\left(\dot{Q}^{*2/5} - 1\right) && \dot{Q}^* \geq 1.0 \\ \frac{z_0}{D} &= 2.4\left(\dot{Q}^{*2/3} - \dot{Q}^{*2/5}\right) && \dot{Q}^* < 1.0 \end{aligned} \tag{13.33}$$

For normal ambient conditions, these correlations can be written in terms of the variable $\dot{Q}^{2/5}/\mathrm{D}$ (cf. Equation 13.32) as

$$\begin{aligned} \frac{z_0}{D} &= -2.4 + 0.145\frac{\dot{Q}^{2/5}}{D} && \frac{\dot{Q}^{2/5}}{D} \geq 16.5 \\ \frac{z_0}{D} &= 0.0224\left(\frac{\dot{Q}^{2/5}}{D}\right)^{5/3} - 0.145\frac{\dot{Q}^{2/5}}{D} && \frac{\dot{Q}^{2/5}}{D} < 16.5 \end{aligned} \tag{13.34}$$

Cetegen et al. [70] have proposed correlations for the virtual origin on the basis of their air entrainment measurements in fire plumes and attempts to apply entrainment theory for a point source to the laboratory fires. Their experiments involved gas burners (natural gas) with diameters of 0.10, 0.19, 0.30, and 0.50 m. The experiments were performed with and without a floor mounted flush with the upper surface of the burners located some distance above the floor of the laboratory. Their correlations for the virtual origin are

$$\begin{aligned} \frac{z_0}{D} &= c + 1.09\dot{Q}^{*2/5} && \dot{Q}^* > 1 \\ \frac{z_0}{D} &= c + 1.09\dot{Q}^{*2/3} && \dot{Q}^* \leq 1 \end{aligned} \tag{13.35}$$

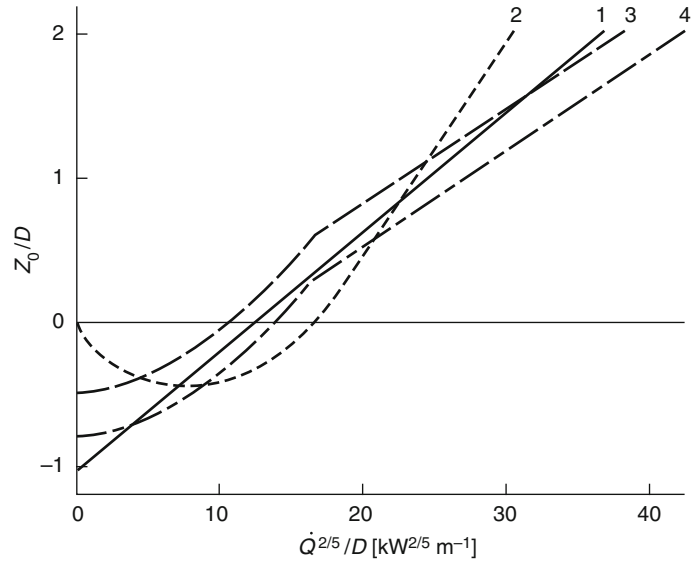

Fig. 13.7 Correlations for the virtual origin of pool fires. *Curve 1*: Equation 13.32; *Curve 2*: Equation 13.34; *Curve 3*: Equation 13.36 with floor; *Curve 4*: Equation 13.36 without floor

where $\dot{Q}^*$ has been defined by Equation 13.1, and where $c = -0.50$ with a flush floor around the burners and $c = -0.80$ without a flush floor. Using Equation 13.1, Equation 13.35 can be written in terms of $\dot{Q}^{2/5}/D$ yielding

$$\begin{aligned} \frac{z_0}{D} &= c + 0.0659\frac{\dot{Q}^{2/5}}{D} \qquad & \frac{\dot{Q}^{2/5}}{D} &> 16.5 \\ \frac{z_0}{D} &= c + 0.01015\left(\frac{\dot{Q}^{2/5}}{D}\right)^{5/3} \qquad & \frac{\dot{Q}^{2/5}}{D} &\le 16.5 \end{aligned} \tag{13.36}$$

where $c = -0.50$ and $c = -0.80$ with and without a flush floor, respectively.

Figure 13.7 is a composite plot of the various correlations for the virtual origin of pool fires, plotted as z_0/D versus $\dot{Q}^{2/5}/D$. Despite the diverse approaches, the overall correlations are surprisingly similar. Precise measurements are not yet available to clearly identify an optimal correlation. In the meantime, curve 1 in Fig. 13.7 (i.e., Equation 13.32) is recommended for its simplicity, clear foundation in theory [68], and central position among the other correlations.

Other Fire Types The original derivation of Equation 13.31 for pool fires [68] includes the following expression:

$$z_0 = L - 0.175\dot{Q}_c^{2/5} \qquad (L \text{ and } z_0 \text{ in m}; \dot{Q}_c \text{ in kW}) \tag{13.37}$$

In addition to representing pool fires, Equation 13.37 has also been verified to represent deep storage fires [42], allowing the location of the virtual origin to be calculated from knowledge of the mean flame height and the convective heat release rate. As discussed earlier, mean flame heights above the base of a fire in storages can be determined from Equation 13.3 when the flames extend above the storage, which implies that values of z_0 calculated refer to the distance above the base of the fire (usually the base of the storage). Equation 13.37 may also be assumed to be valid for turbulent jet fires.

EXAMPLE 8 Example *1* concerned a 1.5-m-diameter methyl alcohol fire generating $\dot{Q} = 884$ kW. Calculate the virtual origin.

SOLUTION In this example, $D = 1.5$ m. Direct substitution into Equation 13.32 gives

$$\frac{z_0}{D} = -1.02 + \frac{0.083(884)^{2/5}}{1.5} = -1.02 + 0.83 = -0.19$$

from which

$$z_0 = -0.19 \cdot 1.5 = -0.29 \text{ m}$$

This is the value for z_0 (rounded off) used in Example 5.

EXAMPLE 9 Negative values for z_0 are often calculated for low heat release fires and sufficiently large fire diameters, as in Example 8. Positive virtual origins are often found for high heat release fires. Substituting heptane for methyl alcohol in Example 8 (2500 kW/m^2 rather than 500 kW/m^2 measured for methyl alcohol) [17], calculate the new virtual origin.

SOLUTION The new heat release rate is

$$\dot{Q} = \frac{\pi 1.5^2}{4} 2500 = 4420 \text{ kW}$$

From Equation 13.32,

$$\frac{z_0}{D} = -1.02 + 0.083 \cdot \frac{4420^{2/5}}{1.5} = 0.57$$

from which

$$z_0 = 0.57 \cdot 1.5 = 0.85 \text{ m}$$

EXAMPLE 10 A 3-m-deep storage is known to produce a heat release rate per unit floor area of 4000 kW/m^2 when fully involved. At a stage of fire development in such a storage, a heat release rate of 1500 kW is reached. What is the location of the virtual origin?

SOLUTION First determine the flame height. Evaluate the effective fire diameter from $\pi D^2/4 = 1500/4000 = 0.375$ m^2, which gives $D = 0.69$ m. From Equation 13.8, calculate the flame height as 3.67 m (above base of storage), which is 0.67 m above the top of the storage. The height of the virtual origin above the base of the storage is calculated from Equation 13.37, assuming $\dot{Q}_c = 0.7\ \dot{Q} = 1050$ kW, yielding $z_0 = 3.67 - 0.175 \times 1050^{2/5} = 0.84$ m.

Entrainment

After ignition, the fire plume carries fire products diluted in entrained air to the ceiling. A layer of diluted fire products, or smoke, forms under the ceiling, which thickens and generally becomes hotter with time. The fire environment is intimately tied to the behavior of this layer, which, in turn, depends to a major extent on the mass flow rate of plume fluid into the layer. Consequently, it is important to be able to predict the mass flow rate that may occur in a fire plume.

The mass flow at a particular elevation in a fire plume is almost completely attributable to air entrained by the plume at lower elevations. The mass flow contributed by the fire source itself is insignificant in comparison.

For a weak plume, the mass flow rate at a cross section can be written

$$\dot{m}_{\text{ent}} = E \rho_\infty u_0 b_u^2 \tag{13.38}$$

where E is a nondimensional constant of proportionality. With the aid of Equation 13.23 and the equivalent of Equation 13.21 written for b_u (setting $T_0/T_\infty = 1$ because of the weak plume assumption), Equation 13.38 becomes

$$\dot{m}_{\text{ent}} = E \left(\frac{g \rho_\infty^2}{c_p T_\infty} \right)^{1/3} \dot{Q}_c^{1/3} (z - z_0)^{5/3} \tag{13.39}$$

Early measurements by Yih [71] indicated a value $E = 0.153$.

Cetegen et al. [70, 72] concluded from theoretical analysis that Equation 13.39 also applies to strongly buoyant plumes. From extensive entrained-flow measurements for natural gas burners of several diameters, these authors proposed a coefficient $E = 0.21$ based on the total

heat release rate, corresponding to $E = 0.24$ based on the convective heat release rate as in Equation 13.39 (assuming a convective fraction of 0.7). However, the plume flow rates at large heights were somewhat overpredicted and those at low heights, approaching the flames, were somewhat underpredicted.

Heskestad [73] reconsidered the entrainment problem for strong plumes, assuming self-preserving density deficiency profiles instead of self-preserving excess temperature profiles as traditionally assumed. This approach led to the following extension of Equation 13.39:

$$\dot{m}_{\text{ent}} = E\left(\frac{g\rho_\infty^2}{c_p T_\infty}\right)^{1/3} \dot{Q}_c^{1/3}(z - z_0)^{5/3} \cdot \left[1 + \frac{G\dot{Q}_c^{2/3}}{\left(g^{1/2} c_p \rho_\infty T_\infty\right)^{2/3}(z - z_o)^{5/3}}\right] \tag{13.40}$$

Equation 13.40, with $E = 0.196$ and $G = 2.9$, was found to represent the data of Cetegen et al. [70, 72] very well over the entire nonreacting plume for all their fire diameters, ranging from 0.10 to 0.50 m [73]. At large heights, the bracketed term involving G approaches unity, and at levels approaching the flame tip (Equation 13.3), this term approaches 1.5, approximately. Equation 13.40, with $E = 0.196$ and $G = 2.9$ is the recommended relation for calculating mass flow rates in plumes, at and above the mean flame height.

The entrained flow at the mean flame height, $\dot{m}_{\text{ent},L}$, follows from setting $z - z_0 = L - z_0$ in Equation 13.40 (with $E = 0.196$ and $G = 2.9$), taking L from Equation 13.3 and z_0 from Equation 13.31 (with substitution of full expression for F), with the result,

$$\dot{m}_{\text{ent},L} = 0.878\left[\left(\frac{T_L}{T_\infty}\right)^{5/6}\left(\frac{T_\infty}{\Delta T_L}\right) + 0.647\right]\frac{\dot{Q}_c}{c_p T_\infty} \tag{13.41}$$

The numerical values are linked to the experimental calibration coefficient for F (based on $F = 0.083$ m kW$^{-2/5}$ at normal atmospheric conditions as indicated under Equation 13.31) and taking $\Delta T_L = 500$ K. Interestingly, $\dot{m}_{\text{ent},L}$ is independent of the acceleration of gravity, g.

Mass flow rates in fire plumes at levels below the flame tip have been found to increase linearly with height for fire diameters of 0.3 m and greater [73], where the flames are substantially turbulent, from zero (essentially) at the fire base to the flame-tip value in Equation 13.41, that is,

$$\dot{m}_{\text{ent}} = \dot{m}_{\text{ent},L} z/L \tag{13.42}$$

Measurements in the flaming region for fire diameters *smaller* than 0.30 m do not show a linear variation of mass flow rate with height, including data by Cetegen et al. [70, 72] (fire diameters of 0.10 and 0.19 m) and Beyler [74] (0.19 and 0.13 m). (It is important to note, however, that all these data are consistent with an approach to the mass flow rate at the mean flame height given by Equation 13.41 [73].) Neither do the mass flow measurements in turbulent jet flames by Delichatsios and Orloff [75] show a linear variation with height (estimated values of N in range 50–6300 and momentum parameter R_M in range 0.0015–0.010); in fact, these measurements indicate a 5/2 power dependence, within the flames, of mass flow rate on height above the nozzle exit. As a guide to entrainment estimates in the flaming region for sources smaller than 0.30 m in diameter, it appears that a second power variation of mass flow rate with height is quite representative of the fire sources referred to above of diameters 0.13 and 0.10 m, in which case Equation 13.42 is replaced by

$$\dot{m}_{\text{ent}} = \dot{m}_{\text{ent},L}\left(\frac{z}{L}\right)^2 \tag{13.43}$$

The 0.19-m-diameter sources generated scattered results between the linear and second power variation [73]. Delichatsios [76] as well as Quintiere and Grove [77] have also analyzed mass flow rates in the flaming region.

We digress briefly on the appropriateness of relating entrainment behavior to the diameter of the fire source. The governing parameters for fire plumes from horizontal, circular sources have been considered so far to be the parameter N and the momentum parameter R_M. However,

for small fire sources it is common to see a laminar flame sheet preceding transition to turbulence around the rim of the fire source, and the degree to which such laminar regions and effects exist will depend on the flame Reynolds number. A flame Reynolds number can be formulated as $u_{0m}b_{um}/v_m$, where u_{0m} is the characteristic gas velocity in the flame, proportional to $\dot{Q}^{1/5}$ according to Equation 13.28; b_{um} is the associated characteristic flame radius, proportional to [78] $\dot{Q}^{2/5}$; and v_m is the kinematic viscosity evaluated at the mean maximum flame temperature, which can be considered constant. Hence, the flame Reynolds number can be considered proportional to $\dot{Q}^{3/5}$. Assuming the discharge momentum is not important (small R_M), the flame entrainment behavior should be a function of N and $\dot{Q}$. When the entrainment behavior is represented on $N, \dot{Q}$ coordinates for the various test fires indicated above, it is found that the fires with linear increase of mass flow rate with height in the flame plot above a line $\dot{Q} \propto N^{1/2}$, with some uncertainty about the precise level. With the aid of Equation 13.4 it becomes clear that this relation implies an equivalent limit line $D =$ *constant,* which justifies relating the entrainment behavior to the source diameter.

For normal atmospheric conditions Equations 13.40, 13.41, and 13.42 can be written as follows for the plume mass flow rate at various heights:

Above the mean flame height, L ($\dot{Q}_c$ in kW, z and z_0 in m)

$$\dot{m}_{\text{ent}}(\text{kg/s}) = 0.071\dot{Q}_c^{1/3}(z - z_0)^{5/3} \cdot \left[1 + 0.027\dot{Q}_c^{2/3}(z - z_0)^{-5/3}\right] \tag{13.44}$$

At the mean flame height, $L(\Delta T_L = 500\ \text{K})$

$$\dot{m}_{\text{ent},L}(\text{kg/s}) = 0.0058\dot{Q}_c(\text{kW}) \tag{13.45}$$

At and below the mean flame height, L, for fire source diameters of 0.3 m and greater

$$\dot{m}_{\text{ent}}(\text{kg/s}) = 0.0058\dot{Q}_c(\text{kW}) \cdot \frac{z}{L} \tag{13.46}$$

Under the prevailing assumptions, and the further assumption $\dot{Q}_c/\dot{Q} = 0.7$ and $H_c/r \approx 3100$ kJ/kg, Equation 13.45 implies that the mass flow at the flame tip is 13 times the mass stoichiometric requirement of the fuel [73].

Fires with very low flame height-to-diameter (L/D) ratios have not been investigated extensively. It is not clear to what L/D limit the entrained-flow relations presented here apply, but this limit is smaller than 0.9, the lowest L/D ratio associated with the data of Cetegen et al. [70, 72] For plume mass flows above the flames, there is no L/D limit for predictions at the higher elevations, but predictions of mass flows at levels just above the flames may begin to deteriorate before $L/D = 0.14$ is reached, as seems to be implied in the observations following Equation 13.28.

Further, mention should be made of a plume mass flow formula often used because of its simplicity, originally developed for the flaming region of large fires by Thomas et al. [79]

$$\dot{m}_{\text{ent}} = 0.096\left(g\rho_\infty\rho_{f\ell}\right)^{1/2}W_f z^{3/2} \tag{13.47}$$

Here $\rho_{f\ell}$ is the gas density in the flames and W_f is the fire perimeter. This formula has also been tested against mass flow data above the flames by Hinkley [80], who claims it is very satisfactory for heights up to 10 times the linear dimension (or diameter) of a fire, although there is little theoretical justification for its use above the flames. The following version of Equation 13.47 is often used [80] (based on normal atmospheric conditions and an assumed flame temperature):

$$\dot{m}_{\text{ent}}(\text{kg/s}) = 0.188W_f(m)z(m)^{3/2} \tag{13.48}$$

It is instructive to compare the predictions of Equations 13.44 and 13.48 for plume regions above the flames. In a number of comparisons for heat release rates in the range 1000–8000 kW, heat release rates per unit area in the range 250–1000 kW/m^2, and heights varying from the flame level to 128 m, the predictions of Equation 13.48 range from 0.64 to 1.38 times the predictions of Equation 13.44.

Cetegen et al. [70, 72], whose data have contributed most to the mass flow recommendations in this text, have carefully pointed out that their fire plumes were produced in as quiet an atmosphere as could be maintained in their laboratory. They report that small ambient disturbances could provide 20–50 % increases in the measured plume mass flows. Clearly, there is need for further research.

Grove and Quintiere [45] have developed new correlations for entrainment, including linear sources (not considered here). They state their near-field entrainment correlations show some differences with others.

EXAMPLE 11 Calculate plume mass flow rates for the methyl alcohol fire of Examples *1*, 5, and 8.

SOLUTION From Example *1*, $\dot{Q} = 884$ kW and $L = 1.83$ m; from Example 5, $\dot{Q}_c = 0.8\ \dot{Q} = 707$ kW; from Example 8, $z_0 = -0.29$ m. At the mean flame height, 1.83 m, the mass flow rate follows from Equation 13.45:

$$\dot{m}_{\text{ent},L} = 0.0058 \cdot 707 = 4.1 \text{ kg/s}$$

Mass flow rates in the flaming region are calculated using Equation 13.46 as

$$\dot{m}_{\text{ent}}(\text{kg/s}) = 4.1 \cdot \frac{z}{1.83} = 2.2\, z \text{ (m)}$$

Mass flow rates above the flames are obtained from Equation 13.44; for example, at a height of 3.66 m (twice the flame height)

$$\begin{aligned}\dot{m}_{\text{ent}} &= 0.071 \cdot 707^{1/3}(3.66 + 0.29)^{5/3} \\ &\quad \cdot \left[1 + 0.027 \cdot 707^{2/3}(3.66 + 0.29)^{-5/3}\right] \\ &= 6.24(1 + 0.22) \\ &= 7.6 \text{ kg/s}\end{aligned}$$

Illustration

In addition to the previous examples, it is instructive to work through a somewhat larger problem to illustrate handling of the equations and their limitations. Units used throughout this section are kW for heat release rate, m for length, s for time, K for temperature, and m/s for velocity.

The example can be used of a large building that will allow clear, uncontaminated air to exist around a particular growing fire for at least 10 min before smoke begins to recirculate into the region. Normal atmospheric conditions prevail. Wood pallets are stored in a large, continuous array on the floor to a height of 1.2 m. This array is ignited locally at an interior point, and the fire spreads in a circular pattern at constant radial speed (as predicted and observed for wood cribs) [81], such that the heat release rate grows with the second power of time as

$$\dot{Q}(kW) = 1000\left(\frac{t}{t_g}\right)^2 \tag{13.49}$$

Here, t is time and t_g is the so-called growth time. When t_g is 60 s, the fire grows through a magnitude of 1000 kW in 60 s. When t_g is 600 s, the fire grows through a magnitude of 1000 kW in 600 s, a much slower growth rate. In this illustration, it is assumed that the growth time is $t_g = 140$ s. It is also assumed that the fully involved pallet storage generates a total heat release rate of 2270 kW/m^2 of floor area. [17] The objective is to determine flame height as a function of time, as well as the variation of plume centerline temperature, plume centerline velocity, and plume width at an elevation of 5 m above the base of the fuel array where a structural member may cross and be heated by the plume.[5]

For the assumed growth time, $t_g = 140$ s, the variation of total heat release rate with time comes from Equation 13.49 as follows:

$$\dot{Q} = 5.10 \times 10^{-2} t^2 \tag{13.50}$$

The convective heat release rate is assumed at 70 % of the total heat release rate as

[5] In addition to convective heating, which depends on gas temperature and velocity, radiative heating would also be important in such cases and might even dominate over convective heating if the structure is immersed in flames.

$$\dot{Q}_c = 3.57 \times 10^{-2} t^2 \tag{13.51}$$

The instantaneous fire diameter, D, is determined as follows. Since the heat release rate per unit floor area is 2270 kW/m^2,

$$\dot{Q} = 2270 \frac{\pi D^2}{4} \tag{13.52}$$

Upon eliminating $\dot{Q}$ between Equations 13.50 and 13.52, the following can be obtained:

$$D = 5.35 \times 10^{-3} t \tag{13.53}$$

First, the behavior of flame height may be calculated using Equation 13.8. Substitution of Equations 13.50 and 13.53 into Equation 13.8 gives the following relation of flame height as a function of time:

$$L = -5.46 \times 10^{-3} t + 7.15 \times 10^{-2} t^{4/5} \tag{13.54}$$

This relation is plotted in Fig. 13.8 for the 10-min (600-s) fire interval and is labeled L.

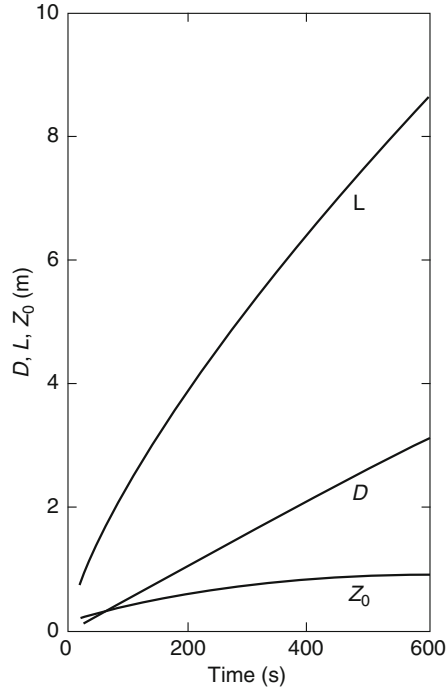

Fig. 13.8 Growing fire illustration: fire diameter, D, flame height, L, and virtual origin, z_0

The fire diameter, D, is also plotted in Fig. 13.8, based on Equation 13.53.

The virtual origin, z_0, is determined from Equation 13.32, with substitutions for $\dot{Q}$ from Equation 13.50 and for D from Equation 13.53

$$z_0 = -5.46 \times 10^{-3} t + 2.52 \times 10^{-2} t^{4/5} \tag{13.55}$$

The curve labeled z_0 in Fig. 13.8 represents the virtual origin according to Equation 13.55. It is seen that z_0 nearly levels off in the time interval plotted in the figure; actually, z_0 begins to decrease again at somewhat larger times.

With this foundation, there is sufficient information to calculate gas temperatures, velocities, and plume widths at the 5 m height above the base of the fuel array.

The temperature rise on the plume centerline at the selected height is determined from Equation 13.22 by substituting $z = 5$ (m); z_0 from Equation 13.55; $\dot{Q}_c$ from Equation 13.51; and values of T_∞, g, c_p, and ρ_∞ for the normal atmosphere, yielding

$$\Delta T_0 = \frac{2.71 t^{4/3}}{\left(5 + 5.46 \times 10^{-3} t - 2.52 \times 10^{-2} t^{4/5}\right)^{5/3}} \tag{13.56}$$

This relation is valid up to the time that a temperature rise associated with the flame tip, $\Delta T_0 = 500$ K, is felt at the selected height, which occurs at $t = 303$ s. The plot of ΔT_0 in Fig. 13.9 is according to Equation 13.56 up to the time $t = 303$ s. At larger times, ΔT_0 is determined from Fig. 13.5 in the following manner: at each selected time, $z - z_0$ is calculated using Equation 13.55; $\dot{Q}_c$ is calculated from Equation 13.51; the quantity $(z - z_0)/\dot{Q}_c^{2/5}$ is determined and ΔT_0 is read from Fig. 13.5. The resulting extension of the ΔT_0 curve is seen in Fig. 13.9.

The centerline gas velocity at the 5 m height above the base of the fuel array can then be considered. Equation 13.23 can be used up to the moment that the flame tip reaches the 5 m height, that is, at $t = 303$ s. After substitution of

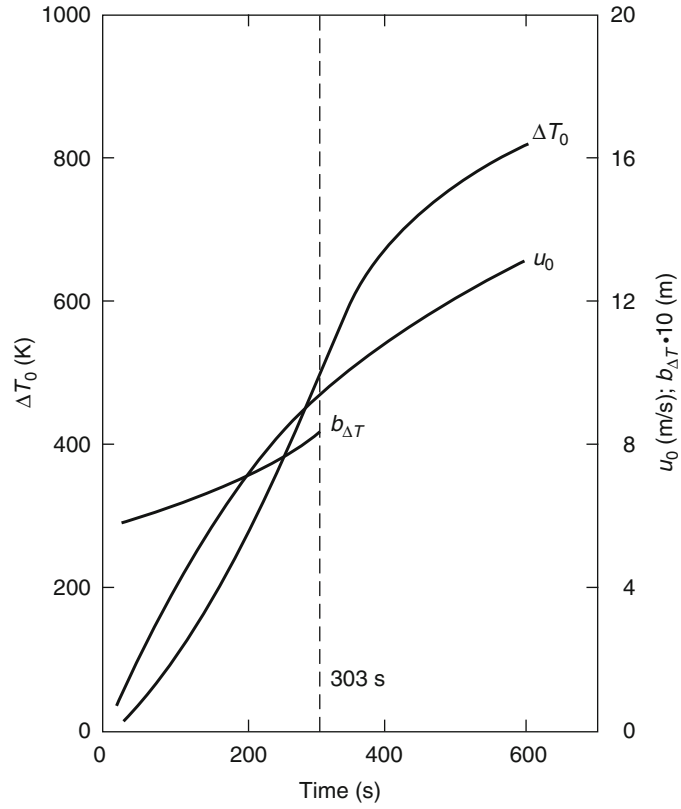

Fig. 13.9 Growing fire illustration: plume width, $b_{\Delta T}$, and centerline values of temperature rise, ΔT_0, and velocity, u_0, at 5 m above the base of the fuel

$z = 5$ (m), z_0 from Equation 13.55, $\dot{Q}_c$ from Equation 13.51, and normal ambient conditions, Equation 13.23 becomes

$$u_0 = \frac{0.339 t^{2/3}}{\left(5 + 5.46 \times 10^{-3} t - 2.52 \times 10^{-2} t^{4/5}\right)^{1/3}} \tag{13.57}$$

The u_0 curve in Fig. 13.9 follows Equation 13.57 to the limit, $t = 303$ s. As stated in conjunction with Equation 13.27, the maximum velocity (for a given size fire) occurs just below the mean flame height where $\Delta T_0 = 650$ K, which corresponds to $(z - z_0)/\dot{Q}_c^{2/5} = 0.135$ according to Fig. 13.5. Using $z = 5$ (m), and z_0 and $\dot{Q}_c$ from Equations 13.55 and 13.51, the 0.135 limit is found to correspond to a time of $t = 385$ s, where Equation 13.28 gives the centerline velocity in terms of $\dot{Q}_c$. In fact, it appears that Equation 13.28 can be used with good accuracy to even larger times, at least to times associated with a lower limit of $(z - z_0)/\dot{Q}_c^{2/5} = 0.08$, according to available measurements [12, 16]. Since the largest time in Fig. 13.9 corresponds to $(z - z_0)/\dot{Q}_c^{2/5} = 0.092$, Equation 13.28 has been used to calculate the entire extension of the u_0 curve in Fig. 13.9.

The temperature radius of the plume at the 5 m height above the fuel array is calculated from Equation 13.21, which can be written

$$b_{\Delta T} = 0.12 \left(1 + \frac{\Delta T_0}{T_\infty}\right)^{1/2} (z - z_0) \tag{13.58}$$

With substitution of $z = 5$ (m), ΔT_0 from Equation 13.56, and z_0 from Equation 13.55, Equation 13.58 becomes

$$b_{\Delta T} = 0.12 \left[\frac{1 + 9.25 \cdot 10^{-3} t^{4/3}}{\left(5 + 5.46 \cdot 10^{-3} t - 2.52 \cdot 10^{-2} t^{4/5}\right)^{5/3}}\right]^{1/2} \cdot \left(5 + 5.46 \cdot 10^{-3} t - 2.52 \cdot 10^{-2} t^{4/5}\right) \tag{13.59}$$

This equation is plotted in Fig. 13.9 up to the time the flames reach the 5 m height at $t = 303$ s. The temperature radius at the 5 m height is seen to vary from 0.59 m early in the fire to 0.83 m at 303 s. Plume fluid will reach a minimum of twice the temperature radius, $b_{\Delta T}$; hence, the total width of the plume in this example will be at least four times $b_{\Delta T}$, growing from a minimum of 2.4 m early in the fire to a minimum of 3.3 m as the flames reach the 5 m height.

Additional Plume and Flame Topics

Other aspects of fire plumes than those already discussed have been studied and may be of interest, including (1) flame intermittency length scale, (2) flame pulsations and (3) the rise of a plume front or cap after ignition into undisturbed air. Both of these aspects are essentially axisymmetric, whereas three others are not: (4) effects on a fire plume of proximity to a wall or corner, (5) effects of wind, and (6) behavior of turbulent jet diffusion flames in horizontal discharge. These topics are discussed briefly here.

Flame Intermittency Length Scale

The flame intermittency has been discussed in connection with the definition of flame height in Fig. 13.2, based on the work of Zukoski et al. [23]. Zukoski and coworkers [82] also defined a flame intermittency length scale, L_I, with the aid of the maximum (negative) slope of the intermittency (I) curve and the intersections of this slope with $I = 0$ and $I = 1$. L_I was defined as the difference in elevations z between these two intersections.

Figure 13.10 presents results [27] from simultaneous measurements of the flame height ratio, L/D, and the flame intermittency length scale to flame height ratio, L_I/L, for the three circular porous bed fires of natural gas investigated by

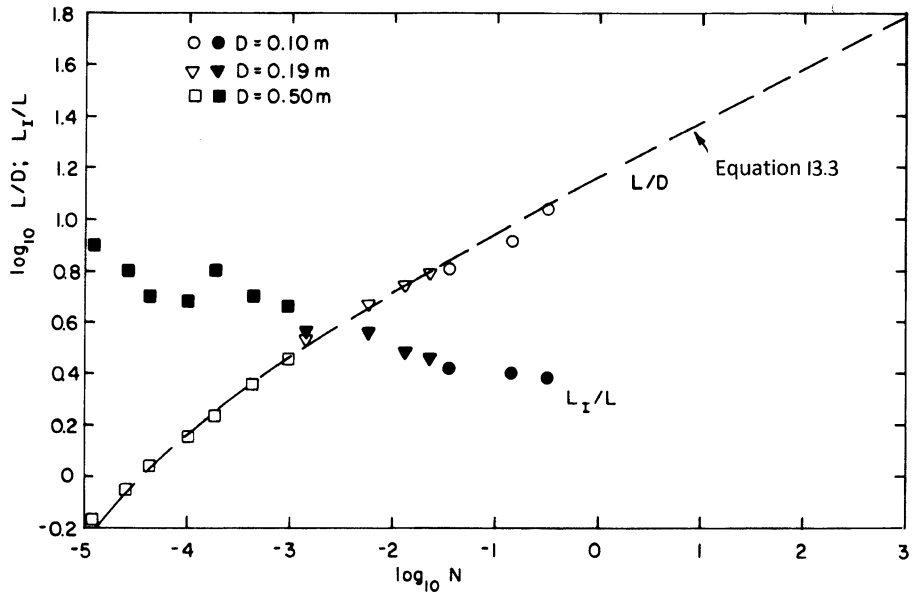

Fig. 13.10 Flame heights and intermittency scales according to flame-intermittency data of Zukoski et al. [82]

Zukoski et al. [23, 82] The open symbols represent the nondimensional flame heights L/D, which compare well with the reference curve according to Equation 13.3. It is seen that L_f/L generally increases as N and the nondimensional flame height decrease, implying an accompanying increase in flame fluctuations. Wood et al. [40] reported that coherent flaming in their pool fires changed to distributed flamelets for L/D values smaller than about 0.5 ($\log_{10} L/D = -0.30$), which occurs near $\log_{10} N = -5$ ($N = 10^{-5}$) in Fig. 13.10. This behavior seems to correlate well with L_f/L near unity.

Flame Pulsations

Flame pulsations have been studied by a number of investigators, tracing at least as far back as Rashbash et al. [83] and reviewed in conjunction with an investigation reported by Cetegen and Ahmed [84]. Byram and Nelson [85] describe the pulsation cycle as starting with the expansion of the flames near the base of the fire, followed by a sudden collapse of these flames toward the center of the fire. A flame bulge then travels upward to the flame tip in an even, wavelike motion. Expansion of the lower part of the flames starts the cycle again.

Cetegen and Ahmed [84] summarize the published data on pulsation frequency in a single plot for burner or pool diameters ranging from 0.03 to 20 m and propose the simple curve fit

$$f(Hz) = 1.5[D(m)]^{-1/2} \tag{13.60}$$

As a measure of the data scatter it is noted that measured frequencies near a given diameter agree within a factor of two.

Flame pulsations are not always easy to detect visually. For example, Wood et al. [40] reported visual pulsations for a flame on their 1.52-m diameter sandfilled pan when initially saturated with methanol, but not when initially saturated with acetone. Other than visually, pulsations have been detected based on temperature and velocity records in the flames, motion picture records, or pressure fluctuations on the surface of the fire source.

Rise of Plume Front

Measurements by Tanaka et al. [86] of the rise times of plume fronts from suddenly initiated fires at steady heat release rate (such as pool fires) have been represented by Heskestad [87] in the following formula:

$$t_R^* = 0.46 \tag{13.61}$$

Here, $t_R{}^*$ is the nondimensional rise time to a given height, z, defined as

$$t_R^* = \left[g/\left(c_p T_\infty \rho_\infty\right)\right]^{1/3} \dot{Q}_c^{1/3} z^{-4/3} t_R \tag{13.62}$$

where t_R is the physical rise time to the elevation z.

As an example, if $\dot{Q} = 100$ kW and assuming $\dot{Q}_c = 0.7 \cdot 100 = 70$ kW, the physical rise time to an elevation of 30 m in a normal atmosphere is calculated as

$$t_R = 0.46 \cdot [9.81/(1.00 \cdot 293 \cdot 1.2)]^{-1/3} \cdot 70^{-1/3} \cdot 30^{4/3}$$
$$t_R = 34\,\text{s}$$

New measurements by Hu et al. [88] have closely reproduced the result in Equation 13.61 (0.43 compared to 0.46). In addition, these investigators measured rise times for plumes near a building wall, giving essentially the same result as the case of a free plume, and near a building corner (interior) where the rise times were about ¾ of the free plume values.

Wall/Corner Effects

McCaffrey [24] has reviewed effects on flame height of placing fire sources next to a wall or in a corner, referring to experiments by Hasemi and Tokunaga [89], Back et al. [90], Mizuno and Kawagoe [91], and Kokkala [92]. The effects are generally reported to be small. In more recent

work, Poreh and Garrad [93] and Lattimer and Sorathia [94] have made further studies.

Windblown Flames

The main effect of wind is to bend or deflect the flames away from the vertical. Another effect, observed in wind tunnel studies by Welker and Sliepcevich [95], is "flame trailing," in which the flames trail off the burner along the floor in the downwind direction for a significant distance. Flame trailing was thought to be associated primarily with fuel vapors of greater density (higher molecular weight) than air, as was the case with all the various liquid fuels used in the experiments.

Wind tunnel measurements of flame deflection angle, involving fire diameters in the range 0.10–0.60 m, and large-scale data for square LNG pools in the effective diameter range 2–28 m, obtained by Attalah and Raj [96], have been found to correlate well against the ratio of wind velocity to the maximum velocity in the flame according to Equation 13.28 [65]. The relationship indicates that a flame deflection angle of approximately 25° can be expected for a velocity ratio of 0.10. Effects of wind on flame length were minor for velocity ratios up to 0.35 (flame deflection angle of approximately 60°). Data by Huffman et al. [97] indicate that at the considerably higher velocity ratio of 1.0, flame lengths are approximately 30 % greater than under quiescent conditions.

For turbulent jet diffusion flames, discussed under the subheading "Momentum Regime" of the section "Flame Heights," Brzustowski et al. [98] found reduced flame length in a range of small wind velocities for a laboratory hydrogen flame. Related to this finding is an observation reported to the author by a staff member of a major supplier of flare equipment that the flames of flares are typically seen to increase in length by some 30 % when winds calm down from about 0.4 m/s. Finally we call attention to measurements by Sönju and Hustad [99], conducted mostly outdoor, which indicate agreement of measured flame lengths with laboratory results in one case (a methane series) and 10–40 % smaller lengths in another case (a propane series) [53]. The smaller lengths may have been associated with a slight wind.

Jet Flames in Horizontal Discharge

Becker et al. [100] have studied flame geometries resulting from horizontal gas discharge and have provided extensive data and correlations. For ease of application, their results have been reformulated by the author as functions of the momentum parameter R_M of Equation 13.9 (and Fig. 13.4), using supporting data from Becker and Liang [25].

The flames were stabilized against blow-off with hydrogen or oxygen, when necessary, and photographed from the side in 1-s exposures. The results are presented in Fig. 13.11, where the inset defines the selected measures of flame geometry with X and Y being the maximum horizontal and vertical flame excursions, respectively. In the figure, maximum excursions (derived from faired curves [100]) have been made nondimensional with flame heights in vertical discharge (from faired curves [24]), L, and plotted as functions of R_M. Seven different gases were employed in the experiments, as indicated. Note that the vertical flame heights, L, were interpreted as the highest points "at which flaming gas was seen to dwell with an appreciable frequency." [25]

Calculation of R_M has been illustrated in Example 4. Note in the figure that as R_M approaches 1, the entire flame practically projects horizontally and has a length nearly the same as in vertical discharge (X/L near 0.9). There is some uncertainty in this comparison since the bases of the X and L measurements are not quite identical.

The inset sketch in Fig. 13.11 is actually the outline of an ethane flame from a photograph [100] at $R_M = 0.14$.

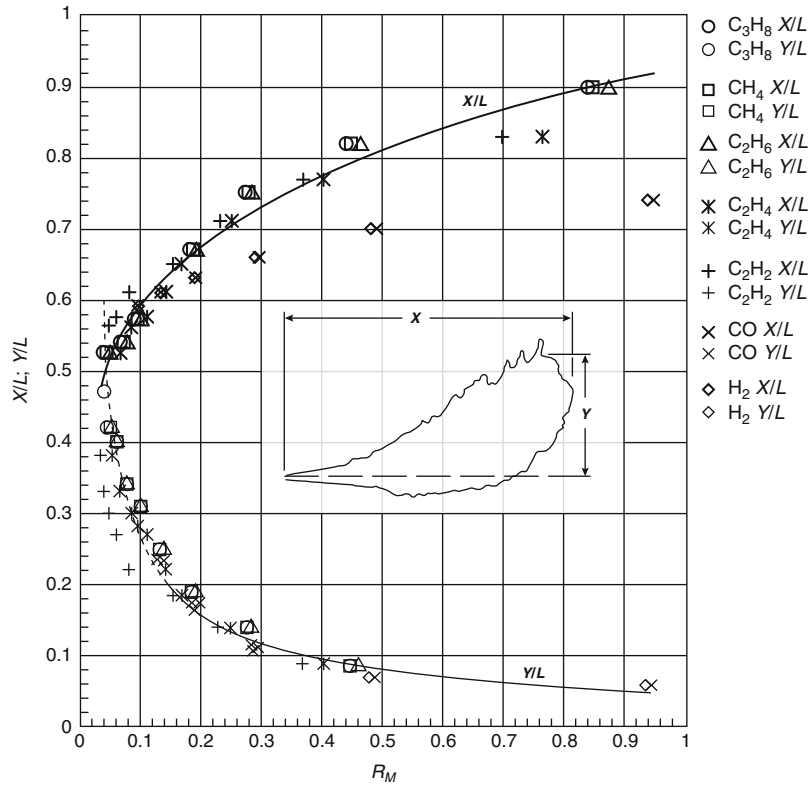

Fig. 13.11 Data from Becker et al. [100] on maximum nondimensional horizontal and vertical flame excursions of turbulent jet diffusion flames in horizontal gas discharge, formulated as functions of the momentum parameter R_M of Equation 13.9 and Fig. 13.4

Research Needs

All of the areas discussed in this chapter will benefit from further study. However, certain needs stand out from the discussion.

Temperature measurements in fire with bare-bead thermocouples usually involve radiation errors and undoubtedly such errors were present in the measurements for Fig. 13.5. Newman and Croce [101] in their study of aspirated thermocouples determined radiation errors for a centerline location close to the flame tip of a 0.230-m diameter acetone pan fire. For a 1-mm diameter bare-bead thermocouple their measurements translate to a thermocouple temperature 170 K less than the actual gas temperature as a result of radiation to the environment. (The aspirated thermocouple design of Newman and Croce nearly eliminated the radiation error.) Careful experiments are needed to establish near error-free temperatures.

Fires with low flame height-to-diameter ratios were discussed following Equation 13.28 and several uncertainties noted. Research on such fires can fill in areas of uncertainty.

There may be secondary effects on flame height (and other flame properties) of variables enumerated in the paragraph before Equation 13.6, which should be investigated, including nonuniform volatilization rate across the fuel bed, departure of fire area from circular, density of volatiles, and effect of flame Reynolds number (which depends on fire diameter and heat release rate).

Attention is directed to the end of subsection "Pool Fires" of the section "Virtual Origin," where more precise measurements of virtual origins for pool fires are recognized as a need.

Near the end of subsection "Entrainment," the observations of Cetegen et al. [68, 70] on the sensitivity of air entrainment in a plume to ambient disturbances were noted. Since air entrainment scenarios (as in room fires) often involve disturbances, it is important to be able to account for these.

Data Sources

NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces* [103], was referenced in this chapter for tables of heat release rate per unit floor area, kW/m^2, and growth times, t_g, of a number of fuel arrays. The same information has been incorporated by Alpert and Ward [104], together with additional data.

In Appendix 3 tables are provided to estimate combustion efficiencies as well as total and convective heat release rates per unit exposed area of materials under full-scale burning conditions.

Nomenclature

A	Defined in Equation 13.6 (m·kW$^{-2/5}$)
B	Buoyancy flux defined in Equation 13.15 (m^4·s^{-3})
b	Plume radius (m)
$b_{\Delta T}$	Plume radius to point where $\Delta T/\Delta T_0 = 0.5$ (m)
b_u	Plume radius to point where $u/u_0 = 0.5$ (m)
b_{um}	b_u at level of maximum gas velocity near flame tip (m)
c	Adjustable constant, Equation 13.35
c_p	Specific heat of air at constant pressure (kJ/kg·K)
D	Diameter (m)
F	Function (c_p, T_∞, ρ_∞, g); see Equation 13.31 (m·kW$^{-2/5}$)
f	Frequency (s^{-1})
g	Acceleration due to gravity (m/s^2)
H_c	Actual lower heat of combustion (kJ/kg)
ΔH_O	Tewarson's [44] lower heat of combustion per unit mass of oxygen consumed (kJ/kg)
I	Intermittency
k	Ratio of specific heats, constant-pressure versus constant-volume
L	Mean flame height above base of fire (m)
L_B	Buoyancy controlled flame height (m)
L_I	Intermittency length scale
L_M	Momentum controlled flame height (m)
$\dot{m}_{ent}$	Entrained mass flow rate in plume (kg/s)
$\dot{m}_{ent,L}$	$\dot{m}_{ent}$ at the mean flame height, L(kg/s)
$\dot{m}_f$	Mass burning rate (kg/s)
N	Nondimensional parameter defined in Equation 13.4
p_s	Pressure in source gas discharge stream (Pa)
p_{s0}	Pressure in source gas reservoir (Pa)
$\dot{Q}$	$\dot{m}_f H_c$ total heat release rate (kW)
$\dot{Q}_c$	Convective heat release rate (kW)
$\dot{Q}_r$	Radiative heat release rate (kW)
$\dot{Q}^*$	Nondimensional parameter defined in 13.1
R	Radius (m)
r	Actual mass stoichiometric ratio, air to fuel volatiles
R_M	Momentum parameter defined in Equation 13.8
T	Mean temperature (K)
T_0	Mean centerline temperature in plume (K)
T_∞	Ambient temperature (K)
T'	rms temperature fluctuation (K)
$T_a(z)$	Ambient temperature at level z (K)
T_{a1}	Ambient temperature at source level (K)
T_L	T_0 at mean flame height (K)
ΔT	$T - T_\infty$, mean temperature rise above ambient (K)
ΔT_0	Value of ΔT on plume centerline (K)
ΔT_L	$T_L - T_\infty$(K)
t	Time (s)
t_g	Growth time; see Equation 13.49 (s)
t_R	Rise time of plume front (s)
t_R^*	Nondimensional rise time of plume front, see 13.62
u	Mean axial velocity (m/s)
u_0	Mean axial velocity on centerline (m/s)
u_{0m}	Maximum value of u_0, near flame tip (m/s)
u'	rms velocity fluctuation in axial direction (m/s)

W_f	Fire perimeter (m)
z	Height above base of fire (m)
z_0	Height of virtual origin above base of fire (m)
z_m	Maximum vertical penetration of plume fluid in stratified ambient (m)
α	Entrainment coefficient
ξ	Nondimensional parameter defined in Equation 13.26
ν_m	Kinematic viscosity of flame gases at maximum flame temperature ($m^2 \cdot s^{-1}$)
ρ	Mean density (kg/m^3)
ρ_{a1}	Ambient density at source level (kg/m^3)
ρ_{fe}	Mean density in flames (kg/m^3)
ρ_s	Density of source gas discharge stream (kg/m^3)
ρ_{s0}	Density of source gas in reservoir (kg/m^3)
$\rho_{s\infty}$	Density of source gas at ambient temperature and pressure (kg/m^3)
ρ_∞	Ambient density (kg/m^3)
$\Delta\rho$	$\rho_\infty - \rho$, mean density deficiency (kg/m^3)
$\sigma_{\Delta T}$	Plume radius to point where $\Delta T/\Delta T_0 = e^{-1}$ (m)
σ_u	Plume radius to point where $u/u_0 = e^{-1}$ (m)

Ceiling Jet Flows

14

Ronald L. Alpert

Introduction

Much of the hardware associated with detection and suppression of fire in commercial, manufacturing, storage, and modern residential buildings is located near the ceiling surfaces. In case of a fire, hot gases in the fire plume rise directly above the burning fuel and impinge on the ceiling. The ceiling surface causes the flow to turn and move horizontally under the ceiling to other areas of the building remote from the fire position. The response of smoke detectors, heat detectors, and sprinklers installed below the ceiling so as to be submerged in this hot flow of combustion products from a fire provides the basis for building fire protection.

Studies quantifying the flow of hot gases under a ceiling resulting from the impingement of a fire plume have been conducted since the 1950s. Studies at the Fire Research Station in Great Britain [1, 2], Factory Mutual Research Corporation [3–7], the National Institute of Standards and Technology (NIST) [8, 9], and at other research laboratories [10, 11] have sought to quantify the gas temperatures and velocities in the hottest portion of the flow produced by steady fires beneath smooth, unconfined horizontal ceilings.

Ceiling jet refers to the relatively rapid gas flow in a shallow layer beneath the ceiling surface that is driven by the buoyancy of the hot combustion products from the plume. Figure 14.1 shows an idealization of an axisymmetric ceiling jet flow at varying radial positions, r, beneath an unconfined ceiling. In actual fires within buildings, the simple conditions pictured—a hot, rapidly moving gas layer sandwiched between the ceiling surface and tranquil, ambient-temperature air—exist only at the beginning of a fire, when the quantity of combustion gases produced is not sufficient to accumulate into a stagnant, heated gas layer in the upper portion of the compartment. Venting the ceiling jet flow through openings in the ceiling surface or edges can retard the accumulation of this heated gas layer.

As shown in Fig. 14.1, the ceiling jet flow emerges from the region of plume impingement on the ceiling, flowing radially away from the fire. As it does, the layer grows thicker by entraining room air at the lower boundary. This entrained air cools the gases in the jet and reduces its velocity. As the hot gases move out across the ceiling, heat transfer cools the portion adjacent to the ceiling surface.

Steady Flow Under Horizontal, Unconfined Ceilings

Weak Plume-Driven Flow Field

A generalized theory to predict gas velocities, gas temperatures, and the thickness (or depth) of a steady fire-driven ceiling jet flow has been developed by Alpert [4] for the case of a weak

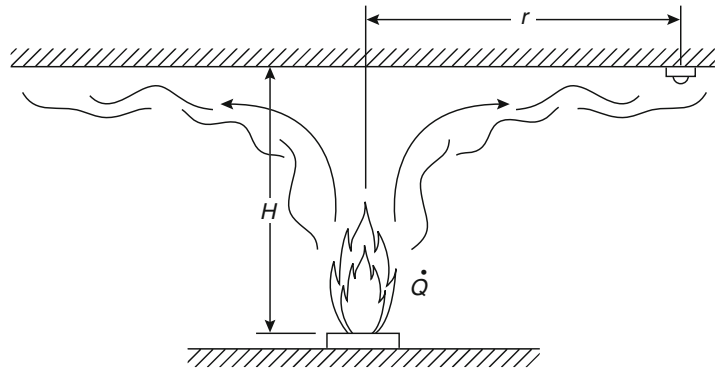

Fig. 14.1 Ceiling jet flow beneath an unconfined ceiling

plume, when flame height is much less than the height, H, of the ceiling above the burning fuel. This work involves the use of several idealizations in the construction of the theoretical model, but results are likely to provide reasonable estimates over radial distances of one or two ceiling heights from the point of fire plume impingement on the ceiling.

Ceiling Jet Thickness Alpert defined the thickness of the ceiling jet, ℓ_T, as the distance below the ceiling where the excess of gas temperature above the ambient value, ΔT, drops to $1/e$ (1/2.718 ...) of the maximum excess temperature. Based on this definition, measurements obtained with a liquid pool fire 8 m beneath a ceiling show that ℓ_T/H is about 0.075 at an r/H of 0.6, increasing to a value of 0.11 for r/H from about 1 to 2. These results are in good agreement with detailed measurements and analysis for the region $r/H < 2$ performed by Motevalli and Marks [12] during their small-scale (0.5- and 1.0-m ceiling heights) experiments. The following correlation for ℓ_T/H developed by Motevalli and Marks from their temperature data confirms the predicted constancy of ceiling jet thickness (at about 10–12 % of H) for r/H from Alpert's theory:

$$\frac{\ell_T}{H} = 0.112\left[1 - \exp\left(-2.24\frac{r}{H}\right)\right] \quad \text{for } 0.26 \le \frac{r}{H} \le 2.0 \tag{14.1}$$

Additional measurements of ceiling jet thickness, for steady flows induced by strong plumes and for transient flows, are discussed later.

Within the ceiling jet flow, the location of maximum excess temperature and velocity are predicted [4] to be highly scale dependent, even after normalization by the ceiling height. Measurements of the distance below the ceiling at which these maxima occur have been made mainly for 1-m scale experiments [12, 13]. Results show distances below the ceiling ranging from about 1 % to 2 % of the ceiling height for r/H from less than 1 to 2, with predicted reductions in the percent of ceiling height at larger scales.

Much of the discussion below deals with predictions and correlations of the maximum excess temperature and velocity in the ceiling jet flow, which occur, as already noted, relatively close to the ceiling surface. Often fire detectors or sprinklers are placed at ceiling standoff distances that are outside of this region and therefore will experience cooler temperatures and lower velocities than predicted. In facilities with very high ceilings, the detectors could be closer to the ceiling than 1 % of the fire source-to-ceiling separation and will fall in the ceiling jet thermal and viscous boundary layers. In low-ceiling facilities, it is possible for sprinklers or detectors to be placed outside of the ceiling jet flow entirely if the standoff is greater than 12 % of the fire source-to-ceiling height. In this case, response time could be drastically increased.

Ceiling Jet Excess Temperature and Velocity Alpert [3] has developed easy-to-use correlations to quantify the maximum excess gas temperature (above the ambient value) and velocity at a given position in a ceiling jet flow

produced by a steady fire. These correlations are widely used in hazard analysis calculations. Evans and Stroup [14] have employed the correlations in the development of a generalized program to predict heat detector response for the case of a detector totally submerged in the ceiling jet flow. The correlations are based on measurements collected during fire tests involving fuel arrays of wood and plastic pallets, empty cardboard boxes, plastic materials in cardboard boxes, and liquid fuels. Heat release rates for these fuels range from 600 kW to 98 MW, total ceiling heights range from 4.6 to 18 m, and radial positions for most measurements range out to a little more than twice the ceiling height. In SI units, Alpert's [3] correlations for maximum ceiling jet excess temperatures and velocities are as follows:

$$T - T_\infty = 16.9 \frac{\dot{Q}^{2/3}}{H^{5/3}} \qquad \text{for } r/H \leq 0.18 \tag{14.2}$$

$$T - T_\infty = 5.38 \frac{\dot{Q}^{2/3}/H^{5/3}}{(r/H)^{2/3}} \quad \text{for } r/H > 0.18 \tag{14.3}$$

$$U = 0.947 \left(\frac{\dot{Q}}{H}\right)^{1/3} \qquad \text{for } r/H \leq 0.15 \tag{14.4}$$

$$U = 0.197 \frac{(\dot{Q}/H)^{1/3}}{(r/H)^{5/6}} \qquad \text{for } r/H > 0.15 \tag{14.5}$$

where temperature, T, is in °C; velocity, U, is in m/s; total heat release rate, $\dot{Q}$ is in kW; and radial position and ceiling height (r and H) are in m.

Data from these fire tests are correlated using the rate at which heat is actually released in the fire, $\dot{Q}$, based on measured fuel mass loss rates and the best estimates for actual heat of combustion that were available in 1970–1971. Even though it is the convective component of this total heat release rate that is directly related to the buoyancy of the fire, accurate estimates for this convective component were not readily available for all the fuels tested when the correlations were first developed. For the liquid alcohol pool fires that constitute the primary basis of the correlation developed by Alpert, the convective heat release rate, $\dot{Q}_c$, is now known to be about 74 % of the actual heat release rate. However, for the remaining solid commodities and pallets, the convective heat release rate varies from about 60 % to 70 % of the actual heat release rate for mixed plastic/cardboard commodities and wood, respectively, with flammable liquids similar to heptane being in the middle of this range. Hence, for general commodities, it would be desirable to use ceiling jet excess temperature and velocity correlations based on convective heat release rate (see such correlations in Equations 14.7 and 14.8).

The preceding correlations for both temperatures and velocities (Equations 14.2, 14.3, 14.4, and 14.5) are broken into two parts. One part applies for the ceiling jet in the area of the impingement point where the upward flow of gas in the buoyant plume turns to flow out beneath the ceiling horizontally, with an assumed unchanged velocity magnitude. The impingement point or turning region correlations (Equations 14.2, 14.3 and 14.4) are independent of radius and represent plume temperatures

and velocities calculated at the ceiling height above the fire source. The other correlations (Equations 14.3 and 14.5) apply outside of this turning region as the flow moves away from the impingement area. It is important to recognize that these correlations implicitly assume that there is a point buoyancy source for the impinging plume located at the top surface of the burning fuel. Hence, there is no dependence on the horizontal dimension (e.g., effective diameter) of the fire source in the correlations, and the height of the fuel array is restricted to being a small fraction of the ceiling height.

In order to remedy deficiencies discussed above in the existing correlations, much of the original data from the 1970s has been reanalyzed by the author. This new analysis ignores a small number of measurements where an accurate estimate of convective heat release rate for the corresponding fire sources (plastic pallets and one cardboard box commodity) would be very difficult to obtain. For the remaining large-scale fire tests, the convective heat release rate is calculated from measurements of fuel mass loss rate and handbook values of the convective heat of combustion. Instead of arbitrarily correlating measurements with the ceiling elevation above the top fuel surface, H, the new analysis uses the ceiling elevation above the location of the virtual plume origin, $z_H - z_v$. The location, z_v, of the virtual plume origin above a reference location is given (see Chap. 13) by a correlation based on the actual heat release rate, $\dot{Q}$, and the effective diameter, D_{eff}, of the fuel array. When height in the plume, z, is measured from the base of the flame zone instead of the top surface of the burning fuel, the following expression for virtual origin height has been found to be applicable even to complex fuel arrays:

$$z_v = 0.083\dot{Q}^{2/5} - 1.02D_{\text{eff}} \tag{14.6}$$

In Equation 14.6, z_v is the distance above the base of a burning fuel array and D_{eff} is the diameter of a circle having the same plan area as for the actual array. The result of correlating excess temperature and velocity measurements from full-scale tests using the same functional relationships as in Equations 14.3 and 14.5 but based on $\dot{Q}_c$ instead of $\dot{Q}$ and $z_H - z_v$ instead of H is shown in Figs. 14.2 and 14.3. Further details of this reanalysis of ceiling jet data from the early 1970s is provided in a recent lecture by the author [15].

In Figs. 14.2 and 14.3, the ordinates are the dimensional quantities

$$\frac{(T - T_\infty)(z_H - z_v)^{5/3}}{\dot{Q}_c^{2/3}} \quad \text{and} \quad \frac{U(z_H - z_v)^{1/3}}{\dot{Q}_c^{1/3}}$$

respectively. Values for these ordinates at the plume axis (see Chap. 13) are shown for comparison with the ceiling jet values. Regression fits based on data only from the ethanol pool fires, for which heat release rates are known most accurately, are also shown in these figures. Based on the data from all of the full-scale fire tests, the following new correlations are obtained for excess gas temperature and velocity in the ceiling jet:

$$T - T_\infty = 7.22\frac{\dot{Q}_c^{2/3}}{(z_H - z_v)^{5/3}}\left(\frac{r}{z_H - z_v}\right)^{-0.678} \tag{14.7}$$

$$\text{for } \frac{r}{z_H - z_v} > 0.16$$

$$U = 0.229\frac{\dot{Q}_c^{1/3}}{(z_H - z_v)^{1/3}}\left(\frac{r}{z_H - z_v}\right)^{-1.017}$$

$$\text{for } \frac{r}{z_H - z_v} > 0.228 \tag{14.8}$$

where the limits on $\frac{r}{z_H - z_v}$ in Equations 14.7 and 14.8 are obtained from the respective intersections of the ceiling jet regression fits with the axis values shown from the plume correlations. Within the turning region (i.e., for $\frac{r}{z_H - z_v} \leq$ the limits shown) existing correlations for maximum temperature and velocity in the plume can be used.

A further improvement to the ceiling jet excess temperature and velocity correlations can be obtained [15] by using just the ethanol pool and heptane spray fire data, not only because these are the best documented fire

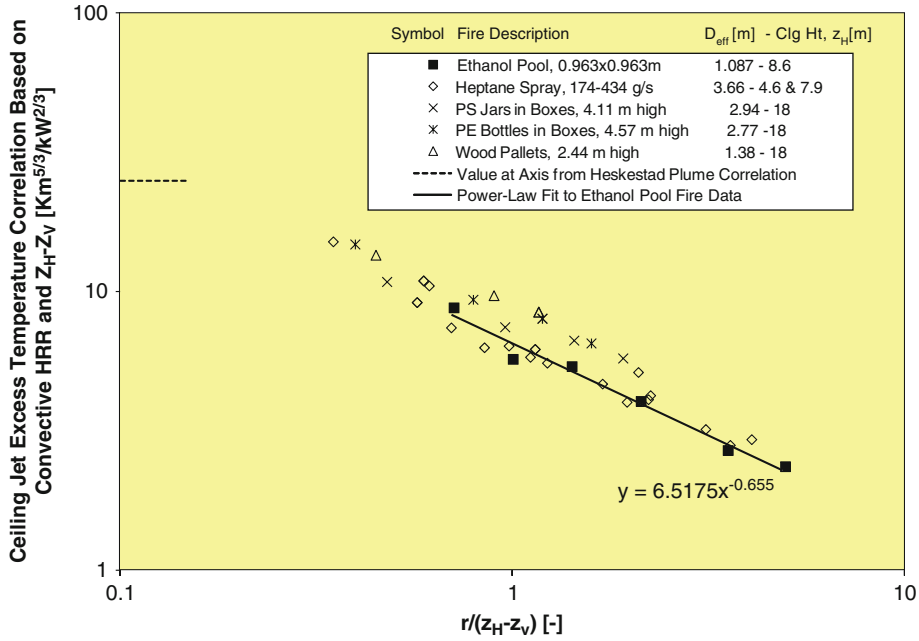

Fig. 14.2 Correlation of maximum ceiling jet excess temperature data from full-scale fire tests (Note that "PE bottles" previously was called "PVC bottles," an error discovered by comparing known test numbers involving the commodity with descriptions in a test report; Also note that previously, data for heptane sprays had not contained the virtual origin correction applied to data for the other commodities, due to a spreadsheet error)

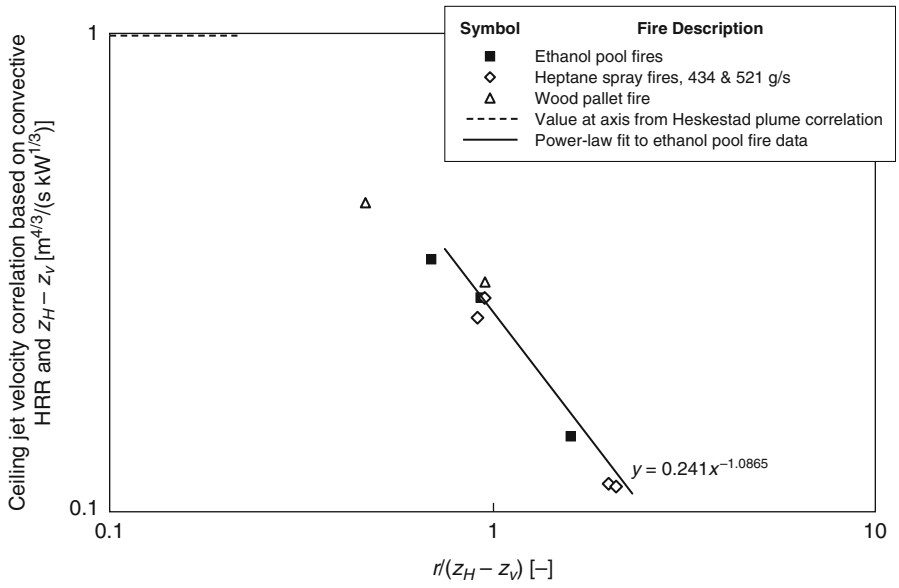

Fig. 14.3 Correlation of maximum ceiling velocity data from full-scale fire tests (See legend from Fig. 14.2)

sources from the original study, in terms of combustion parameters, but also because these are the only near steady-state fire sources. Fires in piles of solid fuels are inherently transient, which makes a data correlation difficult when transient velocity and temperature data are not available.

Modern handbook values [16] for actual and convective heats of combustion for the two fuels selected will now be used instead of what had been assumed (from the knowledge available at time) in the original ceiling-jet study. As a result, the value of $\dot{Q}$ is 13 % greater for ethanol and 8 % less for heptane compared to the values used for the correlations in Equations 14.7 and 14.8. With these new values, virtual source heights and convective heat release rates can be obtained [15]. For both the heptane spray and ethanol pool data taken together, the resulting regression fit equations and regression coefficients (R^2 values) are given below:

$$T - T_\infty = 6.721 \frac{\dot{Q}_c^{2/3}}{(z_H - z_v)^{5/3}} \left(\frac{r}{z_H - z_v} \right)^{-0.6545} \quad R^2 = 0.958 \quad \text{for} \frac{r}{z_H - z_v} > 0.134 \tag{14.7A}$$

$$U = 0.2526 \frac{\dot{Q}_c^{1/3}}{(z_H - z_v)^{1/3}} \left(\frac{r}{z_H - z_v} \right)^{-1.0739} \quad R^2 = 0.972 \quad \text{for} \frac{r}{z_H - z_v} > 0.246 \tag{14.8A}$$

Certain constraints should be understood when applying these correlations in the analysis of fire flows. The correlations apply only during times after fire ignition when the ceiling flow may be considered unconfined; that is, no accumulated warm upper layer is present. Walls close to the fire affect the temperatures and velocity in the ceiling jet independent of any effect on the fire-burning rate due to radiant heat received from the walls. The correlations were developed from test data to apply in cases where the fire source is at least a distance 1.8 times the ceiling height from the enclosure walls. For special cases where burning fuel is located against a flat wall surface or two wall surfaces forming a 90° corner, the correlations are adjusted based on the method of reflection. This method makes use of symmetry to account for the effects of the walls in blocking entrainment of air into the fire plume. For the case of a fire adjacent to a flat wall, $2\dot{Q}$ is substituted for $\dot{Q}$ in the correlations. For a fire in a 90° corner, $4\dot{Q}$ is substituted for $\dot{Q}$ in the correlations [3]. More accurate formulas for ceiling jet gas temperature, as well as ceiling heat flux, in a 90° corner that were obtained from experiments with a propane burner can be found in the section following on "Corner Configuration with Strong Plumes".

Experiments have shown that unless great care is taken to ensure that the fuel perimeter is in contact with the wall surfaces, the method of reflection used to estimate the effects of the walls on ceiling jet temperature will be inaccurate. For example, Zukoski et al. [17] found that a circular burner placed against a wall so that only one point on the perimeter contacted the wall behaved almost identically to a fire far from the wall with plume entrainment only decreasing by 3 %. When using Equations 14.2, 14.3, 14.4, and 14.5, this fire would be represented by replacing $\dot{Q}$ with $1.05\dot{Q}$ and not $2\dot{Q}$ as would be predicted by the method of reflections. The value of $2\dot{Q}$ would be appropriate for a semicircular burner with the entire flat side pushed against the wall surface.

Consider the following calculations, which demonstrate typical uses of the correlations, Equations 14.2, 14.3, 14.4, and 14.5.

(a) The maximum excess temperature under a ceiling 10 m directly above a 1.0-MW heat-release-rate fire is calculated using Equation 14.2 as

$$T - T_\infty = \frac{16.9(1000)^{2/3}}{10^{5/3}}$$
$$= \frac{16.9(100)}{46.42}$$
$$\Delta T = 36.4°\text{C}$$

(b) For a fire that is against noncombustible walls in a corner of a building and 12 m below the ceiling, the minimum heat release rate needed to raise the temperature of the gas below the ceiling 50 °C at a distance 5 m from the corner is calculated using Equation 14.3 and the symmetry substitution of $4\dot{Q}$ for $\dot{Q}$ to account for the effects of the corner as

$$T - T_\infty = 5.38\frac{(4\dot{Q})^{2/3}/H^{5/3}}{(r/H)^{2/3}}$$
$$50 = 5.38\frac{(4\dot{Q})^{2/3}}{12^{5/3}(5/12)^{2/3}}$$
$$\dot{Q} = \frac{5}{4}\left[\frac{50(12)}{5.38}\right]^{3/2}$$
$$\dot{Q} = 1472\ \text{kW} = 1.472\,\text{MW}$$

(c) The maximum velocity at this position is calculated from Equation 14.5, modified to account for the effects of the corner as

$$U = 0.197\frac{(4\dot{Q}/H)^{1/3}}{(r/H)^{5/6}}$$
$$= \frac{0.197(5888)^{1/3}}{(5/12)^{5/6}12^{1/3}}$$
$$U = 3.2\ \text{m/s}$$

Nondimensional Ceiling Jet Relations Heskestad [7] developed correlations[1] for maximum ceiling jet excess temperature and velocity based on alcohol pool-fire tests performed at the U.K. Fire Research Station in the 1950s. These correlations are cast in the following heat release rate, excess temperature, and velocity variables that are nondimensional (indicated by the superscript asterisk) and applicable to steady-state fires under unconfined ceilings (indicated by the subscript 0):

$$\dot{Q}_0^* = \frac{\dot{Q}}{\rho_\infty c_p T_\infty g^{1/2} H^{5/2}} \tag{14.9}$$

$$\Delta T_0^* = \frac{\Delta T/T}{\left(\dot{Q}_0^*\right)^{2/3}} \tag{14.10}$$

$$U_0^* = \frac{U/\sqrt{gH}}{\left(\dot{Q}_0^*\right)^{1/3}} \tag{14.11}$$

Figure 14.4 shows a plot of the Heskestad correlation for excess temperature and velocity data as solid line curves. The correlations developed by Alpert [3] are plotted as broken curves, using the same dimensionless parameters with assumed ambient temperature of 293 K (20 °C), normal atmospheric pressure, and convective heat release rate equal to the total heat release rate, $\dot{Q}_c = \dot{Q}$. Generally, the results of Heskestad [7] predict slightly higher excess temperatures and substantially greater gas velocities than Alpert's [3] results. Another curve shown in Fig. 14.2 is a fit to the mean ceiling jet velocity predicted by the generalized theory of Alpert [4], which also predicts that the turning-region boundary should be at $r/H = 0.17$. This predicted velocity is reasonably close to Heskestad's [7] experimental correlation for velocity. Based on the results shown in Fig. 14.4, the nondimensional excess temperature from the Heskestad [7] correlation and the nondimensional velocity from Alpert's theory [4, 13] are recommended for the prediction of steady ceiling jet flows beneath unobstructed ceilings. The Heskestad correlation and the Alpert theory are adequately fit, respectively, by the following expressions:

[1] Originally developed by G. Heskestad and C. Yao in "A New Approach to Development of Installation Standards for Fired Detectors," *Technical Proposal No. 19574,* prepared for The Fire Detection Institute, by Factory Mutual Research Corporation, Norwood, MA (1971).

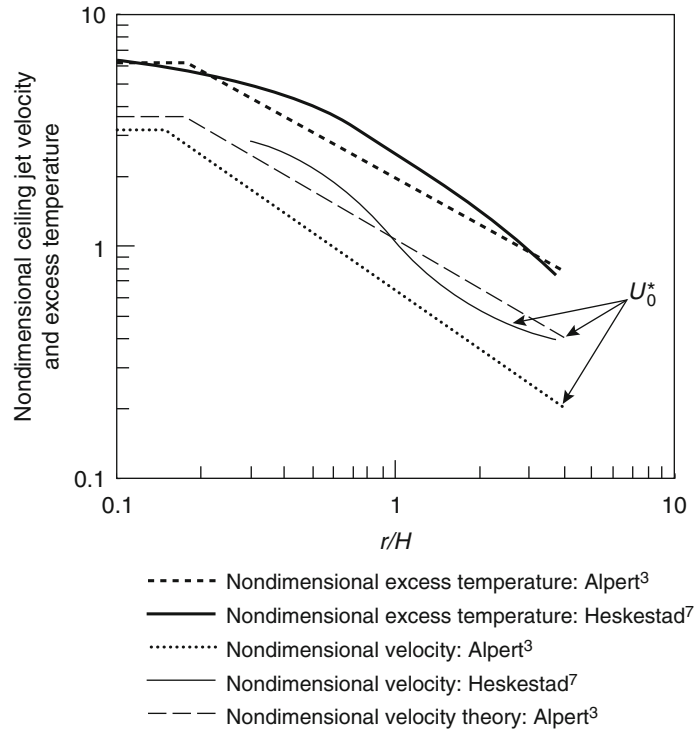

Fig. 14.4 Dimensionless correlations for maximum ceiling jet temperatures and velocities produced by steady fires. *Solid line*: Heskestad [7]; *dotted line*: Alpert [3]

$$\Delta T_0^* = \left(0.225 + 0.27\tfrac{r}{H}\right)^{-4/3} \quad \text{for } 0.2 \le r/H < 4.0 \tag{14.12}$$

$$\Delta T_0^* = 6.3 \quad \text{for } r/H \le 0.2 \tag{14.13}$$

$$U_0^* = 1.06\left(\frac{r}{H}\right)^{-0.69} \quad \text{for } 0.17 \le r/H < 4.0 \tag{14.14}$$

$$U_0^* = 3.61 \quad \text{for } r/H \le 0.17 \tag{14.15}$$

Heskestad and Delichatsios [18] examined the original data from Heskestad [7] and concluded that nondimensional velocity and temperature could be related by the following equation:

$$\frac{U_0^*}{\sqrt{\Delta T_0^*}} = 0.68\left(\frac{r}{H}\right)^{-0.63} \quad \text{for } r/H \ge 0.3 \tag{14.16}$$

The preceding relation has been found applicable to a much wider range of conditions than just steady-state alcohol pool fires having weakly buoyant plumes. For example, this relationship between ceiling jet velocity and excess temperature is consistent with measurements [18] for time-dependent fires having strong plumes.

Other methods used to calculate ceiling jet velocity and maximum possible (when the ceiling is adiabatic) ceiling jet temperatures are reported by Cooper and Woodhouse [9]. A critical review of correlation formulas for excess temperature and velocity in the ceiling jet under

a variety of conditions has been assembled by Beyler [19]. To apply these and the preceding expressions to realistic burning situations, it is recommended that the convective heat release rate should be used.

Strong Plume-Driven Flow Field

When the flame height of a fire plume is comparable to the height of the ceiling above the burning fuel, the resultant ceiling jet is driven by a strong plume. Additional information about this type of flow field is provided in the section on "Sloped Ceilings" (see the special case of zero inclination angle, i.e., a horizontal ceiling).

Ceiling Jet Temperature Heskestad and Hamada [6] measured ceiling jet temperatures for ratios of free flame height (in the absence of a ceiling, obtained from existing knowledge of flame heights) to ceiling height ranging from 0.3 up to 3. A correlation of excess temperatures could be achieved by using the plume radius, b, at the ceiling as a normalizing length scale, rather than the ceiling height used for the case of a weak plume. This correlation takes the form:

$$\frac{\Delta T}{\Delta T_p} = 1.92\left(\frac{r}{b}\right)^{-1} - \exp\left[1.61\left(1-\frac{r}{b}\right)\right] \quad \text{for } 1 \le \frac{r}{b} \le 40 \tag{14.17}$$

where ΔT_p is the excess temperature on the plume centerline at the level of the ceiling (obtained from Equations 14.2 or 14.13 or other fire-plume relations) and b is the radius where the velocity of the impinging plume is one-half the centerline value. The expression for this characteristic plume radius is given by

$$b = 0.42\left[\left(c_p\rho_\infty\right)^{4/5} T_\infty^{3/5} g^{2/5}\right]^{-1/2} \frac{T_p^{1/2}\dot{Q}_c^{2/5}}{\Delta T_p^{3/5}} \tag{14.18}$$

The Heskestad and Hamada [6] correlation is derived from measurements made with propane burner fires having heat release rates from 12 to 764 kW and beneath ceilings up to 2.5 m in height. This correlation is found to be accurate for ratios of free flame height to ceiling height less than or equal to about 2.0. At greater flame-height ratios, significant heat released in the ceiling jet itself appears to be the cause for a lack of agreement with the correlation.

Flame Lengths in the Ceiling Jet It is very interesting to note an often-overlooked finding of Heskestad and Hamada [6]. When there is flame impingement on the ceiling (flame-height ratio >1), the mean flame radius along the ceiling from the plume centerline is observed to be about equal to the difference between the free flame height and the ceiling height. Hence, Heskestad and Hamada find that the total average length of flame from the burning fuel to the flame tip under the ceiling is virtually the same as the free flame height.

In an earlier study involving small (0.36–8 kW) pool fires beneath ceilings up to 0.336 m in height, Yu (You)[2] and Faeth [10] measure the mean flame radius along the ceiling. Their results yield a flame radius about one-half the difference between the free flame height and the ceiling height, or one-half that of Heskestad and Hamada, perhaps due to the smaller scale of their experiment.

Ceiling Jet Thickness For strong plumes, Atkinson and Drysdale [20] demonstrate that much of the plume kinetic energy is lost (possibly 75 % of that in the incident plume) during the process of ceiling impingement. As a result of this kinetic energy loss, the initial ceiling jet thickness after the turning region may be twice that expected for the case of weak plumes, about 11 % of the ceiling height at $r/H = 0.2$. Measurements made by Atkinson and Drysdale and by Yu [5] show that the ceiling jet thickness may reach a minimum of 8 % of ceiling height at $r/H = 0.5$ and then increase up to 12 % of ceiling height at large radial distances, as for weak plumes.

[2] H. Z. Yu formerly published under the spelling *You*.

Convective Heat Transfer to Horizontal Unconfined Ceilings

Convection is the dominant mode of heat transfer for the case of weak plumes impinging on ceilings. This heat-transfer regime is important for the prediction of activation times for detection devices and the prediction of damage for objects, such as cables or pipes, suspended below the ceiling. However, damage to the ceiling structure itself will much more likely be the result of strong plume (flame) impingement, for which heat transfer due to thermal radiation will be just as important or more important than convection [21]. The maximum convective heat flux to a ceiling occurs when the ceiling surface is at or near ambient temperature, T_∞, before there has been any significant heating of the ceiling material. This maximum convective flux is the subject of the following discussion. For additional discussion of ceiling heat loss, see Chap. 25.

Weak Plume Impingement (Turning) Region

Quantification of convective heat transfer from weak fire plumes impinging on ceiling surfaces has been an area of research activity for many years. In the turning region, a widely used correlation is derived by Yu and Faeth [10] from experiments with small pool fires (convective heat release rates, $\dot{Q}_c$, from 0.05 to 3.46 kW; ceiling heights, H, less than 1 m). This correlation gives convective heat flux to the ceiling, $\dot{q}''$, as

$$\frac{\dot{q}'' H^2}{\dot{Q}_c} = \frac{31.2}{\mathrm{Pr}^{3/5}\mathrm{Ra}^{1/6}} = \frac{38.6}{\mathrm{Ra}^{1/6}} \qquad (14.19)$$

where Pr is the Prandtl number, and the plume Rayleigh number, Ra, is given by

$$\mathrm{Ra} = \frac{g\dot{Q}_c H^2}{3.5 p \nu^3} = \frac{0.027\dot{Q}_c H^2}{\nu^3} \qquad (14.20)$$

for gases similar to air, having ambient absolute pressure, p, and kinematic viscosity, ν. It is recommended that when these expressions are applied to actual heat-transfer problems, the ceiling height should be corrected for the location of the virtual point source for the plume.

Note that the heat-flux parameter on the left side of Equation 14.19 is proportional to the classic heat-transfer Stanton number and that the Rayleigh number is proportional to the cube of the plume Reynolds number, Re (defined in terms of centerline velocity, characteristic plume diameter, $2b$, and kinematic viscosity at the plume centerline temperature).

Equation 14.19 has been established for mainly weak plumes with Rayleigh numbers from 10^9 to 10^{15}. Kokkala [22] has verified this impingement zone heat-transfer correlation, using up to 10 kW natural gas flames, for flame heights up to 70 % of the ceiling height. For greater flame height to ceiling height ratios, Kokkala [22] finds that heat-transfer rates are many times higher than predicted, partly due to thermal radiation.

Alpert [23] performed small-scale (0.3 m ceiling height) experiments at elevated air pressures, which allow Rayleigh numbers greater than 2×10^{15} to be achieved while maintaining somewhat better control of ambient disturbances than in 1-atm experiments. Results of these experiments essentially confirm the predictions of the correlation in Equation 14.19, as well as an expression recommended for the plume impingement region by Cooper [8]. The latter expression yields nondimensional ceiling heat transfer, in terms of the plume Reynolds number defined by Alpert [23], as follows:

$$\frac{\dot{q}'' H^2}{\dot{Q}_c} = 49 \times \mathrm{Re}^{-1/2} = 105\left(\frac{\dot{Q}_c^{1/3} H^{2/3}}{\nu}\right)^{-1/2} \qquad (14.21)$$

Although Equations 14.19 and 14.21 have identical dependence of impingement heat flux on fire heat release rate and ceiling height, heat-flux values from Equation 14.21 are about 50 % higher, since this expression is derived from data on turbulent jets.

Ceiling Jet Region

Outside of the turning region, the convective flux to the ceiling is known to drop off sharply with increasing radial distance from the plume axis. The experiments of Yu and Faeth [10] described in the preceding section were also used to determine this radial variation in ceiling jet convective flux. Their own data, as well as data from small-scale experiments (ceiling heights of 0.5 to 0.8 m) by Alpert [13] and by Veldman [11] are all consistent with the following correlation that is given by Yu and Faeth [10][3]:

$$\frac{\dot{q}'' H^2}{\dot{Q}_c} = 0.04\left(\frac{r}{H}\right)^{-1/3} \quad \text{for } 0.2 \le \frac{r}{H} < 2.0 \tag{14.22}$$

An alternate derivation of Equation 14.22 can be obtained by using Alpert's correlation for ceiling jet excess temperature (Equation 14.3) and Alpert's theory for average ceiling jet velocity (Equation 14.14) with the Reynolds/Colburn analogy, as discussed by Yu and Faeth [10] and Veldman [11]. From the Reynolds/Colburn analogy, the heat-transfer coefficient at the ceiling, h, should be related to ceiling jet average velocity and density as follows:

$$\frac{h}{\rho_\infty U c_p} = \mathrm{Pr}^{-2/3}\frac{f}{2} \tag{14.23}$$

where Pr is the Prandtl number and f is the ceiling friction factor. By using Equation 14.14 for average ceiling jet velocity, U, the ceiling heat-transfer coefficient becomes

$$h = 0.246 f \left(\frac{\dot{Q}_c}{H}\right)^{1/3}\left(\frac{r}{H}\right)^{-0.69} \quad \text{for } 0.17 \le \frac{r}{H} < 4.0 \tag{14.24}$$

With $f = 0.03$, Equation 14.24 is identical to the simplified expression listed in Beyler's extensive compilation [19]. The nondimensional heat flux to a ceiling at ambient temperature can then be expressed as follows, since $\dot{q}'' = h\Delta T$, with ΔT given by Equation 14.3:

$$\frac{\dot{q}'' H^2}{\dot{Q}_c} = 1.323 f \left(\frac{r}{H}\right)^{-1.36} \quad \text{for } 0.2 \le \frac{r}{H} < 4.0 \tag{14.25}$$

Equations 14.22 and 14.25 are in good agreement for a friction factor of 0.03, which is comparable with the value of 0.02 deduced from Alpert's [4] theory.

Sloped Ceilings

There have been very few studies of the ceiling jet flow resulting from plume impingement on an inclined, flat ceiling, i.e., where the ceiling is inclined at some angle, θ, to the horizontal. One such study, by Kung et al. [24], obtained measurements showing pronounced effects in the velocity variation along the steepest run from the point of impingement of a strong plume, both in the upward and downward directions. In the upward direction, the rate of velocity decrease with distance, r, from the intersection of the plume vertical axis with the ceiling was reduced significantly as the ceiling slope increased. In the downward direction, the flow separated from the ceiling and turned upward at a location, $-r$, denoted by Kung et al. [24] as the penetration distance. These results were the outcome of experiments with 0.15- and 0.228-m-diameter pan fires located 0.279 to 0.889 m beneath an inclined 2.4-m square ceiling and were limited to convective heat release rates in the range of 3–13 kW.

Following Heskestad and Hamada [6], Kung et al. developed correlations by scaling near-maximum excess temperature and velocity, as well as radial distance along the ceiling, in terms of the quantities in the undeflected plume at the impingement point. These correlations take the following form:

$$\frac{\Delta T}{\Delta T_p} = \exp\left[(0.12\sin\theta - 0.42)\left(\frac{r}{b} - 1\right)^{0.7}\right] \tag{14.26}$$

[3] Note that there is a typographical error in the exponent of r/H in Equation 14.17 of this reference.

$$\frac{U}{V_p} = \exp\left[(0.79\sin\theta - 0.52)\left(\frac{r}{b} - 1\right)^{0.6}\right] \tag{14.27}$$

for $r/b \geq 1$(upward direction from the impingement point, i.e., r = r_{up}) and θ = 0 − 30°;

$$\frac{\Delta T}{\Delta T_p} = (0.15\sin\theta - 0.11)\left(\frac{r}{b}\right) + 0.97 - 0.06\sin\theta \tag{14.28}$$

$$\frac{U}{V_p} = (0.21\sin\theta - 0.10)\left(\frac{r}{b}\right) + 0.99 - 1.17\sin\theta \tag{14.29}$$

for $r/b < 0$ (downward direction from the impingement point), valid only for θ = 0 − 30°, and for ΔT and U ≥ 0.

In Equations 14.26, 14.27, 14.28, and 14.29, the characteristic plume radius is proportional to that defined in Equation 14.18 but with a slightly different magnitude, namely,

$$b = 0.548\left[\left(c_p\rho_\infty\right)^{4/5}T_\infty^{3/5}g^{2/5}\right]^{-1/2}\frac{T_p^{1/2}\dot{Q}_c^{2/5}}{\Delta T_p^{3/5}} \tag{14.30}$$

Equation 14.29 shows that the ceiling jet velocity first becomes zero in the downward direction at values of r/b equal to −5.6, −3.5, and −2.0 for ceiling slopes of 10°, 20°, and 30°, respectively.

About 10 years after the work by Kung et al., additional measurements of gas temperature and velocity under inclined ceilings with thermocouples and bidirectional tubes, respectively, were obtained by Sugawa et al. [25]. These experiments involved nearly full-scale conditions (ceiling clearance, H, on the fuel centerline of 1.25–2.5 m) with a 200 mm diameter propane gas burner fire providing 10–100 kW heat release rates. Formulas for ceiling jet excess temperature and velocity along the "upslope" and perpendicular to the "upslope" directions are provided for slope angles from 0° to 60°. In many of these experiments, there is flame impingement on the ceiling and flame in the ceiling jet.

Very recently (about 10 years after the preceding studies by Sugawa et al.), new correlations have been developed by Y. Oka and colleagues at Yokohama National University from significant additional measurements under ceilings inclined from the horizontal up to a maximum angle, θ, of 40° and having a centerline clearance, H, above the fuel surface of 1 m. In these studies [26, 27], ceiling jet gas velocity is measured not only with bi-directional tubes but also with a Particle Imaging Velocimetry (PIV) system that makes use of smoke particles naturally present in the plume from the 0.285 m square heptane pan fire (heat release rate of 43 kW). By having two methods for measuring velocity, the authors [26] determined that the bidirectional probe generally provided a bulk mean velocity whereas the high resolution PIV system could provide a true maximum velocity. The ratio of the former to the latter is determined to be 0.828 instead of 0.707, as would be expected for the classic half-Gaussian velocity profile. Algebraic expressions for ceiling jet velocity have been obtained [26] both for the case of the flame tip below the inclined ceiling and for flame impingement on the inclined ceiling. In the latter case, gas velocity continues to increase in the flame zone in the steepest upward direction from the impingement point (as occurs in the fire plume itself) before becoming nearly constant and then decreasing with distance in the upward direction. Oka et al. [27] have now developed, from data for $0 < \theta < 40°$, a single algebraic expression for maximum ceiling jet gas velocity, U_{up}, at the steepest upward radial distance, r_{up}, from plume impingement, which covers cases both with and without flame impingement on a ceiling, as follows:

$$\frac{U_{up}}{\sqrt{g\left(H + r_{up}\sin\theta\right)}} = \alpha\left[\frac{r_{up}\cos\theta}{H + r_{up}\sin\theta}\right]^{\beta}\left\{Q_c^*(1 + \sin\theta)\right\}^{1/3} \tag{14.31}$$

where, for

$$\begin{array}{lll} 0.037 < r_{\text{up}} \cos\theta / \left(H + r_{\text{up}} \sin\theta\right) \leq 0.151 & \alpha = 6.051, & \beta = 0.458 \\ 0.151 < r_{\text{up}} \cos\theta / \left(H + r_{\text{up}} \sin\theta\right) \leq 0.350 & \alpha = 2.540, & \beta = 0 \\ 0.350 < r_{\text{up}} \cos\theta / \left(H + r_{\text{up}} \sin\theta\right) \leq 1.80 & \alpha = 0.855, & \beta = -1.040 \end{array}$$

and $Q_c^* =$ the usual definition (see Equation 14.9) with $\dot{Q}$ the convective component of heat release rate

The corresponding algebraic expression for near-maximum excess ceiling jet gas temperature from extensive thermocouple measurements that covers cases both with and without flame impingement on the ceiling is given by the following:

$$\frac{\Delta T}{T_\infty} = 2.778 \left[\frac{r_{up} \cos\theta}{H}\right]^{-0.781} \left\{Q_c^* (1 + \sin\theta)\right\}^{2/3} \quad 0.1 \leq r_{up} \cos\theta / H \leq 2.4 \tag{14.32}$$

The detailed velocity and excess temperature measurements discussed above have allowed Oka et al. [26] also to derive algebraic expressions for Gaussian ceiling jet velocity and excess temperature thickness under sloped ceilings. They determined that ceiling jet thickness was not affected by flame impingement as long as data corresponding to any region of continuous flaming are excluded. The expression for Gaussian thermal thickness under a sloped ceiling is given by:

$$\frac{L_T}{H} = \{0.00254\theta + 0.112\}\left[1 - exp\left(\beta_T \frac{r_{up}}{H}\right)\right] \tag{14.33}$$

where $\beta_T = -2.91 + 2.20[1 - \exp(-0.0662\theta)]$ and valid for $0.4 \leq r_{up}/H \leq 2.4$; $0 \leq \theta \leq 40°$.

Time-Dependent Fires

Quasi-Steady Assumption

For time-dependent fires, all estimates from the previous section may still be used, but with the constant heat release rate, $\dot{Q}$, replaced by an appropriate time-dependent $\dot{Q}(t)$. In making this replacement, a "quasi-steady" flow has been assumed. This assumption implies that when a change in heat release rate occurs at the fire source, full effects of the change are immediately felt everywhere in the flow field. In a room-sized enclosure, under conditions where the fire is growing slowly, this assumption is reasonable. However, in other cases, the time for the heat release rate to change significantly may be comparable to or less than the time, $t_f - t_i$, for gas to travel from the burning fuel to a detector submerged in the ceiling jet. The quasi-steady assumption may not be appropriate in this situation, unless the following condition is satisfied, depending on the accuracy desired:

$$\frac{\dot{Q}}{d\dot{Q}/dt} > t_f - t_i \tag{14.34}$$

where t_i is an ignition reference time.

The quasi-steady assumption, together with the strong plume-driven ceiling jet analysis of Heskestad and Hamada [6], has been used by Kung et al. [28] to correlate ceiling jet velocity and temperature induced by growing rack-storage fires. Although gas travel times for these large-scale experiments may amount to many seconds, Equation 14.34 shows that a sufficiently small fire-growth rate allows a quasi-steady analysis to be used.

Testing has shown that the heat release rate during the growth phase of many fires can often be characterized by simple time-dependent polynomial or exponential functions. The most extensive research and analysis have been performed with heat release rates that vary with the second power of time.

Power-Law Fire Growth

The growth phase of many fires can be characterized by a heat release rate increasing proportionally with a power, p, of time measured from the ignition reference time, t_i, as follows:

$$\dot{Q} = \alpha(t - t_i)^p \tag{14.35}$$

Figure 14.5 shows one case where the heat release rate for a burning foam sofa during the growth phase of the fire, more than 80 s (t_i) after ignition [29], can be represented by the following equation:

$$\dot{Q} = 0.1736(t - 80)^2 \tag{14.36}$$

Heskestad [30] used the general power-law behavior given by Equation 14.35 to propose a set of theoretical modeling relations for the transient ceiling jet flow that would result from such a time-varying heat release rate. These relations were validated in an extensive series of tests conducted by Factory Mutual Research Corporation [18, 31], where measurements were made of maximum ceiling jet temperatures and velocities during the growth of fires in three different sizes of wood crib. Subsequent to this original experimental study, Heskestad and Delichatsios [32] corrected the heat release rate, $\dot{Q}$, computed for the crib tests and also generalized their results to other types of fuels by using the more relevant convective heat release rate, $\dot{Q}_c$. The resulting dimensionless correlations for maximum ceiling jet temperatures and velocities are given by

$$\Delta T_2^* = 0 \quad t_2^* \le \left(t_2^*\right)_f \tag{14.37}$$

$$\Delta T_2^* = \left(\frac{t_2^* - \left(t_2^*\right)_f}{0.126 + 0.210r/H}\right)^{4/3} \quad t_2^* > \left(t_2^*\right)_f \tag{14.38}$$

$$\frac{U_2^*}{\sqrt{\Delta T_2^*}} = 0.59\left(\frac{r}{H}\right)^{-0.63} \tag{14.39}$$

where

$$t_2^* = \frac{t - t_i}{\left(A\alpha_c H^{-4}\right)^{-1/5}} \tag{14.40}$$

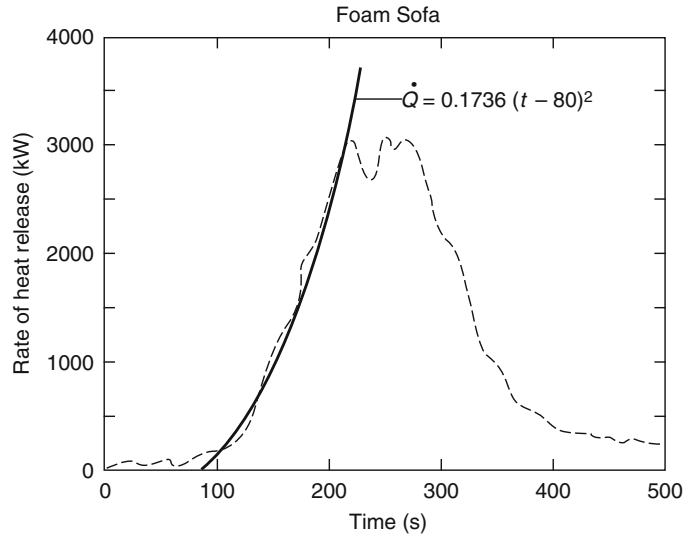

Fig. 14.5 Heat release rate history for a burning foam sofa [29]

$$U_2^* = \frac{U}{(A\alpha_c H)^{1/5}} \tag{14.41}$$

$$\Delta T_2^* = \frac{(T - T_\infty)/T_\infty}{(A\alpha_c)^{2/5} g^{-1} H^{-3/5}} \tag{14.42}$$

$$A = \frac{g}{\rho_\infty c_p T_\infty} \tag{14.43}$$

$$\alpha_c = \frac{\dot{Q}_c}{(t - t_i)^2} \tag{14.44}$$

$$(t_2^*)_f = 0.813\left(1 + \frac{r}{H}\right) \tag{14.45}$$

and where dimensionless variables are indicated with the superscript asterisk.

Notice that in Equation 14.38 the dimensionless time, t_2^* , has been reduced by the time $(t_2^*)_f$. This reduction accounts for the gas travel time, $t_f - t_i$, between the fire source and the location of interest along the ceiling at the specified r/H. For dimensionless times after ignition less than $(t_2^*)_f$, the initial heat front has not yet arrived at r/H so the gas temperature is still at the ambient value, as shown in Equation 14.37. In dimensional terms, the gas travel time is given by the following, after using the definition of t_2^* in Equation 14.45:

$$t_f - t_i = H^{4/5} \frac{0.813(1 + r/H)}{(A\alpha_c)^{1/5}} \tag{14.46}$$

Substitution of Equation 14.35 into Equation 14.34 shows that for power-law fire growth, the quasi-steady assumption will always be valid beginning at a sufficiently long time after ignition. For the specific case of t^2 fire growth, substitution of Equation 14.44 and the expression for the gas travel time, Equation 14.46, into Equation 14.34 results in the following requirement if a quasi-steady analysis is to be appropriate:

$$\frac{t - t_i}{2} > H^{4/5} \frac{0.813(1 + r/H)}{(A\alpha_c)^{1/5}} \tag{14.47}$$

In the limit of very large values of $t - t_i$, Equation 14.47 will always be satisfied and a quasi-steady limit is achieved, as shown by an alternative method by Heskestad [18]. The value of the quasi-steady excess temperature, $(\Delta T_2^*)_{qs}$, in this limit of $t_2^* \gg (t_2^*)_f$ becomes, from Equation 14.38

$$(\Delta T_2^*)_{qs} = \left(\frac{t_2^*}{0.126 + 0.210 r/H}\right)^{4/3} \tag{14.48}$$

The preceding correlations of ceiling jet temperatures and velocities are the basis for the calculated values of fire detector spacing found in *NFPA 72®*, *National Fire Alarm Code®*, Appendix B, "Engineering Guide for Automatic Fire Detector Spacing" [33]. In *NFPA 72,* three or four selected fire heat release rates assumed to increase proportionally with the square of time are used as the basis for the evaluation. These fire heat release rate histories are chosen to be representative of actual fires involving different commodities and geometric storage arrangements. The chosen release rate histories are as follows:

Slow $\dot{Q} = 0.00293 t^2$ (14.49)

Medium $\dot{Q} = 0.01172 t^2$ (14.50)

Fast $\dot{Q} = 0.0469 t^2$ (14.51)

Ultrafast $\dot{Q} = 0.1876 t^2$ (14.52)

where $\dot{Q}$ is in kW and t is in s.

EXAMPLE Sofa fire: Consider how the following calculation demonstrates a use of the correlation (Equations 14.38 and 14.39) for calculating the ceiling jet maximum temperature and velocity produced by a t^2 fire growth.

A foam sofa, of the type analyzed in Fig. 14.5, is burning in a showroom 5 m below a suspended ceiling. The showroom temperature remote from the fire remains at 20 °C at floor level as the fire begins to grow. Determine the gas temperature and velocity at the position of a ceiling-mounted fire detector submerged in the ceiling jet flow 4 m away from the fire axis when the convective heat release rate (assumed to equal the total heat release rate) first reaches 2.5 MW.

Figure 14.5 shows that the heat release rate from the sofa first reaches 2.5 MW (2500 kW) at about 200 s after ignition. Using the analytic formula for the time-dependent heat release rate, Equation 14.36, the time from the virtual ignition of the sofa at 80 s to reach 2500 kW is

$$2500 - 0.1736(t - 80)^2$$
$$(t - 80) = 120 \text{ s}$$

In this problem, the low-level heat release rate up to 80 s after actual ignition of the sofa is ignored. Thus, the sofa fire can be treated as having started at $t = 80$ s and grown to 2.5 MW in the following 120 s. Equations 14.40, 14.41, 14.42, 14.43, 14.44, and 14.45 are used to evaluate parameters of the problem, using the dimensionless correlations for ceiling jet temperature and velocity.

For the sofa fire in the showroom example, $T_\infty = 293$ K, $\rho = 1.204$ kg/m^3, $c_p = 1$ kJ/kg·K, $g = 9.8$ m/s^2, $\alpha_c = 0.1736$ kW/s^2, $A = 0.0278$ m^4/kJ · s^2, $r = 4$ m, $H = 5$ m, $\left(t_2^*\right)_f = 1.46$, $t - t_i = 120$ s, and $t_2^* = 11.40$. For the conditions of interest, $t_2^* > \left(t_2^*\right)_f$, so the correlation (Equation 14.38) is used to evaluate the dimensionless ceiling jet temperature

$$\Delta T_2^* = \left[\frac{11.40 - 1.46}{0.126 + 0.210(4/5)}\right]^{4/3}$$
$$\Delta T_2^* = 109.3$$

Equation 14.39 is used to calculate the dimensionless ceiling jet velocity

$$U_2^* = 0.59(4/5)^{-0.63}\sqrt{109.3} = 7.10$$

The dimensional excess temperature and velocity are calculated using Equations 14.42 and 14.41, respectively, to yield

$$\Delta T = 147\,\text{K}$$
$$T = 147\,\text{K} + 293\,\text{K} = 440\,\text{K} = 167^\circ\text{C}$$
$$U = 3.37\,\text{m/s}$$

The corresponding gas temperature calculated with the quasi-steady analysis of Equation 14.48 instead of the fire analysis is 197 °C.

EXAMPLE Rack storage: Yu and Stavrianidis [34] were interested in predicting activation times of quick-response sprinklers protecting high rack storage of plastics. Since the sprinklers are activated typically in less than 1 min by the ceiling jet flow, information on flow temperature and velocity shortly after ignition is required. The objective was to correlate properties of the ceiling jet induced by fires in 2- to 5-tier-high rack storage, consisting of polystyrene cups packaged in corrugated paper cartons on pallets. When this fuel array is ignited at its base, the initial growth period ($t_f - t_i \approx 25$ s) can be characterized as heat release rates increasing by the third power of time, as follows:

$$\dot{Q}_c = \alpha_c (t - t_i)^3 \tag{14.53}$$

where $\alpha_c = 0.0448$. Because of upward and lateral flame propagation during the transient rack-storage fire, the virtual origin elevation, z_o, of the plume changes during the course of fire growth, as follows:

$$z_o = -2.4 + 0.095\dot{Q}_c^{2/5} \tag{14.54}$$

thereby complicating the effort to correlate ceiling jet properties. Nevertheless, Yu and Stavrianidis were able to develop correlations based on the following dimensional temperature and velocity variables, which are similar to those first proposed by Heskestad [30] for power-law fire growth:

$$\Delta\hat{T}_m = \alpha_c^{-1/3}(H - z_o)^{1/3}\frac{\Delta T_m}{T_\infty} \tag{14.55}$$

$$\hat{U}_m = \alpha_c^{-1/6}(H - z_o)^{-1/3}U_m \tag{14.56}$$

where the maximum ceiling jet excess temperature, $\Delta\hat{T}_m$, and velocity, $\hat{U}_m$, variables depend on the following heat release rate and radial distance parameters, respectively:

$$X = \alpha_c^{-1/6}(H - z_o)^{-2/3}\dot{Q}_c^{1/3} \tag{14.57}$$

$$\hat{R} = \frac{r}{H - z_o} \tag{14.58}$$

The exact form of the preceding correlations, in terms of detailed formulas, is provided by Yu and Stavrianidis [34].

In addition to maximum excess gas temperature and velocity, Yu and Stavrianidis [34] also measured the depth of the ceiling jet, in terms of the distance below the ceiling where the velocity and excess temperature are $1/e$ of the respective maximum values. Results show the ceiling jet depth based on velocity to be very similar to that based on excess temperature and both depths to be fairly insensitive to the transient fire growth process. Typical values for the ratio of ceiling jet temperature depth to effective ceiling height, $\ell_T/(H - z_o)$, for radial positions, $r/(H - z_o)$ of 0.217, 0.365, 1.75, and 4.33 are about 0.07, 0.1, 0.14, and 0.2, respectively.

Confined Ceilings

Channel Configuration

Previous discussions of ceiling jets in this chapter have all dealt with unconfined radial spread of the gas flow away from a ceiling impingement point. In practice this flow may be interrupted by ceiling beams or corridor walls, creating a long channel that partially confines the flow. Knowledge of the resultant ceiling jet flows is important in determining fire detector response times. For the channel configuration, the flow near the impingement point will remain radial (i.e., axisymmetric), but after spreading to the walls or beams that bound the ceiling, the flow will become generally parallel with the confining boundary. Delichatsios [35] has developed correlations for steady-state ceiling jet temperature and velocity, which apply to the channel flow between beams and down corridors. In the case of corridors, the correlations apply when the corridor half-width, ℓ_b, is greater than 0.2 times the ceiling height, H, above the fire source. Note that this value of ℓ_b corresponds approximately to the outer radius of the ceiling jet turning region. In the case of beams, the flow must also be contained fully so that only a flow in a primary channel results, without spillage under the beams to the adjoining secondary channels. For the latter condition to be satisfied, the beam depth, h_b, must be greater than the quantity $(H/10)(\ell_b/H)^{-1/3}$. Downstream of where the ceiling jet flow is parallel to the beams or corridor walls and in the absence of spillage, Delichatsios [35] determined that the average excess ceiling jet temperature and velocity within the primary channel are given by the following:

$$\frac{\Delta T}{\Delta T_p} = \mathrm{a}\left(\frac{H}{\ell_b}\right)^{1/3} \exp\left[-6.67\mathrm{St}\frac{Y}{H}\left(\frac{\ell_b}{H}\right)^{1/3}\right] \tag{14.59}$$

$$U = 1.102\sqrt{H\Delta T}\left(\frac{H}{\ell_b}\right)^{1/6} \tag{14.60}$$

under the conditions

$$Y > \ell_b$$
$$h_b/H > 0.1(\ell_b/H)^{-1/3}$$
$$\ell_b/H > 0.2$$
$$0.5 < \frac{Y}{H}\left(\frac{\ell_b}{H}\right)^{1/3} < 3.0$$

where

ΔT_p = Excess temperature on the plume centerline defined previously in Equation 14.17

Y = Distance along the channel measured from the plume impingement point

St = Stanton number, whose value is recommended to be 0.03

Based on the minimum value of $\ell_b/H = 0.2$, the limit on h_b/H implies that the beam depth to ceiling height ratio must be at least 0.17 for the fire gases to be restricted to the primary channel. The constant a in Equation 14.59 is determined by Delichatsios to be in the range 0.24–0.29. This equation is based on the concept that the channel flow has undergone a hydraulic jump, which results in greatly reduced entrainment of cooler, ambient air from below. Reductions in ceiling jet temperature or velocity are then mainly due to heat losses to the ceiling and would thus be dependent on ceiling composition to some extent.

Additional detailed measurements of the ceiling jet flow in a primary beamed channel have been obtained by Koslowski and Motevalli [36]. Their data generally validate the

Delichatsios beamed ceiling correlation (Equation 14.61) and ceiling jet flow behavior, but additional measurements for a range of beam depth to ceiling height ratios has allowed the correlation to be generalized. Furthermore, Koslowski and Motevalli recast the correlation in terms of the nondimensional heat release rate defined by Heskestad and Delichatsios (Equations 14.9 and 14.10), instead of centerline plume conditions at the ceiling, with the following result:

$$\Delta T_0^* = \mathrm{C}\left(\frac{H}{\ell_b}\right)^{1/3} \exp\left[-6.67\,\mathrm{St}\frac{Y}{H}\left(\frac{\ell_b}{H}\right)^{1/3}\right] \tag{14.61}$$

where the Stanton number is recommended to be 0.04, rather than 0.03, and the constant, C, has the following dependence on the ratio of beam depth, h_b, to ceiling height, H:

$$\mathrm{C} = -25.38\left(\frac{h_b}{H}\right)^2 + 13.58\frac{h_b}{H} + 2.01 \quad \text{for } 0.5 \le \frac{Y}{H} \le 1.6 \tag{14.62}$$

To derive Equation 14.62, Koslowski and Motevalli vary the h_b/H ratio from 0.07 up to 0.28. In so doing, they note that C increases steadily with this ratio until leveling off near $h_b/H = 0.17$, determined by Delichatsios as the condition for the fire gases to be restricted to the primary channel. Between values of h_b/H of 0.07 (or even much less) and 0.17, spillage from the primary channel to adjacent secondary channels is steadily reduced, thereby increasing temperatures in the primary channel. Characteristics of the ceiling jet flow in the secondary channels, as well as the primary channel, have also been studied by Koslowski and Motevalli [37].

Corner Configuration with Strong Plumes

An open configuration of two walls at a 90° angle to form a corner, covered by a ceiling, with a fire source at the base of and in close contact with the corner, is often used as a hazardous environment in which to test the flammability of wall and ceiling linings. This wall-ceiling-corner configuration also occurs naturally in many types of enclosures (see below) where hot gases from the fire source may be partially or completely confined by more than just the ceiling and corner walls themselves, resulting in the formation of a hot gas layer near the ceiling. In this section, the environment of an open corner with inert lining surfaces is discussed, where a ceiling jet develops due to impingement of a fire plume or flames from the source fire at the base of the wall corner onto the ceiling covering the wall-corner. A careful study of this environment based on full-scale tests was conducted by Lattimer and Sorathia [38]. These tests used a ceiling clearance of 2.25 m above the surface of a 0.17–0.50 m^2 or L-shaped line (each leg being 0.17–0.50 m) sand burner having propane heat release rates from 50 to 300 kW.

Thermocouple measurements [38] of excess gas temperature at a radial distance from the corner, r, in the ceiling jet could be correlated (with a regression coefficient of 0.85) by the following formulas:

$$T - T_\infty = 950 \quad \text{for} \quad \frac{r+H}{L_{f,tip}} \le 0.55 \tag{14.63}$$

$$T - T_\infty = C\left[\frac{r+H}{L_{f,tip}}\right]^{-2} \quad \text{for} \quad \frac{r+H}{L_{f,tip}} > 0.55 \tag{14.64}$$

The specific value of 950 for the maximum excess of corner fire gas temperature above ambient in Equation 14.63 may vary for fire sources other than the propane burner or for corner walls having thermal characteristics different from those used in these specific tests. However, it is expected that the functional dependencies for ceiling jet temperature should be preserved. Note that the constant, C, in Equation 14.64 is 288 for the square burner of side, D, and 340 for the L-shaped line burner, each leg of which is length, D and that $L_{f,tip}$ is the flame length from the surface of either type burner to the flame tip, the furthest location where flame

tips are observed visually, as determined from the correlation [38],

$$\frac{L_{f,tip}}{D} = 5.9\sqrt{Q^*} \qquad (14.65)$$

where Q^* is based on actual fire heat release rate and the burner length-scale, D (instead of the usual ceiling clearance, H).

Lattimer and Sorathia [38] also used twenty Schmidt-Boelter gauges to measure heat flux to the bounding surfaces of the corner configuration from the propane sand burner flames. Their measurements of total heat flux, $\dot{q}''$, to the ceiling surface from the ceiling jet flames and/or hot gases could be correlated by the following for either the square or L-shaped line burner:

$$\dot{q}'' = 120 \quad \text{for} \quad \frac{r+H}{L_{f,tip}} \leq 0.58 \qquad (14.66)$$

$$\dot{q}'' = 18\left[\frac{r+H}{L_{f,tip}}\right]^{-3.5} \quad \text{for} \quad \frac{r+H}{L_{f,tip}} > 0.58 \qquad (14.67)$$

where the flame tip total length is given by Equation 14.65, above. This same formula is found also to predict the maximum heat flux to the top portion of the wall from the ceiling jet flow, where now the variable, r, represents distance from the corner along the top of the wall.

Again, the specific maximum heat flux of 120 kW/m^2 that was measured in the corner configuration by Lattimer and Sorathia [38] may vary for fuels with thermal radiation characteristics much different from those of propane or for different burner configurations. For example, it is well known that peak heat fluxes in pool and solid fuel fires can exceed 140–160 kW/m^2, as discussed by Coutts [39].

General Enclosure Configurations

The analyses in preceding sections for unconfined ceiling jet flows may be sufficient for large industrial or commercial storage facilities. In smaller rooms, or for very long times after fire ignition in larger industrial facilities, a quiescent, heated layer of gas will accumulate in the upper portion of the enclosure. This heated layer can be deep enough to totally submerge the ceiling jet flow. In this case, temperatures in the ceiling jet can be expected to be greater than if the ceiling jet were entraining gas from a cooler, ambient-temperature layer. It has been shown by Yu and Faeth [10] that the submerged ceiling jet also results roughly in a 35 % increase in the heat transfer rate to the ceiling.

There are analytical formulas to predict temperature and velocity in such a two-layer environment, in which the ceiling jet is contained in a heated upper layer and the fire is burning in a lower, cool layer. This type of prediction, which has been developed by Evans [40, 41], Cooper [42], and Zukoski and Kubota [43], can best be used to check the proper implementation of readily available numerical models (e.g., zone or field/CFD) of fire-induced flows in enclosures. An example of a zone model to predict activation of thermal detectors by a ceiling jet submerged in a heated layer is the algorithm developed by Davis [44]. This model, which assumes that thermally activated links are always located below the ceiling at the point of maximum ceiling jet temperature and velocity, is based partly on a model and thoroughly documented software developed by Cooper [45].

Formulas to predict the effect of the heated upper layer in an enclosure are based on the assumption that the ceiling jet results from a fire contained in a uniform environment at the heated upper-layer temperature. This substitute fire has a heat release rate, $\dot{Q}_2$, and location below the ceiling, H_2, differing from those of the real fire. Calculation of the substitute quantities $\dot{Q}_2$ and H_2, depends on the heat release rate and location of the real fire, as well as the depths and temperatures of the upper and lower layers within the enclosure.

Following the development by Evans [41], the substitute source heat release rate and distance below the ceiling are calculated from Equations 14.68, 14.69, 14.70, and 14.71. Originally developed for the purpose of sprinkler and heat detector response time calculations, these

equations are applicable during the growth phase of enclosure fires.

$$\dot{Q}^*_{I,2} = \left(\frac{1 + C_T \dot{Q}^{*\,2/3}_{I,1}}{\xi C_T} - \frac{1}{C_T} \right)^{3/2} \tag{14.68}$$

$$Z_{I,2} = \left\{ \frac{\xi \dot{Q}^*_{I,1} C_T}{\dot{Q}^{*\,1/3}_{I,2} \left[(\xi - 1)(\beta^2 + 1) + \xi C_T \dot{Q}^{*\,2/3}_{I,2} \right]} \right\}^{2/5} Z_{I,1} \tag{14.69}$$

$$\dot{Q}_{c,2} = \dot{Q}^*_{I,2} \rho_{\infty,2} c_{p\infty} T_{\infty,2} g^{1/2} Z^{5/2}_{I,2} \tag{14.70}$$

$$H_2 = H_1 - Z_{I,1} + Z_{I,2} \tag{14.71}$$

Further explanation of variables is contained in the nomenclature section.

Cooper [42] has formulated an alternative calculation of substitute source heat release rate and distance below the ceiling that provides for generalization to situations in which portions of the time-averaged plume flow in the lower layer are at temperatures below the upper-layer temperature. In these cases, only part of the plume flow may penetrate the upper layer sufficiently to impact on the ceiling. The remaining portion at low temperature may not penetrate into the hotter upper layer. In the extreme, when the maximum temperature in the lower-layer plume flow is less than the upper-layer temperature, none of the plume flow will penetrate significantly into the upper layer. This could be the case during the decay phases of an enclosure fire, when the heat release rate is small compared to earlier in the fire growth history. In this calculation of substitute fire-source quantities, the first step is to calculate the fraction of the plume mass flow penetrating the upper layer, m^*_2, from Equations 14.72 and 14.73.

$$m^*_2 = \frac{1.04599\sigma + 0.360391\sigma^2}{1 + 1.37748\sigma + 0.360391\sigma^2} \tag{14.72}$$

where

$$\sigma = \left(\frac{\xi}{\xi - 1} \right) \left[\frac{1 + C_T \left(\dot{Q}^*_{I,1} \right)^{2/3}}{\xi} - 1 \right] \tag{14.73}$$

Then, analogous to Equations 14.69, 14.70, and 14.71 of the previous method:

$$Z_{I,2} = Z_{I,1} \xi^{3/5} \left(m^*_2 \right)^{2/5} \left(\frac{1 + \sigma}{\sigma} \right)^{1/3} \tag{14.74}$$

$$\dot{Q}_{c,2} = \dot{Q}_{c,1} \left(\frac{\sigma m^*_2}{1 + \sigma} \right) \tag{14.75}$$

$$H_2 = H_1 - Z_{I,1} + Z_{I,2} \tag{14.76}$$

The last step is to use the substitute source values of heat release rate and distance below the ceiling, as well as heated upper-layer properties for ambient conditions, in the correlations developed for ceiling jet flows in uniform environments.

To demonstrate the use of the techniques, the previous example in which a sofa was imagined to be burning in a showroom may be expanded. Let all the parameters of the problem remain the same except that at 200 s after ignition ($t - t_i$ = 120 s), when the fire heat release rate has reached 2.5 MW, a quiescent heated layer of gas at a temperature of 50 °C is assumed to have accumulated under the ceiling to a depth of 2 m. For this case, the two-layer analysis is needed to determine the ceiling jet maximum temperature at the same position as calculated previously (a radial distance of 4 m from the plume impingement point on the ceiling).

All of the two-layer calculations presented assume quasi-steady conditions. From Equation 14.47 with the values of parameters in the single-layer calculation, it can be shown that the time after sofa ignition must be at least 31 s for a quasi-steady analysis to be acceptable. Since the actual time after ignition is 120 s, such an analysis is appropriate. It will be assumed that this finding will carry over to the two-layer case.

Using Equations 14.68, 14.69, 14.70, and 14.71 from the work of Evans [41], values of the heat release rate and position of the substitute fire source that compensates for the two-layer effects on the plume flow can be calculated. The dimensionless heat release rate of the real fire source evaluated at the position of the interface between the upper and lower layers is as follows:

$$\dot{Q}^*_{I,1} = \frac{\dot{Q}}{\rho_\infty c_{p\infty} T_\infty g^{1/2} Z_{I,1}^{5/2}} \qquad (14.77)$$

For an actual heat release rate of 2500 kW, ambient temperature of 293 K, and distance between the fire source and the interface between the lower and upper layers of 3 m, Equation 14.77 becomes

$$\dot{Q}^*_{I,1} = \frac{2500}{1.204 \times 1 \times 293 \times 9.8^{1/2} \times 3^{5/2}} = 0.1452$$

Using the ratio of upper-layer temperature to lower-layer temperature, $\xi = 323/293 = 1.1024$, and the constant, $C_T = 9.115$, the dimensionless heat release rate for the substitute fire source is

$$\dot{Q}^*_{I,2} = 0.1179$$

Using the value for the constant $\beta^2 = 0.913$, the position of the substitute fire source relative to the two-layer interface is

$$Z_{I,2} = 3.161$$

Now, from Equations 14.76 and 14.77, the dimensional heat release rate and position relative to the ceiling are found to be

$$\dot{Q}_2 = 2313\,\text{kW} \quad H_2 = 5.161\,\text{m}$$

The analogous calculations for substitute fire-source heat release rate and position following the analysis of Cooper [42], Equations 14.72, 14.73, 14.74, 14.75, 14.76, and 14.77, are

$$\sigma = 23.60$$
$$m_2^* = 0.962$$
$$Z_{I,2} = 3.176$$
$$\dot{Q}_2 = 2308\,\text{kW}$$
$$H_2 = 5.176\,\text{m}$$

These two results are essentially identical for this type of analysis.

Since it has been shown that the quasi-steady analysis is appropriate for this example, the dimensionless maximum temperature in the ceiling jet flow, 4 m from the impingement point, can now be calculated from $(\Delta T_2^*)_{qs}$ in Equation 14.48. Using the ceiling height above the substitute source, this equation yields the result

$$(\Delta T_2^*)_{qs} = \left[\frac{11.40}{0.126 + 0.210(4/5.161)}\right]^{4/3} = 134.4$$

For the given time after ignition of 120 s and the assumed fire growth, the calculated $\dot{Q}_2$ value implies that α equals 0.1606, instead of the original sofa fire growth factor of 0.1736. Substitution of this new α in Equation 14.42, along with H_2 and the upper-layer temperature as the new ambient value, yields the following dimensional excess temperature at the 4-m radial position in the ceiling jet:

$$\Delta T = \frac{134.4 \times 323 \times (0.0278 \times .01606)^{2/5}}{9.8 \times 5.161^{3/5}}$$
$$\Delta T = 190\,\text{K}$$
$$T = 190\,\text{K} + 323\,\text{K} = 513\,\text{K} = 240^\circ\text{C}$$

This is 73 °C above the temperature calculated previously using the quasi-steady analysis and a uniform 20 °C ambient, demonstrating the effect of flow confinement on gas temperature.

Ceiling Jet Development

At the beginning of a fire, the initial buoyant flow from the fire must spread across the ceiling, driven by buoyancy, to penetrate the cooler ambient air ahead of the flow. Research studies designed to quantify the temperatures and velocities of this initial spreading flow have been initiated [46]. At a minimum, it is useful to become aware of the many fluid mechanical phenomena embodied in a description of the ceiling jet flow in a corridor up to the time when the ceiling jet is totally submerged in a quiescent, warm upper layer. Borrowing heavily from a description of this flow provided by Zukoski et al. [46], the process is as follows.

A fire starts in a small room with an open door to a long corridor having a small vent near the floor at the end opposite the door. As the fire

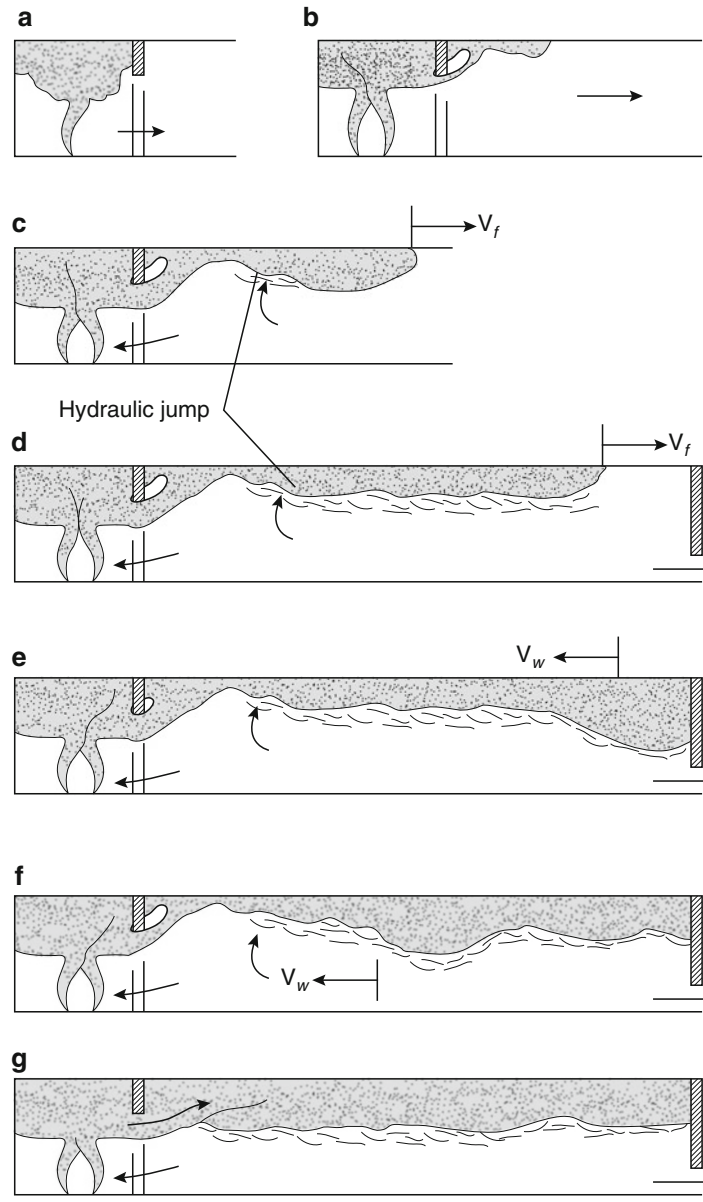

Fig. 14.6 Transient ceiling jet flow in a room and corridor [45]

starts, smoke and hot gases rise to form a layer near the fire room ceiling. The layer is contained in the small room by the door soffit (Fig. 14.6a). As the fire continues, hot gas from the room begins to spill out under the soffit into the hallway. The fire grows to a relatively constant heat release rate.

The outflowing gas forms a short, buoyant plume (Fig. 14.6b) that impinges on the hallway ceiling, producing a thin jet that flows away from the fire room in the same manner that the plume within the room flows over the interior ceiling. The gas flow in this jet is supercritical, analogous to the shooting flow of liquids over a weir. The velocity of the gas in this flow is greater than the speed of gravity waves on the interface between the hot gas and the cooler ambient air. The interaction of the leading edge of this flow with the ambient air ahead of it produces a hydraulic, jumplike condition, as shown in Fig. 14.6c.

A substantial amount of ambient air is entrained at this jump. Downstream of the jump, the velocity of the gas flow is reduced and mass flow is increased due to the entrainment at the jump. A head is formed at the leading edge of the flow. Mixing between this ceiling-layer flow and the ambient cooler air occurs behind this head.

The flow that is formed travels along the hallway ceiling (Fig. 14.6c, d) with constant velocity and depth until it impinges on the end wall (Fig. 14.6e). A group of waves are reflected back toward the jump near the fire room, traveling on the interface. Mixing occurs during the wall impingement process (Fig. 14.6f), but no significant entrainment occurs during the travel of the nonbreaking reflected wave. When these waves reach the jump near the fire room door, the jump is submerged in the warm gas layer, eliminating the entrainment of ambient lower-layer air at this position (Fig. 14.6g).

After several wave reflections up and down the corridor along the interface, the wave motion dies out, and a ceiling layer uniform in depth is produced. This layer slowly grows deeper as the hot gas continues to flow into the hallway from the fire room.

It is clear from the preceding description that quantification of effects during development of a submerged ceiling jet flow is quite complex.

Analyses and experiments have been performed to better understand the major features of a developing ceiling jet flow in a corridor [47, 48]. One such study [49] contains a description somewhat different from that already given.

Summary

Reliable formulas are available to predict maximum gas temperatures and velocities and approximate temperature/velocity profiles in fire-driven ceiling jet flows beneath unobstructed ceilings for both steady and power-law fire growth. These predictive formulas, which also apply to certain situations where the ceiling jet flow is confined by beams or corridor walls, are very useful for verifying that detailed numerical models of fire phenomena (e.g., Hara and Shinsuke [50]) have been implemented properly. The predictive techniques are the basis for acceptable design of fire detection systems, as exemplified by Appendix B of *NFPA 72®, National Fire Alarm Code* [33].

Nomenclature

A	$g/(\rho_\infty c_p T_\infty)$ (m^2/kg)
a	Constant in Equation 14.59, equal to 0.24–0.29
b	Effective plume radius at the intersection with the ceiling elevation (m)
C_T	Constant [17], related to plume flow, equal to 9.115
c_p	heat capacity at constant pressure (J/kg K)
D	Burner dimension (m)
D_{eff}	Effective diameter of the base of the flame zone or the burning fuel
f	Ceiling friction factor
g	Gravitational acceleration (m/s^2)
H	Ceiling height above fire source; for sloped ceiling, on the fire axis (m)
h	Heat transfer coefficient (kW/m^2 K)
h_b	Depth of beams in a primary beam channel (m)
$L_{f,tip}$	Visible flame length from burner to furthest flame tip (m)
ℓ_b	Half-width for corridor or primary beam channel (m)
ℓ_T	Ceiling jet thickness based on $1/e$ depth of excess temperature profile (m)
m_2^*	Fraction of fire-plume mass flux penetrating upper layer
p	Ambient air pressure (Pa); also, as exponent of time for general power-law fire growth
Pr	Prandtl number
$\dot{Q}$	Total heat release rate (kW)
$\dot{Q}_c$	Convective heat release rate (kW)

$Q^*, \dot{Q}_0^*$	$\dot{Q}/\left(\rho_\infty c_p T_\infty \sqrt{g} H^{5/2}\right)$
Q_{fc}^*	$\dot{Q}_c/\left(\rho_\infty c_p T_\infty \sqrt{g} H^{5/2}\right)$
$\dot{q}''$	Rate of heat transfer per unit area (heat flux) to the ceiling surface (kW/m^2)
R	Radial distance to detector (m)
$\hat{R}$	$r/(H - z_o)$
Ra	Rayleigh number
Re	Reynolds number
r	Radial distance from axis of fire plume (m)
r_{up}	Radial distance in steepest upward direction from axis of fire plume (m)
St	Stanton number, $h/(\rho U c_p)$
T	Ceiling jet gas temperature (K)
T_∞	Ambient air temperature (K)
T_p	Peak gas temperature in plume at the intersection with ceiling elevation (K)
ΔT	Excess gas temperature, $T - T_\infty$ (K) or (°C)
t	Time (s)
U	Ceiling jet gas velocity (m/s)
U_{up}	Maximum ceiling jet gas velocity in the steepest upward direction (m/s)
V_p	Maximum plume velocity at the intersection with ceiling elevation (m/s)
Y	Distance along channel or corridor, measured from plume axis (m)
Z_I	Distance of layer interface above the real or substitute fire source (m)
z	Vertical distance above the base of the flame zone
z_H	Distance of ceiling above the base of the flame zone
z_o	Virtual origin elevation in a transient rack storage fire
z_v	Distance of virtual plume origin above the base of the flame zone
$d\dot{Q}/dt$	Rate of change of heat release rate with time (kW/s)

Greek Letters

α	Growth parameter for t^2 fires (kW/s^2)
β^2	Constant [17] related to plume flow, equal to 0.913
ν	Kinematic viscosity (m^2/s)
θ	Angle of inclination of the ceiling with respect to the horizontal (degrees)
ρ	Gas density (kg/m^3)
σ	Parameter defined in Equation 14.73
ξ	Ratio of temperatures, $T_{\infty,2}/T_{\infty,1}$

Subscripts

0	Based on steady-state fire source
1	Associated with lower layer
2	Associated with upper layer; or parameter associated with t^2 fire growth
∞	Ambient, outside ceiling jet or plume flows
c	Convective fraction
f	Associated with gas travel time delay
I	Value at the interface position between the heated upper layer and cool lower layer
i	Reference value at ignition
p	Associated with plume flow
qs	Quasi-steady flow condition

Superscripts

*	Dimensionless quantity
^	Quantity related to transient rack-storage fire

Dr. Ronald L. Alpert received his undergraduate and graduate education at the Massachusetts Institute of Technology, where he majored in mechanical engineering. For nearly 35 years, he was with FM Global in various technical and managerial positions, ending his career there as an assistant vice president and manager of the Flammability Technology Research Program. Dr. Alpert was editor in chief of the *Journal of Fire Protection Engineering for 10 years and a section editor of the NFPA Fire Protection Handbook, 20th edition. He has published numerous papers in refereed journals and technical reports.*

Vent Flows

15

Takeyoshi Tanaka

Introduction

Fire releases a great amount of heat that causes the heated gas to expand. The expansion produced by a fire in a room drives some of the gas out of the room. Any opening through which gas can flow out of the fire room is called a *vent*.

The most obvious vents in a fire room are open doors and open or broken windows. Ventilation ducts also provide important routes for gas release. A room in an average building may have all of its doors and windows closed and, if ventilation ducts are also closed, the gas will leak around normally closed doors and windows and through any holes made for pipes or wires. These holes will act as vents. (If a room were hermetically sealed, a relatively small fire would raise the pressure in the room and burst the window, door, or walls.)

Gas will move only if it is pushed. The only forces acting on the gas are the gas pressure and gravity. Since gravity acts vertically, it might seem that gas could only flow through a hole in the floor or ceiling. Gravity, however, can produce horizontal pressure changes, which will be explained in detail below. A gas flow that is caused directly or indirectly by gravity is called a *buoyant flow*.

When a pressure difference exists across a vent, fluid (liquid or gas) will be pushed through. Precise calculation of such flows from the basic laws of nature can only be performed today by the largest computers. For fire purposes, and all engineering purposes, calculations are carried out with sufficient precision using the methods of hydraulics. Since these formulas are only approximate, they are made sufficiently accurate (often to within a few percent) by a flow coefficient. These coefficients are determined by experimental measurements.

Calculation Methods for Nonbuoyant Flows

If a pressure drop, $\Delta p = p_1 - p_2$, exists across a vent of area, A, with a fluid density, ρ, the flow through the vent has (Fig. 15.1) [1]

$$\text{Velocity} \quad u = \sqrt{\frac{2\Delta p}{\rho}} \tag{15.1}$$

$$\text{Volume flow} \quad \dot{V} = CA\sqrt{\frac{2\Delta p}{\rho}} \tag{15.2}$$

and

$$\text{Mass flow} \quad \dot{m} = CA\sqrt{2\rho\Delta p} \tag{15.3}$$

In these formulas C is flow coefficient and the SI units are $\Delta p = (\text{Pa}) = (\text{N/m}^2)$, $A = (\text{m}^2)$, $\rho = (\text{kg/m}^3)$, $u = (\text{m/s})$, $\dot{V} = (\text{m}^3/\text{s})$, $\dot{m} = (\text{kg/s})$.

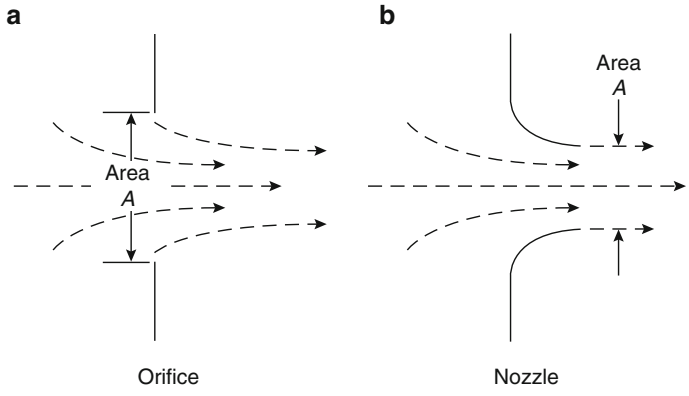

Fig. 15.1 Most fire vents are orifices

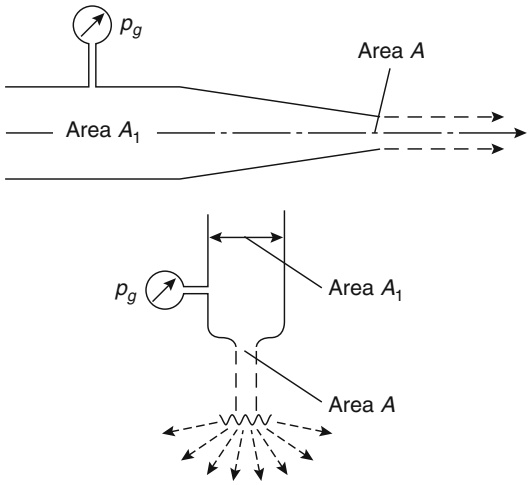

Fig. 15.2 A hose nozzle and a sprinkler nozzle

If the flow of water from a fire hose or sprinkler (Fig. 15.2) is to be calculated and the pressure, p_g, is read on a gauge (in lb/in.^{2}) at the entrance to the nozzle where the area is A_1, the previous formulas provide the velocity, volume flow, and mass flow by using

$$\Delta p = \frac{6895\, p_g}{1 - (A/A_1)^2} \tag{15.4}$$

where A is area of vent and A_1 is area of supply pipe. The factor 6895 converts pressure in lb/in.^{2} to Pascals while the factor $\left[1 - (A/A_1)^2\right]$ corrects Δp for the dynamic effect of the inlet velocity in the supply hose or pipe.

In the atmosphere, the pressure at the ground, p_a, is just sufficient to support the weight of the air above. If the air density is ρ_a, the pressure, p, at height, h, is less than p_a by the weight of the air below height, h. Thus the pressure difference is

$$\Delta p = p_a - p = \rho_a g h \tag{15.5}$$

It is sometimes convenient when considering fire gases to use $h = \Delta p/\rho a\, g$, the pressure head, in meters of ambient air, in the velocity and flow rate formulas given above.

The previous discussion supposes that the flowing fluid is of constant density. For liquids this is true for all practical situations. The density of air or fire gases will not change significantly during the flow through the vent so long as the pressure change is small, so they can also be treated as constant density fluids.

If the pressure drop is large, the equations become more complicated [2]. If the pressure and density upstream of the vent are p_1 and ρ_1 while the pressure after the vent is p_2, the equations for velocity and mass flow become

$$u = \sqrt{\frac{2p_1}{\rho_1}}\left\{\frac{\gamma}{\gamma - 1}\left(\frac{p_2}{p_1}\right)^{2/\gamma}\left[1 - \left(\frac{p_2}{p_1}\right)^{(\gamma-1)/\gamma}\right]\right\}^{1/2} \tag{15.6}$$

$$\dot{m} = CA\sqrt{2\rho_1 p_1}\left\{\frac{\gamma}{\gamma-1}\left(\frac{p_2}{p_1}\right)^{2/\gamma}\left[1-\left(\frac{p_2}{p_1}\right)^{(\gamma-1)/\gamma}\right]\right\}^{1/2} \tag{15.7}$$

where $\gamma = c_p/c_v$.

The value of γ depends on the complexity of the molecules of the flowing gas. For fire gases (which always contain a large amount of air) the value of γ will fall between 1.33 and 1.40. For most fire purposes the diatomic gas value (air) of 1.40 is sufficiently accurate.

The mass flow given by the previous equation has a maximum at

$$\frac{p_2}{p_1} = \left(\frac{2}{\gamma+1}\right)^{\gamma/(\gamma-1)} \tag{15.8}$$

For $\gamma = 1.40$, the maximum flow is reached for a downstream pressure $p_2 = 0.528\,p_1$. For all lower back pressures the flow remains constant at its maximum

$$\dot{m} = CA\sqrt{\rho_1 p_1}\left[\gamma\left(\frac{2}{\gamma+1}\right)^{(\gamma+1)(\gamma-1)}\right]^{1/2} \tag{15.9}$$

With these equations, the mathematical description of the rate of flow of liquids and gases through holes is complete as soon as the appropriate flow coefficients are known. The coefficients, found by experiment, correct the formulas for the effect of the fluid viscosity, the nonuniformity of the velocity over the vent, turbulence and heat transfer effects, the details of nozzle shape, the location of the pressure measurement points, and so forth. The corrections also depend on the properties and velocity of the fluid. The most important coefficient correction for any given vent geometry is the dimensionless combination of variables called the Reynolds number, Re, and

$$\mathrm{Re} = \frac{uD\rho}{\mu} \tag{15.10}$$

where

u = Velocity of the fluid given by the previous equations

D = Diameter of the nozzle or orifice

ρ = Density of the fluid approaching the vent

μ = Viscosity of the fluid approaching the vent

A door or window vent is almost always rectangular, not circular. The D to be used in the Reynolds number should be the hydraulic diameter

$$D = \frac{4A}{P} \tag{15.11}$$

where

A = Area of the vent

P = Perimeter of vent

For a rectangular vent, a wide and b high, $A = ab$, $P = 2(a+b)$.

$$D = \frac{2ab}{(a+b)} \tag{15.12}$$

The experimental values of the flow coefficients for nozzles and orifices, C, are given in Fig. 15.3 [2]. Flow coefficients for nozzles are near unity while for orifices are approximately 0.6, as can be seen in Fig. 15.1, where the flow from an orifice separates from the edge of the orifice and decreases to a much smaller area, in fact about 0.6 of the orifice area.

For most fire applications the Reynolds number will be about 10^6. Sprinklers and fire nozzles are small but the velocity is quite high. Conversely, ventilation systems of buildings are larger but have a lower velocity. Finally, doors and windows in the areas of a building not too near the fire are still larger but the velocity is still smaller. For most purposes the flow coefficient can be set as $C = 0.98$ for a nozzle and $C = 0.60$ for an orifice.

Buoyant Flows Through Vertical Vents

A fire in a room causes gases to flow out through a vent by two processes. The heating of the air in a room causes the air to expand, pushing other air

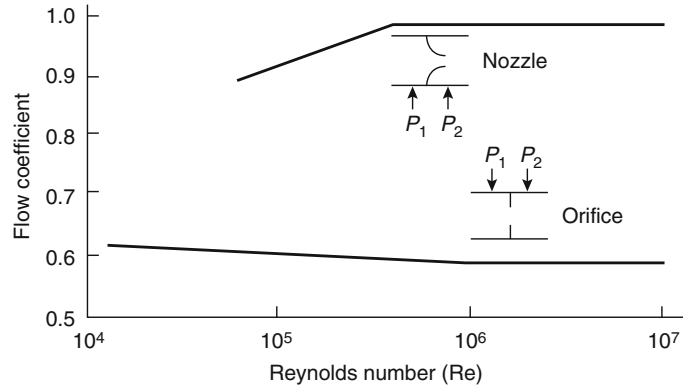

Fig. 15.3 Orifice and nozzle flow coefficients

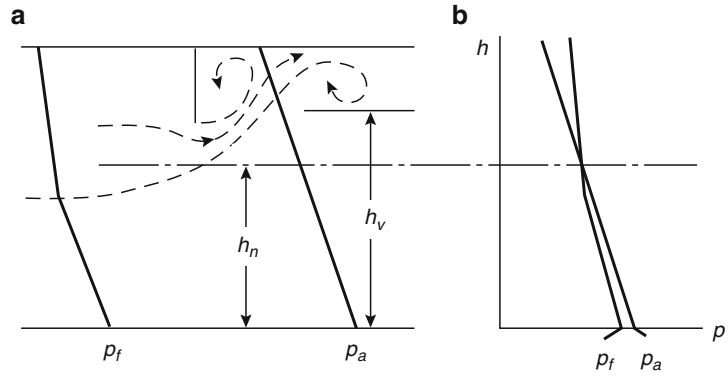

Fig. 15.4 Pressure gradients: (**a**) each side of a door; (**b**) superimposed on a pressure versus height graph

out through all available vents and hence throughout the entire building. At the same time, the heated air, with products of combustion and smoke, rises in a plume to the ceiling. When the hot layer of gas at the ceiling becomes deep enough to fall below the top of a vent, some hot gas will flow out through the vent. As the fire grows, the buoyant flow out will exceed the gas expansion by the fire. Thus the pressure in the fire room at the floor will fall below atmospheric, and outside air will flow in at the bottom. A familiar sight develops, where smoke and perhaps flames issue out the top of a window while fresh air flows in near the bottom. This buoyant flow mechanism allows a fire to draw in new oxygen so essential for its continuation.

For these buoyantly driven flows to occur, there must be a pressure difference across the vent. Figure 15.4 illustrates how these pressure differences are produced. The pressure difference at the floor is

$$\Delta p_f = p_f - p_a \tag{15.13}$$

where

$p_f =$ Pressure at the floor inside the room in front of the vent

$p_a =$ Pressure at the floor level outside of the room just beyond the vent

The pressure at height y is less than the pressure at the floor and can be found by the following hydrostatic equations:

$$\text{Inside} \quad p_1 = p_f - \int_0^y \rho_1 g dy \tag{15.14}$$

$$\text{Outside} \quad p_2 = p_a - \int_0^y \rho_2 g dy \tag{15.15}$$

The pressure difference at height, h, is

$$\Delta p = p_1 - p_2 = \Delta p_f + \int_0^h (\rho_2 - \rho_1) g \, dy \tag{15.16}$$

Since the outside density, ρ_2, is greater than the inside density, ρ_1, the integral is positive so that Δp is often positive (outflow) at the top of the vent and negative (inflow) at the bottom. The flow properties at the elevation, h, are the same as previously given.

$$u = \sqrt{\frac{2\Delta p}{\rho}} \tag{15.17}$$

$$\frac{\dot{V}}{A} = C\sqrt{\frac{2\Delta p}{\rho}} \tag{15.18}$$

$$\frac{\dot{m}}{A} = C\sqrt{2\rho\Delta p} \tag{15.19}$$

Since they are not the same at different heights in the vent, the volume and mass flow are given as flow per unit area.

Measuring Vent Flows in a Fire Experiment

Sufficient measurements must be made to evaluate ρ and Δp to allow use of Equation 15.19. There are four different available methods that differ in simplicity, accuracy, and cost.

Method 1 The dynamic pressure distribution can be measured in the plane of the vent. This measurement requires a sensitive pressure meter. The pressure difference is almost always less than the atmospheric pressure difference between the floor, p_f, and the ceiling, p_c. For a room 2.5 m in height the atmospheric pressure difference is

$$p_f - p_c = \rho_a g H = 1.176 \times 9.81 \times 2.5$$
$$= 28.84 \text{ Pascals} \quad (3.0 \text{ mm } H_2O)$$

This is only

$$\frac{p_f - p_c}{p_a} = \frac{28.84}{101,325}$$
$$= 0.00028 \text{ fraction of atmospheric pressure}$$

Thus the buoyantly driven flow velocities induced by a room fire could be as high as

$$u = \sqrt{\frac{2\Delta p}{\rho}} = \sqrt{\frac{2 \times 28.84}{1.176}} = 7.00 \text{ m/s} \quad (23 \text{ ft/s})$$

Since the pressure varies with height and time, a series of pressure probes is required and each should have its own meter or a rapid activation switch. Although standard pitot tubes are the most accurate dynamic pressure probes, they are sensitive to flow direction and would have to be adjusted at each location for the direction of the local flow, especially for outflow and inflow. The probe orientation would need to be continually changed as the fire progressed.

A single string of fixed-orientation pressure probes arranged vertically down the center of the door increases convenience of the measurement but forces a decrease in accuracy. The out-in flow problem is avoided by use of bidirectional probes in place of pitot tubes [3] (Fig. 15.5). These probes give velocities within 10 % over an angular range of ±50 degrees of the probe axis in any direction.

Determination of the local velocity also requires the measurement of the local gas density. The density of fire gases can be determined from measured gas temperatures with sufficient accuracy by the ideal gas law

$$\rho = \frac{Mp}{RT} \tag{15.20}$$

where

M = Average molecular weight of flowing gas

$R = 8314 \frac{\text{J}}{\text{kg mol K}}$ = Universal gas constant

As noted previously, the pressure changes only by a very small percentage throughout a building so its effect on gas density is negligible.

Fire gases contain large quantities of nitrogen from the air and a variety of other compounds. The average molecular weight of the mixture will be close to but somewhat larger than that of air. Incomplete knowledge of the actual composition of fire gas prevents high-accuracy calculations. For most fire calculations, it is accurate enough

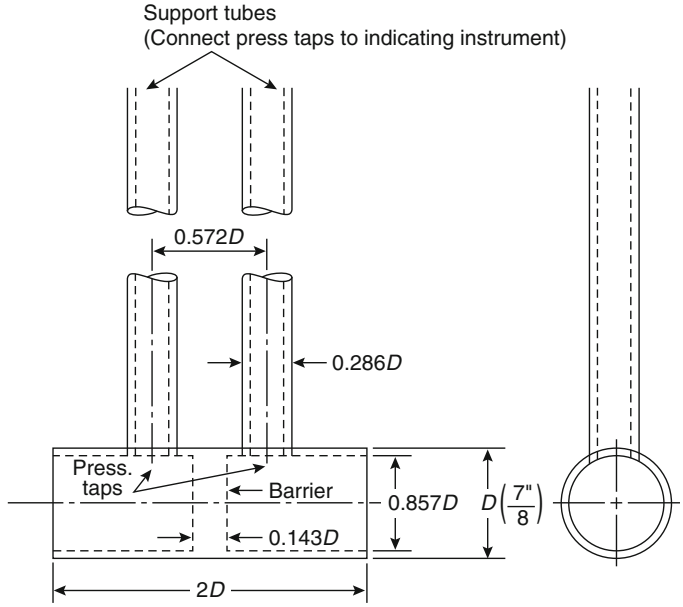

Fig. 15.5 A bidirectional flow probe

to neglect the effect of the change of molecular weight from that of air ($M_a = 28.95$). Density of gas is determined primarily by its temperature (which may vary by a factor of 4 in a fire). Thus

$$\rho = \frac{352.8}{T}\ \frac{\text{kg}}{\text{m}^3} \tag{15.21}$$

where T is temperature in Kelvin (= °C + 273).

A string of thermocouples must be included along with the bidirectional probes to measure vent flows. For higher accuracy, aspirated thermocouples must be used or a correction made for the effect of fire radiation [3]. The temperature and, hence, the gas density will vary over the entire hot vent outflow. To determine the temperature distribution so completely would require an impracticably large number of thermocouples. Fortunately, the temperature in the vent is a reflection of the temperature distribution in the hot layer inside the room, which normally is stratified, and hence varies most strongly with the distance from the ceiling. Thus a string of thermocouples hanging vertically on the centerline of the vent is usually considered to be the best that can be done in a practical fire test. Special care must be exercised to keep the test fire some distance away from the entrance to the vent. Since a fire near a vent has effects at present unknown, fire model calculations of real fire vent flows under such conditions will be of unknown accuracy. The velocity distribution vertically in the vent is given by

$$u = 0.93\sqrt{\frac{2\Delta p}{\rho}} \tag{15.22}$$

where ρ follows from Equation 15.21 using the temperature distribution *in the vent* with a calibration factor of 0.93 for the bidirectional probes [4]. Using ρ from Equation 15.21 gives the directly useful forms

$$u = 0.070\sqrt{T\Delta p} \qquad \Delta p\left(\frac{N}{\text{m}^2}\right)$$
$$u = 5.81\sqrt{T\Delta p} \qquad \Delta p\left(\frac{\text{lb}}{\text{in.}^2}\right) \qquad \text{pressure measured with bidirectional probe} \tag{15.23}$$

where

$$u \text{ is in (m/s)}$$

$$T \text{ is in (K)}$$

Except for very early stages of a room fire, there will be flow out at the top (u, $\Delta p > 0$) and flow in at the bottom (u, $\Delta p > 0$).[1] Thus there is a position in the vent at which $u = 0$, which is the vertical location where the pressure inside is equal to that outside. This elevation, h_n, is called the neutral axis. Defining the elevation of the vent sill as h_b ($h_b = 0$ for a door) and the elevation of the soffit as h_t, the flows are given by

$$\text{Flow out} \quad \dot{m}_u = C\int_{h_n}^{h_t} \rho u b \; dy \tag{15.24}$$

$$\text{Flow in} \quad \dot{m}_d = C\int_{h_b}^{h_n} \rho u b \; dy \tag{15.25}$$

where

b = Width of the vent

C = Experimentally determined flow coefficient (= 0.68) [5]

Using Equations 15.21 and 15.22 and $C = 0.68$ into these equations, the most convenient forms are

$$\text{Flow out} \quad \dot{m}_u = 16.79\int_{h_n}^{h_t} b\sqrt{\frac{\Delta p}{T_v}}dy \quad \text{(kg/s)} \tag{15.26}$$

$$\text{Flow in} \quad \dot{m}_d = 16.79\int_{h_b}^{h_n} b\sqrt{\frac{\Delta p}{T_v}}dy \quad \text{(kg/s)} \tag{15.27}$$

where

Δp = Pressure drop in Pascals measured with bidirectional probe as a function of y

b = Width of the vent in m

T_V = Temperature (K) in the vent measured as a function of y

[1] Equation 15.23 should be written $u = (\text{sign } \Delta p)K\sqrt{\mathrm{T}|\Delta p|}$ since when $\Delta_p < 0$ the absolute value must be used to avoid the square root of a negative number and the sign of the velocity changes since the flow is in and not out.

If the bidirectional probe pressures are measured in psi, the coefficient 16.79 must be replaced by 1394.

Method 2 A somewhat simpler but less accurate procedure to measure vent flows requires the measurement of the pressure difference at the floor (or some other height). One pressure difference measurement together with the vertical temperature distribution measurement, T_1, *inside the room* (about one vent width in from the vent) and T_2, *outside the vent* (well away from the vent flow), provides the density information required to find the pressure drop at all elevations (Equation 15.16).

$$\Delta p = \Delta p_f + 3461\int_0^y \left(\frac{1}{T_2} - \frac{1}{T_1}\right) dy \tag{15.28}$$

For most fires, Δp_f will be negative; that is, the pressure at the floor inside the fire room will be less than the pressure outside. This is only true for a fire room with a normal size vent (door, window). For a completely closed room the inside pressure is well above the outside pressure. Since the temperature inside the fire room is higher than that outside, Equation 15.28 gives a Δp that becomes less negative, passes through zero at the neutral axis, h_n, and becomes positive at higher levels in the fire room. The vertical location of the neutral axis is, therefore, readily found from Equation 15.28.

The calculation of the pressure distribution requires measurement of the temperature distribution both inside, T_1, and outside, T_2, of the vent. However, calculation of the flow requires a knowledge of the density distribution in the vent itself. Thus a third thermocouple string is required to measure the temperature distribution, T_u, in the vent. The desired flow properties [6] are

Velocity

$$u = \sqrt{\frac{2\Delta p}{\rho}} = 4.33\sqrt{T_v\int_{h_n}^{y}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) dy} \quad \text{(m/s)} \tag{15.29}$$

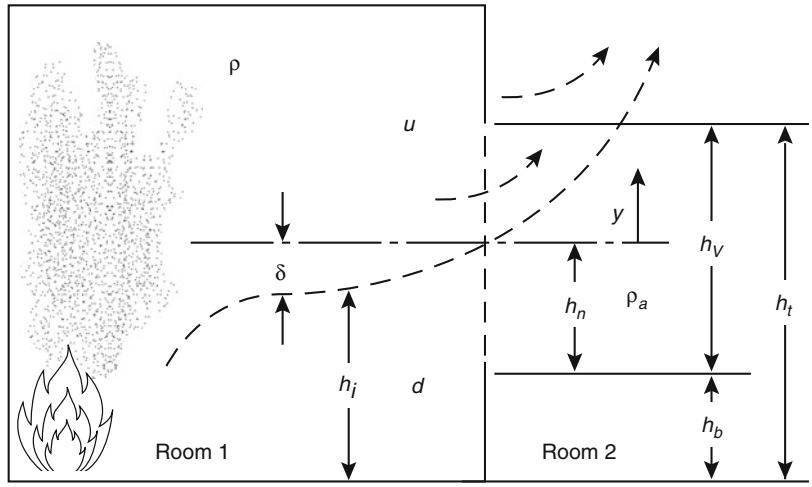

Fig. 15.6 Buoyant flow out of the window of a fire room

Flow out

$$\dot{m}_u = C\int_{h_n}^{h_t} \rho bu \; dy$$

$$= 1063\int_{h_n}^{h_t} b\left[\frac{1}{T_v}\int_{h_n}^{y}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)dy\right]^{1/2} dy \tag{15.30}$$

Flow in

$$\dot{m}_d = C\int_{h_b}^{h_n} \rho bu \; dy$$

$$= 1063\int_{h_n}^{h_t} b\left[\frac{1}{T_v}\int_{h_b}^{y}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)dy\right]^{1/2} dy \tag{15.31}$$

where

b = Width of the vent at height y

Δp = Calculated from Equation 15.16 using the temperatures (and thus densities) *inside and outside of the room*

ρ = Density computed from the temperature *in the vent*

(Note that for inflow Δp is negative. Therefore, the equation takes the square root of the magnitude $|\Delta p|$ while its sign gives the flow direction.)

Method 3 The use of a sensitive pressure meter can be avoided entirely by visually (or better, photographically) locating the bottom of the outflow *in the vent* during the test at the position of the neutral axis, h_n, where $\Delta p = 0$. Method 3 is the same as Method 2 except that the neutral axis location is found directly by experiment rather than being deduced from the pressures. The distribution of pressure drop across the vent is found by integrating Equation 15.16 above ($\Delta p > 0$) and below ($\Delta p < 0$) h_n using the density distribution *inside*, ρ_1, and *outside*, ρ_2, *the room*. The flow properties are computed as before from Equations 15.29, 15.30 and 15.31.

Method 4 A simpler but less accurate method uses the fair assumption that the gas in the fire room soon separates into a nearly uniform hot layer of density, ρ, with a nearly uniform cold layer below of density, ρ_d. This separation with appropriate notation is shown in Fig. 15.6. In this approximation the appropriate flow formulas [5] are

$$\text{Outflow} \quad u_u = \left(2g\frac{\rho_a - \rho}{\rho}y\right)^{1/2} \tag{15.32}$$

where y is distance above the neutral plane

$$\dot{m}_u = \frac{2}{3}Cb\sqrt{2g\rho(\rho_a - \rho)}(h_v - h_n)^{3/2} \tag{15.33}$$

The inflow by this two-layer method depends on δ, which is small and cannot be determined

with sufficient accuracy because of the effect of gas motions in the fire room.

The neutral axis may be found in several ways:

1. It may be located visually or photographically during the test.
2. It may be found from the vent temperature distribution by locating [visually on a plot of $T_V(y)$] the position just below the most rapid temperature rise from bottom to top of the vent.

The lower-layer temperature, T_d, of the two-layer model is taken as the gas temperature just above the vent sill. The upper-layer temperature, T_u, is chosen so that the two-layer model has the same total mass (i.e., the same mean density) in the vent as the real flow.[2]

$$\left(\frac{1}{T}\right) = \frac{1}{h_v}\int_0^{h_v} \frac{dy}{T} = \frac{h_n}{h_v T_d} + \frac{h_v - h_n}{h_v T_u} \qquad (15.34)$$

The densities ρ_a and ρ are found using Equation 15.21 from the temperatures T_a and T_u, respectively.

The outflow velocity and mass flow are found from Equations 15.32 and 15.33.

An estimate of the air inflow rate can be found if the test has included the measurement of the oxygen concentration in the gases leaving the fire room. The gas outflow rate is equal to the inflow rate plus the fuel vaporized, except for the effect of transient variations in the hot layer depth. Thus

$$\dot{m}_d = \dot{m}_u \left(\frac{1 + y_{O_2}\lambda}{1 + 0.23\lambda}\right) \qquad (15.35)$$

where λ is the effective fuel-air ratio.

[2] Sometimes the mean temperatures, $\overline{T}$ of the two-layer model and the real flow are also used and both h_n and T_u are determined (using T_d as above). The requirement of identical $\overline{T}$ is arbitrary, sometimes leads to impractical results, and is not recommended.

The flow coefficient to be used for buoyant flows is 0.68 as determined by specific experiments designed for the purpose. For nonbuoyant flows (nozzles and orifices), the flow coefficients are determined to better than 1 % and presented as a function of the Reynolds number as in Fig. 15.3. This accuracy is possible because the fluid can be collected and measured (by weight or volume).

For buoyant flows the experiments are much more difficult because the hot outflow and cold inflow cannot be collected and weighed. The best fire-gas vent flow coefficient measurements to date [6, 7] have ±10 % accuracy with occasional values as bad as ±100 % (for inflow). The most accurate buoyant flow coefficients were measured not for fire gases but for two nonmiscible liquids (kerosene and water) [7]. In this case the two fluids could be separated and measured, and the value 0.68 was found except for the very low flow rates (near the beginning of a fire). When buoyant flow coefficients can be measured within a few percent accuracy, they will be a function of the Reynolds number, $\mathrm{Re} = uh_v\rho/\mu$; the Froude number, $\mathrm{Fr} = u^2\rho_a/gh_v(\rho - \rho_a)$; and the depth parameter, h_n/h_v.

The best option now available is to use $C = 0.68$ and expect ±10 % errors in flow calculations.

Note that the above four methods require a knowledge of h_n, the dividing line between outflow above and inflow below. It would be useful to have a simple formula by which h_n could be calculated without any special measurements. What determines h_n?

The fire at the start sends a plume of heated gas toward the ceiling and, by gas expansion, pushes some gas out of the vent. The hot plume gases accumulate at the ceiling with little, if any, flowing out the vent. After a time, depending on the size of the room, the hot layer depth becomes so large that its lower surface falls below the top of the vent. Hot gas begins to flow out.

When a fire has progressed to a second room, there is a hot layer on each side of a connecting vent. Thus (with two layers on each side) there

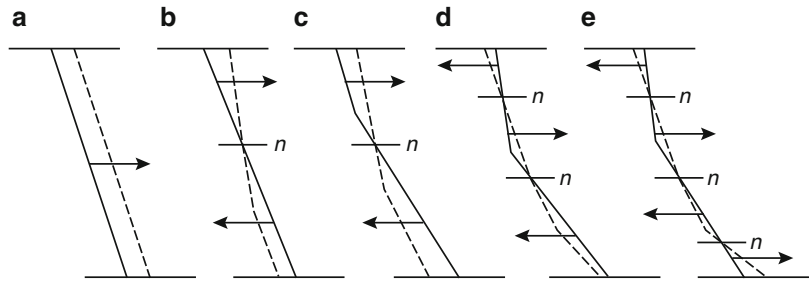

Fig. 15.7 Some selected two-layer vent pressure drop distributions. *Dotted line* is pressure distribution in room 1; *solid line* is pressure distribution in room 2

are as many as four different gas densities: ρ_{d_1} is greater than ρ_1, densities below and above in room 1, and ρ_{d_2} is greater than ρ_2, densities below and above in room 2. There are also four pertinent levels: h_b, sill height (0 if the vent is a door); h_t, soffit height; h_{i_1}, interface height in room 1; h_{i_2}, interface height in room 2. There are many different flow situations possible depending on these eight values.

The pressure variation from floor to ceiling in each room depends on the densities and layer heights in the room. In addition, the pressure difference between the two rooms (at the floor, for example) may have any value depending on the fire in each room, all the room vents, and especially the vent (or vents) connecting the two rooms. Figure 15.7 shows a few of the possible pressure distributions. The pressure distribution in room 1 is shown with a dotted line while that in room 2 is shown as a solid line.

In Fig. 15.7a, there are no hot layers, the pressure in room 1 at every level is higher than that in room 2, and the flow is everywhere out (positive) (room 1 to room 2).

In Fig. 15.7b, a common situation exists. The density in room 2 is uniform (perhaps the outside atmosphere). Room 1 has a hot layer and a floor pressure difference such that there is outflow at the top, inflow at the bottom, and a single neutral axis somewhat above the hot-cold interface in the room.

In Fig. 15.7c, the flow situation is similar to that in Fig. 15.7b, although there are hot layers in both rooms (but with a neutral axis above the interface in room 1 and below the interface in room 2).

In Fig. 15.7d, the densities (slopes of pressure distribution lines) are somewhat different than those in Fig. 15.7c (the hot layer in room 2 is less deep but hotter than that in room 1). Consequently, there are two neutral axes with a new small inflow layer at the top, three flow layers in all—two in and one out.

In Fig. 15.7e, the densities and floor level pressure difference are such that there are four flow layers, two out and two in, with three neutral axes.

These five cases do not exhaust the possible vent flow situations.

Figure 15.7a, b accounts for all cases early in a fire and all cases of vents from inside to outside of a building. They are also the only cases for which experimental data are available. The case illustrated in Fig. 15.7c is common inside a building after a fire has progressed to the point that hot layers exist in the two rooms on each side of a vent. The cases illustrated in Fig. 15.7d, e have not been directly observed but probably account for an occasional confused flow pattern. (In fact, the above discussion assumes two distinct layers in each room.) The layers are seldom sharply defined and in this case there may be many neutral axes, or regions, with a confusing array of in-out flow layers. These confused flow situations are probably not of much importance in a fire since they seldom occur and when they do they don't last very long.

The previous discussion of the possible two-layer flow situation is very important for the zone modeling of a fire. Fire models to date are all two-layer models (a three- or more layer model will present far more complex vent flows than those pictured in Fig. 15.7). In fire computation by a zone model, cases such as (d) and

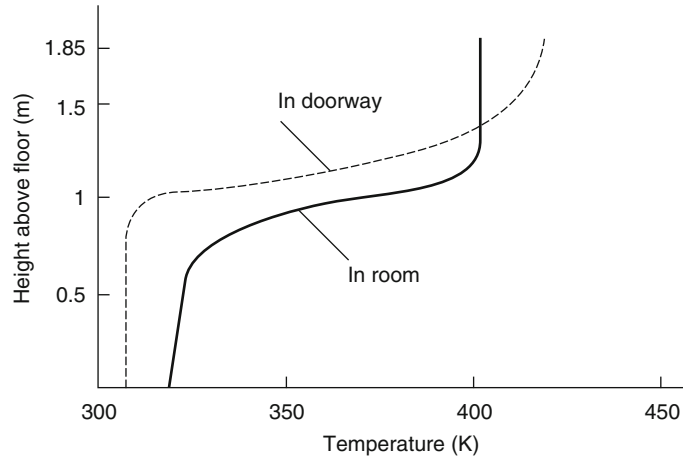

Fig. 15.8 Sample fire room and doorway temperature distributions

(e) in Fig. 15.7 will be unimportant to fire development. However, since these situations can arise, they should be handled via fire computation, that is, by computing the flow layer by layer. Each layer has a linear pressure variation from sill, interface, or neutral axis up to the next interface, neutral axis, or soffit.

By use of the pressure drop at the floor and the room densities on each side of the vent in Equation 15.16, the position, h_i, of all layers and the sill, interfaces, neutral axes, and soffit will be known. Thus, for each layer (defined as j) the pressure drop at the bottom, Δp_j, and at the top, Δp_{j+1}, will be known. Since the room densities are constant in each room for each layer, the vent pressure drop will vary linearly from Δp_j to Δp_{j+1}. The flow in each layer from room 1 to room 2, found by integration [8], is given by

$$\dot{m}_i = (\operatorname{sign}\alpha) C \frac{2}{3} b \left(h_{j+1} - h_j\right) \sqrt{2\rho} \times \left(\frac{|\Delta p_j| + \sqrt{|\Delta p_j \Delta p_{j+1}|} + |\Delta p_{j+1}|}{\sqrt{|\Delta p_j|} + \sqrt{|\Delta p_{j+1}|}} \right) \tag{15.36}$$

where

$\alpha = \left(\dfrac{\Delta p_j + \Delta p_{j+1}}{2} \right)$ whose sign determines the in-out direction of the flow

ρ = Density of the gas flowing in the flow layer i

Thus

$$\rho = \begin{cases} \text{Density in room 1 at height } h_j^+ & \textit{if } \alpha > 0 \\ \text{Density in room 2 at height } h_i^+ & \textit{if } \alpha < 0 \end{cases}$$

This flow calculation appears complex but can be coded quite easily for computer use and then used to calculate all the possible cases.

Although all vent flows can now be calculated, the path of each layer of gas flow when it enters a room is still needed for fire modeling. If the two-layer model is to be preserved, each inflow must mix with the hot layer or the cold layer, or be divided between them. No information is yet available as to the best solution to this problem.

To illustrate these various methods of flow calculation, some test data from a steady burner fire in a room at the U.S. Bureau of Standards [6] are used. Some typical data are shown in Fig. 15.8. Accurate results, even in a steady-state fire, are difficult to obtain and questions about the data in this figure will be noted as appropriate. The vent temperatures were measured by small-diameter bare thermocouples for which there is some unknown radiation correction. This unknown correction may account for the top vent temperature being higher than that in the fire room.

The vent was 1.83 m high, 0.737 m wide, and the outflow measured with bidirectional probes (not corrected for flow angle) was 0.588 kg/s for a fire output of 0.63 kW. The ambient

temperature was 21.3 °C (= 294.3 K). This flow was determined by using Method 1.

Method 2 uses the known location of the neutral axis and requires the integration of Equations 15.30 and 15.31. In this way the data of Fig. 15.8 gives outflow of 0.599 kg/s, 1.8 % higher compared to Method 1 and inflow of 0.652 kg/s. A measured (by bidirectional probes) inflow is not given, but it seems odd that the inflow is greater than the outflow since inflow must be smaller than the outflow by the mass rate of fuel burned at steady state.

Data for use of Method 3 are not available.

Method 4 requires the selection from Fig. 15.8 of a neutral axis location and inlet temperature. In the figure the rapid temperature rise *in the vent* begins at about 1 m. Hence this height is chosen as the neutral axis. The lowest inlet temperature is $T_d = 308$ K. By computing $(1/T_v)$ the average value was found to be $(1/T_v) = 2.875 \times 10^{-3}$. Now by Equation 15.34

$$2.875 \times 10^{-3} = \frac{1.00 - 0}{1.83 \times 308} + \frac{1.83 - 1.00}{1.83 T_u}$$

Thus $T_u = 411.9$ K. The corresponding density is $\rho = 352.8/411.9 = 0.8565$ kg/m^3. From the ambient temperature, T_a, we find $\rho_a = 352.8/294.3 = 1.199$ kg/m^3. Thus the outflow by Equation 15.33 is

$$\dot{m}_u = \frac{2}{3} 0.68 \times 0.737 [2 \times 9.81 \times 0.8565 (1.199 - 0.8565)]^{1/2} \times (1.83 - 1)^{3/2} = 0.607 \ \text{kg/s}$$

This value is 3.2 % higher compared to Method 1.

Buoyant Flows Through Horizontal Vents

Unlike flows through vents in a vertical wall or non-buoyant flows through orifices, not ample quantitative works have been done on buoyant flows through vents in horizontal or slightly sloped surfaces. Such buoyant flows through horizontal vents can become issue in some situations associated with fire, particularly in such a configuration as exemplified in Fig. 15.9, which may arise in fires in basements of buildings, holds in ships and multi-floor building containing rooms closed to the outdoors.

The flow rate through a horizontal opening can be treated, as done in vertical vents, by using Bernoulli's equation if there is no temperature difference between the connecting spaces

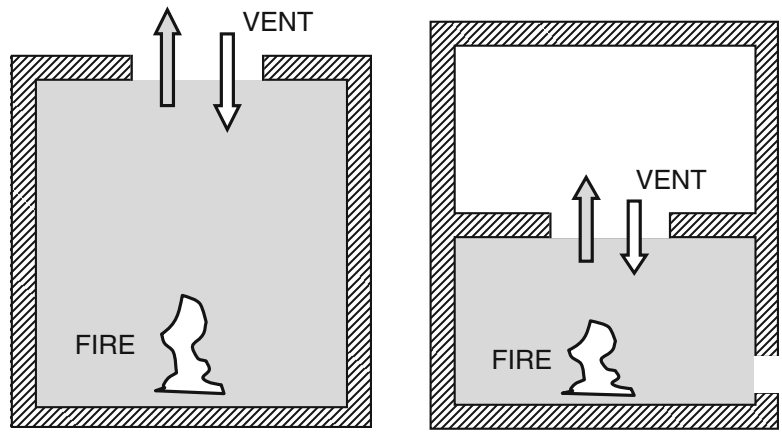

Fig. 15.9 Possible scenarios of horizontal vent flow in fire where the standard Bernoulli's flow equation becomes inadequate

or if there is a large enough pressure difference across the vent. Let Δp be the pressure difference across the vent defined by

$$\Delta p = p_U - p_L \tag{15.37}$$

where

p_U and p_L = Pressures at the vent elevation in the upper and lower spaces, respectively.

The standard vent flow model using Bernoulli's equation would predict the flow rate through a horizontal vent as follows according to the value of Δp, illustrated in Fig. 15.10:

$$\text{(a)} \quad \text{when } \Delta p < 0: \quad \dot{V}_U = CA_V\sqrt{2\Delta p/\rho_L}; \quad \dot{V}_L = 0 \tag{15.38a}$$

$$\text{(b)} \quad \text{when } \Delta p = 0: \quad \dot{V}_U = 0; \quad \dot{V}_L = 0 \tag{15.38b}$$

$$\text{(c)} \quad \text{when } \Delta p > 0: \quad \dot{V}_U = 0; \quad \dot{V}_L = CA_V\sqrt{2|\Delta p|/\rho_U} \tag{15.38c}$$

where

$\dot{V}_U$ and $\dot{V}_L$ = Volume rates of flows to upper and lower spaces through the vent, respectively

A_V = Vent area

C = Vena contracta

ρ_L and ρ_U = Air densities in lower and upper spaces, respectively.

However, this method will fail, over certain ranges of pressure difference, when temperature difference exists between the spaces due to the antagonistic effect of buoyancy to pressure gradient. Consider the situation where the lower space temperature is higher than upper space temperature, for example. There is a flow across the vent due to the air density difference $\Delta\rho(=\rho_U - \rho_L)$ even if the pressure difference, Δp, is basically zero. In such a case as mentioned earlier in Fig. 15.9, where a pace has no other air passage besides the vent between the connecting spaces, a bidirectional flow will occur through the vent in a certain range around $\Delta p = 0$ and the upward and downward flow rates will become equal due to continuity.

The horizontal vent flows under zero pressure difference, $\Delta p = 0$, was investigated by Epstein [9], Tan and Jaluria [10] and others, using brine-water scale models. In these experiments, the effects of vent configuration on the flow characteristics were investigated for a large range of opening size and aspect ratio. Also, Heiselberg [11] conducted the experiments for the same purpose using a single opening test room set in a full-scale thermostatic chamber, where the air in the test room was heated by an electric heating system while the temperature in the thermostatic chamber was controlled by an air conditioning system. While circular orifices were used in the brine-water experiments by Estein and others, square openings were adopted in the Heiselberg's experiments as the vent. The conceptual configuration of the vents in their experimental setup is illustrated in Fig. 15.11.

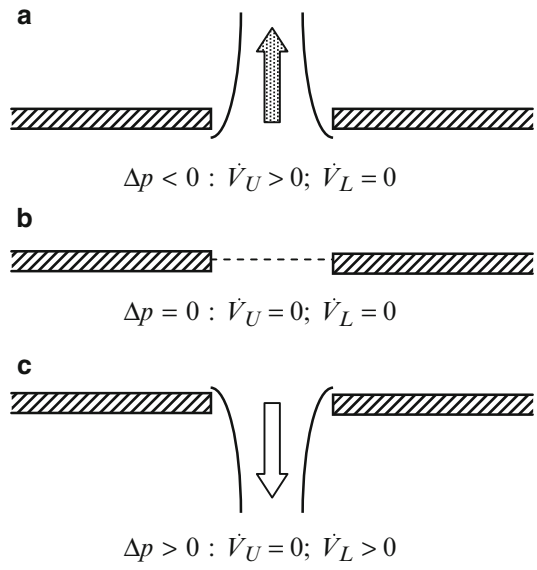

Fig. 15.10 The standard vent flow model for horizontal vents

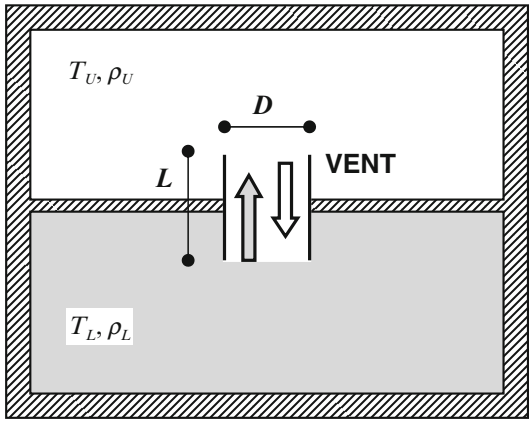

Fig. 15.11 Schematic configuration of vents in the existing experiments for horizontal vent flow

The flow through a horizontal vent under $\Delta p = 0$ condition is often unstable. Epstein [9] identified four regimes of the exchange flow as a function of aspect ratio of the vent as follows:

Regime I ($L/D < 0.15$): Oscillatory exchange flow

Regime II ($0.15 < L/D < 0.4$): Countercurrent orifice flow

Regime III ($0.4 < L/D < 3.25$): Combination of an orifice flow and turbulent diffusion flow

Regime IV ($3.25 < L/D$): Turbulent and slow exchange flow, where counterflow within the tube appears to be mixture of warm and cold fluids with chaotic motion

where

D = Diameter of the vent

L = Length of the vent

Epstein defined the Froude number, Fr, as

$$Fr = \frac{\dot{V}_{EX}}{\sqrt{\frac{g(T_L - T_U)L^5}{T_L}}} \tag{15.39}$$

and developed the formulas for the exchange flow through a horizontal vent according to the above regimes based on his brine-water experiment data as follows:

$$Fr = \begin{cases} 0.055 & \left(\frac{L}{D} < 0.15\right) \\ 0.147\left(\frac{L}{D}\right)^{1/2} & \left(0.15 < \frac{L}{D} < 0.4\right) \\ 0.093\frac{1}{\sqrt{1 + 0.084\left(\frac{L}{D} - 0.4\right)^3}} & \left(0.4 < \frac{L}{D} < 3.25\right) \\ 0.32\left(\frac{L}{D}\right)^{-3/2} & \left(3.25 < \frac{L}{D} < 10\right) \end{cases} \tag{15.40}$$

where

$\dot{V}_{EX}$ = Exchange volume flow rate

T_L = Temperature in lower space

T_U = Temperature in upper space

g = acceleration due to gravity

Heiselberg, adopting the same Fr as Equation 15.39, developed a similar formula based on his experimental data using the airs at different temperature as follows:

$$Fr = \begin{cases} 0.050 & \left(\frac{L}{D} < 0.115\right) \\ 0.147\left(\frac{L}{D}\right)^{1/2} & \left(0.115 < \frac{L}{D} < 0.55\right) \\ 0.077\left(\frac{L}{D}\right)^{-1/2} & \left(0.55 < \frac{L}{D} < 4.455\right) \end{cases} \tag{15.41}$$

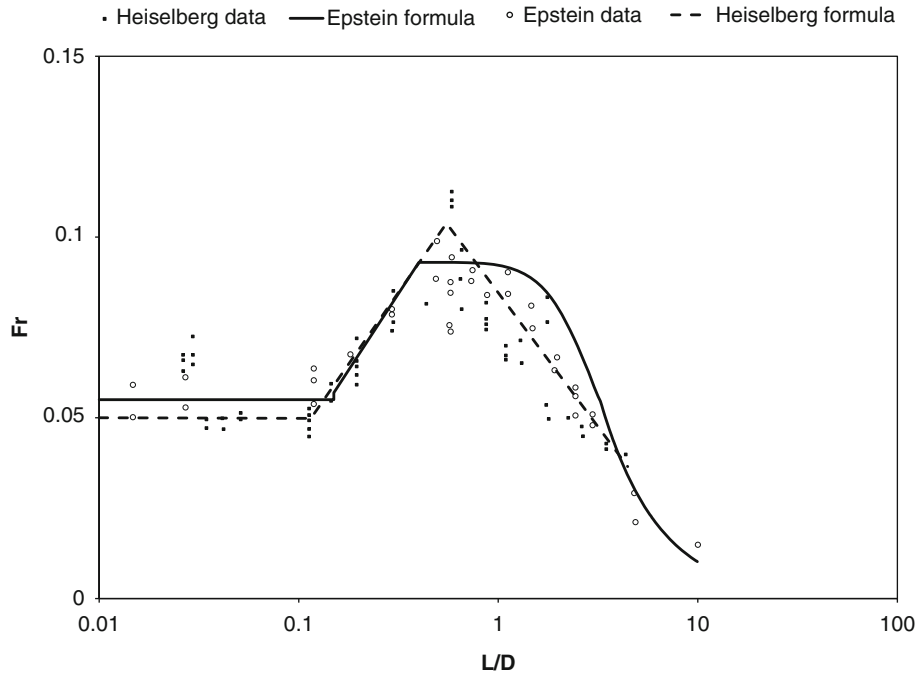

Fig. 15.12 Comparison of Epstein's brine-water scale experiments and Heiselberg's full-scale experiments for horizontal vent flow

Since the vents in Heiselberg's experiments were square, the vent diameter D was converted from the side length of the square vent, A_V, in his experiments as

$$D = \sqrt{\frac{4}{\pi}}S \approx 1.128S \tag{15.42}$$

Figure 15.12 plots the experimental data and the equations from Epstein and Heiselberg together. Albeit the difference of the fluids used in their experiments, the distributions of the measured data seem to show a similar trend when plotted in terms of the Fr.

In such an unstable configuration as where a high density fluid is above and low density fluid is below, a bi-directional flow takes place through the vent in the region of pressure around $\Delta p = 0$. However, as the pressure difference, Δp, is increased the exchange flow in the direction of opposing to the pressure gradient decreases. If Δp exceeds some critical value, Δp_C, then the flow becomes uni-directional. The flows in such ranges of Δp were investigated by Epstein and Kenton [12], Tan and Jaluria [10] and Heskestad and Spaulding [13]. Of these, the pressure difference, Δp, was not directly measured in the experiments by Epstein and Kenton so the critical condition of transition from bi-directional to uni-directional flow was determined by the flow rate. The critical (flooding) condition is dependent on vent condition and buoyancy strength. For analyzing the above existing results, Cooper [14] introduced the following non-dimensional parameters defined as follows:

Grashof number

$$Gr = \frac{2gD^3\overline{\rho}\Delta\rho}{\mu^2} \tag{15.43}$$

Froude number

$$Fr = \frac{\dot{V}_U}{A_V\sqrt{2gD\dfrac{\Delta T}{\overline{T}}}} \tag{15.44}$$

Non-dimensional pressure difference

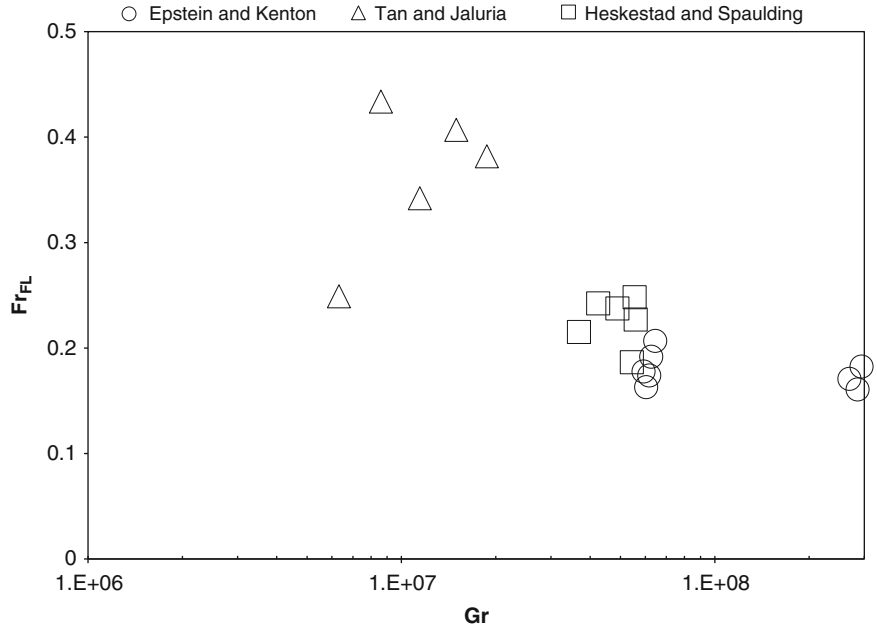

Fig. 15.13 Plot of Fr_{FL} as a function of Gr for small L/D data

$$\Pi = \frac{\Delta p}{4g\Delta\rho D} \tag{15.45}$$

where

A_V = Vent area

$\overline{T} = (T_U + T_L)/2$

$\overline{\rho} = (\rho_U + \rho_L)/2$

$\Delta\rho = \rho_L - \rho_U$

$\Delta T = T_L - T_U$; Temperature difference

$\Delta p = p_U - p_L$

Let the critical volume flow rate and pressure difference where transition from bi-directional flow to uni-directional flow just occur be $\dot{V}_{U,FL}$ and Δp_{FL}, respectively, and let the corresponding Fr and Π be Fr_{FL} and Π_{FL}, respectively. Figure 15.13 plots the critical (flooding) Froude number, Fr_{FL}, vs Grashof number, Gr, which were reduced from the existing experiments. As seen in this figure, Fr_{FL} is relatively insensitive to changes in Gr in the range about $3 \times 10^7 < Gr < 3 \times 10^8$. However, there is a significant increase in Fr_{FL} for $Gr < 1.4 \times 107$, i.e., for the data of Tan and Jaluria [10], which seems to be attributed to the relatively small vent size in their experiments. Similar dependence of Fr_{FL} on Gr is found by Heskestad and Spaulding [13]. The experiments for $Gr < 1.4 \times 10^7$ may be in the range of laminar or transitional flow.

From the viewpoint of practical applications to realistic building fire configurations, the horizontal vent flows of interest are probably in the large Gr range, i.e., turbulent flow regime. The critical Froude number, Fr_{FL}, from the existing data in large Gr range are plotted vs non-dimensional temperature difference, $\Delta T/\overline{T}$, in Fig. 15.14. Note here that when $\Delta T < 0$, Fr_{FL} denotes the critical Froude number to purge the downward flow and attain the upward flooding flow. The critical (flooding) non- dimensional pressure difference, Π_{FL}, is plotted also vs $\Delta T/\overline{T}$ in Fig. 15.15 although the data are only available from Heskestad and Spaulding [13].

The effect of buoyancy will not disappear as soon as the pressure difference exceeds the critical value and the vent flow has changed from bi-directional to uni-directional. Even after uni-directional flow has been established, significant buoyancy effect still remains. For this

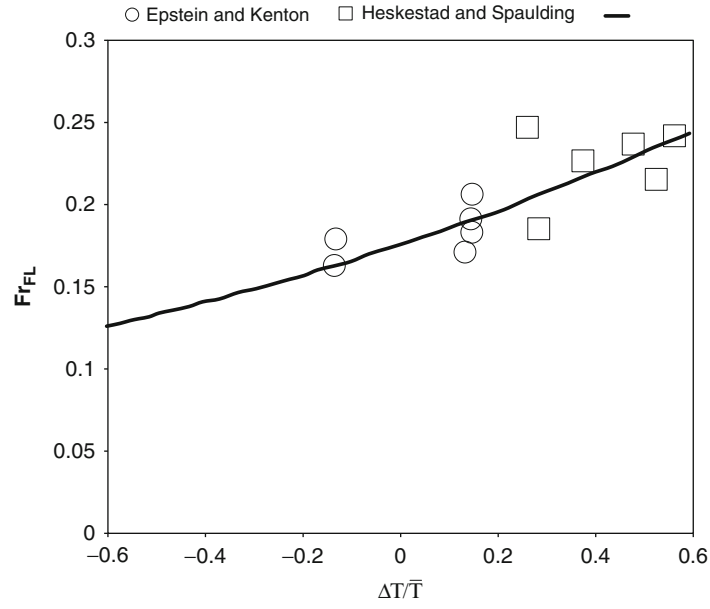

Fig. 15.14 Plot of Fr_{FL} as a function of $\Delta T/\overline{T}$ for small L/D data

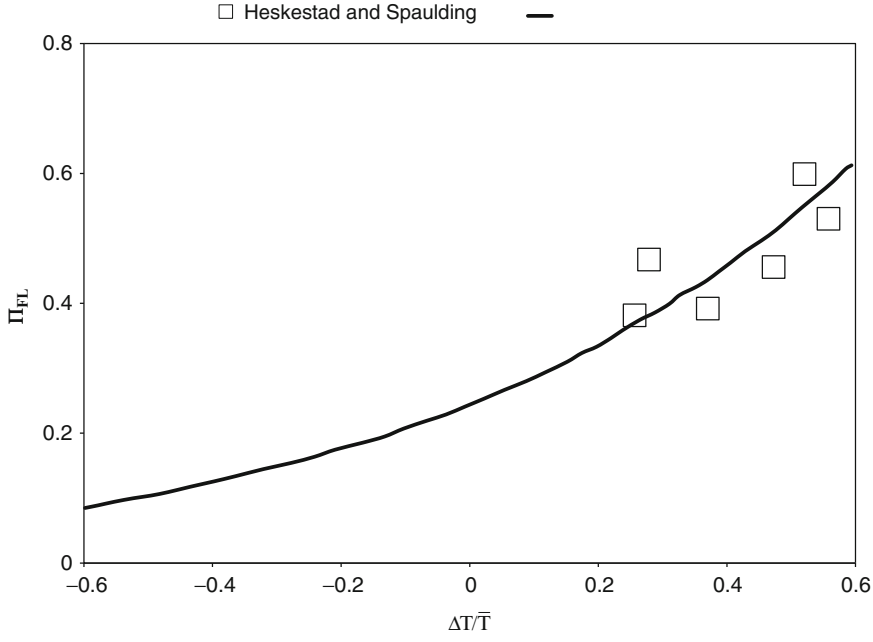

Fig. 15.15 Plot of Π_{FL} as a function of $\Delta T/\overline{T}$ for small L/D data

uni-directional flow regime, Cooper presented a plot of $\dot{V}_U/\dot{V}_{U,FL}$ vs $\Delta p/\Delta p_{FL}$ as seen in Fig. 15.16, where $\dot{V}_{U,FL}$ and Δp_{FL} are critical (flooding) volume flow rate and pressure difference, respectively. From this figure, it can be seen that the standard Bernoulli flow equation, expressed by dashed line, overestimates the expected flow rate by a factor in excess of 3, and that only after $\Delta p/\Delta p_{FL}$ exceeds 3 or 4 the standard model provides flow estimate

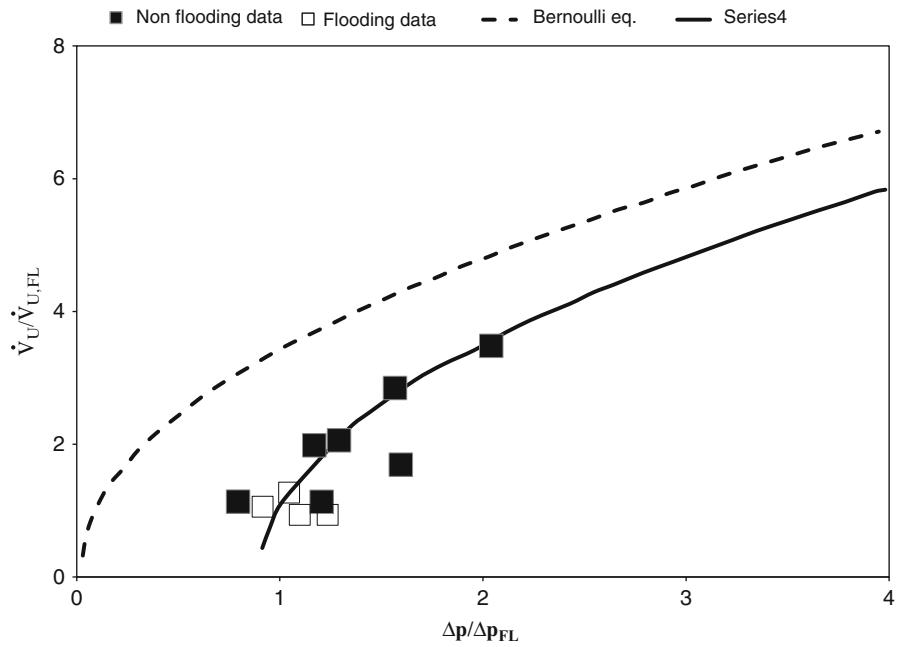

Fig. 15.16 Plot of $\dot{V}_U/\dot{V}_{U,FL}$ as a function of $\Delta p/\Delta p_{FL}$ ($= Fr/Fr_{FL}$ as a function of $\Pi/\Pi p_{FL}$) for uni-directional flow regime

correct to within a few tens of percent. If the values of Fr_{FL} and Π_{FL}, which depend on temperature difference, are determined using Figs. 15.14 and 15.15, respectively, $\dot{V}_{U,FL}$ and Δp_{FL} can be calculated using Equations 15.44 and 15.45, respectively. Then it follows that uni-directional flow rate, $\dot{V}_U$, can be obtained for arbitrary pressure difference, Δp, from Fig. 15.16.

The range of pressure $0 \leq \Delta p \leq \Delta p_{FL}$ is the mixed flow regime where there will be a bi-directional flow through the vent, i.e., a flow from the upper to the lower space, $\dot{V}_U$, and a flow from the lower to the upper space, $\dot{V}_L$. The $\dot{V}_L$ is also called exchange flow, $\dot{V}_{EX}$. At the two extremes of the mixed flow regime, $\dot{V}_U = \dot{V}_L$ at $\Delta p = 0$ and $\dot{V}_U = \dot{V}_{U,FL}$; $\dot{V}_L = 0$ at $\Delta p = \Delta p_{FL}$. Let $\dot{V}_N$ be the net volume flow rate from the upper, or the higher pressure, space to the lower space, i.e., $\dot{V}_U - \dot{V}_L$. Generally, in the intermediate range $0 < \Delta p < \Delta p_{FL}$, $\dot{V}_N = \dot{V}_U - \dot{V}_L = \dot{V}_U - \dot{V}_{EX} \geq 0$. This net volume flow rate, $\dot{V}_N$, can be said pressure-driven part of the flow.

The maximum value of the exchange flow rate, $\dot{V}_{EX,MX}$, is attained at $\Delta p = 0$. For shallow circular vents, this is obtained from Epstein [9] as

$$\dot{V}_{EX,MX} = 0.055\left(\frac{4}{\pi}\right)A_V\sqrt{gD\frac{\Delta T}{\overline{T}}} \qquad (15.46)$$

Cooper [14] presented the relationship of $\dot{V}_L/\dot{V}_{Ex,MX}$ and $\dot{V}_N/\dot{V}_{U,FL}$ as a function of $\Delta p/\Delta p_{FL}$ as shown in Fig. 15.17. Then, it follows that using this figure and Equation 15.46 together with the critical (flooding) pressure and volume flow rate, the exchange flow rate and the net flow rate can be estimated. Cooper also showed that his method well correlated the data of the flow through tube-like vents (i.e., moderate-to-large L/D) rather than shallow vents, as shown in Fig. 15.18.

Accuracy of Vent Flow Calculations

For nonbuoyant flows (using nozzles or orifices in a straight run of pipe made and calibrated with a specific geometry over a known Reynolds

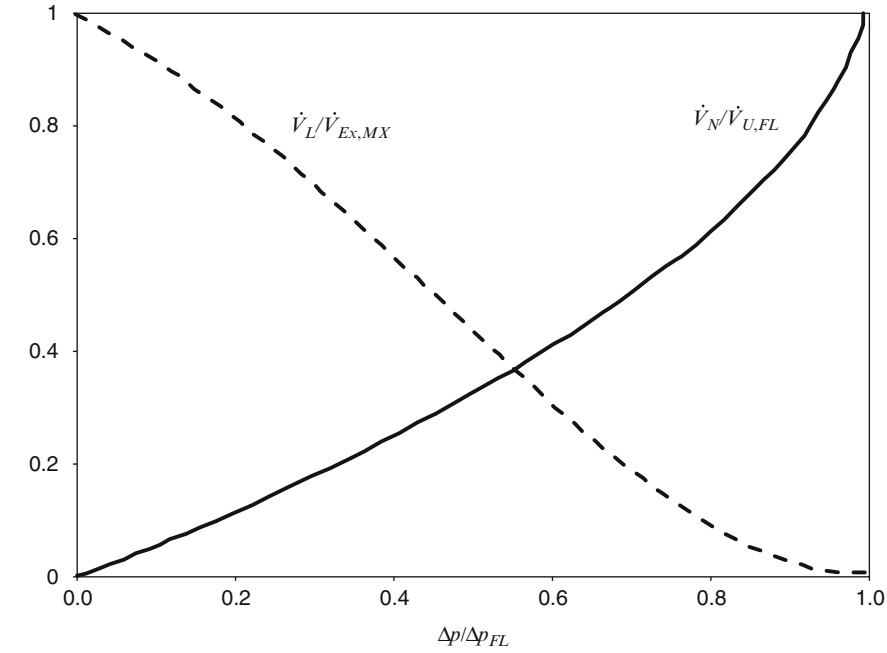

Fig. 15.17 Plots of $\dot{V}_L/\dot{V}_{Ex,MX}$ and $\dot{V}_N/\dot{V}_{U,FL}$ as a function of $\Delta p/\Delta p_{FL}$

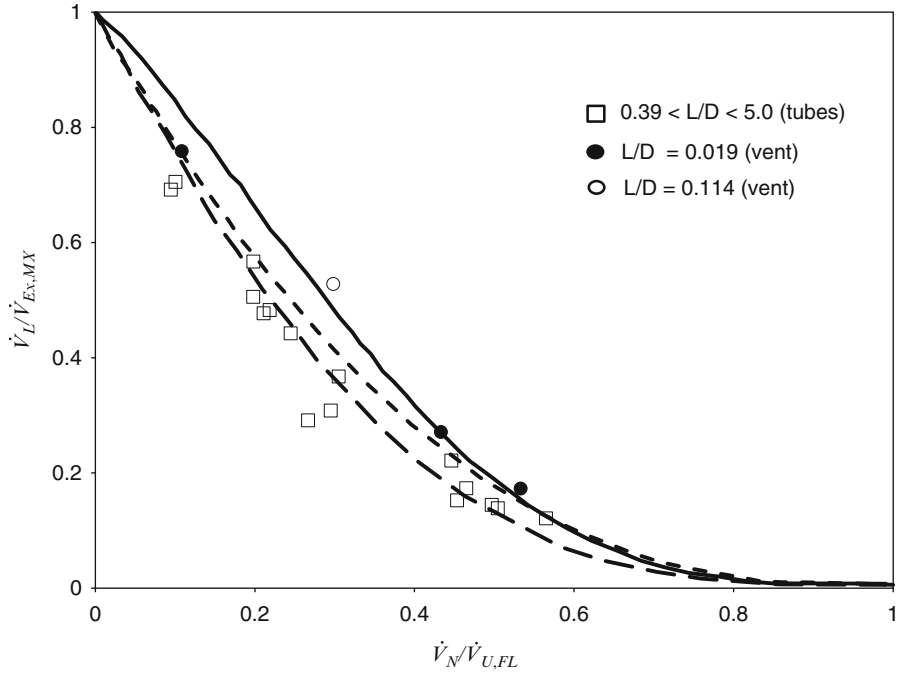

Fig. 15.18 Plots of $\dot{V}_L/\dot{V}_{Ex,MX}$ from Epstein and Kenton [12] as a function of $\dot{V}_N/\dot{V}_{U,FL}$

number range) one easily obtains 2 % accuracy. Thus, Equations 15.1, 15.2, 15.3, 15.4, 15.5, 15.6, 15.7, 15.8, and 15.9 are capable of high accuracy.

For vents in vertical walls with limited internal room fire circulations, the best methods of measurement may get 5 % accuracy. However, in real fires, induced circulations are often severe and unknown. Thus, errors of 10 % or higher must be expected. Even if flow instrumentation is located in the vent itself, there is never enough to really account for variations over the vent surface and time fluctuations originating in the fire phenomena inside the fire room.

For vents in a horizontal surface, the majority of the results presented here are from water-brine experiments in small holes. The experimental accuracy is 10 %. However, for a real fire, the errors are probably much higher. A typical case is a hole in the ceiling burned through by the flames from below. The hole geometry is very irregular and is completely unknown. Furthermore, a fire directly below the hole supplies hot gas with a considerable vertical velocity. Also, the ceiling jet flow often provides considerable cross flow.

Full-scale experimental results determining the effects of fire circulation, large density ratios, and large Reynolds numbers are needed.

Vents as Part of the Building Flow Network

A building is an enclosed space generally with floors and walls that divide the space both vertically and horizontally into rooms, corridors, and stairwells. A fire that starts at any place in the building causes gas expansion, which raises the local pressure and pushes air throughout the building through all pathways leading to the outside. If a window is open in the room of fire origin, and there is little or no wind, little flow moves through the remainder of the building. If there is no open window, the flow will move toward cracks and leaks wherever they may be in the building. All these flows are initially nonbuoyant. The flow through the building is simply flow through a complex system of pipes and orifices. As the fire grows larger, hot gas flows buoyantly out of the place of origin, while cold gas flows in below. Thus, while the net flow (out-in) is just sufficient to accommodate the fire gas expansion, the actual volumetric hot gas outflow may be 2.5 times larger than the inflow. A layer of hot gas moves along the ceiling of connected spaces and at the first opportunity proceeds up a stairwell or other ceiling (roof) opening into regions above [15]. The accumulating hot gas will help spread the fire while the newly created hot fire gases build a new hot layer in the adjacent spaces. The flow and pressure drop across each vent will then progress through a succession of situations as previously discussed. The flow throughout the building is, therefore, determined by the vent and flow friction drops along *all* of the available flow paths from the fire to the outside of the building.

The vent flow calculation procedures described in this section are sufficiently accurate and general to compute the required flow-pressure drop relations for building flow networks (except slow buoyant flows through horizontal vents).

Room Pressure

General Equation to Control Room Pressure

The above vent flow equations give flow rates of air and smoke through a vent as a function of pressure difference between the spaces at both sides of an arbitrary vent. The next question is "How could we know the pressure difference?" It can be obtained from the conservations of mass and heat of the rooms concerned and the ideal gas law. That is, the following equations hold for an arbitrary room, *i:*

Mass conservation

$$\frac{d}{dt}(\rho V_R) = \sum \left(-\dot{m}_{ij} + \dot{m}_{ji}\right) \tag{15.47}$$

Heat conservation

$$c_p \frac{d}{dt}(\rho V_R T) = \dot{Q} - \dot{Q}_h + c_p \sum \left(-\dot{m}_{ij} T + \dot{m}_{ji} T_j\right) \tag{15.48}$$

Ideal gas law

$$\rho T = \frac{M p}{\mathrm{R}} \tag{15.49}$$

where

j = Index of adjacent room connected by vents with the room considered
V, V_R = Volume of the room
$\dot{m}_{ij}$ = Mass outflow rate from room i to an adjacent room j
$\dot{m}_{ji}$ = Mass inflow rate to room i from an adjacent room j
$\dot{Q}$ = Heat release rate of fire source
$\dot{Q}_h$ = Heat loss from the room gas due to heat transfer
$\sum$ = Summation with respect to all the vents between all the adjacent rooms

In these equations subscript i is omitted for ρ, T, $\dot{Q}, \dot{Q}_h$, and V_R of the room considered for simplicity of equation form. Normally, $\dot{Q} = 0$ for rooms other than the fire room. Strictly speaking, the terms for mass fuel input and heat input due to temperature rise of the fuel gasification should be added to Equations 15.47 and 15.48, respectively, if the room being considered is a fire room. Here these terms are disregarded for clarity of the equations and for their relatively small significance.

Since the room volume, V_R, is constant, the left-hand side of Equation 15.48 can be extended as

$$c_p \frac{d}{dt}(\rho V_R T) = c_p \rho V_R \frac{dT}{dt} + c_p T \frac{d}{dt}(\rho V_R) \tag{15.50}$$

Hence, using Equation 15.47 into Equation 15.48 yields the equation for temperature as follows:

$$c_p \rho V_R \frac{dT}{dt} = Q - \dot{Q}_h + c_p \sum \dot{m}_{ji}\left(T_{ji} - T\right) \tag{15.51}$$

Now consider a leaky room condition in which the magnitude of pressure buildup induced by the heat release of the fire is insignificant compared with the absolute atmospheric pressure, which is the case in most building fires. Since ρT is a constant under such conditions, the left-hand side of Equation 15.48 becomes 0; hence,

$$\dot{Q} = \dot{Q}_h + c_p \sum \left(-\dot{m}_{ij} T + \dot{m}_{ji} T\right) = 0 \tag{15.52}$$

The mass flow rates in Equation 15.52, $\dot{m}_{ij}$ and $\dot{m}_{ji}$, are given as a function of the differences of the pressure between room i and adjacent spaces; in other words, this equation can be regarded as the condition that the pressure of room i must satisfy. Incidentally, the same equation can be obtained by using $d\rho/dt = -(\rho/T)dT/dt$, from ρT = constant, and Equation 15.51 into Equation 15.47, the mass conservation.

In case a room contains stratified upper and lower layers, the heat conservation equations for the layers are written as

$$c_p \frac{d}{dt}(\rho_u V_u T_u) = \dot{Q}_{(u)} - \dot{Q}_{h(u)} + c_p \sum_u \left(-\dot{m}_{ij} T + \dot{m}_{ji} T_j\right) \tag{15.53a}$$

$$c_p \frac{d}{dt}(\rho_l V_l T_l) = \dot{Q}_{(l)} - \dot{Q}_{h(l)} + c_p \sum_l \left(-\dot{m}_{ij} T + \dot{m}_{ji} T_j\right) \tag{15.53b}$$

where (u) and (l) denote that only the quantities associated with the upper and lower layers are considered, respectively. It is meant in the above equations that heat transfer by radiation and mass transport through a fire plume and/or entrainment of opening jet that can occur between the upper and lower layers are included as well as those between adjacent rooms.

Now, adding up Equations 15.53a and 15.53b, noting that $\rho_u T_u = \rho_l T_l$ = constant and $V_u + V_l = V_R$ (constant) and that the heat and mass transport between the upper and lower layers in the same room offset each other, yields the same equation as Equation 15.52; that is,

Equation 15.52 holds for the two-layer configuration also. Note also that Equation 15.52 holds universally for transient as well as steady-state conditions.

EXAMPLE 1 For a clearer understanding of the relationship between the conservations of mass and heat and the room pressure, consider the simple example shown in Fig. 15.19. An upper hot layer is developing under the ceiling due to the fire plume flow above a fire source in a room. The room has only one vent at the bottom. The mass conservations in this configuration can be written for the upper and lower air layers, respectively, as

$$\frac{d(\rho_u V_u)}{dt} = \dot{m}_p \tag{15.54a}$$

$$\frac{d(\rho_a V_l)}{dt} = -\dot{m}_p - \dot{m}_d \tag{15.54b}$$

where m_d is the rate of air flow through the bottom vent. Adding up these equations yields the mass conservation of the room as a whole as follows:

$$\frac{d}{dt}(\rho_u V_u + \rho_a V_l) = -\dot{m}_d \tag{15.55}$$

This equation implies that, in the smoke-filling stage, the upper-layer volume with smaller density is increasing while the lower layer with greater density is decreasing; thereby the total mass in the room is decreasing just at the rate of the vent flow.

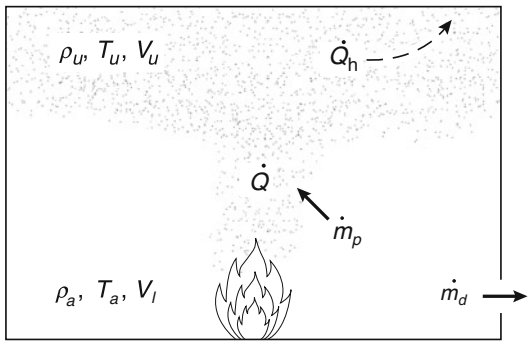

Fig. 15.19 Fire room at the stage of smoke layer filling

The vent flow rate can be obtained by considering the heat conservations for the layers as follows:

$$c_p \frac{d(\rho_u V_u T_u)}{dt} = \dot{Q} - \dot{Q}_h + c_p T_a \dot{m}_p \tag{15.56a}$$

$$c_p \frac{d(\rho_a V_l T_a)}{dt} = -c_p T_a \dot{m}_p + c_p T_a \dot{m}_d \tag{15.56b}$$

Noting that $\rho_u T_u = \rho_a T_a$ and $V_u + V_l = V_R$ (constant) so that

$$c_p \frac{d}{dt}(\rho_u T_u V_u + \rho_a T_a V_l) = c_p \rho_a T_a \frac{d(V_u + V_l)}{dt} = c_p \rho_a T_a \frac{dV_R}{dt} = 0$$

adding up Equations 15.56a and 15.56b yields

$$\dot{Q} - \dot{Q}_h - c_p \dot{m}_d T_a = 0 \tag{15.57}$$

Therefore, the air flow rate through the vent at such a stage of fire is given by

$$\dot{m}_d = \frac{\dot{Q} - \dot{Q}_h}{c_p T_a} \tag{15.58}$$

Invoking Equation 15.3, the vent flow equation, in Equation 15.58 or 15.57, the pressure difference between the room and the outside can be obtained as [16]

$$\Delta p = \frac{1}{2\rho_a (CA)^2} \left(\frac{\dot{Q} - \dot{Q}_h}{c_p T_a} \right)^2 \tag{15.59}$$

That is, the room pressure in this configuration depends on the net heat input (i.e., heat release – heat loss to boundary walls). At the very first stage the upper layer is thin in thickness and low in temperature, so the heat transfer rate, $\dot{Q}_h$, is small but as the upper layer develops the $\dot{Q}_h$ increases. Therefore, if the heat release rate, $\dot{Q}$, is constant, the room pressure will rise very rapidly at first and then will go down gradually.

Although it is not necessary to know the room pressure to calculate the vent flow rate in this particular case, it is required to know the pressure in general cases such as when there is a pressure

difference distribution over the height of a vent and when multiple vents are involved.

Equation to Control Pressure at Steady State

Strictly speaking, there is no steady state in building fire phenomena but there are stages at which fire behavior can be regarded as nearly steady. At steady state $dT/dt = 0$ in Equation 15.51; hence, Equation 15.52 becomes

$$\begin{aligned}\dot{Q} - \dot{Q}_h + c_p \sum \left(-\dot{m}_{ij} T + \dot{m}_{ji} T_j\right) &= \left[\dot{Q} - \dot{Q}_h + c_p \sum \dot{m}_{ji}\left(T_j - T\right)\right] \\ &\quad + c_p T \sum \left(-\dot{m}_{ij} + \dot{m}_{ji}\right) \\ &= 0 + c_p T \sum \left(-\dot{m}_{ij} + \dot{m}_{ji}\right) = 0\end{aligned}$$

Hence, Equation 15.52 is reduced to

$$\sum \left(-\dot{m}_{ij} + \dot{m}_{ji}\right) = 0 \tag{15.60}$$

that is, the mass conservation equation. Of course, this relation can also be obtained by letting $d\rho/dt = 0$ in Equation 15.47.

EXAMPLE 2 Consider a room with only one vent that is at steady state and uniform temperature as shown in Fig. 15.20. Letting Δp be the room pressure difference relative to the outdoor space at the height of the sill of the vent, the neutral plane height, h_n, is

$$h_n = -\frac{\Delta p}{(\rho_a - \rho)g} \tag{15.61}$$

Since Δp and h_n are in one-to-one correspondence, solving the pressure and solving the neutral plane height means the same. Incidentally, Δp in Equation 15.61 is negative in this particular case. The mass inflow and outflow rates through the vent, m_d and m_u, are given as a function of h_n as follows:

$$\dot{m}_d = \frac{\sqrt{2}}{3} Cb \sqrt{2g\rho_a(\rho_a - \rho)}\, h_n^{3/2} \tag{15.62a}$$

$$\dot{m}_u = \frac{\sqrt{2}}{3} Cb \sqrt{2g\rho_a(\rho_a - \rho)}\, (h_v - h_n)^{3/2} \tag{15.62b}$$

The neutral plane height, h_n, can be solved by invoking Equation 15.60, which is simply $\dot{m}_d = \dot{m}_u$ in this case, as follows:

$$h_n = \frac{h_v}{1 + \left(\frac{\rho_a}{\rho}\right)^{1/3}} = \frac{h_v}{1 + \left(\frac{T}{T_a}\right)^{1/3}} \tag{15.63}$$

Using Equation 15.63 into Equations 15.62a and 15.62b, the vent mass flow rates can be concretely obtained. Incidentally, Equation 15.63 is identical to the following pressure difference at the height of the sill of the vent:

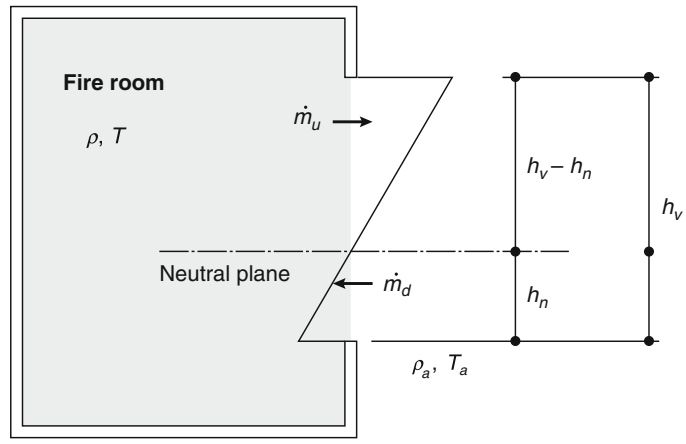

Fig. 15.20 Single room at steady state with uniform temperature

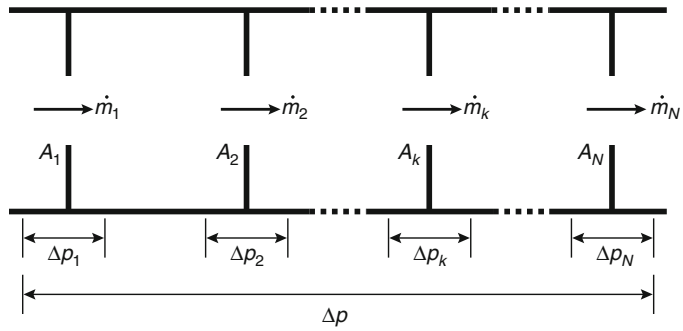

Fig. 15.21 Effective vent area of a series of vents

$$\Delta p = -(\rho_a - \rho)h_n = -\frac{(\rho_a - \rho)h_v}{1 + \left(\frac{T}{T_a}\right)^{1/3}} \quad (15.64)$$

EXAMPLE 3 Equivalent vent area of a series of vents may be a typical example in which steady-state mass conservation law is invoked. Figure 15.21 illustrates a system of spaces connected by N vents with different areas through which vent airflows are induced due to a given pressure difference between both ends, Δp. In this case, from the mass conservation for the $N - 1$ rooms involved in the system of spaces, all the vent flow rates have to be the same; that is,

$$\dot{m}_1 = \dot{m}_2 \cdots = \dot{m}_k \cdots \dot{m}_N (\equiv \dot{m}) \quad (15.65)$$

The pressure difference across an arbitrary vent, Δp_k, is unknown but the following equation holds

$$\Delta p_1 + \Delta p_2 + \cdots + \Delta p_k + \cdots + \Delta p_N = \Delta p \quad (15.66)$$

and the pressure difference across an arbitrary vent, Δp_k, is expressed as

$$\Delta p_k = \frac{\dot{m}^2}{2\rho(CA_k)^2} \quad (15.67)$$

where ρ is the flowing air density.

Substituting Equation 15.67 into Equation 15.66 reveals that the mass flow rate, $\dot{m}$, can be calculated using the given pressure difference, Δp, as

$$\dot{m} = CA_e\sqrt{2\rho\Delta p} \quad (15.68)$$

where A_e is the equivalent vent area, which is given by

$$A_e = \left(\frac{1}{A_1^2} + \frac{1}{A_2^2} + \cdots + \frac{1}{A_k^2} + \cdots + \frac{1}{A_N^2}\right)^{-1/2} \quad (15.69)$$

Incidentally, since the equation

$$\dot{m} = CA_k\sqrt{2\rho\Delta p_k} = CA_e\sqrt{2\rho\Delta p} \quad (15.70)$$

holds for any of the vents, the pressure difference across an arbitrary vent, Δp_k, can be calculated simply by

$$\Delta p_k = \left(\frac{A_e}{A_k}\right)^2 \Delta p \quad (15.71)$$

EXAMPLE 4 Natural smoke venting is a smoke control method that removes smoke from fire in a building space to the outdoor space through a smoke vent arranged in a roof or upper part of a wall of a room. Figure 15.22a illustrates a typical configuration of natural smoke venting at an early stage of fire in a room having a smoke vent at height, h_e, and an inlet above the floor, where we assume a constant heat release rate of fire source, $\dot{Q}$, and steady-state smoke layer properties such as temperature, T, and layer interface height, y. Under such a condition, the pressure difference as shown by Fig. 15.22b develops with height due to the temperature difference between the indoor and the outdoor space. As a result, the pressure difference across the smoke vent, $\Delta p(h_e)$, which is the driving force of the smoke discharge, is induced. If the indoor pressure at the floor level is $-\Delta p(0)$, relative to

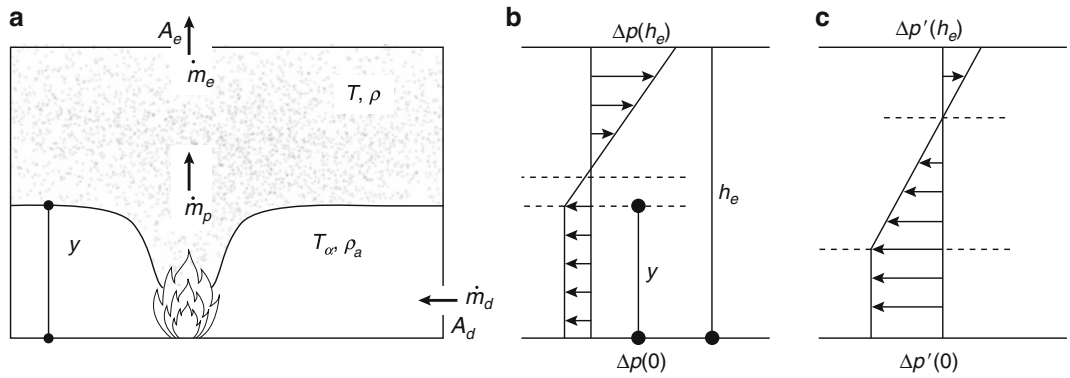

Fig. 15.22 Configuration and pressure profile of natural smoke venting. (**a**) Natural smoke venting configuration. (**b**) Pressure difference profile for large A_d. (**c**) Pressure difference profile for small A_d

the outdoor space, the pressure difference at height, h_e, is

$$\Delta p(h_e) = -\Delta p(0) + (\rho_a - \rho)\, g\,(h_e - y) \qquad (15.72)$$

so that the rate of smoke exhaustion through the vent, m_e, is

$$\dot{m}_e = CA_e\sqrt{2\rho\Delta p(h_e)} = CA_e\sqrt{2\rho[-\Delta p(0) + (\rho_a - \rho)g(h_e - y)]} \qquad (15.73)$$

In Equation 15.73, $-\Delta p(0)$, ρ, and y are unknown so we need to seek additional relationships.

The air inflow rate through the inlet above the floor, $\dot{m}_d$, is expressed as

$$\dot{m}_d = CA_d\sqrt{2\rho_a\Delta p(0)} \qquad (15.74)$$

The plume flow rate at the layer interface height, m_p, can be estimated using some appropriate plume formula such as

$$\dot{m}_p = 0.08\dot{Q}^{1/3}y^{5/3} \qquad (15.75)$$

At steady state, mass conservation holds for the smoke and the air layers so that

$$\dot{m}_e = \dot{m}_p = \dot{m}_d (\equiv \dot{m}) \qquad (15.76)$$

Furthermore, an additional equation to obtain smoke layer density is necessary. It can be provided from some appropriate energy conservation equation for the smoke layer; for example,

$$\dot{Q} = c_p\dot{m}(T - T_a) + \alpha_k A_W(T - T_a) \qquad (15.77)$$

where A_W is the boundary wall area exposed to heat transfer from the smoke layer and α_K is the effective heat transfer coefficient [17–19].

Using the above equations and the equation of gas state, we can obtain the smoke layer temperature and interface height, the vent flow rates, the plume flow rate at the interface height, and the pressure differences, although some trial-and-error method must be invoked because of the nonlinearity of Equation 15.75.

On the other hand, it is more practical to know the necessary smoke vent area to assure a certain level of clear height for evacuation or fire fighting than to predict the behaviors of the smoke layer and vent flows under arbitrary conditions. If the critical layer interface height, y_c, is specified, the required smoke vent area, A_e, can be obtained by simply following the procedure below one by one, without invoking any trial-and-error method [18].

1. Calculate the plume flow rate at height, y_c:

$$\dot{m} = 0.08\dot{Q}^{1/3}y_c^{5/3} \qquad (15.78a)$$

2. Calculate the smoke layer temperature:

$$T = T_a + \frac{\dot{Q}}{c_p m + \alpha_K A_W} \tag{15.78b}$$

3. Calculate the smoke layer density:

$$\rho = \frac{352.8}{T} \tag{15.78c}$$

4. Calculate the pressure at floor level:

$$\Delta p(0) = \frac{\dot{m}^2}{2\rho_a (CA_d)^2} \tag{15.78d}$$

5. Calculate the pressure at the smoke vent:

$$\Delta p(h_e) = -\Delta p(0) + (\rho_a - \rho) g (h_e - y_c) \tag{15.78e}$$

6. Calculate the smoke vent area:

$$A_e = \frac{\dot{m}}{C\sqrt{2\rho \Delta p(h_e)}} \tag{15.78f}$$

Incidentally, Equation 15.73 might suggest that the smoke exhaust rate would increase in proportion to the smoke vent area, but it is not necessarily the case. It is true that the larger the smoke vent area the larger the smoke exhaust rate, but the smoke exhaust rate is affected by the size of the air inlet at the bottom. This is because the mass conservation expressed by Equation 15.76 requires the smoke venting rate, $\dot{m}_e$, be the same as the air inflow rate through the inlet, $\dot{m}_d$. Even though the smoke vent area, A_e, is very large, the indoor pressure at floor height, $-\Delta p(0)$, becomes low when the inlet area is small, which eventually results in a small pressure difference across the smoke vent, $\Delta p(h_e)$, as understood from Equation 15.72 and illustrated by Fig. 15.22c.

Numerical Computation of Room Pressure

Except in particularly simple cases such as the above examples, solving room pressure problems requires using numerical computation. Even in the case of single fire rooms, it is too difficult to solve room pressure problems without using numerical methods if multiple vents, mechanical ventilation, transient condition, and fuel mass input are involved.

When considering the pressures in building rooms, it is convenient to take them relative to the outdoor space rather than to use absolute atmospheric pressure since vent flows in fire are induced by only trivial fractions of the atmospheric pressure. In the case of a single room, if the room pressure, p, is taken as such a relative pressure to the outdoor space at the level of the room floor, any vent flow rate can be given as a function of the only pressure. Therefore, Equation 15.52 can be expressed as

$$\begin{aligned} f(p) \equiv \dot{Q} - \dot{Q}_h &+ c_p \sum (-\dot{m}_u T + \dot{m}_d T_a) \\ &= 0 \end{aligned} \tag{15.79}$$

Because the vent flow terms in Equation 15.79 are a function of p, the problem is reduced to the solution of $f(p) = 0$ for p.

If the room is at uniform temperature, for example, the neutral plane height is given as a function of p as

$$h_n = \frac{-p}{g(\rho_a - \rho)} \tag{15.80}$$

Pressure profile across a vent varies depending on the height of the vent relative to the neutral plane as shown in Fig. 15.23. The vent flow rates are given as a function of the neutral plane height as follows:

1. when $h_n < h_b$

$$\begin{aligned} \dot{m}_u &= \frac{2}{3} C b \sqrt{2\rho g (\rho_a - \rho)} \times \left[(h_t - h_n)^{3/2} - (h_b - h_n)^{3/2} \right] \\ \dot{m}_d &= 0 \end{aligned} \tag{15.81a}$$

2. when $h_b < h_n < h_t$

$$\begin{aligned} \dot{m}_u &= \frac{2}{3} C b \sqrt{2\rho g (\rho_a - \rho)} (h_t - h_n)^{3/2} \\ \dot{m}_d &= \frac{2}{3} C b \sqrt{2\rho g (\rho_a - \rho)} (h_n - h_b)^{3/2} \end{aligned} \tag{15.81b}$$

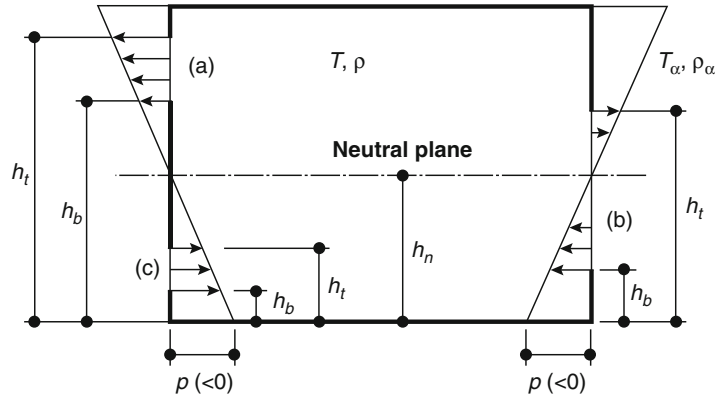

Fig. 15.23 Pressure profile across vents for nonstratified room condition

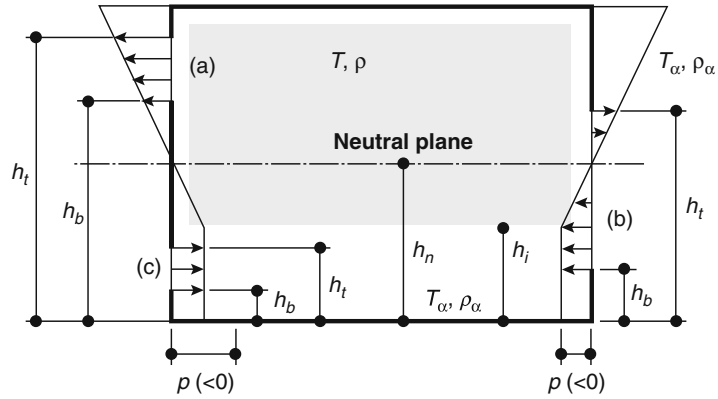

Fig. 15.24 Pressure profile across vents for stratified room condition

3. when $h_t < h_n$

$$\begin{aligned}\dot{m}_u &= 0\\ \dot{m}_d &= \frac{2}{3}Cb\sqrt{2\rho_a g(\rho_a-\rho)}\\ &\quad\times\left[(h_n-h_b)^{3/2}-(h_n-h_t)^{3/2}\right]\end{aligned} \tag{15.81c}$$

From Equations 15.80 and 15.81, it is easily understood that Equation 15.79 is a nonlinear function with respect to p.

If the room is stratified into two uniform layers, a little more complicated situation can emerge; that is, the pressure profile across a vent is affected by the layer interface as well as the neutral plane as exemplified in Fig. 15.24. In this particular example in which the lower layer is at the same temperature as the outdoor space, the neutral plane height is given by

$$h_n = \frac{-p}{g(\rho_a-\rho)} + h_i \tag{15.82}$$

The neutral plane height, h_n, can be lower than the interface height, h_i, under some conditions, such as rapid transient expansion of the upper layer and mechanical air supply to the room, although most often h_i is lower than h_n. In case h_i is lower than h_n, the vent flow rates are calculated as follows: [15, 20, 21]

1. when $h_n < h_b$

$$\begin{aligned}\dot{m}_u &= \frac{2}{3}Cb\sqrt{2\rho g(\rho_a-\rho)}\\ &\quad\times\left[(h_t-h_n)^{3/2}-(h_b-h_n)^{3/2}\right]\\ \dot{m}_d &= 0\end{aligned} \tag{15.83a}$$

2. when $h_b < h_i < h_n < h_t$

$$\begin{aligned}\dot{m}_u &= \frac{2}{3}Cb\sqrt{2\rho g(\rho_a - \rho)}(h_t - h_n)^{3/2} \\ \dot{m}_d &= \frac{2}{3}Cb\sqrt{2\rho g(\rho_a - \rho)}\,(h_t - h_n)^{3/2} \\ &\quad + Cb\sqrt{2\rho_a(-p)}(h_i - h_b)\end{aligned} \tag{15.83b}$$

3. when $h_t < h_i$

$$\begin{aligned}\dot{m}_u &= 0 \\ \dot{m}_d &= Cb\sqrt{2\rho_a(-p)}(h_t - h_b)\end{aligned} \tag{15.83c}$$

Needless to say, Equation 15.79 becomes a nonlinear function with respect to p in this case also.

If the lower temperature is different from the outdoor space, the pressure profiles across the vents are generally more complex. Nevertheless, the vent flow rates can be given as a function of p.

Since Equation 15.79 is nonlinear, it is impossible to obtain an analytical solution except in very limited cases, so usually a numerical method is employed. The idea of the Newton–Raphson method, which is a typical example of iterative numerical solution methods, is illustrated in Fig. 15.25. In this method the pressure is estimated successively starting from the first estimate until the pressure acceptably satisfies $f(p) = 0$ according to the procedure as follows:

$$p^{(k+1)} = p^{(k)} - \left(\frac{df}{dp}\right)^{-1} f\left(p^{(k)}\right) \tag{15.84}$$

where $p^{(k)}$ is the kth estimate of the pressure.

In the case of a structure having multiple rooms, every room has to satisfy Equation 15.52 and the flow through the vents in the boundary of the room is a function of the pressure difference with the adjacent rooms. If a structure consists of N rooms connected arbitrarily to each other, Equation 15.52 for an arbitrary room i may be expressed in the most general form as [20, 21]

$$\begin{aligned}&f_i(p_1, \ldots, p_i, \ldots, p_N) \\ &\equiv \dot{Q} - \dot{Q}_h + c_p \sum \left(-\dot{m}_{ij}T + \dot{m}_{ji}T_j\right) = 0\end{aligned} \tag{15.85}$$

Since every room in the structure must satisfy the identical equation, the problem is reduced to the solution of the coupling equations as follows:

$$\left.\begin{aligned}&f_1(p_1, \ldots, p_i \ldots, p_N) = 0 \\ &\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ &f_i(p_1, \ldots, p_i \ldots, p_N) = 0 \\ &\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ &f_N(p_1, \ldots, p_i \ldots, p_N) = 0\end{aligned}\right\} \tag{15.86}$$

A multidimensional Newton–Raphson method may be used for the solution of Equation 15.86. The iteration procedure is expressed by

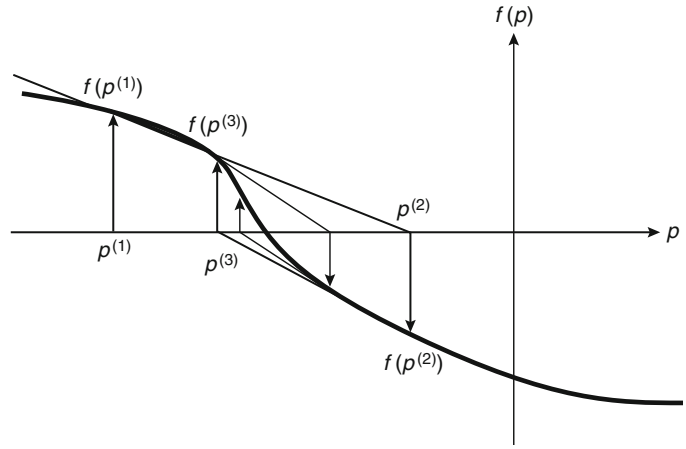

Fig. 15.25 Iterative numerical solution of room pressure by Newton–Raphson method

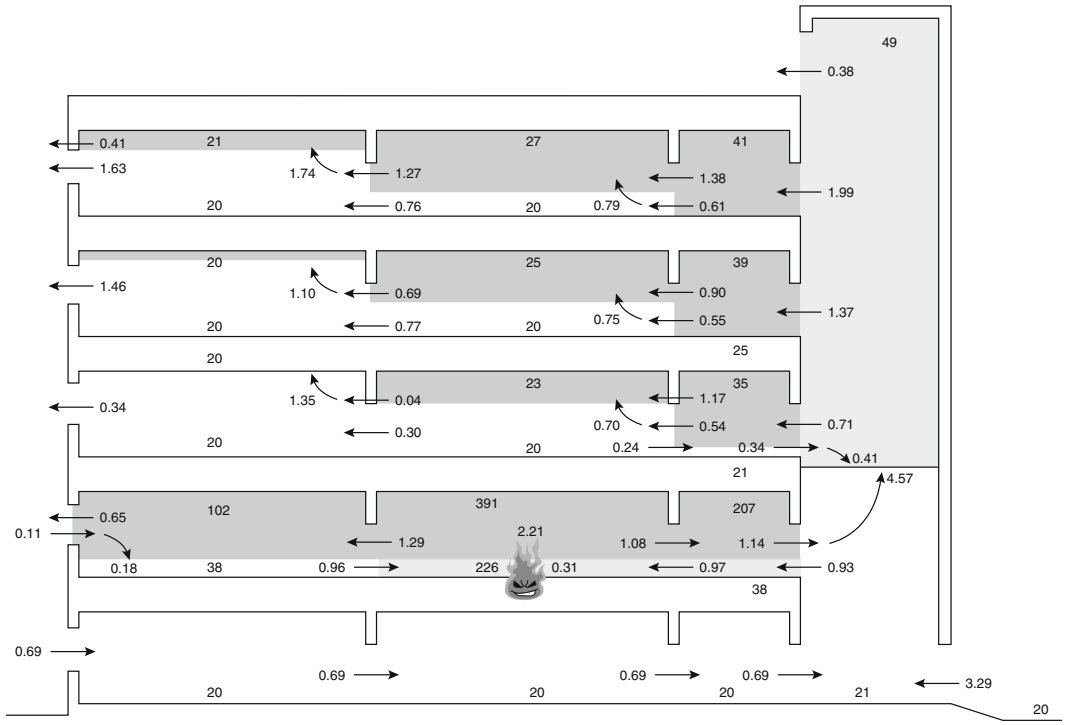

Fig. 15.26 An example of smoke movement prediction by a two-layer zone model (Number: temperature [°C], number →: vent flow rate or plume flow rate [kg/s])

$$\boldsymbol{p}^{(k+1)} = \boldsymbol{p}^{(k)} - \left[\boldsymbol{J}^{(k)}\right]^{-1} \boldsymbol{f}\left[\boldsymbol{p}^{(k)}\right] \tag{15.87}$$

where $\boldsymbol{p} = (p_1, \ldots, p_i, \ldots, p_N)$ and $\boldsymbol{f} = (f_1, \ldots, f_2, \ldots, f_N)$ and $[J]$ is the Jacobian matrix defined by

$$[J] = \begin{bmatrix} \partial f_1/\partial p_1 & \cdots & \partial f_1/\partial p_j & \cdots & \partial f_1/\partial p_N \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \partial f_i/\partial p_1 & \cdots & \partial f_i/\partial p_j & \cdots & \partial f_j/\partial p_N \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \partial f_N/\partial p_1 & \cdots & \partial f_N/\partial p_j & \cdots & \partial f_N/\partial p_N \end{bmatrix} \tag{15.88}$$

In actual calculation, the inverse matrix of the Jacobian matrix, $[J^{(k)}]^{-1}$, is not calculated but the coupling linear equations

$$\left[J^{(k)}\right] \Delta \boldsymbol{p} = -\boldsymbol{f}\left[\boldsymbol{p}^{(k)}\right] \tag{15.89}$$

are directly solved using an appropriate method such as Gaussian elimination for correction pressure increments Δp and the new estimate is calculated as

$$\boldsymbol{p}^{(k+1)} = \boldsymbol{p}^{(k)} + \Delta \boldsymbol{p} \tag{15.90}$$

Figure 15.26 shows an example of smoke movement in a building predicted using the two-layer zone model BRI2, in which vent smoke and air flows were calculated using the above multidimensional Newton–Raphson method.

Summary

Most of the equations for vent flows in this chapter are basically derived from Bernoulli's equation for steady flow of ideal and incompressible fluid. The mass and volume vent flows are given as a function of the flowing gas density, area of the vent, and the pressure difference across the vent with a coefficient called flow coefficient or opening coefficient. The value of the flow coefficient, C, varies depending on the size and shape

of a vent. For usual doorway openings and windows in a building, the value of the C is known to be from 0.6 to 0.7 from many experimental measurements.

In a building fire, the heat release and the flows induced by the fire cause temperature distributions in spaces in the building, which then cause vertical pressure difference distribution across a vent. When such a vertical temperature distribution exists across a vent, it is often convenient for calculation of the vent flow rates to first obtain the neutral plane height, which is given as a function of the pressure difference at a reference height and gas density difference in the spaces at both sides of the vent.

The equation to control the space (room) pressures at a reference height in building spaces can be obtained by considering the mass and heat conservations in the spaces and the equation of gas state. In general, the equation is a function of the vent flow rates, the temperatures of the spaces, and the heat addition and loss, but at steady state, it is reduced to be the mass conservations of the spaces. When multiple spaces are involved in a calculation of the flows in fire, analytical solutions are only possible for very limited conditions, so generally some numerical calculation method must be invoked to solve the coupling nonlinear equations for the space pressures.

Nomenclature

A	Area (m^2)
a	Length (m)
b	Width (m)
C	Flow coefficient (−)
c_p	Specific heat at constant pressure (kJ/kg K)
c_v	Specific heat at constant volume (kJ/kg K)
D	Orifice diameter (m)
Fr	Froude number (−)
g	Gravity constant (m/s^2)
Gr	Grashof number (−)
h	Height (m)
$[J]$	Jacobian matrix
L	Orifice length (m)
M	Molecular weight (kg/kg mol)
$\dot{m}$	Mass flow rate (kg/s)
P	Perimeter (m)
p	Pressure (Pa)
$\dot{Q}$	Heat release rate of fire source (kW)
$\dot{Q}_h$	Heat loss by heat transfer (kW)
R	Gas constant (J/kg mol K)
Re	Reynolds number (−)
T	Temperature (K)
u	Velocity (m/s)
V	Volume (m^3)
$\dot{V}$	Volume flow rate (m^3/s)
V_R	Room volume (m^3)
y	Vertical coordinate (m)
α_K	Effective heat transfer coefficient (kW/m^2K)
Δ	Increment of
δ	Depth (see Fig. 15.6) (m)
$\gamma = c_p/c_v$	Isentropic exponent (−)
Π	Non-dimensional pressure (−)
ρ	Density (kg/m^3)
μ	Viscosity (Ns/m^2)

Subscripts

a	Atmosphere
b	Sill of vent
c	Ceiling of room
d	Lower
f	Floor
g	Gauge
i	Hot-cold interface
ij	From room (layer) i to room (layer) j
j	Index of layer
L, l	Lower
n	Neutral axis
O_2	Oxygen
t	Soffit of vent
u, U	Upper
v, V	Vent, in the vent
0	Reference height
1	Upstream of orifice
2	Downstream of orifice

Effect of Combustion Conditions on Species Production

16

Daniel T. Gottuk and Brian Y. Lattimer

Introduction

A complete compartment fire hazard assessment requires a knowledge of toxic chemical species production. Although combustion products include a vast number of chemical species, in practical circumstances the bulk of the product gas mixture can be characterized by less than 10 species. Of these, carbon monoxide (CO) represents the most common fire toxicant (see Chap. 63). Over half of all fire fatalities have been attributed to CO inhalation [1, 2]. Concentrations as low as 4000 ppm (0.4 % by volume) can be fatal in less than an hour, and carbon monoxide levels of several percent have been observed in full-scale compartment fires. A complete toxicity assessment should not only include the toxicity of CO but also include the synergistic effects of other combustion products, such as elevated CO_2 and deficient O_2 levels.

The transport of combustion products away from the room of the fire's origin is of the utmost importance, because nearly 75 % of the fatalities due to smoke inhalation occur in these remote locations [3]. However, conditions close to the compartment of origin will govern the levels that are transported to remote locations. The research in this area has focused on characterizing species levels produced under a variety of conditions, both inside and nearby the compartment of fire origin.

Species product formation is affected by the compartment geometry, ventilation, fluid dynamics, thermal environment, chemistry, and mode of burning. The mode of burning and ventilation are two of the key conditions that dictate product formation. These conditions can be used to classify fires into three general categories: (1) smoldering, (2) free- (or open-) burning fires, and (3) ventilation-limited fires. Smoldering is a slow combustion process characterized by low gas temperatures and no flaming. Under these conditions, high levels of CO can be generated. Chapters 63, 19, and 36 discuss this mode of burning in detail; thus, it will not be discussed further here. Free-burning fires are flaming fires that have an excess supply of air. These well-ventilated fires (discussed in Chap. 36) are generally of little concern in terms of generating toxic species. This chapter focuses primarily on the third category, ventilation-limited flaming fires. These fires consist of burning materials inside an enclosure, such as a room, in which airflow to the fire is restricted due to limited ventilation openings in the space. As a fire grows, conditions in the space will transition from overventilated to underventilated (fuel rich). It is normally during underventilated conditions that formation of high levels of combustion products, including CO, creates a major fire hazard.

This chapter discusses the production of species within a compartment fire and the transport of these gases out of the fire compartment to adjacent areas. Engineering correlations are presented along with brief reviews of pertinent work on

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_16, © Society of Fire Protection Engineers 2016

species production in compartment fires. These sections provide the background and basis for understanding the available engineering correlations and the range of applicability and limitations. An engineering methodology is presented to utilize the information given in this chapter.

This chapter is organized according to the following outline:
Basic Concepts
Species Production Within Fire Compartments
Hood Experiments
Compartment Fire Experiments
Chemical Kinetics
Fire Plume Effects
Transient Conditions
Species Transport to Adjacent Spaces
Engineering Methodology

Basic Concepts

In a typical compartment fire, a two-layer system is created. The upper layer consists of hot products of combustion that collect below the ceiling, and the lower layer consists of primarily ambient air that is entrained into the base of the fire (Fig. 16.1). Initially, the fire plume is totally in the lower layer, and the fire burns in an overventilated mode similar to open burning. Due to excess air and near-complete combustion, little CO formation is expected in this mode. (See Chap. 36, for yields.) As the fire grows, ventilation paths in the room restrict airflow, creating underventilated (fuel-rich) burning conditions. It is generally under these conditions that products of incomplete combustion are created. Typically, the fire plume extends into the upper layer, such that layer gases recirculate through the upper part of the plume.

Depending on both the size of the room and the size of the fire, it is possible to have a fire plume that cannot be contained within the room, resulting in flame extension out of windows or doors. Flame extension can occur when the fire plume impinges on the ceiling and the ceiling jets are longer than the distance from the plume to outside vent openings (Fig. 16.2). Flame extension is different from a second burning phenomenon outside of the fire compartment, called external burning, which is discussed below. The main point to understand is that flame extension outside of the fire compartment is a result of a fire that is too large to be contained in the room. Flame extension can occur during both over- and underventilated burning conditions. To estimate when flame extension may occur, the maximum heat release rate that can be supported by the compartment ventilation needs to be determined. Flame length correlations can then be used to determine whether flames will extend outside of the compartment.

As a fire progresses and the upper layer descends, the layer will spill below the top of doorways or other openings into adjacent areas. The hot, vitiated, fuel-rich gases flowing into adjacent areas can mix with air that has high O_2 concentrations to create a secondary burning zone outside of the compartment (Fig. 16.3). This is referred to as external burning. External

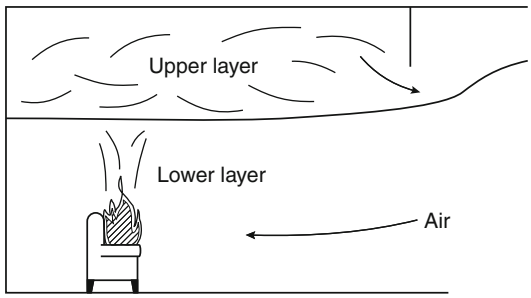

Fig. 16.1 An overventilated compartment fire with the fire plume below the layer interface

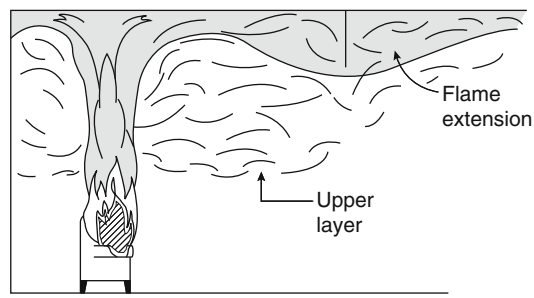

Fig. 16.2 A fire compartment with flame extension out of the doorway

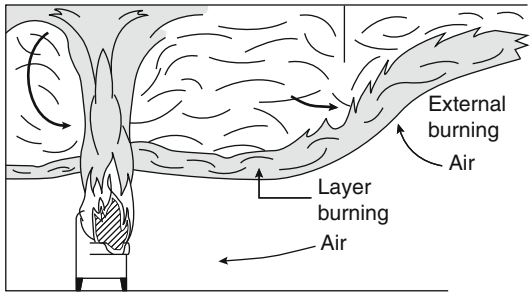

Fig. 16.3 An underventilated compartment fire with external burning of fuel-rich upper layer gases

burning can also be accompanied by layer burning. Layer burning is the ignition of fuel-rich upper-layer gases at the interface between the upper and lower layers. External burning and layer burning occur due to the buildup of sufficient fuel in an atmosphere that is able to mix with available oxygen. These phenomena can only occur during underventilated burning conditions. In some circumstances, external burning can decrease human fire hazard through the oxidation of CO and smoke leaving the fire compartment (see the section in this chapter, "Species Transport to Adjacent Spaces").

The occurrence of external burning has been predicted using a compartment layer ignition model developed by Beyler [4] (see Chap. 17). Beyler derived a relationship called the ignition index to predict the ignition of gases at the interface of the upper and lower layers inside a compartment. The ignition index, I, is defined as

$$I = \sum_j \frac{\left(C_j/100\right)\Delta H_{c,j}}{\int_{T_o}^{T_{SL,j}} n_{\text{prod}} C_p dT} \geq 1.0 \qquad (16.1)$$

where

j = Fuel species of interest

C_j = Volume concentration of fuel j when fuel stream is stoichiometrically mixed with oxidant stream

$\Delta H_{c,j}$ = Heat of combustion of the species j (kJ/g·mol)

$T_{\text{SL},j}$ = Adiabatic flame temperature at the stoichiometric limit for fuel species j (K)

T_o = Temperature of the gas mixture prior to reaction (K)

n_{prod} = Number of moles of products of complete combustion per mole of reactants (stoichiometric mixture of fuel and oxidant streams)

C_p = Heat capacity of products of complete combustion (kJ/g·mol K)

The use of the ignition index is discussed in detail in Chap. 17, of this book. An ignition index greater than 1.0 indicates that ignition is expected if the mixture contains sufficient fuel.

Species Yields

The generation of fire products in compartment fires can be quantified in terms of species yields, Y_i, defined as the mass of species i produced per mass of fuel burned (g/g):

$$Y_i = \frac{m_i}{m_f} \qquad (16.2)$$

Similarly, oxygen is expressed as the depletion of O_2 (i.e., D_{O2}), which is the grams of O_2 consumed per gram of fuel burned:

$$D_{O_2} = \frac{m_{O_2}}{m_f} \qquad (16.3)$$

The normalized yield, f_i, is the yield divided by the theoretical maximum yield of species i for the given fuel, k_i. For the case of oxygen, f_{O_2} is the normalized depletion rate, where k_i is the theoretical maximum depletion of oxygen for the given amount of fuel. As a matter of convenience, the use of the term yield throughout this chapter will also include the concept of oxygen depletion. As in Chap. 36, the normalized yield is also aptly referred to as the "generation efficiency" of compound i. By definition, the normalized yields range from 0 to 1, and are thus good indicators of the completeness of combustion. For example, under complete combustion conditions the normalized yields of CO_2, H_2O, and O_2 are 1. As a fire burns more inefficiently, these yields decrease. The use of normalized yields is also useful for establishing mass balances. The conservation of carbon requires that

$$f_{CO} + f_{CO_2} + F_{THC} + f_{resid.C} = 1 \quad (16.4)$$

where f_{THC} is the normalized yield of gas-phase total hydrocarbons and $f_{resid.C}$ is the normalized yield of residual carbon, such as soot in smoke or high molecular weight hydrocarbons that condense out of the gas sample.

For two-layer systems the yield of all species except oxygen can be calculated as follows:

$$Y_i = \frac{X_{i_{wet}}(\dot{m}_f + \dot{m}_a)M_i}{\dot{m}_f M_{mix}} \quad (16.5)$$

where

$X_{i_{wet}}$ = The wet mole fraction of speciesi
$\dot{m}_a$ = The mass air entrainment rate into the upper layer
$\dot{m}_f$ = The mass loss rate of fuel
M_i = The molecular weight of speciesi
M_{mix} = The molecular weight of the mixture (typically assumed to be that of air)

The depletion rate of oxygen is calculated as

$$D_{O_2} = \frac{0.21\dot{m}_a M_{O_2}/M_a - X_{O_{2wet}}(\dot{m}_f + \dot{m}_a)M_{O_2}/M_{mix}}{\dot{m}_f} \quad (16.6)$$

The normalized yield, f_i, is simply calculated by dividing the yield by the maximum theoretical yield

$$f_i = \frac{Y_i}{k_i} \quad (16.7)$$

Typical operation of common gas analyzers requires that water be removed from the gas sample before entering the instrument. Consequently, the measured gas concentration is considered dry and will be higher than the actual wet concentration. Equation 16.8 can be used to calculate the wet mole fraction of species $X_{i_{wet}}$, from the measured dry mole fraction, $X_{i_{dry}}$. As can be seen from Equation 16.8, the percent difference between $X_{i_{dry}}$ and $X_{i_{wet}}$ is on the order of the actual H_2O concentration which, depending on conditions, is typically 10–20 % by volume.

$$X_{i_{wet}} = (1 - X_{H_2O_{wet}})X_{i_{dry}} \quad (16.8)$$

Reliable water concentration measurements are difficult to obtain. Therefore, investigators have calculated wet species concentrations using the above relationship with the assumption that the molar ratio, C, of H_2O to CO_2 at any equivalence ratio is equal to the calculated molar ratio at stoichiometric conditions [5, 6]. Based on this assumption, Equation 16.9 can be used to calculate wet species concentrations from dry concentration measurements.

$$X_{i_{wet}} = \frac{X_{i_{dry}}}{1 + CX_{CO_{2dry}}} \quad (16.9)$$

Equivalence Ratio

The concept of a global equivalence ratio (GER) can be used to express the overall ventilation of a control volume, such as a fire compartment. However, due to the complex interaction between the plume and the upper and lower layers, as well as the potential extension of the fire beyond the initial compartment, a unique definition for the GER does not exist. Therefore, if one uses the term GER, it must be associated with a defined control volume.

The first efforts in developing the GER concept were based on hood experiments [7–11] (e.g., as in Fig. 16.4) in which the idea of a plume equivalence ratio was introduced. The plume equivalence ratio, ϕ_p, is the ratio of the mass of fuel burning, m_f, to the mass of oxygen entrained, m_a, into the fire plume (below the upper layer) normalized by the stoichiometric fuel-to-oxygen ratio, r_{O_2}.

$$\phi_p = \frac{m_f/m_{O_2}}{r_{O_2}} \quad (16.10a)$$

Since oxygen is typically entrained into a fire plume via air, ϕ_p is commonly defined as

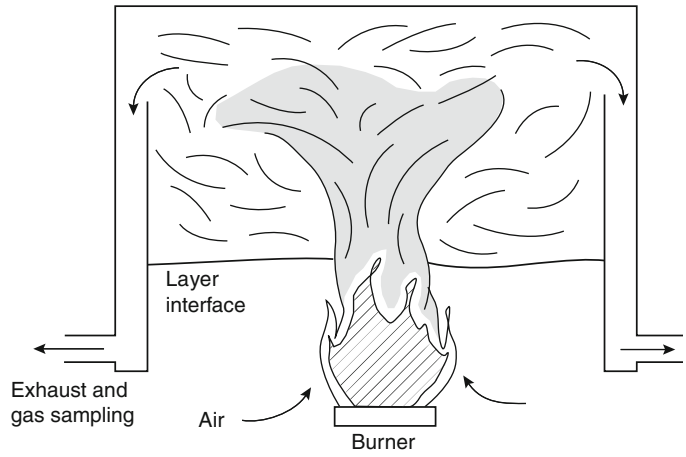

Fig. 16.4 Schematic of the two-layer system created in the hood experiments of Beyler [8, 9]

$$\phi_p = \frac{m_f/m_a}{r} \qquad (16.10b)$$

where m_a is the mass of air entrained into the plume (in the lower layer) and r is the stoichiometric mass fuel-to-air ratio. As discussed in the section on species production within fire compartments, this simple characterization of the equivalence ratio well represented the global conditions that existed in the first hood and compartment fire experimental configurations.

In order to more accurately describe the time integrated conditions within the upper layer, a second equivalence ratio was defined for this control volume [7, 10, 11]. The upper-layer equivalence ratio, ϕ_{ul}, is the ratio of the mass of the upper layer that originates from fuel sources, to the mass of the upper layer that originates from any source of air into the upper layer, divided by the stoichiometric fuel-to-air ratio.

The two equivalence ratios (ϕ_p and ϕ_{ul}) are not necessarily the same. As a fire grows, the upper-layer composition represents a collective time history of products. In an ideal two-layer fire, where all air enters the upper layer through the plume, ϕ_{ul} is the same as ϕ_p only during steady burning conditions. If the burning rate of the fire changes quickly compared to the residence time of the gases in the upper layer, the upper-layer equivalence ratio lags behind the plume equivalence ratio. The residence time, t_R, can be defined as the time required for a unit volume of air to move through the upper-layer volume, and can be characterized according to Equation 16.11.

$$t_R = \frac{V_{ul}\rho_{ul}}{\dot{m}_{\text{exhaust}}} \qquad (16.11)$$

where

$\dot{m}_{\text{exhaust}}$ = Mass flow rate of gases out of the layer (kg/s)
ρ_{ul} = Density of the upper-layer gases (kg/m^3)
V_{ul} = Volume of the upper layer (m^3)

For example, consider a compartment fire burning with a plume equivalence ratio of 0.5 with upper layer gases that have a residence time of 20 s. If the fire grows quickly such that ϕ_p increases to a value of 1.5 in about 5 s, ϕ_{ul} would now lag behind (less than 1.5). The fuel rich ($\phi_p = 1.5$) gas mixture from the plume is effectively diluted by the upper-layer gases since there has not been sufficient time (greater than 20 s) for the layer gases to change over. The result is that ϕ_{ul} will have a value between 0.5 and 1.5. Another instance when ϕ_{ul} can differ from ϕ_p is when additional fuel or air enters the upper layer directly. An example of this would be the burning of wood paneling in the upper layer.

The calculation of ϕ_{ul} can be a complex task. Either a fairly complete knowledge of the gas composition is needed [7] or time histories of ventilation flows and layer residence times are needed to be able to calculate ϕ_{ul}. Toner [7] and Morehart [12] present detailed methodologies

for calculating ϕ_{ul} from gas composition measurements. Equation 16.12 can be used to calculate ϕ_{ul} if the mass flow rates can be expressed as a function of time.

$$\phi_{ul} = \frac{1\int_{t-t_R}^{t} \dot{m}_f(t')dt'}{r\int_{t-t_R}^{t} \dot{m}_a(t')dt'} \tag{16.12}$$

Although termed the upper-layer equivalence ratio, ϕ_{ul} actually represents the temporal aspect of the equivalence ratio no matter what the control volume. For instance, the control volume may be the whole compartment, as shown in Fig. 16.1. In this case, the compartment equivalence ratio, ϕ_c, is defined as the ratio of the mass, m_f, of any fuel entering or burning in the compartment to the mass, m_a, of air entering the compartment normalized by the stoichiometric fuel-to-air ratio.

In a compartment fire, air is typically drawn into the space through a door or window style vent. If all of the air drawn into the compartment is entrained into the lower layer portion of the plume, then the plume equivalence ratio can be an adequate representation of the fire environment. However, if layer burning occurs, or multiple vents cause air to enter the upper layer directly, the use of a compartment equivalence ratio is more appropriate. As a practical note, for fires within a single compartment, the equivalence ratio is calculated (and experimentally measured) based on the instantaneous fuel mass loss rate, $\dot{m}_f$, and air flow rate, $\dot{m}_a$, into the compartment (Equation 16.13a).

$$\phi = \frac{\dot{m}_f \dot{m}_a}{r} \tag{16.13a}$$

As noted previously, r is defined as the stoichiometric fuel-to-air ratio. Unfortunately, the ratio r is sometimes defined as the air-to-fuel ratio, r_a. Therefore, consideration must be given to values obtained from tabulated data. Keeping with the nomenclature of this chapter, the equivalence ratio can also be expressed as

$$\phi = \frac{\dot{m}_f}{\dot{m}_a} \cdot r_a = \frac{\dot{m}_f}{\dot{m}_a} \frac{r_o}{Y_{O_2,\text{air}}} \tag{16.13b}$$

where

r_a = Mass air-to-fuel ratio
r_o = Oxygen-to-fuel mass ratio
$Y_{O_2,\text{air}}$ = Mass fraction of oxygen in air (0.23)

The formulation of Equation 16.13b allows direct use of values tabulated for various fuels in Appendix 3, Table 3.2, of this handbook. Another useful expression for ϕ can be derived from Equation 16.13b by multiplying the numerator and denominator by the fuel heat of combustion, Δh_c, and recognizing that the heat release per mass of oxygen consumed, E, is equal to Δh_c over r_o, yielding

$$\phi = \frac{\dot{Q}}{\dot{m}_a} \cdot \frac{1}{EY_{O_2,\text{air}}} = \frac{\dot{Q}}{\dot{m}_a} \cdot \frac{1}{3030} \tag{16.13c}$$

where

$\dot{Q}$ = Ideal heat release rate of the fire (kW)
$\dot{m}_a$ = Air flow rate (kg/s)
$E \approx 13{,}100$ kJ/kg (Drysdale [13])

Note that Q is the ideal heat release rate, which is determined by multiplying the mass loss rate by the heat of combustion, and is not limited by the amount of air flowing into the compartment or control volume. To date, Equation 16.13c has not been utilized in the literature and therefore has not been well established. However, it offers a convenient means to calculate the equivalence ratio without the need to know the fuel chemistry.

The equivalence ratio is an indicator of two distinct burning regimes, overventilated (fuel lean) and underventilated (fuel rich). Overventilated conditions are represented by equivalence ratios less than one, while underventilated conditions are represented by equivalence ratios greater than one. An equivalence ratio of unity signifies stoichiometric burning, which, in an ideal process, represents complete combustion of the fuel to CO_2 and H_2O with no

excess oxygen. During underventilated conditions there is insufficient oxygen to completely burn the fuel; therefore, products of combustion will also include excess fuel (hydrocarbons), carbon monoxide, and hydrogen. It follows that the highest levels of CO production in flaming fires is expected when underventilated conditions occur in the compartment on fire. This basic chemistry also suggests that species production can be correlated with respect to the equivalence ratio. Although the not-so-ideal behavior of actual fires prevents accurate theoretical prediction of products of combustion, experimental correlations have been established.

A simple model for the most complete combustion of a fuel can be represented by the following expressions: [8]

$$f_{CO_2} = f_{O_2} = f_{H_2O} = 1 \quad \text{for } \phi < 1 \tag{16.14a}$$

$$f_{CO_2} = f_{O_2} = f_{H_2O} = 1/\phi \quad \text{for } \phi > 1 \tag{16.14b}$$

$$f_{CO} = f_{H_2} = 0 \quad \text{for all } \phi \tag{16.14c}$$

$$f_{THC} = 0 \quad \text{for } \phi < 1 \tag{16.14d}$$

$$f_{THC} = 1 - 1/\phi \quad \text{for } \phi < 1 \tag{16.14e}$$

These expressions assume that for ϕ greater than 1, all excess fuel can be characterized as unburned hydrocarbons. Since compartment fire experiments have shown that significant levels of both CO and H_2 are produced at higher equivalence ratios, Expression 16.14c is not always representative, and reveals a shortcoming of assuming this simple ideal behavior. However, for the products of complete combustion (CO_2, O_2, and H_2O), this model serves as a good benchmark for comparison of experimental results.

Example 1 Consider a piece of cushioned furniture to be primarily polyurethane foam. The nominal chemical formula of the foam is $CH_{1.74}O_{0.323}\,N_{0.07}$. Calculate the stoichiometric fuel-to-air ratio, the maximum yields of CO, CO_2, and H_2O, and the maximum depletion of O_2.

Solution For complete combustion of the fuel to CO_2 and H_2O, the following chemical equation can be written

$$CH_{1.74}O_{0.323}N_{0.07} + 1.2735(O_2 + 3.76\,N_2) \rightarrow 1.0CO_2 + 0.87H_2O + 4.823N_2$$

The molecular weight of the fuel, M_f, $= 1(12) + 1.74(1) + 0.323(16) + 0.07(14) = 19.888$.

The stoichiometric fuel-to-air ratio is

$$r = \frac{(1 \text{ mole fuel})\,(M_f)}{(\text{moles of air})\,(M_a)} = \frac{19.888}{1.2735\,(4.76)\,(28.8)}$$

$$r = 0.1139$$

The stoichiometric air-to-fuel ratio is

$$\frac{1}{r} = 8.78$$

The maximum yield of CO (i.e., k_{CO}), is calculated by assuming that all carbon in the fuel is converted to CO. Therefore, the number of moles of CO formed, n_{CO}, equals the number of moles of carbon in one mole of fuel. For the polyurethane foam, $n_{CO} = 1$.

$$k_{CO} = \frac{n_{CO}(M_{CO})}{n_f(M_{fuel})} = \frac{(1)\,(28)}{(1)\,(19.888)} = 1.41$$

Similarly, k_{CO_2} and k_{H_2O} are calculated as

$$k_{CO_2} = \frac{(1)\,(44)}{19.888} = 2.21$$

$$k_{H_2O} = \frac{(0.87)\,(18)}{19.888} = 0.787$$

The maximum depletion of oxygen, k_{O_2}, refers to the mass of oxygen needed to completely combust one mole of fuel to CO_2 and H_2O. This is the same as the stoichiometric requirement of oxygen.

$$k_{O_2} = \frac{n_{O_2}(M_{O_2})}{n_f M_f} \quad \frac{(1.2735)\,(32)}{(1)19.888} = 2.05$$

Example 2
The fuel specified in Example 1 is burning at a rate of 9 g/s and entraining air at a rate of 56 g/s. Measurements of the upper layer gas composition reveal dry concentrations of 3.7 % by volume CO, 14.3 % CO_2, and 0.49 % O_2. Correct the concentrations for the water removed during the gas analysis process (i.e., calculate the wet concentrations).

Solution In order to use Equation 16.9 to calculate the wet mole fractions, the stoichiometric molar ratio of H_2O to CO_2 for C needs to be calculated. This ratio is simply obtained from the stoichiometric chemical equation in Example 1.

$$C = \frac{n_{H_2O}}{n_{CO_2}} = \frac{0.87}{1} = 0.87$$

Once C is obtained, the wet mole fractions can be calculated as

$$X_{CO_{wet}} = \frac{0.037}{1 + 0.87(0.143)} = 0.033$$

$$X_{CO_{2wet}} = \frac{0.143}{1 + 0.87(0.143)} = 0.127$$

$$X_{O_{2wet}} = \frac{0.0049}{1 + 0.87(0.143)} = 0.0044$$

The estimated mole fraction of water is

$$X_{H_2O} = CX_{CO_{2wet}} = 0.87(0.127) = 0.11$$

Therefore, the corrected gas concentrations on a percent volume basis are 3.3 % CO, 12.7 % CO_2, and 0.44 % O_2.

Example 3 Continuing from Example 2, calculate the yields and normalized yields for each species measured. The wet mole fractions are $X_{CO_{wet}} = 0.033$, $X_{CO_{2wet}} = 0.127$, and $X_{O_{2wet}} = 0.0044$.

Solution Using Equations 16.5 and 16.7, the yield and normalized yield of CO, CO_2, and H_2O can be calculated. The maximum yields calculated in Example 1 are $k_{CO} = 1.41$, $k_{CO_2} = 2.21$, $k_{H_2O} = 0.787$, and $k_{O_2} = 2.05$.

$$Y_{CO} = \frac{X_{CO_{wet}}(\dot{m}_f + m_a)M_{CO}}{\dot{m}_f M_a} = \frac{(0.033)(9+56)(28)}{9(28.8)} = 0.23$$

$$f_{CO} = \frac{Y_{CO}}{k_{CO}} = \frac{0.23}{1.41} = 0.16$$

$$Y_{CO_2} = \frac{(0.127)(9+56)(44)}{9(28.8)} = 1.40$$

$$f_{CO_2} = \frac{1.40}{2.21} = 0.63$$

$$Y_{H_2O} = \frac{(0.11)(9+56)(18)}{9(28.8)} = 0.50$$

$$f_{H_2O} = \frac{0.50}{0.787} = 0.63$$

The depletion of oxygen is calculated using Equation 16.6, assuming the molecular weight of the gas mixture, M_{mix}, to be approximately that of air.

$$D_{O_2} = \frac{0.21\dot{m}_a M_{O_2}/M_a - X_{O_{2wet}}(\dot{m}_f + \dot{m}_a)M_{O_2}/M_{mix}}{\dot{m}f}$$

$$D_{O_2} = \frac{0.21(56)32/28.8 - 0.0044(9+56)32/28.8}{9}$$

$$D_{O_2} = 1.42$$

The normalized yield is calculated as

$$f_{O_2} = \frac{D_{O_2}}{k_{O_2}} = \frac{1.42}{2.05} = 0.69$$

Species Production Within Fire Compartments

Hood Experiments

Beyler [8, 9] was the first to publish major species production rates in a small-scale two-layer environment. The experiments performed consisted of situating a burner under a 1-m-diameter, insulated collection hood. The result was the formation of a layer of combustion products in the hood similar to that found in a two-layer compartment fire (see Fig. 16.4). By varying the fuel supply rates and the distance between the burner and layer interface, and, consequently, the air entrainment rate, a range of

equivalence ratios was obtained. Layer gases were exhausted at a constant, metered flow rate from the periphery of the hood at a depth of 15 cm below the ceiling. The general procedure was to allow steady-state burning conditions to develop, so the layer maintained a constant depth below the exhaust flow location. Tests revealed a reasonably well-mixed uniform layer both in temperature and chemical composition during the steady-state conditions. Gas analysis was performed on samples taken from the exhaust stream. Table 16.1 shows the physicochemical properties of the fuels tested.

Beyler's results show that species yields correlate very well with the plume equivalence ratio. Figure 16.5 shows normalized yields of major species for propane fires plotted against the plume equivalence ratio. The trends seen in these plots for propane are fairly representative of the other fuels tested. For overventilated conditions, the yield of CO_2 and H_2O and depletion of O_2 are at a maximum, and there is virtually no production of CO, H_2, or unburned hydrocarbons (*THC*). As underventilated burning conditions ($\phi \geq 1$) are approached, products of incomplete combustion (CO, H_2, and *THC*) are generated.

For comparison, the expressions for ideal complete combustion (Equations 16.14a, 16.14b, 16.14c, 16.14d, and 16.14e) are shown on each plot in Fig. 16.5. The CO_2 yield departs from Equation 16.14b as CO production increases at higher equivalence ratios. This departure, which is fairly independent of ϕ for $\phi > 1$, has been described by the yield coefficient [5]. The ratios of the normalized yield of CO_2, H_2O, or normalized depletion of O_2 to the theoretical maximums expressed by Equations 16.14a, 16.14b, 16.14c, 16.14d, and 16.14e are defined as the yield coefficients, B_{CO_2}, B_{H_2O}, and B_{O_2} respectively [5].

$$B_{CO_2} = \frac{f_{CO_2}}{1} \qquad \text{for } \phi < 1 \qquad (16.15a)$$

$$B_{CO_2} = \frac{f_{CO_2}}{1/\phi} \qquad \text{for } \phi > 1 \qquad (16.15b)$$

$$B_{H_2O} = \frac{f_{H_2O}}{1} \qquad \text{for } \phi < 1 \qquad (16.16a)$$

$$B_{H_2O} = \frac{f_{H_2O}}{1/\phi} \qquad \text{for } \phi > 1 \qquad (16.16b)$$

$$B_{O_2} = \frac{f_{O_2}}{1} \qquad \text{for } \phi < 1 \qquad (16.17a)$$

Table 16.1 Physicochemical data for selected fuels

Fuel	Empirical chemical formula of volatiles	Empirical molecular weight	Maximum theoretical yields				
			k_{CO}	k_{CO_2}	k_{O_2}	k_{H_2O}	$1/r^c$
Acetone	C_3H_6O	58	1.45	2.28	2.21	0.93	9.45
Ethanol	C_2H_5OH	46	1.22	1.91	2.09	1.17	8.94

Wood (ponderosa pine[a])	$C_{0.95}H_{2.4}O$	30	0.89	1.40	1.13	0.73	4.83
Wood (spruce[b])	$CH_{3.584}O_{1.55}$	40	0.69	1.09	0.89	0.80	3.87

[a]From Beyler [9] chemical formula estimated from $\phi < 1$ yield data
[b]Gottuk et al. [5]
[c]r = stoichiometric fuel-to-air ratio

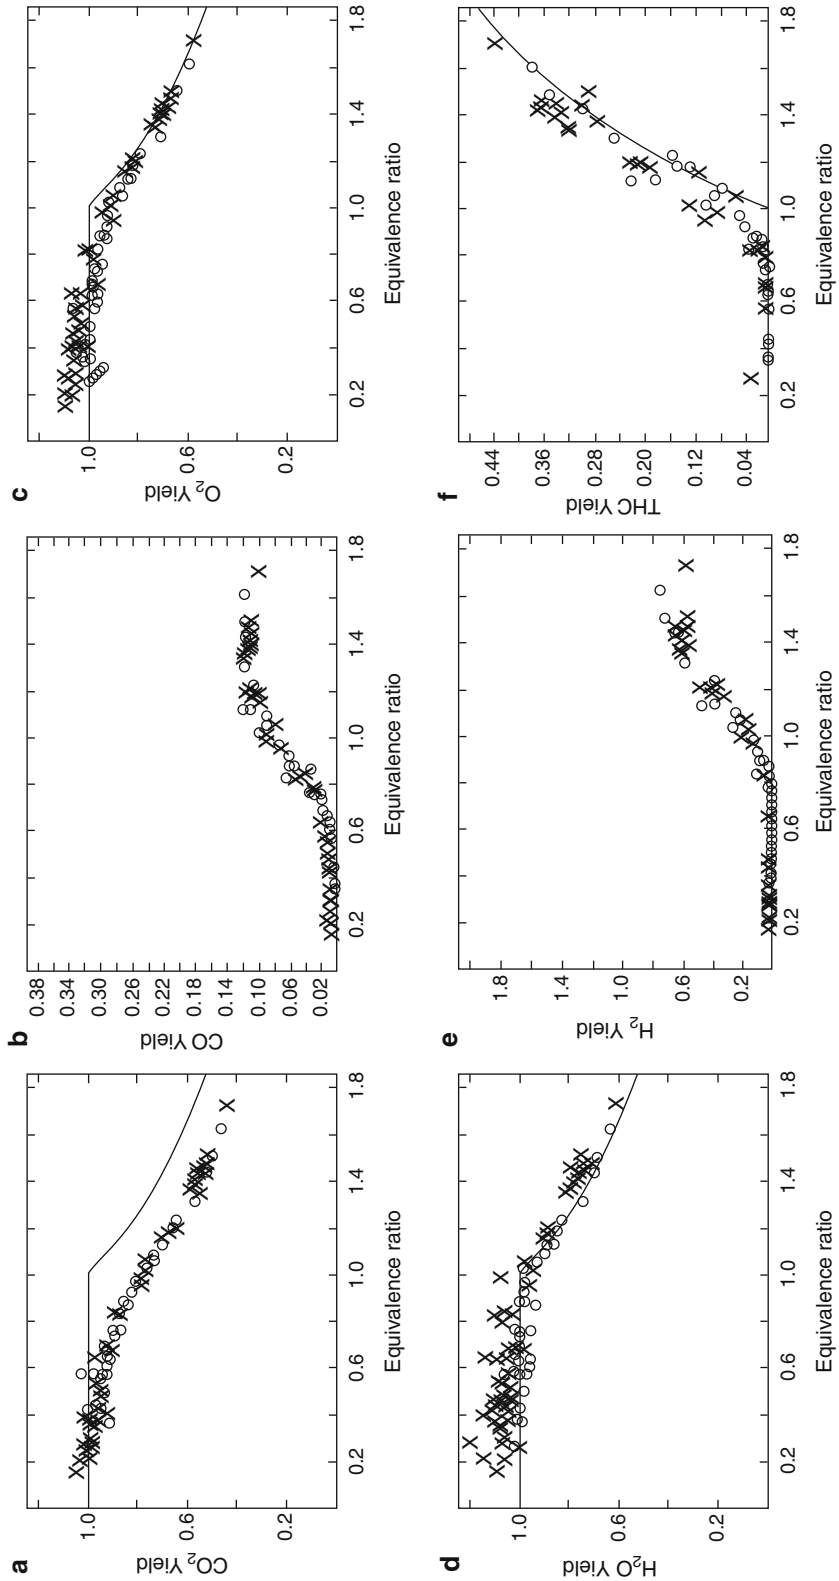

Fig. 16.5 Normalized yields of measured chemical species as a function of the equivalence ratio for propane experiments using a 13 cm (o) or 19 cm (x) burner with supply rates corresponding to 8 to 32 kW theoretical heat release rate [8]

$$B_{O_2} = \frac{f_{O_2}}{1/\phi} \quad \text{for } \phi > 1 \qquad (16.17b)$$

These terms are useful in discussing characteristics of the combustion efficiency. For example, an O_2 yield of 1 indicates complete utilization of available O_2. In the case of CO_2 and H_2O, deviation from the model (as indicated by B_{CO_2} or $B_{H_2O} < 1$) is a measure of the degree of incomplete combustion. It can be seen from Fig. 16.5 that the production of CO is primarily at the expense of CO_2 (i.e., B_{O_2} and B_{H_2O} remain nearly 1, while B_{CO_2} is about 0.8). Table 16.2 shows average yield coefficients for underventilated fires.

Figure 16.6 shows unnormalized CO yields plotted against the plume equivalence ratio for fuels tested by Beyler [8, 9]. The correlations agree quite well for all fuels. Below an equivalence ratio of 0.6, minimal CO production is observed. Above ϕ_p equal to 0.6, carbon monoxide yield increases with ϕ_p and, for most fuels, tends to level out at equivalence ratios greater than 1.2. Toluene, which creates large amounts of soot, is anomalous compared to the other fuels studied. As can be seen in Fig. 16.6, the CO yields from toluene fires remain fairly constant at about 0.09 for both overventilated and underventilated burning conditions.

It should be noted that Beyler originally presented all correlations with normalized yields, f_{CO}. However, better agreement is found between unnormalized CO yield-equivalence ratio correlations for different fuels, Y_{CO} (shown in Fig. 16.6), rather than normalized yields. One point of interest, though, is that when CO production is correlated as normalized yield, a more distinct separation of the data occurs for ϕ_p greater than 1. The degree of carbon monoxide production (represented as f_{CO}) during underventilated conditions can be ranked by chemical structure according to oxygenated hydrocarbons greater than hydrocarbons greater than aromatics. This ranking is not observed for unnormalized yield correlations.

Toner et al. [7] and Zukoski et al. [10, 11] performed similar hood experiments with a different experimental setup. The hood used was a 1.2 m cube, insulated on the inside with ceramic fiber insulation board. The layer in the hood formed to the lower edges where layer gases were allowed to spill out. Gas sampling was done using an

[a]Values have been calculated from data found in the cited references. Values for Toner et al. [7], Beyler [8], Beyler [9], and Morehart et al. [12] are from hood experiments, and values for Gottuk et al. [5] are for a reduced-scale enclosure

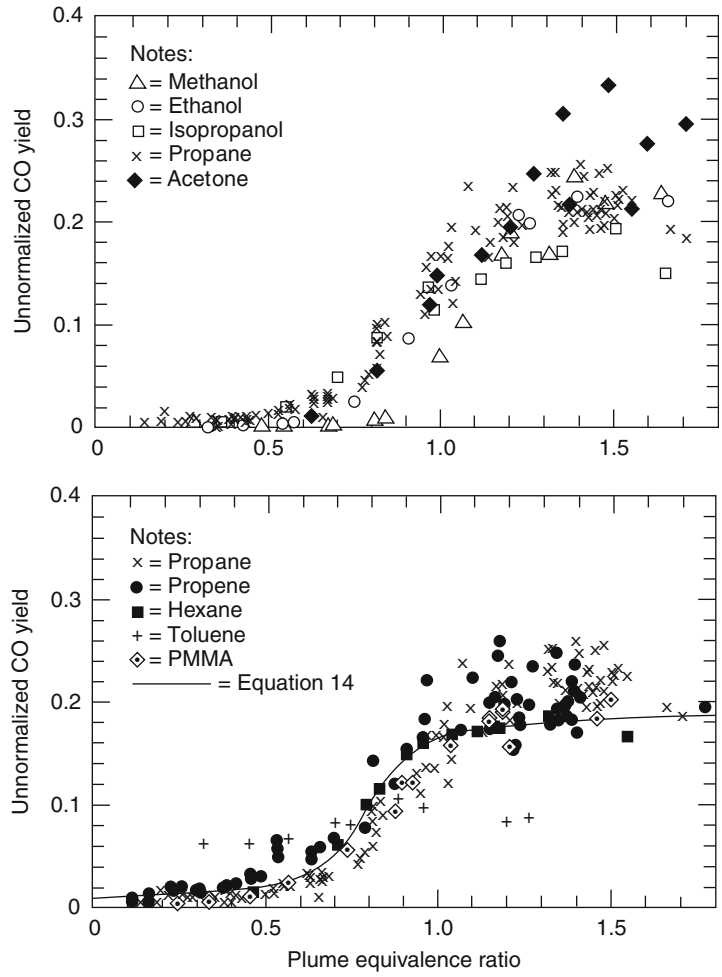

Fig. 16.6 Unnormalized carbon monoxide yields as a function of the plume equivalence ratio for various fuels studied by Beyler in a hood apparatus [8, 9]

uncooled stainless-steel probe inserted into the layer. Detailed gas species measurements were made using a gas chromatograph system. The upper-layer equivalence ratio was determined from conservation of atoms using the chemical species measurements, the measured composition of the fuel, and the metered fuel flow rate. Natural gas flames with heat release rates of 20–200 kW on a 19-cm-diameter burner were studied. The layer in the hood was allowed to form and reach a steady-state condition before gas sampling was performed.

It was concluded that species concentrations were well correlated to the upper-layer equivalence ratio, ϕ_{ul}, and insensitive to temperatures for the range studied (490–870 K). Since these experiments were conducted during steady-state conditions, with mean upper-layer residence times of about 25–180 s, it can be concluded that ϕ_p and ϕ_{ul} were equal.

The data of Toner et al. [7] have been used to plot CO and CH_4 yields versus upper-layer equivalence ratio in Figs. 16.7 and 16.8, respectively. The correlations are qualitatively similar to the correlations obtained by Beyler for different fuels. An analysis of these test results also showed that normalized CO_2 and O_2 yield versus equivalence ratio data is represented reasonably well by Equations 16.15, 16.16, and 16.17. Similar to Beyler's propane results, the average B_{O_2} value is about 1 and B_{CO_2} is 0.8 for underventilated burning conditions (the use of yield coefficients is discussed further in the section on engineering correlations).

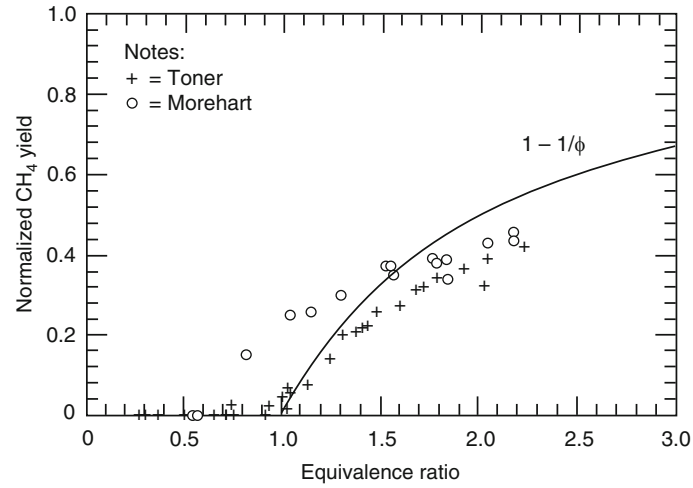

Fig. 16.8 Normalized yields as a function of equivalence ratio for methane fires studied by Toner et al. [7] and Morehart et al. [12] in hood experiments

Toner compared the measured species concentrations to the calculated equilibrium composition of the reactants at constant temperature and pressure. The layer composition was modeled quite well by the chemical equilibrium composition for very overventilated conditions but not for underventilated conditions. His observance of CO production for near-stoichiometric and underventilated fires, at the expense of CO_2 production, led them to suggest that the oxidation of CO was "frozen out" before completion. (At low temperatures, there is insufficient energy for CO to chemically react to CO_2.) [7] Since the results showed that species production was independent of temperature for the range studied (490–870 K), Toner et al. concluded that, if a freeze-out temperature existed, it must be higher than 900 K. Work by Pitts [14] and by Gottuk et al. [15], discussed later, shows that a freeze-out temperature does exist in the range of 800–900 K, depending on other factors.

Zukoski, Morehart, et al. [11] performed a second series of tests similar to that described above for Zukoski et al. [10] and Toner et al. Much of the same apparatus was used except for a different collection hood. The hood, 1.8 m square by 1.2 m high, was larger than that used by Toner et al. and was uninsulated.

Morehart et al. [12] experiments consisted of establishing steady-state burning conditions such

that the burner-to-layer interface height was constant. A constant ϕ_p was maintained based on this constant interface height in conjunction with the fact that the mass burning rate of fuel was metered at a constant rate. Additional air was then injected into the upper layer at a known flow rate until a new steady-state condition was achieved. This procedure established a ϕ_{ul} that was lower than the ϕ_p, since ϕ_p was based on the ratio of the mass burning rate to the mass of air entrained into the plume from room air below the layer interface. By increasing the air supply rate to the upper layer, a range of ϕ_{ul} was established while maintaining a constant ϕ_p.

Although similar, the correlations obtained by Morehart et al. deviated from those obtained by Toner et al. Figs. 16.7 and 16.8 compare the CO and CH_4 yields calculated from the data of Morehart et al. with the yields calculated from the data of Toner et al. For overventilated conditions, Morehart et al. observed higher CO and CH_4 yields, signifying that the fires conducted by Morehart et al. burned less completely. For underventilated methane fires, Morehart et al. observed lower CO, CO_2, and H_2O and higher CH_4 and O_2 concentrations than Toner et al. The only apparent differences between experiments was that Morehart found layer temperatures were 120–200 K lower for fires with the same equivalence ratio as those observed by Toner, that is, they ranged from 488 to 675 K. Due to the similarity in experimental apparatus, except for the hood, Morehart concluded that the temperature difference resulted from having a larger uninsulated hood.

Morehart studied the effect of increasing temperature on layer composition by adding different levels of insulation to the hood. Except for the insulation, the test conditions (e.g., ϕ of 1.45 and layer interface height) were held constant. Residence times of layer gases in the hood were in the range of 200–300 s. For the range of temperatures studied (500–675 K), substantial increases in products of complete combustion (i.e., CO_2 and H_2O) and decreases in fuel and oxygen occurred with increasing layer temperature. Upper-layer oxygen mass fraction was reduced by approximately 70 % and methane was reduced by 25 % [11, 12]. Excluding one outlier data point, CO concentrations increased by 25 %. This is an important result. Although the gas temperatures were well below 800 K, an increase in the layer temperature resulted in more fuel being combusted to products of complete combustion and additional CO (see the section "Chemical Kinetics" later in this chapter).

Compartment Fire Experiments

The hood experiments performed by Beyler and Zukoski et al. differ from actual compartment fires in several ways. The hood setup allowed considerable radiation to the lab space below. Conversely, a real compartment would contain most of the radiation, thus resulting in higher wall and upper-layer temperatures. Consequently, higher fuel mass loss rates for pool fires would be expected for an actual compartment fire. Also, the hood setup results in a lower layer that has an infinite supply of air which is neither vitiated nor heated. In a real compartment fire, the air supply is limited by ventilation openings (doors, windows, etc.) and the depth of the upper layer. The air that is entrained into the lower layer of an actual compartment fire can be convectively heated by hot compartment surfaces prior to fire plume entrainment. The hood experiments did not include any significant ceiling and wall flame jets. These dynamic flame structures enhance mixing of the upper layer in actual compartment fires and extend the flame zone beyond the plume. Lastly, the hood experiment correlations were developed from sustained steady-state burning conditions. Actual fires of interest are usually in a continual growth stage, and, thus, are more transient in nature.

Tewarson reported that CO and CO_2 yields and O_2 depletion were correlated well by the air-to-fuel stoichiometric fraction (i.e., the reciprocal of the equivalence ratio) for wood crib enclosure fires [16]. Enclosure fire data was taken from previous work in the literature for cellulosic-base fiberboard and pine wood cribs burned in various compartment geometries, 0.21–21.8 m^3 in volume, with single and dual

horizontal and vertical openings centered on the end walls. Additional data were obtained for pine wood cribs burned in a small-scale flammability apparatus that exposed the samples to variable external radiant heat fluxes with either natural or forced airflow from below.

The characteristics of the correlations presented by Tewarson are similar to the correlations developed by Beyler. The CO_2 yield and O_2 depletion are relatively constant for low equivalence ratios and decrease sharply as the equivalence ratio increases for underventilated conditions. The CO yield correlates with the equivalence ratio but with a fair amount of scatter in the data.

Due to the lack of measurements, the air entrainment rate used to calculate the mass air-to-fuel ratio was estimated from the ventilation parameter, $Ah^{1/2}$, where A is the cross-sectional area and h is the height of the vent. Although the general shape of the correlations are valid, the use of the ventilation parameter assumption causes the equivalence ratio data to be suspect. In addition, the elemental composition of the fuel volatiles for the wood was not corrected for char yield. A correction of this sort would tend to decrease the calculated equivalence ratio and increase the CO and CO_2 yields.

Gottuk et al. [5, 17] conducted reduced-scale compartment fire tests specifically designed to determine the yield-equivalence ratio correlations that exist for various fuels burning in a compartment fire. A 2.2 m^3 (1.2 m $\times$ 1.5 m $\times$ 1.2 m high) test compartment was used to investigate the burning of hexane, PMMA, spruce, and flexible polyurethane foam. The test compartment was specially designed with a two-ventilation path system that allowed the direct measurement of the air entrainment rate and the fuel volatilization rate. The setup created a two-layer system by establishing a buoyancy-driven flow of air from inlet vents along the floor, up through the plume, and exhausting through a window-style exhaust vent in the upper layer. There was no inflow of air through the exhaust vent. The upper-layer gas mixture was sampled using an uncooled stainless steel probe placed into the compartment through the center of the exhaust vent. This location for the probe was chosen after species concentration and temperature measurements, taken at several locations in the upper layer, showed a well-mixed, uniform layer.

Table 16.1 shows the physicochemical properties used for the four fuels. It should be noted that in determining properties of a fuel, such as maximum yields or the stoichiometric fuel-to-air ratio, the chemical formula must characterize the volatiles, not necessarily the base fuel. For liquid fuels or simple polymers, such as PMMA, the composition of the volatiles is the same as the base fuel. However, more complex fuels can char or contain nonvolatile fillers, as found in polyurethane foams. As a result, the composition of the volatiles differs from that of the base material. As an example, the composition of the wood volatiles used in this study was obtained by adjusting the analyzed wood composition for an observed average of 25 % char [5].

The results of these compartment tests showed similarities to Beyler's hood experiments. However, some significant quantitative differences exist. Figure 16.9 compares the CO yield correlations from Beyler's hood study and that of these compartment tests for hexane fires. This plot illustrates the primary difference observed between the hood and compartment hexane and PMMA fire test results. An offset exists between the rise in CO yield for the two studies. For the hood experiments, higher CO production was observed for overventilated ($\phi_p < 1$) and slightly underventilated burning conditions. For the compartment fire experiments, negligible CO was produced until underventilated conditions were reached. Consistent with the increased CO production and the conservation of carbon, CO_2 yields were lower for the hood experiments compared to the compartment fires. The spruce and polyurethane compartment fires produced similar CO yield-equivalence ratio correlations to those observed by Beyler in hood experiments (i.e., high CO yields were observed for overventilated fires).

The differences in CO formation can be explained in terms of temperature effects. For the region of discrepancy between equivalence

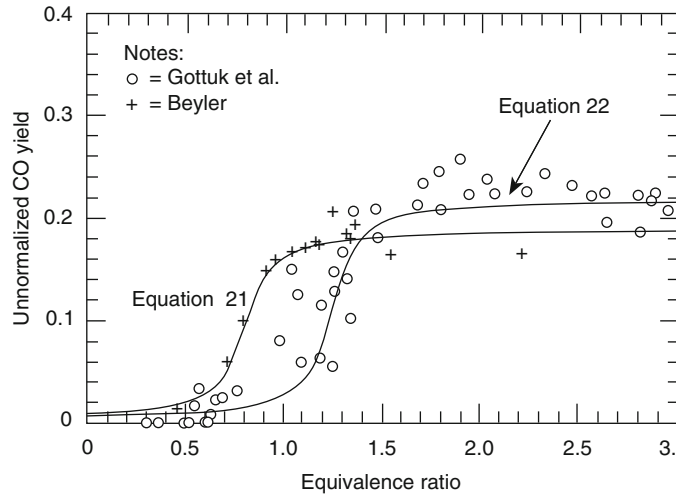

Fig. 16.9 Comparison of unnormalized CO yield correlations for hexane fires in a compartment and under a hood apparatus. (Figure taken from Gottuk et al. [5])

ratios of 0.5 and 1.5, upper-layer temperatures in Beyler's hood experiments and the spruce and polyurethane compartment fire experiments were typically below 850 K, whereas temperatures for the hexane and PMMA fires were above 920 K (temperatures typically associated with postflashover fires) [18].

As is detailed in the section on chemical kinetics, the temperature range between 800 and 900 K is a transition range over which the oxidation of CO to CO_2 changes from a very slow to a fast reaction. That is, for upper-layer temperatures below 800 K, the conversion of CO to CO_2 does not occur at an appreciable rate to affect CO yields. Since the oxidation of a fuel first results in the production of CO, which then further reacts to form CO_2, the low temperatures (<800 K) prevent CO from oxidizing. This results in high CO yields. For temperatures greater than 900 K, the reactions that convert CO to CO_2 occur faster as temperature increases. Therefore, for the overventilated conditions discussed above, the high temperatures associated with the hexane and PMMA compartment fires resulted in virtually all CO being oxidized to CO_2 for $\phi_p < 1$.

Overall, the compartment fire test results revealed that the production of CO is primarily dependent on the compartment flow dynamics (i.e., the equivalence ratio) and the upper-layer temperature.

The National Institute of Standards and Technology (NIST), Building and Fire Research Laboratory, has also performed reduced-scale compartment fire experiments using a natural gas burner for the heat source [6]. The compartment (0.98 m × 1.46 m × 0.98 m high) had a single ventilation opening consisting of a 0.48 m wide by 0.81 m high doorway. A large number of tests were conducted covering a range of heat release rates from 7 to 650 kW. Fires greater than 150 kW resulted in upper-layer temperatures greater than 870 K and flames 0.5–1.5 m out of the door. This single ventilation opening and the large fires (up to 650 kW) produced nonuniform upper-layer conditions. For fires with heat release rates greater than about 250 kW ($\phi > 1.5$), carbon monoxide concentrations in the front of the compartment were approximately 30–60 % higher than in the rear. Temperature gradients of 200–300 °C were observed from the back to the front of the compartment. Due to the nonuniform air entrainment at the base of the fire and possible mixing of additional air near the front, it is difficult to determine the local equivalence ratio for each region. The concentration gradient from front to rear of the compartment may have been due to differences in the local equivalence ratios. Nonetheless, plots of concentration measurements in the rear of the compartment versus equivalence ratio are quite similar to the data of Zukoski

et al. and Toner et al. Yield data for these results have not been reported.

A second set of experiments was performed by NIST to investigate the generation of CO in wood-lined compartments [19]. Douglas fir plywood (6.4 mm thick) was lined on the ceiling and on the top 36 cm of the walls of the compartment described above. Natural gas fires ranging from 40 to 600 kW were burned in the compartment. The results showed that, for tests in which wood pyrolysis occurred, increased levels of CO were observed compared to burning the natural gas alone. Carbon monoxide concentrations (dry) reached levels of 7 % in the front and 14 % in the rear of the compartment. These are extremely high concentrations compared to the peak levels of 2–4 % observed in the unlined compartment fire tests with the methane burner only. Typical peak CO concentrations observed for a range of fuels (including wood) in hood experiments [8–11] and the compartment fire experiments of Gottuk et al. [5] also ranged from 2 % to 4 %. However, concentrations greater than 5 % have also been reported for cellulosic fuels burning in enclosures [16, 20].

Since wood is an oxygenated fuel, it does not require additional oxygen from entrained air to form CO. This enhances the ability of the wood to generate CO in a vitiated atmosphere. Therefore, there are two reasons that high CO concentrations can result in fires with oxygenated fuels in the upper layer. First, the fuel-bound oxygen allows the fuel to generate CO during pyrolysis. Second, due to preferential oxidation of hydrocarbons over CO, the limited oxygen in the upper layer reacts with the pyrolyzing wood to form additional CO. Aspects of this chemistry are discussed in the next section.

These initial test results for fires with wood on the walls and ceiling emphasized the importance of adding additional fuel to the upper layer. The practical implications are significant, as many structures have cellulosic-based wall coverings and other combustible interior finishes. Because of the initial studies by NIST, Lattimer et al. [21] conducted a series of tests to evaluate the effect on species production from the addition of wood in the upper layer of a reduced-scale enclosure fire. The enclosure was the same as used by Gottuk et al. [5], measuring 1.5 m wide, 1.2 m high, and 1.2 m deep. Two primary sets of tests were conducted for cases with and without Douglas fir plywood suspended below the ceiling, with (1) a 0.12 m^2 window vent opening and (2) a 0.375 m^2 doorway opening, both leading to a hallway.

In the compartment with a window opening and wood burning in the upper layer, Lattimer et al. measured CO concentrations of 10 % on average, which is nearly three times greater than the levels measured without the wood. Peak concentrations were as high as 14 %, the same as measured by Pitts et al. [19] CO concentrations were similarly high when the doorway opening was used. In this case, the quasi-steady state average CO concentrations were 8 % with peaks greater than 10.6 % with wood compared to approximately 5.7 % average levels with a doorway vent and no wood. Regardless of the vent opening, these tests showed that wood in the upper layer resulted in CO concentrations increasing dramatically (10.1 %, vs. 3.2 % without wood) with only small increases in the CO_2 concentrations (11.6 %, vs. 10.4 % without wood). These trends are summarized in Table 16.3, which presents the

Table 16.3 Summary of quasi-steady state average species concentrations (percent volume dry) for underventilated reduced-scale compartment fire tests with and without wood in the upper layer [21, 22]

Window vent tests [21]	No wood in upper layer	Wood in upper layer
CO	3.2	10.1
CO_2	10.3	11.6
O_2	0.2	0.04
Doorway vent test [21]		
CO	5.7	8.0
CO_2	8.7	9.6
O_2	0.2	0.1
	NIST results [22]	
Doorway vent		
CO	2.6/1.8[a]	5.5/11.5[a]
CO_2	6.5/7.5[a]	10/15.5[a]
O_2	0.1/0[a]	0/0.5[a]

[a]Front and back, respectively

average upper-layer species concentrations for tests with and without wood for both window and doorway vent conditions. For comparison, the data from the NIST research has also been included.

The compartment equivalence ratio was calculated for both the tests with and without wood in the upper layer when the window vent was used. Figures 16.10, 16.11, and 16.12 show the corresponding calculated yields of CO_2, O_2, and CO plotted as a function of equivalence ratio. Also included in these plots are the data from the compartment fires of Gottuk et al. [5] The results show that the global equivalence ratio concept is capable of predicting the CO_2, O_2, and CO yields, although somewhat fortuitously, in a compartment with wood pyrolyzing in the hot, vitiated upper layer. These tests also indicate that the correlations hold to fairly high equivalence ratios of about 5.5, as observed for the tests with wood. More work is needed to determine whether the global equivalence ratio concept can predict species levels when

[21] with wood in the upper layer (▲). Also shown in this plot is the normalized O_2 yield estimated using the complete combustion model of Equation 16.14 (—)

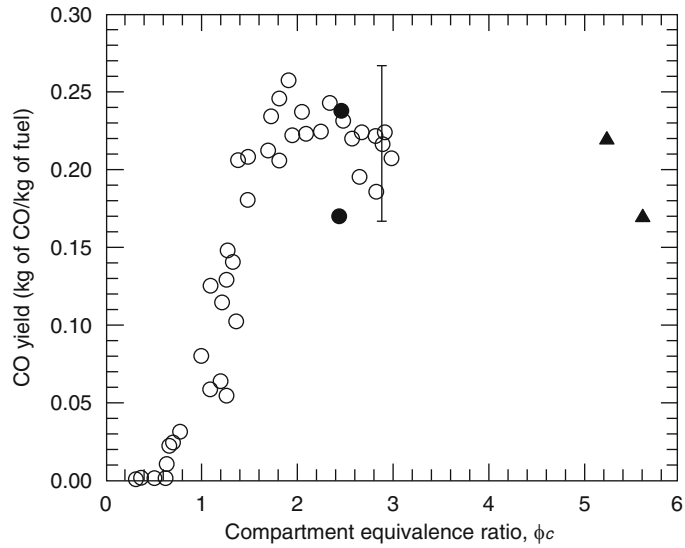

Fig. 16.12 The unnormalized CO yield data of Gottuk et al. [5] (○), data from Lattimer et al. [21] with no wood in the compartment upper layer (●), and data from Lattimer et al. [21] with wood in the upper layer (▲)

nonoxygenated fuels are in the upper layer. It is also unclear whether other oxygenated fuels will follow the correlations as well as the available wood fire data.

The data in Table 16.3 should provide an assessment of the effect of the ventilation opening on species generation. However, it is uncertain whether the differences are due more to differences in sampling locations relative to the flame regions. In the tests with a doorway vent, the larger opening resulted in larger air flow rates and, thus, larger fires in the compartment (approximately 500 kW vs. 220 kW with the window vent). The larger fires increased the flame zone within the compartment. Consequently, the sampling probe was probably within the flame zone at times, which would yield higher CO and lower CO_2 concentrations than measurements from the window vent tests in which the sampling probe was not sampling from a flame zone. With the window vent, the fires were small enough such that there were no ceiling jets at the level of the sampling probe.

The research discussed thus far has concentrated on reduced-scale enclosures. Limited full-scale studies have been reported in the literature to date. One study by NIST systematically examined the production of species in light of the global equivalence ratio concept. NIST conducted a set of tests using a standard enclosure (as defined by ISO 9705) to compare the results from the NIST reduced-scale enclosure tests to fires conducted in a full-scale enclosure [23–26]. The enclosure measured 2.44 m wide, 3.67 m deep, and 2.44 m tall, with a door (0.76 m by 2 m) centered at one end of the compartment. The fires consisted of a 35-cm-diameter natural gas burner centered in the enclosure. The burner was scaled to provide the same exit gas velocities as in the reduced-scale enclosure tests. Twelve tests were conducted, with fires ranging in size from 0.5 to 3.4 MW. In one test, the ceiling and upper portions of the walls were lined with 12.7 mm thick plywood.

In the full-scale enclosure, fires greater than 1250 kW created underventilated conditions. The NIST researchers concluded that although the reduced-scale and full-scale enclosures were geometrically similar, with good agreement between predicted mass flows, the differences in measured gas concentrations indicated that the generation of combustion products is not entirely controlled by the ventilation within the compartment. CO concentrations (upwards of 6 % by volume) were as much as two times higher in the full-scale enclosure than in the reduced-scale tests. These results also coincided with higher upper-layer temperatures, approaching 1400–1500 K. The variation in CO concentrations from front to back in the

enclosure was reversed in the full-scale enclosure compared to the reduced-scale enclosure. In the full-scale enclosure, higher CO concentrations were observed in the back of the compartment. In the reduced-scale enclosure, higher concentrations were measured in the front. Pitts primarily associates the higher CO concentrations with the high layer temperatures that are in the range that strongly favor the formation of CO toward equilibrium concentrations (values can approach 16 % at ϕ of 3) [26].

One full-scale enclosure test was conducted with wood in the upper layer. This test resulted in high CO concentrations of 8 % in the front and 12 % in the rear for a 2 MW fire. The temperatures were lower than those observed in the full-scale tests without wood. These results are similar to those observed in the NIST reduced-scale enclosure.

Chemical Kinetics

The field of chemical kinetics can be used to describe the changes in gas composition with time that result from chemical reactions. The kinetics of actual combusting flows are dependent on the initial species present, temperature, pressure, and the fluid dynamics of the gases. Due to the inability to adequately characterize the complex mixing processes and the significant temperature gradients in turbulent flames, the use of kinetic models is restricted to simplified combusting flow processes. Consequently, the fire plume in a compartment fire is beyond current chemical kinetics models. However, the reactivity of the upper-layer gas composition can be reasonably modeled if one assumes that the layer can be characterized as a perfectly stirred reactor, or that the layer gases flow away from the fire plume in a plug-flow-type process [14, 15]. Pitts has shown that no significant differences between results exist for either modeling approach when applied to these upper layers [14].

Several kinetics studies have been performed to examine aspects of the reactivity of upper-layer gases [12, 14, 15]. Comparisons between different hood experiments and between hood and compartment fire experiments have indicated that upper-layer temperatures have an effect on CO production. The results of these chemical kinetics studies provide insights into CO generation in compartment fires, which also serve to explain the differences in CO yields between experiments with respect to temperature effects. These studies primarily focused on the question "What would the resulting composition be if the upper-layer gases in the hood experiments existed at different isothermal conditions (constant temperature)?" A particular focus was to examine the resulting compositions for cases modeled under the high temperatures characteristic of compartment fires. Chemical kinetics models calculate the change in species concentrations with respect to time. Calculations are dependent on the reaction mechanism (i.e., the set of elementary reactions and associated kinetic data) and the thermodynamic data base used.

Thermodynamic data are fairly well known and introduce little uncertainty into the modeling. However, reaction mechanisms do vary. Pitts presents a comparison of the use of various mechanisms in the literature [14]. The comparison indicates that reaction kinetics for high temperatures (greater than 1100 K) are fairly well understood. However, the elementary reactions for the range of 800–1000 K are not as certain; therefore, quantitative modeling results in this range may be suspect. Nevertheless, the general trends presented below are valid despite any uncertainty associated with the mechanisms used.

Chemical kinetics modeling shows that significantly different trends occur for overventilated and underventilated burning conditions. This can be seen in Figs. 16.13 and 16.14, which present major species concentrations with respect to time for an overventilated and underventilated condition, respectively. Figure 16.13 shows a modeled case for ϕ equal to 0.91 and a temperature of 900 K. The initial composition is taken from Beyler's data for a fire with a layer temperature of 587 K. The temperature of 900 K corresponds to the temperature observed by Gottuk et al. for a

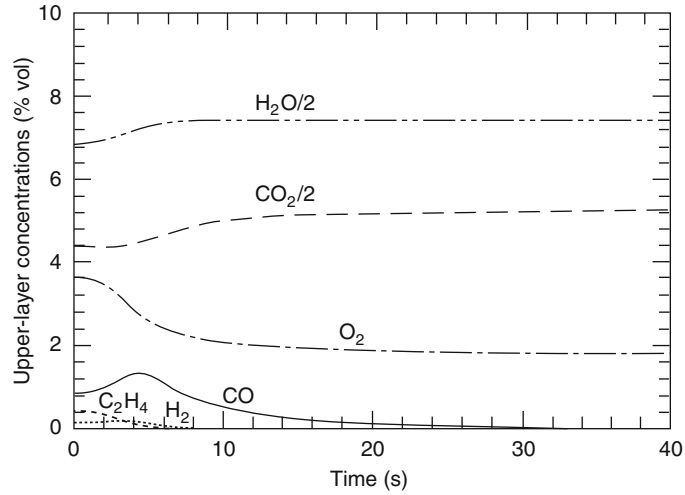

Fig. 16.13 Chemical kinetics model calculated species concentrations versus time for an overventilated ($\phi = 0.91$) burning condition with an upper-layer temperature of 900 K [15]

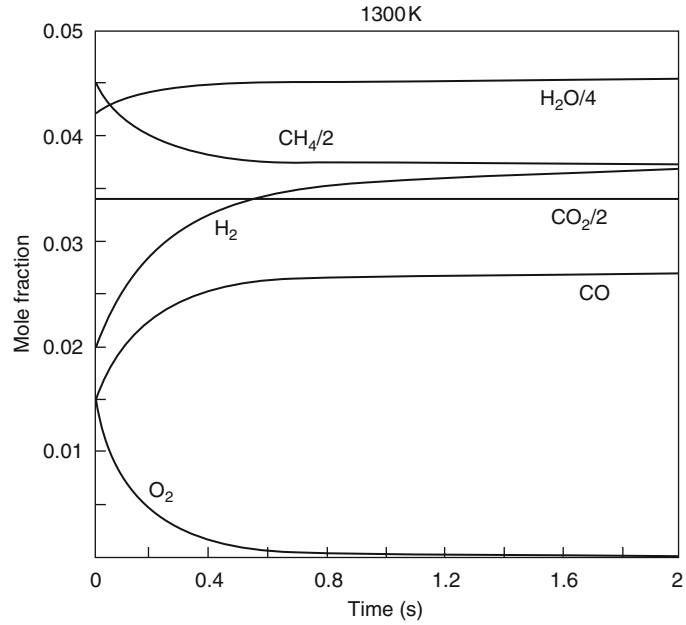

Fig. 16.14 Chemical kinetics model calculated species concentrations versus time for an underventilated ($\phi = 2.17$) burning condition with an upper-layer temperature of 1300 K [14]

hexane compartment fire at the same global equivalence ratio. For overventilated conditions, increased temperatures cause CO concentrations to initially increase. As can be seen in Fig. 16.13, this is due to the incomplete oxidation of hydrocarbons (modeled as C_2H_4). Once the hydrocarbons are consumed, available O_2 is used in the oxidation of CO to CO_2. Since overventilated conditions indicate excess oxygen, CO concentrations are reduced to zero given sufficient time. This is representative of the case of the overventilated hexane and PMMA compartment fires studied by Gottuk et al., in which the higher compartment temperatures, compared to the hood tests of Beyler, resulted in near-zero CO yields for ϕ less than 1.

Figure 16.14 shows an underventilated case for ϕ equal to 2.17 and a temperature of 1300 K. The initial composition is taken from Morehart et al.

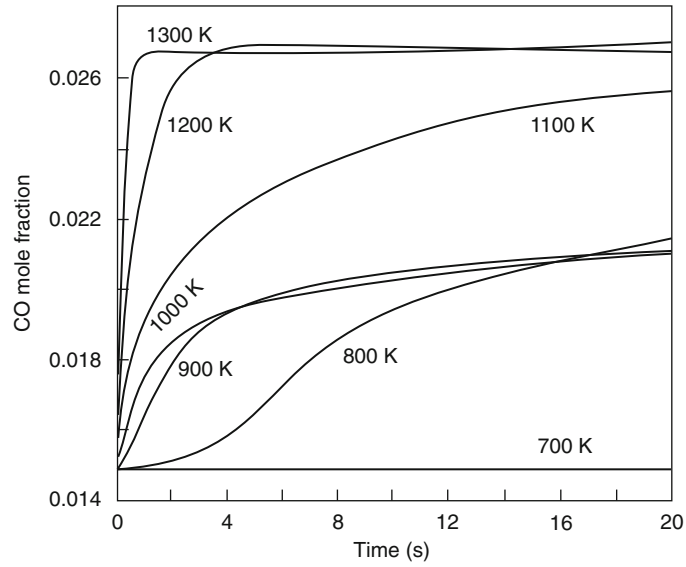

Fig. 16.15 Carbon monoxide concentrations as a function of time for a range of isothermal conditions. Initial concentrations from a methane hood fire at $\phi = 2.17$ [14]

for a methane hood experiment [12]. Similar to the overventilated conditions, CO increases due to the oxidation of hydrocarbons (CH_4). However, the available oxygen is depleted before the hydrocarbons are fully oxidized. The resulting composition consists of higher levels of CO and H_2 and decreased levels of unburned fuel. Carbon dioxide levels remain virtually unchanged. The much higher temperature studied in this case results in much quicker reaction rates, as is reflected in the 2 s time scale for Fig. 16.14 compared to 30 s for Fig. 16.13.

It is clear from Figs. 16.13 and 16.14 that hydrocarbon oxidation to CO and H_2 is much faster than CO and H_2 oxidation to CO_2 and H_2O, respectively. This is a result of the preferential combination of free radicals, such as OH, with hydrocarbons over CO. Carbon monoxide is oxidized almost exclusively by OH to CO_2 [27]. Therefore, it is not until the hydrocarbons are consumed that free radicals are able to oxidize CO to CO_2.

The formation and consumption of CO in a reactive gas mixture is dependent on both the temperature of the mixture and the amount of time over which the mixture reacts. This point is illustrated in Fig. 16.15, which shows the resulting CO concentrations at different isothermal conditions from an initial gas mixture taken from an underventilated fire ($\phi = 2.17$). Pitts noted that there are three distinct temperature regimes. At temperatures under 800 K, the gas mixture is unreactive and the CO to CO_2 reactions are said to be "frozen out." As the temperature increases in the range of 800–1000 K, the mixture becomes more reactive and CO is formed at faster rates, due to the oxidation of unburned hydrocarbons. For the time period shown, it is interesting to note that the ultimate concentration is approximately constant[1] for each case in this temperature range. The third regime of high temperatures above 1100 K is characterized by fast reaction rates and much higher CO production for the 20 s reaction time shown. With sufficient time, the ultimate CO concentration for the 800–1000 K conditions would approach the same value as that seen for the higher temperatures.

Results of Zukoski et al. [10] and Gottuk et al. [15] indicated that layer temperatures of 850–900 K or higher are needed for the layer gases to be reactive. Considering that the

[1] Note that although the ultimate CO concentration is roughly constant, the value of 2.1 % for this illustration is not to be taken as a universal limit for this temperature range. In general, the resulting CO concentration will depend on the initial gas composition and the time over which the mixture is allowed to react.

minimum (freeze out) temperature above which a gas mixture is reactive is dependent on the time scale evaluated. These values are consistent with the results shown in Fig. 16.12. In terms of compartment fires, the time over which the gases react can be taken as the residence time of the gases in the upper layer, which is calculated according to Equation 16.11. In many practical cases of high-temperature compartment fires, it would be reasonable to assume that the residence time of layer gases would be longer than the time needed for the gas mixture to react fully.

Fire Plume Effects

Although a fire plume is too complex to adequately model the chemistry, the hood experiments discussed earlier provide significant insights with respect to the fire plume and species production in compartment fires. Results of Beyler's hood experiments suggest that the production of upper-layer gases is independent of the structure and fluid dynamics of the flame.

Beyler modified a 19 cm propane burner by including a 2.8 cm lip to enhance turbulence and the large-scale structure of the flame [8]. Compared to the no-lip burner, the flame was markedly changed, and air entrainment was increased by 30 %. Yet, the upper-layer species-equivalence ratio correlations were the same for both burners. Additionally, as shown in Fig. 16.5, correlations for different size burners are also identical.

The insensitivity of species yields to the details of the flame structure is also suggested by the compartment fire hexane results of Gottuk et al. [5] The correlations include data from fires utilizing various size burn pans and with a wide range of air entrainment rates. In several cases, nearly equal steady-state equivalence ratio fires were obtained with quite different burning rates and air entrainment rates. Although the conditions varied significantly, the positive correlation between yields and equivalence ratio suggests that the yields are not sensitive to the details of the flame structure.

The temperature of the fire plume has a significant effect on species production from the fire plume. It is reasonable to assume that differences in upper-layer temperature are also reflective of a similar trend in the average temperature of the fire plume gases. An increase in the upper-layer temperature can increase the fire plume temperature in two ways. For plumes that extend into the upper layer, entrainment of hotter upper-layer gases will result in increased plume temperatures compared to plumes in layers with lower temperature gases. Secondly, an increase in the surrounding temperature (both gases and compartment surfaces) reduces the radiant heat loss from the plume, thus resulting in a higher plume temperature.

The effect of temperature on species generation in a fire plume can be found in the methane hood experiments of Morehart et al. [12] and Zukoski et al. [11] Morehart studied the effect of increasing temperature on layer composition by adding different levels of insulation to his hood. Except for the insulation, the test conditions (e.g., ϕ of 1.45 and layer interface height) were held constant. For the range of temperatures studied (500–675 K), substantial increases in products of complete combustion and decreases in fuel and oxygen occurred with increasing layer temperature. Upper-layer oxygen mass fraction was reduced by approximately 70 % and methane was reduced by 25 %. Excluding one outlier data point, CO concentrations increased by 25 %. The temperatures of the Morehart et al. upper layer were well below 700 K. Therefore, based on kinetics modeling, these layers were unreactive at these low temperatures. It follows that the change in layer composition must have been due to changes in the plume chemistry. The more complete combustion can be attributed to an extension of the flammability limits (or reaction zone) in the plume due to raising the flame temperature. The above discussion demonstrates that increasing the plume temperature substantially increases the consumption of O_2 and fuel, and primarily increases the levels of products of complete combustion.

The effect of changing temperature on a compartment fire upper-layer composition is twofold: (1) the generation of species in the fire plume is changed, and (2) oxidation of post-flame gases in the layer is affected. Elevated compartment temperatures correlate with increased fire plume temperatures and more complete oxidation of the fuel to CO_2 and H_2O within the fire plume. The layer temperature dictates post-flame oxidation in the upper layer.

Upper-layer temperatures below about 800 K indicate chemically unreactive layers. As such, combustion within the fire plume controls the final CO levels that would be measured in the upper layer. At these low temperatures significant levels of CO can be generated even for some overventilated conditions ($0.5 < \phi < 1$). The yield of CO is inversely proportional to temperature for overventilated conditions and directly proportional to temperature for underventilated conditions.

Upper-layer temperatures of about 900 K and higher indicate chemically reactive layer gases. As such, reactions in the layer dictate final CO production. Temperatures above 900 K allow nearly complete oxidation of CO to CO_2 for overventilated conditions. For underventilated fires, chemical kinetics modeling indicates that higher temperature environments may result in slightly higher CO yields due to preferentially accelerated hydrocarbon oxidation compared to CO oxidation.

During underventilated conditions, two mechanisms affecting net CO formation compete (i.e., CO and hydrocarbon oxidation). Increasing gas temperatures above 900 K depletes CO by accelerating the CO to CO_2 conversion. However, incomplete oxidation of unburned hydrocarbons increases the CO production. Since hydrocarbon oxidation is much faster than CO oxidation, net CO levels increase until all available oxygen is consumed.

Transient Conditions

Transient conditions cause the upper-layer equivalence ratio to differ from the plume equivalence ratio. A fast-growing fire will tend to have a ϕ_{ul} that is less than ϕ_p. Conversely, a fire that is dying down quickly, such that ϕ_p is decreasing rapidly, will have a ϕ_{ul} that is higher than ϕ_p. These trends result due to the upper layer being a temporary collection reservoir for the gases from the fire plume.

In an effort to characterize transient conditions, Gottuk et al. defined a steady-state time ratio, τ_{SS}, as the ratio of the residence time, t_R, to a characteristic growth time of the fire. Since fire growth is directly related to the fuel volatilization rate, a representative growth time of the fire was defined as the ratio of the fuel mass loss rate, $\dot{m}_f$, to the derivative of the fuel volatilization rate, $\ddot{m}_f$. An increase in τ_{SS} is indicative of more transient conditions.

$$\tau_{SS} = \frac{t_R}{\dot{m}_f / \ddot{m}_f} \tag{16.18}$$

An analysis of the transient nature of the compartment fires studied by Gottuk et al. showed that values well below 1 indicated near steady-state conditions, such that the plume and upper-layer equivalence ratios could be considered equal. Investigation of individual fires showed that the steady-state time ratio decreased below 1.0 at very early times in the fire. Typically, the ratio was 0.1 or less for the quasi-steady-state periods over which data was averaged. For some fires, during the highly transient transition from overventilated to underventilated conditions, the τ_{SS} increased quickly, approaching a value of 1.

The correlations presented in the engineering methodology represent data that have been averaged over steady-state (hood experiments) or quasi-steady-state (compartment fires) periods. For the purpose of modeling fires with respect to time it is of interest to know how the species yields correlate with the equivalence ratio during transient conditions (i.e., as the fire is growing). Determining this correlation was accomplished by plotting the yield to equivalence ratio data for individual fires from the time of ignition to the steady-state period. These transient correlations were compared to the steady-state correlations obtained from steady-state averaged data from all tests (e.g., the CO yield correlation shown in

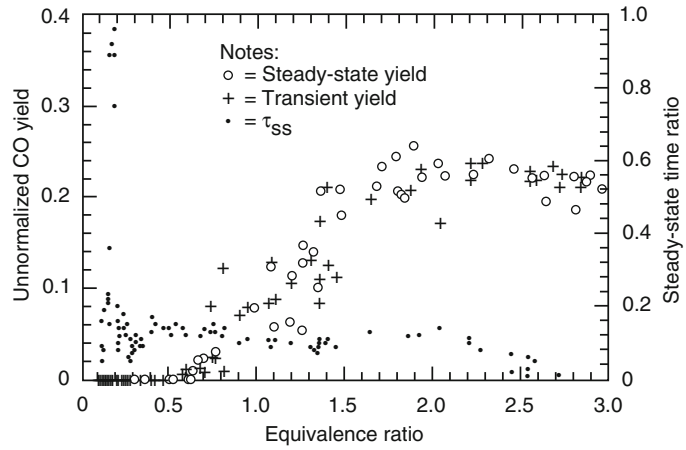

Fig. 16.16 Comparison between a transient, unnormalized CO yield correlation for a hexane fire with an average steady-state ϕ_p of 3 and the steady-state correlation for all hexane fires studied by Gottuk et al. The steady-state time ratio, τ_{SS}, data are shown as solid dots [17]

Fig. 16.9). An example of one comparison is shown in Fig. 16.16. Figure 16.16 shows the steady-state hexane CO yield correlation along with the transient yield vs. equivalence ratio data for a hexane compartment fire that obtained a steady-state average ϕ_p of 3. The solid dots in Fig. 16.16 represent the steady-state time ratio data, τ_{SS}. For this example, τ_{SS} remained fairly constant at about 0.1 for the entire fire. And as can be seen, the agreement between the transient and steady-state correlations is quite good, even for the transition to underventilated conditions. Good agreement between transient and steady-state data was also observed for CO_2 and O_2 yield correlations.

Although more transient in nature than the hood experiments, the compartment fires are characterized as primarily quasi-steady and, therefore, do not differ significantly from Beyler's hood experiments in this respect. This analysis also shows that the species yield correlations developed for steady-state conditions are representative of the transient growth periods of these fires.

In terms of full-scale application, these results suggest that ϕ_p and ϕ_{ul} are approximately equal for compartment fires characterized by relatively slow growth compared to the upper-layer residence time (i.e., $\tau_{SS} \ll 1$). However, the low τ_{SS} values observed in the reduced-scale compartment fires may not always be representative of full-scale fires. The reduced-scale compartment fires had residence times typically between 4 and 20 s. These short residence times were a result of having relatively large fires compared to the compartment volume. Until flashover conditions are approached, a full-scale compartment fire will most likely have smaller fires compared to the volume of the space. As a result, the residence time of gases in the upper layer of a full-scale fire may be much longer. Times on the order of 5–10 min may not be unrealistic in some cases. Therefore, in the case of a fast-growing full-scale fire, values of ϕ_p could increase relative to ϕ_{ul}. The application point is that the control volume used for the equivalence ratio must be considered with respect to the residence time of gases in the upper layer.

Species Transport to Adjacent Spaces

The species levels transported from a compartment depend on a variety of conditions produced during the course of the fire. As compartment fire gases exit the compartment, they entrain the gases present in the adjacent space (Fig. 16.17). If a fuel-rich mixture is produced in the compartment, the gases flowing out may ignite, causing burning in the adjacent space. This burning is an indication that oxidation reactions are taking place, which ultimately affects the species levels transported to remote areas. As the gases continue to flow through the adjacent space, they are cooled by mixing with surrounding gases and heat losses to the boundaries. Eventually, gases are cooled to a temperature below which

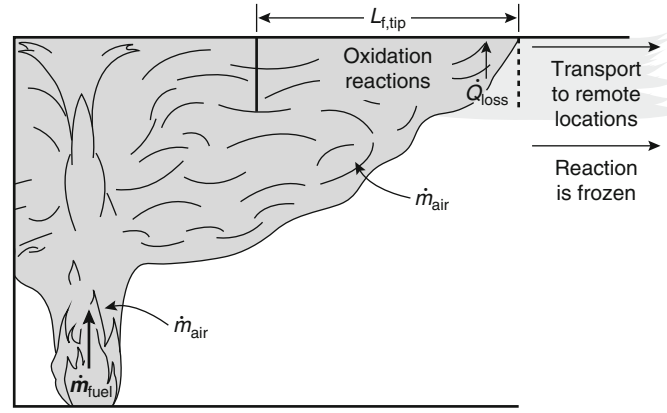

Fig. 16.17 Phenomena controlling species transport to remote locations

oxidation reactions do not readily occur. At this point the reactions are said to be frozen. The amount of combustion products that exist at this point will continue to flow throughout the rest of the structure. As a result, combustion product levels in the overall structure will accumulate as the fire inside the compartment persists and/or additional items in the structure begin to burn.

Conditions inside the fire compartment and in the directly adjacent space will govern the species levels transported to remote locations. The primary consideration is the conditions that develop inside the compartment. If burning outside of the fire compartment occurs due to either flame extension or external burning, gases will continue to react outside of the compartment influencing the species levels transported to remote areas. The degree to which gases react outside the compartment depends on the mixing of oxygen with the fuel-rich gases flowing out of the compartment, and the addition of fuel to the gases flowing along the adjacent space.

General Effects of Burning Outside the Compartment

Species levels transported to remote locations will be equivalent to those formed inside the compartment unless burning occurs outside. Chemical kinetics indicate that oxidation reactions cannot occur efficiently outside the compartment unless gas temperatures are near those produced at the onset of flashover (775–875 K) (see the section "Chemical Kinetics" in this chapter). In the presence of oxygen, hydrocarbons begin to react efficiently when temperatures are above 700 K [14]. Perhaps more importantly, the oxidation of CO to CO_2 does not readily occur until temperatures rise above 800 K. The occurrence of burning outside the compartment, either from flame extension or the onset of flashover, will result in local temperatures in excess of 1300 K [4]. At these temperatures, oxidation reactions for both hydrocarbons and CO occur in the presence of available oxygen.

The occurrence of burning outside the compartment has been shown, in most situations, to reduce the incomplete combustion products (including smoke and CO levels) transported to remote locations [5, 28–30]. The burning in unconfined adjacent areas (e.g., open surroundings) has been measured to decrease incomplete combustion products more efficiently than burning in confined adjacent areas (e.g., a corridor). In addition, the consumption of incomplete combustion products during burning in confined areas was found to be sensitive to the air entrainment into the plume/ceiling jet flow. This entrainment is a function of the mass flow from the compartment, the geometry of the opening between the compartment of fire origin and the adjacent space, and the geometry of the adjacent space itself. Smoke layers that develop in confined adjacent spaces can cause lower oxygen levels to be entrained into the plume/ceiling jet flow in the adjacent space, increasing the incomplete combustion product levels transported to remote areas.

Burning in Unconfined Adjacent Areas

Unconfined adjacent areas are those areas where the flame extending from the compartment of origin is not redirected by the boundaries of the adjacent area, and the gases are allowed to burn as a buoyant plume. Examples of unconfined adjacent areas include outdoor surroundings, atriums, and corridors with high ceilings relative to the door height of the burning compartment. Gottuk et al. [15, 31] investigated the impact of external burning on combustion products downstream of an unconfined jet. The compartment was connected to its surroundings through a window opening. Tests were performed with compartment fires with and without external burning. In these tests, a compartment equivalence ratio of 1.6 was the lowest ϕ_c where external burning was noted to occur. The effects of external burning on the CO levels downstream of the fire are shown in Fig. 16.18. With a compartment equivalence ratio greater than 1.6, CO levels were measured decreasing below the fire compartment levels. The CO yield is shown to decrease to a minimum of 0.02 at ϕ greater than 2.0. The decrease in CO represents a 75–90% reduction of the CO generated in the fire compartment.

Burning in Confined Adjacent Areas

Burning in a confined adjacent area, such as a corridor or room, causes the external flame to impinge on a ceiling, and possibly on walls. Compared with flow in an unconfined area, the ceiling and walls in the confined area will reduce the amount of air entrainment into the gas jet exiting the fire compartment. The effects of burning in confined areas on species transport have been investigated by Ewens et al. [28, 32] and Lattimer et al. [29, 30] using the same fire compartment design in the unconfined external burning study (Figs. 16.19 and 16.20) [17, 31]. The transport of species to remote locations is geometry dependent and can be affected by smoke layers that develop in the confined area. However, species levels transported to remote areas can be predicted by defining an equivalence ratio for a control volume involving both the fire compartment and the burning in the adjacent space.

Species transport has been evaluated for two common compartment-hallway configurations. Ewens [28] and Lattimer et al. [30] evaluated species transport in a configuration with the fire compartment on the end of a hallway (see

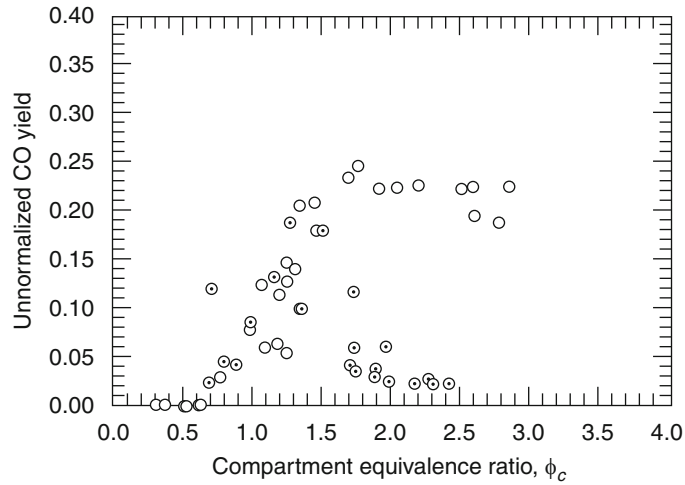

Fig. 16.18 Effect of external burning on CO levels downstream of an unconfined adjacent area. CO yield versus compartment equivalence ratio for hexane compartment fires with an exhaust jet to the open atmosphere through a window opening; (○) compartment levels, (⊙) downstream levels [17, 31]

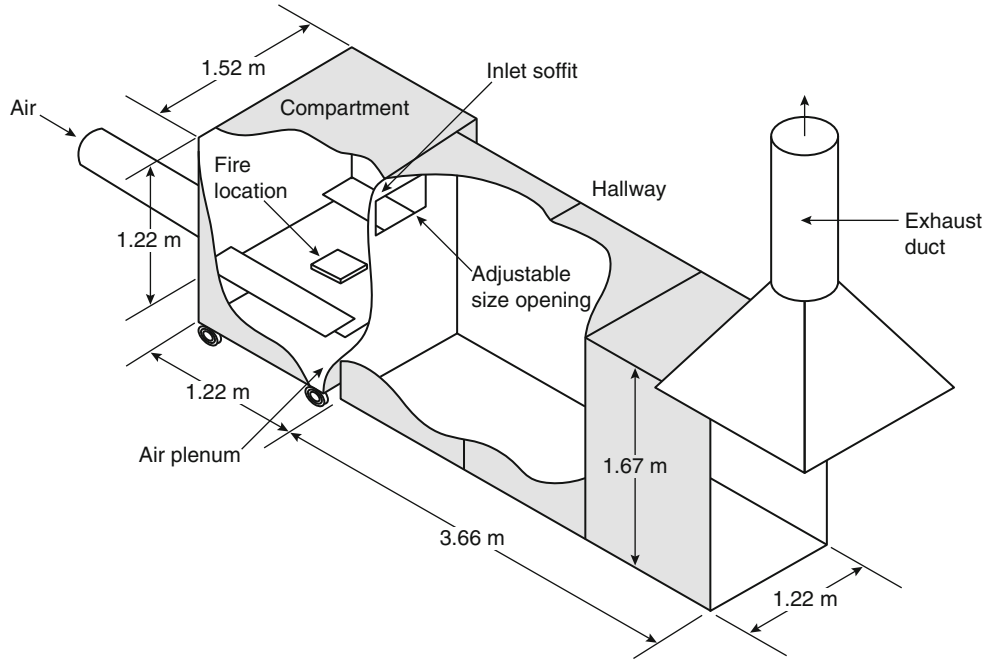

Fig. 16.19 Compartment on the end of a hallway [28, 30, 32]

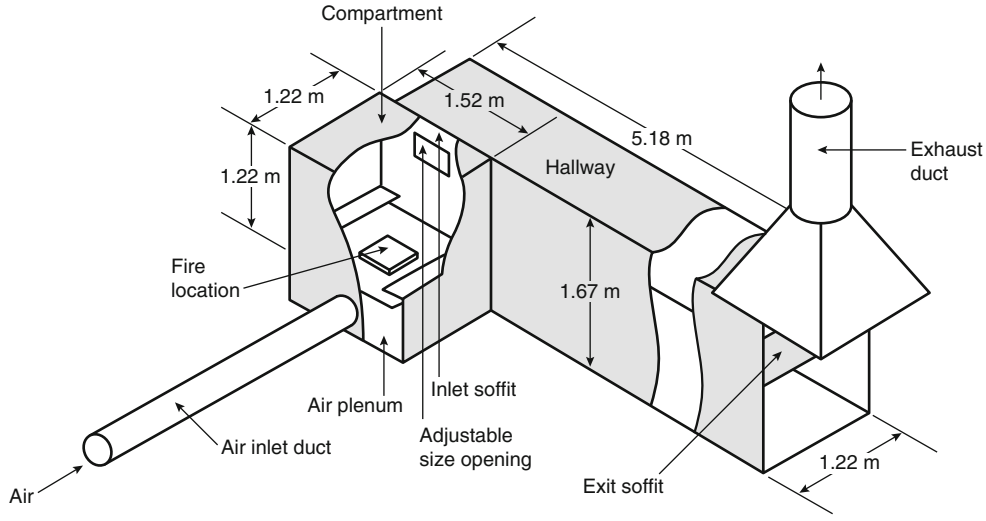

Fig. 16.20 Compartment on the side of a hallway [29, 30]

Fig. 16.19). Lattimer et al. [29, 30] performed a study with the fire compartment on the side of a hallway (see Fig. 16.20). In both studies, most tests were performed with a window connecting the compartment and hallway.

Using the apparatus shown in Fig. 16.19, Ewens [28] evaluated the effects of different geometric variables and compartment stoichiometry on CO levels (in addition to other species) downstream of the external burning where

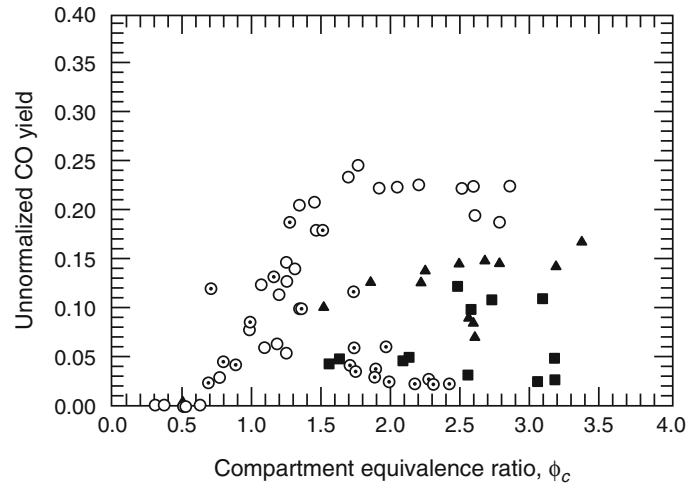

Fig. 16.21 Effect of external burning on CO levels downstream of a postflashover compartment fire. Adjacent hallway with a (▲) 0 m inlet soffit and (■) 0.20 m inlet soffit. (⊙) Unconfined area and (○) inside the compartment [17, 28, 31, 32]

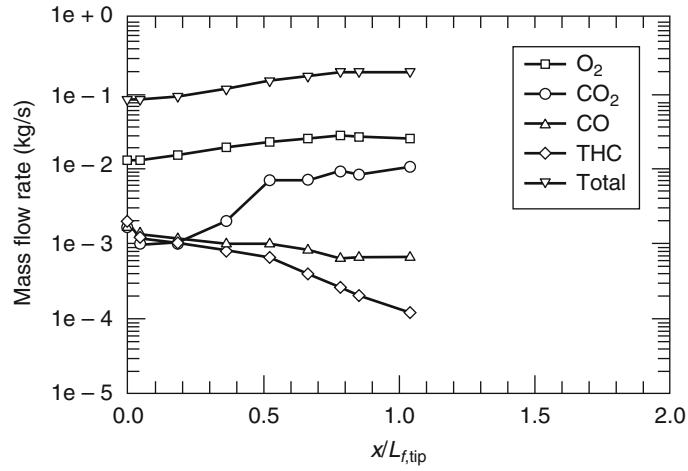

Fig. 16.22 The mass flow rates in a space adjacent to a postflashover fire with external burning plotted versus the ratio of the distance down the hall, x, to the length of the flame to its tip, $L_{f,tip}$. Opening of 0.12 m^2, no inlet soffit above the opening, and an average compartment ϕ = 2.0 [28]

reactions were considered frozen. As shown in Fig. 16.21, Ewens [28] demonstrated that burning in confined areas outside the compartment decreases incomplete combustion product levels, but not always to the same extent as when the fire gases spill into an unconfined space. The degree of oxidation was found to be dependent on both air entrainment into the gases exiting the compartment and the fuel flowing out of the compartment. The data of Ewens show that both fire size and geometric parameters will affect species production. The two important results to understand are that geometries which increase air entrainment in the adjacent space (e.g., an inlet soffit vs. no soffit) or reduce the layer depth in the adjacent space will enhance the oxidation reactions and result in lower levels of incomplete combustion products, such as CO.

Fire gases flowing into and through the adjacent space entrain surrounding gases as they flow away from the fire compartment. These gases can undergo chemical reactions, particularly as they are within the flaming region. A sample plot of the species variation along the flame length in the hallway is shown in Fig. 16.22 [28]. Results shown in Fig. 16.22 are from postflashover hexane fire tests with an average compartment equivalence ratio of ϕ = 2.0, a 0.12 m^2 opening

(0.50 m wide × 0.24 m high) connecting the compartment and adjacent space, and no inlet soffit above the opening in the hallway. These data represent time-averaged conditions 0.025 m below the ceiling along the hallway during the quasi-steady-state period of the fire, when external burning was occurring.

Gases entered the adjacent space as a ceiling jet, but were allowed to expand horizontally until intersecting the walls of the hallway. For this geometry, the largest increase in the total mass flow rate was during the first half of the flame length, which was 2.7 m (on average) from the compartment. By $x/L_{f,\text{tip}} = 0.75$, the total mass flow rate had reached a maximum. This indicated that all of the entrainment into the ceiling jet flow occurred by $x/L_{f,\text{tip}} = 0.75$. The majority of the oxidation reactions had also occurred by $x/L_{f,\text{tip}} = 0.75$. The mass flow rates of CO, CO_2, and O_2 were essentially constant downstream of $x/L_{f,\text{tip}} = 0.75$. This indicates that the oxidation of CO to CO_2 was frozen by an $x/L_{f,\text{tip}} = 0.75$. Small amounts of total hydrocarbons (THC) continued to react from $0.75 < x/L_{f,\text{tip}} < 1.0$; however, this was not measured to significantly increase CO levels.

Analysis of data in Fig. 16.22, as well as other data by Ewens et al. [28, 32] and Lattimer et al. [29, 30], indicates that by the flame tip all of the oxidation reactions have occurred. As a result, the mass flow rates of the major combustion products beyond the flame tip will be transported to remote locations. The mass flow rate levels will be influenced by the oxygen availability in the flaming region. Based on test results from Ewens et al. [28, 32] and Lattimer et al. [29, 30], mixing near the compartment has been shown to have the most significant influence on the combustion products transported to remote areas.

Predicting Species Levels

Lattimer [33] performed additional analysis on Ewens' data to develop a correlation between species transported and ϕ for a control volume consisting of part of the area in the adjacent space where burning occurred. In this set of data, the mixing in the adjacent space (hallway) was varied by using windows with different areas and aspect ratios to connect the compartment to the adjacent space, and by adding a 0.20 m soffit above the window. The equivalence ratio in this analysis was calculated using a control volume that extended to the sampling point located in the adjacent space. Using this control volume, the mass flow rate of air for the ϕ_{cv} calculation in Equation 16.13 was the air flow rate into the compartment plus the air entrainment into the plume/ceiling jet flow in the adjacent space, up to the sampling location. In these experiments, gas sampling was always performed in or just downstream of the flame within the hallway.

In Figs. 16.23, 16.24, 16.25, and 16.26 the species yields are plotted vs. the control volume equivalence ratio, ϕ_{cv}. Note that CO yields are not normalized because for various fuels unnormalized CO yields were found to correlate best with ϕ. The lines in the normalized O_2 depletion and CO_2 and THC yield plots represent the results from the complete combustion model presented in Equation 16.14. Due to limited data near the compartment, there are few data points at high ϕ_{cv}.

The trends in the species data were similar to those observed in the hood experiments by Beyler [8, 9] and in the compartment experiments by Gottuk et al. [5] The normalized O_2 depletion is approximately unity at ϕ_{cv} less than 1.0 and decays at the rate prescribed by the complete combustion model at higher ϕ_{cv}. CO_2 normalized yields are near unity up to a ϕ_{cv} of approximately 0.8. At ϕ_{cv} greater than 0.8, the CO_2 levels begin to decay and are consistently less than the level predicted by the complete combustion model. This behavior is consistent with the rise in incomplete combustion products, such as CO and THC, at ϕ_{cv} ranging from 0.6 to 0.8. These results indicate that species levels in adjacent spaces can be adequately correlated by the same global equivalence ratio correlations obtained for species production in fire compartments as long as ϕ_{cv} is calculated using the appropriately defined control volume. ϕ_{cv} accounts for the effects of external burning on

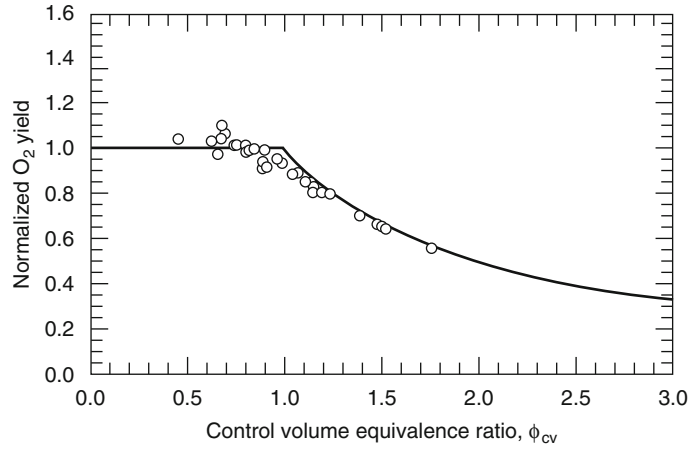

Fig. 16.23 Normalized O_2 depletion of gases in a space adjacent to a postflashover compartment fire. Control volume includes fire compartment and a portion of the adjacent space where burning occurs

species levels and can be used with Equations 16.19, 16.20, 16.21, 16.22, 16.23, 16.24, and 16.25 to estimate species transported to remote areas.

Effects of Oxygen-Deficient Smoke Layers in Adjacent Spaces

The development of hot, oxygen-deficient smoke layers in the adjacent space affects both the entrainment into the plume/ceiling jet and the amount of oxygen mixing with the fuel-rich gases flowing from the fire compartment.

Ewens et al. [28, 32] demonstrated that layers as thin as 0.20 m may have an impact on incomplete combustion products being transported to adjacent areas. Lattimer et al. [29, 30] performed a series of tests with different oxygen-deficient layer depths in the space directly adjacent to a postflashover fire (see Fig. 16.20). Tests were performed with three different opening sizes connecting the compartment to the adjacent space, but the compartment stoichiometry was approximately the same in all tests. In each test, the layer depth was kept at a constant level by the use of an exit soffit. In order to change the layer depth from test to test, the height of the exit soffit was adjusted for each test.

Except for cases with a deep smoke layer in the adjacent space, external burning occurred in all tests. Figure 16.27 contains a plot of time to ignition for tests with different layer depths. Layer depth is represented as a dimensionless depth, $\gamma = \delta/z$, which relates the distance between the ceiling and the bottom of the visible smoke layer, δ, to the distance between the ceiling and the bottom of the gases flowing out of the compartment, z. (For a window configuration, z is measured to the bottom of the window.) As shown in Fig. 16.27, the smoke layer did not affect the time to ignition until the visible smoke layer was nearly deep enough to prevent ignition altogether (indicated by the infinite time to ignition). At layer depths greater than $\gamma = 1.7$, external burning did not occur since the exiting fire gases were not able to entrain sufficient fresh air to provide the necessary oxygen for combustion. Rather, the gases exiting the fire compartment entrained primarily vitiated gases in the upper layer of the adjacent space.

The CO, CO_2, and THC yields measured at a remote location (in the exhaust duct) for the different window opening sizes are shown plotted in Figs. 16.28, 16.29, and 16.30 with respect to the smoke layer depth. Each data point is the time-averaged yield during the quasi-steady-state part of the fire. For this geometry, combustion product levels were not significantly affected by the smoke layer until it fell below the bottom of the opening ($\gamma > 1.0$). As the layer depth increased from $\gamma = 1.0$–1.8, the burning outside the compartment became increasingly less efficient. This resulted in an increase in CO and

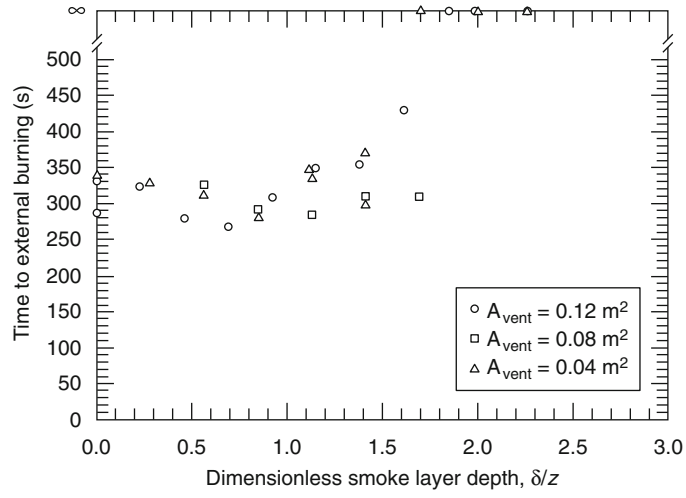

Fig. 16.27 Time for external burning in tests with a range of layer depths in the adjacent space with a 6.32 m^2 floor plan area [30]

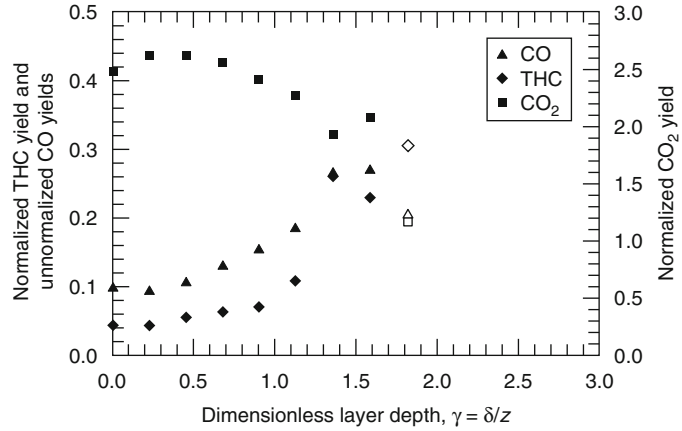

Fig. 16.28 The effect of an oxygen-deficient upper layer on downstream species yields from a postflashover fire extending into a hallway. Opening of 0.12 m^2, 0.20 m soffit above the opening, and an average $\phi_c = 3.1$. Open symbols are tests with no external burning. $\gamma > 1$ indicates layer is below the bottom of the vent [28, 29]

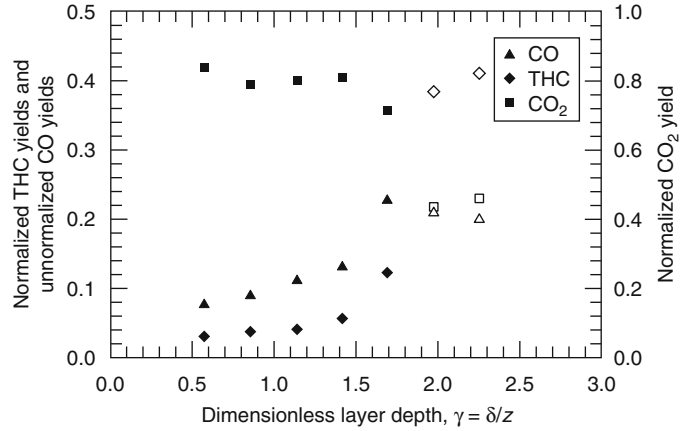

Fig. 16.29 The effect of an oxygen-deficient upper-layer on downstream species yields from a postflashover fire extending into a hallway. Opening of 0.08 m^2, 0.20 m soffit above the opening, and an average $\phi_c = 2.8$. Open symbols are tests with no external burning [30]

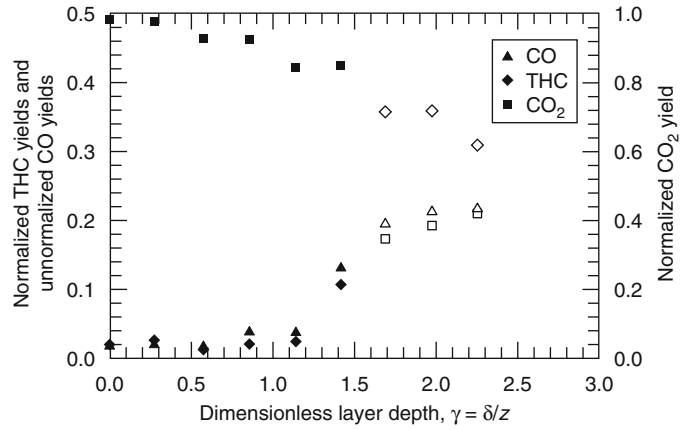

Fig. 16.30 The effect of an oxygen-deficient upper layer on downstream species from a postflashover fire extending into a hallway. Opening of 0.04 m^2, 0.20 m soffit above the opening, and an average $\phi_c = 2.8$. Open symbols are tests with no external burning [29, 30]

THC yields and a decrease in the CO_2 yield. The increase in CO and THC yields was attributed to reducing the oxygen available to oxidize the combustion products. When the smoke layer was increased to a dimensionless layer depth of $\gamma = 1.7–1.8$, external burning was not observed and downstream species yields were consistent with levels inside the fire compartment.

External burning in some tests with deep oxygen deficient upper layers actually caused additional CO formation in the adjacent space. As shown in Fig. 16.28, in tests with the largest opening, 0.12 m^2, and a dimensionless layer depth of $\gamma = 1.3–1.5$, CO yields increased to approximately 0.27 kg/kg, which is approximately 0.05 kg/kg higher than compartment levels. In addition, corresponding normalized THC yields were on average 0.06 kg/kg lower than compartment levels. These results indicate that available oxygen is being used to preferentially oxidize THC instead of CO. This oxidation of THC forms additional CO, causing an increase in CO levels transported to remote locations. The exact conditions in the adjacent space necessary to produce these results have not been fully established.

Other Considerations

There are other variables that may influence the combustion product levels being transported to remote locations that have not been fully explored. These variables include the effects of air addition through forced ventilation, additional fuel decomposition in the adjacent space, and heat losses to the ceiling and walls.

The addition of air to the system through forced ventilation may have an influence on species levels, depending on where the air is added relative to the external burning. Forced ventilation in the region where external burning is occurring will introduce additional oxygen into the flow, and possibly induce additional mixing. This may result in better oxidation of incomplete combustion products, such as CO. Addition of air to the system downstream of the external burning will dilute the gases, but will not reduce the amount (in terms of mass) of incomplete combustion products being transported to remote locations.

Decomposition of fuel in the adjacent space may affect species levels transported to remote locations. This effect may be sensitive to the location of the decomposing fuel, the type of fuel, whether it is flaming or smoldering, and the conditions surrounding the fuel.

Heat losses to the ceiling and walls can cause gas temperatures in the adjacent space to decrease more readily for some materials, compared to well-insulated boundaries. An example of this may be steel decks and bulkheads on ships. A decrease in gas temperature may cause temperatures to reach levels where no reactions can occur sooner than those observed in well-insulated cases. As a result, higher heat loss to

the boundaries may result in higher incomplete combustion products, including CO, to be transported to remote areas.

Species concentrations may not always be transported away from the compartment in a uniform manner. In experiments performed by Lattimer et al. [29, 30] with the compartment located on the side of a hallway, the bulk flow from the compartment was measured to flow across the hallway and down the side of the hallway opposite the fire compartment. This resulted in higher CO, CO_2, and THC levels (and lower O_2) flowing along the side of the hallway opposite the fire compartment. For example, CO levels were measured to be as high as 1.9 % along the side of the hallway opposite the fire compartment, while on the side of the hallway with the fire compartment the maximum CO level was measured to be 1.0 %. As these gases flow farther from the compartment, they are expected to become more uniform across the hallway. However, the distance away from the compartment where mostly uniform flow occurs was not quantified.

Engineering Methodology

In light of the experimental work and chemical kinetics considerations discussed previously, several correlations can be used as guidelines for fire protection engineering. The production of chemical species in compartment fires has been shown to be correlated with the control volume equivalence ratio, ϕ_{cv}. For most purposes, the equivalence ratio can be calculated using instantaneous fuel burning rates and air mass flow rates assuming quasi-steady-state conditions. The following methodology presents a guide to determining bounds on species production as well as comments on the limits of this approach.

The methodology for estimating species transported to remote locations is provided in Fig. 16.31. This approach considers the occurrence of external burning outside the compartment. In general, the primary steps in the analysis are:

1. Determine the compartment equivalence ratio, ϕ_c.
2. If ϕ_c is less than 1, estimate species levels using the global equivalence ratio-yield correlations presented in Equations 16.19, 16.20, 16.21, 16.22, 16.23, 16.24, and 16.25 with the ϕ_c.
3. If ϕ_c is greater than 1, determine whether external burning will occur outside of the compartment. External burning can be assumed to occur at a ϕ_c (plume or compartment) of 1.6, or by calculating the ignition index using Equation 16.1.
4. If there is no external burning, use the ϕ_c and Equations 16.19, 16.20, 16.21, 16.22, 16.23, 16.24, and 16.25 to calculate the species transported.
5. If external burning is occurring, determine the effect of the smoke layer using the dimensionless smoke depth, $\gamma = \delta/z$, where δ is the depth of the layer below the ceiling and z is the lowest elevation of gases exiting the compartment.
6. If γ is greater than 1.0 and external burning is predicted, the smoke layer can be assumed to inhibit oxidation in the adjacent space. CO and other incomplete-combustion products are not reduced. The ϕ_c and Equations 16.19, 16.20, 16.21, 16.22, 16.23, 16.24, and 16.25 can be used to estimate the species transported to remote locations.
7. If γ is less than 1.0 and external burning is predicted, the smoke layer does not inhibit the oxidation in the adjacent space and incomplete-combustion products, such as CO, will be reduced. The species transported can be estimated using Equations 16.19, 16.20, 16.21, and 16.22 and the equivalence ratio for a control volume, ϕ_{cv}, that incorporates the compartment and the adjacent space out to the flame tip (see Fig. 16.17).

It should be noted that this methodology may not provide the maximum levels of incomplete combustion products that can be produced in a fire. Equations presented in this methodology for species yields as a function of equivalence ratio have been shown to provide good correlations

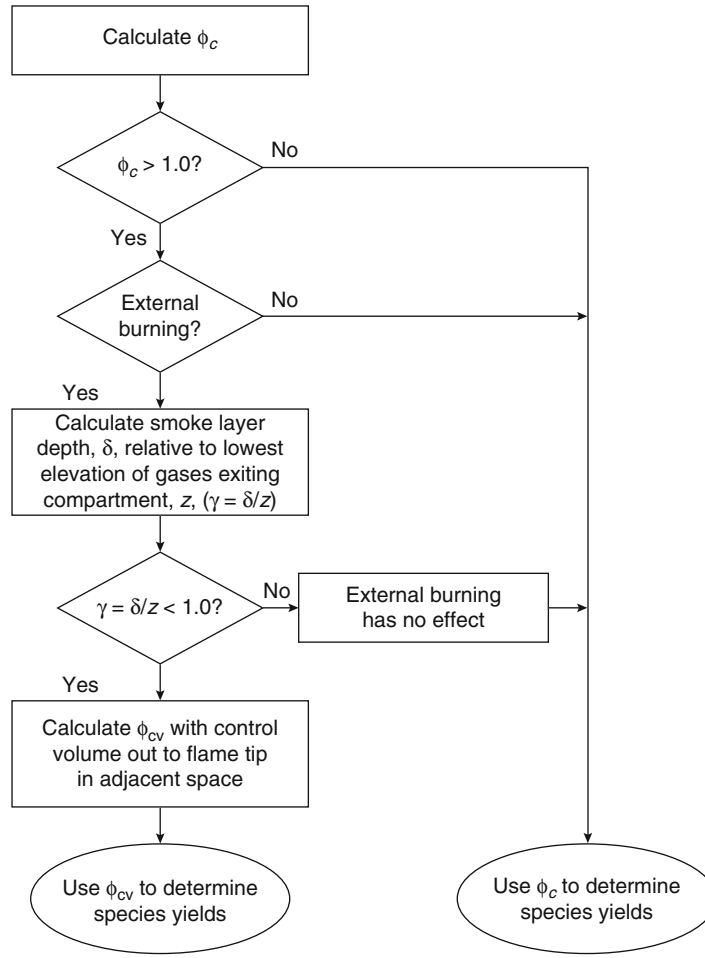

Fig. 16.31 General methodology for predicting species levels transported to remote locations from a fire compartment

even for wood as a secondary fuel pyrolyzing in the hot upper layer. However, it is not clear whether these correlations will hold for nonoxygenated fuels in the upper layer or how well they will represent other oxygenated fuels.

Several empirical correlations have been developed to predict species levels at a range of equivalence ratios. Different correlations are given in the following paragraphs to accommodate analyses of various levels of complexity.

Due to its toxicity, CO production is of primary importance. Four correlations (see Equations 16.19, 16.20, 16.21, and 16.22) are presented, representing varying degrees of complexity. In each case, the correlations basically represent a lower bound for the yield of CO. Equations 16.19a and 16.19b represents a "zeroth order" correlation between CO yield and equivalence ratio. For overventilated burning conditions, there is no CO production and for underventilated conditions CO is produced at a yield of 0.2 g per gram of fuel burned. This correlation applies best to fires with average upper-layer temperatures greater than 900 K.

$$f_{CO} = 0 \quad \text{for } \phi < 1 \tag{16.19a}$$

$$f_{CO} = 0.2 \quad \text{for } \phi > 1 \tag{16.19b}$$

Equations 16.20a, 16.20b, and 16.20c accounts for some of the temperature effect by including a linear rise in CO yield over the transition region from ϕ of 0.5 to 1.5.

$$f_{CO} = 0 \quad \text{for } \phi < 0.5 \tag{16.20a}$$

$$f_{CO} = 0.2\phi - 0.1 \quad \text{for } 0.5 < \phi < 1.5 \tag{16.20b}$$

$$f_{CO} = 0.2 \quad \text{for } \phi > 1.5 \tag{16.20c}$$

The temperature effect on CO production is best represented in the following two correlations. Equation 16.21, which represents a fit to the hexane data of Beyler's hood experiments, is suggested for compartment fires with average upper-layer temperatures below 800 K. Equation 16.22 is used for fires with upper-layer temperatures above 900 K. Equation 16.15 is an approximate fit to the compartment fire hexane data of Gottuk et al. For the most part, CO yields from hexane fires represent lower limits observed for the fuels studied to date [5, 8]. Therefore, these equations provide a *minimum* CO production that can be used for hazard analysis.

$$Y_{CO} = (0.19/180)\tan^{-1}(X) + 0.095 \text{ for } T < 800\text{ K} \tag{16.21}$$

where $X = 10(\phi - 0.8)$ and $\tan^{-1}(X)$ is in degrees

$$Y_{CO} = (0.22/180)\ \tan^{-1}(X) + 0.11 \text{ for } T > 900\text{ K} \tag{16.22}$$

where $X = 10(\phi - 1.25)$ and $\tan^{-1}(X)$ is in degrees

The figures presented earlier of CO yield versus equivalence ratio also show plots of Equations 16.21 and 16.22. Figure 16.7 shows the CO yield data for methane hood experiment fires in which upper-layer temperatures ranged from 490 to 870 K. The CO yield data of Zukoski et al. and Toner et al. lie between the curves of Equations 16.21 and 16.22, particularly for slightly overventilated and stoichiometric conditions. This is consistent with the fact that these fires had temperatures that were higher than those represented by Equation 16.14 and some were within the transition range of 800–900 K.

The simple model presented as Equations 16.14a, 16.14b, 16.14c, 16.14d, and 16.14e with the inclusion of the empirically determined yield coefficients, is fairly adequate for predicting CO_2, O_2, and H_2O normalized yields (see Equations 16.23, 16.24, and 16.25). Suggested average yield coefficients for compartment fires of elevated temperatures ($T > 900$ K) are 0.88 for B_{CO_2} and 0.97 for B_{O_2} [5]. Suggested values for low upper-layer temperatures ($T < 800$ K) are 0.77 for B_{CO_2}, 0.92 for B_{O_2}, and 0.95 for B_{H_2O}. Average yield coefficients for underventilated fires are shown in Table 16.2.

$$f_{CO_2} = 1 \quad \text{for } \phi < 1 \tag{16.23a}$$

$$f_{CO_2} = B_{CO_2}/\phi \quad \text{for } \phi > 1 \tag{16.23b}$$

$$f_{O_2} = 1 \quad \text{for } \phi < 1 \tag{16.24a}$$

$$f_{O_2} = B_{O_2}/\phi \quad \text{for } \phi > 1 \tag{16.24b}$$

$$f_{H_2O} = 1 \quad \text{for } \phi < 1 \tag{16.25a}$$

$$f_{H_2O} = B_{H_2O}/\phi \quad \text{for } \phi > 1 \tag{16.25b}$$

As presented in Equations 16.23, 16.24, and 16.25, normalized chemical species yields, *f*, can be correlated quite well by the global equivalence ratio. This is true for a wide range of fuel types. However, it is worthwhile to point out that for different fuels, the CO_2, O_2, and H_2O yields to equivalence ratio correlations only collapse down to a single curve when the yields are normalized by the maximum possible yield for a given fuel (i.e., presented as *f* rather than *Y*). Although complete combustion does not occur, combustion efficiencies with respect to equivalence ratio are similar enough between fuels that the stoichiometry of a particular fuel will dictate the generation of CO_2 and the depletion of O_2. Therefore, the species associated with complete combustion (CO_2, O_2, and H_2O) are not expected to have equal yields for different fuels, since varying fuel compositions will dictate different limits of CO_2 and H_2O that can be generated and O_2 that can be consumed for a gram of fuel burned. By normalizing the yields, the variability of fuel composition is removed.

On the other hand, carbon monoxide production is best correlated by the equivalence ratio when represented as a simple yield, Y_{CO}, rather than a normalized yield, f_{CO}. This is one indicator that CO production is not strongly dependent on fuel type, as is production of CO_2 and O_2. The reason for this is believed to be due to the fact that CO is effectively an intermediate product that depends more on the elementary chemistry than on fuel composition, which determines products of complete combustion.

Once yields are determined using the above correlations, species gas concentrations can be calculated. Equation 16.26 can be used to calculate the concentration of species i for all species except oxygen. Oxygen concentrations can be calculated from the depletion of oxygen using Equation 16.27.

$$X_{i_{\text{wet}}} = \frac{Y_i \dot{m}_f M_{\text{mix}}}{(\dot{m}_f + \dot{m}_a) M_i} \tag{16.26}$$

$$X_{O_{2\text{wet}}} = \frac{0.21 \dot{m}_a M_{O_2}/M_a - D_{O_2} \dot{m}_f}{(\dot{m}_f + \dot{m}_a) M_{O_2}/M_a} \tag{16.27}$$

The yield-equivalence ratio correlations shown in Fig. 16.9, which are also represented by Equations 16.21 and 16.15, have been replotted as CO concentration vs. equivalence ratio in Fig. 16.32. As indicated previously, the yield correlations in Fig. 16.9 (and thus, the concentrations in Fig. 16.32) represent a reasonable lower bound for a range of typical fuels. Higher concentrations of CO can be created, particularly when additional fuel is added to a vitiated upper layer. Corresponding to Fig. 16.32, CO_2 and O_2 concentrations for hexane compartment fires are shown in Figs. 16.33 and 16.34, respectively. Even though the peak concentrations of CO_2 will be dependent on the fuel type, the oxygen concentration as a function of will be similar for most hydrocarbons [5].

The ratio of CO to CO_2 concentrations can be used as an indicator of the combustion mode. Higher combustion efficiency is obtained as more fuel is burned completely to CO_2 and H_2O and is indicated by a ratio of CO to CO_2 near zero. Since CO is a product of incomplete combustion, the ratio of CO to CO_2 concentrations will increase as fires burn less efficiently. The ratio increases with equivalence ratio even for underventilated conditions, as evidenced by experimental data (e.g., Gottuk et al. [5]) and the engineering correlations presented above.

Example 4 Consider that the piece of furniture described in Example 1 is burning in a room such that a two-layer system develops. The only ventilation to the room is an open doorway through which 217 g/s of air is being entrained. The material is burning at a rate of 37 g/s, and the

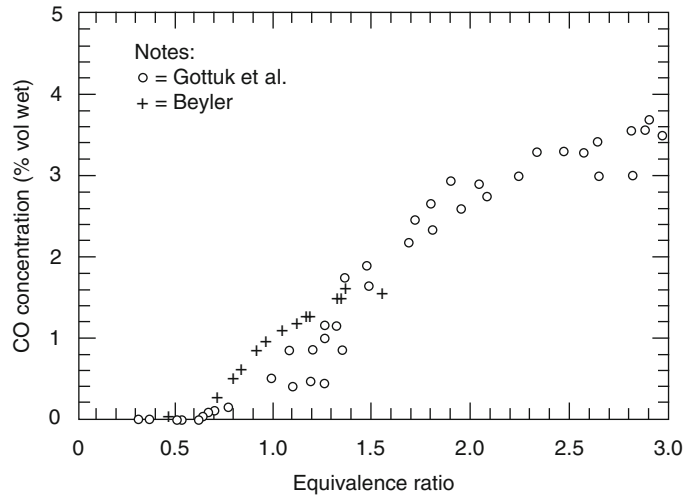

Fig. 16.32 Carbon monoxide concentrations as a function of equivalence ratio for hexane fires in a compartment (o) and under a hood (+). Data represent the same tests shown in Fig. 16.9 as unnormalized yields

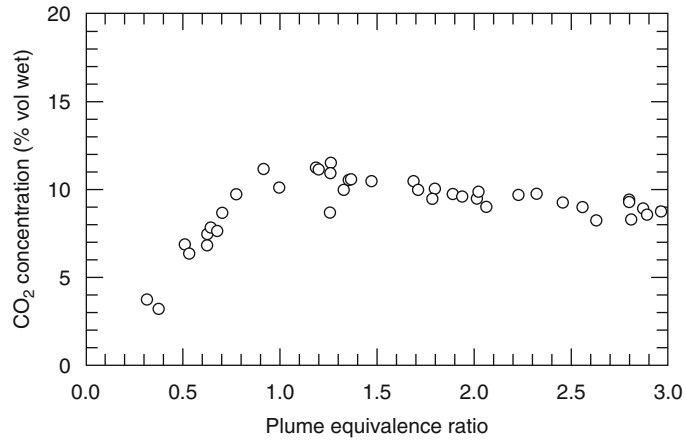

Fig. 16.33 CO_2 concentrations as a function of equivalence ratio for hexane compartment fires [5]

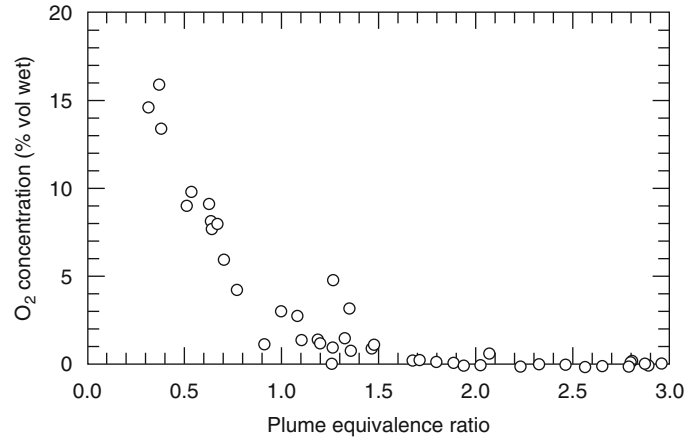

Fig. 16.34 O_2 concentrations as a function of equivalence ratio for hexane compartment fires [5]

average temperature of the upper layer is 700 °C. Calculate the plume equivalence ratio and determine the yield of CO and depletion of O_2.

Solution The plume equivalence ratio is calculated using Equation 16.10b. The stoichiometric fuel-to-air ratio, *r,* has already been calculated in Example 1.

$$\phi_p = \frac{\dot{m}_f/\dot{m}_a}{r} = \frac{37/217}{0.1139} = 1.5$$

Because the average upper-layer temperature $(700°\text{C} + 273 = 973\ \text{K})$ is above 900 K, Equation 16.22 is used to calculate the yield of CO. The argument, *X,* of the inverse tangent is

$$X = 10(\phi_p - 1.25) = 10(1.5 - 1.25) = 2.5$$

$$Y_{\text{CO}} = \left(\frac{0.22}{180}\right)\tan^{-1}(X) + 0.11$$

$$Y_{\text{CO}} = \left(\frac{0.22}{180}\right)\tan^{-1}(2.5) + 0.11$$

$$Y_{\text{CO}} = 0.19$$

Therefore, 0.19 g of CO are produced for every gram of polyurethane foam that burns. The production rate of CO is equal to that yield, Y_{CO}, multiplied by the fuel burning rate (0.19 × 37 g/s = 7.0 g/s).

The normalized yield of oxygen is determined using Equation 16.24, and the recommended yield coefficient, B_{O_2}, of 0.97.

$$f_{O_2} = \frac{B_{O_2}}{\phi} = \frac{0.97}{1.5} = 0.65$$

From Example 1, we obtain the maximum theoretical depletion of oxygen, k_{O2}, and calculate the depletion of oxygen as

$$D_{O_2} = f_{O_2} k_{O_2} = 0.65\,(2.05)$$
$$= 1.33 \text{ g of } O_2 \text{ per gram of fuel burned}$$

The depletion rate of oxygen is 49.2 g/s (1.33 × 37 g/s).

Example 5 For the piece of furniture burning in Example 4, calculate the CO and O_2 concentrations in the upper layer.

Solution Gas concentrations can be calculated from the yields determined in Example 4 using Equation 16.26 for CO and Equation 16.27 for O_2.

$$X_{CO_{wet}} = \frac{Y_{CO}\dot{m}_f M_{mix}}{(\dot{m}_f + \dot{m}_a)M_{CO}} = \frac{0.19(37)\,(28.8)}{(37+217)\,(28)} = 0.028$$

$$X_{O_2} = \frac{0.21\dot{m}_a M_{O2}/M_a - D_{O_2}\dot{m}_f}{(\dot{m}_a + \dot{m}_f)M_{O_2}/M_a}$$
$$= \frac{0.21(217)\,32/28.8 - 1.33(37)}{(32+217)\,32/28.8}$$
$$X_{O_2} = 0.005$$

The resulting concentrations of CO and O_2 are 2.8 and 0.5 % by volume, respectively.

Example 6 A fire is burning in a room that has one door open and no other ventilation. The room is 7 m wide and 4 m deep with a 2.43 m high ceiling. The door measures 0.76 m wide and 2.05 m high (area = 1.56 m^2). The peak heat release rate of the fire has been estimated to be 4.5 MW. Determine how much CO can be transported to other rooms in the building.

Solution The first step is to calculate the compartment equivalence ratio, ϕ_c. Since details of the fire are not provided, the mass burning rate of the fuel is not known. Therefore, ϕ_c is estimated via Equation 16.13c using the heat release rate, Q, of 4.5 MW.

$$\phi_c = \frac{Q}{\dot{m}_a} \cdot \frac{1}{3030} = \frac{4,500 \text{ kW}}{\dot{m}_a \cdot 3030}$$

The mass flow rate of air, $\dot{m}_a$, into the room is estimated using the ventilation parameter [33] as follows:

$$\dot{m}_a = 0.5A\sqrt{h} = 0.5 \cdot 1.56\sqrt{2.05} = 1.12\,\text{kg/s}$$

Substituting $\dot{m}_a$ into the equation above for the compartment equivalence ratio yields a ϕ_c of 1.3. Since ϕ_c is greater than 1, the occurrence of external burning must be considered. However, using the criteria that ϕ_c is less than 1.6, it is assumed that no external burning will occur. Species levels inside the room are calculated by Equations 16.19, 16.20, 16.21, 16.22, 16.23, 16.24, and 16.25 using ϕ_c. The yield of CO is calculated using Equation 16.21 or 16.22, depending on the temperature of the upper layer. The upper-layer temperature can be estimated using the McCaffrey, Quintiere, and Harkleroad (MQH) correlation [34] that is presented in Chap. 30 of this book. According to the MQH correlation, the upper-layer gas temperatures exceed 900 K for fires above 1100 kW. For temperatures above 900 K, Equation 16.22 is used to calculate the CO yield as

$$Y_{CO} = (0.22/180) \cdot \tan^{-1}[10(\phi - 1.25)]$$
$$+ 0.11 = 0.14$$

Since there is no external burning, the CO generated in the compartment (0.14 kg of CO per kg of fuel burned) will flow to other parts of the building. Before dilution occurs away from the fire compartment, the initial concentration of CO in the gases from the fire compartment can be calculated using Equation 16.26:

$$X_{CO_{wet}} = \frac{Y_{CO}\dot{m}_f M_{mix}}{(\dot{m}_f + \dot{m}_a)M_{CO}} = \frac{0.14(\dot{m}_f)28.8}{(\dot{m}_f + 1.12)28}$$

Since there is no information on the contents burning in the room, an accurate assessment of the fuel mass burning rate, $\dot{m}_f$, cannot be obtained. An estimate of $\dot{m}_f$ can be made using Equation 16.13a, with an assumed value of r, the stoichiometric fuel-to-air ratio. Values of r are presented in Table 16.1 for various fuels as $1/r$. In order to bound the possible CO

concentrations, values of $1/r$ of 4–15 are chosen to represent a reasonable range of hydrocarbon fuels that may be burning in the room. The following shows an example of the $\dot{m}_f$ calculation using Equation 16.13a and $1/r = 4$:

$$\dot{m}_f = \frac{\phi \cdot \dot{m}_a}{1/r} = \frac{1.3(1.12\ \text{kg/s})}{4} = 0.36\ \text{kg/s}$$

The corresponding calculation for $1/r$ of 15 yields an $\dot{m}_f$ of 0.097 kg/s. Substituting the values for $\dot{m}_f$ into the above equation for $X_{\text{CO}_{\text{wet}}}$ results in CO concentrations of 3.5 and 1.1 %, respectively.

Nomenclature

B_i	yield coefficients of species i
C	stoichiometric molar ratio of water to carbon dioxide
C_j	volume concentration of fuel j when fuel stream is stoichiometrically mixed with oxidant stream
C_p	heat capacity of products of complete combustion, (kJ/g · mol K)
D_{O_2}	mass depletion of oxygen per gram of fuel burned (g/g)
E	energy released per kg of oxygen consumed
F	normalized yield or generation efficiency
$\Delta H_{c,j}$	heat of combustion of the species j, (kJ/g · mol)
j	fuel species of interest
k	maximum theoretical yield
$L_{f,\text{tip}}$	length of flame tip for flame extending down a corridor ceiling
M	molecular weight
m_a	mass of air
$\dot{m}_a$	mass flow rate of air
m_f	mass of fuel
$\dot{m}_f$	mass loss rate of fuel
$\ddot{m}_f$	derivative of the fuel mass loss rate
$\dot{m}_{\text{exhaust}}$	mass flow rate out of the layer
n	molar quantity
n_{prod}	number of moles of products of complete combustion per mole of reactants (stoichiometric mixture of fuel and oxidant streams)
Q	ideal heat release rate
r	stoichiometric fuel-to-air ratio
r_a	stoichiometric air-to-fuel ratio
r_{O_2}	stoichiometric fuel-to-oxygen ratio
T	temperature
$T_{\text{SL},j}$	adiabatic flame temperature at the stoichiometric limit for fuel species j (K)
T_o	temperature of the gas mixture prior to reaction (K)
t	time
t_r	residence time of gases in the upper layer
τ_{SS}	steady-state time ratio
V_{ul}	volume of the upper layer
X	mole fraction
$X_{i_{\text{dry}}}$	dry mole fraction of species i (H_2O removed from sample)
$X_{i_{\text{wet}}}$	wet mole fraction of species i
Y	yield (g/g) also refers to D_{O_2}
$Y_{O_2,\text{air}}$	mass fraction of oxygen in air
z	distance between the bottom of the compartment outflow and the ceiling in the adjacent space
γ	dimensionless layer depth in adjacent space ($\gamma = \delta/z$)
δ	layer depth in the adjacent space
ϕ	equivalence ratio
ϕ_c	compartment equivalence ratio
ϕ_{cv}	equivalence ratio defined per a specified control volume
ϕ_p	plume equivalence ratio
ϕ_{ul}	upper-layer equivalence ratio
ρ_{ul}	density of the upper layer

Subscripts

A	air
f	fuel
CO	carbon monoxide
O_2	oxygen
CO_2	carbon dioxide
H_2O	water
H_2	hydrogen

THC	total unburned hydrocarbons
resid,C	residual carbon
$X_{i_{\text{wet}}}$	wet gas concentration with water in the mixture
$X_{i_{\text{dry}}}$	dry gas concentration with no water in the mixture

Flammability Limits of Premixed and Diffusion Flames

17

Craig Beyler

Introduction

It is well known that not all fuel/oxidant/diluent mixtures can propagate flame. Normal flame-type combustion cannot be sustained outside certain limits definable in terms of fuel/oxidant/diluent composition. Definition of these limits has received a great deal of attention in premixed combustion conditions, that is, in systems where the fuel and oxidant are mixed prior to combustion. Despite scientific interest in the subject dating back to the nineteenth century, the mechanism responsible for flammable limits is not yet understood. Nonetheless, a great deal has been learned that has practical application.

Much less investigation into the nature and cause of limits in diffusion flames has been undertaken. Empirically, clear parallels exist between diffusion and premixed limits, and these will be explored in the latter portion of this chapter.

Premixed Combustion

Premixed flame fronts can only propagate within a range of compositions of fuel and oxidant. The composition limits within which a flame can propagate are known as the upper and lower flammable limits and are expressed as concentrations of the fuel in a specified oxidant/diluent mixture at a specified temperature and pressure. For instance, the lower flammable limit (LFL) of methane in air at normal temperature and pressure is 5 % by volume, and the upper flammable limit (UFL) is 15 % by volume. As such, only methane/air mixtures with methane concentrations between 5 % and 15 % methane will support propagation of flame. For most simple hydrocarbons, the lower and upper flammable limits in air correspond to an equivalence ratio of approximately 0.5 and 3, respectively. The lower flammable limit concentrations for these fuels is approximately 48 g/m^3 (Fig. 17.1) [1].

The most widely used method of measuring flammable limits was developed by the U.S. Bureau of Mines [2]. The apparatus consists of a 1.5-m-long, 0.05-m-diameter vertical tube which is filled with the fuel/oxidant/diluent mixture to be tested. The top of the tube is closed, and the base of the tube can be closed until the start of the test to prevent diffusion of the mixture from the tube. With the base of the tube open, the mixture is ignited by a spark or small pilot flame at the base of the tube, and the travel of the flame front up the tube is observed. The mixture is deemed to be within the flammable limits if the flame can propagate halfway up the 1.5 m tube. The test is designed to identify the range of mixture compositions capable of flame propagation remote from the ignition source.

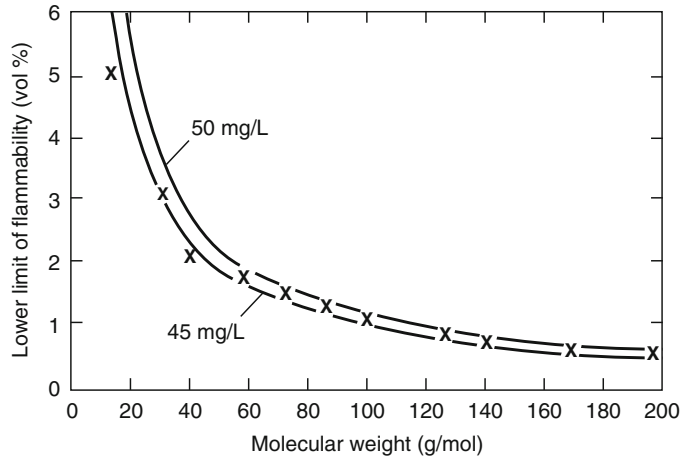

Fig. 17.1 Effect of molecular weight on lower limits of flammability of alkanes at 25 °C [1]

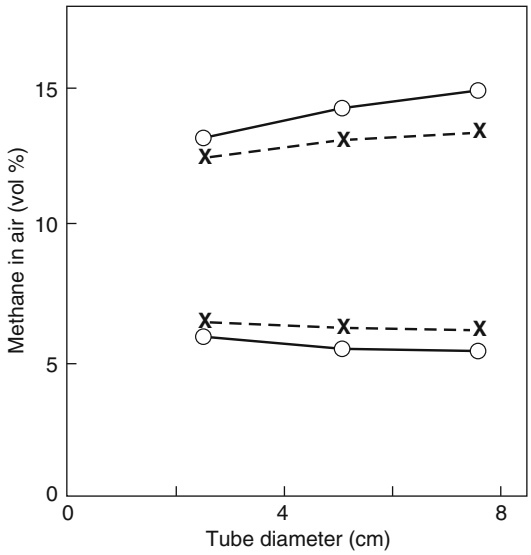

Fig. 17.2 Upper and lower flammable limits of methane as determined in a vertical tube apparatus for upward propagation (*circles*), and for downward propagation (*crosses*) [3]

The apparatus can be used with ignition at the top of the tube, but the flammable limits determined for downward propagation are narrower than for upward propagation. The 0.05 m diameter of the tube was chosen as the smallest diameter at which the heat losses from the flame to the tube wall had minimal effect on the flammable limits determined (Fig. 17.2) [3]. Several other methods for determining flammable limits are available [4–7]. Some methods are designed for use in special conditions, and others simply reflect national differences. Although each method gives substantially similar results, some variations in results do exist (see, for example, Smedt et al. [8] and Goethals et al. [9]).

Mixtures are capable of combustion outside the flammable limits, but external energy must be provided throughout the mixture volume in order to allow propagation of a flame [10]. An example of this behavior is shown in Fig. 17.3. A small hydrogen diffusion flame is used as a pilot source in a lean methane/air mixture. At methane concentrations less than 5 %, combustion occurs only in the wake of the pilot flame. Above 5 %, the flame can propagate away from the pilot flame, regardless of the orientation of the pilot flame.

Flammable limits are a function of the oxygen and inert concentrations, as well as the mixture temperature and pressure. As the concentration of inerts is reduced and the oxygen concentration is increased, the upper flammable limit is increased, whereas the lower limit is relatively unchanged. This result can be understood by observing that at the lower flammable limit there is always more than enough oxygen present for complete combustion, but at the upper limit less than the stoichiometrically required oxygen is present. Hence, at the upper limit the additional oxygen participates in the combustion process, whereas at the lower limit the additional oxygen simply replaces inert gas.

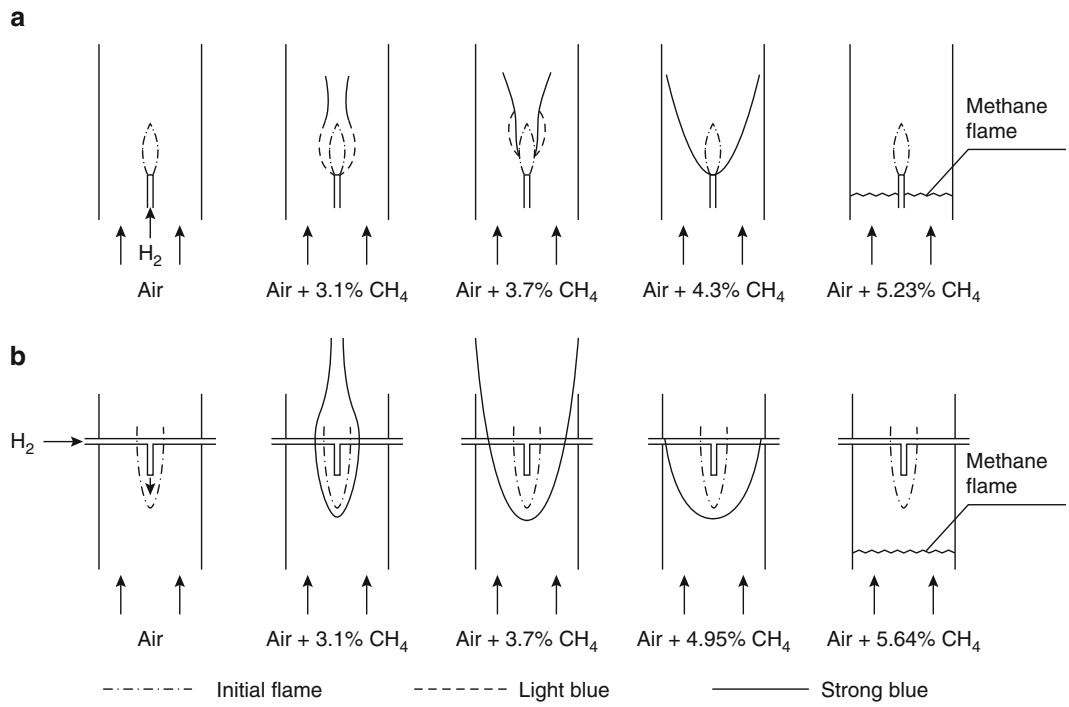

Fig. 17.3 A small jet diffusion flame in a coflowing (**a**) and contraflowing (**b**) stream as the concentration of the fuel in the stream is gradually increased up to ignition. The stream velocity is 0.222 m/s, and the hydrogen jet diameter is 1.52 mm [10]

The lower flammable limit is also insensitive to the pressure, except at pressures well below atmospheric. The upper limit shares this insensitivity at subatmospheric pressures, but the upper limit increases with increasing pressure above atmospheric (Fig. 17.4) [1].

The flammable limits widen with increases in mixture temperature as illustrated in Fig. 17.5; [1] this aspect will be discussed further later in this chapter. Figure 17.5 also relates flammable limits with the saturation vapor curve and the autoignition temperature (AIT). The flashpoint of a liquid is given in the figure as T_L. At that temperature, the vapor pressure at the liquid surface is at the lower flammable limit. The corresponding upper limit temperature is given as T_U. If a liquid is contained within a closed vessel and the vapors are allowed to come into equilibrium at temperatures above the upper limit temperature, the vapors in the vessel will be above the upper flammable limit, for example, as typically occurs in an automobile gas tank. If the liquid is not enclosed fully, there will be a location above the surface of the liquid where the fuel/air mixture will be diluted below the upper flammable limit and will ignite if an ignition source is present.

Predicting Lower Flammable Limits of Mixtures of Flammable Gases (Le Chatelier's Rule)

Based on an empirical rule developed by Le Chatelier in the late nineteenth century, the lower flammable limit of mixtures of multiple flammable gases in air can be determined. A generalization of Le Chatelier's rule was given by Coward et al. [11]

$$\sum_{i=1}^{n} \frac{C_i}{\mathrm{LFL}_i} \geq 1 \qquad (17.1)$$

where C_i is the volume percent of fuel gas, i, in the fuel/air mixture, and LFL_i is the volume

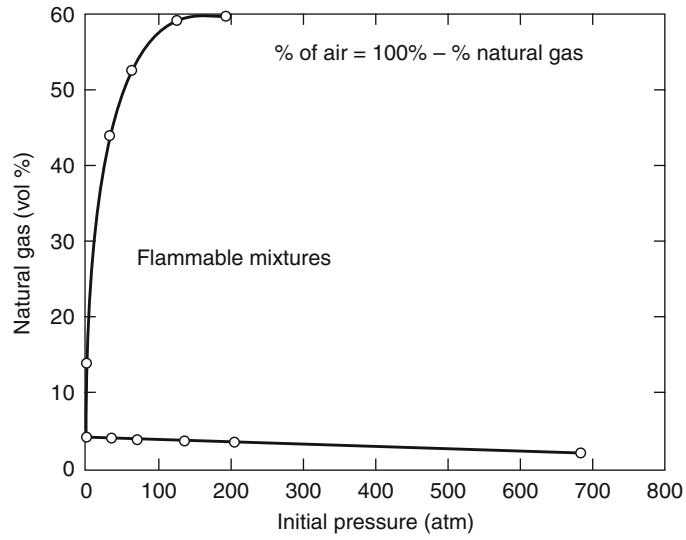

Fig. 17.4 Effect of pressure on the limits of flammability of natural gas in air at 28 °C [1]

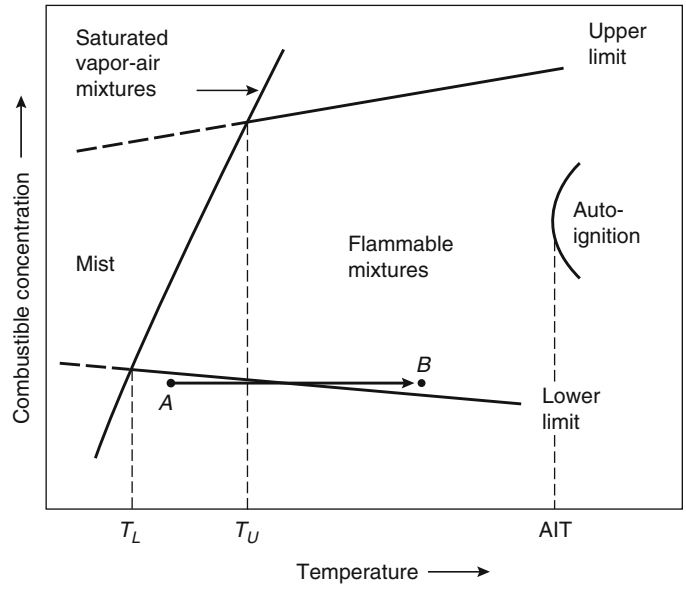

Fig. 17.5 Effect of temperature on limits of flammability of a combustible vapor in air at constant initial pressure [1]

percent of fuel gas, *i,* at its lower flammable limit in air alone. If the indicated sum is greater than unity, the mixture is above the lower flammable limit. This relationship can be restated in terms of the lower flammable limit concentration of the fuel mixture, LFL_m , as follows:

$$\mathrm{LFL}_m = \frac{100}{\sum_{i=1}^{n} \left(C_{f_i}/\mathrm{LFL}_i\right)} \tag{17.2}$$

where C_{f_i} is the volume percent of fuel gas i in the fuel gas mixture.

Example 1 A mixture of 50 % methane, 25 % carbon monoxide, and 25 % hydrogen is mixed with air. Calculate the lower flammmable limit of this fuel gas mixture.

Solution Referring to Table 17.1, LFLs of methane, carbon monoxide, and hydrogen are

5.0 %, 12.5 %, and 4.0 % by volume, respectively. Using Equation 17.2 we find

$$\mathrm{LFL}_m = \frac{100}{50/5 + 25/12.5 + 25/4} = 5.48\%$$

The composition of the lower flammable limit fuel/air mixture is 2.74 % methane, 1.37 % carbon monoxide, 1.37 % hydrogen, and 94.5 % air.

Critical Adiabatic Flame Temperature at the Lower Flammable Limit

As early as 1911, Burgess and Wheeler [12] noted the constancy of the potential heat release rate per unit volume of normal alkane/air lower flammable mixtures at room temperature. Since the heat capacity of the products of complete combustion are nearly the same for all hydrocarbons, their observation also implies that the adiabatic flame temperature (AFT) at the lower flammable limit is a constant. Examination of a wide range of C,H,O-containing fuels indicates that the adiabatic flame temperature at the LFL is approximately 1600 K (±150 K) for most C,H,O-containing fuels, with the following notable exceptions: hydrogen, 980 K; carbon monoxide, 1300 K; and acetylene, 1280 K. This result indicates that the adiabatic flame temperature at the lower flammable limit is an indication

of the reactivity of the fuel. The lower the adiabatic flame temperature, the more reactive the fuel.

The utility of the concept of a critical adiabatic flame temperature at the lower flammable limit goes beyond that outlined above. It has been demonstrated that the adiabatic flame temperature at the lower flammable limit is relatively insensitive ($\pm$100 K) to the diluent used and to the initial temperature of the mixture [13–15].

The adiabatic flame temperature at the limit is insensitive to initial temperature only so long as significant preflame combustion reactions do not occur. As such, for a mixture near or above its autoignition temperature (AIT) for a significant length of time, the adiabatic flame temperature at the limit is not expected to be constant. Weinberg [15] has shown that a mixture of 1 % methane (LFL = 5 % at 293 K) in air can burn if it is preheated to 1270 K, even though the flame only increases that temperature by about 250 K, in accordance with the expected adiabatic flame temperature. This result was achieved by mixing the methane and air just before the flame so that preflame reactions were not allowed to proceed significantly.

Due to the constancy of the adiabatic flame temperature at the lower limit, the concept can be utilized to predict the effect of variable mixture temperature and diluents on the flammable limits of a mixture. Coward and Jones [2] have examined variable oxygen/diluent ratios, using nitrogen, carbon dioxide, water, argon, and helium as diluents. Their work shows that the limit temperature is insensitive to the oxygen/diluent ratio. Figure 17.6, adapted from Macek [16], illustrates the change in adiabatic flame temperature at the lower flammable limit as additional nitrogen is added to decrease the oxygen/nitrogen ratio. The figure shows an increase in the adiabatic flame temperature at the lower flammable limit from 1550 K to over 1700 K as we move from normal air to the stoichiometric limit. Beyond the stoichiometric limit, no fuel-lean mixture can burn. The region beyond the stoichiometric limit can be best understood in the context of flammability diagrams and upper flammable limits. We will examine these later in the chapter.

The insensitivity of the limit temperature to the chemical structure of C,H,O-containing fuels contributes significantly to the utility of the concept of a critical adiabatic flame temperature at the lower flammable limit. No systematic evaluation of the limit temperature concept for fuels containing sulfur, nitrogen, or halogens has been undertaken. Existing data indicate that

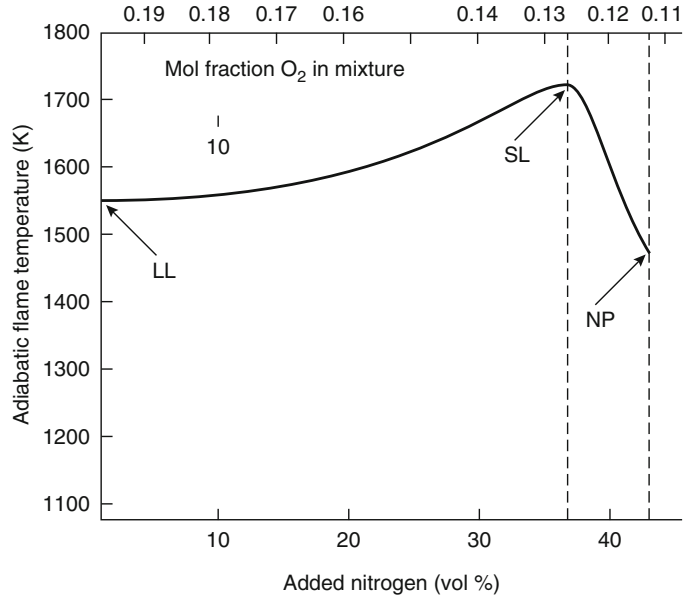

Fig. 17.6 Computed adiabatic flame temperature along the lower branch of the flammability limits of propane (Adapted from Macek) [16]. SL and NP are defined in Fig. 17.9

halogen-containing fuels have limit temperatures several hundred degrees higher than C,H,O fuels. Since halogens are combustion inhibitors, this conclusion is consistent with the idea that the adiabatic flame temperature at the lower flammable limit is indicative of the reactivity of the fuel. Thus, possible exceptions to the generalization that the adiabatic flame temperature at the lower flammable limit is approximately 1600 K may be identifiable by considering the reactivity of the fuel gas.

Egerton and Powling [17] have shown that the limit temperatures at the upper flammable limit for hydrogen and carbon monoxide are equal to their limit temperatures at the lower flammable limit. Stull [18] has reported the same result for methane. However, it is not generally possible to calculate the adiabatic flame temperature for other fuels, since the products of combustion under fuel-rich conditions include a mixture of products of combustion and pyrolysis, which cannot be predicted by assuming chemical equilibrium is achieved or by detailed chemical kinetics calculations. Equilibrium calculations indicate that the only carbon-containing species that should be produced are CO, CO_2, CH_4, and solid carbon. This conclusion is not generally a good approximation under fuel-rich conditions.

Example 2 The lower flammable limit of propane at 20 °C is 2.1 % by volume. Find the lower flammable limit at 200 °C.

Solution For adiabatic combustion, all the heat released is absorbed by the products of combustion:

$$\left(\frac{\text{LFL}}{100}\right)\Delta H_c = \int_{T_0}^{T_{f,\text{LFL}}} nC_p dT \qquad (17.3)$$

where

ΔH_c = Heat of combustion of the fuel
LFL/100 = Mole fraction of fuel
n = Number of moles of products of combustion per mol of fuel/air mixture
C_p = Heat capacity of the products of combustion
T_0 = Initial temperature of the fuel/air mixture
$T_{f,\text{LFL}}$ = Adiabatic flame temperature of a lower flammable limit mixture

This equation uses concepts developed in Chap. 5. For the present purposes, it is suitable to use an average value of the heat capacity. This adjustment reduces Equation 17.3 to

$$\left(\frac{\text{LFL}}{100}\right)\Delta H_c = nC_p\left(T_{f,\text{LFL}} - T_0\right) \qquad (17.4)$$

We know that $T_{f,\text{LFL}} = 1600$ K, and for $T_0 = 20$ °C, we also know that LFL = 2.1 %. Rearranging Equation 17.4 yields

$$\begin{aligned}\frac{\Delta H_c}{nC_p} &= \frac{\left(T_{f,\text{LFL}} - T_0\right)}{\text{LFL}/100} \\ &= \frac{1600\ \text{K} - 293\ \text{K}}{2.1/100} \\ &= 6.22 \times 10^4 \text{K}\end{aligned}$$

Both the heat of combustion and the heat capacity are weak functions of temperature, and these effects will be ignored. As such we can use the above expression to predict the lower flammable limit for an initial temperature of 200 °C.

$$\begin{aligned}\frac{T_{f,\text{LFL}} - T_0}{\text{LFL}/100} &= \frac{1600\ \text{K} - 473\ \text{K}}{\text{LFL}/100} \\ &= 6.22 \times 10^4 \text{K} \\ \text{LFL} &= 1.8\ \text{percent}\end{aligned}$$

Flammability Diagrams

Whereas the flammable limits of a fuel in air can be characterized by the lower and upper flammable limits, it is necessary to represent flammable limits of more general fuel/oxidant/inert mixtures by using flammability diagrams. Examples of flammability diagrams for methane/oxygen/nitrogen mixtures are shown in Figs. 17.7 and 17.8. Based on an extensive series of tests with a range of mixture compositions, a flammability diagram can be constructed indicating the regions of mixture compositions within the flammable limits.

Two types of flammability diagrams are often used. The first type uses three axes in which each of the three constituent gases is explicitly represented, and the second diagram utilizes only two axes in which the third gas concentration is determined by the difference between the sum

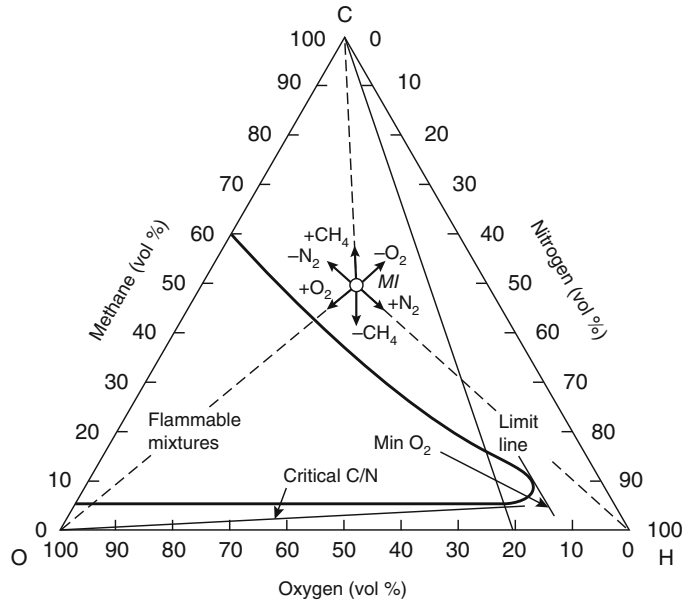

Fig. 17.7 Three-axis flammability diagram for the system methane/oxygen/nitrogen at atmospheric pressure and 26 °C [1]

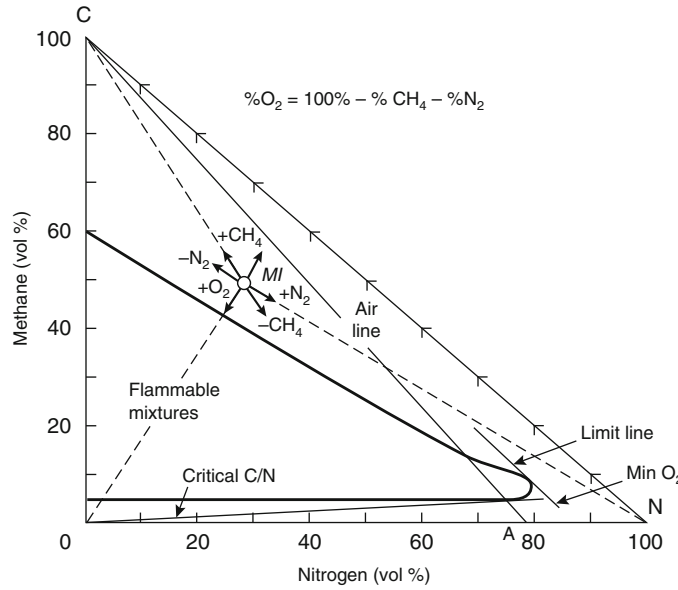

Fig. 17.8 Two-axis flammability diagram for the system methane/oxygen/nitrogen at atmospheric pressure and 26 °C [1]

of the other two gases and 100 %. Both types give the same information.

Shown in Figs. 17.7 and 17.8 are the air and limit lines. Anywhere along the air line the ratio of oxygen to nitrogen is the same as in air. The limit line represents a range of mixtures with a fixed oxygen-to-nitrogen ratio which is tangent to the flammable region. Any oxygen/nitrogen mixture with an oxygen-to-nitrogen ratio less than that of the limit line will not support flame propagation when mixed with any amount of methane. This condition is known as the limiting oxygen concentration (LOC).

The LOC is an important concept in inerting. If the oxygen concentration can be maintained below the LOC, then premixed burning can be

prevented. The LOC is a function of the temperature, pressure, fuel, and inert gas. Table 17.2 shows the LOC [19–23] of a wide range of fuels with nitrogen and carbon dioxide as the inert diluents. The tabulated values apply to diluted air/fuel mixtures at normal temperature and pressure. Like flammable limits, the dynamics of the LOC can generally be understood using the AFT concepts.

As can be seen in Table 17.2 with nitrogen diluent, the LOC is generally in the 10–12 % range. Fuels like carbon monoxide and hydrogen

Source: Adapted from Table C-1, NFPA 69, *Standard on Explosion Prevention Systems*

have lower LOCs, and chlorinated fuels have higher values. These trends are expected based on AFT concepts at the LFL. For carbon dioxide as a diluent, the LOCs are generally 2–3 % higher than for nitrogen diluent. Again this is expected based on AFT concepts due to the higher molar heat capacity of carbon dioxide.

Figure 17.9 is yet another representation of the flammable limits of fuel/oxidant/inert mixtures. The dilution of a fuel/air mixture is given by the percent of inert gas in excess of the nitrogen present in air. Figure 17.9 includes only mixtures that lie to the right of the air line, and as such is a magnification of a portion of the region included in Figs. 17.7 and 17.8. Also shown in Fig. 17.9 are several lines and points of specific interest. The highest concentration of nitrogen that will allow propagation of a flame is known as the nitrogen point (NP). Of course, this concept can be generalized to any inert (IP). If the concentration of the inert is greater than that at the inert point, no mixture of fuel and oxidant will propagate a flame remote from the ignition source.

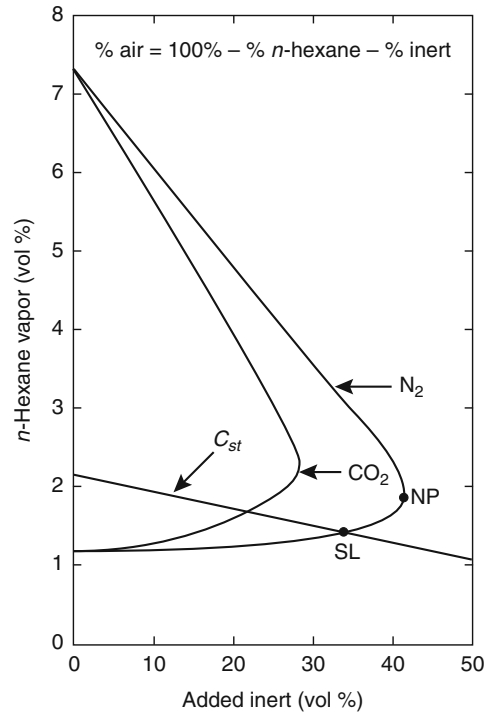

Fig. 17.9 Limits of flammability of various n-hexane/inert gas/air mixtures at 25 °C and atmospheric pressure [1]

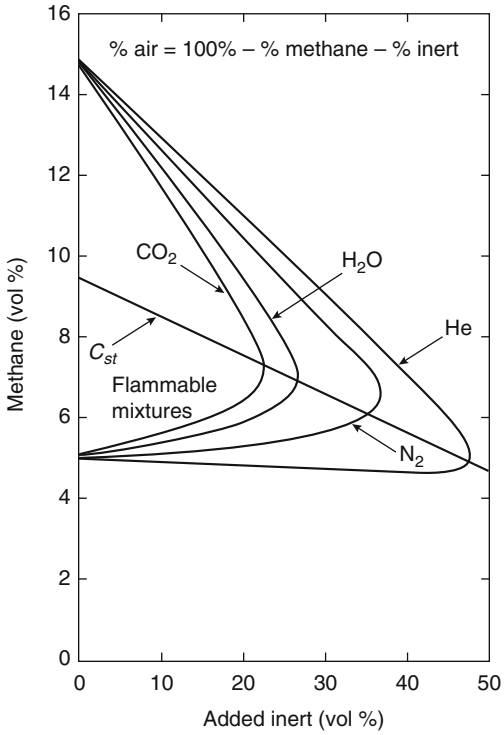

Fig. 17.10 Limits of flammability of various methane/inert gas/air mixtures at 25 °C and atmospheric pressure [1]

As shown in Fig. 17.9, the stoichiometric line passes through the flammable region. The point at which the stoichiometric line intersects the boundary of the flammable region is known as the stoichiometric limit (SL). The SL is the most dilute stoichiometric mixture that will propagate a flame remote from the ignition source. In the case of methane, the peak of the flammable region occurs near the stoichiometric limit (Fig. 17.10). For longer chain alkanes, the peak shifts to the rich side of the stoichiometric line (Fig. 17.9). For C_5 and higher hydrocarbons, the peak of the flammable region is bisected by the stoichiometric line defined by combustion to CO rather than to products of complete combustion. This shift has been attributed to incomplete combustion [16] and to preferential diffusion of reactants [24]. A similar shift of the maximum burning velocity to the rich side of stoichiometry is also observed. In this case, preferential diffusion of reactants has been shown to be the responsible factor.

Flammability diagrams are useful not only in determining the flammability of a given mixture, but also in developing strategies for avoiding flammable mixtures while diluting fuel-rich mixtures. In order to make use of the diagrams in this fashion, we must examine the change in position on the diagram when fuel, oxygen, or inert gas is added to the mixture. Consider a mixture given by point MI in the three-axis diagram (Fig. 17.7). The arrows indicate the change in the mixture composition with the addition or removal of each gas species. In the three-axis diagram, moving toward the vertex corresponding to 100 % of any one of the gases corresponds to the addition of that gas, since adding an infinite amount of a single gas will reduce the concentrations of the other gases to zero. Adding air corresponds to moving toward the point on the air line at which there is no fuel. Clearly, following these examples, the effect of adding any gas or gas mixture can be plotted in the three-axis diagram. In the two-axis diagram in Fig. 17.8, moving toward the vertex with 0 % inert, 0 % fuel corresponds to the addition of oxygen. In Fig. 17.9 moving toward the 0 % inert, 0 % fuel vertex corresponds to adding air.

Figure 17.10 shows the effect of various inert diluents on the flammable region. As indicated by the critical adiabatic flame temperature concept, the lower flammable limit is increased in proportion to the heat capacity of the diluent (see Chap. 5).

Example 3 A methane leak fills a 200 m^3 room until the methane concentration is 30 % by volume. Calculate how much nitrogen must be added to the room before air can be allowed in the space.

Solution The initial mixture in the room is given by the point B in Fig. 17.11. Adding nitrogen moves along the line toward pure nitrogen (the N point). Drawing the line from the air point, A, tangent to the flammable region defines the mixture C: the mixture with the least nitrogen added that, on mixing with air, will not form a flammable mixture. Referring to Fig. 17.11 we see that

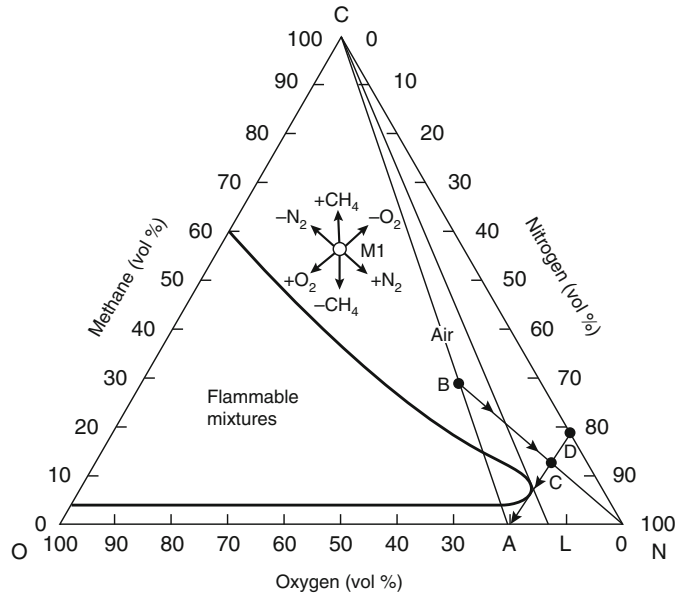

Fig. 17.11 Graphic solution of Example 3 (Adapted from Zubetakis) [1]

point C corresponds to a methane concentration of 13 %. In order to reduce the methane concentration from 30 % to 13 %, an as yet unknown amount of nitrogen must be added. If we could remove only the initial mixture and replace it with nitrogen, the amount of nitrogen would simply be

$$\frac{30-13}{30} \times 200\ \mathrm{m}^3 = 113\ \ \mathrm{m}^3$$

However, there is generally no way to prevent mixing of the initial mixture to be exhausted and the nitrogen being introduced to replace it. As such, inerting nitrogen is also lost. We can model this occurrence by assuming that the room is well mixed during nitrogen injection so that the concentrations are uniform everywhere. Under these conditions the methane concentration, C, is given by

$$C = C_0 \exp\left(\frac{-V_\mathrm{N}}{V}\right)$$

where
C_0 = Initial methane concentration
V_N = Volume of nitrogen added
V = Volume of the room

Rearranging this equation we find

$$V_\mathrm{N} = -V \ln\left(\frac{C}{C_0}\right) = -200\ \ \mathrm{m}^3 \ln\left(\frac{13}{30}\right)$$
$$= 167\ \ \mathrm{m}^3$$

Of course, the flow of gases out of the room contains methane and may burn on mixing with air. Mixing air and the initial gases in the room results in mixtures along the line AB (see Fig. 17.11), some of which are clearly flammable. As such, ignition sources must be excluded near the room exhaust, or the exhaust also needs to be inerted.

Example 4 A 1 kg/s flow of methane is being dumped into the atmosphere. How much nitrogen must be mixed with methane to avoid a flammable mixture in the open?

Solution In order to make the methane nonflammable, it needs to be diluted with enough nitrogen so that on further addition of air the flammable region is missed. Such a mixture of methane and nitrogen is given by extrapolating the line AC back to zero oxygen; that is, point D

on Fig. 17.11, where the mixture is 82 % nitrogen, 18 % methane. The ratio of the flow rates of nitrogen to methane must equal the ratio of the concentrations of nitrogen and methane. Since concentrations expressed as volume percent are directly related to mole fractions, the flow rates of nitrogen and methane must be expressed as molar flow rates, $\dot{n}$,

$$\frac{\dot{n}_{N_2}}{\dot{n}_{CH_4}} = \frac{C_{N_2}}{C_{CH_4}}$$

The molar flow rate of methane is given by

$$\dot{n}_{CH_4} = \frac{\dot{m}_{CH_4}}{MW_{CH_4}}$$

where MW is the molecular weight and $\dot{m}$ is the mass flow rate.

$$\begin{aligned}
\dot{n}_{N_2} &= \left(\frac{\dot{m}_{CH_4}}{MW_{CH_4}}\right)\left(\frac{C_{N_2}}{C_{CH_4}}\right) \\
&= \left(\frac{100\ \text{g/s}}{16\ \text{g/mol}}\right)\left(\frac{82\%}{18\%}\right) \\
&= 285\ \text{mol/s} \\
\dot{m}_{N_2} &= \dot{n}_{N_2} MW_{N_2} \\
&= (285\ \text{mol/s})(28\ \text{g/mol}) \\
&= 7970\ \text{g/s}\ \text{ or }\ 7.97\ \text{kg/s}
\end{aligned}$$

Ignition Energies and Quenching Diameters

The energy required to ignite flammable mixtures is generally quite low, on the order of a few tenths of a millijoule (mJ) for near-stoichiometric mixtures in air and as low as a few thousandths of a millijoule in oxygen. Here again, preferential diffusion causes the minimum to occur for rich mixtures for fuels with molecular weights greater than that of air [24]. As the flammable limits are approached, the ignition energy increases sharply.

Several methods exist for preventing the initiation of an explosion. These include avoiding flammable mixtures, excluding ignition sources whose energy is greater than the minimum ignition energy, and enclosing any ignition sources in an enclosure that will not allow the propagation of the flame to the outside. We have already discussed the first of these. Some low-power electrical equipment can be designed such that the worst fault condition cannot produce the minimum ignition energy for a specified gas. Such equipment is termed "intrinsically safe" and may be used where there is a risk of a flammable atmosphere being formed.

Where this method is not feasible, the electrical equipment may be housed in an "explosionproof" enclosure that will not allow propagation of the flame out of the enclosure, which is accomplished by making the size of the openings small enough that sufficient heat is lost by the flame as it passes through the opening that it is quenched. The quenching distance is most often determined by placing a pair of flanged electrodes in a gas mixture and attempting to ignite the gases. The flanges are parallel plates, and if the mixture can be ignited in the presence of the plates, the separation of the plates is greater than the quenching distance. The quenching distance with parallel plates, $d_{||}$, is 65 % of the quenching diameter in circular tubes. Figure 17.12 [25] shows the relation of the quenching distance to the minimum ignition energy for a number of hydrocarbon/air mixtures. The relation can be expressed as $E_{min} = 0.06 d_{||}^2$, where E_{min} is the minimum ignition energy in air given in mJ and $d_{||}$ is the quenching distance in air given in mm.

Because the hot quenched flame gases in an enclosure will expand through the opening, they may autoignite outside the enclosure. It has been found that the minimum experimental safe gap (MESG) for most hydrocarbons is approximately half the quenching distance [25].

Dusts and Mists

The lower flammable limit of dusts and mists would be expected to be higher than their gaseous counterparts due to the need to volatilize the dust or mist. For very small particles with high surface-area-to-volume ratios, the lower flammable limit is independent of particle diameter, and the limit concentrations are approximately the same as the analogous gaseous fuel for fuels that volatilize completely. Hertzberg et al. [26] have

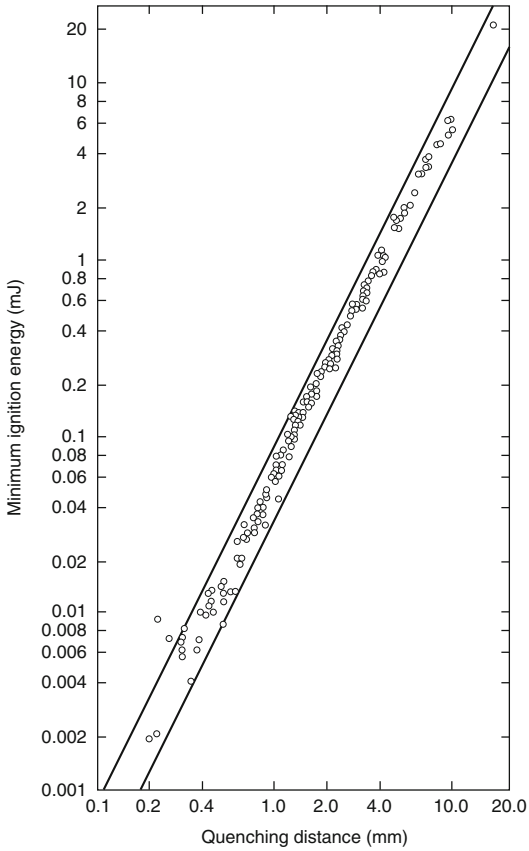

Fig. 17.12 The relation between flat-plate quenching and spark minimum ignition energies for a number of hydrocarbon-air mixtures [25]

shown that bituminous coal dusts with particle diameters of 50 mm or less and polyethylene dusts with particle diameters of 100 μm or less have lower flammable limits in air that are independent of particle diameter. Figure 17.13 shows the measured lower flammable limit concentration for Pittsburgh bituminous coal as a function of average particle diameter and oxygen concentration. Notice that the lower flammable limit in the small-particle limit is a function of the oxygen concentration, unlike gaseous fuels. Also note that the lower flammable limit concentration is much higher than the 48 g/m^3 typical of gaseous hydrocarbons. These effects are due to the fact that not all the coal dust is volatilized. The fraction of dust that is volatilized is a function of the particle diameter and the oxygen concentration. As the oxygen concentration affects the maximum flame temperature and, hence, the heat flux to the particle, both the ability of heat to penetrate the particle and the rate of heating are affected. It is well known that the fraction of the material volatilized increases with the rate of heating. It is not expected that the lower flammable limit can be reduced below 50 g/m^3, even at 100 % oxygen.

As the particle size increases, it would be expected that the lower flammable limit would also increase due to the difficulty of getting the fuel into the gas phase where combustion will take place. This result does in fact occur, but depending on the geometry of the test, the apparent lower flammable limit of mists can actually decrease with increasing particle diameter due to the effects of gravity [27]. If the ignition source is at the bottom of the container and the aerosol is not kept well mixed, the particles can begin to settle out, causing the local concentration in the lower portions of the apparatus to be higher. This laboratory effect can also be expected to operate under actual conditions, depending on the degree of mixing of the aerosol.

Although it is in principle possible for flame propagation to occur as a result of heterogeneous combustion of particles, this appears not to be an important mechanism for organic materials. Lower flammable limits of anthracite coal dusts with only a 20 % volatile yield can be explained solely on the basis of gas-phase combustion [28]. On the other hand, flame propagation by heterogeneous combustion is important for metal and graphite dusts.

Diffusion Flame Limits

The limits of flammability for diffusion flames were first examined by Simmons and Wolfhard [29]. In their experiments, they determined the minimum level of dilution of the oxidant stream necessary to prevent the stabilization of a diffusion flame for a variety of gas and liquid fuels. The oxygen mole fraction, X_{O_2}, of the oxidant stream at the flammability limit is known as the limiting oxygen index (LOI), or simply the oxygen index (OI). Simmons and Wolfhard's results are included in Table 17.3. They observed that the oxygen index of their diffusion flames

[a]Expressed as mole fraction of oxygen

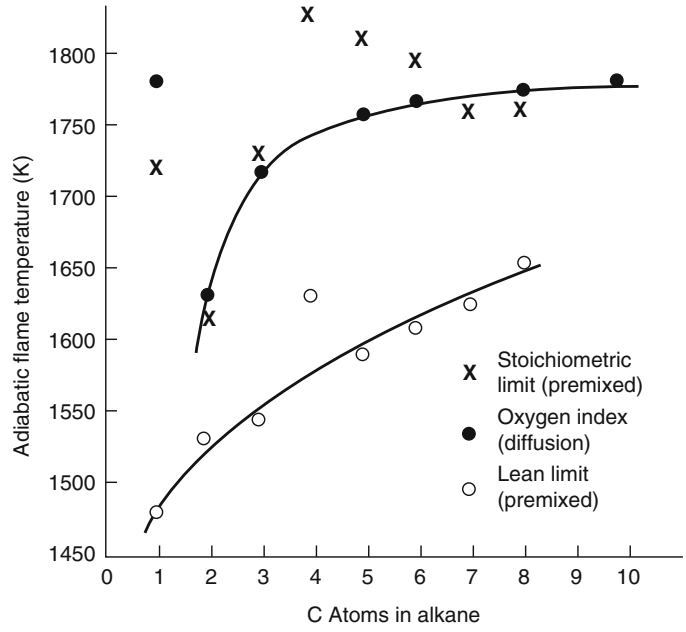

Fig. 17.14 Computed adiabatic flame temperatures at flammability limits for n-alkanes (Adapted from Macek) [16]

equaled the ratio, $X_{O_2}/(X_{O_2} + X_{\text{diluent}})$, found in a premixed stoichiometric-limit mixture involving the same fuel. This result implies that the adiabatic flame temperature for the limit diffusion flame, calculated on the basis of stoichiometric combustion of the fuel and oxidant streams, is equal to the adiabatic flame temperature at the stoichiometric limit of a premixed system involving the same fuel, oxidant, and diluent.

Figure 17.14 graphically illustrates the relationship of the adiabatic flame temperatures at the lean, premixed limit in air, at the stoichiometric limit (premixed), and at the oxygen index (premixed). As the figure shows, the adiabatic flame temperature at the stoichiometric limit and the oxygen index are essentially equal, and the adiabatic flame temperature at the lower flammable limit in air is approximately 150 K less. Ishizuka and Tsuji [30] verified Simmons and Wolfhard's results for methane and hydrogen, and showed that the adiabatic flame temperature at the limit is the same whether dilution is of the fuel or oxidizer stream.

The information in Fig. 17.14 forms the basis of a method for the evaluation of diffusion flame limits for fuel mixtures. In essence, the ability of a fuel and oxidant pair to react in a diffusion flame is evaluated by examining the flammability of a premixed stoichiometric mixture of the fuel and oxidant.

To do this, we assume that Le Chatelier's rule holds at the stoichiometric limit; that is,

$$\sum_{i=1}^{n} \left(\frac{C_i}{\text{SL}_i} \right) \geq 1 \tag{17.5}$$

and that the adiabatic flame temperature at the stoichiometric limit for each fuel is a constant, leading to the expression

$$\sum_{i=1}^{n} \frac{(C_i/100)\Delta H_{c,i}}{\int_{T_0}^{T_{f,\text{SL},i}} n_p C_p dT} \geq 1 \tag{17.6}$$

where

C_i = Volume percent of fuel species, i, when the fuel stream is mixed stoichiometrically with the oxidant stream

$T_{f,\text{SL},I}$ = Adiabatic flame temperature of the stoichiometric limit mixture for fuel species i
- = 1700 K for most hydrocarbons
- = 1450 K for carbon monoxide
- = 1080 K for hydrogen

T_0 = Temperature of the stoichiometric mixture prior to reaction

$\Delta H_{c,I}$ = Heat of combustion of fuel species
=620 kJ/mol for hydrocarbons (per carbon, assuming $H/C = 2$)
=283 kJ/mol for carbon monoxide
=242 kJ/mol for hydrogen

n_p = Number of moles of products of combustion per mole of reactants (stoichiometric mixture of the fuel and oxidant streams)

C_p = Heat capacity of the products of combustion

This approach has been successfully used to predict the flammability of the hot gas layer formed in enclosure fires [31].

Although the hot gas layer formed in enclosure fires can become flammable, under some conditions the oxygen concentration in the hot layer can cause extinction of flames fully immersed in the hot layer. Based on the analogies between premixed and diffusion flames, one would expect the oxygen concentration in the layer at extinction to be approximately equal to the premixed LOC. In fact, comparing the nitrogen diluent in Table 17.2 with Table 17.3, one can see a very close correspondence between the LOC and the LOI.

Morehart, Zukoski, and Kubota [32] examined the oxygen concentration at extinction of flames by dilution of air with combustion products. They found that flames were extinguished at oxygen concentrations of 12.4–14.3 %, with the lower value occurring for a 50-cm-diameter pool burner and the higher value occurring for a 9 cm pool burner. These results are consistent with diesel pan fire tests (0.62 m and 0.84 m diameters) conducted by Peatross and Beyler [33] in which oxygen concentrations below 14 % could not be achieved during pool burning in a compartment. It is also consistent with the results of Back et al. [34], who measured oxygen concentrations at extinction in water mist extinguishment tests in obstructed machinery space fires. They found an average oxygen concentration of 14.5 % for heptane spray fires and 13.5 % for pool fires at extinction. Since the molar heat capacity of water vapor is midway between nitrogen and carbon dioxide, one would expect water mist and combustion product extinction limits to be between nitrogen and carbon dioxide.

All of the above results are for relatively quiescent conditions. It is well known that at higher strain rates, the oxygen concentration at extinction increases. This phenomenon can most easily be seen in counterflow diffusion flame extinction experiments such as Hamins et al. [35]

Example 5 As part of a hazard analysis of a particular room fire, the composition of the hot layer during fire development has been estimated. The results of the analysis indicate that the following composition represents the highest concentration of fuel gases expected:

Hot layer—700 K, 10 % total hydrocarbons (THC), in the form of CH_2, 2 % CO, 1 % H_2, 15 % CO_2, 2 % O_2, 70 % N_2

Cold layer—300 K, 21 % O_2, 79 % N_2

Will the hot layer burn?

Solution The working equation is Equation 17.6. The first step is to write a balanced chemical equation for stoichiometric burning:

$$0.1\,CH_2 + 0.02\,CO + 0.01\,H_2 + 0.02\,O_2 + 0.7\,N_2 + 0.15\,CO_2 + x(O_2 + 3.78\,N_2) \rightarrow 0.27\,CO_2 + 0.11\,H_2O + (0.7 + 3.78X)N_2$$

We can find x by requiring that both sides of this equation have the same amount of oxygen:

$$\underset{\frac{0.02}{2}}{CO} + \underset{0.02}{O_2} + \underset{0.15}{CO_2} + \underset{x}{air} = \underset{0.27}{CO_2} + \underset{\frac{0.11}{2}}{H_2O} \rightarrow x = 0.145$$

The concentrations in the stoichiometric mixture can be determined from the balanced chemical equation:

$$C_i = \left(\frac{n_i}{n_T}\right) \times 100\%$$

$$n_T = 0.1 + 0.02 + 0.01 + 0.02 + 0.7 + 0.15 + 0.145 + 0.145(3.78) = 1.693$$

$$C_{THC} = \left(\frac{0.1}{1.693}\right) \times 100\% = 5.9\%$$

$$C_{CO} = \left(\frac{0.02}{1.693}\right) \times 100\% = 1.2\%$$

$$C_{H_2} = \left(\frac{0.01}{1.693}\right) \times 100\% = 0.6\%$$

Similarly, the number of moles of products per mole of reactants can be determined from the chemical equation

$$n_p = \frac{[0.27 + 0.11 + 0.7 + 0.145(3.78)]}{1.693} = 0.962$$

This result is lower than typical values of 1–1.1, because the unknown hydrocarbon mixture is taken as CH_2 . This choice is not an error, since CH_2 has been consistently used for the heat release and heat capacity as well. For convenience, we will use constant average specific heats taken from Drysdale: [3]

	C_p (J/mol · K)	C (%)[a]
CO_2	54.3	16.2
H_2O	41.2	6.6
N_2	32.7	77.2

Calculated by the same method as the fuel gas concentrations

$$\begin{aligned} n_p C_p &= n_p \sum \left(\frac{C_i}{100}\right) C_{p,i} \\ &= 0.96[(0.162)(54.3) + (0.066) \\ &\quad \times (41.2) + (0.772)(32.7)] \\ &= 35.3 \text{ J/mol K} \end{aligned}$$

Notice that the average specific heat is near that of nitrogen, since it is the major constituent of the mixture. In calculating T_0 , the initial temperature of the mixture, we will ignore variations in C_p between the hot and cold layers.

$$T_0 = \frac{n_h Th + n_c Tc}{n_h + n_c} \quad n_h + n_c = n_T$$
$$= \frac{(1)(700\ K) + (0.69)(300\ \text{K})}{1.69} = 537\ \text{K}$$

where n_h and n_c are the number of moles originating in the hot and cold layers, respectively. Substituting into Equation 17.5,

$$\sum_{i=1}^{n} \frac{(C_i/100)\Delta H_{c,i}}{C_p(T_{f,SL,i} - T_0)} = \frac{(0.059)(620)10^3}{35.3(1700 - 537)} + \frac{(0.012)(283)10^3}{35.3(1450 - 537)} + \frac{(0.006)(242)10^3}{35.3(1080 - 537)} = 1.07 \tag{17.7}$$

Since the result is greater than one, the hot layer *will* ignite and burn.

Although the approach to the onset of layer burning used in Example 5 has a great deal of generality, it requires a very detailed characterization of the upper and lower layers. It has been shown by Beyler [31] that a much simpler method can be used to evaluate the conditions required for layer burning.

The method [31] is based on the very simple chemical model

$$\text{Fuel} + \text{Oxidizer} \rightarrow \begin{cases} \text{Products} + \text{Excess oxidizer for } \phi < 1 \\ \text{Products} + \text{Excess fuel for } \phi > 1 \end{cases} \tag{17.8}$$

where the equivalence ratio, ϕ, is given by

$$\phi = \frac{\dot{m}_f}{\dot{m}_{air} \cdot r} \qquad r = \left(\frac{m_f}{m_{air}}\right)_{\text{Stoichiometric}} \tag{17.9}$$

According to this model, the fuel mass fraction in the upper layer is

$$\begin{aligned} Y_f &= 0 && \text{for } \phi < 1 \\ Y_f &= \frac{1 - 1/\phi}{1 + 1/\phi r} && \text{for } \phi > 1 \end{aligned} \tag{17.10}$$

Equation 17.6 can be expressed on a mass basis for this application as

$$\frac{Y_f \Delta H_c}{m_p C_p (T_{SL} - T_0)} \geq 1 \tag{17.11}$$

where ΔH_c is the heat of combustion of the fuel, and m_p is the mass of products resulting from burning a unit mass of upper layer gases.

Substituting the $\phi > 1$ relationship for Y_f into Equation 17.6, expressing the heat release in terms of oxygen consumed using

$$\Delta H_c = \frac{\Delta H_{O_2} Y_{O_2}}{r} \tag{17.12}$$

and recognizing that

$$m_p = 1 + \frac{Y_f}{r} \tag{17.13}$$

Yields

$$\left(\frac{1 - 1/\phi}{1 + r}\right)\left[\frac{\Delta H_{O_2} Y_{O_2}}{C_p(T_{SL} - T_0)}\right] \geq 1 \tag{17.14}$$

Equation 17.14 can be solved for the equality condition to give the equivalence ratio at which layer burning begins, ϕ_{ig},

$$\phi_{ig} = \frac{k}{k - r - 1} \tag{17.15}$$

where

$$k = \frac{\Delta H_{O_2} Y_{O_2}}{C_p(T_{SL} - T_0)}$$

T_0 is the precombustion temperature resulting from stoichiometric mixing of the air and fuel streams. Here, the upper layer contains the fuel and the lower layer contains the air. T_0 can be expressed as

$$T_0 = \frac{T_u + (Y_f/r)T_l}{1 + Y_f/r} \tag{17.16}$$

Using Equations 17.15 and 17.16, a relationship between the critical ignition equivalence ratio and the layer temperatures can be developed. Using normal values for the semi-universal constants, $\Delta H_{O_2} = 13.4$ MJ/kg, $C_p = 1.1$ kJ/kg K, $T_{SL} = 1700$ K. Using air properties for the lower layer, $Y_{O_2} = 0.233$ and $T_l = 300$ K. Using a typical $r = 0.07$ yields the relationship between ϕ_{ig} and T_u shown in Fig. 17.15. The results shown in Fig. 17.15 are consistent with the measurements of Beyler [31], where ϕ_{ig} was found to be 1.7 for T_u of 500–600 K. Gottuk [36] found that external burning was first observed in flashes at $\phi = 1.4 \pm 0.4$, and sustained external burning was first observed at $f = 1.9 \pm 0.3$ when T_u was in the range 900–1100 K. While in Gottuk's [36] experiments it was difficult to observe burning at the layer interface due to soot deposits on the viewing ports, layer interface burning was

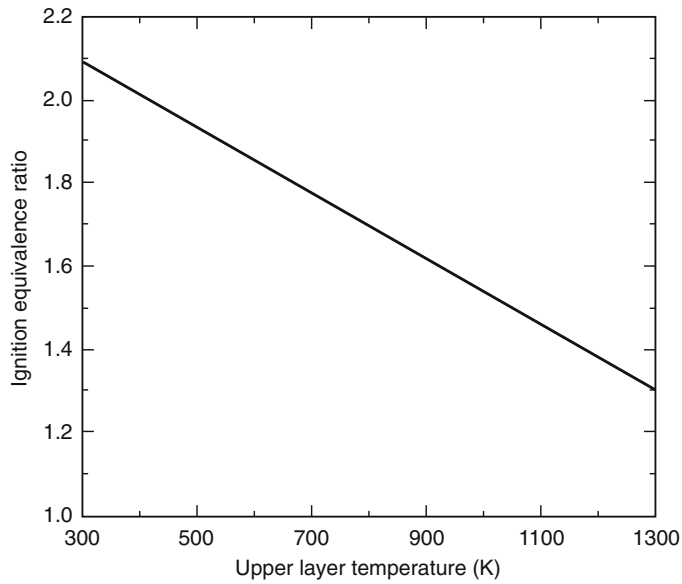

Fig. 17.15 Equivalence ratio required for upper layer ignition as a function of the upper layer temperature determined using Equations 17.15 and 17.16 with typical properties. Using normal values for the semi-universal constants, $\Delta H_{O_2} = 13.4$ MJ/kg, $C_p = 1.1$ kJ/kg K, $T_{SL} = 1700$ K. Using air properties for the lower layer, $Y_{O_2} = 0.233$, $T_l = 300$ K. Using a typical $r = 0.07$ yields the relationship between ϕ_{ig} and T_u

generally observed shortly after the initiation of flashes in the exhaust. Because the exhaust flow was isolated from the inflow in the experiment, there is some issue of the availability of a pilot flame which does not arise in normal two-directional vents found in most fires. Thus, Gottuk's work is generally consistent with Fig. 17.15.

Oxygen Index Test Method

The original oxygen index test method, used to determine the oxygen index of liquid and gas fuels, utilizes a counterflow diffusion flame formed at the stagnation region of a porous cylinder or sphere through which fuel vapors are fed. A low-velocity oxidant stream passes over the porous body. This arrangement yields the most favorable aerodynamic conditions for flame stabilization. As such, fuel and oxidant streams that can burn in the low-velocity counterflow system may not burn under less favorable aerodynamic conditions characterized by higher velocities and shear.

It is also important to point out the difference between the oxygen index as measured for gas and liquid fuels and the oxygen index of solids as measured using a candle-type test [37, 38]. The oxygen indexes of the gas and liquid fuels as tested by Simmons and Wolfhard [29] were governed by gas-phase effects. In the American Society for Testing and Materials test [33] for solids, the extinction can be caused by gas- and solid-phase effects. As such, the oxygen index of a solid fuel is not directly relevant to gas-phase diffusion flame limits and should not be used to calculate adiabatic flame temperature at the limit for use in the expressions presented here.

Nomenclature

AIT	Autoignition temperature (C or K)
C	Concentration (volume percent)
Cp	Heat capacity (J/kg K)
LFL	Lower flammable limit (volume percent)
M	Mass (kg)
n	Moles
NP	Nitrogen point
OI	Oxygen index
r	Stoichiometric fuel/air ratio
SL	Stoichiometric limit (volume percent)
T	Temperature (C or K)
V	Volume (m^3)
X	Mole fraction
Y	Mass fraction
ΔH_c	Heat of combustion (J/kg)
ϕ	Equivalence ratio

Subscripts

C	Combustion
i	Species
ig	Ignition
f	Flame or fuel
l	Lower layer
L	Liquid or lower limit
m	Mixture
N	Nitrogen
O	Initial or ambient
p	Products of combustion
u	Upper layer
U	Upper limit

Ignition of Liquids

18

D.D. Drysdale

Introduction

The purpose of this chapter is to discuss the ignition characteristics of combustible liquids that are in widespread use as fuels and solvents and are encountered as process fluids in the chemical and process industries. Ignition leads to flaming combustion in which the fuel undergoes a change of state and is converted from liquid to vapor.

Unlike the flaming combustion of solid fuels, this conversion does not involve any chemical change to the fuel molecules that simply evaporate from the exposed surface.[1] The flammable vapors mix with air to burn as a diffusion flame. When combustible solids exhibit flaming combustion, the change of state from solid to vapor involves chemical decomposition (see Chap. 7). Unlike liquids for which the process of evaporation is reversible (the evolved vapors can be converted back to the original liquid by cooling or by compression), the conversion is irreversible, breaking down the large polymeric molecules of which the solid is composed into fragments that are small enough to vaporize and enter the gas phase. Some solids, such as the thermoplastics (e.g., polypropylene and polystyrene), first soften and liquefy before producing molecular fragments that are small enough to vaporize. Others such as wood do not liquefy but release gases and vapors directly leaving behind an involatile carbonaceous char that, if permitted to do so, will undergo surface oxidation (smoldering) at a much slower rate. As a general rule, fires involving combustible liquids are associated only with flaming combustion, but there are exceptions that will be discussed later.

The underlying physics of the vaporization process for liquids provides a relatively simple key to understanding the conditions under which liquids can be ignited. The vapors from combustible liquids are flammable and exhibit exactly the same properties and behavior as the common flammable gases such as methane and propane (see Chap. 17). Thus, we can identify flammability limits, autoignition temperatures, minimum ignition energies, quenching distances, and so on. Of these, the most important are the flammability limits. If the concentration of vapor above a liquid surface is below the lower flammability limit, then the vapors cannot be ignited, flame will not propagate through the vapor-air mixture, and the liquid will not "burn." The limiting condition of the liquid at which the vapors are at the lower flammability limit is known as the flashpoint. Experimentally, this can be measured in a closed cup apparatus in which the vapor-air mixture in the closed volume above the surface (the "headspace") is at equilibrium with the liquid—the vapor will be at a pressure (the

[1] There are exceptions to this generalization. High molecular weight liquids with high flashpoints (e.g., cooking oil, flashpoint 321 °C) will be undergoing some chemical decomposition at temperatures associated with vapor formation.

DOI 10.1007/978-1-4939-2565-0_18, © Society of Fire Protection Engineers 2016

saturation vapor pressure) that is defined by the temperature of the liquid. This "closed cup flashpoint" provides us with a relatively simple method of ranking flammable liquids according to the hazard they present in everyday use. In principle, the concept of flashpoint can also be applied to combustible solids, but because the phase change (solid to vapor) is irreversible there is no corresponding simple method for classifying solids according to their ignition hazard. The ignition of solids depends on a large number of factors including the physical form of solid and the mode and intensity of the heat transfer process. Such issues are discussed in Chap. 21.

For combustible liquids, the flashpoint is closely linked to the flammability limits of the vapor. If the liquid is in an unconfined cup or present as a pool, the minimum liquid temperature at which the vapors can be ignited and burn is found to be higher than the "closed cup flashpoint" as defined above and is called the "open cup flashpoint." The reason for this is simply that the vapors will diffuse away from the liquid surface and for successful ignition from a "pilot" (a small flame or a spark) the pilot must be located in a region where the mixture is flammable. In general, a higher liquid temperature is required to ensure that the pilot is in a flammable zone. However, the "flash" of flame that occurs as flame propagates through the flammable mixture is not necessarily followed by sustained burning of the liquid. A criticality must be exceeded before this will occur. It is only then that the liquid can properly be said to have been ignited to flaming combustion. This is known as the firepoint, which will be discussed in a later section entitled "Measurement of Flashpoint and Firepoint."

Vaporization of Liquids

The liquids of general interest to the fire protection engineer are those that are stable at normal atmospheric temperatures and pressures (say, 10–30 °C and 101.3 kPa). These include common liquid fuels (such as gasoline and kerosene), many solvents (e.g., acetone, diethyl ether, etc.), some paints and varnishes, and so on. Most are blends, but for convenience and clarity in the following discussion, a one-component system (such as pure *n*-hexane) will be considered.

The classic phase diagram for a one-component system is shown schematically in Fig. 18.1. The variables are pressure and temperature and the so-called "phase space" is divided into three areas corresponding, respectively, to solid, liquid, and gas (vapor). For a pure compound at constant pressure (illustrated by the horizontal dashed line) we can identify the melting point (T_M) and the boiling point (T_B), which are uniquely defined at any given pressure. The values quoted in the literature refer to normal atmospheric pressure. The upper pair of lines that intersect at the point T in Fig. 18.1 represent equilibrium states between solid and liquid and between liquid and vapor, respectively.[2]

The line (TC) defines how the vapor pressure of the liquid varies with temperature. Thus, for *n*-hexane at normal atmospheric pressure, $T_B = 69$ °C, which corresponds to the temperature at which the (saturated) vapor pressure is 101.3 kPa. The variation of boiling point with pressure is best illustrated using pure water as the example. At sea level (101.3 kPa) it has a boiling point of 100 °C, but, as with all other liquids, this point decreases with elevation. In Banff, Scotland (at sea level), water boils at 100 °C but in Banff, Alberta (elevation 1463 m), it boils at about 95 °C. On the summit of Mount Everest (8848 m) where the pressure is approximately 33 kPa, or one-third of the value at sea level, it boils at about 72 °C. As will be seen, the flashpoints of combustible liquids also change with a change of atmospheric pressure but for a subtly different reason, as will be discussed later.

On the phase diagram, temperature and pressure may be varied independently provided that only one phase is present: there are two degrees

[2] The third line in Fig. 18.1, below the intersection at T, represents the equilibrium states between solid and vapor. Solid converts directly to vapor by the process of sublimation. It will not be considered further here.

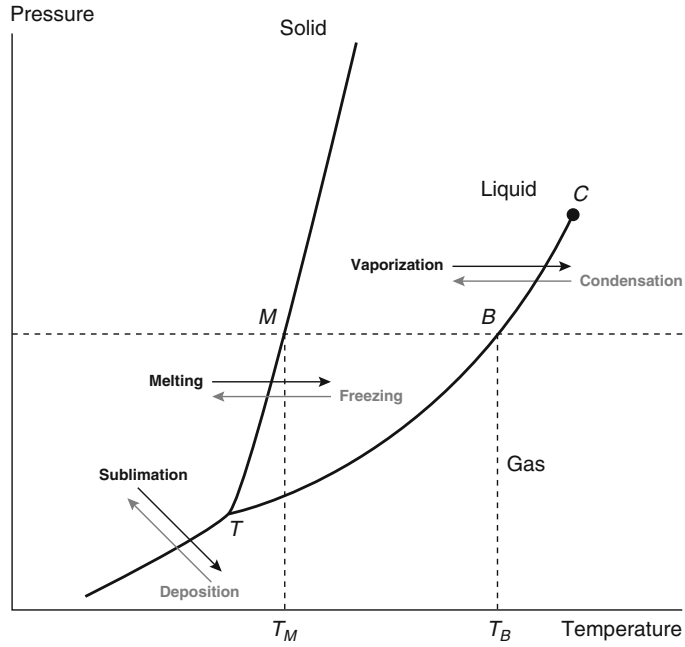

Fig. 18.1 Typical phase diagram for a one-component system. Points on the curve TC correspond to the equilibrium ("saturated") vapor pressure of the liquid, as given in Equation 18.3. T is the "triple point" and C defines the critical temperature and pressure (Table 18.1)

of freedom (i.e., independent variables), which in this case are temperature and pressure. Thus, a gas can be compressed and heated at the same time and still remain a gas (no change in state). The ideal gas law encapsulates this in the equation

$$PV = n\mathrm{R}T \tag{18.1}$$

where
P = Pressure
V = Volume
T = Temperature (K)
n = Number of moles of gas present (mass divided by the molecular weight)
R = Ideal gas constant[3]

However, when two phases are present and in equilibrium, corresponding to a point on one of the lines on the phase diagram, then P and T cannot be varied independently without changing the number of phases present. For example, at point B, liquid and vapor are in equilibrium, with the saturated vapor pressure of n-hexane equal to 101.3 kPa (760 mmHg, or 1 bar) at 69 °C. If we increase the temperature, the resulting vapor pressure is defined by the line BC and (unless atmospheric pressure is increased in step) complete conversion of liquid to vapor will occur, and the number of phases present is reduced from two to one as expressed in Gibbs's phase rule:

$$F = c - p + 2 \tag{18.2}$$

where f is the number of degrees of freedom (independent variables), c is the number of components, and p is the number of phases present (e.g., see Moore [2] and Atkins and de Paula [3]). For the one-component system (e.g., pure n-hexane), $c = 1$, so that when $p = 2$ (liquid *and* vapor present) the number of degrees of freedom $f = 1$. That is, we can change either the temperature or the pressure, but we cannot change them independently without changing the number of phases present. (Note that the intersection of the three lines on the phase diagram marked T is known as the triple point, where the three phases are in equilibrium; that is, $p = 3$. The number of degrees of freedom is, therefore, zero so that this point is uniquely defined.)

In summary, the lines that divide the phases in Fig. 18.1 represent equilibrium states: the line

[3] The numerical value of R depends on the units used for P and V (see Chap. 5).

Table 18.1 Critical temperatures and pressures [1]

	Normal boiling point (°C)	Critical temperature (°C)	Critical pressure (bar)
Hydrogen (H_2)	−252.9	−240	13
Nitrogen (N_2)	−195.8	−146.9	34
Oxygen (O_2)	−183.0	−118.5	50.5
Methane (CH_4)	−164	−82.3	46.5
Ethane (C_2H_6)	−88.6	32.2	48.3
Propane (C_3H_8)	−42.1	96.6	42.5
n-Butane (*n*-C_4H_{10})	−0.5	152.3	37
n-Hexane (*n*-C_6H_{14})	69	234.5	29.9

that separates the liquid and gaseous phases defines how the saturated vapor pressure of the liquid varies with temperature. However, this line does not continue indefinitely but ceases at the critical point marked *C*. At temperatures and pressures above the critical point, only one phase exists—the distinction between the liquid and gas disappears. Some values of critical temperatures and pressures are given in Table 18.1. A gas such as propane (boiling point −42 °C) is below its critical temperature at ambient temperatures and can be liquefied by pressurization. However, the so-called "permanent gases," which include oxygen and nitrogen, are above their respective critical temperatures and cannot exist as liquids at ambient temperature (e.g., 25 °C) regardless of the pressure. They are stored under pressure as gases in cylinders, typically at 140 bar. A single phase then exists within the cylinder. The only way that a permanent gas can be stored as a pressurized liquid is to cool it below its critical temperature. Large quantities of natural gas (mainly methane) can be stored economically as a refrigerated (cryogenic) liquid: its critical temperature is −82.3 °C and its normal boiling point is −164 °C as given in Table 18.1.

If a liquid is in an enclosed space, such as a can, tank, or bottle, the vapor will be contained within the headspace and quickly reach equilibrium (i.e., the saturated vapor pressure will be reached). This value is predicted in the phase diagram and is a function of temperature (see Equations 18.3, 18.4, and 18.5). It represents a dynamic state in which vaporization continues but at a rate that is balanced exactly by condensation of vapor back to the liquid state (see Fig. 18.1). For this reason, if the liquid is unconfined (e.g., forming a pool in the open), the liquid will eventually undergo complete evaporation as vapor continuously diffuses away from the surface of the liquid. Consequently, the vapor pressure at the surface will be less than the saturated vapor pressure and equilibrium cannot be achieved. The rate of mass loss by evaporation will be determined by the temperature of the liquid, the exposed area of the pool, and any air movement over the liquid surface (see, for example, Wade [4] and Clancy [5]). Boiling occurs when the vapor pressure is equal to atmospheric pressure, as discussed above.

However, if the liquid is in a closed (sealed) container capable of withstanding high internal pressures, the two phases (liquid and vapor) will remain in equilibrium at temperatures well above the atmospheric boiling point. Thus, propane and butane (which have normal boiling points of −42.1 °C and −0.5 °C, respectively) can be stored as liquids at 25 °C at 9.6 bar and 2.3 bar (957 and 231 kPa), respectively, in appropriate pressure vessels. These pressures correspond to the saturated vapor pressures of these two hydrocarbons at 25 °C. The reduction in volume associated with condensation is very large, making liquefaction a particularly effective means of storing these and similar gases. They can be liquefied simply by compression, although this is not possible with the so-called permanent gases, as discussed above.

Clearly, methane, propane, and butane cannot exist as stable liquids at normal temperatures and pressures. If liquefied methane (at −163 °C) is

released from a refrigerated tank and spilled on the ground, it will form a pool and boil vigorously until the surface of the ground has cooled to about −163 °C. Thereafter, it will behave as a stable liquid, evaporating at a rate dictated by the rate of heat transfer from the ground (see Thyer [6]).

Although methane is much lighter than air at ambient temperature, the vapor that evolves from the pool will be initially at −163 °C and much denser than the surrounding air. Consequently, it will spread horizontally until it gains sufficient heat from the surroundings to regain its buoyancy. Although propane is sometimes stored as a cryogenic liquid, propane and butane are more commonly stored in pressure vessels. Catastrophic release due to vessel failure gives rise to a BLEVE (boiling liquid expanding vapor explosion), a term originally coined for a pressure burst of a boiler containing superheated water (see Chap. 66). (It is defined by the Centre for Chemical Process Safety as "an explosion resulting from the failure of a vessel containing a liquid at a temperature significantly above its boiling point at normal atmospheric pressure." [7]) The liquid boils throughout its volume once the pressure is released and a substantial quantity will convert to vapor. The heat of vaporization is taken from the remaining liquid so that the BLEVE produces a vapor cloud containing a significant proportion of the original mass as liquid droplets. These may fall to the ground, although if ignition occurs (as it will if the pressure burst has been the result of exposure of the vessel to fire), there will be a fireball that will burn out rapidly (see, for example, Abbassi and Abbassi [8]).

Calculation of Vapor Pressure

If the space above the liquid is enclosed (as in a bottle or other container), evaporation will take place until the vapor pressure reaches its saturation value. This equilibrium is described by a form of the Clapeyron-Clausius equation, which gives the saturated vapor pressure (p°) as a function of the temperature of liquid (T K).

$$\frac{d(\ln p^\circ)}{dT} = \frac{L_v}{RT^2} \tag{18.3}$$

where L_v is the latent heat of evaporation of the liquid (kJ/kg) and R is the ideal gas constant. The derivation of this expression requires a number of approximations and may be found in most texts on physical chemistry [2, 3]. Integration of the equation gives the vapor pressure as a function of temperature; thus,

$$p^o = \text{Cexp}[-L_v/\text{R}T] \tag{18.4}$$

or

$$\ln p^\circ = \ln C - \frac{L_v}{\text{R}T} \tag{18.5}$$

A plot of ln p° versus $1/T$ will be a line of slope $-L_v$/R, although it is not strictly linear over an extended temperature range. However, it may be assumed to be linear within the range of temperatures with which we are concerned (i.e., we can assume that L_v is constant). Values of L_v for a range of liquids are given in Table 18.2.

The expression for vapor pressure is normally given in the form shown in Equation 18.5. The 53rd edition of the CRC *Handbook of Chemistry and Physics* [13] (and perhaps some later editions) gives an extensive table of data on p° (T), but in a modified form as follows:

$$\log_{10} p^o = -0.2185\frac{A}{T} + B \tag{18.6}$$

where p° is given in mmHg. Values of A and B for some typical liquid fuels are given in Table 18.3 (converting the data from $\log_{10}$ to $\log_e$ [i.e., ln] and from mmHg to kPa is a hazardous process that has not been attempted here). Vapor pressures may also be calculated from data in Yaws [12].

Example 1 Using the data in Table 18.3, calculate the pressure in a cylinder containing liquid isobutane at 25 °C. How can you determine how much fuel remains in the cylinder after drawing gas from it for a period of time?

Solution For isobutane, $A = 5416.2$ K and $B = 7.349085$. $T = 25 + 273$ K $= 298$ K. Substituting these values in Equation 18.4 gives

Table 18.2 Selected ignition properties of some fuels in air[a]

n-Dodecane ($C_{12}H_{26}$)	11,857.7	8.150997

Data for Equation 18.5 [13]

$\log_{10}(p^o) = 3.378$, or $p^o = 2386.7$ mmHg, or 3.14 bar. If the temperature remains 25 °C, this pressure will remain unchanged for as long as there is any liquid isobutane left in the container. Pressure is no guide to the amount of isobutane remaining. The only way to determine how much liquid is left is to weigh the container, assuming that you know the tare.

Example 2 Calculate the normal boiling point of *n*-hexane from the data in Table 18.3, assuming the atmospheric pressure is 760 mmHg.

Solution Take $p^o = 760$ mmHg, so that $\log_{10}(760) = 2.881$. For *n*-hexane, $A = 7627.2$ K and $B = 7.717119$, so by substitution and rearrangement:

$$2.881 = -0.2185\frac{7627.2}{T} + 7.717119$$

$$4.836T = 1666.543$$

$$T = 344\,\text{K} = 71.6^\circ\text{C}$$

which is about 2 K higher than the measured value quoted in Table 18.2.

Example 3 Calculate the temperature at which the vapor pressure of *n*-decane corresponds to the lower flammability limit for *n*-decane vapor. Assume that this vapor pressure is 0.75 % by volume (Table 18.3) and that the atmospheric pressure is 760 mmHg.

Solution The vapor pressure corresponding to the lower flammability limit of *n*-hexane is 0.75 % of 760 mmHg, or 5.7 mmHg. The calculation is exactly the same as for the previous example, except that $\log_{10}(p^\circ) = \log_{10}(5.7) = 0.756$. Thus

$$0.756 = -0.2185\frac{10,912.0}{T} + 8.24809$$

$$7.4922T = 2384.272$$

$$T = 318.2\,\text{K} = 45.2^\circ\text{C}$$

The closed cup flashpoint of *n*-decane is given in Table 18.2 as 317 K, or 44 °C. Sources of the difference between the calculated flashpoint and that measured in a standard test will be discussed below.

Vapor Pressure of Liquid Blends

Most commonly encountered fuels are in fact blends of different compounds. Gasoline, for example, contains several hundred individual hydrocarbons including a significant proportion of aromatics. The total vapor pressure is the sum of the partial vapor pressures of the individual components, which in turn depend on the concentration of the individual components in the blend. To illustrate how the vapor pressures of the components may be calculated, consider a mixture of two hydrocarbon liquids, A and B. At a given temperature, the partial vapor pressures of components A and B are given by Raoult's Law [2, 3]:

$$p_A = x_A p_A^o \quad p_B = x_B p_B^o \tag{18.7}$$

where x_A and x_B are the mole fractions of A and B, respectively, given by

$$x_A = \frac{n_A}{n_A + n_B} \quad x_B = \frac{n_B}{n_A + n_B} \tag{18.8}$$

and n_A and n_B are the number of moles of A and B present (i.e., the mass of the component present divided by its molecular weight).

Suppose that A and B are *n*-hexane and *n*-decane, respectively, and the mixture is at a temperature of 25 °C. These hydrocarbons form an "ideal mixture" in that the molecules of A and B are so similar that they do not interact with one another, either physically or chemically

(i.e., the interactions between A and B are no different from the interactions between A and A, or B and B).

As an example, consider a mixture containing 5 % hexane (by mass) in *n*-decane. Would its flashpoint be above or below 25 °C? (The flashpoints of *n*-hexane and *n*-decane are −29 °C and 44 °C, respectively.) This can be ascertained by calculating the partial vapor pressures of the two components at 25 °C and using Le Chatelier's Principle (see Chap. 17) to discover if the total vapor pressure ($p_{\text{total}} = p_{n\text{-hexane}} - p_{n\text{-decane}}$) is above or below the lower flammability limit. The principle states that a mixture of flammable vapors in air will be at the lower flammability limit if

$$\sum_i \frac{l_i}{L_i} = 1 \tag{18.9}$$

where l_i is the percentage composition (molar proportion) of component i in the vapor-air mixture and L_i is the corresponding value for the lower flammability limit of component i. To calculate the equilibrium partial vapor pressures of *n*-hexane and *n*-decane above a 5 % hexane/95 % *n*-decane mixture (*by mass*), the respective mole fractions must be calculated; thus,

$$\begin{aligned} x_{n-\text{hexane}} &= \frac{0.05/MW_A}{0.05/MW_A + 0.95/MW_B} \\ x_{n-\text{decane}} &= \frac{0.95/MW_B}{0.05/MW_A + 0.95/MW_B} \end{aligned} \tag{18.10}$$

where the molecular weights are $MW_A = 86$ and $MW_B = 142$. According to Equation 18.6 and Table 18.3, the partial pressures of *n*-hexane and *n*-decane are 10.66 mmHg and 1.65 mmHg, respectively. Using Equation 18.8 with $L_{n\text{-hexane}} = 1.2$ % and $L_{n\text{-decane}} = 0.75$ % (see Table 18.2),

$$\frac{10.66/760}{0.012} + \frac{1.65/760}{0.0075} = 1.46 \tag{18.11}$$

indicating that the mixture is above the lower flammability limit at 25 °C (i.e., the flashpoint of this mixture is below 25 °C).

Example 4 Determine by calculation whether *n*-decane containing 1 % *n*-pentane (*by volume*) would be classified as a Class 1C or a Class II flammable liquid according to the NFPA Standard. [14] (This is equivalent to posing the question, "Is the flashpoint above or below 37.8 °C?")

Solution This calculation is identical to that discussed previously, but the densities of the two liquids must be taken into account and the calculation carried out at 37.8 °C. The mixture can be taken as 0.01 × 626 kg of *n*-pentane + 0.99 × 730 kg of *n*-decane (where the densities of *n*-pentane and *n*-decane are 626 kg/m^3 and 730 kg/m^3, respectively). The mole fractions are

$$\begin{aligned} x_{n-\text{pentane}} &= \frac{(0.01 \times 626)/MW_A}{(0.01 \times 626)/MW_A + (0.99 \times 730)/MW_B} \\ x_{n-\text{decane}} &= \frac{(0.99 \times 730)/MW_B}{(0.01 \times 626)/MW_A + (0.99 \times 730)/MW_B} \end{aligned} \tag{18.12}$$

where now $MW_A = 72$ (the molecular weight of pentane) and $MW_B = 142$. These give $x_{n\text{-pentane}} = 0.0141$ and $x_{n\text{-decane}} = 0.986$. From Equation 18.6 and Table 18.3, the saturated vapor pressures of *n*-pentane and *n*-decane at 37.8 °C are 713.11 mmHg and 3.773 mmHg, respectively, so that the partial pressures are 10.05 mmHg and 3.72 mmHg. Applying the Le Chatelier Principle (with the lower flammability limit of *n*-pentane vapor as 1.4 %),

$$\sum_i \frac{l_i}{L_i} = \frac{10.05/760}{0.014} + \frac{3.72/760}{0.0075} = 1.6 \tag{18.13}$$

This is above the lower flammability limit and, consequently, the mixture has a flashpoint below 37.8 °C and is definitely not a Class II liquid. (Further calculation could be carried out to ascertain if the mixture is Class IB or IC; see below.)

This calculation reveals that the partial vapor pressure of the more volatile component can be disproportionately high and for this reason it will evaporate from the mixture much more rapidly than the less volatile component. Consequently, care must be taken when determining the flashpoints of such mixtures. The liquid to be tested should be kept in a closed container and a sample transferred to the flashpoint apparatus as quickly as possible to minimize evaporative loss. In some circumstances, it might be wise to refrigerate the liquid and chill the apparatus. The author has experience of assessing the flashpoint of a sample of crude oil that (without refrigeration) gave a flashpoint of 28 °C, but a flashpoint of 15 °C occurred if the liquid (and the apparatus) was cooled to 0 °C before opening the sample container. (The problem of evaporative loss is also encountered in the more extreme example of trying to identify traces of gasoline or other flammable liquids that may have been used in an arson attack.)

In the examples discussed above, the vapor pressure of liquid mixtures was calculated using Raoult's Law (Equation 18.7), which applies only to ideal mixtures such as blends of hydrocarbons. It is important to note that many other liquid mixtures, such as alcohol and water, are not ideal as there is some interaction between the molecules of the different components (*A* and *B*). Instead of Equation 18.7, it is necessary to use Equation 18.14:

$$p_A = \alpha_A p_A^o \qquad p_B = \alpha_B p_B^o \tag{18.14}$$

where α_A is known as the activity of component *A* in the mixture, and $p_A{}^o$ is the saturation vapor pressure of pure *A*, and so on. The activity coefficient α_A is the product of the mole fraction of *A* (Equation 18.15) and the activity coefficient γ_A:

$$\alpha_A = \gamma_A n_A \qquad \alpha_B = \gamma_B n_B \tag{18.15}$$

where γ_A is the activity coefficient of component *A* in the mixture (note that for a pure liquid, $\gamma = 1$). For a two-component mixture of *A* and *B*, the activity coefficients are given by the Van Laar equations:

$$\log_{10}\gamma_A = \frac{C_A}{[1 + (C_A x_A / C_B x_B)]^2}$$
$$\log_{10}\gamma_B = \frac{C_B}{[1 + (C_B x_B / C_A x_A)]^2} \tag{18.16}$$

Table 18.4 Examples of data for the Van Laar equation for binary (two-component) systems [15]

Component A	Component B	C_A	C_B
Ethanol	Water	0.67	0.42
Methanol	Water	0.25	0.20
Acetone	Water	0.89	0.65
n-Heptane	CCl_4	0.2164	0.0618

Essentially the same set of calculations can be carried out to establish the flammability properties of nonideal mixtures, but the activity coefficients (Equations 18.15 and 18.16) must be calculated from Equations 18.16 using data such as those contained in Table 18.4.

Another more general data set than that given in Table 18.4 is given by Babrauskas [16].

Effect of Atmospheric Pressure on Flashpoint

The calculations that are provided above all refer to the standard atmosphere at sea level where the pressure is 101.3 kPa (760 mmHg), conventionally normalized as 1 bar. If the atmospheric pressure changes, this change has no significant effect on the vapor pressure, which is a function of the temperature of the liquid. At a constant temperature but a reduced pressure, the vapor-air ratio in the headspace will be increased (i.e., it will become richer in fuel). This has significant consequences for liquid fuels because it will reduce the flashpoint.

Consider the following argument. In Example 3, the temperature at which the saturated vapor pressure of *n*-decane corresponds to the lower flammability limit was shown by calculation to be 45.2 °C, which compares well with the measured value of the closed cup flashpoint (44 °C). At 45.2 °C, the vapor pressure was

assumed to be 5.7 mmHg, which is 0.75 % of normal atmospheric pressure (760 mmHg). If the temperature remains the same (45.2 °C) but the pressure is reduced—say to the value appropriate to Denver, Colorado (at 1 mile high, 631 mmHg)—then the volumetric concentration of *n*-decane vapor in air becomes 5.7/631 = 0.009, or 0.9 %. It has been shown that the lower flammability limit is remarkably insensitive to a reduction in pressure until it falls below 200–300 mmHg (27–40 kPa) [17, 18]. Clearly, at 45 °C the saturated vapor pressure of *n*-decane is above the lower flammability limit. The effect on the flashpoint can be shown in the following example.

EXAMPLE 5 Calculate the flashpoint of *n*-decane if measured in Denver, Colorado, where the atmospheric pressure is 631 mmHg. Assume that the lower flammability limit of *n*-decane vapor is 0.75 %.

SOLUTION The vapor pressure corresponding to the lower flammability limit of *n*-hexane is 0.75 % of 631 mmHg, or 4.73 mmHg. The calculation is exactly the same as in Example 3, except that $\log_{10}(p^\circ) = \log_{10}(4.73) = 0.675$. Thus,

$$0.075 = -0.2185\frac{10,912.0}{T} + 8.24809$$

$$7.573T = 2384.272$$

$$T = 314.8\,\mathrm{K} = 41.8^\circ\mathrm{C}$$

The value obtained in Example 3 at normal atmospheric pressure was 45.2 °C. The difference is not insignificant and could be very important for liquids close to the boundary between two classifications (see later discussion). The issue becomes more significant at higher altitudes such as Mexico City (2240 m) and Lhasa in Tibet (3650 m). In these cities, the flashpoint of *n*-decane would be approximately 39.4 °C and 35.9 °C, respectively.

An interesting consequence of this relates to the headspace in the fuel tanks of aircraft. The kerosene grades of commercial aviation fuel have closed cup flashpoints in the range of 35–63 °C [19], as measured at sea level. As an aircraft gains altitude after takeoff, the air pressure in the headspace will fall relatively rapidly, while the fuel will cool rather slowly. There is the potential for the vapor-air mixture in the headspace to become flammable. On long-haul flights, of course, the hazard will be relatively short-lived as the fuel loses heat and cools to below the local flashpoint, relevant to the pressure at cruising altitude. This phenomenon is discussed in NFPA's *Fire Protection Handbook* [19].

Measurement of Flashpoint and Firepoint

There are a number of standard tests available for measuring the closed cup [20, 21] and open cup [22, 23] flashpoints (Fig. 18.2). The former measurement is directly related to the lower flammability limit of the fuel vapor and is used to classify liquids according to their ignition hazard [18]. Its relationship to equilibrium vapor pressure of the liquid is discussed in an earlier section.

Closed Cup Flashpoints

In the closed cup test, such as the Pensky-Martens apparatus [20] and the Tag tester [21], the flammability of the saturated (equilibrium) vapor-air mixture in the space above the liquid surface (i.e., the headspace) is tested by introducing a small pilot flame (see Fig. 18.2). The apparatus is designed to allow the miniature explosion within the headspace to vent through an aperture that is opened to admit the pilot ignition source, which also allows the "flash" of flame to be observed. The procedure involves raising the temperature of the liquid slowly from approximately 10–20 K below the anticipated flashpoint at a rate of 5–6 K/min, introducing the ignition source at intervals corresponding to about a 1 °C (1 K) temperature rise. The slow rate of heating is intended to allow enough time for equilibrium conditions to be

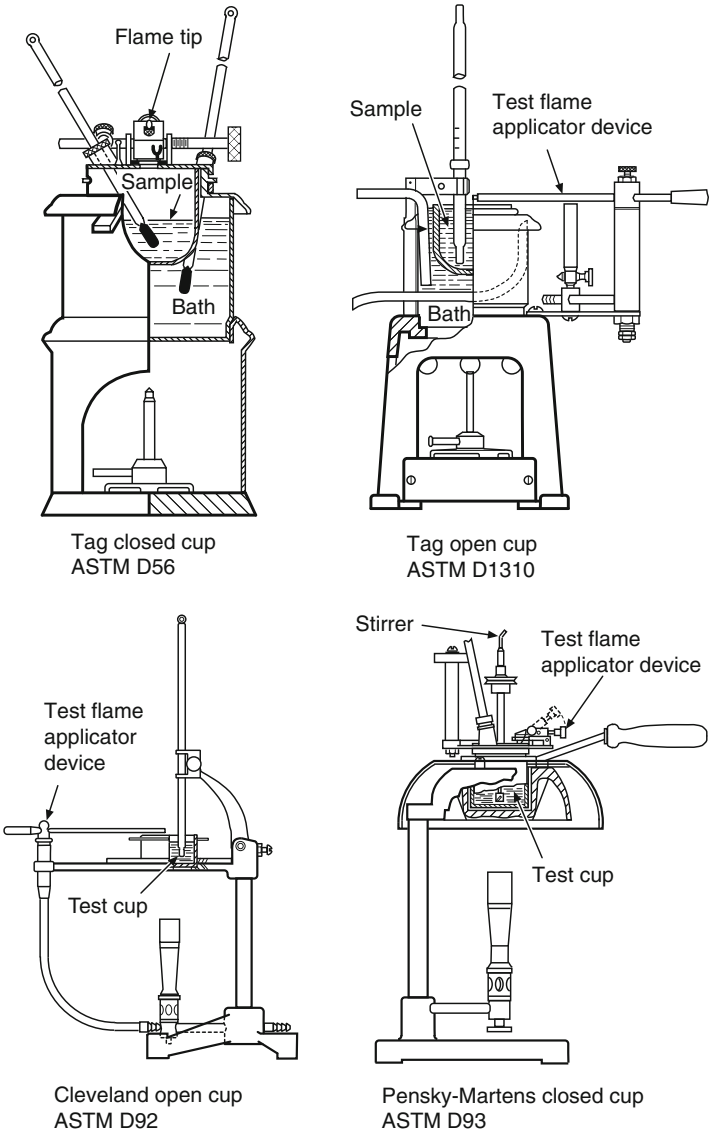

Fig. 18.2 Four of the commonly used apparatuses for determining flashpoints of flammable or combustible liquids [19]

reached within the headspace (see below). The lowest temperature at which a flash of flame is observed is recorded as the closed cup flashpoint. It is expected that it can be determined to an accuracy of better than ±1 °C for liquids with flashpoints below 100 °C. Values of the closed cup flashpoint for a range of liquids are given in Table 18.2. All refer to standard atmospheric pressure (101.3 kPa). If the closed cup flashpoint is measured when the atmospheric pressure differs from 760 mmHg, the value may be corrected using Equation 18.17:

$$\text{Corrected flashpoint} = T - 0.033\,(760\ - P) \tag{18.17}$$

where T is the measured flashpoint (°C) and P is the ambient atmospheric (barometric) pressure (mmHg). This is intended for relatively small excursions that are commonly experienced on a day-to-day basis. No guidance is given that is relevant to high-altitude locations.

In general, there is reasonable but not exact agreement between measured values and those calculated on the basis that the vapor pressure

must correspond to the lower flammability limit. The reason for this may be that the lower flammability limit is based on the ability of a flame to propagate approximately 75 cm inside a vertical tube, 5 cm in diameter [24], whereas the flashpoint is observed as a localized ignition in the vicinity of the ignition source. Similar localized ignition occurs in the flammability limit apparatus but at a concentration of fuel in air that sustains only limited flame propagation. If this explanation is accurate, the "calculated" flashpoint would be expected to be greater than the measured one—as indeed the calculation above shows (Example 3).

Care should be taken when testing liquids of reduced flammability, such as certain chlorinated hydrocarbons. James and Tyler [25] investigated reports of fire and explosions that involved a commercial cleaning fluid, of which the principal component was methyl chloroform (1,1,1 trichloroethane, CCl_3CH_3). This compound does not give a flashpoint in the standard test, but a flashpoint of 12 °C was recorded in vessels of diameter greater than 12.4 cm [26]. Babrauskas [16] draws attention to a problem with blends containing halogenated components. If these are of high volatility, the blend may give a high flashpoint as a consequence of the inhibiting effect of the halogenated component. However, if this halogenated component is lost as a result of preferential evaporation over a period of time, the effective flashpoint can decrease, which is the reverse of the effect of the preferential loss of lighter hydrocarbons from fuel blends as discussed above.

The closed cup flashpoint is sometimes referred to as the "lower flashpoint." Although not widely used, this term does emphasize the link to the lower flammability limit of the vapor and allows the concept of the "upper flashpoint" to be introduced. This term corresponds to the temperature at which the vapor concentration in the headspace is at the upper flammability limit, signifying that the mixture will not ignite when an ignition source is introduced, although a weak diffusion flame may exist briefly at the open aperture. Upper flashpoint is seldom measured, although Hasegawa and Takishi [27] have obtained some results in the Setaflash apparatus [16]. It is useful in identifying the temperature range within which the vapor-air mixture in the headspace is flammable. For example, at ambient temperatures, the vapor-air mixture in the headspace of a gasoline tank is well above the upper flammability limit and cannot be ignited. However, the upper flashpoint of the lower alcohols (in particular methanol and ethanol) appears to be in the mid-20s, only 10–15 K or so above the lower flashpoint. This means that at ambient temperatures (say, 15–20 °C) a partially full can of alcohol contains a flammable vapor-air mixture that can be easily ignited. This is a significant hazard that can give rise to serious consequences. For example, if an attempt is made to top-up a conventional flambé lamp directly from the fuel container before the flame has extinguished and if the temperature of the alcohol in the container is between the lower and upper flashpoints, flame will propagate into the container, perhaps causing it to burst or otherwise expel burning liquid. Such occurrences have led to a number of serious accidents in restaurants [28]. Provision of a flame arrester in the opening of the container would prevent such an occurrence.

Open Cup Flashpoints and Firepoints

Open cup flashpoints are not routinely available in the literature although they are clearly relevant to the ignition of open pools of liquid. They are determined using an open cup, the most common of which is the Cleveland apparatus [22] as shown in Fig. 18.2. Instead of the vapor accumulating immediately above the liquid surface, it is lost to the atmosphere by diffusion. Consequently, the concentration of vapor in air deceases with height above the liquid surface. In the standard test, the ignition source (a small diffusion flame at the end of a swivel arm) is moved across the top of the cup, no more than 2 mm above its rim, in a trajectory that carries the flame over the center. The process of heating the fuel is essentially the same as for the closed cup test, but in this case the result is more strongly apparatus

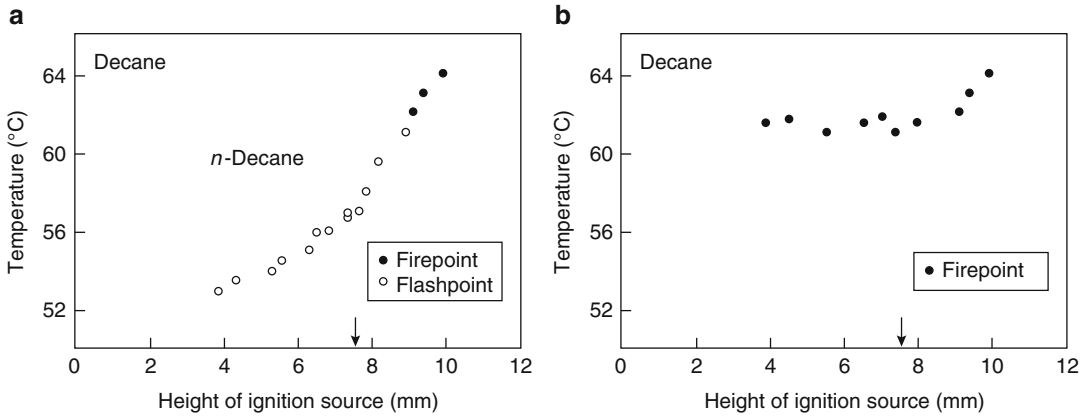

Fig. 18.3 Open cup flashpoint (o) and firepoint (•) of n-decane as a function of the height of the ignition source above the liquid surface. (**a**) Flashpoint, revealing how the onset of sustained burning occurs when the temperature of the liquid is above the firepoint (61.5 °C); (**b**) Firepoint as a function of the height of the ignition source, showing that it is relatively insensitive to heights less than about 9 mm. The arrow shows the height of the ignition source in the standard test [29]

dependent. A flash of flame is observed when the ignition source first encounters a mixture at the lower flammability limit. For this reason, the measured open cup flashpoint is very sensitive to the height of the ignition source above the surface. This was demonstrated very clearly by Glassman and Dryer [29], as shown in Fig. 18.3a. Clearly, this measurement is apparatus-specific and cannot provide information about the ignitability of the liquid that can properly be generalized—the flashpoint of an open pool of liquid will depend on the distance the vapor has to travel before meeting a suitable ignition source. Indeed, instead of observing a flashpoint, the liquid may catch fire and continue to burn (i.e., its temperature is above the firepoint [see Fig. 18.3a]).

This burning will occur when fuel vapors are being released at a high enough rate to support a diffusion flame. At the flashpoint (closed cup and open cup), the mixture is fuel lean and all the fuel vapor is consumed in the premixed flame. However, if the temperature of the liquid is high enough to produce a fuel-rich vapor-air mixture, a self-sustained diffusion flame becomes possible, as illustrated clearly in Fig. 18.3a, which reveals that a minimum fuel temperature must be achieved for this result to occur. This minimum temperature at which a self-sustaining diffusion flame becomes possible is known as the firepoint. Glassman and Dryer [29] found the firepoint to be much less sensitive to the height of the ignition source, as shown in Fig. 18.3b.

In general, firepoints are not routinely measured and there is not a good database. Some values quoted by Babrauskas [16] are given in Table 18.5. A different selection is given by Kanury [9], but these are all blends that are poorly defined. Typically the firepoint is 10–20 K above the closed cup flashpoint, but one cannot rely on this generalization. The difference appears to be erratic and can be much greater and more uncertain for high-flashpoint liquids (see Babrauskas [16]). The lower alcohols seem to behave in a very different manner. Glassman and Dryer [29] found the open cup flashpoints and the firepoints of methanol and ethanol were equal and—even more surprisingly—considerably less than the closed cup flashpoint. This anomaly disappeared if a spark ignition source was used instead of a flame in the open cup measurement: the open cup flashpoint and the firepoint remained equal but were now higher than the closed cup flashpoint (see Table 18.5). This observation has still to be explained satisfactorily, but clearly the behavior of the alcohols is not typical.

Several attempts have been made to define the firepoint of liquids (and indeed solids) in terms of the heat and mass transfer processes involved

Table 18.5 Some values of closed cup flashpoint, open cup flashpoint, and firepoint temperatures

	Closed cup FP (°C)	Open cup FP (°C)	Firepoint (°C)
n-Hexane	−22	[a]	NA

Unless otherwise stated, these data come from the *Factory Mutual Handbook,* as quoted by Babrauskas [16]
NA Not available
[a]The open cup flashpoint of *n*-hexane is quoted as −26 °C in the original *Factory Mutual Handbook* and repeated in Babrauskas [16]. This is incorrect
[b]Data from Glassman and Dryer [29]. The lower values were obtained with ignition by a pilot flame. The upper values refer to spark ignition

in the combustion of the fuel vapors close to the fuel surface. For a diffusion flame to become established at the surface of the liquid, the rate of evolution of flammable vapor must be greater than a certain critical value. It has been argued that it is determined by the need to establish a self-sustaining process whereby the energy required to maintain (and promote) the evolution of vapors comes from the flame by convective and radiative heat transfer. However, if the flow rate of vapors is too small, the flame will be too close to the surface and self-extinguish as a consequence of heat losses to the surface.

Valuable contributions to the definition of firepoint as a criticality have been made by Roberts and Quince [30], Rasbash [31], and Beyler [32]. In particular, they have used Spalding's *B*-number, first used to describe the rate of burning of fuel droplets [33], to develop the concept of ignition [30, 31] and extinction [31, 32] criticalities. It is a dimensionless transfer number that can be used to express the conservation of heat (B_H) or mass (B_M), the values of which can be used to define the rates of heat and mass transfer, respectively. They can be expressed as follows:

$$B_H = \frac{\left(m_{og}H/r\right) - c\left(T_g - T_{ls}\right)}{Q} \tag{18.18}$$

and

$$B_M = \frac{m_{fs} - \left(m_{og}/r\right)}{1 - m_{fs}} \tag{18.19}$$

where m_{og} is the mass fraction of oxygen in the atmosphere, m_{fs} is the mass fraction of fuel vapor immediately above the liquid surface, H is the heat of combustion of the fuel vapor, r is the stoichiometric ratio (mass of O_2 required to burn unit mass of fuel), c is the specific heat, T_g is the ambient air temperature, and T_{ls} is the temperature of the surface of the liquid. B_H and B_M are assumed equal when the diffusivities of heat and mass are equal (the Lewis number is unity). However, this assumption carries with it the hidden assumption that radiative heat transfer can be ignored and only convection need be considered. For small flames—particularly those associated with the burning of small droplets for which this approach was developed—this approximation is reasonable.

The rate of burning can be expressed as a mass flux ($\dot{m}''$, the rate of mass transfer per unit surface area) in terms of the *B*-number using the following equation:

$$\dot{m}'' = \frac{h}{c}\ln(1 + B) \tag{18.20}$$

where h is the (convective) heat transfer coefficient. Following the argument developed by Roberts and Quince [9], which invokes the concept that there is a critical temperature below

which a flame will extinguish (see Chap. 5), a critical B-number can be formulated as

$$B_{crit} = \frac{m_{og}}{r}\left(\frac{T_{f,\max} - T_{ls}}{T_{f,\max} - T_{f,crit}}\right) \qquad (18.21)$$

where $T_{f,\max}$ is the theoretical flame temperature assuming no heat losses to the surface of the liquid, $T_{f,crit}$ is the critical flame temperature below which the flame will extinguish, and T_{ls} is the surface temperature of the liquid—the firepoint temperature. B_{crit} can be calculated from Equation 18.19 for B_M, substituting for m_{fs} the mass concentration of fuel vapor above the liquid surface at the firepoint (calculated from the saturation vapor pressure derived from data similar to that contained in Table 18.3), allowing the critical temperature hypothesis to be tested. The theoretical temperature $T_{f,\max}$ can be deduced from a heat balance at the surface, assuming that the flame loses no heat to the surface (i.e., it is adiabatic). For a range of fuels (identified in Table 18.2), $T_{f,crit}$ was found to have a mean value of 1350 °C (albeit ±100 K), which is not inconsistent with measured and predicted values for premixed flames close to the lower flammability limit (about 1300 °C) (see Chap. 5).

Observations of the firepoint temperatures of a number of fuels reveal that the saturated vapor pressure at the firepoint is above stoichiometric. Roberts and Quince [9] reported values from 1.33× to 1.92× stoichiometric. Clearly, the mixture immediately above the surface is rich by a significant margin but is still within the flammability range. (Zabetakis [24] has shown that the upper flammability limit is between 2.5× and 4× the stoichiometric concentration.) The firepoint represents a criticality, the rate of evolution of vapors being just sufficient to allow the establishment of a diffusion flame at the surface. It is closely linked to the "quenching distance," a characteristic of premixed flames that are quenched (extinguished) within 1 or 2 mm of the surface due to heat losses and (probably) the loss of free radicals (see Chap. 12). The flow rate of vapors at the firepoint must be sufficient to allow a nascent diffusion flame to form far enough from the surface so that the quenching process does not occur. The critical flow rate of vapors at the firepoint will, therefore, be given by

$$\dot{m}''_{crit} = \frac{h}{c}\ln(1 + B_{crit}) \qquad (18.22)$$

$\dot{m}''_{crit}$ has not been determined for any liquid fuels but values have been reported for a range of solids (see Chap. 36).

Classification of Liquid Fuels

Although this chapter is entitled "Ignition of Liquids," most of the emphasis has been on understanding the flashpoint, the minimum liquid temperature at which the vapor can be ignited. It is clear that it is the firepoint that determines whether or not sustained flaming of the liquid will occur, yet combustible liquids are classified—quite properly—in terms of their flashpoints. Measurement of the closed cup flashpoint provides a method of classifying flammable liquids according to the hazard they represent. Systems of classification have been developed in several countries, but they have as the common basis the need to identify and make provision for those liquids that can be easily ignited at ambient temperatures. Thus, in the United Kingdom under the Highly Flammable Liquids and Liquefied Petroleum Gases (HFL/LP-gas) Regulation 1972 [34], liquids with closed cup flashpoints less than 32 °C were classified as "highly flammable liquids." NFPA 30, *Flammable and Combustible Liquids Code* [14], assigns liquids with flashpoints less than 37.8 °C (100 °F) to a similar category, known as Class I. Figure 18.4 compares the U.K. and U.S. systems and shows how the Class I liquids are subdivided into three subclasses A, B, and C. The boundary between I (A and B) and IC is set at 22.8 °C (73 °F), whereas Class IA liquids are distinguished from Class IB in having normal boiling points less than 37.8 °C (100 °F).

"Flammable liquids" (1972 Regulations, U.K.) and Class II liquids (U.S.) have a common upper bound of 60 °C. These are liquids that must

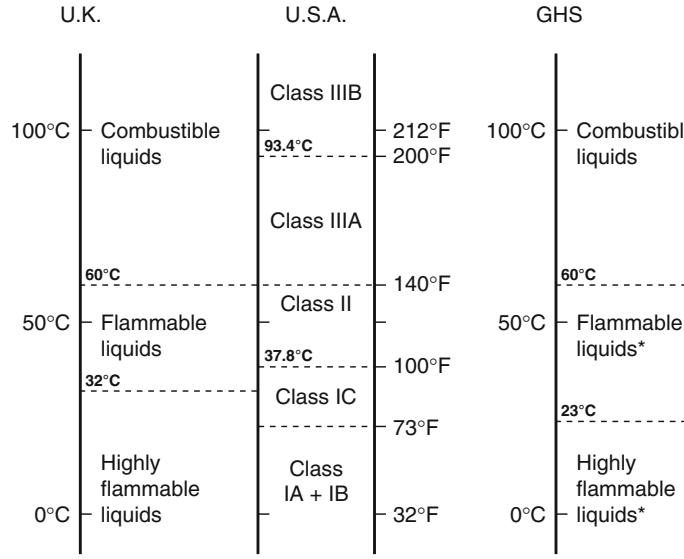

Fig. 18.4 A comparison of the U.K. and U.S. classifications of flammable and combustible liquids with the UN Globally Harmonized System

be heated significantly above ambient temperature before the evolved vapor can be ignited, although it is clear that some caution is required if ambient temperatures above 32–37.8 °C are encountered. For example, strict application of the U.K. Highly Flammable Liquid Regulations or NFPA 30 would be highly inappropriate in Dubai where the average maximum temperature during the summer months is about 40 °C. Liquids with flashpoints above 60 °C are considered to be relatively "safe" in that significant temperature increases are required before they can be ignited. In the United Kingdom these are called "combustible liquids," whereas in the United States they belong to Class III (which is further divided into Class IIIA and Class IIIB, as shown in Fig. 18.4).

Within the European Union (EU), new classification systems have evolved following the introduction of new regulations arising from EU Directives. These relate, rather confusingly, to the three main "endpoints" (i.e., storage, supply, or transport, each slightly different[4]). Over the years, the United Kingdom has modified the HFL/LP-gas regulations to conform to the EU system and as a consequence the 1972 U.K. Regulations have effectively been replaced by the Dangerous Substances and Explosive Atmospheres Regulations (DSEAR 2002) in which the classification system shown in Table 18.6 has been adopted.

Table 18.6 Classification system used in DSEAR 2002 [35]

Classification	Flashpoint	Boiling point
Extremely flammable	<0 °C	<35 °C
Highly flammable	<21 °C	>35 °C
Flammable	≥21 °C and <55 °C	

This is not the place to attempt to describe the finer points of these classification systems (of which there are many), but it is relevant to

[4] Storage: "The Highly Flammable Liquids and Liquefied Petroleum Gases Regulations (HFL/LP-gas)"; Supply: "The Chemical (Hazard Information and Packaging for Supply) Regulations (CHIPS)"; and Transport: "The Carriage of Dangerous Goods and Use of Transportable Pressure Equipment Regulations (CDG)."

Table 18.7 Classification developed by the UN for transport of hazardous chemicals, known as the GHS system [36]

Category	Criteria
1	Flashpoint <23 °C and initial boiling point ≤35 °C
2	Flashpoint <23 °C and initial boiling point >35 °C
3	Flashpoint ≥23 °C and ≤60 °C
4	Flashpoint >60 °C and ≤93 °C

draw the reader's attention to the classification that has recently been adopted for transportation by the United Nations (UN) to facilitate international trade. It defines four categories of liquid, as shown in Table 18.7. This classification is the UN Globally Harmonized System (GHS) and is compared in Fig. 18.4 with the original U.K. (1972 Regulations) and U.S. systems of classification.

Sustained Ignition of Liquids

Provided that the temperature of a liquid is above its firepoint, ignition of the vapors above a pool will be followed by the establishment of a flame at the surface. If the temperature is only slightly above the firepoint, the initial diffusion flame will be weak but will strengthen as it transfers heat to the surface, causing the temperature to rise thus generating an increased rate of supply of fuel vapors. Eventually, a steady-state rate of burning will be achieved, controlled by the heat and mass balance of the surface of the fuel at a temperature close to the normal boiling point. [18] The standard open cup tests are designed to heat the liquid uniformly (bulk heating), but in practice such bulk heating is difficult to achieve unless the liquid is used in some process that requires an elevated temperature. An obvious example is the deep fat fryer and similar devices used in cooking, but oils and other high-flashpoint liquids may be used in heat exchangers and other devices at temperatures above their firepoints. If they are released, then in principle a small ignition source may ignite the vapors and cause a fire. This form of ignition is known as piloted ignition: spontaneous ignition, or "autoignition," is discussed below.

A pool of a high-firepoint liquid at ambient temperature is difficult to ignite by means of a locally applied ignition source, such as a flame. If a flame is applied to the surface (e.g., using a blowtorch), convection currents are established that remove hot liquid from the point of flame application, replacing it with cooler (cold) liquid from below. This process occurs because of a surface tension–driven flow at the surface, first identified by Sirignano and Glassman [37] in their study of flame spread over liquid surfaces. It is a consequence of the fact that surface tension decreases with temperature so that there is a net force at the surface that draws the hotter liquid on the surface at the point of flame impingement toward the cooler regions. The movement at the surface created by this force effectively disperses the heat transferred to the surface and delays ignition. However, if the liquid is absorbed onto a porous substrate—a "wick"—then application of an ignition source in the form of a small flame will quickly raise the temperature of the liquid to its firepoint and burning will be established. There are two factors that contribute to this behavior: first, the liquid is held as a thin film on the material of the wick and surface tension–driven flows are suppressed; and, second, most wick materials have low thermal conductivities and insulate the liquid from heat loss through the wick (by conduction). The best-known example of the effectiveness of a wick in promoting ease of ignition is with the common candle. The wax melts at a relatively low temperature (about 100 °C), but the wick holds the molten wax in place, permitting easy ignition by a match flame. The amount of energy required has never been measured, but in principle it could be calculated assuming the liquid film acts as a thermally thin "solid." However, the heat transfer characteristics of such ignition sources are difficult to quantify and the calculation would be rather academic.

Burgoyne and Roberts [38] studied the ignition of pools of high-flashpoint liquids from flames established on wicks that dipped into the liquid at one end of a 0.4-m-long tank. They

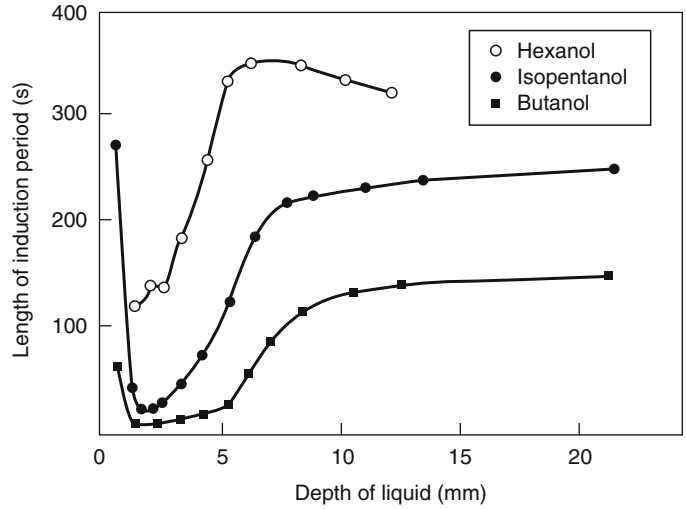

Fig. 18.5 Spread of flame over the surface of a liquid from a flame established on a wick at one end of a pool contained in a long trough [38]. Effect of liquid depth on the duration of the induction period (the time taken for flame to begin to spread over the surface). The open cup flashpoints of hexanol, isopentanol (aka isoamyl alcohol) and butanol, are 74 °C, 46 °C and 43 °C, respectively. (The firepoints are not available)

found that ignition of the pool would occur after a delay (induction period), the length of which was determined by the depth of the pool. In this case, ignition of the pool comprised gradual heating of the surface layers by heat transfer from the flame on the wick until the firepoint temperature was achieved in the vicinity of the wick, after which the flame would spread over the surface of the pool. Minimum induction periods were observed for layers less than 5 mm, increasing by as much as an order of magnitude as the depth was increased to 8–10 mm, depending on the fuel. As an illustration, Fig. 18.5 shows the results obtained by Burgoyne and Roberts for three alcohols [38]. There appears to have been no further systematic studies of this mode of ignition, but it is reasonable to assume that the time to full ignition of a pool of liquid fuel will depend both on the firepoint of the liquid and the depth of the pool.

It is appropriate to note at this point that high-flashpoint liquids (both "flammable" and "combustible" according to the U.K. classification system as shown in Fig. 18.4) can be ignited very easily if dispersed in air as a spray or mist. This behavior is analogous to a dust explosion, which involves dispersion of fine solid particles in air (see Chap. 70). The concept of flammability limits applies and in all other respects a mist of combustible liquid exhibits the same properties as a flammable vapor-air mixture. Spray ignition is discussed in the review by Aggarwal [39].

Autoignition

If the temperature of a flammable vapor-air mixture is increased sufficiently, it can ignite spontaneously without the introduction of a source of ignition—a "pilot"—such as a flame or spark. The concentration of fuel in air at which the autoignition temperature is a minimum corresponds to the stoichiometric vapor-air mixture, which is known to be the most reactive [24]. Values of the (minimum) autoignition temperatures (AIT) of a large number of liquid fuels (gases and liquids) are given in Table 18.2. These have been obtained in a standard test using the Setchkin apparatus [40, 41]. The measurement is made (for liquids) by dropping a small quantity of the liquid (0.1 ml) into a 500 ml spherical flask that has been heated to a carefully controlled temperature [18, 41]. If ignition is not observed within 10 min, the experiment is repeated at higher temperatures. The minimum autoignition temperature (AIT) is determined by repeated experiments, "bracketing" the final value. The values of AIT quoted in Table 18.2 were obtained in this way, but in fact these measurements are highly apparatus dependent. Lower values of AIT are found if the test is carried out in a larger vessel, specifically with a lower surface-to-volume ratio (Table 18.8). This is entirely consistent with the theory of spontaneous combustion (see Chap. 20).

Table 18.8 Comparison of the AIT (°C) of combustible liquids in spherical vessels of different sizes [41]

	Volume of vessel ($m^3 \times 106$)				
	8	35	200	1000	1200
Diethylether	212	197	180	170	160
Kerosene	283	248	233	227	210
Benzene	668	619	579	559	–
Methanol	498	473	441	428	386
n-Pentane	295	273	–	258	–
n-Heptane	255	248	–	223	–

However, the Setchkin test [40] provides data on autoignition under highly idealized conditions in which the liquid vaporizes inside an enclosed volume at a uniform temperature. A relatively uniform fuel/air mixture will be formed that will undergo autoignition if the temperature is high enough. However, this scenario is rarely encountered in practice: more commonly, a liquid fuel may come into contact with a hot surface, such as a bearing assembly or an exhaust manifold, which is exposed to the open atmosphere. The liquid evaporates from the hot surface and the vapor mixes with air at ambient temperature, or at a temperature that is significantly lower than that of the hot surface. Under these circumstances, the minimum AIT derived from the Setchkin test is not relevant as neither the temperature nor the concentration of vapor in air will be uniform. Logically one would expect the autoignition process to take place where the fuel concentration is at or close to stoichiometric (the most reactive mixture) and the local temperature is sufficiently high. To achieve this, the surface temperature will have to be much higher than the quoted literature value of the corresponding AIT.

If the boiling point of the liquid is lower than the AIT (e.g., for *n*-decane, these temperatures are 174 °C and 201 °C, respectively), then spilling the liquid onto a hot, open surface cannot give rise to autoignition because the vapor cannot be at a temperature greater than the boiling point of the liquid. The situation would be different for a combustible liquid with a boiling point much higher than the AIT. Paraffin wax (a solid at room temperature but melting at temperatures less than 100 °C) boils at >370 °C, but the AIT is quoted as 245 °C. In principle, if the conditions are right, the hot vapor produced when paraffin wax is dropped onto a hot surface (>370 °C) may autoignite if a flammable vapor/air mixture is formed near the surface at a sufficiently high temperature (certainly >245 °C). However, the temperature of the surface at which autoignition will occur cannot be defined uniquely. Colwell and Resa [42] studied the autoignition of a range of liquid fuels and engine lubricants when single drops fell on to a flat, heated plate. It was necessary for them to present their results in terms of the probability of ignition, carrying out a large number of tests over a range of plate temperatures. Jet A fuel (similar to kerosene) did not autoignite at temperatures below 510 °C, despite the fact that the AIT (of kerosene) as measured in the Setchkin Test is quoted as 233 °C (see Table 18.8). If the plate temperature was 583 °C, the ignition probability was 50 %, increasing to 100 % above 650 °C. The probability distribution for kerosene and other fuels and lubricants, as determined by Colwell and Resa, is shown in Fig. 18.6. Similar studies, with similar conclusions, have been carried out by Shaw and Weckman [43] for diesel fuels and Davis et al. [44] for high performance fuels used in motorsports. Note that these results are specific to a flat surface, 0.579 m by 0.108 m which is horizontal and unconfined: the distribution will shift to lower temperatures if the surface is confined, or significantly profiled, or to higher temperatures if the surface is vertical or significantly smaller in area.

If a high-boiling point liquid (such as cooking oil) is overheated, autoignition can occur, with flame appearing spontaneously in the plume of hot vapor rising from the surface. As the liquid is already very hot (perhaps close to its boiling point), the fire that follows will immediately be burning at or close to its maximum rate. This type of behavior can be demonstrated using corn oil in a Cleveland open cup and is likely to be the cause of flaming fires in deep fat fryers. This cannot occur with low-boiling liquid fuels such as gasoline (as explained above), which accounts for the fact that if gasoline is spilled

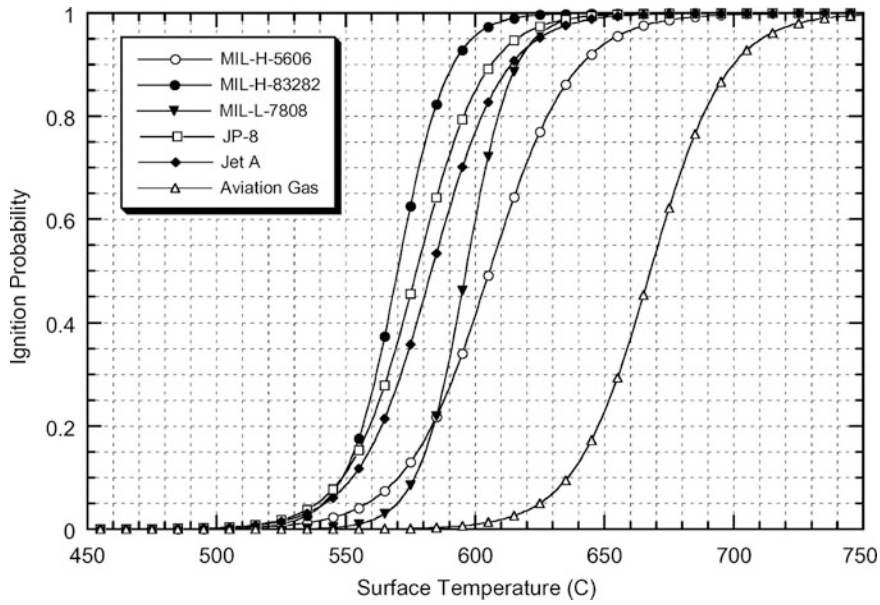

Fig. 18.6 Ignition probability as a function of the surface temperature of a flat plate for aviation fluids [42]. With kind permission from Springer Science+Business Media B.V.

on to a hot exhaust, autoignition will not occur, although ignition will occur if there is a pilot source (e.g. a spark or flame) nearby. On the other hand, heavier fuels and lubricating oils (with high boiling points) may autoignite under these circumstances. There has been much interest in this issue [16].

Ignition of Liquids in Porous Materials

This chapter has so far dealt with the ignition of liquids, leading either to a transient premixed flame or to sustained, flaming combustion. However, under the right conditions, liquid fuels with high boiling points can undergo a form of smoldering combustion, although this form of combustion is normally associated with combustible solids that yield a solid char on heating (see Chap. 19). Clearly, a bulk liquid cannot undergo charring, but if it is dispersed as a thin film within a porous substrate (such as an insulating material) and provided it is of low volatility, it may undergo a slow exothermic reaction that leaves a charlike residue on the fibers of the substrate. The process starts insidiously, by a self-heating process in which the liquid reacts heterogeneously with oxygen from the air. If there is sufficient insulation, the rate of heat released by this process will be greater than the rate at which it can be removed and the temperature will rise. The phenomenon of self-heating in solids is discussed at length in Chap. 20.

The best-known example of self-heating (and spontaneous combustion) of liquids involves the so-called "drying oils," such as linseed oil and tung oil. To quote Bowes [45], "The risk of self-heating and ignition in textile fibres impregnated with readily oxidisable oils has been recognised for a long time," citing a paper by Hapke that refers to such incidents dating back to the eighteenth century. Self-heating of some of the vegetable oils that were used in wool blending in the nineteenth century were known to be the cause of fires and for this reason a test was devised in the United Kingdom to identify the oils that were particularly hazardous (the Mackey Test [45, 46]). The most hazardous are the unsaturated vegetable oils containing a high proportion of carbon–carbon double bonds, which are prone to oxidation. The proportion of these unsaturated linkages can be quantified in terms of the "iodine number,"

which is effectively the percentage of iodine absorption due to the reaction of iodine at the carbon–carbon double bonds. The higher the iodine number, the greater the propensity of the oil to exhibit self-heating when dispersed onto rags, and so on. Typical ranges of values are shown in Table 18.9 (extracted from Bowes [45]).

The most hazardous oils can self-heat when dispersed onto quite small amounts of material—as low as 25 g has been reported. This means that rags used to apply linseed oil or tung oil–based finishes to wood surfaces can self-heat if they are not disposed of properly. The less reactive oils will present problems if dispersed on much larger quantities of porous material, such as bales of wool. Qualitative information on a wide range of liquids may be found in NFPA's *Fire Protection Handbook®* [47], which provides a list of materials that are subject to spontaneous heating. This information has been extracted and is presented in Table 18.10.

Under the right conditions, self-heating of these dispersed liquids will lead to the onset of smoldering combustion. The self-heating process is a slow oxidation involving the carbon–carbon double bonds, resulting in changes to the structure of the absorbed liquid. The chemical mechanism has not been studied in detail, but the consequence appears to be that char is produced on the fibers, which can then oxidize more vigorously, producing a smolder that has the potential to undergo transition to flaming. The smolder will involve the substrate if it is combustible (e.g., cotton rags, wool, etc.), but it is not necessary for the substrate to be combustible, at least for the more reactive oils.

Table 18.9 Ranges of iodine values [45]

Oil	Iodine number	Hazard
Tung, linseed	160–185	Most hazardous
Sunflower seed	127–136	↑
Soya bean	124–133	
Cottonseed	103–111	
Olive oil	80–85	
Coconut oil	8–10	Least hazardous

Another situation in which liquids can initiate self-heating, leading to spontaneous fires, is in the case of oil-soaked lagging [45, 48]. This situation is encountered in industrial plants where thermal insulation is provided around vessels and pipework to conserve heat and maintain process fluids at high temperatures. If the fluid leaks into the insulation, it will be dispersed through the open structure of the insulant. If the leak is too large, then the material will become logged with the fluid and self-heating will not occur. However, if the leak is small, then the fluid will become dispersed onto the fibers of the insulation material, creating a large area of fuel exposed to air within the interstices of the material—an ideal situation to promote self-heating, particularly as both the fluid and the insulation are already hot. The volatility of the fluid is important here: if at the relevant temperature its vapor pressure is too high, then the oxygen concentration in the pores of the insulation may be too low to allow the self-heating process to develop sufficiently.

There have been studies of the propensity of different fluids to undergo self-heating when dispersed on porous insulation materials and an empirical expression has been derived to assess the hazard. This is reported by Lindner and Seibring [49] and developed by Britton [50]. Self-heating may be an issue if

$$\frac{AIT}{AIT - FP} > 1.55 \qquad (18.23)$$

where AIT is the autoignition temperature and FP is the (closed cup) flashpoint. Although it may seem illogical to incorporate AIT (which refers to autoignition in the gas phase) into a correlation that deals with a heterogeneous process, the significance of AIT is that it is a measure of the reactivity of the fuel. FP is also associated with a gas-phase process, but in this expression, it is a surrogate for a measure of the volatility of the fuel as it correlates with the boiling point (see, for example, Babrauskas [16]). A "reactive fuel" (low AIT) of low volatility (high FP) will, therefore, give a high value of AIT/(AIT – FP)—consistent with the above inequality. However, this is at least two steps removed from

Table 18.10 Liquids capable of self-heating when dispersed on fibrous materials [47]

Name	Tendency to spontaneous heating	Usual shipping container or storage method	Precautions	Remarks
Castor oil	Very slight	Metal barrels, metal cans in wooden boxes	[a]	Possible heating of saturated fabrics in badly ventilated piles
Coconut oil	Very slight	Drums, cans, glass	[a]	Only dangerous if fabrics, etc., are impregnated
Cod liver oil	High	Drums, cans, glass	[a]	Impregnated organic materials are extremely dangerous
Corn oil	Moderate	Barrels, tank cars	[a]	Dangerous heating of meals, etc., unlikely unless stored in large piles while hot
Cottonseed oil	Moderate	Barrels, tank cars	[a]	May cause heating of saturated material in badly ventilated piles
Fish oil	High	Barrels, drums	[a]	Impregnated porous or fibrous materials are extremely dangerous. Tendency of various fish oils to heat varies with origin
Lanolin	Negligible	Glass, cans, metal drums, barrels	[a]	Heating possible in contaminated fibrous matter
Lard oil	Slight	Wooden barrels	[a]	Dangerous on fibrous combustible substances
Linseed oil	High	Tank cars, drums, cans, glass	[a]	Rags or fabrics impregnated with oil are extremely dangerous. Avoid piles etc.
				Store in closed containers, preferably metal
Menhaden oil	Moderate to high	Barrels, drums, tank cars	[a]	Dangerous on fibrous product
Mustard oil, black	No	Barrels	[a]	Avoid contamination of fibrous combustible materials
Olive oil	Moderate to low	Tank cars, drums, cans, glass	[a]	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil
Paint containing drying oil[b]	Moderate	Drums, cans, glass	[a]	Fabrics, rags, etc. impregnated with paints that contain drying oils and dryers and extremely dangerous. Store in closed containers, preferably metal
Palm oil	Low	Wooden barrels	[a]	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil
Peanut oil	Low	Wooden barrels, tin cans	[a]	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil
Perilla oil	Moderate to high	Tin cans, barrels	[a]	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil
Pine oil	Moderate	Glass, drums	[a]	Impregnated fibrous materials may heat unless ventilated. Tendency varies with origin of oil
Red oil	Moderate	Glass bottles, wooden barrels	[a]	Impregnated porous or fibrous materials may heat unless ventilated. Tendency varies with origin of oil
Soybean oil	Moderate	Tin cans, barrels, tank cars	[a]	Impregnated fibrous materials may heat unless well ventilated
Tung oil	Moderate	Tin cans, barrels, tank cars	[a]	Impregnated fibrous materials may heat unless well ventilated. Tendency varies with origin of oil
Whale oil	Moderate	Barrels and tank cars	[a]	Impregnated fibrous materials may heat unless well ventilated. Tendency varies with origin of oil

[a]In every case, the recommended precaution to prevent spontaneous heating is to "avoid contact of leakage from containers with rags, cotton, or other fibrous combustible materials"

[b]This is a well-known hazard in the trade. Impregnated rags are laid out flat to dry. Self-heating will only occur if the rags are left in a crumpled state, providing insulation for the interior

understanding the process involved. The theory of self-heating is described in Chap. 20, but it is only recently that the parameters relevant to understanding lagging fires have been examined in detail [51].

Summary

Flammable and combustible liquids present a range of fire hazards in our everyday lives, whether it be in industry, commerce, or the home. In this chapter, an attempt has been made to outline the fundamental parameters that determine the flammability of liquids, bearing in mind that the hazard may present itself in a number of ways: as an unconfined pool of liquid, as a dispersion of droplets, or as liquid absorbed on a porous substrate. The simplest way of classifying the flammability of a liquid is in terms of its flashpoint, the lowest temperature at which the saturated vapor pressure of the liquid corresponds to the lower flammability limit of the vapor in air at normal atmospheric pressure. The classification schemes used in the United States and the United Kingdom are based simply on the flashpoint, but it is important to recognize that the flashpoint temperature decreases with atmospheric pressure, while the actual flashpoint is not relevant if the liquid is presented to an ignition source as a mist or spray. Indeed, liquids with flashpoints above 300 °C may be ignited by a small flame or a spark if they are dispersed in droplet form.

A distinction must be made between flashpoint, as defined above, and firepoint. The latter refers to the lowest temperature at which a liquid will continue to burn following ignition of the vapors by a pilot ignition source. It is higher than the flashpoint, generally by 10–20 K. Values of autoignition temperature (AIT) are quoted in the literature, but these are not related to either the flashpoint or the firepoint. The AIT represents the lowest temperature at which flame develops spontaneously in a uniformly heated closed vessel into which a small sample of liquid is introduced. This idealized configuration must be taken into account when "autoignition" of liquids in practical situations is considered (e.g., spilling gasoline onto a hot exhaust).

If a combustible liquid is absorbed into a porous medium, such as a rag or the insulation around a hot pipe, then it may undergo a self-heating process leading initially to a smoldering-type reaction. Reactive drying oils such as linseed will undergo this process at ambient temperatures and can lead to flaming combustion under suitable conditions. Similarly, hot process fluid contaminating the insulation around pipework in industrial plants can lead to "lagging fires," which are difficult to control. The hazard associated with liquids under these conditions is poorly understood, which makes awareness of the problem even more important.

Smoldering Combustion

19

Guillermo Rein

Introduction

Smoldering combustion is the slow, low temperature, flameless burning of porous fuels and the most persistent type of combustion phenomena. The heat is released when oxygen directly attacks the surface of a solid fuel [1]. It is especially common in porous fuels which form a char on heating [2], like cellulosic insulation, polyurethane foam or peat. Smoldering combustion is among the leading causes of residential fires [3, 4], and it is a source of safety concerns in industrial premises as well as in commercial and space flights. Smoldering is also the dominant combustion phenomena in wildfires of natural deposits of peat and coal which are the largest and longest burning fires on Earth [5]. These fires contribute considerably to global greenhouse gas emissions, and result in widespread destruction of ecosystems and the waste of natural resources.

Smoldering constitutes a hazard in the built environment, as emphasized in this chapter, for two main reasons. First, it typically yields a higher conversion of the fuel to toxic compounds than flaming, though this occurs more slowly. Second, smoldering provides a path to a flaming fire via heat sources too weak to directly ignite a flame. A burning cigarette or charcoal embers are familiar examples of smoldering combustion. The latter is illustrated in Fig. 19.1 (left). A less familiar case but more common fire threat is the burning of foam in upholstery as seen in Fig. 19.1 (right). The smouldering combustion of polymer foams and other building insulation materials is gaining importance because of their extensive use by the construction industry which is seeking higher energy efficiency.

Despite its broad implications to safety and the environment, our current understanding of smoldering combustion is limited, and considerably less advanced than flaming combustion. This is due to its complexity and coupling of transport and thermochemical processes inside a reactive porous media, The most comprehensive reviews of smouldering combustion in the literature include Ohlemiller [1], T'ien et al. [6], Ohlemiller [7], Babrauskas [8], Rein [9] and Drysdale [2].

Smoldering vs. Flaming Combustion

The core of any combustion process is a global exothermic reaction that results in the release of heat, and both gaseous and solid products. Whether smoldering or flaming will be the dominant mode is dictated by which chemical species is oxidized. If the oxidation takes place in the solid phase, smouldering is dominant; if the oxidation takes place in the gas phase then flaming dominates.

In general, the combustion of a solid fuel involves countless elementary chemical reactions, but the global reaction, in its simplest form, can be approximated by two lumped chemical pathways: pyrolysis (Equation 19.1) followed by oxidation (Equations 19.2a or 19.2b).

Pyrolysis:

$$\text{Fuel (solid)} + \text{Heat} \rightarrow \text{Pyrolyzate (gas)} + \text{Char (solid)} + \text{Ash (solid)} \tag{19.1}$$

Heterogeneous oxidation:

$$\text{Char (solid)} + \text{O}_2\text{ (gas)} \rightarrow \text{Heat} + \text{CO}_2 + \text{H}_2\text{O} + \text{other gases} + \text{Ash (solid)} \tag{19.2a}$$

Gas-phase oxidation:

$$\text{Pyrolyzate (gas)} + \text{O}_2\text{ (gas)} \rightarrow \text{Heat} + \text{CO}_2 + \text{H}_2\text{O} + \text{other gases} \tag{19.2b}$$

Pyrolysis[1] results in gaseous and solid products. Of these, both the pyrolysate and the char are susceptible to subsequent oxidation.[2] Char oxidation (Equation 19.2a) is a heterogeneous reaction (involving solid and gaseous species) and takes place on the char produced by the pyrolysis reaction and leads to smoldering combustion. Oxidation of the pyrolysate (Equation 19.2b) is airborne and takes place in the gas phase, which is a homogenous reaction (involving only gaseous species) and leads to flaming combustion.

Char is a carbon-rich porous material, also called charcoal or black carbon, with a high surface-to-volume ratio and a high heat of reaction. The attack of oxygen is facilitated by metal and mineral impurities which can catalyze the oxidation process. The other important solid species is ash, a mineral-rich residue of negligible reactivity that is left after the fire.

[1] Pyrolysis in this context is the chemical decomposition of a solid material solely by heating. It does not involve oxidation reactions and it is endothermic. It involves the irreversible and simultaneous change of chemical composition and physical phase.

[2] Oxidation in this context is the reaction of a species with the oxygen in the air. It is an exothermic reaction.

General Characteristics of Smoldering Combustion

The characteristic temperature, spread rate and power of smoldering combustion are low compared to flaming combustion. Typical peak temperatures for smoldering are in the range from 450 °C to 700 °C, although very energetic and dense fuels such as coal can reach peaks at around 1000 °C. The effective heat of combustion taking into account the combustion efficiency is in the range from 6 to 12 kJ/g. These are much lower compared to typical values of around 1500 °C and 16–30 kJ/g respectively for flaming combustion. The heat release rate per unit area of burning front is low and ranges from 10 to 30 kW/m^2 [10]. Because of these characteristics and despite the considerable variation in the chemical nature of smoldering fuels, smoldering spreads in a creeping fashion, typically around 1 mm/min, which is two orders of magnitude slower than flame spread.

As we will see in the following sections, smoldering combustion can be initiated with weaker ignition sources and is more difficult to suppress than flaming combustion. This makes smoldering the most persistent combustion mode. In the presence of a large quantity of fuel, a smoldering fire can burn for very long periods (days, weeks, months) despite fire-fighting attempts, extensive rain or weather changes. Indeed, the longest-burning urban fire in modern history occurred

Fig. 19.1 (*Left*) Smoldering embers and ash residue (Photo by J. B. Nielsen, Public domain, via Wikimedia Commons). (*Right*) Cross-section of a polyurethane slab 125 mm in diameter smoldered in microgravity conditions (Photo by NASA)

after the collapse of the Word Trade Center towers on Sept. 11, 2001. The immense piles of debris smoldered for 3–5 months in the middle of one of the most heavily populated cities of the world, resisting all suppression attempts until the slow removal of debris cleared the pile [11]. The oldest continuously burning fire on Earth is *The Burning Mountain* in New South Wales, Australia, a large coal seam which has been smoldering for more than 6000 years [12].

Many materials can sustain a smoldering fire. These include synthetic fuels such as charring polymers, polyurethane foam, cellulosic insulation, particleboard and sawdust, and natural fuels like wood, peat, forest litter, and coal. In chemical terms, most smoldering fuels form a char on heating. In physical terms, smoldering fuels consist of a permeable medium formed by grains, fibers or some other porous matrix. This aggregate nature provides a large surface area per unit volume, which facilitates the heterogeneous reaction with oxygen, and permits transport of oxygen through the fuel bed [1]. For example, synthetic foams prone to charring, like polyurethane foam (see Fig. 19.1, right), are highly susceptible to smoldering combustion. Liquid fuels soaked in an inert porous matrix can also sustain smoldering fires, examples include lagging fires (Drysdale [2], Chap. 18) and soil remediation based on the assisted burning of liquid contaminants [13].

For most smoldering fuels under typical conditions, the two mechanisms controlling the rate of spread are the oxygen supply and the heat transfer [1]. Both mechanisms are dictated by heat and mass transfer in porous media. At the micro scale, smoldering takes place on the surface of the pores of a solid fuel, while at the macro scale, it is a bulk phenomenon affecting the fuel bed at large. The fire can penetrate deep into the bed of fuel if oxygen can be transported from a free surface (open atmosphere, crack or channel). Depending on the depth of the fire, the importance of the heat and mass transfer mechanisms vary. The rate of oxygen supply to the reaction zone enhances the spread. But this oxygen supply decreases with depth inside a fuel bed. The rate of heat loss to the environment from the reaction zone hinders the spread. But this heat loss decreases with depth inside a fuel bed. Thus, depending on the fuel bed characteristics and wind conditions, there are minimum and maximum depths between which smoldering can spread, and an optimal depth at which burning is fastest. The concept of an optimal depth is not sufficiently studied yet and could vary for different systems in the scale from cm to m.

Each location of a burning fuel bed sees the successive arrival of four distinct thermal and chemical subfronts that form the structure of a smoldering fire. These are the preheating, drying, pyrolysis and oxidation subfronts [1, 14].

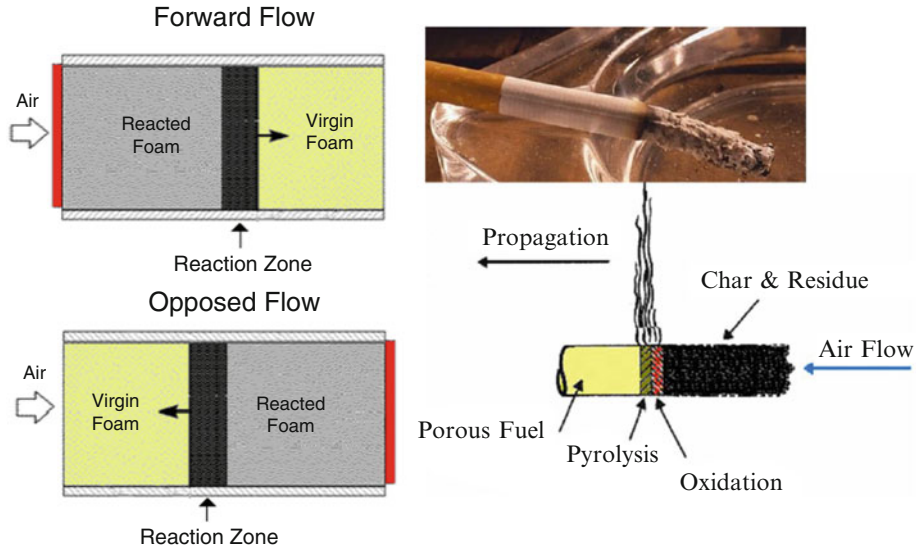

Fig. 19.2 (*Left*) Forward and opposed configurations of one-dimensional smoldering propagation inside a slab of porous fuel. (*Right*) Structure of a one-dimensional front in forward smoldering and approximate correspondence with a burning cigarette (By G. Rein, CC BY license)

The endothermic preheating, drying and pyrolysis subfronts store or consume thermal energy and move ahead of the oxidation subfront The heat that sustains the spread is released at the oxidation subfront, and from there it is transferred via a combination of conduction, convection and radiation to the other subfronts. The preheating subfront does not involve chemical reactions or gas emissions in any significant quantity. The drying subfront follows with evaporation becoming significant above 50 °C, emitting water vapour and leaving behind dry fuel. Drying is most significant for fuels with substantial moisture contents (>10 % in dry weight), so it is negligible in most residential fire scenarios but important in the natural environment (see section "Smoldering Wildland Fires"). The pyrolysis subfront (Equation 19.1) follows the preheating and drying when the fuel temperature increases above a certain threshold. This threshold[3] is approximately at 200 °C for polyurethane, and to 250 °C for cellulose [15]; subsequent heating above this temperature increases the pyrolysis rate and char production. The oxidation subfront consumes char and oxygen, releasing heat. It involves the oxidation of the fuel and the char, but char oxidation (Equation 19.2a) is much more exothermic. The oxidation and pyrolysis subfronts may overlap in space. The extent of this overlap depends on the propagation conditions [16] and is discussed in the section "Smoldering Kinetics".

It is convenient to characterize one-dimensional smoldering by its direction of propagation relative to the direction of the oxygen supply. Two one-dimensional modes exist. Forward propagation occurs when the oxygen supply is moving in the direction of the smolder front. Opposed propagation (also called reverse) occurs when the oxygen supply is moving opposite to the smolder front. These are illustrated in Fig. 19.2. The most familiar example of forward propagation is a cigarette, as seen in Fig. 19.2 (right). Although one-dimensional spread is an idealized situation, it can occasionally be found in fires, but in general, real smoldering fires are multidimensional and cannot be classified into a single mode.

[3] The onset of pyrolysis or oxidation does not occur at one fixed temperature but it is known to be a function of the heating rate and start over a range of temperatures; higher onset temperatures are observed for higher heating rates. See Rein et al. [15] and the section "Smoldering Kinetics" for evidence of this.

In forward propagation, the pyrolysis subfront is located at the leading edge of the front, and the oxidation subfront at the trailing edge, where oxygen is drawn (see Fig. 19.2, right). The oxygen supply flows first through the char where it is consumed. Then the hot, oxygen-depleted gases of combustion flow through the virgin fuel. This convective transport results in enhanced drying and preheating, but it also results in water condensation on the virgin fuel as the combustion gases cool down.

In opposed propagation, the oxygen supply flows first through the virgin fuel, and through the preheating and evaporation subfronts before reaching the char where the oxidation subfront is located. Then the hot, oxygen-depleted gases of combustion flow through the char and ash residues. This means that heat is transferred by convection in the opposite direction to the virgin fuel, reducing the extend of the drying and preheating, which in turn results in a weaker smoldering process. Consequently, forward smolder is faster than opposed under the same fuel and oxidizer supply, and allows for more complete combustion of the fuel [17]. In opposed propagation, the pyrolysis and oxidation subfronts overlap on top of each other from the leading edge to the trailing edge [16].

Ignition

The process of smoldering ignition requires the supply of heat, and is governed by heat transfer and fuel kinetics, with the oxygen supply rate playing a secondary role. Above a critical threshold of heat supply, the temperature increase initiates endothermic pyrolysis, which is followed by the onset of oxidation. When the heat released by oxidation is high enough to balance the heat required for the endothermic processes (heat losses, pyrolysis, drying and preheating of fuel), propagation occurs and the reaction might become self-sustaining (only then oxygen supply rate will play an important role). This section discusses four types of ignition sources: radiant, conductive, ember and self-heating. For all four, it is proven that the critical energy condition needed for smoldering is significantly lesser than that for flaming. The results discussed here are on individual fuel samples. But note that a particularly important smoldering scenario, that of upholstery and bedding fires, is a composite problem with the ignition propensity of both the fabric and the substrate contributing to the overall behavior [18].

Radiant Ignition

The effects of exposing polyurethane foam to an external radiant heat flux of increasing magnitude is illustrated in Fig. 19.3. The heat flux needed to initiate smoldering is significantly lower than that for flaming (see Table 19.1). For instance, the critical radiation heat flux for smolder ignition of polyurethane foam is

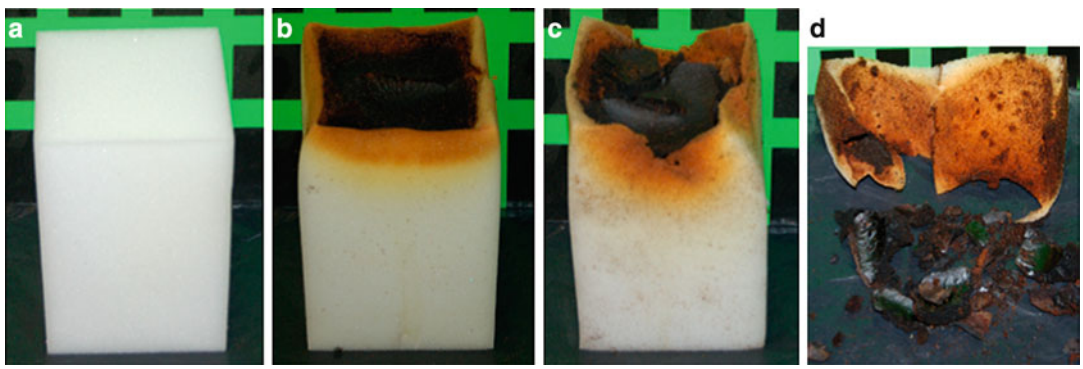

Fig. 19.3 Images of polyurethane foam samples exposed to increasing levels of radiation (from *left* to *right*): (**a**) virgin foam (not exposed to radiation), (**b**) charred foam in which a smoldering front did not propagate, (**c**) sample in which smoldering propagated, and (**d**) sample which underwent flaming ignition (By R. Hadden [19], CC BY license)

7 kW/m^2, while for spontaneous flaming is 30 kW/m^2 [19]. For piloted flaming ignition, the critical level is 13 kW/m^2 (Chap. 36).

It has been shown that the onset of smoldering involves a range of threshold temperatures. A single threshold temperature is not a valid criterion for ignition but it is part of a multi-criteria signature [20]. Several experimental studies have found that the minimum temperature measured during ignition of polyurethane foam is in range from 300 °C to 450 °C [19–21]. This is much lower than the threshold surface temperature of 600 °C required for spontaneous flaming ignition of the same material [19]. Figure 19.4 (left) shows the experimental data on the peak temperature reached inside a slab of polyurethane foam for the cases of no ignition, smoldering or flaming ignition. The same experiments (see Fig. 19.4 (right)) also show that the time to smoldering ignition by radiation depends on the heat flux level and ranges from 1 to 20 min for a heat flux of 45–7 kW/m^2 respectively. Flaming ignition was observed for heat fluxes above 30kW/m^2 and was fast, less than 1 min. The dependence of the time to ignition with radiant heat flux shown in Fig. 19.4 (right) resembles a an inverse square-root law with the incident heat flux. This suggests that smoldering ignition can be explained in terms of heat transfer, in the same way that a an inverse square-root law explains the flaming ignition of a thermally thick fuel (Chap. 21). This law originates from the time it takes for heat conduction to result in a critical temperature at a key location. For flaming, the key location is the free surface of the fuel, but for smoldering the key location is inside the fuel bed, at a sufficient depth such that an insulating layer of char is formed over the oxidation front [21]. The concept of a critical depth for ignition is not sufficiently studied yet but could be expected to vary for different materials and external conditions in the scale from 1 to 10 cm roughly.

Table 19.1 Critical heat fluxes found experimentally for the ignition of smoldering and spontaneous flaming combustion in samples of different sizes (Data from Hadden et al. [19])

Sample size (mm)	Critical heat flux for smoldering ignition (kW × m^{-2})	Critical heat flux for flaming ignition (kW × m^{-2})
50	18–19	32–45
100	8–9	32–37
140	7–8	30–31

Conductive Ignition

The heat source that can start a smoldering fire with the lowest heat flux is the conductive type.

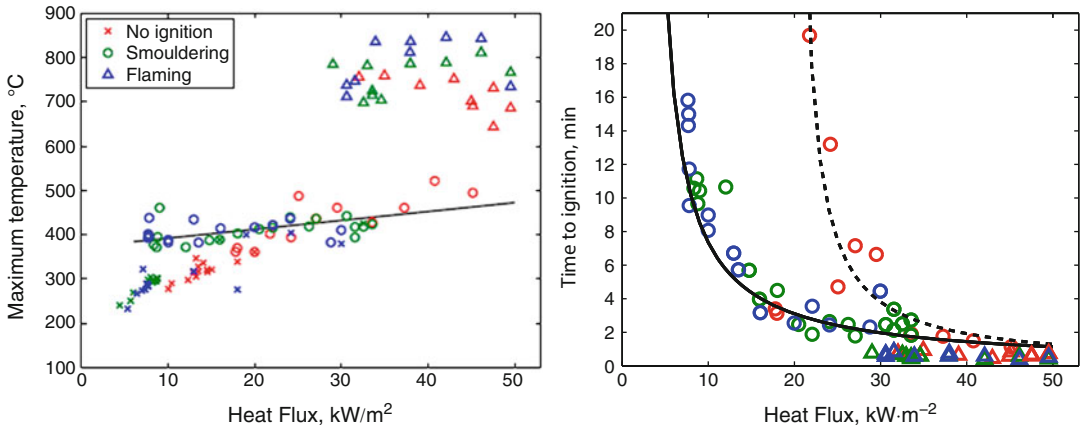

Fig. 19.4 Radiant ignition of smoldering and flaming in polyurethane samples of different sizes in still air. (*Left*) Maximum temperatures observed. (*Right*) Time to ignition. *Red*, *green* and *blue* represent 50, 100 and 140 mm side square samples respectively (Data from Hadden et al. [19])

This scenario occurs when a large and hot object is in direct contact with the fuel bed. Heat is transferred by conduction, but in porous fuels, convection also plays a role. Anthenien and Fernandez-Pello [21] studied the initiation of smoldering using an electric heater in contact with a sample of polyurethane foam under forced airflow. Ignition was reported at heat fluxes as low as 3 kW/m^2 and the relationship between time to ignition and heat flux was shown to follow a an inverse square-root law. Ignition was found to be weakly dependent on the airflow.

Conductive ignition has also been studied on a bed of particles [22]. A series of beds of anthracitic coal particle of uniform diameter ranging from 7 to 45 mm was investigated inside a cubic box (side of 100 mm) with the top side open to the atmosphere and multiple perforations on the other sides. The heat source was an electric wire that delivered 80 W. Figure 19.5 shows that the relationship of the time to ignition with particle diameter has a 'U' shape. It was not possible to ignite a bed which particle diameter was smaller than 7 mm. For very small particle sizes, the bed exhibits poor internal convection which limits the airflow and a long ignition time is required. But as the particle sizes increase, the porosity and the flow permeability of the fuel bed increase and a minimum time to ignition of 130 min (average) is required for a particle diameter of 25 mm. As particles become larger, the inter-particle conduction rate decreases resulting in a longer time to ignition.

Ignition by Embers

In close connection with conductive sources, a fuel bed can also be ignited by hot embers. This is related to ignition by hot works and also to the phenomenon of spotting in wildland fires, when lofted embers land downwind, leading to secondary fires in the wildland or in urban areas remote from the originating flame front. Ignition by embers is a transient phenomenon involving the loss of heat from the ember to the fuel by conduction and convection. Embers can be classified by material (metal or biomass) and thermal state (hot, smoldering or flaming).

Manzello et al. [23] compared the ember ignition of three fuel types and found that a bed of shredded paper was much more prone to smoldering than pine needles or mulch. The experimental study of Hadden et al. [24] found a relationship between ember size and the critical initial temperature required for ignition of a bed of cellulose powder. They used steel spheres with diameters in the range 0.8–19 mm at initial temperatures between 500°C and 1300°C. Smaller embers require higher temperatures to initiate combustion. Their data shows two distinct boundaries as the ember temperature

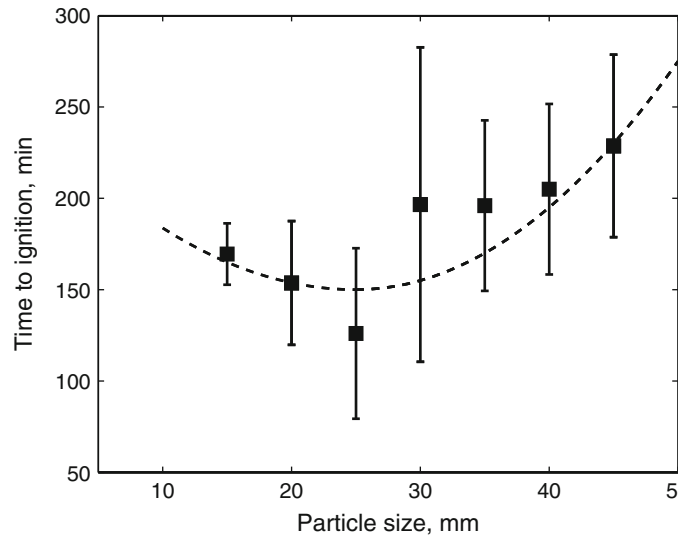

Fig. 19.5 Experimentally observed relationship between time to ignition and particle size in a bed of anthracite coal (Data from Hadden and Rein [22])

increases, one separating no-ignition from smoldering ignition, and the other from smoldering to flaming ignitions. The minimum ember temperature at which smoldering could be initiated was 550 °C, and the minimum temperature for flaming ignition occurred at 650 °C. Krause and Schmidt [25] also observed a decrease of the critical temperature with ember size for a series of organic powder samples (cork, beech and cocoa), and reported a minimum temperatures of 400 °C for smoldering ignition.

Self-Heating Ignition

Self-heating of a solid fuel can initiate smoldering fire deep within a pile of fuel without any external source, even at ambient temperatures. Self-heating refers to the tendency of certain porous solid fuels to undergo spontaneous exothermic reactions in oxidative atmospheres at low temperatures ([2, 26], Chap. 20). It is a well-known problem in the store of large amounts of carbon-rich materials (e.g., waste, coal heaps, organic powders) and in the process industries. The process is as follows: initially, the pile of the material releases small amounts of heat by very slow oxidation at ambient temperature. Somewhere near the center of the pile, where the fuel is most insulated, the heat accumulates in the long term and results in a sustained increase of the local temperature, which in turn accelerates the oxidation rate. Large pile sizes and poor ventilation conditions facilitate the buildup of heat. The process self-accelerates for some time (hours, days or weeks) and above a certain threshold temperature it leads to a thermal runaway. This results in a smoldering fire that can spread from the inside to the outside, and may undergo transition to flaming at a later stage when it reaches the free surface (discussed in section "Transition to Flaming").

Size Effects and Ignition

There is a minimum size below which a fuel sample will not undergo ignition. This is determined by the balance between the rates of heat generation and heat loss from the system. The rate of heat loss scales with the surface area, and the rate of heat generation scales with the volume. Consequently, as the size of a sample decreases, the surface -to-volume ratio[4] of the smoldering front increases. Below a certain size, heat losses overwhelm heat generation and ignition will not occur.

Palmer [27] found experimentally that the minimum thickness for smoldering of horizontal layers of sawdust was around 10 mm. Ohlemiller and Rogers [28] found the minimum thickness for cellulosic insulation to be 35 mm. A more recent experimental investigation of the effect of sample size [19] is reported in Table 19.1 and Fig. 19.4. Both the critical heat fluxes for smoldering and flaming ignition increase with decreasing sample size, with smoldering ignition being significantly more sensitive to the sample size than flaming. Krause and Schmidt [25] studied the ignition of organic dust samples by embers, and found that the larger the samples, the lower the critical ember temperature. The fact that large samples are easier to ignite than small samples has implications for testing standards and the translation of results from small-scale testing to real scale.

The process of ignition is related to self-sustained propagation (as discussed in the section "Smoldering Spread") which allows an approximate analytical treatment. The critical size L_c for self-sustained propagation in a prismatic sample of square cross-section can be estimated by Equation 19.3 provided by Rein [9] based on the energy balance by Torero and Fernandez-Pello [14] and Bar-Ilan et al. [29, 30].

$$L_c = \frac{4\delta U(T_s - T_0)}{Q_s \dot{m}''_{O_2}} \qquad (19.3)$$

where δ is the smolder-front thickness perpendicular to the propagation direction, T_s is the peak temperature, and Q_s is the heat of smoldering, which all depend on the fuel. The overall heat loss coefficient U, the ambient temperature T_0 and

[4] The surface-to-volume ratio of a sample is inversely proportional to its characteristic length (e.g., thickness for a very wide layer, diameter for a cylinder, side length for a prism or diameter for a sphere).

the supply of oxidizer $\dot{m}''_{O_2}$ depend on the geometry and external conditions. For polyurethane foam, Equation 19.3 says the critical size is around 160 mm [19]. If a sample is below the critical size L_c, sustained smoldering will not be achieved. Smoldering will only spread if the heat losses are reduced or the rate of heat generation is increased, or both. The former would involve insulating the reaction front or supplying additional heat from an external source, and the latter would involve increasing the supply of oxidizer.

Smoldering Spread

The spread of smoldering is controlled by the oxygen supply and heat transfer [1]. Conditions sufficient to yield smolder initiation, especially near an external heat source, might not be sufficient for self-sustained spread away from the ignition region. If the external heat supply continues, assisted propagation is possible. Otherwise, once the external heat supply ceases, smoldering reaction will be self-sustained or lead to extinction.

Experimental and modeling work has demonstrated that the smolder spread rate is linearly dependent on the total air supply rate to the smoldering front [1, 29, 30]. Some of these results are presented in Fig. 19.6. Torero and Fernandez-Pello [14] reported than this linear increase breaks down for opposed propagation at high airflows and stars decreasing (at ~3 mm/s for polyurethane foam slabs of 150 mm square cross section). In general, air is transported to the reaction front by convection and diffusion. Convection can be natural (buoyant) or forced. In the absence of forced flow, buoyancy tends to dominate over diffusion in regions of lesser flow resistance, for example near the free surface or in a bed of large particles. The diffusion flux is dominant when deep layers of a pile of fine particles is ignited [27]. Forced convection in smoldering fires usually takes the form of an air current flowing through the fuel bed or over the free surface of the bed. Forced convection directly flowing through the bed of the fuel is often used in laboratory studies (e.g., see Fig. 19.6). The advantage is that it provides controllable conditions to investigate the phenomena also deeper into the bed. These studies have found a critical air supply rate required for self-sustaining propagation (around 0.6 g/m^{2}s of oxygen flow for opposed mode in a 120 mm diameter slab of polyurethane foam [30]). This critical supply

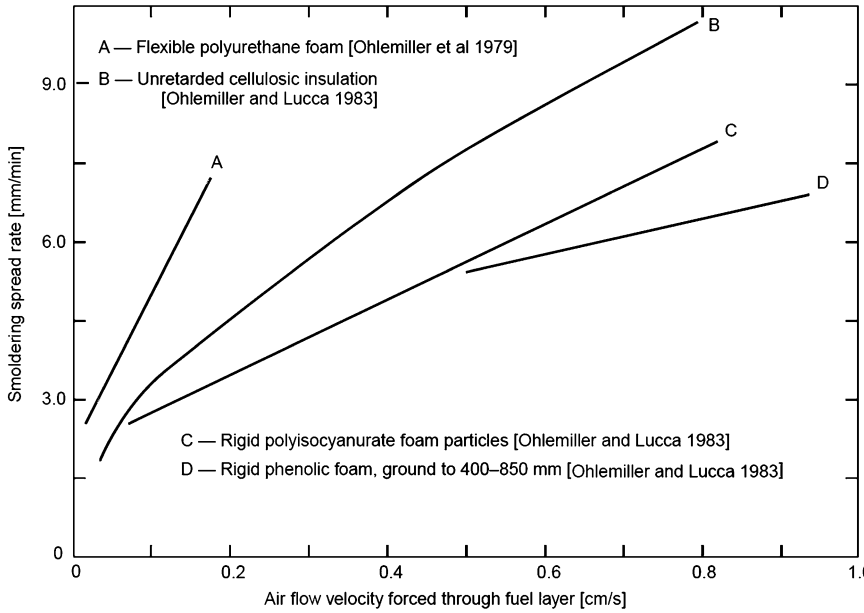

Fig. 19.6 Spread rate of smoldering assisted by airflow forced through the bed in opposed mode for a variety of materials (After Ohlemiller [7])

rate is known to be a function of the heat losses. For example, microgravity experiments on the same polyurethane samples [30] have shown that the removal of lateral heat losses by natural convection allows self-sustained propagation at significantly lower oxygen supplies (0.3 g/m^{2}s).

When a bed of fuel is ignited locally, in general the spread will be multidimensional and include both horizontal and vertical spread. Each front will be dominated by forward or opposed propagation (or a combination) depending on the roles of buoyancy, wind and diffusion. Two important configurations are presented in Fig. 19.7 where the spread is either downwards or upwards though the fuel bed.

If initiation occurs on the top surface of the fuel bed, the fire will spread laterally and downward. It leads to a void or hole in the general shape of a semi-ellipsoid or pan. Downward spread is dominated by forward smoldering (Fig. 19.7, left), and creates a growing layer of ash that only decreases if wind carries the particles away. The horizontal spread is enhanced by a direct supply of atmospheric oxygen, which is readily available, and the rate is significantly greater than downward spread where oxygen transfer is limited by the layer of ash and char. Combustion of the uppermost layer is typically quenched due to large convective and radiant heat losses; this leaves a very thin layer of charred material on top while smoldering continues below. The fact that horizontal spread is faster a few cm below the surface leads to the formation of an overhang pointing inwards at the rim of the void (overhang not shown in figure 19.7). Horizontal spread accelerates in response to an increased wind. Palmer [27] examined this in thin horizontal layers (3–57 mm) of

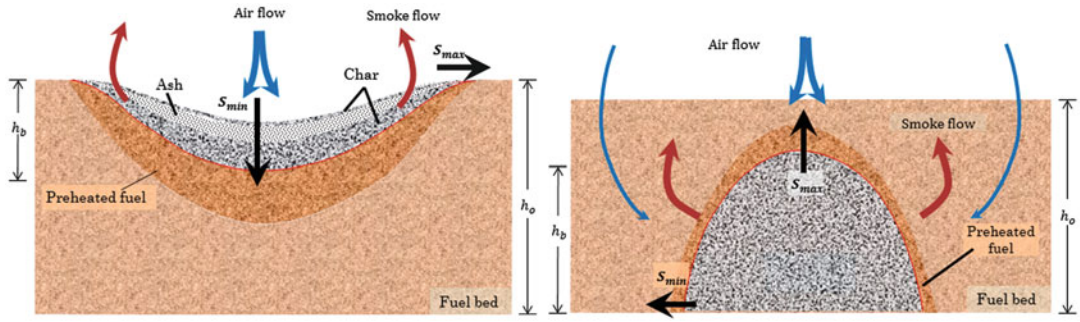

Fig. 19.7 Diagrams of downward (*left*) and upward (*right*) propagation in a porous fuel bed Huand and Rein [31]

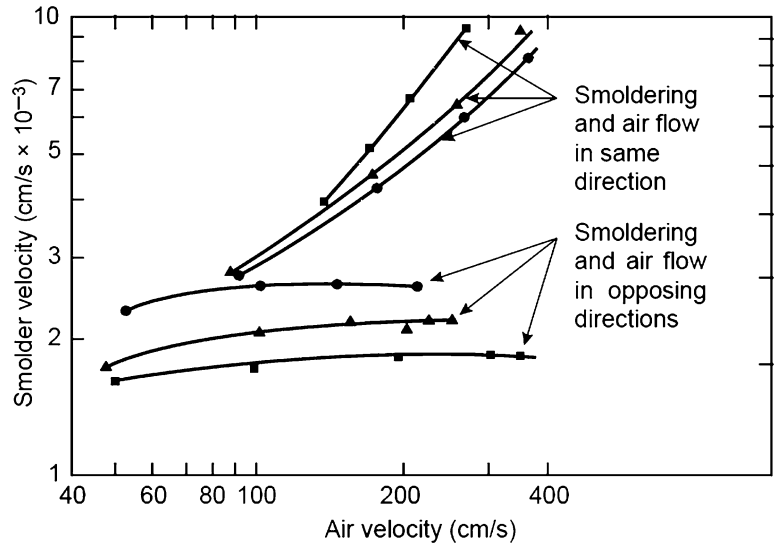

Fig. 19.8 Smoldering spread rate through horizontal layers of sawdust as a function of the horizontal airflow over the topmost layer. *Circles*: 120 mm particle size; *triangles*: 190 μm particle size; *squares*: 480 mm particle size (Data from Palmer [27], after Ohlemiller [7])

various cellulosic particles (cork, pine, beech, grass). The results in Fig. 19.8 show that the horizontal airflow has a greater effect in forward propagation, but that airflow in opposed propagation and the particle size have a weaker effect. In the absence of any forced flow over the fuel layer, the flow induced by the buoyant plume supplies oxygen for the horizontal spread at the topmost fuel layer. Oxygen then penetrates into the layer mostly by diffusion [32].

If initiation occurs deep within a layer of fuel and the nearest free surface is on the top, the fire will slowly spread upwards dominated by opposed smoldering (Fig. 19.7, right). The thick layer of virgin fuel above the reaction front hinders the oxygen supply, but also reduces the rate of heat losses. Ultimately, the spread is faster towards the free surface driven by oxygen diffusion, thus leading to fronts in the shape of an elongated bell. The reaction front usually spreads without fully consuming the char left behind. The upward case was studied in Palmer's work [27], which consists of a collection of observations from simple experiments involving the initiation of a smoldering front at the base of sawdust heaps (cork, elm and mixed wood). Some of the results are shown in Fig. 19.9. Note the scales reported in this data; the time to smolder up through a layer 1 m deep is about 2 weeks, and the process gave little hint of its presence until it was close to the surface of the fuel heap (smoke gets trapped inside the porous bed). The slope of the curve indicates that the time for upward smolder to penetrate a fuel layer is proportional to the square of the layer depth. Palmer showed that such dependence suggests the smolder front spread is proportional to the diffusion rate of oxygen from the free surface, through the unburned fuel, to the reaction front.

Data from other experiments on a variety of fuels and air supply conditions are summarized in Table 19.2.

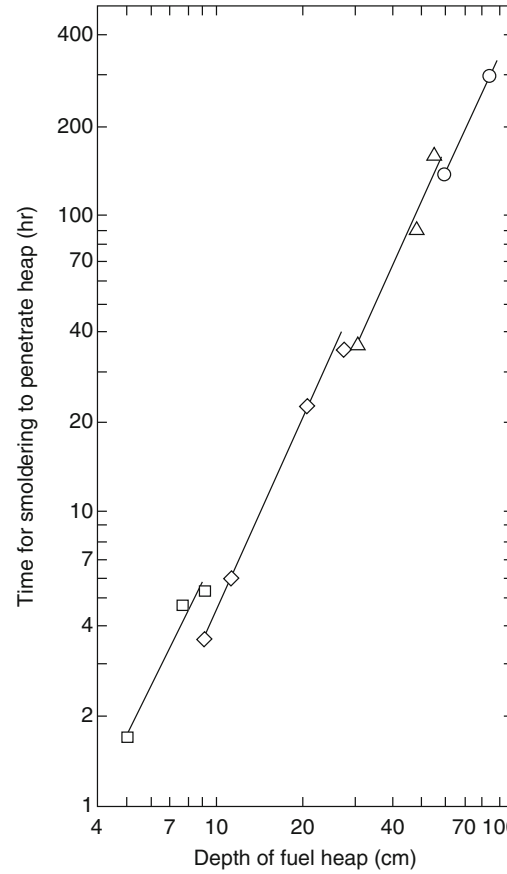

Fig. 19.9 Upward spread of smouldering through a bed driven by air diffusion. Smoldering Kinetics

The spread rate of self-sustained smoldering is typically controlled by oxygen transport and heat transfer. Yet, heterogeneous chemical kinetics governs the front structure and is ultimately responsible for determining the conditions under which a material ignites and extinguishes.

Smoldering combustion of a solid fuel involves multiple pathways to chemical reactions, and these pathways are not yet fully understood. In spite of the complex kinetic behavior, experimental evidence suggests that mechanisms consisting of only a few global reactions capture the most important characteristics of the chemical process and allow an approximate analysis. Smoldering chemistry in its simplest form can be understood as a two-step process: pyrolysis of fuel (Equation 19.1) produces the char that is then oxidized

Table 19.2 Experimental data on smoldering in various fuels and configurations (After Ohlemiller [7])

Fuel	Configuration	Air supply	Spread rate	Peak temperature	Reference	Comments
Pressed fiber insulation board, 230–290 kg/m^3	13 mm thick horizontal strip, width large compared to thickness	Natural convection	0.8–1.3 mm/min	NA	Palmer [27]	Smolder velocity increased ≈ 50 % for strips with width ≈ thickness
Pressed fiber insulation board, 230–290 kg/m^3	13 × 13 mm strip at varied vertical inclinations	Natural convection	1.6–2.8 mm/min	NA	Palmer [27]	Smolder velocity highest for upward spread; lowest for horizontal spread
Fiber insulation board	13 × 50 mm strip forward smolder	Airflow over 20–1500 cm/s	2.1 mm/min (20 cm/s airflow) 7.8 mm/min (1400 cm/s airflow)	790 °C (900 cm/s airflow)	Palmer [27]	Some samples extinguished due to cooling at airflows >1450 cm/s
Fiber insulation board	13 × 50 mm strip opposed smolder	Airflow over strip, 80–900 cm/s	1.7–2.1 mm/min	NA	Palmer [27]	Extinguishment >900 cm/s
Fiber insulation board (pine or aspen)	13 mm thick sheet, horizontal, forward smolder	Airflow over sheet, 10–18 cm/s	1 mm/min	NA	Brenden and Schaffer [33]	
Cardboard	Vertical rolled cardboard cylinder, downward propagation, diameter 1.9–3.8 mm	Natural convection	3–5 mm/min	NA	Kinbara et al [34]	Small dia. ≈2× faster than large dia.; ambient temp. effect measured
Shredded tobacco	8 mm diameter cigarette, horizontal, in open air	Natural convection	1.8–3 mm/min	820 °C	Egerton et al. [35]	
Cotton upholstery fabric	Double fabric layer, 2 mm thick, horizontal, forward smolder	Airflow over fabric, 10 cm/s	~6 mm/min	770 °C	Donaldson and Yeadon [36]	Smolder behavior dependent on alkali metal content
Cellulosic upholstery fabric on substrates	Various weight fabrics horizontal on fiberglass, PU foam, cotton	Natural convection	1.8–45 mm/min (depends on substrate)	Reported values suspiciously low	Donaldson and Yeadon [36], Stiefel et al. [37]	Smolder fastest on inert fiberglass substrate
Cotton batting, densities 5–100 kg/m^3	15 cm cube, hold together by metal mesh and open to the air on all sides	Natural convection	2–4 mm/min (decrease as density increases)	690 °C	Hagen et al. [38]	Lower densities or repeated heating of sample result in higher ignition temperature
Wood char, densities 290–435 kg/m^3	22 cm tall packed bed of particles, diameter 1–3 mm	Natural convection	Upward ~0.4 mm/min. Downward ~0.05 mm/min	Upward 530 °C. Downward 800 °C	He and Behrendt [39]	Downward peak temperature decreases as the height of ash layer increases
Cork, beech and cocoa powders	Mesh wire baskets with volumes of 0.8–200 l	Natural convection	0.1–1.5 mm/min and decreasing relationship with basket volume	260–375 °C and decreasing relationship with basket volume	Krause and Schmidt [25]	Ignition sources tested include hot body, glowing nest and electric coil

in situ (Equation 19.2a). In this section we explore more comprehensive kinetics.

To begin with, the simple two-step scheme proposed in Equations 19.1 and 19.2a can be extended to include the direct oxidation of the fuel. Char oxidation (Equation 19.2a) is the principal heat source in most self-sustained smolder propagation processes; the potential for smoldering combustion thus exists with any material that forms a significant amount of char during thermal decomposition. The fuel is oxidized as well (Equation 19.4) but the most exothermic reaction is that of char, and therefore the simplest overall mechanisms does not include fuel oxidation. Fuel oxidation is also related to self-heating when it takes place at low temperature close to ambient (see Chap. 20).

Direct heterogeneous oxidation of the fuel:

$$\text{Fuel (solid)} + O_2 \rightarrow \text{Heat} + CO_2 + H_2O + \text{other gases} + \text{Char (solid)} + \text{Ash (solid)} \tag{19.4}$$

The materials for which smoldering kinetics are best known are polyurethane foam and cellulose. Kashiwagi and Nambu [40] provided a quantified three-step mechanism for cellulose, including cellulose pyrolysis, cellulose oxidation and char oxidation and accounting for three solid species; cellulose, char and ash. In flexible polyurethane foam, the presence of oxygen during degradation plays another key role, because without oxygen, many foams do not form char [41]. Rein et al. [15] provided a five-step mechanism for polyurethane consisting of two foam pyrolysis, two foam oxidations and one char oxidation reaction, and accounting for four solid species (foam, β-foam, char and residue). This mechanism was developed and the kinetic constants found from thermogravimetric experiments, as shown in Fig. 19.10. This multi-step mechanism allows explaining the different contributions of the pyrolysis and oxidation reaction to the degradation of the foam in the presence of air, as seen in Fig. 19.11.

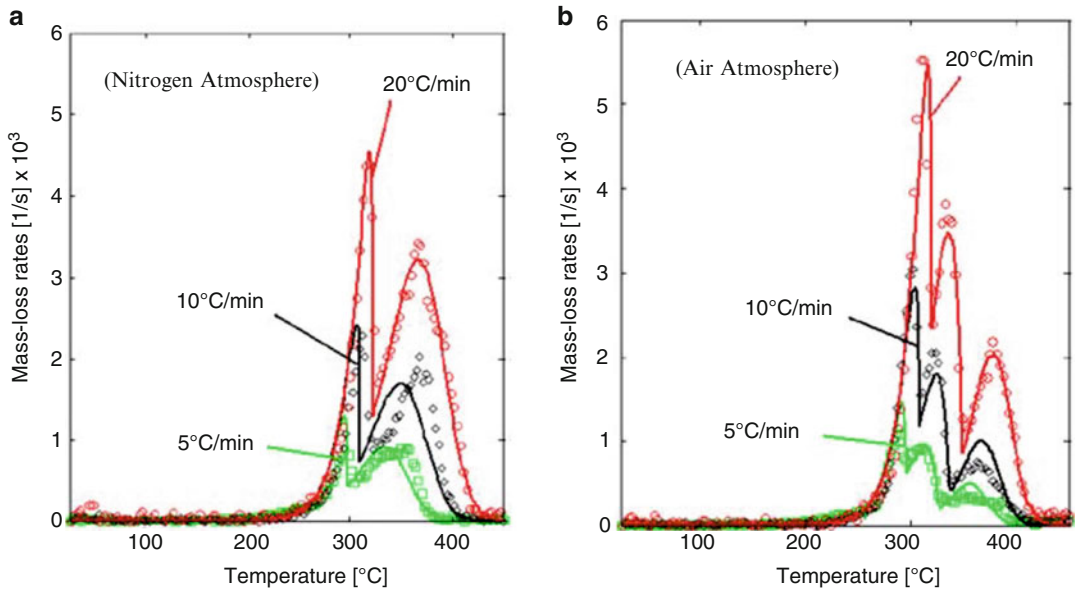

Fig. 19.10 Thermogravimetric mass loss rate of polyurethane foam in; (**a**) nitrogen atmosphere, and (**b**) air atmosphere, as a function of temperature for three heating rates (Symbols are data from experiments of Chao and Wang [42], and lines are data from numerical simulations of Rein et al. [15])

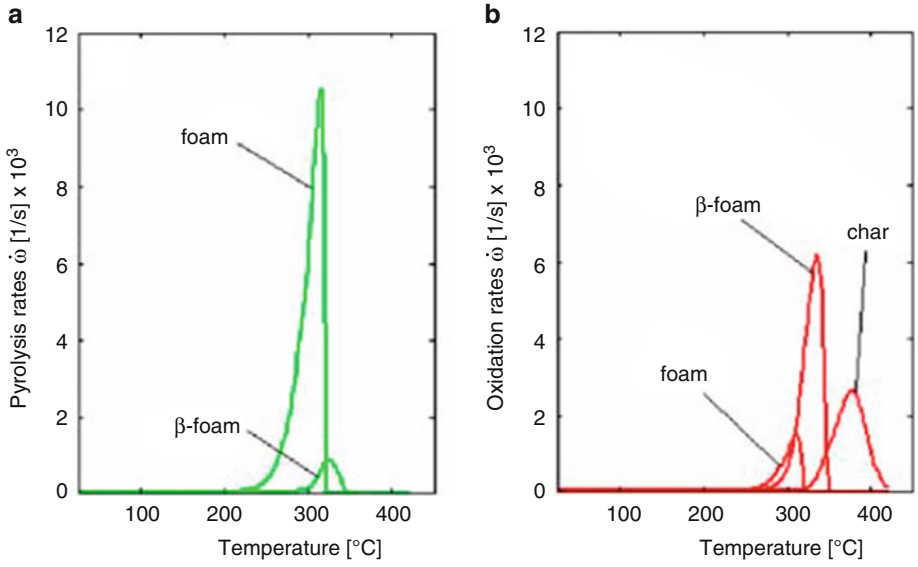

Fig. 19.11 Numerical results for the different reactions rates (pyrolysis on the *left*, oxidation on the *right*) in polyurethane foam decomposition in air atmosphere. This simulates the experimental thermogravimetric data of Fig. 19.10 (*right*) and allows explaining the origin of the three mass-loss peaks (Data from Rein et al. [15])

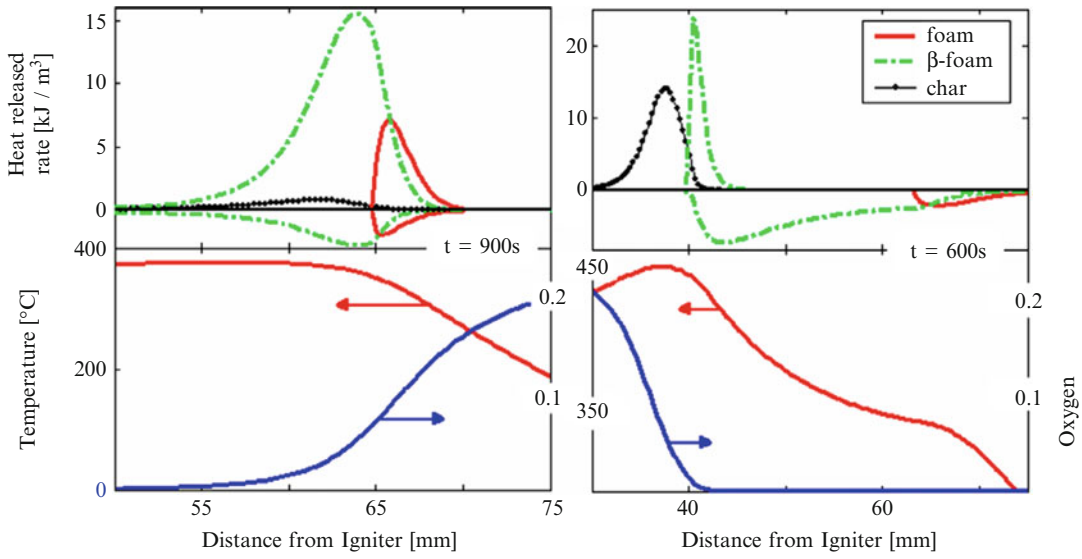

Fig. 19.12 Numerical results for the front structure during self-propagation; (*left*) opposed smoldering; and (*right*) forward smoldering. *Top* figures show the heat-released rate of each reaction (positive for oxidation, negative for pyrolysis). *Bottom* figures show the temperature and oxygen profiles (Data from Rein et al. [16])

The separation of pyrolysis from oxidation is essential in any smouldering kinetics scheme.

It was the work of Rein et al. [16] that proved that the same kinetic mechanism was able to explain both forward and opposed smoldering. In forward smoldering propagation (Fig. 19.12, right), the oxidation and the pyrolysis reactions form two distinct propagating sub fronts. The pyrolysis sub front arrives first to the virgin foam and then followed by the oxidation sub front. In opposed smoldering (Fig. 19.12, right), the oxidation and the pyrolysis reactions overlap

to form a single front. Previously to the work of Rein et al. [16], smoldering chemistry had been described as a function of the propagation mode: forward smoldering with two-step chemistry, and opposed smoldering with one-step chemistry.

Smoldering kinetics is an immature field of solid phase chemistry due to is complexity and secondary role in fire spread. It has been the objective of few studies to date. Despite the recent advances reviewed in this section, the topic remains mostly undeveloped.

Suppression

A smoldering fire can be extraordinarily difficult to suppress. Experiments on heaps of coal show that smoldering requires large amounts of water. For example, the amount of water required to suppress smoldering coal was measured to be in the range from 1 to 2 l of water per kg of burning fuel. Moreover, smoldering requires lower oxygen concentration to be smothered, around 10 % O_2, compared to 16 % O_2 for flaming [43, 44]. Oxygen removal is insufficient unless it is continued until the whole fuel bed is cooled to a point where oxygen readmission will not cause re-ignition. Because volumetric cooling of a fuel bed is a very slow process (long thermal response time), this means that the holding time for smothering are much longer for smoldering than for flaming[5] (months vs. hours) [22].

One practical problem in suppressing a large fuel bed is the tendency of the extinguishing fluid agents to follow higher permeability channels and thereby miss significant in-depth burning zones. Channeling arises when a substantial fraction of the fluid takes the same flow path through the bed, resulting in limited contact surface area between the agent and the burning fuel. This, coupled with the lower residence times in regions of high permeability because of the high flow velocities, requires large quantities of water for suppression.

[5] Avoidance of flaming re-ignition of a non-porous fuel requires cooling of the surface layer only.

Hadden and Rein [22] investigated three water suppression methods (pipe, shower and spray) on a small-scale coal bed. They showed that the most efficient method with respect to total water required is the shower. However, using a spray results in less water runoff and thus offers a higher efficiency. The injection pipe is significantly less efficient, requiring three times more water than a spray, and resulting in >80 % lost as run-off. Tuomisaari et al. [45] tested a number of extinguishing agents (liquids: water, water with additives; gases: N_2, CO_2, Ar and Halon) in series of tests on a small bed of smoldering wood chips. The result was that gaseous CO_2, injected from the bottom, was found to be the most effective.

Gas Emissions

Gas emissions from smoldering fires differ significantly to those from flaming fires. First, the emissions rate per unit area is much lower but also the chemistry is different. Smoldering is characteristically an incomplete combustion, releasing species and quantities that substantially depart from that in stoichiometric and complete combustion. For example, the CO/CO_2 ratio which can be thought of as an index of the incompleteness of combustion is ~0.4 in smoldering but ~0.1 in flaming combustion [46]. The presence of pyrolysate in the products of smouldering, significantly contributes to of a complex gaseous mixture including volatile organic compounds (VOC), polyaromatic hydrocarbons (PAH), other hydrocarbons and particulate matter (PM). While the yield of toxic species is larger in smoldering fires than in flaming fires [47], the production rate, which is proportional to the spread rate, is much lower. This means that inside an enclosure, a smoldering fire of long duration (in the range from 1 or 3 h for a single bedroom size compartment [48]) can lead to a lethal dose of toxicity, especially CO. But there are not as yet sufficient data on the toxicity of smoldering materials to definitively understand the issue of life safety. Some more information is presented in Chap. 62 and in [47].

Limited information is available on the aerosol emitted by a smolder source. The residual char left behind the smolder front and the original porous bed act as filters for aerosol. This finding explains the observation by Palmer [27] that upward smoldering in a thick layer of fuel was not detected until it neared the surface (like in Fig. 19.7 right). The mean particle size of the aerosol in smoldering cellulose was measured to be in the range from 2 to 3 μm [49]; this is about 50–200 times larger than the sooty particulates produced by flaming combustion.

The low heat release rate of smoldering fires means that the buoyant plume is weak, which has implications on the location of smoke detectors in rooms. The morphology of the smoke from smouldering is different to smoke from flaming, and this affects smoke detection. This means smoke is slow to reach the ceiling, or it may never reach it, and often the building mechanical ventilation controls the smoke movement [50] (see also Chap. 13).

In the natural environment, the low buoyant strength of large smoldering fires leads to haze episodes because the plume accumulates near the ground and can slide into populated areas, choking towns and cities for weeks [5]. The composition of haze measured by Bertschi et al. [51] in the tropical savanna shows it contains 130 % more CO and 670 % more hydrocarbons in mass basis, but 15 % less CO_2 and no NO_x when compared to the flaming wildfires.

Smoldering Wildland Fires

In the natural environment, smoldering fires burn two types of biomass: thick fuels, like tree branches or logs, and organic soil, like the duff layer or peat [5]. These are characterized by having a significantly greater thermal time compared to fine fuels like foliage. Thick fuels favor the slow burning of smoldering combustion. The persistent smoldering of thick fuels is typically observed for a few days after a flaming wildfire has passed, and it is often referred to as *residual smoldering combustion*. Overall, smoldering is responsible for up to 50 % or more of the total burned biomass during wildfires [51–53].

But it is the soil rich in organic matter, in particularly that in peatlands, which is most affected ecosystem by smoldering fires, both in frequency and size. Peat soils are made by the natural accumulation of partially decayed biomass and are the largest reserves of terrestrial organic carbon [54]. Because of this vast accumulation of fuel, once ignited, smoldering peat fires burn for very long periods of time (e.g., months, years) despite extensive rains, weather changes or fire-fighting attempts. These are the largest fires on Earth and large contributors of greenhouse gases [5, 54]. Peat fires occur with some frequency worldwide in tropical, temperate and boreal regions (e.g., in Indonesia, Australia, Alaska, Canada, Florida, British Isles, Siberia). Droughts, drainage and changes in land use are thought to be main causes leading to the high flammability conditions of dry peatlands. Possible ignition events can be natural (e.g., lightning, self-heating, volcanic eruption) or anthropogenic (land management, accidental ignition, arson).

The most studied peat megafire took place in Indonesia in 1997 and led to an extreme haze event. The smoke covered large parts of South-East Asia, even reaching Australia and China, and induced a surge of respiratory emergencies in the population and disruption of shipping and aviation routes for weeks. It was estimated that these fires released between 0.81 and 2.57 Gton of carbon gases [55]. This is equivalent to 13–40 % of global man-made emissions of the year 1997. The 1997 megafire was not an isolated case in the region. Analysis of 1960–2006 data shows that smoldering haze episodes have drifted to South East Asian countries once every 3 years on average [56]. Rough figures at the global scale estimate that the average greenhouse gas emissions from peat fire is equivalent to >15 % of man-made emissions. Moreover, because peat is ancient carbon, and smoldering is enhanced under warmer and drier climates, it creates a positive feedback mechanism in the climate system, a self-accelerating global process [5].

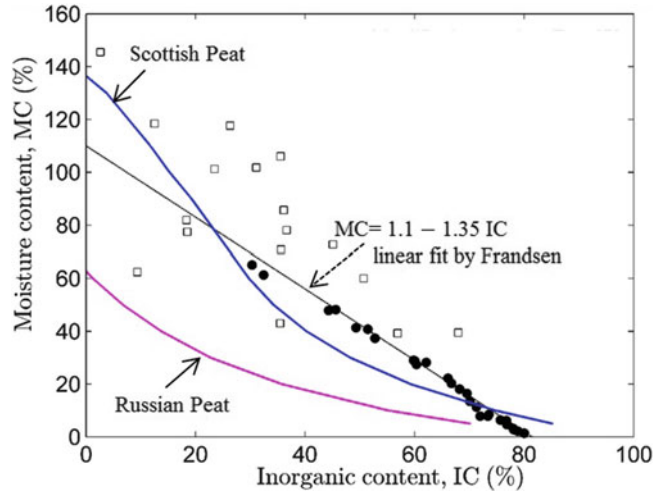

Fig. 19.13 The data separates the ignition (bottom) from the no-ignition (top) limits for a mixture of peat, moisture and mineral contents. Circles and sequre symbols are experimental data by Frandsen [58]. Lines are computational simulations by [59].

Because the water content of wildland fuels like peat can vary naturally over a wide range of values (from dry to flooded in water), and because water represents a significant energy sink, moisture content is the single most important property governing the ignition and spread of smoldering wildfires. The critical moisture content for ignition (related to the moisture of extinction [57]) of boreal peat has been measured in the range 110–120 % in dry basis[6] [16, 58]. Any peat drier than this is susceptible to smoldering. The prominent role of moisture is such that natural or anthropogenic-induced droughts are the leading cause of smoldering megafires.

The second most important property is the mineral content.[7] As found experimentally by Frandsen [58] and computationally by Huang et al [59], there is a decreasing relationship between the mineral content and the critical moisture content: higher mineral loads mean soil can only ignite at lower moistures. This is because the inert content is a heat sink to the fire. The results are shown in Fig. 19.13. This rule can be applied to most organic soils or fuel beds to determine if they are susceptible to smoldering. Any soil which composition is more than 80 % mineral, cannot be ignited [58, 59]. After moisture and mineral contents, other important properties are bulk density, porosity, flow permeability and organic composition.

Because the fuel layers found in the natural environment (soil depths from 0.5 to 30 m) can be much thicker than those in the built environment (~0.1 m), smoldering wildfires can be classified in shallow or deep fronts. Each has significantly different dynamics because of the different role played by the controlling mechanisms of oxygen supply and heat losses.

Organic material located close to the surface of the soil burns in shallow fires (roughly <1 m under the surface). These have a good supply of atmospheric oxygen, but are exposed to large convective heat losses. They propagate laterally and downwards along the organic layers of the ground, leave voids or holes in the soil (see Fig. 19.7 left). This has prompted that fuel consumption can be estimated using the depth of burn to calculate the volume of the void. Depth of burn is the vertical distance between the original soil

[6] The water content in dry basis is the mass of water divided by the mass of a dried sample expressed as a %.

[7] The mineral content is the % of the fuel mass (on dry basis) that will not burn or react at high temperatures. It results in ash.

location and the post-fire soil location. A typical value for the depth of burn reported in several field studies is around 0.5 m, which means that the average fuel consumptions per unit area is around 75 kg/m^2. This value is more than two orders of magnitude larger than that in flaming fires [5]. For this reason and in terms of fuel consumption, these are classed as megafires.

Deep fires take place in organic the subsurface layers fed by oxygen infiltrating the ground via large cracks, piping systems or channels. For example, it is known that peatlands have an in-built natural piping system for water movement; when drained this system becomes the delivery network for oxygen transport to deeper locations and smoke exhaust to the atmosphere. Deep fires have a poorer supply of atmospheric oxygen but are better insulated from heat losses than shallow fires.

Smoldering fires have detrimental effects on the forest soil, its microflora and microfauna. This is because it consumes the soil (>90 % mass loss) and also because the long residence time of smoldering means that heat penetrates deep into the soil layers [5]. On the contrary, flames produce high temperatures above the ground for short periods of time (in the order of 15 min). This results in minimal heating of the soil below depths of a few cm, reaching peak temperatures of 300 °C at superficial layers (<10 mm) and below 80 °C at layers more than 40 mm deep [60]. This superficial heating can leave the soil system relatively unharmed. However, smoldering fires lead to enhanced heat transfer into the soil (see the discussion on the depth of burn above) for much longer durations (i.e. in the order of 1 h) and peak temperatures of 500 °C [61]. As a comparison, these thermal conditions are more severe than medical sterilization treatments, and mean that the soil is exposed to conditions that are lethal to biological agents.

Coal Seam Fires

Coal fires are a smoldering phenomenon that has attracted a larger amount of research, especially from geologists and petrologists [37, 62] and share many similarities with deep smoldering wildfires. Due to the higher density and higher fraction of carbon in coal, the fire spreads slower (~0.1 mm/min) but burns hotter (~1000 °C peak temperature) compared to other smoldering fuels. Because of these characteristics, coal particles smoldering near the free surface are more frequently accompanied by flames than any other fuel.

There is evidence to suggest that burning coal seams are the oldest continuously burning fires on Earth. The best examples is *The Burning Mountain* in New South Wales, Australia is a large coal seam which has been smoldering for more than 6000 years [12]. Thousands of underground coalmine fires have been identified around the world, especially in China, the United States, and India [63]. Elusive, unpredictable and costly, coal fires burn indefinitely while there is fuel, choking the life out of a community and the environment while consuming a valuable energy resource. The associated financial costs run into millions of dollars including the loss of coal, closure of mines, damage to the environment and fire-fighting efforts. There are some well-documented cases. In 1962, an abandoned mine pit in Centralia, Pennsylvania, USA was accidentally lit. Several unsuccessful attempts were made to extinguish it, letting the fire continue to burn after more than 40 years. It is currently being monitored with the front advancing at ~20 m/year [64].

Transition to Flaming

Smoldering and flaming combustion are closely related, and one can lead to the other. Figure 19.14 shows snapshots of an experiment on the transition to flaming in a foam slab. The transition from smoldering to flaming is a severe threat in residential fires, and together with the slow buildup of CO and other incapacitating gases, they pose the largest life hazards of bedding or upholstery fires. The transition to flaming is also a concern in wildfires, since it offers the means for flaming fronts to re-establish in unexpected locations (e.g., across a fire break) and at unexpected times (e.g., long after burn out of the initial flaming front).

Fig. 19.14 Series of photographs of a combustion experiment illustrating the transition to flaming in a smoldering polyurethane slab 40 cm high under external forced flow (Photo by group of Prof. Carlos Fernandez-Pello, University of California at Berkeley). After 1 h of smoldering only half the sample has burned (Photo 1, far *left*). When the rapid transition to flaming takes place (Photos 2 and 3), the whole sample is engulfed in flames in just a few seconds (Photos 4 and 5, far *right*)

However, it has received little attention so the current understanding of this transition is limited. In particular, whether the transition is possible or not or when it will occur cannot be predicted because of a lack of valid models. Babrauskas and Krasny [65] did a literature survey of fire tests on a variety of upholstered furniture items (chairs, sofas and mattresses) where a smoldering fire was ignited and allowed to progress. Out of the 102 fire tests examined, 64 % did transition to flaming. The time to transition observed ranged from 22 to 306 min, with an average of 88 min. Revisiting the data from previous experiments on smoldering of furniture, Quintiere et al. [48] showed that the likelihood of having transition to flaming occur peaks with a 36 % probability at 50–100 min after ignition. They also showed that within the time period from 50 to 200 min, the likelihood of a transition event is comparable with the likelihood of reaching a lethal CO dose inside a single bedroom compartment.

The transition is a spontaneous gas-phase ignition supported by the smoldering reaction, which acts both as the source of gaseous fuel, the pyrolysate produced in Equation 19.1, and the source of the heat required to initiate the flame (Equation 19.2b) [2, 32]. The transition occurs not at the foam/air interface, but rather within the depth of the char left by the smolder front [66, 67]. This is the location where both critical conditions of flammability of the pyrolysate mixture and the net excess of heat released by char oxidation are met. The heat driving the transition is released mostly by the secondary char oxidation [14, 66], which is more exothermic and takes places at higher temperatures (~700 °C for polyurethane [68]) than char oxidation in Equation 19.2a. This temperature range is towards the highest temperatures typical of smoldering combustion and hence secondary char oxidation is only of importance during the transition to flaming [66].

A smoldering fuel responds to an increased oxygen supply (e.g., wind) by becoming faster and hotter until, eventually, flames might erupt. This effect was first studied quantitatively by Palmer [27] for airflows over horizontal layers of wood sawdust. Depending on the material, the transition occurred at airflow velocities from about 0.9 to 1.7 m/s. Ohlemiller [69] did obtain transition to flaming in layers of fibrous insulation materials in forward smolder at air velocities

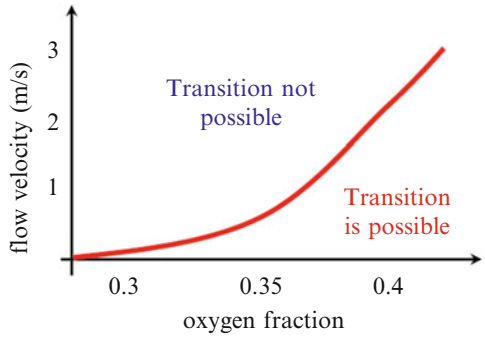

Fig. 19.15 Transition map from smoldering to flaming on polyurethane samples (Data from [70])

of about 2 m/s. Bar-Ilan et al. [70] conducted experiments on small samples of polyurethane foam and showed that the transition can be triggered by a combination of increasing the airflow velocity, the oxygen concentration or the external radiant heat. A map of airflow vs. oxygen fraction is shown in Fig. 19.15. A similar map is presented in Bar-Ilan et al. [70] for airflow vs. external heat. They also provide an analytical expression for the transition boundary.

The transition to flaming has only been observed in forward propagation. Ohlemiller [69] argued that this is because in forward mode, the hot gases of combustion preheat the fuel ahead and thereby enhancing the combustion; while in opposed mode, the cool air reduces preheating. However, upward propagation inside a pile of fuel (Fig. 19.7 right), which is mostly in opposed mode, can lead to the transition to flaming once the reaction breaks through to the free surface and finds a good supply of oxygen.

Concluding Remarks

We have seen that smoldering fires are a source of safety and environmental concerns. It is a type of combustion quite distinct from that in flaming fires, but as diverse and complex. The most studied fuels to date are cellulose and polyurethane foam.

The most important concepts to bear in mind are the following. Smoldering combustion can be initiated with weaker ignition sources (radiant, conductive, embers and self-heating) and is more difficult to suppress than flaming combustion. This makes smoldering the most persistent combustion mode. Large samples are easier to ignite than small samples, which affects the translation of laboratory testing results to the real scale. Smoldering fuels include synthetic materials such as charring polymers or cellulosic insulation, and natural fuels like peat or coal. In chemical terms, most smoldering fuels form a char on heating. In physical terms, smoldering fuels consist of a permeable medium formed by grains, fibers or some other porous matrix. The chemistry involves multiple pathways to chemical reactions, but in its simplest form can be understood as a two-step process: the pyrolysis of fuel and char oxidation. It is characteristically an incomplete combustion reaction, releasing pollutants in greater yields than flaming but at a lower rate. The transition from smoldering to flaming is a severe threat and can be triggered by a combination of increasing airflow, oxygen concentration and external heat.

An emerging topic is smoldering wildland fires of organic soils, like peat, which are megafires in terms of the fuel consumption, and together with coal seam fires are the largest and oldest continuously burning fires on Earth.

Regrettably, the state of the art is incomplete, and accurate calculations on smoldering phenomena are not possible. Current understanding is fragmented in different areas, as suggested by the many different names applied to it: non-flaming combustion, oxidative pyrolysis, glowing combustion, filtering combustion, low oxygen combustion, deep seated fire, hidden fire, lagging fire, smoking material, in-situ combustion, fireflood or underground gasification [9]. More experimental and theoretical studies, and a multidisciplinary research approach to smoldering combustion are needed.

Acknowledgements I am most grateful to Thomas J. Ohlemiller whose pioneering research and reviews on smoldering combustion provided not only the best sources of knowledge and inspiration for my own research and understanding but also contributed to this chapter in the form of material that I reused from his previous version [7]. This chapter is the culmination of 15 years of work on

smoldering combustion that I have conducted at four universities. These are, in chronological order University of Texas at Austin, University of California at Berkeley, University of Edinburgh and Imperial College London. This work would not have been possible without the contributions and encouragements of my mentors, collaborators and PhD students. Of these, I am especially thankful to Carlos Fernandez-Pello, José Torero, Rory Hadden, Claire Belcher, Chris Lautenberger, Matt Davies and Xinyan Huang. A series of institutions have funded this work along the way: Royal Academy of Engineering, Leverhulme Trust, UK Engineering and Physical Science Research Council, IFIC Forensics, Met Office and NASA Space flight Program.

Guillermois Rein is Reader (Associate Professor) in Mechanical Engineering at Imperial College London, and Editor-in-Chief of *Fire Technology*. His professional activities are centered on research in fire and combustion, and teaching of thermofuild sciences to engineers. He has studied a wide range of fire dynamics topics in the built and the natural environments, including pyrolysis, fire modeling, wildfires, structures and fire, and forecasting techniques. Over the course of the last 15 years he has also specialized in smoldering combustion, conducting both computational and experimental studies on a variety of fuels like polyurethane foam, cellulose, peat and coal.

Spontaneous Combustion and Self-Heating

20

Brian F. Gray

Introduction

The term *spontaneous combustion* will be used here to refer to the general phenomenon of an unstable (usually oxidizable) material reacting and evolving heat, which to a considerable extent is retained inside the material itself by virtue of poor thermal conductivity of either the material or its container. Under some circumstances this process can lead to flaming combustion and overt fire, in which case it is properly called *spontaneous ignition,* which here is regarded as a special case of spontaneous combustion. This has been responsible for significant losses of life and enormous losses of property. Fire loss statistics from many sources show that spontaneous ignition is quoted as the cause in a much greater proportion of cases with multimillion-dollar losses than in smaller fires. Of course, one should also note that the proportion of "cause unknown" results follows a similar trend, probably due to the greater degree of destruction, and hence evidence loss, in larger fires.

In other circumstances, clearly delineated from the former, only relatively mild self-heating occurs. This may be referred to as *self-heating,* spontaneous combustion, or by research scientists as *subcritical* behavior. By the same token, spontaneous ignition would be referred to as *supercritical* behavior. The well-defined boundary between the two types of behavior is referred to as the *critical condition,* and it plays an absolutely central role in the area, both conceptually and pedagogically. It can crudely but pictorially be thought of as a watershed.

The critical condition is actually a whole set of combinations of parameters that affect the behavior. The most important of these are the ambient (surrounding) temperature, and the size and shape of the body of material involved. Thus for a given body of a particular material we would normally talk about the *critical ambient temperature* (CAT). If we were dealing with a situation where the size of the body were always fixed by commercial practice, for instance, this would be the normal statement of the critical condition. However, in the case of storage of a variable amount of material in a constant temperature environment, then one would talk about the critical size or the critical diameter of the body for a given fixed temperature. The CAT is the most commonly used and stated critical condition.

For both fire prevention and fire cause investigation, it is essential to be able to identify the critical condition if spontaneous ignition is a possibility either before or after the event. It is also important to be aware of other possible factors operating in particular cases, such as solar irradiation in outdoor storage and preheating if recently manufactured or processed goods are involved. In such cases as hot laundry; hot new chipboard; hot, oily, porous food products (instant noodles, fried fish scraps);

bagasse[1]; and the like, the temperature of the material itself is a most important parameter affecting criticality in addition to the usual ones. In such cases we have to deal with and determine a *critical stacking temperature* (CST), which refers to the temperature of the material itself not the ambient temperature. The CST is dependent on the CAT and the size of the body so such cases are a degree more complicated than the traditional ones involving usually agricultural materials stacked at ambient temperature. In addition, in such cases with preheated materials the time to ignition (defined precisely later) is usually very much shorter than it is where the material is stacked at ambient temperature.

Because the basic processes competing with each other in spontaneous combustion are heat generation by chemical reaction and heat loss to the surroundings mainly by conduction, it is easy to see qualitatively why both a larger body and a higher ambient temperature will favor ignition rather than subcritical behavior as they both decrease the rate of heat loss. Generally the temperature profile across the body itself is roughly parabolic in shape with a peak at the center. Most chemical reaction rates increase almost exponentially with temperature, whereas heat loss processes such as conduction increase only linearly. Thus the center of the body where the temperature is highest is the region where ignition, or *thermal runaway*, will commence if it is going to take place at all. Many bodies that have undergone spontaneous ignition show this telltale signature of charring or complete destruction to ash in the center while retaining an almost pristine appearance on the outside, sometimes presenting rather dangerous situations for fire fighters in large-scale examples such as bagasse, woodchip, or peat piles. Similarly, the deep-seated nature of the burning started by spontaneous ignition can be difficult to extinguish completely, often reigniting days after apparent extinction.

[1] Bagasse is the residue from sugar cane after extraction, usually containing 50 % water.

The purpose of this article is to expound the detailed nature of the situations described above in a manner that approaches the principles involved in a way that minimizes mathematical formulation as far as is reasonable. The subject will be approached from the point of view of its relevance to fire cause and fire investigation and as such will refer mainly to solid systems. Many of the basic principles used were actually clarified by experimental work on gaseous systems; such systems still play a central role in current research on this topic, particularly ones where the chemical kinetics are simple and well understood in their own right.

A closely related aspect to be discussed here is the subject of *runaway reaction,* or *thermal runaway*. In the past two decades this topic has developed a literature of its own [1] and threatened to lose contact with the extensive literature on spontaneous combustion. These two terms, which can be taken as synonymous, are applied to supercritical conditions as defined above but only in the context of a chemical reactor. The reactor may be of batch, semibatch, or continuous flow type, but it will almost invariably be well stirred either mechanically or by deliberate turbulent mixing. Therein lies the attraction from a pedagogical point of view of such studies because the main difficulties in mathematical modeling of solid spontaneous combustion arising from spatial temperature variation and gradually decreasing concentration of reacting material are not present. Thus a mathematical theory describing such processes exactly serves as a first approximation, and a tractable one at that, to the more complex topic of solid spontaneous combustion. In addition, the difficult and messy "corrections" to the simplest possible theories due to Semenov [2] and Frank-Kamenetskii [3] are often impossible to apply in practical situations due to the dearth of data and/or their numerical uncertainties.

In addition, in the rare event that precise input data are available and detailed chemical kinetics are known, it is now entirely feasible for particular cases to invoke numerical integration of the relevant equations directly without use of the empirical and semiempirical curve fits involved

in the classical corrections to the simplest theories. At the time of writing, average laptop computers are quite capable of such calculations for all but the most irregularly shaped bodies where finite element methods need to be invoked and custom written.

Accordingly we will spend some time here expounding the simplest possible theory (Semenov), which contains all the essential concepts for the understanding of criticality, the tangency between heat release and heat loss curves, and the existence (or otherwise) of stable and unstable steady states. We then move on briefly to the application of such ideas to more complex chemistry and the idea of thermal runaway in continuous stirred tank reactors (CSTR).

We then discuss the Frank-Kamenetskii version of thermal explosion theory, which considers temperature gradients within the self-heating body (thereby generalizing Semenov) and often gives better agreement with experiment for solid bodies with low thermal conductivity. For this reason it is much used in fire investigations, particularly when it is necessary to predict the CAT for a large-scale industrial body from small-scale laboratory tests. However, this type of extrapolation requires great care in its application to all but the simplest chemistry.

We then present some ways in which corrections can be made to the predictions of the Frank-Kamenetskii theory occurring under conditions where some of its assumptions are not sufficiently accurate. This occurs when the heat of reaction is relatively small and/or when the resistance to heat flow in the boundary of the body (or container wall) is relatively large compared to that inside the body itself (case of small Biot number). Corrections are also necessary when more than one chemical reaction generates heat and when oxygen diffusion into the interior of the body is rate limiting.

All of these factors are difficult to handle quantitatively, but fortunately none of them really alter the *qualitative* conceptual nature of what is going on. It is important in gaining an understanding of spontaneous combustion *not* to be confused by these corrections, although in certain cases they can be quite large.

We will then move on to discuss experimental testing methods, both on a laboratory and a larger scale where possible. A large array of calorimetric methods can be used to obtain relevant information, but not all of them, particularly differential scanning calorimetry (DSC) and differential thermal analysis (DTA), can give other than very general information and therefore can often be misleading. Nevertheless, such methods have their purpose when material of unknown origin and composition is involved. Sometimes one needs to know whether the unknown is capable of exothermic reaction at all as postulation of spontaneous ignition because a fire cause looks rather silly in its absence (this happens!). However, activation energies, in particular those obtained from DSC tests, should be treated with great suspicion.

A characteristic of fires where spontaneous ignition is suspected as the cause is that they often occur on premises that have been closed up or unoccupied for a significant period of time. A question of very great interest in such a context is, What is the time scale expected for a body of a given size in a given ambient temperature to reach ignition, that is, the appearance of overt flame? As one would expect, by application of Murphy's law, this question is very difficult to answer with confidence except in the simplest of cases. The time to ignition is a parameter that is not only extremely sensitive to many factors that are often unknown but is also extremely sensitive to the degree of supercriticality, that is, how far the body is from the watershed. Not only does it depend on how far the body is from the watershed, but it depends sensitively on the direction as well. In other words, the term *degree of supercriticality* needs to be refined before any idea of time to ignition can be properly formulated.

A number of investigations of this problem have been carried out, and it is essential to recognize that most of the earlier ones addressed the question of time to ignition for the initial temperature of the body equal to the ambient temperature—such as would be the case in the building of a haystack. Hot stacked material requires totally different considerations for the evaluation

of times to ignition, and classical formulas cannot be used in such situations. Such bodies can ignite in times that may be an order of magnitude shorter than predicted by uncritically using classical formulas.

In the penultimate section of this article, we move on to discuss the actual fire scene where spontaneous ignition has been the cause, or suspected cause, of the fire. We discuss factors that would be either positive or negative indicators of spontaneous ignition, and also the appropriate examination of the aftermath of the fire for pointers as to whether or not spontaneous ignition was the cause. We then proceed to illustrate all of the above with a number of case histories, some of them common and illustrative of the basic principles expounded here, others of a novel nature involving quite subtle and detailed investigations that nevertheless can give very definite results.

The Literature

There is a large and varied literature on the topic of spontaneous combustion ranging from sophisticated mathematical theory to technical measurements on industrial and agricultural products. It is scattered over a very wide range of journals, magazines, and disciplines. The most comprehensive publication is probably the book written by Bowes [4], *Self-Heating: Evaluating and Controlling the Hazards.* This book was published in 1984 and contains references to work published up to 1981, so at the present time it is in need of updating. However, it is the most useful reference available for those working, or commencing work, in the field from either an academic or a technical viewpoint. The *Ignition Handbook* by Babrauskas [5], published in 2003, contains a very useful chapter on self-heating and has become an indispensable reference for anyone working in the area of ignition.

Although much of the understanding of spontaneous combustion has come from the basic study of gas-phase reactions, where it is generally referred to as *autoignition,* this article will be limited to spontaneous combustion of solid materials generally. Many advances have been made in the field of gaseous autoignition over the last decade or so, stemming from accurate and detailed kinetic measurements and considerable advances in computing power. The critical condition for gaseous systems is a very complex locus in the parameter space characterized by ambient temperature (as for solids), pressure, and composition. Many organic materials, such as hydrocarbons, exhibit more than one autoignition temperature, and many also exhibit the phenomenon of igniting on *decreasing* ambient temperature. Many older tabulations of autoignition temperatures do not recognize these peculiarities and should be used with great caution. A detailed description of the reasons for such complexities and their importance in a hazard context is given by Griffiths and Gray [6] in the twenty-fourth Loss Prevention Symposium of the American Institute of Chemical Engineers (1990). A comprehensive list of references up to 1990 can be found in this article.

Reference to liquid reactions and related spontaneous ignitions and thermal instabilities will be given later in this article in the section on spatially homogeneous or "well-stirred" systems. Otherwise, references will be given at points throughout this text resulting in a reasonably complete bibliography.

Concept of Criticality

Over the last two decades the concept of criticality, which has been present in the thermal context for many years [7], has been recognized as a branch of bifurcation theory [8], an area of nonlinear applied mathematics that has grown rapidly and proven to be extremely powerful in solving nonlinear problems. In our case the nonlinearity comes from the temperature dependence of the chemical reaction (and therefore heat production) rate. The Arrhenius form for this for a single reaction is $Ze^{-E/RT}$, where E is the activation energy and R is the universal gas constant. T is the absolute temperature, of course. At temperatures rather less than E/R (which can typically be 10,000 K or more), the Arrhenius

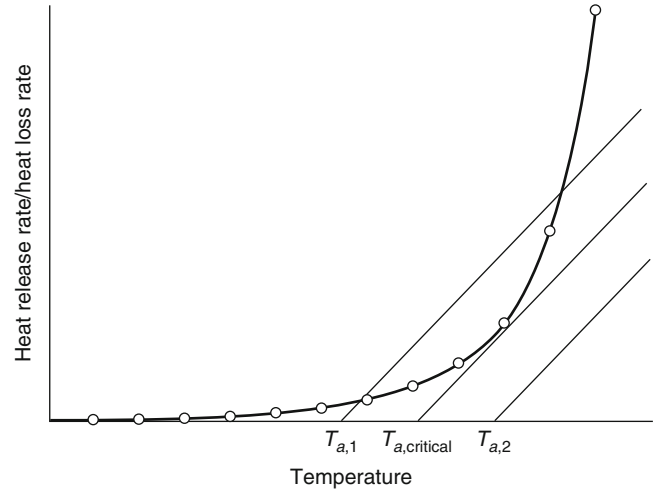

Fig. 20.1 Typical Arrheniusheat release and loss curves

function is very convex; that is, it curves upward rather rapidly with temperature. In contrast, the rate of heat loss from a reacting body is generally only a linear function of temperature, for example, conduction. Although radiation losses are nonlinear functions of temperature, they are much more weakly nonlinear than the Arrhenius function and also generally rather small at the low temperatures involved in solid spontaneous combustion although they are important in flame extinction. Typical heat generation per unit volume and heat loss (proportional to surface volume ratio as plotted) loci are shown in Fig. 20.1.

The low temperature range of the Arrhenius curve is seen here to be rather convex and rapidly increasing with temperature. The three straight lines represent the rate of heat loss from a body of fixed given size at various ambient temperatures $T_{a,1}$, $T_{a,\text{critical}}$, and $T_{a,2}$.

At $T_{a,1}$ it can be seen that the heat production and loss curves intersect at two points. At $T_{a,2}$ they do not intersect at all, and at $T_{a,\text{critical}}$ they intersect at only one point and, in fact, touch tangentially.

Because intersections represent conditions where heat production and loss balance exactly, we expect them to represent some sort of "equilibrium" or stationary point where the temperature of the body remains constant in time. It is important to remember that they do not represent equilibrium in any thermodynamic sense.

In the region of the lower intersection at $T_{a,1}$ it can be seen from the diagram that the temperature of the body will increase up to the balance point from below as heat release is greater than heat loss in this region. On the other hand, just above this balance point the temperature of the body will move down to it because the heat release is lower than the heat loss in this region. Thus the lower balance point occurring at ambient temperature $T_{a,1}$ is recognized as a *stable* balance, or stationary, point. Small perturbations from it will be nullified, and the body in this region will tend to stay at the balance point. Note that the temperature of the balance point is not $T_{a,1}$ but slightly above it, usually by 5–20 °C. It represents subcritical self-heating and can cause loss of the material but not by overt ignition or fire. It can appear as degradation or discoloration of many materials, making them useless for their required purpose. For example, woodchips degraded in this way are not suitable for paper or cardboard production, and dried milk powder when discolored is unacceptable.

The second balance point at the ambient temperature $T_{a,1}$ can be seen by a similar simple analysis to be *unstable* in the sense that, in the temperature region just below it, the heat production is *lower* than the heat loss, so the temperature tends to drop. In the temperature region just above it, the converse is true, so the body temperature tends to rise and leave the balance point.

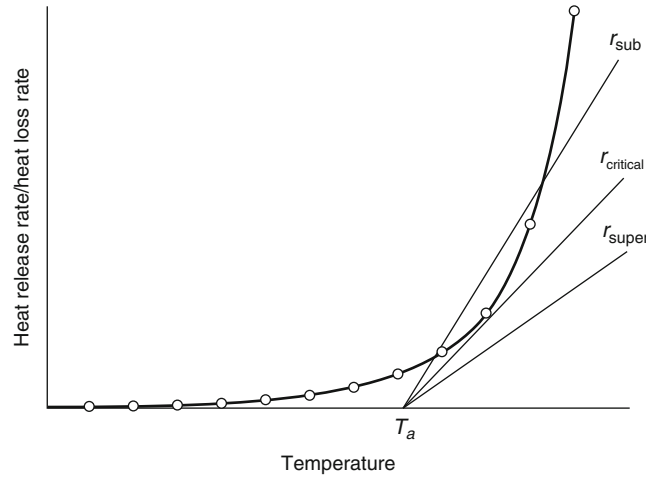

Fig. 20.2 Disappearance of balance points with body size increase

The latter acts as a watershed between two totally distinct types of behavior, that is, the temperature of the body dropping to the lower balance point or running away to the right of the diagram and much higher temperatures, representing ignition.

Here the temperature at the higher balance point would actually be the *critical stacking temperature,* or CST, for this particular body when stored at ambient temperature $T_{a,1}$. We can immediately see that if the ambient temperature is increased, that is, the straight line is moved to the right with fixed slope (which is determined by the size and shape of the body as we shall see later), the CST will *decrease,* a physically reasonable and intuitive result.

Thus this oversimplified but extremely useful model gives a simple understanding of what Bowes refers to as *thermal ignition* of the second kind, that is, what is probably better referred to as the *hot stacking problem,* a much more descriptive term. Not only that, but it also gives us a qualitatively correct picture of the more common or "normal" type of thermal ignition when the body self-heats from ambient to ignition without any preheating. At $T_{a,1}$ if we very slowly increase the ambient temperature after the steady state has been reached, we can see that the now "quasi-steady state" will also slowly increase until at $T_{a,\text{critical}}$ the quasi-steady state and the CST merge at the point of tangency. Beyond this ambient temperature there is no balance point, and in this temperature region the heat release curve is now *always above the loss line* and therefore the temperature can only increase. Subsequent ignition will then occur. It will occur after some delay because the rate of temperature increase in this simple model is proportional to the imbalance between heat production and loss (i.e., the vertical distance between the two curves). This is initially quite small, increasing as the temperature rises. In this observation lie the seeds of the calculation of the *ignition delay* or *time to ignition* (TTI) to be examined later.

Even more insights can be obtained from this simple type of reasoning. As we shall see later, the slope of the heat loss line is dependent on the surface area/volume ratio of the body in question. Thus for a body of given shape the surface/volume ratio increases as the body gets smaller and decreases as the body gets larger. In Fig. 20.2 we can see the effect of increasing the size of a body at a fixed ambient temperature. For this fixed ambient temperature we can speak of subcritical, critical, and supercritical sizes for the body, depending on whether any balance points exist.

Thus for a body with characteristic dimension r_{sub} we see the existence of both a CST and a balance point. For a larger body with dimension r_{super} we see that neither exists and we expect temperature to rise to ignition. The critical condition, in this case expressed as a radius or body dimension, is given again by the tangency condition. This critical condition, of course, is

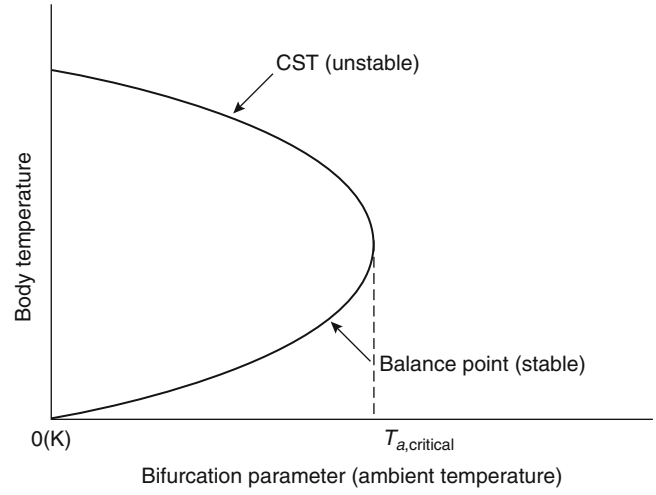

Fig. 20.3 Variation of CST and stable subcritical temperature with ambient temperature and fixed body size

identical with that obtained by thinking of the quasi-static variation of the ambient temperature as well. The critical radius for a given ambient temperature will be identical with the CAT for a body of that same radius. How we describe it is simply a matter of where we are coming from.

Of course, we do not usually continuously vary the size of a body but we *do* often stack bodies together, for example, bales of cotton, bales of hay, and so on, and allow larger than normal quantities to accumulate, for example, coal stockpiles. Even from the point of view of this very rudimentary theory, it is obvious that the CAT of two bales in contact will be considerably less than that for a single bale. Thus tests of the CATs of single bodies that are going to be stacked in groups for either transport or storage are useless unless a theory is available enabling calculation of the dependence of CAT on body size. The theory allowing this is thus extremely useful in relating practical tests on small bodies to be applied to storage of large numbers of them (with certain caveats to be discussed later).

To conclude this section it remains to show a convenient method of representing the behavior of the stable balance point and the unstable CST as a control parameter is varied (i.e., the ambient temperature or size of the body). This method enables a quick and convenient representation of the discussion given above on a single diagram (a bifurcation diagram) and also gives us a useful link to the mathematical developments of bifurcation theory.

Figure 20.3 shows what happens to the balance point temperature and the CST when T_a is varied continuously from below its critical value to above it. This takes place at constant body size. In this case the ambient temperature is known as the bifurcation parameter. We should note that, even at very low ambient temperatures, the CST tends to a finite limit. In fact it becomes very insensitive to the ambient temperature, and no matter how cold the ambient temperature, there is no corresponding *rise* in the CST. Storing hot products in a cold warehouse does not help the problem much!

Conversely Fig. 20.4 shows how the CST rises indefinitely as the size of the body decreases at fixed ambient temperature. Regardless of ambient temperature it does pay to keep hot stored bodies small! Figure 20.4 also shows how, for sizes above the critical radius, there is no alternative but ignition. Of course the critical radius depends on the ambient temperature, and as the latter goes down the critical radius goes up. It is sometimes very useful to draw a critical radius versus critical ambient temperature graph, and we will see how to do this later.

The whole discussion above assumes that we are dealing with a given material so that the thermal and chemical properties do not vary. The effects of varying thermal conductivity, heat transfer coefficients, and density on the

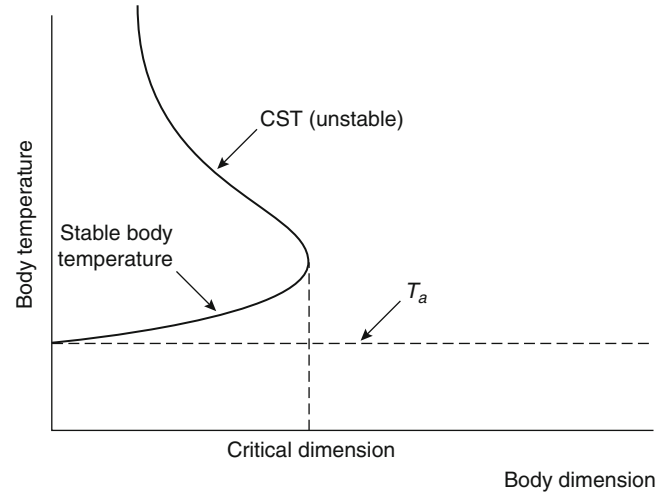

Fig. 20.4 Variation of CST and stable subcritical temperature with body dimension and fixed ambient temperature

critical condition are also important but only when comparing different materials. The dependence of the critical condition on these properties will be enunciated in a later section.

One final point needs to be mentioned here. The Arrhenius function does actually level out to an asymptote at very high temperatures, which are off the scale in Figs. 20.1 and 20.2. Thus theoretically there is another balance point at very high temperatures, but in fact this point is not physically significant as it usually occurs at many thousands of degrees, well beyond the region where the assumptions of the model are valid. It also gives rise to a high temperature branch of the curves in Figs. 20.3 and 20.4, which is disjoint from the curves shown. Again it can be ignored from the point of view of low-temperature spontaneous ignition.

The Semenov (Well-Stirred) Theory of Thermal Ignition

The Semenov theory represents the simplest mathematical formulation of the ideas presented above in qualitative form. As such it is a valuable introduction to quantitative aspects of spontaneous ignition without introducing the technical difficulties associated with more elaborate forms of theory where spatial variations of temperature and reaction rate within the body are considered.

Assumptions of the Semenov Theory

The three assumptions of the Semenov theory are as follows:

1. **The temperature within the reacting body is spatially uniform:** A spacially uniform temperature implies that either the material of the body is well stirred (i.e., it would have to be liquid or gas) or the resistance to heat flow within the body is so low compared to that within the container or boundary that it can all be assumed to be concentrated within the boundary. The latter results in a temperature discontinuity at the boundary of the material and is a good approximation in deliberately stirred fluids [9].

   It is not a good approximation for materials of vegetable origin where thermal conductivities of materials such as cellulose are low and of the order of 0.05 W/mK. Nevertheless, even for such materials semiquantitative conclusions can be drawn from this theory if the spatially averaged temperature of the body is used.
2. **The heat generation is assumed to be due to a single chemical reaction:** This assumption is often a reasonably good approximation, particularly when a "lumped" or empirically determined rate law has been measured independently. It does not mean that the chemical reaction taking place is only a single-step

reaction. In fact this empirical approximation works quite well in many cases that are not single-step reactions.

3. **Both the heat of reaction and activation energy are assumed to be sufficiently large to support ignition behavior:** The reasons for these assumptions will become clearer later, but it is intuitively obvious that if there is zero heat of reaction, ignition cannot occur. Likewise with zero activation energy (acceleration of reaction rate with temperature increase), ignition cannot occur either.

With these assumptions we can write down two equations that determine the temperature and fuel concentration as functions of time (but uniform in space). These are simply the conservation of energy and the kinetic rate law, respectively. They are

$$C_v \rho V \frac{dT}{dt} = VQf(c)e^{\frac{-E}{RT}} - S\chi(T - T_a) \quad (20.1)$$

$$\frac{dc}{dt} = -f(c)e^{\frac{-E}{RT}} \quad (20.2)$$

where

C_v = Heat capacity at constant volume
ρ = Density
V = Volume
T = Temperature of the reacting material (in K)
T_a = Ambient temperature of the surroundings (assumed constant in time)
Q = Heat of reaction per unit concentration of fuel
$f(c)$ = Kinetic rate law
c = Concentration of fuel
E = Activation energy of the reaction
R = Universal gas constant
S = Surface area of the interface across which heat is lost to the surroundings
χ = Heat transfer coefficient

The independent variable is time.

The first term on the right-hand side of Equation 20.1 represents the rate of heat generation by the self-heating reaction. The second term represents the heat lost to the surroundings. The left-hand side represents the difference between these two. Equation 20.2 simply expresses the fact that as the reaction proceeds, the concentration c decreases as the fuel is used up. The commonest and simplest form for $f(c)$ is Zc where Z is known as the pre-exponential factor, a constant. This case is known as a first-order reaction. These two terms are shown graphically in Fig. 20.1 for any particular value of c.

Despite their apparent simplicity these two equations are not soluble by classical methods, so we cannot write down their solution. Nevertheless, we can in fact write down the critical condition exactly (and other important quantities) using bifurcation theory. We will illustrate this for the simplest possible case only, remembering that it can also be done for more realistic and complicated cases as well within the confines of the Semenov theory.

First we write Equations 20.1 and 20.2 in dimensionless form (see nomenclature for details),

$$\frac{du}{d\tau} = \nu e^{\frac{-1}{u}} - \ell(u - u_a) \quad (20.3)$$

$$\frac{d\nu}{d\tau} = -\varepsilon \nu e^{\frac{-1}{u}} \quad (20.4)$$

where

u = Dimensionless temperature
ν = Fuel concentration
ε = A dimensionless version of the ratio C_v/Q (i.e., a measure of the amount of fuel decomposition required to produce a temperature rise of 1 °C)
τ = A dimensionless time
ℓ = A dimensionless heat transfer coefficient

The most frequently used version of this theory, without fuel consumption, corresponds to taking the limit $\varepsilon \to 0$, thus maintaining ν at its initial value ν_0. We have only a single equation to deal with now, that is,

$$\frac{du}{d\tau} = \nu_o e^{\frac{-1}{u}} - \ell(u - u_a) \quad (20.5)$$

Even this much-simplified equation is not analytically soluble. However, it relates exactly to Fig. 20.1 and can be used to calculate the critical condition readily. We first note that the balance points in Fig. 20.1 must satisfy the equation

$$v_0 e^{\frac{-1}{u_s}} - \ell(u_s - u_a) = 0 \qquad (20.6)$$

For subcritical values of the ambient temperature, this equation will have three solutions for a given set of parameter values, v_0, u_a, and ℓ. From Fig. 20.1 it can be seen that at the critical condition ($T_{a,\text{critical}}$ corresponding to $u_{a,\text{critical}}$) not only do the two terms of Equation 20.6 balance, but their *slopes* also balance at this condition. Mathematically this means that their differential coefficients with respect to temperature must also be equal, that is,

$$\left[\frac{\partial\left(v_0 e^{\frac{-1}{u}}\right)}{\partial u}\right]_{u=u_s} = v_0 e^{\frac{-1}{u_s}}/u_s^2 = \ell \qquad (20.7)$$

The critical value of u_s is then obtained by solving Equations 20.6 and 20.7 simultaneously, which interestingly can be done in closed form simply by eliminating the exponential, leaving a quadratic equation:

$$u_{s,\text{ critical}}^2 - u_{s,\text{ critical}} + u_{a,\text{ critical}} = 0 \qquad (20.8)$$

From our definition of $u = RT/E$ and the general knowledge that $R/E \cong 0.0001$ for most combustion reactions, we can see that at normal ambient temperatures for ignition we will have $u_{a,\text{critical}} \cong 0.02$, or in any case $u_{a,\text{critical}} \ll 1$. Using the standard formula for the solution of a quadratic equation and expanding the radical occurring, we can derive

$$u_{s,\text{ critical}} = u_{a,\text{ critical}} + u_{a,\text{ critical}}^2 + \ldots \qquad (20.9)$$

which is the lower of the two roots (the upper one is unphysical).

If we substitute this back into either Equation 20.6 or 20.7 we get a relationship between the parameters of the problem, *that holds at criticality only*. Thus if we use Equation 20.6, we obtain, after some rearrangement,

$$\ell_{\text{critical}} = \frac{-1}{v_0 e^{u_{a,\text{ critical}}\left(1+u_{a,\text{ critical}}\right)}} \Big/ u_{a,\text{ critical}}^2\left(1+u_{a,\text{ critical}}\right)^2 \qquad (20.10)$$

We can interpret this equation in a number of ways. Since ℓ_{critical} involves the size of the body as the only physically variable parameter, and v_0 is proportional to the bulk density of the material, we can take this equation to give us the critical size body for a given ambient temperature and bulk density. $u_{a,\text{critical}}$ is the only parameter here that cannot easily be made the argument of the equation.

Converting Equation 20.9 into dimensional form quickly gives us the relationship:

$$T_{s,\text{critical}} - T_{a,\text{critical}} \equiv \Delta T_{\text{critical}} \cong RT_{a,\text{critical}}^2/E \qquad (20.11)$$

at the critical condition. $\Delta T_{\text{critical}}$ would typically be 20–30 °C for ambient temperatures around 30–40 °C. Not surprisingly, it is independent of the body shape, being dependent only on the total surface area through which heat is lost. Nevertheless, even this oversimplified result can be very useful in an emergency situation. If E is not known, it is a useful rule of thumb (especially for agricultural cellulosic materials) that self-heating of more than 30° above ambient, that is, typically a body temperature of more than 60–70 °C, represents imminent spontaneous ignition, whereas an internal body temperature of 35–40 °C represents subcritical heating unlikely to run away but quite likely to lead to degradation of the material.

Two further points need to be made before leaving this simplified model. First, in order for Equation 20.8 to have real roots, it is necessary to require that

$$E \geq 4RT_{a,\text{critical}} \qquad (20.12)$$

Physically this means that the chemical heat generation rate is sufficiently accelerative to produce the phenomenon of criticality. If it is not satisfied, there is only a single stable balance point for all conditions and no abrupt change in behavior can occur.

Second, if we examine Equation 20.10, the critical condition, we should note that where the concentration v_0 appears, in the case of gases we would normally convert this to pressure. Thus, in this case, Equation 20.10 gives a relationship between ambient temperature and

pressure at the critical condition. This is the familiar explosion limit curve extensively used in the study of gaseous explosions.

Inclusion of Fuel Consumption

If we do not make the assumption $\varepsilon \to 0$ in Equation 20.4, the clear distinction between subcritical and supercritical behavior no longer exists. We can no longer define the critical condition as the disappearance of two balance points. Equations 20.3 and 20.4 possess only a single balance point, $u = u_a$ and $c = 0$ for all possible parameter values; and this refers to the equilibrium state when all fuel has been exhausted and nothing is happening—clearly a condition of no interest. For the definition of criticality in such a case it is helpful to examine the *experimental* or *phenomenological* definition. The experimentalist determines the critical condition by performing various tests at differing ambient temperatures (we will outline the details of test procedure in a later section) and by measuring the temperature-time history at the center of the sample. He or she will plot the maximum temperature attained against ambient temperature and will find there is a very steep increase in slope over a narrow region of ambient temperature. This is illustrated in Fig. 20.5.

The distinction between points 1 and 2 is very clear in terms of both the maximum temperature attained and the physical condition of the material itself after the test is finished. Typically at point 2 the material is hardly different visually from the initial condition, whereas at point 1 there is usually no more than a small amount of ash remaining. The temperature attained at point 1 is often of the order of hundreds of degrees above ambient compared with probably 30° above ambient at point 2.

It is impossible to get points between 1 and 2 experimentally without wasting a great deal of time due to the extreme sensitivity in this region, so the convention is to define the CAT as the arithmetic mean of $T_{a,1}$ and $T_{a,2}$. With good equipment these will be only 3° or 4° apart at the most.

From the point of view of theoretical calculation of the CAT in this case, we note that the points in Fig. 20.5 can be joined by a smooth curve with a very steep region around an inflection point. It has been shown (Gray [10]) that this definition of the CAT, when fuel consumption is significant, leads to a relation between the usual parameters and this relation passes over smoothly to the one derived from the tangency condition as $\varepsilon \to 0$. For $\varepsilon \cong 0.05$ or less, which is the case for most practically important materials, the corrections arising from fuel consumption are not usually significant. This is especially the case in fire investigations where a posteriori numerical knowledge of parameter values is rather limited, and this correction (and others) is not justified.

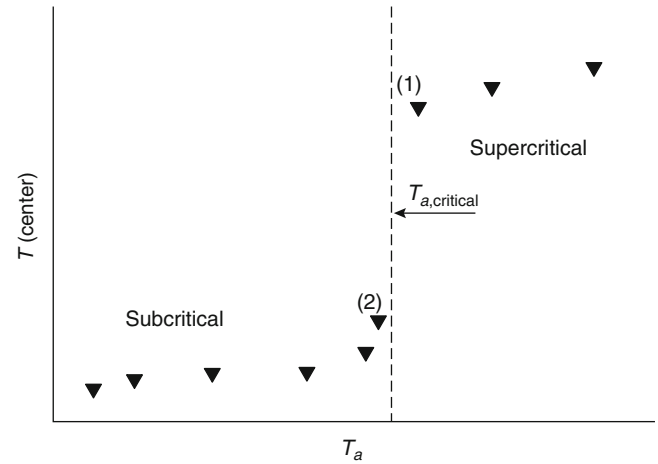

Fig. 20.5 Typical experimental results for criticality tests

Extensive discussion of earlier work on the fuel consumption correction is given in Bowes's book [4]. Many empirical and semiempirical corrections were devised based on approximated integration of Equations 20.3 and 20.4. These corrections will not be discussed here because the advent of powerful PC and laptop computational capabilities has rendered them irrelevant. Equations 20.3 and 20.4 can be integrated with great speed and precision if accurate parameter values are available. Even so, it is necessary to have a definition of criticality when a computed or experimental version of Fig. 20.5 has been obtained. With the definition given in Gray [10] allied with numerical integration, the problem can be regarded as solved for all practical purposes.

Extension to Complex Chemistry and CSTRs

Complex Chemistry

Other than elementary gas-phase reactions, very few examples of chemical change occur via a single step as assumed above. As already remarked, the simple theory is more useful than might be expected because many complex chemical reactions behave as if they were a single step, over limited temperature ranges. This is usually because a single step does dominate the heat production rate, for example, when two reactions occur in parallel. If the activation energies are rather different, they will each in turn dominate the heat generation in two different temperature ranges, and in each of these ranges the simple theory will hold. Of course, it will not hold in the changeover region.

Another case where the simple theory can hold unexpectedly is when a number of reactions are in series and one is particularly slow. The slow reaction will determine the overall heat generation rate and its parameters will dominate the critical condition. If none of the above conditions hold, it is still possible to derive a generalization of the theory that is conceptually very closely related. It is possible to prove (Gray [11]) that if the heat release rate is defined as the sum of the heat release rates of all reactions taking place in the system, then the critical condition can be defined as the tangency of this quantity with the heat loss line. Thus a diagram like Fig. 20.1 can be drawn and the same constructions used, provided the total heat release curve for all the reactions is used.

The heat release curve in this case can have a complex shape, and thus *more than one* critical condition can occur. This state of affairs is extremely important in the ignition of most organic vapors, particularly hydrocarbons [6] where some critical conditions occur on *decreasing* the ambient temperature. Also in the ignition of some commonly occurring solids, particularly when wet, more than one heat-generating reaction can be important, for example, in the spontaneous ignition of moist bagasse [12]. In this case there are two critical conditions, one where a jump from virtually no self-heating to self-heating of ~35 °C occurs, and a second critical condition where this intermediate state jumps to full-fledged ignition. Modelling of such situations is possible but beyond the scope of this chapter; however, similar behavior is likely to occur in other moist cellulosic materials, including hay, chipboard, and so forth.

At this stage it is worth pointing out that for bagasse at least, microbial "heat production" is not a factor in these phenomena. Although natural bagasse contains large numbers of microorganisms, sterilization by various methods *does not affect heat production or self-heating* at all, as measured by Dixon [13] and predicted on the basis of bacterial microcalorimetric data by Gray [14]. Similar work on hay is under way.

CSTRs and Thermal Runaway

Strangely, this topic has become uncoupled from work on spontaneous ignition over recent years even though the basic principles and mathematical methods used are similar. It is a huge problem in the chemical process industry and receives much attention. For example, in 1998 the Joint

Research Centre of the European Commission, Institute for Systems Informatics and Safety, produced a book describing the proceedings of a European Union seminar held in Frankfurt in 1994 that managed to avoid almost completely any reference to the fundamentals of the problem or related material. *Risk analysis* appears to have replaced fundamental scientific understanding in some aspects of this problem.

We will confine ourselves here to writing down the basic equations governing a single exothermic chemical reaction taking place in a CSTR (continuously stirred tank reactor) to exhibit their similarity to the equation describing a spontaneously ignitable material, that is, Equations 20.3 and 20.4.

The appropriate equations for this case are in fact 3 and 4 with terms representing inflow and outflow of reactants and products, that is,

$$V\rho C_v \frac{dT}{dt} = QVf(c)e^{\frac{-E}{RT}} - S\chi(T - T_a) - FC_v\rho\left(T - T_f\right) \tag{20.13}$$

$$V\frac{dc}{dt} = -Vf(c)e^{\frac{-E}{RT}} + F\left(c_f - c\right) \tag{20.14}$$

F is a volumetric flow rate and the subscript f refers to feed values. These equations can be cast in dimensionless form also. Here we simply note that they possess steady-state (balance point) solutions without making any approximations at all (such as neglect of fuel consumption), and Fig. 20.1 can be applied directly in slightly modified form. The critical condition referred to earlier occurs here also, but it can now be stated in terms of the CAT or a critical feed temperature or, indeed, a critical flow rate.

A critical size also occurs and this is particularly prominent in CSTR considerations where "scaleup" from prototype size to commercially viable size has resulted in exceeding the critical condition. Some references to this are given in *Safety and Runaway Reactions* [1], and there are many more in the chemical engineering literature and the study of self-heating in catalyst particles. See Aris [15] for an excellent discussion of this area.

The Frank-Kamenetskii Theory of Criticality

In its original form, the Frank-Kamenetskii theory included a more realistic model of heat transfer within the reacting solid, that is, by incorporating the heat conduction law of Fourier. This law allows a calculation of the variation of temperature within the self-heating body itself and allows comparison of measured and calculated self-heating to take place. However, it sacrifices the simple description of time-dependent behavior given by the Semenov model because such considerations involve the solution of partial differential equations. This is now much faster than even a few years ago, in terms of numerical computation, and improving day by day. Nevertheless, such numerical solutions do not lend themselves to simple interpretation even with the use of rapidly developing visualization techniques. Construction of appropriate meshes for finite element computation, necessary for practically occurring three-dimensional shapes, is also far from trivial.

As a result, the Frank-Kamenetskii theory is still mainly used for interpretation of testing experiments on self-heating and subsequent evaluation of parameters for individual systems. This is a viable proposition for materials with sufficiently large heats of reaction and activation energies. In such cases we shall see that the stationary (in time) conditions assumed in the Frank-Kamenetskii theory are indeed well approximated for the duration of typical tests in practical cases. In its original form this theory also neglects fuel consumption, as does the Semenov theory, with similar consequences. With these assumptions, the equation describing the theory is

$$\kappa\nabla^2 T + Qf(c_0)e^{\frac{-E}{RT}} = 0 \tag{20.15}$$

with the boundary condition $T = T_a$ on the wall(s) of the body. T_a is the ambient temperature of the surroundings. This boundary condition assumes instantaneous transfer of heat from the surface of the body to the surrounding medium (usually air).

When this is not approximately correct, very important consequences follow, as we shall see in a later section on the interaction of self-heating bodies with each other. In this formulation the shape of the body and its size both enter the mathematical formulation through the boundary condition only.

As usual, Equation 20.15 is not analytically soluble. However for a one-dimensional infinite slab of material by using an approximation to the Arrhenius function (Frank-Kamenetskii [3]), the modified equation can be solved analytically. The same approximation was later shown to be analytically soluble for an infinite cylinder by Chambre [16].

With this approximation, Equation 20.15 takes the form

$$\nabla^2\theta + \delta e^{\vartheta} = 0 \tag{20.16}$$

with $\theta = 0$ on the boundary. θ is a dimensionless temperature defined by

$$\theta = \frac{E(T - T_a)}{RT_a^2} \tag{20.17}$$

that is, it is a measure of the temperature excess within the body at various points. The dimensionless parameter δ is defined by Equation 20.18:

$$\delta = \frac{QEr^2 f(c_0) e^{\frac{-E}{RT_a}}}{\kappa RT_a^2} \tag{20.18}$$

where the symbols are already defined apart from r, which is usually one-half of the smallest dimension of the body, that is, the radius of a cylinder, the radius of a sphere, or the half-width of a slab. Mathematical treatment of Equation 20.16, whether it is exactly soluble or not, indicates that a solution satisfying the boundary conditions exists only when δ is less than or equal to δ_{critical} where δ_{critical} is some number depending on the shape of the body only. For an infinite slab of material $\delta_{\text{critical}} = 0.878$, and for an infinite cylinder it has the value 2.000. For other shape bodies, the critical value has to be obtained either numerically or by semiempirical methods outlined in some detail by Bowes [4]. For convenience, a few of the values are listed in Table 20.1.

Table 20.1 Values of δ_{critical} for various geometries

Geometry	Dimensions	δ_{critical}
Infinite plane slab	Width 2_r	0.878
Rectangular box	Sides *2 l, 2r, 2 m;* $r < l, m$	0.873 $(1 + r^{2/12} + r^2/\text{m}^2)$
Cube	Side 2_r	2.52
Infinite cylinder	Radius $_r$	2.00
Equicylinder	Height 2_r, radius $_r$	2.76
Sphere	Radius $_r$	3.32
Infinite square rod	Side 2_r	1.700

The tabulation of figures for infinite slab or infinite square rod is useful insofar as they are often rather good approximations for real bodies, provided one or more of their dimensions are much larger than the others. Thus for the rectangular box, if we take $r = l = 1$, $m = 10$, we get $\delta_{\text{critical}} = 1.75$ compared to 1.700 for the infinite square rod. If we now look at Equation 20.18 for the particular case of a cube as an example, we get

$$\frac{QEf(c_0)r^2 e^{\frac{-E}{RT_{a,\text{critical}}}}}{\kappa RT_{a,\text{critical}}^2} = 2.52 \tag{20.19}$$

at the critical condition. We have a number of choices as to interpretation of this equation depending on which parameter can be made the argument. If r is chosen as the argument, then the equation would be interpreted as giving a critical size for the body at a fixed ambient temperature T_a. Because c_0 depends on the density of the material, Equation 20.19 could be rearranged to give a critical density for that particular size body at ambient temperature T_a. What is not possible is isolation of T_a as the argument of the equation, and this is often the most easily varied parameter in a typical test oven.

This complex dependence of the critical condition on T_a is dealt with by rearranging Equation 20.18 and taking natural logarithms as follows:

$$\ln\left[\frac{\delta_{\text{critical}} T_{a,\text{critical}}^2}{r^2}\right] = \ln\left[\frac{QEf(c_0)}{R\kappa}\right] - E/RT_{a,\text{critical}} \tag{20.20}$$

from which it can be seen that a plot of $\ln[\delta_{\text{critical}} T_{a,\text{critical}}^2/r^2]$ against $1/T_{a,\text{critical}}$ will be a straight line with slope $-E/R$ and intercept $\ln[QEf(c_0)/\kappa R\delta_{\text{critical}}]$. The traditional and recommended test protocol for spontaneous ignitions makes explicit use of this logarithmic form of the critical condition. Not only does it yield the activation energy from the slope, but the occurrence of a straight line plot assures us that the assumption of an Arrhenius temperature dependence for the heat-generating reaction is correct over the temperature range investigated.

Equation 20.20 can also be regarded as a scaling law, in principle enabling the prediction of CATs for large-scale bodies from measured CATs for much smaller laboratory-sized samples. However, as we shall see, it is necessary to ensure that the same chemical kinetics applies over the whole temperature range involved, that is, $f(c_0)$ *does not vary*. Finally, if it becomes necessary to estimate the CAT for a complex shape, not included in Table 20.1, an excellent and comprehensive discussion of approximation methods is given by Boddington, Gray, and Harvey [17].

Experimental Testing Methods

Experimental testing methods are traditionally based on the scaling relationship (Equation 20.20). Appropriate containers (usually stainless steel gauze baskets) of various dimensions are used, being limited only by the size and heating capability of an accurately thermostatted oven, which must also have a spatially homogeneous ambient-temperature distribution (±0.5 °C is recommended). The gauze containers may be any convenient shape, equicylindrical or cubic being preferred due to ease of construction. The gauze does not restrict oxygen ingress through the boundary, nor does it restrict egress of carbon dioxide and other product gases during combustion. If the air inside the oven is sufficiently turbulent, usually the boundary conditions of the Frank-Kamenetskii theory will hold quite well.

The boundary condition is easier to satisfy when the thermal conductivity of the material inside the gauze baskets is relatively low, as it is with many agricultural materials containing cellulose ($\kappa \sim 0.05$ W/mK). The efficacy of the boundary condition is determined by the heat transfer rate from the gauze to the oven air relative to the conduction rate within the material itself. This ratio ($\chi r/\kappa$) is known as the Biot number, and the larger it gets, the more accurate the Frank-Kamenetskii boundary condition ($T = T_a$) becomes. In practice a Biot number greater than 30 is effectively infinite as the CAT becomes extremely insensitive to it. We will return to this topic in a later section where the dependence of the critical condition on the Biot number will be outlined.

The test procedure involves starting with the smallest basket and a trial oven temperature. The sample is equipped with one or more fine thermocouples placed at the center of the sample and, if desired, at various places along a radius if a spatial profile is wanted (this is generally not necessary). The sample is placed in the preheated oven and the center temperature followed as a function of time. If the oven temperature is well below the CAT, the sample will simply approach the oven temperature asymptotically. If it is slightly below, but getting close, it will cross above the oven (ambient) temperature and attain a maximum of the order of 1–30 °C above ambient before declining. This represents the subcritical condition.

The sample is discarded and replaced with a fresh, similar one. If the previous run was subcritical, the oven temperature will be increased by usually 20 °C or less depending on the experience of the operator. The run is then repeated. If it is still subcritical, the procedure is again repeated until a supercritical oven temperature is attained. The arithmetic mean of the lowest supercritical temperature and the highest subcritical temperature is taken as the first estimate of the CAT. The uncertainty may be quite large at this stage so the process is usually continued by testing at the estimated CAT. The process is repeated, halving the difference between highest subcritical and lowest supercritical temperatures each time until the desired errors are obtained. Typical

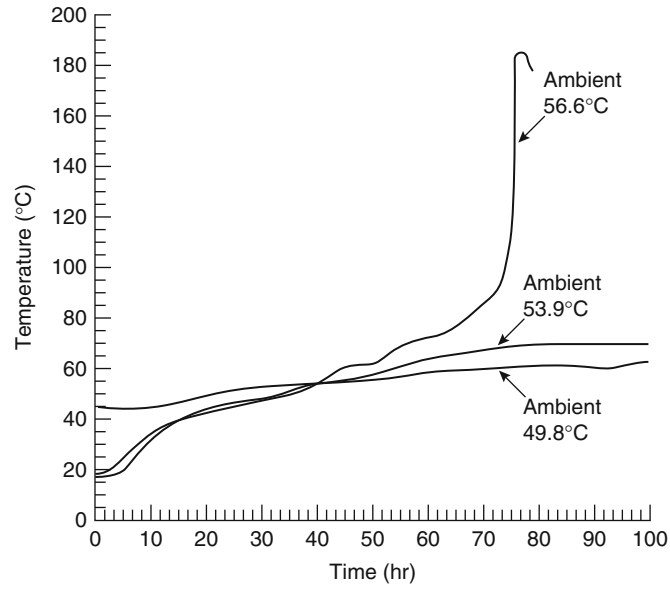

Fig. 20.6 Two subcritical and one supercritical center temperature/time traces for a 0.175-m-radius equicylinder of hydrated calcium hypochlorite [17]

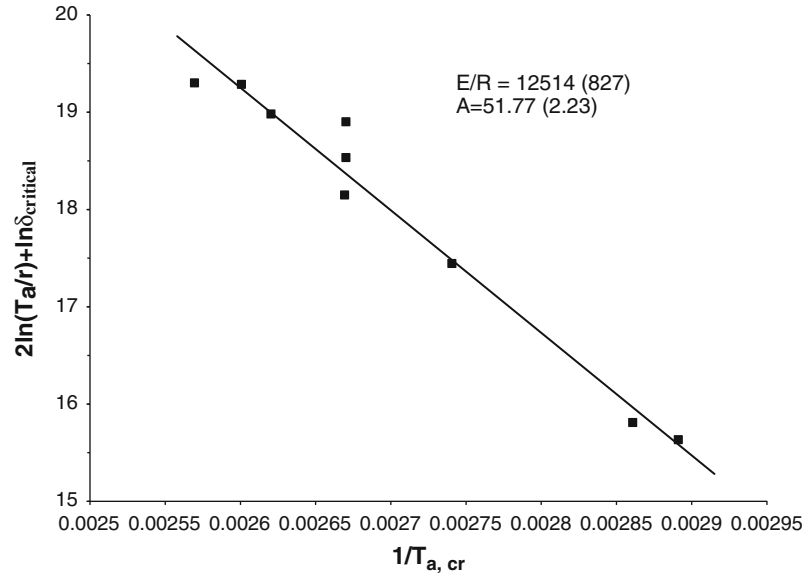

Fig. 20.7 Recalculated Frank-Kamenetskii plot for the data of Uehara et al. on anhydrous calcium hypochlorite [19]

temperature-time plots showing the critical separation are shown in Fig. 20.6.

This reaction is an exothermic decomposition evolving oxygen [18]. From these measurements one would conclude that the CAT was 55.2 ± 1.34 °C. For greater accuracy the next test would be run at an ambient temperature of 55.2 °C. After at least four or five such sets of runs have been carried out in different size containers, giving four or five CATs at various radii, then the next step is to construct the Frank-Kamenetskii plot of the scaling Equation 20.20. A typical plot is shown in Fig. 20.7.

This plot shows a range of CATs for cylinders ranging in radius from 0.191 m down to 0.026 m, the larger radii corresponding to commercial containers. From the slope of this line, E/R can be read off directly, and, from the intercept, so

can the dimensionless group occurring in the scaling equation. Sometimes components of this group may be known from independent measurements, for example, Q from calorimetry, κ from direct measurement, or $f(c_0)$ from kinetic measurements, in which case all the parameters can be obtained.

Special Cases Requiring Correction

Presence of Water

When water is present in spontaneously combustible material, special considerations apply. First it is necessary to note that endothermic evaporation would be expected to partly offset some of the heat generation by the exothermic reactions taking place. Although this is true, it is often the case that at the high oven temperatures used in testing small samples, the low activation energy for evaporation (~40 kJ/mol) leads to rapid evaporation before the exothermic process has got under way fully. Many spontaneous combustion reactions have activation energies around 100 kJ/mol, particularly the group of reactions of cellulosic materials.

As a result, the high-temperature CATs reflect the properties of the dry material, in particular the thermal conductivity. Consequently, extrapolations to temperatures well below 100 °C will be questionable for this reason alone. In the lower temperature range the heat transfer will be significantly affected by the presence of water and its transport from the hotter to the cooler regions of the body by evaporation, diffusion, and condensation.

Many cellulosic materials are known to exhibit a "wet reaction" [20, 21] in addition to the dry exothermic reaction. This reaction involves liquid water as a reactant and further complicates the picture as far as high-temperature testing is concerned. Simultaneous evaporation, diffusion, condensation, and reaction involving water have been modeled recently in connection with bagasse [22, 23], using an experimentally measured rate law for the wet reaction [24] giving results that are in good agreement with measured results for commercial-size piles of this material (minimum dimension 5–10 m).

The detailed nature of the wet reaction with a rate maximum around the 50–60 °C mark has led to false identification with microbial activity. In bagasse at least it has been shown [25] that microbial activity does not contribute to self-heating to any significant degree. Piles sterilized by various methods showed self-heating rates indistinguishable from those of nonsterile piles. Microbial counts were carried out in all cases and large decreases did not affect the self-heating rates. It would be rather surprising if similar results were not obtained from tests on hay and straw where microbiological activity (but not necessarily heating) are known to occur, and it is surprising that such tests have not yet been carried out.

Parallel Reactions

If more than one exothermic reaction can take place in the material, and these reactions have rather different activation energies, then each will dominate in its own temperature range. Thus the higher activation energy reaction will cut in at higher temperatures and be insignificant at lower temperatures when the low activation energy reaction will dominate the heat generation. The wider the divergence in activation energies, the sharper the discontinuity in slope, that is, the narrower the temperature range over which both will contribute. Hydrated calcium hypochlorite shows a clear example of this, and it is reflected in a sharp break in the slope of the Frank-Kamenetskii plot where the changeover occurs. Figure 20.8 shows this plot. The low temperature activation energy for this system is about 48 kJ/mol while that of the higher temperature reaction is around 125 kJ/mol, the transition temperature being around 120 °C [17]. Extrapolation of the high temperature line in this case gives CATs for large commercial-size containers that are seriously in error; that is, they are predicted to be much higher than they actually are. In the general case of two reactions

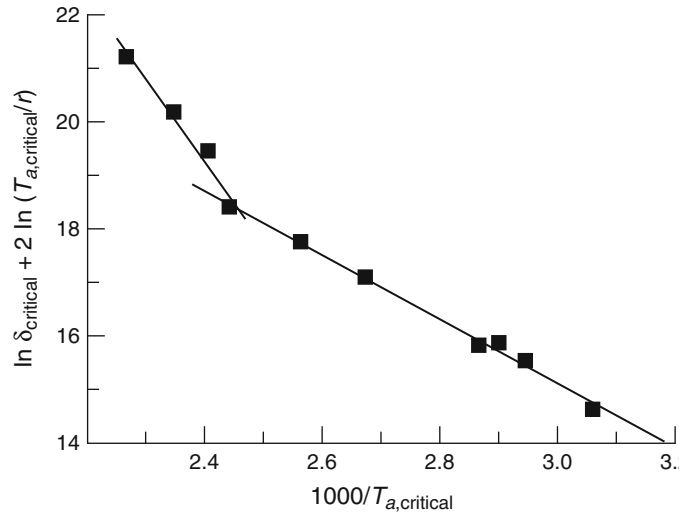

Fig. 20.8 Frank-Kamenetskii plot for hydrated calcium hypochlorite with reaction mechanism change

with different activation energies, this will always be the case as the high activation energy reaction is "frozen out" at low temperatures, and the low activation energy reaction is "swamped" at higher temperatures.

The spontaneous decomposition of calcium hypochlorite has caused extensive container ship losses, particularly in the late nineties. Some due to *hydrated* calcium hypochlorite (UN 2880), defined by the International Maritime Organization [26] to contain not less than 5.5 % moisture and not more than 16 % moisture result from faulty extrapolation as can be seen from Fig. 20.8.

The discontinuity in slope of the F-K plot is undoubtedly due to the effect of moisture mediating chain reactions, the decomposition becoming extremely sensitive to trace metal concentrations.

This is confirmed by the work of Uehara et al. [19] on UN 1748 ("anhydrous") calcium hypochlorite where the lower section of the line is missing. Thus the samples with lower moisture content (<1 %) are much less prone to thermal runaway. So are samples of UN 2880 tested in gauze baskets which allow rapid evaporation of moisture during the tests themselves, behaving in a very similar manner to Fig. 20.7.

Unfortunately the IMO has been inactive in defining moisture content limits for UN 1748 and some manufacturers have taken anything up to 5.5 % to be admissible resulting in large variations in the thermal stability of this product.

On the other hand the P and I (Protection and Indemnity) clubs have taken a proactive stance and largely refused to insure such cargoes unless they are shipped in refrigerated containers (reefers). The resultant increase in cost is probably leading to failure to declare some cargoes of this material as dangerous goods.

Also strategies have yet to be worked out to minimize the possibility of thermal runaway in the event of a power failure on board ship. The heat transfer coefficients of reefers are a fraction of those for normal containers, reducing the effective CATs of reefers without power to very low figures indeed. An obvious emergency strategy would be to open the doors of reefers in such a situation, but this would put serious restrictions on stowage possibilities.

Other examples of mechanism change are known and discussed by Bowes [4]. In such cases accurate predictions of CATs can still be made within each temperature range. This type of example emphasizes the need for tests covering as wide a range of temperatures as possible. Recent methods put forward as viable alternatives to the standard method, for example, Jones [27] and Chen [28], are restricted to either measurement at a single temperature or over a

limited temperature range and can give dangerously flawed results. Empirical tests such as the Mackey test [29] and the crossover test [30] are not reliable and cannot be properly related to the basic principles of spontaneous ignition theory.

Finite Biot Number

The Biot number is defined as

$$\mathrm{Bi} = \frac{\chi r}{\kappa} \tag{20.21}$$

where
χ = Surface heat transfer coefficient
r = Smallest physical dimension of the body
κ = Thermal conductivity of the material

It is the dimensionless measure of the ratio of the resistance to heat transfer within the body to that from the surface to the surroundings. Thus the Semenov theory is often referred to as *zero Biot number* and the Frank-Kamenetskii theory as *infinite Biot number*. They are both special cases of a more general (and more exact) formulation, as was originally pointed out by Thomas [31, 32].

In general the boundary condition at the edge of a self-heating body has the form of a *continuity condition,* which refers to the energy flux across the boundary. It states that the energy flux within the body (given by Fourier's law) and the energy flux from the body surface to the surrounding air must be equal, that is,

$$-\kappa \frac{\partial T}{\partial n} = \chi(T - T_a) \tag{20.22}$$

In dimensionless form this becomes

$$-\frac{\partial T}{\partial n} = Bi(u - u_a) \tag{20.23}$$

This boundary condition does not hold if there exist any heat sources on the boundary of the body itself, as can occur when there is incidence of radiation or when there is heat generated by friction as can occur in pulverization of materials capable of self-heating. Such cases (in the shape of an infinite cylinder) have been treated and the modified critical condition obtained [33, 34]. Similarly modified boundary conditions must be used when surface reactions occur due to catalysis by surface material.

The values of the critical parameter δ quoted for the Frank-Kamenetskii theory are all for the limiting case $Bi \to \infty$, and both Thomas and Barzykin have given semiempirical functions exhibiting the dependence of $\delta_{\mathrm{critical}}$ on Bi, which are detailed in the book by Bowes. As the Biot number decreases so does $\delta_{\mathrm{critical}}$ and hence so does the CAT, all compared with the standard Frank-Kamenetskii theory. For Biot numbers greater than 30, the correction is rather small but is significant for smaller values. Typical heat transfer coefficients from smooth solid surfaces to rapidly stirred air (in a test oven, for example) are of the order of 20 W/m^{2}K, and thermal conductivities of typical cellulosic materials (such as sawdust) are around 0.05 W/mK, giving a ratio of 400/m. Clearly for laboratory-size test bodies ($r \sim 0.1$ m), the Biot number is rather large.

For this reason a significant amount of work has simply *assumed* a sufficiently large Biot number without investigation of its actual numerical value. Sometimes the assumption is not justified, particularly where inorganic materials are involved, as their thermal conductivities can be quite large. For example, typical inorganic salt thermal conductivities lie in the range 0.2–3.0 W/m·K, giving for the ratio (χ/κ) a value of 7–100/m. Clearly for test bodies with $r \sim 0.1$ m, the Biot number will be only 0.7–10. The effect of the small Biot number on $\delta_{\mathrm{critical}}$ is to reduce it by a factor ranging from 0.21 to 0.83, respectively. Clearly for such materials, the more general boundary condition suggested by Thomas must be used, and it is good practice for all but the most strongly insulating materials to estimate the thermal conductivity (particularly in the presence of water) independently of the standard testing regime.

A further important feature of self-heating bodies with a finite Biot number is that their CATs will be sensitive to the heat transfer coefficient from their surface to the surrounding air.

Thus the value of the CAT obtained may well be test-oven sensitive and be strongly influenced by air movement. For example, it has been shown for hydrated calcium hypochlorite [18] that in stirred air in a typical test oven the CAT is 60 °C for a 0.175-m-radius container, but in still air the CAT is 55 °C.

This observation raises serious questions about the value of empirical testing methods such as the SADT test for shipping of self-heating materials [35] that determines criticality-related parameters under vaguely defined conditions of forced airflow in a test oven. The results are then used to determine "safe" conditions for shipping such materials in *still air* inside, for example, a shipping container. Almost invariably many self-heating bodies are stacked inside the same still air inside a container, and they will interact with each other to a very significant extent if the transfer of heat through the container wall is not very rapid. In practice such transfer is rather slow, involving two successive air-metal transfers. As a result the self-heating bodies collectively heat the air inside the container and produce a "cooperative CAT," which can be tens of degrees lower than the CAT of a single body. The Semenov-type theory for this collective ignition has been formulated by Gray [36]. A more accurate version, where the individual bodies are assumed to obey the general boundary condition put forward by Thomas, has also been formulated. The predictions of this theory have been compared to the experimental CAT for eighteen 14 kg equicylinders packed in a rectangular steel box with good agreement [37]. The CAT was reduced from 62.5 °C for a single keg in still air to 54 °C for 18 kegs in still air.

Times to Ignition (Induction Periods)

The terms *time to ignition* and *induction periods* tend to be used synonymously. Here we will abbreviate using TTI. This represents the most difficult area of spontaneous combustion insofar as prediction is concerned. There are three principal reasons for this:

1. The theoretical treatment is much more difficult than that of criticality itself.
2. The actual definition has been greatly confused from case to case.
3. The TTI, however defined, can be extremely sensitive to quantities that have hardly any effect on the position of the critical condition.

Theoretical Treatment

We refer the reader to Bowes [4] and Babrauskas [5] for discussion of earlier treatments. For illustrative purposes we will initially follow Bowes and define TTI from Equation 20.5 by integration from ambient temperature to some value u_1, say

$$\tau_i = \int_{u_a}^{u_1} \left[\nu_0 e^{\frac{-1}{u}} - \ell(u - u_a) \right]^{-1} du \qquad (20.24)$$

This is, of course, in dimensionless form. Our present interest is the implicit use of u_a as the lower limit; that is, it is the time for the sample to go from ambient temperature to some predetermined arbitrary figure, possibly the maximum temperature attained (it turns out that the integral is not sensitive to this limit, provided it is sufficiently high).

Although the maximum temperature attained is a meaningful figure for laboratory tests under some circumstances, it does not always correspond to practical large-scale circumstances. For example, it requires recording the time taken for the center of the sample to heat up in a test oven to ambient temperature and using this as the reference time for TTI. Unfortunately, when the center has reached this point, other parts of the body have often attained rather higher temperatures [38], and the subsequent TTI will be reduced compared to a large-scale body that may well have been built at ambient temperature and be quite uniform initially. Extrapolations of such laboratory tests will not then be reliable since the initial condition will not be appropriate.

The TTI for the hot stacking problem is qualitatively different from that in which the body is

formed uniformly at ambient temperature. Generally this time is *much shorter* than the TTI for the more common case of initially ambient temperature throughout the body. The reasons have been given, with a comparison of the two cases, by Gray and Merkin [39]. Similar considerations apply when part of the body is at a high temperature (hot spot), and this case has been discussed in detail by Thomas [40].

With the ready availability of powerful and fast numerical techniques, it is now feasible to integrate routinely the time-dependent heat conduction equation for this problem, which is probably the best solution. Zinn and Mader [41] were early participants in this effort, and more recently Gray, Little, and Wake [38] have noted that such numerical results can be usefully used to predict a very good lower bound to the TTI. These results are desirable as they err on the side of safety.

Very close to criticality, perturbation treatments have been formulated [42–46], but these are mainly of theoretical interest. At the critical condition the TTI becomes infinite, and close to this condition it is extremely sensitive to the degree of criticality, so unless this is known accurately (hardly ever the case), use of such formulas is not advised.

Other, Largely Chemically Kinetic, Difficulties

In addition to the difficulties discussed above, which apply even when only a single simple reaction is assumed, there are others that are largely chemically kinetic. It has long been known that chain reactions, whether branching or not, can exhibit very long induction periods followed by very rapid onset of (sometimes non-explosive) reaction. Many exothermic spontaneous ignition reactions do possess some chain characteristics even though these do not manifest themselves once the reaction is well underway. Thus it is feasible for complex chain mechanisms to determine the details of the TTI but not be at all important in determining the critical condition where gross heat balance considerations are crucial. In many cases this leads to extremely irreproducible TTIs without similar variation of CATs or other properties. In case this list of difficulties leads to an overly pessimistic view of the topic of TTI, there are some things that can generally be relied on as far as the practical situation of fire investigation is concerned.

Very crudely speaking, notwithstanding the above discussion, the larger the body, the longer the TTI will usually be. Thus a fire thought to have been caused by spontaneous ignition of a pile of linseed oil–contaminated rags contained in a wastepaper basket will usually appear within a few hours of the rags being placed there. On the other hand, a fire resulting from spontaneous ignition of thousands of metric tons of woodchips would occur only after some months of assembly, assuming the pile was assembled at ambient temperature. For such bodies it is generally true that the TTI increases with size in this manner. Accordingly haystacks tend to ignite (if they are supercritical) after a few weeks and coal stockpiles after a few months. However, the TTI can decrease dramatically if the body is very far beyond the CAT.

For hot stacked bodies, on the other hand, times are generally much shorter and not particularly sensitive to the ambient temperature. Thus stacks of freshly manufactured chipboard with a volume of a few cubic meters can ignite much more quickly—that is, hours rather than days—than a similarly sized body self-heating from ambient. Beyond these general comments one has to treat each separate case on its merits with a careful eye for exceptions to any general rules. For example, the presence of any catalytic material, such as rusty metal (a common contaminant of many materials), can dramatically decrease the TTI. This indicates the presence of free-radical or chain reactions and is fairly common, although the CATs and CSTs are only slightly affected.

In summary, in fire cause investigation, where spontaneous ignition is suspected, it is wise to be very circumspect about time factors without very thorough investigation and detailed knowledge of the initial conditions likely to have existed when the body was put in place. Even the

traditional linseed-oil rag example can be thrown out of the normal pattern by the presence of mineral turpentine, a very common diluent for oil-based stains. The evaporation of this from the rags can greatly prolong the TTI by virtue of the consequent cooling effect and also the exclusion of air by the vapor. Depending on the circumstances, these factors could add 2 or 3 days to a TTI that would normally be no more than a few hours.

Investigation of Cause of Possible Spontaneous Ignition Fires

From the investigative point of view, it is helpful to list the practical factors that enhance the possibility of spontaneous ignition as a possible fire cause.

The Size of the Body of Material The larger the size of the body of material, the greater the likelihood of spontaneous ignition. By *size of the body* we mean the parts that are in thermal contact. A large pile of cotton bales with aisles through it would not necessarily be a large body in the thermal sense used here. This classification would be true even if (as often happens), once ignited, fire could spread easily from one section to the next.

High Ambient Temperatures Because the air around the body in question has to act as a heat sink, the higher the ambient temperature, the more inefficient is the air as a coolant. Also direct placement underneath a metal roof or adjacent to a northwest- (southern hemisphere) or southeast- (northern hemisphere) facing wall is a positive factor.

Thermal Insulation Sometimes spontaneously ignitable materials are stored in chemical warehouses or elsewhere packed against inert solids that prevent free airflow over the surface, thus reducing heat losses. This effect is evidenced by the appearance of maximum charring or self-heating that is off center and closer to the insulated side of the body. It also results in a reduced CAT.
