Step 7—Consideration of Probability

The probabilities of the various events shown in the event trees produced in Step 6 can be determined from statistical data and other sources. However, because at this stage of the process the analysis is qualitative, expert

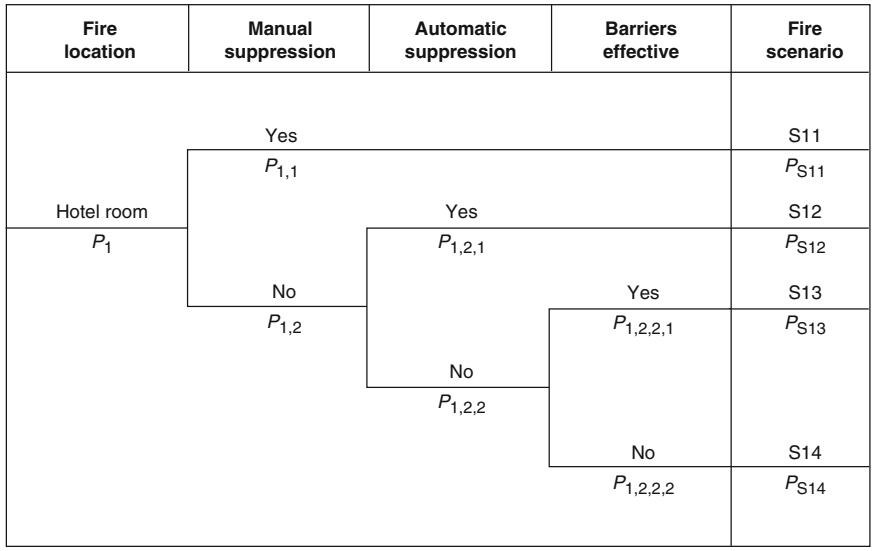

Fig. 38.7 Event tree for hotel room fire

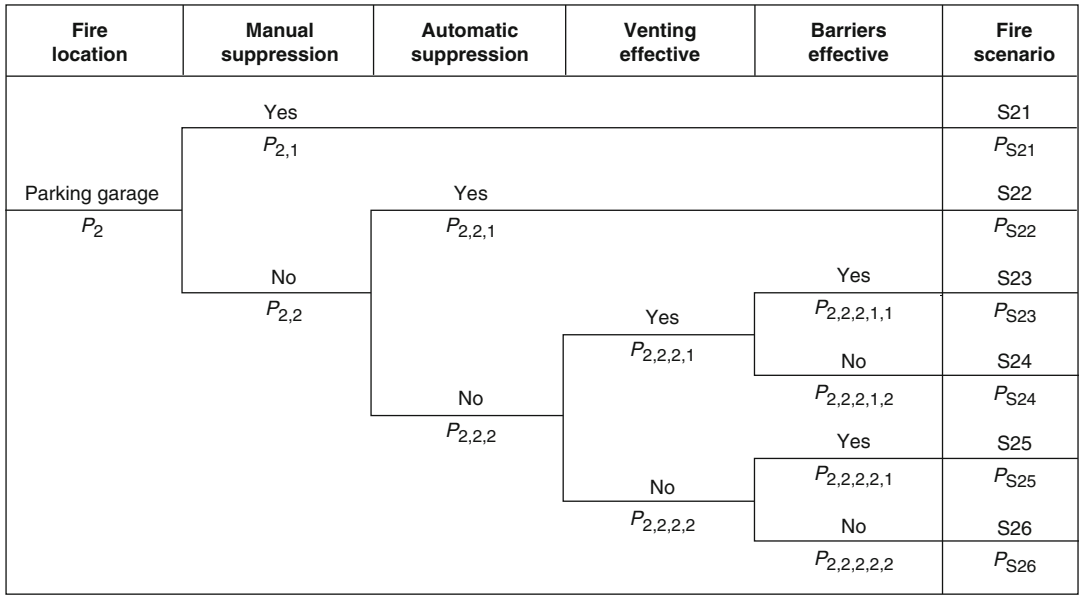

Fig. 38.8 Event tree for parking garage fire

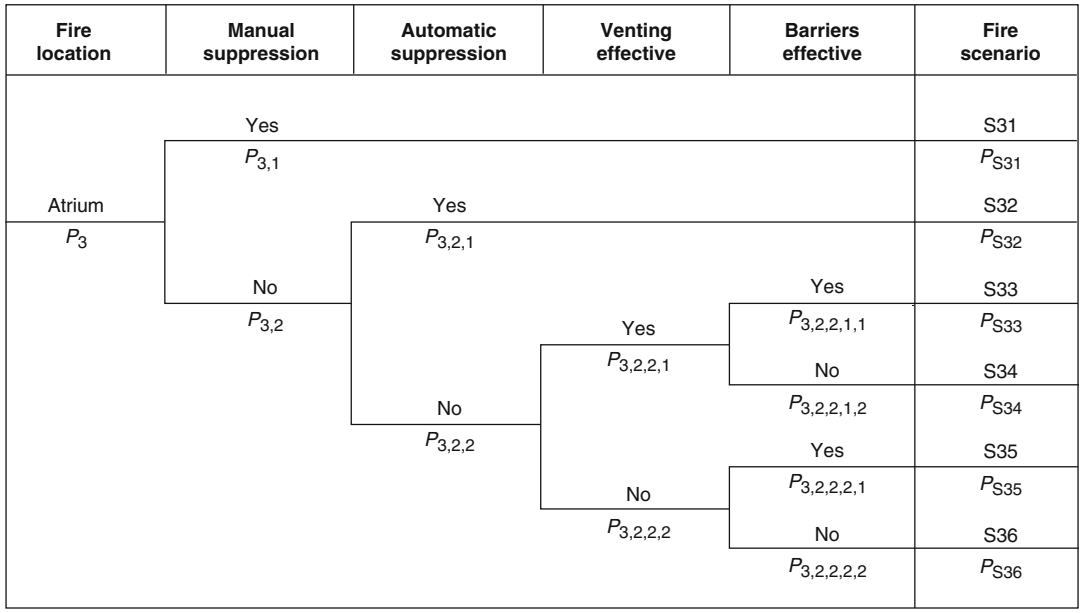

Fig. 38.9 Event tree for atrium fire

judgment can be used for the initial screening of the fire scenarios. For this example, the probabilities of each of the events will be described in qualitative terms and then converted to probability values to facilitate the calculation of the scenario probabilities. For this, the descriptions and values shown in Table 38.4 are used.

The very high value of 0.95 corresponds to the probability of effectiveness of sprinkler

systems in hotel rooms, whereas the value of 0.7 is associated with the probability of smoke detector activation. Using these values, the probabilities of the events of the event trees are assigned and the scenario probabilities are calculated, as shown in Figs. 38.10, 38.11, and 38.12.

Step 8—Consideration of Consequence

In this step, a qualitative evaluation of the consequence of each of the scenarios is performed. This evaluation is done using engineering judgment based on the type of fire, the location of the fire, and the effectiveness of the active fire protection systems. This evaluation considers the impact of the fire on both property as well as life safety. To facilitate this assessment, Table 38.5 shows the different consequence levels that are chosen for this example. The level is determined by considering both the property losses and the occupant impact. For example, the consequence level of a scenario with $30,000 in losses and serious injuries is "high."

Based on the levels shown in Table 38.5 and considering the fire type, fire location, and effectiveness of the active fire protection systems, the consequences of the scenarios in the three event trees are determined as shown in Figs. 38.13, 38.14, and 38.15.

Step 9—Risk Ranking

Figure 38.16 presents the risk-ranking matrix developed based on the results of Steps 7 and 8. The matrix has six levels of probabilities of occurrence, from extremely low to very high, and five levels of consequence estimates. The levels for the probabilities of scenario occurrence for this example have been set as shown in Table 38.6.

The three levels of shaded areas in Fig. 38.16 represent areas of different risk levels, with the darker area representing high risk and the lighter area representing low risk. The white areas represent very low-risk scenarios.

Table 38.4 Values associated with probability descriptions

Quantitative description	Associated value
Very low	0.05
Low	0.3
Moderate	0.5
High	0.7
Very high	0.95

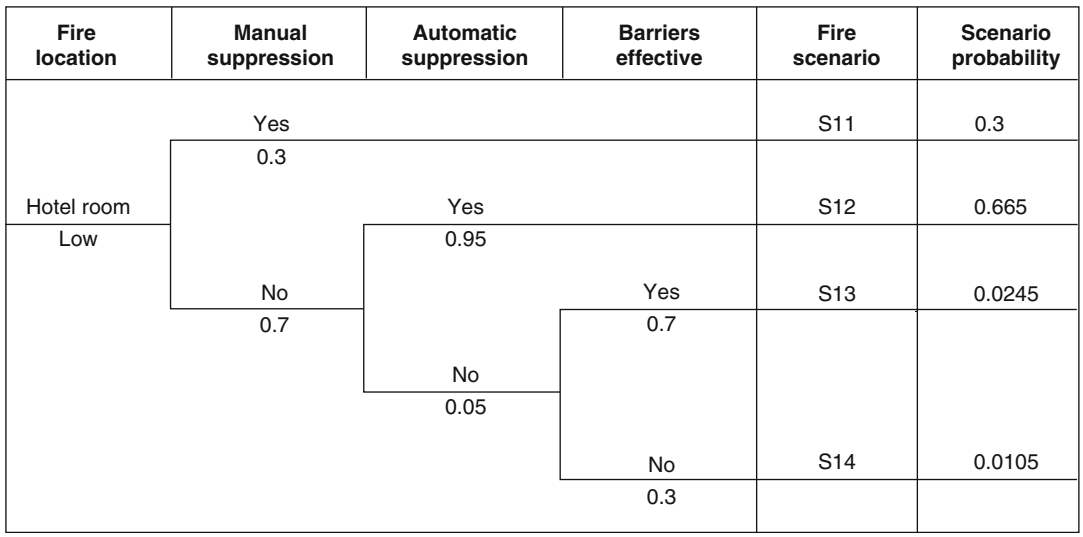

Fig. 38.10 Probabilities of scenarios for hotel room fire

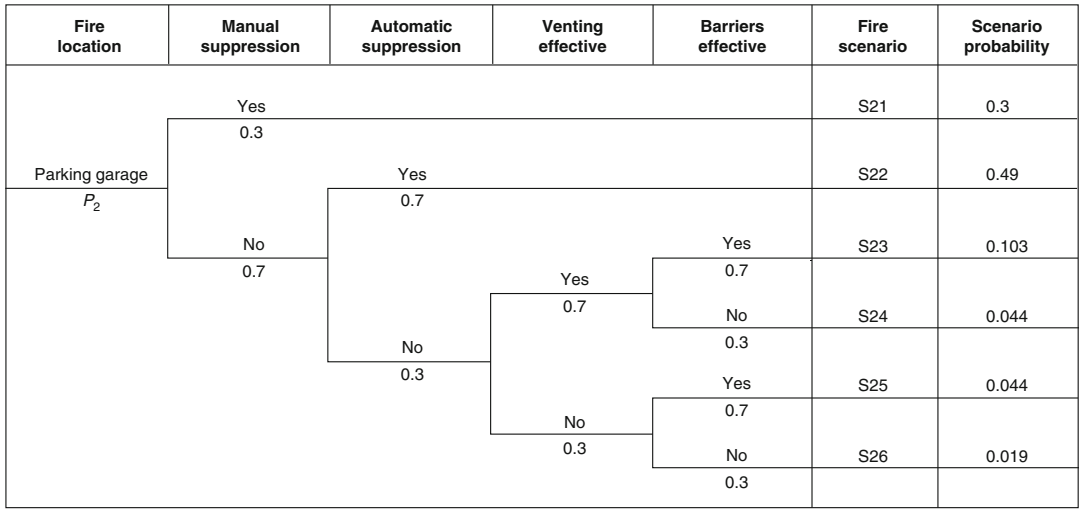

Fig. 38.11 Probabilities of scenarios for parking garage fire

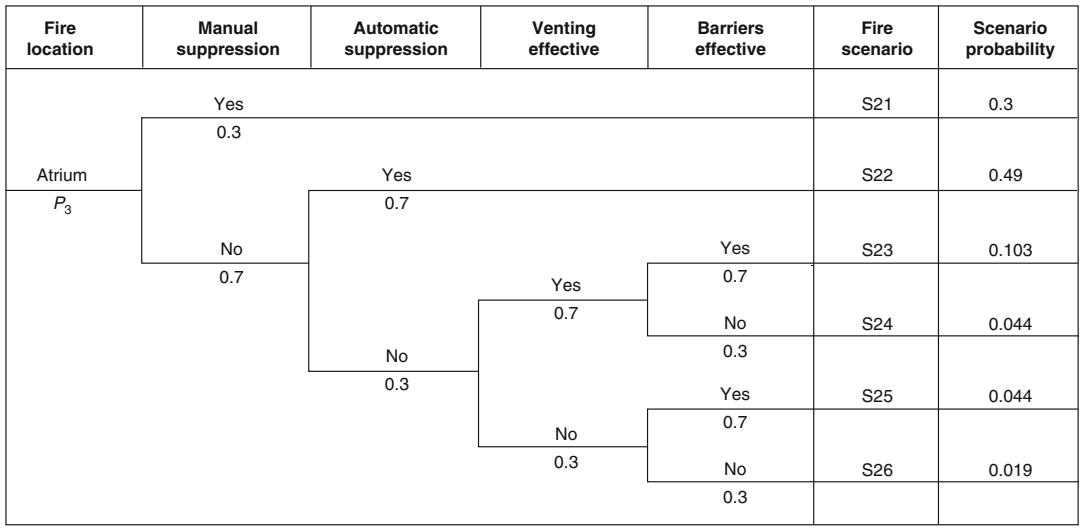

Fig. 38.12 Probabilities of scenarios for atrium fire

Table 38.5 Consequence levels and associated loss estimates

	Associated loss estimate	
Qualitative description	Property losses ($1000)	Occupant impact
Very low	0–5	No deaths or injuries
Low	5–20	No deaths or injuries
Moderate	20–100	No deaths, minor injuries
High	100–1000	No deaths, serious injuries
Very high	1000–10,000	Small number of deaths and injuries
Extremely high	>10,000	Multiple deaths and injuries

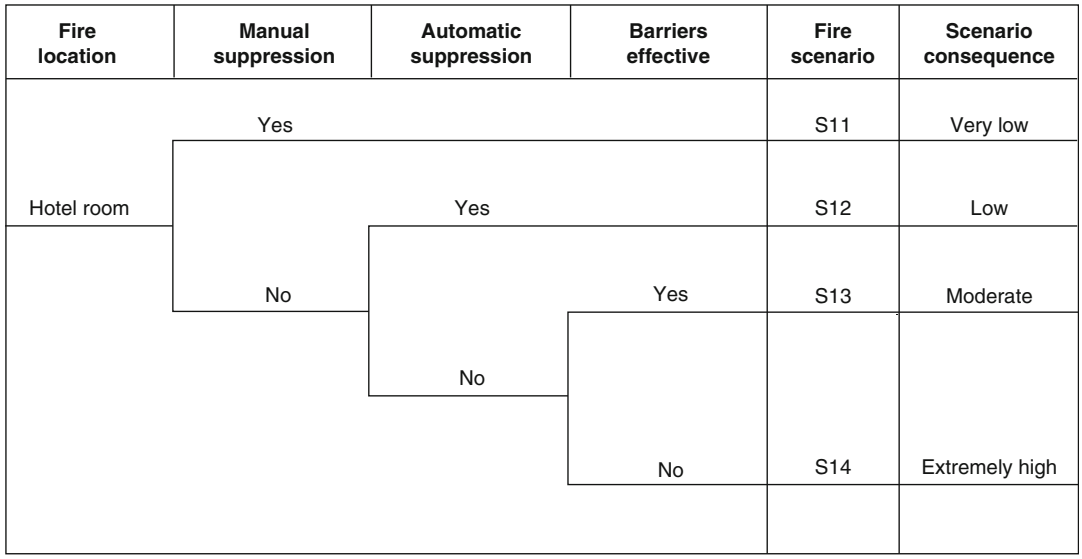

Fig. 38.13 Consequence of hotel room fire scenarios

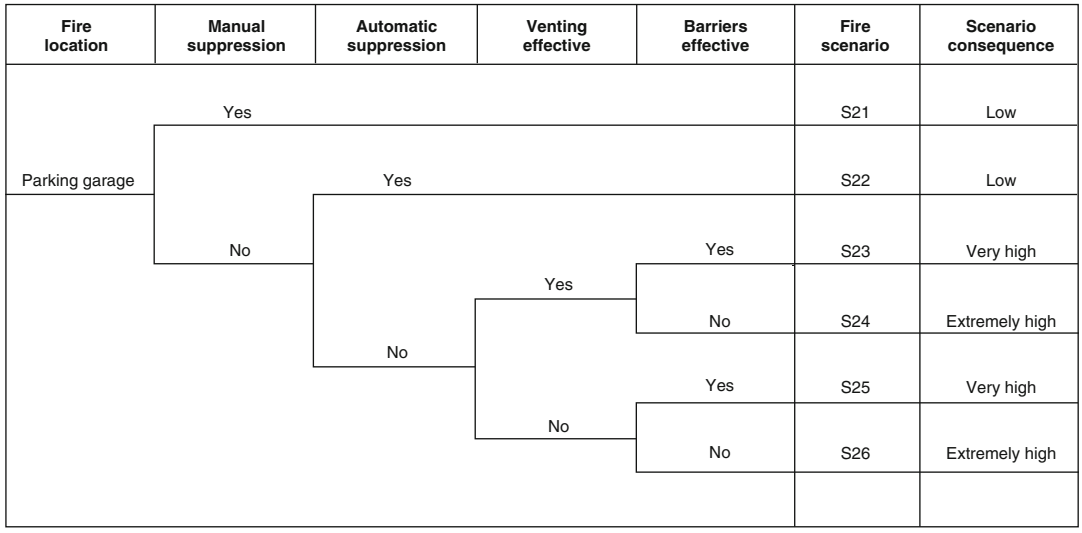

Fig. 38.14 Consequence of parking garage fire scenarios

As shown in Fig. 38.16, no scenario falls in a high-risk area. Scenarios S23 and S24 are moderate-risk scenarios and should be considered for quantitative analysis. Scenarios S25, S33, and S34 are low-risk scenarios that can also be considered further. In addition, Scenario S14, although it falls into a very low-risk area, may be considered for further analysis, as it is a scenario in a different section of the building with different fire protection

Fire location	Manual suppression	Automatic suppression	Venting effective	Barriers effective	Fire scenario	Scenario consequence
Atrium	Yes				S31	Low
	No	Yes			S32	Moderate
		No	Yes	Yes	S33	High
				No	S34	Very high
			No	Yes	S35	High
				No	S36	Extremely high

Fig. 38.15 Consequence of atrium fire scenarios

	Probability of scenario occurrence					
Consequence	Extremely low	Very low	Low	Moderate	High	Very high
Extremely high	S26, S36, **S14**		**S24**			
Very high			**S25** **S26**	**S23**		
High			S35	**S33**		
Moderate		S13			S32	
Low				S21	S22	S12
Very low				S11, S31		

Fig. 38.16 Risk-ranking matrix of identified scenarios

Table 38.6 Scenario probability values used for risk-ranking matrix

Probability level	Scenario probability
Extremely low	0.0–0.02
Very low	0.02–0.04
Low	0.04–0.1
Moderate	0.1–0.3
High	0.0–0.5
Very high	0.5–1.0

systems and different impacts, and it has an extremely high consequence. All other scenarios do not require further analysis and can be dropped.

Step 10—Final Selection and Documentation

The final selection of the design fire scenarios is done in this step, and the fire scenarios are documented in detail. As indicated in Step 9, scenarios S14, S23, S24, S25, S33, and S34 should be considered for further analysis. To facilitate the quantitative analysis, Table 38.7 describes the characteristics of these scenarios. The quantitative analysis of these scenarios should consider both the impact of the fires on life safety and property. The procedure outlined in the section "Development of Fire Scenarios" in this chapter can be followed for the analysis.

Table 38.7 Description of design fire scenarios

Scenario ID	Location	Design fire	Description
S14	Hotel room	Fire involving curtains and mattress	Fire started in a garbage container and spread to the curtain and mattress. Nobody was in the room of fire origin. The sprinkler system did not activate because the water supply was turned off for repairs. The fire spread from the room door to the corridor of the hotel. For life safety calculations, assume that occupants were asleep when the fire started
S23	Parking garage	Vehicle fire	Fire started in a vehicle parked in the parking garage. The sprinkler systems activated but could not control the fire. The exhaust ventilation system operated, and it was effective in removing smoke from the parking garage to the outside. The barriers were effective in containing the fire on the floor of fire origin
S24	Parking garage	Vehicle fire	Fire started in a vehicle parked in the parking garage. The sprinkler systems activated but could not control the fire. The exhaust ventilation system operated, but it was not effective in removing smoke from the parking garage to the outside. The barriers failed to contain the fire on the floor of fire origin
S25	Parking garage	Vehicle fire	Fire started in a vehicle parked in the parking garage. The sprinkler systems activated but could not control the fire. The exhaust ventilation system operated, but it was not effective in removing smoke from the parking garage to the outside. The barriers were effective in containing the fire on the floor of fire origin
S33	Atrium	Christmas tree fire	Fire started involving a Christmas tree and stage at the center of the atrium. The sprinklers failed to control the fire. The smoke management system was effective in maintaining smoke levels to the design level, and the fire was contained in the atrium
S34	Atrium	Christmas tree fire	Fire started involving a Christmas tree and stage at the center of the atrium. The sprinklers failed to control the fire. The smoke management system was not effective in maintaining smoke levels to the design level; however, the fire was contained in the atrium

George V. Hadjisophocleous is a professor at Carleton University and holder of the Industrial Research Chair in Fire Safety Engineering and President of CHM Fire Consultants Ltd. Prior to moving to Carleton University, he was a senior research officer and group leader at the Fire Risk Management Program of the National Research Council of Canada. He holds a PhD in Mechanical Engineering from the University of New Brunswick and he is the author of over 150 publications in the areas of fire research, fire risk assessment, performance-based codes, and CFD modeling. His research areas include fire risk analysis and fire and smoke movement modeling using CFD and zone models. Dr. Hadjisophocleous is a Fellow of SFPE and member of NFPA, IAFSS, ASHRAE, and CIB W14 and a Registered Professional Engineer in the Provinces of Ontario and British Columbia.

Jim R. Mehaffey From 1980 to 1987, Dr. Jim R. Mehaffey was a research scientist at the National Research Council where he developed models to predict the growth and severity of building fires. From 1988 to

2009, he was a research scientist with FPInnovations (Forintek) where he modeled the performance of wood-frame assemblies exposed to fire. From 1993 to 1997, he was seconded to the University of British Columbia where he was director and associate professor in UBC's Fire Protection Engineering Program. He is currently an adjunct professor in the Department of Civil and Environmental Engineering at Carleton University and a Principal with CHMfire Consultants. He holds a PhD in physics from the University of Toronto and is the author of over 80 scientific publications.

Engineering Considerations for Fire Protection System Selection

39

Milosh Puchovsky and Craig Hofmeister

Introduction

A fundamental responsibility of an engineer is the design of systems that satisfy the overall goals and objectives for a given facility. When it comes to fire and life safety, the fire protection engineer (FPE) is called upon to design those systems deemed necessary to meet the performance objectives for the project. However, before specific protection systems can be designed, decisions must be made regarding what systems are most appropriate and necessary in light of the fire events of concern, and the overall outcomes to be achieved at the conclusion of these events.

While FPE's may not always make the final decision about system type, their decision making approach, input and recommendations are vital to the overall success of the enterprise. Ideally, the ultimate choice about system type is given the proper priority, is well informed, and is made well before any system design work or construction commences. Furthermore, such a decision needs to fit into the overall fire safety strategy, which addresses the fire related concerns specific to site conditions, operations and personnel in question.

When considering a specific fire fighting agent and accompanying system, numerous questions that impact the selection arise. The more obvious pertains to the agent's effectiveness and compatibility with the types of fuels and fires events, i.e., can the agent extinguish, suppress or control the fire in the time period needed. However, other considerations must also be dealt with.

For instance, can the agent be discharged on electrically energized components? Can a fire be detected and an agent discharged in the timeframe necessary to be effective? Does agent discharge sound frequency affect electronic and computer equipment performance? Will the discharged agent leave a residue or otherwise impact the equipment or contents it is intended to protect? Is the agent chemically and physically compatible with the fuel, e.g. physical reaction of water on tissue paper, or chemical reaction of discharge on metal fires involving aluminum or magnesium? Does the agent decompose in the presence of the fire or heat and do such agent decomposition products have an affect on the components to be protected? Can the agent be discharged in an occupied area and/or are there health or environmental concerns associated with the agent? Should the agent once discharged be reclaimed or otherwise contained? What are the costs for the overall system including those associated with necessary maintenance activities? How quickly can the agent supply be replenished? Has the fire protection system operation been sufficiently coordinated with facility operations and other equipment? If multiple systems are utilized to protect specific areas or hazards, how are the systems interconnected to operate effectively? Does system operation

require specialized training of building staff and emergency responders? As should be appreciated, the above only presents a partial list of possible considerations that require attention.

Additionally, the necessary comprehensive approach in addressing fire protection and life safety can at times be met with resistance due to cost and other factors. Some owners view fire protection systems as a cost without a direct return on investment, unless they have experienced a previous fire event or truly understand the associated risks. Similarly, some design team members might view fire protection as a required inconvenience and do not want to spend time or effort beyond the simplest path to meet minimum code requirements. Therefore it is important to open lines of communication with the stakeholders early in the process and discuss the importance and benefits of developing the most appropriate protection schemes.

A generic prescribed approach for selecting the most effective system does not exist within a regulatory document or general application guides. Neither does any comprehensive guidance exist that facilitates the decision as to why one type of agent or system should be chosen over another. The responsible FPE typically needs to develop their own approach that guides and influences their final recommendations.

This chapter puts forth, in a single reference, a collection of topics and other information pertaining to various types of fire fighting agents and their associated systems that can impact a FPE's approach and final recommendations about selecting a specific type of fire protection system. The material presented here should not be interpreted as a formalized step-by-step procedure, but rather an assembly of information that can underpin an FPE's decision-making process. Further to this point, the order of subjects presented is not intended to represent the only sequence in which they can be considered.

Structuring the Decision Making Process

A comprehensive and coordinated decision making process is the basis for selecting the appropriate fire protection system(s) for a given application. The FPE needs to possess a thorough knowledge of the facilities under consideration and the limitations and uses of the various types of fire protection systems he or she might consider as part of the overall fire protection package. As noted above, it often falls upon the individual FPE to develop his or her own approach for selecting and recommending the most appropriate system to meet the overall objectives. While approaches may differ, the key concepts are relatively typical regardless of the application.

Information from applicable building, fire and safety regulations and relevant system design and installation standards as well as from other sources such as system manufacturer materials, listing protocols and fire tests is essential in developing an effective approach. Ideally, a comprehensive fire risk assessment should serve as the basis for structuring any application guide or method for recommending a specific fire protection system. As a minimum the decision process should be at least risk-informed.

A fire risk assessment is a process used to characterize the risk associated with fire for specific scenarios. Both the probability of the scenarios occurring, and their potential consequences are addressed. Within the context of the risk assessment, fire protection systems largely serve to mitigate or moderate the consequences. However, fire protection systems could also be used to decrease the likelihood of an undesirable event from occurring, i.e. inerting an atmosphere before an ignition source occurs.

In undertaking a fire risk assessment, the level of acceptable fire risk needs to be sufficiently considered and articulated, i.e. the desired outcome or consequence at the conclusion of a fire event or scenario. The fire risk assessment will help crystalize the overall intent and purpose of any fire protection system, and how it fits into the overall fire safety strategy, i.e. will the system be used to protect the overall facility or just specific areas or operations. Preferably, the fire protection systems need to be linked to the overall goals and objectives of not only the building owners, but also all key stakeholders involved with the project.

Certain fire protection standards specifically call out the use of fire risk assessments. For example, NFPA 75, *Standard for the Fire Protection of Information Technology Equipment*, indicates that a fire risk analysis can be used to determine the construction, fire protection and fire detection requirements for information technology equipment, information technology rooms, and information technology areas [1]. NFPA 75 identifies factors such as the effect of loss of function of information technology equipment on life safety, e.g. process controls; life safety functions controlled by particular equipment; threat of fire from burning equipment to occupants and other property; and economic impact from loss of function, loss of records or loss of physical assets, among others that need to be considered to determine the level of acceptable fire risk. Numerous resources on fire risk assessments including several chapters in this Handbook, the SFPE Engineering Guide to Fire Risk Assessment [2], and NFPA 551, *Guide for the Evaluation of Fire Risk Assessments* [3] are available to the FPE in this regard.

Another resource available for structuring the decision making process is NFPA 550, *Guide to the Fire Safety Concepts Tree*. The "Tree" can be used to develop and analyze the potential impact of fire safety strategies, and help identify gaps or areas of redundancy. The logic of the "Tree" is directed toward the achievement of specified fire safety objectives that need to be sufficiently articulated. Strategies for achieving the objectives are divided into two general categories: "Prevention of Fire Ignition" and "Managing Fire Impact". Active fire protection systems can be employed to address both categories: preventing a fire from starting, e.g., inerting the atmosphere once a certain concentration of flammable vapors of a particular fuel are detected, and by managing the impact of the fire once ignition has occurred, e.g., suppressing or controlling the fire, and/or safeguarding exposure concerns. The Guide can be used to protect the entire facility or just specific areas or operations [4].

The decision methodology or structure of the analysis can be similar to other types of fire protection engineering analysis such as performance-based design or a particular calculation methodology. The structure of such analyses as outlined in documents including the SFPE Performance-Based Design Guide or the SFPE Guide to Substantiating a Fire Model as Appropriate for a Given Application can provide good reference for a coordinated decision making process.

Considering Stakeholders Concerns

It is important that the various stakeholders are involved in the decision making process leading to the selection of the appropriate fire protection system. Each stakeholder may not provide direct guidance or information to the FPE, but it is important that the FPE have an understanding of the goals and objectives of each stakeholder or their perspective. Typically, the stakeholders will include representatives from the owner, facility operators, tenants, insurer(s), other members of the design team, and the authorities having jurisdiction, but may also include others depending on the facility type and use. See the SFPE Performance-Based Design Guide for more specific information on the role of stakeholders in a coordinated decision making process.

The active participation of each of the individual stakeholder categories may vary from project to project but the FPE should consider the viewpoint for each category in the decision making process. The individual viewpoints may vary significantly and the FPE should consider and address each as it relates to the overall fire safety objectives and the expected role of fire protection system(s). Some stakeholders may view fire protection systems as a cost without a direct return and would therefore want to minimize the process. Other stakeholders may have experienced a previous fire event or have specific operational or business interruption goals that make them more sensitive to the impact of a fire event. Ideally, the different viewpoints can be discussed in a meeting or conference and the general impact of each viewpoint on the systems purpose can be addressed.

As an example, a large multi-tenant data center design would likely have a variety of stakeholders and viewpoints as it relates to the fire protection systems performance for the facility. The owner may have specific goals related to facility and space flexibility, cost, and potential liability, the facility operators and tenants may have specific goals related to equipment protection and business continuity, the insurer may have specific goals related to structure and maximum loss, the design team may have specific goals related to sustainable design and energy usage, and the authorities having jurisdiction may have specific goals related to not only code compliance but also the operations and safety of responding emergency personnel safety. The FPE is then responsible for understanding, considering and integrating the individual stakeholders concerns and objectives in the decision making process, and addressing each in the establishment of system performance criteria and in the selection of the most appropriate fire protection system(s).

Given that many projects and applications will include a variety of viewpoints from the relevant stakeholders, good communication and documentation throughout the process is critical. Ideally, the FPE is leading, organizing, and taking responsibility for the process to ensure that all stakeholder concerns are addressed and sufficiently satisfied, and each stakeholder subsequently understands the reasoning for the final decisions.

Understanding the Facility's Intended Purpose and Operation

Any building project and commercial enterprise is a significant investment and undertaken with specific design and end-use goals and outcomes in mind. Once built, the structure serves the purposes and needs of its owners. The building and its associated systems enable the operations of the overall enterprise contained within, i.e. provide a workplace, facilitate heath care services, support manufacturing processes, shelter people and assets, etc.

Before any fire safety concerns can be properly addressed, the fire protection engineer must possess a functional understanding of the facility operations, their purpose and what the owners expect from their investment. The detail of the facility and operational review may vary but should include features including the site configuration, geographical location and climate; building construction and materials; equipment and/or industrial/manufacturing processes; storage configuration and commodities; presence and categories of hazardous materials; utilities location and configuration; occupancy/occupant loading, occupant locations and responsibilities; and overall building operations. Additionally, seasonal variances should also be reviewed and considered. Do manufacturing or processing operations ramp up due to market conditions? Is there an increase in occupants, including temporary occupants less familiar with their surroundings at different times of the year? Is there a different procedure or an increase in storage at a specific time of the year? Is weather or an accumulation of snow an additional consideration? Are seasonal decorations a notable fire load that needs to be considered, etc? Regardless of the facility type, the operational conditions can vary significantly and therefore it is important that the review and analysis are specific to the subject facility and not a "typical" facility type.

As an example, if the facility is a wood working operation, the details of the site layout and building construction should be reviewed as a baseline; however, the FPE should also invest the time to gain sufficient knowledge about the associated workflow, processes, storage configuration, equipment, materials, operation and configuration, and occupant loading and locations. The operations in each wood working facility will differ to some degree and therefore it is important the FPE understand the specific operation and configuration of the subject facility, such as the type of wood species processed, raw material delivery and storage, cutting, drying, veneer preparation, panel manufacturing, milling, laminating, sanding, finishing, final product storage and distribution, and wood waste management. Further, does the facility have additional

operation shifts or modified hours at different times of the year or during periods of equipment maintenance or outage? Do the materials or storage methods/configuration change for peak or slow operational periods? Are there peak times for raw material or hazardous material delivery? Are there weather or other environmental considerations for the specific facility location?

The full appreciation of the facility, its key processes and configuration, and the operational considerations provides the background to identify and properly understand potential hazards and fire scenarios.

Characterizing How Fire Can Impact the Facility and Its Operations: Defining Fire Hazards and Scenarios

Once the make-up and purpose of the facility is properly understood, the potential fires that could affect its occupants, operations, and contents can be addressed. An important step is to conduct a general hazard assessment to define potential fire events or scenarios. After reviewing the details of the construction and operation as outlined above, a review of potential fire hazards can be conducted specific to the facility and its operations. In general, the hazard assessment should be conducted without considering any protection systems, as the ultimate intent is to identify the most appropriate system to eliminate, mitigate or manage the associated fire hazards. The assessment should consider fire hazards associated with the processes contained within, with specific attention given to the likely range of combustible contents, fuel loads and ignition sources. Potential hazards associated with normal and abnormal operational functions need to be considered, i.e. various failure modes of process equipment and their effects should be investigated.

Overall, the assessment would include a review of potential fire scenarios pertaining to the contents and equipment located within the facility; normal processes and operations; and events resulting from malfunctioning equipment. General fire scenarios should consider all combustible materials and fuel loading locations, and would likely involve building construction materials, storage and packaging materials, furniture and equipment, and other transient items such as trash, decorations, and normal use items. The operations related scenarios would involve a thorough review of potential fire hazards associated with the various aspects of the process housed within the facility and would consider the production or release of dusts, ignitable liquids, flammable gases, etc. Failure scenarios should include a review of reasonable potential events as a result of a single failure of a piece of equipment, process, or even in some cases a malicious event such as arson or security concern.

For example, a fire hazard assessment for a laboratory facility may consider scenarios involving the ignition of general combustibles such as a trash receptacle, a furniture grouping, a computer station, material storage, etc. Operational related scenarios for the laboratory may consider an ignitable liquid spill due to a dropped container or liquid transfer operation, a bench fire resulting from an experiment or non-compatible materials, etc. Failure scenarios may consider a flammable gas line and/or fitting leak, a ruptured flammable liquid container, failure of a critical ventilation fan, etc.

The depth and detail of the hazard assessment is often related to the complexity of the facility use and operation, its range and type of occupants, the value of its contents, and the magnitude of potential loss. As an example, the assessment for a small office building would likely focus more on general combustible scenarios while the assessment for a manufacturing and production facility would include a wider range of operational and failure scenarios. The assessment may also need to consider the potential for outside influences, which may range from exposure from a fire event in an adjacent structure to a wildland fire to a terrorist event. However, regardless of the scenario type, the hazard assessment should include a review of fuel and oxidizer arrangements, ignition sources, and environmental conditions, as well as, the degree to which the outcome of the scenario could impact occupant life safety,

property, operations, responding emergency personnel safety, etc.

The assessment should also consider the timelines for the development and impact of potential fire scenarios. For instance does the scenario involve a smoldering fire that would provide a longer time frame for detection and active protection measures or does the scenario involve an explosive hazard which would result in a very limited time frame for detection and active measures? Further, does the scenario involve isolated combustibles or does it include adjacent fuel sources that can result in accelerated fire spread, significantly increasing the potential for severe consequences? In the laboratory example, a trash receptacle fire may have a relatively slow growth rate; however, if the fire is not initially controlled, fire spread to other items such as flammable liquids may significantly increase the fire growth rate, size, and severity. Scenarios can be represented as a function of fire effect such as fire size and time, i.e. the fire is expected to become larger as time from ignition increases. The details of the developed scenarios should include a complete timeline to better define the potential outcomes. In general, if the scenario is terminated earlier along its potential timeline, less damage would result.

The development of fire scenarios is a well-established technique for FPE's and is often used in the design process. However, it should also be employed when deciding on which type of fire protection system to use. Fire scenarios are typically developed to encompass a range of events that often include smaller more likely scenarios with limited potential consequences to larger less likely scenarios that could result in significant consequences. In the laboratory example previously discussed, a small trash receptacle fire scenario may have a higher likelihood of occurrence but also may have a lesser potential for severe consequences, while a flammable gas line leak scenario may have a lower likelihood of occurrence but may have much higher potential for severe consequences. The resulting time frame for the development of these two scenarios is also quite different.

Describing the Desired Outcomes and Consequences If a Fire Should Occur: Defining Overall Fire Safety Goals

The description of the range and likelihood of specific fire scenarios in combination with the established goals of the stakeholders helps outline the necessary protection scheme. It is important to recognize that the establishment of the potential fire scenarios and their outcomes articulates how and what could go wrong in a particular facility if the scenario is allowed to run its full course. The degree to which a particular scenario runs its course is dependent, in part, upon the overall risk tolerance of the stakeholders, i.e. their fire safety goals, and the recommended fire protection system(s). In other words, a fire protection system should be selected to ensure that the fire scenario is terminated at some specific point along its timeline. This termination point should align with and represent the goals and desired outcomes of the stakeholders. The review of the potential hazards and the development of the fire scenarios and timelines, along with the establishment of stakeholder goals, facilitate the quantification of specific performance objectives for the fire protection systems.

An initial stakeholder viewpoint may be to prevent all potential fire scenarios and, therefore, eliminate any potential detrimental consequences. Realistically however, the associated costs and/or operational tradeoffs might make such a strategy unattainable. Further, some fire outcomes are the result of a combination of a long string of unlikely events that sometimes cannot be reasonably accounted for ahead of time. Therefore it is important that the developed fire scenarios encompass a range of reasonably expected fuel loads, ignition sources and events that adequately capture the relevant and agreed upon concerns.

As discussed above, each of the stakeholders is likely to also have distinct objectives and concerns based upon their responsibilities, perspective and experience. Some of these objectives and concerns may be in general alignment such as those pertaining to occupant safety

and structural protection and which are generally addressed by applicable building and fire regulations. However there may also be differences among some of the stakeholders concerns and objectives such as those relating to preservation of historic fabric and culturally significant items, business continuity and protection of physical assets such as equipment, finished product or raw materials. Even when stakeholders are in general agreement about their respective concerns and objectives, the best means by which to address them can be a topic of debate. In any event, the overall goals and objectives need to be assimilated and quantified as performance criteria for the fire protection systems in light of the relevant hazards and fire scenarios for the facility under consideration. For instance, typical objectives such as the assurance of life safety for occupants not intimate with initial fire growth, isolation of a fire to the room or area of origin, or limiting business interruption to a specific length of time need to be expressed as measurable and quantifiable performance criteria that can be associated with fire protection system performance. This process might involve an iterative approach in which initial objectives and performance criteria are assessed and refined.

Articulating Goals and Objectives

Ideally, the objectives necessary to achieve the stated goals will be quantified in some manner and translated into performance criteria, i.e. expressed as a maximum permitted fire size or a specific concentration of products of combustion that can be achieved within some time period. In other words, how big a fire and for what duration can the owner or other stakeholder (s) tolerate and still achieve the life safety or property protection goals? From a fire protection engineering perspective, especially through the application of performance-based design approaches, the fire can be quantified in terms of heat release rate as a function of time, i.e. a timeline as was previously discussed.

Target maximum fire size and growth rate, factors not explicitly described in building regulations and most design standards, will help inform the decision as to whether extinguishment, suppression or control of the fire is needed; and by when how soon after ignition fire signatures must be detected and system activation is to be initiated; and what quantity and flow of agent will be needed. The type of fuel including its location and orientation, ignition source, enclosing construction, if any, availability of oxygen and ventilation, greatly influence a fire's growth and heat release rate and need to be addressed when considering the previously discussed fire scenarios.

With respect to the various types of systems that can be used, some systems are more appropriate for fire suppression after a relatively short period of agent discharge followed by a longer time period in which the concentration of agent is held in the vicinity or room of the fire. Other systems are better suited for fire control in which the agent is directly applied to the burning and adjacent surfaces for an extended period of time. For many of these systems a supplemental detection system may be necessary to activate and control discharge. Such detection systems and devices need to be integrated into the overall fire safety strategy, and selected and designed so that they initiate fire protection system discharge within the time period necessary to achieve the overall fire safety goals and objectives.

Associating Fire Event Outcomes with Building and Fire Regulations

Governmental building, fire and safety regulations are typically applicable to most new facility and renovation projects and must be adhered to. One of the principle needs and goals of the stakeholders is identification of and compliance with the relevant regulations. Failing to comply with the applicable rules can prevent occupancy, delaying or interrupting the use of the facility, and significantly impacting the overall return on investment for the facility.

The intent of most regulations is to establish the minimum requirements for safeguarding

public health, safety, and general welfare. The key term here being "minimum", and most regulations are based upon establishing the minimum level of safety for building occupants and responding emergency personnel with limited application to property protection, business interruption, and similar related fire protection goals. So the following questions need to be addressed. Do the minimum requirements of the applicable regulations align with the expected outcomes of the stakeholders, and the intended operations of the enterprise? Has it been determined that the "minimum" requirements provide the desired level of life safety, property protection, continuity of business operations or preservation of cultural resources should a fire occur? They might, but has this decision been given proper priority and consideration, and have the overall fire safety goals and objectives of the operation been adequately articulated?

As previously noted, building regulations have traditionally only addressed property protection to the extent necessary for occupant and fire fighter safety. How might this realization impact the overall implementation of the fire protection strategy during not only the design and construction process but throughout the life of the building and its operations? Conversely, how does any modification to the fire protection strategy account for specific goals such as business continuity or equipment protection, and how does this compare to the baseline applicable code requirements and subsequently the basic goal of occupant and fire fighter safety? A typical example is the use of a special total flooding or local application suppression system for a critical computer room. Oftentimes the building owner, operator, or designer may have a goal to use the special suppression system in place of otherwise required sprinkler protection for the room. Most building codes allow the installation of a special suppression system to protect the room and/or specific equipment; however, a sprinkler system is often still required to protect the building and in turn the occupants throughout the remainder of the building. The combination of systems must then be integrated to ensure proper operation and coordination.

It is worthy to note that while model codes and standards serve as the basis for building regulations in various locations, many jurisdictions and governmental agencies amend the various adopted versions of the model regulations, or enact bylaws that override one or more rules of the adopted model codes and standards. Thus, a uniform level of safety from fire is not necessarily prescribed nor implemented. The FPE must be aware of this and clearly identify the applicable rules of the jurisdiction in which the facility is located.

Addressing Property Protection, Business Continuity and Historic Preservation Goals

Depending upon the facility or operation under consideration, certain fire protection codes and standards do indeed address fire safety beyond life safety, and include provisions for property protection, business continuity and historic preservation. However, these codes and standards are not necessarily mandated and referenced by the applicable building, fire and safety regulations. The FPE needs to be aware of these other documents and how they could possibly impact the overall project, and serve to satisfy the overall fire protection goals of the stakeholders.

An example of one such document is NFPA 76, *Standard for the Fire Protection of Telecommunications Facilities,* which has three identified goals. As noted in its purpose, NFPA 76 establishes a minimum level of fire protection in telecommunications facilities to: (1) provide a minimum level of life safety for occupants; (2) protect the telecommunications equipment; and (3) preserve service continuity of the equipment.

Another example is NFPA 914, *Code for Fire Protection of Historic Structures.* This code addresses ongoing operations, renovation, and restoration of historic structures, and acknowledges the need to preserve historically significant and character-defining building features. Additionally, the code provides provisions for the continuity of

operations of historic structures. The code covers those construction, protection, operational, and occupancy features that are necessary to minimize danger to life, structures, and historic fabric from the effects of fire, including smoke, heat, and fumes.

These types of reference documents can provide valuable information for developing the specific protection scheme including the need for specific types of fire fighting systems, however, as noted above the FPE must be cognizant of the integration and coordination of the different protection goals, and provisions of the applicable regulations.

Insurance Company Objectives

The FPE also needs to understand and address any specific insurance company requirements. Insurance loss control and underwriting recommendations often serve to address property protection and business continuity concerns and can have specific requirements for operations or processes deemed too hazardous or with significant loss potential. For example, one insurance company's guidelines state that typically, special protection systems are recommended where the potential property damage and business interruption from fire for a particular process or occupancy is considered unacceptably high. It is further stated that the above protection rationale applies whether automatic sprinklers are provided as backup protection or not. Occasionally, a special protection system may be acceptable as sole protection without backup sprinkler protection to achieve an acceptable loss potential [5].

Considering the above, the owner's desired level of fire protection for the facility needs to be considered and gauged with that of any applicable insurance interests and recommendations. The degree of property protection recommended by the insurance company is normally based upon the policy purchased and the overall philosophy of the insurer, not necessarily the long-term objectives and needs of the building owner and other stakeholders. The degree to which the insurance company policy is based on the expected fire events and desired outcomes specific to the facility in question requires prudent consideration.

Identifying Candidate Fire Fighting Agents

Various types of fire fighting and/or inerting agents are available for achieving specific fire safety goals and objectives under certain scenarios. A brief overview of such agents follows. The agents can take the form of liquids, solids and gases, with the physical form of some agents changing as they flow from the storage container through a piping network and discharge nozzle, and are delivered to the fire area. Each agent, whether water, an aqueous solution, gas, or chemical powder, possesses certain characteristics and limitations. A proper understanding of the various agents, their means of fighting the fire, diluting vapor concentrations, associated system operations and corresponding system design principles is essential in making the correct decision about which type of agent and system to recommend.

When considering fire-fighting agents, the following qualities should be investigated as noted by Friedman [6].

1. Flammability
2. Heat of vaporization
3. Boiling point with respect to the pyrolysis temperatures of solid fuels under consideration
4. Ability to be transported through distribution networks at expected ambient temperatures
5. Toxicity
6. Formation and effect of decomposition products
7. Potential to cause property damage
8. Ability to conduct electricity

Other factors associated with the agent also come into play and deserve appropriate consideration. These include but are not limited to:

1. Environmental concerns and/or limitations.
2. Cost
3. Availability
4. Storage requirements

5. Means of generating the necessary system flow and pressure
6. Ease of reaching the combustion zone
7. Ability to achieve and maintain design discharge concentrations
8. Effect of discharge sound frequency on protected equipment
9. Overall clean up
10. Containment once discharged
11. Compatibility with other agents, fuels and surrounding equipment,
12. Corrosive effects with respect to system piping and components,

Water

Water, the most common fire-fighting agent, is generally low in cost and normally readily available. It possesses many of the qualities noted above that make it uniquely desirable. Its heat of vaporization is relatively high, allowing for the greater absorption of energy from the fire. Water possesses a rather ideal boiling point because it is well above most ambient room temperatures and well below the decomposition temperature of most solid combustibles. It is also considered nontoxic. The two most common means of applying water are: (1) manually through a hose nozzle, and (2) through an automatic sprinkler system. The practical aspects of fire protection hydraulics and automatic sprinkler system design calculations are addressed elsewhere in this handbook.

Water as a fire fighting agent can take the form of a solid stream when discharged from a firefighter's nozzle, a range of relatively course droplets when discharged from an automatic sprinkler or water spray nozzle, as finely divided droplets when discharge from a water mist nozzle, or as a fog when discharged from a fog generating device. Depending upon the form in which it is applied, water may extinguish a fire by a combination of mechanisms—cooling the solid or liquid combustible; diluting water-soluble flammable liquids; cooling the flame itself; generating steam that prevents oxygen access; and as fog, blocking radiative heat transfer. Although all of these mechanisms may contribute to extinguishment, probably the most important is cooling a gasifying or vaporizing combustible [7]. Most fuels, whether liquid or solid, need to gasify in order for combustion to occur.

There are situations, however, where water might not be the best fire-fighting agent for the application in question. Water freezes below 32 °F (0 °C), and does conduct electricity. It can irreversibly damage some items, although, in certain cases, it is possible to salvage wet items. When applied in bulk or in sprays consisting of large droplets, water can have limited positive effect on ignitable liquid fires, especially for those liquids such as hydrocarbons that are insoluble and float on water. Water is also not compatible with certain hot metals, where it can yield hydrogen, and certain chemicals. The application of water to some substances such as food-stuffs and pharmaceuticals can also initiate undesirable reactions. In some cases, excessive corrosion concerns for system piping exist with water. While this can be a function of the water supply and type of system and its installation, it warrants proper attention.

It is possible to improve the properties of water by using additives. For example, introducing antifreeze such as ethylene glycol or glycerin can lower the freezing point of water. However, at certain concentrations and discharge pressures the solution of antifreeze and water can become flammable [8]. Restrictions have been placed on the use of antifreeze with sprinkler systems. The use of dry-pipe or pre-action systems provides a potential alternative to using antifreeze additives where cold temperatures are a concern. However, there is a water delivery time delay with some of these systems that needs to be considered.

Other additives are intended to improve other qualities of water as a fire-fighting agent. For instance NFPA 18A, *Standard on Water Additives for Fire Control and Vapor Mitigation*, notes that water additives might provide enhanced cooling, emulsification, foaming and insulating characteristics of water [9].

Other additives, referred to "wetting agents" can reduce the surface tension of water and improve water's ability to penetrate porous materials and spread across surfaces [10]. A recent Fire Protection Research Foundation Project has been initiated to provide a comprehensive evaluation of water additives used for fire control and vapor mitigation, with the intent to clarify the fire protection benefit of using water with additives for fire suppression versus water without additives [11]. As noted in the report, "various water additives are available in today's marketplace that claim to provide advantageous performance characteristics for fire control and vapor mitigation. Of particular interest are additives that report to provide superior fire suppression capabilities through emulsification or encapsulation. However, a scientific assessment of these various additives is lacking, and the fire protection community would benefit from an evaluation of the various available water additives for fire control and vapor mitigation".

Emulsification can be described as a forced mixture of two or more liquids that are normally immiscible. From a fire protection standpoint, the two liquids could be a hydrocarbon and water, with or without additives. The water is applied to the surface of the hydrocarbon with some energy so that the two liquids are agitated together and the water is dispersed within in the hydrocarbon, in the vicinity of its surface, in the form of droplets which in some cases appear as a froth. This solution of dispersed droplets within the hydrocarbon is referred to as an emulsion. The presence of the emulsion serves to cool the hydrocarbon surface mitigating the release of flammable vapors, thus rendering the hydrocarbon less flammable or more benign [12]. In some cases, depending upon the agents used, usually not just plain water, the emulsion hardens forming a crust. This process is referred to as saponification.

The fire protection qualities of water might also be improved for specific applications without the use of additives. Misting systems have received attention especially since the initiation of the phase-out of halons in the late 1980s. Mist systems typically deliver water in finely divided droplets so that some drops remain suspended in the air entrained with the spray and fire plume, and others fall due to gravity. Water mist system standards such as NFPA 750, *Standard on Water Mist Fire Protection*, set limits on the size of water droplets produced.

For some applications, water mist serves to control or extinguish fire by various mechanisms. The mist droplets evaporating near the combustion zone, can remove heat, either at the surface of the combustible potentially reducing pyrolysis or vapor generation, or within the flame, reducing the flame temperature. The mist droplets evaporating in the hot environment might do so before reaching the combustion zone, generating steam, which could displace air and dilute the oxygen concentration. Before they evaporate, the mist droplets might block the radiative heat transfer from the flame to the combustible fuel. Various system designs utilizing a range of operating pressures, droplet sizes, and discharge nozzles have been developed and are discussed elsewhere in this Handbook. The limits and specific applications of mist systems need to be confirmed with system manufacturers and third party testing organizations.

Aqueous Foams

Fire-fighting foam consists of a mass of bubbles formed by various methods from aqueous solutions consisting of specially formulated foaming agents and water. Some foams are intended to be gently applied to the surface of ignitable liquids, and float on the liquid surface, creating an air-excluding, cooling, continuous layer of vapor-sealing, water-bearing material that can terminate or prevent combustion. Other foams expand rapidly and are intended for use as large volumes of wet gas cells for inundating spaces and filling cavities. Yet other foams are thick, pasty and viscous, and when applied through a nozzle form a tough heat-resistant blanket covering three-dimensional burning areas and vertical surfaces. Foam concentrates can also be added to sprinkler and water spray systems to aid in the control of certain types of ignitable liquid and storage commodity fires. It needs to be noted that as foam systems are

largely water-based, many of the concerns associated with water and fuel interactions previously discussed also apply.

Fire-fighting foams are usually formulated by mechanical means in which a certain percentage of foam concentrate is added to a flow of water to form a foam solution. Air is then induced into the foam solution by various means such as foam generators or discharge nozzles, and the foam solution is created and applied. Different types of foam concentrates exist and are intended for certain types of applications and fuels. Foam concentrate types are described as: (1) protein, which contain natural protein polymers; (2) flouroprotein, which in addition to the natural protein polymers contains surface-active agents; (3) aqueous film-forming, which consists entirely of synthetic materials; (4) alcohol-resistant types; (5) high-expansion foams; and (6) Class A foams. A further description of the foams produced by these concentrates, and the various methods for applying them are addressed in other chapters of this Handbook.

It needs to be recognized that foam breaks down because it is a rather unstable air-water emulsion. The water content is vaporized when exposed to heat and flame. In the case of liquid surface fires, the foam should be applied at a sufficient rate and volume to compensate for this loss, and to provide an additional amount to ensure that a residual foam layer remains over the extinguished portion of the fuel. Sufficient quantities of foam concentrate and water need to be available to form and sustain a cohesive foam blanket of some depth over the entire anticipated burning surface for some time period. Failing to do so can result in only partial extinguishment, allowing the fire to reach its original intensity after the foam supply has been depleted.

In addition to foam breakdown by heat, physical or mechanical forces can also break down the foam concentrate. As an example, certain chemical vapors or fluids can destroy foam quickly and where certain other extinguishing agents are used in conjunction with foam, severe breakdown of the foam can occur. Turbulent air or violently convective combustion gases can divert light foam from its intended area of application.

As with some other agents, consideration of foam needs to extend beyond the fire fighting characteristics. The growing awareness of environmental issues in many parts of the world has focused on the potential adverse impact of foam solution discharge. Primary areas of concern pertain to toxicity, biodegradability, persistence, treatability in wastewater treatment plants, and nutrient loading when foam solutions reach natural or domestic water systems. While the release of foam solutions into the environment can occur with fire suppression system discharge, all manufacturers are required to address foam retention, clean-up and disposal procedures in Material Safety Data Sheets (MSDS). Therefore, fire fighting foams should be used in a responsible manner to limit the associated environmental concerns associated with their use [13].

Inert Gases and Carbon Dioxide

Inert gases serve to extinguish fires or prevent ignition by displacing the combustion air in the vicinity of the reaction zone and diluting the concentration of oxygen below that necessary for combustion, typically below 12 %. Inert gases can also have an effect on increasing the heat capacity of the atmosphere supporting the flame. Application of an inert gas in sufficient quantity can extinguish the flame over a liquid or solid. Upon their release, inert gases leave no residue and therefore no clean up of agent after a fire incident is needed. Additionally, inert gases do not form potentially harmful decomposition products when subject to high temperatures. Another potential advantage of inert gases is their suitability for suppressing fires in the presence of physical barriers or obstructions. Inert gases in the context of this chapter pertain to the agent's affect on the combustion chemical reaction, i.e. rendering it chemically inactive due largely to the displacement of oxygen. Depending upon the specific design standard or regulation applied, different definitions of the term inert gas might be employed.

Inert gases for fire protection use consist largely of carbon dioxide, nitrogen and certain

formulations of inert gas mixtures classified as clean agents. Note that carbon dioxide is not considered a clean agent because of its toxic effects. In this instance, carbon dioxide is not inert with respect to human physiology. Quantity and unit cost are usually the driving factors when considering a specific inert gas agent. Certain agents are more efficient on a volume and weight basis due to their heat capacity. The use of inert gases becomes problematic in occupied areas necessitating additional safeguards, as the premise is to reduce oxygen concentrations below that necessary to support combustion, which is typically below the level required to sustain human life. However certain inert gas mixtures have been approved and shown safe for occupied spaces [14].

Depending upon the fuel and the type of inert gas used, specific concentrations of inert gas are to be achieved and maintained near the reaction zone for a period of time. This time duration is referred to as hold time. In sufficient quantity, an inert gas will prevent the combustion of most fuels with the exception of certain metals or unstable chemicals such as pyrotechnics, solid rocket propellants, etc. Inert gases generally have limited affect on fuels that contain or liberate oxygen during combustion such as nitrates for the former and conjugated ketones for the latter. Deep-seated fires of ordinary cellulosic fuels also require prudent consideration, as extinguished surface fires can be re-ignited.

Inerting concentrations can be achieved and maintained due to the presence of an enclosure around the anticipated combustion zone. In this case, successful extinguishment is tied to the integrity and ventilation aspects of the enclosure in which the agent is discharged. Inerting concentrations can also be maintained by continuously saturating the combustion zone with the inert gas for some specified period of time. If the necessary concentration of inert gas cannot be maintained and dissipates before the fire is completely extinguished and the reaction zone does not cool, remaining glowing embers or hot surfaces could reignite any lingering flammable vapors. Depending upon the value of the equipment or contents to be protected, providing a reserve supply of agent or a redundant system serves to minimize the associated risk.

Minimum design concentrations for specific inert gases are fuel dependent, but the lowest referenced concentration for most is about 34 %. Even at these minimum design concentrations, the oxygen level in the vicinity of the agent discharge will be reduced to levels that are generally hazardous to exposed humans with some exceptions. In the case of carbon dioxide, an additional serious physiological effect will occur at concentrations much lower than that necessary to extinguish a fire [15]. Minimum design concentrations must be confirmed with design standards and system manufacturer's data.

See Chap. 44 and Chap. 45 for more discussion on inerting agents.

Halocarbon Clean Agents

Clean agents were developed in response to the Montreal Protocol, which called for the phase-out of the production of chlorofluorocarbon agents (halons) in the late 1980s. With respect to fire protection, Halon 1301 and Halon 1211 were the most notable agents affected. Clean agents are generally described as electrically non-conducting fire extinguishing agents that vaporize readily and leave no residue. They are subject to specific evaluation with regard to their hazards to personnel and their potential effect on the environment, specifically Ozone Depletion Potential (ODP) and Global Warming Potential (GWP) [14]. Depending upon the agent, they are stored under high pressure as a liquid or a gas, and are utilized in their gaseous state when released from their storage containers. Clean agent halon replacements fall into two broad categories: (1) halocarbon compounds and (2) inert gas mixtures.

Halocarbon clean agents include compounds containing carbon, hydrogen, bromine, chlorine, fluorine, and iodine. They extinguish fires by a combination of chemical and physical mechanisms depending on the compound. Chemical suppression mechanisms of certain compounds are similar to Halon 1301 in that the bromine and iodine species scavenge flame

radicals and interrupt the chemical combustion chain reaction. However, such compounds of clean agents are not widely used.

Most halocarbon compounds suppress fires primarily by extracting heat from the flame reaction zone, reducing the flame temperature below that necessary to sustain combustion. Halocarbon agents also decompose which further absorbs energy from the combustion reaction. As noted in Chap. 44, decomposition products of halocarbons merit consideration. Oxygen depletion by halocarbons also plays a role in reducing flame temperature and extinguishing the fire, similar to the effect that inert gases have. The lack of significant chemical reaction inhibition in the flame zone by most halocarbon compounds results in reduced performance on a volumetric basis and requires higher extinguishing concentrations relative to Halon 1301.

Halocarbon agents can be considered for applications similar to those intended for carbon dioxide and other inert gases. One potential advantage of halocarbons over inert gases is that halocarbons are effective in lower volumetric concentrations so that sufficient oxygen necessary to support human life remains in area of discharge. As with inert gases, a certain concentration of the halocarbon needs to be maintained in the vicinity of the combustion reaction zone. The potential drawbacks to using halocarbons relate to their potential toxicity, and the toxicity and corrosive nature of potential decomposition products during a fire. In general, halocarbon agents are not appropriate for use on certain burning metals such as, but not limited to, aluminum, magnesium, iron, chromium, cobalt, copper, nickel and the alkali metals. These fuels reduce the extinguishing agent to liberate halogenated acids, metal salts, organometallic compounds and metal carbonyls, all of which can pose consequential hazards to both occupants and property. Therefore, in addition to a halocarbon's fire extinguishing characteristics, consideration also needs to be given to the agent's impact on safety to exposed personnel, its decomposition products and its environmental impact.

Dry Chemicals

A dry chemical is a finely divided powdered material that has been specially treated to be water repellent and capable of being fluidized and free-flowing so that it can be discharged through piping under expellant gas pressure. Dry chemicals are sodium bicarbonate, potassium or mono-ammonium phosphate-based, and certain agents are more effective than others on specific types of fires. For example, potassium-based dry chemicals are not generally recommended for the extinguishment of fires involving ordinary, Class A, combustibles [16]. Once discharged, dry chemical will settle on and coat surrounding surfaces and objects.

It is generally understood that dry chemicals act to suppress the flame of a fire by chemical mechanism that stops the chain reaction taking place in the flame combustion. It is presumed that the dry chemical interacts with the flame to form volatile species that react with hydrogen atoms or hydroxyl radicals similar in some ways to the effect of halon. Dry chemicals also discourage combustion by absorbing heat, by blocking radiative energy transfer, and in the case of mono-ammonium phosphate, by forming a surface coating [7].

Dry chemicals have been used to effectively protect hazards involving flammable and combustible liquids and gases, combustible solids, electrical hazards, such as oil-cooled transformers and circuit breakers, textile operations subject to flash surface fires, and ordinary combustibles such as wood, paper and cloth [17]. Surface coating by dry chemical can be especially effective on elevated objects and vertical surfaces. In cases where other agents would run-down vertical surfaces, dry chemical is more likely to adhere to surfaces, and provide a coating and insulation of the object.

Upon discharge, dry chemical residue will remain on surrounding objects and potential corrosion and staining concerns exist. Prompt cleanup will minimize these concerns. Certain dry chemicals can corrode metals such as steel, cast iron, and aluminum among others. In most

cases, dry chemical agents can be readily removed from surfaces by wiping, vacuuming or washing exposed surfaces. Consideration of environmental restrictions is prudent if dry chemical residue is washed away into bodies of water or wastewater systems. Some dry chemicals will require scraping and washing if the exposed surfaces were hot when the chemical was applied.

Health affects of dry chemicals also warrant attention. While dry chemicals are considered non-toxic from a physiological perspective, they are finely divided powders and can produce irritation affects when discharged, especially in enclosed areas. Discharge can reduce visibility, and cause breathing difficulty and irritation to the eyes. Suitable safeguards should be provided to ensure prompt evacuation of any exposed occupants during discharge [16].

While there are specific types of dry chemicals based on certain chemical compounds, they are produced by different manufacturers. As such, dry chemicals produced by different manufacturers are usually not identical in all characteristics, and each manufacturer develops equipment for use with a specific dry chemical. System design principles applicable to the products of one manufacturer are not applicable to the products of another manufacturer.

Wet Chemicals

A wet chemical fire-fighting agent consists of organic or inorganic potassium-based salts or both, mixed with water to form an alkaline solution capable of being discharged through piping or tubing when pressurized by an expellant gas. The primary use of wet chemical agents is for the protection of fires in cooking oils and fats [18].

Upon discharge, the wet chemical results in a vapor-suppressing foam-like substance that rapidly spreads across the fuel known as saponification. The wet chemical application extinguishes and secures the flame by forming a barrier between the liquid fuel and the surrounding air. The barrier prevents oxygen from reaching the combustion reaction zone, and mitigates the release of flammable vapors from the fuel surface. The cooling affect of the wet chemical also lowers the temperature of the oil or fat further decreasing the release of ignitable vapors.

Wet chemicals are usually discharged in the form a fine spray. As such some of the agent can settle on surrounding surfaces and can have a corrosive effect on electrical components and cooking equipment. As with dry chemicals, prompt clean-up will minimize staining or corrosion.

Similar to dry chemicals, wet chemicals produced by various manufacturers are usually not identical in all characteristics, and each manufacturer develops equipment for use with a specific wet chemical. Therefore, system design principles applicable to the products of one manufacturer are not applicable to the products of another manufacturer.

Aerosols

Aerosols are a relatively new type of fire fighting agent first appearing in the marketplace in the mid 1990s. Two types of aerosol agents exist: condensed aerosols and dispersed aerosols. Condensed aerosols are described as an extinguishing medium consisting of finely divided solid particles, generally less than 10 microns in diameter, and a gaseous matter, generated by a combustion process of a solid aerosol-forming compound. Dispersed aerosols are described as an extinguishing medium consisting of finely divided solid particles, generally less than 10 microns in diameter, already resident inside a pressurized agent storage container, suspended in a halocarbon or inert gas [19]. At the time of the writing of this chapter, dispersed aerosol systems are not commercially available.

Fixed condensed aerosol extinguishing system units include condensed aerosol generators with mounting brackets, actuating mechanisms,

and other accessory equipment (as applicable). Condensed aerosol generators are normally non-pressurized devices incorporating an aerosol-forming compound consisting of a mixture of oxidant(s) and combustible component(s) that, when pyrotechnically actuated, produces an aerosol extinguishing agent of gaseous matter and finely divided solid particles that flow through a cooling mechanism within the device prior to exiting through discharge port(s) and into the protected space.

The primary mechanism of fire extinguishment by condensed aerosols is reported to be the interruption of the chemical combustion chain reaction taking place in the flame, similar to the affects of halon and dry chemicals. Some cooling near the combustion zone also occurs due to heat absorption by the aerosol particles.

For total flooding applications, the hazard is surrounded by a fixed enclosure to enable the required aerosol extinguishing agent concentration to be achieved and maintained for the required hold time to effectively extinguish the fire within the enclosure. Aerosol-generating extinguishing system units, when assembled into a system with one or more condensed aerosol generators, are designed for automatic and manual actuation. Aerosol-generating automatic extinguisher units are self-contained units designed for automatic thermal actuation and do not have a manual means of actuation. The extinguisher units are also limited to a single protected enclosure.

The use of condensed aerosol agents might present hazards to personnel. The discharge of aerosol extinguishing systems to extinguish a fire could create a hazard to personnel from the natural form of the aerosol or from certain products of aerosol generation, including combustion products and trace gases from condensed aerosols. Acid by-products, such as hydrofluoric acid, can also be formed and present a hazard to exposed personnel. Unnecessary exposure of personnel to either the natural agent or the decomposition products should be avoided. Potential hazards associated with noise, turbulence, reduced visibility, cold temperature, toxicity, thermal hazards and irritation to persons in the protected spaced and other areas where the aerosol agent can migrate should to be evaluated [19].

Code Mandated Fire Protection Systems

Building regulations mandate active fire protection systems, largely automatic sprinkler systems, based upon the occupancy types associated with the building, the size and location of the fire area, and the expected occupant load. For instance the *International Building Code* (IBC) requires automatic sprinkler systems in Group A-2 occupancies, e.g. restaurants, where one of the following conditions exist: i) the fire area exceeds 5000 sq ft; ii) the fire area has an occupant load of 100 or more; or iii) the fire area is located on a floor other than the level of exit discharge. Similar requirements are found in NFPA 5000, *Building Construction and Safety Code,* and NFPA 101, *Life Safety Code*. Additionally, model codes require sprinkler systems for certain types of buildings regardless of the occupancy type. For example, sprinkler systems are required for all high-rise buildings.

The basis for mandating such fire protection systems is largely based on the premise that the building owner is obligated to provide a safe environment for the building occupants, or the public at large. In general, building regulations do not force a building owner to protect his or her own property.

Fire regulations typically have more specific occupancy related requirements that can include specific requirements for special fire protection systems. As an example, the *International Fire Code* (IFC) contains requirements for the application of foam systems for flammable and combustible liquid storage tank protection for certain configurations. However, similar to building regulations, the detail of such requirements are typically limited and based upon the goal of occupant and emergency personnel safety.

Building regulations also allow for "Alternative Automatic Fire-Extinguishing Systems" or "Other Automatic Extinguishing Equipment",

but provide limited direction on when such systems are needed, or should be considered. Although, the terms "Alternative" and "Other" with respect to fire protection systems are not specifically defined, it is often interpreted that such systems are used to protect against "special hazards". Harrington [20] describes special hazards as a fuel array that for one or more reasons cannot be effectively protected by standard spray sprinkler systems. Numerous alternatives to standard spray sprinkler systems have been developed to protect special hazards, each having certain characteristics uniquely suited to effectively protect specific aspects of certain special hazards. Special hazard fire protection systems employ various types of agents including water as previously described. The term "special protection system" is also sometimes used to describe these systems.

Depending upon the model code, these "Alternative" or "other" systems are identified as wet chemical, dry chemical, foam, carbon dioxide, halon, clean-agent, water spray, foam-water, and water mist. Reference is normally made to the associated NFPA standards for the specific type of system under consideration for relevant design, installation and related provisions, i.e. NFPA 2001, *Standard for Clean Agent Fire Extinguishing Systems,* or NFPA 17, *Standard on Dry Chemical Extinguishing Systems*.

It needs to be recognized that when a building or fire regulation references an "alternative" or "other" system it is usually done so in the context of providing life safety for building occupants, usually as an alternative to the requirement for installing an automatic sprinkler system. It needs to be further recognized that although building and fire regulations typically mandate the installation of sprinkler systems for life safety, sprinkler systems were initially invented and developed for property protection and business continuity concerns and they continue to serve this purpose for various types of commercial, residential and industrial applications. For instance, the provisions of NFPA 13 pertaining to the protection of storage facilities were developed specific to property protection goals. However, certain types of systems have been developed and are intended primarily to enhance life safety, e.g., residential sprinkler systems.

Facility Specific Standards

In addition to regulatory provisions found in applicable building and fire codes, other fire protection related documents specific to certain types of facilities and operations exist and might provide some insight as to the type of fire protection system to be used. Examples of such documents include NFPA 34, *Standard for Dipping, Coating, and Printing Processes Using Flammable or Combustible Liquids*; NFPA 45, *Standard for Laboratories Using Chemicals*; NFPA 76, *Standard for the Fire Protection for Telecommunications Facilities*; and NFPA 409, *Standard on Aircraft Hangers* among others. The FPE needs to confirm whether or not these facility specific standards are mandated by the jurisdiction in which the facility is located or if any governmental regulations come into play. A summary of the relevant provisions of NFPA 34, NFPA 76 and NFPA 409 pertaining to fire protection systems follows.

NFPA 34 specifically states that processes are to be protected with any of the following approved automatic fire protection systems: (1) a water spray extinguishing system especially on liquids having flash points above 60 °C (140 °F); (2) a foam extinguishing system; (3) a carbon dioxide system; (4) a dry chemical extinguishing system; and (5) a gaseous clean agent extinguishing system. It is further noted that fixed, automatic carbon dioxide systems historically have been provided to protect: (a) Flexograph presses and rotogravure presses using Class I and Class II inks, with CO2 nozzles arranged to protect printing heads, ink reservoirs, and other areas likely to contain flammable liquid-based inks; and (b) presses using flammable liquid-based inks having shielded spaces where automatic sprinkler installation is impractical. Additional considerations for CO2 systems include providing a connected reserve supply for high-pressure carbon dioxide systems, and

sufficient agent for two complete discharge cycles for low-pressure carbon dioxide systems. It is further noted that if a foam extinguishing system is used, hoods and ducts are to be protected by other approved fire protection systems.

NFPA 34 also allows for the use of standard automatic sprinkler system protection for certain components of the associated coating, dipping and printing processes. These components specifically include tanks containing liquids having flash points above 93 °C (200 °F) and their associated process hazards, and tanks equipped with covers arranged to close automatically in the event of fire.

NFPA 45 requires, and assumes as a baseline, that all laboratory units be provided with full automatic sprinkler protection, and provides guidance on the hazard classification dependent upon the laboratory unit classification. The standard also recognizes that other types of special hazard extinguishing systems and non-water automatic extinguishing systems may be used and provides reference to the appropriate design standards, but provides no specific design criteria. In the standard's purpose section, it states that "This standard is designed to control hazards and protect personnel from the toxic, corrosive, or other harmful effects of chemicals to which personnel might be exposed as a result of fire or explosion [21]. " Given the types of hazards that may be present in a laboratory, the protection scheme must include a comprehensive fire protection strategy to ensure that the utilized system does not result in unintended consequences, i.e. the use of a standard sprinkler system for a laboratory with notable and/or exposed quantities of water reactive chemicals, or the use of a fire protection system that may produce a hazardous atmosphere as part of the extinguishing process.

NFPA 45 provides guidance on the fire protection systems as noted above, and also provides guidance on construction, ventilation, chemical storage, handling, and disposal, chemical container sizes, and laboratory operations to result in a coordinated protection approach. It is the FPE's responsibility to understand the various requirements and controls to review the impact on the fire protection system decision making process.

As part of its fire protection provisions, NFPA 76 makes reference to several types of automatic fire suppression systems, but does not specifically mandate their use. Some commentary is provided on when a particular type of system could be used. For instance, NFPA 76 notes that automatic or manual fire suppression equipment should be considered as an element in the overall fire protection plan for a telecommunications facility. However, the standard seems to caution on the use of such suppression systems, as it states that telecommunications facilities have experienced an excellent fire loss record due to the high standards of construction, compartmentation of hazards, and high quality of telecommunications equipment, mostly without the use of automatic extinguishing systems. The standard notes that automatic suppression should be considered when other fire protection elements cannot be employed. Furthermore, the potential impact of the suppression agent on energized telecommunications equipment requires thorough evaluation as accidental discharge of agents can cause damage to equipment or otherwise harm personnel. The standard also states that fire suppression agents are not to cause severe damage to the telecommunications equipment, and those agents containing dry chemicals or corrosive wet chemicals in fixed systems should not be used in any area containing telecommunications equipment.

NFPA 76 states that wet pipe, dry pipe, and pre-action systems are acceptable for use in the protection of technical support, administrative and building service areas, and support areas of telecommunications facilities, but they are not recommended for the power area, main distributing frame (MDF) areas, signal processing area, and standby power areas. The need to introduce water piping into telecommunications power areas, MDF areas, or signal-processing areas needs thorough evaluation, as water is a risk to telecommunications signal-processing equipment and, by extension, to public safety. The use of special sprinkler configurations, such

as double-interlock pre-action systems, can minimize the risk of inadvertent water discharge.

With regard to aircraft hangers, NFPA 409 states that the protection of aircraft storage and servicing areas of Group II aircraft hangars is be with any one of the following systems: (1) foam-water deluge systems with or without air-aspirating discharge devices; (2) a combination of automatic sprinkler protection and an automatic, low-level, low-expansion foam system; (3) a combination of automatic sprinkler protection and an automatic, high-expansion foam system; or (4) a closed-head foam-water sprinkler system.

As can be observed, the four referenced facility standards noted above that pertain to four very different types of facilities and hazards, make no clear recommendation on the type of fire protection system to be used, or whether fire control, suppression or extinguishment are intended. However, even in the absence of a stated fire protection goal, the selection of a specific fire protection system will usually imply the overall objective of fire suppression or fire control. Naturally, any decision needs to be coordinated with the overall outcomes to be achieved for the expected fire scenarios.

Rather than providing specific recommendations, each facility standard provides options on the types of systems that could be used, and in some cases includes additional commentary or precautionary statements about the use of the various types of fire suppression systems. Specifically, NFPA 34 cautions about the flash points of liquid fuels, the position and location of certain types of discharge nozzles, the need for reserve supply of fire fighting agent and the limitation of certain types of systems. NFPA 76 cautions about accidental system discharge, the affect of agent discharge on equipment, and the corrosive affects of certain types of agents. NFPA 409 identifies four different types of systems for a specific type of aircraft hangar. NFPA 484 specifically cautions against the use of automatic sprinkler protection where certain types of metals are produced or handled. It should be obvious that in many cases, the stakeholders and the FPE cannot rely solely on the on the facility standards or the applicable building and fire regulations for a prescriptive mandate on the most appropriate type of system to be used.

Insurance Company Guidelines

Some insurance companies issue guidelines that address the use of special hazard or special protection systems. One company notes that such systems are used to extinguish or control fires in easily ignitable, fast-burning substances such as flammable liquids, some gases and chemicals. It is further stated that the systems can also be used to protect ordinary combustibles in certain high-value occupancies especially susceptible to damage and in certain high-piled storage occupancies. The quick action of these systems can keep production downtime at a minimum [5].

Insurance company recommendations for application of special protection systems include dip tanks, drainboards, flow coaters, engine test rooms, foil mills, electronic computer installations, storage tanks of flammable liquid or liquefied gas, fur vaults, oil-filled transformers, rotating electrical equipment, aircraft hangars, rubber tire storage, and chemical processing equipment. In certain cases, recommendations for specific types of systems for specific applications are identified. In other cases, options are provided.

Depending upon the insurance company, special protection systems might only be considered a supplement to automatic sprinkler systems, and not a substitute for them. Sprinkler systems are usually designed to operate for longer periods of time than most special protection systems, and can be restored to service more quickly. Special protection systems are more complex than conventional sprinkler systems, and consequently subject to more electrical and mechanical failure modes. Reflash or reignition potential is also a concern, especially for total flooding systems and certain types of extinguishing agents. However, sprinkler systems are usually designed for fire control over a longer period of time, where as special protection systems are usually designed for suppression or extinguishment in a much shorter time frame.

Fire Protection System Reference Standards

As previously noted, standards addressing certain types of fire protection systems are referenced by building and fire regulations and specific facility standards. These system reference standards, especially those promulgated by NFPA, are generally intended for use by those responsible for purchasing, designing, installing, testing, inspecting, approving, listing, operating, and maintaining such systems, and contain various information in this regard.

System reference standards usually make it clear that it is not within their purview to identify where such systems are required to be used, e.g. NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam,* specifically states that it is not the intent of this standard to specify where foam protection is required. However, such system reference standards might include some information about the fire hazards and conditions under which the systems could be used. For example, NFPA 12, *Standard on Carbon Dioxide Systems*, includes Annex B, *Examples of Hazard Protection,* in which five applications of Carbon Dioxide Systems are specifically identified. These applications include (1) Commercial/Industrial Food Processing Deep-Fat (Hot Oil) Cookers; (2) Restaurant Range Hoods, Connected Ducts, and Associated Equipment, (3) Newspaper Printing and Rotogravure Presses; (4) Open-Top Pits and (5) Below Raised Floors.

Another example includes NFPA 2001, which provides advisory annex language indicating that clean agent fire extinguishing systems are useful within certain limits for extinguishing fires in specific hazards or equipment, and in occupancies where an electrically non-conductive medium is essential or desirable, or where cleanup of other media presents a problem. Such total flooding clean agent systems are used primarily to protect hazards that are enclosed or equipment that in itself includes an enclosure to contain the agent. A list of typical hazards that could be suitable for protection by clean agent systems is provided and includes (1) electrical and electronic hazards, (2) subfloors and other concealed spaces, (3) flammable and combustible liquids and gases, (4) high-value assets, and (5) telecommunications facilities. NFPA 2001 also states that clean agent systems could be used for explosion prevention and suppression where flammable materials collect in confined areas. Again, the standard does not explicitly prescribe where such systems are to be used but rather provides some commentary about their potential application.

Even when a system reference standard does not explicitly identify the application of such a system, the standards might include design and installation requirements that address the types of hazards or fuels for which the fire protection agent and system could be used and oftentimes includes reference data such as fuel specific extinguishing and/or inerting concentrations. Referring again to NFPA 12, provisions about the design of carbon dioxide systems for specific hazards are provided and can be applied once a decision has been made to install a carbon dioxide system. Specifically, CO2 design concentrations for certain fuels such as acetone, gasoline and propane among others are identified.

Other reference standards do not directly identify the hazards they are intended to protect, but rather tie the appropriateness of the system to specific listing and testing requirements. For example, NFPA 750, *Standard on Water Mist Fire Protection Systems*, states that water mist protection systems are to be designed and installed for the specific hazards and protection objectives specified in the listing. An Annex note in NFPA 750 includes a list of fire test protocols and the associated listing organizations. It should be obvious that the FPE needs to be sufficiently familiar with the application and limits of the listing protocols, as well as the design and installation manual for each type of water mist system that might be under consideration. More discussion on listing protocols is discussed below.

It is important to recognize that with many of these "alternative" or "other" systems, not just water mist systems, a generic design approach such as for automatic sprinkler systems as outlined in NFPA 13, *Standard for the*

Installation of Sprinkler Systems, does not exist. Many of these "alternative" systems are of a proprietary nature and the design and installation provisions are specific to the manufacturer of each type of system. For a given hazard, the design, installation and operational details of one manufacturer's water mist system is likely to be significantly different from that of another manufacturer. It is worth noting, that even with sprinkler systems more specialized devices are entering the marketplace.

Manufacturer's Literature

It should not be concluded, that the only applications appropriate for a certain type of special hazard system are those identified in a particular system reference standard or a specific facility document. System and component manufacturer literature typically includes information on the possible applications of such systems. However, any claims on system appropriateness for specific hazards needs to be verified by the FPE. The question is how?

If a system manufacturer's literature state that its system is appropriate for use in addressing specific fire scenarios, it is reasonable to expect that the system manufacturer possesses specific fire test data and, therefore, more detailed and comprehensive information about such system performance and the verification of such performance. This information, which can take the form of test reports and other evaluation protocols, should be requested by the FPE and examined during the system selection process.

Key considerations in the examination of such information include the degree to which evaluation protocols, acceptance criteria, overall hazard dimensions, etc. correlate with those of the desired outcomes and identified hazards of the specific facility and operation in question. Simply relying on the manufacturer's marketing information should not be considered adequate justification by the FPE that the system is appropriate for the specific scenarios under consideration. More discussion of listing protocols and system testing is provided in the next section.

Listing Protocols

The majority of fire protection systems and their components, including special hazard systems, are associated with some type of listing requirements. A generally accepted definition of the term "listed" means equipment, materials, or services included in a list published by an organization that is acceptable to the authority having jurisdiction and concerned with evaluation of products or services, that maintains periodic inspection of production of listed equipment or materials or periodic evaluation of services, and whose listing states that either the equipment, material, or service meets appropriate designated standards or has been tested and found suitable for a specified purpose [22].

When a fire protection system or its components are "listed" as noted above, it is understood that such equipment has been evaluated for a specified purpose, and that such evaluation has been done in accordance with appropriate standards or has been otherwise tested and found suitable. Therefore an examination of listing protocols will provide some insight as to the appropriateness and applicability of a certain system for a specific hazard. Here again, the FPE needs to confirm that the information presented in the listing protocols correlates with that of the facility operation in question, the fire hazards to be protected against and the desired outcomes.

Listing organizations usually contain on-line databases and other recourses that FPE's and others can use to verify if a particular manufacturer's system or equipment has been evaluated and "listed" by the organization. However, the fact that a system or piece of equipment is listed does not serve as validation that the system or equipment is appropriate for the given situation or application. As noted above, the listing protocols and evaluation reports should be further examined. Even within a given listing organization, the evaluation and testing protocols for the various types of fire protection systems and equipment differ. Depending upon the system and equipment, attributes about their associated performance vary.

Listing organizations might provide some detail about the application or intended use of the system. Referring to Factory Mutual Global (FM) Approvals on-line guide [23] with respect to CO2 systems, it notes that carbon dioxide discharge falls into two broad categories, total flooding and local application. The approvals guide further states that total flooding systems are intended to protect enclosed special hazards such as rooms or spaces involving flammable liquids or containing electrical equipment, records, furs, or other storage where a fire would be extinguished. Local application systems are intended to protect flammable liquids in unenclosed special hazards such as dip tanks and drain boards by discharging carbon dioxide directly on the burning material.

Further information might be found in the listing organization's published listing protocol. For instance, FM Approvals Standard 5420 on Carbon Dioxide Extinguishing Systems [24] includes specific fire tests for carbon dioxide extinguishing systems for the protection of wet benches and similar processing equipment. Additional criteria pertain to other performance characteristics such as those associated with salt fog corrosion, thermal shock and areas of coverage among others.

In some cases, system reference standards refer directly to any associated listing protocols for information about system application. As previously noted, NFPA 750, requires that water mist protection systems be designed and installed for the specific hazards and protection objectives specified in the listing. NFPA 750 goes on to state that the characteristics of the specific application, e.g. compartment variables and hazard classification, are to be consistent with the listing of the system. Furthermore, an evaluation of the compartment geometry, fire hazard, and system variables are to be performed to ensure that the system design and installation are consistent with the system listing. As such, the listing of water mist fire protection systems are to be based on a comprehensive evaluation designed to include fire test protocols, system components, and the contents of the manufacturer's design and installation manual.

While the following concepts are paraphrased from NFPA 750, they are pertinent to any fire protection system for which no generalized application guide and design method are readily available. Listings about system performance should be obtained through full-scale fire tests and thorough system component evaluations conducted by recognized laboratories to demonstrate that performance objectives can be met. Where full-scale assessments are not possible or practical, an extrapolation and assessment of available data and information might be appropriate. However, the setting of practical limits of any extrapolated data needs to be well informed with good intuitive reasoning applied.

Where fire tests are employed as part of a listing protocol, they should reflect, to the extent possible, the intended conditions under which the special hazard system is expected to operate. It needs to be verified that the fire tests are sufficiently and appropriately challenging so that the performance of the system can be adequately assessed. It also needs to be confirmed that any performance objectives outlined in a listing protocol are consistent with those of the intended application of the system.

New potential applications of fire protection systems can occur. In these cases, existing listing protocols might not necessarily address the intended application of the system. Ad hoc test procedures for such applications could be developed and completed. Where ad-hoc tests protocols are developed, they should adequately address the associated concerns and be: (1) based on an evaluation of the fire hazard, the compartment and space conditions where the fire hazard is located, and the performance objectives for the system; and (2) developed, executed, and interpreted by recognized fire testing professionals acceptable to the stakeholders. Only those ad-hoc test protocols developed in such a manner should be recognized.

Listing evaluations typically consist of an approval report describing the results of the fire testing and component evaluations, and are associated with the manufacturer's design, installation, maintenance and operations manual. For special hazard systems, nozzle characteristics;

spacing between nozzles; distances from ceilings, walls, or obstructions; minimum operating pressures; and agent supply requirements, among other criteria are all usually documented in the listing report. Again, where the listing protocols for such system component performance cannot be correlated with the intended outcomes and scenarios under consideration, it is incumbent on the responsible FPE to make appropriate assessments.

Long Term System Performance

When deciding on those fire protection systems that best serve the intended fire and life safety purposes, the long-term effectiveness, reliability and performance of the systems should be incorporated into the decision making process. Once the systems are commissioned, the occupancy certificate is issued and the building is in operation, the design team moves on. It is now the owner's responsibility to keep the building and the respective fire and life safety systems in proper working order. The applicable fire code, which normally applies to existing buildings, will address the need to maintain an appropriate level of safety. As previously noted, most regulations primarily address life safety rather than property protection. Nonetheless, any provision promulgating effective system performance should be translated and implemented into an effective inspection, testing and maintenance program for the installed fire and life safety systems. Details of this program should be incorporated into the early stages of the system selection and design process, as it will have a distinct impact on the building's overall operational costs.

Most design and installation standards contain some information about the necessary inspection, testing and maintenance activities. For instance NFPA 2001 includes a chapter entitled Inspection, Testing, Maintenance and Training. However, these provisions can be generic in nature. When it comes to specific types of proprietary or pre-engineered systems, the design, installation and operation manual furnished by the system manufacturer should be obtained and evaluated before any system is selected. While these manuals tend to be tailored for each individual system installed, sample manuals for the types of applications under consideration can be requested and made available.

Designing the system to facilitate the work of inspection, testing and maintenance personnel, as well as contemplating the availability of replacement parts and system supplies should also receive proper priority. Designing the system to best facilitate testing and maintenance activities is not necessarily a provision mandated by the applicable design and installation standard, but doing so will help ensure more cost-effective long-term performance of the system. Additionally, if replacement parts and supplies are not readily available but are needed, the resulting disabled or impaired system means that life safety and the owner's investment are unduly compromised. While not within the scope of routine inspection and maintenance, consideration of future building expansion and anticipated changes in building operations also deserve attention. Can the fire protection system once installed be expanded or otherwise modified to address the related change in fire hazard, or will an entirely new replacement system be necessary?

Concluding Remarks

In the absence of any standardized generic application guides for the selection of fire protection systems, validating one's choice is not always a straightforward matter. Providing the appropriate systems will often require more than just code consulting and compliance with the applicable regulations. As has been discussed, building and fire regulations are often not likely to give much guidance on the selection and use of systems other than sprinkler systems for life safety

concerns. Where other types of systems are permitted in place of, or in combination with sprinkler systems, or needed for other purposes, limited guidance is provided with regard to the conditions under which such so called special hazard systems could be used, and the reasons why such systems should be used.

A comprehensive fire and life safety strategy needs to be developed and implemented with the overall long-term goals of the stakeholders clearly articulated, agreed upon and properly documented. A competent fire safety analysis and assessment will facilitate the overall strategy, identify if the applicable regulations adequately serve the fire and life safety needs over the expected lifespan of the facility, and more effectively address any gaps in protection. Specific attention needs to be given to any property protection, business continuity and historic preservation goals that might not be sufficiently addressed by the prescribed solutions embodied in applicable building and fire regulations.

The FPE needs to be knowledgeable and well versed with the application and limitations of the different types of fire protection systems that could be used to satisfy the overall fire and life safety goals and objectives. This requires not only an unbiased in-depth grasp of the applicable rules, regulations, available technologies, design principles and testing protocols, but also a sufficient understanding of the operations for the planned building and the associated fire and life safety risks. Information about the appropriateness of the proposed system, especially if it is a special hazard system, typically needs to be obtained from a combination of building and fire regulations; stakeholder viewpoints; system design, installation and testing standards; insurance company recommendations; listing protocols and evaluations; manufacturer's information and in certain cases the completion of calculations.

In the end, the FPE needs to confirm that all applicable regulations are complied with, and that the proposed system will satisfy the goals and objectives of the stakeholders under the conditions specified, i.e. validation that the expected outcomes can be achieved for the fire scenarios to be considered. Naturally, the right choice is predicated on the assumption that the recommended system is properly designed, installed, and maintained.

Design of Detection Systems

40

Robert P. Schifiliti, Richard L.P. Custer,
and Brian J. Meacham

Introduction

Fire detection and alarm systems are recognized as key features of a building's fire prevention and protection strategy. This chapter presents a systematic technique to be used by fire protection engineers in the design and analysis of detection and alarm systems. The majority of discussion is directed toward systems used in buildings. However, many of the techniques and procedures also apply to systems used to protect planes, ships, outside storage yards, and other nonbuilding environments.

Scientific research on fire growth and the movement of smoke and heat within buildings provides fire protection engineers with information and tools that are useful in the design of fire detection systems. Also, studies of sound production and transmission allow communication systems to be engineered, thus eliminating the uncertainty in locating fire alarm sounders. All of this information allows engineers and designers to design systems that meet specific, identifiable goals.

Previous chapters in this handbook introduced and discussed a series of concepts and tools for use by fire protection engineers. This chapter shows how some of these tools can be used collectively to design and evaluate detection and alarm systems.

A Note About Precision

When solving multiple equations with numerous variables from many sources, it is often easy to overlook the importance of precision and confidence in the final answer. This acknowledgment is particularly true since engineers have progressed from slide rulers to calculators to computers in a relatively short span of time. Most calculations in this chapter have been done using a computer—most often with a simple spreadsheet. The generally accepted practice for these types of tools is to round off only the final answer to the correct number of significant digits.

The standard and most widely taught rule for rounding is to round off using the same number of significant digits as the least precisely known number used in the calculation. An alternate rule suggests using one more significant figure than suggested by the standard rule. It has been shown that the alternate rule is more accurate and does not lead to loss of data as does the standard rule [1, 2]. The alternate rule for rounding has been used in this chapter. For more information or to refresh your knowledge of precision, rounding, and significant figures, consult the references or

a standard text on engineering and scientific measurements.

Overview of Design and Analysis

To design a fire detection and alarm system, it is first necessary to establish the system's goals. These goals are established by model codes, the property owner, risk manager, insurance carriers, and/or the authority having jurisdiction. Ultimately, the goals of the system can be put in the following four basic categories:

1. Life safety
2. Property protection
3. Business protection
4. Environmental concerns

Some designers include heritage conservation in the list of goals. However, the protection of historic property is really another form of property and mission protection, although the methodology and extent for protection may vary.

When designing for life safety, it is necessary to provide early warning of a fire condition. The fire detection and alarm system must provide a warning early enough to allow complete evacuation of the danger zone before conditions become untenable. The fire detectors or fire alarm system may be used to activate other fire protection systems, such as special extinguishing systems and smoke control systems, that are used to help maintain a safe environment during a fire.

In some situations, the life safety mission of a detection system is enhanced by providing information to occupants. This situation is often the case in *stay-in-place* or *defend-in-place* strategies or partial evacuation/relocation strategies. The detection system is used to provide information about the location and extent of the fire. Instructions are then given to the target audience.

Property protection goals are principally economic. The objective is to limit damage to the building structure and contents. Maximum acceptable losses are established by the property owner or risk manager. The goal of the system is to detect a fire soon enough to allow manual or automatic extinguishment before the fire exceeds acceptable damage levels.

Goals for the protection of a mission or business are determined in a manner similar to that used in property protection. Here fire damages are limited to prevent undesirable effects on the business or mission. Some items that need to be considered are the effects of loss of raw or finished goods, loss of key operations and processes, and loss of business to competitors during downtime. Other concerns include the availability and lead time for obtaining replacement parts. If the equipment to be protected is no longer available or requires several months for replacement, the ability to stay in business during and after an extended period of downtime may be jeopardized.

Protection of the environment is also a fire protection concern. Two examples are (1) toxicity of products of combustion and (2) contamination by fire protection runoff water. Should large quantities of contaminants be expected from a large fire, the goal of the system may well be to detect a fire and initiate appropriate response prior to reaching a predetermined mass loss from burning materials or quantity of fire suppression agent discharged.

Once the overall goals have been set, specific performance and design objectives for a performance-based design can be established [3–5]. Performance-based fire protection design requires that specific performance objectives, rather than generic prescriptive requirements, be met. A typical prescriptive requirement would be to provide a smoke detector for every 84 m^2 (900 ft^2) or 9-m (30-ft) spacing. In prescriptive design, speed of detection and the fire size at detection for such an installation are not known or considered explicitly. In addition, if some action must be taken in response to the alarm in order to control the fire, the expected damage is also unknown.

Implementation of a fire safety performance objective requires that the objective be stated first by the client in terms of acceptable loss. The client loss objectives must then be (1) expressed in engineering terms that can be quantified using fire dynamics, and (2) related to design fires, design fire environments, and the performance characteristics of fire suppression equipment. For example, the client loss objective may be to prevent damage to essential electronic equipment in the compartment of origin. To meet this objective, one must first define what *damage* is. This

damage could be expressed in terms of the thickness of the smoke layer. Other criteria, such as temperature or concentration of corrosive combustion products, or a combination of criteria, could also be used.

Based on a study of the likelihood of ignition and fire growth scenarios, a design fire needs to be established. The design fire is characterized by its heat release rate, $\dot{Q}$, at any moment in time; its growth rate, dq/dt; a combustion product rate, dcp/dt, such as smoke particulate, toxic or corrosive species, and so forth; and production rate, dp/dt. The design fire may be determined by (1) a combination of small- and large-scale testing specific to the application or (2) analysis of data taken from studies reported in the literature.

For a given fire safety design objective, there will be a point, $\dot{Q}_{do}$, on the design fire curve where the energy and product release rates will produce conditions representative of the design objective. Given that there will be delays in detecting the fire, notifying the occupants, accomplishing evacuation, or initiating suppression actions, the fire will need to be detected at some time in advance of $\dot{Q}_{do}$. In order to account for these delays, a critical fire size, $\dot{Q}_{cr}$, can be defined as the point on the design fire curve at which the fire must be detected in order to meet the design objectives for a given spacing or radial distance from the fire.

There are two types of delays that influence the size of the fire at detection: (1) those that are variable and (2) those that are fixed. Variable delays represent transport lag and are related to radial distance of the detector from the fire, ceiling height, and the convective heat release rate of the fire. Fixed delays are associated with system characteristics, such as alarm verification time. Adding the fixed delays to $\dot{Q}_{cr}$ defines another point on the design fire curve: $\dot{Q}_i$ or the *ideal* fire; that is, the fire that would be detected with no transport delay.

The design fire, $\dot{Q}_{do}$, has been defined as the fire size (in terms of peak heat release and given growth rate history) that corresponds to the maximum acceptable loss fire, and the critical fire, $\dot{Q}_{cr}$, as the maximum fire size at time of detection that allows actions to be taken to limit the continually growing fire to the design fire limit. The time needed to take the limiting actions is the response lag. The total system response time, then, is the amount of time required between the critical fire and the design fire for all the actions to take place before $\dot{Q}_{do}$ is reached, and is the sum of the fixed and variable delays and the response lag. The various design and evaluation points on a design fire curve are shown in Fig. 40.1.

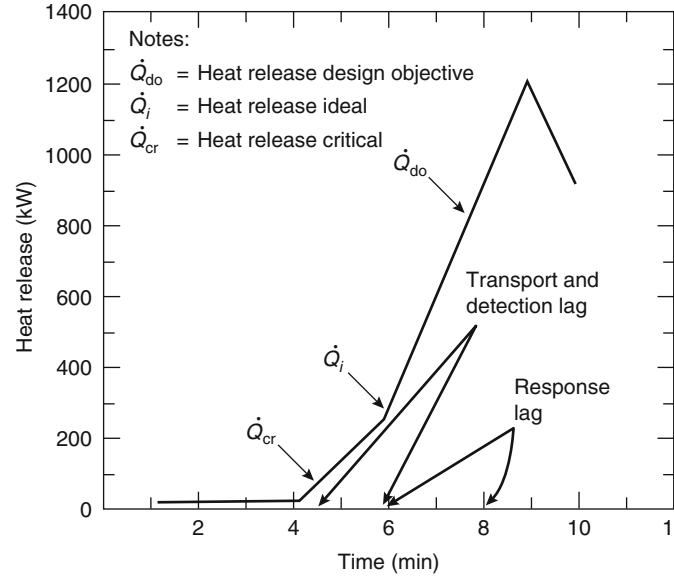

Fig. 40.1 Design fire curve

For example, if the design fire is determined to be 1500 kW and manual suppression will be employed, the critical fire can be selected at a moment in time that permits detection, notification, and response before the 1500 kW fire size is reached. If the total system response time is estimated to be 3 min, the critical fire would be at the size determined at 3 min prior to reaching 1500 kW using the estimated fire growth rate.

Expressing fire size or fire load as an energy release and growth rate may be thought of in the same way that structural engineers use earthquake zone maps to design for potential earthquakes. Electrical engineers might compare fire loads to fault currents used in designing overcurrent protection devices. At the present time, design fire, critical fire, and total system response time requirements are not established by any building codes. It is the job of the design engineer to work with the building owner and local code officials to establish the performance requirements for a given system application.

Once the goals of a system have been established, several probable fire scenarios should be outlined. The occupancy of the building and the expected fuels should be analyzed to establish an expected fire growth rate and an expected maximum heat release rate. Fire loss reports and fire test data can be used to help estimate heat release rates and the production of smoke and fire gases. It is important that different fire scenarios be evaluated to establish how the system design or response might change as a result of varying fire conditions. Several possible fire scenarios should be outlined using the techniques presented elsewhere in this handbook.

When designing a system, select the most likely fire scenario as the basis of the design. Once the design requirements for spacing and detector type are established, the system's response can be analyzed using the other possible fire scenarios. If the alternate fire scenarios cause the design not to meet the established goals, design changes can be made and retested, if warranted.

The several fire scenarios used when analyzing a system will produce upper and lower bounds or a range of system performance characteristics. The fire scenarios selected should include best- and worst-case fires as well as several likely scenarios for the particular building characteristics and occupancy.

For the purposes of design or analysis, detection and alarm systems have three basic elements: detection, processing, and signaling. The first, detection, is that part of the system that senses fire. The second element involves the processing of signals from the detection portion of the system. Finally, the processing section of the system activates the signaling portion in order to alert occupants and perform other auxiliary signaling operations. Auxiliary functions may include smoke control, elevator capture, fire department signaling, and door closing.

This chapter focuses on the detection and signaling elements of a fire alarm system. Engineering methods for the design and analysis of heat detector response are presented along with several examples. A method to calculate the audibility of fire alarm sounders is also presented. The selection of a system's control panel and the design of auxiliary functions is beyond the scope of this chapter.

Detection

To design the detection portion of a fire alarm system, it is necessary to determine where fire detectors should be placed in order to respond within the goals established for the system. Several different detector types might respond to the expected fire, so it may be necessary to develop several candidate system designs, using various combinations of detector types in order to optimize the system's performance and cost.

A fire signature [6] is some measurable or sensible phenomenon present during combustion. Table 40.1 is a cross-reference of fire signatures and commercially available detector types. The table shows the predominant fire signature to which the detector responds.

Table 40.1 Fire signatures and commercially available detectors

Fire signature/ detector type	Electromagnetic radiation wave length 1700–2900 angstroms	Electromagnetic radiation (thermal) 6500–8500	Invisible products of combustion less than 0.1 μm	Visible smoke and products of combustion more than 0.1 μm	Rapid change in temperature	High temperature

Heat Detection

This section discusses an engineering method for determining the placement of heat detectors on a large flat ceiling.

The present practice in designing fire detection systems using heat detectors is to space the detectors at intervals equal to spacings established by tests at Underwriters Laboratories Inc. Listed spacings are determined in full-scale fire tests [7].

In the Underwriters Laboratories Inc. (UL) test, a burning pan of 190-proof denatured alcohol is located in the center of a test room. Sprinkler heads having a 160 °F (71 °C) rated operating temperature are located on the ceiling in a square array having 10 ft (3 m) sides. The fire is in the center of the square. The distance between the fire and the ceiling is varied so that the 160 °F (71 °C) sprinkler head being used operates in approximately 2 min.

As shown in Fig. 40.2, detectors of the type being tested are located at the corners of squares having 20, 30, 40, and 50 ft (6.1, 9.1, 12.2, and 15.2 m) sides. The spacing of the last detector to operate prior to a sprinkler head operating becomes the detector's listed spacing. A similar test procedure is employed by Factory Mutual Research Corporation (FMRC) to arrive at an approved detector spacing.

Most codes require that detectors be spaced at intervals equal to the UL or FMRC spacing. *NFPA 72®*, *National Fire Alarm Code®* [8], 2007 edition, requires that the installed spacing be less than the listed spacing to compensate for high ceilings, beams, and air movement. High ceilings mean that the fire plume will entrain more ambient air as it rises. This condition has the effect of cooling the gases and reducing the concentration of fire products. Beams, joists, walls, or sloped ceilings alter the flow of combustion products. This situation can serve to restrict or enhance the operation of a fire

detector. For instance, consider the case where a fire detector is located on a ceiling between two parallel beams and a fire occurs at floor level between the beams. If the distance between the beams is small compared to the horizontal distance from the fire to the detector, the beams will act as a channel directing the flow of hot gas to the detector, thus speeding operation. *NFPA 72* allows detector spacing to be increased beyond the listed spacing in areas, such as corridors, with narrow walls to confine the smoke and heat produced by the fire. Systems can be designed using this type of code approach; however, this approach will not permit quantitative assessment of detector response or measure the ability of a given system design to meet specific design goals relating to fire size, allowable damage, or hazard.

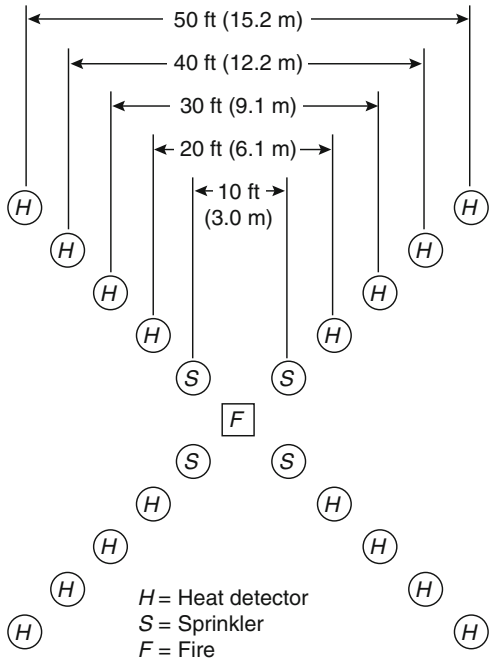

Fig. 40.2 Detector test layout

The best possible location for a heat detector is directly over the fire. If there are specific hazards to be protected, the design should include detectors directly overhead or inside of the hazard. In areas without specific hazards, detectors should be spaced evenly across the ceiling. When detectors are evenly spaced, as shown in Fig. 40.3, the point that is farthest from any detector will be in the middle of four detectors. The spacing between detectors is

$$S = 2^{1/2}r \tag{40.1}$$

For a given detector, the problem is to determine the maximum distance the detector can be located from the fire and still respond within the

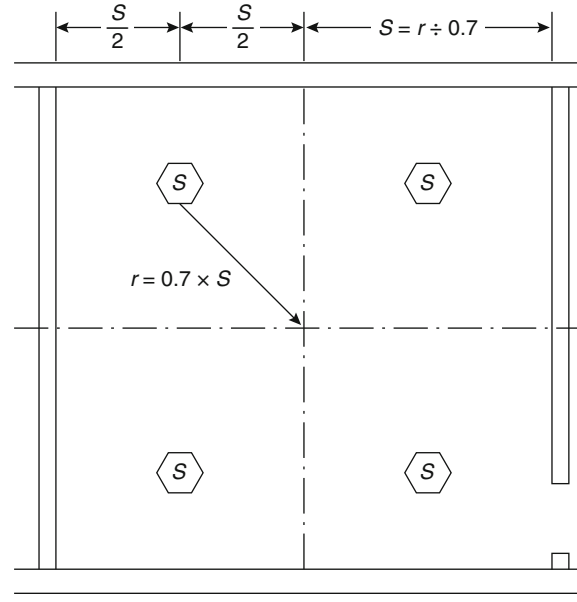

Fig. 40.3 Detector spacing

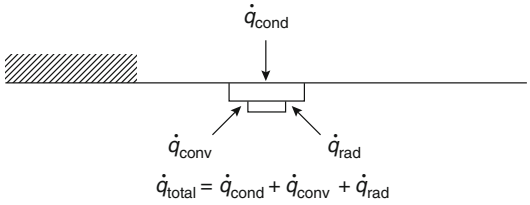

Fig. 40.4 Heat transfer to a ceiling-mounted detector

design goals of the system. This determination requires a method for predicting detector response, based on fire size and growth rate, ceiling height, and detector characteristics.

Fire plume and ceiling-jet models can be used to estimate the temperature and velocity of fire gases flowing past a detector. The heat transfer can be calculated, and the response of the detector can be modeled.

Figure 40.4 describes the heat transfer taking place between a heat detector and its environment. The total heat transfer rate to the unit, $\dot{q}_{\text{ltotal}}$, can be expressed by the relationship

$$\dot{q}_{\text{total}} = \dot{q}_{\text{cond}} + \dot{q}_{\text{conv}} + \dot{q}_{\text{rad}} (\text{kW or Btu/s}) \tag{40.2}$$

where

$\dot{q}_{\text{cond}}$ = Conduction
$\dot{q}_{\text{conv}}$ = Convection
$\dot{q}_{\text{rad}}$ = Radiation heat transfer rates

During the initial stage of fire growth, radiation heat transfer can be neglected. Also, the elements of most commercially available heat detectors are thermally isolated from the remainder of the unit. In these cases, it can be assumed that the heat lost from the heat-sensitive element by conduction to other parts of the detector, and to the ceiling by conduction, is negligible in comparison to the convection heat transfer taking place. This exclusion leaves a net rate of heat transfer to the detector equal to $\dot{q}_{\text{conv}}$. The convective heat transfer rate to the detector is described by

$$\dot{q} = q_{\text{conv}} = hA\left(T_g - T_d\right) \ (\text{kW or Btu/s}) \tag{40.3}$$

where

h = Convective heat transfer coefficient in kW/(m^2 · °C) or Btu/(sft^2 · °F)
A = Area being heated
T_d = Detector temperature
T_g = Temperature of the gas heating the detector

Treating the detector element as a lumped mass, m (kg or lbm), the change in its temperature is found by

$$\frac{dT_d}{dt} = \frac{\dot{q}}{mc} \text{deg/s} \tag{40.4}$$

where c is the specific heat of the element being heated and has units of kJ/(kg · °C) or Btu/(lbm · °F) and $\dot{q}$ is the heat transfer rate. This equation leads to the following relationship for the change in temperature of the detector with respect to time:

$$\frac{dT_d}{dt} = \frac{hA\left(T_g - T_d\right)}{mc} \tag{40.5}$$

Heskestad and Smith [9] have proposed use of a time constant, τ, to describe the convective heat transfer to a particular detector element:

$$\tau = \frac{mc}{hA} \text{s} \tag{40.6}$$

$$\frac{dT_d}{dt} = \frac{T_g - T_d}{\tau} \tag{40.7}$$

Note that is a function of the mass, area, and specific heat of the particular detector element being studied. For a given fire-gas temperature and velocity and a particular detector design, an increase in mass increases τ. A larger τ results in slower heating of the element.

The convective heat transfer coefficient, h, is a function of the velocity of the gases flowing past the detector element and the shape of the detector element. For a given detector, if the gas velocity is constant, h is constant. It has been shown [10] that the convective heat transfer coefficient for spheres, cylinders, and other objects similar to a sprinkler or heat detector element is approximately proportional to the square root of the Reynolds number, Re:

$$\text{Re} = \frac{ud}{v} \tag{40.8}$$

where
u = Gas velocity
d = Diameter of a cylinder or sphere exposed to convective heating
v = Kinematic viscosity of the gas

For a given detector, this equation means that h and, hence, τ, is approximately proportional to the square root of the velocity of the gases passing the detector. This relationship can be expressed as a characteristic response time index, RTI, for a given detector:

$$\tau u^{1/2} \simeq \tau_0 u_0^{1/2} = \text{RTI} \qquad (40.9)$$

Thus, if τ_0 is measured in the laboratory at some reference velocity u_0, this expression is used to determine the τ at any other gas velocity, u, for that detector. The product, $\tau^{1/2}$, is the response time index, RTI.

The use of RTI as a heat transfer function is a simplification. The determination of RTI assumes that τ (and, therefore, h) is proportional to the square root of the gas velocity, regardless of the magnitude of the velocity. The flow of gases past irregularly shaped objects such as detectors and sprinklers is very complex. Even the flow past cylinders is too complex to use a simple relationship for the heat transfer coefficient (i.e., constant RTI). Hollman showed that the heat transfer coefficient (and, therefore, τ) is actually proportional to the Reynolds number raised to a fractional power, n, that varies from 0.330 to 0.805 depending on the value of the Reynolds number [10]. For values of Re between 40 and 4000, which is probably the range for most fire detection scenarios, the value of n is given as 0.466. This value is close to 0.5 (square root), but may explain some of the variation found in the experimental determination of τ and RTI.

Plunge tests performed on a variety of heat detectors by Bissell [11] show variations in τ and RTI, whereas other tests produced reasonable results for a variety of test parameters. It is possible that further analysis may show that an RTI based on $n = 0.5$ is reasonable and that the potential errors are insignificant in the context of fire and detector modeling. On the contrary, it may be found that some other value for n produces better results.

The exponent n may vary over ranges of Reynolds numbers less than those reported by Hollman. Some detector geometries are aerodynamically designed to channel fire gases to the detector element. The ability to affect the gas flow is a function of both the flow velocity and whether the flow is turbulent or laminar. These effects introduce additional variables that complicate the determination of a heat transfer function.

An added source of error in heat transfer modeling is that the temperature-sensing element of a heat detector is never completely isolated from the detector body. This setup results in conductive heat loss that may not be accounted for when using only one time constant. Kokkala has shown that for some detectors as much as 10 % of the heat gained by convection is lost by conduction to the detector body [12]. A two-time-constant approach, similar to the C parameter used in modeling the response of sprinkler heads, is suggested by Kokkala. In a plunge test, the velocity may be high enough so that the conduction heat loss is negligible when compared to the heat gain by convection. In actual fire conditions, this conduction heat loss may contribute to the variation in RTI as it is currently used.

The magnitude of the potential error resulting from the assumption that RTI is constant has not been investigated. Future research and analysis should also consider the possibility that it might be best to test and report several discrete values for τ (hence, h) [13]. An example is using a plunge test to find τ at three different velocities. The slow, medium, and fast velocities should be representative of the range of possible fire-gas velocities.

A continuous curve of τ versus u for every model detector would be ideal. However, the economic feasibility of testing must be considered. At the present time, heat detectors are tested in ovens to determine their operating temperatures and are tested in full-scale fire tests to determine their listed spacing (relative sensitivity). A single oven could be used to test for operating temperature and τ at several different velocities as discussed above. This type of

testing would be more repeatable (precise), have a lower environmental impact, and give results that can be directly used by engineers in performance-based analysis and design. The test data could be used to calculate a listed spacing comparable to that determined in the present full-scale test so that current code-based design methods could continue to be used.

The remainder of the calculations in this chapter will be made using RTI as a heat transfer function. The user will readily see how other functions, when available, can be incorporated into the equations to effect other solutions.

Heskestad and Smith [9] developed a test apparatus at Factory Mutual Research Corporation to determine the RTI of sprinkler heads. In the test, called a *plunge test*, the sprinkler head is suddenly lowered into the flow of a hot gas. The temperature and velocity of the gas are known and are constant during the test. The equation for the change in the detector temperature is then

$$\frac{dT_d}{dt} = \left(\frac{1}{\tau}\right)\left(T_g - T_d\right) \tag{40.10}$$

Since the gas temperature is constant during the test, the solution to this equation is

$$T_d - T_g = \left(T_g - T_a\right)\left[1 - \exp\left(\frac{-t}{\tau}\right)\right] \tag{40.11}$$

where T_a is the ambient, or initial, temperature of the sprinkler or detector at time $t = 0$. T_d is the temperature of the detector at time t. Rearranging the equation gives

$$\tau = \frac{t}{\ln\left[\left(T_g - T_a\right)/\left(T_g - T_d\right)\right]} \tag{40.12}$$

By measuring the response time, t_r, of the unit in the plunge test, this equation can be used to calculate τ_0 at the test velocity u_0. This calculation is done by substituting the response temperature and time for T_d and t. The sensitivity of the detector or sprinkler can then be expressed as

$$\tau_o(at\,u_0) = \frac{t}{\ln\left[\left(T_g - T_a\right)/\left(T_g - T_r\right)\right]}(s) \tag{40.13}$$

In terms of the response time index, this equation becomes

$$\mathrm{RTI} = \frac{t_r u_0^{1/2}}{\ln\left[\left(T_g - T_a\right)/\left(T_g - T_r\right)\right]} \tag{40.14}$$

The RTI has units of $\mathrm{m}^{1/2}\mathrm{s}^{1/2}$ or $\mathrm{ft}^{1/2}\mathrm{s}^{1/2}$.

A plunge test can be used to determine the RTI for a heat detector or a sprinkler. Knowing the RTI, the change in temperature of similar units can be calculated for any history of fire gases flowing past it. The form of the heat transfer equation is

$$\frac{dT_d}{dt} = \frac{u^{1/2}\left(T_g - T_d\right)}{\mathrm{RTI}} \tag{40.15}$$

This equation is used to calculate the temperature of a fixed-temperature heat detector or sprinkler exposed to fire gases. The equation can be used to determine the time at which the unit reaches its operating temperature.

The use of a lumped mass model may not hold for rate-of-rise heat detectors and rate-compensated heat detectors. The heat transferred to a fixed-temperature heat detector either heats a sensing element until it melts, or it heats two dissimilar metals of a snap disk. In each case, the element itself is exposed to the hot gases. This result is not true for rate-of-rise heat detectors or rate-compensated heat detectors.

Most commercial rate-of-rise heat detectors operate when the expansion of air in a chamber exceeds the rate at which the air can escape through a small vent hole. For this type of detector, it is also necessary to model heat transfer from the detector body to the air in its chamber. Then the expansion of the air and its escape through a vent hole must be accounted for. The response time index determined in a plunge test may not be constant as fire-gas velocities or temperatures vary. Hence, RTI is only an approximation of how the detector responds. Also, it has been hypothesized, but not tested, that rate-of-rise detectors may be modeled by simply comparing the rate of change of gas temperature to their rated response threshold [13]. This hypothesis may be true since their rated response in

degrees per minute or degrees per second is actually the measured rate of gas temperature change in the test apparatus. Thus, it would be expected that if the velocity of the fire gases was on the same order of magnitude as in the test, the rate of change of gas temperature would be the measure for detector response.

A rate-compensated detector consists of a metallic shell surrounding two bowed metal struts. There are electrical contacts on the struts. The struts and shell expand at different rates as the detector is heated. When heated fast, the outer shell expands and causes the bowed struts to straighten and close the contacts, signaling an alarm. This condition usually occurs at temperatures below the rated operating temperature. However, if the unit is heated more slowly, the difference between the expansion rates of the inner and outer parts is such that the contacts close at or near the unit's rated temperature. For rates of temperature rise up to approximately 22 °C/min (40 °F/min), rate-compensated detectors tend to respond when the surrounding gas temperature reaches the unit's rated operating temperature [14].

Obviously, the rate-compensated type of heat detector cannot be treated as a lumped mass when calculating its response to a fire. However, at rates of temperature rise less than approximately 22 °C/min (40 °F/min), they can be modeled by simply assuming that they respond when the surrounding gas temperature reaches their operating temperature.

From the discussion above, it is evident that the response of fixed-temperature heat detectors can be modeled. It is necessary to know the temperature at which the detector is rated to operate. For rate-of-rise heat detectors, it is necessary to know the rate of change in the detector's temperature at which it will alarm. The RTI or τ_0 and u_0 for the detector are also needed.

In order to calculate the response of a heat detector, it is necessary to know the temperature and velocity of the gases flowing past it. Some fire plume models or ceiling-jet models may give functional relationships for temperature and velocity that can be substituted into the heat transfer equation and integrated. Other models may not be suitable for an analytical solution. In this case, the fire model should be used to produce data on time-versus-temperature and time-versus-gas velocities. These data can then be used to numerically solve the detector heat transfer equation.

Most fire and ceiling-jet models do not model the temperature and velocity profile as a function of distance from the ceiling. This lapse introduces error and uncertainty in the results. Marrion [15] showed that maximum temperature and velocity occurs between 1 and 3 in. (25 and 76 mm) below the ceiling for small (5- to 7-in. [127- to 178-mm] diameter) gasoline pan fires with a ceiling clearance of about 14 ft (4.3 m). Others have reported maximums at a distance down from the ceiling of approximately one-tenth the distance from the fuel to the ceiling. Alpert [16] reports ceiling-jet thickness to be approximately 5–12 % of the ceiling to fuel distance. Users are cautioned when modeling detector mechanisms that are not within this range.

When the responses of multiple detectors or sprinklers are modeled, no provisions are made to account for sprinkler spray cooling of the room and, therefore, the activation of additional elements (beyond the first) may be inaccurately predicted. For more information on this topic the reader is referred to the references for works by Cooper [17], Delichatsios and Alpert [18], and Heskestad [19].

Heat Detection: Steady-State Fires

Alpert [16] presented the following series of equations to calculate temperature and velocity of fire gases in a ceiling jet as a function of heat release rate and position for steady-state fires:

$$T_g - T_a = \frac{\left[5.38\left(\dot{Q}/r\right)^{2/3}\right]}{H}\,^{\circ}\mathrm{C} = \frac{\left[4.74\left(\dot{Q}/r\right)^{2/3}\right]}{H}\,^{\circ}\mathrm{F}$$

where $r/H > 0.18$, and

$$T_g - T_a = \frac{\left[16.9\dot{Q}^{2/3}\right]}{H^{5/3}}\,^{\circ}\mathrm{C} = \frac{\left[14.9\dot{Q}^{2/3}\right]}{H^{5/3}}\,^{\circ}\mathrm{F}$$

where $r/H \leq 0.18$, and

$$u = \frac{\left(0.20\dot{Q}^{1/3}H^{1/2}\right)}{r^{5/6}}\,\mathrm{m/s} = \frac{\left(0.25\dot{Q}^{1/3}H^{1/2}\right)}{r^{5/6}}\,\mathrm{ft/s}$$

where $r/H > 0.15$, and

$$u = 0.95\left(\frac{\dot{Q}}{H}\right)^{1/3}\mathrm{m/s} = 1.2\left(\frac{\dot{Q}}{H}\right)^{1/3}\mathrm{ft/s}$$

where $r/H \leq 0.15$.

In the above series of equations,

T_g = Maximum, near ceiling, fire-gas temperature in °C or °F

T_a = Ambient temperature in °C or °F

$\dot{Q}$ = Total heat release rate of the fire in kW or BTU/min

r = Radial distance from the axis of the fire plume in m or ft

H = Height above the origin of the fire in m or ft

u = Maximum, near ceiling, fire-gas velocity in m/s or ft/s

This model assumes that the temperature and velocity of the fire gases at a point away from the source are related to the instantaneous heat release rate of the fire. This assumption neglects the time required for transport of the fire gases from the source to the detector. Also, because the correlations are based on the total heat release rate rather than only the convective heat release rate, errors will be introduced when the convective fraction differs from that in the tests used to develop the correlations.

For a constant gas temperature and constant gas velocity, the basic heat transfer equation can be solved:

$$\frac{dT_d}{dt} = \frac{T_g - T_d}{\tau}$$

$$dT_d = \int_0^t \frac{1}{\tau}\left(T_g - T_d\right)dt$$

$$\Delta T_d = T_d - T_a - \left(T_g - T_a\right)\left[1 - \exp\left(\frac{-t}{\tau}\right)\right]^{\circ}\mathrm{C} \tag{40.7}$$

or, substituting the equation for RTI

$$\Delta T_d = T_d - T_a = \left(T_g - T_a\right)\left[1 - \exp\left(\frac{-tu^{1/2}}{\mathrm{RTI}}\right)\right]^{\circ}\mathrm{C}$$

The response of heat detectors to fires with ceiling jets having a near constant gas temperature and velocity can be modeled using the above equations.

Heat Detection, Growing Fires, and Quasi-Steady-State Modeling

A growing fire can be modeled by assuming the fire to be composed of a series of increasing steady heat release rates. This model is referred to as quasi-steady-state modeling. The first step is to break the heat release rate curve into a series of small time intervals. For each interval, use the average heat release rate for that interval to calculate the fire-gas temperature and velocity. Then, starting at ambient temperature, calculate the change and resulting temperature of the detector at the end of the first interval. Using that new detector temperature at the start of the next interval, use the next gas temperature and velocity to calculate the detector temperature at the end of the interval. Continue until you have reached the time of interest or until the detector temperature exceeds its operating temperature.

Example 1 A stack of wood pallets is burning under a flat ceiling that is 6 m high. Table 40.2, showing heat release rates, is given below. The ambient temperature is 20 °C. What would be the temperature of a ceiling-mounted heat detector having an RTI of 55 $\mathrm{m}^{1/2} \cdot \mathrm{s}^{1/2}$ after a 180-s exposure if it were located 6 m from the center of the plume?

Solution The detector is located in the developed ceiling jet. The first step is to calculate the change in temperature and the velocity for each heat release rate in the table. For the period 0 to 10 s, the heat release rate is given as 5 kW. The change in temperature and the velocity of the ceiling jet at the detector are

Table 40.2 Example 1: heat release rates

Δt	$\dot{Q}$	Δt	$\dot{Q}$
0	0	100	469
10	5	110	567
20	19	120	675
30	42	130	792
40	75	140	919
50	117	150	1055
60	169	160	1200
70	230	170	1355
80	300	180	1519
90	380		

$$T_g - T_a = \frac{\left[5.38\left(\frac{\dot{Q}}{r}\right)^{2/3}\right]}{H}\,^{\circ}\mathrm{C}$$

$$T_{g,1} - T_a = \frac{\left[5.38\left(\frac{5}{6}\right)^{2/3}\right]}{6} = 0.794^{\circ}\mathrm{C}$$

$$T_{g,1} = 20.794^{\circ}\mathrm{C}$$

$$u = \frac{\left(0.20\dot{Q}^{1/3}H^{1/2}\right)}{r^{5/6}}\,\mathrm{m/s}$$

$$u_1 = \frac{\left[0.20(5)^{1/3}(6)^{1/2}\right]}{6^{5/6}} = 0.188\,\mathrm{m/s}$$

Next calculate the change in detector temperature ΔT_d as a result of that exposure by assuming the temperature and velocity to be steady over short intervals;

$$\frac{dT_d}{dt} = \frac{T_g - T_d}{\tau} = \frac{u^{1/2}\left(T_g - T_d\right)}{\mathrm{RTI}}$$

$$\Delta T_d = T_{d,n} - T_{d,n-1} = \frac{u_n^{1/2}\left(T_{g,n} - T_{d.n-1}\right)}{\mathrm{RTI}}\Delta t^{\circ}\mathrm{C}$$

$$T_{d,n} = \left[\frac{u^{1/2}\left(T_{g,n} - T_{d,n-1}\right)}{\mathrm{RTI}}\Delta t\right] + T_{d,n-1}{}^{\circ}\mathrm{C}$$

Initially, the detector is not exposed to hot gases and is at ambient temperature. For the first step or interval, the detector is exposed and the resulting detector temperature at the end of the interval ($T_{d,1}$) is calculated:

$$T_{d,1} = \left[\frac{u^{1/2}\left(T_{g,1} - T_{d,0}\right)}{\mathrm{RTI}}\Delta t\right] + T_{d,0}{}^{\circ}\mathrm{C}$$

$$T_{d,1} = \left[\frac{(0.188)^{1/2}(20.794 - 20)}{50}10\right] + 20$$

$$= 20.063^{\circ}\mathrm{C}$$

To simplify the process, set up a table or a spreadsheet, as shown in Table 40.3, to complete the calculations. Rounding to two significant digits is done last.

After 180 s of exposure, the detector temperature is approximately 46 °C. If the detector were rated at 57 °C, it would not have responded.

Heat Detection: Potential Errors: Steady-State and Quasi-Steady-State Modeling

There are many sources of potential error in these calculations. These include uncertainty in the operating temperature, uncertainty in the ambient temperature, and inaccuracies in the fire-gas temperature and velocity correlations. Because the magnitude of these potential errors is unknown or unreported, a tolerance or confidence interval for the answer cannot be estimated.

In addition, it has been assumed that use of the ceiling-jet model is valid for the previous example. The model assumes an infinite ceiling for the ceiling jet to flow outward without encountering walls and developing a layer. In the example, the velocity of the ceiling jet for each interval can be used to estimate the approximate position of the leading edge of the ceiling jet. If the ceiling jet is a sufficient size to have reached the bounding walls or draft curtains in a space, a layer will begin to develop. This analysis can be used as a test to determine if additional error is possible because limitations of the model have been exceeded.

Evans and Stroup [20] published a computer program called DETACT-QS, which uses Alpert's equations to calculate the response of heat detectors. That program requires the

Table 40.3 Example 1: spreadsheet calculations

Step, n	t	Q	ΔT_g	T_g	u	ΔT_d	T_d

following input: ceiling height, H; ambient temperature, T_a; distance from fire axis to detector, r; detector response or activation temperature, T_r; and detector response time index (RTI). The user must also input history of time versus heat release rate for the fire. The program uses the quasi-steady-state method demonstrated above to calculate the detector response.

Heat Detection: Power-Law Fires

Heskestad and Delichatsios [8] presented functional relationships for modeling the temperature and velocity of fires whose heat release rates grow according to the power-law relationship:

$$\dot{Q} = \alpha t^p \text{ kW}$$

where

α = Constant for a particular fuel describing the growth of the fire (kW/s^2)
t = Time (s)
p = Positive exponent
$\dot{Q}$ = Heat release rate (kW)

NFPA 72, Appendix B, uses a constant called the *fire growth time*, t_g, in lieu of α to describe the fire intensity. The fire growth time is defined as the time at which a power-law fire would reach a heat release rate of 1055 kW (1000 Btu/s). In terms of t_g, the power-law equation becomes

$$\dot{Q} = \left(\frac{1055}{t_g^2}\right) t^p \text{ kW}$$

The nondimensional functional relationships given by Heskestad and Delichatsios [21] for temperature and velocity of fire gases in a ceiling jet are

$$u_p^* = \frac{u}{\left(A^{1/(3+p)} \alpha^{1/(3+p)} H^{(p-1)/(3+p)}\right)}$$
$$u_p^* = f\left(t_p^*, \frac{r}{H}\right) \tag{40.16}$$

$$\Delta T_p^* = \frac{\Delta T}{A^{2/(3+p)} (T_a/g) \alpha^{2/(3+p)} H^{-(5-p)/(3+p)}}$$
$$\Delta T_p^* = g\left(t_p^*, \frac{r}{H}\right) \tag{40.17}$$

where

$$A = \frac{g}{C_p T_a \rho_o} \tag{40.18}$$

$$t_p^* = \frac{t}{A^{-1/(3+p)} \alpha^{-1(3+p)} H^{4/(3+p)}} \tag{40.19}$$

All variables are described in this chapter's nomenclature section.

For $p = 2$ power-law fires, the above nondimensional equations reduce to the following:

$$u_2^* = \frac{u}{\left(A^{1/5} \alpha^{1/5} H^{1/5}\right)}$$

$$\Delta T_2^* = \frac{\Delta T}{A^{2/5} (T_a/g) \alpha^{2/5} H^{-3/5}}$$

$$t_2^* = \frac{t}{A^{-1/5} \alpha^{-1/5} H^{4/5}}$$

Heskestad and Delichatsios [21] presented correlations to the functional relationships for fires whose release rates vary according to the power-law equation, with $p = 2$. These fires are referred to as t^2 fires. It has been shown [22, 23] that the $p = 2$ power-law fire growth model can be used to model the heat release rate of a wide range of fuels. The original correlations were used in several publications and popular calculation programs for ceiling-jet and heat-detector modeling, including the first two editions of this handbook [8, 9, 20, 23–26].

Subsequently Heskestad and Delichatsios found that an incorrect value for the heat of combustion of wood resulted in the correlations being in error. All examples in this chapter that use these correlations have been updated or replaced. The corrected data correlations are as follows: [27]

$$t_{2f}^* = 0.861 \left(1 + \frac{r}{H}\right)$$

t_{2f}^* is the nondimensional time at which the heat front reaches the detector. When $t_2^* < t_{2f}^*$, the heat front has not reached the detector position. Therefore, $\Delta T_2^* = 0$.

For $t_2^* < t_{2f}^*$,

$$\Delta T_{2f}^* = \left[\frac{\left(t_2^* - t_{2f}^*\right)}{(0.146 + 0.242 r/H)}\right]^{4/3}$$

This relationship may also be expressed as

$$\Delta T_2^* = \left[\frac{\left(t_2^* - t_{2f}^*\right)}{D}\right]^{4/3}$$

where

$$D = 0.146 + 0.242 \frac{r}{H}$$

$$\frac{u_2^*}{\left(\Delta T_2^*\right)^{1/2}} = 0.59 \left(\frac{r}{H}\right)^{-0.63}$$

The above correlations assume that the convective heat release rate is approximately 75 % of the total heat release rate.

When the convective fraction differs from 75 %, the following equations are more useful forms and are used with the nondimensional equations for ΔT_2^* and u_2^* by first multiplying α by the convective fraction X: [2]

$$\begin{aligned} \alpha_c &= X\alpha \ \text{kW/s}^2 \\ t_{2f}^* &= 0.813 \left(1 + \frac{r}{H}\right) \end{aligned} \tag{40.20}$$

When $t_2^* < t_{2f}^*$ $\Delta T_2^* = 0$

For $t_2^* \le t_{2f}^*$,

$$\Delta T_2^* = \left[\frac{\left(t_2^* - t_{2f}^*\right)}{(0.126 + 0.210 r/H)}\right]^{4/3} \tag{40.21}$$

This may also be expressed as

$$\Delta T_2^* = \left[\frac{\left(t_2^* - t_{2f}^*\right)}{D}\right]^{4/3}$$

where

$$D = 0.126 + 0.210 \frac{r}{H} \tag{40.22}$$

$$\frac{u_2^*}{\left(\Delta T_2^*\right)^{1.2}} = 0.59 \left(\frac{r}{H}\right)^{-0.63} \tag{40.23}$$

Beyler found that these correlations for temperature and velocity could be substituted into the heat transfer equation and integrated [28].

Beyler's analytical solution was published in *Fire Technology* [29] and is repeated here.

The analytical solution for the instantaneous rate of change of detector temperature is

$$\frac{dT_d(t)}{dt} = \frac{4}{3}\frac{\Delta T}{\Delta T_2^*}\Delta T_2^{*1/4}\frac{(1-e^{-\gamma})}{(t/t_2^*)D} \tag{40.24}$$

The analytical solution for change in detector temperature is

$$\begin{aligned}\Delta T_d &= T_d(t) - T_d(0) \\ &= \frac{\Delta T}{\Delta T_2^*}\Delta T_2^*\left[1 - \frac{(1-e^{-\gamma})}{\gamma}\right]\end{aligned} \tag{40.25}$$

where

$$\gamma = \frac{3}{4}\sqrt{\frac{u}{u_2^*}}\sqrt{\frac{u_2^*}{(\Delta T_2^*)^{1/2}}}\left(\frac{\Delta T_2^*}{\mathrm{RTI}}\right)\left(\frac{t}{t_2^*}\right)D \tag{40.26}$$

and as previously defined,

$$D = 0.126 + 0.210\frac{r}{H} \tag{40.22}$$

In a design situation, the objective is to determine the spacing of detectors required to respond to a specific fire scenario. The detector must respond when the fire reaches a certain threshold heat release rate or in a specified amount of time. Time and heat release rate are interchanged using the fire growth model. The steps in solving this type of problem using the $p = 2$ power-law model are outlined below and are discussed in more detail in the examples following this section. The referenced equation numbers assume that the correlations used are the ones for a variable convective fraction. The procedure would be the same if using the correlations for the fixed, 75 % convective fractions except that α is not multiplied by the convective fraction when used in the equations. For design problems,

1. Determine the environmental conditions of the area being considered.
   (a) ambient temperature, T_a (convert to absolute temperature)
   (b) ceiling height or height above fuel, H
2. Estimate the fire growth characteristic α or t_g for the fuel expected to be burning. If t_g is used, calculate the corresponding α. Multiply α by the convective fraction to get α_c before using in the equations.
3. Establish the goals of the system: required response time t_r or maximum permitted threshold heat release rate $\dot{Q}_T$.
4. Select the detector type to be used. For fixed-temperature units, this choice establishes the detector response temperature T_r and its RTI, or τ_0 and u_0.
5. Make a first estimate of the distance, r, from the fire to the detector necessary to meet the system goals.
6. Assume that the fire starts obeying the power-law model at time $t = 0$.
7. Set the initial temperature of the detector and its surroundings at ambient temperature.
8. Using Equation 40.20, calculate the nondimensional time, t_{2f}^*, at which the initial heat front reaches the detector.
9. Calculate the factor A defined in Equation 40.18.
10. If the equations for a variable convective fraction are used, multiply α by the convective fraction X to get α_c and use result that with the required response time in Equation 40.19 to calculate the corresponding value of t_2^*.
11. If t_2^* is greater than t_{2f}^*, continue with Step 12. If not, try a new detector position, r, closer to the fire and return to Step 8.
12. Calculate the ratio u/u_2^* using Equation 40.16.
13. Calculate the ratio $\Delta T/\Delta T_2^*$ using Equation 40.17.
14. Use Equation 40.21 to calculate ΔT_2^*.
15. Equation 40.23 is used to calculate the ratio $u_2^*/(\Delta T_2^*)^{1/2}$.
16. Use Equations 40.22 and 40.26 to calculate D and Y.
17. Equation 40.25 can now be used to calculate the resulting temperature of the detector.
18. If the temperature of the detector is below its operating temperature, this procedure must be repeated using a smaller r. If the

temperature of the detector exceeds its operating temperature, a larger r can be used.

19. Repeat this procedure until the detector temperature is about equal to its operating temperature. The required spacing of detectors is then $S = 141r$.

This same procedure is used to estimate the response of rate-of-rise heat detectors. The difference is that in Step 17, Equation 40.24 is used to calculate rate of change of the detector temperature. This result is then compared to the rate at which the detector is designed to respond.

The discussion and procedure so far has centered around the solution of a design problem. The question asked was, How far apart must detectors of a specific design be spaced to respond within specific goals to a certain set of environmental conditions and a specific fire scenario?

The second type of problem that must be addressed is the analysis of an existing system or the analysis of a proposed design. Here the spacing of detectors or sprinklers is known. The engineer must still estimate the burning characteristics of the fuel and the environmental conditions of the space being analyzed. The equations can then be solved in a reverse fashion to determine the rate of heat release or the time to detector response. The technique is as follows:

1. Determine the environmental conditions of the area being considered.
   (a) ambient temperature, T_a (convert to absolute temperature)
   (b) ceiling height or height above fuel, H
2. Estimate the fire growth characteristic α or t_g for the fuel expected to be burning. If t_g is used, calculate the corresponding α. Multiply α by the convective fraction to get α_c before using in the equations.
3. Determine the spacing of the existing detectors or sprinklers. The protection radius is then $r = S/\sqrt{2}$.
4. Determine the detector's rated response temperature and its RTI, or τ_0 and u_0.
5. Make a first estimate of the response time of the detector or estimate the heat release rate at detector response and calculate the corresponding response time using the power-law equation.
6. Assume that the fire starts obeying the power-law model at time $t = 0$.
7. Set the initial temperature of the detector and its surroundings at ambient temperature.
8. Using Equation 40.20, calculate the nondimensional time, t^*_{2f}, at which the initial heat front reaches the detector.
9. Calculate the factor A defined in Equation 40.18.
10. Use the estimated response time along with Equation 40.19 to calculate the corresponding value of t^*_2.
11. If t^*_2 is greater than t^*_{2f}, continue with Step 12. If not, try a longer estimated response time or a larger estimated heat release rate and return to Step 8.
12. Calculate the ratio u/u^*_2 using Equation 40.16.
13. Calculate the ratio $\Delta T/\Delta T^*_2$ using Equation 40.17.
14. Use Equation 40.21 to calculate ΔT^*_2.
15. Equation 40.23 is used to calculate the ratio $u^*_2/(\Delta T^*_2)^{1/2}$.
16. Use Equations 40.22 and 40.26 to calculate D and Y.
17. Equation 40.25 can now be used to calculate the resulting temperature of the detector.
18. If the temperature of the detector is below its operating temperature, this procedure must be repeated using a longer estimated response time. If the temperature of the detector exceeds its operating temperature, a smaller t_r can be used.
19. Repeat this procedure until the detector temperature is about equal to its operating temperature. The resulting response time, t_r, can be used to calculate either the total heat release rate or the convective heat release rate at response using the power-law equation.

As in the design problem, this technique can be used to estimate the response of existing systems of rate-of-rise heat detectors. The difference is that in Step 4 the set point or rate of temperature rise at which the detector will

respond must be determined from the manufacturer's data. In Step 17, Equation 40.24 is used to determine the rate at which the temperature of the detector is changing.

Heat Detection: Potential Errors: Power-Law Fire Modeling

When the exact conditions of velocity and temperature of fire gases flowing past a detector are not known, errors are introduced in the design and analysis of fire detector response. Graphs in Heskestad and Delichatsios's report show the errors in calculated fire-gas temperatures and velocities [22]. An exact treatment of these errors is beyond the scope of this chapter, though some discussion is warranted.

Plots of actual data and calculated data show that errors in ΔT_2^* can be as much as 50 %, though generally there appears to be much better agreement [22, 23]. The maximum errors occur at r/H values of about 0.37. All other plots of actual and calculated data, for various r/H, show much smaller errors. In terms of the actual change in temperature over ambient, the maximum errors are on the order of 5–10 °C. The larger errors occur with faster fires and lower ceilings.

At $r/H = 0.37$, the errors are conservative when the equations are used in a design problem. That is, the equations predicted lower temperatures. Plots of data for other values of r/H indicate that the equations predict slightly higher temperatures.

Errors in fire-gas velocities are related to the errors in temperatures. The equations show that the velocity of the fire gases is proportional to the square root of the change in temperature of the fire gases [22]. In terms of heat transfer to a detector, the detector's change in temperature is proportional to the change in gas temperature and the square root of the fire-gas velocity. Hence, the expected errors bear the same relationships.

Based on the discussion above, errors in predicted temperatures and velocities of fire gases will be greatest for fast fires and low ceilings. Sample calculations simulating these conditions show errors in calculated detector spacings on the order of plus or minus 1 m, or less [23].

Similar to Alpert's steady-state model, the power-law ceiling-jet model assumes a flat infinite ceiling. If the leading edge of the ceiling jet has passed the detector position and not reached a wall or other obstruction, then the model is within its stated parameters. The nondimensional time that the heat front reaches some position, r/H, is given by the equation for t_{2f}^*. The corresponding nondimensional time at response is given by the equation for t_2^*. Setting these equal to each other and solving for r at $t = t_r$ gives the radial distance from the fire to the leading edge of the heat front. Using the equations for a user-entered convective fraction,

$$t_{2f}^* 0.813\left(1 + \frac{r}{H}\right)$$

and

$$\begin{aligned} t_2^* &= \frac{t_r}{A^{-1/5}\alpha_c^{-1/5}H^{4/5}} \\ t_{2f}^* &= t_2^* \\ 0.813\left(1 + \frac{r}{H}\right) &= \frac{t_r}{A^{-1/5}\alpha_c^{-1/5}H^{4/5}} \\ r &= \left\{\left[\left(t_r/ = A^{-1/5}\alpha_c^{-1/5}H^{4/5}\right)/0.813\right] - 1\right\}H \\ r &= \left(t_2^*/0.813 - 1\right)H \end{aligned}$$

Selection of Data for Design and Analysis

In order to calculate the required spacing of heat detectors or sprinklers to respond to a given fire, the following information is required:

1. *System goals*: desired fire size (heat release rate) at response or time to detector response from the start of open flaming
2. Fire growth constant α or t_g
3. Ambient temperature
4. Height above the fuel or ceiling height

In addition to the above, the heat capacity of air at constant pressure, C_p, the density of air, ρ, and the gravitational constant, g, are used in the calculations. It is also necessary to know the characteristics of the detector for which the spacing calculations are being made. Specifically, the response temperature and the RTI of the detector must be known.

Establishing system goals is not within the scope of this chapter. However, it should be pointed out that, no matter what the goals are, they must be expressed in terms of heat release rate or time to detector response. The system's goals may actually be to limit damages to some dollar value, provide adequate escape time, or limit the production of toxic gases. In order to calculate required detector spacing using this system, these goals would have to be translated. For instance, as the fire grows, at what time or heat release rate must the detector respond so that the fire department can be summoned and extinguish the fire before damage levels are exceeded or conditions become untenable due to toxic gases?

Table 40.4 is a list of furniture calorimeter tests done at the National Bureau of Standards [16, 24]. The tests provide a database of heat release rate, particulate production, and radiation from a variety of common furnishings. The table provides the corresponding α or t_g for the calorimeter tests [23]. The virtual time data in the table is the approximate time at which the heat release rate in the test began to follow the $p = 2$ power-law model ($\dot{Q} = \alpha t^2$ kW). Prior to this time, the behavior of the fire cannot be predicted with this model. Figure 40.5 shows some test data along with a power-law curve superimposed.

The data in Table 40.4 can be used to select α or t_g for use in spacing calculations. However, in many cases the data in this table will not match the scenario being studied. If the heat release rate versus time history can be obtained or approximated for the expected fuel, the α or t_g can be calculated using curve-fitting techniques [23].

In most cases, since the exact fuel that will be involved in a fire cannot be known, the rigorous calculation of α is not warranted. Engineering judgment can be used to select α or t_g that approximates the severity of the fire. The data in Table 40.4 suggest a range of 50–500 s for t_g. Only a few rapidly developing fires had a t_g below 50 s. Three slow fires had values above 500 s for t_g.

Table 40.4 also lists the maximum heat release rate reached during the power-law growth. The heat release rate model $\dot{Q} = \alpha t^2$ does not predict when a fuel package stops following the model or when the fuel is depleted. This task is an important point often missed by many designers. A simple test is to calculate the mass of fuel consumed from $t = 0$ to the time of interest. For $p = 2$ power-law fire growth rate, the total energy consumed is

$$E = \int_{t=0}^{t} \dot{Q} = \int_{t=0}^{t} \alpha t^2 \ \text{kJ}$$

$$E = \frac{\alpha t^3}{3} \text{kJ}$$

Knowing the heat of combustion, H_c, for the fuel permits calculation of the mass of fuel necessary to release a given amount of energy in the time period:

$$E = mH_c \ \text{kJ}$$

$$m = \frac{E}{H_c} \text{ g or kg (depending on the units for } H_c)$$

When doing a design or analysis, try several different fire growth rates to determine the effect of their variance on the calculations. In some

Table 40.4 Summary of NBS calorimeter tests

Test no.	Description	Fire growth time (s) (t_g)	α (kW/s^2)	Virtual time (s)	Maximum heat release rate (kW)

cases, the effect will be minimal. In other cases, this type of sensitivity analysis will show that a more thorough analysis of the possible fuels and fire scenarios is warranted.

The selection of an ambient temperature can have a measurable effect on the calculations. The calculations assume that the detector or sprinkler starts out at the same temperature as the ambient air when the fire starts. Hence, if a temperature of 20 °C is assumed for the spacing calculations and the actual temperature at the time of the fire is 10 °C, the system's goals will not be met. For design calculations to be conservative, the lowest expected ambient temperature should be used.

The relationships presented by Heskestad and Delichatsios [21] are correlated to fire test data using the ceiling height above the fuel surface for H. If this height varies, the larger value of H will produce more conservative results in the calculations for detector spacing or response. The most conservative results are obtained when the floor-to-ceiling height is used, since this height is the maximum vertical distance from fuel to detector.

The values for C_p, ρ_0, and g should be 1.040 kJ/(kg·K), 1.1 kg/m^3, and 9.81 m/s^2, respectively. Slight variations in these constants have negligible effects on the calculations.

As previously mentioned, the design or analysis calculations are done for a particular detector or sprinkler. Therefore, it is necessary to know the unit's operating temperature. The response time index or τ_0 and u_0 are also needed. Operating temperature is obtained from manufacturer's data. The detector's sensitivity is best determined by conducting a plunge test [9].

In the absence of plunge test data, a detector's UL-listed spacing can be used as a measure of detector sensitivity. Heskestad and Delichatsios analyzed UL test data and calculated time constants, τ_0, for various combinations of UL-listed spacing and detector operating temperature [22]. The Appendix Subcommittee of *NFPA 72* expanded the table to include a larger selection of detectors [8]. That table is reproduced here as Table 40.5.

Heat Detection Design and Analysis Examples Using the Power-Law Fire Model

Analysis and design problems will be used to show how fire protection engineers can use the techniques presented in this chapter. The examples show the sensitivity of these techniques to changes in variables and input parameters. A design problem is first worked by hand to solve the equations presented earlier in the section on heat detection. The remaining examples were worked using a spreadsheet written to solve the equations.

Example 2 A fire detection system is being designed for an unsprinklered manufacturing building. The area being considered has a large, flat ceiling 5.0 m high. Ambient temperature is normally 20 °C, but on weekends it is cut back to 10 °C. It will be assumed that the fire scenario involves the ignition of a stack of wood pallets. The pallets are stacked 1.5 m (5 ft) high. Fire tests [8] show that this type of fire follows the $p = 2$ power-law equation with a t_g of approximately 150 s. The corresponding α can be calculated:

$$\dot{Q} = \alpha t^2 \text{ kW}$$

$$\alpha = \frac{1055}{t_g^2} = \frac{1055}{150^2} = 0.047 \text{ kW/s}^2$$

The goal is to detect the fire before it reaches a total heat release rate of 2500 kW. Fixed-temperature heat detectors will be used. The detectors have a 57 °C (135 °F) operating temperature and a UL-listed spacing of 30 ft. From Table 40.5 the time constant is found to be 80 s. This time constant is referenced to a gas velocity of 1.5 m/s and can be used with Equation 40.9 to calculate the detector's RTI.

First, use the power-law equation to calculate the time that the fire would reach a total heat release rate of 2500 kW:

$$\dot{Q} = \alpha t^2 \text{ kW}$$

$$t = \sqrt{\frac{\dot{Q}}{\alpha}} = \sqrt{\frac{2500}{0.047}} = 231 \text{ s}$$

The RTI is calculated using Equation 40.9 and a reference velocity, u_0, of 1.5 m/s (5 ft/s):

$$\text{RTI} = \tau_0 u_0^{1/2} = 80\sqrt{1.5} = 98 \text{ m}^{1/2}\text{s}^{1/2}$$

As described previously in Step 5 for design of a proposed system, it is necessary to make a first guess at the required detector spacing. In this case, try using $r = 6.0$ m. Use Equation 40.20 to calculate the nondimensional time, t_{2f}^*, at which the initial heat front reaches the detector. Use the distance from the top of the fuel package to the ceiling for H.

$$t_{2f}^{*} = 0.813\left(1 + \frac{r}{H}\right)$$

$$t_{2f}^{*} = 0.813\left(1 + \frac{6.0}{3.5}\right) = 2.207$$

Next, Equation 40.18 is used to calculate A. Note that in this equation the ambient temperature, T_a, must be expressed as an absolute temperature. In this case add 273 to °C to get K (Kelvin).

$$A = \frac{g}{C_p T_a \rho_o}$$

$$A = \frac{9.81}{1.040(10 + 273)1.1} = 0.030$$

The nondimensional time corresponding to the required response time is now calculated. However, first we must calculate α_c. Assuming a convective fraction of 70 %:

$$\alpha_c = X\alpha = 0.70(0.047) = 0.033\ \text{kW/s}^2$$

$$t_2^{*} = \frac{t}{A^{-1/5}\alpha_c^{-1/5}H^{4/5}}$$

$$t_2^{*} = \frac{231}{(0.030)^{-1.5}(0.033)^{-1/5}(3.5)^{4/5}} = 21.256$$

Since $t_{2f}^{*} > t_2^{*}$, we know that the heat front has passed the detector location. Next, the ratio of the velocity to the nondimensional velocity is calculated:

$$u_2^{*} = \frac{u}{\left(A^{1/5}\alpha_c^{1/5}H^{1/5}\right)}$$

$$\frac{u}{u_2^{*}} = A^{1/5}\alpha_c^{1/5}H^{1/5}$$

$$\frac{u}{u_2^{*}} = (0.030)^{1/5}(0.033)^{1/5}(3.5)^{1/5} = 0.322$$

The ratio of the change in gas temperature to the nondimensional gas temperature is calculated:

$$\Delta T_2^{*} = \frac{u}{A^{2/5}(T_a/g)\alpha_c^{2/5}H^{-3/5}\big)}$$

$$\frac{\Delta T}{\Delta T_2^{*}} = A^{2/5}\left(\frac{T_a}{g}\right)\alpha_c^{2/5}H^{-3/5}$$

$$\frac{\Delta T}{\Delta T_2^{*}} = (0.030)^{2/5}\left(\frac{283}{9.81}\right)(0.033)^{2/5}(3.5)^{-3/5} = 0.855$$

The nondimensional change in gas temperature is now calculated:

$$D = 0.126 + 0.210\left(\frac{6.0}{3.5}\right) = 0.486$$

$$\Delta T_2^{*} = \left[\frac{\left(t_2^{*} - t_{2f}^{*}\right)}{D}\right]^{4/3}$$

$$\Delta T_2^{*} = \left[\frac{(21.256 - 2.207)}{0.486}\right]^{4/3} = 133.142$$

Next, the ratio $u_2^{*}/(\Delta T_2^{*})^{1/2}$ is calculated:

$$\frac{u_2^{*}}{\left(\Delta T_2^{*}\right)^{1/2}} = 0.59\left(\frac{r}{H}\right)^{-0.63}$$

$$\frac{u_2^{*}}{\left(\Delta T_2^{*}\right)^{1/2}} = 0.59\left(\frac{6.0}{3.5}\right)^{-0.63} = 0.420$$

Y is now calculated:

$$\Upsilon = \frac{3}{4}\sqrt{\frac{u}{u_2^{*}}}\sqrt{\frac{u_2^{*}}{(\Delta T_2)^{1/2}}}\left(\frac{\Delta T_2^{*}}{\text{RTI}}\right)\left(\frac{t}{t_2^{*}}\right)D$$

$$\Upsilon = \frac{3}{4}\sqrt{0.322}\sqrt{0.420}\left(\frac{133.142}{98}\right)\left(\frac{231}{21.256}\right)(0.486) = 1.979$$

The resulting temperature of the detector at $t = 231$ s, $T_d(t)$, can now be calculated. Assume that the temperature of the detector at the start of the fire, $T_d(0)$, is the same as ambient temperature, T_a.

$$\Delta T_d = T_d(t) - T_d(0)$$
$$= \frac{\Delta T}{\Delta T_2^*} \Delta T_2^* \left[1 - \left(\frac{1 - e\Upsilon}{\Upsilon}\right)\right]$$
$$\Delta T_d = T_d(t) - T_d(0)$$
$$= 0.855(133.142)\left[1 - \left(\frac{1 - e^{-1.979}}{1.979}\right)\right]$$
$$\Delta T_d = T_d(t) - T_d(0) = 64.264$$
$$T_d(t) = \Delta T_d = T_d(0) = 64.264 + 10$$
$$= 74.264 = 74°C$$

After 231 s, when the heat release rate has reached 2500 kW, the detector located 6 m from the fire axis has reached an approximate temperature of 74 °C. Note that the answer has been rounded to two significant digits, one more than the least precision of any of the variables. This rule is the alternate rule for rounding as discussed in the introduction of this chapter.

The detector actuation temperature is 57 °C. This result indicates that the detector has responded before the fire has reached 2500 kW. Since the calculated temperature is higher than the actuation temperature, a larger r can be tried. The calculations should be repeated until the calculated detector temperature is approximately equal to the actuation temperature.

For this example the answer converges on a radial distance of approximately 7.4 m. The spacing between detectors is

$$S = r\sqrt{2} = 7.4\sqrt{2} = 10.5 \text{ m}$$

Example 3 This example will show how an existing heat detection system or a proposed design can be analyzed to determine its response time or fire size at response. The scenario used in Example 2 will be repeated, except that the manufacturing building has an existing system of heat detectors, which are spaced evenly on the ceiling at 15.0-m intervals. The detector characteristics are the same as above. The actuation temperature is 57 °C and the RTI is 98 $m^{1/2} \cdot s^{1/2}$. The ceiling height is 5 m, and the height of the pallets is 1.5 m. Ambient temperature is 10 °C. α is 0.047 kW/s^2 (t_g = 150 s) and α_c is 0.033 kW/s^2.

The maximum radial distance from the fire axis to a detector is calculated first, using Equation 40.5.

$$S = r\sqrt{2} \text{ m}$$
$$r = \frac{S}{\sqrt{2}} = \frac{15.0}{\sqrt{2}} = 10.6 \text{ m}$$

The next step in the analysis is to estimate the response time of the detector or the fire size at response. In the design above, the fire grew to about 2500 kW in 231 s when the detector at a distance of 7 m responded. The radial distance in this example is larger and should result in a slower response and larger fire size at response. A first guess at response time might be 6 min or 360 s. The fire size (total heat release rate) at 360 s is

$$\dot{Q} = \alpha t^2 \text{ kW}$$
$$\dot{Q} = 0.047(360)^2 = 6091 \text{ kW}$$

The remaining calculations for the resulting detector temperature are similar to those in Example 2. Rather than show the detail, a spreadsheet was used to complete the calculations. The resulting detector temperature at 360 s was calculated to be approximately 84 °C.

This result indicates that the detector response time is less than the estimated 6 min. Therefore, a smaller response must be tried. If the calculated temperature were lower than the actuation temperature, a larger t would be tried. The calculations are repeated until the calculated detector temperature is approximately equal to the actuation temperature. In this case, the response time converges at 295 s. This result corresponds to a fire size at response of 4070 kW. It is at this time and heat release rate that the detector temperature reaches its actuation temperature of 57 °C.

This example assumes that the fire continues to follow the power-law relationship through the burning period. If there is not enough fuel available, it is possible for the heat release rate curve to flatten out before reaching 4070 kW. These calculations do not predict when this development will happen. These calculations also do

not predict how the detector temperature changes after the fire stops following the power-law relationship. It may be that sufficient heat continues to be released and the detector eventually responds. It is also possible for the fire gases to cool sufficiently to preclude detector actuation unless additional fuel becomes involved in the fire.

Comparing Example 2 with Example 3 shows how detector spacing affects response time. A difference in spacing of 4.4 m (15–10.6 m) results in a difference of approximately 64 s in the detector response time. Because the fire is accelerating according to the $p = 2$ power-law relationship, the resulting difference in fire size at response is 1570 kW.

Example 4 A warehouse is used to store sofas and other furniture. The sofas are similar to one tested by the National Bureau of Standards in their furniture calorimeter [30]. Burning characteristics are assumed to be similar to the sofa used in Test 38: [23, 30] $\alpha = 0.1055\ \text{kW/s}^2$, $t_g = 100$ s; peak heat release rate = 3000 kW. The sofas are stored one or two high. Assume a convective fraction of 65 %.

The building has a flat roof and ceiling. The distance from the floor to the ceiling is 4.6 m. When the sofas are stacked two high, the distance from the top of the fuel package to the ceiling is 2.4 m. Ambient temperature in the warehouse is kept above 10 °C (Fig. 40.6).

Based on maximum allowable property loss goals established by the owner, it is desirable to detect a fire and notify the fire department prior to a second fuel package becoming involved. The original NBS report [30] contains data on radiation measured during Test 38. This information can be used along with other techniques presented in this handbook to determine when a second item might ignite. For instance, it might be determined that furniture across a 2-m aisle might ignite when the fire reaches a total heat release rate of 3000 kW. The objective would then be to detect the fire soon enough so that the fire can be extinguished or controlled before the fire reaches a total of 3000 kW. In this example, it is assumed that the fire must be detected when it reaches a total heat release rate of about 2000 kW.

The fire detection system will consist of fixed-temperature heat detectors connected to a control panel that is, in turn, connected to the local fire department. The detector to be used has a fixed-temperature rating of 57 °C and an RTI of $42\ \text{m}^{1/2} \cdot \text{s}^{1/2}$.

The problem is determining the spacing of detectors required to detect this fire. When the computer program runs, the user is prompted for all of the above information. In this example, the data are fixed except for the distance from the ceiling to the flame origin. If the distance between the top of the fuel and the ceiling (2.4 m) is used, the calculations indicate that the

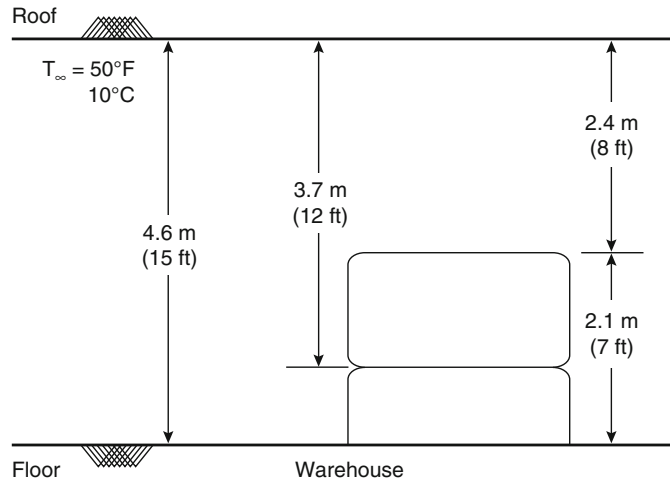

Fig. 40.6 Example 4: warehouse

detectors must be spaced 7.3 m apart to respond when the fire reaches a heat output of 2000 kW.

For a worst-case analysis, the distance from the floor to the ceiling (4.6 m) is used. This distance results in a required detector spacing of 5.9 m.

A more realistic worst-case scenario would be when the sofas are not stacked two high. With one sofa on the floor, the distance from the fuel to the ceiling would be about 3.7 m. The required detector spacing would then be 6.5 m.

These results are summarized in Table 40.6. This table clearly shows the relationship between ceiling height and detector response. The greater the distance from the fire to the ceiling, the closer the detectors must be spaced to respond within the goals of the system. Designs based on the floor-to-ceiling distance are conservative and representative of a worst-case condition. More realistic designs are based on the most probable or the greatest expected vertical clearance between fuel and detector.

Example 5 For the same conditions in Example 4, if the detector spacing is fixed at 10.3 m ($r = 7.3$ m), how does the ceiling height affect the response time of the system?

Using the spreadsheet, the results, after rounding, are summarized in Table 40.7.

Example 6 This example will show how to select a detector type to economically meet the system's goals. The fire scenario and goals used in Examples 4 and 5 will be used: $H = 2.4$ m; $T_a = 10$ °C; RTI = 42 $m^{1/2} \cdot s^{1/2}$; X = 65 %, $t_g = 100$ s.

Table 40.6 Example 4: ceiling height or height above fuel versus detector spacing

Ceiling height, H (m)	Required spacing, S (m)
2.4	10.3
3.7	9.2
4.6	8.4

Table 40.7 Example 5: ceiling height or height above fuel versus response time

Ceiling height, H (m)	Required spacing, t_r (s)
2.4	140
3.7	150
4.6	160

In Example 4, it was found that heat detectors with a fixed temperature rating of 57 °C and an RTI of 42 $m^{1/2} \cdot s^{1/2}$ must be spaced 10.3 m apart to meet the system's goals—a response at 2000 kW. Here, the spacing of rate-of-rise heat detectors will be estimated.

The detector to be used is rated to respond when its temperature increases at a rate of 11 °C minutes or more. The detector's RTI will be assumed to be the same as the detector in Example 4. The calculation procedure is the same as for fixed temperature detectors except that, in the last step, the equation for the rate of temperature change is used:

$$\frac{dT_d(t)}{dt} = \frac{4}{3}\frac{\Delta T}{\Delta T_2^*}\Delta T_2^{*1/4}\frac{\left(1 - e^{-\Upsilon}\right)}{\left(t/t_2^*\right)D}$$

Solving the equations, it is found that the rate-of-rise heat detectors can be spaced up to 25 m apart and respond at approximately 2000 kW total heat release rate.

If the total area of the warehouse is 5000 m^2, approximately 48 fixed-temperature heat detectors would be required to meet the established goals. The same goals can be met with approximately eight rate-of-rise heat detectors. Additional detectors might be required due to obstructing beams or walls. It should also be pointed out that the use of m^2 for calculating the required number of units is only an estimate. The detector does not cover an area that is 625 m^2 (25 m × 25 m). It is covering a circular area having a radius no more than about 17.7 m. That is, all points on the ceiling must be within the protection radius of a detector for the calculations to be valid. If one used a "rated area" for a detector rather than a radial measurement, it could be concluded that a single detector in this example could cover a space that was 125 m long if it were only 5 m wide.

By trying different detector types or detectors with higher sensitivities, project goals might be met with a fewer number of detectors. The scenario in this example shows that, to detect the

same fire, a much greater number of fixed-temperature heat detectors than rate-of-rise heat detectors is required. This conclusion is not always the case. Many fires will develop slowly and cause high ceiling temperatures without ever exceeding the rate of temperature rise necessary to actuate a rate-of-rise heat detector. As a backup, most commercially available rate-of-rise heat detectors have a fixed-temperature element also. The rate-of-rise element and the fixed-temperature element should be considered separately when designing or analyzing a system.

Example 7 In this example, a combination fixed-temperature and rate-of-rise heat detector will be analyzed and the response of the two elements will be compared. For an installed spacing of 10.0 m ($r = 0.707$ m), the effect of fire growth rate on response time will be shown. The following conditions from Examples 4, 5, and 6 will be repeated: $H = 2.4$ m; $T_a = 10\,^{\circ}\text{C}$; RTI $= 42\ \text{m}^{1/2} \cdot \text{s}^{1/2}$; X = 65 %. The fixed-temperature element response threshold is $T_r = 57\,^{\circ}\text{C}$, and the rate-of-rise threshold is $dTr/dt = 11\,^{\circ}\text{C/min}$.

The results are shown in Table 40.8 and Fig. 40.7. For fire growth times up to $t_g = 509$ s, the rate-of-rise element responds faster. For fires that grow slower (increasing t_g), the fixed-temperature element will respond faster.

For larger installed spacings, such as the 25 m spacing calculated in the previous example for the spacing of the rate-of-rise detector, the cross-over point occurs sooner. The results for a 25 m spacing are shown in Table 40.9 and Fig. 40.8. For fire growth times up to $t_g = 228$ s, the rate-of-rise element responds faster. For fires that grow slower (increasing t_g), the fixed-temperature element will respond faster.

Table 40.8 Response time as a function of fire growth time, t_g

	Response time, t_r (s)	
t_g	Fixed temperature	Rate of rise
50	85	31
100	135	53
200	219	98
300	297	155
400	373	241
500	447	426
509	454	454
600	521	835

Example 8 In this example, the effects of fire growth rate on detector spacing will be examined. The scenario used in Examples 4 through 7 will be used again. The following conditions from these examples will be repeated: $H = 2.4$ m; $T_a = 10\,^{\circ}\text{C}$; RTI $= 42\ \text{m}^{1/2} \cdot \text{s}^{1/2}$; X = 65 %. The fixed-temperature element response threshold is $T_r = 57\,^{\circ}\text{C}$ and the rate-of-rise threshold is $dT_r/dt = 11\,^{\circ}\text{C/min}$.

In Examples 4, 5, and 6, the rate of fire growth followed the power-law equation with an α of 0.1055 kW/s^2 or $t_g = 100$ s. Calculations were done for several values of t_g. The results are summarized in Table 40.10 and Fig. 40.9.

For fixed-temperature detectors, if the fire grows at a faster rate (smaller t_g), a smaller spacing is required to meet the system's goals. If the fire grows at a slower rate, a larger detector spacing is allowed. This relationship clearly shows the effects of thermal lag on detector response. At slow rates of growth, the detector is immersed in the hot fire gases and, despite thermal lag, has time to absorb the heat before the fire reaches the maximum permissible heat release rate. The effects of thermal lag are less important at slow rates of fire growth.

The rate-of-rise detector also experiences thermal lag. However, the curve peaks at approximately $t_g = 110\ \text{m}^{1/2} \cdot \text{s}^{1/2}$ and $S = 25$ m. For the rate-of-rise detector, as the fire growth rate slows (larger t_g), thermal lag decreases as it did for the fixed-temperature detector. However, as the rate of fire growth slows, so does the rate of change of the detector's temperature. For this particular detector and fire scenario, at fire growth times greater than about 110 s, the detector spacing must be reduced so that the threshold rate of change of the detector temperature is reached before the maximum permissible heat release rate is reached.

Example 9 In this example a detector is exposed to the ceiling jet for a fire with $t_g = 150$ s and a 75 % convective fraction. Ambient temperature is 10 °C. The ceiling is 4 m high, and the detector is located at a radial distance of 5 m from the fire.

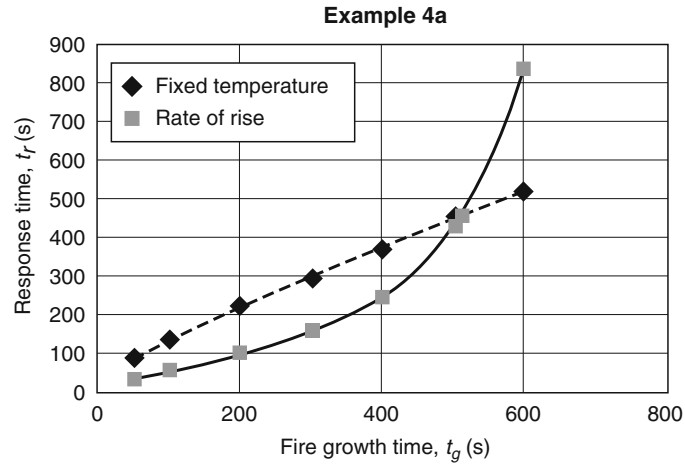

Fig. 40.7 Response time as a function of fire growth time, tg

Table 40.9 Response time as a function of fire growth time, t_g

	Response time, t_r (s)	
t_g	Fixed temperature	Rate of rise
50	168	77
100	269	140
200	448	355
228	497	497
300	619	1330

The RTI of the detector is 50. Plot the detector temperature and the fire-gas temperature at the detector location for t up to 240 s.

The detector remains at ambient temperature until the ceiling jet first reaches the detector position. At what time does the ceiling jet first reach the detector? This result is found by setting $t_{2f}^* = t_2^*$ and solving for t. First, α_c is calculated:

$$\alpha = \frac{t_g^2}{1055} = \frac{1055}{150^2} = 0.047\ \text{kW/s}^2$$

$$\alpha_c = X\alpha = 0.75(0.047) = 0.035\ \text{kW/s}^2$$

$$t_{2f}^* = t_2^*$$

$$0.813\left(1 + \frac{r}{H}\right) = \frac{t}{A^{-1/5}\alpha_c^{-1/5}H^{4/5}}$$

$$t = 0.813\left(1 + \frac{r}{H}\right) = A^{-1/5}\alpha_c^{-1/5}H^{4/5}\ \text{s}$$

$$t = 0.813\left(1 + \frac{5}{4}\right)$$

$$= \left(0.030^{-1/5}\right)\left(0.035^{-1/5}\right)\left(4^{4/5}\right)$$

$$= 21.86 = 22\ \text{s}$$

The heat front reaches the detector at about 22 s, and heating begins. Prior to this point, the detector and gas temperature surrounding the detector are at ambient temperature.

The method to calculate the detector temperature is the same as in previous examples. To calculate the change in ceiling-jet gas temperature, combine the following equations and solve to ΔT:

$$\Delta T_2^* = \frac{\Delta T}{A^{2/5}(T_a/g)\alpha_c^{2/5}H^{-3/5}}$$

and

$$\Delta T_2^* = \left[\frac{\left(t_2^* - 2_{2f}^*\right)}{(0.126 + 0.210r/H)}\right]^{4/3}$$

$$\Delta T = A^{2/5}\left(\frac{T_a}{g}\right)\alpha_c^{2/5}H^{-3/5} \times \left[\frac{\left(t_2^* - 2_{2f}^*\right)}{(0.126 + 0.210r/H)}\right]^{4/3}$$

A spreadsheet solution is shown in Table 40.11 and graphed in Fig. 40.10.

Example 10 A sprinkler system is being installed in a large exhibition hall. The building has a flat roof deck supported by open space frame trusses. The distance from the underside

of the roof deck to the floor is 12 m. Ambient temperatures do not usually fall below 5 °C.

Three different designs for the sprinkler system have been proposed. All three are designed to provide the same water density over a specified area. Each proposal uses a sprinkler with a temperature rating of 74 °C and an RTI of 110 $m^{1/2} \cdot s^{1/2}$. The only difference among the three systems is the spacing of the sprinklers and the branch lines that feed them. The first proposal uses a square array with a spacing of 3.0 m. The second and third proposals are based on square array spacings of 3.7 m and 4.6 m, respectively.

200	116	88
210	124	96
220	132	104
230	140	112
240	148	120

What effect will the three different spacings have on the size of the fire when the system responds? Assume two different fire scenarios. In the first, the fire grows at a moderate rate with $t_g = 200$ s. The second fire scenario has a slower fire growth rate with $t_g = 500$ s. For both, assume a convective fraction of 75 %. Results of the calculations are shown in Table 40.12 after rounding.

The calculations show an increase of about 25 % in the fire size at response when the spacing is increased 50 % from 3.0 to 4.6 m. The increased spacing may result in a lower system cost. However, closer spacings mean that the sprinkler system will probably respond sooner. The fire protection engineer can use this type of analysis to assist in choosing a system that best meets the project's overall goals.

Example 11 A fire impacting elevator machinery can result in passengers or fire fighters being carried to a fire floor or being trapped between floors. Elevator safety codes generally do not require any sprinkler protection or detection at

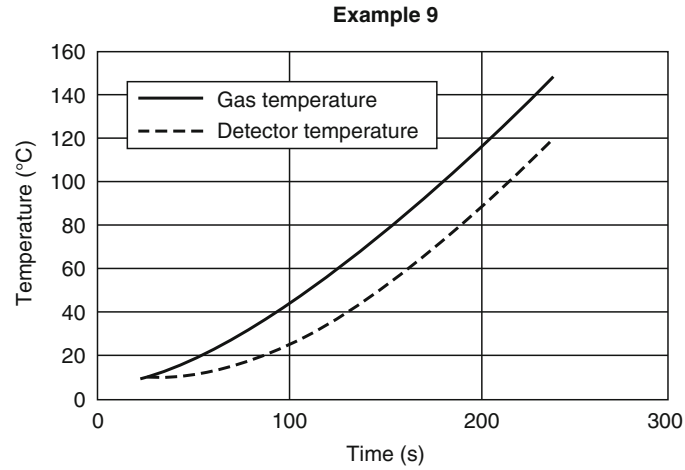

Fig. 40.10 Example 9: ceiling jet and detector temperature as a function of time

4.6	400	4100	890	3400

the top of shafts since the fuel load is typically insufficient to actuate a sprinkler or affect persons in the cars.

Smoke detection is used in elevator lobbies and machine rooms to recall elevators to a safe level when smoke threatens the elevator shaft. The presence of sprinklers in the elevator machine room presents another risk: the possibility of water discharge on energized controllers and motors and on the elevator brakes. To reduce this risk, in addition to smoke detection, heat detectors may be used to ensure that equipment is de-energized on or prior to the discharge of water. To accomplish this task, some codes may require a heat detector with a lower temperature rating and a lower RTI within 0.61 m of every sprinkler in an elevator machine room. Are these requirements sufficient to assure response before the sprinkler to a range of possible fire scenarios?

Solution For this example, use an ambient temperature of 15 °C and a ceiling height or clearance of 4 m. Assume the actuation temperature of the sprinklers is 74 °C and the actuation temperature of the heat detectors is 57 °C. The RTI of the sprinklers is 110 $m^{1/2} \cdot s^{1/2}$, and the RTI of the detectors is 42 $m^{1/2} \cdot s^{1/2}$. Spacing of the sprinklers is 3.0 m. Calculate the response of the sprinkler and the heat detector to a fast fire, $t_g = 50$ s, and a slow fire, $t_g = 600$ s. Assume a 75 % convective fraction.

A sprinkler spacing of 3.0 m results in a worst-case radial distance of 2.12 m. The heat detector could be an additional 0.61 m beyond at $r = 2.73$ m. The results of the calculations are summarized in Table 40.13.

These calculations show that the heat detector will respond before the sprinkler. Depending on the actual conditions, additional calculations should be tried for different fire scenarios and for changes in other variables such as RTI, ambient temperature, ceiling clearance, and so forth.

Table 40.13 Example 11: sprinkler and heat detector response to different fire growth rates

	Response time (s)	
	$t_g = 50$ s	$t_g = 600$ s
Sprinkler	65	370
Heat detector	50	300

Smoke Detection

In order to determine whether or not a smoke detector will respond to a given $\dot{Q}_{cr}$, a large number of factors must be evaluated. These include smoke aerosol characteristics, aerosol transport, detector aerodynamics, and sensor response.

Smoke aerosol characteristics at the point of generation are a function of the fuel composition, the combustion state (smoldering or flaming), and the degree of vitiation of the combustion air. The characteristics considered include particle size and distribution, particle number or concentration at various sizes, composition, color, and refractive index. Given the dynamic nature of fire growth and spread and fuels involved, ventilation conditions will change over time, thus affecting the smoke produced.

Transport considerations include (1) changes to the aerosol characteristics that occur with time and distance from the source and (2) transport time. Changes in the aerosol largely relate to the particle size and concentration and result from the processes of sedimentation, agglomeration, and coagulation. Transport time is a function of the characteristics of the travel path from the source to the detector, which include ceiling height and configuration (sloped, beamed, etc.), intervening barriers such as doors, and buoyancy effects such as layering and thermal inversions.

Once smoke reaches the detector, other factors become important, namely the

aerodynamic characteristics of the detector and the type of sensor. The aerodynamics of the detector relate to the ease with which smoke can pass through the detector housing and enter the sensor. In addition, the location of the entry portion of the housing relative to the velocity profile of the detector normal to the plane of the ceiling is also a factor. Finally, different sensing modes (e.g., ionization or photoelectric) will respond differently, depending on the characteristics of the transported aerosol. Within the family of photoelectric devices, there will be variations depending on the wavelengths of light and the scattering angles employed. Also, algorithms used to sample and weight the sensor's response are introduced by the manufacturer and affect the detector's response.

Standard practice for the design of smoke detection systems is much the same as that for heat detection systems. Recommended spacing criteria are established based on detector response to a specific parameter, such as the optical density within an enclosure. A variety of smoke tests are used to verify that the detector responds between defined upper and lower activation thresholds and within required response times to a range of different types of smoke. This information translates into recommended spacing criteria intended to ensure that the detector responds within defined parameters. In some cases, the recommended spacing can be increased, or must be decreased, depending on factors such as compartment configuration and air flow velocity [8].

In applications where estimating the response of a detector is not critical, the recommended spacing criteria provide sufficient information for the design of a basic smoke detection system. If the design requires detector response within a certain time frame, optical density, specified heat release rate, or temperature rise, then additional analysis may be required. In this case, information concerning the expected fuel, fire growth, sensor, and compartment characteristics is required. The following examples show various performance-based approaches to evaluating smoke detector response.

Modeling Smoke Detector Response: General

The response of smoke detectors to fire conditions is not easily modeled. The response characteristics of smoke detectors vary widely compared with thermal detectors. In addition, less is known about the production and transport of smoke in the early stages of a fire. Natural and forced air currents have a larger effect on the movement of smoke at the time of interest (very early in the fire) than they do on the stronger thermal currents required to alarm heat detectors.

A comparison of how smoke detectors operate with the smoke measurement methods most often employed and reported by researchers shows that smoke measurements do not generally include the factors that we need to model smoke detector response [13]. Thus, there is a gap between the data generated by fire researchers and the data needed to model smoke detector response.

For example, fire researchers most often measure and report data on heat release rate, temperature and velocity of fire gases, and the optical density or obscuration per unit distance of the smoke at various locations. Of these, only optical density and obscuration relate to smoke. Although called *obscuration*, it is more accurately called *attenuation* since the light beam may be absorbed, reflected, or refracted by the smoke. These are calculated as follows:

Percent obscuration, O:

$$O = 100\left(I - \frac{I}{I_0}\right)$$

Percent obscuration per unit distance, O_u

$$O_u = 100\left[1 - \left(\frac{I}{I_0}\right)^{1/I}\right]$$

Optical density, D

$$D = \log_{10}\left(\frac{I_0}{I}\right) = -\log_{10}\left(\frac{I}{I_0}\right)$$

Optical density per unit distance, D_u (m^{-1})

$$D_u = \frac{D}{l} = \frac{1}{l}\log_{10}\left(\frac{I_0}{I}\right) = -\log_{10}\left(\frac{I}{I_0}\right)\mathrm{m}^{-1}$$

where I_0 is the initial intensity of a light beam reaching a photocell, I is the intensity of the light beam in the presence of smoke, and l is the distance between the source and the photocell.

Optical density and obscuration are useful data for evaluating visibility. However, the only commercially available smoke detector that operates by sensing the attenuation of a light beam is the projected-beam-type smoke detector. Further, these measurements are sensitive to the wavelength of light used. Thus, to be valuable for estimating the response of a projected-beam smoke detector, the data must be measured and reported using the same wavelength as the light source used by the detector.

The two most common types of smoke detectors are ionization type and photoelectric type. Neither type operates using light attenuation. Without a correlation between the optical density data and the response characteristics of a particular detector, accurate modeling is not possible.

In addition, detectors often use complex response algorithms rather than simple threshold or rate-of-change response levels. The algorithms are used to reduce false and nuisance alarms and to enhance fire signature matching. These algorithms vary from detector to detector and are generally not published by the manufacturers. Thus, even if correlations between optical density and the response of scattering- and ionization-type smoke detectors were available, the actual response of each model is affected by the signal sampling algorithm.

Nevertheless, there are methods that can be used to grossly estimate smoke detector response. These estimation methods may not provide accurate prediction of time to detector response because the potential errors in the estimation methods are not generally known and the response algorithms for a particular detector are not known. Without knowledge of the accuracy of the models and the potential errors, these estimation methods should not be used to compare detector response to other model calculations such as egress time calculations or time to untenability. Estimation methods are best used to compare changes in the response of a particular detector as a result of changes in spacing or location, while holding all other variables constant.

In addition to these estimation methods, actual fire tests with detectors present may provide information to compare smoke detector response to other factors such as egress time, structural response, heat release rate, and so forth. Product performance tests may be sources of data. Although the actual response may not be reported in manufacturer's literature, the minimum and maximum permissible performance imposed by the test standard provides ranges of possible response.

Modeling Smoke Detector Response: Light Obscuration Smoke Detectors

For projected-beam-type detectors, fire or smoke models that calculate the optical density per unit length, D_u, in a space or the total optical density in the path of the detector, D, may be used to determine when the detector would respond. Manufacturer specifications will typically indicate at what levels of total obscuration or total optical density the detectors respond. Projected-beam smoke detectors generally have adjustable response thresholds.

Many fire models estimate the unit optical density, D_u, in a uniform upper layer or volume. This method is referred to as zone modeling. The optical density over the entire length of the beam is then determined by multiplying D_u by the path length, l. The path length is the distance between the source and receiver or the projected-beam smoke detector. This method assumes homogenous distribution of smoke throughout the path, an assumption that may not be valid.

Another method to model the response of projected-beam obscuration-type detectors is to calculate the unit optical density, D_u, at several discrete points or in several discrete segments between the source and the receiver of the projected-beam smoke detector. This approach

is a form of field modeling. The optical density per unit length is then multiplied by the length of that particular segment. The total optical density of the path is then the sum of all of the densities for the individual segments.

Modeling Smoke Detector Response: Light Scattering (Photoelectric) Smoke Detectors

The amount of light scattered by smoke is very complex and is related to factors such as the particle number density and size distribution, refractive index, the wavelength of the light source, and the angle between the source and the receiver. Some of these variables can be described by the manufacturer for a particular detector. Some require information about the smoke produced by the fuel and its transport to the detector location.

Information about smoke properties related to light scattering is presently limited to a few types of fuels and is not readily available to practicing fire protection engineers. In addition, the data may not be in a useable format. For instance, the data must match the wavelength of the light source used in the detector being modeled. Scattering data at other wavelengths introduces errors and uncertainties.

Meacham has shown that it is possible to model the response of light-scattering detectors using information about smoke properties obtained by small-scale testing of various fuels [31, 32]. However, the recommended test methods have not been further developed, tested, or incorporated into fire test programs.

At the present time, there are no practical methods available to directly model the response of light-scattering-type detectors. However, obscuration or optical density modeling, as discussed above for obscuration-type detectors, can be used in a limited way to estimate scattering-type smoke detector response.

A scattering-type detector responds at different optical densities for different types of smoke. For example, a scattering-type smoke detector that responds at an optical density of .029 m^{-1} (2.0 %/ft obscuration) to smoke produced by a smoldering gray cotton lamp wick may not respond until an optical density of 0.15 m^{-1} (10 %/ft) is reached for smoke from a kerosene fire. At the response threshold, both types of smoke are scattering the same amount of light to the receiver of the scattering photoelectric smoke detector. There are many factors involved in this effect. One is that the darker smoke from the kerosene fire does not reflect as much light as the lighter colored smoke from the lamp wick.

Another way to understand the differing response of a scattering-type detector to two types of smoke is to consider the amount of light being scattered when both smoke samples have the same optical density. Both samples of smoke equally block our vision of the light reflected by an object. One type of smoke may be composed of large, highly reflective smoke particles that cause the incident light to scatter in many directions. Thus, it reduces the amount of light in the forward direction. The other type of smoke may consist of a smaller number of larger particles that absorb light more readily than they reflect it. Though they have equal optical densities, one is more likely to scatter light and set off a scattering-type detector.

In order to model the response of a scattering-type detector using obscuration or optical density, it is necessary to know the optical density required for a particular type of smoke to alarm a particular model detector. For example, many manufacturers label their smoke detectors with a unit optical density, D_u, or unit obscuration, O_u, based on a calibration test that is part of UL standard number 268 [33]. That number indicates the unit optical density required for that detector to respond to smoke having very specific characteristics. The optical density required to alarm a particular detector as quoted by the manufacturer is just one value for a given particle size distribution, concentration, color, and so on used in the laboratory calibration test of that model detector. If the smoke and conditions are similar to that used in the test of the detector, the specified alarm threshold can be used in calculations.

It is not sufficient to have data for a particular fuel and detector combination. It is known that smoke changes as it moves away from a fire [34]. There may be changes in the number, size, shape, and velocity of the particles. The optical density at response to any smoke signature other than the laboratory calibration test will be different and will vary with different fuels and burning modes.

Threshold response data to various fuels for a particular detector are not readily available. Some manufacturers may provide data if available and when requested. Product performance and safety tests as well as fire tests with detectors present are useful sources of limiting performance data. Product standards typically test detectors in rooms with specified fuels and smoke buildup rates and velocities. The detectors must respond at certain levels or within certain time limits. Although the exact performance data may not be made available, the test limits are useful for estimating the range of possible detector response.

Geiman and Gottuk [35] have provided further guidance on selecting general optical density (OD) at alarm thresholds. This guidance was developed from data collected from full-scale tests conducted by the U.S. Navy [36, 37], the Fire Research Station [38], and the Indiana Dunes Tests [39] using a wide variety of ion and photoelectric smoke detectors with smoldering and flaming fires. Table 40.14 presents the arithmetic means of the cumulative 20, 50, and 80 % of the OD at alarm thresholds for each combination of detector and fire type. The data represent nominal sensitivity values ranging from 0.0071 to 0.0288 OD/m (0.5–2 %/ft) for ionization detectors and from 0.0071 to 0.0508 OD/m (0.5–3.5 %/ft) for photoelectric detectors. These ranges capture most alarm settings for which the detectors will be used in practice.

Geiman and Gottuk also investigated using the "nominal" detector sensitivity, that determined by a standard laboratory test such as UL. They determined that using the nominal sensitivity as the alarm threshold provides extremely poor results. They found the majority of the 20 % OD alarm thresholds were greater than the nominal sensitivity levels of the detectors indicating that premature detector response was predicted. Except for ionization detectors with flaming fires, using the nominal sensitivity of the detector as the alarm threshold with OD/m data would only have been approximately 21 % effective at signifying an actual alarm based on the data studied. The use of the nominal detector sensitivity as an alarm threshold will generally result in predicting alarms before they actually occur. However, their results suggested that typical responses (i.e., 50 %) of ionization detectors with flaming fires could be reasonably predicted using the nominal sensitivity.

The Geiman and Gottuk work evaluated the use of an alarm threshold of 0.14 OD/m (9.4 %/ft) for modeling. This OD/m value represents the upper bound in the UL smoke detector tests [40, 41] and was compared to the optical density measurements at the time of alarm for all cases in the test data set. They found that, using the nominal detector sensitivity, the alarm threshold of 0.14 OD/m provided a much higher level of certainty that a detector will have alarmed. At a measured smoke optical density of 0.14 OD/m in the tests, 91 % of the ionization detectors alarmed for flaming fires and

Table 40.14 Average OD alarm thresholds for all test series and nominal detector sensitivities

OD alarm threshold (%)	Fire type	Ionization detectors (OD/m)	Photoelectric detectors (OD/m)
20	Flaming fires	0.007 ± 0.004	0.031 ± 0.016
	Smoldering fires	0.045 ± 0.028	0.032 ± 0.016
50	Flaming fires	0.021 ± 0.005	0.063 ± 0.029
	Smoldering fires	0.113 ± 0.048	0.059 ± 0.019
80	Flaming fires	0.072 ± 0.027	0.106 ± 0.039
	Smoldering fires	0.176 ± 0.052	0.110 ± 0.034

Source: Geiman and Gottuk [35, p. 204]

65 % for smoldering fires. Similarly, 86 % of the photoelectric detectors alarmed for flaming fires and 85 % for smoldering fires at a measured smoke optical density of 0.14 OD/m. For all but one case, over 75 % of the photoelectric detectors alarmed for both flaming and smoldering fires.

According to Geiman and Gottuk [35], an alarm threshold of 0.14 OD/m provides a relatively high level of confidence in predicting detector alarms. However, that value is not necessarily optimized or narrowly defined. For example, many detectors alarmed at OD/m values less than 0.14 OD/m. The use of this alarm threshold will lead to estimated alarm response times that are potentially longer than would actually occur [35].

Modeling Smoke Detector Response: Ionization Smoke Detectors

The signal produced by the chamber of an ionization detector has been shown to be proportional to the product of the number of particles and their diameter [42–45]. The exact signal produced by an ionization smoke detector is given by a more complex equation in the literature and requires an additional number called the chamber constant. The chamber constant varies with each different model of detector.

Given the quantity and size distribution of smoke particles and the chamber constant (from the manufacturer), it is possible to model the ionization smoke detector. Unfortunately, there are no fire models that provide the required detector model input. In addition, manufacturer specifications do not presently include chamber constants.

Newman modified the chamber theory to account for ionization detector sensitivity to the small electrical charge carried by some fire aerosols [46]. Newman also developed a method to model ionization smoke detector sensitivity as a function of the soot yielded by a particular fuel. Using his method, the change in a detector's signal, ΔI, can be related to the optical density of smoke measured at a particular wavelength, $D_{u\lambda}$.

To use the method proposed by Newman it is necessary to know what change in detector chamber signal, ΔI, will cause a detector or system to alarm. Although manufacturers do not presently provide these data, they may be persuaded to do so in the future.

Newman's work was done using a small-scale apparatus and three ionization smoke detectors. A wider range of tests, including some full-scale testing, is needed to verify this method. Presently, the only way to model ionization detector response is to use the optical density estimations as discussed for scattering-type photoelectric smoke detectors.

Modeling Smoke Detector Response: Entry Resistance

In addition to smoke characteristics and the detector's operating mechanism, the ability to get the smoke into the chamber affects the response of the unit. For spot-type photoelectric- and ionization-type smoke detectors, entry resistance is caused by bug screens, chamber design, and the detector's aerodynamic characteristics.

In a scenario where the optical density at the detector location is increasing with time, the optical density inside the detector chamber will always be less than that outside the detector chamber. Similarly, if a detector is placed in a smoke stream having a constant optical density, there will be a time delay before the optical density inside the chamber approaches that outside the detector. As with heat transfer to heat detectors, smoke entry resistance can be characterized by a detector time constant, τ:

$$\frac{dD_{\mathrm{ui}}}{dt} = \frac{1}{\tau}(D_u - D_{\mathrm{ui}})\mathrm{s}^{-1} \cdot \mathrm{m}^{-1}$$

where

$D_{\mathrm{ui}}(\mathrm{m}^{-1})$ = Optical density per unit length inside the detector chamber
$D_u(\mathrm{m}^{-1})$ = Optical density per unit length outside the detector
τ = Detector time constant (s)

If the time constant and the rate of change of optical density outside the detector are constant,

then this equation can be solved. Further, substituting D_{ur} for the optical density outside the detector at response and D_{uo} for the optical density required inside the detector to produce response yields the following: [47, 48]

$$D_{ur} = D_{uo} + \tau\left(\frac{dD_u}{dt}\right) \times \left\{1 - \exp\left[-D_{ur}\frac{1}{\tau}\left(\frac{dD_u}{dt}\right)\right]\right\} \mathrm{m}^{-1}$$

Heskestad proposed that the time constant could be represented by the following:

$$\tau = \frac{L}{u} \mathrm{s}$$

where L is the detector's characteristic length and u is the velocity of the ceiling jet flowing past the detector.

The characteristic length is thought to be a property of the detector that is independent of the smoke and ceiling-jet properties. It is interpreted as the distance the smoke would travel at the velocity u before the optical density inside the detector reaches the value outside of the detector. Combining the equations,

$$D_{ur} = D_{uo} + \frac{L}{u}\left(\frac{dD_u}{dt}\right) \times \left\{1 - \exp\left[-D_{ur}\frac{u}{L}\left(\frac{dD_u}{dt}\right)\right]\right\} \mathrm{m}^{-1}$$

The exponential term is small compared to the rest of the equation, allowing the equation to be simplified [47]. Simplification of the equation is not necessary when calculations are made using a computer. However, the simplified form clearly shows the effect of entry resistance:

$$D_{ur} = D_{uo} + \tau\left(\frac{dD_u}{dt}\right) m^{-1}$$

or

$$D_{ur} = D_{uo} + \frac{L}{u}\left(\frac{dD_u}{dt}\right) m^{-1}$$

This form of the entry resistance equation clearly shows that when the optical density outside a detector is increasing with time, the optical density inside the detector will lag behind if there is any entry resistance.

Heskestad and, later, Bjorkman et al. [49] have plotted test data to determine the L number for a variety of smoke detectors. Additional work has been done by Marrion and by Oldweiler to study the effects of detector position and gas velocity on the L number [15, 50].

Bjorkman et al., Marrion, and Oldweiler all observed variations in L that may be attributed to a dependence on velocity. Marrion's and Oldweiler's data also imply that there may also be a dependence on the characteristics of the smoke. Table 40.15 below summarizes the results from the works cited above.

Examination of the data and analysis work cited above shows that more work needs to be done to study the effects of low velocities

Table 40.15 Range of characteristic length (L) numbers

Researcher	Ionization detector L (m)	Scattering detector L (m)
Heskestad [47]	1.8	15[a]
Bjorkman et al. [49]	3.2 ± 0.2[b]	5.3 ± 2.7[c]
Marrion [15]	Not tested	7.2,[d] 11.0–13.0[e] 18.4[f]
Oldweiler [50]	4.0–9.5[g]	Not tested
	4.3–14.2[h]	

[a]Older style detector with more elaborate labyrinth
[b]L determined by best fit for three test velocities
[c]L based on a single test velocity and a limited number of tests (complete equation used)
[d]Low L number at low test velocity
[e]Range of L for several fuels and detector positions
[f]L increased by adding "fence" to further restrict smoke entry
[g]Range of L for a variety of velocities using simplified equation for entry resistance
[h]Range of L for a variety of velocities using simplified equation for entry resistance

and smoke characteristics on detector entry characteristics. The sharp increase in L at lower velocities appears to indicate that entry resistance may be related to smoke particle size. It is also possible that L is a function of the smoke momentum at low velocities. Thus, the time lag would be inversely proportional to the velocity squared.

Engineers can use L as a measure of entry resistance and the resulting time lag. However, in scenarios where the ceiling-jet velocity is low, there will be greater uncertainty in the results.

Without validation of L as a measure of lag time, manufacturers and test laboratories are not measuring or reporting L in their literature. Nevertheless, the range of L numbers reported in Table 40.15 can be used to estimate possible errors in detector response time.

Smoke Detection Calculation Examples

Example 12 The smoke level measured outside of a detector at the time of response in a laboratory calibration test is listed on manufacturers' specifications as the optical density or obscuration required to alarm the unit. Because of entry resistance, the smoke level inside the detector will be less. The specified response is for a particular type of smoke and is measured in a laboratory test apparatus. An example of one calibration test is the gray smoke test listed in the UL 268 smoke detector test standard [33].

In the test, the smoke detector response threshold must not exceed 0.0581 m^{-1} (4.0 %/ft). Velocity in the test chamber is 9.8 m/min. The test starts with clear air. A smoldering cotton lamp wick is used to increase the optical density in the test chamber. The rate of increase of optical density in the chamber must fall within the following limits:

$$3.7 \times 10^{-3} \leq \frac{dD_u}{dt} \leq 5.3 \times 10^{-3}\ \mathrm{m}^{-1} \cdot \mathrm{min}^{-1}$$

What is the range of optical density inside of the detector at the time of response (D_{uo}) if the detector has an L of 3 m? What would it be if the detector had an L of 14 m?

Solution For $L = 3$ m and $dDu/dt = 3.7 \times 10^{-3}\ \mathrm{m}^{-1} \cdot \mathrm{min}^{-1}$,

$$D_{\mathrm{ur}} = D_{\mathrm{uo}} + \frac{L}{u}\left(\frac{dD_u}{dt}\right)\ \mathrm{m}^{-1}$$

$$D_{\mathrm{uo}} = D_{\mathrm{ur}} - \frac{L}{u}\left(\frac{dD_u}{dt}\right)\ \mathrm{m}^{-1}$$

$$D_{\mathrm{uo}} = 0.0581 - \frac{3}{9.8}\left(3.7 \times 10^{-3}\right) = 0.057\ \mathrm{m}^{-1}$$

For $L = 3$ m and $dD_u/dt = 3.7 \times 10^{-3}\ \mathrm{m}^{-1} \cdot \mathrm{min}^{-1}$,

$$D_{\mathrm{uo}} = 0.0581 - \frac{3}{9.8}\left(5.3 \times 10^{-3}\right) = 0.056\ \mathrm{m}^{-1}$$

For $L = 14$ m and $dD_u/dt = 3.7 \times 10^{-3}\ \mathrm{m}^{-1} \cdot \mathrm{min}^{-1}$,

$$D_{\mathrm{uo}} = 0.0581 - \frac{14}{9.8}\left(3.7 \times 10^{-3}\right) = 0.053\ \mathrm{m}^{-1}$$

For $L = 14$ m and $dD_u/dt = 5.3 \times 10^{-3}\ \mathrm{m}^{-1} \cdot \mathrm{min}^{-1}$,

$$D_{\mathrm{uo}} = 0.0581 - \frac{14}{9.8}\left(5.3 \times 10^{-3}\right) = 0.051\ \mathrm{m}^{-1}$$

These calculations indicate that the actual quantity of this particular type of smoke required to alarm the detector varies from 0.051 to 0.057 m^{-1} or from 3.5 to 3.9 %/ft.

Smoke Production and Characteristics The fuel characteristics of primary concern for smoke detection are (1) material and (2) mode of combustion. These two parameters are important for determining pertinent features of expected products of combustion, such as particle size, distribution, concentration, and refractive index. The importance of these features with regard to smoke detection are well documented [6, 31, 32] and are discussed by Mulholland [34] Assuming a well-mixed smoke-filled volume, data on smoke characteristics for given fuels can provide an estimation of detector response.

Example 13 The design objective is to detect the smoke from a flaming 200 g (0.5 lb)

polyurethane pillow in less than 2 min. The pillow is located in a 36 m^2 room with a ceiling height of 2.5 m (8 ft). Assume that the pillow is burning at a steady rate of 50 g/min. Can the design objective be met? What assumptions are required?

Solution The total mass loss at 2 min is 100 g. Given this information, the optical density in the room can be calculated from the relationship [34]:

$$D_u = \frac{D_m M}{V_c} \tag{40.27}$$

where D_m (mass optical density [m^2/g]) can be taken from Mulholland [34] as 0.22 m^2/g.

$$D_u = \frac{(0.22\ \text{m}^2/g)\,(100\ \text{g})}{(36\ \text{m}^2)\,(2.5\ \text{m})} = 0.244\ \text{m}^{-1}$$

Assuming the detector will respond at the UL upper sensitivity limit of 0.14 m^{-1} (black smoke) [33], it can be assumed that the detector will respond within 2 min. This approach is simplified, however, and assumes that the smoke is confined to the room, is well mixed, can reach the ceiling level, and can enter the detector.

Example 14 Polyurethane mattresses are stored in a room that is 50 m × 75 m × 10 m high. A goal has been set to detect a flaming fire before approximately 350 g of fuel has been consumed. Using a projected beam smoke detector with sensitivity settings that can vary from 20 % to 70 % total obscuration in 10 % increments, what is the minimum sensitivity setting for response to this fire? Assume the smoke is mixed evenly throughout the space.

Solution The mass optical density, D_m, for a flaming polyurethane mattress is given in this handbook on page 2–298 as 0.22 m^2/g. The volume of the room is 37,500 m^3.

From the equation for mass optical density, calculate the resulting unit optical density in the room when 350 g of fuel is consumed:

$$D_m = \frac{D_u V}{\Delta m}\ \text{m}^2/\text{g}$$

$$D_u = \frac{\Delta m D_m}{V}\ \text{m}^{-1}$$

$$D_u = \frac{350(0.22)}{37,500} = 0.002\ \text{m}^{-1}$$

Knowing D_u and assuming the path length of the beam to be 75 m, the ratio of light reaching the receiver of the unit can be calculated:

$$\frac{I}{I_0} = 10^{-D_u I}$$

$$\frac{I}{I_0} = 10^{-0.002(75)} = 0.708$$

Next, the percent obscuration caused by the smoke is calculated:

$$O - 100\left(1 - \frac{I}{I_0}\right)$$

$$O = 100(1 - 0.708) = 29.2$$

Thus, a projected-beam smoke detector would have to be set to respond at about 30 % total obscuration or less to meet the design objective.

Discussion Related to the Use of D_m The previous two examples used the mass optical density, D_m, to calculate the expected optical density, D_u, in a space when a certain mass of fuel was consumed. D_m data are typically measured in small-scale tests due to the need for accurate measurements of mass loss and optical density. The use of D_m from small-scale tests to calculate the resulting D_u in a large-scale scenario introduces error. Some comparisons show qualitative correlation. However, it has been reported that the correlation breaks down with complex fires [34].

Stratification In the context of this chapter, smoke dilution refers to a reduction in the quantity of smoke available for detection at the location of the detector. This dilution can occur either through natural convection (entrainment in the plume or the ceiling jet) or by effects of a heating or ventilation system. In many cases, forced

ventilation systems with high exchange rates cause the most concern. In the early stages of fire development, when smoke production rate is small and the plume is weak, smoke can easily be drawn out of the room and away from area smoke detectors. In addition, high velocity air flows out of supply and into return vents creating defined patterns of air movement within a room. Such flows can either keep smoke away from detectors that are located outside of these paths, or, in some cases, inhibit smoke from entering a detector located directly in the air flow path.

Although there currently are no quantitative methods for estimating either smoke dilution or air flow effects on smoke detector siting, these factors must be considered qualitatively. It should be clear, however, that the air flow effects become larger as the required fire size at detection, $\dot{Q}_{cr}$, gets smaller. If the application warrants, it may be useful to obtain velocity profiles of the air movement within a room or to perform small-scale smoke tests under various conditions to aid in the smoke detector placement analysis.

The potential for smoke stratification is another concern in the detection of low-energy fires and fires in rooms or volumes with very high ceilings. Stratification occurs when the temperature within the plume equals that of the surrounding air, and there is insufficient thermal energy from the fire to force the smoke higher. Once this point of equilibrium is reached, the smoke layer will maintain its height above the fire, regardless of the ceiling height, until additional energy is provided.

Unlike the effects of air flow on smoke dilution, stratification effects can be calculated using the relationship [51]

$$\dot{q}_{\text{conv}} > 0.352 H^{5/2} T_s^{3/2} \qquad (40.28)$$

where

$\dot{q}_{\text{conv}}$ = Convective heat release rate in W

H = Distance from the top of the fuel package (base of the fire) to the ceiling level in m

T_s = Difference in ambient gas temperature in °C between the fuel location and ceiling level

This same relationship can also be found in NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Areas*, 2005 edition [52]. A more through treatment of stratification can be found in Chapter 2-1 of this handbook.

Example 15 The design objective is to detect the pyrolysis of overheated PVC cable insulation in a 7-m (23-ft) high, 100 m^2 (1076 ft^2) room. The room is air conditioned with a temperature differential of 10 °C (18 °F) between the base of the switch equipment and the ceiling. The proposed design has smoke detectors mounted at the ceiling level. Assuming the critical fire size is 1000 W, will there be sufficient thermal energy to force the smoke to the ceiling level?

Solution In this case, one can rearrange Equation 40.28 and solve for H:

$$H < \left(\frac{\dot{q}_{\text{conv}}}{0.352 T_s^{3/2}} \right)^{2/5}$$

where $\dot{Q}_{cr} = 1000$ W, and $T_s = 10$ °C (18 °F). This result indicates that the highest level of smoke rise is estimated to be 6 m (20 ft). As a result, the design objective may not be achieved by the proposed design. This approach is also valid for evaluating the effects of stratification in a high-ceiling room where a larger fire might be expected. However, the effects of heating and air conditioning systems and warm or cold walls are not considered.

Example 16 The design objective is to detect the flaming combustion of a chair located in the lobby of an office building in order to initiate smoke management functions. The lobby is located at the lowest level of a 20-m (64-ft) high atrium. The atrium has offices on three sides and a glass facade to the outside on the other. The atrium is air conditioned with a temperature differential of 20 °C (36 °F) between the lobby and the ceiling level. The proposed design is for smoke detectors to be mounted at the ceiling level. Is there sufficient thermal energy to force the smoke to the ceiling level?

Solution First, a value for $\dot{Q}_{cr}$ must be selected for the burning chair. From an analysis of the

chair and a review of published heat release data, it is determined that the chair most closely resembles the metal frame chair with padded seat used in Test 53 of the NIST furniture heat release rate tests [8]. This chair had a maximum heat release rate of 280 kW, which can be used as $\dot{q}_{\text{conv}}$ (or in this case $\dot{Q}_{cr}$, the critical fire) in Equation 40.28. Equation 40.28 can then be rearranged to solve for H:

$$H < \dot{Q}_{cr} / \left(0.352 T_{\text{s}}^{3/2}\right)^{2/5}$$

where $\dot{Q}_{cr} = 280{,}000$ W and $T_s = 20$ °C (36 °F). In this case, the highest point of smoke rise is estimated to be 38 m (125 ft). Thus, the smoke would be expected to reach the ceiling-mounted detector.

It should be noted that air flow concerns were not considered in Examples 10, 11, and 12. In some cases, a system supplying air at a low level and exhausting at an upper level may actually help transport the smoke to the upper levels of a room, where in other cases it may serve to inhibit smoke movement. It should also be noted that, simply because the smoke reaches the level of the detector, there is no guarantee that it can enter the sensor chamber.

Velocity Analog Spot-type smoke detectors, whether commercial or residential, or ionization- or light-scattering type, all require smoke to enter the detection chamber in order to be sensed. This requirement is another factor that must be considered when attempting to estimate smoke detector response. Smoke entry into the detector can be affected in several ways, for example, due to insect screens, chamber configuration, and proximity of the detector to the ceiling.

As previously discussed in this chapter, Heskestad [53] introduced the concept of smoke detector lag to explain the difference between the optical density outside (D_{ur}) and inside (D_{uo}) of a detector at the time of activation. Although studies of this relationship have provided useful information concerning smoke detector lag [15, 48], the difficulty in quantifying L for different detectors and relating it to siting requirements has limited its usefulness. In its stead, the concept of critical velocity (u_c) has been introduced [4, 54].

Critical velocity, in this context, refers to the lowest gas velocity required for smoke entry into the sensor chamber at a level to sound an alarm at a given threshold. Experimental work has shown this requirement to be in the range of 0.15 m/s for the detectors tested in one study [54]. When velocities fell below this value, the smoke level outside the detector at the time a specified analog output level was reached rose dramatically compared to levels when the velocity was above the critical value. This figure can be useful for design and evaluation purposes, as it is close to the low-velocity value (0.16 m/s) at which a detector must respond in the UL smoke detector sensitivity chamber in order to be listed [33]. Thus, the location of a velocity of 0.16 m/s in the ceiling jet for a given fire and ceiling height can be considered as a first approximation design radius for detector siting purposes. It should be noted that the ceiling-jet velocity correlations assume a horizontal, smooth ceiling. A detailed discussion of ceiling-jet flows by Alpert is presented in Chap. 14, "Ceiling Jet Flows." The critical velocity approach can be illustrated with a simplified example.

Example 17 The new owners of a hotel have established a fire detection design objective that the smoke detection system in the grand ballroom must be able to detect a 50 kW fire. The ballroom is 50 m (160 ft) long by 30 m (96 ft) wide with a 7.1-m (23-ft) high smooth ceiling. The existing smoke detectors are installed at a listed spacing of 10 m on center and have a critical velocity of 0.15 m/s. Assuming the fire starts at a point equally spaced between the existing smoke detectors, will the velocity of the ceiling jet from a 50 kW fire be sufficient to force smoke into the detection chamber? Assume there will be no ventilation system effects.

Solution The stated design objective is to detect a 50 kW fire. Because it is not stated whether the fire is steady state or growing, this solution will assume a steady-state fire of 50 kW. This

assumption allows the use of Alpert's [16] velocity correlations for a steady-state fire. Alpert provides two equations that can be used: one for $r/H = 0.15$, and the other for $r/H > 0.15$. This correlation is generally considered to be valid when r/H is between 0.15 and 2.1. Therefore, the ratio r/H must be determined first. In addition, the fire source should be at a distance of at least 1.8 times the ceiling height from the nearest enclosure wall.

The installed spacing is 10 m (32 ft) on center. Using the relationship $S = 2^{1/2}r$, the radial distance is found to be approximately 7.1 m (23 ft). Given that H is also 7.1 m (23 ft), the ratio r/H is found to be 1.0. This value is greater than 0.15; thus, the following equation can be used:

$$u = \frac{0.195\dot{Q}^{1/3}H^{1/2}}{r^{5/6}}$$

By entering the values of $\dot{Q} = 50$ kW, $H = 7.1$ m (23 ft), and $r = 7.1$ m (23 ft), a velocity of 0.37 m/s is calculated. This indicates that, for a steady-state 50 kW fire, there will be sufficient velocity to force smoke into the detectors at their existing locations.

However, if the 50 kW fire as stated is the design fire, $\dot{Q}_{do}$, and it was determined that the critical fire, $\dot{Q}_{cr}$, was only 5 kW, the resulting velocity using the steady-state correlation at 5 kW would be 0.17 m/s—very close to the critical velocity of 0.16 m/s. Furthermore, with a relatively small fire and a relatively high ceiling, stratification is likely to be a factor and should be considered. Assuming the room is air conditioned, with a temperature differential of 10 °C from the top of the fuel package to the ceiling level, the smoke from a 5 kW fire would stratify at a level of about 7.3 m (23.4 ft)—very close to the ceiling height of 7.1 m (23 ft). Given probable dilution of smoke and errors in approximations, it could be considered unlikely that a 5 kW fire would be detected under the defined conditions.

In addition to illustrating how the concept of critical velocity can be used for the design of smoke detection systems, it clearly points out the need to adequately define performance and design objectives, and to select correlations that fit those objectives. First, the objectives should be stated in terms of both the design fire and the critical fire. A 50 kW design fire is significantly different from a 50 kW critical fire, and the design for one may not meet the requirements for the other. Second, care should be taken in selecting a ceiling-jet velocity correlation that most closely fits the design objectives. Unless the hazard analysis indicates that the maximum fire size of $\dot{Q}_{do}$ will be 50 kW, it may be better to apply a ceiling-jet velocity correlation, based on a growing fire. In this case, the fire growth rate must also be estimated as part of the evaluation. The following example shows the importance of these factors by using the same ballroom as described in Example *17*, and provides more specific performance and design parameters.

Example 18 After additional consultation, the owners of the hotel described in Example 17 have modified their objectives as follows: assuming that a fire will begin in a chair, the smoke detection system for the grand ballroom must be able to detect the fire and initiate an internal response before it spreads beyond the chair of origin. The typical fuel load within the room consists of metal-framed chairs with padded seats and backs and plywood tables with cotton tablecloths.

The response time from when the alarm signal is indicated at the annunciator until the first staff member arrives is estimated to be 60 s. The delay time from detector activation until alarm initiation, as measured at the sensor, is 10 s. Because of the potential for nuisance alarms, the detection system employs an alarm verification feature that has a minimum delay time of 15 s and a maximum delay time of 60 s.

The existing smoke detectors are installed at a UL-listed spacing of 10 m on center and have a critical velocity of 0.15 m/s. Assuming the fire starts at a point equally spaced between the existing smoke detectors, and there are no ventilation system effects, can the existing smoke detection system be expected to meet the design objectives?

Solution The complete solution to a problem like this one may require several steps; for example, determination of the design fire, determination of the critical fire, estimation of ceiling jet velocity at $\dot{Q}_{cr}$, estimation of smoke production or optical density, and analysis of possible stratification effects. In all cases, however, determination of the design fire and the critical fire is essential.

Given that the goal is to detect the fire while in the chair of origin, a first step might be to estimate the fire size within the chair that could ignite the cotton tablecloth. From analysis of the chair and a review of published heat release data, it is determined that the chair most closely resembles the metal frame chair with padded seat and back used in Test 53 of the NIST furniture heat release rate tests [8]. This chair had a maximum heat release rate of 280 kW; a fire growth rate of ≈ 0.0086 kW/s^2; a growth time, t_g, of 350 s; and a virtual start time, t_v, of 50 s.

Assuming that the fire would likely grow up the seatback of the chair and that the seatback is located approximately 0.5 m from the tablecloth, an estimate of the energy output required for ignition of the tablecloth can be made. In this case, using the radiant ignition routine in FIREFORM [55] and assuming the fuel is easy to ignite (ignition flux of 10 kW/m^2) with a separation distance of 0.5 m, it is estimated that the tablecloth will ignite when the total energy output from the burning chair reaches 139 kW. These parameters define the design fire.

The next step is to calculate the time for the design fire to reach the threshold limit of 139 kW. Using the relationship $\dot{Q} = \alpha t^2$, a time of 118 s (about 2 min) is calculated. This calculation is growth time of the fire after it begins to follow an exponential growth rate until the design fire size is reached. Given that the fire would probably start as smoldering combustion, the actual growth time could be considerably larger (1 to 2 h possible).

The critical fire size can then be estimated by subtracting the various response times and estimating the heat release rate at that moment in time. In this regard, reasonable time delays should be used based on the information provided. The focus should be on obtaining the "most reasonable" worst-case delay for the situation. From the problem statement, this delay is estimated based on the response times given, using the following equation:

$$t_{\text{response}} = t_{\text{transport}} + t_{\text{verify}} + t_{\text{system}} + t_{\text{staff}}$$

where

$t_{\text{transport}}$ = Smoke transport time (unknown)
t_{verify} = Verification time (60 s maximum)
t_{system} = System response time (10 s)
t_{staff} = Staff response time (60 s)

Momentarily ignoring the smoke transport time and assuming prompt staff response, the result is a maximum detection system response time of 130 s. However, in an actual fire situation, the smoke detector verification time should be at its minimum of 15 s, and not at its maximum of 60 s. Making this assumption, the total response time (still ignoring smoke transport time) is 85 s. This result is less than the 127 s time to ignition of the tablecloth and is used to help define the critical fire size ($\dot{Q}_{cr}$).

Here, the 85 s is subtracted from the 127 s (that defines the design fire), and the relationship $\dot{Q} = \alpha t^2$ is used to calculate the heat release rate at that moment in time. The result is a heat release rate of 15 kW. Assuming no smoke transport time, this result would be the critical fire size at which detection must occur in order to detect the fire and cause the required response before the design fire size is reached.

The next step is to factor in a lag due to the smoke transport time. In order to account for smoke transport lag, Brozovsky [54] suggests a safety factor that is equivalent to a heat release rate that is 80 % of the maximum fire size at the time of detection. This factor would result in a critical fire size of 12 kW and a corresponding response time of 37 s. These values can then be used to determine if the ceiling-jet velocity will exceed 0.16 m/s.

Although several simplifications have been made, this example outlines a methodology for

estimating the potential for detector response, given the concepts of design fire and critical fire. In addition, the cross-checking utilized points out the importance of understanding the limitations and boundary conditions of correlations and empirical relationships (i.e., simply because one condition can be met, it does not automatically mean that all others will be met as well, and the complete scenario should be considered). Engineering of smoke detection, especially for low-energy fires, can be a difficult task, and the application of any method for this purpose should include clear statements of all assumptions made.

Temperature Approximation Method for Modeling Smoke Detection The temperature approximation theory is another method used to estimate the optical density produced by flaming fires. The theory hypothesizes that the mass concentration of smoke particles at a point is proportional to the change in temperature due to the fire (at that point) [56]. The following assumptions are necessary:

1. Particle size distribution is constant in space and time.
2. Mass generation rate is proportional to mass burning rate.
3. There is no heat transfer between particles or between the particles and the confining surfaces.
4. The smoke does not continue to react as it travels.

Heskestad then hypothesized that the ratio of optical density to temperature rise would be a constant for a particular fuel and burning mode (flaming, smoldering, vertical combustion, horizontal combustion, etc.). There are actually three parts to this hypothesis.

The first is that each fuel and burning mode results in a unique optical density required to alarm a particular model and type of detector. This aspect was discussed previously regarding photoelectric, ionization, and projected-beam smoke detectors. This phenomenon is regularly observed, explained by theory, and accepted by the scientific and engineering community.

The second part of the hypothesis is that for each fuel and burning mode the optical density at a point is proportional to the mass concentration of particles:

$$D_u \propto C$$

The final part of the hypothesis is that, for each fuel and burning mode, the mass concentration of particles is proportional to the change in temperature at a point:

$$C \propto \Delta T$$

Combining these proportionalities, optical density is proportional to the change in gas temperature for a given fuel and combustion mode:

$$D_u \propto \Delta T$$

Therefore, the ratio of optical density to temperature rise is constant for a given fuel:

$$\frac{D_u}{\Delta T_g} = \text{Constant}$$

This hypothesis assumes that the only way to move the smoke particles from the source to the detector at the ceiling is by buoyant forces.

Heskestad and Delichatsios examined experimental data for obscuration and temperature rise at various locations on a ceiling for different fuels. They concluded that while the data showed some variation in time at different radial positions relative to the fire source, the ratio could be approximated as a constant. Table 40.16 lists the ratios recommended by Heskestad and Delichatsios for various fuels.

Examining the original data, the last column has been added to show the range of values for each fuel. Averages have also been calculated and listed in the last row of the table for reference.

Others experiments have resulted in data that differ from that of Heskestad and Delichatsios. Bjorkman et al. reported values for polyurethane that are approximately one half that reported by Heskestad and Delichatsios [49]. The data produced by Heskestad and Delichatsios show the ratio of optical density to temperature rise was

Table 40.16 Ratios recommended by Heskestad and Delichatsios for various fuels

Material	$D_u/\Delta T$ (1/m °C)	Range of values
Wood	1.2×10^{-3}	8.9×10^{-4} to 3.2×10^{-3}
Cotton	$5.9 \times 10^{-4}/1.2 \times 10^{-3}$	3.0×10^{-4} to 1.8×10^{-3}
Paper	1.8×10^{-3}	Data not available
Polyurethane	2.4×10^{-2}	1.2×10^{-2} to 3.2×10^{-2}
Polyester	1.8×10^{-2}	Data not available
PVC	$3.0 \times 10^{-2}/5.9 \times 10^{-2}$	5.9×10^{-3} to 5.9×10^{-2}
Foam rubber PU	7.7×10^{-2}	Data not available
Average	2.4×10^{-2}	3.0×10^{-4} to 7.7×10^{-2}

not constant. The authors concluded that the variation was the result of slowly changing characteristics of the smoke particles as they left the flaming source and traveled in the plume and ceiling jet. Nevertheless, they concluded that a constant value could be used as a rough approximation to allow engineers to model optical density produced by a fire. Although it has not yet been done, it is possible to examine their original data and place error bars on the values recommended in Table 40.16.

A fire model can be used to calculate the temperature rise at a smoke detector location or in a layer. Then, using the ratios reported by researchers, the optical density at that location as a function of time can be approximated.

Discussion Related to the Use of fire Models for Heat and smoke Detector Modeling Some computer fire models or sets of computational tools include routines for calculating heat or smoke detector response. It is important for users to understand the underlying detector models being used so that limitations and potential errors can be understood. For heat detection, most computational tools use a lumped mass model as described in this chapter. However, for smoke detection some use a temperature rise model, and some use a mass optical density or specific extinction area model. The specific extinction area is similar to the mass optical density except that it is based on calculations using the natural log, e, rather than $\log_{10}$. Most do not include entry resistance modeling. Some permit the use of fuel-specific parameters for smoke yield and mass optical density. Others use preset values.

Radiant Energy Detection

During the combustion process, electromagnetic radiation is emitted over a broad range of the spectrum. Currently, however, fire detection devices operate only in one of three bands: ultraviolet (UV), visible, or infrared (IR), where the wavelengths are defined within the following ranges: [8]

Ultraviolet	0.1–0.35 μm
Visible	0.35–0.75 μm
Infrared	0.75–220 μm

Selection of a specific sensor type for fire detection is based on a number of factors, including fuel characteristics, fire growth rate, ambient conditions, resulting control or extinguishing functions, and environmental conditions in the detection area. More specifically, it includes evaluation of the radiant energy absorption of the atmosphere, presence of nonfire-related radiation sources; the electromagnetic energy of the spark, ember, or fire to be detected, the distance from the fire source to the sensor; and characteristics of the sensor.

These factors are important for several reasons. First, a radiation sensor is primarily a *line-of-sight* device, and must "see" the fire source. If there are other radiation sources in the area, or if atmospheric conditions are such that a large fraction of the radiation may be absorbed in the atmosphere, the type, location, and spacing of the sensors may be affected. In addition, the sensors react to specific wavelengths, and the fuel must emit radiation in

the sensors' bandwidth. For example, an infrared detection device with a single sensor tuned to 4.3 μm (the CO_2 emission peak) cannot be expected to detect a noncarbon-based fire. Furthermore, the sensor must be able to respond reliably within the required time, especially when activating an explosion suppression system or similar fast-response extinguishing or control system.

Once the background information has been determined, the detection system can be designed. Standard practice for the design of radiant energy detection devices is based on application of generalized fire size versus distance curves that are derived using the inverse square law: [8]

$$S = \frac{kP\exp^{\zeta d}}{d^2}$$

where

S = Radiant power reaching the detector (W)
k = Proportionality constant for the detector
P = Radiant power emitted by the fire
ζ = The extinction coefficient of air
d = The distance between the fire and the detector

This relationship is used to produce sensor response information for specific fuels. By then plotting the normalized fire size versus the normalized distance, the resulting curve defines the maximum distance at which the tested sensor can be expected to consistently detect a fire of a defined size (usually provided in m^2). By testing a sensor using various fuels, a family of curves can be developed to assist in system design. These curves (sometimes given in tabular form) are usually provided by the sensor manufacturer.

Before applying the distance obtained from such a curve, one must also consider the sensor's field of view. Because the radiation sensor is a line-of-sight device, the sensitivity of the device to a defined fire size decreases as the fire location is moved off the optical axis of the device. This result means that a fire of X m^2, which is detectable at a distance Y m on axis from the sensor, may not be detectable at the same distance Y m if it is located 30° off axis. Limitations of viewing angles are also provided by manufacturers.

Ambient conditions should also be considered as part of the evaluation and design process. Factors such as humidity and dust can affect the absorption of radiation in the atmosphere, thus limiting the amount of radiation reaching the sensor for a given fire size. Similarly, temperature can affect the relative sensitivity of a sensor. As the ambient temperature increases, the relative sensitivity can decrease. Even if the decrease is small, it can affect the response of the sensor to the expected fire.

Radiation Detection Example

Example 19 The design objective is to detect a 1.0 m^2 (11 ft^2) pool fire of JP4 aircraft fuel in a large hangar in order to activate a fixed suppression system. The hangar dimensions are 50 m (160 ft) by 80 m (257 ft) with a 20 m (64 ft) ceiling height. The ambient temperature at the ceiling level varies between 15 °C (59 °F) and 60 °C (140 °F), depending on time of day and season. The humidity also varies by season, with relative humidity of 90 % possible. What steps should be taken during system design?

Solution The first step should be selection of a detection device. Because the hazard is carbon based, IR detection at 4.3 μm is suitable. Also, because IR detectors generally provide a larger surveillance area per device than UV detectors, they could be more cost effective than UV detection in this case.

One should then determine possible sources of interfering radiation and select a device that is resistant to these extraneous sources. Such resistance to false response can be obtained by filtering, use of multiple sensors (e.g., two- or three-channel detector), or a combination.

The next step is to review the manufacturer's data to determine mounting criteria based on the size of the critical fire [1.0 m^2 (11 ft^2)]. Generally, this step begins with the fire size versus distance curve or table. If only a curve is provided, one must then determine the mounting height and lateral distance limits of the detector. Lateral distances are important as related to the sensors' field of view.

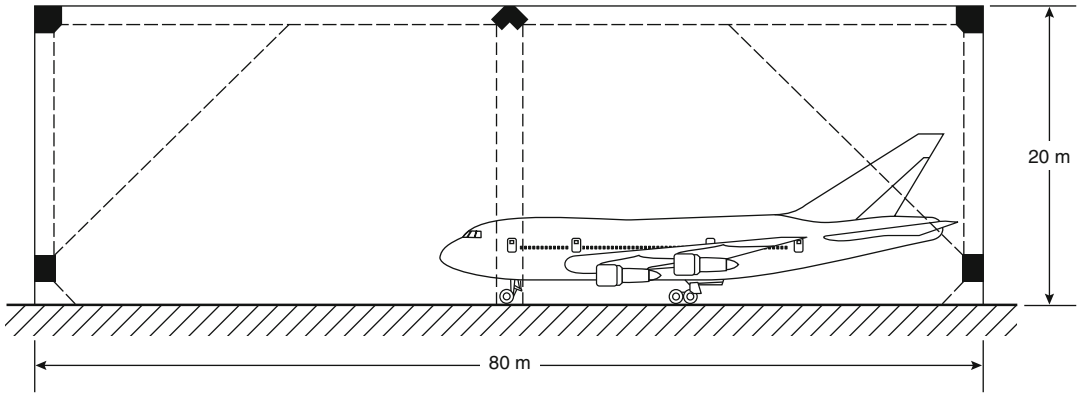

Fig. 40.11 IR detector layout for an aircraft hangar

Given this information, a device layout design can be made. This design should consider all possible obstructions, and result in all parts of the hangar being monitored. One such design is illustrated in Fig. 40.11.

As part of the layout, one should consider the possible effects of reduced device sensitivity due to angular displacement, temperature, and humidity. Because manufacturers' criteria vary on these parameters, typical values are used in this solution to illustrate their effects.

For example, the proposed layout has devices utilizing a field of view of 45°. Assuming the nominal sensitivity is such that a 1.0 m^2 (11 ft^2) fire can be detected at 40 m (128 ft), and there is a reduction in sensitivity of 30 % due to angular displacement, the distance at which a 1.0 m^2 (11 ft^2) fire can be detected at 45° is reduced to 28 m (90 ft). If the manufacturers' data indicate a further reduction in sensitivity for temperature, for example 3 % at 50 °C (122 °F) the distance is reduced to about 26.8 m (86 ft). If there are further reductions due to humidity, for example a 3% reduction at 90% relative humidity, the resulting detection distance at 45° is about 25.6 m (82 ft).

In this example, the viewing distance at 45° is a maximum of 20 m (64 ft), and the design can be considered valid. Had the sensitivity decreased such that the distance dropped below 20 m (64 ft), an alternative layout or different devices must be used. In all cases, the manufacturers' literature should be consulted to determine all pertinent increases or reductions in detector sensitivity due to fuel, distance, angular displacement, and environmental conditions.

Designing Fire Alarm Audibility

In most cases, the purpose of a fire detection and alarm system is to alert the occupants of a building that an emergency exists and to initiate evacuation. In situations such as high-rise or industrial buildings, it may be desirable to provide the occupants with more information, such as the nature and location of the fire. In either case, the purpose of the system is defeated if the signal is not heard and understood by the occupants.

This section demonstrates a method for fire protection engineers to estimate the relative effectiveness and cost of various fire alarm alerting systems during the design process. In the past, the selection and location of fire alarm devices has been based on experience and engineering judgment. The use of this simplified methodology can save thousands of dollars in retrofit costs required to correct deficiencies in an alarm system.

The transmission of sound from a source to a target is a function of many factors, such as humidity; air viscosity and temperature; the frequency of the signal; the location of the source relative to the target; the construction of walls, floors, and ceilings; and the furnishings in the

area. *Architectural Acoustics* [57] contains a good discussion of these and many other factors affecting sound transmission and loss.

Sound power and sound pressure levels are expressed in decibels (dB) relative to a reference. It is assumed that the reader is familiar with this system of measurement. Throughout this chapter sound power level (SWL or L_W) in decibels is referenced to 10^{-12} W. Sound pressure level (SPL or L_P) in decibels is referenced to 2×10^{-5} Pa. This discussion also assumes that the reader is familiar with the concept of A-weighting. The purpose of A-weighting is to adjust sound pressure level measurements to correspond as closely as possible to the way humans perceive the loudness of the many different frequencies we hear. For instance, a 1000 Hz signal at an SPL of 20 dB would be clearly audible. A 100 Hz signal at the same SPL would not be heard. A-weighting allows a single number to describe the SPL produced by a signal containing frequencies between 20 and 20,000 Hz. The weighting of the various frequencies is established by an internationally accepted A-weighting curve [58].

Typical fire alerting systems consist of a combination of audible and visual signals activated by fire detection systems. The audible devices are usually horns, bells, chimes, or speakers. The visual indicators are usually strobe lights, incandescent lamps, or, occasionally, revolving beacons.

In residential occupancies, fire alerting systems should be capable of awakening a sleeping person and informing him or her that a fire emergency exists. Several studies have been done to establish the sound pressure level required to achieve this goal [59, 60]. These studies suggest an SPL between 55 and 70 dBA will awaken a college-age person with normal hearing. The minimum required SPL is also a function of the background noise or signal-to-noise ratio. These levels establish the SPL required to alert or be audible. They do not address the problem of how the person will perceive the sound or react to it.

Until recently, fire codes did not set forth the SPL that a fire alarm system must produce within a building. *NFPA 72* [8] requires signals to be 15 dBA above ambient in areas where people may be sleeping. British standards require fire alarm signals to produce a sound pressure level of 65 dBA or 5 dBA above ambient noise in areas where occupants are not sleeping [61]. A sound pressure level of 75 dBA at the head of the bed is required in occupancies where people may be sleeping.

The audible design requirements listed above and the remaining discussion and examples in this section all use dBA as a measure of audibility. However, it should be pointed out that for a sound to be perceived as audible, it need only penetrate or be greater than the background noise level at one particular frequency bandwidth. For example, certain facilities such as manufacturing plants may have a background noise level in excess of 85 dBA. An installed fire alarm may produce only 75 dBA at a certain location. Nevertheless, occupants will hear and respond to the fire alarm system. Why? The reason is because the background noise that contributes to the 85 dBA is mostly low frequency sound and the fire alarm is mostly high and midrange frequencies. Figure 40.12 illustrates this concept. Like two picket fences, one behind the other, only one picket or octave band must be taller for us to perceive the presence of the second fence or signal. More discussion on this approach can be found in the *National Fire Alarm Code*. While the balance of this section uses dBA, the procedure and methods apply equally well to work done in a single frequency band.

Visual signals are located to assist people in deciphering potentially confusing alarm signals. The visual signals also help alert occupants in high background noise environments.

Butler et al. [58] have described a method to estimate sound pressure levels at some location remote from the sound source. Formulas presented in their study are analogous to standard sound attenuation formulas found in other references [59, 62]. They have been simplified by replacing complex terms with constants for which they have provided tables of data (see Tables 40.17, 40.18, 40.19, 40.20, 40.21, 40.22, 40.23, 40.24, 40.25, 40.26, 40.27, 40.28, 40.29, and 40.30). The equations and data presented in

their study provide a straightforward method for analyzing proposed designs. The same equations and data can be used to determine the power requirement and maximum allowable spacing of signaling devices required to achieve a specified sound pressure level. The technique presented in their study is suitable for acoustically simple buildings only and may not be suitable on their own for voice alarm systems. Complex building arrangements and materials may require a more rigorous analysis using other methodologies which are beyond the scope of this chapter.

In assessing signaling system design, one may have to consider estimating required sound levels for devices located within a space, external to the space, or in combination. With respect to the sound at a point within an enclosed space, one may need to consider direct and reverberant components [58]. The direct component is a function of the sound pressure level (SWL or L_W) and distance from the source. The reverberant component is affected by the characteristics and contents of the enclosure, including type and quantity of finishes and furnishings, with acoustically soft materials absorbing sound waves and acoustically hard materials reflecting them. In large open spaces, such as open plan offices or ballrooms, it has been found for sound power

assessment of nonvoice signals, the reverberant component has little contribution and can be effectively ignored (note: this does not apply to voice signals where intelligibility is a concern and reverberation does play a role). For basic analysis of the situation where the alarm sounding device is located within the enclosed space, the sound pressure level needed at a defined point from the source can be determined by the following relationship:

$$L_P = L_W + C_1 + C_2 \text{ dBA}$$

where C_1 is a function of the mounting position of the sounder and C_2 is a function of the distance

from the sounder to the point of concern. The values for C_1 and C_2 are given in Tables 40.17 and 40.18.

If the space of concern is large enough that the receiver (e.g., person in the room) can receive alarm signals (noise, sound) from more than one source, the combined noise level should be estimated. The combined noise level is not the arithmetic sum of the individual sound pressure levels (dBA); rather, it will be a level that corresponds to the arithmetic addition of the individual sound powers in watts. For the purpose of this methodology, the combined noise level at a particular receiver position can be estimated by first estimating the noise level from each sounder in the space (ignoring the existence of the other sounders) and then combining the noise level based on the difference in sound pressure levels using the values in Table 40.22. For example, if an estimated sound pressure level from one device is 65 dBA and is 63 dBA from another, the resulting total sound pressure level will be 67 dBA (from Table 40.22, the difference in noise level between the two sounders is 2 dBA, so 2 dBA is added to the higher sound pressure level value).

For sounders located outside of the space of concern, one needs to consider additional factors, particularly if the arrangement is from a corridor to another space, such as an office, a hospital suite, or a hotel guest room. If the sounder is located in a corridor, for example, there may be directional considerations for the sounder, and consideration must also be given to the distance from the sounder to the partition separating the corridor and space of concern, in addition to the acoustical characteristics of the corridor. One then needs to consider the attenuation of the sound through the partition and the distance to the receiver. These factors are addressed in more detail in the following examples.

To demonstrate how signaling systems can be designed and analyzed, two scenarios will be considered. Both scenarios are based on a typical dormitory or office layout. The building has long corridors with rooms of equal size on each side. Each room is approximately 5 m wide by 6 m deep. The walls consist of two layers of Sheetrock (total of 25.4 mm thick) separated by wood studs. The wall cavities contain 75-mm-thick mineral fiber insulation. The floors are concrete with carpeting. The ceiling is 3 m high and consists of acoustical tiles. The room doors are solid core with good edge seals. The alerting systems will be designed to achieve a 75 dBA sound pressure level at the farthest point in the rooms.

In the first scenario, wall-mounted fire alarm speaker/light combinations are spaced equally in the corridor with a nonvoice alarm signal being transmitted. Calculations determine the maximum allowable spacing of the speakers in order to achieve the design goal of 75 dBA in the rooms.

In the second scenario, speakers are placed in each room as well as in the corridor. Calculations determine the size of the speaker and the power needed to drive that speaker to achieve the design goal of 75 dB. Calculations are also presented to determine the required spacing of speakers in the corridor to achieve a sound level of 65 dB.

Unless otherwise noted, the following formulas and data are from Butler, Bowyer, and Kew [58].

Scenario A In this scenario, the fire alerting system, or sounder, will consist of wall-mounted speaker/light combinations in the corridors only.

L_W is the sound power level of a horn, bell, speaker, or any sounder (dBA referenced to 10^{-12} W).

$$L_W = L + 20 \log_{10} r + 11 \text{ dB}$$

where L is the manufacturer's stated output in dBA at a distance r meters. A typical compression driver-type fire alarm speaker powered at 2 W has an L equal to 94 dBA at 3.05 m [63]. Therefore,

$$L_W = 94 + 20 \log_{10}(3.05) + 11$$

$$L_W = 115 \text{ dB}$$

L_{P1} is the sound pressure level (dBA referenced to 2×10^{-5} Pa) produced outside of a room wall from one speaker.

$$L_{P1} = L_W + C_3 + C_4 + C_5$$

where

C_3 = Correction for the number of directions that the sounder propagates

C_4 = Correction for the characteristics of the corridor walls, ceiling, and floor

C_5 = Function of the distance from the sounder to the center of the bedroom wall

From Table 40.19 [58] C_3 is −3 dB, because the speaker propagates in two directions along the corridor; from Table 40.20 is C_4 is −9 dB, because the floor and ceiling are acoustically soft; and C_5 is unknown since the required spacing of the corridor speakers has not yet been determined. Table 40.21 provides C_5 values for determined distances.

A worst-case condition exists for a room located farthest from a speaker. In this situation the room is located equally between two speakers. Since each unit propagates sound to the room, the sound pressure level outside of the room is higher than if there were only one speaker. The sound pressure level is not double that for a single speaker. For equally spaced sounders, Table 40.22 indicates to add 3 dB to the level expected from a single unit. Therefore,

$$L_{P1} = 115 - 3 - 9 + C_5 + 3$$
$$L_{P1} = 106 + C_5$$

L_{P2} is the sound pressure level at the farthest point in a room. To achieve the established goals, L_{P2} must be 75 dBA. In this situation, with the speaker located outside of the occupied space,

$$L_{P2} = L_{P1} - R + C_2 + C_6 + C_7 + 11 \text{ dBA}$$

where

R = Average sound reduction index for the wall

C_2 = Function of the distance from the wall to the point of interest

C_6 = Function of the area of the room wall (see Table 40.23)

C_7 = Function of the frequency of the sound reaching the wall (see Table 40.24)

In this case, from data presented by Butler, Bowyer, and Kew [58], the sound reduction index R for the wall is about 40 dB (see Table 40.25). This value is based on incident sound in the range of 100–3150 Hz. Sound attenuation through the door is about 26 dB (see Table 40.25). The average sound reduction index, R, for the combined door and wall is 34 dB, if the door is 10 % of the area (see Table 40.26). C_2 is found to be −27 dB, because there are 6.5 m from the center of the wall to the corner of the room (see Table 40.26). Since the wall is 15 m^2, C_6 is +11.5 dB (see Table 40.23). If it is assumed that the sound reaching the wall is at a maximum at a frequency of 2000 Hz, $C_7 = 15$ dB (see Table 40.24). Therefore,

$$L_{P2} = (106 + C_5) - 34 - 27 + 11.5 - 5 + 11 \text{ dBA}$$
$$L_{P2} = 62.5 + C_5 \text{ dBA}$$

If there were no loss of sound pressure level between the speaker and the room wall due to distance, C_5 would be zero and L_{P2} would be 62.5 dBA. This result shows that even if the two speakers were right outside the room, the goal of 75 dBA in the room would not be met. In fact, the resultant noise level in the room would be slightly less than the 65 dBA required by British standards [61] to alert nonsleeping persons. The sound level of 62.5 dBA would exceed the 55 dBA reported by Nober et al. [32] to alert sleeping college-age persons in a quiet ambient setting.

To meet the goal of 75 dBA in the room, either the sound system or the environment would have to be changed. Fire alarm speakers are normally available with multiple power taps such as 4, 2, 1, 1/2, and 1/4 W. A single unit may allow choice of two or three different power levels, which allows balancing of the system after installation.

If a 4-W power input were used, this would be a doubling of the 2 W originally tried in the previous calculation. Because decibels are logarithmic, a doubling of power results in a change of 3 dB in L_W ($10 \times \log_{10} 2 = 3$).This action alone would not be sufficient to meet the 75-dBA goal. In addition, the higher sound pressure level

in the immediate vicinity of the speaker might be discomforting. If the fire alarm system were also used for voice communication, a speaker tapped at 4 W in a small corridor might sound very distorted and be unintelligible.

It is also possible to change the sound pressure level in dBA by changing the frequency of the source. In general, the higher the frequency, the higher the attenuation as the sound waves pass through a wall. Hence, a lower frequency would increase the sound pressure level in the room. In the calculations above, it was assumed that the predominant frequency of the source was 2000 Hz. This frequency resulted in a C_7 of −5 dBA. According to Table 40.24, if this frequency were 500 Hz, C_7 would be 0 dBA. This adjustment would increase the SPL in the room by 5 dBA.

Changes could be made to the building design that would make it possible to meet the design goal. For instance, the use of a lighter-weight door or one without good edge sealing could increase sound transmission to the room by as much as 12 dBA (see Tables 40.27, 40.28, 40.29, and 40.30). However, changes such as this one would tend to defeat other goals such as fire resistance and resistance to smoke spread. If the floor and ceiling were hard surfaces without carpeting or tiles, C_4 could be increased from −9 to 0 dBA (Table 40.31). Changes such as this would probably be resisted for reasons other than fire safety. The only remaining alternative is to provide speakers in each of the rooms.

Scenario B In this case, a speaker in each room powered at only 1/4 W will be tried in addition to the speaker in the corridor. The building use is a dormitory space. The problem, then, is to select a speaker with a sound power output that can meet the goal of 75 dB at the pillow.

$L = ?$ $r =$ at 305 m (3.05 m is a commonly used reference point).

$$L_W = L + 20 \log_{10} r + 11 \text{ dB}$$

$$L_W = L + 20 \log_{10}(3.05) + 11 \text{ dB}$$

$$L_W = L + 21 \text{dB}$$

L_{P2} is the sound level at the bed. In this case, with the speaker in the occupied space,

$$L_{P2} = L_W + C_1 + C_2 \text{ dBA}$$

where C_1 is a correction for how close the sounder is to an adjacent surface, and C_2 is a correction for the distance from the speaker to the bed. In this case, the speaker is on the wall and close to the ceiling. Therefore [58], C_1 is +7 dB, and C_2 is −27 dB (approximately 6.5 m from the speaker to the bed) (see Tables 40.17 and 40.18). Therefore,

$$L_{P2} = (L + 21) + 7 - 27 \text{ dBA}$$

$$L_{P2} = L + 1 \text{ dBA}$$

To get $L_{P2} = 75$ dBA, L must be at least 74 dBA. The smallest and least expensive fire alarm speaker available is a 4-in. paper cone speaker. A typical speaker of this size and type, powered at 1/4 W, has an L equal to 75 dB at 3.05 m [64]. This speaker would meet the design goal in the room, without even

Table 40.31 Average sound reduction indices (dB) of partitions incorporating single glazing (100–3150 Hz frequency range)

Percentage of glazing (24 dB) (%)	25 dB	30 dB	35 dB	40 dB	45 dB	50 dB
100	24	24	24	24	24	24
75	24	25	25	25	25	25
50	24	26	27	27	27	27
33	25	27	28	29	29	29
25	25	27	29	30	30	30
10	25	29	31	33	34	35
5	25	29	33	35	36	37
2½	25	30	34	37	39	40
—	25	30	35	40	45	50

considering any sound contribution from corridor-mounted speakers.

For the corridor speakers in Scenario B, L_{P1} is the sound pressure level at a point farthest from a speaker.

$$L_{P1} = L_W + C_3 + C_4 + C_5 \text{ dBA}$$

where C_3 and C_4 are the same as in Scenario A (-3 and -9 dB, respectively). C_5 is a function of the spacing, which is to be determined. If a single corridor speaker tapped at only 1/4 W is used, with an L of 85 dB at 3.05 m [63],

$$L_W = L + 20 \log_{10} r + 11 \text{ dB}$$
$$L_W = 85 + 20 \log_{10}(3.05) + 11 \text{ dB}$$
$$L_W = 106 \text{ dB}$$
$$L_{P1} = 106 - 3 - 9 + C_5 \text{ dBA}$$
$$L_{P1} = 94 + C_5$$

The goal is to maintain a 65 dBA sound pressure level in the corridors (L_{P1}).

Therefore, C_5 must be -29 dBA or more for L_{P1} to be 65 dBA or higher. From Table 40.20 [58], it is found that distance of 50 m between source and target in the corridor could be exceeded and still meet the 65 dBA goal.

Earlier in this section it was noted that designing for alarm audibility alone is not always sufficient, especially when voice alarm signals are involved. This is because speech is not necessarily intelligible simply because it is audible: adding more sound level to speech that has been blurred by reverberation, echoes, or distortion does not make it more intelligible [65]. A sufficiently loud but overly reverberant speech signal can be almost completely unintelligible. There are many examples of this in airports, train stations, and other large spaces, particularly those with hard acoustical surfaces.

When considering intelligibility, there are a variety of factors which are important, starting with the person who is speaking, the mode and features of the transmission system, the characteristics of the space wherein the signal is received, and the listener. This is illustrated in Fig. 40.13.

For fire alarm signaling system design, major facility use concerns include the characteristics of the space and the intended occupant population. The population matters from the perspective of understanding the message (e.g., language and abilities). The space matters from the perspective of how the signal, once introduced into the space, may become distorted or otherwise affected such that intelligibility is diminished. Factors that can corrupt the integrity of a voice signal on its path from talker to listener are summarized below [65].

- *Speech-signal-to-noise ratio*. Noise has the effect of masking or obscuring the voice signal. Remarkably, we are able to tolerate a great deal of noise before intelligibility

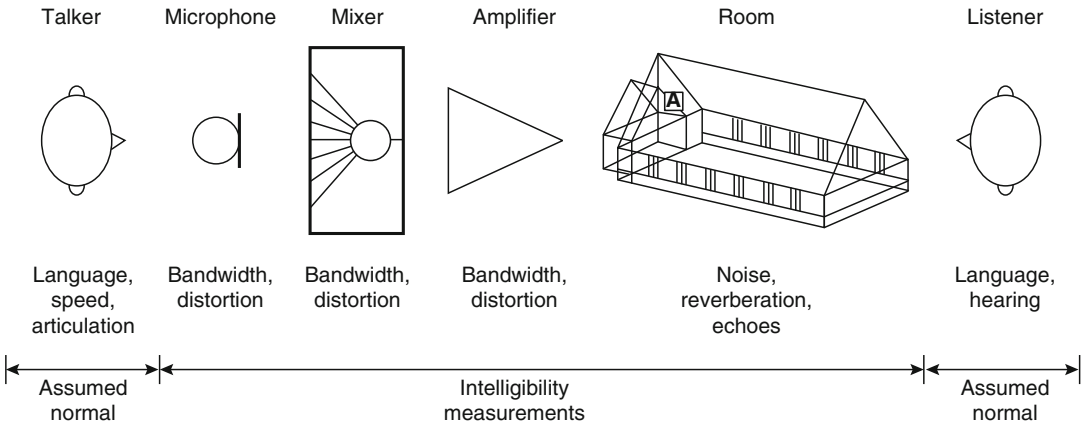

Fig. 40.13 Talker-to-listener transmission path [65]

diminishes appreciably, but once it begins to diminish, it diminishes rapidly.

- *Reverberation*. Most are familiar with how difficult it can be to understand speech in a reverberant environment such as a cathedral or gymnasium. Reverberation is made up of sound reflections that have the effect of smearing or blurring speech, making it less clear and distinct and therefore more difficult to understand.
- *Echoes*. If echoes arrive much later in time than the first arrival of sound, they can harm intelligibility. In continuous speech, the echo from a previously uttered syllable masks or obscures the sound of subsequent syllables, making speech more difficult to understand. The time delay and level of the echo are key variables in determining the impact of echoes on intelligibility.
- *Distortion*. If one of the electrical or electro-acoustical components in the sound system is distorting, it is generating a form of noise that masks the original speech signal. Severe amplifier clipping, for example, can make an otherwise perfect speech signal at the input to the amplifier more difficult to understand at the output.

To accurately account for the effect of the above factors, they must be measured in at least octave-band resolution; a single broadband measurement is insufficient and more than octave-band resolution is almost always unjustified. Various documents exist for guiding the measurement of intelligibility [66–69], and appropriate instrumentation is available for obtaining the speech transmission index (STI) and other acoustical data necessary for better siting speakers for emergency voice communication. Descriptions of how to collect and use these data can be found in the literature (e.g., Woycheese [70]).

Cost Analysis

Scenario A For comparison purposes, assume that sufficient changes could be made to the building and alarm system to allow speakers to be mounted in the corridor only at a spacing of 3 m. A typical dormitory with about 30 bedrooms per floor requires approximately 24 speakers per floor in the corridors. In a building with seven floors, this requirement amounts to 168 speakers. At 2 W per speaker, the result would be 336 W. This setup requires three 125 W power amplifiers at an installed cost of about $3500.00 each. This amount does not include other fixed costs, such as control equipment and detectors, that are the same for each of the scenarios.

Assume each corridor unit to be a speaker/light combination. The average installed cost, including backbox, wiring back to a control panel on the first level, and conduit, would total to about $250.00 per unit. The total cost is then

$$\text{TOTAL} = (3 \times \$3500.00) + (168 \times \$250.00)$$
$$\text{TOTAL} = \$52,500$$

Scenario B In this case, there are thirty 4-in. paper cone speakers per floor at an average cost of $200.00, installed. Assume a total of four speaker/light units per floor in the corridors. The calculations show that the system goals are met with only one or two units in the corridors. However, the halls may be split by smoke doors or they may be irregular in shape. Also, system reliability is increased by using more than one unit.

Each bedroom speaker and corridor speaker is powered at 1/4 W. For seven floors, this setup gives a total power requirement of 59.5 W. Therefore, one 60 W amplifier, at a unit cost of $1500.00, is needed. The total cost is then

$$\text{TOTAL} = (3 \times \$1500.00) + (7 \times 30 \times \$200.00) + (7 \times 4 \times \$250.00)$$
$$\text{TOTAL} = \$50,500.00$$

The estimates show the relative costs of the different scenarios, not the actual costs. The real costs of the systems are affected by factors such as whether the building is new or existing. If existing, the price is affected by the extent of other renovations. Also, the estimates do not reflect the cost of other parts of the system. The balance of the system includes such items as

smoke and heat detectors, equipment for elevator capture, and air handler controls.

The relative costs of the two systems in Scenarios A and B under "Cost Analysis" differ by only about 4 %. In a building of this size and type, such a small margin cannot be considered significant enough to conclude that one system is more economical than the other.

The small difference in the costs of the two systems is due to the additional cost of amplifiers needed to power the system that has only corridor units. The total number of units (corridor + room) in Scenario B is 70 more than in Scenario A. The reduced power requirement offsets the added cost of their installation.

Scenario A has a higher equipment cost but a lower installation cost than Scenario B. This result means that the relative costs of the two systems will be slightly sensitive to the type of equipment used and the cost of installation labor. By changing the figures used in the cost estimates, it can be shown that the variance is only a few percent and probably not significant.

If the building were four stories or less in height, the difference in relative cost rises to about 5 %. Again, this amount is not considered to be a significant difference.

By increasing the size of the building to 12 stories, Scenario B becomes significantly less expensive than Scenario A. Above this height, the combined use of room and corridor units becomes increasingly economically attractive.

Changing the size of each floor has about the same effect as changing the height of the building. Therefore, increasing the floor area makes Scenario B more viable. A reduction in floor area and building height does not make the corridor-only system attractive, unless the building is only a few stories in height. Then a voice system is probably not needed. From an economics standpoint, a corridor-only horn/light system is probably best, since the cost of these units is generally less than that of speakers. Again, this conclusion assumes that sufficient changes could be made to the building design to increase the level of sound penetrating the corridor walls.

Obviously, if the sound loss from the corridor to the individual rooms is less, Scenario A starts to look better. This situation has the effect of raising the height above which Scenario B becomes significantly less expensive. However, changing construction features to reduce sound loss may reduce the passive fire resistance of the structure below an acceptable level as well as decrease the privacy level.

There are other factors to consider when choosing between different systems. In Scenario A, the quantity of speakers in the corridors and the high power levels driving each speaker (2 W each) can cause sound distortion. Voice messages may not be intelligible in the bedrooms even though there is enough sound to wake a sleeping occupant. Also, the high sound levels (106 dBA plus) in the corridors approach uncomfortable levels.

It is clear from the discussions above that a system with room speakers in conjunction with corridor units is the most desirable case. That system has the added advantage of eliminating most of the uncertainties in the design of the system. It is easier and more accurate to calculate sound levels at a point in the same room as the sound source than it is to estimate sound losses through composite walls.

This cost-benefit analysis shows that a fire alarm alerting system with units in each office or bedroom can be installed at about the same cost or less than a corridor-only system. In addition, there is a higher confidence level that the system with the sounders in each room will perform its intended function: to awaken and alert sleeping occupants.

Designing Fire Alarm Visibility

Visual alarm notification is an important part of a fire alarm system. This visual aspect is especially important in cases where the ambient noise level is high, building occupants may be sleeping, or building occupants or their visitors may have hearing impairments. In these cases, it should be expected that the visual alarm will be required to alert occupants and initiate evacuation or

relocation. As such, one first needs to determine a suitable intensity required to obtain this function.

In many cases, a suitable intensity can be obtained from regulatory documents, such as building codes, fire codes, or the Americans with Disabilities Act. These references typically give a required appliance intensity and a maximum size space that can be covered by an appliance with that intensity. If additional guidance is needed, reference can be made to appropriate documentation on alerting of persons by visual means [71]. It is also possible that a reference may cite a required level of illumination to alert someone. This requirement should not be confused with the intensity of the lamp providing the signal. The two are related by the inverse square law where E is the illumination (lumens per unit area), I is the intensity of the light source (candela), and d is the on-axis distance between the light source and the point where the illumination is measured (Fig. 40.14).

$$E = \frac{I}{d^2}$$

In cases where flashing signals are required, the source strength or output is cited as *effective intensity*. Effective intensity is used to equate the perceived brightness of a flashing light to that of a steady light. It can be calculated using the relationship [64],

$$I_e = \frac{\left(\int_{t_1}^{t_2} I\,dt\right)}{(a + t_2 - t_1)} \tag{40.29}$$

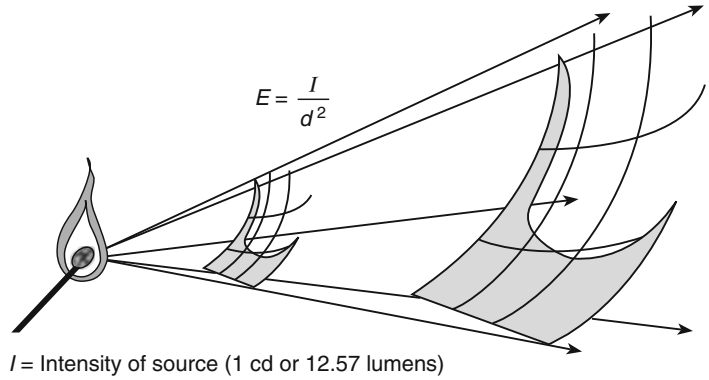
where

I_e = Effective intensity
I = Instantaneous intensity
t_1 = The time (s) of the beginning of that part of the flash where I exceeds I_e
t_2 = The time (s) of the ending of that part of the flash where I exceeds I_e

In the United States, the value of 0.2 is usually used for the constant a. This relationship is shown graphically in Fig. 40.15.

There are two ways to use light as a notification method. The first is direct viewing where the person must be "see" the appliance in their direct or peripheral vision. The second is indirect viewing where the person is alerted by light reflected off of adjacent surfaces.

Equation 40.29 is referred to as the Blondel-Rey equation and was adopted as a product metric in the early 1990s. This allowed different light sources to be evaluated as being equivalent. The research by Blondel and Rey was published in 1912 and is based on direct viewing of a flashing light in a dark environment [72]. Equation 40.29 has worked as a metric to compare two light sources that use the same technology and that have similar pulse durations and pulse shapes.



I = Intensity of source (1 cd or 12.57 lumens)

E = Illumination (1 lumen/ft^2 or 1 footcandle [1 lumen/m^2 or 1 lux or 0.0926 footcandle])

d = Distance from source to object (ft or m)

Fig. 40.14 Relationship between intensity of lamp and level of illumination required to alert someone

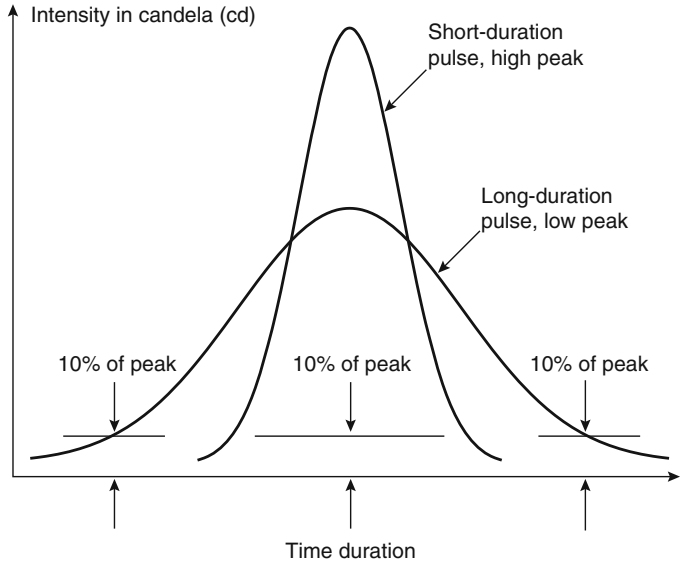


Fig. 40.15 Peak versus effective intensity (Source: R.P. Schifiliti Associates, Inc., Reading, MA)

Until recently, all lights used for occupant notification in the fire alarm industry have been based on Xenon flash tubes. These strobe lights all have pulse durations less than 1 millisecond (ms) and have the similarly shaped response curves.

Recent research has indicated that Equation 40.29 it is not suitable for comparing the detection of indirect flashing lights or for comparing different light technologies, such as Xenon strobes versus LED lights that have rectangular pulse curves [73]. Additional research is being done to define a new metric that allows different technologies to be compared and that is well correlated to actual indirect alerting effectiveness. The examples that follow are valid only for strobe lights that use Xenon flash tube technology.

If the duration of the flash is less than 1 millisecond, Equation 40.29 can be further simplified to [64]

$$I_e = 5\int I \; dt$$

where the integration is performed over the complete flash cycle.

As part of a test program to determine signaling applications for the hearing impaired, UL determined that an illumination of 0.398 lm/m^2 (0.037 lm/ft^2) as viewed on axis from a single flashing light source located in the center of one wall of a 6.1 m by 6.1 m (20 ft by 20 ft) room was the minimum required by their objective. It was also determined that, by increasing the "square" dimensions in increments of 3 m (10 ft) in both directions (length and width), the minimum illumination value of 0.398 lm/m^2 could be used to extrapolate the required signal intensity as the room size increased.

For example, if the room size were increased to 12.2 m by 12.2 m (40 ft by 40 ft), the effective intensity, cd eff, of the flashing strobe signal could be determined using the inverse square law and solving for I:

$$E = \frac{I}{d^2}; \text{ therefore}$$

$$I = Ed^2 = (0.398 \text{ lumens/m}^2)(12.2 \text{ m}^2)$$

$$= 59.2 \text{ candela}$$

Thus, one signal rated at 60 cd eff would be sufficient for the space. Using the same approach, but smaller squares, one would also find that two signals rated at 30 cd eff, or four signals rated at 15 cd eff each, would also be applicable.

Designers should check with the authority having jurisdiction or the current edition of *NFPA 72* regarding the use of multiple flashing lights.

Example 20 The design objective is to evaluate the visual alarm notification system installed in a large open space for suitability in providing signals for the hearing impaired. The space is 21 m (70 ft) by 37 m (120 ft), with a 6.5 m (20 ft) ceiling height. The notification appliances are located 2 m (6.5 ft) above floor level and are spaced as shown in Fig. 40.16. The signals are rated at 45 cd eff each. Is the required illumination of 0.398 lm/m^2 currently provided?

Solution The first step is to section off the space into blocks that are anticipated to be covered for each signal. In this case, the result is six blocks, each 12.2 m (40 ft) long by 10.5 m (34 ft) wide. This step is illustrated in Fig. 40.17.

Given these dimensions, one could calculate the illumination at point A, where

$$E = \frac{45 \text{ cd}}{(10.5 \text{ m}^2)} = 0.41 \text{ lumens/m}^2$$

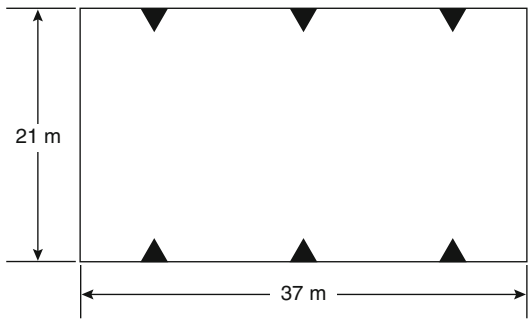

Fig. 40.16 Notification appliance (▲) locations

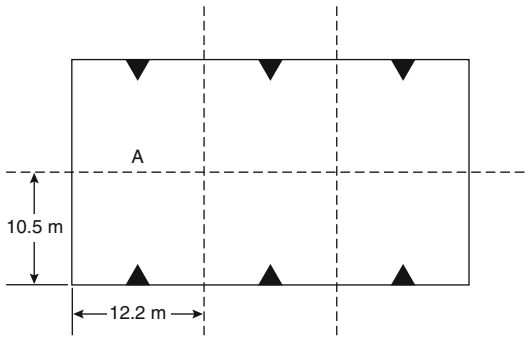

Fig. 40.17 Sections for anticipated signal (▲) coverage

This illumination is greater than the minimum required of 0.398 lm/m^2. However, application of this method requires the blocks of coverage by a signal to be square with the lateral distance (90°) being equal to one-half the coverage distance on-axis. In this case, the lateral distance is 12.2 m (40 ft), and this is the figure that should be used to calculate the illumination throughout the entire block. In doing this, one finds that the illumination provided is

$$E = \frac{45 \text{ cd eff}}{(10.5 \text{ m}^2)} = 0.29 \text{ lumens/m}^2$$

which is below the minimum required 0.398 lm/m^2. This outcome results in areas of the space not having the required illumination. This outcome is illustrated in Fig. 40.18.

To determine what intensity is required for the signals in order to provide the required 0.398 lm/m^2, the inverse square law can be applied using the value $d = 12.3$ m. This application results in a required incident intensity of 60 cd eff for each existing signal location.

By applying this method of dividing spaces into squares and applying the inverse square law, the intensity of signals and their required spacing can be calculated for spaces of any shape and size. Trade-offs can be made between the number of signals and the intensity of signals to best fit the application (e.g., one signal of 60 cd eff

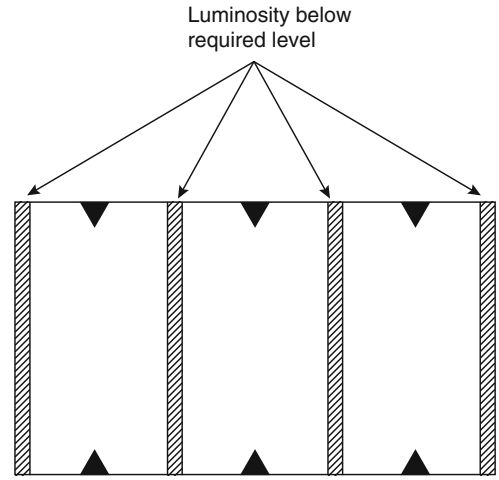

Fig. 40.18 Diagram of subadequate luminosity intensity

versus four properly spaced signals of 15 cd eff each).

In cases where a minimum required illumination at all points in a space is specified (as opposed to the minimum effective intensity on-axis within a square), the illumination can be calculated using the inverse square law, the cosine law, and the cosine cubed law. In this case, the inverse square law provides the illumination on-axis, application of the cosine law provides the illumination at a perpendicular surface within the same plane as the signal, and application of the cosine cubed law provides the illumination at parallel surfaces within the same plane as the signal.

With this information, it should be possible to calculate visual fire alarm signals for most situations. In all cases, a value for the required effective intensity at some point within the room is required. If not provided at the beginning of the design process, one should determine an effective intensity based on the specific application and the condition of the occupants being alerted.

Nomenclature

α	Fire intensity coefficient (Btu/s^3 or kW/s^2)
A	Area (m^2 or ft^2)
A	$g/(C_pT_a\rho_0)$ [m^4/(s^2·kJ) or ft^4/(s^2·Btu)]
c	Specific heat of detector element [Btu/(lbm·R) or kJ/(kg·K)]
C_p	Specific heat of air [Btu/(lbm·R) or kJ/(kg·K)]
d	Diameter of sphere or cylinder (m or ft)
D	Nondimensional change in gas temperature
Δt	Change in time (s)
ΔT	Increase above ambient in temperature of gas surrounding a detector (°C or °F)
ΔT_d	Increase above ambient in temperature of adetector (°C or °F)
ΔT_p^*	Change in reduced gas temperature
f	Functional relationship
g	Functional relationship
g	Gravitational constant (m/s^2 or ft/s^2)
h_c	Convective heat transfer coefficient [kW/(m^2·°C) or Btu/(ft^2·s·°F)]
H	Ceiling height or height above fire (m or ft)
ΔH_c	Heat of combustion (kJ/mol)
H_f	Heat of formation (kJ/mol)
L_p	Sound pressure level
L_W	Sound power level
m	Mass (lbm or kg)
p	Positive exponent
$\dot{q}$	Heat release rate (Btu/s or kW)
$\dot{q}_{cond}$	Heat transferred by conduction (Btu/s or kW)
$\dot{q}_{conv}$	Heat transferred by convection (Btu/s or kW)
$\dot{q}_{rad}$	Heat transferred by radiation (Btu/s or kW)
$\dot{q}_{total}$	Total heat transfer (Btu/s or kW)
$\dot{Q}$	Heat release rate (Btu/s or kW)
$\dot{Q}_{cr}$	Critical heat release rate
$\dot{Q}_{do}$	Design heat release rate
$\dot{Q}_i$	Ideal heat release rate
$\dot{Q}_p$	Predicted heat release rate (Btu/s or kW)
$\dot{Q}_T$	Threshold heat release rate at response (Btu/s or kW)
r	Radial distance from fire plume axis (m or ft)
ρ_0	Density of ambient air (kg/m^3 or lb/ft^3)
Re	Reynolds number
RTI	Response time index (m$^{1/2}$·s$^{1/2}$ or ft$^{1/2}$·s$^{1/2}$)
S	Spacing of detectors or sprinkler heads (m or ft)
t	Time (s)
t_c	Critical time—time at which fire would reach a heat release rate of 1000 Btu/s (1055 kW) (s)
t_r	Response time (s)
t_v	Virtual time of origin (s)
t_{2f}	Arrival time of heat front (for $p = 2$ power-law fire) at a point r/H (s)
t_{2f}^*	Reduced arrival time of heat front (for $p = 2$ power-law fire) at a point r/H (s)
t_p^*	Reduced time
T	Temperature (°C or °F)
T_a	Ambient temperature (°C or °F)
T_d	Detector temperature (°C or °F)
T_g	Temperature of fire gases (°C or °F)
T_s	Rated operating temperature of a detector or sprinkler (°C or °F)

U Velocity (m/s)
u Instantaneous velocity of fire gases (m/s or ft/s)
u_0 Velocity at which τ_0 was measured (m/s or ft/s)
u_p^* Reduced gas velocity
v Kinematic viscosity (m^2/s or ft^2/s)
x Vectorial observation point (m or ft)
Y Defined in Equation 40.26
τ Detector time constant—$mc/(hA)$ (s)
τ_0 Measured at reference velocity u_0 (s)

Hydraulics

41

Kenneth E. Isman

Introduction

Hydraulics may be regarded as the application of knowledge about how liquids behave in static and flowing conditions to solve practical fluid related problems. It is generally held to describe the behavior and effects of water in motion in both closed conduits and open channels. In the field of fire protection we are concerned primarily with the closed conduit flow regime. In this chapter we will restrict our discussion to the behavior and properties of water flowing in pipes as the phenomenon of paramount interest, although other fluids such as antifreezes at room temperature and foam/water solutions are similar enough to water that the discussion will be applicable to them as well. Additionally some of the principles presented here also apply to system designs utilizing other fluids such as foam concentrate or antifreeze at low temperatures.

A significant portion of this chapter was written by John J. Titus. Editorial and technical updates were incorporated and additional information on pumps and water supplies have been provided for this edition.

K.E. Isman (✉)

Physical Properties of Fluids

The solution of any flow problem requires a basic knowledge of the physical properties of the fluid being considered. A brief description of the most basic properties follows.

Density

The density of a fluid (ρ) is the mass of the fluid (m) per unit volume (V) as shown in the equation below:

$$\rho = \frac{m}{V}$$

Density is expressed in SI units as kg/m^3 and in English, or U.S. customary, units as slugs/ft^3 (or lbf · s^2/ft^4). The density of water at 4 °C (~40 °F) is 1000 kg/m^3 (1.94 lbf · s^2/ft^4).

Specific Weight

The specific weight of a fluid (γ) is the representation of the force exerted by gravity on a unit volume of the fluid. The specific weight can also be calculated by multiplying the density of a fluid (ρ) by the gravitational constant (g) as shown below:

$$\gamma = \rho g$$

Specific weight takes on units of weight per unit volume, which in SI units would be kN/m^3 and in

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_41, © Society of Fire Protection Engineers 2016

English customary units would be lb/ft^3. At 4 °C, the specific weight of water is 9.81 kN/m^3 (62.4 lb/ft^3) [1].

Specific Gravity (Relative Density)

Specific gravity (SG) is the ratio of a liquid's density (ρ) or specific weight (γ) to that of water (ρ_{water} or γ_{water}) as shown by the following formulas:

$$SG = \frac{\rho}{\rho_{water}} \quad \text{or} \quad SG = \frac{\gamma}{\gamma_{water}}$$

Where the specific gravity of a fluid is greater than 1.0, it means that the fluid is heavier than water. Where the specific gravity of a fluid is less than 1.0, it means that the fluid is lighter than water. If the fluid is also not miscible with water, it will float or settle on top of the water creating a defined interface.

Viscosity

The term *viscosity* refers to a proportionality constant in the equation relating cross-sectional velocity variations (or rate of fluid deformation) to shear stresses developed in the fluid flow. (See the subsection of this chapter titled "Fluid Flow Energy Loss Equations" to see how viscosity is used.) Viscosity can be considered a measure of a fluid's resistance to deformation or shear or, alternatively, its readiness to flow when acted upon by an external force. In engineering analyses it is useful to think of viscosity as a momentum diffusivity term.

Viscosity is commonly expressed in one of two forms: absolute (or dynamic) viscosity (μ), which is the proportionality constant referred to above, or kinematic viscosity (ν), which is related to the absolute viscosity divided by the density (ρ) as follows:

$$\nu = \frac{\mu}{\rho}$$

Note that the kinematic viscosity is expressed with the Greek letter "nu", which looks like a "v", but is not a "vee". This means that the kinematic viscosity often gets mixed up with the velocity. Engineers must understand and distinguish the meanings of the variables in the equations that they use. For this reason, some engineers use the Greek letter kappa (κ) for kinematic viscosity.

A wide variety of units is used to express absolute (or dynamic) viscosity, depending not only on U.S. customary or SI formulations but also on older English and metric conventions as well as on the type of instrument used to measure this fluid property. In S.I. units, absolute (or dynamic) viscosity is measured in kilograms per meter-seconds (kg/(m-sec)). In customary English units, absolute or dynamic viscosity is measured in pounds per foot-seconds (lb/(ft-sec)). A unit based on the c.g.s. (centimeter, gram, second) convention of the old metric system has gained wide favor in the representation of absolute (or dynamic) viscosity. This unit, called the *poise,* has dimensions of dyne · seconds per square centimeter or grams per centimeter · second. The centipoise, which equals 0.01 P, is the form of preference for many engineers because the viscosity of water at 20 °C (68 °F) is very close to one centipoise. One centipoises is equal to 6.72×10^{-4} lb/(ft-sec).

For kinematic viscosity, there is also a wide variety of units used. In the S.I. system, the units of kinematic viscosity are square meters per second (m^2/s) and in the customary English system the units are square feet per second (ft^2/s). Another unit has also gained favor in the engineering community called the centistoke (named after George Gabriel Stokes, a late nineteenth century English mathematician and physicist). One centistoke is equal to 0.000001 m^2/s or 0.0000107639 ft^2/s.

Fluid Pressure

Pressure is a force per unit area that arises when a fluid is subjected to a compressive stress. Units may be newtons/m^2, lb/ft^2, lb/in.^{2}, or any similar equivalent of force over area. Pascal's law states that the pressure in a fluid at rest is the same in all directions, a condition different from that for a

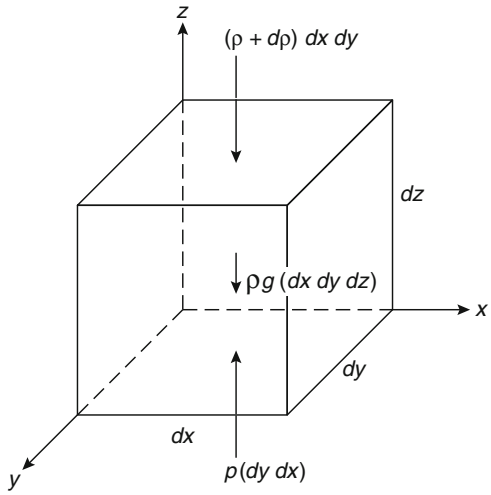

Fig. 41.1 Notation for basic eq. of fluid statics

stressed solid where the stress on a plane depends upon the orientation of that plane. For an infinitesimal fluid element in a larger static body of fluid, a free body diagram of the vertical forces can be drawn as shown in Fig. 41.1. The pressure difference $[(p + dp) - p]$ is due only to the weight of the fluid element. Since the weight of the element is given by $mg = \rho g\, dz\, dA$, a summing of forces in the vertical direction gives:

$$dp\ dA = -\rho g\ dz\ dA \tag{41.1a}$$

$$dp = -\rho g dz \tag{41.1b}$$

In integral form, Equation 41.1b becomes

$$\int_1^2 \frac{dp}{\rho g} = -\int_1^2 dz = -(z_2 - z_1) \tag{41.2}$$

where the path endpoints 1 and 2 refer to different elevation levels.

To integrate Equation 41.2, it is necessary to establish a functional relation between the pressure p and the product of the density times the gravitational constant (ρg). Where density varies with pressure, the fluid is considered compressible, and the functional relation may be complex. For fluids that may be considered incompressible, such as water, ρ is a constant at any specified temperature. Equation 41.2 then becomes

$$p_2 - p_1 = -\rho g(z_2 - z_1) \tag{41.3}$$

The term (z_2–z_1) may be called a static *pressure head,* which can be expressed in units of length such as feet, inches, or meters of water. A simplified form of Equation 41.3 is often written

$$\rho = \gamma h \tag{41.4}$$

where h is height (elevation) of the column of liquid above a reference surface (i.e., (z_2–z_1). For water at 60 °F (15.6 °C), γ is taken to equal 62.4 lb/ft^3 (16.02 kg/m^3). The pressure corresponding to a head of h feet, then, is 0.433 h lb/in.^{2} (psi), or approximately 3 kPa per meter elevation. The head corresponding to a pressure of 1 psi (0.07 bar) is, inversely, 2.3 ft (0.7 m). Note that Equation 41.4 is valid only for a homogeneous, noncompressible fluid at rest, and that regardless of the shape of the container, points in the same horizontal plane experience the same pressure.

The vertical distance h is termed the *head* of a fluid. A pressure due only to the weight of a column of fluid is called a static pressure and can be measured by a standard Bourdon-type gauge (see Fig. 41.4). Such a measure is generally referred to as *gauge pressure*. The term *absolute pressure* takes into account the pressure exerted by the atmosphere as well, which at sea level is approximately 14.7 psi (1 bar), equivalent to a 33.9 ft (10.3 m) column of water. A pressure less than atmospheric is called a vacuum pressure, a perfect vacuum being zero absolute pressure. Since most fluid properties of interest are not significantly affected by small changes in atmospheric pressure, most fluids calculations are in terms of gauge pressure, although this fact is not often indicated in standard calculation nomenclature. When they are explicitly identified, gauge pressure is denoted by the term psig and absolute pressure by psia. If not stated otherwise, psi may be taken to designate gauge pressure.

Pressure Measuring Devices

Manometer Tube

Pressure measurement in a manometer tube is obtained by measuring the vertical displacement of a relatively heavy fluid (usually mercury),

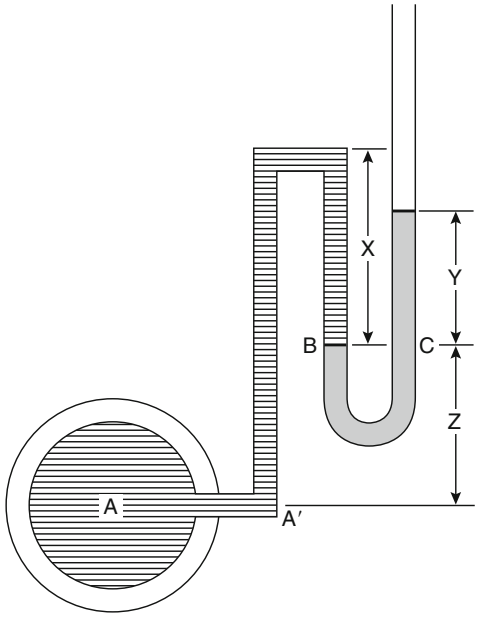

Fig. 41.2 Manometer

which will rise a smaller vertical distance than water in proportion to the ratio of its specific weight to that of water. Depending on the actual arrangement of the manometer tubing, a gauge equation can be written to solve for the pressure head. For the manometer shown in Fig. 41.2, the gauge equation is written by proceeding from the open end through the tube to point A', adding terms when descending a column and subtracting when ascending. Using mercury as the manometer fluid, we can write

$$(y+z)\gamma_{H_g} - z\gamma_{H_g} - x\gamma + (x+z)\gamma = p_A \quad (41.5)$$

Combining terms, generalizing the result, and expressing in terms of feet of water (head),

$$\frac{P_A}{\gamma} = ys + z \quad (41.6)$$

where s is the specific gravity of the manometer fluid.

Piezometer Tube

Literally a *pressure measuring tube,* a piezometer consists essentially of a narrow tube rising from a container enclosing a fluid under pressure (Fig. 41.3). Through the relation among pressure, height, and specific weight, the height to which the fluid rises in the tube represents the pressure of the contained fluid. While useful for some laboratory work, piezometer tubes are not generally feasible in practical applications.

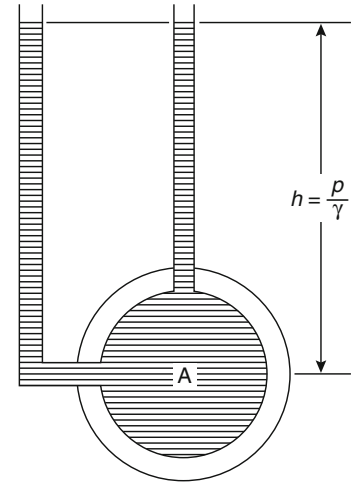

Fig. 41.3 Piezometer

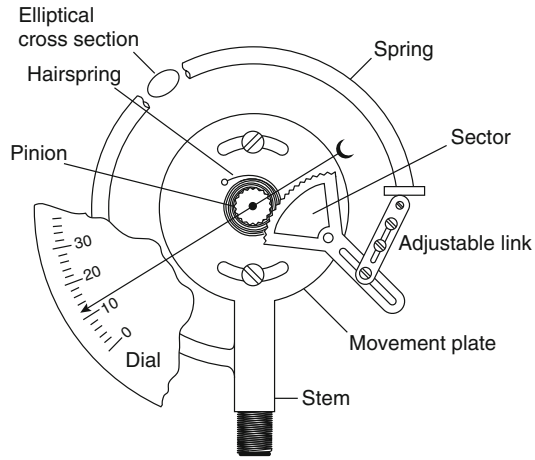

Fig. 41.4 Standard Bourdon gauge

Bourdon Gauge

The standard pressure measuring device used in a wide variety of fluid pressure measurement applications is the Bourdon gauge (Fig. 41.4).

The gauge contains a curved tube of elliptical cross section that undergoes a change in curvature with change in pressure. A dial hand, connected to the inner tube through a linkage system, indicates gauge pressure on a numerical dial face. Bourdon gauges are factory calibrated and reasonably accurate instruments if not damaged by pressure surge or impact force. A field reading, unless known to be correct, cannot be assumed to be accurate and should be checked by independent means.

Forces on Submerged Plane Areas due to Fluid Pressure

It is sometimes of interest to determine the magnitude of the resultant force on a submerged area and the location of the center of pressure where the resultant force can be assumed to act. Consider the following example of a tank that has a plate in a vertical wall (Fig. 41.5). The magnitude of the resultant force can be determined from

$$F_R = \gamma h_c A \tag{41.7}$$

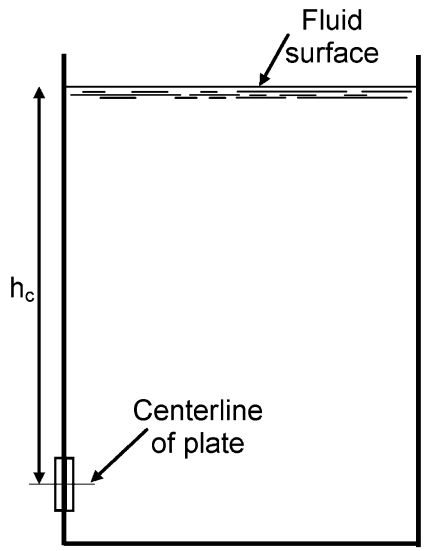

Fig. 41.5 Tank with a plate in a vertical wall

Fluid Dynamics

While the study of fluids in a static condition (at rest) yields some interesting information, it is the study of fluids in motion that is the most relevant to the fire protection engineer. Water, the most common fluid for fire protection needs to be available at the location of the fire, and therefore, needs to be moved from its source of supply though a series of conduits, typically pipes and hoses. The study of fluids in motion is called Fluid Dynamics.

Conservation Laws in Fluid Flows

Fluid flow may be characterized as uniform or nonuniform, steady or unsteady, compressible or incompressible, laminar or turbulent, rotational or irrotational, and one-, two-, or three-dimensional or some combination thereof. Real flows may be modeled as approximations of ideal flows when real properties do not depart significantly from the ideal characteristics defined by these terms.

For example, uniform flow occurs when the average velocity of a fluid does not change in either magnitude or direction anywhere along the flow path. Thus, liquid flow in a constant head pipeline of unchanging diameter is considered uniform flow. Steady flow, on the other hand, is determined with reference to a stationary point in the flow path. For steady flow to occur, the velocity of flow at that point must remain constant with time. This condition implies that the fluid density, the pressure head, and the volume rate of flow also are invariant with time. Thus, liquid flow in a constant head pipeline of varying diameter may be considered steady, nonuniform flow. It is important to note that a flow may be considered uniform (no change in magnitude or direction of the velocity) in a curved pipeline as long as the reference direction of the velocity vector is taken in the direction of the flow. We can then say that the velocity of the fluid does not change direction with respect to its enclosing boundaries.

We can also consider this flow one-dimensional whenever it is permissible to say that velocities or accelerations normal to the general direction of the flow are negligible. Clearly, real flow in a real-world structure has three dimensions, but a one-dimensional analysis is highly desirable as it represents a considerable mathematical simplification. Fortunately, a very large number of practical engineering flow problems involving water can be modeled as one-dimensional, steady flow problems, particularly many pipeline flows. In such cases it is possible to apply basic physical principles of conservation of mass and conservation of energy in the direction of flow to obtain the energy balance at any point in the flow. In fire flow hydraulics, it is common practice to introduce additional simplifying assumptions, such as the requirements that the fluid be incompressible and that flow properties be invariant with temperature and pressure. It then follows directly that with no flow additions or subtractions, the volumetric flow rate at any point in a fluid stream must be a constant. This statement of mass conservation, known as the equation of continuity, can be expressed mathematically as

$$\rho_1 A_1 v_1 = \rho_2 A_2 v_2 = \text{Constant} \tag{41.9}$$

If the fluid is considered incompressible, as is the case with water, the density will not change with respect to the fluid at different locations in the flow, so Equation 41.9 becomes

$$A_1 v_1 = A_2 v_2 = \text{Constant} = Q \tag{41.9a}$$

By applying the principal of conservation of energy to a flowing fluid, an expression can be derived that gives the theoretical net energy balance of the fluid at any point along its flow path. This is known as the Bernoulli equation, which can be written as:

$$\frac{p_1}{\gamma} + \frac{v_1^2}{2g} + z_1 = \frac{p_2}{\gamma} + \frac{v_2^2}{2g} + z_2 \tag{41.10}$$

In Equation 41.10, p_1, v_1, and z_1 represent the pressure, velocity, and elevation (above a given data plane) of the fluid at one location in the flow stream while p_2, v_2, and z_2 represent the pressure, velocity, and elevation of the same fluid at a second point in the same flow stream. In this form, units are feet (or meters) of fluid. Each term thus represents a fluid head with the addition of the three terms representing the total head (or energy) of the fluid at any point. Multiplying each term by the specific weight, γ, converts the equation to units of pressure. Changes in internal energy of the fluid are ignored and are assumed to be negligible. The form of Equation 41.10 suggests that the flow of liquid (or transport of fluid energy) results from three principal causes: pressure difference, gravity, and inertia. Equation 41.10 expresses an ideal condition fulfilled by the three components of head corresponding to these three causes.

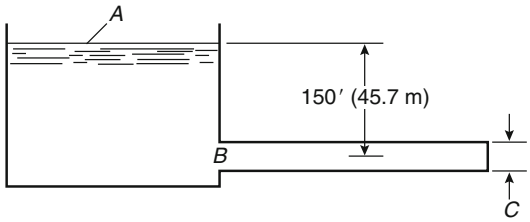
The assumption of incompressibility (i.e., constant density) requires that the product of the velocity of flow and the cross-sectional area of the flow of any conserved portion of the stream be constant; the ideal flow streamlines, therefore, converge as the velocity increases and diverge as the velocity decreases. If it could be assumed that the total Bernoulli head were, indeed, constant or, equivalently, if it were possible to obtain total head simply as a function of the coordinates of the moving fluid element, then many hydrokinetic problems could be solved theoretically by mathematically manipulating and extrapolating the Bernoulli equation. Unfortunately, this is not the case. Other energy transfers are possible, and these require use of a more general form of the equation. In addition to the pressure, velocity, and position (elevation) energies possessed by the fluid at sections 1 and 2, energy may be added to the fluid (work done on the fluid by a pump), lost by the fluid (through friction), or extracted from the fluid (work done by the fluid). Therefore, we write the Bernoulli energy conservation expression in the more general form:

$$\left(\frac{p_1}{\gamma} + \frac{v_1^2}{2g} + z_1\right) + h_A - h_L - h_E = \left(\frac{p_2}{\gamma} + \frac{v_2^2}{2g} + z_2\right) \tag{41.10a}$$

In Equation 41.10a, the value of h_A represents the energy being added to the fluid, h_L represents the

energy lost from the fluid due to friction loss, and h_E represents the energy taken from the fluid. An example of how the Bernoulli equation can be used to solve a simple water flow problem follows as Example 1.

Example 1 Water flows from a reservoir through a pipeline as shown in the following diagram. The flow is considered frictionless and discharges freely at point *C*.



(a) What is the total head (total specific energy) at point *A*?
(b) What is the total head (total specific energy) at point *B*?
(c) What is the discharge velocity at point *C*?

Solution

(a) At *A*, both the velocity and gauge pressures are considered to be zero. Assuming that the plane at the middle of the discharge outlet at *C* is the reference data place, by Bernoulli, then, the total head would be written as:

$$h_A = 0 + 0 + 150 \text{ ft} = 150 \text{ ft}$$

or, in SI unit equivalents,

$$h_A = 0 + 0 + 45.7 \text{ m} = 45.7 \text{ m}$$

(b) At *B*, the fluid has a nonzero velocity head and is under hydrostatic pressure. As long as we consider the flow frictionless, the total head is constant. Therefore,

$$h_B = h_A = 150 \text{ ft } (45.7 \text{ m})$$

(c) At *C*, the pressure head is again zero, since the discharge is at atmospheric pressure and the discharge of the water is at the reference data elevation, so it is also zero. Once more by Bernoulli,

$$h_C = 0 + \frac{v^2}{2g} + 0$$

Since the total energy at one point in the flow is equal to the total energy at another point, we know that h_C is also equal to h_A and h_B, which are 150 ft. Using this knowledge, we can solve the equation for "v" as follows:

$$150 = \frac{v^2}{2g}$$
$$v^2 = (150)2g = (150)2(32.2) = 9,660$$
$$v = 98.3$$

or, in SI unit equivalents,

$$v^2 = 2(9.81)(45.7)$$
$$v = 29.9 \text{ m/s}$$

Note that we could calculate the actual values of the pressure and velocity heads at point *B* if we had more information about the system. For example, we could determine the flow at the discharge point (*C*), if we knew the area and type of discharge opening (see section "Free Discharge at an Opening"). This determination is simply an application of the continuity equation. Knowing the pipeline diameter at point *B* allows us to apply continuity constraints once again to calculate v_B from which the velocity head may be determined. The pressure head at *B* is simply a function of the weight of the vertical column of water.

The components of the Bernoulli equation may be expressed graphically in terms of energy levels existing at any points in the flow regime. In Fig. 41.6 a simple system representing a realistic flow is shown. Water flows from a reservoir (with presumed constant surface elevation) to atmosphere. The flow is accompanied by losses of energy represented by h_L. The losses may occur in many places such as at valves, bends, and sudden changes in pipe diameter. Generally, the most important loss is that due to friction between the moving fluid and the pipe wall. Since there are always energy losses in real flows, the total energy of the system decreases in the direction of flow. Graphically, the linear curve in Fig. 41.6 connecting all points

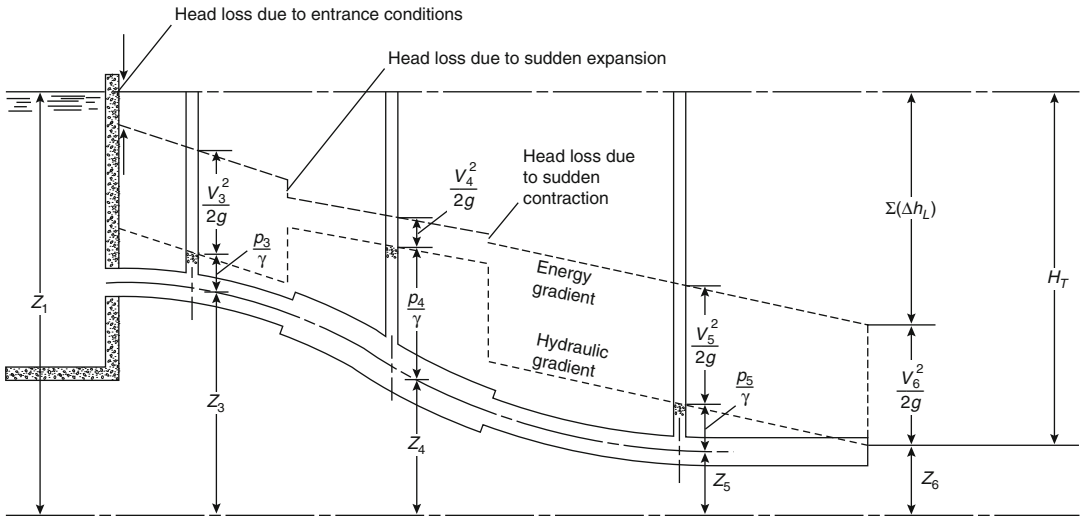


Fig. 41.6 Realistic flow characteristics

represents the total energy in the piping system and is referred to as the *energy gradient* (EG). It must always decrease in the direction of flow unless energy is added to the system such as by a pump. The *hydraulic gradient* (HG) connects the points representing the sum of static pressure and elevation energies (i.e., the heights to which water in piezometer tubes would rise in a flow path). Note that the hydraulic gradient may increase in the direction of flow if velocity head is converted to pressure head at a given point in the system (such as at an increase in pipe diameter). Thus, the relationship between the energy and hydraulic gradients can be written as

$$\mathrm{EG} = \mathrm{HG} + \frac{v^2}{2g} \tag{41.11}$$

General Considerations for Fluid Energy Losses in Pipe Flows

Energy losses in fluids due to friction in piping are of key importance in fire protection engineering. Losses due to friction are due to shear stresses set up within a moving fluid in a conduit by an imposed pressure gradient. Flow driven by the pressure force is restrained by drag forces acting at the conduit wall. To better visualize this phenomenon, it is useful to introduce the concept of the boundary layer. For many fluids, such as air or water, motion through a stationary conduit or pipe is characterized in most practical situations by a nearly constant velocity cross section everywhere except in a very thin layer near the wall of the pipe. This layer may be as little as 0.1 mm thick, but may vary significantly with the nature of the fluid, the velocity of flow, and the surface roughness of the conduit. We may visualize boundary layer flow in terms of a velocity profile (Fig. 41.7). Theories developed primarily by Prandtl [2, 3] hold that a very thin (molecular) layer of fluid sticks to the conduit wall. The tendency of the next fluid layer to move due to an imposed force creates a shearing stress, τ, between the layers. If the boundary is thought of as many thin fluid plates (lamina) sliding on each other, then we can expect the velocities of these lamina to increase with distance y from the wall until, at the edge of the boundary layer, the local velocity reaches the free-stream velocity of the fluid. The factor relating the velocity profile to the developed stress in the fluid is termed the fluid viscosity. The relationship was expressed mathematically by Newton as

$$\tau = \mu \frac{du}{dy} \tag{41.12}$$

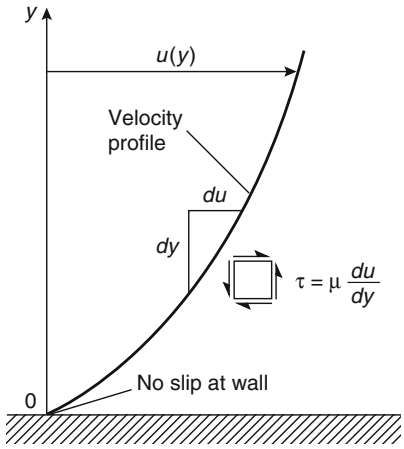

Fig. 41.7 Velocity profile

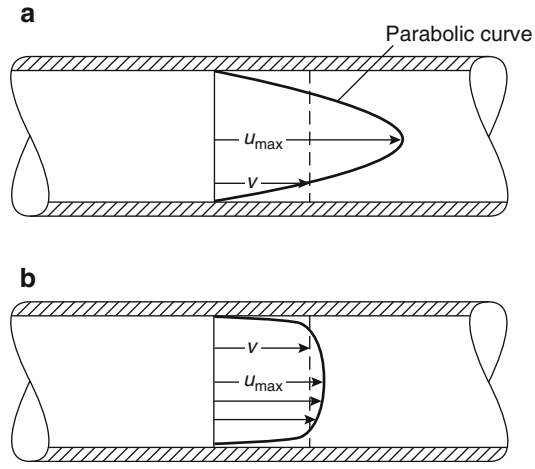

Fig. 41.8 Laminar (**a**) and turbulent (**b**) pipe flow velocity profiles for the same volume

The smaller the value of fluid viscosity, the thinner the boundary layer will be. The first layer of fluid sticks or adheres to the surface of the conduit while lamina above it successively slide on each other, exerting drag forces that, for most fluids, are proportional to the viscosity (so-called Newtonian fluids). The rate of change of the velocity between successive lamina is a measure of the unit shearing force between them. A curve joining the tips of velocity vectors plotted for the different lamina in the boundary layer is called a velocity profile. Laminar (smooth, streamline) flow (Fig. 41.8a) is characterized by a parabolic velocity profile with maximum velocity attained at the theoretical centerline of the flow. Turbulent flow, by contrast, is rough (nonstreamline) flow (Fig. 41.8b), characterized by an essentially uniform average velocity across the flow section, with only a very thin boundary layer close to the wall where viscous forces predominate. The velocities associated with laminar flows are generally so low that they are not representative of typical velocities in fire protection systems. Most flows of interest are turbulent, and the use of an approximated uniform or average velocity in calculating kinetic energy and velocity pressures does not introduce notable errors. In those situations where relatively large velocity heads are involved (such as where a pump adds a large amount of energy), a correction factor may be used to relate the actual average kinetic energy to the kinetic energy calculated using average velocity. From continuity considerations,

$$\mathrm{KE} = \int_A \rho u^3 dA = \alpha\rho \int_A v^3 dA \qquad (41.13)$$

where

KE = True kinetic energy of the flow

v = Average velocity of flow

α = Kinetic energy correction factor

For incompressible fluids, α can be represented by the following:

$$\alpha = \frac{1}{A}\int_A \left(\frac{u}{v}\right)^3 dA \qquad (41.14)$$

The value of α is approximately 1.1 for most turbulent flow problems. However, since the velocity head in most water distribution fire protection piping systems is relatively small, this correction factor is usually ignored.

While the development of boundary layer theory and the theory of viscous forces has led to an improved theoretical understanding of the mechanics of pipe flows, most flows of interest in fire protection cannot be fully analyzed from theoretical considerations alone. Fire protection flows are almost always turbulent flows. Despite a great expenditure of effort to develop a general predictive theory of turbulent flow phenomena, a fully descriptive theory does not yet exist.

While it is postulated that head losses arise because of friction between the fluid and the pipe wall, there is an additional head loss contribution due to turbulence within the flowing fluid. In turbulent flows the rate of head loss, unfortunately, is not simply a function of fluid velocity but depends also on pipe wall roughness. The determination of head loss is further complicated by the changing interaction among these variables at different flow velocities, interior pipe surface roughness and actual pipe sizes. Within the last century, however, a large body of empirical flow data has been collected, analyzed, and reproduced by several investigators. The major features and limits of applicability of the more important results are presented in the following paragraphs.

Fluid Flow Energy Loss Equations

Chezy Equation

Theoretical development of the physical relationships describing pipe flows dates from about the middle of the nineteenth century, when Chezy postulated a fundamental proportionality between volumetric flow and pipe size based on the continuity equation. His formula is commonly given as

$$Q = \frac{\pi D^2}{4} v = \frac{\pi D^2}{4} \frac{C}{2} \sqrt{DS} \tag{41.15}$$

and may also be written as

$$S = \left(\frac{8Q}{\pi C}\right)^2 D^{-5} \tag{41.16}$$

where D and S are pipe diameter and slope of the energy gradient, respectively. The factor, C, is a proportionality factor incorporating a significant degree of physical uncertainty. Since, by definition

$$S = \frac{h_L}{L}$$

the equation can be rewritten as an expression for pipe flow head loss as a function of pipe diameter and discharge as follows:

$$h_L = \left(\frac{8}{\pi C}\right)^2 \frac{L}{D^5} Q^2 \tag{41.17}$$

Use of the Chezy equation was limited by uncertainties relating to evaluations of the C-factor, which is not, in fact, a constant for a given size conduit or wall condition as was originally thought.

Darcy-Weisbach Friction Loss

A theoretically more satisfying approach was taken by Darcy, Weisbach, and others. Their formula, which bears the names of the two primary investigators, is generally written as:

$$h_L = f \frac{L}{D} \frac{v^2}{2g} \tag{41.18}$$

It postulates a basic proportionality between head loss and the kinetic energy of the flow, as well as to pipe length and diameter. The proportionality factor f, known as the friction factor, became the subject of extensive theoretical and experimental investigation. The value of f for laminar flow can be shown theoretically to be a simple linear function of the Reynolds number, Re, where:

$$\mathrm{Re} = \frac{D_e v \rho}{\mu}$$

The term D_e is the equivalent flow diameter, which is the actual inside diameter of a circular pipe. The equivalent diameter, D_e, can be found from the hydraulic radius, r_h, which is defined as the area in flow divided by the wetted perimeter. The wetted perimeter does not include the free fluid surface.

$$D_e = 4 r_h$$

For Re less than about 2000 (corresponding to low velocity flows or fluids of high viscosity) the relation is

$$f = \frac{64}{\mathrm{Re}} \tag{41.19}$$

In turbulent flows (higher Reynolds numbers) the roughness of the pipe walls becomes a much more significant factor, and a simple expression to determine f is unavailable.

A systematic investigation of the actual characteristics of piping inner wall surfaces was first performed by Nikuradse in 1933. To simulate varying degrees of roughness in commercial pipes due to corrosion or surface finish, Nikuradse glued sand grains of known sizes to the inside walls of test pipes. The resulting logarithmic plot of friction factor versus Re is shown in Fig. 41.9. Although the tests are from Nikuradse, the plot is called Stanton's diagram in recognition of his earlier (1914) elucidation of the relation between friction factor and Reynolds number. Note that at sufficiently high Re, the friction factor depends almost entirely on pipe roughness and is essentially independent of Re. In these plots the roughness parameter is expressed as the ratio of the root mean square grain diameter to the pipe diameter. The resulting ratio is termed the relative roughness and is represented mathematically as ε/D. Typical values for the roughness (ε) of new commercial pipes are shown in Table 41.1. However, fire protection engineers are expected to build safety factors into their calculations, so the use of pipe roughness values that correspond to new pipe should not be used. To be consistent with fire protection standards, values for aged pipe should be used. Also shown in Table 41.1 are a number of recommended roughness values that should be considered for aged pipe in fire protection system calculations.

Moody plotted various solutions for the friction factor (f) using different Reynolds numbers and relative roughness of pipes on a graph. The resulting Moody diagram (Fig. 41.10) is widely used today in conjunction with the Darcy-Weisbach equation to compute friction losses for water flowing in pipe. Figure 41.11 presents relative roughness values for use with the Moody diagram over a wide range of conditions. Other diagrams have been developed for use with the Darcy-Weisbach equation [6, 7] when parameters other than h_L are sought. Essentially, the alternative graphical formulations employ a rearrangement of variables to facilitate solving for some other unknown variables such as Q or D.

Both experimental and theoretical investigations have yielded uncertain results in

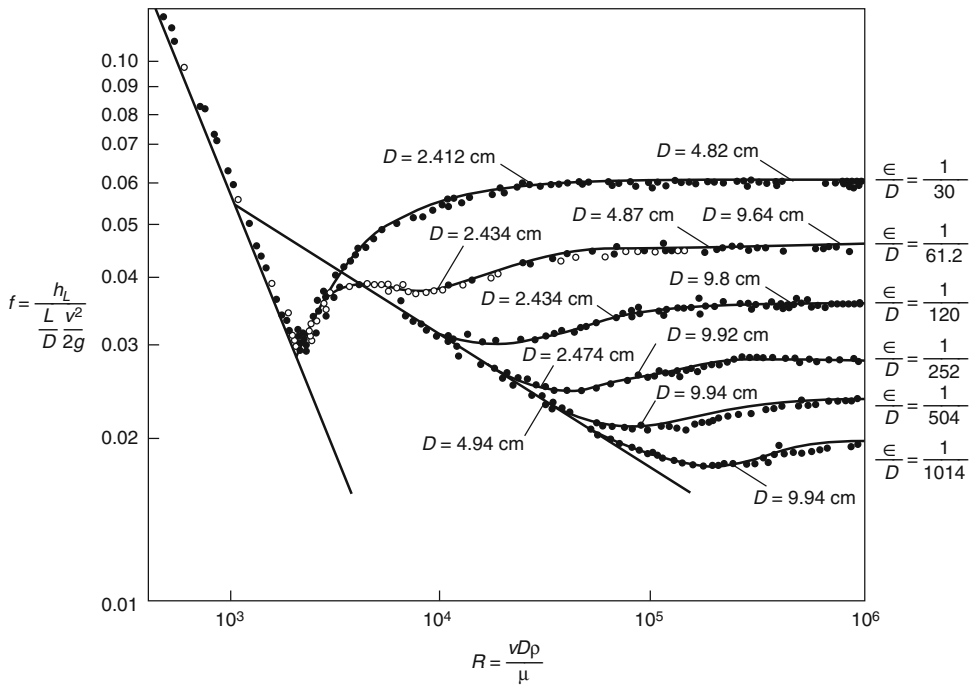

Fig. 41.9 Nikuradse's sand-roughened-pipe tests

Table 41.1 Values of absolute roughness of commercial pipes

Type of pipe or tubing	ε in ft × 10^{-6} Range	Design	Probable maximum variation of f from design (%)
New clean pipe [4]			
Asphalted cast iron	400	400	−5 to +5
Brass and copper	5	5	−5 to +5
Concrete	1000–10,000	4000	−35 to +50
Cast iron	850	850	−10 to +15

Wrought iron	150	150	−5 to +10
Steel	150	150	−5 to +10
Riveted steel	3000–30,000	6000	−25 to +75
Wood stave	600–3000	2000	−35 to +20
Aged pipe [5]			
Steel, dry system		1250	
Steel, wet system		333	
Plastic		7	
Copper		7	

Notes: For ε values in meters, multiply the above numbers by 0.3048
For ε values in inches, multiply the above numbers by 12

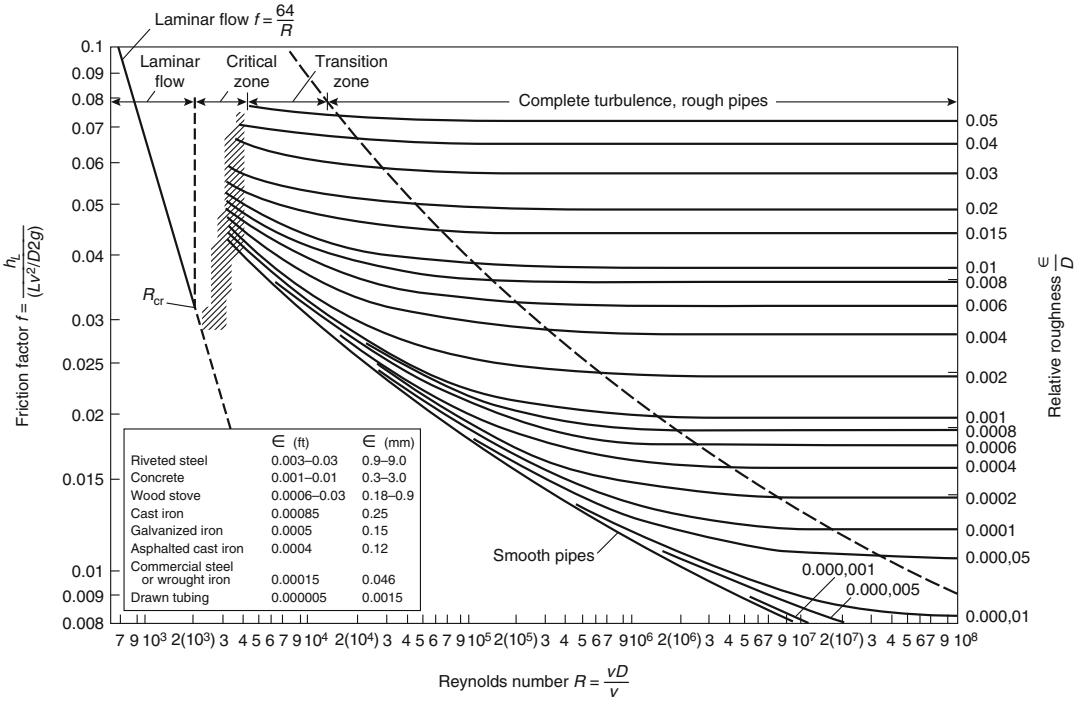

Fig. 41.10 Moody diagram

the region known as the *critical zone,* wherein the flow changes from laminar to turbulent. Uncertainty may be expected since the transition point is difficult to define precisely and, in fact, varies over a considerable range of Re depending upon the direction of the transition (i.e., flow going from laminar to turbulent or from turbulent to laminar) and the local

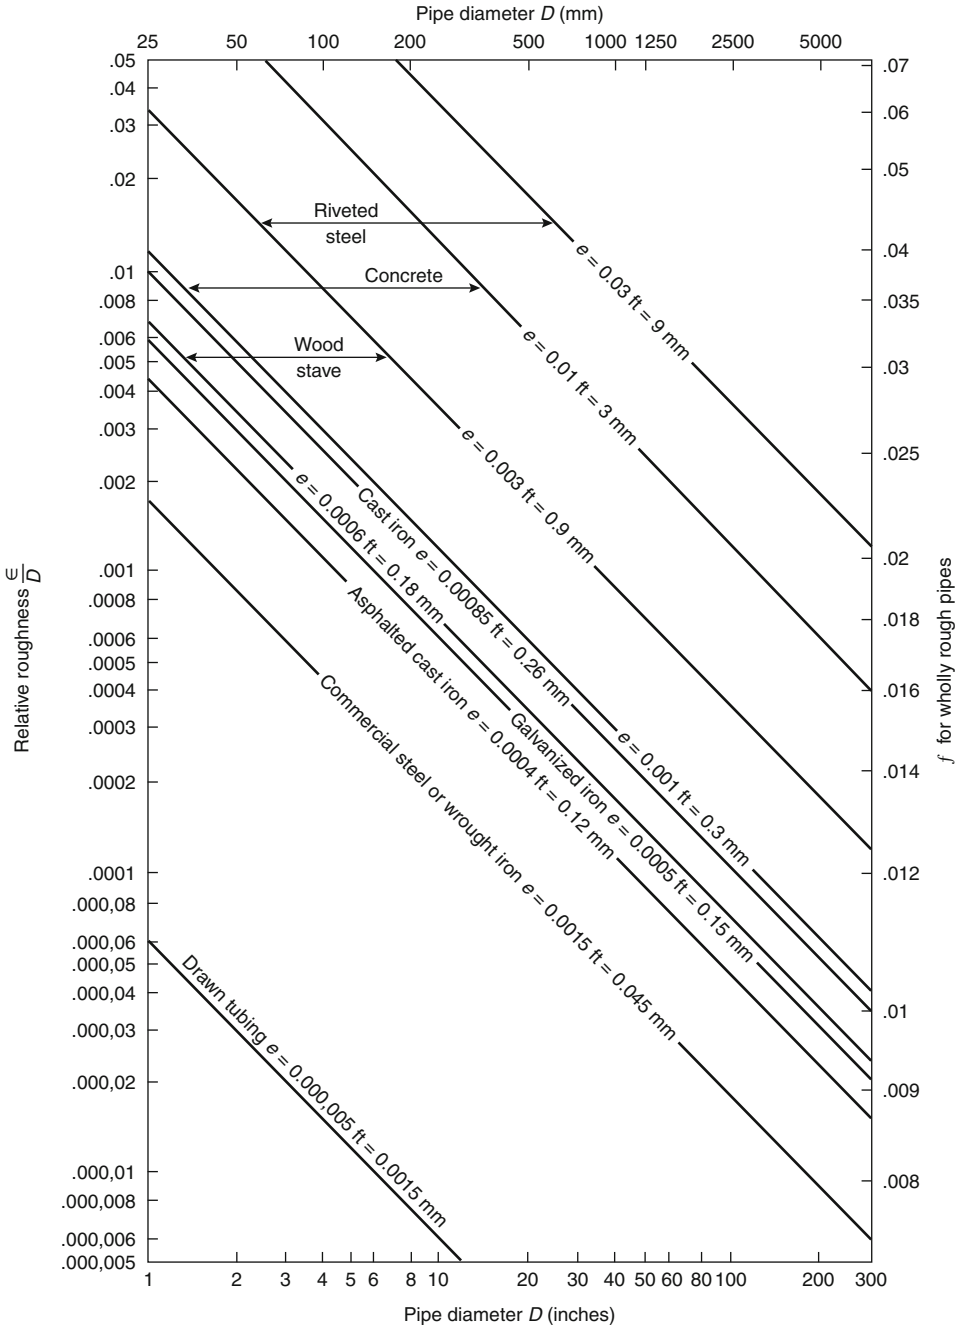

Fig. 41.11 Relative roughness chart

conditions affecting flow stability. As a practical consideration, however, this uncertainty is of little importance in fire protection, since most real flows of interest fall well into the turbulent range.

Colebrook developed an empirical transition function for the region between smooth flow and complete turbulence. Flow in this region is sometimes referred to as hydraulically smooth or turbulent smooth. The equation has been presented

in various forms, the following expression being commonly used:

$$\frac{1}{\sqrt{f}} = -0.86 \ln\left(\frac{\varepsilon/D}{3.7} + \frac{2.51}{\mathrm{Re}\sqrt{f}}\right) \qquad (41.20)$$

An alternate and equivalent expression is

$$f = \left[1.14 - 2\log\left(\frac{\varepsilon}{D} + \frac{9.35}{\mathrm{Re}\sqrt{f}}\right)\right]^{-2} \qquad (41.20a)$$

This relation forms the primary basis for the Moody diagram.

VonKarman used boundary layer theory to derive an expression characterizing the friction factor for fully turbulent flow within rough-walled pipes. The final numerical form of the equation

$$\frac{1}{\sqrt{f}} = 1.4 + 2\log\frac{D}{\varepsilon} \qquad (41.21)$$

was adjusted to agree more closely with Nikuradse's experimental results. As pipe roughness decreases, this expression approaches Colebrook's equation.

The Darcy-Weisbach equation and the Reynolds number calculation both force the engineer to utilize variables in unusual units. Typically, engineers deal with flow in gallons per minutes instead of cubic feet per minute or velocity in feet per second. Similarly, the diameter of the pipe is typically in inches and not in feet. The formulas for the Darcy-Weisbach equation and the Reynolds number can be rewritten in terms of variables that are much more commonly used (ΔP is friction loss in psi, Q is flow in gpm, d is the internal diameter of the pipe in inches, and μ is the viscosity in centipoises) as follows:

$$\Delta P = 0.000216 f \frac{l\rho Q^2}{d^5} \quad \mathrm{Re} = \frac{50.6 Q\rho}{d\mu}$$

Hazen-Williams Friction Loss

While the Darcy-Weisbach method of friction loss calculation yields sufficiently accurate results for a broad range of flow conditions, it can be difficult to use because of the associated variables that need to be determined. The density and viscosity of a fluid are not always known at every temperature at which the fluids are going to be used. In addition, since the friction factor cannot be solved for directly, it needs to be obtained from the Moody diagram, which introduces some potential error into the use of the technique because the engineer can arrive at some widely different friction factors based on very small changes in how the curves on the Moody diagram are interpreted.

A much more straight forward calculation technique was developed by Hazen and Williams (two civil engineers affiliated with the University of Michigan) around the turn of the nineteenth to the twentieth Century. Due to its simplicity, this technique has become one of the most widely used flow-energy loss relations. The empirically based Hazen-Williams formula was developed from observations of a very large number of pipeline flows. The Hazen-Williams equation was originally written in the form

$$V = 0.113 C D^{0.63} S^{0.54} \qquad (41.22)$$

where V is the average velocity in feet per second, S is the slope of the energy gradient—that is, the loss of energy per unit length of the pipe—and D is the actual internal pipe diameter in inches. The coefficient C is a *friction* factor introduced as a constant to represent the roughness of the pipe walls. Table 41.2 presents a representative list of C coefficients for various piping materials. Note that the value of C can vary significantly with the piping material, the age of the pipe, and the corrosive qualities of the water.

The Hazen-Williams formula is also encountered in the form

$$Q = 0.285 C D^{2.63} S^{0.54} \qquad (41.22a)$$

where Q is volumetric flow rate in gpm and D is in inches. Yet another form, also in the same units for Q and D, is widely used in automatic sprinkler system design. It is arranged to solve for the pressure drop in psi per linear foot of pipe:

$$p = \frac{4.52 Q^{1.85}}{C^{1.85} D^{4.87}} \qquad (41.22b)$$

Table 41.2 Values of C in Hazen-Williams formula[a]

[a]The above table has been compiled from an examination of 372 records. It is emphasized that the Hazen-Williams formula is not suitable for the coefficient *C* values appreciably below 100, but the values in the above table are approximately correct at a velocity of 0.9 m/s (3 ft/s)

For other velocities the following approximate corrections should be applied to the values of *C* in the table above [8]

Values of *C* at 0.9 m/s	Velocities below 0.9 m/s for each halving Rehalving of velocity relative to 0.9 m/s	Velocities above 0.9 m/s for each doubling Redoubling of velocity relative to 0.9 m/s

(continued)

Table 41.2 (continued)

Values of C at 0.9 m/s	Velocities below 0.9 m/s for each halving Rehalving of velocity relative to 0.9 m/s	Velocities above 0.9 m/s for each doubling Redoubling of velocity relative to 0.9 m/s
C below 100	Add 5 % to C	Subtract 5 % from C
C from 100 to 130	Add 3 % to C	Subtract 3 % from C
C from 130 to 140	Add 1 % to C	Subtract 1 % from C
C above 140	Subtract 1 % from C	Add 1 % to C

In SI units,

$$p = \frac{6.05Q^{1.85}}{C^{1.85}D^{4.87}} \times 10^5 \qquad (41.22c)$$

where the units of Q are L/min, D is in mm, and p is in bars per meter of pipe.

Many manufacturers of fire protection equipment, many fire underwriters, and others have published Hazen-Williams-based pipe friction loss data (usually in tabular format) over applicable ranges of pipe sizes, flow rates, and C-factors. A useful calculation aid in a more compact format is the Hazen-Williams nomograph (Fig. 41.12), which is reproduced here in its generalized form.

The Hazen-Williams formula is most appropriate for water flow at or around 60 °F (15.6 °C), as it does not contain any factors relating to the physical properties of the fluid. The formula gives acceptable results in practice with a judicious choice of the C-factor. Fundamentally, the C-factor is a proportionality constant and, as such, its *true* value depends as much upon the values chosen for the associated exponent in the accompanying formula as it does upon actual pipe roughness. The suggested values are the result of curve-fitting exercises and cannot be expected to accurately and evenly represent flow parameter relationships across the full range of observed flow velocities. Allowing fpr the desirability of retaining constant exponent values for D and S (i.e., a presumed theoretically stable correlation among all flow parameters in the equation), the value of C for any given flow scenario becomes a narrowly bounded variable that reflects the pipe roughness. Although, as in the Chezy formula, C is not actually a constant, for practical use it is assigned a constant value for a given presumed roughness. Unfortunately, as Table 41.2 shows, the Hazen-Williams equation is a much better model of smooth pipe flow than of rough pipe flow. As long as the flow velocity is close to that at which C was measured and as long as the pipe roughness is not excessive, the Hazen-Williams relation can be expected to give reliable results. It has been noted, however, that in rough pipes head loss varies with flow (and velocity) to the power of 2 rather than the power of 1.85 characteristic of smooth pipes [9]. This observation introduces a significant element of uncertainty into the hydraulic analysis of rough pipe with higher velocity flows.

Example 2 Water at 50 °F (10 °C) flows through 4 in. (102 mm) Schedule 40 welded steel pipe at a rate of 500 gpm (1892.7 l/m). Compare the friction head losses calculated by the Darcy-Weisbach and Hazen-Williams equations for flow through 100 ft of pipe.

Solution

Basic Data:

For 50 °F water, kinematic viscosity, $\nu = 1.41 \times 10^{-5}\text{ft}^2/\text{s}$

Pipe flow area $= 0.0884\ \text{ft}^2$

$\varepsilon = 0.0002$ (very close to new pipe)

Pipe inside diameter $= 0.3355\ \text{ft} = 4.026\ \text{in.}$

Using the Darcy approach, we first determine the Reynolds number (Re), and then we determine the relative roughness of the pipe as a ratio of the roughness to the diameter (ε/D). After obtaining these values, we enter the Moody diagram (Fig. 41.10) to get the friction factor (f). In order to get the Reynolds number, we need the velocity associated with the flow:

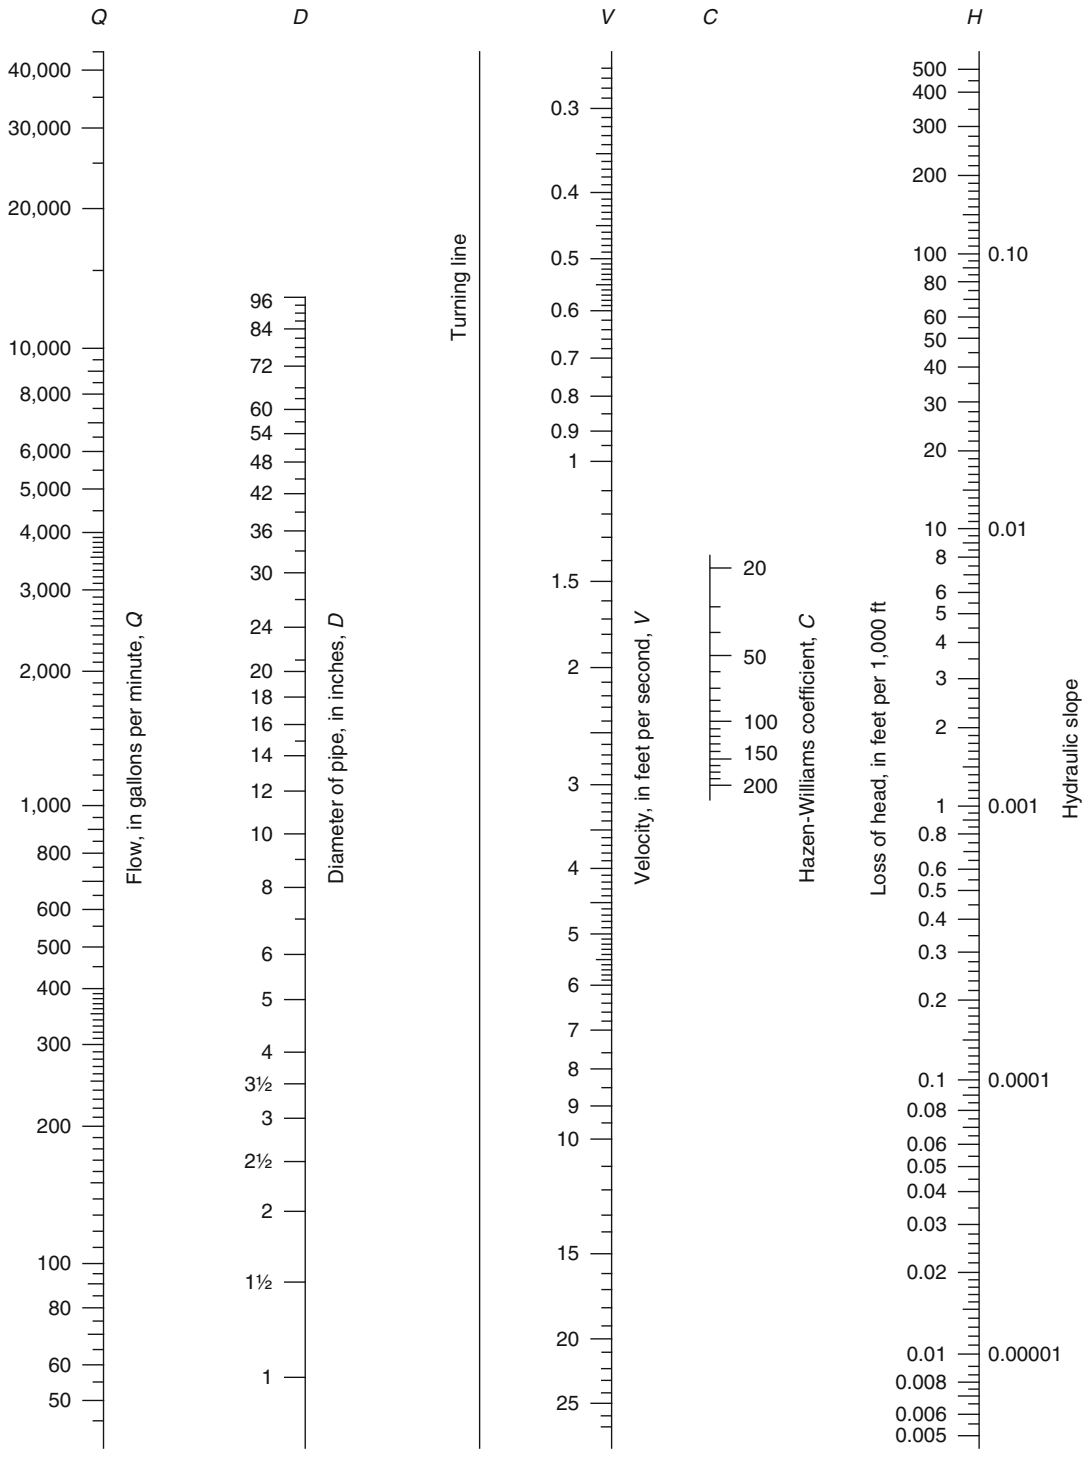

Fig. 41.12 Nomograph for solution of the Hazen-Williams formula

$$\text{Flow quantity} = Q = 500 \text{ g pm}$$
$$\equiv 1.1140 \text{ cfs } (31.54 \text{ L/s})$$
$$\text{Velocity} = v = \frac{Q}{A} = \frac{1.1140}{0.0884}$$
$$= 12.60 \text{ fps } (3.8 \text{ m/s})$$

$$\text{Re} = \frac{Dv}{\nu} = \frac{0.3355(12.60)}{1.41 \times 10^{-5}} = 3.0 \times 10^5$$
$$\frac{\varepsilon}{D} = \frac{0.0002}{0.3355} = 0.0006$$

From the Moody friction chart, $f = 0.0188$.

From Equation 41.18,

$$h_L = \frac{0.0188(100)\ (12.60)^2}{2(0.3355)\ (32.2)} = 13.8 \text{ ft}$$
$$= 5.98 \text{ psi } (0.41 \text{bar})$$

For the Hazen-Williams approach (Equation 41.22b) a C-factor for the pipe needs to be selected. Since the Darcy-Weisbach method used an ε value associated with new pipe, it would make sense to use a C-factor for new pipe in order to make an accurate comparison. As Table 41.2 shows, new steel pipe has C-factors between 134 and 150. If we assume $C = 140$,

$$\Delta p = \frac{4.52(100)\ (500)^{1.85}}{(140)^{1.85}(4.026)^{4.87}}$$
$$\Delta p = 5.40 \text{ psi } (0.37 \text{ bar})$$

The Hazen-Williams formula comes within 10 % of the value obtained using the Darcy-Weisbach equation, with significantly less effort. This is considered to be within the range of acceptable values in an engineering exercise involving fire protection system piping. Note that the system design and installation standards such as NFPA 13 do not allow the use of C-factors for new pipe for this very reason. Using a C-factor of 100, to simulate the aged pipe associated with dry-pipe systems and solve directly for pressure drop in psi per 100 ft we would obtain:

$$\Delta p = \frac{4.52(100)\,(500)^{1.85}}{(100)^{1.85}(4.026)^{4.87}} = 10.06 \text{ psi } (0.69 \text{ bar})$$

Note that the friction loss with the aged pipe is nearly twice what would have been predicted with the use of the value for new pipe. Accuracy in using Hazen-Williams clearly depends on a careful choice of C-factor. The Darcy-Weisbach result does not seem to be so sensitive to choice of roughness.

Minor Losses

Flows through pipe fittings, valves, or other pipeline fixtures generate additional turbulence and, therefore, additional energy losses. These losses, although termed minor, can be rather significant fractions of the total energy loss. In particular, losses due to pipeline obstructions such as swing-type check valves and certain types of flow meters are equivalent to adding many feet (or meters) of piping to the system. Thus, in some instances minor losses may have to be considered major, particularly in systems where there are many fittings, valves, or other appurtenances. Empirical methods are used to determine these losses for a range of flow or obstruction geometries. One common method is to define a *minor loss coefficient* to express head loss as a function of velocity head. Thus,

$$h_L = k\frac{v^2}{2g} \tag{41.23}$$

where k is a dimensionless loss coefficient. It is sometimes convenient to express such losses in terms of *equivalent length of straight pipe*, or as pipe diameters that produce the same head loss. Thus, by Darcy-Weisbach,

$$\frac{L}{D} = \frac{k}{f} \tag{41.24}$$

Table 41.3 shows local loss coefficients for a number of fittings and flow patterns. Wherever possible, manufacturers' data should be used, particularly for valves because of the wide variety of designs for the same generic valve type. Such data are often published in the form of flow coefficient or C_v values, which may be used in the equation

Table 41.3 Local loss coefficients

Use the equation $h_L = kv^2/2g$ unless otherwise indicated. Energy loss E_L equals h_v head loss in feet.

$$Q = C_v\sqrt{h_L} \tag{41.25}$$

C_v is determined from the relation

$$C_v = \pi D^2\sqrt{\frac{g}{8k}} \tag{41.26}$$

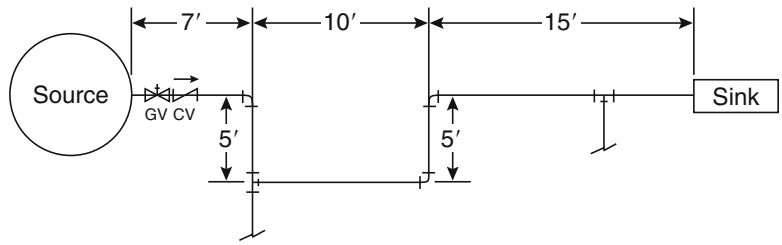
which results directly from a combination of the continuity equation with the equations above.

Use the equation $h_L = kv^2/2g$ unless otherwise indicated. Energy loss EL equals h_v head loss in feet.

Table 41.4 Typical equivalent lengths of schedule 40 straight pipe for screwed steel fittings and valves for any fluid in turbulent flow

	Equivalent length		
	Pipe size (ft)		
Fitting type	1 in. (25.4 mm)	2 in. (50.8 mm)	4 in. (101.6 mm)
Regular 90° elbow	5.2	8.5	13.0
Long radius 90° elbow	2.7	3.6	4.6
Regular 45° elbow	1.3	2.7	5.5
Tee, flow through line (run)	3.2	7.7	17.0
Tee, flow through stem	6.6	12.0	21.0
180° return bend	5.2	8.5	13.0
Globe valve	29.0	54.0	110.0
Gate valve	0.84	1.5	2.5
Angle valve	17.0	18.0	18.0
Swing check valve	11.0	19.0	38.0
Coupling or union	0.29	0.45	0.65

Example 3 Table 41.4 lists a number of equivalent lengths of standard Schedule 40 pipe for screwed steel fittings and valves. Using the table determine the equivalent length of the 2-in.-diameter pipe network shown below.



Solution The line comprises

1 check valve	19.0 ft (5.7 m)
3 90° standard elbows	$3 \times 8.5 = 25.5$ ft (7.7 m)
1 tee (flow through run)	7.7 ft (2.4 m)
1 tee (flow through branch or stem)	12.0 ft (3.7 m)
1 gate valve	1.5 ft (0.5 m)
1 straight pipe	42.0 ft (12.8 m)
	$L_e = 107.7$ ft (32.8 m)

The Darcy equation for determining friction losses through the network would then have the form

$$h_L = \frac{fL_e v^2}{2Dg}$$

Alternately, the loss coefficient approach may be used, where

$$h_L = k\frac{v^2}{2g}$$

This method must be used to find entrance and exit losses. For this example, however, we either refer to manufacturer's data for valve and fitting C_v values or calculate k from the relation

$$k = \frac{fL_e}{D}$$

Energy Losses in Pipe Networks

Flow networks can consist of pipes arranged in series, parallel, or combinations or multiples thereof. In any case, an evaluation of friction losses for the flows is based on energy conservation principles applied to the flow junction points. Methods of solution depend on the particular piping configuration. In general, however, they involve establishing a sufficient number of simultaneous equations or employing a friction loss formula where the friction coefficient depends only on the roughness of the pipe (e.g., Darcy-Weisbach or Hazen-Williams).

Pipes in Series When two pipes of different sizes or roughnesses are connected in series (Fig. 41.13a), head loss for a given discharge, or discharge for a given head loss, may be calculated by applying the energy equation between the bounding points, taking into account all losses in the interval. Thus, head losses are cumulative.

Series pipes may be treated as a single pipe of constant diameter to simplify the calculation of friction losses. The approach involves determining an equivalent length of a constant diameter pipe which has the same friction loss and discharge characteristics as the actual series pipe system. Minor losses due to valves and fittings are also included. Referring again to Example 3, we note that application of the continuity equation to the solution allows the head loss to be expressed in terms of only one pipe size.

The lost head in equivalent feet of 6-in. pipe is then given in Darcy-Weisbach form by

$$h_L = f\left(\frac{L_e}{D}\right)\left(\frac{v2}{2g}\right)$$

L_e can be obtained if f is known. Exact hydraulic equivalence in the velocity head terms depends upon f being a constant over the range of velocities applicable to the problem. In fact, f is not a constant over wide ranges of velocity. Since it varies only slightly with Reynolds number, however, solutions are sufficiently accurate.

Pipes in Parallel Two or more pipes connected as in Fig. 41.13b, so that flow is first divided among the pipes and is then rejoined, comprise a parallel pipe system. Flows in pipes arranged in parallel are also determined by application of energy conservation principles—specifically, energy losses through all pipes connecting

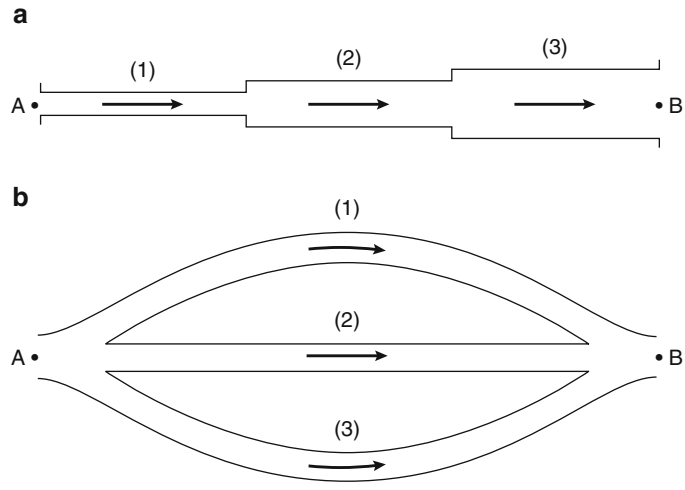


Fig. 41.13 Energy losses in pipe network: (**a**) pipes in series, (**b**) pipes in parallel

common junction points must be equal. Each leg of the parallel network is treated as a series piping system and converted to a single equivalent length pipe. The friction losses through the equivalent length parallel pipes are then considered equal and the respective flows determined by proportional distribution. For a given Q, an outline of the procedure is as follows:

1. Express each branch of the parallel system as an equivalent length of a single pipe size, including all minor losses between the bounding junction points.
2. Assume a discharge Q_1' through pipe branch 1.
3. Solve for h_L, using Q_1'.
4. Using h_L, find Q_2' and Q_3' for the remaining branches.
5. Knowing the proportional distribution of flow among the legs, Q_1', Q_2', and Q_3' are adjusted so that their sum equals the known Q; thus,

$$Q_1 = \frac{Q_1'}{\sum Q'} Q \quad Q_2 = \frac{Q_2'}{\sum Q'} Q \quad Q_3 = \frac{Q_3'}{\sum Q'} Q \tag{41.27}$$

6. h_{L_1}, h_{L_2}, and h_{L_3} are computed for the values of Q_1, Q_2, and Q_3 as a check for correctness.

For judicious choice of assumed discharges, solutions are obtained rapidly that agree within a few percent, well within the range of accuracy of the assumed friction factors.

In the case where the head loss is known between points A and B, Q for each branch is found simply by solution of the equation for pipe discharge. The discharges are added to obtain the total flow through the system.

Compound Piping Networks Energy loss calculations in compound piping configurations or networks employ the same basic physical principles as for single pipes. That is, conservation of energy and conservation of mass (continuity) must be satisfied throughout the network. In particular, at each pipe junction

$$\sum Q = Q_1 + Q_2 + \cdots + Q_n = 0 \tag{41.28}$$

and around each closed loop or circuit

$$\sum h_L = h_{L_1} + h_{L_2} + \cdots + h_{L_n} = 0 \tag{41.29}$$

The general solution procedure involves setting up a sufficient number of independent equations of these two types and solving simultaneously for the unknowns. For complicated networks, straightforward algebraic solution is clearly impractical. A very widely used relaxation method for systematic solution of large networks was developed by Hardy Cross in 1928. The method is well suited for solution by hand and is readily adaptable for machine computation.

We have seen that loss of head in a pipe may be represented generally by an equation of the form $h_L = KQ^n$ (where, for the Hazen-Williams formula, $n = 1.85$). For any single pipe in a network, we may write

$$Q = Q_0 + \Delta \tag{41.30}$$

where
Q = Corrected flow
Q_0 = Assumed flow
Δ = Flow correction

The problem, so stated, reduces to finding Q to a desired degree of accuracy by successive evaluations of Δ based on updated estimates of Q_0. We solve for Δ as follows:

$$\begin{aligned} h_L &= KQ^n = K(Q_0 + \Delta)^n \\ &= K\left(Q_0^n + nQ_0^{n-1}\Delta + \cdots\right) \end{aligned} \tag{41.31}$$

If Δ is small relative to Q_0, the higher-order terms in the expansion may be neglected. Since, for any circuit, $\Sigma h_L = 0$, we may write

$$\sum KQ^n = 0 = \sum \left(KQ_0^n + KnQ_0^{n-1}\Delta\right) \tag{41.32}$$

to a good approximation. Solving for Δ we have

$$\Delta = \frac{-\sum KQ_0^n}{n\sum KQ_0^{n-1}} = \frac{\sum h_{L_0}}{n\sum \left(h_{L_0}/Q_0\right)} \tag{41.33}$$

The overall formulation is made algebraically consistent by designating clockwise flows positive and counterclockwise flows negative.

The calculation procedure is controlled by the requirement that the algebraic sum of all assumed flows must equal zero at each pipe junction. The originally assumed flows are repeatedly and cyclically corrected until the Δ values are negligible, indicating that a hydraulic balance has been reached. Note that pipes common to two circuits are corrected twice in each cycle, once for each circuit. For a system where total head loss is known, flows can be balanced by correcting assumed head losses instead of flows.

Several other methods exist for determining flows and head losses in compound pipe networks. Many can be performed manually, although computer analysis is desirable and necessary for the more complex methods, particularly those involving unsteady flow. For a review of alternative methods, the reader is referred to Stephenson [10] and Walski [9].

Flow Measurement and Discharge

Flow Measuring Devices

This section deals primarily with the basic principles of operation of some flow measuring devices in common use and, in particular, with the pitot tube and the pipeline differential flow meters that have been standardized by the ASME (American Society of Mechanical Engineers): namely, the Venturi, the flow nozzle, and the square-edge thin-plate concentric orifice.

In general, an incompressible fluid of density ρ, viscosity μ, flows with average velocity v through a metering element of diameter d. The metering element is located in a horizontal metering tube of roughness ε and diameter D. The flow through the element produces a pressure differential Δp sensed by pressure taps located a distance L apart. It can be shown by dimensional analysis that the fundamental parameters involved in fluid metering, namely L, ε, v, ρ, μ, d, D, and Δp, yield relational solutions conventionally formulated as follows:

$$\frac{d\rho v}{\mu} = \mathrm{Re}_d \quad \text{Metering element Reynolds number}$$

$$\frac{L}{D} \quad \text{Tap location ratio}$$

$$\frac{d}{D} = \beta \quad \text{Beta ratio}$$

$$\frac{\varepsilon}{D} \quad \text{Relative roughness}$$

$$\frac{v}{\sqrt{2g\Delta p/\rho}} = \overline{K} \quad \text{Flow coefficient (pressure coefficient)}$$

Since $v = \overline{K}\sqrt{2g\Delta p/\rho}$, the continuity equation allows the volumetric flow rate measured by the meter to be expressed as

$$Q = \overline{K} A_d \sqrt{2g\Delta p/\gamma} \tag{41.34}$$

where A_d is the flow area of the metering element.

Typically, flow meter calculations are based on the idealized flow of a one-dimensional, frictionless, incompressible fluid in a horizontal metering tube. Real conditions require corrections to the ideal formulation. Conventional corrections for the effects of variations from ideal geometry and flow velocity profile are achieved through the use of modification factors. Thus, in Equation 41.34 above, $\overline{K}$ includes pressure and flow modifications which are conventionally defined as

$$\overline{K} = CE \tag{41.35}$$

where C is the coefficient of discharge defined as the ratio of actual flow rate to ideal flow rate and

$$E = \frac{1}{\sqrt{1-\beta^4}}$$

where E is known as the velocity of approach factor, since it accounts for the one-dimensional kinetic energy at the inlet tap.

The general volumetric flow metering equation is then given as,

$$Q = \overline{K} A_d \sqrt{\frac{2g\Delta p}{\gamma}} = CEA_d \sqrt{\frac{2g\Delta p}{\gamma}} \tag{41.36}$$

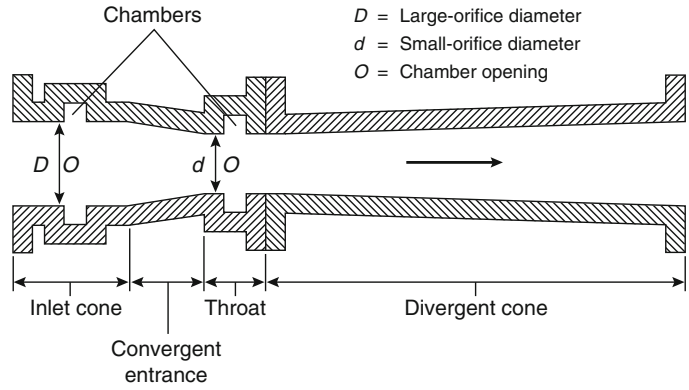

Fig. 41.14 Venturi tube

Table 41.5 ASME coefficients for venturi tubes

	Re_2			
Type of inlet cone	Minimum	Maximum	Value of C	Tolerance (%)
Machined	—	1,000,000	0.995	±1.00
Rough welded sheet metal				
	500,000	2,000,000	0.985	±1.50
Rough cast	—	—	0.984	±0.70

Venturi Flow Meter Figure 41.14 shows a schematically typical Venturi-type flow tube. The divergent cone section reduces the overall pressure loss of the meter. Pressure is sensed through a series of holes in the inlet cone and throat. These holes lead to an annular chamber, and the two chambers are connected to a pressure differential sensor such as a U-tube manometer. Standardized discharge coefficients, C, as reported by ASME are given in Table 41.5. Venturi tubes must be individually calibrated to obtain coefficients outside range identified in the table.

Determination of volumetric flow rate is a simple calculation employing the general flow metering formula—Equation 41.36—where C is obtained from Table 41.5 based on Re_d, and E is calculated directly from the beta ratio.

ASME Flow Nozzle This nozzle is depicted in Fig. 41.15. The pressure differential is sensed by either throat taps or appropriately located pipe wall taps. Coefficients of discharge for ASME flow nozzles may be accurately computed from the following equation:

$$C = 0.9975 - 0.00653\left(\frac{10^6}{\mathrm{Re}_d}\right)^a \qquad (41.37)$$

where

$$a = \frac{1}{2} \quad \text{for } \mathrm{Re}_d < 10^6$$

$$a = \frac{1}{5} \quad \text{for } \mathrm{Re}_d < 10^6$$

Volumetric flow rates are calculated in the same manner as for the Venturi tube.

ASME Orifice Meters Fluid flowing through a thin, square-edged orifice plate experiences a contraction of the flow stream some distance downstream from the orifice. The minimum cross sectional area of flow is called the *vena contracta* and its location is a function of the beta ratio. Figure 41.16 shows the relative pressure difference due to the presence of the orifice plate and the location of the *vena contracta* with respect to beta. By inspection of Fig. 41.16 it is clear that the actual location of the pressure taps is critical. Three distinct arrangements for tap locations are specified by the ASME for

accurately measuring the pressure differential. These types of tap arrangements are called the flange, *vena contracta,* and the 1*D* and ½*D*. Each has certain advantages and disadvantages and affects the value of the discharge coefficient.

Discharge coefficients for orifice metering plates may be calculated from the equation

$$C = C_o + \frac{\Delta C}{\mathrm{Re}_d^a} \tag{41.38}$$

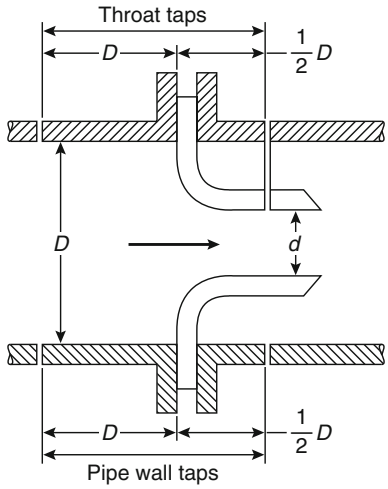

Fig. 41.15 ASME flow nozzle

where C_o and α are obtained from Table 41.6. Since the jet contraction downstream of the orifice can amount to nearly half of the orifice area, orifice discharge coefficients are in the order of 0.6 compared to the near-unity coefficients obtained with Venturi tubes and flow nozzles.

Pitot Tube A pitot tube is a device designed to sense stagnation or total pressure for the determination of velocity and volumetric flow rate. A number of commercial devices are available, some of which include a static pressure tap, that are designed for insertion into a water main under pressure through a standard pipe tap or corporation cock. The installed pitot tube measures velocity at a point in the fluid. Conventional practice assumes that the conversion of kinetic energy to flow work in the tube is frictionless. Thus, applying the energy equation to the generalized pitot tube diagram (Fig. 41.17) we obtain

$$\frac{u_s^2 - u_i^2}{2g} + \frac{p_s - p_0}{\rho_0 g} = 0 \tag{41.39}$$

where
u_s = Stagnation point velocity
u_i = Ideal streamtube velocity
p_s = Stagnation pressure
p_0 = Static pressure

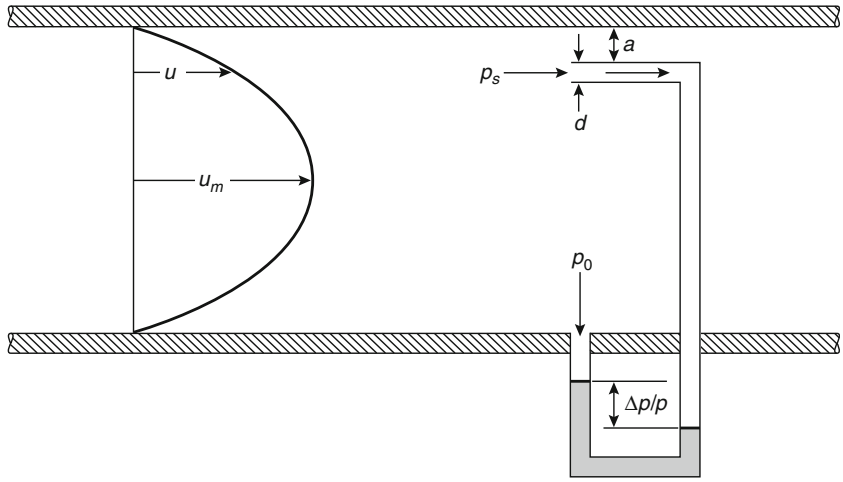

Fig. 41.17 Pitot tube study

Since, by definition $u_s = 0$, solving for u_i we obtain

$$u_i = \sqrt{\frac{2g(p_s - p_0)}{\gamma_0}} = \sqrt{\frac{2g\Delta p}{\gamma_0}} \qquad (41.40)$$

Typically, a pipe coefficient, C_p, which is independent of the geometry of the velocity profile, is defined as

$$C_p = \frac{\text{Average velocity}}{\text{Centerline velocity}}$$

For typical velocity profiles, C_p, varies from about 0.75 to 0.97 but usually lies within a narrower range of about 0.80–0.90. Knowing the centerline velocity, the flow can be obtained simply by

$$Q = C_p A v_{CL} \tag{41.41}$$

In situations where pipe velocity profiles are unknown, and therefore average velocities are not available, it may be necessary to obtain velocity measurements at many individual points. Given n velocities, the flow is then

$$Q = \sum_{i=1}^{n} v_i A_i \tag{41.42}$$

where

v_i = Velocity at the ith point

A_i = Area of annular ring of flow cross section for which velocity v_i is accurate

Detailed procedures for obtaining accurate pitot traverses are available in the literature along with suggestions for assessing the reliability of water audits, C-factor tests, and so forth, based on pitot gauge measurements [6, 9]. See the next section for a discussion of discharge measurements using pitot tubes.

Free Discharge at an Opening

Flow discharging to the atmosphere from a tank, hydrant, nozzle, or open conduit is affected by the area and shape of the opening. The total energy of the fluid is converted into kinetic energy at the orifice according to an appropriate form of the Bernoulli equation. In the most general case of a closed pressurized tank,

$$\frac{v_0^2}{2g} = z_1 + \frac{p_1}{\rho} \tag{41.43}$$

$$v_0 = \left[2g\left(z_1 + \frac{p_1}{\rho}\right)\right]^{1/2} \tag{41.44}$$

Accounting for losses at the point of discharge,

$$v_0 = C_v\sqrt{2gh} \tag{41.45}$$

where C_v, the coefficient of velocity, is determined from the coefficients of discharge and contraction

$$C_v = \frac{C_d}{C_c}$$

Commonly used values of orifice coefficients for water are given in Table 41.7. The orifice discharge can then be expressed as

Table 41.7 Orifice coefficients for water

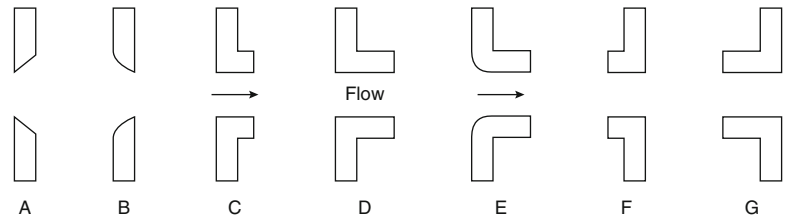

Illustration	Description	C_d	C_c	C_v
A	Sharp-edged	0.62	0.63	0.98
B	Round-edged	0.98	1.00	0.98
C	Short tube (fluid separates from walls)	0.61	1.00	0.61
D	Short tube (no separation)	0.82	1.00	0.82
E	Short tube with rounded entrance	0.97	0.99	0.98
F	Reentrant tube, length less than one-half of pipe diameter	0.54	0.55	0.99
G	Reentrant tube, length 2–3 pipe diameters	0.72	1.00	0.72
Not shown	Smooth, well-tapered nozzle	0.98	0.99	0.99

$$Q_o = C_d A_0 \sqrt{2gh} \tag{41.46}$$

and the head loss due to turbulence at the orifice as

$$h_L = \left(\frac{1}{C_v^2} - 1\right)\frac{v_0^2}{2g} \tag{41.47}$$

where

$\left(\frac{1}{C_v^2} - 1\right)$ = Minor loss K-factor

For the general case of a tank of varying cross-sectional area being replenished with inflow, $\dot{Q}_{IN}$, the time to empty from height z_1 to z_2 is given by

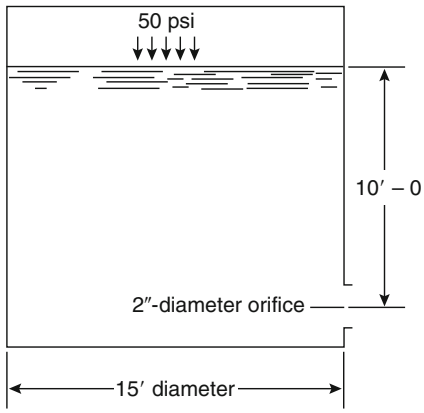
$$t = \int_{z_1}^{z_2} \frac{A_t dz}{c_d A_o \sqrt{2gh} - \dot{Q}_{\mathrm{IN}}} \tag{41.48}$$

where A_t is expressed as a function of z.

For a tank of constant cross section this simplifies to

$$t = \frac{2A_t\left(\sqrt{z_1} - \sqrt{z_2}\right)}{C_d A_o \sqrt{2g}} \tag{41.49}$$

Example 4 A 15-ft-diameter tank discharges water at 50 °F through a 2-in.-diameter sharp-edged orifice. If the initial water depth in the tank is 10 ft and the tank is continuously pressurized to 50 psig, how long will it take to empty the tank?



Solution At 50 °F (10 °C),

$$\gamma = 62.4 \text{ lbm/ft}^3 \ \left(16.02 \text{ kgm/m}^3\right)$$

For the orifice:

$$A_o = \frac{\pi D^2}{4} = 3.14 \text{ ft}^2 \left(0.29 \text{ m}^2\right)$$

$$C_d = 0.62 \text{ (sharp-edged orifice)}$$

For the tank:

$$A_t = \frac{\pi D^2}{4} = 176.7 \text{ ft}^2 \left(16.4 \text{ m}^2\right)$$

$$h_0 = 10 + \frac{50(144)}{62.4} = 125.38 \text{ ft } (38.2 \text{ m})$$

$$h_1 = 0 + \frac{50(144)}{62.4} = 115.38 \text{ ft } (35.2 \text{ m})$$

The total pressure head on the discharging fluid results from both an elevation and a static pressure head. Therefore,

$$t = \frac{2A_t\left[(z_0 = p_0/\gamma)^{1/2} - (z_1 + p_1/\gamma)^{1/2}\right]}{C_d A_o \sqrt{2g}}$$

$$t = 10.4 \text{ s}$$

Discharge stream coordinates are given by

$$x = v_0 t = v_0 \sqrt{\frac{2y}{g}} = 2C_v \sqrt{zy} \tag{41.50a}$$

$$y = \frac{gt^2}{2} \tag{41.50b}$$

For the simpler case of a hydrant discharging to atmosphere, the flow can be determined by an appropriate form of Equation 41.36,

$$Q = 29.8 D^2 C_d \sqrt{p} \tag{41.51}$$

where

Q = Discharge (gpm)

D = Outlet diameter (in.)

p = Pressure detected by pitot gauge (psi)

C_d = Coefficient based on hydrant outlet geometry (usually taken to be 0.90 for full flow across a standard 2½-in. outlet)

In the absence of a pitot gauge, hydrant flows may be estimated by observing the trajectory of the discharge stream. The horizontal component of the velocity does not change appreciably over time, thus allowing calculation of the velocity

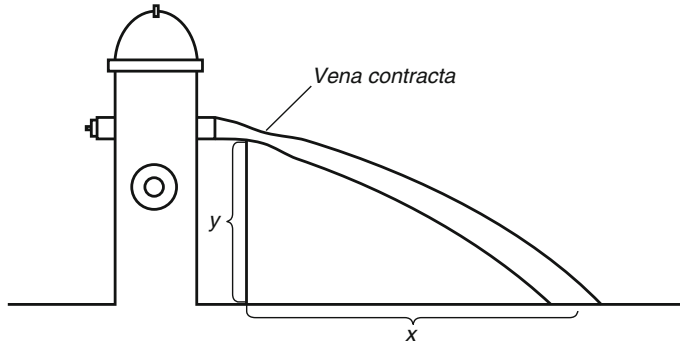


Fig. 41.18 Determining discharge by the trajectory method

based on the height of the outlet and the distance traveled by the stream. Figure 41.18 presents the basic parameters. The velocity determined in this manner is at the *vena contracta* and is given by

$$v = \frac{x}{\sqrt{2y/g}} \tag{41.52}$$

The discharge is simply the product of this velocity and the area of the *vena contracta*. The method is relatively inaccurate due to the obvious difficulty of measuring the required area and the distance x. It is a useful bounding guide, however, in the absence of precision measuring devices.

Water Hammer

Water hammer in a pipeline is caused by a sudden stoppage of flow and is characterized by loud noise and vibration.[1] The kinetic energy from the interrupted flow is transferred to the walls of the enclosing pipe or equipment. Associated pressures, or shock waves, can be severe enough to damage the pipe network and attached equipment.

Density changes due to pressure are assumed zero for nearly all hydraulic calculations, as water is considered incompressible for practical purposes even though it is about 100 times more compressible than steel. When shock waves arise in confined water, however, the compressibility of water becomes very significant, and water's elastic properties must be taken into account. The primary property of interest is the bulk modulus of elasticity, E, which is defined as the ratio of pressure change to the corresponding change of volume as determined by compression tests on volumes. (The bulk modulus is analogous to Young's modulus in solid mechanics, which is the ratio of linear stresses to linear strains as determined by tension tests.) The formula expressing the relationship between pressure and volume is

$$\Delta p = -E\frac{\Delta V}{V_0} \tag{41.53}$$

where the minus sign indicates that a positive change in pressure produces a decrease in volume. A modulus of compressibility, K, is also defined as the inverse of E.

Under normal conditions, water confined and flowing under pressure in a pipeline exerts pressure on the pipe walls according to the pressure-energy term of the energy equation. Any change in discharge within the system (due to valve closure, pump stoppage, etc.) results in a change of flow momentum. By virtue of the impulse-momentum relation, the momentum change will cause an impulse force to be created. This force in a pipeline is commonly referred to as water hammer.

The theory of water hammer, as developed by Zhukovsky, can be briefly illustrated as follows: a valve in a pipeline is closed instantaneously;

[1] This discussion is patterned after the theory of water hammer as developed by N. J. Zhukovsky and as presented in Andrew L. Simon's *Practical Hydraulics,* 2nd ed. [6].

the fluid impacts the closed gate and is decelerated to zero velocity, thereby creating a pressure shock. By Newton, pressure shocks in fluids of infinite extent travel at a velocity given by

$$c^* = \sqrt{\frac{KE}{\rho}} \tag{41.54}$$

where c^* is called the celerity (velocity) of the shock wave, KE is the kinetic energy of the fluid, and ρ is the fluid density. The pipe, however, also posses certain elastic properties. Therefore, if the fluid in the pipe is subject to a sudden force, the force will be transmitted to the pipe and associated equipment and fittings. Depending upon the magnitude of the force, the pipe and fittings will resist the force as they remain rigid, expand and compress, based upon the associated limits of elasticity of the pipe and fitting materials, or fail via a rupture. The modulus of elasticity, E_c, of a system composed of fluid and pipe may be determined from the equation

$$\frac{1}{E_c} = \frac{1}{E} + \frac{D}{E_p w} \tag{41.55}$$

where
D = Pipe diameter
w = Thickness of the pipe wall
E_p = Modulus of elasticity of the pipe material

Table 41.8 gives the modulus of elasticity for common pipe materials. The celerity of a shock wave in a pipe system of finite extent can then be computed from

$$\frac{c}{c^*} = \frac{1}{\sqrt{1 + ED/(E_p w)}} \tag{41.56}$$

which is plotted in Fig. 41.19. The graph indicates the considerable influence of pipe rigidity on the velocity of the shock.

The shock waves that travel upstream and downstream from the valve closure eventually reach points in the system that correspond to large stationary energy stores (e.g., reservoirs) or other sudden closure points, which may vary in their ability to absorb or reflect the shock wave. If the shock is absorbed into a larger energy field it will disappear, and it will do so in a certain amount of time as indicated by Equation 41.57,

$$t = \frac{L}{c} \tag{41.57}$$

where L is the distance from the energy reservoir to the shock wave point of origin. At the instant of shock absorption the compressed fluid, that is no longer balanced, begins to flow backward, creating a relief pressure shock that travels back to the valve. The time period T that the initial shock or impulse pressure acts on the valve is, therefore, the time required for the pressure wave to travel away from and back to the valve. T can be determined as follows:

Table 41.8 Modulus of elasticity Ep of various pipe materials

	E_p		
Pipe material	(psi)	(lb/ft^2)	(kg/m^2)
Lead	0.045 × 106	6.48 × 106	31.64 × 106
Lucite (at 73 °F)	0.4 × 106	57.6 × 106	281.23 × 106
Rubber (vulcanized)	2 × 106	288 × 106	1406 × 106
Aluminum	10 × 106	1440 × 106	7030 × 106
Glass (silica)	10 × 106	1440 × 106	7030 × 106
Brass, bronze	13 × 106	1872 × 106	8489 × 106
Copper	14 × 106	2016 × 106	9842 × 106
Cast iron, gray	16 × 106	2304 × 106	11,249 × 106
Cast iron, malleable	23 × 106	3312 × 106	16,170 × 106
Steel	28 × 106	4023 × 106	19,685 × 106

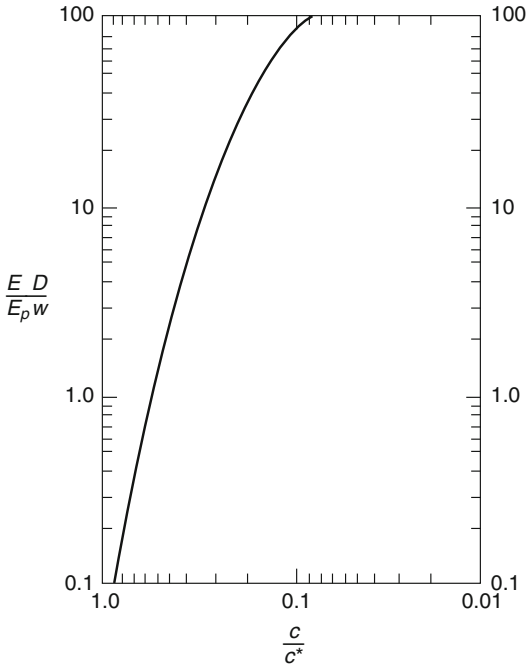

Fig. 41.19 Celerity of pressure waves in pipes, c equals celerity in elastic pipe; c* equals celerity in fluid of infinite extent

$$T = 2t = \frac{2L}{c} \tag{41.58}$$

At time T, all the fluid is moving backward at some velocity v. Since the valve is closed, there is no supply for this flow. A negative pressure shock is created at the valve. The shock travels to and back from the reservoir, as the flow is reversed. Such oscillations of pressure and periodic flow reversals persist until the kinetic energy is dissipated by friction. The process described will occur both upstream and downstream from the point of origin, though the initial shock will be positive upstream and negative downstream and the periodicities would not likely be equal.

The theoretical magnitude of the pressure shock at instantaneous valve closure can be determined directly from

$$p^* = \rho c \Delta v \tag{41.59}$$

and the pressure will oscillate in the pipe within the range

$$p = p_0 \pm p^* \tag{41.60}$$

In actuality, the time of closure of a valve is not zero but some finite time period which we may call T_c. The water hammer pressure increases gradually with the rate of closure of the valve. Depending on whether T_c is smaller or larger than T, we distinguish between quick and slow closure. For T_c less than T, the shock pressure will attain its maximum value p^*. (In this sense, quick closure is equivalent to instantaneous closure.) For T_c greater than T, maximum pressure will be somewhat less than p^* and may be calculated by the Allievi formula

$$p = p_0 \left(\frac{N}{2} + \sqrt{\frac{N^2}{4} + N} \right) \tag{41.61}$$

in which

$$N = \left(\frac{Lv\rho}{p_0 T_c} \right)^2 \tag{41.61a}$$

In general the calculation of water hammer pressure rises, regardless of method, will tend to underestimate the actual values. Real systems will tend to experience superimposition of positive or negative pressure waves due to complex piping configurations. Discontinuities introduced by a variety of auxiliary valving and metering equipment complicate the analysis considerably. Other methods are available for analyzing water hammer effects on systems that may not be reasonably handled by the above idealized method [11]. Since water hammer can be extremely detrimental, often resulting in complete loss of the system, it is desirable to perform an analysis wherever such effects are of concern. Control over the development of damaging shock waves is achieved through use of slow-closing valves, pressure relief valves, or shock-absorbing devices.

Water Supplies

An adequate supply of water is essential to any water-based fire protection system. Water can be provided from a number of sources: public

mains, private mains, elevated tanks, ground level tanks, pressure tanks, ponds, rivers, or oceans. Each of these sources has its advantages and disadvantages.

Public mains, private mains, elevated tanks, and pressure tanks are typically associated with a positive pressure, that in certain cases can be sufficient to supply the flow and pressure demands for the water-based fire protection system for some specified period of time. In other cases, a means of providing supplemental pressure, such as through a fire pump, or augmenting the quantity of water is needed.

Ground level tanks, ponds, rivers, or oceans are typically not associated with a positive pressure capable of forcing the water through a pipe network. This, however, is dependent upon the relative elevation of the water supply with respect the fire protection system. These water supplies usually need to be served by a fire pump.

Water Mains

Water mains can be either public or private. The only real difference between the two is ownership. Public mains are owned and operated by municipalities or public utilities that serve the citizens of a particular community. Generally any tax-paying entity in the associated community has a right to access to the mains, albeit through a fee. Private mains are generally owned and operated by a single property owner or cooperative group that makes the water available for their own use.

Before deciding whether a water main (public or private) can be used as a water supply for a fire protection system, two questions need to be addressed. The first pertains to whether or not the water supply is "reliable". There are no universal measurements or criteria to determine whether or not a water supply is "reliable". This is a judgment to be made by the stakeholders of a given project after evaluating the availability of waterflow while considering the length and frequency of any potential disruption of service. Factors to consider in this regard are associated with the means of supplying and ensuring pressure for the mains including the reliance on pumps, availability of power supply for any electrically motor driven pumps, fuel supplies and condition of any diesel engine driven pumps, use of elevated tanks and the overall condition and maintenance of the water mains.

The second question pertains to the adequacy of the supply. In other words, can the supply provide the necessary flow and pressure to meet the demand of the fire protection system? Testing of the water supply along with detailed hydraulic calculations are undertaken to assess if the main can meet the demand of the fire protection system. In assessing water supplies, the system demand in terms of flow, pressure and duration are needed. As exact system layouts and designs are not usually finalized until the later stages of a project, a series of assessments might need to be made during the design process, and possibly even during the installation phase of the project. Engineers can use an estimating technique to facilitate the process.

The simplest technique for estimating the flow demand for the system is to first determine the number of sprinklers that are expected to operate should a fire occur. The number of sprinklers can be determined from design and installation standards based upon the occupancy, commodity or fire hazard under consideration. Additional factors also need to be considered including the type of sprinkler used, its spacing, and required discharge density or discharge pressure. From this basic information, the minimum flow from each sprinkler can be determined.

The minimum estimated total flow (Q_d) needed for the sprinkler system will then be the number of sprinklers (N) multiplied by the minimum flow necessary from each sprinkler (q) multiplied by an "overage factor" (O) as indicated in Equation 41.62. The overage factor is an approximation of the added pressure that needs to be introduced into the system to overcome the pressure losses associated with waterflow through the system. It accounts for the extra flow that occurs at sprinklers closer to the water supply due to the fact that higher pressures are expected closer to the water supply and this condition will produce a greater flow

discharge. Average "overage factors" are about 15 %, but consideration needs to be given to relative pipe sizes, piping arrangements, i.e. tree, looped or gridded, and piping elevation changes.

$$Q_d = N \times q \times O \tag{41.62}$$

The estimation of the required system pressure will involve consideration of two pressure components. As previously noted, the water supply needs to possess sufficient pressure to overcome friction and other losses, and elevation changes while meeting the demand of the fire protection system. To estimate the pressure demand for a sprinkler system (P_d), add an estimate of the total friction loss in the system (P_f) to an estimate of the pressure due to elevation (P_e) to the pressure needed by the most demanding sprinkler (P_s).

$$P_d = P_f + P_e + P_s \tag{41.63}$$

To determine P_f an estimate of the average friction loss per foot from the main to the most remote sprinkler is needed. A value sometimes used is 0.15 psi/ft. However, smaller pipes in tree systems would have larger friction losses and larger pipes in looped and gridded systems would have smaller friction losses.

The above formulas can be used to generate a rough "ball-park" approximation of the system demand when assessing an available water supply. Any early estimates would need to be confirmed by the completion of more detailed hydraulic calculations usually completed with the aid of a computer. The following example illustrates the estimation technique.

Example 5 Estimate the demand of a sprinkler system utilizing 12 ESFR (K25.2) sprinklers requiring a discharge pressure of 25 psi. (each discharging at least 126 gpm) where The sprinklers are located 40 ft above the elevation where the water supply was measured. The piping system will be installed in a gridded arrangement under the flat roof of the building. The total pipe length from the water supply to the most remote sprinkler is about 400 ft. This includes equivalent lengths for pipe fittings and valves.

Solution The minimum flow demand for each sprinkler is 126 gpm ($25.2 \times (25)^{1/2}$)). The flow demand can be estimated by multiplying the number of sprinklers in the design area (12 for ESFR's) times the minimum flow per sprinkler (126 gpm) times an overage factor. Given the flat roof and the gridded piping arrangement, the overage factor is likely to be less than the average of 15 %. However, as a conservative estimate a value of 15 % is used. The flow demand is estimated to be 1739 gpm ($12 \times 126 \times 1.15$).

The friction loss that is likely to occur in the system can be estimated by first estimating the average friction loss per linear foot for waterflow through the system. Given that the piping is going to be gridded, the average friction loss is likely to be less than 0.15 gpm per ft. However, as conservative estimate, the value of 15 gpm/ft will be used. The friction loss associated with water flowing from the main to the most remote sprinkler can be estimated at 60 psi (0.15 gpm/ft $\times$ 400 ft). The change in elevation will be responsible for another 17 psi (0.433 psi/ft $\times$ 40 ft = 17 psi). The hydraulically most remote sprinkler requires a minimum of 25 psi to operate properly. The pressure demand can then be estimated as 102 psi (60 + 17 + 25). The demand for this sprinkler system can be estimated at 1739 gpm at 102 psi.

To determine whether a the main can sufficiently meet the demand of a fire protection system, some analysis of the water supply needs to take place. One way to analyze the water supply is to conduct a water flow test in close proximity to the project and apply appropriate safety factors to account for daily and seasonal fluctuations that might occur. Another way to analyze the water supply without physical testing is to use existing data about the main and a computer model to determine the flow and pressure available at any location along the main. Certain models might account for daily and seasonal fluctuations in water usage, so additional adjustments would not be necessary.

Whether the information is obtained from a specific flow test or a computer model, the engineer is looking for at least two data points: a static pressure (pressure when no water is flowing out of the main) and a residual pressure at a known flow out of the main. These points can be plotted to characterize the water supply over a range of flows and pressures. The relationship between flow and pressure is exponential (to the 1.85 power). Therefore, the water supply curve can be drawn as a line if the associated graph is scaled to log-1.85 as shown in Fig. 41.20. The figure shows four different flow scales. Other scales can be created by picking one of the scales and multiplying the number on it by a consistent factor. The correct or applicable flow scale needs to be clearly indicated. Example 6 illustrates the graphing technique.

Example 6 A proposed sprinkler system for a specific building is estimated to have a flow demand of 750 gpm. The main that will serve as the sprinkler system supply has recently been tested. The test locations are relatively close to the effected building. Test results, which have been adjusted for reasonable worse-case daily and seasonal fluctuations, are a static pressure of 50 psi and a residual pressure of 35 psi at 1600 gpm. Plot the water supply curve and determine what pressure is available at a flow of 750 gpm.

Solution The water supply curve is plotted as shown on Fig. 41.21. The "X" on the curve is approximately at the location of 750 gpm, showing that the pressure at this flow would be about 46 psi, but it is difficult to tell exactly which pressure is associated with the flow due to the inaccuracies involved in reading numbers on graphs, especially when one of the axes is not linear.

Rather than representing the water supply as a graph, the water supply can also be expressed as a function of the flow as shown in Equation 41.64

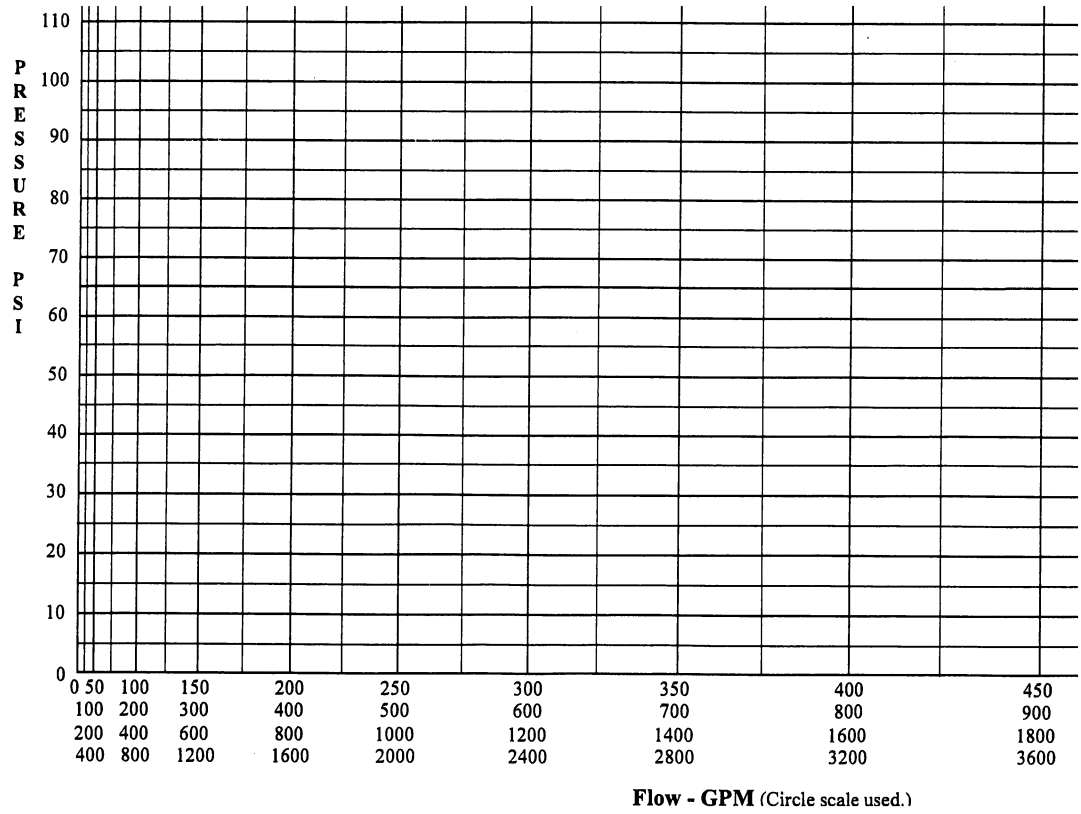

Fig. 41.20 Log-1.85 graph paper

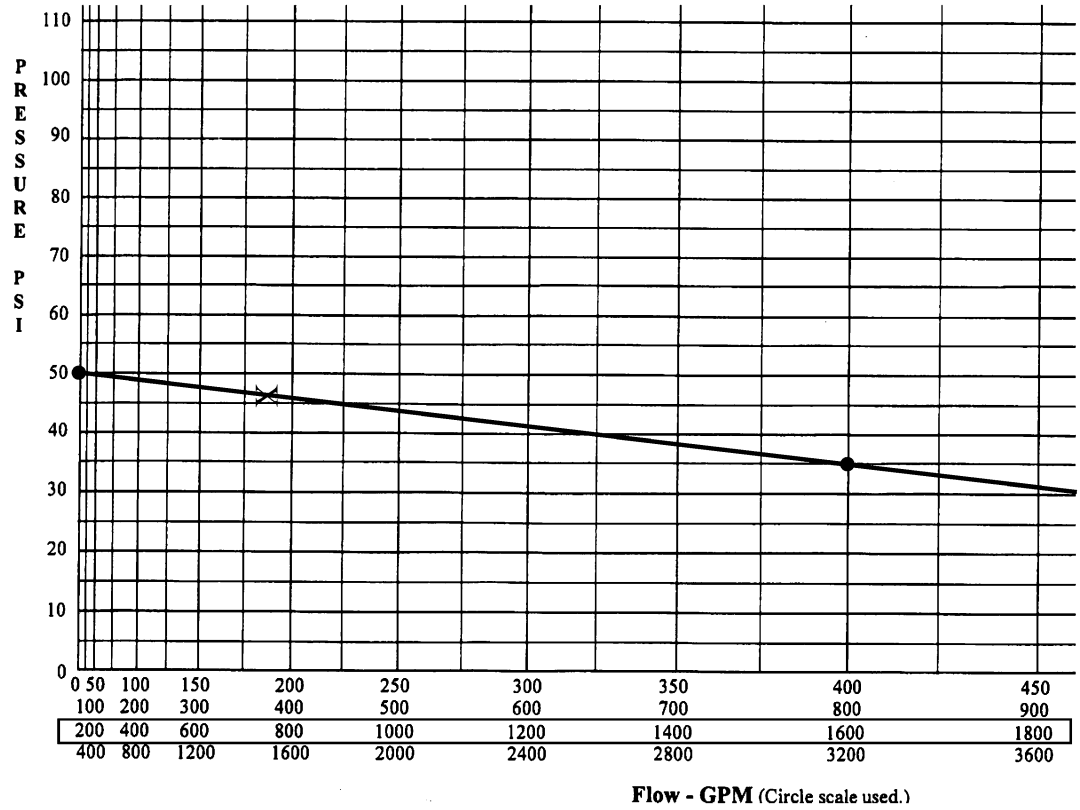

Fig. 41.21 Water supply graph for Example 6

where P is the pressure that you want to know at some flow (Q), P_S is the static pressure from the test, P_R is the residual pressure from the test and Q_R is the residual flow from the test.

$$P = (P_R - P_S)\left(\frac{Q}{Q_R}\right)^{1.85} + P_S \qquad (41.64)$$

Equation 41.64 can be used to develop an equation for a given water supply. For example, the water supply in Example 6 can be represented as follows:

$$P = (35 - 50)\left(\frac{Q}{1{,}600}\right)^{1.85} + 50$$

$$P = -15\left(\frac{Q^{1.85}}{(1{,}600)^{1.85}}\right) + 50 \qquad (41.65)$$

$$\mathrm{P} = 50 - 1.77 \times 10^{-5}\mathrm{Q}^{1.85}$$

Equation 41.65 represents the water supply in Example 6. The pressure at 750 gpm can be calculated by inserting 750 into Equation 41.65 as Q and solving for P as follows:

$$\mathrm{P} = 50 - 1.77 \times 10^{-5}(750)^{1.85}$$

$$\mathrm{P} = 50 - 3.7 = 46.3$$

When evaluating a water supply, it is sometimes advantageous to determine the flow that will be available at a certain pressure. In these cases, Equation 41.64 can be solved for Q and rewritten as shown in Equation 41.66.

$$Q = \left(\frac{P - P_S}{P_R - P_S}\right)^{0.54} Q_R \qquad (41.66)$$

Elevated Tanks

There are at least four basic situations, as noted below, where a tank or some other stored body of water such as a pond, reservoir, river or ocean

might be considered as the water supply for a fire protection system:

1. Where a public or private main is not available.
2. Where a public or private main is available, but does not produce sufficient flow for the fire protection system.
3. Where a public or private main is available and sufficient, but a redundant supply is desired improve overall reliability of the fire protection system.
4. Where a public or private main is available and sufficient, but a redundant supply is required such as in active seismic zones.

Once it has been determined that a tank or other body of water is needed, an elevated tank might be considered. The advantage of an elevated tank is that it is inherently associated with potential energy without the need for any pumps or supplemental pressurization. The amount of energy is function of the height of the tank. As discussed earlier in this chapter, water will develop 0.433 psi for every foot that it raised above some datum plane, i.e. the base of a sprinkler riser. As a further example, if a tank is elevated so that its bottom discharge flange is 150 ft above the location where the water from the tank will be used (such as the outlet of a hydrant), the water in the tank will posses a static pressure head of 65 psi (150 ft × 0.433 psi/ft). Of course, friction losses associated with waterflow need to be considered in determining the available pressure at the hydrant. The further from the tank the hydrant is located, the greater the friction losses and less of a residual pressure would be available at a hydrant.

While some elevated tanks are actually built some distance above the ground, other elevated tanks are built at ground level but located on hilltops at higher elevations that the building and systems they are intended to serve. Similarly, tanks can be located un upper floors of tall buildings where the water is used for fire protection systems on lower floors.

There are situations when it is necessary to determine the maximum flow that can be generated from an elevated tank. To accomplish this, an energy balance needs to be established by equating the energy gained from gravity to the energy lost due to friction and flow effects. Using the Hazen-Williams friction loss method of calculation, Equation 41.67 can be set up with P_E representing the energy gained from elevation and L representing the length of pipe between the tank and the location where the water will be used for fire protection:

$$P_E = \frac{4.52LQ^{1.85}}{C^{1.85}d^{4.87}} \tag{41.67}$$

P_E is equal to 0.433 multiplied by the height of the elevation of the tank (H in feet). Equation 41.67 can be rewritten and solved for Q so that the flow can be determined as shown in Equation 41.68.

$$Q = \frac{0.28CH^{0.54}d^{2.63}}{L^{0.54}} \tag{41.68}$$

Example 7 A tank is going to be installed at the top of a hill to serve an industrial park located at the base of the hill. The bottom of the tank is estimated to be 200 ft above the point of connection to the water main in the industrial park served by the elevated tank. It is further estimated that the pipe from the tank to the center of the industrial park will be 500 ft in length including equivalent lengths for fittings and valves. What is the maximum fire flow that would be available at the center of the industrial park if the pipe material is lined ductile iron (Hazen-Williams C-factor of 140) with an actual inside diameter of 8.27 in.? Note that no other pressure producing devices, such as pumps, will be used.

Solution Using Equation 41.68, the maximum flow that could develop from this tank on the hill is 6186 gpm, calculated as follows:

$$Q = \frac{0.28CH^{0.54}d^{2.63}}{L^{0.54}}$$

$$= \frac{0.28(140)\,(200)^{0.54}(8.27)^{2.63}}{(500)^{0.54}} = 6,186$$

The duration for which the above flow can be maintained will depend upon the size of the tank. The above solution assumes that the flow is

taking place at a pressure of about 86 psi (200 ft × 0.433 psi/ft) not including friction losses. As the tank drains, the flow and available pressure will decrease until they both reach a value of zero once the tank is drained. Many public utilities and operators of water mains require that pressures within the main not drop below a certain value, typically 20 psi. Some private operates might allow lower pressures. Equation 41.69 is a variation of Equation 41.68 with P_M representing the minimum pressure that needs to be maintained in the piping system:

$$Q = \frac{Cd^{2.63}[(0.433H) - P_M]^{0.54}}{2.26L^{0.54}} \qquad (41.69)$$

Example 8 For the situation is Example 7, what is the available fire flow if the plan is to keep a minimum pressure of 20 psi in the main?

Solution

$$Q = \frac{Cd^{2.63}[(0.433H) - P_M]^{0.54}}{2.26L^{0.54}}$$
$$= \frac{(140)(8.27)^{2.63}[(0.433(200)) - 20]^{0.54}}{2.26(500)^{0.54}}$$
$$= 5,399$$

As the solution above shows, for the situation described in Example 7, the available fire flow drops from 6186 to 5399 gpm when the decision is made to maintain a minimum of 20 psi in the mains.

While elevated tanks inherently posses some amount of potential energy so that water can be discharged from them, the adequacy of the elevated tank with respect to any associated fire protection systems still needs to be properly accessed to ensure that the elevated tank can meet the flow and pressure demands of the fire protection system.

Pumps and Tanks

For tanks that are not elevated, a supplemental means of adding pressure is needed to provide and maintain the proper water flow rate from the tank into the fire protection system. Depending upon the size of the tank, a fire pump usually serves this purpose.

Fire pumps serve to increase the pressure in a given fluid system, thereby increasing the flow rate. While fire pumps can increase the flow rate, they cannot increase the capacity of a water supply, i.e. they cannot create water. If a given water supply consisting of a public main cannot produce the necessary flow anywhere along its representative water supply curve or can only produce the necessary flow at a point below the pressure permitted by the water utility, i.e. at less than 20 psi, a fire pump on it own will not solve the problem. A pump and a tank will likely be needed.

Brief details on selecting fire pumps and designing a fire protection system with a fire pump are included later in this chapter. More detailed information on fire pumps is available from a number of sources including the text *Pumps for Fire Protection Systems.*.

Pumps and Other Stored/Static Water Sources

As previously stated, other relatively static water sources such as ponds, reservoirs, rivers, lakes and even oceans can be used for fire protection. From a hydraulic design perspective, these sources are very similar to tanks. However, these water sources also challenge the engineer with additional considerations for corrosion protection and concerns for sediment and other particulate in the water being deposited in the fire protection system. Typically, screens and strainers are used to minimize the amount of sediment and other debris from entering the system. Cleaning of these screens is critical to good performance of such systems. In addition, it is also common to use upright sprinklers on such systems, so that sediment does not accumulate on the sprinkler orifice, or pendent sprinklers on return bends. A return bend is a pipe that is connected to the top of a branch line with an elbow, a lateral piece of pipe, and then another elbow to a drop in order to feed a pendent

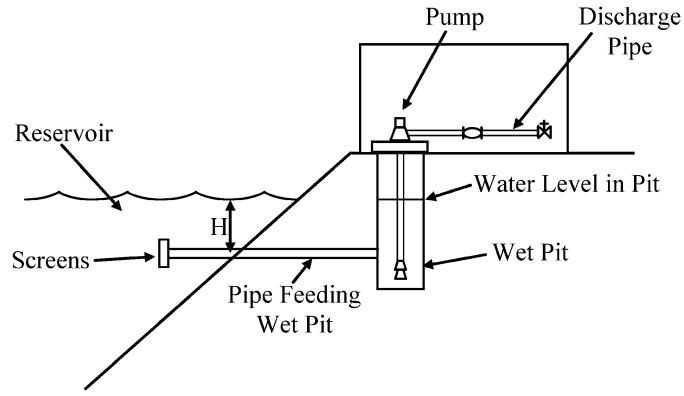

Fig. 41.22 Vertical shaft turbine pump taking suction from a reservoir

sprinkler. In this manner, sediment in the water is more likely to settle at the bottom of the branch line rather than at the sprinkler.

When a pump takes suction from a static source such as a pond or reservoir, that is located below the pump, vertical shaft turbine type pumps, as shown in Fig. 41.22, is typically used. In some cases, a pipe arrangement can be used to feed a pit with water from the pond or reservoir, and a fire pump is then arranged with the pit.

In situations where a pipe is used to feed the wet pit as shown in Fig. 41.22, it is necessary to ensure that the pump will receive a sufficient amount of water to continuously operate at maximum flow, which is typically defined as 150 % of the rated pump flow. A calculation needs to be completed to ensure that the maximum flow will occur between the reservoir and the pit. Equation 41.68 can be used to determine whether the flow will be acceptable.

Example 9 For a situation where a 1500 gpm rated vertical shaft turbine pump is installed similar to Fig. 41.22 with the pipe at least 10 ft under the lowest expected water level in the reservoir and a 50 ft long lined ductile iron pipe with an internal diameter of 8.27 in. used to feed the wet pit, will the maximum flow needed for the pump ($1500 \times 1.5 = 2250$ gpm) be achieved for this arrangement?

Solution Using Equation 41.68, the maximum flow that can be achieved with this arrangement is 4255 gpm (as shown below), which well exceeds the requirement for the pump of 2250 gpm. This arrangement would be acceptable (assuming that the friction loss for the strainer was accounted for in the 50 ft of pipe through an equivalent length assumption).

$$Q = \frac{0.28CH^{0.54}d^{2.63}}{L^{0.54}} = \frac{0.28(140)\,(10)^{0.54}(8.27)^{2.63}}{(50)^{0.54}} = 4,255$$

Pumps

Pump Operating Characteristics

Pumps are mechanical devices that convert electrical or mechanical energy into hydraulic energy (net pressure). There are many types of pumps—for example, reciprocating, rotary, jet, ram, centrifugal—with each type name referring to the different means by which the pump increases the energy of the liquid. The most common type of pump used for fire protection is the centrifugal pump due to its simplicity and reliability. However, for some applications such as high pressure water mist systems and foam concentrate pumps, centrifugal pumps are not ideal and rotary gear or other types of positive displacement pumps are used.

For centrifugal pumps, the impeller (the rotating component) imparts energy to the water

using centrifugal force. Vanes within the impeller improve the efficiency to which energy is transferred. Centrifugal pumps may be divided into several categories. Turbine or radial flow centrifugal pumps force water outward at right angles to the rotating axis. Mixed flow pumps force water in both radial and axial directions. Propeller pumps move water in the axial direction only. Any of these types may be single or multistage with the stage number referring to the number of impellers on the pump's rotating shaft. For example, a two-stage pump has two impellers on the same shaft whereas a four-stage pump would have four impellers on the same shaft. The orientation of the shaft may be vertical or horizontal. The following discussion, while broadly applicable, is directed mainly to centrifugal pumps.

Figure 41.23 illustrates several of the terms commonly used to describe pump performance conditions. In general, pumping of liquids requires that the pressure at any point in the intake line be greater than the vapor pressure of the liquid to avoid the loss of prime (water entering the pump due to its own pressure head) and the highly destructive phenomenon known as cavitation. The pressure gradient that causes a liquid to move through the intake line to the pump impeller is termed the net positive suction head (NPSH). In pump selection, it is essential to determine that the *available* NPSH of the water supply exceeds the *required* NPSH for the pump under consideration so that prime is provided. Required NPSH depends upon many factors relating to pump geometry and construction and intake system operating conditions, but it is defined simply as the difference between net suction head and vapor pressure at a given flow, or the energy needed to fill the pump on the intake side and overcome intake system head

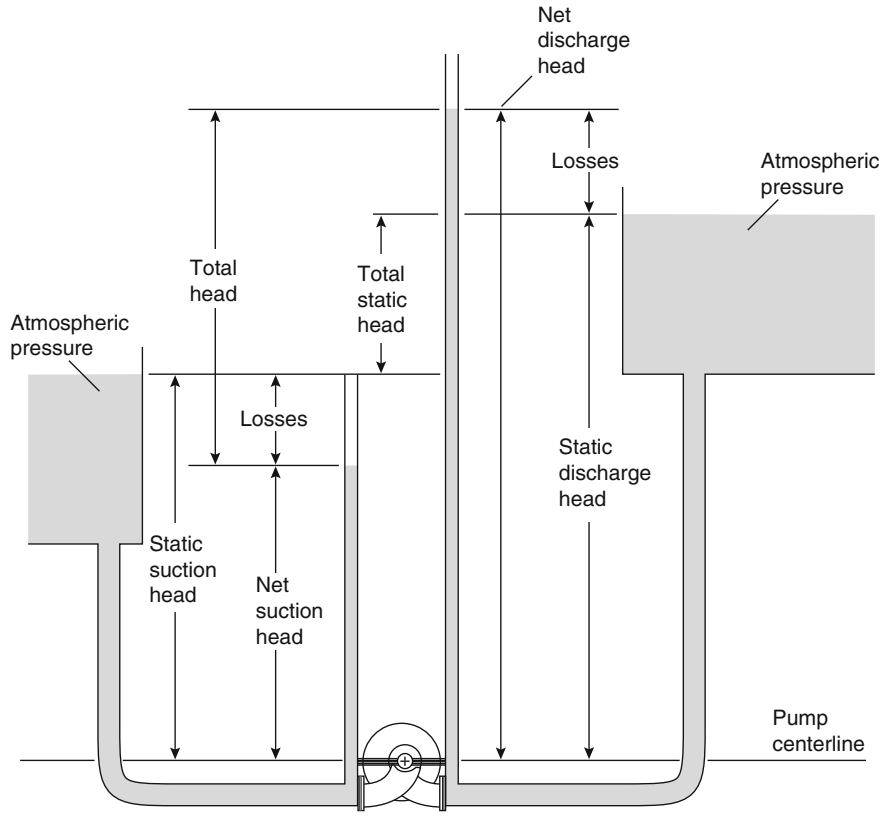

Fig. 41.23 Pump head definitions

losses. If the net suction head is less than the vapor pressure of the incoming water, the water will form small vapor bubbles or cavities within the pump. Where the small vapor bubbles formed in the low-pressure region collapse violently upon entering regions of high pressure, they cause localized stress concentrations and vibrations, ultimately leading to mechanical failure of the pump. This phenomenon is referred to as cavitation.

The required net positive suction head ($NPSH_{req}$) for any pump can be obtained from the manufacturer. The available net positive suction head ($NPSH_{av}$) must be calculated for each system. Because the total energy of a system is constant, the available NPSH may be determined at any point in the system. The general expression at the pump centerline follows from Bernoulli as

$$NPSH_{av} = \frac{(p_{gauge} + p_{atm})}{\rho g} + z - h_L - \frac{p_{vp}}{\rho g} \tag{41.70}$$

where

h_L = Friction head loss in intake system piping (in feet of water)

p_{vp} = Vapor pressure (0.256 psia for water at 20 °C)

Knowing the pressure and pipe friction loss terms, the pump can be set at a height, z, which will ensure that $NPSH_{av}$ is greater than $NPSH_{req}$.

Where a free surface exists on the intake side (such as at the surface of an intake reservoir) and the velocity at a point on the surface is negligible, the above expression simplifies to

$$NPSH_{av} = z - h_L + \frac{(p_{atm} - p_{vp})}{\rho g} \tag{41.71}$$

For pumps of relatively low heads and large discharge capacities (common in fire protection applications) the available NPSH may be less than zero (h_L is large). These pumps should be installed well below the reservoir water level to eliminate the possibility of cavitation. For this reason and also to avoid accidental loss of prime, authorities having jurisdiction generally require *positive suction* installation. In such instances the pump should be of the vertical shaft type so that the pump impellors sit in the water supply and the pump driver is installed at an elevation above any possible flood level.

The useful work done by a pump is the product of the weight of the liquid pumped and the head developed by the pump. The work per unit time in this context is the hydraulic horsepower, commonly called the water horsepower (WHP). For discharge, Q, in gpm, total dynamic head, h, in feet, and specific weight, γ, for water at 20 °C (68 °F),

$$WHP = \frac{Qh}{3,960} \tag{41.72}$$

The power required to actually drive the pump is the brake horsepower (BHP). The difference between water horsepower and brake horsepower is the power lost within the pump due to mechanical and hydraulic friction. The ratio of WHP to BHP is the pump efficiency, η_p. Similarly, the ratio of BHP to electrical or engine horsepower (EHP) is the motor efficiency, η_m . The overall efficiency is, then, the pump efficiency multiplied by the motor efficiency:

$$\eta = (\eta_p)(\eta_m) = \frac{WHP}{BHP} \cdot \frac{BHP}{EHP} \tag{41.73}$$

Although WHP should be calculated using the specific weight of the fluid at known conditions of temperature and pressure, the variation for water is very small; it should be noted that pump motor and engine sizes are chosen from standard available sizes in any case.

The interrelations of head, capacity, power, and efficiency for a given pump are known as the characteristics of the pump. They can be expressed graphically in the form of pump characteristic curves. Figure 41.24 shows a standard plot of the several variables at constant impeller speed (N). Note that the point of maximum operating efficiency on the head-capacity curve corresponds to the maximum value of the efficiency curve. The actual operating point of the

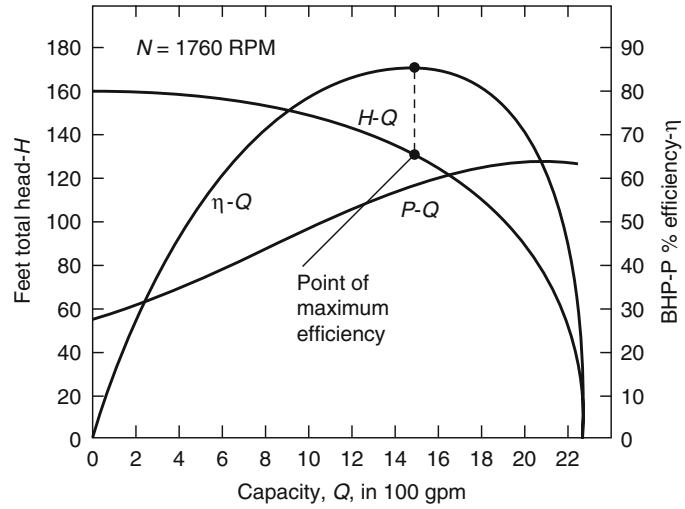

Fig. 41.24 Centrifugal pump characteristics

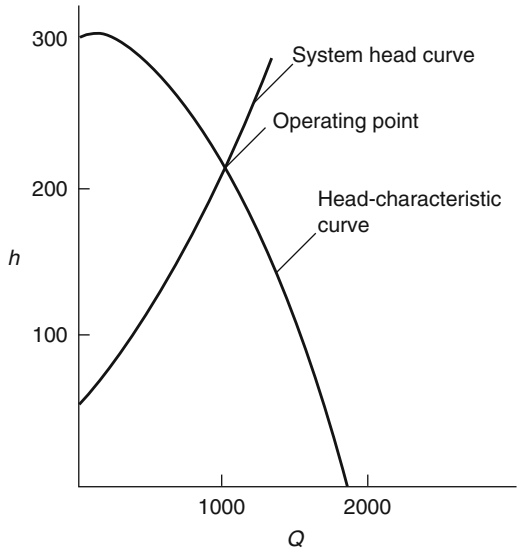

Fig. 41.25 Graphical determination of operating point

pump, however, depends on the system demand (or system head) curve. The system head loss for any flow rate is the sum of the system friction head loss at that rate plus the total static head to be overcome in the system. Figure 41.25 illustrates the relationship. Recall from Fig. 41.23 that the total static head is the difference in elevation between the discharge level and the suction level. System friction losses may be determined by calculations methods given in previous sections.

Pump Selection

Economical pump selection for fire protection applications requires consideration of the following factors:

1. The maximum discharge rate required under the most demanding design conditions
2. The total head-capacity relation (characteristic curve)
3. The suction head—in particular, the net positive suction head available
4. Pump speed and power source requirements
5. Pump spatial and environmental requirements
6. The maximum allowable system head downstream of the pump discharge

The usual design condition is that a system will be given or will be chosen from a very limited range of possibilities, and the proper pump must be selected. As shown in Fig. 41.25, when the system demand curve and the pump head-capacity curve are superimposed, their intersection will determine the operating point of the pump. This point also locates the efficiency and, therefore, the power requirements. It is often economically desirable to select a pump such that its operating point is at or near its peak efficiency. In many fire protection applications, however, a pump may be called upon to operate very infrequently. Power consumption may, therefore, not be a significant factor relative to initial cost. Common practice in fire protection applications

is to select a pump to operate at 150 % of rated capacity at 65 % of rated head (see NFPA 20[8])—that is, an operating point farther out along the characteristic curve. A pump is chosen such that its operating point so defined meets or exceeds the system demand curve at that point.

If the pump is to be used as a *booster* to increase supply main pressure, it must be confirmed that when selecting a pump having a maximum discharge head at zero flow (also known as *churn* head), which, when added to the maximum water main's supply head, does not exceed the maximum allowable working pressure on the system. The maximum allowable working pressure typical for many components in fire sprinkler systems is 175 psig [12], although higher rated components are available.

Centrifugal Pump Affinity Relations

The abstract concept of *pump specific speed* has been developed to simplify the description of pump performance characteristics. It consolidates the discharge, head, and speed (rpm) at optimum performance into a single number. For a single stage, single suction pump, specific speed may be calculated from

$$N_s = \frac{NQ^{1/2}}{H^{3/4}} \tag{41.74}$$

where Q (in gpm) is taken at pump rpm, N, and total dynamic head, H. The specific speed of a pump is not actually a speed for that pump in any physical sense; it is defined as the speed in revolutions per minute at which a homologous (geometrically similar) pump would run if constructed to deliver 1 gpm against 1 ft total head at its peak efficiency. For pump impeller designs of identical proportions but different sizes, the specific speed is a constant performance index. That is, the performance of any impeller can be predicted from knowledge of the performance of any other geometrically similar impeller.

Changing the impeller diameter results in changes in discharge, total head, and delivered power. These changes occur according to the follow relations:

$$\frac{Q_1}{Q_2} = \left(\frac{D_1}{D_2}\right)^3 \frac{n_1}{n_2} \tag{41.75a}$$

$$\frac{H_1}{H_2} = \left(\frac{D_1}{D_2}\right)^2 \left(\frac{n_1}{n_2}\right)^2 \tag{41.75b}$$

$$\frac{Q_1}{Q_2} = \left(\frac{H_1}{H_2}\right)^{1/2} \left(\frac{D_1}{D_2}\right)^2 \tag{41.75c}$$

$$\frac{\mathrm{BHP}_1}{\mathrm{BHP}_2} = \left(\frac{D_1}{D_2}\right)^5 \frac{\rho_1}{\rho_2} \frac{n_1^3}{n_2^3} \tag{41.75d}$$

Since

$$\frac{N_1}{N_2} = \frac{D_1}{D_2} \tag{41.76}$$

a change in motor speed only will yield similar results. That is, a change in impeller size has the same effect on pump performance as a change in speed provided, of course, that there is no marked change in operating efficiency.

Example 10 A 6 in. (152.4 mm) pump operating at 1770 rpm discharges 1500 gpm (5678 l/m) of water at 40 °F against a 120 ft (36.6 m) head.

(a) What discharge capacity and total head can be expected from a homologous 8 in. (203 mm) pump operating at 1170 rpm?

(b) If the pumps operate at an overall 80 % efficiency, what is the 8 in. (203 mm) pump power requirement?

Solution

(a) From Equation 41.75b,

$$H_2 = \left[\frac{8^2(1,170)^2}{(6)^2(1,170)^2}\right](120) = 93.2 \text{ ft } (28.4\,\text{m})$$

From Equation 41.75a,

$$Q_2 = \left[\frac{8^3(1,170)}{(6)^3(1,170)}\right](1,500)$$
$$= 2,350 \text{ gpm } (8,895.5\,\text{L/m})$$

(b) From Equation 41.72,

$$\mathrm{WHP} = \frac{2,350(93.2)}{3,960} = 55.3 \text{ HP}$$

Therefore,

$$\text{BHP} = \frac{55.3}{0.8} = 69.1 \text{ HP}$$

The motor chosen would be the next highest standard horsepower rating.

If more discharge or more head is required than a single pump can provide, two or more pumps may be combined to provide the necessary output. For example, when discharge is too little, pumps may be installed in parallel, sharing the same suction and inlet conditions. Figure 41.26 illustrates the principle. If a pump provides sufficient discharge but too little head, a second pump may be installed in series, the output of the first pump being fed directly into the suction of the second pump. Figure 41.27 depicts the

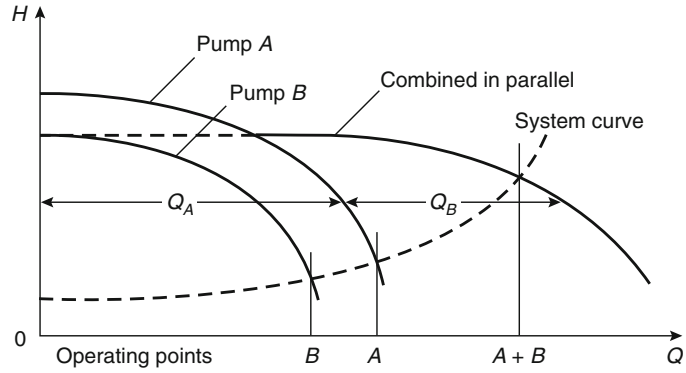

Fig. 41.26 Two pumps combined in parallel

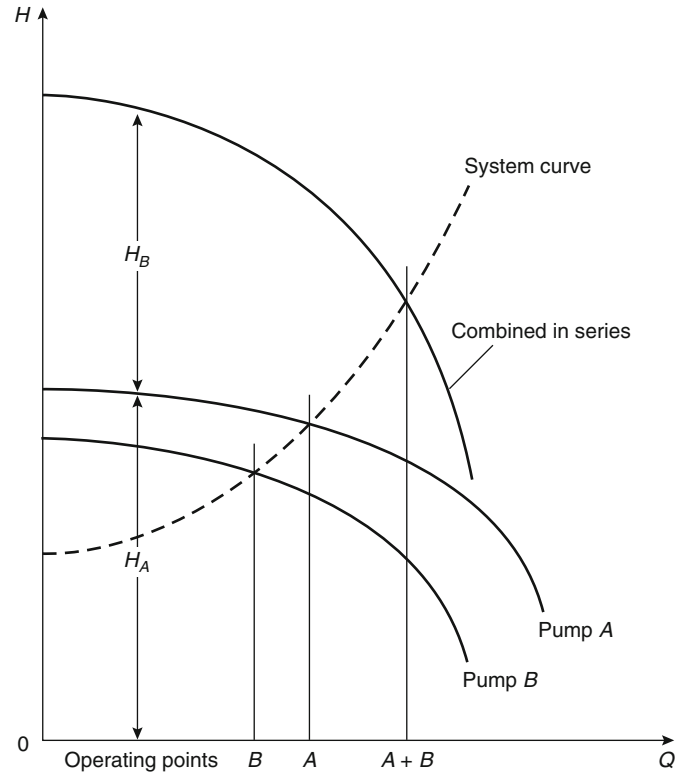

Fig. 41.27 Two pumps combined in series

series arrangement. A variety of compound arrangements are possible, depending on details of actual supply and demand, with economics being the prime arbiter.

Nomenclature

A	area
C	proportionality constant or flow coefficient, Hazen-Williams C-factor
c	celerity of a shock wave
D	pipe diameter
d	element diameter
E	velocity of approach factor, bulk modulus of elasticity
f	Darcy-Weisbach friction loss factor
G	gravitational acceleration constant, 9.8 m/s^2
H	head of water
h	head
h_c	height of centroid
h_L	head loss
I	moment of inertia
K	proportionality constant or flow coefficient
k	proportionality constant or flow coefficient
L	length of conduit (in friction loss equations)
l	length or distance
m	mass
N	pump rpm
p	pressure
Q	volumetric discharge rate
Re	Reynolds number
S	slope of energy gradient
s	specific gravity
u	stream velocity at a given point in flow cross section
V	volume
v	average stream velocity
z	height above a reference datum (potential head)
α	kinetic energy correction factor
β	beta ratio
γ	specific weight
Δ	increment
ε	pipe wall absolute roughness
η	efficiency
μ	absolute (dynamic) viscosity
ν	kinematic viscosity
ρ	density
τ	fluid shear stress

Russell P. Fleming

Introduction

Applications Where Water Is Appropriate

Water is the most commonly used fire fighting agent, mainly due to the fact that it is widely available and inexpensive. It also has very desirable fire extinguishing characteristics such as a high specific heat and high latent heat of vaporization. A single gallon of water can absorb 9280 Btus (2586.5 kJ) of heat as it increases from a 70 °F (21 °C) room temperature to become steam at 212 °F (100 °C).

Water is not without limits as an extinguishing agent, however, and is considered inappropriate for the protection of certain water reactive materials. In some cases, the application of water can exacerbate the production of heat, flammable or toxic gases, or cause an explosive reaction. The quantities and arrangement of such products must be considered, however, because the sufficient application of water can overcome the combustion reaction in some cases.

Another drawback of water is that it is more dense than most liquid hydrocarbon fuels, and immiscible with these liquids as well. Therefore, water will not effectively cover the burning liquid hydrocarbons, nor will it mix with them and dilute the volatile concentrations to the point where they will no longer sustain combustion. Instead, the hydrocarbons will float on top of the water, continuing to burn. In certain cases, the application of water could spread unconfined ignitable liquids and the associated fire. However, water additives such as foam concentrates can be added to the water discharge to produce foams that will float on the hydrocarbon surfaces to provide an effective cover and smother the fire. Applying water in a fine mist has also been successful for certain types of fires involving ignitable liquids. Other types of additives and discharge methods are also available to improve the effectiveness of water for specific applications.

Even when water from sprinklers will not suppress the fire, its cooling ability can protect structural elements of a building by controlling the fire until it can be extinguished by other means.

Types of Sprinkler Systems

For the majority of applications, automatic sprinkler systems are considered to be the most effective and economical way to apply water to control, suppress, or extinguish a fire. There are four basic types of sprinkler systems:

1. A *wet pipe* system is by far the simplest and most common type of sprinkler system. It consists of a network of piping containing water under pressure. Automatic sprinklers activated by internal heat responsive elements are connected to the piping such that each

R.P. Fleming (✉)

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_42, © Society of Fire Protection Engineers 2016

sprinkler protects an assigned horizontal building area, usually a floor area. The application of heat to any sprinkler will cause that single sprinkler to operate, permitting water to discharge over its area of protection.

2. A *dry pipe* system is similar to a wet system, except that water is held back from the piping network by a special dry pipe valve. The valve is kept closed by air or nitrogen pressure maintained in the system piping. The operation of one or more sprinklers will allow the air pressure to escape, causing operation of the dry valve, which then permits water to flow into the piping network to control or suppress the fire. Dry systems are used where the water in the piping would be subject to freezing.
3. A *deluge* system is one that does not use automatic sprinklers, but rather open sprinklers. A special deluge valve holds back the water from the piping, and is activated by a separate fire detection system. When activated, the deluge valve admits water to the piping network, and water flows simultaneously from all of the sprinklers comprising the system. Deluge systems are used for protection against rapidly spreading, high heat release fires.
4. A *preaction* system is similar to a deluge system except that automatic sprinklers rather than open sprinklers are used. A small amount of air pressure is usually maintained in the piping network to ensure that the system is air tight. As with a deluge system, a separate detection system is used to activate a deluge valve, admitting water into the piping network. However, because automatic sprinklers are used, the water is only discharged from activated sprinklers, i.e. those that were fused by heat from the fire. Some special arrangements of preaction systems permit variations on detection system interaction with sprinkler operation. Preaction systems are generally used where there is special concern for accidental discharge of water, as in data processing computer rooms or flash freeze warehouses.

These four basic types of systems differ in terms of the most fundamental aspect of how the water is discharged into the fire area. There are other variations of sprinkler system arrangements, classified according to the hazard they protect (such as residential, in-rack, or exposure protection); additives to the system (such as antifreeze or foam concentrate); or special connections to the system (such as multipurpose piping). However, all sprinkler systems can still be categorized as one of the basic four types.

Applicable Standards

Various sprinkler system design and installation standards are in use around the world. NFPA 13, *Standard for the Installation of Sprinkler Systems* (hereafter referred to as NFPA 13), is the most widely used, and is referenced by most building and life safety codes in the United States and Canada [1]. This standard, in turn, references other NFPA standards for design and installation requirements relating to water supply or interconnection with other systems. These standards include NFPA 14, *Standard for the Installation of Standpipe and Hose Systems*, NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection*, and NFPA 22, *Standard for Water Tanks for Private Fire Protection*.

For protection of warehouse storage, NFPA 13 traditionally referenced special storage standards that contained sprinkler system design criteria, including NFPA 231, *Standard for General Storage Materials*, NFPA 231C, *Standard for Rack Storage of Materials*, NFPA 231D, *Standard for Storage of Rubber Tires*, and NFPA 231F, *Standard for Storage of Roll Paper*. However, beginning with the 1999 edition of NFPA 13 these standards were all merged into NFPA 13 to produce a consolidated sprinkler system design and installation standard.

Other standards contain design and installation criteria for specific types of facilities or water-based systems, including NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and*

Manufactured Homes, NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection*, NFPA 16, *Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems*, NFPA 30, *Flammable and Combustible Liquids Code*, NFPA 30B, *Code for the Manufacture and Storage of Aerosol Products*, and NFPA 409, *Standard on Aircraft Hangars*.

The European standard addressing sprinkler system design and installation is EN 12845—*Fixed Firefighting Systems, Automatic Sprinkler Systems, Design, Installation and Maintenance*. The standard was first published in 2004, but is the successor to European insurance standards that in turn were based on sprinkler design and installation rules originally published by the Fire Offices Committee of the United Kingdom.

Insurance companies may also develop and enforce their own standards for their customers. For example, FM Global has developed Property Loss Prevention Data Sheet 2-0, *Installation Guidelines for Automatic Sprinklers*. In Europe, may insurers reference the use of CEA 4001-*sprinkler systems: planning and installation*. In some cases insurance companies or other authorities might modify the provisions or a given standard such as NFPA 13. While this chapter addresses the calculations and engineering considerations associated with the general design of sprinkler systems, the reader needs to confirm the applicable rules and regulations in effect for the particular project under consideration.

Trends in Sprinkler System Development

Since the 1970s, there have been a number of new developments in a technology with more than a century of performance history. Hydraulic calculations allowed system designers to take advantage of strong water supplies in order to use smaller pipe sizes. More aesthetically pleasing sprinklers entered the marketplace to appeal to architects and owners as sprinkler system installation spread from factories and warehouses to public spaces and private homes. New types of piping offered options. Fast response sprinklers enhanced safety to life while reducing design areas and water supplies based on fewer sprinklers expected to open during a fire event. Larger sprinkler orifice sizes were developed to better address the hazards of high challenge industrial and storage fires.

Almost all of these developments were aimed at equal or better fire protection at less cost, made possible through improved allocation of resources. The more efficient use of resources remains a challenge today, with a great deal of focus on sustainability. Because fire sprinklers systems utilize water for periodic testing as well as fire suppression, conservation will increase in importance, and the potential impact of reduced available water supplies on sprinkler system performance will need to be monitored [2]. Proposed environmental solutions such as the use of gray water supplies must be evaluated for their potential to reduce the long-term performance and reliability of fire sprinkler systems. For this reason, NFPA 13 requires that any source of recycled or reclaimed water and its proposed treatment process be analyzed before being made available to the sprinkler system, with a specific concern for compatibility with system components.

Limits of Calculation in an Empirical Design Process

Engineering calculations are best performed in areas where an understanding exists as to relationships between parameters. This is not the case with the technology of automatic sprinkler systems. Calculation methods are widely used with regard to only one aspect of sprinkler systems: water flow through piping. There are only very rudimentary calculation methods available with regard to the most fundamental aspect of sprinkler systems, that is, the ability of water spray to suppress fires.

The reason that calculation methods are not used is simply the complexity of the mechanisms by which water suppresses fires. Water-based fire suppression has to this point not been thoroughly

characterized to permit application of mathematical modeling techniques. As a result, the fire suppression aspects of sprinkler system design are empirical at best.

Some, but not all, of the current sprinkler system design criteria are based on full-scale testing, including the criteria originally developed for NFPA 231C, NFPA 13D, and parts of NFPA 13, such as the provisions pertaining to the use of CMSA (control mode specific application) and ESFR (early suppression fast response) sprinklers. Most of the protection criteria of NFPA 13 and other sprinkler system design standards, however, are the result of the evolution and application of experienced judgment and intuitive reasoning. In the 1970s, the capabilities of pipe schedule systems, which had demonstrated a hundred years of satisfactory performance, were codified into a system of density/area curves [3]. This permitted the introduction of hydraulic calculations to what had become a cookbook-type method of designing sprinkler systems. Hydraulic calculations allowed system designers to take advantage of strong water supplies to produce more economical systems. It also permitted the determination of specific flows and pressures available at various points of the system, opening the door to the development and use of new types of sprinklers. The number of different types of sprinklers available in the global marketplace has increased dramatically in the past few decades, and the fire protection engineer needs to be knowledgeable with regard to the variety of fire sprinkler products.

Even where design criteria were developed on the basis of full-scale testing, the number and sequence of operating sprinklers has been found to be variable. Some of this variability is due to the variability in fire growth itself and prevailing air currents within a building, but there are also observed phenomena such as "sprinkler skipping," in which a sprinkler will operate substantially prior to a nearby sprinkler that is closer to the fire plume. Generally associated with high challenge fire scenarios, skipping has been attributed to water drop impingement from nearby operating sprinklers [4], and there is evidence that steps can be taken to shield a sprinkler's heat sensing element from such impingement [5].

Because of this history, the calculation methods available to the fire protection engineer in standard sprinkler system design are only ancillary to the true function of a sprinkler system. The sections that follow in this chapter address hydraulic calculations of flow through piping, simple calculations commonly performed in determining water supply requirements, and optional calculations that may be performed with regard to hanging and bracing of system piping. The final section of this chapter deals with the performance of a system relative to a fire, and the material contained therein is totally outside the realm of standard practice. This material is not sufficiently complete to permit a full design approach, but only isolated bits of total system performance. The technical reference guide to the current version of the Fire Dynamics Simulator (FDS), a computational fluid dynamics model that has become the most popular tool in fire protection engineering, includes the statement that "simulating the effects of a sprinkler spray involves a number of elements beyond just activation: computing the droplet trajectories and tracking the water as it drips onto the burning surface" [6]. Efforts are underway to develop a mathematical model of sprinkler spray discharge based on first principles [7], with the hope of ultimately being able to model the impact of a fire sprinkler system on a fire.

Hydraulic Calculations

Density-Based Sprinkler Demand

Occupancy hazard classification, or commodity classification in the case of protecting storage, is the most critical aspect of the sprinkler system design process. If the hazard or commodity class is underestimated, it is possible for fire to overpower the sprinklers, conceivably resulting in a large loss of property or life. Hazard classification is not an area in which calculation methods are presently in use, however. The proper classification of hazard requires experienced judgment

and familiarity with relevant design and installation standards, and an understanding of sprinkler system performance. Commodity classification is also not possible by means of calculation, but intermediate scale fire testing is sometimes used as the basis of classifying a specific product.

Once the hazard or commodity classification is determined and a sprinkler spacing and piping layout has been proposed in conformance with the requirements of the applicable standard, the system designer can initiate a series of calculations to demonstrate that the delivery of a prescribed rate of water application will be accomplished for the maximum number of sprinklers that might be reasonably expected to operate. This number of sprinklers, which must be supplied regardless of the location of the fire within the building, is the basis of the concept of the remote design area. The designer needs to demonstrate that the shape and location of the sprinkler arrangement in the design area will be adequately supplied with water in the event of a fire. Adequacy of water relates to flow, pressure and quantity of water available through the sprinklers expected to operate in response to the fire.

Prior to locating the design area, there is the question of how many sprinklers are to be included in the expected maximum simultaneous flow area. This question is primarily addressed by the occupancy hazard classification, but the designer also has some freedom to decide this matter.

For example, in the 2013 edition of NFPA 13, Figure 11.2.3.1.1 contains density/area curves from which the designer can select a design area and density appropriate for the occupancy hazard classification. Any point on or to the right of the curve in the figure is acceptable. The designer may select a high density over a small area, or a low density over a large area. In either event, the fire is expected to be controlled by the sprinklers within that design area, without opening any additional sprinklers. For the protection of storage, similar curves or individual density/area specifications can be found in Chaps. 12, 13, 14, 15, 16, 17, 18, 19, 20, and 21. Chapter 22 of NFPA 13 (2013) contains some sprinkler design density/area specifications or hazard classifications from other NFPA codes and standards relating to the protection of specific occupancies.

Example 1 Using the sample density/area curve shown in Fig. 42.1, many different design criteria could be selected, ranging from a density of

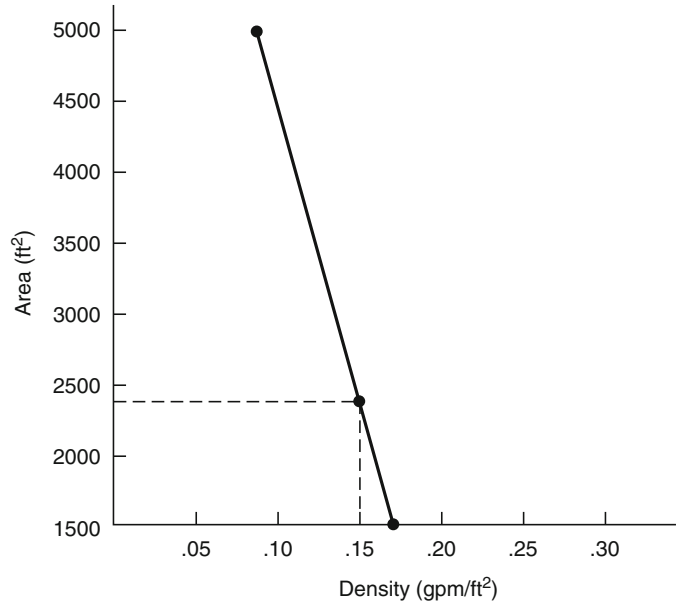

Fig. 42.1 Sample density/area curve

0.1 gpm/ft^2 (3.7 mm/min) over 5000 ft^2 (500 m^2) to 0.17 gpm/ft^2 (6.9 mm/min) over 1500 ft^2 (139 m^2). Either of these two points, or any point to the right of the curve (such as 0.16 gpm/ft^2 [6.5 mm/min] over 3000 ft^2 [276 m^2]) would be considered acceptable. A selection of 0.15 gpm/ft^2 (6.1 mm/min) over 2400 ft^2 (221 m^2) is indicated.

Water is provided only for the number of sprinklers in the design area, since no water is needed for the sprinklers that are not expected to open. The design area will be located in the hydraulically most demanding portion of the system. The actual number of sprinklers in the design area depends, of course, on the spacing of the individual sprinklers. NFPA 13 requires that the design area be divided by the maximum sprinkler spacing used, and that any fractional result be rounded up to the next whole sprinkler, as illustrated below.

Example 2 Based on the point selected from the sample density/area curve above and the proposed maximum spacing of sprinklers, the number of sprinklers to be included in the design area can be determined. If sprinklers are spaced at 12 × 15 ft (3.66 × 4.57 m) so as to each protect an area of 180 ft^2 (16.72 m^2), the design area of 2400 ft^2 (221 m^2) would include.

$$\frac{2,400}{180} = 13.33 = 14 \text{ sprinklers}$$

The remote design area is required to have a rectangular shape, with the long side of the rectangle parallel to the branch lines. The length of the long side of the design area needs to be determined to calculate the number of sprinklers to be included on each branch line in the design area. This length is normally determined by multiplying the square root of the design area by a factor of 1.2 in accordance with the rules of NFPA 13. Again, any fractional result is rounded to the next whole sprinkler as indicated below. Note that other standards or design methods may use multiplication factors other than 1.2. The higher the factor, the more conservative the design, since it requires more water to be available through individual branch lines.

Example 3 If the 14 sprinklers from Example *2* were spaced 12 ft (3.66 m) along the branch lines and the branch lines were spaced 15 ft (4.57 m) apart, the number of sprinklers along the length of the branch lines in the design area would be

$$\frac{1.2(2,400)^{1/2}}{12} = \frac{1.2(49)}{12} = 4.9 = 5 \text{ sprinklers}$$

If the sprinklers were spaced 15 ft (4.57 m) along the branch lines with the branch lines spaced 12 ft (3.66 m) apart, the design area rectangle would include only 4 sprinklers along its length.

NFPA 13 (2013) contains some exceptions to this method of locating a remote design area and determining the number of sprinklers to be supplied. Chapters 11 and 12 of the standard include special adjustments to the design area based on factors such as the use of a dry system, the use of quick response sprinklers under flat smooth ceilings of limited height, and the existence of nonsprinklered combustible concealed spaces within the building. These chapters also contain rules for the use of a room design method, which can reduce the number of sprinklers expected to operate in a highly compartmented occupancy. Also, beginning in 1985, the standard adopted a four sprinkler design area for dwelling units and their adjacent corridors when residential sprinklers are installed in accordance with their listing requirements. Listing requirements are specific to the applicable standard but normally pertain to the independent laboratory evaluation of performance of a product, system or service, in this case a residential sprinkler.

A step-by-step hydraulic calculation procedure is usually applied. For example, see Chapter 23 of the 2013 edition of NFPA 13. The starting point is the most remote sprinkler in the design area. For tree systems, in which each sprinkler is supplied from only one

direction, the most remote sprinkler is generally the end sprinkler on the farthest branch line from the system riser. This sprinkler, and all others in the design area, must be provided with a sufficient flow of water to meet the density appropriate for the point selected on the density/area curve.

Where a sprinkler protects an irregular area, NFPA 13 prescribes that the area of coverage for the sprinkler must be based on the largest sides of its coverage. In other words, the area which a sprinkler protects for calculation purposes is equal to

$$\text{Area of coverage} = S \times L$$

where S is twice the larger of the distances to the next sprinkler (or wall for an end sprinkler) in both the upstream and downstream directions, and L is twice the larger of the distances to adjacent branch lines (or wall in the case of the last branch line) on either side. This reflects the need to flow more water with increasing distance from the sprinkler, since increased flow tends to expand the effective spray umbrella of the sprinkler.

The minimum flow from a sprinkler must be the product of the area of coverage multiplied by the minimum required density

$$Q = \text{Area of coverage} \times \text{Density}$$

Most of the special listed sprinklers and residential sprinklers have a minimum flow requirement associated with their listings, which is often based on the spacing at which they are used. These minimum flow considerations override the minimum flow based on the density/area method.

Example 4 If a standard spray sprinkler protects an area extending to 7 ft (2.1 m) on the north side (half the distance to the next branch line), 5 ft (1.5 m) on the south side (to a wall), 6 ft (1.8 m) on the west side (half the distance to the next sprinkler on the branch line), and 4 ft (1.2 m) on the east side (to a wall), the minimum flow required for the sprinkler to achieve the density requirement selected in Example *1* can be found by completing two steps. The first step involves determining the area of coverage. In this case:

$$S \times L = 2(6\text{ ft}) \times 2(7\text{ ft}) = 12\text{ ft} \times 14\text{ ft} = 168\text{ ft}^2\ (15.6\text{ m}^2)$$

The second step involves multiplying this coverage area by the required density:

$$Q = A \times \rho = 168\text{ ft}^2 \times 0.15\text{ gpm/ft}^2 = 25.2\text{ gpm}\ (95.4\text{ L/min})$$

Pressure Requirements of the Most Remote Sprinkler

When flow through a sprinkler orifice takes place, the energy of the water changes from the potential energy of pressure to the kinetic energy of flow. A formula can be derived from the basic energy equations to determine how much water will flow through an orifice based on the water pressure inside the piping at the orifice:

$$Q = 29.83 c_d d^2 P^{1/2}$$

This formula contains a factor, c_d, which is a discharge coefficient characteristic of the sprinkler orifice that is determined by laboratory testing. For sprinklers, the product listing organizations determine the orifice discharge coefficient for each particular model of sprinkler. To simplify matters, all physical factors of the sprinkler orifice are lumped into what is experimentally determined as the K-factor of a sprinkler, such that

$$Q = \text{K} \times P^{1/2}$$

where K has units of gpm/(psi)$^{1/2}$ [L/min/(bar)$^{1/2}$].

Since the required minimum flow at the most remote sprinkler is known, determined by either the density/area method or the special sprinkler listing, the minimum pressure needed at the most remote sprinkler can easily be calculated.

Since $Q = \text{K}(P)^{1/2}$ then $P = (Q/\text{K})^2$

Many sprinklers require a minimum operating pressure of 7 psi (0.48 bar) to ensure proper spray pattern development.

Example 5 The pressure required at the sprinkler in Example 4 can be determined using the above formula once a specific sprinkler is selected. The K-factor for any sprinkler needs to be confirmed with the manufacturer and listing organization. For the purposes of this example, a K-factor of 5.6 is assumed, since this is a common value for what are considered standard ½-inch orifice sprinklers.

$$P = \left(\frac{Q}{\mathrm{K}}\right)^2 = \left(\frac{25.2}{5.6}\right)^2 = 20.2 \text{ psi} (1.4 \text{ bar})$$

Once the minimum pressure at the most remote sprinkler is determined, the hydraulic calculation method proceeds backward toward the source of water supply. If the sprinkler spacing is regular, it can be assumed that all other sprinklers within the design area will be flowing at least as much water, and the minimum density is assured. If sprinkler spacing is irregular due to walls and obstruction, or sprinklers with different K-factors are used, it must be verified that each sprinkler is provided with sufficient flow.

As the calculations proceed toward the system riser and water supply, the minimum pressure requirements increase, because additional pressures are needed to overcome losses associated with elevation changes, pipe friction, and turbulence caused by fittings, so that the minimum design densities for all sprinklers in the design area are maintained. The determination of the friction and elevation losses are discussed below, with their values added to the total pressure requirements.

It should be noted that each sprinkler closer to the source of supply will show a successively greater flow rate, since a higher total pressure is available at that point in the system piping. This effect on the total water demand is termed hydraulic increase, and is the reason why the total water demand of a system is not simply equal to the product of the minimum density and the design area. When calculations are complete, the sprinkler system demand will be known, stated in the form of a specific flow at a specific pressure. A hose demand is also sometimes added to the sprinkler system demand. The total quantity of water will be determined based upon the duration of required flow that will be specified by applicable standards.

Pressure Losses Through Piping, Fittings, and Valves

Friction losses resulting from water flow through piping can be estimated by several engineering approaches, but the most common is the Hazen-Williams method. This approach is based on the formula developed empirically by Hazen and Williams:

$$p = \frac{4.52Q^{185}}{C^{1.85}d^{4.87}}$$

where
p = Friction loss per ft of pipe in psi
Q = Flow rate in gpm
d = Internal pipe diameter in in.
C = Hazen-Williams coefficient

The choice of C is critical to the accuracy of the friction loss determination, and is therefore normally stipulated by design standards. C values for various types of pipe materials are shown in Fig. 42.1. The values assigned for use are intended to simulate the expected interior roughness of aged pipe (Table 42.1).

Rather than make the Hazen-Williams calculation for each section of piping, it has become standard practice, when doing hand calculations, to use a friction loss table, which contains all values of p for various values of Q and various pipe sizes. In many cases the tables are based on

Table 42.1 C values for pipes

Type of pipe	Assigned C factor
Steel pipe—dry and preaction systems	100
Steel pipe—wet and deluge systems	120
Galvanized steel pipe—dry and preaction systems	100
Galvanized steel pipe—wet and deluge systems	120
Cement lined cast or ductile iron	140
Copper tube	150
Plastic (listed)	150

the use of Schedule 40 steel pipe for wet systems. The use of other pipe schedules, pipe materials, or system types may require the use of multiplying factors. Most commercially available sprinkler system hydraulic calculation programs have these values programmed into the software.

Once the value of friction loss per foot is determined using either the previous equation or friction loss tables, the total friction loss through a section of pipe is found by multiplying p by the length of pipe, L. Since some standards use p to designate loss per foot, total friction loss in a length of pipe can be designated by p_f, where

$$p_f = p \times \mathrm{L}$$

In the analysis of complex piping arrangements, it is sometimes convenient to lump the values of all factors in the Hazen-Williams equation (except flow) for a given length of pipe into a constant, K, identified as a friction loss coefficient. To avoid confusion with the nozzle coefficient K, this coefficient can be identified as FLC, friction loss coefficient.

$$\mathrm{FLC} = \frac{(L \times 4.52)}{\left(C^{1.85} d^{4.87}\right)}$$

The value of p_f is therefore equal to

$$p_f = \mathrm{FLC} \times Q^{1.85}$$

Example 6 If the most remote sprinkler on a branch line requires a minimum flow of 25.2 gpm (92.1 L/min) for a minimum pressure of 20.2 psi (1.4 bar) as shown in Examples 4 and 5, and the second sprinkler on the line is connected by a 12 ft (3.6 m) length of 1 in. (25.4 mm) Schedule 40 steel pipe, with both sprinklers mounted directly in fittings on the pipe (no drops or sprigs), the minimum pressure required at the second sprinkler can be found by determining the friction loss caused by a flow of 25.2 gpm (92.1 L/min) through the piping to the end sprinkler. Typically, pressure losses associated with straight-through fittings can be ignored in the calculation process if there is no change in flow direction. Also, the fitting directly attached to each sprinkler is generally ignored, since K-factors of sprinklers are determined with such a fitting in place.

Using the Hazen-Williams equation with values of 25.2 for Q, 120 for C, and 1.049 for d (the inside diameter of Schedule 40 steel 1 in. pipe) results in a value of $p = 0.20$ psi (0.012 bar) per foot of pipe. Multiplying by the 12 ft (3.6 m) length results in a total friction loss of $p_f = 2.4$ psi (0.17 bar). The total pressure required at the second sprinkler on the line is therefore 20.2 psi + 2.4 psi = 22.6 psi (1.6 bar). This will result in a flow from the second sprinkler of $Q = \mathrm{K}(P)^{1/2} = 26.6$ gpm (100.7 L/min).

Minor losses through fittings and valves are not friction losses but energy losses, caused by turbulence in the water flow, which increase as the velocity of flow increases. Nevertheless, it has become standard practice to simplify calculation of such losses through the use of "equivalent lengths," which are added to the actual pipe length in determining the pipe friction loss. NFPA 13 contains a table of equivalent pipe lengths for this purpose (Table 42.2). As an example, if a 2 in. (50.8 mm) 90-degree long turn elbow is assigned an equivalent length of 3 ft (0.914 m), this means that the energy loss associated with turbulence through the elbow is expected to approximate the energy loss to friction through 3 ft of 2 in. pipe (0.914 m of 50.8 mm pipe). As with the friction loss tables, the equivalent pipe length chart is based on the use of steel pipe with a C-factor of 120, and the use of other piping materials requires multiplying factors. The equivalent pipe length for pipes having C values other then 120 should be adjusted using the following multiplication factors: 0.713 for a C value of 100; 1.16 for a C value of 130; 1.33 for a C value of 140; 1.51 for a C value of 150.

Example 7 If the 12 ft (3.6 m) length of 1 in. (25.4 mm) pipe in Example 6 had contained four elbows so as to avoid a building column, the pressure loss from those elbows could be approximated by adding an equivalent length of pipe to the friction loss calculation. Table 42.2 gives a value of 2 ft (0.610 m) as the appropriate equivalent length for standard elbows in 1 in. (25.4 mm) Schedule 40 steel pipe. For four elbows, the equivalent fitting length would be 8 ft (2.4 m). Added to the actual pipe length of

Table 42.2 Equivalent pipe length chart (for C = 120)

	Fittings and valves expressed in equivalent feet of pipe													
Fittings and valves	¾ in.	1 in.	1¼ in.	1½ in.	2 in.	2½ in.	3 in.	3½ in.	4 in.	5 in.	6 in	8 in.	10 in.	12 in.
45° elbow	1	1	1	2	2	3	3	3	4	5	7	9	11	13
90° standard elbow	2	2	3	4	5	6	7	8	10	12	14	18	22	27
90° long turn elbow	1	2	2	2	3	4	5	5	6	8	9	13	16	18
Tee or cross (flow turned 90°)	3	5	6	8	10	12	15	17	20	25	30	35	50	60
Butterfly valve	—	—	—	—	6	7	10	—	12	9	10	12	19	21
Gate valve	—	—	—	—	1	1	1	1	2	2	3	4	5	6
Swing check[a]	—	5	7	9	11	14	16	19	22	27	32	45	55	65

For SI units: 1 ft = 0.3048 m

[a]Due to the variations in design of swing check valves, the pipe equivalents indicated in the above chart are to be considered average

12 ft (3.6 m), the total equivalent length would be 20 ft (6 m). This results in a new value of $p_f = 20$ ft × 0.20 psi/ft = 4.0 psi (0.28 bar). The total pressure at the second sprinkler would then be equal to 20.2 psi + 4.0 psi = 24.2 psi (1.67 bar). The total flow from the second sprinkler in this case would be $Q = K(P)^{1/2} = 27.5$ gpm (100.4 L/min).

Some types of standard valves, such as swing check valves, are included in Table 42.2, the equivalent pipe length chart. Equivalent lengths for pressure losses through system alarm, dry, and deluge valves are determined by the approval laboratories at the time of product listing.

Use of Velocity Pressures

The value of pressure, P, in the sprinkler orifice flow formula can be considered either the total pressure, P_t, or the normal pressure, P_n, since design standards typically permit the use of velocity pressures at the discretion of the designer. Total pressure, normal pressure, and velocity pressure, P_v, have the following relationship:

$$P_n = P_t - P_v$$

Total pressure is the counterpart of total energy or total head, and can be considered the pressure that would act against an orifice if all of the energy of the water in the pipe at that point were focused toward flow out of the orifice. This is the case where there is no flow past the orifice in the piping. Where flow does take place in the piping past an orifice, however, normal pressure is the portion of the total pressure acting perpendicular to the direction of flow in the piping, and therefore acting in the direction of flow through the orifice. The amount by which normal pressure is less than total pressure is velocity pressure, which is acting in the direction of flow in the piping. Velocity pressure corresponds to velocity energy, which is the energy of motion. There is no factor in the above expression for elevation head, because the flow from an orifice can be considered to take place in a datum plane.

When velocity pressures are used in calculations, it is recognized that some of the energy of the water is in the form of velocity head, which is not acting normal to the pipe walls (where it would help push water out the orifice), but rather in the downstream direction. Thus, for every sprinkler (except the end sprinkler on a line), slightly less flow takes place than what would be calculated from the use of the formula $Q = K(P_t)^{1/2}$ (Fig. 42.2).

Design standards typically permit the velocity pressure effects to be ignored, however, since they are usually rather minor for most sprinkler system configurations. Additionally, ignoring the effects of velocity pressure tends to produce a more conservative design in that the calculated system demand (flow and pressure) increase when velocity pressures are not taken into account.

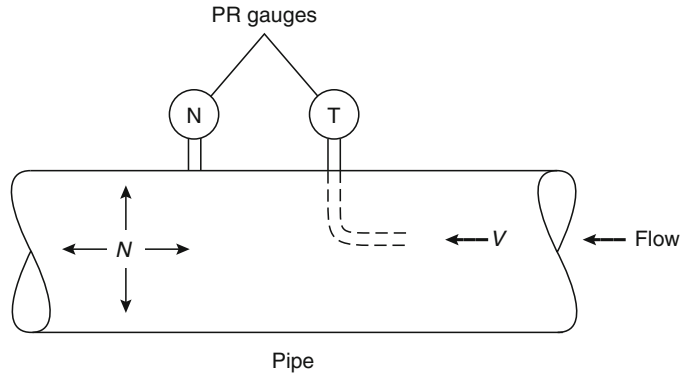

Fig. 42.2 Velocity and normal pressures in piping

If velocity pressures are considered, normal pressure rather than total pressure is used when determining flow through any sprinkler except the end sprinkler on a branch line, and through any branch line except the end branch line on a cross main. The velocity pressure, P_v, which is subtracted from the total pressure in order to determine the normal pressure, is determined as

$$P_v = \frac{v^2}{2g} \times 0.433 \text{ psi/ft } (0.098 \text{ bar/m})$$

or

$$P_v = 0.001123Q^2/d^4$$

where Q is the upstream flow through the piping to an orifice (or branch line) in gpm and d is the actual internal diameter of the upstream pipe in inches.

Because design standards typically mandate the use of the upstream flow, an iterative approach to determining the velocity pressure is necessary. The upstream flow cannot be determined unless the flow from the sprinkler (or branch line) in question is known. Since the flow from the sprinkler (or branch line) is affected by the velocity pressure resulting from the upstream flow, an estimate of the upstream flow is needed to start the iteration.

Example 8 If the pipe on the upstream side of the second sprinkler in Example 6 were 3 in. Schedule 40 steel pipe with an inside diameter of 1.38 in. (35 mm), the flow from the second sprinkler would be considered to be 26.6 gpm (100.2 L/min) as determined at the end of Example 6, if velocity pressures were not included.

If velocity pressures were to be considered, an upstream flow would first be assumed. Since the end sprinkler had a minimum flow of 25.2 gpm (95.2 L/min) and the upstream flow would consist of the combined flow rates of the two sprinklers, an estimate of 52 gpm (196.8 L/min) appears reasonable. Substituting this flow and the pipe diameter into the equation for velocity pressure gives

$$\begin{aligned} P_v &= \frac{0.001123Q^2}{d^4} \\ &= \frac{0.001123(52)^2}{(1.38)^4} \\ &= 0.8 \text{ psi } (0.06 \text{ bar}) \end{aligned}$$

This means that the actual pressure acting on the orifice of the second sprinkler is equal to

$$\begin{aligned} P_n &= P_t - P_v \\ &= 22.6 \text{ psi} - 0.8 \text{ psi} \\ &= 21.8 \text{ psi } (1.50 \text{ bar}) \end{aligned}$$

This would result in a flow from the second sprinkler of

$$\begin{aligned} Q &= \mathrm{K}(P)^{1/2} \\ &= 26.1 \text{ gpm } (98.7 \text{ L/min}) \end{aligned}$$

Combining this flow with the known flow from the end sprinkler results in a total upstream flow of 51.3 gpm (194.2 L/min). To determine if the initial guess was close enough, determine the velocity pressure that would result from an upstream flow of 51.3 gpm (194.2 L/min).

This calculation also results in a velocity pressure of 0.8 psi (0.06 bar), and the process is therefore complete. It can be seen that the second sprinkler apparently flows 0.5 gpm (1.9 L/min) less than the estimated flow due to velocity pressures.

Elevation Losses

Variation of pressure within a fluid at rest is related to the density or unit (specific) weight of the fluid. The unit weight of a fluid is equal to its density multiplied by the acceleration of gravity. The unit weight of water is 62.4 lbs/ft^3 (1000 kg/m^3).

This means that one cubic foot of water at rest weighs 62.4 lbs (1000 kg). The cubic foot of water, or any other water column one foot high, thus results in a static pressure at its base of 62.4 lbs/ft^2 (304.66 kg/m^2). Divided by 144 in.^{2} per ft^2 (1.020 $\times$ 10^4 kg/m^2 bar), this results in a pressure of 0.433 lb per in.^{2} per ft (0.099 bar/m) of water column.

A column of water 10 ft (3.048 m) high similarly exerts a pressure of 10 ft $\times$ 62.4 lbs/ft^2 $\times$ 1 ft^2/144 in.^{2} = 4.33 psi (3.048 m $\times$ 999.5 kg/m^2 $\div$ 1.020 $\times$ 10^4 kg/m^2 bar = 0.299 bar). The static pressure at the top of both columns of water is equal to zero (gauge pressure), or atmospheric pressure.

On this basis, additional pressure must be available within a sprinkler system water supply to overcome the pressure loss associated with elevation, i.e. when water flow is acting against the force of gravity. This pressure is equal to 0.433 psi/ft (0.099 bar/m) of elevation of the sprinklers above the level where the water supply information is known.

Sometimes the additional pressure needed to overcome elevation is added at the point where the elevation change takes place within the system. If significant elevation changes take place within a portion of the system that is likely to be considered as a representative flowing orifice (such as a single branch line along a cross main that is equivalent to other lines in the remote design area), then it is considered more accurate to wait until calculations have been completed, and simply add an elevation pressure increase to account for the total height of the highest sprinklers above the supply point.

Example 9 The pressure that must be added to a system supply to compensate for the fact that the sprinklers are located 120 ft (36.6 m) above the supply can be found by multiplying the total elevation difference by 0.433 psi/ft (0.099 bar/m).

$$120 \text{ ft} \times 0.433 \text{ psi/ft} = 52 \text{ psi} \ (3.62 \text{ bar})$$

Loops and Grids

Hydraulic calculations become more complicated when piping is configured in loops or grids, such that water feeding any given sprinkler or branch line can be supplied through more than one route. A number of computer programs that can quickly complete the repetitive calculations have therefore been developed specifically for fire protection systems, and are being marketed commercially.

Determining the flow split that takes place in the various parts of any loop or grid is accomplished by applying the basic principles of conservation of mass and conservation of energy. For a single loop, it should be recognized that the energy loss across each of the two legs from one end of the system to the other must be equal. Otherwise, a circulation would take place within the loop itself. Also, mass is conserved by the fact that the sum of the two individual flows through the paths is equal to the total flow into (and out of) the loop (Fig. 42.3).

Applying the Hazen-Williams formula to each leg of the loop

$$p_f = L_1 \frac{4.52 Q_1^{1.85}}{C_1^{1.85} d_1^{4.87}} = L_2 \frac{4.52 Q_2^{1.85}}{C_2^{1.85} d_2^{1.85}}$$

Substituting the term FLC for all terms except Q,

$$p_f = \text{FLC}_1 Q_1^{1.85} = \text{FLC}_2 Q_2^{1.85}$$

This simplifies to become

$$\left(\frac{Q_1}{Q_2}\right)^{1.85} = \frac{\text{FLC}_2}{\text{FLC}_1}$$

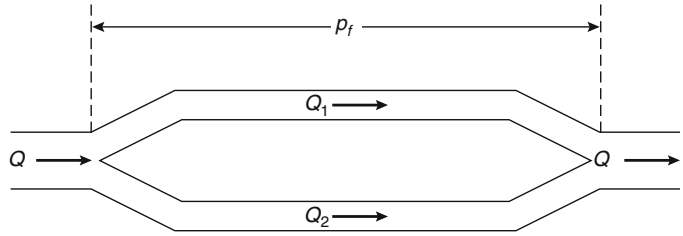

Fig. 42.3 Example of a simple loop configuration

Since Q_1 and Q_2 combine to create a total flow of Q, the flow through one leg can be determined as

$$Q_1 = \frac{Q}{\left[(\mathrm{FLC}_1/\mathrm{FLC}_2)^{0.54} + 1\right]}$$

For the simplest of looped systems, i.e. a single loop, hand calculations are not complex. Furthermore, sometimes a seemingly complex piping system can be simplified by substituting an "equivalent pipe" for two or more pipes in series or in parallel.

For pipes in series

$$\mathrm{FLC}_e = \mathrm{FLC}_1 + \mathrm{FLC}_2 + \mathrm{FLC}_3 + \cdots$$

For pipes in parallel

$$\left(\frac{1}{\mathrm{FLC}_e}\right)^{0.54} = \left(\frac{1}{\mathrm{FLC}_1}\right)^{0.54} + \left(\frac{1}{\mathrm{FLC}_2}\right)^{0.54} + \cdots$$

For gridded systems, which involve flow through multiple loops, computers are generally used since it becomes necessary to solve a system of nonlinear equations. When hand calculations are performed, the Hardy Cross [8] method of balancing heads is generally employed. This method involves assuming a flow distribution within the piping network, then iterating, i.e. applying successive corrective flows until differences in pressure losses through the various routes are nearly equal.

The Hardy Cross solution procedure applied to sprinkler system piping is as follows:

1. Identify all loop circuits and the significant parameters associated with each line of the loop, such as pipe length, diameter, and Hazen-Williams coefficient. Reduce the number of individual pipes where possible by finding the equivalent pipe for pipes in series or parallel.
2. Evaluate each parameter in the proper units. Minor losses through fittings should be converted to equivalent pipe lengths. A value of all parameters except flow for each pipe section should be calculated (FLC).
3. Assume a reasonable distribution of flows that satisfies continuity, proceeding loop by loop.
4. Compute the pressure (or head) loss due to friction, p_f, in each pipe using the FLC in the Hazen-Williams formula.
5. Sum the friction losses around each loop with due regard to flow direction, i.e. assume clockwise flow positive and counter-clockwise flow as negative. Flows are correct when the sum of the losses, dp_f, is as small as desirable, typically 0.5 psi (0.03 bar).
6. If the sum of the losses is not sufficiently small for each loop, divide each pipe's friction loss by the presumed flow for the pipe, p_f/Q.
7. Calculate a correction flow for each loop as

$$dQ = \frac{-dp_f}{\left[1.85 \sum \left(p_f/Q\right)\right]}$$

8. Add the correction flow values to each pipe in the loop as required, thereby increasing or decreasing the earlier assumed flows. For cases where a single pipe is in two loops, the algebraic difference between the two values of dQ must be applied as the correction to the assumed flow.
9. With a new set of assumed flows, repeat steps 4–7 until the values of dp_f are sufficiently small.

10. As a final check, calculate the pressure loss by any route from the initial to the final junction. A second calculation along another route should give the same value of pressure loss within the range of accuracy expected, again typically 0.5 psi (0.03 bar).

Design standards typically require that pressures be shown to balance within 0.5 psi (0.03 bar) at hydraulic junction points. The designer, with or without the use of a computer program, must continue to make successive guesses as to how much flow takes place in each section of pipe until the pressure loss from the design area back to the source of supply is approximately the same (within 0.5 psi [0.03 bar]) regardless of the path chosen.

Example 10 For the small two-loop grid shown in Fig. 42.4, the total flow in and out is 100 gpm (378.5 L/min). It is necessary to determine the flow taking place through each pipe section. The system has already been simplified by finding the equivalent pipe for all pipes in series and in parallel. The following values of FLC have been calculated:

$$\begin{aligned} &Pipe\ 1\ FLC = 0.001 \\ &Pipe\ 2\ FLC = 0.002 \\ &Pipe\ 3\ FLC = 0.003 \\ &Pipe\ 4\ FLC = 0.001 \\ &Pipe\ 5\ FLC = 0.004 \end{aligned}$$

Recall that FLC pertains to the length, internal diameter, and Hazen-Williams C-factor for each pipe segment.

Under step 3 of the Hardy Cross procedure, flows that would satisfy conservation of mass are estimated as shown in Fig. 42.5. Steps 4–9 are then carried out in a tabular approach as shown in Table 42.3.

As the difference between dp_f for loop 1 and loop 2 is greater than 0.5 psi (0.03 bar), at least another iteration is necessary to balance flows. Using the calculated flow estimates from the first iteration, another set of calculations is completed as shown in Table 42.4. Revised flows after the first iteration are shown in Fig. 42.6.

With regard to the flow in pipe #3, which is common to both loops, the first iteration indicates that the estimated flow should be reversed. For loop 1, the flow calculates to −11.4 gpm but was estimated to be +5 gpm.

					=0.61	0.157	$dQ = -2.1$	

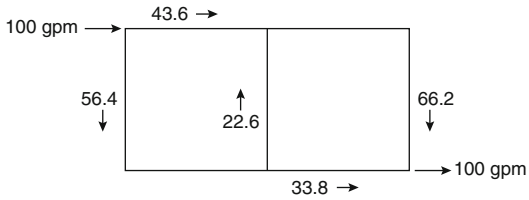

Fig. 42.6 Corrected flows after first iteration

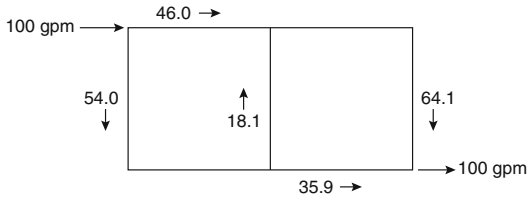

Fig. 42.7 Corrected flows after second iteration

For loop 2, the flow calculates +6.2 gpm but was estimated to be −5 gpm. As indicated in step 8, where a pipe segment is common to another loop, the algebraic difference between the two values of dQ is to be applied as the correction to the assumed flow. In other words, the flow correction for the common pipe is the net effect of the corrections for both loops. For pipe #3, the algebraic difference in dQ for loops 1 and 2 is 27.6 gpm (16.4 gpm + 11.2 gpm). This results is a corrected flow for pipe #3 of 5–27.6 = −22.6 gpm for loop 1 and +22.6 for loop 2.

After completion of the second iteration, the difference in dp_f between loops 1 and 2 is still too large, so a third iteration is needed. The flows after the second iteration are shown in Fig. 42.7. The third iteration calculations, as shown in Table 42.5, indicate that the In starting the pressure losses around both loops are balanced within 0.5 psi. Therefore, the flow split assumed after two iterations can be accepted. As a final check, step 10 of the above procedure calls for a calculation of the total pressure loss through two different routes, requiring that they balance within 0.5 psi (0.03 bar):

Water flow route through pipes 1 and 5:

$$\begin{aligned} &\mathrm{FLC}_1\,(Q_1)^{1.85} + \mathrm{FLC}_2(Q_2)^{1.85} \\ &= 0.001(54.0)^{1.85} + 0.004(35.9)^{1.85} \\ &= 1.6 + 3.0 = 4.6 \text{ psi } (0.32 \text{ bar}) \end{aligned}$$

Water flow route through pipes 2 and 4:

$$\begin{aligned} 0.002(46.0)^{1.85} + 0.001(64.1)^{1.85} &= 2.4 + 2.2 \\ = 4.6 \text{ psi } (0.32 \text{ bar}) & \end{aligned}$$

This is acceptable. Note that this example required less than three full iterations to achieve a successful solution, i.e. correctly balanced flow, despite the fact that the initial flow assumption called for reverse flow in pipe #3. The initial assumption was for a clockwise flow of 5 gpm (18.9 L/min) in pipe 3, but the final solution shows a counterclockwise flow of 18.1 gpm (68.5 L/min).

Water Supply Calculations

Determination of Available Supply Curve

Depending upon the location of the sprinkler system, public or private water main networks might be available to serve as the water supply

Table 42.5 Third iteration

Loop	Pipe	Q	FLC	p_f	dp_f	(p_f/Q)	$dQ = -dp_f/1.85\left[\Sigma\left(p_f/Q\right)\right]$	$Q + dQ$
1	1	−54.0	0.001	−1.60

	4	64.1	0.001	2.20				
	5	−35.9	0.004	−3.01				
					= −0.17			

for the system. For instance, the municipal underground water mains of many large cities in North America are permitted to be used for fire protection purposes.

Flow testing of public or private water supply mains permits an evaluation of the strength of the available water supply in terms of both quantity of flow and available pressures. The strength of a water supply is the key to whether it will adequately serve a sprinkler system.

Each test of a water supply must provide at least two pieces of information—a static pressure and a residual pressure at a known flow. The static pressure is sometimes referred to as the "no flow" condition, as no water is being discharged from the main in the vicinity of the test. However, it must be recognized that rarely is any public water supply network in a true no flow condition. This condition is intended represent a situation where the fire protection system is not creating an additional flow demand beyond that which is ordinarily placed on the system. The residual pressure reading is taken with an additional flow being taken from the system, preferably a flow that approximates the likely maximum system demand.

Between the two (or more) points, a representation of the water supply (termed a water supply curve) can be made. For the most part, this water supply curve is a fingerprint of the system supply and piping arrangements, since the static pressure tends to represent the effect of elevated tanks and operating pumps in the system, and the drop to the residual pressure represents the friction and minor losses through the piping network that result from the increased flow during the test.

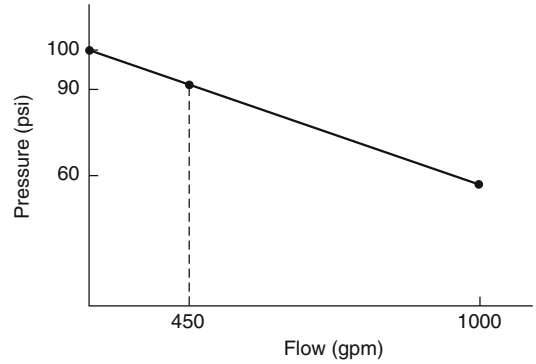

Fig. 42.8 Pressure available from 450 gpm flow water supply

The static pressure is read directly from a gauge attached to a hydrant. The residual pressure is read from the same gauge while a flow reading is taken from another hydrant, preferably downstream. A pitot tube is usually used in combination with observed characteristics of the nozzle through which flow is taken in order to determine the amount of flow.

Figure 42.8 is an example of a plot of water supply information. The static pressure is plotted along the *y*-axis, reflecting a given pressure under zero or no-flow conditions. The residual pressure at the measured flow is also plotted, and a straight line is drawn between these two points. Note that the *x*-axis is not linear, but rather shows flow as a function of the 1.85 power. This corresponds to the exponent for flow in the Hazen-Williams equation. Using this semi-exponential graph paper demonstrates that the residual pressure effect is the result of friction loss through the system, and permits the water supply curve to be plotted as a straight line.

Since the drop in residual pressure is proportional to flow to the 1.85 power, the available pressure at any flow can be read directly from the water supply curve.

For adequate design, the system demand point, including hose stream allowance, should lie below the water supply curve.

Example 11 If a water supply is determined by test to have a static pressure of 100 psi (6.9 bar) and a residual pressure of 80 psi (5.5 bar) at a flow of 1000 gpm (3785 L/min), the pressure available at a flow of 450 gpm (1703 L/min) can be approximated by plotting the two known data points on the hydraulic graph paper as shown in Fig. 42.8. At a flow of 450 gpm (1703 L/min), a pressure of 90 psi (6.2 bar) is indicated.

Pump Selection and Testing

Specific requirements for pumps used in sprinkler systems are normally contained in separate design and installation standards such as NFPA 20.

Fire pumps provide a means of making up for pressure deficiencies where an adequate volume of water is available at a suitable net positive suction pressure. Plumbing codes or municipal water supply regulations sometimes set a minimum allowable net positive suction pressure of 10–20 psi (0.69–1.38 bar) for water taken from public mains. If insufficient water is available at such pressures from such sources, then it becomes necessary to use a stored water supply.

Listed centrifugal fire pumps are available with either diesel or electric drivers, and with capacities ranging from 25 to 5000 gpm (95–18,927 L/min), although fire pumps are most commonly found with capacities ranging from 250 to 2500 gpm (946–9463 L/min) in increments of 250 up to 1500 gpm (946 up to 5678 L/min) and 500 gpm (1893 L/min) increments beyond that point. Each pump is specified with a rated flow and rated pressure. Rated pressures vary extensively, since manufacturers can control this feature with small changes to impeller design.

Pump affinity laws govern the relationship between impeller diameter, D, pump speed, N, flow, Q, pressure head, H, and brake horsepower, bhp. The first set of affinity laws assumes a constant impeller diameter.

$$\frac{Q_1}{Q_2} = \frac{N_1}{N_2} \quad \frac{H_1}{H_2} = \frac{N_1^2}{N_2^2} \quad \frac{\text{bh p}_1}{\text{bh p}_2} = \frac{N_1^3}{N_2^3}$$

These affinity laws are commonly used when correcting the output of a pump to its rated speed, such as during a fire pump acceptance test when the installed pump is not operating precisely at its rated speed.

The second set of the affinity laws assumes constant speed with change in impeller diameter, D.

$$\frac{Q_1}{Q_2} = \frac{D_1}{D_2} \quad \frac{H_1}{H_2} = \frac{D_1^2}{D_2^2} \quad \frac{\text{bh p}_1}{\text{bh p}_2} = \frac{D_1^3}{D_2^3}$$

Pumps are selected to fit the system demands on the basis of three key points relative to their rated flow and rated pressure (Fig. 42.9). Fire pump standards such as NFPA 20 specify that centrifugal fire pumps meet these three points as noted below, and the listing laboratories verify this and establish pump performance curves for each pump.

1. A minimum of 100 % of rated pressure at 100 % of rated flow
2. A minimum of 65 % of rated pressure at 150 % of rated flow (overload)
3. A maximum of 140 % of rated pressure at 0 % of rated flow (churn)

While each fire pump has its individual performance curve, a pump specifier knows the basic performance characteristics of a pump even before the performance curve is available, since it must meet the three points described above. It is usually possible to have more than one option when choosing pumps, since the designer is not limited to using a specific point on the pump performance curve.

There are limits to flexibility in pump selection, however. For example, it is not permitted to install a pump in a situation where it would be expected to operate with a flow exceeding 150 % of rated capacity, since the performance is not a

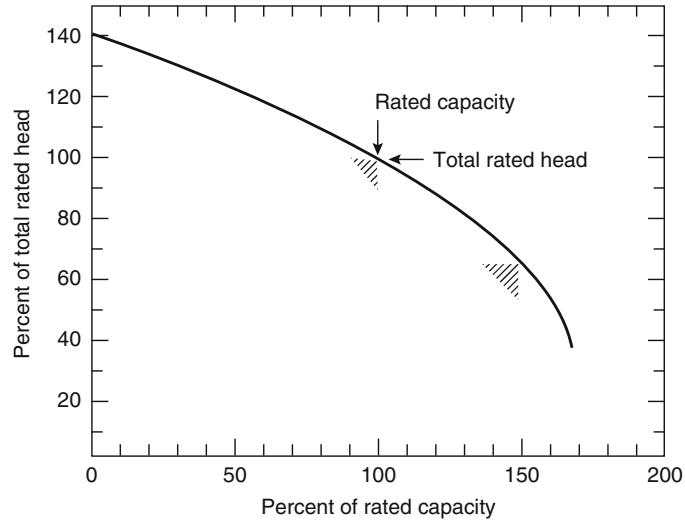

Fig. 42.9 Pump performance curve

known factor, and indeed available pressure is usually quick to drop off beyond this point.

NFPA 20 has traditionally provided guidance on what part of the pump curve to use. A centrifugal fire pump should be selected in the range of operation from 90 % to 150 % of its rated capacity. The performance of the pump when applied at capacities over 140 % of rated capacity may be adversely affected by the suction conditions, but if suction conditions can be properly assured, the pump can operate at any point on its characteristic curve from shutoff to 150 % of its rated capacity.

Application of the pump at capacities less than 90 % of the rated capacity is not recommended.

Where specific pump performance curve is not available, the adequacy of a pump can be determined on the basis of the required performance points. For design capacities below the rated capacity, the rated pressure should be used. For design capacities between 100 % and 150 % of rated capacity, the pressure used should be found by the relationship made apparent by similar triangles.

$$\frac{0.35P}{0.5Q} = \frac{P' - 0.65P}{1.5Q - Q'}$$

where P and Q are the rated pressure and capacity, and P' is the minimum available pressure at capacity, Q', where $Q < Q' < 1.5Q$.

Example 12 A pump is to be selected to meet a demand of 600 gpm (2271 L/min) at 85 psi (5.86 bar). To determine whether a pump rated for 500 gpm (1893 L/min) at 100 psi (6.90 bar) would be able to meet this point without having an actual pump performance curve to work from, the above formula can be applied, with $P = 100$, $Q = 500$, and $Q' = 600$.

Inserting these values gives

$$\frac{(0.35)(100)}{(0.5)(500)} = \frac{\left[P' - (0.65)(100)\right]}{\left[(1.5)(500) - 600\right]}$$

$$\frac{35}{250} = \frac{\left(P' - 65\right)}{(750 - 600)}$$

$$P' = 65 + 21 = 86 \text{ psi } (5.93 \text{ bar})$$

Since the value of P' so calculated is greater than the 85 psi (5.86 bar) required, the pump will be able to meet the demand point.

Tank Sizing

Tank selection and sizing are relatively straightforward compared to fire pump selection. The most basic question is whether to use a standalone elevated storage (gravity) tank, or a pressure tank, or a suction tank in combination with a fire pump. Standards such as NFPA 22 describe the types of tanks in terms of suitable

construction materials, and provide design and installation requirements.

From a calculation standpoint, tanks must be sized to provide the minimum durations specified by NFPA 13 or other applicable standards for the system design. Required pressures must still be available when the tanks are nearly depleted of their water supplies. Durations are based on consideration of the full hydraulic demand (i.e., all sprinklers flowing in the design area). This is a conservative assumption for an automatic sprinkler system, due to the fact that the design area itself is considered to include some conservatism, with the additional understanding that sprinkler operations take place incrementally. Because of this conservatism, it is not necessary that the duration also be provided for a hydraulically less demanding design area, which would be a design area closer to the tank. Minimum durations are generally based on hazard classification, with shorter minimum durations allowed for systems with remote alarm service to a constantly attended location.

If the tank is intended to provide the needed supply without the use of a fire pump, the energy, i.e. pressure for the sprinkler system must be available due to the height of the bottom of a gravity tank or the air pressure held within a pressure tank.

An important factor in gravity tank calculations is the requirement that the pressure available from elevation (calculated using 0.433 psi per foot [0.099 bar/m]) must be determined using the lowest expected level of water in the tank. This is normally the point at which the tank would be considered empty.

In sizing pressure tanks, the percentage of air in the tanks must be controlled so as to ensure that the last remaining quantity of water leaving the tank will be flowing at an adequate pressure. While a common rule of thumb has been that one-third of the tank's volume consist of air at a minimum pressure of 75 psi (5.17 bar), this rule does not hold true for systems with high pressure demands or where the tank is located a considerable distance below the level of the highest sprinkler.

For pipe schedule systems, two formulas have traditionally been used, based on whether the tank is located above the level of the highest sprinkler or some distance below.

For the tank above the highest sprinkler

$$P = \frac{30}{A} - 15$$

For the tank below the highest sprinkler

$$P = \left(\frac{30}{A} - 15\right) + \left(\frac{0.434H}{A}\right)$$

where

A = Proportion of air in the tank
P = Air pressure carried in the tank in psi
H = Height of the highest sprinkler above the tank bottom in ft

It can be seen that these formulas are based simply on the need to provide a minimum pressure of 15 psi (1.03 bar) to the system at the level of the highest sprinkler, and an assumption of 15 psi (1.03 bar) atmospheric pressure.

Using the same approximation for atmospheric pressure, a more generalized formula has come into use for hydraulically designed systems:

$$P_i = \frac{P_f + 15}{A} - 15$$

where

P_i = Tank air pressure to be used
P_f = System pressure required per hydraulic calculations
A = Proportion of air in the tank

Example 13 A pressure tank is to be used to provide a 30 min water supply to a system with a hydraulically calculated demand of 140 gpm (530 L/min) at a pressure of 118 psi (8.14 bar). Due to nearby component pressure ratings, it is important that air pressure in the tank not exceed 175 psi (12.0 bar). To determine the minimum size tank that can be used, it is important not only to consider the total amount of water needed, but also the amount of air necessary to keep the pressures within the stated limits of 118 and 175 psi.

The above equation for hydraulically designed systems can be used to solve for A.

$$P_i = \left[\frac{(P_f + 15)}{A}\right] - 15$$

If

$$A = \frac{(P_f + 15)}{(P_i + 15)}$$
$$A = \frac{(118 + 15)}{(175 + 15)} = \frac{133}{190} = 0.70$$

then

This means that the tank will need to be 70 % air if the air pressure in the tank is to be kept to 175 psi (12.0 bar).

The minimum water supply required is 30 min $\times$ 140 gpm = 4200 gal (15,898 L).

Thus, the minimum tank volume will be such that 4200 gal (15,898 L) can be held in the remaining 30 % of volume.

$$0.3V = 4,200 \text{ gal}$$
$$V = \frac{4,200}{0.3} = 14,000 \text{ gal tank } (53,000\,\text{L})$$

Hanging and Bracing Methods

Hangers and Hanger Supports

Sprinkler design standards such as NFPA 13 contain a great deal of specific guidance relative to hanger spacing and sizing based on pipe sizes. It should be recognized that performance-based approaches are also often permitted. Different criteria can exist for individual hangers and their connection to the supporting building structure. For example, NFPA 13 considers any hanger and installation method is acceptable if certified by a registered professional engineer to meet the following criteria:

1. Hangers are capable of supporting five times the weight of the water-filled pipe plus 250 lb (114 kg) at each point of piping support.
2. Points of support are sufficient to support the sprinkler system.
3. Spacing between hangers does not exceed the limits within the standard for the various types of piping materials.
4. Ferrous materials are used for hanger components.
5. Detailed calculations are submitted when required by the reviewing authority.

The building structure itself must be capable of supporting the weight of the water-filled pipe plus 250 lbs (114 kg) applied at the point of hanging. The 250 lb (114 kg) weight is intended to represent the extra loading that would occur if a relatively heavy individual were to hang on the piping.

Trapeze Hangers

Trapeze hangers are used where structural members are not located, so as to provide direct support of sprinkler lines or mains. This can occur when sprinkler lines or mains run parallel to structural members such as joists or trusses.

Because they are considered part of the support structure, the criteria within NFPA 13 call for the hangers to support the weight of 15 ft (5 m) of water-filled pipe plus 250 lbs (114 kg) applied at the point of hanging. An allowable bending stress of 15 ksi (103 MPa) is used for steel members. Two tables are provided in the standard, one of which presents required section moduli based on the span of the trapeze and the size and type of pipe to be supported, and the other of which presents the available section moduli of standard pipes and angles typically used as trapeze hangers.

In using the tables, the standard allows the effective span of the trapeze hanger to be reduced if the load is not at the midpoint of the span. The equivalent length of trapeze is determined from the formula

$$L = \frac{4ab}{(a + b)}$$

where L is the equivalent length, a is the distance from one support to the load, and b is the distance from the other support to the load.

Example 14 A trapeze hanger is required for a main running parallel to two beams spaced 10 ft (3.048 m) apart. If the main is located 1 ft 6 in. (0.457 m) from one of the beams, the equivalent span of trapeze hanger required can be determined by using the formula

$$L = \frac{4(1.5\,\text{ft})\,(8.5\,\text{ft})}{(1.5\,\text{ft} + 8.5\,\text{ft})} = 5.1\ \ \text{ft}(1.554\,\text{m})$$

Earthquake Braces

Protection for sprinkler systems in earthquake areas is provided in several ways. Flexibility and clearances are added to the system where necessary to avoid the development of stresses that could rupture the piping. Too much flexibility could also be dangerous, however, since the momentum of the unrestrained piping during shaking could result in breakage of the piping under its own weight or on collision with other building components. Therefore, lateral and longitudinal bracing is required for all mains and lateral bracing is required for branch lines exceeding 2 in. (50 mm) in diameter. Smaller branch lines are required to be restrained against movement, which involves a less rigorous means of holding the piping in place.

Calculating loads for earthquake braces is based on the assumption that the normal hangers provided to the system are generally capable of handling vertical forces. However, the upward vertical component of strong horizontal forces must be addressed where braces are insufficiently angled from the horizontal. Traditionally, horizontal forces were conservatively approximated by a constant acceleration equal to one-half that of gravity.

$$a_h = 0.5g$$

Due to advances in earthquake engineering, more specific mapping of expected earthquake accelerations is now available. Current codes call for the design of mechanical building systems to be based on maximum short-period (0.2 s) accelerations expected for the 500 year earthquake. NFPA 13 (2013) contains a seismic coefficient table that allows a simplified method by which these accelerations can be converted to the horizontal seismic load for braces using the formula

$$F_{pw} = C_p W_p$$

where F_{pw} is the force acting on the brace, C_p is the seismic coefficient selected in the table on the basis of short period response, and W_p is 1.15 times the weight of water-filled piping supported by the brace.

Table 42.6 contains some of the NFPA 13 seismic coefficients based on short period accelerations, where the horizontal accelerations S_s are expressed relative to gravity. The seismic coefficients are based on the assumption of fairly soft soil and other conservative assumptions.

Since the braces can be called on to act in both tension and compression, it is necessary not only to size the brace member to handle the expected force applied by the weight of the pipe in its zone of influence, but also to avoid a member that could fail as a long column under buckling.

The ability of the brace to resist buckling is determined through an application of Euler's formula. Tables provide loads based on maximum slenderness ratios of 100, 200, and 300. The 300 value corresponds to the maximum slenderness ratio generally used under steel construction codes for secondary framing members. This is expressed as

Table 42.6 Seismic coefficient table

Ss	*Cp*
0.33 or less	0.35
0.50	0.40
0.75	0.42
0.95	0.50
1.00	0.51
1.25	0.58
1.50	0.70
2.00	0.93
2.40	1.12
3.00	1.40

Source: NFPA 13, Table 9.3.5.9.3 (2013)

$$\frac{\ell}{r} \leq 300$$

where ℓ is the length of the brace and r is the least radius of gyration for the brace.

The least radius of gyration for some common shapes is as follows:
pipe

$$r = \frac{\left(r_0^2 + r_i^2\right)^{1/2}}{2}$$

rod

$$r = \frac{r}{2}$$

flat

$$r = 0.29h$$

Special care must be taken in the design of earthquake braces so that the load applied to any brace does not exceed the capability of the fasteners of that brace to the piping system or the building structure, and that the braces are attached only to structural members capable of supporting the expected loads.

Performance Calculations

Sprinkler Response as a Detector

Automatic sprinklers serve a dual function as both heat detectors and water distribution devices. As such, the response of sprinklers can be estimated using the same methods as for response of heat detectors (see Chap. 40). Care should be taken, however, that these calculations are used within their limitations. Factors pertaining to sprinkler orientation, air flow deflection, radiation effects, heat of fusion of solder links, and convection within glass bulbs are all considered to introduce minor errors into the calculation process. Heat conduction to the sprinkler frame and distance of the sensing mechanism below the ceiling have been demonstrated to be significant factors affecting response, but are ignored in some computer models. Efforts have been made to quantify the prediction capability of the models, including DETACT-QS and the more recent Fire Dynamics Simulator (FDS) [9].

Modeling of sprinkler response can be useful, particularly when used on a comparative basis. Beginning with the 1991 edition, an exception within NFPA 13 permitted variations from the rules on clearance between sprinklers and ceilings "...provided the use of tests or calculations demonstrate comparable sensitivity and performance."

Example 15 Nonmetallic piping extending 15 in. (0.38 m) below the concrete ceiling of a 10-ft (3.048 m) high basement 100 ft by 100 ft (30.48 × 30.48 m) in size makes it difficult to place standard upright sprinklers within the 12 in. (0.30 m) required by NFPA 13 for unobstructed construction. Using the LAVENT [10] computer model, and assuming RTI values of 400 $ft^{1/2} \times s^{1/2}$ (221 $m^{1/2} \times s^{1/2}$) for standard sprinklers and 100 $ft^{1/2} \times s^{1/2}$ (55 $m^{1/2} \times s^{1/2}$) for quick-response sprinklers, it can be demonstrated that the comparable level of sensitivity can be maintained at a distance of 18 in. (0.457 m) below the ceiling. Temperature rating is assumed to be 165 °F, and maximum lateral distance to a sprinkler is 8.2 ft (2.50 m) (10 ft × 13 ft [3.048 m × 3.962 m] spacing). Assuming the default fire (empty wood pallets stored 5 ft [1.52 m] high), for example, the time of actuation for the standard sprinkler is calculated to be 200 s, as compared to 172 s for the quick-response sprinkler. Since the noncombustible construction minimizes concern relative to the fire control performance for the structure, the sprinklers can be located below the piping obstructions.

Dry System Water Delivery Time

Total water delivery time consists of two parts. The first part is the trip time taken for the system air pressure to bleed down to the point where the system dry valve opens to admit water to the piping. The second part is the transit time for

the water to flow through the piping from the dry valve to the open sprinkler. In other words

$$\text{Water delivery time} = \text{Trip time} + \text{Transit time}$$

where water delivery time commences with the opening of the first sprinkler.

Sprinkler standards such as NFPA 13 have traditionally not contained a maximum water delivery time requirement if system volume is limited, generally to no more than 750 gal (2839 L). Larger systems were permitted only if water flow from a remote inspector's test connection took place within 60 s. As such, the rule of thumb for dry system operation is that no more than a 60-s water delivery time should be tolerated, and that systems should be divided into smaller systems if necessary to achieve this 1-min response. Beginning with the 2007 edition of NFPA 13, the 60-s water delivery time was mandated for dry pipe systems protecting dwelling unit portions of any building. Dry system response is simulated in field testing by the opening of an inspector's test connection. The inspector's test connection is required to be at the most remote point of the system from the dry valve, and is required to have an orifice opening of a size simulating the smallest orifice sprinkler installed on the system.

The water delivery time of the system is recorded as part of the dry pipe valve trip test that is conducted using the inspector's test connection. However, it is not a realistic indication of actual water delivery time for two reasons:

1. The first sprinkler to open on the system is likely to be closer to the system dry valve, reducing water transit time.
2. If additional sprinklers open, the trip time will be reduced since additional orifices are able to expel air. Water transit time may also be reduced since it is easier to expel the air ahead of the incoming water.

FM Global researchers have shown [11] that it is possible to calculate system trip time using the relation

$$t = 0.0352 \frac{V_T}{A_n T_0^{1/2}} \ln\left(\frac{p_{a0}}{p_a}\right)$$

where

t = Time (s)
V_T = Dry volume of sprinkler system (ft^3)
T_0 = Air temperature (°R)
A_n = Flow area of open sprinklers (ft^2)
p_{a0} = Initial air pressure (absolute)
p_a = Trip pressure (absolute)

Calculating water transit time is more difficult, but may be accomplished using mathematical models. FM Global researchers developed the first such model in the 1970s. In 2003 a dry system water delivery model was introduced to the commercial marketplace [12], following the incorporation of acceptance criteria into the 2002 edition of NFPA 13. A literature review conducted in 2007, intended to develop data to assist in the evaluation of the traditional 60-s water delivery requirement of NFPA 13, observed that "the water delivery time limit of 60 s has some, but not overwhelming data to support requiring or not requiring a time limitation for small systems" [13].

Droplet Size, Penetration and Motion

For geometrically similar sprinklers, the median droplet diameter in the sprinkler spray has been found to be inversely proportional to the $^1/_3$ power of water pressure and directly proportional to the $^2/_3$ power of sprinkler orifice diameter such that

$$d_m \propto \frac{D^{2/3}}{p^{1/3}} \propto \frac{D^2}{Q^{2/3}}$$

where

d_m = Mean droplet diameter
D = Orifice diameter
P = Pressure
Q = Rate of water flow

The relationship of droplet size production to pressure and orifice diameter has been confirmed using high-magnification shadow imaging [14].

A sprinkler "penetration ratio" has likewise been observed to be proportional to the median droplet diameter, which is needed for fire plume penetration when the sprinkler spray is in the

gravity mode [15]. However, fire plumes can also be penetrated by water sprays using a momentum mode. Fire plume penetration is considered essential to the early suppression of the fire by automatic sprinklers, as compared to fire control, in which the spread of the fire is stopped and the impact mitigated.

Total droplet surface area has been found to be proportional to the total water discharge rate divided by the median droplet diameter

$$A_s \propto \frac{Q}{d_m}$$

where A_s is the total droplet surface area.

Combining these relationships, it can be seen that

$$A_s \propto \left(Q^3 pD^{-2}\right)^{1/3}$$

When a droplet with an initial velocity vector of **U** is driven into a rising fire plume, the one-dimensional representation of its motion has been represented as [16]

$$\frac{m_1 d\mathrm{U}}{dt} = m_1 g - \frac{C_D \rho_g (\mathrm{U} + V)^2}{2S_f}$$

where

U = Velocity of the water droplet
V = Velocity of the fire plume
m = Mass of the droplet
ρ_g = Density of the gas
g = Acceleration of gravity
C_D = Coefficient of drag
S_f = Frontal surface area of the droplet

The first term on the right side of the equation represents the force of gravity, while the second term represents the force of drag caused by gas resistance. The drag coefficient for particle motion has been found empirically to be a function of the Reynolds number (Re) as [17]

$$C_D = 18.5\,\mathrm{Re}^{-0.6} \text{ for } \mathrm{Re} < 600$$
$$C_D = 0.44 \text{ for } \mathrm{Re} > 600$$

Mathematical modeling comparing the drag force of a sprinkler spray to the buoyancy of a smoke layer in the vicinity of sprinklers, validated by full scale experiments, has been used recently to address the long-standing question of the value of automatic smoke vents in sprinklered buildings. The modeling indicated that increases in sprinkler operating pressure eventually lead to ineffective smoke venting, and that the area of smoke venting has very little influence on smoke flow once sprinkler operation causes a loss in smoke flow efficiency [18].

Spray Density and Cooling

The heat absorption rate of a sprinkler spray is expected to depend on the total surface area of the water droplets, A_s, and the temperature of the ceiling gas layer in excess of the droplet temperature, T. With water temperature close to ambient temperature, T can be considered excess gas temperature above ambient.

Chow [19] has developed a model for estimating the evaporation heat loss due to a sprinkler water spray in a smoke layer. Sample calculations indicate that evaporation heat loss is only significant for droplet diameters less than 0.5 mm. For the droplet velocities and smoke layer depths analyzed, it was found that the heat loss to evaporation would be small (10–25 %), compared to the heat loss from convective cooling of the droplets.

FM Global researchers [20] have developed empirical correlations for the heat absorption rate of sprinkler spray in room fires, as well as convective heat loss through the room opening, such that

$$\dot{Q} = \dot{Q}_{\mathrm{cool}} + \dot{Q}_c + \dot{Q}_l$$

where

$\dot{Q}$ = Total heat release rate of the fire
$\dot{Q}_{\mathrm{cool}}$ = Heat absorption rate of the sprinkler spray
$\dot{Q}_c$ = Convective heat loss rate through the room opening
$\dot{Q}_l$ = Sum of the heat loss rate to the walls and ceiling, $\dot{Q}_s$, the heat loss rate to the floor, $\dot{Q}_f$, and the radiative heat loss rate through the opening, $\dot{Q}_r$

Test data indicated that

$$\dot{Q}_{\text{cool}}/\dot{Q} = 0.000039\Lambda^3 - 0.003\Lambda^2 + 0.082\Lambda$$

For

$$0 < \Lambda \leq 33/\left(\text{min} \times \text{kW}^{1/2} \times \text{m}^{5/4}\right)$$

where Λ is a correlation factor incorporating heat losses to the room boundaries and through openings as well as to account for water droplet surface area.

$$\Lambda = \left(AH^{1/2}\dot{Q}_l\right)^{-1/2}\left(W^3PD^{-2}\right)^{1/3}$$

for

$$P = \frac{p}{(17.2\ \text{kPa})} \quad \text{and} \quad D = \frac{d}{0.0111\,\text{m}}$$

where

A = Area of the room opening (m)
H = Height of the room opening (m)
P = Water pressure at the sprinkler (bar)
d = Sprinkler nozzle diameter (m)
W = Water discharge (L/min)

The above correlations apply to room geometry with length-to-width ratio of 1.2–2 and opening size of 1.70–2.97 m^2.

Suppression by Sprinkler Sprays

In 1993, researchers at the National Institute of Standards and Technology (NIST) developed a "zeroth order" model of the effectiveness of sprinklers in reducing the heat release rate of furnishing fires [21]. Based on measurements of wood crib fire suppression with pendant spray sprinklers, the model was described as conservative. The model assumed that all fuels have the same degree of resistance to suppression as a wood crib, despite the fact that tests have shown furnishings with large burning surface areas can be extinguished easily compared to the deep-seated fires encountered with wood cribs.

The recommended equation, which relates to fire suppression for a 610-mm-high crib, has also been checked for validity with 305 mm crib results. The equation is

$$\dot{Q}(t - t_{\text{act}}) = \dot{Q}(t_{\text{act}})\exp\left[\frac{-(t - t_{\text{act}})}{3.0\left(\dot{w}''\right)^{-1.85}}\right]$$

where

$\dot{Q}$ = Heat release rate (kW)
t = Any time following t_{act} of the sprinklers (s)
$\dot{W}''$ = Spray density (mm/s)

The NIST researchers claimed the equation was appropriate for use where the fuel is not shielded from the water spray, and the application density is at least 0.07 mm/s (4.2 mm/min [0.1 gpm/ft^2]). The method does not account for variations in spray densities or suppression capabilities of individual sprinklers.

The model must be used with caution, since it was developed on the basis of fully involved cribs. It does not consider the possibility that the fire could continue to grow in intensity following initial sprinkler discharge, and, for that reason, should be restricted to use in light hazard applications.

Sprinklers are assumed to operate within a room of a light hazard occupancy when the total heat release rate of the fire is 500 kW. The significance of an initial application rate of 0.3 gpm/ft^2 (0.205 mm/s) as compared to the minimum design density of 0.1 gpm/ft^2 (0.07 mm/s) can be evaluated by the expected fire size after 30 s. With the minimum density of 0.07 mm/s (0.1 gpm/ft^2), the fire size is conservatively estimated as 465 kW after 30 s. With the higher density of 0.205 mm/s (0.3 gpm/ft^2), the fire size is expected to be reduced to 293 kW after 30 s. Corresponding values after 60 s are 432 and 172 kW, respectively.

More recent efforts to model suppression by automatic sprinklers have taken place as part of the NIST's development of the Fire Dynamics Simulator (FDS) computational fluid dynamics model. Within that model, simulating the effects of a sprinkler spray involves predicting activation, computing droplet trajectories, and tracking water as it drips onto the burning fuel. In order to compute droplet trajectories, the initial size and velocity of each droplet must be estimated, a process that is one of the limiting factors in the use of the model for practical applications. As stated earlier, efforts have been under way to

develop atomization models for integration with FDS to better characterize the formation and distribution of droplets from the impact of a water stream on a sprinkler deflector [22, 23]. The effect of droplets on burning surfaces is another area in which additional work is needed. When dealing with liquid droplets hitting a solid surface, the current Version 5 of FDS assigns a random horizontal direction and moves at a fixed velocity on the order of 0.5 m/s until it reaches the edge, at which point it is assumed to drop down at the same velocity. While on the surface, the droplet is assumed to contribute to the formation of a surface film of water that participates in heat transfer. If the surface is burning, assumptions need to be made about the extent to which the water reduces the pyrolysis rate of the fuel. Most of the available correlations are based on fires involving rack storage of standard commodities in corrugated cartons. Work at Factory Mutual [24] has led to the following expression:

$$\dot{Q} = \dot{Q}_o e^{k(t-to)}$$

where $\dot{Q}_o$ is the total heat release at the time of water application t_o and k is a fuel-dependent constant, which in turn is dependent on the rate of water application.

Nomenclature

C	coefficient of friction
FLC	friction loss coefficient
Q	flow (gpm)
$\dot{Q}$	heat release rate (kW)
$\dot{W}''$	spray density (mm/s)
C_p	seismic coefficient
K	fuel-dependent constant

Halon Design Calculations

43

Casey C. Grant

Introduction

Fire protection systems using halogenated extinguishing agents provide a classic example of a fire protection technology with a comprehensive evolutionary lifespan. These systems are a relatively recent innovation in fire protection, but, despite this, they already face extinction. As of January 1, 1994, the production of fire protection halons in most countries ceased, based on international treaties.

The phase-out of halon agent production has obviously created significant limitations on the proliferation of this technology. Yet despite this phase-out numerous systems still exist today based on agent reserves. Although global production of fire protection halons essentially ceased on January 1, 1994, this technology continues to linger. Accordingly, a need remains to address the modification and maintenance of existing systems, and new essential systems that will use recycled surplus stock of halon.

The stratospheric ozone layer depletion issue is a problem confronting the global community unlike any other. Late in 1987, the United States and 24 other countries (including the European Economic Community) signed the Montreal Protocol to protect stratospheric ozone [1]. Originally, the protocol restricted the consumption of ozone-depleting chlorofluorocarbons (CFCs) to 50% of the 1986 use levels by 1998, and halon production was to be frozen in 1993 at 1986 production levels. But the November 1992 Copenhagen revision to the Montréal Protocol accelerated this, such that all production of the chemicals ceased worldwide as of January 1, 1994.

The Montreal Protocol is based on unprecedented trade restrictions and is the first time nations of the world have joined forces to address an environmental threat in advance of fully established effects. The trade restrictions concern nations not participating in the agreement (the nonsignatories). Within 1 year of the agreement taking effect, each party shall ban the import of the bulk chemicals from the nonsignatory nations. About 4 years after the effective date of the agreement, imports of products containing the identified chemicals from nonsignatory nations are banned. Within 5 years, products made with the chemicals (but not containing them) are banned or restricted. This is truly significant since many products, including many electronic components, are currently manufactured using some of these chemicals.

Characteristics of Halon

Background, Definition, and Classifications of Halon Compounds

Although there are a variety of methods available for applying halogenated agents, the most common is the total flooding system. The most

popular halogenated agent is Halon 1301, with its superior fire extinguishing characteristics and low toxicity.

Halogenated extinguishing agents are hydrocarbons in which one or more hydrogen atoms have been replaced by atoms from the halogen series: fluorine, chlorine, bromine, or iodine. This substitution confers flame extinguishing properties to many of the resulting compounds that made them ideal for certain fire protection applications.

The halogenated extinguishing agents are currently known simply as halons, and are described by a nomenclature that indicates the chemical composition of the materials without the use of chemical names. This simplified system was proposed by James Malcolm at the U.S. Army Corps of Engineers Laboratory in 1950 and avoids the use of possibly confusing names [2]. The United Kingdom and parts of Europe have been known to use the initial capital "alphabet" system, that is, bromotrifluoromethane (Halon 1301) is BTM and bromochlorodifluoromethane (Halon 1211) is BCF. The number definition for the chemical composition of Halon 1301, perhaps the most widely recognized halogenated extinguishing agent, is 1 (carbon), 3 (fluorine), 0 (chlorine), 1 (bromine), and 0 (iodine).

By definition, the first digit of the number represents the number of carbon atoms in the compound molecule; the second digit, the number of fluorine atoms; the third digit, the number of chlorine atoms; the fourth digit, the number of bromine atoms; and the fifth digit, if any, the number of iodine atoms. Trailing zeros in this system are not expressed. Figure 43.1 graphically demonstrates this concept by illustrating Halon 1301 in comparison to methane.

There are three halogen elements commonly found in halon extinguishing agents used for fire protection: fluorine (F), chlorine (Cl), and bromine (Br). Compounds containing combinations of fluorine, chlorine, and bromine can possess varying degrees of extinguishing effectiveness, chemical and thermal stability, toxicity, and volatility. In general, the relevant properties of these three halogen elements are characterized as shown in Table 43.1.

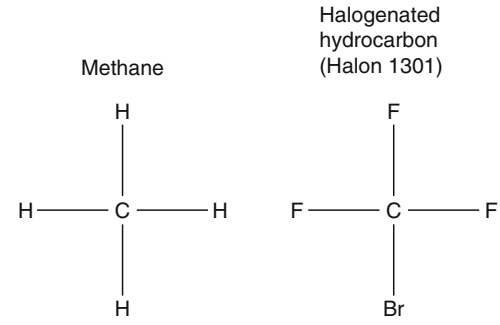

Fig. 43.1 Molecular composition of methane and Halon 1301

Table 43.1 Contributing characteristics of fluorine, chlorine, and bromine

	Fluorine	Chlorine	Bromine
Stability to compound	Enhances	—	—
Toxicity	Reduces	Enhances	Enhances
Boiling point	Reduces	Enhances	Enhances
Thermal stability	Enhances	Reduces	Reduces
Fire extinguishing Effectiveness	—	Enhances	Enhances

Due to the many chemical combinations available, the characteristics of halogenated fire extinguishing agents differ widely. It is generally agreed that the agents most widely used for fire protection applications are Halon 1301, Halon 1211, Halon 1011, and Halon 2402. Also somewhat common is Halon 122, which has been used as a test gas because of its economic advantages. However, because of its widespread use as a test agent, many individuals have wrongly assumed that Halon 122 is an effective fire extinguishing agent. Table 43.2 illustrates the halogenated hydrocarbons most likely to be used today.

History

The earliest halogenated fire extinguishing agent known to be used for industrialized fire protection was carbon tetrachloride (Halon 104) [3]. First becoming available as early as 1907, it was most widely used in handpump portable extinguishers and was popular due to its low electrical conductivity and lack of residue

following application. Also referred to as "pyrene" extinguisher fluid, Halon 104 caused a number of accidental deaths and serious injuries due to its toxicity, and eventually its use was halted during the 1950s.

Methyl bromide (Halon 1001) gained popularity after it was discovered in the late 1920s to be a more effective extinguishing agent than carbon tetrachloride. Due to its high toxicity, it was never used in portable extinguishers even though it was used extensively in British and German aircraft and ships during World War II. Interestingly, methyl bromide possesses a narrow flammability range between 13.5 % and 14.5 % in air, though above and below this range it is an efficient fire extinguishant. Germany developed bromochloromethane (Halon 1011) in the late 1930s to replace methyl bromide, but it failed to enjoy widespread use until after World War II [4].

Table 43.2 Halons commonly used for fire protection

Chemical name	Formula	Halon number
Methyl bromide	CH3Br	1001
Methyl iodide	CH3I	10001
Bromochloromethane	CH2BrCl	1011
Dibromodifluoromethane	CF2Br2	1202
Bromochlorodifluoromethane	CF2BrCl	1211
Dichlorodifluoromethane*	CF2Cl2	122
Bromotrifluoromethane	CF3Br	1301
Carbon tetrachloride	CCl4	104
Dibromotetrafluoroethane	C2F4Br2	2402

*A previously popular test gas without substantial fire extinguishing properties

Thus, prior to World War II, three halogenated fire extinguishing agents were available: Halon 104, Halon 1001, and Halon 1011. Yet because of their inherently high toxic nature, these agents slowly disappeared from typical system applications. By the mid-1960s Halon 104 and Halon 1001 were no longer being used, and Halon 1011 was only in limited use for specialized explosion suppression applications. Figure 43.2 represents a chronology chart that indicates the usage of these early halons as well as the halons more commonly used today.

Joint research was undertaken in 1947 by the U.S. Army Chemical Center and the Purdue Research Foundation to evaluate the fire suppression effectiveness and toxicity of the large number of available agents [2]. After testing more than 60 new agents, 4 were selected for further study: dibromodifluoromethane (Halon 1202), bromochlorodifluoromethane (Halon 1211), bromotrifluoromethane (Halon 1301), and dibromotetrafluoromethane (Halon 2402). Further testing revealed that Halon 1202 was the most effective yet also most toxic, while Halon 1301 was the second most effective and least toxic. As a result of this testing, the use of halon to provide fire protection for modern technology took on new dimensions. Halon 1202 was used by the U.S. Air Force for military aircraft engine protection while the Federal Aviation Administration (FAA) selected Halon 1301 for a similar application in commercial aircraft engine nacelles [5]. Portable extinguishers using Halon 1301 were implemented by the U.S. Army. The use of total flooding systems

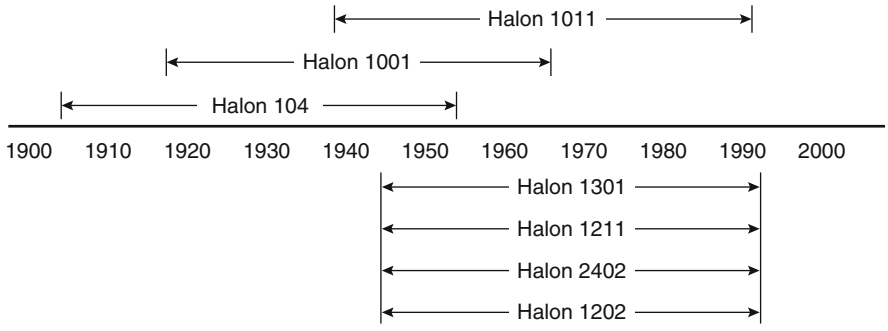

Fig. 43.2 Time span usage of selected halons

originated in 1963, and in the following 5 years several total flooding systems were installed based on carbon dioxide system technology.

In 1966, attention began to focus on the use of Halon 1301 for the protection of electronic data processing equipment. That year, the NFPA organized a Technical Committee (NFPA 12A) to standardize the design, installation, maintenance, and use of halon systems. Their resulting work was officially adopted by the NFPA membership as a standard in 1968 [6]. Subsequent recognition that there were differences among the halon agents made it apparent that separate standards would be necessary. The initial halon standard, NFPA 12A, *Standard for Halon 1301 Fire Extinguishing Systems* (hereinafter referred to as NFPA 12A), focused on the use of Halon 1301 due to its high desirability and growing popularity [7]. Work on an additional standard, NFPA 12B, *Standard on Halon 1211 Fire Extinguishing Systems,* concerning the use of Halon 1211, was started in 1969 and was officially adopted by the NFPA as a standard in 1972 [8]. A tentative standard on the use of Halon 2402 (NFPA 12CT) was developed, but was never officially adopted [9].

Another NFPA committee directly concerned with the use of halon is the NFPA Committee on Electronic Computer/Data Processing Equipment (NFPA 75, *Standard for the Protection of Information Technology Equipment*) [10]. Even though this standard was adopted in 1961, the use of halon was not considered until after 1972, when extensive testing by several major companies demonstrated that the use of Halon 1301 was suitable for protecting electronic computer and data processing equipment [11]. Halon 1301 eventually became the most widely used extinguishing agent for this purpose in the United States and throughout much of the world. However, certain areas of Europe have preferred Halon 1211 and 2402.

In anticipation of the worldwide production phase-out of fire protection halons, which eventually settled at January 1, 1994, a new committee was established during 1992 within the NFPA codes- and standards-making system designated as the Technical Committee on Alternative Protection Options to Halon, and later renamed the Technical Committee on Halon Alternative Protection Options. The committee's first document is NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems,* which addresses the design, installation, maintenance, and operation of total-flooding fire extinguishing systems that use halon replacement agents [12].

Halon 1301

Attributes and Limitations

Of all the halogenated extinguishing agents used in fire protection, Halon 1301 was by a wide margin the most commonly used. The primary use of this agent is for the protection of electrical and electronic equipment, flammable liquids and gases, and surface-burning flammable solids such as thermoplastics. Areas normally or frequently occupied, air and ground vehicle engines, and other areas where rapid extinguishment is important or where damage to equipment or materials or cleanup after use must be minimized were also ideally protected by this agent. However, Halon 1301 was not a panacea, and it is appropriate to recognize its limitations as well as its attributes. The benefits of Halon 1301 are: fast chemical suppression, penetrating vapor, clean (no residue), noncorrosive, compact storage volumes, nonconductive, and colorless (no obscuration). There are also limitations to using Halon 1301: it has minimal extinguishing effectiveness on reactive metals and rapid oxidizers, it may have unfavorable side effects on deep-seated Class A fires, the agent is expensive, and it is potentially harmful to the environment. Obviously, the most significant limitation is the detrimental effect that the halons have on the earth's stratospheric ozone layer.

Because Halon 1301 inhibits the chain reaction of the combustion process, it chemically suppresses the fire very quickly, unlike other extinguishing agents that work by removing the fire's heat or displacing oxygen or air in close proximity to the combustion zone. Stored as a liquid under pressure and released at normal room temperature as a vapor, Halon 1301 gets

into blocked and baffled spaces readily and leaves no corrosive or abrasive residue after use. A high liquid density permits compact storage containers, which on a comparative weight basis, makes Halon 1301 approximately 2.5 times more effective as an extinguishing agent than carbon dioxide. Since it is virtually free of electrical conductivity, Halon 1301 is highly suitable for electrical fires. Halon 1301 is a colorless vapor when discharged into a hazard volume, though it sometimes temporarily clouds the volume due to the chilling of any moisture in the air. But of all its attributes, the most attractive is that of people compatibility; unlike other extinguishing agents, Halon 1301 is essentially nontoxic in the concentrations usually required for fire suppression.

There are several types of flammable materials on which Halon 1301 is ineffective and not recommended. Reactive metals such as potassium, Nak eutectic alloy, magnesium, sodium, titanium, and zirconium burn so intensely that they overpower the agent's extinguishing abilities [5]. Included with these are the metal hydrides such as lithium hydride, and petroleum solvents such as butyl-lithium. Autothermal decomposers and fuels that contain their own oxidizing agent will also burn freely in the presence of halon agents. These latter substances, such as gunpowder, rocket propellants, and cellulose nitrate, have an oxidizer physically too close to the fuel, and the agent cannot penetrate the fire zone fast enough. Halon is also not effective in preventing the combustion or reaction of chemicals capable of autothermal decomposition such as hydrazine or organic peroxides. Even though Halon 1301 is effective with certain surface-burning flammable solids such as thermoplastics, deep-seated Class A fires typically require relatively high agent concentrations for long soaking periods. When exposed to deep-seated fires for long periods of time, Halon 1301 may decompose into toxic and corrosive products of decomposition. Therefore, it is important that the agent be dispersed while the fire is small. The expense necessary to purchase, install, and maintain a properly functioning Halon 1301 system for more specific Class A hazards is often not economically justified. Halon 1301 fire suppression systems are usually not associated with everyday commodities, but instead are found in applications pertaining to highly valued risks.

Properties

Physical Properties

On the average, Halon 1301 requires 10% less agent on a gas-volume basis than does Halon 1211 to extinguish any given fuel [2]. However, both agents are approximately 2.5 times more effective on a weight-of-agent basis than carbon dioxide. Halon 1301 is a gas at 70 F (21 C) with a vapor pressure of 199 psig. Although this pressure would adequately expel the material, it decreases rapidly to 56 psig (4 bar) at 0 F (−18 C) and to 17.2 psig (1.2 bar) at −40 F (−40 C). Therefore, it is necessary to increase the container pressure with dry nitrogen either to 360 or 600 psig (25 or 41 bar) at 70 F (21 C), ensuring adequate performance at all temperatures. Figure 43.3 demonstrates the temperature-pressure profile for Halon 1301 and Halon 1301 superpressurized with dry nitrogen.

Halon 1301 is normally stored in a pressure vessel as a liquid before it is released to occupy the hazard volume as a vapor. With a boiling point of −72 C (−58 C), it is approximately 1.5 times more dense than water in its liquid phase and approximately 5 times heavier than air in its vapor phase. Thus, Halon 1301 vapor will typically escape through openings in the low portions of a totally flooded volume. Other physical properties are shown in Table 43.3.

Traditionally, there were three distinct elements assumed for combustion: heat, fuel, and oxygen. Known as the fire triangle, this theory had to be modified as halons became more widely used and better understood. Typical fire extinguishment involves either removing the fuel from the fire, limiting oxygen to the fire (smothering), or removing the heat (quenching). The halons do not extinguish fire in any of these ways, but instead break up the uninhibited chain reaction of the combustion process. The tetrahedron of the fire, as it is called, is shown in Fig. 43.4.

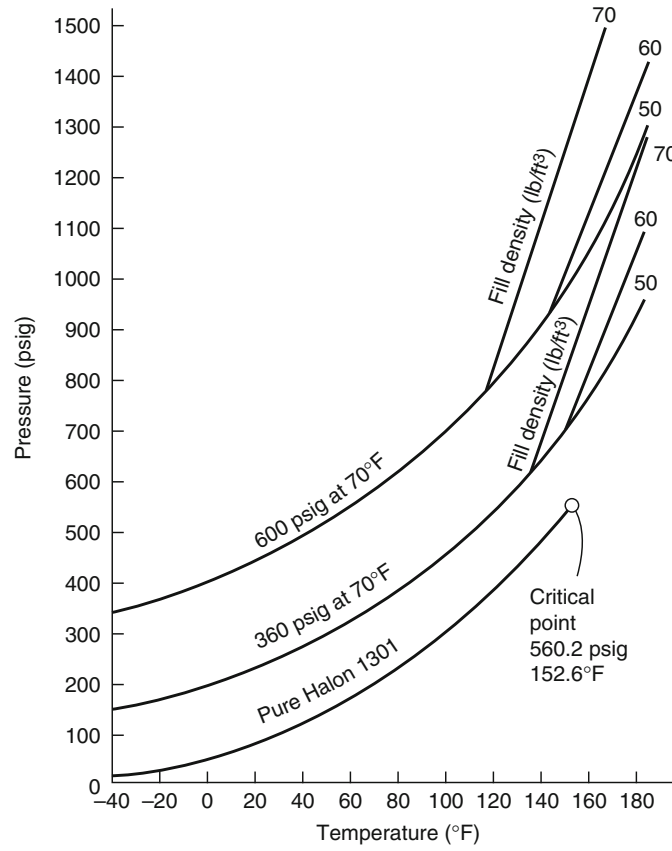

Fig. 43.3 Temperature-pressure relationship for pure Halon

Table 43.3 Selected physical properties of Halon 1301

Boiling point	−72.0 F
Freezing point	−270.4 F
Specific gravity of liquid (@70 F)	1.57
Specific gravity of vapor (@70 F)	5.14
Liquid density @70 F	98.0 lb/ft3
Vapor density @70 F	7.49 lb/ft3 (standard)
Critical temperature	152.6 F
Critical pressure	575 PSIA

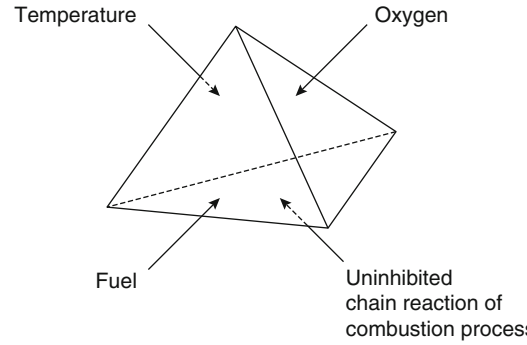

Fig. 43.4 The tetrahedron of fire

The extinguishing mechanism of the halogenated agents is not completely understood, yet there is definitely a chemical reaction that interferes with the combustion process. The halogen atoms act by removing the active chemical species involved in the flame chain reaction. While all the halogens are active in this way, bromine is much more effective than chlorine or fluorine. With Halon 1301 (54% by weight bromine), it is the bromine radical that acts as the inhibitor in extinguishing the fire. Yet the fluorine in the molecule also serves a specific task since it is the fluorine that gives the agent thermal stability and keeps Halon 1301 from decomposing until approximately 900 F (480 C) [13].

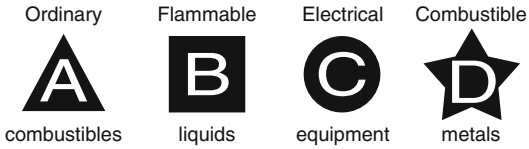

Fig. 43.5 The four classes of fire

Extinguishing Effectiveness

As shown in Fig. 43.5, the four types of fire are ordinary combustibles (Class A), flammable liquids and gases (Class B), electrical (Class C), and reactive metals (Class D) [5].

It was previously mentioned that Halon 1301 is ineffective on Class D fires and is not as desirable as other agents in extinguishing deep-seated Class A fires. The effectiveness of Halon 1301 on Class A fires is not as predictable as with other classes of fire. It depends to a large extent upon the burning material, its configuration, and how early in the combustion cycle the agent is applied. Most plastics behave as flammable liquids and can be extinguished rapidly and completely with 4–6% concentrations of Halon 1301 [14].

Other materials, particularly cellulosic products, can in certain forms develop deep-seated fires in addition to flaming combustion. The flaming portion of such fires can be extinguished with low 4–6% Halon 1301 concentrations, but the glowing deep-seated portion of the fire may continue under some circumstances. Even so, the deep-seated fire can be controlled since its rate of burning and consequent heat release will be reduced. Considerably higher concentrations (18–30%) of Halon 1301 are required to achieve complete extinguishment, but these levels are seldom economical to apply and their application may result in unwanted products of decomposition. However, the concept of controlling deep-seated fires with halogenated agents has been accepted in the respective NFPA standards [14].

It is Class B and Class C fires for which halon is particularly well suited. The most common applications involve Class C electrical hazards, with the increase in popularity of Halon 1301 keeping well in stride with the development of high technology. Typically, electrical and electronic equipment are protected with a concentration of 5% Halon 1301 by volume, though a significantly lower concentration will suitably extinguish a potential fire [15]. The concentrations necessary to extinguish Class B fires have been the subject of much testing with results that vary widely. The effectiveness of halogenated agents on flammable liquid and vapor fires is quite dramatic, especially in total flooding systems. Rapid and complete extinguishment is obtainable with low concentrations of the agent [14]. To be effective, the fire must be contained (such as inside a room or chamber) so that the agent can react with it; Halon 1301 applied to large exterior running pool fires dissipates into the atmosphere without penetrating the flame zone.

Corrosive Effects of Undecomposed Halons

Unlike Halon 1301 and Halon 1211, the early nonfluorinated halogenated agents had significant corrosive problems. Laboratory tests by DuPont in a 44-month exposure period with aluminum, magnesium, steel, stainless steel, titanium, and brass exposed to undecomposed Halon 1301 support the fact that this agent will not corrode these metals, which may all commonly be used in fixed fire extinguishing systems. [13] This is not surprising from a chemical standpoint because the presence of the fluorine atom in a molecule generally reduces its chemical reactivity and corrosive properties and increases its stability.

The presence of free water in systems containing Halon 1301 should be avoided. Free water is defined as the presence of a separate water phase in the liquid halon. When present in a small quantity, free water can provide a site for concentrating acid impurities into a corrosive liquid [16]. Free water should not be confused with dissolved water, which is not a problem in a Halon 1301 system.

Halon 1301 is inert toward most elastometers and plastics. In general, rigid plastics that are normally unaffected include polytetrafluorethylene, nylon, and acetal copolymers. Most of the commonly used plastics undergo little, if any, swelling in the presence of Halon 1301, with the

exception of ethyl cellulose and possibly cellulose acetate/butyrate. Elastomers are particularly suitable when exposed to Halon 1301 for extended periods of time with the notable exception of silicone rubber [13]. Halons decomposed at high temperatures during suppression produce halogen acids such as HF and HBr and free halons that can be corrosive.

Toxicity

General Toxic Properties

The relative safety of Halon 1301 has been established through more than 30 years of medical research involving both humans and test animals. No significant adverse health effects have been reported from the proper use of Halon 1301 as a fire extinguishant since its original introduction into the marketplace [14].

Early studies by the U.S. Army Chemical Center on Halon 1301 determined the approximate lethal concentration for a 15 min exposure to be 83% by volume [2]. Animals exposed to concentrations below lethal levels exhibit two distinct types of toxic effects. Concentrations greater than 10% by volume produce cardiovascular effects such as decreased heart rate, hypotension, and occasional cardiac arrythmias [17]. Concentrations of Halon 1301 greater than 30% by volume result in central nervous system changes including convulsions, tremors, lethargy, and unconsciousness. Effects are considered transitory and disappear after exposure [18].

Human exposure to concentrations of Halon 1301 greater than 10% by volume have shown indications of pronounced dizziness and a reduction in physical and mental dexterity [19]. With concentrations between 7% and 10% by volume, subjects experienced tingling of the extremities and dizziness, indicating mild anesthesia. Exposure to Halon 1301 concentrations less than 7% by volume have little effect, with the exception of a deepening in the tone of voice caused by a higher density in the medium between the vocal chords. The effects at all levels of concentration disappear quickly after removal from the exposure. Testing of Halon 1301 for potential teratogenic (i.e., altering the normal process of fetal development) and mutagenic (a carcinogen in humans) effects has indicated that no serious problems exist. [5]

Table 43.4 Permitted exposure time for Halon 1301

Concentration (percent by volume)	Permitted time of exposure
Normally occupied areas	
0–7 %	15 min
7–10 %	1 min
Above 10 %	Not permitted
Normally unoccupied areas	
0–7 %	15 min
7–10 %	1 min
10–15 %	30 s
Above 15 %	Prevent exposure

Most fire protection applications today have a design concentration of 5% by volume, thus the question of toxicity is usually not a serious concern. Exposure limitations for Halon 1301 (indicated by NFPA 12A) are summarized in Table 43.4 [14].

In addition to possible toxic effects, liquid Halon 1301 (including the spray in the immediate proximity of a discharge) may freeze the skin on contact and cause frostbite. However, direct contact is necessary for this to occur and is unlikely, since with engineered Halon 1301 fire extinguishing systems the discharge nozzles are typically distant from all occupants.

Products of Decomposition

Consideration of the life safety of Halon 1301 must also include the effects of breakdown products which have a relatively higher toxicity than the agent itself. Upon exposure to flames or hot surfaces above approximately 900 F (480 C), Halon 1301 decomposes to form primarily hydrogen bromide (HBr) and hydrogen fluoride (HF) [20]. Trace quantities of bromine (Br2), carbonyl fluoride (COF2), and carbonyl bromide (COBr2) have been observed, but the quantities are generally too small to be of concern. Although small amounts of carbonyl halides (COF2 and COBr2) were reported in early tests, more recent studies have failed to confirm the

Table 43.5 Predominant Halon 1301 decomposition products

Compound	Formula	ALC* for 15 min exposure ppm by volume in air
Hydrogen fluoride	HF	2500
Hydrogen bromide	HBr	4750
Bromine	Br2	550
Carbonyl fluoride	COF2	1500
Carbonyl bromine	COBr2	—

* = acute lethal exposure

Table 43.6 Selected physical properties of typical halogenated fire extinguishing agents

Halon number	Type of agent	Approximate boiling point (°F)	Approximate freezing point (°F)	Specific gravity of liquid (@70 F)
104	Liquid	170	−8	1.59
1001	Liquid	40	−135	1.73
1011	Liquid	151	−124	1.93
1202	Liquid	76	−223	2.28
1211	Liquefied gas	25	−257	1.83
1301	Liquefied gas	−72	−270	1.57
2402	Liquid	117	−167	2.17

presence of these compounds. Table 43.5 summarizes the predominant products of decomposition for Halon 1301 [21].

The primary toxic effect of the decomposition products is irritation. Even in concentrations of only a few parts per million, the decomposition products have characteristically sharp, acrid odors. This characteristic provides a built-in warning system since the irritation becomes severe well in advance of truly hazardous levels. In addition, the odor also serves as a warning that carbon monoxide and other potentially toxic products of combustion may be present. Prompt detection and rapid extinguishment of a fire will produce the safest postextinguishment atmosphere.

Other Halons

Physical Properties

The predominant halogenated agent still in existence today for total flooding fire extinguishing systems is Halon 1301, though some areas of Europe have utilized Halon 1211 for this purpose. One reason for this use of Halon 1301 (besides low toxicity) is the ability of the agent to vaporize and penetrate all portions of the hazard volume. Table 43.6 shows that Halon 1301 has the lowest boiling point and Halon 1211 has the second lowest.

With the discharge of a halon system at ambient temperature, Halon 1301 flashes to a vapor almost instantaneously, while Halon 1211 tends to pool momentarily. Agents with boiling points exceeding the temperature of the hazard volume will stay liquid until heated by the fire itself. These high boiling point halogenated agents have two distinct attributes: they can be projected in a liquid stream and they have a quenching effect in addition to breaking the uninhibited chain reaction. Thus, portable extinguishers generally use Halon 1301 as a propellant for other halon agents.

Toxicity

One of the primary reasons that Halon 1301 is the most preferred of the halogenated agents is its relatively low toxicity, as discussed earlier. Table 43.7 compares the approximate lethal concentration of both the natural and decomposed vapors for a variety of fire extinguishing halon

Table 43.7 Approximate lethal concentrations (ppm) for 15 min exposure to vapors of various fire extinguishing agents

Formula	Halon number	Natural vapor	Decomposed vapor
CCl4	104	28,000	300
CH3Br	1001	5900	9600
CH2ClBr	1011	65,000	4000
CF2Br2	1202	54,000	1850
CF2ClBr	1211	324,000	7650
CF3Br	1301	832,000	14,000
C2F4Br2	2402	126,000	1600
CO2	—	658,000	658,000

Table 43.8 Necessary control measures for computer room fire stage sequence

Fire stage	Control	Serious danger concern
1. Pre-ignition	Good housekeeping practices, control combustible furnishings and interior finish	
2. Initial pyrolysis	Smoke detection system	Occupants and business interruption
3. Incipient	Portable fire extinguishers, Halon 1301 automatic suppression system	Occupants and contents
4. Preflashover	Automatic sprinklers	Occupants and structure
5. Postflashover	Fire walls, compartmentalization	Surrounding structures

agents and carbon dioxide (CO2). For sake of comparison, carbon dioxide is included with this list of halon agents. As a natural vapor, Halon 1301 is the least toxic halogenated agent. Carbon dioxide may appear to compare favorably with Halon 1301, yet high concentrations of carbon dioxide are necessary for fire extinguishment, which also makes the hazard volume lethal to human occupants.

Halon in the Fire Protection Spectrum

Halogenated agent extinguishing systems are only one segment of the total fire protection spectrum. Good engineering judgment is necessary when trying to determine the applicability of halon and whether it should be used instead of, or in addition to, other fire protection measures. It must be clearly understood that halogenated agent extinguishing systems are not the panacea for all fire hazards, yet they do offer a safe method to extinguish certain fires in their very early stages. Thus, these systems have been commonly applied to situations where even the smallest fire is absolutely unthinkable.

As an example, total computer room fire protection might involve several different control measures addressing different possible fire conditions. Table 43.8 illustrates this concept, based on the different stages of a growing fire. The table is not a rigid description of the fire protection requirements of every computer room, but instead an example of how total fire protection is the overall objective when approaching a design situation.

An important factor of developing halogenated agent extinguishing systems is the interaction of all concerned individuals. To design, install, maintain, and operate a halon system requires a cooperative effort from a number of different groups. As shown in Fig. 43.6, these individuals include the end users, consultants, manufacturers, installers, insurance representatives, and other selected authorities. Representatives from all these groups work together to develop and enhance model codes, which provide guidance and understanding for proper halon system usage.

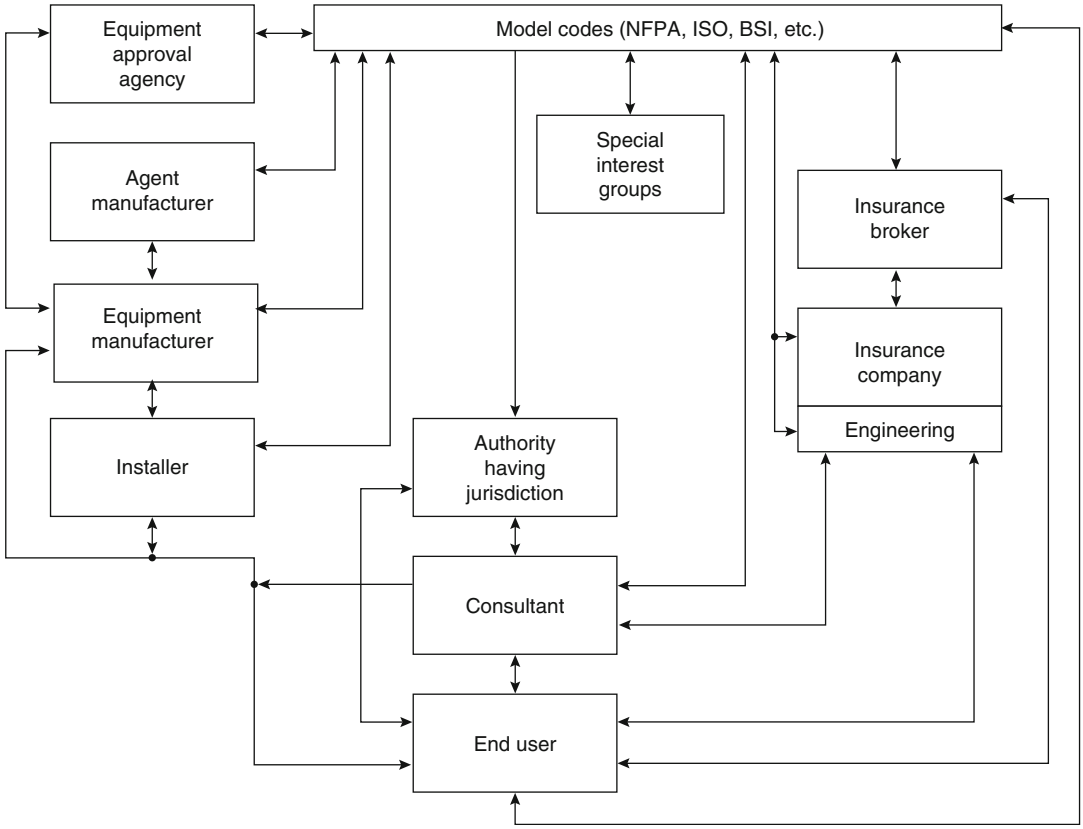

Fig. 43.6 Typical interrelationship of halon fire protection interests

System Configurations

Detection

The three primary parts of every halogenated agent extinguishing system are detection, control panel, and agent delivery. Since there is no single type of detector that offers the ultimate for every application, consideration must be given to the best detection made for the types of combustibles and combustion that are likely to occur in the protected area and the required response time (see the section on design of detection).

Photoelectric and ionization smoke detectors have different response characteristics to fires, depending on the situation, and can be susceptible to certain types of false or unwanted alarms. Thermal detectors, although more reliable, react more slowly to fire conditions. In certain applications, speed is critical and optical detectors would be required.

To optimize the speed and reliability of detection systems, it is important to use two different types of detectors on two separate detection loops within the hazard area. This method is referred to as cross-zone detection. Each detection loop functions independently to provide both added reliability and a comforting degree of redundancy [22].

Control Panels

Features

As its name implies, the control panel is the device that controls system operation and allows the system to function as designed. When a control panel protects more than one area, each individual area is referred to as a zone of

Table 43.9 Typical control unit features

	Halon zone	Fire alarm zone
Initiating circuit	Two cross-zone detection circuits	One circuit for detection
Signaling circuit	Multiple signaling sequence	Multiple signaling sequence
Release circuit	One circuit	None

Table 43.10 Modes of control panel operation

Unpowered condition	Off
Normal condition	On
Alarm condition:	
Prealarm	One detector activates.
Prerelease	Two cross-zoned detectors activate.
	Time delay starts.
Release	Time delay ends or manual pull station activates. Halon is released.
Postrelease	Halon has been released.
Trouble condition	Failure or disruption of field wiring.
	Insufficient power input.

protection. Each zone of every halon control panel has three different types of circuits: initiating, signaling, and release. A fire alarm zone and halon zone are compared in Table 43.9 to illustrate the differences between these circuit types. It is unusual for a single halon control panel to protect more than five zones at once due to the high number of circuits required. Fire alarm control panels, on the other hand, may have dozens of individual zones.

Initiating circuits provide the input into the panel and support automatic detectors, manual pull stations, and other initiating devices. Automatic detectors are normally cross-zoned, which implies two separate detection circuits. One circuit is required for prealarm and both circuits are necessary for halon release. The signaling circuits, sometimes referred to as bell or auxiliary circuits, are used for audible/visual alarms and other auxiliary functions. The release circuits allow the halon to release from the containers and are sometimes referred to as firing, solenoid, initiator, dump, or halon circuits.

Modes of Operation

At any time, a halon control panel and the halon system could be in one of four modes of operation; as shown in Table 43.10 these include unpowered, normal, alarm, and trouble condition. The alarm condition is further definable with prealarm, prerelease, release, and postrelease conditions. Typical systems utilizing cross-zoning detection activate, when required, into prealarm and/or release condition, but this often becomes more complicated with time delays, abort switches, and other auxiliary functions. Unless otherwise specified, manual pull stations activate all alarm conditions, override abort switches, if present, and immediately release the halon. These different alarm conditions provide a convenient mechanism for sequential operation of audible/visual signaling, equipment shutdown, fire service notification, and other auxiliary functions.

Control Panel Economics

Large-scale projects with multiple halon zones in a single facility are not uncommon. For example, in the past entire data processing centers and telecommunications buildings were protected throughout with Halon 1301 systems. To protect a large building with many halon zones, it may appear that the most effective way of configuring the system is by using a single large control panel with the capacity for all required halon zones. This is not true, since there is a limitation to the number of halon zones that any one halon panel can effectively manage. Figure 43.7 illustrates an

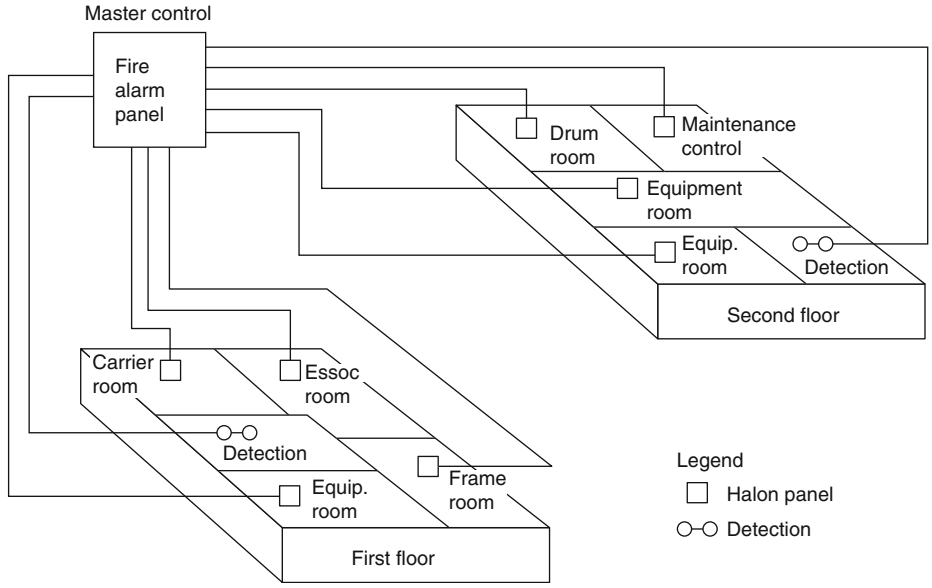

Fig. 43.7 The network concept of control panel interface for a typical halon application

alternative method, where the individual halon zones of a large building each have their own halon panel wired to give an alarm or trouble signal to a central fire alarm panel.

A typical halon zone required an average of 12 wires to support all the necessary system functions. Thus, the cost of running multiple wires and large conduit instead of only two wires (for interpanel communication) often offsets the cost of smaller, more numerous panels located near the halon zones. This configuration offers flexibility for future consolidations or additions, which are common for high-technology facilities. Aesthetics are enhanced at the master control location, and system operation is simplified. Installation checkout and servicing is easier when the halon control panel is within the hazard area. Finally, the overall system is more reliable due to less wiring, lack of design complexity, simplified maintenance, and multi-source dependence.

Agent Delivery

In addition to the control panel and detection, the other primary part of every halogenated agent extinguishing system is agent delivery. The agent delivery includes the discharge nozzles, agent storage container(s), release mechanism, and associated piping. As shown in Table 43.11, three methods of agent delivery exist: (1) central storage, (2) modular, and (3) shared supply. Central storage has the container(s) centrally located, with the agent piped accordingly. This method is popular due to its similarity with carbon dioxide system technology (which helped develop early systems), along with usually having the lowest initial cost. Modular systems use smaller containers strategically located throughout the hazard area, with minimal piping. The high reliability of modular systems is based on lack of dependency on piping integrity, negligible piping calculations, total system supervision, multi-source dependence, and the inherent ability to be heat actuated regardless of catastrophic system failure. Modular systems are simple to design, are relatively easy to install, and have a high degree of future flexibility. Systems utilizing shared supply are essentially central storage systems with a container(s) shared by more than one hazard volume. Even though fewer containers are used, directional valves and extensive piping do not often allow shared

Table 43.11 Comparison of different methods of agent delivery

	Central storage	Modular	Shared supply
Hardware cost	Moderate	High	Moderate
Installation cost	Moderate	Low	Moderate
Design simplicity	Difficult	Simple	Difficult
Installation simplicity	Difficult	Medium	Difficult
Operation and maintenance simplicity	Medium	Medium	Medium
Reliability	Moderate	High	Low
Future flexibility	Low	High	Low

supply systems to be cost effective. Adding to its unpopularity are its design and installation complexity, low reliability, and impaired future flexibility. When a shared supply halon system activates for one hazard, the remaining hazards become unprotected until the system is completely recharged.

Design Concepts and Methodology

Definitions and Terminology

Halogenated agent extinguishing systems are typically classified as either total flooding or local application systems. A total flooding system is designed to develop and maintain a concentration of halon that will extinguish fires in combustible materials located in an enclosed space. Local application systems are designed to apply the agent directly to a fire that may occur in an area or space that is not immediately enclosed. In addition to these, there are specialized applications, which may include combination total flooding/local application or partial flooding. The vast majority of existing halon systems today are the total flooding type using Halon 1301.

The definitions of halon system and halon zone are often confusing. This is especially true to individuals closely associated with the fire alarm industry, since fire alarm terminology is similar. Figure 43.8 defines the basic features of a halon system and halon zone and offers a comparison with each respective fire alarm counterpart.

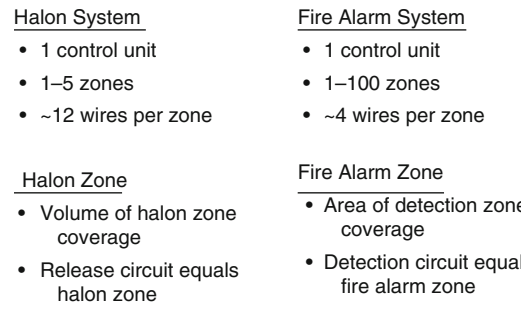

Fig. 43.8 Halon/fire alarm differences

A halon zone usually equates to an area of halon coverage functioning on a single release circuit, while the zones in a fire alarm system typically are each detection circuit. As an example, one halon zone could be a single computer room, whereas a fire alarm zone could be the entire floor of a building. A halon system also has much fewer (though more comprehensive) zones than a fire alarm system.

Halon Design Guidelines

The design process necessary for total flooding systems is easily quantified. The procedure can be separated into five definable steps: (1) hazard identification, (2) determination of agent quantity, (3) specification of operating requirements, (4) determination of hardware requirements, and (5) generation of postdesign information.

The initial step is to provide a definition of the hazard. This includes determining the fuels involved, the dimensions and configuration of the enclosure, the maximum and minimum net volumes, the status of occupancy, the expected

hazard area temperature range, and possible unclosable openings. Based on this information, the minimum design concentration can be established. Next, the agent quantity is determined based upon the design concentration, the volume, minimum expected temperature, leakage due to ventilation or unclosable openings, and altitude above sea level. Usually, the gross volume is used to calculate the agent quantity to allow for extra agent to replace that lost through normal building leakage. However, agent concentrations must conform with the applicable toxicity criteria with respect to the minimum net volume and maximum temperature. The operating specifications are then required if they have not already been established. These will indicate how the system is to operate, the modes of operation, the type of agent delivery, and so forth. When these are known, the necessary hardware requirements must be obtained and the design of the system completed. The final step is to generate the postdesign information necessary for others to install, test, operate, and maintain the system. Postdesign information should contain all design calculations (including hydraulic calculations), complete blueprint drawings, and detailed information describing the testing, operation, and maintenance of the system.

Local Application and Special Systems

Local application systems were typically installed to extinguish fires involving flammable liquids, gases, and surface burning solids. Such systems are designed to apply the agent directly to a fire that may occur in an area or space not immediately enclosed. They must be designed to deliver halon agent to the hazard being protected in such a manner that the agent will cover all burning surfaces during discharge of the system. Because of its lower volatility, Halon 1211 may be better suited than other forms of halon for local application systems. The lower volatility, plus a high liquid density, permits the agent to be sprayed as a liquid and thus propelled into the fire zone to a greater extent than is possible with other vaporized agents. Examples of areas protected by local application are spray booths, dip and quench tanks, oil-filled electric transformers, printing presses, heavy construction equipment, and vapor vents. An example of a local application system is shown in Fig. 43.9.

Traditionally, NFPA standards have not set a minimum limit on the discharge time for a local application design. The rate of discharge and the amount of agent required for a given application must be determined by experimentation and evaluation. The most critical components of these systems are the discharge nozzles; the discharge velocity and rate must be sufficient to penetrate the flames and produce extinguishment but not be so great as to cause splashing or spreading of fuel and thus increase the fire hazard. The minimum design discharge quantity should not be less than 1.5 times the minimum quantity required for extinguishment at any selected design rate [21]. Also of critical importance are type and location of detectors.

As with other types of gaseous suppression systems, local application systems have been designed according to the rate-by-volume

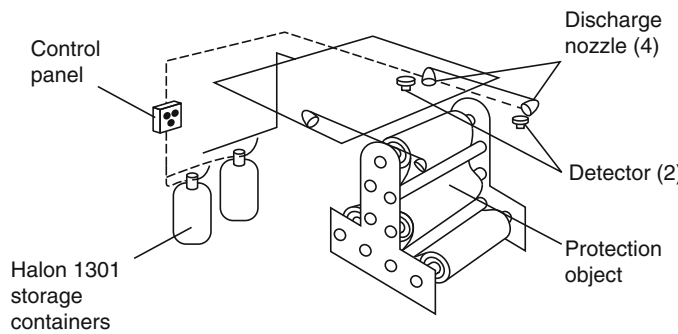

Fig. 43.9 Local application system

method or the rate-by-area method. The rate-by-area method determines nozzle discharge rates based on the exposed surface area of the hazard being protected. This method is less popular than the rate-by-volume method, which requires discharge rates sufficient to fill (within the discharge time) a volume whose imaginary boundaries extend a limited distance from the protected hazard. This method is favored since it performs similarly to total flooding systems. Important factors to be considered in the design of a local application system are the rate of agent flow, the distance and area limitations of the nozzles, the quantity of agent required, the agent distribution system, and the placement of detectors.

Unlike total flooding systems, only the liquid portion of the discharge is effective for local application systems. The computed quantity of agent needed for local application must be increased to compensate for the residual vapor in the storage container at the end of liquid flow. An additional 25% storage capacity is required in the absence of an enclosure that would prevent gas dissipation. Systems should also compensate for any agent vaporized in the pipe lines due to heat absorption from the piping. The heat transfer is important when the piping is at a higher temperature than the agent. The following equation determines the amount of agent increase necessary to compensate for this effect: [14]

$$W_x = \frac{2\pi kL\left(T_p - T_a\right)(t)}{3600h(\ln r_o/r_i)} \qquad (43.1)$$

where

Wx = Amount of agent increase, kg (lb)
k = Thermal conductivity of the piping, W/m · K (Btu · t/h · ft2 · F)
L = Linear length of the piping, m (ft)
Tp = Pipe temperature, C (°F)
Ta = Agent temperature, C (°F)
t = System discharge time
h = Heat of vaporization of the agent at Ta, kJ/kg (Btu/lb)
ro = Outside pipe radius, mm (in.)
ri = Inside pipe radius, mm (in.)

Specialized systems using a variety of agents are in wide use throughout the world to protect hazards such as aircraft engine nacelles, military vehicles, emergency generator motors, earth moving equipment, and racing cars. The characteristic common to all these systems is that they can only be applied to the specific hazard for which they were designed and tested. One unusual concept used to protect aircraft flight simulator areas is known as partial flooding, where only the volume containing the simulator equipment receives the total flooding concentration, and not the expansive open areas above it. A design concentration of 7% is recommended to achieve a 5% concentration in the hazard area and should provide for a minimum agent height level relative to the agent concentration of approximately 1.5 m (5 ft) above the highest part of the hazard. The placement of the nozzle is critical and should be designed to direct agent discharge approximately 30° below the horizontal plane. As shown in Fig. 43.10, the savings associated with partial flooding systems can be substantial, especially in areas with very high ceilings [20].

Agent Requirements: Total Flooding

Design Concentrations: Solid Fuels

Flammable solids may be classified as those that do not develop deep-seated fires and those that do. Class A combustible solids that develop deep-seated fires do so after exposure to flaming combustion for a certain length of time, which varies with the material. Some materials may begin as deep seated through internal heating such as spontaneous ignition. With respect to Halon 1301 total flooding systems, a fire is considered deep seated if a 5% concentration will not extinguish the fire within 10 min after agent discharge [14]. Materials that do not become deep seated undergo surface combustion only and may be treated much the same as those in a flammable liquid fire.

The presence of Halon 1301 in the vicinity of a deep-seated fire will extinguish the flame and reduce the rate of burning, yet the quantity of agent required for complete extinguishment of

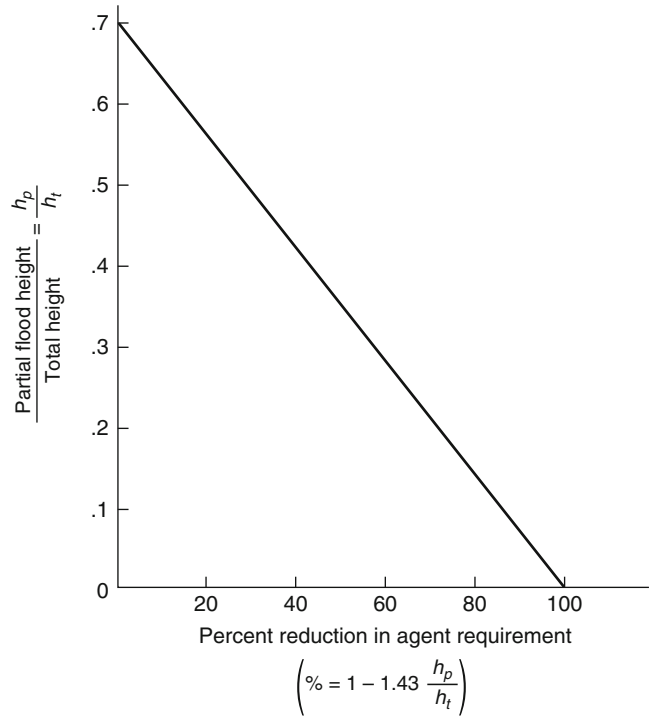

Fig. 43.10 Agent reduction associated with partial flooding systems

all embers is difficult to assess. Often it is impractical to maintain an adequate concentration of Halon 1301 for a sufficient time to ensure the complete extinguishment of a deep-seated fire. Factors affecting this concentration include:

1. Nature of fuel
2. Time during which it has been burning
3. Availability of oxygen within the enclosure
4. Ratio of burning surface area to the volume of the enclosure
5. Geometric characteristics of the fuel
6. Fuel distribution within the enclosure

Table 43.12 illustrates the extinguishing concentrations of selected flammable solid fires as indicated by six different halon industry groups [23].

Even where the fire has inadvertently become deep seated, application of a low Halon 1301 concentration has two benefits. First, all flaming combustion is halted, preventing rapid spread of the fire to adjacent fuels. Second, the rate of combustion is drastically reduced. These two characteristics justify the ability of Halon 1301 to control, if not extinguish, deep-seated fires. However, Halon 1301 systems that are specifically designed to extinguish deep-seated fires are seldom economical to apply and may not be as effective in these fires as other types of extinguishing systems.

Design Concentrations: Liquid and Gas Fires

There are two general types of flammable liquid or gas fires. First, a flammable or explosive mixture of vapors exists that must be prevented from burning; and second, fuel is burning that must be extinguished. Associated with each of these conditions is a minimum level of Halon 1301 extinguishing concentration, respectively known as inerting and flame extinguishment. When determining the halon design concentration, proper consideration must be given to the quantity and type of fuel involved, the conditions under which it normally exists in the hazard, and any special conditions of the hazard itself. If certain hazards have explosion potential either before or following a fire due to the presence of volatile, gaseous, or atomized fuel, then special

Table 43.12 Extinguishing concentrations of selected flammable solid fires

consideration should be given to vapor detection and explosion suppression measures.

As its name implies, the flame extinguishment concentration assumes that the given fuel is burning and that Halon 1301 injected into the air surrounding the fuel at the stated concentration will extinguish the fire [14]. Design concentrations for flame extinguishment are given in Table 43.13. These concentrations are not considered effective with premixed flames or explosive mixtures of fuel vapor in air, but instead apply to diffusion flames, where the flames emanate from pure fuel vapor, and oxygen suffuses into the flame zone from the outside. If the possibility of a subsequent reflash or explosion exists, then the flame extinguishing concentration is not sufficient. NFPA 12A [14] defines these conditions as "when both:

1. The quantity of fuel permitted in the enclosure is sufficient to develop a concentration equal to or greater than one-half of the lower flammable limit throughout the enclosure, and
2. The volatility of the fuel before the fire is sufficient to reach the lower flammable limit in air (maximum ambient temperature or fuel temperature exceeds the closed cup flash point temperature) or the system response is not rapid enough to detect and extinguish the fire before the volatility of the fuel is increased to a dangerous level as a result of the fire."

Most fuels exhibit about a 30–40% higher concentration for inerting than for flame extinguishment. The minimum inerting concentration suppresses the propagation of the flame front at the "flammability peak" or stoichiometric fuel/air composition and inerts the enclosure so that any fuel/air mixture will not burn. The higher inerting concentration is often considered safer to use even if the flame extinguishment concentration is feasible, yet the sacrifices include

Table 43.13 Design concentration for flame extinguishment

Fuel	Minimum design concentration (percent by volume)
Acetone	5.0
Benzene	5.0
Ethanol	5.0
Ethylene	8.2
Methane	5.0
n-Heptane	5.0
Propane	5.2

Table 43.14 Halon 1301 design concentrations for inerting

Fuel	Minimum concentration (percent by volume)
Acetone	7.6
Benzene	5.0
Ethanol	11.1
Ethylene	13.2
Hydrogen	31.4
Methane	7.7
n-Heptane	6.9
Propane	6.7

Note: Includes a safety factor of 10% added to experimental values

higher system cost and higher concentrations to which personnel may be exposed (Table 43.14).

It is possible to calculate whether the flame extinguishing concentration is acceptable by determining if the fuel present in the hazard will permit attainment of the one-half lower flammable limit of the fuel. The equation to determine the maximum allowable fuel loading (MFL) for flame extinguishment concentrations is

$$\mathrm{MFL} = \frac{(K_c)(LFL)(\mathrm{MW})}{T} \qquad (43.2)$$

where

MFL = Maximum allowable fuel loading, kg/m3 (lb/ft3)

Kc = Conversion factor, 0.06093 (0.00685)

LFL = Lower flammable limit of fuel in air, percent volume

MW = Molecular weight of fuel

T = Temperature, K (R)

This can be compared with the actual fuel loading (FL), which is calculated by

$$\mathrm{FL} = \frac{(VF)(W_{h_2O})(SG)}{V} \qquad (43.3)$$

where

FL = Fuel loading, kg/m^3 (lb/ft^3)

VF = Volumetric quantity of fuel, m^3 (ft^3)

W_{h_2C} = Specific weight of water, 997.9 kg/m^3 (62.3 lb/ft^3)

SG = Specific gravity of fuel

V = Volume of enclosure, m^3 (ft^3)

If the fuel loading, FL, exceeds the maximum allowable fuel loading, MFL, then the inerting concentration for the particular fuel should be used. Most applications involve a variety of fuels within a single enclosure. If the sum of the actual fuel loadings, FL, is greater than any single maximum allowable fuel loading, MFL, then the most stringent inerting concentration is recommended. If it is determined that a flame extinguishment concentration is sufficient, the value for the fuel requiring the greatest concentration is most applicable.

Calculation of Agent Quantity

The calculations necessary for determining the Halon 1301 total flooding quantity are dependent on temperature, volume of the enclosure, agent concentration, altitude with respect to sea level, and losses due to ventilation and leakage. Most applications are based on a static volume enclosure with all openings sealed and all ventilation systems shut down prior to discharge. This simplifies the calculation significantly. Often the ventilation system does not shut down but instead is dampered to allow recirculating air (without makeup air) to continue cooling sensitive electronic equipment and promote the mixing of halon and air. Total flooding quantities are still based on a static volume for these applications. However, in this instance, it may be necessary to include the volume of the ventilation ductwork in addition to the volume of the

Table 43.15 Correction factors for altitudes

Altitude		
Feet	Meters	Correction factor
3000	914	0.90
4000	1219	0.86
5000	1524	0.83
6000	1829	0.80
7000	2134	0.77
8000	2438	0.74
9000	2743	0.71
10,000	3048	0.69
11,000	3353	0.66
12,000	3658	0.64
13,000	3962	0.61
14,000	4267	0.59
15,000	4572	0.56

enclosure. The equation to determine the Halon 1301 total flooding quantity is

$$W = \frac{(V)(C)(A_c)}{S(100 - C)} \tag{43.4}$$

where

W = Weight of Halon 1301 required, kg (lb)
C = Halon 1301 concentration, percent by volume
Ac = Altitude correction factor (Table 43.15)
S = Specific vapor volume based on temperature, m3/kg (ft3/lb)
$S = 0.14781 + 0.000567\ T$; T = temperature C
$S = 2.2062 + 0.005046\ T$; T = temperature F

Application Rate

Discharge Time and Soaking Period

When designing a Halon 1301 total flooding system, it is important to determine the system discharge time and soaking period.

As indicated in NFPA 12A, "the agent shall be completed in a nominal 10 s or as otherwise required by the authority having jurisdiction." [14] The reasons for a rapid discharge time include keeping unwanted products of decomposition to a minimum and achieving complete dispersal of agent throughout the enclosure. Sometimes a much faster application rate is required due to the possibility of a fast spreading fire; yet, discharge times longer than 10 s are sometimes necessary for areas such as museums requiring that turbulence be kept to a minimum, or areas with unavoidably difficult piping configurations.

The soaking time is another important requirement for a Halon 1301 total flooding system. This is especially true for deep-seated fire or fires that may reflash. The most common application today for total flooding systems is the protection of valuable electronic equipment. Fires in these applications are almost always extinguished within a few seconds by the Halon 1301 agent, yet a 10-min soaking period is usually required. This estimated time period allows responsible individuals to arrive at the scene to take follow-up action. It is important to remember that halogenated agent extinguishing systems in most cases have only a single chance to control an unwanted fire.

Effects of Ventilation

When Halon 1301 is discharged into a total flooding enclosure that is ventilated, some agent will be lost with the ventilating air. Assuming that ventilation must continue during and after discharge, a greater amount of agent is required to develop a given concentration. Also, to maintain the concentration at a given level requires continuous agent discharge for the duration of the soaking period. If an enclosure initially contains pure air, the Halon 1301 discharge rate required to develop a given concentration for agent at any given time after the start of discharge is [14]

$$R = \frac{(C)(E)}{(S)(100 - C)[1 - e^{(-Et_1/V)}]} \tag{43.5}$$

where

R = Halon 1301 discharge rate, kg/s (lb/s)
E = Ventilation rate, m3/s (ft3/s)
$t1$ = Discharge time, s
e = Natural logarithm base, 2.71828

The Halon 1301 discharge rate necessary to maintain a given concentration of agent is [14]

$$R = \frac{(C)(E)}{(S)(100 - C)} \tag{43.6}$$

After the agent discharge is stopped, the decay of the agent concentration with respect to time is [14]

$$C = C_0 e^{(-Et_2/V)} \tag{43.7}$$

where

C_0 = Agent concentration at end of discharge, percent volume

t_2 = Time after stopping discharge, s

Compensation for Leakage

Occasionally a Halon 1301 total flooding system is designed for an enclosure that has openings that cannot be closed. An example may be a conveyor belt penetrating an enclosure wall, yet even these openings can sometimes be closed using inflatable seals. Halon 1301 discharged into an enclosure for total flooding will result in an air/agent mixture that has a higher specific gravity than the air surrounding the enclosure. Therefore, any openings in the lower portions of the enclosure will allow the heavier air/agent mixture to flow out and the lighter outside air to flow in. Fresh air entering the enclosure will collect toward the top, forming an interface between the air/agent mixture and fresh air. As the leakage proceeds, the interface will descend toward the bottom of the enclosure. The space above the interface will be completely unprotected, whereas the lower space will essentially contain the original extinguishing concentration. There are two methods of compensating for unclosable openings: initial overdose and extended discharge.

The initial overdose method provides for an adequate overdose of Halon 1301 to ensure a pre-established minimum of agent at the end of the desired soaking period. Mechanical mixing is required within the enclosure to prevent stratification of agent concentration and a descending interface. Also, caution must be used to prevent personnel exposure to the high initial concentrations. The necessary initial concentration depends upon the extended protection time required, the opening height, the opening width, and the volume of the enclosure. Referring to Fig. 43.11, the equation used to determine the initial concentration for a final concentration of 5% is [14]

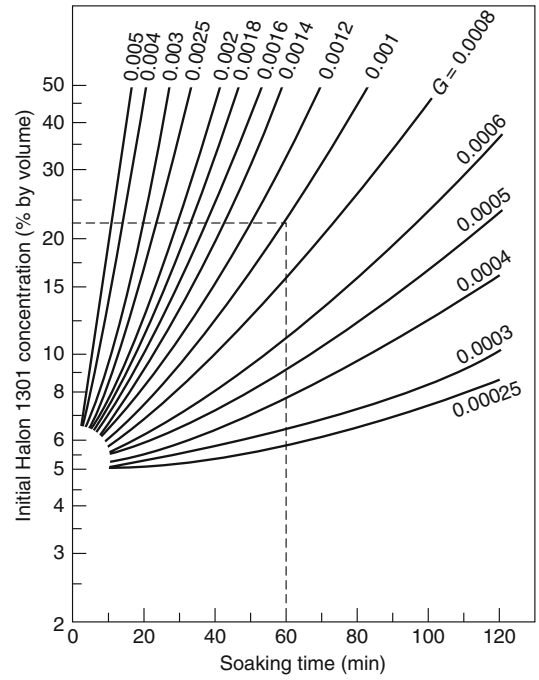

Fig. 43.11 Initial amount of Halon 1301 to produce a 5% residual concentration in enclosures equipped for mechanical mixing

$$\mathrm{G} = \frac{(K)(W_o)\left(2g_c H^3\right)^{1/2}}{3V} \tag{43.8}$$

where

G = Geometric constant

K = Orifice discharge coefficient, 0.66

W_o = Opening width, m (ft)

g_c = Acceleration due to gravity, 9.81 m/s^2 (32.2 ft/s^2)

H = Opening height, m (ft)

The other method used to compensate for unclosable openings is extended discharge. This involves at least two separate piping systems: one to achieve the initial agent concentration, and the other to provide a continuous addition

of Halon 1301 at a rate which will compensate for leakage out of the enclosure during the soaking period. The agent must be discharged in such a way that uniform mixing of agent and air is obtained. This mixing is often difficult due to the extremely low flow rates being discharged over the entire soaking period, occasionally resulting in small nozzles freezing due to air moisture. Based on the design concentration and opening height, Fig. 43.12 can be used to determine the Halon 1301 makeup rate per unit opening width.

Assuming the design concentration of Halon 1301 is established in the enclosure initially, the time required for the interface to reach halfway down the enclosure height can be calculated. Referring to Fig. 43.13, the geometric constant previously calculated for initial overdose is used to find the soaking time based on the initial design concentration.

Flow Calculations

Piping Theory

The overall objective of designing a Halon 1301 piping system is to properly disperse the required concentration of Halon 1301 throughout the hazard volume within the specified time period. Systems must be engineered to operate quickly and effectively. The discharge time (usually a nominal 10 s as indicated by NFPA 12A) is a critical system constraint and is measured as the interval between the first appearance of liquid at the nozzle and the time when the discharge becomes predominantly gaseous [14]. The hydraulic calculations are considered to be the most difficult part of the entire design process, and are almost always calculated with the aid of computer programs due to the tedious nature of manual calculations.

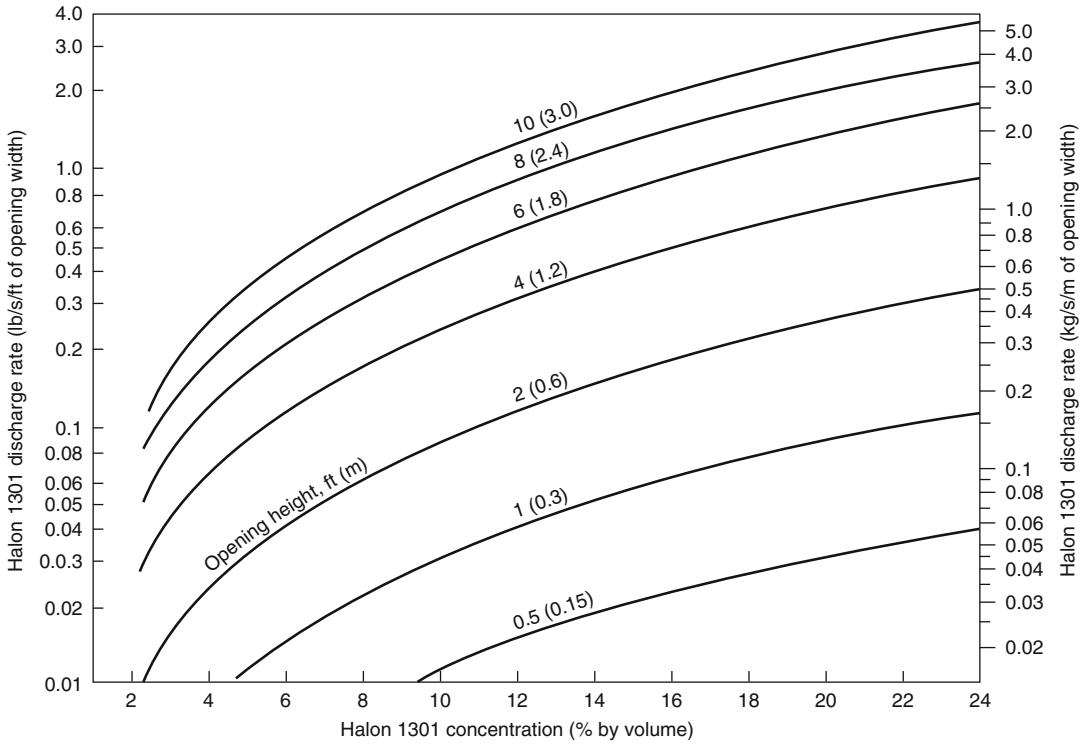

Fig. 43.12 Extended discharge rate of Halon 1301 to maintain constant concentrations in enclosures with openings

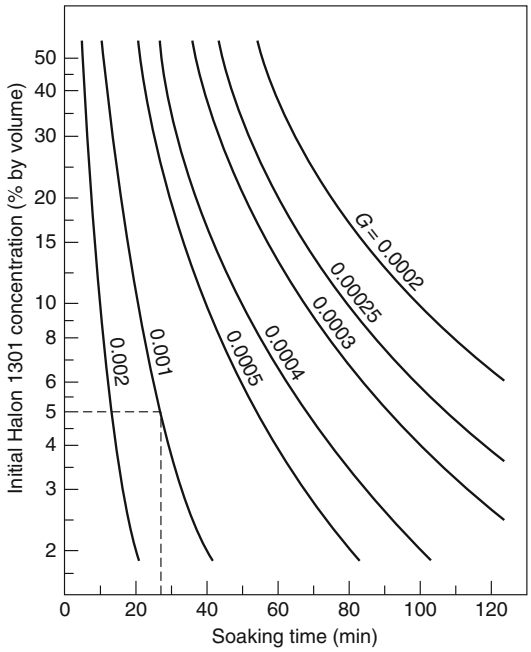

Fig. 43.13 Time required for interface between effluxing Halon 1301/air mixtures and influxing air to descend to center of enclosures not equipped for mixing

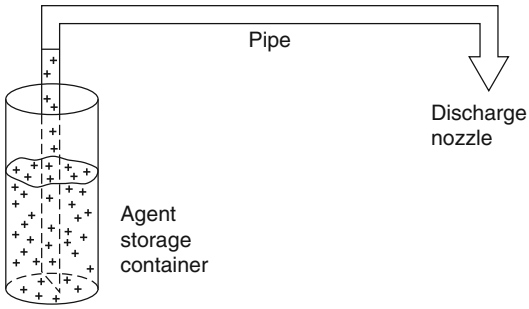

Fig. 43.14 Primary components of a Halon 1301 piping system

As illustrated in Fig. 43.14, the primary components of a Halon 1301 piping system are the agent storage container, the discharge nozzle, and the pipe. Often, more than one nozzle is required, complicating the calculations significantly. An attempt should always be made to keep the piping system simple and if possible, balanced. A balanced system has the actual and equivalent pipe lengths from container to each nozzle within ±10% of each other and has equal design flow rates at each nozzle [14].

As with sprinkler systems or other systems involving fluid flow, the methodology for solving Halon 1301 piping calculations involves seeking terminal characteristics based on property changes encountered due to the movement of the fluid. The system hydraulics are controlled by the selection of the orifice area at the discharge nozzle. This orifice area is calculated from the nozzle pressure, which is based on the starting pressure in the container and pressure losses in the pipe. Because the flow of Halon 1301 is nonsteady and has a change in phase from liquid to vapor, the calculations become highly complex. To simplify calculations, the average discharge conditions are determined so that they might reasonably represent the entire discharge time span. This time-independent model is based on the moment in time when half the liquid phase of the agent has left the nozzle. All the calculations for a 10 s discharge condition shown in Fig. 43.15 would be solved at the mid-discharge condition (5 s). Hence, the critical characteristics that vary with discharge, such as the storage container pressure and the pressure-density relationship in the pipeline, are replaced with average time-independent values [24].

By the time half of the liquid agent is out of the nozzle, the original pressure in the storage container has dropped considerably. To calculate the mid-discharge storage container pressure, the percent of agent still within the pipe must be determined. Also, the initial drop in pressure immediately after the start of discharge is nonlinear. As seen in Fig. 43.16, the pressure recovery is due to the nitrogen vigorously boiling out of the halon/nitrogen mixture within the storage container.

Unlike water-based fluid flow, the pressure drop occurring when Halon 1301 flows through a pipe is nonlinear and is dependent on the pipeline agent density, not the distance traveled. The pipeline flow is two phase, with a mixture of liquid and vapor agent. As the agent travels in the pipe, the pressure and density decrease, which increases the velocity and the amount of halon vapor. Interestingly, the evolution of the nitrogen from the halon/nitrogen mixture in the storage container causes the halon to drop in

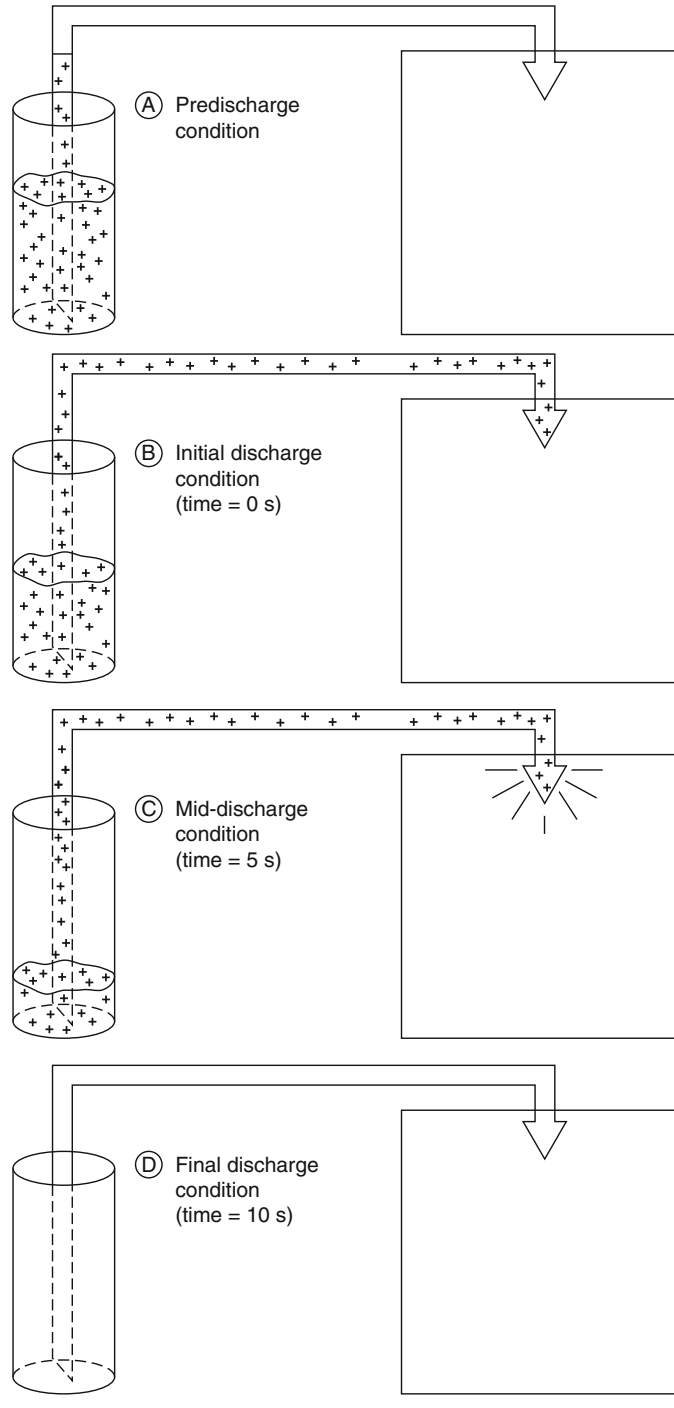

Fig. 43.15 Summary of Halon 1301 discharge conditions based on a 10 s discharge

temperature and become more dense. This phenomenon fortunately is not a factor in the calculations since a time-independent model is being used. The increase in density at any one location over the entire time span should not be confused with the decrease in density that occurs when the agent flows from one location to another.

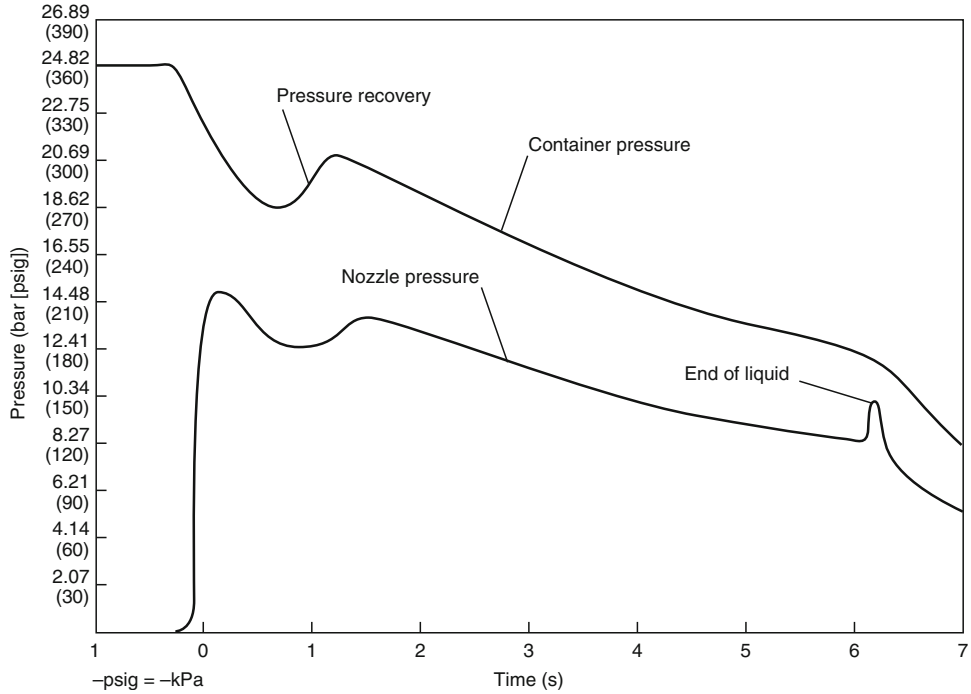

Fig. 43.16 Pressure profile during system discharge

Guidelines and Limitations

Unrealistic distribution networks often fail to perform to specifications and are difficult if not impossible to predict from a calculation standpoint. As the piping system becomes more unrealistic, the calculations become more unreliable. To aid in the development of accurate calculations, certain fundamental limitations are necessary to ensure proper system design. These limitations are especially important with respect to computer programs since these programs have a tendency to be operated abusively with high expectations. Summarized below are the design constraints for Halon 1301 hydraulic calculations [25].

1. Good design practice
2. Discharge time $\leq$10 s
3. Favorable system temperature
4. Initial container pressure = 2482.2 kPa (360 psig) or 4137.0 kPa (600 psig)
5. Initial container fill density $\leq$1121.4 kg/m3 (70 lb/ft3)
6. Percent in pipe $\leq$ maximum value
7. Turbulent flow $\geq$ minimum value
8. Nozzle pressure $\geq$ minimum value
9. Actual nozzle area $\leq$ percentage of feed pipe area
10. Actual nozzle area = calculated nozzle $\pm$5%

Good design practice includes such items as favoring balanced systems, keeping the degree of flow/split imbalance below a maximum value, avoiding vertically installed tees, and avoiding nozzles on different floor levels which may separate the halon gas/vapor mixture. The values for some of the constraints are determined by the individuals developing computer programs that are verified by approval agencies through testing.

Calculation Procedure

The piping calculations comprise four steps:

1. Determining the necessary input data
2. Calculating the average storage container pressure

3. Calculating the nozzle pressure at each nozzle
4. Calculating the nozzle orifice areas

Pipeline calculations are performed for each segment of pipe having both a constant flow rate and a uniform pipe diameter; thus the piping network is divided into sections called *junctions*. Each discharge nozzle is also identified. The forms necessary for the input data, pressure calculations, and nozzle calculations are contained in Figs. 43.17 and 43.18. Assuming the appropriate input data are known, the average storage container pressure is determined from Fig. 43.19 based on the percent agent in pipe, which itself is determined by [14]

$$\%\,\text{in pipe} = \frac{K_1}{(W_i/V_p) + K_2} \tag{43.9}$$

where

W_i = Initial charge weight of Halon 1301, lb
V_p = Internal pipe volume, ft^3 (Table 43.16)
K_1 and K_2 = Constants (Table 43.17)

Once the average storage container pressure is known, Figs. 43.18 and 43.20 and Equations 43.10 through 43.22 can be used to determine the nozzle orifice areas for a 360 psig system. Usually the calculations are based on a 10 s discharge time, though this is sometimes changed

slightly to produce flow rates in accordance with Table 43.18. Turbulent pipeline flow can also be achieved by using smaller pipe sizes. Pipe diameters that are too small result in unacceptably high pressure losses; therefore, care must be used in pipe size selection. It is important to recognize that approximations have been made for Y and Z factors and nozzle coefficients. The calculation procedure presented here is only intended to demonstrate the current methodology and not to provide a rigorous solution. The necessary equations are [14, 26]

Postdesign Considerations

Postdesign considerations are divided into two categories: system documentation and inspection/acceptance practices. Good halon system design is not complete until full documentation is provided for installation, acceptance, and eventual end user operation. Proper documentation is especially important to prevent the inadvertent discharge of a halon system for other than a fire, since replacement of the halon agent could be very difficult with future availability being dependent on recycled stock.

System Documentation

System documentation should include the items listed below. This material is necessary for others to install, test, operate, and maintain the system. Information can be recorded entirely on system drawings or in both a written manual and system drawings.

System Manual

1. Design Data
   (a) Functional and operational description
   (b) Halon 1301 weight calculations
   (c) Hydraulic piping calculations
   (d) Special considerations
2. Installation, Maintenance, and Inspection Instructions

As-Built System Drawings

1. Floor Plan Layout
   (a) Suitable dimensions
   (b) Equipment locations
   (c) Special installation details
2. Electrical Schematic
3. Equipment Identification
4. Special Notes

Inspection and Acceptance

After installation, each system should be inspected and tested by technicians trained by the equipment manufacturer covering the items listed below:

1. Test system wiring for proper connection, continuity, and resistance to ground.
2. Check system control unit in accordance with factory recommended procedures.
3. Calibrate and test each detector in accordance with factory recommended procedures.
4. Test each releasing circuit for proper resistance by means of a current-limiting meter.
5. Test the operation of all ancillary devices such as alarms, dampers, magnetic closers, and so on.
6. Obtain a certificate of inspection signed and dated by the installing contractor and the authority having jurisdiction.

An installation checklist is often used, which expands on the above items in complete detail [27]. These checklists are available from agent

and equipment manufacturers, installers, insurance groups, and consultants.

When accepting a newly installed halon system, it is important to determine compliance with design specifications. In previous years, a full discharge test was required to provide unquestionable evidence of performance, yet this could be a costly and sometimes unnecessary burden carried by the end user. End users with multiple systems would often prove system acceptance based on the performance characteristics of their other systems.

The primary reason for discharge test failure, when it was performed, was because the hazard enclosure would not hold the design concentration over the entire soaking period [28]. Checking the enclosure for possible halon leakage points has always been difficult and is the only questionable part of the acceptance/inspection procedure. A method referred to as the enclosure integrity test has proved to be very effective for this problem, and validates the integrity of the protected enclosure [14]. This technique shows much promise and has potential for substantially enhancing the reliability of proper system operation.

The most effective use of fan pressurization techniques for these types of applications is for leakage path indication [29]. This involves pressurizing or depressurizing the enclosure with the fan pressurization apparatus and using an indicating device, such as a smoke pencil or acoustic sensor, to determine leakage paths. The installers' visual inspection of the enclosure now becomes very effective since even the smallest cracks can be located. Due to low cost and simplicity, a smoke source is usually the most desirable method for locating leaks, but an excellent alternative is the use of a directional acoustic sensor that can be selectively aimed at different sound sources [30]. Highly sensitive acoustic sensors are available that can detect air as it flows through an opening and are sensitive enough to clearly hear a human eye blink [31]. Openings can also be effectively detected by placing an acoustic source on the other side of the barrier and searching for acoustic transmission. Another method is to use an infrared scanning device if temperature differences across the boundary are sufficient [32]. These techniques are not quantitative, but they are effective, inexpensive, and easily performed.

Environmental Considerations

Scientific evidence indicates that fire protection Halon 1301 is one of several man-made substances adversely affecting the earth's ozone layer [33]. Ozone exists naturally as a thin layer of gas in the stratosphere that blocks the sun's harmful ultraviolet rays and thus is vital to life on earth. Several adverse environmental and direct health effects are linked to ozone layer depletion, and its preservation is of paramount concern to mankind. It's believed that Halon 1301 (and other chlorofluorocarbons) chemically destroy ozone when emitted into the atmosphere.

Earlier, the phase-out of full system discharge tests that were used to verify enclosure integrity received special attention since they accounted for a proportionately large percentage of fire protection halon emissions. Fortunately, the amount of fire protection Halon 1301 released for actual fires is relatively small. Testing a system by performing a full discharge test allows the release of Halon 1301, which on a cumulative basis may be potentially harmful to the environment and depletes relatively precious stocks of halon agent that should be dedicated to suppressing fires. The release of Halon 1301 should be minimized.

With regard to ozone layer depletion, halons used for fire protection are different than halons used for other industrial applications [34]. Fire protection halons are unique because of their essential mission to prevent the loss of life, minimize the loss of irreplaceable property, assure the continuity of vital operations, and reduce the amount of fire by-products polluting the atmosphere. Efforts have been made to minimize the release of fire protection halons for noncritical tasks such as training, testing, and research. It is assumed that existing halon systems will remain in existence for an undetermined time into the

future, despite the present worldwide restriction on their production.

Nomenclature

a	constant (see Table 43.19)
A	pipe size factor
Ac	altitude correction factor (see Table 43.15)
b	constant (see Table 43.19)
B	pipe size factor
c	constant (see Table 43.19)
C	Halon 1301 concentration, percent by volume
*C*0	agent concentration at end of discharge, percent by volume
d	constant (see Table 43.19)
D	actual pipe diameter, in.
e	natural logarithm base, 2.71828
E	ventilation rate, m3/s (ft/s)
f	nozzle coefficient (approximately 0.7)
F	nozzle orifice area, in [2].
FL	fuel loading, kg/m3 (1b/ft3)
gc	acceleration due to gravity, 9.81 m/s2 (32.2 ft/s2)
G	geometric constant
h	heat of vaporization of the agent at *Ta,* kJ/kg (Btu/lb)
H	opening height, m (ft)
k	thermal conductivity of the piping, W/m · K (Btu · t/h · ft2 · f)
K	orifice discharge coefficient, 0.66
K*c*	conversion factor, 0.06093 (0.00685)
L	linear length of piping, m (ft)
Le	pipe elevation length, ft
LFL	lower flammable limit of fuel in air, percent volume
MFL	maximum allowable fuel loading, kg/m3 (lb/ft3)
MW	molecular weight of fuel
P	pressure, psig
*P*0	junction starting pressure, psig
Pe	elevation pressure, psig
PT	temporary pressure, psig
Q	flow rate, lb/s
r	agent density, lb/ft3
R	Halon 1301 discharge rate, kg/s (lb/s)
ri	inside pipe radius, mm (in.)
ro	outside pipe radius, mm (in.)
S	specific vapor volume of Halon 1301 based on temperature, m3/kg (ft3/lb)
SG	specific gravity of fuel
t	system discharge time
T	temperature, K (R)
*t*1	discharge time, s
*t*2	time after stopping discharge, s
Ta	agent temperature, C (F)
Tp	pipe temperature, C (F)
V	enclosure volume, m3 (ft3)
VF	volumetric quantity of fuel, m3 (ft3)
Vp	internal pipe volume, ft3 (see Table 43.16)
Wx	amount of agent increase, kg (lb)
W_{h_2O}	specific weight of water, 997.9 kg/m3 (62.3 lb/ft3)
W	weight of Halon 1301 required, kg (lb)
Wo	opening width, m (ft)
Wi	initial charge weight of Halon 1301, lb
*Y*1	first *Y* factor
*Y*2	second *Y* factor
YT	temporary *Y* factor
Z	factor

Clean Agent Total Flooding Fire Extinguishing Systems

44

Philip J. DiNenno and Eric W. Forssell

Introduction

Total flooding clean agents and systems were developed in response to the regulation of Halon 1301 under the Montreal Protocol and its amendments, which culminated in the phase-out of production of halons in the developed countries on December 31, 1993. This regulation engendered tremendous research and development efforts across the world in a search for replacements and alternatives. Since that time, on the order of 15 total flooding clean agent alternatives to Halon 1301 have been commercialized and development continues on others. In addition to clean total flooding gaseous alternatives, new technologies, such as water mist and fine solid particulate, are being introduced. This chapter focuses on total flooding clean agent halon replacements.

Table 44.1 is a summary of common halocarbon and inert gas extinguishing agents developed to date. The most widely used commercialized total flooding agents include HFC-227ea, HFC-125, FK-5-1-12 and all of the inert gases. Perfluorocarbons (PFC) and Hydrochlorofluorocarbons (HCFC) agents are essentially no longer used due to environmental regulations. The best performing replacement agent in terms of effectiveness per unit mass is the Trifluoroiodide but concerns regarding toxicity precluded that agent from widespread commercialization and adoption. The table gives the chemical name; trade name; American Society of Heating, Refrigerating, and Air Conditioning Engineers, Inc. (ASHRAE) designation (for halocarbons); and the chemical formula.

Characteristics of Clean Agents

Clean fire suppression agents are generally defined as electrically nonconducting fire extinguishants that vaporize readily and leave no residue [1]. They are subject to specific evaluation with regard to their hazards to personnel and their effect on the environment. Depending upon the agent, they are stored under high pressure as a liquid or a gas, and are utilized in their gaseous state when released from their storage containers. Clean agent halon replacements fall into two broad categories: (1) halocarbon compounds and (2) inert gases and mixtures.

Halocarbon clean agents include compounds containing carbon, hydrogen, bromine, chlorine, fluorine, and iodine. They are grouped into five categories: (1) hydrobromofluorocarbons (HBFC), (2) hydrofluorocarbons (HFC), (3) hydrochlorofluorocarbons (HCFC), (4) perfluorocarbons (FC or PFC), and (5) fluoroiodocarbons (FIC) and Fluoroketones (FK). The recent introduction of Fluoroketones has enabled the use of halocarbon agents with near zero global warming potential in normally occupied areas.

Table 44.1 Commercialized halon replacement nomenclature

Chemical name	Trade name	ASHRAE designation	Chemical formula
Heptafluoropropane	FM-200	HFC-227ea	CF_3CHFCF_3
Trifluoromethane	FE-13	HFC-23	CHF_3
Chlorotetrafluoroethane	FE-24	HCFC-124	$CHClFCF_3$
Pentafluoroethane	FE-25	HFC-125	CHF_2CF_3
Dodecaflouro-2-methylpentan-3-one	Novec 12330	FK-5-1-12mmy2	$CF_3CF_2C(O)(CF(CF_3))_2$
Hexaflouropropane	FE-36	HFC-236fa	$CF_3CH_2CF_3$
Triflouroiodide	Triodide	FIC-13I1	CF_3I
$N_2/Ar/CO_2$	Inergen	IG-541	N_2 (52 %)
			Ar (40 %)
			CO_2 (8 %)
N_2/Ar	Argonite	IG-55	N_2 (50 %)
			Ar (50 %)
Argon	Argon	IG-01	Ar (100 %)
Nitrogen	Nitrogen	IG–100	N_2

Although the characteristics of halocarbon clean agents vary widely, they share several of the following common attributes:

1. All are electrically nonconductive,
2. All are clean agents; that is, they vaporize readily and leave no residue,
3. All are liquefied gases or display analogous behavior (e.g., compressible liquid),
4. All can be stored and discharged from typical Halon 1301 hardware (with the possible exception of HFC-23, which more closely resembles 600 psig [40 bar] superpressurized halon systems),
5. All (except HFC-23) use nitrogen superpressurization in most applications for discharge purposes,
6. All are less efficient fire extinguishants than Halon 1301 in terms of storage volume and agent weight. The use of most of these agents requires increased storage capacity.
7. All are total flooding gases after discharge. Many require additional care relative to nozzle design and mixing,
8. All produce more decomposition products (primary HF) than Halon 1301, given similar fire type, fire size, and discharge time,
9. All halocarbon agents except FK-5-1-12mmy2 and FIC-13I1 have substantial greenhouse warming characteristics; FK-5-1-12mmy2, a Fluoroketone, has a near zero global warming potential,
10. All of the halocarbon agents have a near zero ozone depletion potential, (ODP) and,
11. All halocarbon agents must be evaluated with respect to health and safety concerns, which are primarily related to cardiac sensitization, as discussed later in this chapter.

Inert gas clean agents include nitrogen and argon and blends of these. One inert gas replacement has a small fraction of carbon dioxide. Carbon dioxide is not an inert gas because it is physiologically active and toxic at low concentrations. However, the approximately 8 % of carbon dioxide used as a component of IG-541 is not considered to pose a safety concern in terms of toxicity. Inert gas clean agents share the following common attributes:

1. All are electrically nonconductive.
2. All are clean agents; that is they leave no residue.
3. All are stored as compressed gases utilizing low capacity high pressure cylinders,
4. All are less efficient fire extinguishants than Halon 1301 in terms of storage volume and agent weight. Storage volumes are much greater than Halon 1301 or the halocarbon clean agents due to the need for high pressure cylinders,

Table 44.2 Comparisons of systems in 500–5000 m^3 range of volumes [2]

	Percentage additional weight when compared to a Halon 1301 system						
	Halon 1301	CO_2	FE-13	FM-200	Novec 1230	Inergen	Water mist
Weight comparison							
500 m^3	0	150	200	50	50	400	625
1000 m^3	0	163	188	38	50	450	613
3000 m^3	0	200	219	48	71	529	671
5000 m^3	0	186	211	36	58	497	522
Footprint comparison							
500 m^3	0	84	105	20	20	327	1119
1000 m^3	0	82	94	20	20	365	889
3000 m^3	0	118	122	19	43	459	1030
5000 m^3	0	99	107	6	19	404	636
Percentage cost comparison							
500 m^3	0	108	315	202	259	277	1032
1000 m^3	0	140	406	267	368	330	723
3000 m^3	0	200	553	351	513	449	478
5000 m^3	0	204	585	361	515	460	376

5. Inert gases do not produce more decomposition products,
6. Inert gas agents have zero global warming potentials,
7. All of the halocarbon agents have a zero ozone depletion potentials, and,
8. All inert gas agents must be evaluated with respect to health and safety concerns, which are primarily related to oxygen depletion, as discussed later in this chapter.

Wickham [2] has provided comparative values for cost and footprint of potential halon, replacement systems for use in marine applications. These comparisons are given for weight, footprint, and cost in Table 44.2. Note that all clean agents require at least 50 % more agent by weight than halon as a consequence of the elimination of bromine in the compounds and subsequent level of catalytic recombination of flame radicals. These data should be taken as representative values, as there are variations among hardware manufacturers. The storage volume equivalent does not translate directly to a required area or volume for storage cylinders. The relative footprint of these storage volume equivalents will vary with the volume of the space protected and the maximum storage cylinder size offered by a manufacturer for a particular gas.

Extinguishing Mechanisms

Halocarbon clean agents extinguish fires by a combination of chemical and physical mechanisms depending on the compound. Chemical suppression mechanisms of HBFC and FIC compounds are similar to Halon 1301; that is, the Br and I species scavenge flame radicals, thereby interrupting the chemical chain reaction. FIC-13I1 is the only HBFC or FIC compound listed in Table 44.1. Other replacement compounds suppress fires primarily by extracting heat from the flame reaction zone, thereby reducing the flame temperature below that which is necessary to maintain sufficiently high reaction rates by a combination of heat of vaporization, heat capacity, and the energy absorbed by the decomposition of the agent. Oxygen depletion also plays a role in reducing flame temperature.

The energy absorbed in decomposing the agent by breaking fluorine and chlorine bonds is quite important, particularly with respect to decomposition production formation. There is undoubtedly some degree of "chemical" suppression action in flame radical combustion with halogens, but it is considered to be of minor importance since it is not catalytic (e.g., one F radical combines with one H flame radical).

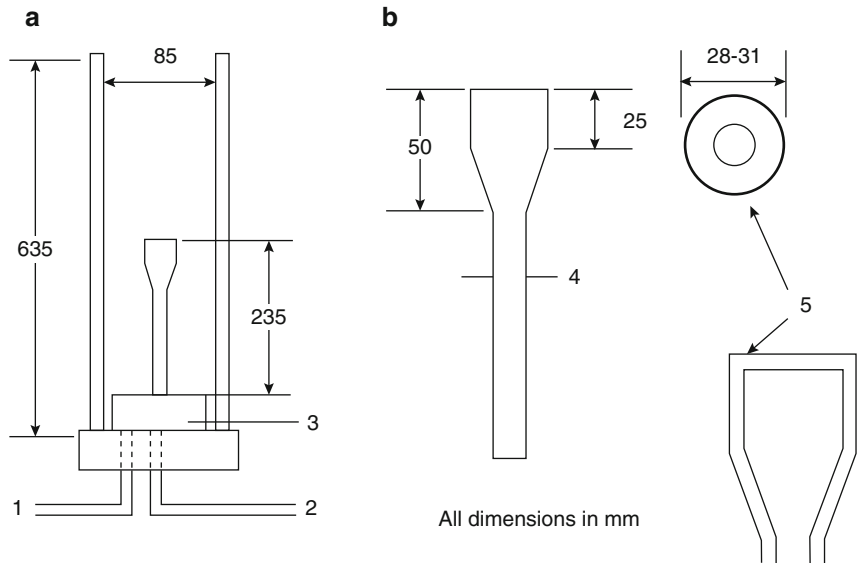

Fig. 44.1 Schematic of cup burner apparatus [3]

The lack of significant chemical reaction inhibition in the flame zone by HCFC, HFC, and FC compounds results in higher extinguishing concentrations relative to Halon 1301. The relative importance of the energy sink represented by breaking halogen species bonds results in higher levels of agent decomposition relative to Halon 1301.

Inert gas clean agents act by reducing the flame temperature below thresholds necessary to maintain combustion reactions. This condition is created by reducing the oxygen concentration and by raising the heat capacity of the atmosphere supporting the flame. The addition of a sufficient quantity of inert gas to reduce the oxygen concentration below 12 % (in air) will extinguish flaming fires. The agent concentration required is also a function of the heat capacity of the inert gas added. Hence, there are differences in minimum extinguishing concentration between inert gases.

Flammable Gas and Liquid Extinguishing Concentration

Flame suppression effectiveness of total flooding clean agents has been evaluated in a number of ways. The predominant small-scale test method for establishing flame extinguishing concentrations for liquid and gaseous fuels is the cup burner or variations thereof.

Figure 44.1 is a schematic of the cup burner apparatus as specified in ISO 14520 [3]. A small laminar flame is established above a "cup" of fuel surrounded by a cylindrical chimney. An air-agent mixture flows up the chimney surrounding the flame. The minimum concentration of agent (in air) at which the flame is extinguished is the minimum extinguishing concentration (MEC). There are many variations of the basic device as used by different laboratories. These variations include cup and chimney diameter, different mixing and measuring methods, chimney height, and agent-air mixture velocity past the flame [3]. Since about 2005, cup burner devices and test procedures have been standardized to the point where very little variation is seen between devices and laboratories. Users are cautioned that older data may not have been obtained using the standardized apparatus and procedures. The current n-heptane cup burner extinguishing values using the more recent standardized device are given Table 44.3. In addition, the validity and utility of the cup burner test apparatus has been verified in part by a theoretical model of the flame extinction process [4].

The cup burner concentration for IG-541 is 31 % as given in Table 44.3. This result is in contrast to concentrations of 32, 41, and 23 % by volume measured by the National Institute of Standards and Technology (NIST) for nitrogen, argon, and carbon dioxide, the components of Inergen. NIST has conducted investigations on a wide range of halon replacement chemicals for aviation use. In order to give a wider perspective on the type and range of chemicals being evaluated for fire suppression use, Table 44.4 is included. The table gives cup burner n-heptane

flame extinction data for a wide range of potential halon replacements.

Table 44.5 presents cup burner MEC for a range of fuels and agents taken from various sources [5–9]. Where multiple values of the MEC were found, they are given. The nitrogen data are presented as representative inert gas values. Argon/N2 blend MEC values would be higher. These data were not all developed using the standardized cup burner device. These data should not be used for design purposes without ensuring that the concentrations are consistent with system manufacturer requirements and third-party approvals.

Table 44.6 presents cup burner and full-scale data from VdS [10]. Table 44.7 is a compilation of "best values" of cup burner data from a range of sources compiled by Tapscott [11].

In addition to the cup burner apparatus, researchers at NIST have utilized an opposed-flow diffusion flame (OFDF) apparatus to rank clean agents (halon replacements) for fire

*Not determined with standard cup burner apparatus

extinguishing effectiveness. The OFDF burner is commonly used for combustion research. It has many advantages as a research tool for fundamental combustion studies. Its primary advantage is in its ability to relate the results to fundamental predictions of flame structure and conditions at flame extinction. The oxidizer (and suppressant) stream is forced down onto the fuel surface, exhaust gases are drawn down through an annulus or jacket around the fuel cup, and a flat flame is established. Water cooling is provided for the fuel cup and exhaust gas.

The OFDF burner can vary the turbulence intensity or strain rate of the flame. For most applications of clean agent fire suppression, the strain rate is not a major concern, but in specialized applications, such as engine nacelles with high fuel and oxidizer flow rates or in high-pressure spray or jet fires, the strain rate will substantially impact the minimum condition for extinguishment. Figure 44.2 is a sample plot showing the variation of the mole fraction of extinguishing agent versus the strain rate at extinction for n-heptane fuels for a range of suppressants. For typical natural fires, the strain rate is approximately 25 s^{-1}. At high strain rates, the flame is extinguished at lower agent concentrations.

Figure 44.3 shows the relationship between MEC for the cup burner and OFDF apparatus. As expected, the cup burner concentration is quite similar to the OFDF concentration at a low strain rate (25 s^{-1}), typical of natural fires. In all cases, the MEC of agent is much lower for high strain rate flames, which further reinforces the value of the cup burner and OFDF apparatus for evaluation of minimum extinguishing concentration. The reduction in extinguishing concentration as a function of the velocity of the agent/air mixture across the flame has important ramifications in the evaluation of extinguishment results when the velocity of the agent/air mixture at the flame is not well controlled. This often gives rise to erroneous and misleadingly low extinguishing concentrations obtained from full-scale room test results. When in doubt the higher extinguishing concentration obtained by small-scale tests at low strain rates should be used. This is particularly important because at near flame extinction conditions there is a very strong dependence of extinguishing concentration and velocity of the agent/air mixture. The practical implications of this fact are discussed later in this chapter under design concentrations.

Solid Fuel Extinguishing Concentrations

Extinguishing concentrations for Class A fuels were traditionally developed using wood cribs as

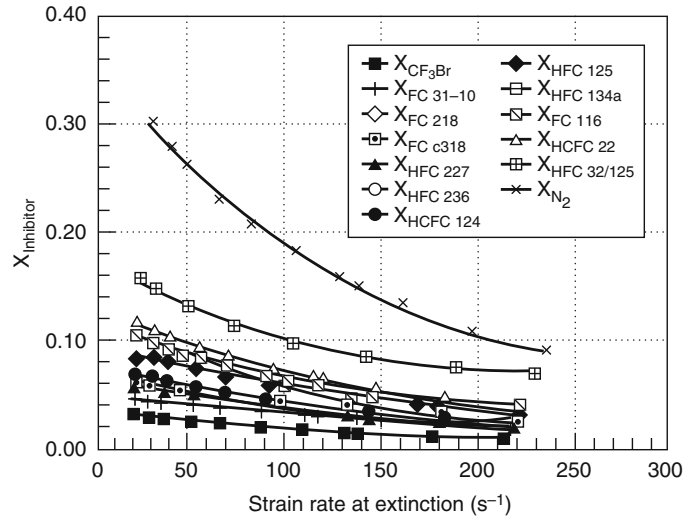

Fig. 44.2 Mole fraction of various suppressants as a function of strain rate at extinction for n-heptane [5]

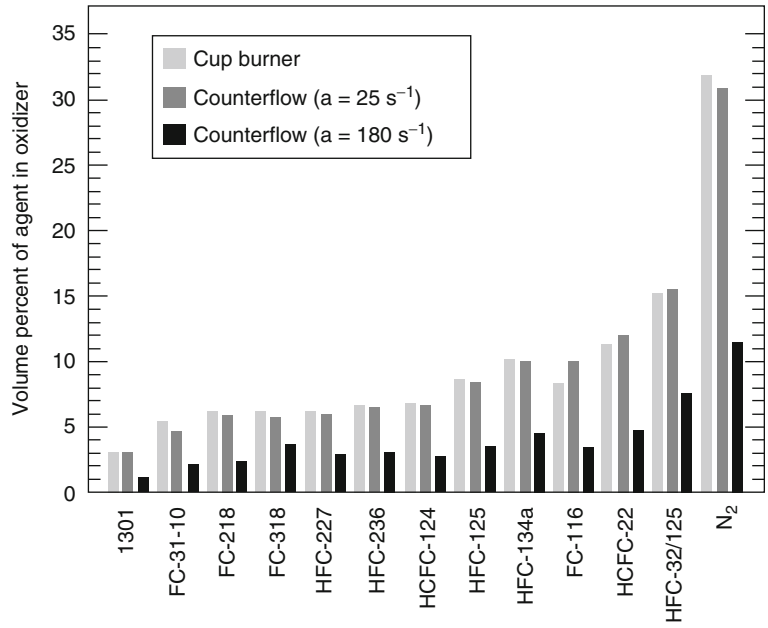

Fig. 44.3 Comparison of n-heptane extinction results for the cup burner and OFDF apparatus at two strain rates [5]

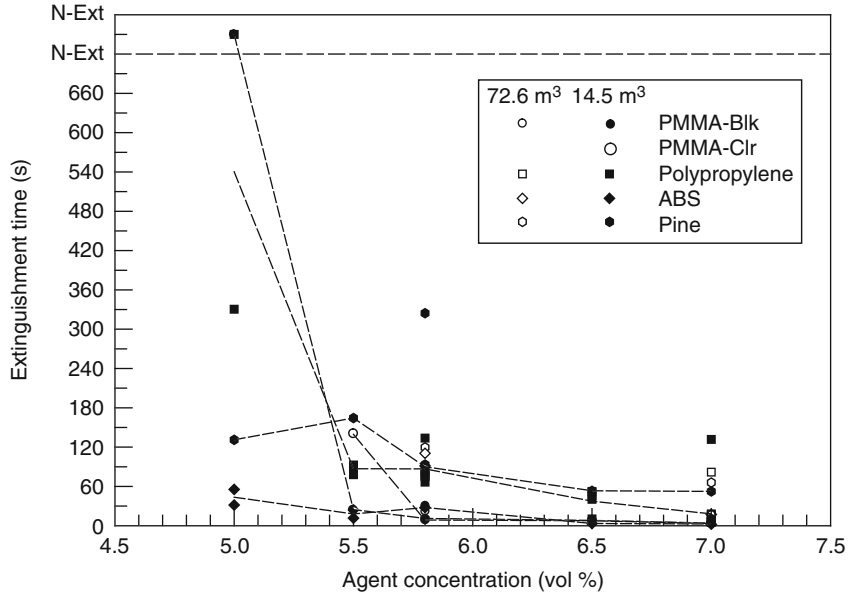

Fig. 44.4 Typical Class A extinguishment results for HFC-227ea

part of the equipment listing/approval process. Further, the minimum Class A extinguishing concentration used for design purposes was required to be greater than or equal to the minimum extinguishing concentration (MEC) for heptane. Additional tests utilizing plastic sheet arrays of polymethylmethacrylate (PMMA), acrylonitrile-butadiene-sytrene (ABS), and polypropylene (PP) have been required [12, 13]. Typical results are shown in Fig. 44.4 for two different room sizes. The results of these tests indicate that for extinguishment times exceeding

3 min, the extinguishing concentrations for these materials are below the heptane cup burner value and in general above the concentration required to cause extinguishment of the wood crib fires. The plastic sheet array fires therefore determine the Class A concentration requirements for these agents. Note that the most recent addition of NFPA 2001[1], imposes a minimum Class A design concentration equal to that of the minimum extinguishing concentration for n-heptane as determined with the cup burner apparatus.

Table 44.8 gives extinguishment and design concentration values for clean agents, using both NFPA 2001, Standard on Clean Agent Fire Extinguishing Systems, and the related UL third-party approval protocols and ISO 14520 installation standard. The extinguishing concentration values designated as test results in the table vary between NFPA 2001 and ISO 14520, primarily due to the slight differences in the test protocols, particularly for Class A solid fuel surface fires. There are differences between some equipment manufacturers for the same agent, which indicates a significant problem with the validity of the test result, in that the extinguishing concentrations should be independent of the system delivery hardware used. To the extent that there are hardware dependencies, the actual extinguishing concentration is, at best, equal to the higher value. Test differences between NFPA 2001 and ISO 14520, particularly for Class A fuels, indicate that the NFPA minimum extinguishing concentrations are artificially low for most agents. This is in part due to efforts by system manufacturers to reduce the minimum extinguishing concentration for Class A fuels with regards to the NFPA 2001 Standard and UL Approval Standards. For example, the HFC-227ea minimum extinguishing concentration for Class A fuels was reduced from 5.8 % to 5.2 % between 1996 and 2010.

At a minimum, the ISO test values for minimum extinguishing concentration should be used. Additional discussion of the design concentration values in the table is presented later in this chapter.

Energized Electrical Equipment Extinguishing Concentrations

Clean agent systems are widely used in electronic equipment areas where fires involving electrically energized cables and equipment are encountered. Extinguishment tests involving PMMA heated externally with Nichrome wire indicated that agent concentrations substantially higher than those typical for plastic fuels were required. For example, minimum extinguishing concentrations of 9.5, 9, 20, and 56.1 % were required for FC-3-1-10, HFC-227ea, HFC-23, and IG-541 respectively at the highest applied energy level (192 W applied to wrapped 7.5 × 5.0 × 0.6 cm (3 × 2 × 0.25 in. block of PMMA). The increase in required concentration was a direct function of the energy applied, consistent with the heat absorption extinguishing mechanism utilized by these agents. Note that increased fire size does not require an increase in agent concentration as the heat flux to the fuel surface does not vary significantly with fire size.

Linteris [14] at NIST obtained similar results that showed that minimum extinguishing concentrations may easily double when even small amounts of external heating are applied, using the Radiant Enhanced Extinguishment Device (REED). For example the minimum extinguishing concentration of Nitrogen more than doubled with the addition of relatively small external heat flux from results reported by Factory Mutual. Additional data from NIST on HFC-23 showed an increase in required extinguishing concentration of 350 %. These data are summarized in Fig. 44.5. Additional data using the same device for the range of current clean agents shows similar results [15].

Extinguishment tests on actual wire and cable materials were reported by McKenna et al. [16]. Three types of tests were conducted: ohmic heating, conductive heating, and printed wiring board arcing. The ohmic heating tests involved deliberate electrical overheating of the conductor. The electrical current applied was just below what would result in melting and breaking the conductor. These results are summarized in

Table 44.8 Summary of the Class a and Class B extinguishing concentrations for various agents and equipment manufacturers

			UL (NFPA 2001)				ISO 14520				
			Class B		Class A		Class B		Class A

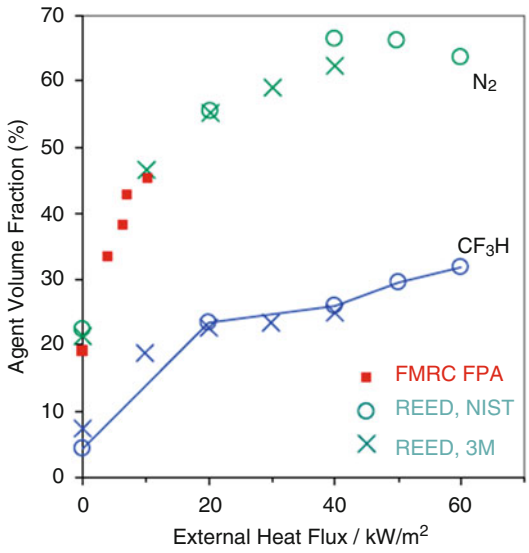

Fig. 44.5 Effect of external applied energy on extinguishment concentration (Linteris [14])

Table 44.9 for HFC-227-ea. This limited testing with low energy single and small cable bundles indicated that for HFC-227ea a concentration of between 6.5 % and 6.8 % was necessary to extinguish small cable bundles or arrays with PVC/PE or PE insulation. These values exceed the minimum Class A extinguishing concentration for HFC-227ea of between 5.2 % and 5.4 % and the design concentration of 6.2–6.5 %, which is supposed to embody a 20 % safety factor.

This dangerous situation has arisen, in part, because the Class A extinguishing concentration for HFC-227ea has been reduced from 5.8 % to 5.2% over time. This further illustrates the weakness of the test method used to determine Class A minimum extinguishing concentrations. A situation now exists in which small energized electrical fires would not be extinguished at either the minimum extinguishing concentration or the design concentration. These same fires would have been expected to be extinguished at the design concentration in 1996. This is due, in part, to poor experimental design of full scale tests where the effects of agent/air velocity at the flame were not sufficiently controlled and erroneous low minimum extinguishing concentrations were obtained.

The 6.5–6.8 % concentration required to extinguish all the test fires in Table 44.9 should be viewed as minimum extinguishing concentration with respect to these fires. A design concentration, suitable for use in actual installations, would incorporate an appropriate safety factor (20–30 % similar to Class A or B applications). This would imply a design concentration between 8.2 % and 8.8 % which would correspond to an approximate 50–60 % increase over the minimum Class A extinguishing concentration for HFC-227ea.

Linteris [14] also included a comprehensive review of suppression of energized electrical equipment and discussed the relevance and weaknesses of various ad hoc electrical equipment tests including those described above. The conclusion of this work is that the current guidance on minimum extinguishing concentrations for energized electrical equipment is inadequate, and insufficient data is available to definitively prescribe these concentrations. It is clear that theoretical and experimental results indicate that substantially higher concentrations than those currently used, are necessary.

These very limited results on small electrically energized conductors are not applicable to large-diameter, high-voltage, and high-power-rated cables, particularly in cable bundles and arrays. Such cables in these arrays have historically required much higher extinguishing concentrations than Class A surface values. For example, Sandia Laboratories and the Nuclear Regulatory Commission required design concentrations of 40 % for carbon dioxide and 6 % for Halon 1301 for such periods of at least 30 min. NFPA 12, Standard on Carbon Dioxide Extinguishing Systems, requires a CO_2 design concentration of >40 % for energized electrical equipment. These values represent increases of at least 20 % (for Halon 1301) over the Class A design value. As indicated in previous discussions, the Class A design value for the Halon 1301 is in the range of 80 % higher than HFC-125 when compared to a common baseline.

ISO 14520 [3], recognizing the more challenging nature of energized electrical fires,

Table 44.9 Summary of ohmic heating tests with HFC-227ea [16]

provides additional guidance for applications involving energized electrical equipment:

> It is recognized that the wood crib and polymeric sheet Class A fire tests may not adequately indicate extinguishing concentrations suitable for the protection of certain plastic fuel hazards (e.g., electrical and electronic type hazards involving grouped power or data cables such as computer and control room under-floor voids, telecommunication facilities, etc.) An extinguishing concentration not less than that determined in accordance with 7.5.1.3 (wood crib and plastic sheet array fire tests), or not less than 95% of that determined from the heptane fire test described in C.6.2 (heptane pan fire test), whichever is the greater, should be used under certain conditions. These conditions may include:
>
> 1. Cable bundles greater than 100 mm in diameter;
> 2. Cable trays with a fill density greater than 20% of the tray cross-section;
> 3. Horizontal or vertical stacks of cable trays (closer than 250 mm);
> 4. Equipment energized during the extinguishment period where the collective power consumption exceeds 5 kW.

Given the uncertainty apparent in the NFPA 2001 Class A and energized electrical equipment values for minimum extinguishing concentrations, designers should consider using ISO 14520 as the basis of any total flooding clean agent system design. Section "Design Concentrations" provides additional guidance and discussion on this topic.

Explosion Inerting

One of the most important application areas of total flooding fire suppressants is explosion inertion. The inerting concentration of an agent is the concentration required to prevent unacceptable pressure increases in a premixed fuel-air-agent mixture subjected to an ignition source. Inertion concentrations are typically measured in small laboratory-scale spheres with an electric spark initiator.

The measured inerting concentration of an agent is dependent on the details of the test apparatus used, particularly the ignition source strength and "allowable" pressure rise. The allowable pressure rise is a surrogate measurement of the distance the flame front travels inside the constant-volume sphere prior to suppression. Inerting concentration is not appropriate for use in explosion suppression either deflagrations or detonations.

Table 44.10 Explosion inerting concentrations, small-scale inertion sphere [6, 17–19]

	Inerting concentration (vol %) of fuel			
Agent	Propane	Methane	i-Butane	Pentane
FC-3-1-10	10.3[a]	~7.8[b]	–	–
	9.5[b]			
HFC-227ea	12.0[b]	8.0[b]	11.3[a]	11.6[c]
	11.6[c]			
HFC-23	20.2[a]	20.2[a]	–	–
	19.8[b]	14.0[b]		
IG-541	49.0[d]	43.0[d]	–	–
HCFC Blend A	18.0[b]	13.3[b]	–	–

[a]From Senecal [17]
[b]From Heinonen [19]
[c]From Robin [6]
[d]From Tamanini [18]

Small-scale sphere data are used to develop flammability diagrams for various fuel-oxidizer-agent concentrations. Chapter 17, which addresses flammability limits, gives an excellent introduction to the subject. There is a wealth of data in the combustion literature on flammability limits of a variety of fuels in the presence of an atmosphere of inert gases, such as nitrogen and argon.

Table 44.10 provides inerting concentration data for several agents and fuels taken from small scale inertion spheres [17–19]. There are some substantial differences in results. Heinonen [20] has identified both ignition source type and strength as important variables with differences of ±40 % for Halon 1301 inerting concentrations reported. Large scale inertion results have been presented by Moore [21]. While the small to large scale agreement is reasonable, there are scale effects.

Explosion Suppression

Explosion suppression systems employ rapid delivery of agent following very early detection of an ignition. Such systems employ significantly

higher agent quantities (than flame suppression or inertion) delivered at higher rates. The total agent delivery time is on the order of 100 ms.

Explosion suppression systems must be specifically designed for a particular application. There are no generic design requirements or standards currently available for such systems. Senecal [22] and Senecal et al. [23] report on explosion suppression testing in occupied armored fighting vehicles and aerosol filling rooms. Results were obtained on premixed fuel droplet (aerosol) sprays. In contrast to flame suppression or inerting, suppression of a deflagration or detonation requires significantly more agent. The tests employed 20 kg of HFC-227ea, FC-3-1-10, and HFC-236fa, and 10 kg of water in an 80 m^3 test room to suppress a 90 g propane release in a simulated aerosol filling station. Suppression of the propane-air deflagration was achieved, and the maximum flame front extension was approximately 1.22 m. Suppression tests of heated diesel fuel droplet cloud deflagrations were also conducted in simulated armored fighting vehicle crew compartments.

Table 44.11 summarizes typical data for flame suppression, inertion, and deflagration suppression concentrations. Note these values are for comparison purposes only. They should not be used in any way for design purposes. Suppression of detonations requires substantially higher agent concentrations than for deflagrations. An excellent discussion on this topic is given in Hamins et al. [5].

Toxicity

A major factor in the use of a clean agent fire suppressant in a normally occupied space is toxicity. Although all halocarbon agents are tested for long-term health hazards, the primary endpoint is acute or short-term exposure. The primary acute toxicity effects of the halocarbon agents described in this chapter are anesthesia and cardiac sensitization. For inert gases, the primary physiological concern is reduced oxygen concentration.

Halocarbon Agents Cardiac sensitization is the primary short-term toxicity problem for fire suppression applications involving halocarbon agents. Cardiac sensitization is an increased potential for cardiac arrhythmia with exposure to the agent in conjunction with the hormone epinephrine or adrenalin. Cardiac arrhythmia is a condition in which the heart beats with an irregular or abnormal rhythm and in an extreme case, can lead to a heart attack. Epinephrine is produced naturally by the body with increased production rates when the body is under stress. Epinephrine can cause arrhythmia on its own at high concentrations. Cardiac sensitization reduces the epinephrine concentration associated with the onset of cardiac arrhythmia when exposed to the agent.

The two toxicity endpoints used to describe cardio-toxicity and allowable exposure levels are (1) no observed adverse effect level (NOAEL) and (2) the lowest observed adverse effect level

Table 44.11 Comparison of concentrations for flame extinguishment, inertion, and deflagration suppression [1, 22]

	Volume (%)		
Agent	Typical value flame suppression	Inerting concentration in propane	Diesel fuel droplet deflagration suppression
Halon 1301	3	6–7	12
FC-3-1-10	5.5	10.3	8
HFC-227ea	5.8	~12	11
HFC-23	12	20.2	–
IG-541	29	49.0	–

(LOAEL). The NOAEL is the highest concentration of an agent at which no "marked" or adverse effect occurred. The LOAEL is the lowest concentration of an agent at which an adverse effect was measured.

The procedures used to evaluate cardiac sensitization vary somewhat. The basic approach involves a stepped method that includes the intravenous dosing of male beagle hounds with epinephrine for 5 min. Continuous inhalation exposure to the agent at a specific concentration follows for 5 min. Following this inhalation exposure, the hound is dosed again with epinephrine and monitored for another 5 min to determine the effect of the agent and epinephrine. The protocol is performed at higher doses until an effect occurs.

Effects are monitored by electrocardiograph (EKG) measurements. An adverse effect is generally considered to be the appearance of five or more arrhythmias or ventricular fibrillation. The data from these tests are evaluated by medical experts, and the appropriate NOAEL and LOAEL values are reported by the United States Environmental Protection Agency (EPA) under the Significant New Alternatives Policy (SNAP) program.

There is no direct correlation between the experimental results from hounds to humans. It is generally accepted, due to the combination of the high doses of epinephrine in the tests and the similarity in cardiovascular function between hounds and humans, that the results can be applied to humans.

For most of the listed halocarbon agents, the concentration where adverse effects are observed is higher than the design concentration required for use in fire suppression. The exceptions to this are FIC-13I1 (CF_3I) and HFC-125 (C_2HF_5). The concentration where cardiac sensitization effects are noted (LOAEL) for FIC-13I1 is 0.4 % by volume [1] while its minimum design concentration for Class B hazards is 4.2 % by volume. For HFC-125, the concentration where cardiac sensitization effects are noted is 10 % by volume which is exceeded by the minimum design concentration for Class B hazards of 11.3 % by volume, however, for Class A hazards, the minimum design concentration is 8.7 % by volume which is less than the LOAEL.

In addition to the short-term chronic exposure limits of interest in fire suppression system design, the EPA evaluates longer-term inhalation data for these compounds. One procedure used to evaluate longer-term effects involves the exposure of a concentration of the halocarbon agent to a population of rats for a period of 4-h. The measure LC_{50} is the concentration of the halocarbon agent lethal to 50 % of the rat population during the 4-h exposure. This is also referred to as the approximate lethal concentration (ALC). Table 44.12 summarizes NOAEL, LOAEL, and

Table 44.12 Toxicity data for halocarbon clean agent fire suppressants [1]

Agent	Trade name	LC_{50} and ALC (%)	NOAEL (%)	LOAEL (%)
FIC-1311	Triodide	>12.8	0.2	0.4
FK-5-1-12	Novec 1230	>10	10	>10
HCFC Blend A	NAFS-III	64	10	>10
HCFC-124	FE-24	23-29	1	2.5
HFC-125	FE-25	>70	7.5	10.0
HFC-227ea	FM-200	>80	9	10.5
HFC-23	FE-13	>65	30	>30
HFC-236fa	FE-36	>45.7	10	15
HFC Blend B	Halotron II	56.7[a]	5.0[a]	7.5[a]

Notes
(1) LC_{50} is the concentration lethal to 50% of a rat population during a 4-h exposure. The ALC is the approximate lethal concentration
(2) The cardiac sensitization levels are based on the observance or non-observance of serious heart arrhythmias in a dog. The usual protocol is a 5 min exposure followed by a challenge with epinephrine
(3) High concentration values are determined with the addition of oxygen to prevent asphyxiation
[a]These values are for the largest component of the blend, HFC Blend B (HFC-134A)

Table 44.13 Exposure limits derived from PBPK modeling for HFC-227ea and HFC-125 [1]

HFC-227ea concentration			HFC-125 concentration		
% V/V	ppm	Human exposure time (min)	% V/V	ppm	Human exposure time (min)
9.0	90,000	5.00	7.5	75,000	5.00
9.5	95,000	5.00	8.0	80,000	5.00
10.0	100,000	5.00	8.5	85,000	5.00
10.5	105,000	5.00	9.0	90,000	5.00
11.0	110,000	1.13	9.5	95,000	5.00
11.5	115,000	0.60	10.0	100,000	5.00
12.0	120,000	0.49	10.5	105,000	5.00
			11.0	110,000	5.00
			11.5	115,000	5.00
			12.0	120,000	1.67
			12.5	125,000	0.59
			13.0	130,000	0.54
			13.5	135,000	0.49

LC_{50} values. Note that the LC_{50} values greatly exceed the NOAEL and typical fire-extinguishing concentrations.

Because the arrhythmia potential is measured in dogs, a means of providing improved human relevance has been established. Physiologically based pharmacokinetic modeling (PBPK) for evaluation of acute exposure to halocarbon agents has been used to establish alternative exposure limits for halogenated agents [1]. PBPK modeling utilizing a computerized tool attempts to account for the time-dependent uptake rate of halocarbons in the body and establishes exposure limits based on the rate of uptake [24–28]. The limits are based on the concentration of agent and the time at which the concentration of agent in the blood equals that of the LOAEL. Typical PBPK results for safe exposure times for HFC227ea and HFC-125 are given in Table 44.13. Note that exposure above the NOAEL limits and up to the LOAEL is permitted.

These limits were derived and supported by the EPA, which has the primary regulatory authority for health and toxicity associated with halon replacements. The use of the PBPK approach partially accounts for the differences between laboratory animal tests and humans. The laboratory results form the basis of the endpoints (NOAEL, LOAEL) and are still conservative due to the nature of epinephrine dosage used during the animal tests [29].

Where PBPK modeling data do not exist, the use of halocarbon agents in occupied areas is subject to the constraint that the design concentration must be less than the NOAEL. Although it is recommended that all systems employ predischarge alarms and that personnel evacuate prior to system actuation, it is understood that inadvertent discharges and short-term exposures will occur, hence, the limitation. It is expected that emergency exposures for up to several minutes at or below the NOAEL are reasonably safe. In no case should systems be designed or installed where intentional exposure of any duration is anticipated. It has been proposed by the EPA that agents be permitted for use at concentrations up to the LOAEL where evacuation will occur in less than 60 s. This proposal has not been integrated into design standards to date due to the uncertainty of accidental exposure conditions. Based on the limitation that the design concentration must be below the NOAEL, it can be seen from Table 44.12 that three agents are acceptable for use in normally occupied areas for flame extinguishant purposes: HFC-227ea, HFC-23, and FK-5-1-12.

Inert Gas Agents Inert gas agents are, in effect, physiologically inert. The primary physiological

problem with these agents is the reduced oxygen concentration caused by the high agent design concentrations. One inert gas blend employs a low concentration of CO_2 (which is not physiologically inert) in order to counter the effects of the reduced oxygen concentration. The mechanism of this effect is discussed in EBRDC Report 10.30.92 [30]. Current limitations on exposure limits for inert gases are as follows: for gas concentrations up to 43 % (a residual oxygen concentration of 12 %), exposure time is limited to 5 min. For agent concentrations between 43 % and 52 % (12 % and 10 % residual oxygen concentration), the exposure time is limited to 3 min. For concentrations greater than 52 %, exposure time is limited to 30 s. There is strong indication that small concentrations of CO_2 added to inert gases (such as IG-541) substantially reduce hypoxic effects and improve human performance at low oxygen levels. Regulatory authorities have not yet differentiated between such agents and other inert gases or blends [30].

Environmental Factors

Two main environmental impacts need to be considered with respect to halocarbon extinguishing agents: (1) ozone depletion and (2) global warming [1]. Another environmental factor, atmospheric lifetime, can be considered in the discussion of each of these environmental impacts. It is also a "stand-alone" environmental concern that needs to be addressed. International, national, state, and local governments currently regulate halocarbon fire-fighting agents based on their effect on ozone depletion. However, the EPA also takes into account atmospheric lifetimes and global warming potentials in the implementation of its SNAP program under Section 612 of the Clean Air Act in the United States, as amended in 1990. Although no specific national environmental regulations cover global warming and atmospheric lifetimes, the consideration of these issues in the EPA's implementation of existing regulations makes these issues of concern.

Ozone Depletion

Ozone (O_3) is a naturally occurring gas that is found in the atmosphere. Most naturally occurring ozone is created by the reaction of O_2 with ultraviolet (UV) light coming from the sun.

$$O_2 + UV \quad O + O$$
$$O + O_2 \quad O_3$$

The UV light causes this reaction to occur. Ozone is also created in nature when the high energy output from lightning initiates a similar reaction.

Ozone is also formed by a number of manufactured sources, mainly as a result of air pollution. When carbon monoxide, methane, and other hydrocarbons meet nitrogen oxide (e.g., from car exhaust) and ordinary sunlight, ozone is produced. It is also produced by laser printers and electric motors and is responsible for the pungent odor often associated with the devices. Man-made ozone is often called "smog" and is a considerable health risk.

Halons, HCFCs, and other halocarbons containing chlorine or bromine have been shown to cause the destruction of stratospheric ozone. The characterization of stratospheric ozone destruction is not a measure of the exact amount of ozone destroyed. Instead, it is the relative amount of ozone destroyed as compared with an arbitrary standard. The standard chosen is trichlorofluoromethane, CFC-11, a compound of chlorine, fluorine and carbon, which has been assigned an ozone depletion potential (ODP) of 1. ODP of all other halocarbons relates to their relative effect on the destruction of ozone as compared with CFC-11. Halon 1301 has an ODP of 12, meaning it will destroy 12 times as much ozone as CFC-11 on a pound-for-pound (kilogram-for-kilogram) basis. A compound having an ODP of 0.1 would have 10 % of the relative ozone-depleting effects of CFC-11. All ODP values are based on mass (weight) and not on moles (numbers of molecules).

The only remaining nonzero ozone-depleting fire-extinguishing gases are HCFC compounds, none of which are widely used for total flooding system applications. All HCFCs are subject to

some degree of environmental regulation in most parts of the world.

Atmospheric Lifetimes

When one thinks of a chemical species lifetime, the term *half-life* is often used. This usage is most common in the nuclear field when calculations are made to determine how long it takes a species to decay to half its original concentration. Atmospheric lifetime values used in the determination of ozone depletion and global warming potentials are *not* half-lives. They are $^1/_e$ lifetimes, sometimes called e-folding lifetimes.

It has been determined that greenhouse gases break down in the atmosphere according to the following equation:

$$C = C_o e^{-kt}$$

where:

C = Concentration at time t
C_o = Initial concentration at time t
k = An experimentally determined rate constant (units = 1/time)

A mathematical manipulation can be made to express this equation as a function of more readily quantifiable terms and is accomplished by defining the atmospheric lifetime, L, as an e-folding lifetime, or the time it takes for the ratio of $C:C_o$ to be equal to $^1/_e$ (e is the base of the natural logarithm system and has a numerical value of approximately 2.718). The resulting equation is as follows:

$$C = C_o e^{-t/L}$$

Although the term *half-life* is most commonly used when describing the decay of a species concentration, the use of the e-folding lifetime allows for quantification of concentration in terms of a compound's atmospheric life-time, as previously shown. A half-life refers to the time it takes for half a given amount of compound to be broken down in the atmosphere; thus, the ratio $C:C_o$ is equal to ½. Using an e-folding lifetime, the ratio is equal to $^1/_e$ or 0.368. After one lifetime, the concentration will be equal to 0.368 times its original value. After two lifetimes, the concentration will be 0.135 or $(0.368)^2$ times its original value. After three lifetimes, the concentration will be 0.0498 or $(0.368)^3$ times its original value, and so on.

An important factor when using the preceding equation to solve for concentration as a function of time is that, no matter what value is used for time, the concentration never equals zero. Some portion will always exist in the atmosphere. When the atmospheric life-time is small, the concentration over hundreds of years may become negligible. When the atmospheric life-time is very large, on the order of tens of thousands of years, the concentration in the atmosphere may not be negligible.

The environmental concern is one of "what if." The halons were believed to be "safe" for many years after their release into the atmosphere began. It was not until many years later that they were linked to ozone depletion. There is a concern that these halocarbons, or other compounds, may cause other environmental impacts that are yet unknown. If the atmosphere is filled with these chemicals and they exist in appreciable amounts for hundreds, thousands, and millions of years, what then? Might the damage we do to our environment be more than humans can cope with? Nature can probably overcome this impact, but it may take tens of millions of years. This is a short time frame for nature but not for man. Current implementation of the EPA SNAP program places restrictions on perfluorocarbons that have very large or "outlying" atmospheric lifetimes as compared with the rest of the halocarbons. This restriction is not based on any known or anticipated environmental problem. It is a response to the "what if" concerns raised previously.

Global Warming Potential

The most important global environmental issue is currently climate change. A basic understanding about the earth's climate and atmosphere is needed to understand what global warming potential (GWP) is and how to attempt its measurement.

Estimates of the average temperature of earth's atmosphere have been made, assuming two theoretical conditions. The first assumes no

atmosphere at all, and the second assumes an atmosphere made up solely of N_2 and O_2 (normally representing 99 % of our atmosphere). In both cases, models have predicted that earth's surface would be some 91 °F (33 °C) cooler than it is. The temperature difference is believed to be a direct result of the very small amounts of trace gases, water vapor, and CO_2. These act very much like the glass on a greenhouse that lets the sunlight in but helps to prevent the heat from escaping, hence, the terms *greenhouse effect and greenhouse gases*. A greenhouse gas is defined as any gas that absorbs infrared (IR) radiation.

Climate change and global warming are not synonymous. Climate change includes cooling and warming of the atmosphere. Global warming only deals with the aspects of climate change that result in warming of the atmosphere.

It is estimated that about one-third of the total solar radiation is reflected off earth's atmosphere. Most of the remaining two-thirds passes through the atmosphere and is absorbed by the earth's surface, causing it to warm [31].

The earth cools itself by releasing heat, or IR. In order for a balance to be maintained, the solar radiation coming in must equal the radiation going out. If more radiation entered the atmosphere than left, the earth would be constantly getting warmer. The opposite would be true if more radiation left the earth than came in; that is, the earth would be constantly getting cooler.

To estimate the amount of global warming expected from a release of a particular greenhouse gas, a scale was developed by the International Panel on Climate Change (IPCC), based on the idea of radiative forcing. This scale is called the global warming potential (GWP) and relates to positive radiative forcing that will cause the atmosphere to heat up. The GWP is the cumulative amount of radiative forcing between the present and some future time caused by a unit mass (weight) of a compound, as compared with the same unit mass (weight) of an arbitrary standard. Carbon dioxide, CO_2, is the most common reference, and 20-year, 100-year, and 500-year time periods, or horizons, are the most common time references cited in the literature. The choice of time horizons is a policy issue and not a technical one.

Since the GWP is a cumulative effect, summed year by year over a given time horizon, the quantity present in the atmosphere must be known year by year over that horizon. The atmospheric lifetime is used to perform these calculations. GWPs are also affected by the specific IR-absorbing capabilities of the chemical. Analogous to ODPs, GWPs are not exact numbers showing the precise effect on global warming. A 100-year horizon GWP of 6200 for Halon 1301 means that 1 lb (0.454 kg) of Halon 1301 will cause as much global warming as 6200 lb (2812 kg) of CO_2. A 500-year horizon GWP for methylene chloride of 0.3 means that 1 lb (0.454 kg) of methylene chloride will cause the same warming as 0.3 lb (0.14 kg) of CO_2.

GWPs are used to determine the future global warming contribution of a substance *over a given time* by multiplying the weight of the greenhouse gas by a specific time-horizon-GWP. The resultant number can be compared with others to decide which will have the least (or greatest) impact *over that time horizon*. Emitting a large quantity of a small GWP greenhouse gas may cause less global warming than a small release of a very large GWP greenhouse gas over a certain time horizon. Different time horizons may lead to different results.

Environmental Regulation of Halon Replacements

The evaluation of clean agent fire suppressants includes a consideration of environmental factors. International, national, and local government regulations control the use of any alternatives in this regard. As described above, a key environmental consideration is ODP. All chemicals with a nonzero ODP are subject to phaseout under the Montreal Protocol and its amendments. Table 44.14 summarizes environmental impact data for halocarbon agents. Note that FC and HFC compounds have zero ODP.

As also discussed above other environmental factors important in a regulatory context are GWP and atmospheric lifetime. The evaluation of GWP is an extremely complex issue, and

Table 44.14 Environmental factors for halocarbon clean agents [31]

Designation	ODP	GWP (100 years)	Atmospheric lifetime (years)
Halon 1301	12.000	7030	65
HFC-227ea	0.000	2900	34.2
HFC-23	0.000	14,310	270
HFC-125	0.000	3450	29
FK-5-1-12	0.000	1	0.038
Inert gas	0.000	0	NA

currently none of these compounds are regulated on that basis in the United States. Long atmospheric lifetime, a measure of the persistence of a chemical in the atmosphere, is of concern not only as it relates to GWP but also due to the uncertainty of the effects of chemicals for long time periods in the atmosphere. The EPA currently has use restrictions on FC-3-1-10 based primarily on its long atmospheric lifetime. These restrictions permit the use of this chemical in applications where no other alternative is technically feasible.

There is regulation of HFCs and PFCs for fire protection use in many parts of the world. There are few blanket prohibitions of HFCs for fire protection use, but regulation relating to minimizing emissions on the basis of global warming currently exists in Europe. As consensus grows at the magnitude and threat posed by global climate change, one would reasonably expect increased regulation worldwide on HFC fire suppressants. Note that some of the inert gases have no GWP impact and that the FK-5-1-12, a halogenated agent, has a GWP of 1; therefore, low climate change impact fire suppression gases currently exist. This agent possesses many of the advantages of a halogenated agent but with an environmental impact similar to inert gases.

It is also important to bear in mind that the total usage relative to total global production of these gases for fire suppression uses is quite low and perhaps more importantly the emissions of these gases relative to other uses is very low. Hence the overall impact of fire suppression agents to climate change can be expected to be minimal if not negligible. The Halon Alternative Research Commission (HARC) estimates that fire protection use of all halocarbons contributes less than .01 % of the impact of all greenhouse gas emissions [32].

Thermophysical Properties

Tables 44.15 and 44.16 give thermophysical properties of clean agent replacements from NFPA 2001 for halocarbon and inert gases. Additional thermophysical and transport property data can be found in Robin [6] for FM-200 and Yang and Bruel [33] for a range of halocarbon alternatives.

Isometric diagrams for halocarbon agents HFC-227ea, pressurized at 360 and 600 psig at 70 °F with nitrogen, and HFC-23 are given in Figs. 44.6, 44.7, and 44.8, respectively. Note that HFC-23 is not pressurized with nitrogen.

Figure 44.9 gives the pressure-temperature relationship for inert gases IG-541, IG-55, and IG-01, pressurized to 2175 psig, at 70 °F. This display is the pressure-temperature relationship for an ideal gas.

Clean Agent System Design

Once an agent has been selected for a specific application, the general discussion on clean agent system design presented in Chapter 43, should be reviewed. Many of the design principles for clean agent systems have been adapted from those principles used for halon systems. The basic process is outlined below:

1. Determine the design concentration.
2. Determine the total agent quantity.
3. Establish the maximum discharge time.

Table 44.15 Physical properties of clean halocarbon agents (Si units) [1]

4. Select piping material and thickness consistent with pressure rating requirements.
5. Design piping network and select nozzles to deliver required concentration at required discharge time to ensure mixing.
6. Evaluate compartment over/underpressurization and provide venting if required.
7. Establish minimum agent hold requirements and evaluate compartments for leakage.

These attributes apply only to the mechanical design of the system.

The detection and actuation systems are critical and integral parts of a clean agent system design. The detection system should be designed to actuate the system, with appropriate predischarge alarms, before unacceptable thermal or nonthermal damage occurs. This aspect is particularly important where the thermal decomposition products of halocarbon clean agents are a concern. Chapter 40, provides engineering methods and calculation procedures for this purpose.

In addition to the detection, actuation, and alarm systems, the enclosure itself is critical in the design of any total flooding suppression system. The most important considerations are that the enclosure be of sufficient integrity to (1) prevent preferential agent loss during discharge and (2) prevent excessive agent-air mixture loss after discharge to ensure adequate hold time.

As a general rule, all openings, notably doors and ventilation fans and/or openings must be secured prior to discharge in conjunction with the detection and alarm systems. Agent system installation in rooms with unclosable openings should not be attempted unless sufficient test data are available to ensure adequate concentrations. Some enclosures, such as very tightly sealed low EMF emission electronics spaces, require additional care to avoid compartment damage due to over/under pressurization during agent discharge.

Table 44.17 Comparison of design concentrations for Class A fires [1, 3, 34–36]

Design Concentration

Flame Extinguishment Design concentrations for various agents and fuel combinations are generally determined by a combination of small-scale testing, large-scale testing, independent laboratory approval of hardware, and addition of design safety factors as discussed above.

Historically, minimum design concentrations for Halon 1301 were set by the cup burner extinguishing concentration plus a 20 % safety factor. A minimum Halon 1301 design concentration of 5 % was also established for all applications. For heptane, the cup burner value ranged from 2.9 % to 3.9 % [34]; with a 20 % safety factor, a design concentration ranging from of 3.5 % to 4.7 % is obtained. At the minimum design concentration set by NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems*, 2009 Edition [35], of 5 %, a safety factor ranging from 28 % to 72 % was achieved. For fuels with cup burner extinguishing concentrations greater than 4.2 %, the safety factor remained at 20 %.

Table 44.17 presents the minimum design concentration of clean agents under the requirements of NFPA 2001 [1] and ISO 14520 [3].

The design concentrations required under the ISO 14520 installation standards are significantly higher due to two factors. First, in general, the extinguishing concentrations measured under the ISO protocols are generally higher than those obtained by the methods required by NFPA 2001; these sometimes larger differences are surprising, given the very minor test differences between test protocols. In general, a designer should select the higher of the extinguishing concentrations.

The second and most important difference between the two installation standards is in the safety factor. NFPA 2001 requires a minimum safety factor of 20 %, whereas the ISO minimum is 30 %. The product designer should bear in mind that for typical Class A hazards, Halon 1301 systems designed at 5 % had a minimum effective safety factor of 65 %; for carbon dioxide, it is in the range of 75–100 %.

There has been some full-scale test work that indicates that the 20 % safety factor may be insufficient. Sheinson et al. noted significant improvement in extinguishing time performance with a safety factor of 40 % [7]. Brockway noted similar results with no performance improvement beyond a safety factor of 40 % [37].

Analysis by Schlosser [38] indicated that the probability of failure of a system was reduced

from approximately 15 % to 10 % when the safety factor increased from 20 % to 30%. In addition to these data, the variation in cup burner values used as a basis for design concentration was significant due in part to a lack of standardization in the method. Some full-scale test results [39] also indicated a need for higher design concentrations.

Based on these factors, the first edition of ISO 14520-1 required a minimum safety factor of 30 % [40]. The current edition of NFPA 2001 [1] requires a 30 % safety factor for Class B hazards and for any system actuated by manual means only.

A review of the adequacy of these minimum required design concentrations can be found in Hanauska and DiNenno [41]. In this report weaknesses are identified in the development of the minimum extinguishing concentrations and the safety factors associated with the minimum required design concentration for Class A and energized electrical equipment fires. The current edition of NFPA 2001 increases the safety factor for energized electrical equipment fires to 35 % over the MEC for Class A hazards. This does not fully address this hazard as discussed previously in section "Energized Electrical Equipment Extinguishing Concentrations."

Table 44.17 shows comparison data for Class A design concentrations in both NFPA 2001 and ISO 14520 against the minimum heptane extinguishing concentration for each agent. In addition, data for carbon dioxide and Halon 1301 are presented for comparison. The heptane minimum extinguishing concentration (MEC) is used as a baseline for the following reasons:

1. The value is independent of system delivery hardware, which is a problem for Class A test results.
2. The MEC can and has been determined for each agent by various laboratories with minimum differences among laboratories.
3. The use of a liquid fuel is a reasonable worst case for a diffusion flame over a solid surface.
4. Comparison data exist for Halon 1301 and CO_2 that form the basis of historical total flooding gases.

An analysis of the data in Table 44.17 indicates the following:

1. The UL/NFPA 2001 design concentration differences for Class A surface fires for clean agents are as high as 47 % (for HFC-125) less than the equivalent concentration for carbon dioxide compared to a cup burner baseline. The design concentration for HFC-125 is approximately 62 % of the value one would expect for carbon dioxide if applying the same safety factor and design concentrations (0.92 vs. 1.48).
2. Similarly, the design concentration for HFC-125 is 63 % of that expected for Halon 1301 (0.92 vs. 1.47).
3. The agent faring the best in comparison to Halon 1301 and carbon dioxide is HFC-23.
4. Design values contained in ISO 14520 are much more reasonable in comparison with the NFPA 2001/UL values due, as previously discussed, to higher safety factors and more demanding extinguishing concentration tests for Class A fuels in ISO 14520.
5. The last column in Table 44.17 shows, in very stark terms, the weakness of NFPA 2001 to ISO 14520. The design value for HFC-125 used by NFPA 2001 is only 71 % of the value used in ISO 14520. The design concentration used in NFPA is lower for all agents, except HFC-23.

The analysis presented in Table 44.17 indicates that the Class A extinguishing concentrations used in NFPA 2001 for clean agents are significantly lower (approximately 30 %) than the equivalent values for Halon 1301 and CO_2, relative to a common baseline. Note that these differences do not exist between Halon 1301 and the clean agents for liquid Class B fuels. In addition, the NFPA 2001/UL values for Class A design concentrations are as much as 30 % lower than the equivalent design value under ISO 14520.

From both a historical perspective and current international practice, the design concentrations for Class A surface fires required in NFPA 2001 appear too low.

It has also been noted by several investigators that higher safety factors result in lower thermal

decomposition products [7, 8, 37]. None of the above referenced investigations utilized listed or approved hardware for the specific agents tested; as in most cases, the tests were performed before such hardware was available.

There is an exception in NFPA 2001 to the general rule that a minimum extinguishing concentration be established by the cup burner method. It was alleged that reliable cup burner data were not available for HCFC Blend A due to the fact that (1) the agent was a blend and (2) one of the blend components heats at a low vapor pressure. In the case of this agent, a minimum extinguishing concentration of 7.2 % and, hence, a design concentration of 8.6 % was established through limited full-scale testing for Class A hazards. Since at the time insufficient data were available to evaluate the claim, the exception that requires full-scale testing at minimum extinguishing concentration consistent with UL 2127, *Inert Gas Clean Agent Extinguishing System Units* [12] and UL 2166, *Halocarbon Clean Agent Extinguishing System Units* [13], were invoked. Since that time, reliable cup burner data were obtained for the blend from several laboratories. The data are consistent with MEC values for the blend components, primarily HCFC-22. Furthermore, some full-scale testing has indicated that the design concentration of 8.6 % may be inadequate [42]. This issue is, however, unresolved at the present time.

For Class A fires, NFPA 2001 requires full-scale testing and third-party approval for evaluating design concentration on solid polymeric materials. In many cases, the MEC for heptane is used as a practical minimum.

There has been no systematic evaluation of these agents under so-called "deep-seated" fire scenarios. Part of the problem is the circular definition of deep-seated fires in NFPA 12A [35]. However, the Underwriters Laboratories Inc. (UL) and Factory Mutual Research Corporation (FMRC) listing procedures require testing on wood cribs subsequent to long preburn times (approximately 6 min). Under these tests, surface oxidation and char reactions do occur.

Design concentrations for fire scenarios involving long preburn times in thick arrays of cellulosic fuels will require additional testing. For most applications where incidental quantities of cellulosic materials may be involved and pre-burn times are relatively short time frames (i.e., automatic actuation), the flame extinguishing concentrations for Class A fuels will be less than, or equal to, that of n-heptane and can be used. Surface oxidation or charring reactions do not occur with most polymers; hence, so-called "deep-seated" fires are not a concern when these Class A fuels are involved.

IG-541 is used at 37.5 % minimum design concentration when Class A materials are involved. Other inert gases should have similar or higher minimum design concentrations. As previously discussed, the minimum design concentration is a function of the fuel, the agent, and the delivery systems. Design concentrations for specific hazards must be determined in accordance with the system manufacturer's approval or listing.

As previously discussed the Class A design concentrations are inadequate for energized electrical equipment or in any scenarios where external heating is applied to the combustion system which may be 2–3 times the Class A fuel design concentration. While the 2012 edition of NFPA 2001 increased the minimum design concentration for energized electrical equipment to a value no less than 90 % of the MEC for Heptane, this is clearly inadequate. Designers are referred to the ISO 14520 for the use of more realistic (and higher) design concentrations.

Design Factors In addition to safety factors, the concept of design factors was first introduced into NFPA 2001 for the 2000 edition. A design factor is used to increase the agent quantity for a specific installation or design that has attributes for which the minimum safety factor may not be sufficient. The only variable for which design factors have been quantified is for systems with multiple flow splits protecting multiple enclosures simultaneously. The motivation for a design factor in these cases is the uncertainty in the split of agent mass flow at unbalanced tee junctions. This uncertainty is compounded as the flow is divided at subsequent unbalanced tees.

Table 44.18 Specific volume constants [1]

Generic name	Trade name	k_1 English units	k_2 English units	k_1 Sl units	k_2 Sl units

IG-100	NN-100	11.976	0.02606	0.7997	0.002927
IG-541	Inergen	9.858	0.02143	0.659	0.00241

The piping tee design factor is used to provide additional agent to compensate for the uncertainty in the flow division when the flow to a nozzle has passed through more than four tees.

Agent Quantity

Once the design concentration is established, the quantity of agent necessary to achieve that concentration is determined. The quantity of halocarbon agent necessary is determined by the following equation:

$$w = \frac{V}{S}\left(\frac{C}{100 - C}\right)$$

where:
V = Net volume of protected space
C = Design concentration (%)
w = Specific weight of agent required
S = Specific volume (ft^3/lb [m^3/kg]) and is determined by

$$S = k_1 + k_2(T)$$

where T is the minimum ambient temperature of the protected space, and k_1 and k_2 are constants. Values for k_1 and k_2 used in Equation 44.2 are given in Table 44.18. The flooding factor in Equation 44.1, (C/[100 – C]) implies that the agent-air mixture leaking from the enclosure as a result of the addition of the agent, exit the enclosure at the final concentration after mixing with the air initially in the enclosure. As these agents are stored as a liquid and vaporize in the enclosure during the discharge, the enclosure is under a negative pressure relative to ambient, early in the discharge allowing the agent to mix with the air in the enclosure, prior to leaking from the enclosure as the pressure in the enclosure goes positive late in the discharge.

For inert gases, the following formula is used:

$$X = 2.303\frac{V}{S}\log\left(\frac{100}{100 - C}\right)\mathrm{V_s}$$

where
X = Volume of inert gas required at 70 °F
V_s = Specific volume at 70 °F
V = Net protected hazard volume
S = Specific volume at ambient temperature in protected volume (from Equation 2) = k_1 + k_2 (T)

The flooding factor used here log(100/[100 – C]) is derived assuming that leakage from the compartment during discharge occurs with a varying concentration of agent from zero to C from beginning to the end of discharge. As the pressure in the enclosure is positive throughout the discharge for these agents and the relatively long agent discharge, the leakage flow from the enclosure has the agent concentration present at that stage of the discharge. It is identical to the expression used in CO_2 system design.

Discharge Time

The maximum discharge time permitted for halocarbon clean agent systems is 10 s. This discharge time is taken to be the moment when all liquid agent has cleared the nozzles. The total discharge time will be longer as agent vapor and nitrogen are expelled from the system.

The 10-s discharge time limitation for halocarbon agents is designed to aid four objectives:

1. Provide high flow rates through nozzles to ensure adequate mixing of agent with air inside the enclosure.
2. Provide sufficient velocity through pipes to ensure homogeneous flow of liquid and vapor.
3. Limit the formation of agent thermal decomposition products.
4. Minimize direct and indirect fire damage, particularly in fast-developing fire scenarios.

The most important of these objectives relative to discharge time is the minimization of agent thermal decomposition product formulation. Items 1 and 2 alone are determined by the piping system design.

The discharge time requirement for inert gases is currently 120 s for Class A and Class C fires and 60 s for Class B fires [1]. Longer discharge times are typically used for these systems in Europe. The two primary reasons to constrain the discharge time of inert gas agents that form no thermal decomposition products are (1) to limit the direct and indirect fire damage and (2) to minimize the length of time that the fire burns in a depleted oxygen atmosphere.

In some applications, such as flammable liquid hazards and explosion inerting, it is necessary to discharge the agent quickly to minimize direct fire damage or to ensure that the agent concentration is achieved prior to the lower explosive limit (LEL) being reached.

Thermal Decomposition Products

All of the halocarbon replacement agents form higher levels of thermal decomposition products than Halon 1301 under similar conditions. For a given fuel, the two primary variables determining the level of decomposition products are (1) the size of the fire at the time of discharge and (2) the time required to reach an extinguishing concentration in the compartment.

The dependence of thermal decomposition product formulation on discharge time and fire size has been extensively evaluated [8, 42–45]. Figure 44.10 from Back et al. [42] is a plot of peak HF concentration as a function of fire size to room volume ratio. Similar data for

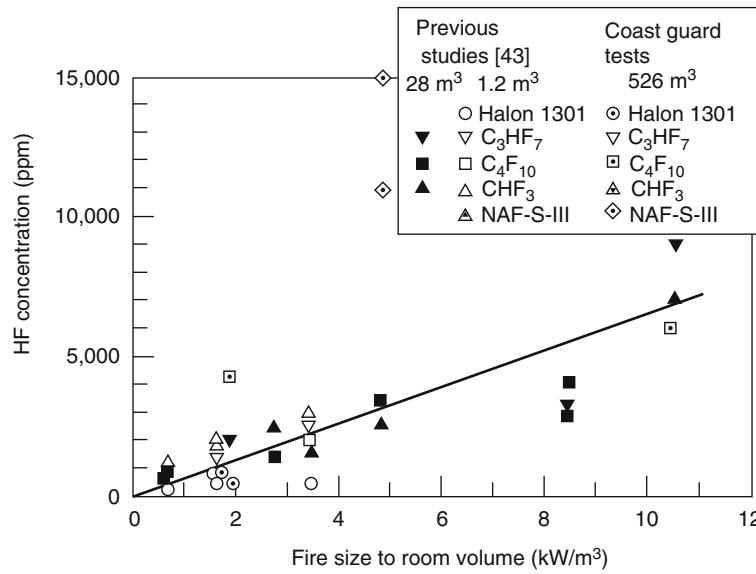

Fig. 44.10 Maximum HF concentration resulting from extinguishment of heptane fires with nominal 10–15 s total discharge times [42]

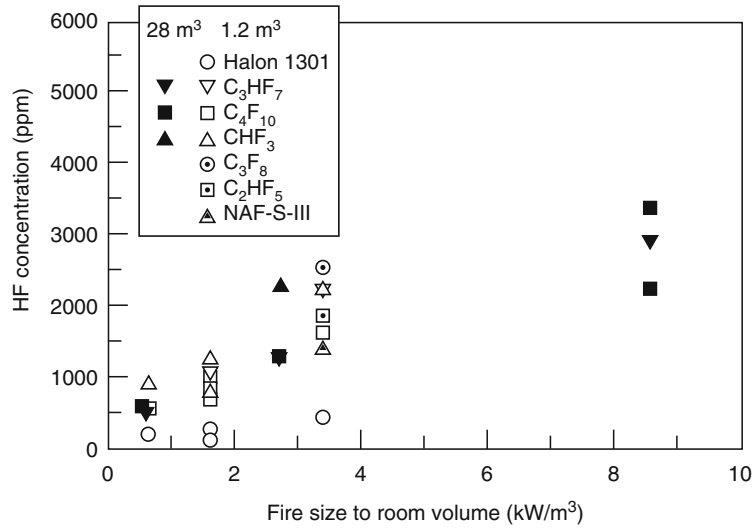

Fig. 44.11 Average HF concentration resulting from extinguishment of heptane pool or heptane pool and spray fires with nominal 15-s total discharge time [43]

10-min average HF concentrations are given in Fig. 44.11. Data are given for Halon 1301, HFC-23, HFC-227ea, FC-3-1-10, and HCFC Blend A from three series of fire tests done at different room scales. The data are for a total discharge time of 15 s, which is analogous to a 10 s discharge time based on nozzle liquid run-out. The data are for heptane pool or heptane pool and spray fires.

The first observation is that the quantity of HF formed is approximately 5–10 times higher for all halocarbon clean agents relative to Halon 1301. There may be differences among the various HFC/HCFC compounds tested, but it is not clear from these data whether such differences (1) occur, (2) are attributable to agent mixing and distribution, or (3) are attributable to locally high velocities or concentrations of agent from the nozzle. In all of the data reported, the fire source, that is, heptane pans of varying sizes, was baffled to prevent direct interaction with the agent jet.

The exception to the similarity of decomposition product formation among the Halocarbon clean agents is the higher concentrations resulting from tests with HCFC Blend A. This agent was tested at the manufacturer's recommended design concentration, which is approximately 40 % lower than the basis for all other agents, which would be expected to correlate with higher decomposition product formation [42].

These data were taken with an FTIR spectrometer at a location approximately 1 m from the floor, or about midflame height, near the wall. The method used was correlated to grab sample and ion-specific electrode (ISE) methods [43]. In all cases, the agreement was good, except for the HCFC blend. In this case, the HF concentration inferred from the treated grab sample was significantly (>50 %) higher than that measured using the FTIR. Since the HCFC blend contains an HF "scrubber," it is postulated that treatment of the grab sample with a basic solution, as required for the ISE measurements, caused formation of additional HF by reentry with F loosely bound up by reaction with the scrubber. Hence, the FTIR data presented for HCFC Blend A represent a significantly lower quantity of HF than would actually be expected if the product were hydrolyzed.

The effect of long discharge times or delayed extinguishing times is shown in Fig. 44.12 [43]. The variation between the HFC/HCFC alternatives and Halon 1301, relative to HF production, is approximately the same as that shown in Fig. 44.11 for different fire sizes.

Although other thermal decomposition products have been identified in some cases, it appears that HF is the primary thermal

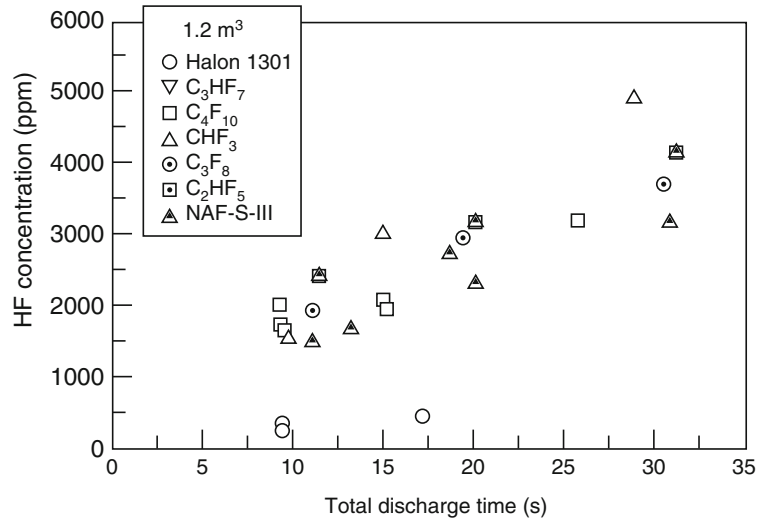

Fig. 44.12 Maximum HF concentration resulting from extinguishment of 4.0-kW heptane fires [43]

Table 44.19 Potential human health effects of hydrogen fluoride in healthy individuals [1]

Exposure time	Hydrogen fluoride (ppm)	Reaction
2 min	<50	Slight eye and nasal irritation
	50–100	Mild eye and upper respiratory tract irritation
	100–200	Moderate eye and upper respiratory tract irritation, slight skin irritation
	>200	Moderate irritation of all body surfaces, increasing concentration may impair escape
5 min	<50	Mild eye and nasal irritation
	50–100	Increasing eye and nasal irritation, slight skin irritation
	100–200	Moderate irritation of skin, eyes, and respiratory tract
	>200	Definite irritation of tissue surfaces, will impair escape at increased concentrations
10 min	<50	Definite eye, skin, and upper respiratory tract irritation
	50–100	Moderate irritation of all body surfaces
	100–200	Moderate irritation of all body surfaces, escape-impairing effects likely
	>200	Escape-impairing effects will occur, increasing concentrations can be lethal without medical intervention

decomposition product of interest relative to human safety and equipment damage. HF, like HCl, is an irritant gas, detectable at very low concentrations. For HF there are very large differences between the approximate lethal concentration (ALC) and human detection and severe sensory irritant thresholds (approximately 2 and 3 orders of magnitude, respectively).

The fire size necessary to generate short-term lethal concentrations of HF in an enclosure (on the order of >1000 ppm) can, in some cases, pose a greater hazard to personnel in the protected space during a discharge in a fire incident, due to the fire and its effects, than the secondary impact of agent thermal decomposition products. This effect, however, should be verified for a particular application under a range of fire scenarios, using engineering methods discussed by Hanauska [46] and Hanauska et al. [47].

The production of HF and other agent decomposition products forms a potential hazard for occupants. Table 44.19 [1] summarizes potential health effects in healthy individuals. Note that

exposures above 200 ppm may begin to impair escape, particularly at exposure times exceeding 5 min.

Emergency Response Planning Guidelines (ERPG) values, developed by the American Industrial Hygiene Association, for 10 min exposures, are as follows: ERPG-2, a level at which mitigating steps such as evacuation should be taken is 50 ppm, and ERPG-3, the maximum nonlethal exposure concentration for 10 min is 170 ppm. The ERPG values are in contrast to an analysis by Meldrum [48] which indicates that a dose of 12,000 ppm/min has 1 % lethality in exposed animals. Additional health-effect and risk-assessment data are given in Dalby [49], Machle and Kitzmiller [50], Machle et al. [51], and Brock [52].

The impact of thermal decomposition products on electronics equipment is another area of concern. There is not sufficient data at present to predict the effects of a given HF exposure scenario on all electronics equipment. Several evaluations of the impact of HF on electronics equipment have been performed relative to the thermal decomposition of Halon 1301, where decomposition products include HF and HBr. One of the more notable was a NASA study where the shuttle orbital electronics were exposed to 700, 7000, and 70,000 ppm HF and HBr [53]. In these tests, exposures up to 700 ppm HF and HBr caused no failures. At 7000 ppm, severe corrosion was noted; there were some operating failures at this level.

Dumayas exposed IBM-PC-compatible multifunction boards to environments produced by a range of fire sizes as part of an evaluation program on halon alternatives [54]. He found no loss of function of these boards following a 15-min exposure to postfire extinguishment atmosphere up to 5000 ppm HF, with unconditioned samples stored at ambient humidity and temperature conditions for up to 30 days. Forssell et al. [55], exposed multifunction boards for 30 min in the postfire extinguishment environment; no failures were reported up to 90 days post-test. HF concentrations up to 550 ppm were evaluated.

Although no generic rule or statement can be made at present, it appears that short-term damage (<90 days) resulting in electronics equipment malfunction is not likely for exposures of between 500 to 1000 ppm HF for up to 30 min. This result, however, is dependent on the characteristics of the equipment exposed, post exposure treatment, exposure to other combustion products, and relative humidity. Important equipment characteristics include its location in the space, existence of equipment enclosures, and the sensitivity of the equipment to damage.

All HCFC and HFC clean agents form more thermal decomposition products than Halon 1301, given similar fire sizes and discharge times. The primary variable controlling the quantity of thermal decomposition products is the size of the fire at the time of agent discharge. Through evaluation of the fire size at the time of system actuation, using engineering methods described in Chap. 40, and subsequent design of the detection system, the potential hazard posed can be managed adequately.

Hanauska [46] and Hanauska et al. [47] have indicated that the degree of thermal decomposition products of agents can be managed safely. Full-scale testing with typical Class A fuel packages, in conjunction with typical detection system installation [55], has shown that the level of thermal decomposition products is acceptable in typical computer/electronics spaces. For installation in hazard areas where very rapidly developing large fires are likely, the degree of thermal decomposition formation should be evaluated in the context of the hazard posed by the fire and the performance of alternative fire protection systems.

System Discharge Effects

When a clean agent system activates, liquid, gas or a two-phase discharge is introduced into the enclosure through a turbulent high velocity jet or spray via a nozzle. The well-known effects of system discharge, including over or under pressurization of the enclosure, and movement of loose objects have been dealt with to a large extent through system and hardware design.

In the case of compartment pressurization it is sometimes necessary to provide relief venting particularly in the case of the use of inert gases.

Another issue might also exist. It has been observed that in certain system configurations used in spaces with sensitive and high speed hard disc computer equipment, the discharge of the clean agent system may cause failure of some of the hard drives in the protected space [56–58]. This has occurred in at least one published case [56] and in this case an inert gas system was involved. It appears from work done by several manufacturers that the failures are caused by acoustic waves resulting from the noise of discharge interacting with hard disc drive storage devices and causing failure of the devices [57, 59]. The problem may be eliminated by the use of longer discharge times and potentially by modified nozzle designs.

Hydraulic Flow Characteristics

All halocarbon replacement agents exhibit two-phase flow behavior. Since all, except HFC-23, are used in cylinders pressurized to 360 or 600 psig, they are also multiple-component flows. Inert gas mixtures are single-phase gas flows with one or more components. As in the case of engineered Halon 1301 systems, all flow calculation procedures used must be listed as further described below or approved by the authority having jurisdiction and be within the limitations of the flow calculation method determined during the engineered system approval and listing process.

The characteristic that differentiates two-phase pipe flow from incompressible fluid (e.g., water) pipe flow is the existence of gas and liquid phases simultaneously in the pipe network. This aspect, coupled with the relatively short flow times, results in significant challenges in correctly predicting the flow. Among the important factors are the change in density of the fluid with pressure, the release of nitrogen in the cylinder and pipe as the fluid pressure and temperature change, differences in agent mass delivered caused by the flow time imbalances between nozzles, and preferential distribution of phases (and subsequently agent mass) at tee splits.

The need for accurate flow predictions is driven by three design requirements:

1. Control of agent discharge time
2. Maintenance of adequate nozzle flow and pressure to ensure agent distribution and mixing at the listed coverage area
3. Delivery of adequate, but not excessive, agent quantities to different rooms within the same protected area, when such rooms are flooded simultaneously.

In addition, agent flow rate and thermodynamic state properties are necessary for estimating compartment pressurization changes during agent discharge.

For pre-engineered systems, those having predetermined flow rates, nozzle pressures, and quantities of agent, limits on discharge time and nozzle pressure are built into the restrictions of piping system geometry. Agent distribution is handled by constraining pre-engineered systems to balanced flow conditions (i.e., the same agent mass is distributed from tee split and each nozzle). For adequate design of engineered systems, accurate methods for predicting these elements are required.

Figure 44.13 is an idealized plot of cylinder and nozzle pressure during discharge. Throughout the discharge process the amount of agent vapor and liquid, as well as dissolved and gaseous nitrogen, varies. As the pressure decreases in the cylinder and piping system, more agent is vaporized and nitrogen is released from the solution in the agent. The formation of additional vapor and nitrogen bubbles lowers the average density of the fluid. The rapid vaporization of agent is more pronounced in low boiling point/high vapor pressure agents. The fluid temperature also varies with time and along the length of the piping network. The fluid temperature also impacts the degree of agent vaporization and nitrogen release as well as liquid agent density. The discharge process can be divided into five sections.

The first is the process of filling the pipe with agent. The rate at which this process occurs is driven by the speed of the agent interface moving

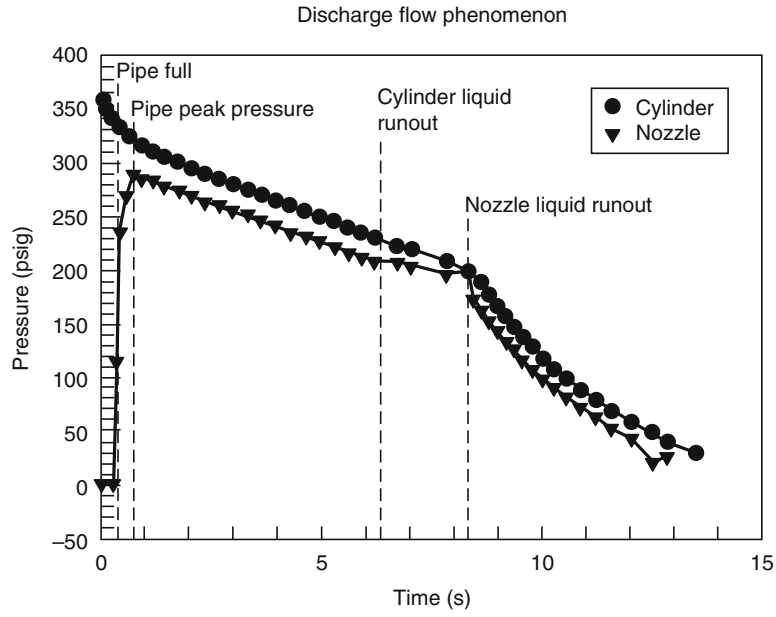

Fig. 44.13 Idealized cylinder and nozzle pressure time curves for halocarbon agents

through the network. This speed is determined by either the sonic velocity at the agent interface or the discharge of displaced air through the nozzle. This phase determines the time at which the agent starts to discharge from each nozzle. For systems with high degrees of imbalance in terms of flow path length or large pipe volume differences between nozzles, there can be significant delay in agent reaching one nozzle before another. This delay has a dramatic effect on the distribution of mass from each nozzle.

Once the agent reaches the nozzle and is compressed in the pipeline, the so-called nozzle peak pressure is reached. At this moment, agent is discharging from each nozzle.

The next step in the discharge process is the so-called quasi-steady agent flow regime. This step is generally the longest portion of the discharge, particularly for systems with low pipe volume to agent volume ratios. This period of the discharge process is the basis for the simplified pressure drop calculations embodied in NFPA 12A for balanced Halon 1301 systems [35].

The next milestone during the discharge process is cylinder liquid runout, where no liquid agent remains in the cylinder. At this moment, an interface between liquid-agent and nitrogen-agent vapor forms and travels through the network.

When the trailing liquid-vapor interface reaches the first nozzle, nozzle liquid run-out occurs. This run-out is important in two ways. First, liquid run-out occurs at different times during the discharge for each nozzle and can significantly impact the quantity of agent flowing from any given nozzle. Second, it is possible in many circumstances to discharge sufficient vapor-gas mixture from the first nozzle at NLRO (nozzle liquid run-out) to reduce the pressure in the piping below that necessary to flow the remaining agent in the network. This aspect is especially important for low vapor pressure agents and for nozzle designs requiring relatively high minimum operating pressures.

Once all of the nozzles have been cleared of liquid agent, the system is discharging a combination of nitrogen and agent vapor. This regime is usually ignored since most (>95 %) of the agent has already been delivered through the nozzles.

The importance of the pipe filling and nozzle run-out with these alternatives is relatively more critical with low vapor pressure alternatives due to (1) the inability of the agent to deliver significant pressure to the system by boiling and (2) the

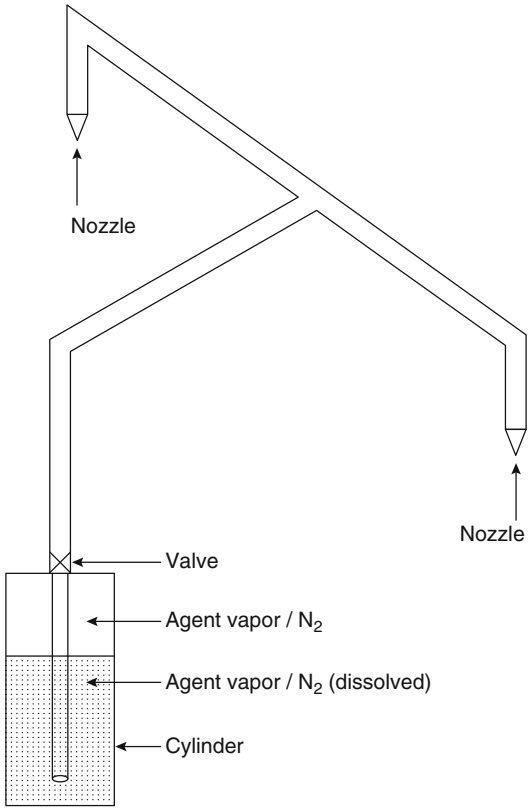

Fig. 44.14 Initial conditions

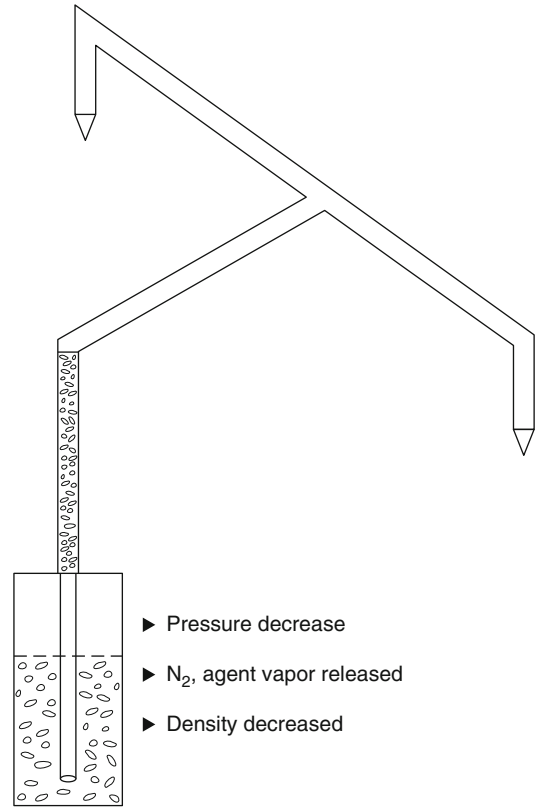

Fig. 44.15 Valve open, pipe filling

higher fluid densities that occur in the piping relative to Halon 1301.

Figures 44.14, 44.15, 44.16 and 44.17 illustrate the stages of the agent discharge network.

Flow Regime If the flow velocity of the agent in the piping is not high enough, the flow may separate into two distinct phases within the piping [60]. This phase separation causes rather unpredictable fluid behavior at tee splits and makes evaluating pressure drop in the piping system more challenging. Therefore, minimum flow rates that ensure a homogeneous mixture of liquid agent and vapor-nitrogen bubbles must be maintained. Various flow regimes are illustrated in Figs. 44.18 and 44.19 for horizontal and vertical pipe, respectively. One of the objectives of approval testing of flow calculation procedures is to ensure that homogeneous flow regimes are maintained in the piping throughout the clean agent discharge process. Figures 44.18 and 44.19 depict the dispersed-bubble and bubble-flow regimes, respectively.

Flow Division at Tees For a single-component (agent only, i.e. no dissolved nitrogen), single-phase flow condition, the flow split at a tee junction can be determined by the flow rate of the nozzles downstream of the tee. For two-phase fluids, flow distribution at the tees is sensitive to four physical conditions: (i) the velocity of the fluid flow along each branch of the tee, (ii) the orientation of the tee, (iii) the pressure at the tee, and (iv) the phase distribution of the fluid (gas or liquid) entering the tee.

The primary cause of preferential flow splits at tees is the inertia of the liquid versus vapor-gas phase. This condition is most readily envisioned for side-flow tees where one branch of the flow is required to turn 90°. Gas-vapor bubbles with lower momentum relative to the liquid agent will make this change of direction more readily.

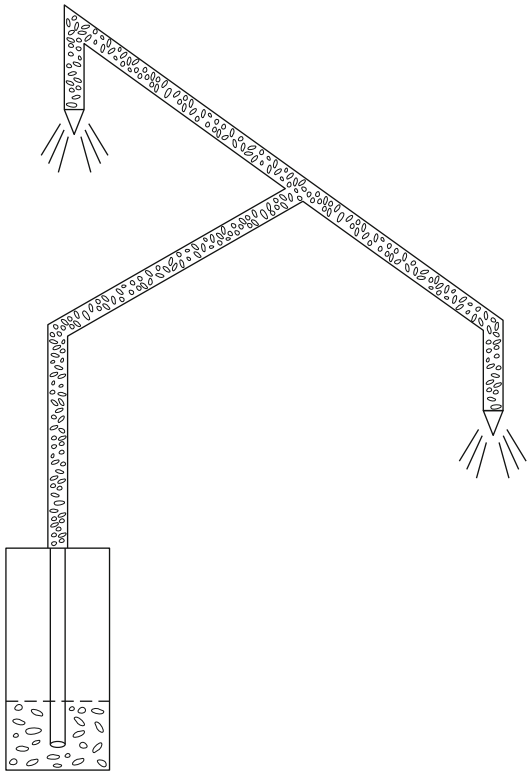

Fig. 44.16 Quasi-steady flow, liquid throughout network

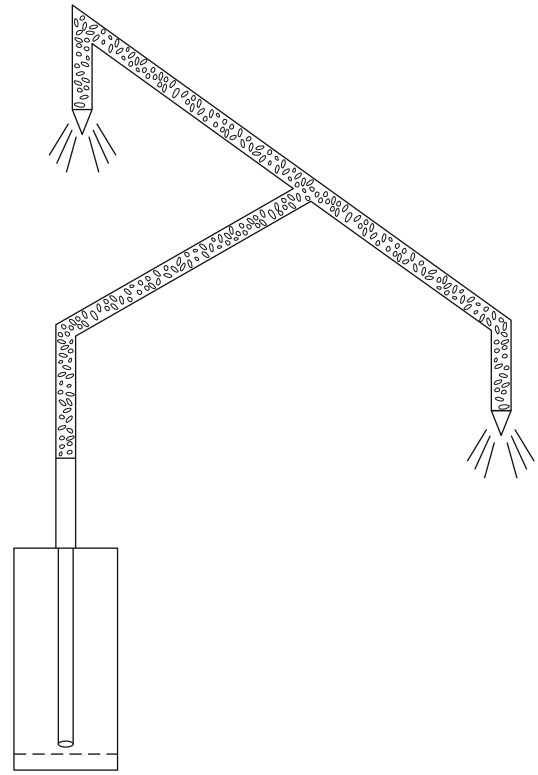

Fig. 44.17 Cylinder liquid runout

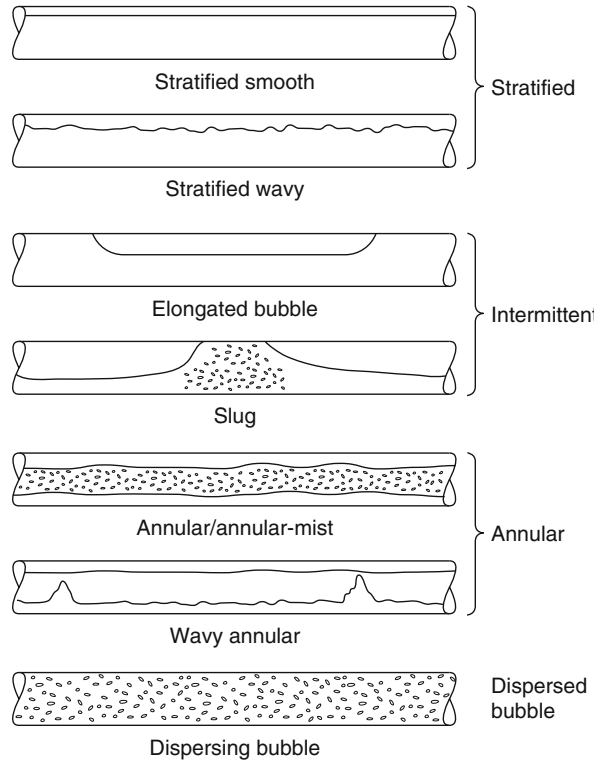
Fig. 44.18 Horizontal pipe flow regimes [60]



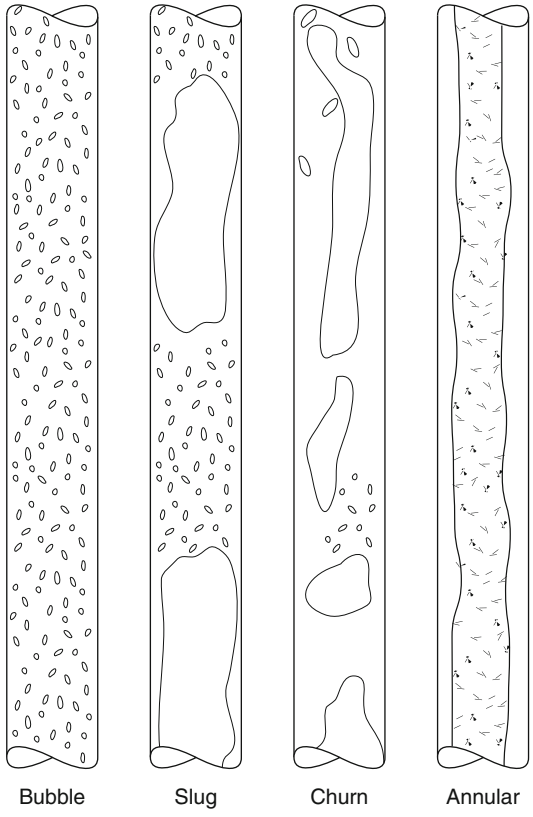


Fig. 44.19 Vertical pipe flow regimes [60]

This change results in relatively less mass flow down the side-flow branch at approximately the same volumetric flow rate or velocity. For bullhead tees, the same phenomenon occurs, except that it is more subtle and involves velocity differences through each branch of the tee. For evenly split (50%/50%) flows, the velocity is identical in both directions, resulting in no flow split correction; as the split becomes greater the velocity differences are greater, and inertial effects of the gas-vapor portion of the fluid relative to the liquid portion cause significant redistribution of mass through each branch of the tee.

The dependence was understood for Halon 1301 and described in detail by Williamson [61]. Similar processes occur in all two-phase flows including air-water, steam- water, and refrigerant flows. In the context of clean agent system design calculations, this flow distribution is dealt with using empirical factors that redistribute the flow relative to the pure pressure-driven flow distribution that would occur without preferential phase distribution at tees.

Figures 44.20 and 44.21 illustrate these correction factors for Halon 1301 flows in bullhead and side-flow tees, respectively [61]. All of the

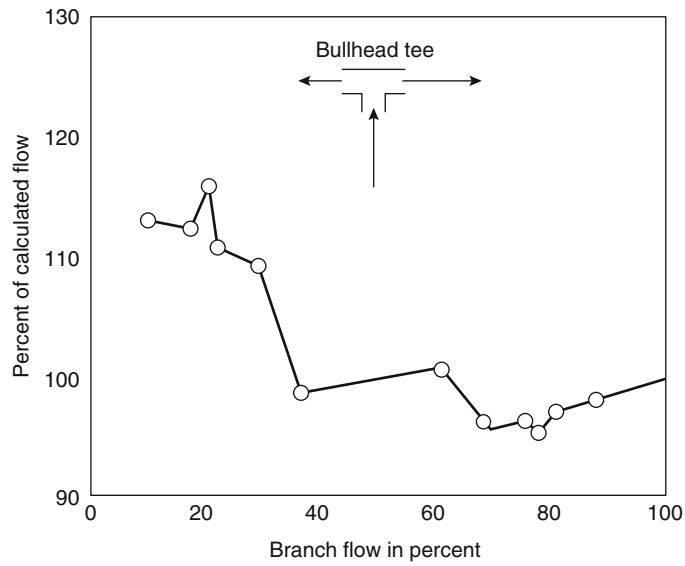

Fig. 44.20 Bullhead-tee-flow split corrections for Halon 1301 [61]

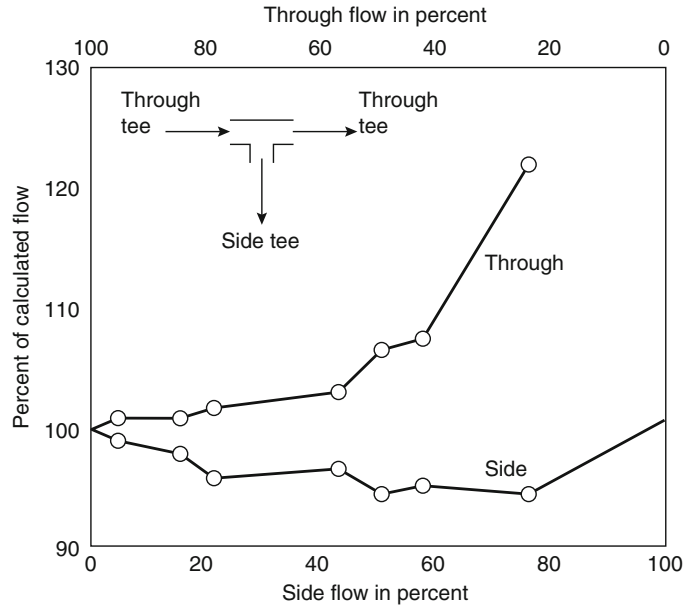

Fig. 44.21 Side- and through tee-flow split corrections for Halon 1301 [61]

halocarbon agent flow predictions require similar treatment. Side-flow tees and bullhead tees require independent empirical correction factors. One of the most important limitations to any flow calculation procedure is the maximum flow split allowed for each type of tee. For a bullhead tee, as one moves farther away from 50%/50% splits, the correction factor becomes greater, and at some point usually in the range of 80%/20%, it becomes so large that the prediction becomes unreliable. For side-allowable flow splits, ranges between 75%/25% and 90%/10% are typical. This correction of flow splits at tees is one reason that final approval of engineered system designs should be constrained to calculation methods that have undergone testing within the range of the flow splits required.

Pressure Drop due to Friction Loss The pressure drop caused by friction in the pipeline is calculated differently for two-phase fluids. The presence of agent vapor and gas affects the pressure drop per unit length of pipe. There are numerous methods for dealing with two-phase fluid pressure drop [62, 63]. Those typically used for fire suppression agent calculations involve either (1) correcting the pressure drop estimated for single-phase fluid as a function of liquid to vapor-gas volume fraction or (2) empirical correlations of the pressure drop to average fluid density. Figure 44.22 illustrates the dependence of pressure drop on liquid volume fraction. In all cases for purposes of design of fire protection systems, the pressure drop is calculated on the basis of a homogeneous flow assumption where changes in the liquid fraction are seen as density changes in the homogeneous fluid.

Testing and Approval of Design Methods The approval or listing of a two-phase flow calculation procedure is part of the overall approval necessary for engineered systems. Since some aspects of two-phase flow calculations are empirically based (e.g., flow regime, pressure drop, and flow splits) and all calculation procedures have some bounds on their validity, testing is performed to verify the predictions and establish the limits of the calculation procedure. These calculation procedure limitations are crucial in helping to ensure overall adequacy of system designs.

One of the most rigorous approval procedures used in verifying design calculation methods for clean agent systems are outlined in UL 2127, *Inert Gas Clean Agent Extinguishing System Unit* [12] and in UL 2166, *Halocarbon Clean*

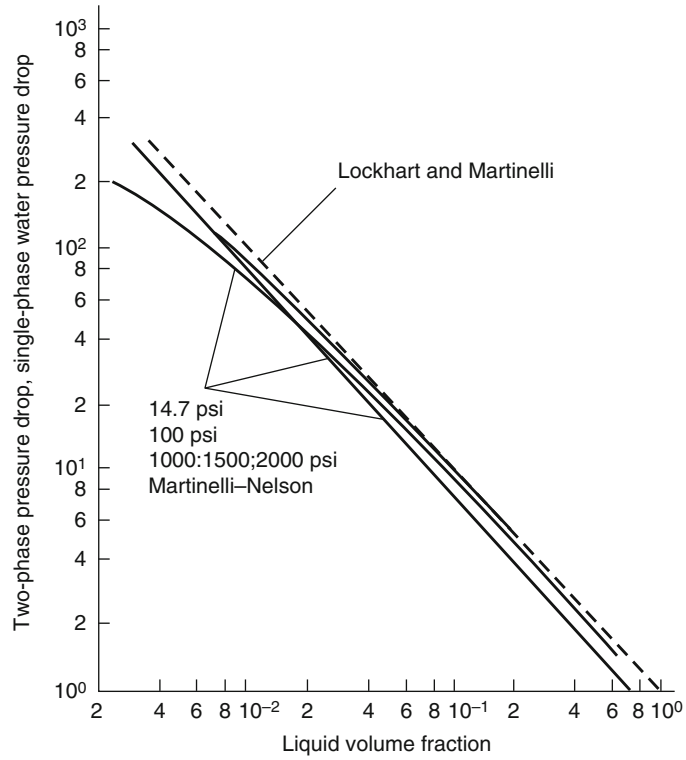

Fig. 44.22 Pressure drop versus liquid volume fraction [62]

Agent Extinguishing System Units [13]. Design method limitations are described by the following 10 parameters:

1. Percentage of agent in piping (maximum)
2. Minimum and maximum discharge times
3. Minimum pipeline flow rates
4. Variance of piping volume to each nozzle
5. Maximum variance of nozzle pressures within a piping arrangement
6. Maximum ratio of nozzle diameter to inlet pipe diameter
7. Arrangement most likely to exhibit vapor time-imbalance condition at nozzle
8. All types of tee splits, including through tees, bullhead tees, and so forth
9. Minimum and maximum container fill density
10. Minimum and maximum flow split for each type of tee.

These parameters are related to the important attributes of the agent discharge process previously discussed. Full-scale testing is performed to evaluate the performance of the design method. The limits on flow calculation method performance are as follows:

1. Actual versus predicted discharge time ±1 s for halocarbon agents and ±10 s for inert gas agents
2. Actual versus predicted nozzle pressure ±10 %
3. Actual versus predicted mass flow through a nozzle, ±10 %

The flow calculation method testing is performed with the specific manufacturer's hardware to ensure that the flow through the hardware is modeled correctly.

Several generic flow calculation routines have been developed [43, 64–67]. Of these, two are directed at single-nozzle systems with very short discharge times [66] or relatively simple balanced networks [65]. It is not recommended that any generic calculation procedure be used for final design purposes unless the procedure has been tested with the specific hardware to be installed, and system performance is within the limitations derived by testing.

In order to preserve a 10 s discharge time, the mass flow rate of these clean agents must be higher than Halon 1301. The increased density of some of the clean agents in the piping, caused by lower vapor pressures and nitrogen solubility differences, may result in high enough mass flow rates to retrofit existing Halon 1301 systems. Although agent cylinders and nozzles will require replacement, it is possible to preserve the existing Halon 1301 pipe network. Preservation often requires the use of lower fill density cylinders to increase the average system pressure throughout the discharge time. Any retrofit using existing Halon 1301 piping must be prudently evaluated with respect to hydraulic performance, with particular attention given to preserving the minimum required nozzle pressures and flow divisions at tees.

Nozzle Area Coverage and Height Limitations

One of the most important requirements of a gaseous total flooding fire suppression system is the ability of the system to deliver a uniform concentration of agent throughout the protected enclosure within the discharge period. The nozzle design and minimum nozzle discharge pressure are critical in ensuring this distribution of agent. The performance of the nozzle is evaluated by full-scale testing, such as through UL 2127 [12] and UL 2166 [13]. The basic testing performed to evaluate nozzles is as follows:

1. Establish minimum nozzle pressure and maximum nozzle height by ensuring extinguishment of heptane fires located throughout a space with a height equal to the maximum allowable, at the minimum allowable nozzle pressure.
2. Establish maximum nozzle coverage area by extinguishing tests in a plenum at the minimum height (generally less than 0.5 m) at the maximum nozzle coverage area (on the order of 100 m^2) and minimum nozzle operating pressure.

There are substantial differences among hardware manufacturers relative to minimum nozzle pressure, maximum ceiling height, and maximum average cover- age. All nozzle anticipated orientations should be evaluated. In general, maximum nozzle heights are on the order of 4–5 m, nozzle area coverage on the order of 90–100 m^2, and minimum nozzle pressure between 3 and 6 bar. It is critical to ensure that the nozzle spacing, height, and minimum pressure limits are not exceeded for a particular manufacturer's hardware in a specific design.

The flow, mixing, and distribution of an agent from a nozzle into an enclosure can be predicted theoretically for relatively simple nozzle designs using sophisticated computer models [65]. Further development of such methods for complex nozzle designs and compartment geometries could eventually form the basis of a design procedure. At present, however, the primary means of ensuring adequate nozzle performance is the hardware approval process and real-scale testing.

Since many of the halocarbon agents have lower vapor pressures than Halon 1301, there is often a much higher percentage of liquid at the nozzle. This liquid makes the task of vaporizing and mixing the agent in the compartment more difficult. In general, nozzle designs used for Halon 1301 systems are not adequate for the halocarbon replacement agents. Due to the increased liquid fraction at the nozzle, it is critical to ensure that no unenclosed openings exist along the trajectory of the nozzle orifices. Increased liquid fraction may result in significant preferential loss of agent through these openings. This condition further emphasizes the need for third-party approval testing and listing of nozzle performance. In any retrofit situation including those of other types of clean agent systems and Halon 1301 systems, the nozzles will need to be replaced even if the piping is adequately sized to deliver proper agent flow rates.

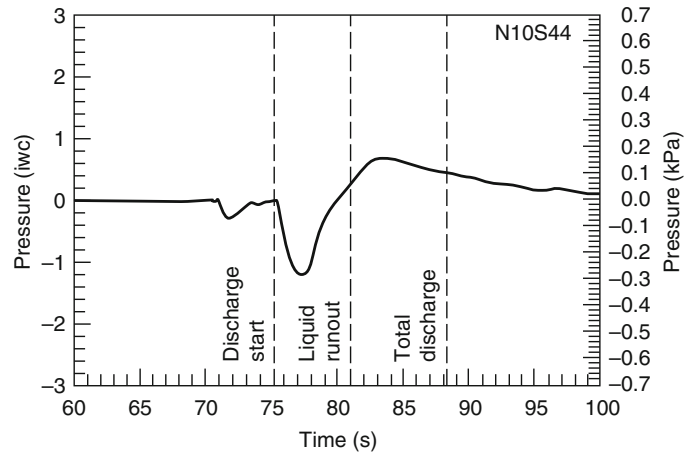

Fig. 44.23 Pressure measured in 28 m^3 enclosure during HFC-227ea (C_3F_7H) discharge, with nominal 15 s discharge time and 5 cm pan of n-heptane [43]

Compartment Pressurization

The rapid discharge of agent into a compartment will cause rapid changes in the compartment pressure. Depending on the agent and rate of discharge, the initial pressure change may be negative. Figure 44.23 is a plot of compartment pressure versus time for the discharge of HFC-227ea into a 28 m^3 room with a 360 cm^2 (56 $in.^2$) leakage area [43]. Immediately after discharge, the pressure in the compartment drops below ambient to a minimum of −0.3 kPa; at approximately 1.5 s after discharge, the pressure then begins to increase to a maximum of approximately 0.14 kPa after nozzle liquid run-out. Similar results were obtained for FC-3-1-10. HFC-23 discharge exhibited much higher compartment overpressurization, without the marked initial negative pressure. The maximum overpressure for HFC-227ea and FC-3-1-10 discharge was similar to that of Halon 1301.

As the halocarbon agent is discharged into the space, it vaporizes rapidly, cooling the compartment and lowering the pressure. As the agent-air mixture gains heat from the walls or other objects in the space, the pressure recovers and, as additional agent is added, the pressure increases over ambient as mass is added to the compartment.

The expected maximum and minimum compartment pressure during discharge will be a function of the following:

1. Thermodynamic state of the agent at the nozzle
2. Nozzle design
3. Compartment volume and wall surface area
4. Size of fire
5. Initial conditions in space
6. Leakage area from compartment
7. Agent flow rate

For inert gases, significant compartment overpressurization can occur during discharge unless adequate free vent area is provided. Calculation of required open area for venting is a part of the design manual for inert gas systems as for IG-541 systems [68].

No generalized design procedure for calculating under/overpressurization has been established. Forssell and DiNenno [43] have developed a procedure for estimating the compartment pressure as a function of agent, agent flow rate, agent thermodynamic state at the nozzle, compartment volume, and surface area and leakage area. However, the method has not been sufficiently tested for general application. The Fire Suppression System Association, FSSA, has developed a guide for estimating the pressure relief vent areas for preventing damage to enclosures during the discharge of clean agent

systems [69]. The guide is based on empirical correlations developed during a experimental research program.

Agent Hold Time and Leakage

Traditionally, total flooding gas systems were required to maintain a minimum concentration for a specified time period (10–20 min) after discharge. The minimum required hold time was based on the following:

1. Soak time required for deep-seated Class A fuels
2. Response time of emergency personnel
3. Prevention of re-flash of the fire due to the presence of hot surfaces, electrical energy and other reignition sources, particularly with flammable and combustible liquid applications.

The absolute minimum hold time requirement is 10 min. The variables described above will vary between installations, and there is no significant database on the performance of these agents on deep-seated fires other than wood cribs. The designer will be required to specify the minimum soak time consistent with the requirements of the hazard being protected.

The ability of a compartment to maintain adequate agent concentrations is a function of the leakage of the compartment. Historically, this was done with Halon 1301 through the use of discharge tests. Discharge testing for this purpose was rendered unnecessary by the introduction of door fan pressurization leakage tests.

The only difference between alternative agents and Halon 1301 in this regard is the density of the agent-air mixture, which is the driving force for leakage in quiescent environments. The mixture density can be estimated as follows [1]:

$$\rho_m = V_d \frac{C}{100} + \left[\frac{\rho_a(100 - C)}{100}\right]$$

where:

ρ_m= Clean agent-air mixture density (kg/m^3)

ρ_a= Air density (1.202 kg/m^3)

C = Clean agent concentration (%)

V_d = Agent vapor density (kg/m^3)

Agent vapor densities are given below:

FC-3-10	$9.85\,kg/m^3\,(0.615\,lb/ft^3)$
HBFC-22B1	$5.54\,kg/m^3\,(0.346\,lb/ft^3)$
HCFC-Blend A	$3.84\,kg/m^3\,(0.240\,lb/ft^3)$
HFC-124	$5.83\,kg/m^3\,(0.364\,lb/ft^3)$
HFC-125	$5.06\,kg/m^3\,(0.316\,lb/ft^3)$
HFC-227ea	$7.26\,kg/m^3\,(0.453\,lb/ft^3)$
HFC-23	$2.915\,kg/m^3\,(0.182\,lb/ft^3)$
IG-541	$1.43\,kg/m^3\,(0.089\,lb/ft^3)$
Halon 1301	$6.283\,kg/m^3\,(0.392\,lb/ft^3)$

All agents, except inert gases, have higher mixture densities than Halon 1301 at 5 % when used at their design concentrations requiring slightly more leak-tight enclosures to maintain the same hold time.

There are several methods available to estimate the hold time of gaseous agent mixtures based on leakage measured by the door fan pressurization method. The first method, initially developed by DiNenno and Forssell [70] and Grant [71], modeled the leakage of a gas-air mixture from a compartment as a two-layer system with a uniform gas-air mixture below a sharp interface and air above the interface. In this idealization, the gas-air mixture leaks out of the bottom of the room and the inter-face descends with time much like a draining bathtub. This method is standardized in NFPA 2001. The interface is modeled as remaining well defined throughout its descent. Spreading of the interface due to diffusion and localized mixing is ignored. Another idealized case treated by DiNenno and Forssell [70] is the case of a uniform mixture of gas and air across the height of the room in which the uniform concentration decays with time as air leaks in and gas-air mixture leaks out. This case is the so-called "uniform mixing" case.

Dewsbury and Whitely [72, 73] also proposed a treatment of a widely spreading interface. In this idealization there are two "zones" in a compartment. At the ceiling, the agent concentration is assumed to be zero and over time a zone where the agent concentration increases from zero at the ceiling to the initial agent concentration at the interface boundary exists. This so-called

spreading interface increases in depth as the agent-air mixture leaves from the bottom of the room. This method is embodied in ISO 14520 and is more conservative than the other methods. Additional refinements to the spreading interface modeling approach have been proposed by Hetrick et al. [74].

A key difference between this wide interface case and the sharp interface case is that the position within the spreading interface, where the agent concentration falls below 70 % or 80 % of the design concentration, is defined to be the position in the room above which the agent concentration is inadequate. In the sharp interface case this position would occur when the agent concentration is 50 % of the initial value (assuming a non-sharp interface actually occurred). Consequently, the allowable leakage will be significantly less than that permitted using the sharp interface model in NFPA 2001. The full-scale data obtained by Dewsbury and Whitely [72, 73] and Klocke [75] for inert gas mixtures indicate widely spreading interfaces are typical.

Additional refinements relying much more on empirical data on interface spread and refinements in the estimation of leakage area were added to the provisions of NFPA 2001.

All of these leakage area measurement methods and leakage calculation estimates are approximate since the precise size and location of the leakage paths are never know. Based on a range of full-scale idealized experiments it appears that the hold time or retention calculations are likely conservative.

Summary

A range of inert gas and halocarbon total flooding clean agents are available. The use of an agent must be consistent with applicable environmental and toxicity regulations. The selection of an agent is driven by its fire performance characteristics, agent and system space and weight concerns, toxicity (particularly for use in occupied areas), and the availability of approved system hardware.

The design of clean agent systems must be thoroughly completed in accordance with third-party listing and approval limitations on the agent, distribution hardware, and hydraulic calculation procedure. Given the specialized knowledge associated with these types of fire protection systems, particular care in the design, installation, inspection, testing, and maintenance of these systems is warranted. It is important to recognize that fire protection standards, such as NFPA 2001, form the minimum requirements for these clean agent technologies.

In the case of all clean agents, system designs are much less robust than those for Halon 1301 systems. Of particular concern is the application of inadequate or unjustified design concentrations particularly where energized electrical equipment is used or deep-seated fires are a concern. Designers and users are encouraged to investigate the means by which the design concentrations are established and consult the ISO 14520 standard for more conservative design concentration requirements.

Carbon Dioxide Systems

45

Jeff Harrington and Joseph A. Senecal

Introduction

Carbon dioxide (CO_2) fire extinguishing systems have been in use continuously since the early 1900s. The National Fire Protection Association (NFPA) first published its design standard on carbon dioxide extinguishing systems in 1929. Since this time, carbon dioxide extinguishing systems have gained wide acceptance around the world, and have successfully protected fire hazards in a large variety of configurations and locales, including in land-based industrial environments, and on ships and mobile drilling platforms at sea. Carbon dioxide is electrically non-conductive and, when used at concentrations recommended in design standards, extinguishes fires relatively quickly leaving no residue.

The health risk associated with carbon dioxide extinguishing systems is notable. Carbon dioxide is lethal at the minimum design concentrations (vol.%) required by the various design standards over relatively short durations of exposure. Death occurs from a severe reduction of oxygen in the blood due to hypercapnia. During the long history of carbon dioxide use in fire extinguishing systems, numerous fatal accidents have occurred, especially during the maintenance and testing of the systems. However, the risk of exposure to carbon dioxide resulting from CO_2 system discharge can be effectively managed.

This chapter provides useful information about the design and safe use of carbon dioxide in fire extinguishing systems to protect industrial and marine fire hazards. There are numerous design standards currently in use. No attempt is made to duplicate all of the information contained in those standards. The intention is to supplement and clarify some of the critical concepts these standards address.

Range of System Configurations

Carbon dioxide fire extinguishing systems are most commonly arranged in either of two configurations: total flooding or local application. The appropriate configuration choice is dependent on the nature of the hazard being protected. In both cases, a stationary, connected supply of carbon dioxide is attached to a fixed network of pipes and discharge nozzles that deliver carbon dioxide to the hazard location and discharge it within, on, or about the protected volume, surface, or area in a manner designed to accomplish fire extinguishment or suppression. Either system configuration can be designed to operate automatically and manually, or manually-only.

Carbon dioxide is also used in manual hose applications. The most common configuration consists of a stationary, connected supply of

carbon dioxide attached to a fixed network of pipes and manual hose stations.

Carbon dioxide can also be configured with a fixed pipe network known as a standpipe system, which does not have a stationary, connected supply of carbon dioxide attached to it. The carbon dioxide supply is a mobile supply on a cart or truck designed to be towed or driven to the scene and quick-connected to the standpipe system for delivery to the protected hazard.

Total Flooding

A total flooding system discharges carbon dioxide into an enclosure that surrounds the hazard. For example, the enclosure may be the walls, floor and ceiling that form a room, which houses electrical switchgear, flammable liquids storage, or paper archival records. Carbon dioxide is discharged into the enclosure in such a manner that promotes mixing of the enclosure atmosphere, achieving a relatively uniform pre-determined concentration of carbon dioxide throughout the enclosure to achieve extinguishment or suppression of the fire. No matter where the fire is located within the enclosure, it will be extinguished or suppressed by a total flooding system.

Local Application

A local application system discharges carbon dioxide directly onto a hazard that is not surrounded by an enclosure. Two design approaches are used as determined by the spatial orientation of the hazard. Relatively flat, two dimensional hazards where the fire will be of the surface type are protected by rate-by-area local application systems. Three dimensional hazards where the fire will be of the surface type are protected by rate-by-volume local application systems.

Extended Discharge Duration

Extending the duration of carbon dioxide discharge is a strategy that can be incorporated into the design of both total flooding and local application systems where the initial discharge of agent cannot be retained about the hazard long enough to ensure fire extinguishment. This approach is important when the nature of the environment surrounding the hazard allows excessive dissipation of the initial carbon dioxide discharge.

Hand Hose Line System—Fixed Supply

A fixed-supply manual hose system discharges significantly more carbon dioxide through the hand-held hose and nozzle than a hand portable or wheeled carbon dioxide fire extinguisher unit. Each manual hose station consists of a length of hose attached to the fixed pipe network equipped with a discharge nozzle [1]. The hose and attached nozzle are commonly stored on a hose reel or a rack. This system of manual hose stations is used to supplement fixed total flooding or local application systems, or as the sole form of protection for a hazard where fixed total flooding or local application system are deemed unsuitable.

Standpipe System—Mobile Supply

Such a system can be arranged as a total flooding or local application system, and manual hose stations may or may not be employed. The carbon dioxide supply is typically not attached to the pipe network, but is transported to the site using a trailer or truck and attached to the standpipe system using a quick-connect coupling. A mobile supply arrangement can also be used as a non-connected reserve to supplement a connected supply.

Range of Applications

Carbon dioxide has been in use since the early 1900s to protect a wide variety of special fire hazards. One study reports that approximately 20 % of all fire protection applications are considered special hazards, where the use of an automatic sprinkler system is not the best

solution, and about 20 % of the protected special hazards are protected by carbon dioxide systems [2].

Between the 1920s and 1960s, carbon dioxide was the only gaseous fire extinguishing agent commercially available. In the late 1960s, halon 1301 was commercialized and grew in popularity as the preferred gaseous agent for total flooding applications where human exposure was probable, such as in normally occupied spaces. There was a corresponding reduction in the use of carbon dioxide systems for these types of applications.

Halons were found to be potent depleters of stratospheric ozone and were targeted for a phased reduction in production and import by the US Clean Air Act, as amended in 1990. Subsequent rulemaking by the EPA established January 1, 1994 as the date to complete this phase-out [3]. Since the halon phase-out, the decline in the use of carbon dioxide in fire extinguishing systems reversed in some use sectors, most notably the marine sector [4].

Classification of Fire Hazards

One system used to classify various fire hazards is found in NFPA 10, *Standard for Portable Fire Extinguishers* [5]. Fire hazards are grouped into five distinct classes, shown in Table 45.1.

Class A Fires and Type of Burning Fires in ordinary combustible materials, such as wood, cloth, paper, rubber, and many plastics are Class A fires. Class A fuel arrays may burn with a predominant surface flame and negligible smoldering combustion. This type of fire is often referred to as a Class A surface fire. Materials made of plastic or rubber often produce Class A surface fires. A surface flame propagates in the gas phase in close proximity to the fuel surface, but not actually in contact with it [6]. Heat from the flame vaporizes the solid or liquid fuel just ahead of the flame front. The flame then ignites the vaporized fuel at the lower limit flammability of the vapor mixture, and the flame advances. The spreading flame vaporizes more solid or liquid fuel and the process continues. Surface-type flame spread can also occur in liquid-fuel fires (Class B).

In Class A fuel arrays that are comprised of cellulosic material in fibrous or particulate form, smoldering may be the predominant form of combustion, either in the absence of any surface flaming, or after the surface flaming has subsided. Wood, pressed fiber insulation board, corrugated paper board, paper, and natural textile fabrics are examples of cellulosic materials or products that will produce significant smoldering combustion. Smoldering is a form of combustion without flame that occurs in fuel that is comprised of finely divided fibers or particles that have a relatively large surface area to mass ratio [7]. Smoldering combustion is commonly referred to as deep-seated combustion. The fuel aggregate must be permeable allowing oxygen transport to the combustion reaction zone below the surface of the fuel. The fuel aggregate must also be dense enough to form an effective insulation layer that slows down heat losses from the reaction zone. Smoldering combustion can occur only in solid fuels.

Class C Fires Fires that involve energized electrical equipment are Class C fires. Examples of Class C fire hazards include telecommunication switches, satellite uplink transmitters, data

Table 45.1 Fire classification and fuel

Fire classification	Fuel
Class A	Ordinary combustible materials, such as wood, cloth, paper, rubber, and many plastics
Class B	Flammable liquids, combustible liquids, petroleum greases, tars, oils, oil-based paints, solvents, lacquers, alcohols, and flammable gases
Class C	Energized electrical equipment
Class D	Combustible metals, such as magnesium, titanium, zirconium, sodium, lithium, and potassium
Class K	Combustible cooking media (vegetable or animal oils and fats)

processing equipment, and industrial process control rooms. When a fire in such hazards results in a planned interruption of power to the equipment, the fire classification is immediately converted from a Class C to a Class. A-type hazard. The polymeric materials used in electric cable insulation and printed circuit boards are inherently Class A materials. When these materials burn, the flame is predominantly a surface burning phenomenon. Class C hazards with combustibles in dense configurations can promote smoldering combustion due to restricted air circulation combined with a relatively large fuel surface area.

Carbon Dioxide Suitability

Carbon dioxide is effective in extinguishing fires in Class A, Class B, Class C, and Class K fire hazards. Where surface type burning is expected, carbon dioxide in both total flooding and local application configurations is effective. For smoldering type combustion, only total flooding should be used because the design concentration of carbon dioxide must be maintained for at least 20 min.

Carbon dioxide is not suitable as an extinguishant for Class D fire hazards [8]. Carbon dioxide is not effective in extinguishing fires involving combustible metals (e.g., aluminum, magnesium, titanium, zirconium), alkali metals (e.g., lithium, potassium, cesium), and metal hydrides [9]. Use of carbon dioxide to extinguish fires in these materials is ineffective, and in some cases can accelerate the fire, making it more severe [10].

Carbon dioxide is also not suitable as an extinguishant for materials that contain and release oxygen when they burn, such as cellulose nitrate [8].

Industrial Applications

Carbon dioxide extinguishing systems can be designed and configured to effectively protect a wide range and variety of fire hazards. The types of applications that are suitably protected by carbon dioxide systems are virtually limitless. A single document listing all possible industrial applications may not exist. Numerous documents were reviewed that contain authoritative information about common carbon dioxide system applications [1, 2, 8, 11–14]. The following list, which is not all exhaustive, was compiled from the information contained in these documents.

- Battery storage rooms
- Cable trays
- Cargo areas (aircraft)
- Coal storage silos
- Computer room subfloor spaces
- Control rooms, industrial process
- Dip tanks
- Dryers
- Dust collectors
- Electrical cabinets
- Electrical rooms (motor control, switchgear, transformers)
- Flammable liquid/gas storage rooms and lockers
- Industrial fryers (fryers, cookers, roasters)
- Lube oil pits
- Mixing tanks
- Ovens
- Paint spray booths
- Particle board chippers
- Printing presses
- Quench tanks
- Records storage rooms
- Rolling mills
- Transformers (high voltage)
- Turbine generators
- Vehicle parking areas
- Wave solder machines
- Wet chemistry benches

Marine Applications

Carbon dioxide fire extinguishing systems are used extensively in a wide range of marine applications, including cargo, passenger and tank vessels, as well as mobile offshore drilling units. These marine environments contain a myriad of fire hazards which are required by the applicable governing regulations to be protected

by fixed fire extinguishing systems. Carbon dioxide fire extinguishing systems are identified by these regulations as acceptable for many types of marine fire hazards.

Marine vessels involved in international commerce are regulated by Safety of Life at Sea (SOLAS), 1974, as amended, and promulgated by the International Maritime Organization (IMO). Fire protection requirements are included in Chapter II-2 of that document which is titled Fire Protection, Fire Detection, and Fire Extinction [15, 16].

Marine vessels are subject to the rules and regulations of the flag administration under which they are registered, and in addition, for commercial vessels, the vessel's classification society [12].

United States-flagged commercial vessels fall under the jurisdiction of the United States Coast Guard, Department of Homeland Security (USCG). The fire safety regulations enforced by the USCG are contained within the Code of Federal Regulations (CFR) under Title 46, Shipping [15, 17].

American Bureau of Shipping (ABS) is the second largest classification society in the world based upon tonnage [18]. Based in Houston, TX, ABS is the classification society generally used by U.S. manufactured and flagged vessels [12]. ABS publishes rules for constructing vessels of various types and contain detailed requirements covering the application and design criteria for fixed gas fire extinguishing systems, including carbon dioxide. For example see Rules for Building and Classing Steel Vessels, Jan. 1, 2013, Part 4, Chap. 7 [19].

Carbon dioxide fire extinguishing systems are commonly used in total flooding configurations to protect marine vessel fire hazards in the following locations:

1. Cargo Holds
2. Cargo Pump Spaces
3. Electrical Spaces (e.g., electrical propulsion, power generation, power distribution)
4. Machinery Spaces (e.g., engines, pumps, oil-filling stations, heating-ventilating-air condition equipment)
5. Paint and Flammable Liquid Storage Lockers
6. Vehicle Spaces (e.g., automobiles, other self-propelled vehicles)

Characteristics of Carbon Dioxide

Carbon dioxide, which depending upon its physical form and chemical make-up, may also be referred to as carbon anhydride, carbonic acid gas, carbonic anhydride and dry ice. Carbon dioxide has certain characteristics that make it well suited for use as a fire extinguishing agent both in manual firefighting equipment and automatic fire protection systems. It is a gas at atmospheric pressure and the full range of ambient temperatures likely to be encountered when there is a need to suppress a fire. Carbon dioxide does not leave a residue, will not chemically react with the fire, or with objects in the environment being protected, and is electrically nonconductive. Most fires will be extinguished when carbon dioxide is supplied in sufficient quantity to the flame zone. These and other favorable characteristics of carbon dioxide are shown in the following list:

1. Gaseous form at atmospheric pressure and expected range of ambient temperatures
2. Is an effective fire extinguishant
3. Does not leave a residue
4. Is not corrosive or otherwise reactive
5. Is electrically non-conductive
6. Its own vapor pressure provides sufficient discharge force
7. It is widely available
8. It is relatively inexpensive

Carbon dioxide also has certain detrimental characteristics that must be carefully accounted for in system design to effectively mitigate them. These include:

1. Is lethal at fire extinguishing concentrations
2. Discharge can create conditions leading to electrostatic charging
3. Discharge can create high sound pressure levels
4. Discharge can create disruptive turbulence

5. Discharge can create harmful pressure changes within an enclosure

Fire Extinguishing Mechanisms

The discharge of carbon dioxide into air results in two effects: (1) a decrease in oxygen concentration, and (2) an increase in the heat capacity per mol of available oxygen. Understanding the latter point is central to understanding how gaseous agents contribute to flame extinction. The combustion of oxygen and ordinary carbonaceous fuels releases heat at the rate of approximately 406 kJ per mol of oxygen consumed. In the adiabatic case (no heat loss), that heat must be absorbed by the combustion product gases resulting in a rise in temperature. The stoichiometric combustion of a hydrocarbon fuel and air results in an adiabatic flame temperature of about 2400 K. As the concentration of carbon dioxide added to air increases, the flame temperature decreases because the total thermal mass per unit mass of oxygen for the gas mixture increases.

$$\frac{1}{m_{O2}}\sum m_i \cdot C p_i \qquad (45.1)$$

The result is a lower flame temperature. Combustion reaction rates are very sensitive to temperature, decreasing exponentially with decreasing temperature. When the concentration of carbon dioxide in air is sufficiently high, the combustion temperature becomes depressed to the point where the rate of heat release falls below the rate of heat loss to the surroundings and the flame is extinguished (in simple cases) or suppressed (in complex geometries). For example, the flame above heptane burning in the cup-burner apparatus is extinguished when the concentration of carbon dioxide added to the air flowing past the "cup" reaches about 21 vol. % [20].

Carbon dioxide is often called an "efficient" extinguishing gas. One reason for this claim lies in the fact that compared with other extinguishing gases such as nitrogen and argon, carbon dioxide has a much larger heat capacity so less of it is required to extinguish a flame. One study reported the relationship between extinguishing agent gas heat capacity and minimum extinguishing concentration (MEC) for n-heptane in the cup-burner test as shown in Table 45.2 [21].

Table 45.2 Agent gas heat capacity and minimum extinguishing capacity

Agent		Cp (298 K)	MEC
Gas	Composition	J/mol-K	vol.%
IG-01	Argon	20.8	42.5
IG-55	50/50 N2/Ar	24.6	36.4
IG-541	52/40/8 N2/Ar/CO2	26.1	34.3
IG-100	Nitrogen	28.5	31.9
CO2	Carbon dioxide	37.5	20.9

The data in Fig. 45.1 illustrates that the extinguishing effectiveness of inert gas agents is an inverse function of their heat capacity.

Thermo-physical Properties

Carbon dioxide for fire extinguishing systems is stored either as a liquefied compressed gas, usually in U.S. DOT 3AA1800 high-pressure steel cylinders, or as a refrigerated liquid in insulated tanks maintained at approximately 0 ± 2 °F. The amount of carbon dioxide that can be safely stored in a container of a given type and size depends on the vapor pressure and densities of the liquid and gas phases. The thermo-physical properties of carbon dioxide are indicated in Table 45.3.

While carbon dioxide is a gas at normal ambient conditions, 21 °C (70 °F) and 101.3 kPa (14.7 psia), it can assume any of the three usual physical forms—as a liquid, gas, or solid—depending on the prevailing pressure and temperature. The thermodynamic properties (vapor pressure, density, enthalpy, entropy, heat capacity, and heat of vaporization) and physical properties (viscosity and thermal conductivity) also vary widely with temperature as indicated in Tables 45.4 and 45.5.

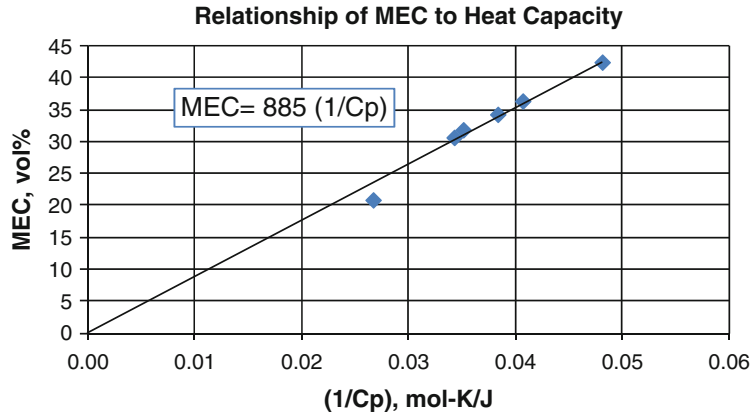

Fig. 45.1 Relationship of MEC to heat capacity

Table 45.3 Reference properties of carbon dioxide [22]

Chemical name	Carbon dioxide
Synonyms	Carbon anhydride; carbonic acid gas; carbonic anhydride; dry ice
CAS Registry No.[a]	124-38-9
Chemical formula	CO2
Property	S.I. units
Molecular weight	44.01 g/mol
Vapor pressure at 2 °F (−16.7 °C)	2181.4 kPa
Specific gravity of gas at 70 °F (21.1 °C) and 1 atm	1.522
Solid to gas expansion ratio at 70 °F (21.1 °C) and 1 atm	0.5457 m3/kg
Gas density at 70 °F (21.1 °C) and 1 atm	1.833 kg/m3
Density of solid (dry ice) at −109.3 °F (−78.5 °C)	1563 kg/m3
Sublimation temperature at 1 atm	−78.5 °C
Critical temperature	31.1 °C
Critical pressure	7381.8 kPa
Critical density	468 kg/m3
Triple point	−56.6 °C at 518 kPa
Latent heat of vaporization at −16.7 °C, 2.18 Mpa	276.8 kJ/kg
Latent heat of fusion at 518 kPa; at −93.8 °C	547 kJ/kg
Latent heat of sublimation at −78.5 °C, 101.3 kPa	571.0 kJ/kg
Specific heat at constant pressure, C_P, gas at 25 °C	0.850 kJ/kg-°C
Specific heat at constant volume, C_V, gas at 25 °C	0.657 kJ/kg-°C
Ratio of gas specific heats, C_P/C_V, at 15 °C	1.304
Solubility in water at 20 °C	0.90 vol/vol
Viscosity of saturated liquid at −16.7 °C	0.000119 kg/m-s

[a]CAS numbers are unique numerical identifiers assigned by the Chemical Abstracts Service to every chemical described in the open scientific literature

The Shomate equations, shown below, and the appropriate coefficients as indicated in Table 45.6, can be used to calculate the heat capacity, molar enthalpy, and molar entropy at specific temperatures. See Table 45.7 for a tabulation of these values for a range of temperatures [24]. The Shomate equation coefficients given in Table 45.6 are for calculations in S.I. units.

Carbon dioxide is soluble in water to an extent that depends on pressure and temperature as shown in Fig. 45.2 below [26].

The dissolution of CO_2 in water (this may be sea water, or the saline water in geological formations) involves a number of chemical reactions between gaseous and dissolved carbon dioxide (CO_2), carbonic acid (H_2CO_3), bicarbonate ions (HCO_3^-) and carbonate ions (CO_3^{2-}) which can be represented as follows:

$$CO_{2(g)} \leftrightarrow CO_{2(aq)} \quad (45.5)$$

$$CO_{2(aq)} + H_2O \leftrightarrow H_2CO_{3(aq)} \quad (45.6)$$

$$H_2CO_{3(aq)} \leftrightarrow H^+_{aq} + HCO^-_{3(aq)} \quad (45.7)$$

$$HCO^-_{3(aq)} \leftrightarrow H^+_{aq} + CO^{2-}_{3(aq)} \quad (45.8)$$

Addition of CO_2 to water initially leads to an increase in the amount of dissolved CO_2. The dissolved CO_2 reacts with water to form carbonic acid. Carbonic acid dissociates to form bicarbonate ions, which can further dissociate into carbonate ions. The net effect of dissolving

52	0.87	−8.92	4.90	110	0.93	−8.87	5.03

Values of the above can be computed for temperatures up to 1600 K, in metric units on a mole basis, using the Shomate equation

anthropogenic CO_2 in water is the removal of carbonate ions and production of bicarbonate ions, with a lowering in pH.

Data on the compatibility of carbon dioxide with specific materials is indicated in Table 45.8 [27]. Although the information has been compiled from what are considered reliable sources (International Standards: Compatibility of cylinder and valve materials with gas content; Part 1: ISO 11114-1 (Jul 1998), Part 2: ISO 11114-2 (Mar 2001), the data should be used with a sufficient degree of prudence. No raw data such as that presented in Table 45.8 can address all scenarios and conditions of concentration, temperature, humidity, impurities and aeration. It is therefore recommended that the data in Table 45.8 be used to initially choose possible materials with a more extensive investigation and testing carried out under the specific anticipated conditions of use. The collected data mainly concern high-pressure applications at ambient temperature and the safety aspect of material compatibility.

Health and Safety

Carbon dioxide is usually described as an asphyxiant gas. However, exposure to atmospheres that contain high concentrations of carbon dioxide result in a condition called hypercapnia (also called hypercarbia). Hypercapnia, is a condition whereby there is too much carbon dioxide in the blood [28]. In severe hypercapnia, generally where the ambient partial pressure of carbon dioxide exceeds approximately 10 kPa, or 10 vol. % at sea level, the symptomatology progresses, over a period of several minutes, to disorientation, panic, hyperventilation, convulsions, unconsciousness, and, eventually, death [29].

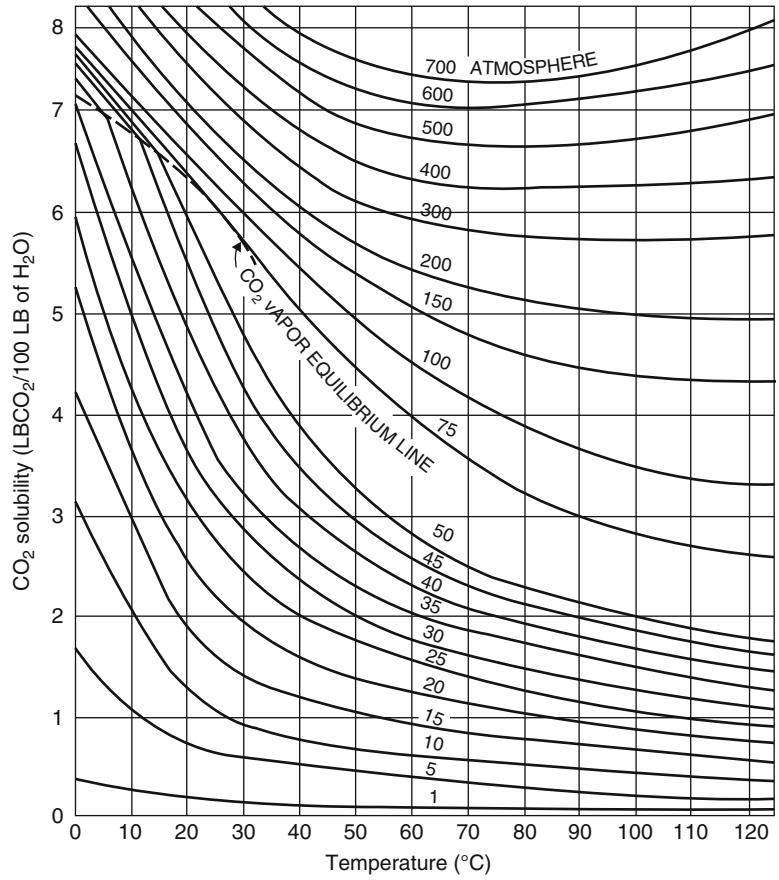

Fig. 45.2 Solubility of carbon dioxide in water [25]

Death will occur because of a lack of oxygen in the blood, leading to complete organ failure as the oxygen has been overtaken by the carbon dioxide. In some cases, victims who have been exposed to very high levels of carbon dioxide in the atmosphere have been known to die almost immediately of asphyxiation, as the carbon dioxide serves to displace, or push out, the oxygen in the air [30].

Treating hypercapnia is best achieved by removing a victim from the exposure to carbon dioxide and providing high concentrations of oxygen. If the exposure was at mild to moderate levels (6–9 kPa), the patient should recover fully. If the exposure was at levels higher than 10 kPa, the patient may suffer from permanent damage of the central nervous system.

The acute physiological effects of exposure to atmospheres containing carbon dioxide depend on the carbon dioxide concentration and the duration of exposure. The effects of exposure have been reported in several sources. Table 45.9 summarizes the effects of exposure to carbon dioxide as reported in three different sources.

Protection standards have been developed for workers who may be exposed to carbon dioxide. (Table 45.10 shows exposure limits as noted in U.S. standards but similar limits are understood to apply in standards of other countries).

A carbon dioxide fire extinguishing system discharges carbon dioxide in sufficient quantity to produce a lethal concentration in a localized or confined atmosphere. Total flooding type systems are required to achieve a minimum design concentration of 34 vol.% [33]. For many fire hazards, the design concentration is required to be substantially higher than 34 vol.%. As indicated in Table 45.9, a carbon dioxide concentration in the range of 17–30 vol.% is lethal to humans within only 1 min of exposure.

Table 45.8 Material compatibility of carbon dioxide [27]

Material	Compatibility
Metals	
Aluminium	Satisfactory
Brass	Satisfactory
Copper	Satisfactory
Ferritic steels (e.g. carbon steels)	Satisfactory but risk of corrosion in presence of CO and/or moisture. cold brittleness
Stainless steel	Satisfactory
Plastics	
Polytetrafluoroethylene (PTFE)	Satisfactory
Polychlorotrifluoroethylene (PCTFE)	Satisfactory
Vinylidene polyfluoride (PVDF) (KYNAR™)	Satisfactory
Polyamide (PA) (NYLON™)	Satisfactory
Polypropylene (PP)	Satisfactory
Elastomers	
Buthyl (isobutene – isoprene) rubber (IIR)	Non recommended, significant swelling
Nitrile rubber (NBR)	Non recommended, significant swelling and significant loss of mass by extraction or chemical reaction
Chloroprene (CR)	Non recommended, significant swelling and significant loss of mass by extraction or chemical reaction
Chlorofluorocarbons (FKM) (VITON™)	Non recommended, significant swelling and significant loss of mass by extraction or chemical reaction
Silicon (Q)	Acceptable but strong rate of permeation
Ethylene – Propylene (EPDM)	Acceptable but important swelling and significant loss of mass by extraction or chemical reaction
Lubricants	
Hydrocarbon based lubricant	Satisfactory
Fluorocarbon based lubricant	Satisfactory

All properly designed total flooding carbon dioxide fire extinguishing systems, therefore, have the potential to be lethal.

In fact there have been numerous incidents with carbon dioxide fire extinguishing systems that have resulted in fatalities and serious injuries. One study by the U.S. Environmental Protection Agency (EPA) reported that between 1975 and 1999, 72 deaths and 145 injuries occurred as a result of 51 incidents involving carbon dioxide fire extinguishing systems [2]. This study also reported on incidents that occurred prior to 1975. Table 45.11, which is reproduced from the EPA study, shows data on deaths and injuries categorized by time frame, geographical region, and military/non-military installations.

The EPA study included a comprehensive data search and analysis of incidents involving carbon dioxide fire extinguishing systems. The search included governmental, public, and private document archives internationally. Many details about each reported incident were collected and presented in the study.

All of the 13 military incidents reported were marine-related. Only 11 of the 49 nonmilitary incidents reported were marine-related. The remaining incidents occurred in a variety of land-based facilities noted below:

- Data processing centers
- Nuclear power plants
- Pilot training centers
- Airplanes
- Bus garages

Table 45.9 Acute health effects of high concentrations of carbon dioxide

	Source	U.S. EPA examining the risks (2004) [2]	Air products (2004) [31]	Rice (2004) [32]
CO2 conc. vol.%	Exposure time	Effects	Effects	Effects
1			Slight increase in breathing rate	Respiratory rate increased by about 37 %
2	Several hours	Headache, dyspnea upon mild exertion	Breathing rate increases to 50 % above normal level. Prolonged exposure can cause headache, tiredness	Ventilation rate raised by about 100 %. Respiratory rate raised by about 50 %; increased brain blood flow
3	1 h	Mild headache, sweating, and dyspnea at rest	Breathing increases to twice normal rate and becomes laboured. Weak narcotic effect. Impaired hearing, headache, increase in blood pressure and pulse rate	Exercise tolerance reduced in workers when breathing against inspiratory and expiratory resistance
4–5	Within a few minutes	Headache, dizziness, increased blood pressure, uncomfortable dyspnea	Breathing increases to approximately four times normal rate; symptoms of intoxication become evident and slight choking may be felt	Increase in ventilation rate by ~200 %. Respiratory rate doubled, dizziness, headache, confusion, dyspnea
5–10	Within minutes		Characteristic sharp odour noticeable. Very labored breathing, headache, visual impairment and ringing in the ears. Judgment may be impaired, followed within minutes by loss of consciousness	
6	1–2 min	Hearing and visual disturbances		
	<16 min	Headache, dyspnea		
	Several hours	Tremors		
7–10	Few minutes	Unconsciousness, near unconsciousness		At 8–10 %, severe headache, dizziness, confusion, dyspnea, sweating, dim vision. At 10 %, unbearable dyspnea, followed by vomiting, disorientation, hypertension, and loss of consciousness
	1.5 min to 1 h	Headache, increased heart rate, shortness of breath, dizziness, sweating, rapid breathing

Table 45.11 Summary of deaths and injuries from carbon dioxide system incidents

Use category		Number of incidents	Deaths	Injuries
United States and Canada				
1975- present	Military	9	10	15
	Nonmilitary	20	19	73
Before 1975	Military	3	11	0
	Nonmilitary	5	3	3
Total		37	43	91
International				
1975-present	Military	1	4	5
	Nonmilitary	21	39	52
Before 1975	Military	0	0	0
	Nonmilitary[a]	3	33	4
Total		25	76	61
Total		**62**	**119**	**152**

[a]Included in in the total international nonmilitary incidents, deaths, and injuries before 1975 are the 20 deaths resulting from the use of carbon dioxide as a fire suppressant in England from 1945 to the mid 1960s, for which the cause is unknown

- Emergency unit communication centers
- Waste storage facilities
- Underground parking garages
- Steel rolling mills
- Motor vehicle assembly lines
- Other facilities

In another study [4] Wickham analyzed the data collected in the EPA study and concluded that maintenance activities on the carbon dioxide systems, or in their vicinity, are the most common cause categories associated with the incidences evaluated. This data are summarized in Table 45.12.

Wickham also reported on a number of carbon dioxide extinguishing system incidents that occurred subsequent to the EPA study, between 2000 and 2003. This data is summarized in Table 45.13.

Clearly, carbon dioxide fire extinguishing systems have the potential to be lethal and cause serious injury. Great care must be taken in the design, installation, testing and maintenance of carbon dioxide systems to prevent harm to persons present in their immediate and general vicinity.

Carbon Dioxide System Design

Design Standards and Guidelines

Carbon dioxide system design is governed by standards applicable to the type and locale of the system. Land-based industrial system design is governed by the design standard adopted and enforced by the governmental jurisdiction in

Table 45.12 Causes of injuries and deaths associated with carbon dioxide discharges (1975–1999) [4]

Type discharge	Circumstances	Incidents	Deaths	Injured
Accidental	During maintenance on the CO2 system	9	8	10
	During maintenance near the CO2 system	8	19	19
	During testing	1	2	6
	During fire situation	2	10	7
	Faulty component or installation	2	4	13
	Operator error	2	1	4
	False alarm	2	1	15
Intentional	During testing or training	3	2	2
	During fire situation	5	15	8
	False alarm	1	2	1
	Total	35	64	85

Table 45.13 Additional death and injury incidents in the US and Mexico (associated with carbon dioxide total flooding fire extinguishing systems) [4]

Event date	Source	Deaths	Injuries	Summary
07/27/2000	OSHA Technical Information Bulletin 12/22/2001	1	0	"...an employee of a securities firm died from CO2 intoxication. The employee was inside the vault with the vault door closed and locked. When the employee pulled a manual fire alarm actuation device that was located inside the vault space, it activated the warning alarm and the total flooding CO2 system."
02/20/2002	Mr. Donald Murray Ansul 03/31/2003	2	0	A carbon dioxide system prematurely connected and manually discharged in error by workers aboard a ship at the Mexican Navy Shipyard in Salina Cruz Oaxaca Mexico. The engine room was occupied at the time by many workers as ship was being overhauled.
03/31/2002	Honolulu Adviser 04/03/2002	2	0	Two civilian crew members died on the 750-foot Ready Reserve Force ship Cape Horn from apparent suffocation when a fire was put out in the engine room, officials said. "The possibility is that it may have been as a result of a fire suppression system ..... The suppression systems replace oxygen with carbon dioxide to smother a fire."
01/19/2003	Associated Press 01/31/2003	2	0	"A couple found dead aboard their docked 58-foot yacht apparently suffocated when a fire suppression system was accidentally set off, using up all the oxygen in the yacht. Marine experts have determined that John Robertson, a leg amputee who wasn't wearing his prosthesis, fell and grabbed a wire that triggered the carbon dioxide powered fire-suppression system. Andreija was overcome by lack of oxygen when she probably tried to rescue her 260-pound husband. The couple was cleaning the yacht's engine room and had begun painting it when the accident happened, police said."

which the system will be installed. Two of the most widely used standards for these systems are NFPA 12 [34] and ISO 6183 [35].

Marine system design is governed by marine standards. The specific standards that apply depend on the several factors including the flag administration under which the vessel is registered, the vessel's classification society if it is a commercial vessel, and whether or not the vessel is used in international commerce. Unites States flag commercial vessels fall under USCG standards [17]. Vessels involved in international commerce fall under SOLAS which requires compliance with the FSS Code [36] There are also many classification societies which have extensive standards and guidelines that their classified marine vessels must be in compliance with, e.g. ABS [37]. NFPA 12 also contains a chapter that provides marine system design requirements [38].

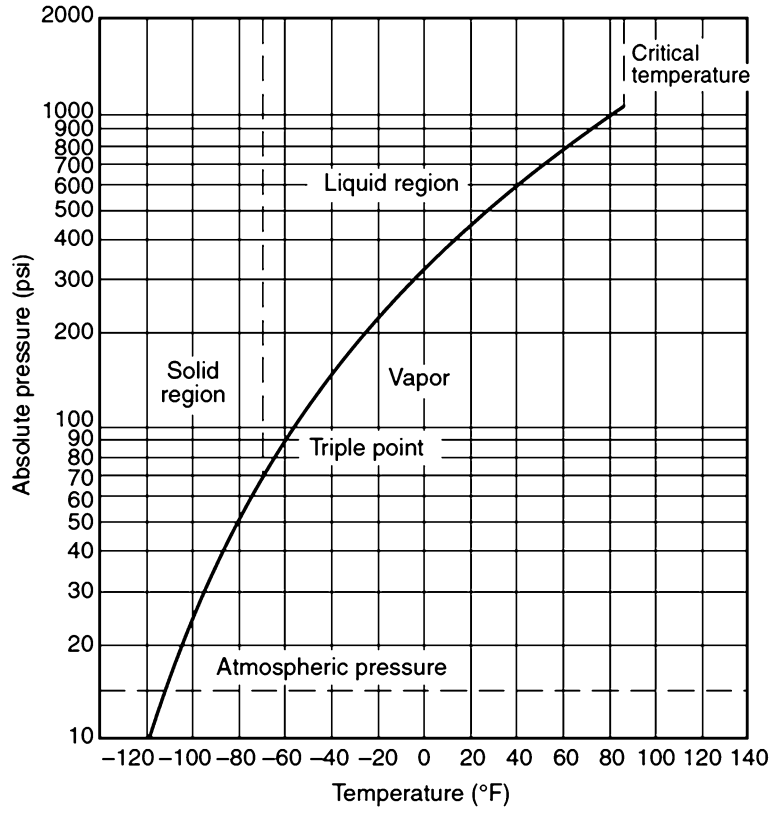
System Configuration

Storage and Distribution

NFPA 12 recognizes two types of storage for carbon dioxide: high pressure and low pressure. Each type has advantages and disadvantages.

High Pressure High-pressure systems utilize carbon dioxide stored in cylinders at an ambient temperature between −18 °C (0 °F) and 54 °C (130 °F) and at a density of 600–680 kg/m^3 (37–42.5 lb/ft^3). This is usually expressed as a percentage of the cylinder's water capacity, which can range from 60 % to 68 %.

The curve shown in Fig. 45.3 illustrates the relationship between the temperature and the pressure of liquid carbon dioxide. Below 31 °C (87.8 °F), carbon dioxide exists as both liquid and gas. At 21 °C (70 °F), the cylinder pressure is approximately 58.6 bar (850 psi) absolute. As the



For SI units, 1 psi = 6.89 kPa; °C = ⅝ (°F – 32).

Fig. 45.3 Variation of pressure of carbon dioxide with change in temperature at constant volume (Courtesy of NFPA)

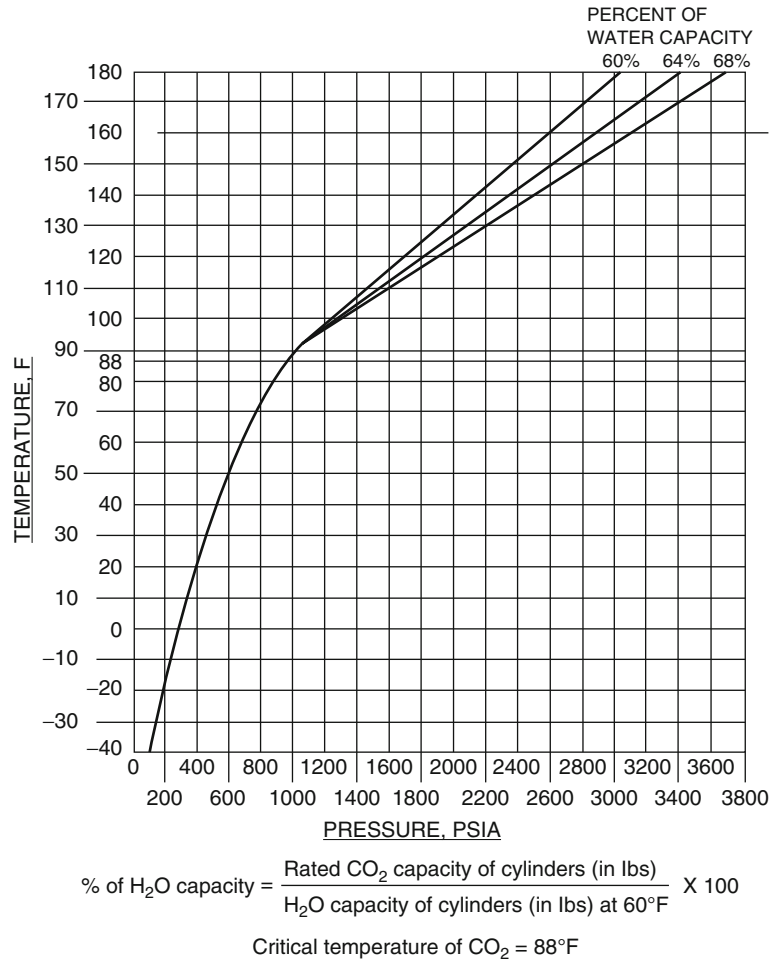


Fig. 45.4 Pressure-temperature curve for carbon dioxide

temperature increases, the vapor pressure and density increase and the liquid density decreases, until the critical temperature is reached. At 31 °C (87.8 °F), the liquid and the vapor have the same density, and the carbon dioxide is in a single-phase.

Above the critical temperature, the relationship between pressure and temperature is dependent on the fill density of the cylinder. Higher fill densities result in a greater rise in pressure with temperature, as demonstrated in Fig. 45.4.

Given such high working pressures, it is generally necessary to use seamless steel cylinders which have pressure strength but relatively small internal volumes. This has traditionally limited the maximum storage capacity of a single cylinder to 120 lb (54.4 kg). However, for most applications, a larger supply of carbon dioxide is required. In order to provide a sufficient quantity of gas, multiple high-pressure cylinders are connected to a manifold and discharged simultaneously through a single pipe network.

All cylinders connected to a common manifold must be of the same design and capacity, such that they are interchangeable. For example, a system that requires a minimum supply of 68 kg (150 lb) of carbon dioxide may be satisfied by two 34.0 kg (75 lb) cylinders, by three 22.6 kg (50 lb) cylinders, or by two 45.3 kg (100 lb) cylinders. However, it is not permissible to connect one 22.6 kg (50 lb) cylinder and one 45.3 kg (100 lb) cylinder to a single pipe network.

It is also permissible to provide a connected reserve supply of carbon dioxide. The reserve supply must be identical to the main supply,

including cylinder size and manifold configuration. The actuation subsystem must be provided with a means, such as a switch or valve, to select between the two cylinder banks. In some cases, the reserve supply is used as a "second shot" in the event that the primary supply does not successfully extinguish a fire. In other cases, the reserve supply is used to provide continuity of protection while the main supply is recharged.

Where the supply consists of a single cylinder, the cylinder valve may be connected directly to the discharge piping. Where multiple cylinders are connected to a manifold, a means, such as a check valve, must be provided at each cylinder connection. This prevents loss of agent in the event that the system is activated while one of the cylinders is removed for service. This requirement also applies where a single main cylinder and a single reserve cylinder are connected to a common system.

High-pressure cylinders must be securely mounted and supported in order to prevent movement during discharge and accidental dislodgement. When multiple cylinders are connected to a manifold, they are required to be mounted in a rack, provided for the purpose and arranged to facilitate inspection and maintenance of the cylinders. To ensure a proper fit, mounting brackets, straps, and/or racking equipment are usually available from the system manufacturer.

Low-pressure systems utilize carbon dioxide stored in refrigerated vessels. The reduced storage temperature results in a lower storage pressure, thus permitting a greater quantity of carbon dioxide to be stored in a single tank. For high capacity systems, this can yield lower installation costs and smaller storage areas, versus high pressure systems.

A carbon dioxide refrigeration system is designed to maintain the carbon dioxide supply at a nominal pressure of 2068 kPa (300 psi). According to Fig. 45.4, this pressure corresponds to a temperature of approximately −18 °C (0 °F). Where the ambient temperature is expected to be lower, a heating system may be required to maintain this temperature/pressure.

The storage vessel is usually designed in accordance with ASME Pressure Vessel Code with a minimum design pressure of 2241 kPa (325 psi) and filled after installation. However, if the container is to be pressurized prior to shipping, it must comply with the laws governing transport of pressurized vessels, such as Section 49 of the U.S. Code of Federal Regulations (Department of Transportation).

Single and Multiple Hazards: Carbon dioxide systems can be designed to protect a single hazard or multiple hazards from a single supply. Further, multiple hazards may be protected simultaneously or independently. See discussion on Selector Valves for more information on using a single supply to independently protect multiple hazards.

System Controls for Industrial Applications

Since carbon dioxide systems are used to protect many different types of hazards, system controls can vary widely and are designed to suit the specific needs of each application. These controls can include automatic detection systems, manual actuation equipment, valve actuators, notification appliances, supervisory switches, and auxiliary controls. Systems may be operated electrically, pneumatically, mechanically, or by a combination of these methods.

Means of Electrical Operation

Electrically operated systems generally offer the greatest flexibility and a high degree of reliability. This control equipment must be installed in accordance with NFPA 72, which generally requires the use of a listed fire alarm control panel (FACP) and listed devices. Ideally, the FACP should be specifically listed for releasing service, which provides additional protection against accidental discharge.

The reliability of electrically operated systems is enhanced by the use of supervised circuits and devices. This provides notification of a system or device fault. In addition, the use of secondary power sources, such as batteries, ensures the continuity of protection in the event of a power outage.

Means of Pneumatic Operation

Pneumatically operated systems use pressure to activate a system component. This includes both pneumatic detection and pneumatic (pressure) actuation.

Pneumatic detection systems are composed of one or more detectors, in the form of an air chamber, connected to a mechanical device through tubing. The device is typically designed with a vent that relieves pressure in the tubing due to normal temperature fluctuations. However, when the air temperature within the chamber increases quickly, as when exposed to a fire, the resulting increase in pressure occurs faster than can be relieved through the vent and causes actuation of the discharge valve, or the master valve in the case of a multi-cylinder system. Because activation relies on the rate of temperature increase, the system may not react to slow-growing fires. The success of pneumatic detection systems is dependent on proper selection of the relief vent size, as well as careful installation practices to ensure that there are no unintended leaks or breaches in the tubing and that the system does not exceed the limitations of the manufacturer's listing and installation instructions. Since the integrity of the tubing cannot be supervised, periodic testing is critically important. Pneumatic detection systems were a historically important component of carbon dioxide systems, particularly in applications involving flammable liquid storage and marine vessels, where the availability of electricity was limited or undesired. This type of detection is less frequently employed in modern systems, as electrical detectors have become more prevalent, but such means of detection still has certain advantages.

Pneumatic (pressure) actuation systems are composed of a stored pressure supply—usually a cylinder filled with nitrogen—connected to a mechanical device through a network of hose, pipe, and/or tubing. When pressure is released into the tubing, a mechanical pressure-operated valve actuator advances an operating pin that causes the discharge valve to open. Frequently, these systems are called "pressure operated", rather than "pneumatic", in order to differentiate them from pneumatic detection systems. This arrangement is typically used as a means to open valves and/or activate auxiliary equipment. There are two primary benefits to this arrangement: (1) the pressure supply can be used to automatically actuate multiple devices from a single manual or automatic control point, (2) the pressure supply can be connected through a pneumatic device that delays activation of the downstream components. Because it relies on activation of the stored pressure supply, this type of system must be coupled with another form of operation. Success is dependent on proper design and installation, the availability of pressure, and the integrity of the network.

Means of Mechanical Operation

Mechanically operated systems rely solely on mechanical advantage to operate a device and are usually used only for manual actuation of the system.

Lever operation is usually encountered as a manual control located directly on a valve or other system component. In some cases, the movement of the lever is translated directly to the actuating element. In other cases, the lever activates a spring-loaded device, which in turn performs the work to open the valve.

Cable operated systems permit a mechanical control to be located remotely from the operating valve. A cable is usually installed inside a protective sheath, such as pipe or conduit, and threaded through pulleys to reduce friction where changes in direction are necessary. Most carbon dioxide systems use a pull-to-trip mechanism, which activates the valve when tension is applied to the cable. Another type, called a release-to-trip mechanism, activates the valve when tension in the cable is relieved.

System Actuation

Actuation of low-pressure systems is usually achieved by the use of an electrically operated valve, located on the discharge port of the storage vessel. Because it is not typically necessary to use more than the contents of one low-pressure

carbon dioxide storage vessel in a single discharge, these controls remain relatively simple, unless multiple independent hazards are protected.

Actuation of high-pressure systems is more complicated because it is usually necessary to actuate more than one cylinder valve. In order to simplify the controls, the cylinder valves are designed (in many but not all cases) to open with back pressure from the manifold. That is, a mechanism in the valve causes the valve to open when a minimum pressure is developed in the manifold pipe. With this arrangement, actuation of the entire system can be achieved by activation of a limited number of pilot cylinders (those that discharge first and serve to pressurize the manifold), thus limiting the number of controls that are required.

Manual Normal Actuation

All carbon dioxide systems are required to be provided with a means of manually actuating the system. This is satisfied by a manual releasing device located on, at, or remotely from the carbon dioxide supply. The manual release must be capable of causing the entire system—including notification and auxiliary devices—to actuate, as intended, as well as initiating the release of carbon dioxide. This can be simplified by the use of a fire alarm control panel to control all of the system functions. However, mechanical and/or pneumatic devices can also be used to ensure the full functionality of the system.

Manual actuation must be accomplished with a pull force of not more than 178 N (40 lb) and a movement of not more than 356 mm (14 in).

Manual Emergency Actuation

All valves that control the release and distribution of carbon dioxide are required to have an emergency manual means of activation. This is a fully mechanical control, located at or near the device being controlled. This is intended only to provide a means of opening the valve in the event that the normal manual and/or automatic controls fail to do so. It is not necessary to achieve full activation of the entire system from this control, as is required for a normal manual control.

Automatic Actuation

All carbon dioxide systems are required to be automatically actuated, unless the authority having jurisdiction approves the use of a manual-only system.

Automatic detection may utilize any listed or approved method or device that is capable of sensing and indicating the presence of heat, flame, smoke, combustible vapors, or an abnormal condition in the protected space such as process trouble that is likely to produce fire.

System Valves

Selector Valves

Selector valves are normally-closed control valves that are used to direct the flow of carbon dioxide to a specific location upon system activation. Selector valves are used where a single supply of carbon dioxide serves more than one protected space. In this arrangement, a single supply of carbon dioxide is piped to a header with multiple branches that can deliver carbon dioxide to a specific location, Each header outlet branch is fitted with a selector valve. Examples are shown in Figs. 45.5 and 45.6. When an automatic detector or manual control in one of the hazards is activated, the control system is designed to open the required quantity of supply cylinders and the appropriate selector valve for that hazard.

Lockout Valves

A lockout valve is a manually-operated normally-open valve that is closed when maintenance is being performed on the system to prevent discharge into the protected space where persons may be present. A lockout valve should be provided with a position switch connected to the Supervisory circuit of the FACP to provide notification of system impairment when the valve is closed. It should also be provided with a means to lock the valve in position, in order to permit use of a lockout/tagout system.

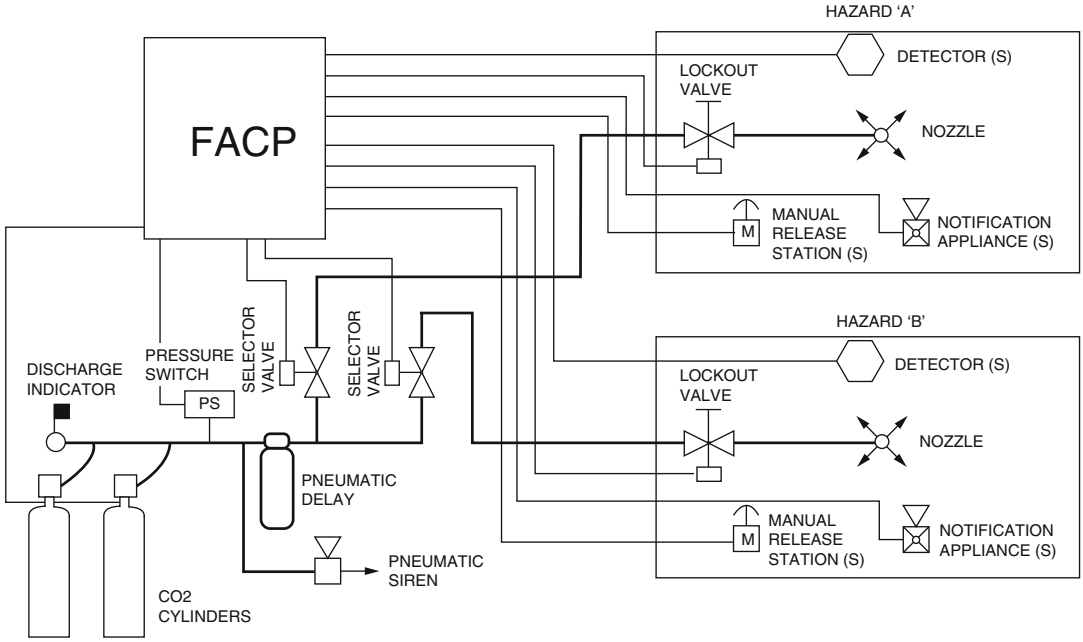

Fig. 45.5 Example of a selector valve arrangement with electric operation

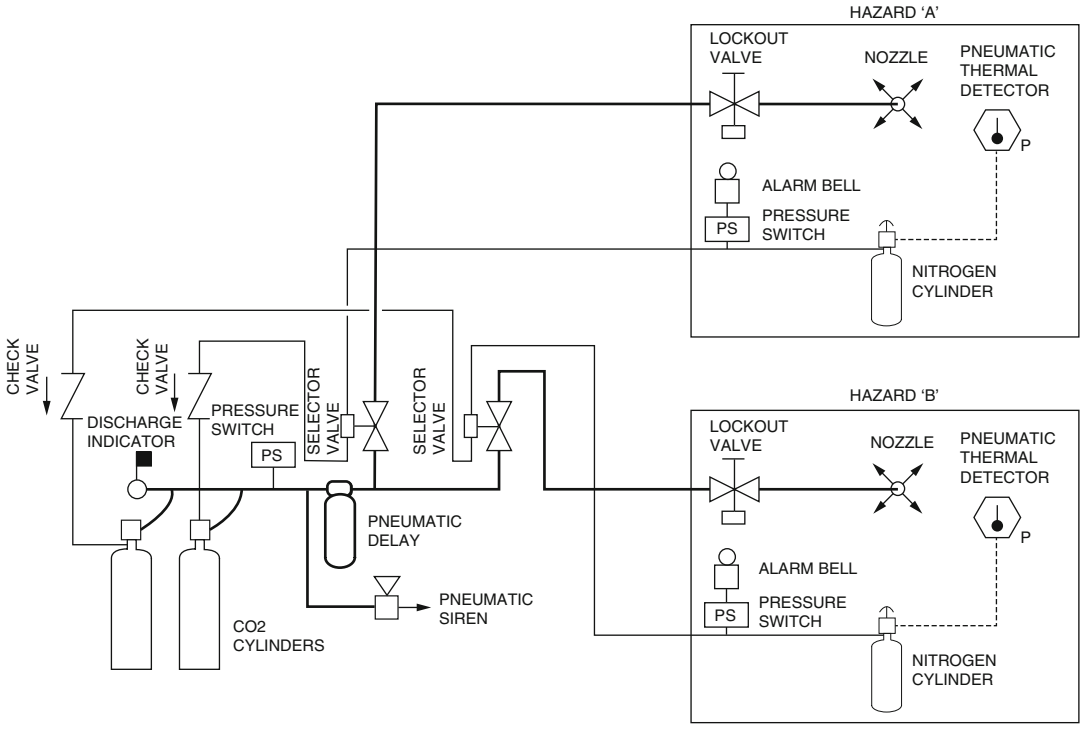

Fig. 45.6 Example of a selector valve arrangement with pneumatic operation

Check Valves

Check valves are frequently used in carbon dioxide systems to isolate main and reserve supplies and to separate pneumatic actuation systems.

Since high-pressure cylinders can be opened by back pressure in the manifold, check valves are required in a system with a reserve supply, in order to prevent the reserve supply from being actuated when the main supply is discharged and vice versa. In addition, the check valve prevents the loss of agent in the event that either supply is discharged while the other supply is disconnected and removed for recharging.

Where multiple pneumatic actuation cylinders are used to actuate a common supply from different locations, check valves are required at the point of connection. This ensures that actuation from either station is not dependent on the condition of the other. In addition, there are practical limitations on the overall size of the actuation piping/tubing system, and the check valves ensure that the entire network does not need to be pressurized.

Notification of System Status

Due to the inherent safety risks associated with carbon dioxide, the role of notification is extremely important in the design of carbon dioxide systems. This encompasses warning and instruction signs, a pre-discharge alarm and discharge time delay, a post-discharge alarm, and discharge indication.

Warning and Instruction Signs

NFPA 12 prescribes a number of warning and instruction signs that are to be placed in various locations, depending on the layout of the building or hazard area. Signs located near or within the hazard provide instruction to evacuate when the alarm sounds; signs located near or outside the hazard provide instruction not to enter the space while the alarm is activated; and signs located at the manual actuation stations indicate the purpose of the release and instruct the user to verify that no personnel are in the protected space before actuating the system.

Pre-discharge Alarm and Time Delay

A pneumatic pre-discharge time delay, and pneumatic pre-discharge alarm, shall be incorporated into any carbon dioxide total flooding system that protects a space that is normally occupied, or that could be occupied even if occasionally. The purpose of this device is to provide a highly reliable means of alerting people within the protected space of an imminent carbon dioxide release, giving them sufficient time to safely egress prior to system discharge.

Certain design standards may allow omission of the time delay under certain conditions where the risk to personnel may be greater with the time delay, or where the physical dimensions of the protected space eliminate the possibility of occupancy at any time.

Certain design standards may also require pre-discharge alarms and time delays for local application systems that present a significant health risks to occupants.

Post-discharge Alarm and Discharge Indication

Visible and audible alarm devices shall be provided outside each entrance to protected spaces that are normally occupied or that could be occupied even if occasionally, where carbon dioxide is discharged directly into the space, or could migrate into the space. These alarm devices should activate prior to system discharge, or at the time of system discharge.

A discharge indicator or alarm shall be provided that alerts personnel to the fact that a carbon dioxide system has discharged and need to be recharged.

System Controls for Marine Applications

Marine carbon dioxide systems generally are arranged for manual release of carbon dioxide into the protected space. A notable exception is a small system of less than or equal to 136 kg (300 lb) carbon dioxide, protecting a normally unoccupied space, whose automatic discharge will not interfere with safe navigation of the vessel.

There are numerous marine carbon dioxide design standards and guidelines, and their requirements regarding the design of carbon dioxide extinguishing systems differ. The design standards that apply to a particular carbon dioxide system to be installed on a marine vessel should be identified and the requirements carefully adhered to.

Manual Operation

It is a common requirement in various marine carbon dioxide design standards that each manually operated system be provided with two separate valves controlling the delivery of carbon dioxide into the protected space. One valve should control discharge from the carbon dioxide storage, while the other controls delivery of carbon dioxide to the protected space.

Each of these two valves should be provided with a manually-operated control device. The set of control devices, one for each valve, should be installed together inside of a single control box. The control box should be located outside of the protected space, in the immediate vicinity of the main egress from the space.

Other Controls and Notification Requirements

Other controls and notification devices are required for marine carbon dioxide systems that are similar to those described for land-based industrial systems. The applicable design standards should be consulted.

Carbon Dioxide Quantity and Rate of Application

The stored quantity, or mass, of carbon dioxide is the amount needed to achieve the design concentration (total flooding) or rate and duration of discharge (local application) in accordance with the applicable system design, plus additional amounts as required for specific design considerations.

Total Flooding Systems, Non-marine Applications

The design principle of a total-flooding system is for carbon dioxide to be discharged into an enclosed space in such manner as to achieve a specific design concentration that will promptly extinguish surface fires under anticipated conditions, or will extinguish deep-seated fires after the concentration is maintained or held within the enclosure for a specified length of time.

Calculation of the design quantity of carbon dioxide assumes (a) that it is discharged into an enclosure as a gas, and (b) that it is well mixed with the enclosure air. The assumption that carbon dioxide enters the enclosure as a gas is an approximation since it leaves the nozzle as a mixture of gas and dry ice snow. The all-gas approximation, however, has been found useful in calculations. In most cases, carbon dioxide discharge causes a rise of pressure in the protected enclosure. Some carbon dioxide is lost from the enclosure as pressurized air escapes through leakage and vent openings, the rate of carbon dioxide loss being progressively greater as its concentration increases during discharge. As such, the quantity of carbon dioxide required to achieve concentration C in an enclosure can be calculated as follows:

$$m = \frac{V}{s}\ln\left(\frac{100}{100 - C}\right) \qquad (45.9)$$

where

m quantity of CO_2, kg
V enclosure volume, m^3
s specific volume of CO_2 vapor at the enclosure temperature, m^3/kg
C CO_2 concentration, vol.%

Carbon dioxide should be discharged in a manner that promotes mixing of the enclosure atmosphere. Under most conditions, the pressure in an enclosure will rise during the discharge period. The displaced atmosphere is exhausted freely from the enclosure through small openings or through a pressure-relief vent if provided. This is referred to as free-efflux flooding [39].

Determining the quantity of agent necessary to achieve fire extinguishment within the protected enclosure is a multistep process, summarized below.

1. Define the fire hazard and the enclosure about the hazard;
2. Determine minimum extinguishing concentration (MEC) for the predominate combustible material;
3. Determine the design concentration (DC);
4. Determine the base design quantity (m_{BD}) of carbon dioxide;
5. Determine additional quantities of carbon dioxide for special conditions;
6. Determine final design quantity (m_{FD}) of carbon dioxide.

The overall process for determining the final design quantity for surface fires and deep-seated fires is the same; however, there are distinct variations within some of the steps. The detailed process for each is, therefore, described separately, first for surface fires, then for deep-seated fires.

Surface Fires

Determining Design Quantity

The detailed steps for determining the final design quantity of carbon dioxide for surface fires are described below.

Step 1: Define the fire hazard and the enclosure about the hazard

Identify the predominate combustible material (fuel) associated with the fire hazard. Determine the type of burning that will characterize the fire; surface or deep-seated (smoldering).

Identify the boundaries of the fixed enclosure about the hazard that is inherently suitable to receive gaseous carbon dioxide and retain it for the required length of time. Calculate the gross volume of the enclosure. The gross volume of all interconnected spaces, wherever free flow of carbon dioxide between them can take place, must be included in the total gross volume calculation. Calculate the total net volume by subtracting the volumes of fixed solid impermeable objects within the enclosure (e.g. pillars). The net volume is the protected volume (V_P) for the purpose of determining the final design quantity of carbon dioxide.

Step 2: Determine minimum extinguishing concentration (MEC) for the predominate combustible material

The minimum theoretical carbon dioxide extinguishing concentration for liquids and gases must be determined by test, or obtained from a recognized source, according to NFPA 12. If the maximum residual oxygen value (O_2) is known, the theoretical carbon dioxide extinguishing concentration may be calculated. The result must be obtained from the following equation [33]:

$$\%CO_2 = \left(\frac{21 - O_2}{21}\right) \cdot 100 \qquad (45.10)$$

NFPA 12 provides a theoretical minimum extinguishing concentration (MEC) value for a number of flammable and combustible liquids [33], and several are given in Table 45.14.

Step 3: Determine the design concentration (DC)

The design concentration (DC) is determined by applying a safety factor, at least 20 %, to the MEC. Furthermore, the design concentration is typically required to be greater than or equal to 34 vol.%. If, after applying the safety factor, the design concentration value is less than 34 vol.%, it must be increased to equal 34 vol.%. NFPA 12 provides a design concentration value for a number of flammable and combustible liquids [33], adjusted to the minimum required 34 vol.% where necessary. Design concentrations for a number of different materials are provided in Table 45.14.

Table 45.14 Minimum extinguishing and design concentrations for selected flammable liquids

Material	MEC, vol.%	DC, vol.%
Acetone	27[a]	34
Acetylene	55	66
Carbon disulfide	60	72
Ethyl alcohol	36	43
Hexane	29	35
Methyl alcohol	33	40
Propane	30	36

MEC minimum extinguishing concentration
DC design concentration
[a]Calculated from accepted residual oxygen values

Table 45.15 Flooding factors vs. hazard volume

Protected volume (V_P), m3	Flooding factor, kg/m^3	Minimum quantity, kg
≤3.96	1.15	–
3.97–14.15	1.07	4.5
14.16–45.28	1.01	15.1
45.29–127.35	0.9	45.4
127.35–1415	0.8	113.5
>1415	0.74	1135

Step 4: Determine the base design quantity (m_{BD}) of carbon dioxide

The base design quantity (m_{BD}) is determined by applying the appropriate carbon dioxide flooding factor provided in Table 45.15 obtained from NFPA 12 [34] to the protected volume (V_P).

$$m_{BD} = V_P \cdot FF \tag{45.11}$$

The result must not be less than the minimum quantity value shown in the appropriate row in the table. If the calculated value of m_{BD} is less than the minimum quantity value, it must be increased to equal the minimum quantity value.

All of the flooding factor values in Table 45.15 were developed based upon a carbon dioxide concentration of 34 vol.%; therefore, the calculated value of m_{BD} for design concentrations exceeding 34 vol.% must be increased by applying a material conversion factor, as described in Steps 5 and 6.

The flooding factors in Table 45.15 are based on a carbon dioxide expansion factor (mass of liquid to volume of gas) of 0.56 m^3/kg (9 ft^3/lb) [39] at a temperature of 30 °C (86 °F). This same value is also inherently or expressly used in other carbon dioxide design standards, including the USCG [17], SOLAS [36] and ABS [37].

The flooding factors in Table 45.15 contain inherent safety factors to account for a reasonable amount of normal leakage [39] for protected volumes equal to 1415 m^3 (50,000 ft^3) or less. For protected volumes greater than 1415 m^3 (50,000 ft^3), no safety factor for normal leakage is included. The reasons for including normal leakage safety factors in the smaller protected volumes is not given in NFPA 12; however, it is assumed to be related to the possibility that the effect of normal leakage on carbon dioxide concentration increases as the volume decreases in proportion to the increasing enclosure surface area to volume ratio.

NFPA 12 has contained the concept of including a normal leakage safety factor in the flooding factors for smaller protected volumes in every edition since the first edition was published in 1929. The flooding factors in the 2015 edition were introduced in the 1955 edition, and have remained unchanged in every edition since.

Step 5: Determine additional quantities of carbon dioxide for special conditions

The base design quantity of carbon dioxide (m_{BD}) determined in the previous steps, may require adjustment based upon the effects of several special conditions. Each of these special conditions must be considered, and adjustments made to the m_{BD} as appropriate, which will lead to the determination of the final carbon dioxide design quantity (m_{FD}).

Step 5a: Material Conversion factor

The base design quantity of carbon dioxide was determined based on a carbon dioxide concentration of 34 vol.%. As such, the calculated value of m_{BD} for design concentrations exceeding 34 vol.% must be increased by applying a material conversion factor (MCF). The MCF for design concentration, C can be determined using Equation 45.12 or from Fig. 45.7. The corrected design quantity of carbon dioxide (m_{cf}) is calculated as the base design quantity (m_{BD}) times the MCF as shown in Equation 45.13.

$$MCF = 2.41 \cdot \ln\left(\frac{100}{100 - C}\right) \tag{45.12}$$

$$m_{cf} = m_{BD} \cdot MCF \tag{45.13}$$

Step 5b: Uncloseable Openings

Determine if the enclosure surrounding the protected volume has openings that cannot be closed. As carbon dioxide is discharged into the

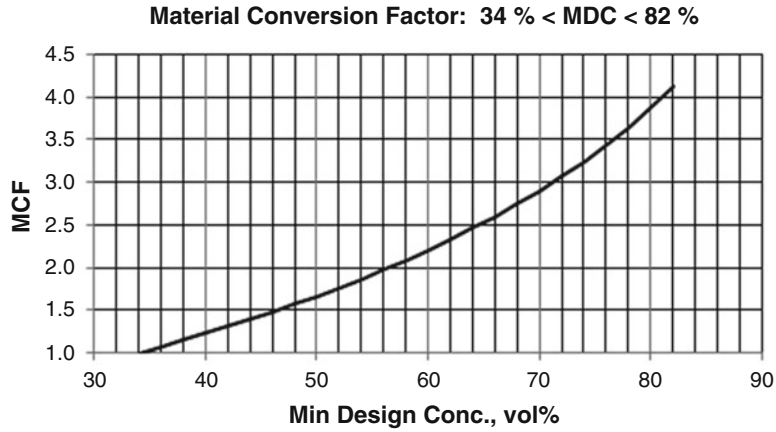

Fig. 45.7 Material conversion factor vs. Minimum design concentration

protected volume, some quantity of carbon dioxide will be expelled through these openings. The quantity of carbon dioxide lost must be calculated so that it can be included in the final design quantity of agent (m_{FD}).

For surface fires, the design concentration must be achieved within 1 min from the start of carbon dioxide discharge. The surface fire is expected to be extinguished during this time period, therefore, it is necessary to account for the loss of carbon dioxide through uncloseable openings during only this time period. It is assumed that the volume of carbon dioxide/air mixture expelled during this 1 min time period will contain carbon dioxide at the design concentration. The total quantity of carbon dioxide lost due to leakage from uncloseable openings (m_{lo}) for a given time period (t) can be estimated by Equations 45.14 (SI units) and 45.15 (U.S. units). A graphical method for estimating the quantity of carbon dioxide lost through uncloseable openings is also provided in NFPA 12 [40].

$$m_{lo} = 116 \cdot A\sqrt{\rho_1 \cdot (\rho_1 - \rho_A)h} \cdot t \qquad (45.14)$$

where

m_{lo} quantity of CO2 leaked through openings, kg
A area of opening, m^2
h height, center of opening to top of protected space, m
ρ_1 density of carbon dioxide-air atmosphere, kg/m^3
ρ_A density of air external to enclosure, kg/m^3
t time duration of leakage, min

At 1 atm pressure (101,300 Pa) and 21 °C

$$\rho_A = 1.202 \ \text{kg/m}^3$$
$$\rho_1 = 0.006220\text{C} + 1.202 \ \text{kg/m}^3$$

$$m_{lo} = 0.6 \cdot C \cdot \rho_{CO2} \cdot A\sqrt{\frac{2g(\rho_1 - \rho_A)h}{\rho_1}} \cdot t \qquad (45.15)$$

where

m_{lo} quantity of CO2 leaked through openings, lb
C CO_2 concentration, vol.%
A area of opening, ft^2
g acceleration of gravity, 32.2 ft/s^2
h height, center of opening to top of protected space, ft
ρ_{CO2} density of carbon dioxide vapor, lb/ft^3
ρ_1 density of carbon dioxide-air atmosphere, lb/ft^3
ρ_A density of air external to enclosure, lb/ft^3
t time duration of leakage, min

At 1 atm pressure, 14.7 psi, and 70 °F

$$\rho_{CO2} = 0.114 \ \text{lb/ft}^3$$
$$\rho_A = 0.0751 \ \text{lb/ft}^3$$
$$\rho_I = 0.000388 \ \text{C} + 0.0750 \ \text{lb/ f}t^3$$

Where an uncloseable opening is on a wall without an opening of comparable size near the

ceiling, the area of the opening (A) in the preceding equations is divided by two since half of the opening acts to allow leakage of carbon dioxide/air mixture while the other half acts to allow ingress of outside makeup air.

Step 5c: Ventilation systems

Mechanical ventilation of a protected volume should be arranged to shut down prior to the discharge of a carbon dioxide system. Where this is not possible, and the ventilation system continues to operate, some quantity of carbon dioxide will be removed from the protected volume. The quantity of carbon dioxide lost due to ventilation (m_{lv}) must be calculated so that it can be included in the final design quantity (m_{FD}). The quantity of carbon dioxide lost is equal to the volume of fresh air introduced into the protected volume by the mechanical ventilation system over a given time period (t) times the flooding factor, as shown in Equation 45.16. For surface fires, the given time period (t) for this calculation is 1 min.

$$m_{lv} = Q_v \cdot t \cdot FF \tag{45.16}$$

where

m_{lv} CO_2 added to compensate for forced ventilation, kg
Q_V ventilation rate, m^3/s
t duration of discharge, s
FF flooding factor, kg/m^3

Step 5d: Temperature Extremes

The quantity of agent must be adjusted to account for extreme temperatures in the protected volume whenever present. Extreme temperatures are those that exceed 93 °C (200 °F) or that are less than −18 °C (0 °F).

SI units: For high temperature extremes, add 0.36 % to carbon dioxide quantity per degree Celsius greater than 93 °C. Refer to Equation 45.17. For low temperatures, add 1.8 % to carbon dioxide quantity per degree Celsius less than −18 °C. Refer to Equation 45.18.

U.S. units: For high temperature extremes, add 1 % to carbon dioxide quantity for each additional 5° Fahrenheit greater than 200 °F. Refer to Equation 45.19. For low temperatures, add 1 % to carbon dioxide quantity for each additional degree Fahrenheit less than 0 °F. Refer to Equation 45.20.

Where the protected volume experiences both high and low extreme temperatures, calculate both the high and low extreme temperature factors, and choose the one with the highest value.

Use the extreme temperature factor in Equation 45.21 to calculate the additional quantity of carbon dioxide required for extreme temperature (m_T), which must be included in the final design quantity (m_{FD}) in Step 6.

$$\tau_H = 0.0036 \cdot (T_H - 93) \tag{45.17}$$

$$\tau_L = -0.018 \cdot (T_L + 18) \tag{45.18}$$

where:

τ_H = Extreme high temperature factor (S.I. units)
T_H = High temperature value (°C)
τ_L = Extreme low temperature factor (S.I. units)
T_L = Low temperature value (°C)

$$\tau_H = 0.002 \cdot (T_H - 200) \tag{45.19}$$

$$\tau_L = 0.01 \cdot (0 - T_L) \tag{45.20}$$

where:

τ_H = Extreme high temperature factor (U.S. units)
T_H = High temperature value (°F)
τ_L = Extreme low temperature factor (U.S. units)
T_L = Low temperature value (°F)

$$m_T = \tau \cdot \left(m_{cf} + m_{lo} + m_{lv}\right) \tag{45.21}$$

where:

m_T = Additional carbon dioxide quantity for extreme temperature
τ = Extreme high or low temperature factor, whichever is greater
m_{cf} = Base quantity of carbon dioxide after applying MCF
m_{lo} = Additional carbon dioxide quantity for leakage through openings
m_{lv} = Additional carbon dioxide quantity for mechanical ventilation

Table 45.16 Design parameters for specific deep-seated fire hazards [41]

Hazard type	Min. design Conc., vol.%	Flooding factor, kg/m^3	Remarks
Dry electrical hazards in general, V < 56.6 m^3	50	1.6	
Dry electrical hazards in general, V > 56.6 m^3	50	1.33	Minimum quantity, 91 kg
Record (bulk paper) storage, ducts, covered trenches	65	2.0	
Fur storage vaults, dust collectors	75	2.66	

Step 6: Determine final design quantity of carbon dioxide

The final design quantity of carbon dioxide is calculated using Equation 45.22, by adding each adjustment quantity determined in Steps 5a through 5d.

$$m_{FD} = m_{cf} + m_{lo} + m_{lv} + m_T \qquad (45.22)$$

Ducts and Covered Trenches

Ducts and covered trenches are a special form of total flooding application. The quantity of carbon dioxide for surface and deep-seated fire hazards in ducts and covered trenches is determined by the protected volume divided by the flooding factor of 2.0 kg/m^3 (0.125 lb/ft^3). The quantity of carbon dioxide so determined will result in a design concentration of approximately 65 vol.%. It is not necessary to further adjust this quantity using the Material Conversion Factor shown in Step 5a. Other special conditions may apply, and if present, should be accounted for as described in Steps 5b through 5d.

Discharge Rate

The discharge rate for surface fires must be sufficient to achieve the design concentration within 1 min from the start of discharge.

Deep-Seated Fires

Determining the Design Quantity

The detailed steps for determining the final design quantity of carbon dioxide for deep-seated fires are described below.

Step 1: Define the fire hazard and the enclosure about the hazard

Identify the predominant combustible material (fuel) associated with the fire hazard. Verify that deep-seated smoldering combustion will characterize the expected fire.

Identify the boundaries of the fixed enclosure about the hazard that is inherently suitable to receive gaseous carbon dioxide and retain it for the required length of time. Calculate the gross volume of the enclosure. Calculate the net volume by subtracting the volumes of any fixed solid, impermeable objects within the enclosure. The net volume is the protected volume (V_P) for the purpose of determining the final design quantity of carbon dioxide.

Step 2: Determine minimum extinguishing concentration (MEC) for the predominate combustible material

There is no theoretical basis for the determination of minimum extinguishing concentrations for deep-seated fires. (See Steps 3 and 4.)

Step 3: Determine the design concentration (DC)

The design concentration (DC) is selected from the Table 45.16. For deep-seated fire hazards not listed in Table 45.16, the DC must be justified to the authority having jurisdiction before the design is finalized and the system is installed.

Step 4: Determine the base design quantity (m_{BD}) of carbon dioxide

There is no theoretical basis for the determination of the base design quantity of carbon dioxide for deep-seated fires. Instead, flooding factors associated with specified design concentrations have been empirically determined by testing and experience for a few common hazards.

Use the flooding factor in Table 45.16 associated with the design concentration selected in Step 3.

For deep-seated fire hazards not listed in Table 45.16, the flooding factor must be justified to the authority having jurisdiction before the design is finalized and the system is installed.

The base design quantity of carbon dioxide is calculated by applying the flooding factor (FF) to the protected volume (Vp) using Equation 45.11.

Step 5: Determine additional quantities of carbon dioxide for special conditions

The base design quantity of carbon dioxide (m_{BD}) determined in the previous steps, may require adjustment based upon the effects of several special conditions. Each of these special conditions must be considered, and adjustments made to the m_{BD} as appropriate, which will lead to the determination of the final carbon dioxide design quantity (m_{FD}).

Step 5a: Material Conversion Factor

The Material Conversion Factor used for surface fires does not apply to deep-seated fires. Proceed to Step 5b.

Step 5b: Uncloseable Openings

Determine if the enclosure surrounding the protected volume has openings that cannot be closed. As carbon dioxide is discharged into the protected volume, some quantity of carbon dioxide will be expelled through these openings. The quantity of carbon dioxide lost must be calculated and added into the final design quantity (m_{FD}).

The total quantity of carbon dioxide lost due to leakage from uncloseable openings (m_{lo}) for a given time period (t) can be estimated by Equations 45.14 and 45.15. For deep-seated fires, time (t) is the entire extinguishing period, which must be a minimum of 20 min, and in some cases may need to be longer. As a result, it is necessary to minimize the normal leakage and close all openings in the enclosures around deep-seated fire hazards. If this is not possible, an extended discharge will likely be required.

Step 5c: Ventilation systems

Mechanical ventilation of a protected volume should be arranged to shut down prior to the discharge of a carbon dioxide system. Where this is not possible, and the ventilation system continues to operate, some quantity of carbon dioxide will be removed from the protected volume. The quantity of carbon dioxide lost due to ventilation (m_{lv}) must be calculated so that it can be included in the final design quantity (m_{FD}). The quantity of carbon dioxide lost is equal to the volume of fresh air introduced into the protected volume by the mechanical ventilation system over a given time period (t) times the flooding factor, as shown in Equation 45.16.

For deep-seated fires, the given time period (t) for this calculation must be a minimum of 20 min, and in some cases may need to be longer. This will normally require the provision of an extended discharge.

Step 5d: Temperature Extremes

The quantity of agent must be adjusted to account for extreme temperatures in the protected volume whenever present. Extreme temperatures are those that exceed 93 °C (200 °F) or that are less than −18 °C (0 °F).

For high temperature extremes, add 0.36 % to carbon dioxide quantity per degree Celsius greater than 93 °C. Refer to Equation 45.17. For low temperatures, add 1.8 % to carbon dioxide quantity per degree Celsius less than −18 °C. Refer to Equation 45.18.

(For high temperature extremes, add 1 % to carbon dioxide quantity for each additional 5° Fahrenheit greater than 200 °F. Refer to Equation 45.19. For low temperatures, add 1 % to carbon dioxide quantity for each additional degree Fahrenheit less than 0 °F). Refer to Equation 45.20.

Where the protected volume experiences both high and low extreme temperatures, calculate both the high and low extreme temperature factors, and choose the one with the highest value.

Use the extreme temperature factor in Equation 45.21 to calculate the additional quantity of carbon dioxide required for extreme temperature (m_T), which must be included in the final design quantity (m_{FD}) in Step 6.

Step 6: Determine final design quantity of carbon dioxide

The final design quantity of carbon dioxide is calculated using Equation 45.22, by adding each adjustment quantity determined in Steps 5a through 5d, where $m_{cf} = 0$.

Discharge Rate

The discharge rate for deep-seated fires must be sufficient to achieve the design concentration within 7 min from the start of discharge, and also achieve a concentration of at least 30 vol. % within 2 min from the start of discharge.

Enclosed rotating electrical equipment: The design concentration of 30 vol.% design concentration must be provided for enclosed rotating electrical equipment, and maintained for the entire deceleration period and not less than 20 min.

This type of equipment is expected to have an enclosure that will leak some carbon dioxide during the deceleration period. This will require an initial discharge followed by an extended discharge of carbon dioxide to maintain 30 vol.% continuously.

For enclosure volumes less than or equal to 56.6 m^3 (2000 ft^3), a flooding factor of 1.6 kg/m^3 (0.1 lb/ft^3) should be used to determine the quantity of carbon dioxide to use for the initial discharge. For enclosure volumes greater than 56.6 m^3 (2000 ft^3), a flooding factor of 1.32 kg/m^3 (0.08 lb/ft^3) should be used.

The values given in Tables 45.17 and 45.18 may be used as a guide in determining the quantity of carbon dioxide for the extended discharge to maintain a carbon dioxide concentration of 30 vol.% as a function of the enclosure volume and equipment deceleration time, and assuming average leakage from the enclosure. For dampered, non-recirculating-type equipment, add 35 % to the quantities indicated.

Example—Total Flooding System What is the CO_2 design quantity and rate of discharge required to protect by total flooding a 500 m^3 (10 m × 12.5 m × 4 m) enclosure of light building construction in which ethyl alcohol is processed?

For combustibles where the MDC is 34 vol.% the flooding factor for a 500 m^3 enclosure is 0.80 kg/m^3 and the basic CO_2 design quantity, m_{BD}, is (500 m^3) (0.80 kg/m^3) = 400 kg CO_2. However, ethyl alcohol has an MDC of 43 % and a corresponding material conversion factor is 1.4. Therefore, the design quantity, m_D, is (400 kg) (1.4) = 560 kg. The design discharge time is 1 min so w = 560 kg/min.

Total Flooding Systems, Marine Applications

Carbon dioxide total flooding systems are used extensively to protect the unique hazards aboard ships and other structures, such as mobile offshore drilling units, that are governed by various marine regulations. These marine systems should be designed to comply with the applicable regulations.

Quantity of Carbon Dioxide

There are several variations in the methods used to determine carbon dioxide design quantity for marine total flooding systems. NFPA 12 specifies a minimum design concentration for several types of hazards, including machinery, vehicle storage and electrical equipment. A flooding factor is specified for general cargo storage hazards rather than a minimum design concentration.

The U.S. Coast Guard specifies flooding factors for all covered hazards, including machinery, general cargo storage, and vehicle storage. SOLAS specifies minimum design concentrations for machinery hazards and a flooding factor for general cargo storage. ABS specifies minimum design concentrations for machinery, general cargo storage and vehicle storage, and does not specify flooding factors for any hazard types.

Tables 45.19 and 45.20 provide the design specifications for various hazard types from NFPA 12, SOLAS, USCG, and ABS.

When a standard specifies a minimum design concentration as the governing design requirement, a calculation method defined by each standard must be followed to determine the final design quantity of carbon dioxide. These design methods vary, so it is important to use the calculation method from the standard being employed.

For example, NFPA 12 specifies a minimum design concentration of 34 vol.% for the

protection of machinery spaces based on the gross volume, including the casing. The method specified for calculating the final design quantity of carbon dioxide associated with the specified design concentration includes the concept of free-efflux flooding (Equation 45.5), and quantity adjustments if necessary to account for uncloseable openings, mechanical ventilation and extreme temperatures. Employing the free-efflux flooding concept results in a quantity of carbon dioxide that will achieve an initial carbon dioxide concentration that is higher than the minimum design concentration to account for the loss of some carbon dioxide during discharge through normal enclosure leakage.

In contrast, SOLAS and ABS do not require the calculation of carbon dioxide quantity using the free-efflux flooding equation, when a minimum design concentration is specified. Instead, a carbon dioxide liquid to gas expansion factor (specific volume) is specified, which must be used to calculate the quantity of carbon dioxide required based upon the minimum design concentration specified for the protected volume of the enclosure surrounding the hazard. Equation 45.23 is used for this calculation.

$$m_{BD} = \frac{V}{s} \cdot \frac{C}{100} \tag{45.23}$$

where

m_{BD} base design quantity of carbon dioxide, kg (lb)

V protected volume, m^3 (ft^3)

C minimum design concentration (vol.%)

s specific volume (expansion factor), 0.56 m^3/kg (9 ft^3/lb)

Equation 45.23 does not account for leakage during discharge. The resulting quantity of carbon dioxide is less than would be determined using the free-efflux model, Equation 45.9. Equation 45.23 is correct only where carbon dioxide-free air is expelled from the protected volume during discharge, which is very unlikely given that the discharge rate requirement under SOLAS and ABS standards is release of 85 % of the design quantity of carbon dioxide in 2 min (Table 45.21). For example, consider a 500 m^3 (17,650 ft^3) enclosure, a design concentration of 35 % (total flooding, machinery spaces, including casing)), and a specific volume, s, of 0.56 m^3/kg (9 ft^3/lb). The required quantity of carbon dioxide by Equation 45.23 is 313 kg (690 lb), and by Equation 45.9 is 385 kg (849 lb). Where gas mixing and leakage occur during discharge (free-efflux model), the quantity of 313 kg (690 lb) would result in a post-discharge carbon dioxide concentration of only

[a]Requirements are not based upon quantity of fuel in vehicles
[b]Carbon dioxide systems are not allowed in these spaces

29.5 vol.%. The USCG requirement for a space of this size (see Table 45.20) is to use a flooding factor of 0.80 kg/m^3 (0.05 lb/ft^3) giving a required quantity of 400 kg (883 lb) which would result in a concentration of 36.1 vol.% per Equation 45.9.

All referenced marine carbon dioxide system design standards require a flooding factor (FF) be applied to the protected volume (V_P) to determine the quantity of carbon dioxide for one or more hazard types (refer to Equation 45.11).

SOLAS does not require adjustments to the base design quantity of carbon dioxide calculated using Equations 45.23 or 45.9 [44]. ABS requires an additional quantity of carbon dioxide equal to that lost through "non-tight" cargo space hatch covers [45] but provides no guidance to calculate this quantity.

Discharge Rate

Marine total flooding carbon dioxide system discharge rate requirements are dependent on both the specific type of hazard being protected and the governing standard. Table 45.21 illustrates this point by summarizing the discharge rates found in the four referenced standards.

Enclosure Venting for Pressure Control for Total Flooding Systems

Carbon dioxide enters a nozzle as a mixture of cold liquid and vapor and exits as a mixture of vapor and solid-phase "dry ice" or "CO_2-snow." Sublimation (vaporization) of the solid carbon dioxide and exchange of the cold vapor with the air in a room results in a temperature reduction. The net effect on the pressure in a tightly sealed room depends on the storage condition of the carbon dioxide (high-pressure or refrigerated low-pressure), total quantity of gas discharged, the size of the protected volume, and its initial temperature. In most cases the enclosure pressure will rise upon carbon dioxide discharge. It is possible, however, under unusual circumstances for the enclosure pressure to decrease.

Discharge of a large quantity of cold carbon dioxide into a tightly sealed room can result in a pressure decrease. Where such conditions are possible it is recommended that an energy balance evaluation be completed for the enclosure air and the quantity, and storage enthalpy of the carbon dioxide discharged, to determine if there is a risk of pressure decrease.

The pressure rise in an enclosure due to carbon dioxide discharge is capable of causing damage to the enclosure construction due to characteristics common to many system installations. The risk of enclosure damage can be greatly reduced by designing and installing a means of pressure relief.

Enclosure construction, including walls, ceilings and floors, are commonly not tightly sealed. Such enclosures contain numerous locations where pressure would be relieved to

some degree. The aggregate effect of such leakage locations is often referred to as "normal leakage" or "average leakage". Normal leakage should not be relied upon to provide adequate pressure venting to prevent unsafe pressure rise resulting from carbon dioxide discharge. The size of the minimum pressure relief area required is based on the maximum flow rate of carbon dioxide and is calculated using Equation 45.24 [46].

$$A_V = \frac{239 \cdot w}{\sqrt{P}} \qquad (45.24)$$

Where:
A_V = vent area, mm^2
w = carbon dioxide flow rate, kg/min
P = allowable enclosure pressure limit, kPa

The pressure relief (vent) area can be provided by passive (e.g. barometric dampers) or actuated vents (motor-controlled louvers that are opened before the onset of carbon dioxide discharge). Where a minimum concentration of carbon dioxide must be maintained in a room for a specific hold time, vents must be located at the highest point in an otherwise tightly closed room and should be arranged to close after discharge ceases.

Assessment of the allowable pressure limit for an enclosure is often a challenge. Table 45.22 indicates approximate pressure limits for three general types of construction. In the absence of a structural analysis of an enclosure, the user should consider discounting the values in Table 45.22 to provide a safety margin for the design.

Pressure Relief Example What size pressure relief vent is necessary to protect the enclosure described in the total-flooding example given above? Assume the pressure limit is 0.6 kPa (0.09 psi), half of the rated strength for light building construction.

The design rate of discharge is 560 kg/min (1,234.6 lb/min). Light building construction has a rated strength of 1.2 kPa (0.17 psi) as shown in Table 45.22. For this example the design pressure limit is half of the rated value, or (½) (1.2 kPa) = 0.6 kPa (0.09 psi). Using half of the rated value in this manner is a choice of the designer to incorporate a design safety margin. Using Equation 45.24, the required vent area is:

$$A_V = \frac{239 \cdot 560}{\sqrt{0.6}} = 172,787 \ mm^2 = 0.173 \ m^2$$

Table 45.22 Allowable pressure for average enclosures [47]

Construction type	P, kPa	Note
Light building	1.2	Venting sash remains open
Normal building	2.4	Venting sash designed to open freely
Vault building	4.8	

Local Application Systems

A total-flooding system discharges carbon dioxide throughout an entire enclosed volume so that the atmosphere can no longer support combustion. By contrast, a local application system projects carbon dioxide directly onto or in close proximity to a defined surface-fire hazard (flammable gases, liquids, or shallow solids) and maintains an extinguishing atmosphere on or about a precisely define geometric space, but only during the discharge period. Local application systems are designed by either of two methods: rate-by-area or rate-by-volume.

Local application systems are used where the fire hazard is either not confined within an enclosure or the defining enclosure is too large to protect by total flooding in a practical manner. Protected hazards may by completely indoors, partly sheltered, or completely outdoors. The discharge of carbon dioxide must be so arranged that extinguishment of the target fire is not impaired by air currents or wind.

A local application system must be designed to protect the entirety of the hazard which must be sufficiently separated from other hazards so as not to pose a risk of fire spread outside of the protected space. The definition of the protected hazard must include the principal process space or equipment as well as locations or items that can be wetted by splashing, leaking, dripping, or

condensing flammable liquids and associated items or materials such as coated objects, drain boards, hood, or ducts that could serve to propagate a fire into or out of the primary protected space. A series of hazards that expose each other to fire propagation can be can be divided and protected as subgroups or sections with the approval of the local authority having jurisdiction.

The basic design quantity of carbon dioxide required is determined by rate of liquid discharge to protect a defined area or volume times the liquid discharge time. The basic design quantity must be increased based upon consideration of the following factors: high-pressure storage supply; carbon dioxide vaporization in distribution pipe system.

High-Pressure Storage Supply

Where carbon dioxide is supplied from high-pressure storage containers the basic carbon dioxide quantity shall be increased by 40 %, i.e. multiplied by a liquid efficiency factor of 1.4, as these containers discharge only about 70–75 % of their contents as liquid which is deemed, in local application, to be the effective part of the discharge.

Vaporization in Pipe System

Some carbon dioxide is vaporized in the pipe system at the start of discharge. The basic quantity of carbon dioxide must be augmented by the amount so vaporized which can be estimated as follows:

$$m_{CO2.V} = \frac{m_P C_P (T_1 - T_2)}{\Delta H_V} \tag{45.25}$$

where

C_P = specific heat of steel pipe, approximately 0.46 kJ/kg-K

ΔH_V = latent heat of vaporization of liquid CO_2 (149 kJ/kg for high-pressure storage and 279 kJ/kg for low-pressure storage)

$m_{CO2,V}$ = mass of CO2 evaporated in the pipe, kg

m_P = mass of pipe system, kg

T_1 = initial pipe temperature, °C

T_2 = average temperature of liquid CO_2 flowing in pipe, taken as 16 °C for high-pressure storage and −21 °C for low-pressure storage

Assuming that $T_1 = 20$ °C and average values of T_2 °C, the amount of CO_2 vaporized in a pipe system will be approximately:

$$m_{CO2,V} = 0.012 m_P \quad \text{high-pressure storage} \tag{45.26}$$

$$m_{CO2,V} = 0.0678 \cdot m_P \tag{45.27}$$

The total rate of discharge of a local-application system will be the sum of the individual discharge rate of all nozzles or other dispensing points in a system. The number of nozzles for a local application system is determined as described under *Nozzle coverage*, in the Rate-by-Area and Rate-by-Volume methods sections below.

Where part of a hazard is to be protected by total flooding and part by local application the following guidance applies:

The total-flooding design concentration must be achieved not later than the end of discharge for the local-application portion of the system.

The discharge rate for the total-flooding part shall be computed by dividing the quantity required for total flooding by the factor 1.4 and by the time of the local application discharge in minutes. Use the following equation:

$$w_{TF} = \frac{m_{TF}}{1.4 \cdot t_{LA}} \tag{45.28}$$

where

w_{TF} flow rate into total-flood part, kg/s

m_{TF} total quantity of CO2 for the total-flood part, kg

t_{LA} discharge time for local-application part, s

The duration of liquid discharge for computing the basic carbon dioxide quantity for a local-application system, or the local-application portion of a combined system, shall be at least 30 s. Where a liquid fuel has an auto-ignition temperature below its boiling point (e.g., cooking oils, paraffin waxes) the minimum discharge time shall be 3 min. Longer discharge times should

be considered to compensate for hazard conditions that may require more time for them to be rendered ineffective as re-ignition sources. For example, additional time may be required to cool hot liquids or heated surfaces to at least 35 °C (95 °F) below the autoignition temperature of exposed flammable liquids or gases. In such cases an engineering analysis may be required to estimate cooling times.

Rate-by-Area Method

The rate-by-area method is used where the fire hazard is primarily characterized by flat surfaces or low-level objects. System designs are based on use of nozzles having approved area coverage based on location and height above the protected surface. Since each nozzle used in the rate-by-area or rate-by-volume method is used to protect a specific portion of a hazard, the flow rate through each nozzle must be within its listed and approved limits.

For each over-head nozzle, its discharge rate is based only on its location and distance from the hazard. The approved discharge rate is determined by testing to establish the design flow rate at which a nozzle should be used for the height at which it is installed above a liquid surface.

The carbon dioxide system manufacturer's manual will contain nozzle tables for each type of nozzle approved for use in local application extinguishing systems. Typically, each table will list a range of nozzle mounting heights. Table 45.23 shows typical format and coverage values for one nozzle type. For each height there will be a corresponding CO_2 flow rate, the maximum coverage area and "side-of-square" for liquid-surface and coated-surface fire hazards. "Side-of-square" is the width of a square corresponding to the allowed area coverage and represents the maximum distance between nozzles, or between rows of nozzles. Table 45.23 (illustrative only) shows how manufacturer's nozzle coverage data would typically be tabulated.

A system protecting multiple hazards can be designed to incorporate both local-application and total-flooding protection. The rate of discharge for the total-flooding portion shall be as described under *Rate of discharge* in the preceding total flooding section.

The discharge rate for a tank-side nozzle is based on its projection of CO_2 required to cover a protected surface. The approved discharge rate is determined by test. Fire tests are conducted to develop curves relating the maximum and minimum flow rates at which a nozzle can be used to the area of fire that the nozzle is capable of extinguishing, with additional limitations regarding maximum width of hazard and spacing requirements between nozzles and to the nearest corner of a hazard.

The rate-by-area method is used to protect fire hazards characterized predominantly by flat surfaces or low-level objects associated with horizontal surfaces. Examples include vats, drip trays, dip tanks, coated rollers or surfaces where liquid drains off and where the area of localized liquid pooling is less than 10 % of the protected area. The maximum area covered by a nozzle is based on its projection distance and maximum rated discharge rate. The shape of area covered by a nozzle is deemed to be square.

Where the area to be protected consists of coated surfaces, and where there is not a heavy accumulation of combustible residue, it is permissible to increase the maximum area coverage of a nozzle by 40 %.

Where a local application nozzle is used to project carbon dioxide across the face of an opening the maximum area coverage of the nozzle may be increased by 20 % over its rated value.

Where flammable liquids having depth are to be protected, a freeboard of at least 152 mm (6 in.) must be provided unless otherwise noted in the approved rating of a nozzle.

The number of nozzles used in an application shall be sufficient to cover the entire hazard area. Tank-side and linear nozzles shall be located within their approved spacing and discharge rate limits. Overhead nozzles must be mounted centered over and perpendicular to the covered hazard area. The nozzle height used to determine the flow rate is based on the distance from the nozzle face to the aiming point.

Nozzles may be installed in non-overhead locations. In such cases nozzles need may be aimed at an angle of 45°–90° (perpendicular) with respect to the plane of the hazard surface provided that the following conditions are met:

- The distance to the nozzle is measured to an aiming point at the near side of the protected area.
- The design area coverage for each nozzle is reduced from its approved rated value by an "aiming factor." See Table 45.24.
- The design nozzle area coverage is calculated as the product of the width of the protected area times the aiming factor.

The flow path from a nozzle to its protected hazard area must be unobstructed. Where an object protects above the protected surface, nozzles shall be arranged to cover the object with an extinguishing atmosphere. The effects of air currents in the protected area shall be compensated for by adjusting nozzle locations or extending the area of coverage beyond the perimeter of the hazard.

Table 45.24 Nozzle aiming factors [48]

Nozzle discharge angle[a]	Aiming factor[b]
45°–60°	0.25

75°–90°	0.375–0.50
90°	0.50

[a]From plane of hazard surface
[b]Fractional amount of nozzle area coverage

To summarize, the quantity of carbon dioxide required for a rate-by-area system can be calculated as follows (assuming initial pipe temperature of 20 °C, and average temperature of carbon dioxide liquid flowing in pipe system of 16 °C for high pressure systems and −21 °C for low pressure systems):

High-pressure storage :

$$m_D = 1.4\left[t_D \sum_i n_i w_i + 0.012 m_P\right] \tag{45.29}$$

Low-pressure storage :

$$m_D = \left[t_D \sum_i n_i w_i + 0.127 m_P\right] \tag{45.30}$$

where
n_i = number of nozzles with flow rate w_i
w_i = flow rate i, kg/min
t_D = liquid discharge time, at least 0.5 min
m_P = mass of pipe, kg

Example—Local Application Rate-by-Area Method Consider a quench tank measuring 5 m × 3 m with a 0.15 m free board as shown in Fig. 45.8. The fuel is quench oil. Nozzle heights are limited to 0.6–1.8 m above the liquid. Describe a high-pressure CO_2 system using 45.4 kg capacity cylinders, number type and arrangement of nozzle to protect the quench tank and a spillage perimeter that extends 0.6 m on all sides. Assume 30 s discharge time and a pipe system with a mass of 300 kg.

Hazard dimensions: length = 5 + 0.6 + 0.6 = 6.2 m ; width = 3 + 0.6 + 0.6 = 4.2 m ; area = (6.2)(4.2) = 26.0 m^2.

Nozzle height: initially select 1.5 m (this dimension is a design choice)

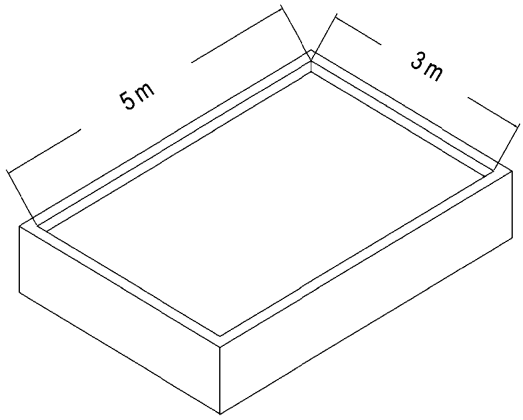

Fig. 45.8 3 m × 5 m quench tank

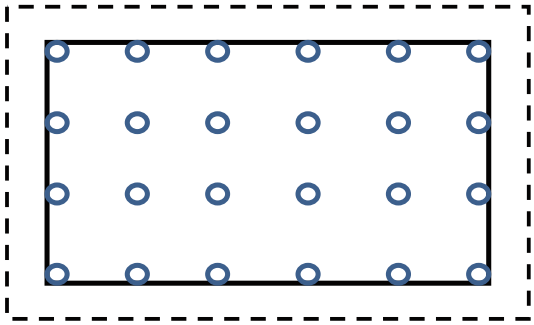

Fig. 45.9 Nozzle arrangement over quench tank hazard

Consult example nozzle table: Flow rate = 32.57 kg/min; side-of-square = 1.17 m

No. nozzle rows parallel to length = 4.2/1.17 = 3.6; round up to 4

No. nozzle rows parallel to width = 6.2/1.17 = 5.3; round up to 6

Total number nozzles = 4 × 6 = 24

CO_2 liquid flow rate = 24 × 32.57 = 781.7 kg/min

Quantity of CO_2: (a) Basic design quantity = rate of discharge x discharge time × high-pressure efficiency factor = 781.7 × 0.5 × 1.4 = 547.2 kg; (b) Quantity to compensate for pipe-cooling: (0.012 kg CO_2/kg-pipe) (300 kg) = 3.6 kg. Total CO_2 requirement = 561 kg. The number of cylinders = 561/45.4 = 12.1, round up to 13 cylinders. The nozzles can be arranged in four rows of six nozzles each centered over the hazard as illustrated in Fig. 45.9.

Rate-by-Volume Method

The rate-by-volume method is used where the fire hazard consists of three-dimensional irregularly shaped objects that cannot be reasonable represented as a simple equivalent surface. The total rate of discharge is based on the gross volume of a virtual hazard enclosure that extends at least 0.6 m beyond the lateral and vertical dimensions of the actual hazard, unless an actual wall or ceiling is closer, and which includes areas of possible spillage, splashing, or leakage. The smallest dimension of the virtual hazard is to be no less than 1.2 m. The floor beneath the virtual volume should be a uniformly closed surface and, if not, special provisions are required to account for openings. If the protected volume is subject to winds or drafts, the virtual hazard volume shall be increased to compensate for losses on the windward sides.

The total discharge rate for the basic system shall be equal to 16 kg/min · m^3 of virtual volume. The discharge rate may be reduced by as much as 12 kg/min · m^3 in proportion to the fraction of the perimeter of the virtual volume that consists of permanent and continuous walls that extend at least 0.6 m above the hazard, and provided that the walls are not actually part of the protected hazard. See Fig. 45.10.

The number of nozzles used to cover the entire protected hazard volume is based on the total discharge rate as determined by the assumed volume. Nozzles are located and aimed so as to promote retention of the discharged carbon dioxide within and throughout the virtual hazard volume to the extent possible and to compensate for the effects of air currents, winds, or forced drafts. The design discharge rates through individual nozzles shall be determined on the basis of location or projection distance in accordance with their approved use for surface fires.

The extinguishing system is to be designed for automatic operation except where the authorities having jurisdiction permit manual operation. The fire detection system should be designed to initiate discharge promptly after ignition to prevent excessive heating of materials within the hazard.

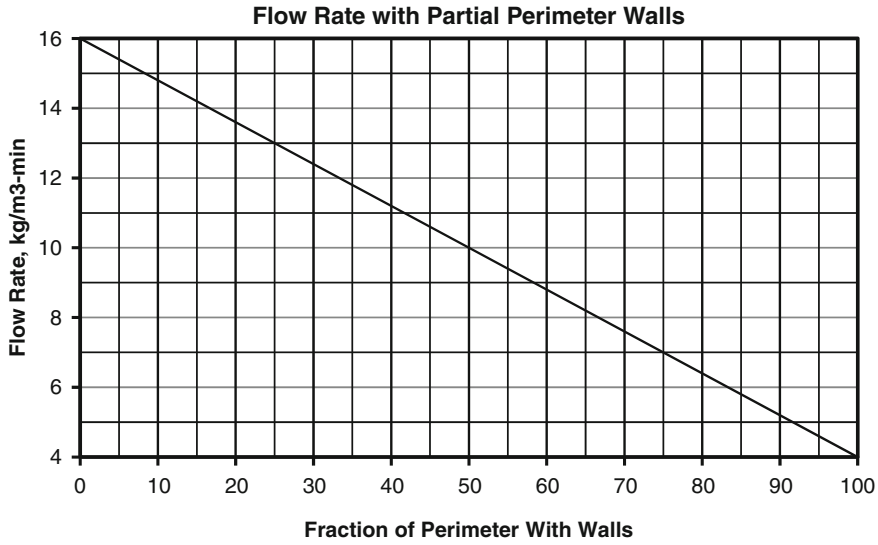

Fig. 45.10 Carbon dioxide flow rate with partial perimeter walls

The carbon dioxide supply should be located as close as practicable to the hazard while not exposing the equipment to a prospective fire. The pipeline should be as short and direct as practicable to minimize the time from cylinder actuation to the onset of carbon dioxide discharge into the protected space. Nozzles shall be used within their approved performance limits (flow rate, range, area coverage), and positioned and aimed in accordance with the system design requirements as previously described.

Example—Rate-by-Volume Method Consider protection of a diesel fuel pumping skid having an equipment arrangement with a footprint measuring 3 m by 4 m and an overall height of 3 m as illustrated in Fig. 45.11. The equipment is located on a solid floor and in a corner where two walls meet at 90°. The ceiling height is 5 m. The equipment is positioned so that each edge of the skid 1 m from a wall. The equipment is not enclosed on the other two sides. Determine the design quantity of carbon dioxide to be delivered from high-pressure storage for a rate-by-volume system assuming a virtual volume that includes the 1 m distance between the equipment and the two walls and a 0.6 m distances above the equipment and beyond the two unenclosed sides. Neglect the amount required to compensate for pipe cooling. The sketch below depicts (a) two confining walls; (b) the equipment volume surrounded by (c) the virtual design volume in dashed lines.

The size of the protected volume is L × W × H = (4 + 0.6 + 1) (3 + 0.6 + 1) (3 + 0.6) = 92.7 m^3. The protected perimeter is (2) [(4 + 0.6 + 1) + (3 + 0.6 + 1)] = 20.4 m. One-half of the protected perimeter, 10.2 m, consists of permanent and impermeable walls. As such, the basic discharge per unit volume can be reduced from 16 kg/min-m^3 by the amount (½) (12 kg/min-m^3) = 6 kg/min-m^3. Thus, the design rate of liquid CO_2 discharge is (92.7 m^3) ([16 – 6] kg/min-m^3) = 927 kg/min. The duration of liquid discharge is 30 s. The total design quantity of CO_2 = rate of discharge × discharge time × high-pressure efficiency factor = 927 × 0.5 × 1.4 = 649 kg. The number of 45.4 kg high-pressure CO_2 cylinders is 649/45.4 = 14.3, rounded up to 15 cylinders.

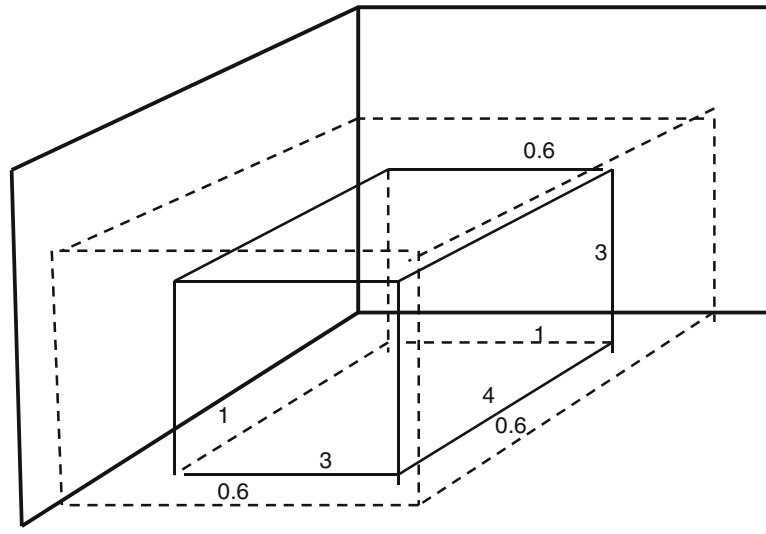

Fig. 45.11 Representation of three-dimensional hazard including virtual boundaries

Carbon Dioxide Hydraulic Calculations to Estimate Nozzle Pressure

Pipeline Pressure Loss due to Flow

A carbon dioxide fire extinguishing system is designed to discharge a certain quantity of carbon dioxide through one or more nozzles within a specified time period as determined by a total flooding or local application system design approach. Each nozzle in a system is selected based on its design flow rate at the average anticipated discharge pressure. The flow rate of carbon dioxide through a nozzle, Q_{NOZ}, is calculated as the product of the mass flow rate per unit of orifice area of the nozzle, i.e. the orifice mass flux, G, times the equivalent nozzle orifice area, A_{NOZ} as indicated in Equation 45.31.

$$Q_{NOZ} = G \cdot A_{NOZ} \qquad (45.31)$$

The equivalent orifice area of a given manufacturer's nozzle is determined through testing. The carbon dioxide orifice mass flux, G, varies depending on the average fluid density which, in turn, depends on the pressure at the discharge outlet. Values of G are tabulated as a function of pressure in Table 45.25.

The design challenge, therefore, is to determine the effective average pressure at each nozzle during discharge. Commercial computer programs are available for facilitating the design and layout of carbon dioxide pipe distribution systems. These programs calculate pressures at key nodes of a pipe network, optimize the pipe-size, nozzle sizes, and determine the mass of liquid and vapor discharged at each nozzle. Flow calculation routines are usually based on, or are at least benchmarked against, the method described in NFPA 12, Annex C. The same method is also documented in ISO 6183 [35]. The following describes how to use the NFPA 12 carbon dioxide flow equation to calculate pressure loss in a pipeline and select nozzle sizes.

As noted previously, carbon dioxide is stored as a liquefied compressed gas in either refrigerated low-pressure tanks, maintained at about −18 °C (0 °F), or in high-pressure cylinders stored at ambient temperatures. Upon discharge, carbon dioxide flows into a pipe system that terminates at one or more nozzles. The average pressure at any point in the pipe system is governed by conservation equations of momentum and energy. The momentum equation relates pressure changes to changes in fluid

density and friction loss along the pipe network. The energy equation accounts for heat exchange between carbon dioxide and the pipe system, particularly during initial flow when the pipe system is cooled to the fluid temperature. Vapor-liquid equilibrium is assumed to prevail everywhere in the pipe system.

The momentum equation is presented as:

$$dp + d\left(\rho u^2\right) + \tfrac{1}{2}\rho u^2 f \cdot \frac{dx}{D} = 0 \qquad (45.32)$$

Here p is pressure, u is velocity, ρ is density, x is distance, D is the internal pipe diameter, and f is the Darcy-Weisbach friction factor. The first term on the left is the pressure change over distance dx; the second term accounts for pressure change due to variations in the fluid density and velocity (e.g. acceleration as liquid vaporizes); and the third term accounts for pressure loss due to friction effects with the pipe wall. The friction factor is a non-linear function of the degree of turbulence in the flow, characterized by the Reynolds number, Re, which is equal to $\rho Du/\mu$, where μ is viscosity, and on the surface roughness, ε, of the pipe [49]. At very high Reynolds numbers the value of f is insensitive to changes in u, ρ, and μ. In this flow regime f is effectively a function of ε and D only. The applicable friction factor relations are assumed to apply during system discharge for three common types of pipe used in carbon dioxide systems:

Uncoated steel pipe	$f = 0.0227\ D^{-0.25}$
Galvanized pipe	$f = 0.032\ D^{-0.35}$
Drawn tubing	$f = 0.011\ D^{-0.117}$

where D is in inches.

The solution of Equation 45.32 over a defined pipe length, L, yields the following governing flow equations for each type of pipe:

$$\text{Uncoated steel pipe} \quad Q^2 = \frac{3647 \cdot YD^{5.25}}{L + 8.08D^{1.25}Z} \qquad (45.33a)$$

$$\text{Galvanized pipe} \quad Q^2 = \frac{2586 \cdot YD^{5.35}}{L + 5.72D^{1.35}Z} \tag{45.33b}$$

$$\text{Drawn tubing} \quad Q^2 = \frac{7524 \cdot YD^{5.117}}{L + 16.66D^{1.117}Z} \tag{45.33c}$$

Where Q is mass flow rate (lb/min), D is inside pipe diameter (in), and L is the equivalent pipe length (ft). Values of Y and Z are non-linear functions of pressure and density defined as follows:

$$Y = -\int_{Po}^{P} \rho dP \tag{45.34}$$

$$Z = -\int_{\rho o}^{\rho} \frac{d\rho}{\rho} \tag{45.35}$$

The values of Y and Z are functions of pressure that depend on the storage method of the carbon dioxide supply which is either as a refrigerated low-vapor pressure liquid or as an ambient-temperature high-vapor pressure liquid. Values of pressure (averaged over the period of discharge) along a pipe system are determined by solving Equations 45.34 and 45.35 for Y and Z and then looking up the corresponding value of pressure in Tables 45.26 and 45.27.[1]

In practice a pipe network is evaluated in sections. A section may be as small as a single pipe fitting or length of pipe, or may consist of multiple lengths of pipe and fittings so long as the pipe diameter is constant. The equivalent length, L, of a section of a pipe system is the sum of the lengths of the included pipe sections and all fittings or flow devices such as valves. Values of equivalent length of manufacturer-supplied components (cylinder discharge valves, check valves, etc.) are determined by testing. Corrections to pressure are made to account for changes in pipe elevation. Values of pipe diameters, equivalent length of standard pipe fittings, and elevation pressure correction factors are indicated in the Tables 45.28, 45.29, 45.30 and 45.31.

Nozzle Selection

A manufacturer's nozzle is characterized by an "equivalent single orifice area" regardless of the actual number of orifices it contains. The standard "Orifice Code No." is equal to the diameter, in increments of 1/32 in., of the equivalent single orifice.

- Orifice Codes 1 to 9.5 are in size increments of 0.5
- Orifice Codes 10 to 64 are in size increments of 1

For example, a nozzle having an equivalent single orifice area of 0.0431 in.^{2} has an equivalent diameter of 15/64 in., or 7.5/32 in., therefore the Orifice Code No. is 7.5. In a design application where a calculated orifice size falls between two standard sizes, choose the nearest size unless the applicable flow rate requirement is a minimum value, in which case choose the next larger size.

Estimation of Nozzle Pressure

The choice of nozzle depends on the estimated value of average pressure at the nozzle. Commercially available computer programs are able to perform the associated calculations to determine average nozzle pressures for complex piping arrangement. While somewhat tedious, the associated calculations can be performed by hand or with the use of a spreadsheet. The procedure for performing hand or spreadsheet calculations is described below.

Calculation of pressure along a pipe network is carried out by solving Equation 45.33 in a stepwise manner, i.e. node-to-node. Here, a node is any component junction and includes: cylinder siphon tube entrance, cylinder valve exit, flex-hose to valve, flex-hose to manifold tee, tee to

[1] Tables 45.26 and 45.27 are expanded versions, in 1 psi pressure increments, of Tables C.1 (a) and C.1 (b) from NFPA 12 [34].

pipe, pipe to elbow, pipe to nozzle, etc. Pressure change calculations can be performed at each node or for a pipe segment between several nodes involving the same pipe diameter.

The procedure uses a variant of Equation 45.33 as follows:

$$\frac{L}{D^d} - \frac{a \cdot Y}{\left(\frac{Q}{D^{(b-d)/2}}\right)^2} + c \cdot Z = 0 \qquad (45.36)$$

The constants a, b, c and d for the different types of pipe are shown in the Table 45.32.

For uncoated steel pipe (sometimes called "black" pipe), Equation 45.36 becomes

$$\frac{L}{D^{1.25}} - \frac{3647 \cdot Y}{\left(\frac{D}{D^2}\right)^2} + 8.08Z = 0 \qquad (45.37)$$

In a given pipe section the total equivalent length, L, the flow rate Q, and diameter, D, are known. The terms Y and Z are functions of pressure (tabulated in Tables 45.26 and 45.27). The end-of-segment pressure, P, having Y and Z values that make the left-hand side (LHS) of Equation 45.37 equal to zero is the solution.

The hand or spreadsheet calculation procedure can be performed as follows:

1. Create a sketch of the required pipe system layout showing the carbon dioxide supply (one or more high-pressure cylinders or a low-pressure tank), discharge manifold, pipe type, size and length, elevation changes, fittings (elbows, tees, check valves, etc.). Label all the nodes at which pressure will be calculated as illustrated in Fig. 45.12.

Table 45.28 Size data for ANSI steel pipe

Nominal size, in.	Pipe schedule	D, in.	$D^{1.25}$	D^2
1/4	40	0.364	0.2827	0.1325
3/8	40	0.493	0.4131	0.2430

3	80	2.900	3.7844	8.4100
4	80	3.826	5.3510	14.6383
5	80	4.813	7.1289	23.1650
6	80	5.761	8.9253	33.1891
7	80	6.625	10.6288	43.8906
8	80	7.625	12.6707	58.1406

2. Set up a table to capture data for each pipe segment as indicated in Table 45.33.
3. Determine the equivalent length, L, between nodes. This is the sum of (1) actual pipe length, (2) equivalent length of fittings in the flow path,[2] and (3) the equivalent length of the pipe system upstream of the section being evaluated. "Up-stream" equivalent length is calculated as follows:

$$L = \frac{a \cdot YD^b}{Q^2} - c \cdot D^d Z \qquad (45.38)$$

Where the values of D and Q are for the pipe segment being evaluated and the values of Y and Z are those of the exit end of the previous pipe segment. Values of a, b, and c are indicated in Table 45.32. The remaining steps indicate how the values for D, Q, Y and Z are determined.

4. Specify the quantity of carbon dioxide liquid to be discharged from each nozzle. For high-pressure cylinders, the total carbon dioxide supply is 140 % of the required liquid quantity.
5. Specify the required liquid discharge time in accordance with the requirements of the design approach and applicable standard..
6. The flow rate, Q, in a pipe segment is the liquid quantity passing through the pipe segment divided by the discharge time.
7. Enter data for pipe system components (D, L, fitting equivalent lengths), and segment flow rates, Q.
8. Segment inlet pressure. For first segment use the supply pressure (750 or 300 psi). Otherwise use exit pressure from prior segment.
9. Segment exit pressure, Y, and Z are determined by determining values of Y and Z that satisfy Equation 45.36. Approaches using trial-and-error and spreadsheet methods are described.
   (a) Calculation by trial-and-error approach. Guess a pressure, P, then look up the corresponding values of Y and Z in Table 45.26 and 45.27. Calculate the value of the left-hand side (LHS) of Equation 45.36. If the result is greater than zero then make a second guess at a lower pressure. If the result is less than zero then make a second guess at a higher pressure.
   (b) Spreadsheet calculation approach.
      (i) Prepare lookup table
         1. Copy, in columns 2, 3, and 4 the table of P, Y, and Z to an area of spread sheet.
         2. In column 1 enter Equation 45.36 (in form for pipe type) with reference to the values of Q, D, and L for the segment and to values of Y and Z in col. 3 and 4. Copy equation to each cell in column 1 for this table.
         3. The calculated values in column 1, the "residue," decrease progressively from the 750 psi row (or 300 psi row) from positive to negative numbers.

[2] The equivalent lengths of the custom components (cylinder valve, hose, check valves) must be obtained from the manufacturer.

		300	0.070

4. By inspection, identify the table row and P value where the residue changes from positive to negative. Interpolate to find the exact value of P where the residue is zero. This is the solution for the given pipe segment.

(ii) Set up spreadsheet table. Referring to example below:

1. Col. 1–9. Pipe segment data.
2. Col. 10–12. Segment equivalent length.
3. Col. 13. Segment inlet pressure.
4. Col. 14. Segment exit pressure due to flow (not elevation-corrected). Determined from the Lookup Table described above.
5. Col. 15. Calculate pressure correction to account for elevation change.
6. Col. 16. Calculate exit pressure (Col. 14 + Col. 15).
7. Col 17–18. Lookup segment exit values of Y and Z, needed calculate the Upstream Equivalent Length in next pipe segment.

While rather complex, the procedures strictly follow the NFPA 12 method and yield results as accurate as the overall method allows.

Example Consider a system that is required to discharge 71.4 lb of carbon dioxide liquid from each of two nozzles in the balanced pipe system shown in the figure. The carbon dioxide supply is two 100 lb high-pressure cylinders. The required quantity of carbon dioxide is $2 \times 71.4 \times 140\ \% = 200$ lb. The carbon dioxide supply is two 100 lb high-pressure cylinders. The liquid discharge time is 30 s. This example shows the design input and calculation results for a balanced two-nozzle high-pressure carbon dioxide system. Use the pipe segment sizes shown in Table 45.33.

Nozzle Selection In this example, nozzle pressure at Nodes 8 and 10 is 554.7 psi. The corresponding mass flux, G, interpolated from

Table 45.32 Pipe flow pressure constants

2	3	3.4	31.2	35.6	703.7	696.5	0.00	696.5	2462	0.185
3	4	1.4	38.7	43.1	696.5	689.7	0.00	689.7	2745	0.206
4	5	2.2	43.1	57.3	689.7	667.0	−3.23	663.8	3772	0.284
5	6	2.2	59.2	91.4	663.8	604.2	0.00	604.2	5837	0.483
6	7	3.4	84.2	101.6	604.2	561.8	0.00	561.8	7062	0.639
7	8	1.7	101.6	104.3	561.8	**554.5**	0.18	554.7	7250	0.666

Table 45.25, is 2142 lb/in.^{2}-min. The required flow rate is 142.8 lb/min. A nozzle having an equivalent area of (142.8 lb/min)/(2142 lb/in.^{2}-min) = 0.0667 in.^{2} is required. The corresponding equivalent orifice diameter is 0.291 (9.32-32nd) inch for which the nearest Nozzle Orifice Code is 9.5.

The preceding calculation shows how each of the seven segments of the example carbon dioxide pipe system contributes to the determination of the nozzle pressure. Shown below is an abbreviated, if slightly less accurate, calculation can be used for estimating purposes. The three-row Table 45.34 shows how the calculation can be performed by combining pipe segments of the same diameter. The nozzle pressure in the abbreviated calculation is 566.1 psi as compared to 554.7 psi in the more detailed calculation. The pressure difference of 1.4 psi arises from the difference in reference pressure (663.8 psi vs. 605.5 psi) used to calculate the pressure loss in the 12 ft riser, Nodes 4–5.

Nozzle Selection In this example, nozzle pressure at Nodes 8 and 10 is 556.1 psi. The corresponding mass flux, G, interpolated from Table 45.25, is 2150 lb/in.^{2}-min. The required flow rate is 142.8 lb/min. A nozzle having an equivalent area of (142.8 lb/min)/(2150 lb/in.^{2}-min) = 0.0664 in.^{2} is required. The corresponding equivalent orifice diameter is 0.291 (9.30-32nd) inch for which the nearest Nozzle Orifice Code is 9.5.

Jeffrey L. Harrington, P.E., FSFPE, is a registered fire protection engineer and has been actively working since 1977 in fire protection engineering, property loss control, and code consulting. He is the President and Founder of Harrington Group, Inc., one of the oldest and largest firms headquartered in the Southeast dedicated solely to fire protection engineering consulting.

Mr. Harrington has served in a leadership capacity on several National Fire Protection Association (NFPA) technical committees, including the Technical Committee on Gaseous Fire Extinguishing Systems (GFE-AAA), which is responsible for three separate NFPA standards: NFPA 12, Carbon Dioxide Extinguishing Systems; NFPA 12A, Halon 1301 Fire Extinguishing Systems, and NFPA 2001, Clean Agent Fire Extinguishing Systems. Additionally, Mr. Harrington is the first Chair of the NFPA Hybrid (Water and Inert Gas) Fire Extinguishing Systems Technical Committee (HYB-AAA).

Mr. Harrington is a frequent author and lecturer on an array of fire protection engineering topics and is a nationally recognized expert, having received numerous awards for his contributions to the fire protection engineering industry. He is also a leader in activities with the Society of Fire Protection Engineers (SFPE), both locally and internationally He has been an SFPE Fellow since 2006.

Joseph A. Senecal has, since 1987, been an employee of Kidde-Fenwal, Inc., a Buildings & Industrial Systems company of United Technologies Corp. He has a Ph.D. in Chemical Engineering, an MBA, and is a Registered Professional Chemical Engineer. During his Kidde-Fenwal career he has been deeply involved in advancing the technology of special-hazard fire and explosion protection systems including product development, materials flammability testing, process hazards consulting, national and international standards development, and trade association representation with a particular interest in gaseous fire extinguishing systems. He is a charter member of the NFPA standard 2001 committee and has continued to serve actively on the since-merged NFPA "GFE" committee (NFPA 2001, 12, and 12a). In 2008 Joe was appointed to *Senior Fellow* (for UTC Fire & Security, since merged with UTC's Carrier and Otis divisions). Joe is one of only a few recipients of both the U.S. EPA's *Stratospheric Ozone Protection Award* (2004) and the *Climate Protection Award* (2009). Joe has presented or published over 50 articles related to fire and explosion protection technology. He is an inventor on five issued patents and on four current patent applications. His reading preferences include biographies of persons of scientific note, history, and character-rich fiction.

Water Mist Fire Suppression Systems 46

Jack R. Mawhinney and Gerard G. Back III

Introduction

This chapter addresses the engineering of fixed fire suppression systems that discharge water mist. The term *water mist,* as currently understood in the fire protection field, relates to fine water sprays with no drops larger than 1.0 mm, or 1000 μm (micrometers or microns) [1, 2]. Such sprays are not true mists, however. A *mist* in the scientific sense consists of drops somewhere on a continuum between *aerosol* (particles with diameter approximately 5 μm) and *fog* (droplet diameters ranging between 10 and 100 μm). Particles less than 20 μm in diameter take a long time to settle out and, hence, create what is recognized in both literature and science as a "mist." A water mist as intended for fire protection purposes is a fine water spray consisting of a range of droplet sizes, many of which are in the range of true mist particles and some of which are considerably larger. Water mist nozzles produce sprays that have a higher fraction of very fine droplets, in the range of mist, than is typical of standard sprinklers or water spray nozzles.

Fire suppression research performed in the past 60 years typically referred to "fine water sprays" or "finely divided water sprays" as the subject of study. Remarkable success at cooling and extinguishing diffusion flames was documented using fine water sprays with mean diameters less than 0.3 mm (300 μm) [3, 4]. Researchers in the 1950s confirmed the expected improvement in the efficiency of heat absorption due to the increase in surface area available for heat transfer as a spray is divided into smaller and smaller particle sizes. Also, as particles become smaller they settle out less quickly (remain suspended), providing more time for heat absorption and evaporation to take place. More heat is absorbed per unit of mass as the particle size decreases. Thus, it was understood that increasing the fraction of very fine water droplets contained in a water spray could reduce the amount of water needed for fire suppression, or in other words, improve the efficiency of application.

The term *water mist* was adopted by the National Fire Protection Association (NFPA) Technical Committee on Water Mist Fire Suppression systems in the early 1990s as part of the renewed interest in efficient use of water in fire suppression systems. This term distinguishes the technology of NFPA 750, *Standard on Water Mist Fire Protection Systems, 2010 edition,* from that of NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protecting,* 2012 Edition [5], and NFPA 13, *Standard for the Installation of Sprinkler Systems,* 2013 Edition [6]. A more thorough discussion of drop size distribution as a significant spray characteristic is presented later in this chapter.

For technical and economic reasons, the knowledge about the advantages of using fine water sprays for fire suppression did not result in an immediate movement to finer sprays for fire protection. Technical concerns included the

negative effects of increasing operating pressures to improve atomization, the potential plugging of small orifices with corrosion products, and doubts about the long-term maintainability of equipment. Economic concerns related to the fact that there were less expensive alternatives: either standard sprinklers or the halogenated hydrocarbons—gaseous agents (halons) such as Halon 1301—could be used. So long as water was an inexpensive resource and halons were available to handle a broad range of special hazards, finer water sprays did not offer enough of a suppression advantage to justify their widespread use.

Three events happened in the 1980s that changed the economic background and revitalized interest in using fine water sprays for fixed fire suppression systems. These were the following:

1. The aviation industry's response to the Manchester air crash in 1984
2. The 1987 signing of the Montreal Protocol, an agreement to phase out the use and manufacture of ozone-depleting substances (halons), and
3. An International Maritime Organization (IMO) ruling that required the installation of marine sprinklers on all existing and new passenger ships capable of carrying more than 35 passengers

The Manchester, England, plane crash in 1984 [7] initiated an international effort to develop a fixed water spray system for passenger compartments on aircraft. The SAVE program, as it was called, was funded by the Civil Aviation Authority in England; the Federal Aviation Administration (FAA) in the United States; Transport Canada; and by the major builders of aircraft, such as Boeing and Airbus. The objective of the program was to increase the time available for evacuation of an aircraft passenger compartment exposed to a ground pool fuel fire after a crash landing. Tests were conducted utilizing water spray to prolong the tenability of the space to allow more time for safe evacuation of passengers. The SAVE program set well-defined performance objectives relating to occupant tenability [8]. The design was constrained by the need to minimize the weight of the system including the stored quantity of fire fighting agent. The choice of a fine water spray to maximize the effectiveness of a small quantity of water was a natural outcome of the work. A water mist system that exceeded all of the performance objectives was accomplished. The system extended tenability for 7 min, within the weight and volume constraints, using approximately 10 L of water. The SAVE study demonstrated that a fine water mist system using a limited supply of water could be custom designed to meet very specific objectives, within the constraints of the industry. The aviation industry regulatory authorities, however, did not make such systems mandatory on aircraft, on the basis that the cost per life saved was unacceptably high [7]. Nevertheless, international awareness of the SAVE research, which was focused on improving the heat absorption qualities of a water spray using a minimum application rate of water, for the purpose of achieving a specific performance objective, meant that the idea of "fine water sprays" was readily picked up by other researchers working on a larger issue that emerged at the same time, that is, the search for an alternative for gaseous fire-extinguishing agents.

The second key event that spurred interest in fine water spray fire suppression systems was the 1987 signing of the Montreal Protocol, an international agreement to reduce the manufacture and use of ozone-depleting substances [9]. Widely used halogenated fire suppression gases were discovered to be ozone-depleting substances. The threat of a phase-out of halon fire-extinguishing agents motivated the release of funds for research into alternative fire suppression agents, water among them. Water at least was not likely to be phased out in the future as an environmentally harmful substance. The high-level research into halon alternatives provided a windfall of improved scientific understanding of the physical and chemical nature of combustion and extinguishment processes. Advances in measurement of suppression phenomena, understanding of fire dynamics, and computer modeling of complex fire scenarios were

applicable to the engineering design of innovative fire suppression systems. The loss of halons as a class of extinguishing agents forced the re-examination of old assumptions about the unsuitability of water for certain types of fires, such as Class B fires in machinery compartments. With improved atomization and reduced flow rates, water could be used where the traditional default had been to use the gaseous clean-agent suppressants. Fine water spray fire suppression systems began to look viable from both performance and economic perspectives as an alternative to gaseous fire suppressants for a number of applications.

A third congruent event that propelled the use of fine water sprays into the realm of practical fire suppression systems was a move by the International Maritime Organization (IMO) to mandate the installation of sprinkler systems on passenger ships. This very influential rule-making body involves the interests of marine shipping societies, marine regulatory authorities (coast guards), and shipping companies worldwide. This regulatory action came about as a result of several large life-loss fires on-board Scandinavian passenger ferries that occurred in the 1980s [10]. In response, the International Maritime Organization mandated the installation of marine sprinklers on all ships capable of carrying 35 or more passengers to come into effect in 1995. Marine architects view marine sprinklers as a negative feature in terms of weight, space, and effects on vessel stability. Adding weight to the upper levels of a ship creates potential stability problems, particularly when sprinklers are retrofitted to an existing ship that was not designed to support the additional weight. There were strong economic and technical incentives to develop a system equivalent to sprinklers that would satisfy the intent of the IMO ruling but use less water and weigh less than traditional marine sprinkler systems. Fine water spray fire suppression systems promised to deliver just that. Research was conducted to develop performance criteria for fine water spray systems that could be impartially evaluated as equivalent to sprinklers installed on Solas II-2/12 [11–13]. The Scandinavian countries Sweden, Norway, and Finland performed development testing that laid the foundation for fire test protocols for marine machinery rooms and for accommodations and public spaces on passenger ships. The Swedish National Testing and Research Institute (SP) in Borås, Sweden; SINTEF, the Norwegian fire research institute in Trondheim, Norway; and VTT Building Technology research facility in Espoo, Finland, were the key centers of development for water mist fire testing. Manufacturers interested in developing water mist nozzles participated in the development of the tests. The test results were discussed, modified, and eventually accepted as consensus test protocols at meetings of the IMO fire protection subcommittees.

The availability of substantial funding to support research for halon alternatives and the creation of a worldwide market for alternatives to marine sprinklers were the two most important factors that changed the economic viability of using fine water sprays for fire suppression systems. Now there was financial incentive to support the cost of overcoming the engineering challenges involved.

As a result of the two distinct origins of renewed interest, there are two basic domains of application for water mist systems. One area of application is as a replacement for gaseous fire suppressants such as Halon 1301. Thus, in applications involving Class B flammable liquid fuels—or where clean agents were used because of concern about water damage—water mist is viewed as a halon system alternative. For applications where the water mist systems are installed for Class A fuels (ordinary cellulosic combustibles), a water mist system is viewed as potential alternative to sprinkler systems.

Water mist systems are not intended to be designed on a “rote” or prescriptive basis. As of 2014, it is becoming evident that water mist systems should be recognized foremost for the opportunity they provide to take a performance based design approach to managing challenging fire hazards. Water mist technology relies on an advanced fire protection engineering understanding of the fire hazard and the fire dynamics that need to be managed. The performance that is

claimed must be verified by conducting fire tests designed by experienced, commercially neutral engineers and testing laboratories. Water mist sytsems present an opportunity for importing types of equipment into fire protection from nontraditional fire protection equipment manufacturers.

Fundamentals of Water Mist Systems

The following review of the fundamentals of water mist system design covers mechanisms of extinguishment and suppression and spray characteristics.

Mechanisms of Fire Extinguishment and Suppression

Excellent discussions of the extinguishing mechanisms of water mist from an engineering perspective can be found in Braidech et al. [3], Rasbash et al. [4], and Mawhinney et al. [14] An understanding of the mechanisms of extinguishment associated with water mist (then called "finely divided water spray") was articulated approximately 50 years ago [3, 4]. Braidech and Rasbash both concluded that fires were extinguished by dilution of the air (oxygen) with water vapor (steam), resulting from evaporation of water droplets in the area local to the flame. They also concluded that the cooling effects of the water may contribute to the extinguishment of flames.

Mawhinney et al. [14] describe five mechanisms associated with extinguishment of hydrocarbon fires. They are the following:

- Gas phase cooling;
- Oxygen depletion and flammable vapor dilution;
- Wetting and cooling of the fuel surface;
- Radiation attenuation; and,
- Kinetic effects

The extinguishing mechanisms apply to extinguishment of Class B liquid fuel fires as well as Class A solid fuels, although with different importance of one mechanism over another. Typically, all mechanisms are involved to some degree in the extinguishment process.

Gas Phase Cooling

Gas phase cooling refers to the removal of heat from the combustion zone due to evaporation of water. The cooling efficacy of water mist is due to the fact that the water is broken up into many fine droplets, which enhances the evaporation rate. The more water that evaporates, the greater the amount of heat that is extracted from the combustion zone, thus reducing the temperature of the flame and hot gases. If the flame temperature is reduced below the critical value necessary to sustain combustion (limiting adiabatic flame temperature), the flame will be extinguished. The limiting adiabatic flame temperature for diffusion flames is approximately 1600 K (1326 °C) [15]. The cooling of the flame also reduces the radiation (thermal feedback) to the fuel surface, thus reducing the pyrolysis or gasification rate of the fuel. Scientific work involving the extinguishment of methane-air counterflow flames has been conducted that has shown that water mist/vapor is more effective on a mass basis than Halon 1301, if it can be delivered at near 100 % efficiency [16, 17]. The reality is that in full-scale compartment fire suppression, the efficiency of application of water is very much less than 100 %.

Various attempts have been made to establish a design relationship between the fire size and amount of water needed to extinguish the fire by gas phase cooling. Wighus [18] defined the term *spray heat absorption ratio* (SHAR), which relates the rate at which heat is absorbed by evaporation of a given mass of water (Q_w), to the rate at which heat is given off by the fire (Q_f).

$$\mathrm{SHAR} = \frac{Q_w}{Q_f} \tag{46.1}$$

Wighus's experiments showed that, for optimized application of mist to an unconfined propane flame, the heat absorption rate in the water needs to be only a fraction of the heat release rate of the fire, as low as 0.3 under optimum conditions. SHAR values in the range of

0.6 were noted for more realistic machinery space conditions, where small flames can persist in shielded areas to cause reignition. (In the absence of reignition sources, only enough heat has to be absorbed from the flame to drop the temperature to the limiting adiabatic flame temperature: it is not necessary to drop the temperature of the compartment or the fuel to ambient.)

On the surface, it seems promising to use a calculation of the amount of water that must be evaporated to extinguish a fire of a certain heat release rate as a design parameter. In real systems, however, the efficiency of delivery of water mist into flame, hence the rate of evaporation of the droplets in the flame zone, is almost unpredictable and certainly uncontrollable over the range of conditions encountered in fire events. The SHAR relationship nonetheless may be useful in a hydrocarbon extinguishment submodel for use in a computational fluid dynamics (CFD) approach to mist system design [19–21].

Andersson et al. [22] present the concept of the required extinguishing medium portion (REMP). This is the ratio of the mass application rate of extinguishing agent required ($\dot{m}_e'$) to the mass rate of fuel consumed ($\dot{m}_g'$). The REMP parameter is similar to the SHAR in that a certain mass of water must be evaporated to extract enough heat to extinguish the flame.

$$\text{REMP} = \frac{\dot{m}_e'}{\dot{m}_g'} \tag{46.2}$$

For propane flames, Andersson et al. [22] measured that the mass application rate of water needed to extinguish a propane flame under laboratory mixing conditions was between 1.2 and 2.2 times the mass burning rate of propane gas. They indicate that this range of REMP values corresponds to a water content volume concentration of 100–200 g/m^3—that is, the mass of water mist suspended in a unit volume of air. Note that both the SHAR and REMP values were measured under conditions of ideal interaction of flame and mist: the mist was discharged downward into the upward rising plume. The velocity vectors of mist and flame were opposite, resulting in the maximum degree of turbulent mixing in the collision zone. The mass flow rate of mist estimated from the REMP values should represent the minimum mass application rate. The mist mass flow rate values for real systems could be expected to be higher to account for inefficiency in delivery of mist to the flame and variability in the directional aspects of interaction.

The REMP parameter suggests that the mass application rate of extinguishing agent would have to be set for the largest expected mass burning rate of fuel. This assumption does not take into account the simultaneous action of other extinguishing mechanisms, however. As will be discussed shortly, for fires in enclosures, it has been observed that larger fires can be extinguished using less water than smaller fires due to the increased efficiency of evaporation attributed to heat confinement in the enclosure and other phenomena. Thus, one would expect the REMP values to go in opposite directions for enclosed fires versus unenclosed fires, indicating that the REMP value is not uniquely a function of the mass rate of fuel consumed.

As was suggested for the SHAR parameter, the REMP parameter is potentially useful in a computer submodel of extinguishment of spray or pool hydrocarbon flame [20]. Today, more complex physical models for evaporation and cooling of hot gases by water sprays are embedded in computational fluid dynamics (CFD) models as will be discussed later in this chapter. The accuracy of the CFD models remains limited by the difficulty of accurately modeling the sprays produced by the different types of water mist nozzles. Furthermore, the ability to model extinguishment of different types of fuels by cooling, wetting and oxygen displacement on principles of physics or chemistry, is limited. The concepts of SHAR and REMP remain conceptually useful for illustrating the principle that not all of the water mass discharged contributes effectively to fire extinguishment.

A number of researchers have sought to estimate a critical extinguishing concentration (in g/m^3) of water mist surrounding a diffusion flame. A number of international laboratories are

able to measure volume concentrations in g/m^3 of mist at various points in a spray, using a phase-Doppler particle size anemometer. Experimental values range from 100 to 200 g/m^3 [21–24] although values as low as 50 g/m^3 have successfully extinguished heptane flames [25]. Newer technology, referred to as "nanomist," generates clouds of suspended ultrafine water droplets with a suspended mass concentration as high as 240 g/m^3, using an ultrasonic transducer assembly and a process technology for aerosolization, extraction, and transport of mist. This technology is likely to be limited by cost to relatively small-scale applications [26–28]. Although the REMP concept appears to be a promising possibility for a universal design parameter, it is difficult to make practical use of this value for selecting spray characteristics or nozzle spacing. It is possible to calculate *nominal* total mass discharge per unit volume values for nozzles discharging into a compartment. On the macroscale of a machinery space, however, it is extremely difficult to predict or control volume concentrations at the point of interaction with flame. There are many randomizing events that alter the local concentrations of water mist at the point of extinguishment.

Oxygen Depletion and Flammable Vapor Dilution

These mechanisms can occur on either a localized or compartmental scale. On the localized scale, as the water droplets are converted to the vapor phase, the volume occupied by the water mist droplets increases over three orders of magnitude. If the vaporization of the water occurs in the flame, the volumetric expansion can disrupt the entrainment of air (oxygen) into the flame. On a compartmental scale, the production of steam resulting from mist interactions with the flame, hot gases, and/or hot surfaces can significantly reduce the oxygen concentration in the space [29]. The oxygen available for combustion is a function of the size of the fire, the compartment volume, and the ventilation conditions in the compartment. As the size of the fire increases, the average temperature in the space increases, and the oxygen concentration decreases due to consumption of the oxygen by the fire and dilution of the oxygen by water vapor. If the combined effects of oxygen depletion due to the fire and dilution by water vapor can reduce the oxygen concentration below the critical value necessary to sustain combustion (i.e., the limiting oxygen concentration [LOC]), the fire will be extinguished [29]. The LOC for most hydrocarbon fuels is approximately 13 % [15].

Wetting and Cooling of the Fuel Surface

Wetting/cooling of the fuel surface will be, in many cases, the dominant extinguishment mechanism for fuels that do not produce combustible mixtures of vapor above the fuel surface at ambient temperatures (i.e., solid fuels and liquid fuels with flashpoints above normal ambient temperatures). Wetting/cooling of the fuel surface reduces the pyrolysis or gasification rate of the fuel. If the vapor-air mixture above the fuel surface is reduced below the lower flammability limit (LFL) of the fuel, the flame will be extinguished.

Radiation Attenuation and Kinetic Effects

Water mist and water vapor measurably reduce radiant heat flux to objects near the fire, which assists in preventing fire spread to unburned fuel. Within the combustion zone, *radiation attenuation* is the result of gas phase cooling and the increase in water vapor concentration between the fuel and the flame. Lowering the flame temperature reduces the radiation feedback to the fuel surface. Also, water vapor in the air above the fuel surfaces acts as a graybody radiator that absorbs radiant energy and reradiates it to the fuel surface at a reduced intensity [19].

Kinetic effects may contribute either to flame intensification or to extinction. Flame intensification has been measured [14] as a flare-up of a flame on first contact with mist. Possibly the turbulence and entrainment associated with the rapid evaporation at the flame surface accelerate the burning rate. Ho [30], who studied the phenomenon in high-flashpoint oils, noted that most of the intensification is due to spray-induced oil splattering, which increased with increasing

Weber number as well as increased oil temperature. He noted that the heat release rate is enhanced by a factor from 2.12 to 5.55 compared to the heat release rate of free burning cooking oil. Kinetic effects may also be involved in flame suppression, the result of both gas phase cooling and oxygen depletion/dilution. When a diluent (in this case water vapor and recycled, vitiated combustion gases) is added to the combustion reaction, combined with flame cooling, it is hypothesized that reaction rates at the molecular level are significantly different from stoichiometric conditions.

Enclosure Effects, Turbulent Mixing, and Cycling

The importance of enclosure effects is described by Mawhinney, Dlugogorski, and Kim [14] and by Liu, Kim, and Su [31]. Enclosure effects maximize the benefits of oxygen depletion and dilution. The hot, vitiated gases collecting in the upper layer of an enclosure are cooled rapidly by the first contact with the water mist. Vitiated gases plus water vapor are forced down by the spray to the seat of the fire and contribute to extinguishment through oxygen depletion. Depending on the temperature and depth of the hot layer, the rapid cooling results in an instantaneous volume reduction, creating a negative pressure that can suck in the windows or walls of a tight enclosure. If the enclosure had reached flashover temperatures before mist activation, assuming that water could flow through the pipes and mist could be introduced, it is hard to say which phenomenon would dominate, the expansion due to steam generation or contraction due to cooling. At least one manufacturer has investigated a means of allowing an initially small injection of spray to initiate cooling, followed by a gradual increase in flow. Such an approach was described as taking the "shock" out of the introduction of mist to the hot enclosure. With reasonably early detection and activation, an automatically activated system will release in the first few minutes of a fire in an enclosure before the upper layer becomes too hot and deep. With systems that are manually activated, some thought should be given to the expected effect on introduction of the water mist into a very hot compartment. The author's experience has shown that the rapid cooling of a deep hot layer (by water mist) in a closed compartment can create a sudden negative pressure pulse strong enough to pull in the walls of the enclosure. The experience is contrary to the often cited but unfounded fear of "steam explosion," that is, a strong positive pressure forcing hot gases out of the compartment.

Some manufacturers have noticed that turning the spray off momentarily and then on again can speed up extinguishment in enclosures. The benefits of pulsing, that is, the on-off action of water sprays, also described as cycling, are well described in Liu et al. [31] and Liu and Kim [32]. Liu et al. [31] showed that pulsing the injection of water mist into an enclosure resulted in more rapid extinguishment, with less total water usage, than continuous application of mist. It was noted that the compartment temperature rose as the fire regrew during the first off-stage, allowing for more evaporation of lingering fine mist. The resurgent fire further reduced the oxygen concentration in the enclosure. The next injection of spray further cooled and mixed the oxygen-depleted gases. In this manner, cycling appeared to lead to greater net evaporation and oxygen reduction than with steady injection. Liu et al. [31] attributed the improvement of the efficacy of water mist in fire suppression using cycling discharges to the faster depletion rate of oxygen in the compartment and the recurrent turbulent mixing created by cycling discharge.

In some systems cycling was used to avoid too rapid cooling of the simulated turbine casing in the FM Global test protocol [33]. That protocol includes a test to ensure that cooling of the turbine casing will not result in damage to the turbine blades. By having spray on for only 50 % of the time, not only was the cooling test passed but also the volume of stored water needed for 10 min of protection was significantly reduced. The manufacturer's design criteria, therefore, incorporated the cycling as an essential element of system performance. Although the repeated off-stages in the cycle had been acceptable for

purposes of passing the FM Global test protocol, the author notes that cycling may not always be acceptable in installations where the equipment cannot tolerate re-exposure to flame during an extended off cycle. Furthermore, the apparent benefit is likely to be very dependent on the volume of the compartment.

Explosion Hazard Mitigation with Water Mist

A number of studies have been done to assess the potential for water mists to mitigate explosion hazards. The interest originates with several plausible hypotheses, such as: (a) that a deflagration flame front in a pre-mixed combustible vapor, moving through a cloud of finely atomized water droplets would be quenched as it encountered sufficiently small water droplets; (b) that the energy of a detonation shock wave moving through a field of water droplets would be "stripped" by the break-up of spherical water drops; and, (c) that the ignition energy required to ignite a vapor/air mixture would be increased by the presence of the water mist.

A review of experimental work performed over the last three decades reveals that there is mixed opinion about "whether application of water spray will quell or invigorate an explosion [34]." In some experiments, the peak overpressure was reduced, although it occurred sooner than if the mist had not been present. In other tests, the peak overpressure was increased by the water mist, presumably due to increased turbulence and stretching of the flame front. Unfortunately, there were major differences in spray characteristics involved in the various experimental programs, so the data are inconclusive. Analytical work supports the idea that benefits of using water mist to mitigate explosions are substantial, provided attention is paid to the details of application [35–38].

Butz et al. [36] investigated the use of water sprays to reduce explosion overpressures from a stoichiometric mixture of hydrogen gas and air released in a test chamber. The test scenario involved creating a mixture of hydrogen and air in a closed chamber, injecting a water spray, and then igniting the mixture. The tests demonstrated that ignition required higher spark energy than without the mist, and the overpressure generated by the deflagration was reduced by about 15 % (Fig. 46.1). Figure 46.1 shows a pressure reduction from 35 to 30 psia "with mist." Butz also measured a significant temperature reduction of the passing flame front, which could reduce the risk of burn injury to personnel who might be exposed to the flash inside a compartment.

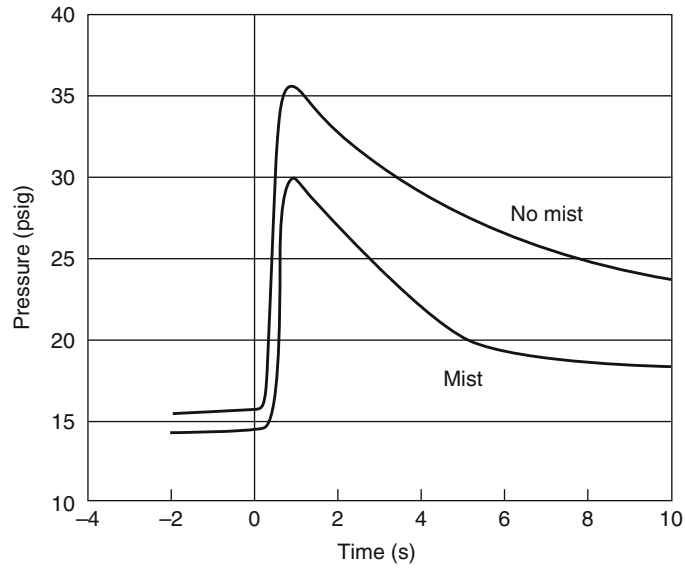

Fig. 46.1 Reduction in explosion chamber overpressure due to presence of water mist [36]

The U.S. Naval Research Laboratory examined the potential for water mist fire suppression systems to perform dual service in suppressing peacetime fires and mitigating blast effects in wartime scenarios [37, 38]. A survey of the use of water (bulk, sprays, mists, etc.) as an agent for blast mitigation was conducted [37]. That survey showed that there are several ways in which the use of water sprays can mitigate the effects of an explosion. It may (1) break up larger droplets into finer mist, (2) directly lead to an attenuation of the shock waves produced, (3) reduce the intensity of secondary shock and pressure waves, (4) slow down or quench the chemical reactions taking place behind the shock waves, and (5) dilute the concentration of explosive gases in the enclosure and, hence, prevent a secondary gas explosion or fire. Studies by Kailasanath and Schwer concluded that water mists will reduce the propagation rate of shock waves. In general, finer droplets increase the attenuation rate. The reduction in propagation rate does not necessarily lead to a reduction in the peak overpressure, however, because the peak overpressure occurs at some distance behind the shock front. In addition, the interaction differs for a shock wave or a flame front.

British Gas (BG) conducted a study aimed at improving the oil industry's confidence in its safety systems with respect to hydrocarbon fires and explosions [39]. A similar study was undertaken at the Christian Mikelson Institute in Norway. In contrast to the results recorded by Butz, the oil industry studies showed that water spray increased the overpressure caused by ignition of a methane-air mixture in a fully enclosed compartment (Fig. 46.2). However, in an open compartment (one wall removed) from the test compartment, a reduction in the overpressure was recorded (Fig. 46.3), but it was a much greater reduction than the 15 % measured by Butz. Both studies also pointed out the role that turbulence plays in accelerating the flame front. Piping clutter and the injection of large drop water sprays increase turbulence in the gas-air mixture and thereby contribute to worsening the deflagration.

There were significant differences in the spray characteristics of the nozzles used in Butz's tests and those used in the BG tests. BG tests used a water deluge nozzle typically used on offshore platforms, which produces spray much coarser than what we now define as water mist. It is believed that subsequent work by Kailasanath and Schwer [38] for example, more accurately

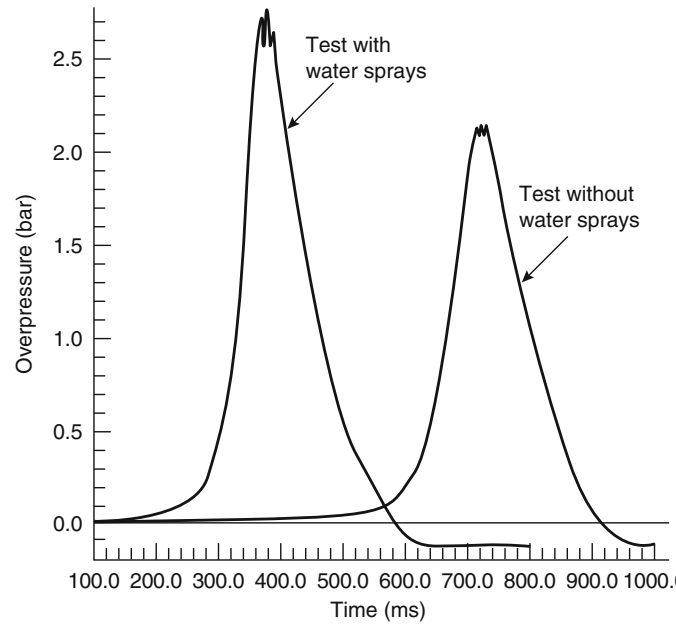

Fig. 46.2 Blast overpressures measured in an enclosure with no open side, with and without water mist, from Selby and Burgan [39]

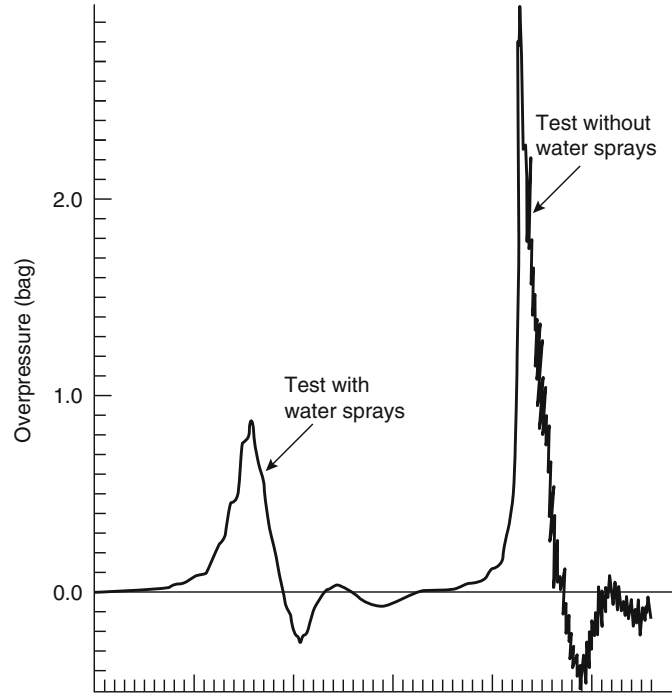

Fig. 46.3 Blast overpressure reduction due to the application of water mist in an enclosure with one open side, from Selby and Burgan [39]

reflects the interaction of blast waves with smaller droplets typical of water mist. The editors of the BG industry report concluded that more work is needed with focus on working with sprays with finer drop size distributions.

During preparation of the first edition of NFPA 750 (1996), a task group of the committee prepared a review of the literature on fine water spray suppression systems. As part of that work, Robert Zalosh of Worcester Polytechnic Institute (WPI) prepared a review of studies on the use of fine water sprays to mitigate explosion hazards [40]. Several relevant conclusions based on his review are summarized as follows:

- In an unconfined environment, high-momentum water spray can entrain air into a gas cloud and dilute it below the lower flammable limit.
- Water vapor can slightly narrow the flammability limits for a gas, and it can dilute the gas-air mixture below the flammability limit. At higher temperatures, higher concentrations of water vapor are possible than at lower temperatures, so warm mist is likely to be more effective than cool mist.
- In near-limit gas-air mixtures, the spray/mist can have either a mitigating effect or an exacerbating effect on flame speeds and pressures depending on the turbulence produced by the spray and the characteristic drop size. The mitigating effect has occurred only with gas concentrations only slightly above the lower flammable limit.
- In the case of a very high flame speed with an accompanying shock wave, the spray/mist can reduce deflagration pressures and possibly extinguish the flame because the shock wave breaks up the drops into a micromist with a characteristic drop size on the order of approximately 1 μm. These tiny drops can evaporate in a sufficiently short time interval to absorb a significant fraction of the combustion energy released during the deflagration.
- The exacerbating effect that occurs in some situations is due to the turbulence produced by the water spray causing the flame speed to increase and/or causing a larger fraction of the flammable gas to burn.
- Generally, drops do not vaporize rapidly enough to absorb the combustion energy

before the deflagration is complete, unless they are very small (i.e., on the order of 1 μm).
- More widespread use of water spray systems for deflagration control will depend on the viability of generating a micromist with sufficiently small drop sizes, which will require water mist systems that are different from those being developed commercially for fire suppression applications.

Spray Characteristics

Measuring and understanding the characteristics of sprays produced by different nozzles are prerequisites for understanding differences in performance. To fully characterize a spray requires information about the following elements:
- Drop size distribution (DSD);
- Cone angle;
- Velocity of the discharge jet(s);
- Mass flow rate; and,
- Spray momentum (product of velocity and mass).

These spray characteristics, which are discussed in more detail below, potentially determine nozzle location and spacing as well as ceiling height limitations.

Drop Size Distribution

Water mist is made up of finely divided water drops of different sizes. Some of the drops may be falling under gravitational force, while other smaller drops may be "floating" in the air entrained with the spray. The drop size distribution of the spray is not yet used explicitly as a parameter in the design of a water mist system. Effective practical application awaits the results of further research. Nevertheless, the drop size distribution of a water spray clearly relates to overall system performance, as it impacts the rate of mist evaporation, how discharge is affected by obstructions, and the momentum of the spray relative to the buoyancy of the fire plume. If the differences in drop size distributions of water sprays are not quantified and understood, an explanation of the differences in performance between different manufacturers' nozzles might not be attainable. When using computer models to approximate the dynamics of suppression with water mist, a quantitative estimation of the drop size characteristics of the mist discharge is essential.

The term *drop size distribution* refers to the range of drop sizes contained in a representative sample of a mist discharge. There is a distribution of small and large drops, which varies with location in the discharge as a function of time. For a continuous discharge, the distribution of drop sizes changes with distance from the source as drops collide, evaporate, or hit surfaces and fall out. For a short burst of discharge, the distribution measured at a point in space changes with time as the larger droplets pass through quickly, leaving increasingly finer drops, which take more time to settle.

There are a number of ways to present data about drop size distributions of sprays [31, 32]. It is customary in some fields to refer to the size of particles in a spray by a single drop size parameter, such as a Sauter mean diameter (SMD) or volumetric median diameter (VMD). Such single-point parameters reveal little about the range of drop sizes in a spray, however. It is important to know the fraction contained in larger drop sizes and the fraction contained in much smaller drop sizes during a given discharge to understand the mist's performance as a fire suppressant.

NFPA 750 has adopted the curve of cumulative percent volume versus diameter to represent the distribution of drop sizes in a water mist. Reasons for this choice are that the cumulative percent volume plot visually reveals the range of sizes, and the volume distribution converts readily to mass distribution, which is the most relevant term for analyzing heat transfer and evaporation rates using computer modeling. The range of drop sizes can be fully described by characteristic parameters such as $D_v0.90$ and $D_v0.50$. The $D_v0.90$ is the drop diameter at which 90 % of the volume of a sample of the spray is contained in drops of that diameter or smaller. Similarly, $D_v0.50$ is the volumetric mean drop diameter; that is, 50 % of the volume of the spray is contained in drops less than that diameter.

Spray Cone Angle

Commercially available nozzles typically produce either 90° or 102° spray cones. Other cone angles are possible but not available as Listed nozzles. Typically the sprays are solid cones, not hollow cone sprays.

Spray Velocity

Velocity is a vector quantity—it has both direction and magnitude. The directions of individual jets define the shape of the spray cone. The magnitude of the jet velocity is the velocity at which water emerges from a small orifice and begins to atomize. There is also a transfer of the velocity of the individual water particles to the surrounding air (through drag effects). In a multijet nozzle, the drag effect of adjacent spray jets pulls surrounding air into the spray cone, adding to the mass flux of the spray cone. It is the combined velocity of the water droplets from all the jets and the air entrained in the flow that contributes to the spray momentum, which dictates the overall impact of the spray on a fire plume.

Discharge Rate

The mass discharge rate of a nozzle is a function of water pressure and the total area of the orifice (s). Ideally the discharge rate per nozzle could be designed around the SHAR or REMP values—theoretical minimum application rates relative to the amount of heat to be absorbed. In reality, discharge rates vary for different manufacturers for the same fire test scenario.

Spray Momentum

Momentum is calculated as mass times velocity. The combination of the mass of water droplets plus the mass of entrained air, multiplied by the velocity of mist particles plus entrained air, constitutes the momentum of a water spray. In general, for a constant mass discharge rate, increasing spray velocity increases the air entrainment rate, which contributes to the spray momentum. Like velocity, momentum has both magnitude and direction—and its direction relative to the fire plume or fuel source has a bearing on its effectiveness. Where the spray direction is opposed to the fire plume direction there is penetration of the flame by the water mist, and any water vapor created in the flame may be carried to the seat of the fire. In contrast, codirectional flows may not create the turbulent flame-mist mixing needed to enhance evaporation and cooling, and the water vapor formed will be carried away from the fuel surface rather than pushed down to it. Studies to evaluate the relative benefits of using high-velocity or low-velocity water mist nozzles must include this directional component of the momentum factor, not only the magnitude of jet velocities. Also, since the entrained air forms a significant proportion of the mass flow rate, it contributes to the momentum of the overall spray cone. Two nozzles with similar initial jet velocities and mass flow rate could have very different degrees of air entrainment—hence, the spray momentum for each could differ significantly. As control over the directional aspects of spray application can be a design choice, spray velocity and spray momentum represent potential first-principles design parameters.

Measurement of Drop Size Distributions

An annex of NFPA 750 describes a methodology for obtaining a statistically meaningful measurement of the drop size distribution of a water spray. Listing organizations typically measure the drop size distribution of a nozzle as part of the component approval process. A phase-Doppler anemometer may be used to measure the drop sizes passing through a small volume of space within the spray cone. The drop size distribution in a spray is not the same at all locations in the spray cone. A single reading taken at one location is not representative of the average drop size in the spray. It is standard practice to take a set of readings and combine them into a statistically representative value [41, 42]. For the purpose of being able to compare water mist sprays, NFPA 750 prescribes the measurement of drop size distribution with the spray cone axis vertically downward over an imaginary plane through the spray cone a distance of 1 m below the nozzle. This distance is usually sufficient so that the atomization process is complete and the average droplet velocity has

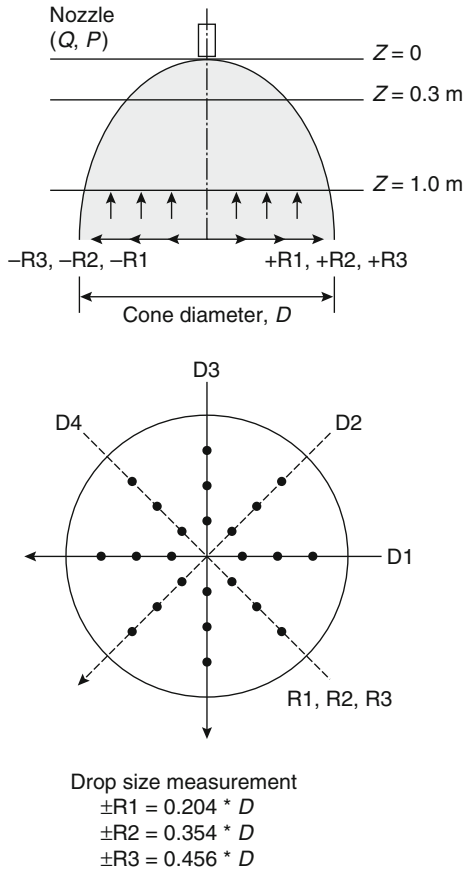

Fig. 46.4 Locations within spray cones for measurement of flux density distribution and drop size distribution. The positions shown are the centroids of segments of equal area [42]

slowed to approximately the velocity of the entrained air.

Figure 46.4 illustrates a setup in which spot readings were taken at 24 locations in the spray, measured on a plane 1 m below the nozzles. The positions for taking a measurement represent the midpoint of sectors of equal area in the circular cross section of a spray cone. A grid of collector pans is used to collect the flux density at each of the measurement locations. It is assumed that the drop size distributions measured in areas of high flux density are more representative of the overall distribution than measurements taken in areas of low flux density. Thus, Equation 46.3 is used to calculate a weighted average drop size distribution curve, weighted according to the flux density measurements at each location.

$$R_k \frac{\sum_i \left(R_{j,i} \times A_i \times V_i\right)}{\sum_i \left(A_i \times V_i\right)} \tag{46.3}$$

where

$R_k =$ Weighted cumulative volume percent readings for sizes equal to and less than d_{upper}

$R_{j,i} =$ Cumulative volume percent readings for sizes equal to and less than d_{upper} at location i

$A_i =$ Area centered at location i in which the size distribution is represented by R_k

$V_i =$ Water flux density measured at location i

The NFPA 750 annex method was used to obtain weighted average cumulative percent volume drop size distribution (DSD) curves for four commercially available water mist nozzles. Figure 46.5 compares the weighted cumulative percent volume DSD curves for the four nozzles investigated [43, 44]. Nozzles A and B were low-pressure single-fluid nozzles; nozzles C and D were high-pressure single-fluid nozzles. It is interesting to note that even the coarsest spray measured (A) had at least 50 % of its volume contained in drop sizes smaller than 300 μm. Spray B shows approximately 80 % of its volume (mass) in drop sizes smaller than 300 μm. However, nozzle B discharged at a rate of 5 l/min (=5 kg/min) whereas nozzle A discharged at a higher rate of 12 kg/min. Therefore, nozzle A, the apparently "coarser" spray, generated about 6 kg/min of drop sizes below 300 μm, whereas nozzle B, the apparently "finer" spray, produced only 4 kg/min of sub-300 m droplets. In terms of potential for heat extraction by rapid evaporation of the smallest droplets, one cannot conclude that one spray is "better" than another on the basis of drop size distribution alone. Factors such as mass flow rate, cone angle, air entrainment, and spray velocity also influence the mixing of mist with fire gases in the compartment.

Spray Velocity

Laboratories involved in measurement of water spray characteristics for research or approvals may use a phase-Doppler anemometer (PDA) instrument to measure drop size distributions and

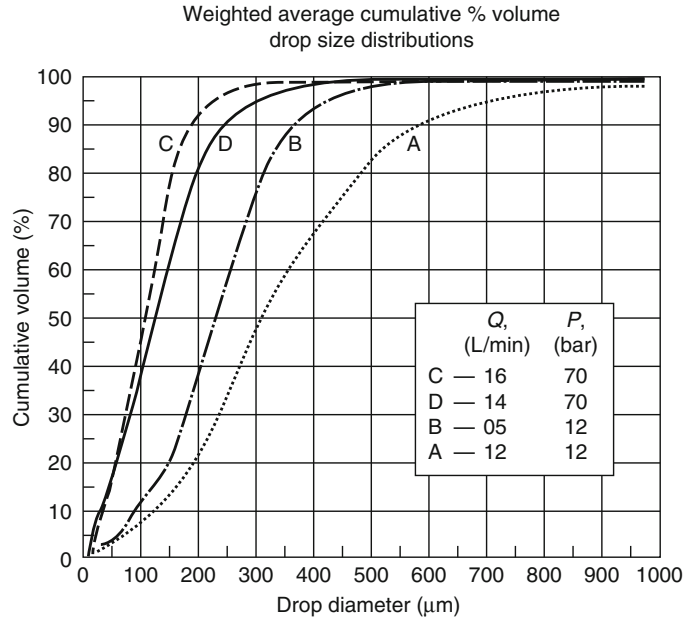

Fig. 46.5 Comparison of statistically weighted cumulative percent volume versus drop size distribution plots for two low-pressure (*A* and *B*) and two high-pressure (*C* and *D*) water mist nozzles

drop velocity, including speed and direction. The PDA may be mounted on a movable structure of vertical and horizontal beams, which can be raised or lowered relative to the position of a nozzle. The PDA measurement focuses two laser beams on a small volume of space and is able to count the number of particles of different sizes at a point inside the spray volume. It determines at least one component of the velocity, using the principle of the Doppler shift that occurs depending on the velocity of the object relative to the viewer. By moving the laser source to different positions around the spray cone, a map of drop size particle size, mass density, and velocity can be constructed.

As part of the same study referred to for the drop size distributions shown in Fig. 46.5, measurements of vertical-downward velocity profiles were taken for two of the nozzles [43, 44]. The velocity was measured by placing a vane-type anemometer horizontally in the spray cone at different locations and at two different distances below the nozzle. The anemometer measured the velocity of the entrained air plus water drops normal to the plane of the anemometer vanes. Individual drops hitting the rotating vane either accelerated or decelerated the vane. It was estimated that the effects of individual water drops on the vane speed approximately canceled out, so that the velocity of the entrained air dominated the measurement. The measured velocity was probably less than the velocity of the fastest-moving drops but close to the average velocity of the entrained air.

Figure 46.6 compares the downward velocity profiles measured 0.3 m and 1.0 m below a high-pressure (C) and a low-pressure (A) nozzle. These data provide a qualitative means of understanding the difference between how a high-pressure and a low-pressure water mist nozzle might interact with the fire plume.

At this time it is not possible to formulate invariable relationships between spray drop size distributions, spray velocity, and the suppression efficiencies of different water mist nozzles. There are many interacting factors involved in suppression, such as enclosure effects and fuel properties. There are, therefore, many possible combinations of spray characteristics and local conditions that will effectively control or extinguish fires. Computational fluid dynamics (CFD) field models present a fruitful means of studying the relative importance of specific spray characteristics. However, it is necessary to measure the physical characteristics of water mist

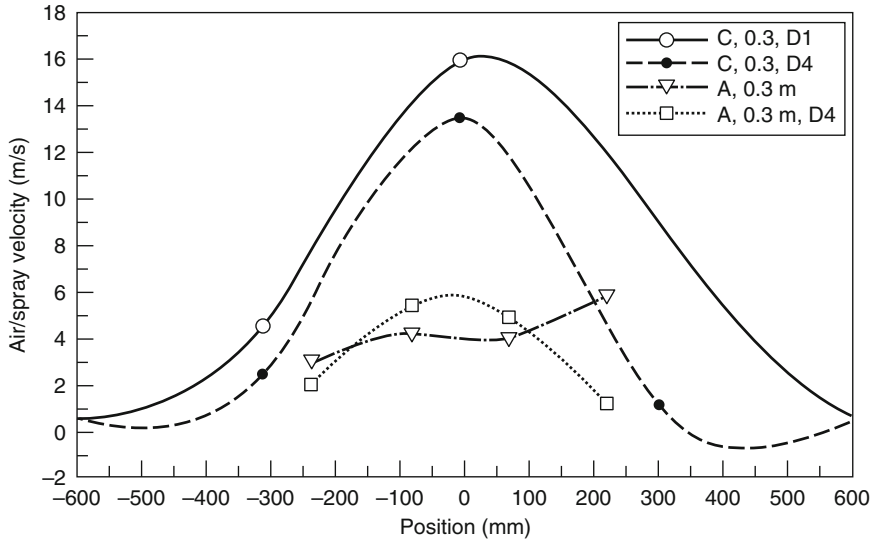

Fig. 46.6 Downward spray velocity profiles, measured 0.3 m and 1.0 m below a high-pressure (*C*) and a low-pressure (*A*) water mist nozzle

sprays as they are needed as input parameters for the field models.

Additives and Health Concerns

In the early 1990s concerns were raised that inhalation of very fine water droplets could cause persons to drown. Various studies were conducted to review the literature on the subject of inhalation of aerosol sized particles into the lungs. Examination of drop size distribution measurements revealed that even the finest water mist sprays do not contain a significant mass of water in drop sizes small enough to be inhaled, and the limited fraction of aerosol-sized particles that could be inhaled are removed as they move through the bronchial tract before reaching the lungs. Consensus was reached that inhalation of "pure" water could be dismissed as a health concern [45]. The use of potentially toxic additives to the water mist, however, was considered to be a potential health concern.

Low concentrations of additives, such as alkali salts and the surfactants in AFFF solution, improve the extinguishment capabilities of water mist [46, 47]. In Class B fires, the surfactant spreads over the liquid pool surface, blocks the generation of fuel vapors, and helps extinguish small flames in hidden corners. Extinguishing the small flames helps break the extinction-reignition cycles that prolong the extinguishment of obstructed pool fires. For enclosed systems, the addition of inert gas (nitrogen) to the spray has been demonstrated to enhance extinguishment by aiding in oxygen depletion [48]. Antifreeze and biocides to prevent algae growth are also potential water mist additives. The use of additives introduces concern about possible negative effects on human health. The U.S. Environmental Protection Agency (EPA) permits the use of water mist as a halon alternative in occupied spaces only when potable water or normal seawater is used [49]. This permission was based on the response of a panel of toxicity experts convened under the Halon Alternatives Research Corporation (HARC) to question the possible adverse health effects of water mist. The report concluded that even the smallest drop sizes in water mist are not present in sufficient quantities to harm humans if breathed into the lungs, provided the water is of potable quality.

The report *Water Mist Fire Suppression Systems Health Hazard Evaluation* (1995) was generated by the Halon Alternatives Research

Corporation (HARC) [45]. Members of the NFPA 750 technical committee provided input to the panel of health experts. The report provided data for discussion of concerns over water mist and additives to the water. The report included a section entitled "Toxicity Profile—Water Mist Spray with Additives" that was prepared for the Army Program Executive Office, Armored Systems Modernization group, by the Toxicology Division, U.S. Army Environmental Hygiene Agency.

The US Army study summarized the available toxicity data on water mist and six potential additives. It identified additives that are the least toxic:

- Propylene and ethylene glycol (antifreeze)—acceptable;
- Potassium acetate and calcium chloride (antifreeze plus fire retardant)—acceptable with reservation; and,
- Potassium iodide and lithium chloride—potentially hazardous to humans.

Since the US Army study was done in the mid-1990s, the fire protection engineering community has become aware that propylene and ethylene glycol antifreeze solutions in excess of 50 % may cause a flash fire deflagration if finely atomized and discharged into an ignition source. If the phenomenon has been observed with sprinkler sprays, it is inadvisable to use such antifreeze solutions in water mist systems, where the fraction of spray that is in very fine droplets is much higher. The army toxicity report does not address the matter of how much additive may be present. Is a product safe at 1 % but unsafe at 5 %? Some antifreeze concentrations may be as high as 30–50 % by weight. The concentrations of biocide needed for bacteria control may be below the harmful threshold for humans. One must distinguish between chronic, or long-term, exposure, and short-term, low-probability exposure that would be less harmful than the exposure to the fire combustion products. At the present time there are no simple answers to such questions.

There are concerns with storage of water in cylinders for water mist systems for crew compartments in military vehicles. The concerns range from toxicology of chemical additives used as antifreeze agents or fire retardants, to bacteriological growth in untreated stored water. The U.S. Environmental Protection Agency (EPA) states that only "pure" (i.e., potable) water or natural seawater can be used without question for water mist systems in occupied spaces. If additives are considered, the onus is on the proponent to prove that there is no toxicological risk. Dr. Martial Pabon, of DuPont de Nemours, France, presented an example of a toxicological study of the effect of a fluorosurfactant additive (2 % Forafac) to water mist at the 2005 conference of the International Water Mist Association [50]. Working with G. LeFort and Dr. André Marshall at the University of Maryland, it was proven that the additive did not alter the atomization process and that the additive improved the extinction capability of the water mist and prevented reignition of a hydrocarbon pool fire [50, 51]. A toxicological study was carried out at Haskell Laboratory by J. Stader and T. Kegelman. This study was based on the "OECD Guideline for the Testing of Chemicals, Section 4: Health Effects, Acute Inhalation Toxicology, Number 403" (1981) [52]. The conclusion of the toxicity study was that "according to the guide for the labeling of dangerous substances published in the Official Journal of the European Communities (EEC Directive 93/21), 2 % (of the Forafac additive) to the water mist is not classifiable ($LC_{50} > 5$ mg/L)."

Addressing health concerns involves not only studying the effect of chemical additives, but also the bacterial content of the water. Heating and air conditioning engineers in the United States have noted that *Legionella* bacteria can be spread to humans by inhalation of fine sprays that may carry the bacteria [53]. In 1976, an unnamed bacterium caused 34 deaths and 221 people at a Legionnaire's convention in Philadelphia to become sick with symptoms of pneumonia. At the time of its discovery and naming as "*Legionella*," it was thought that the bacteria were not present in fresh potable water, but only in stored water associated with the building cooling systems. Experience with worldwide outbreaks since then, however, has shown that *Legionella* bacteria can be present in

potable water systems, particularly in the hot water plumbing systems, and can be spread through any systems involving atomization of water. *Legionella* bacteria thrive in water between 20 °C and 48 °C (68 °F and 108 °F) [53].

Precautions against bacterial growth are also recommended to prevent plugging of the control valves and nozzles by algae growth. Water mist systems often utilize water storage tanks as part of the design. Some marine water mist systems utilize water reservoirs or break tanks. Although in principle only clean potable water goes into the tanks, conditions may change over time, particularly when the tanks are placed in warm machinery rooms. Filtration removes particulates but not bacteria present in the source water. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) produced a guideline with recommendations for controlling the development of *Legionella* in stored water systems [54]. Careful annual maintenance and cleaning are recommended. It notes that during the release of fire water in a fire emergency, fire department personnel wear breathing apparatus, and non-fire-fighting personnel will exit the fire area. However, appropriate precautions should be taken when testing the fire protection system.

Some water mist systems have been designed to provide a high level of cleanliness in the water supply [55]. The system water is circulated continuously between a reservoir and the system piping. An ultraviolet treatment chamber kills bacteria and filters remove particulates on a continuous basis. Pressure loss across the filters can be monitored to indicate when the filters have reduced flow capacity. High-cleanliness water supply precautions are a solution for any applications where there is concern about maintaining the quality of the water, either for health or functional reasons.

Fire Suppression Modeling

The major difficulties with water mist systems are those associated with a standardized approach to their engineering design. The problems arise from the need to generate, distribute, and maintain an adequate concentration of the proper size drops throughout the compartment or fire area for the necessary time period while accounting for the effects of gravity and water deposition on surfaces, which deplete the overall concentration of mist. There is currently no theoretical basis for considering these parameters in the design process. System design parameters are normally extrapolated from large-scale test data on a case-by-case basis for specific applications. This approach is not necessarily cost effective for water mist system manufacturers and poses difficulties for standards-making and regulating authorities. There has been at least one significant effort at developing and applying physical scaling rules (i.e. Froude number scaling) to water mist system design applications [56]. Although the study showed some applicability, the overall approach is significantly limited.

Over the years, an empirical understanding of how water mist systems extinguish a fire has been bounded. The degree of understanding however is still not yet at the stage where water mist systems can be designed from first principles, although some progress continues to be made. The progress that is currently being made is through the application, development and validation of CFD algorithms for specific applications. Now that water mist technology has been fielded for over 15 years, the trends have shifted from basic/fundamental research to the assessment of specific applications.

A basic understanding of the mechanisms of extinguishment associated with water mist was developed over 45 years ago [3, 4]. Braidech and Rasbash both concluded that fires were extinguished by dilution of the air (oxygen) with water vapor (steam), resulting from evaporation of water droplets in the area local to the flame. They also concluded that the cooling effects of the water with respect to the flame and the fuel might contribute to the extinguishment process. Research conducted to date has not altered this understanding. Recent research has, however, identified the primary mechanism(s) associated with extinguishment for a given set

of conditions as well as some additional less predominant extinguishment mechanisms [14].

The mechanisms of extinguishment can be broken down into two basic groups—direct and indirect flame interaction. Direct flame interaction includes gas phase cooling and localized oxygen depletion, and indirect effects include global oxygen depletion and surface wetting/cooling effects.

Direct flame interaction encompasses a broad range of both chemical and thermodynamic relations associated with the release and distribution of energy during the combustion process. Extinguishment by direct flame interaction (primarily gas phase cooling) is basically the removal of energy from the flame and hot gases. As the energy is removed from the flame, the temperature of the flame is reduced. If the flame temperature is reduced below the critical value necessary to sustain combustion (limiting adiabatic flame temperature), the flame will be extinguished. The limiting adiabatic flame temperature for a number of hydrocarbon fuels is on the order of 1600 K (1326 °C) [15].

Recent investigations have bounded some of the parameters associated with direct flame interaction [20, 22, 57]. Numerous research programs have focused on identifying the critical mist concentrations needed to extinguish diffusion flames [17, 58–62] and to extinguish hydrocarbon pool fires [22, 63–67]. Other research agencies have studied the effects of water vapor as an inerting gas [68, 69], as well as the attenuation of radiation to the fuel surface provided by the mist [70–72].

The difficulty in predicting extinguishment by direct effects is associated with being able to predict and/or measure the amount of mist reaching the fire. The ability of mist to diffuse into all areas in the space in the same manner as the gaseous agents is significantly limited for the range of drop sizes produced by current commercially available hardware [63, 73]. Recent studies have shown that the concentration of mist decreases by more than a factor of two after traveling less than a meter horizontally away from the spray pattern of a nozzle. To compensate for this limitation, the higher performance water mist systems rely on high-velocity sprays to mix the mist throughout the compartment (i.e., to create turbulent conditions in the space). The fire size (heat release rate) and fire location are also variables that need to be considered. The fire tends to alter the mist conditions in the compartment by changing the drop size distribution (vaporization and condensation) and affecting the flow patterns throughout the space due to the plume and ceiling jets.

Additional research has bounded the effects of oxygen depletion and dilution (indirect effects) on extinguishment [18, 74–76]. The production of steam resulting from mist interactions with the flame, hot gases, and/or hot surfaces can significantly reduce the oxygen concentration in the space. The oxygen available for combustion on a compartmental scale is a function of the size of the fire, the compartment volume, and the ventilation conditions in the compartment. As the size of the fire increases, the average temperature in the space increases, and the oxygen concentration decreases due to both the consumption of the oxygen by the fire and dilution of the oxygen by water vapor (steam). If the combined effects of oxygen depletion and dilution can reduce the oxygen concentration below the critical value necessary to sustain combustion (limiting oxygen concentration [LOC]), the fire will be extinguished. The LOC for most hydrocarbon fuels is on the order of 13 % [77].

Fuel surface effects can be the predominant extinguishment mechanism for fuels that do not produce combustible mixtures of vapor above the fuel surface at ambient temperatures, that is, solid fuels and liquid fuels with high flashpoints (i.e., diesel $\approx$ 60 °C). Wetting/cooling of the fuel surface reduces the pyrolysis rate of the fuel. If the vapor-air mixture above the fuel surface is reduced below the lower flammability limit (LFL), the flame will be extinguished. The ability to predict extinguishment based on surface cooling has also been investigated in numerous experimental programs [78–82]. This information includes both Class A materials as well as high-flashpoint hydrocarbon pool fires.

Typically, a combination of mechanisms is involved to some degree in the extinguishment

process. In order to accurately predict the conditions required for extinguishment, the combustion chemistry, combined with thermodynamics and fluid dynamics, needs to be covered in detail. These complex relations are best analyzed using computational models that are based on first principles. The current mathematical models used to predict suppression of fires by water mist systems cover the range of approaches from zone fire modeling to computation fluid dynamics (CFD), which are often referred to as field models. A zone model calculates the fire environment by dividing each compartment into one or two homogeneous zones. The energy balance and conservation of mass equations are solved based on a control volume dictated by the boundaries of the compartment for a single-zone model or by the zonal boundaries for a two-zone model.

The input requirements for zone models vary depending on the model and the desired output. The compartment geometry and opening dimensions are needed to define the space and the surroundings. The thermal properties of the compartment boundaries are needed to estimate the heat loss through the walls, ceiling, and floor. The fire size must be entered, though the model may modify the heat release rate as the oxygen concentration in the compartment is reduced by the fire. Some zone models account for effects of mechanical ventilation, which means that the fan flow rate and the location of the vent inlets and outlets are required as input to the model.

CFD models divide the control volume into a large number of small three-dimensional cells and calculate the fire environment within the control volume by numerically solving the conservation equations (mass, energy, momentum, diffusion, species, etc.) within each cell. Solving these equations is accomplished by using finite difference, finite element, or boundary element methods. The results are three-dimensional in nature and are very refined when compared to a zone-type model. The enormous number of computations performed during these modeling exercises is very time consuming and requires powerful computational equipment.

Like zone models, CFD models require a description of the compartment geometry and the openings within the compartment as input. Depending on the sophistication of the extinguishment/fire model, the fire heat release rate may also need to be specified. Heat losses to the compartment boundaries are calculated using the thermal properties of the bounding materials. CFD models have the capabilities to simulate the conditions that occur within complex compartment geometries as well as unenclosed fires since these models are not strictly limited to compartment fire scenarios.

Zone Models

Zone fire suppression models for water mist have been developed by Back et al. [83], Li and Chow [84], Forssell et al. [85], Vaari [86], and Wighus and Brandt [87]. All five models assume a single zone and vary in sophistication from steady-state predictions to transient computations.

Quasi-Steady-State Zone Models

Two quasi-steady-state models have been developed to predict the effectiveness of water mist systems for extinguishing hydrocarbon fuel fires in machinery space applications. The model developed Wighus and Brandt [86] addresses only pool fires whereas the model developed by Back et al. [83] was developed for both pools and spray fires.

Both models were developed for obstructed fires where extinguishment primarily occurs as a result of a reduction in oxygen concentration (consumption and dilution) and neglects the effects of the interaction of mist with the flame. Consequently, the predictions made by these models serve as the limiting case where obstructions prevent direct spray interactions with the fire. The models are based on conservation of energy and mass and require the following input parameters: fire size, compartment geometry, vent area, and water flow rate. The steady-state compartment temperatures and oxygen

concentrations predicted by these models are used to determine the smallest fire (critical fire size) that will sufficiently reduce the oxygen concentration to below the LOC of the fuel.

The energy balance used in these two zone models can be expressed by the following equation:

$$\dot{Q}_{\text{Fire}} = \dot{Q}_{\text{Boundary}} + \dot{Q}_{\text{Vent}} + \dot{Q}_{\text{Vapor}} + \dot{Q}_{\text{Water}} \tag{46.4}$$

where

$\dot{Q}_{\text{Fire}}$ = Heat release rate of the fire
$\dot{Q}_{\text{Boundary}}$ = Energy lost through the walls, ceiling, and floor
$\dot{Q}_{\text{Vent}}$ = Energy lost out of the vent opening
$\dot{Q}_{\text{Vapor}}$ = Heat absorbed by evaporation
$\dot{Q}_{\text{Water}}$ = Energy absorbed by the mist

The following assumptions were made to simplify the calculation:

- Combustion is complete and takes place entirely within the confines of the compartment
- The heat release rate of the fire is a constant (steady state).
- The temperature is uniform within the compartment at all times (after discharge), and the gases exhausted are assumed to be at the compartment temperature.
- The exhaust gases and the gases contained in the compartment are assumed to be saturated with water vapor.
- A single surface heat transfer coefficient is used for the entire inner surface of the compartment.
- The heat transfer through the compartment boundaries is unidimensional; that is, corners and edges are ignored and the boundaries are assumed to be infinite slabs.
- Mist droplets are assumed to be heated to the compartment gas temperature.

The individual components of Equation 46.4 are calculated as follows: the heat release rate of the fire is an input parameter and is calculated based on the known constant fuel spray or mass burning rate of the fire and the heat of combustion of the fuel. The heat lost through the boundaries of the compartment is determined using an overall heat transfer coefficient developed for preflashover fires. The energy losses by vent gas flow are based on the temperature of the exhaust gases and the exhaust rate determined from a vent flow correlation applicable to well-stirred compartment environments. The heat lost by evaporation is based on achieving the equilibrium vapor pressure (assuming saturation), the vent flow rate, and the heat of vaporization. The heat absorbed by the water is determined from the water mist application rate, assuming all the mist is heated to the compartment temperature.

The computational exercise begins by solving the energy balance to predict the steady-state compartment temperatures in the space and the mass flow rate of air/gases through the vent opening. Once the steady-state temperatures and the mass flow rates are known, the steady-state oxygen concentration is then calculated by first determining the amount of oxygen consumed by the fire and then diluting the remaining oxygen with water vapor until the gases are saturated.

The steady-state oxygen concentrations are then used to predict the critical fire size for the selected compartment configuration and water mist system flow rate. In this context, the critical fire size is defined as the smallest fire that will reduce the oxygen concentration below the LOC of the fuel.

The approach used to predict the time of extinguishment varies between the two models. For the model developed by Back, the extinguishment times are predicted using a coupled energy and mass-transfer correlation. The mass transfer is implicit in the following equation, whereas the energy/temperature dependence is embedded in the volumetric flow rate and predicted steady-state oxygen concentration terms. Assuming that steady-state conditions occur quickly and that the extinguishment of these fires becomes related to the time required to dilute the gases in the compartment, the extinguishment times can be approximated using the following equation:

$$\Delta C_{O_2(t)} = \Delta C_{O_2(\text{ss})}\left(1 - e^{\dot{\nu}t/\nu}\right) \tag{46.5}$$

where

$C_{O_2(t)}$ = Oxygen concentration (percent by volume) in the compartment at time t

$C_{O_2(ss)}$ = Predicted steady-state oxygen concentration

v = Volume of the compartment

$\dot{\nu}$ = Volumetric flow rate of air/gas through the compartment

The extinguishment times are determined by setting $C_{O_2(t)}$ equal to the LOC of the fuel (14 % is typically used during this calculation) and solving Equation 46.5 for t. This approach is a first-order approximation and is best suited to predict the extinguishment times of large fires and loses accuracy as the fire size approaches the critical value.

For the model developed by Wighus and Brandt, the extinguishment times are predicted by iterating through the equations in 0.05-s time steps.

The primary outputs of the model are the steady-state compartment temperature and the extinguishment times for a range of fire sizes for a specific compartment configuration and water mist discharge rate. The predictions made by these models compared favorably to the results of four full-scale machinery space investigations conducted for the U.S. Coast Guard. For the range of compartment sizes (100–3000 m^3) and ventilation conditions (closed compartment, naturally ventilated [1.25–5.7 $m^{5/2}$ ventilation factors], and forced ventilation [25 m^3/min]) included in these investigations, the models were able to accurately predict the steady-state compartment temperatures and oxygen concentrations that occurred during the test. In many cases, the larger fires were extinguished before steady-state conditions were reached. This result was also predicted by these models. The models were also able to accurately predict the smallest fire (critical fire size) that could be extinguished due to a reduction in oxygen concentration in the space. Both models were able to accurately predict the extinguishment times for a wide range of fire sizes but lost accuracy as the fire approached the critical value.

Although these models show promise for predicting the steady-state temperatures and oxygen concentrations in an enclosure for a given set of parameters and provide reasonably accurate fire extinguishment time predictions, more sophisticated models are required to accurately predict the transient conditions that occur in a compartment during the discharge of a water mist system. The analysis of these transient conditions significantly increases the complexity of the computations.

Transient Zone Models

Three transient zone models that predict the effectiveness of water mist systems to extinguish hydrocarbon fires have also been developed [84–86]. The models developed by Vaari [85] and Li and Chow [83] are very similar and use the same basic set of equations as described above for the quasi-steady state zone models. The model developed by Forssell et al. [85] is similar in some respects but different in others.

With respect to similarities, all three models solve the conservation of mass and energy equations as a function of time for a given set of conditions. The conservation of mass equations used in the quasi-steady-state models have been replaced by conservation of species. The mass/volumetric flow rate of air through the vent is determined using an orifice flow correlation and the pressure in the compartment similar to the quasi-steady-state models. The compartment pressure is calculated from the density and gas temperature in the compartment using the equation of state for an ideal gas. New mist concentration, droplet evaporation, and extinguishment algorithms have also been developed.

The models are different with respect to how they handle boundary losses, drop evaporation, and predict extinguishment. The models developed by Vaari and Li and Chow neglect all energy losses to the boundaries, whereas the model developed by Forssell et al. includes a lumped mass boundary heat loss algorithm similar to the quasi-steady-state models.

The evaporation algorithms differ significantly among the models. The algorithm developed by Vaari is fairly detailed, as compared to the simplified versions developed by Li and Chow and Forssell et al. In the algorithm developed by Vaari, it is assumed that the heat transfer between the gas and liquid phases is infinitely fast, making the two phases identical temperatures. As a result, all of the heat absorbed by the drop is utilized in the evaporation process. The algorithm includes drop concentration and drop size subroutines that include drop agglomeration and terminal velocity predictions. Using the Clausius-Clapeyron equation to calculate the vapor pressure near the drop surface, the mass transfer number (B) for a single drop is determined. This mass transfer number is then used to determine the evaporation rate for a single drop, which in turn is applied to the entire spray. The algorithm developed by Li and Chow uses a similar approach that has been significantly simplified. In the algorithm developed by Forssell et al., the evaporation model incorporates a correlation constant that represents the combination of the mass transfer number (B) and the surface area–to-volume ratio of the droplet. Rather than including a set of subroutines based on spray characteristics of the nozzle/system that may or may not be available in the public domain, Forssell et al. chose a single empirically fitted correlation constant.

The extinguishment algorithms are also somewhat different among the models. In the algorithms developed by Vaari and Li and Chow, extinguishment is predicted based on a calculated flame temperature determined based on an energy balance conducted in the flame. For this calculation, a limiting flame temperature must be selected (typical values are on the order of 1550 K). This energy balance calculates the temperature of the gases in the flame region by taking into account the species concentrations in the combustion process as well as the mist entrained into the flame. In order to estimate the amount of water droplets entrained into the flame, a simple mist concentration algorithm was developed based on mist discharge rate, terminal drop velocity, and compartment height. Forssell et al. selected a critical oxygen concentration (14 %) to predict extinguishment, similar to the quasi-steady-state models, which is basically equivalent to the previous approach with the exception that the entrainment of mist into the flame is not included in the computation.

All three transient models provide as output the gas (species) concentrations and temperature histories in a compartment for a given set of input parameters (e.g., compartment configuration, ventilation condition, and fire scenario). Transient models provide the capability to study scenarios that never achieve steady-state conditions and that cannot be represented by the steady-state computations. Two examples of these are growing fires (fires with varying heat release rates) and variable flow rate water mist systems. The transient models include more sophisticated evaporation algorithms, which, in theory, should allow them to predict extinguishment more accurately than the steady-state models. The limitations are associated with the single-zone approximation and the need for experimental data to define the unknown parameters used in the model (namely, the spray characteristics of the system). The single-zone approximation may cause the model to fail if the space is not well mixed or the fire is allowed to burn for a significant duration prior to mist system activation. None of the three transient zone models has been thoroughly validated. However, the limited validation performed by Vaari shows promise with respect to the accuracy of these models.

CFD Models (Field Models)

CFD models are much more sophisticated than the previously described zone models and show promise for handling the complex physical and chemical relations that occur. As stated previously, CFD models divide the computational domain into a large number of small three-dimensional cells and solve the conservation equations (Navier-Stokes) in each cell simultaneously. CFD models can provide detailed information on the mass/energy transfer between the

fire and the water mist and on the distribution of water vapor and mist concentration throughout the compartment.

Like zone models, CFD models require a description of the compartment geometry and the openings within the compartment as input. Compartment contents and boundary materials must also be specified. The model is run for a specific set of conditions (compartment configuration, fire scenario, and water mist system). The outputs are very detailed in nature and consist of data files containing information pertaining to the conditions (temperature, velocity, mist concentration, gas/species concentrations, etc.) for each element and time step in the computation. This detailed information allows a graphical/visual representation of the conditions in the compartment during selected time intervals. For example, color contour temperature images and velocity fields represented by small arrows, with the magnitude of the velocity indicated by the length of the arrow, are typical outputs for CFD modeling runs. These outputs allow the visualization of the conditions that occur in the compartment during a specific scenario.

Some of the CFD models currently in use include ALOFT-FT [88], CFX [89], FDS [90], FIRE [91], FLUENT [92], JASMINE [93], KAMELEON [94], KOBRA-3D [95], MEFE [96], PHOENICS [97], RMFIRE [98], SMARTFIRE (sometimes referred to as FIREDASS) [99], SOFIE [100], SPLASH [101], STAR-CD [102], and UNDSAFE [103], but only a limited number of them have been used to characterize water mist applications. Many of these CFD models contain variants of the K-Epsilon submodel required to handle the turbulent conditions produced in this application. K-Epsilon submodels are two additional differential or algebraic equations (where K is turbulence energy and Epsilon is its dissipation rate) that relate turbulent stresses and fluxes to the flow field.

The limitations for applying CFD modeling to water mist applications include the following three general areas: the inability to accurately model the spray characteristics of the nozzle/system discharge, the inability to accurately predict drop transport and flow around obstructions, and the lack of knowledge/algorithms to accurately predict extinguishment.

The ability of CFD models to accurately predict water sprays needs additional research/development and validation. The difficulty with drop transport is associated with linking the liquid water droplets to the gas phase domain and demonstrating the influence of one on the other. Detailed extinguishment algorithms must include an energy balance conducted in the flame and at the fuel surface during the entire combustion process. The approximation of the combustion process must take into account the following species concentrations: fuel vapor, water vapor, oxygen, nitrogen, combustion gases, and water mist concentration. In most cases, the fuel vapor concentration is driven by the radiation from the flame back to the fuel surface and must be solved simultaneously. Although progress continues to be made in all three areas, more work still needs to be done.

The ability of Fire Dynamics Simulator (FDS), Version 4, to reproduce a measured flux distribution map was recently assessed for two multiple-orifice–high-pressure water mist nozzles at two operating pressures [104]. During the study, several flux density distributions were measured under identical conditions in order to achieve an average value. Experimental data were used to define the drop size distribution, the initial drop velocity, and the directional geometry of the nozzle orifices. The cumulative volume fraction curve was reproduced using a Rosin-Rammler/log-normal distribution equation. The study showed that the current nozzle characterization technique used in FDS that employs sectors on the surface of a sphere as source points, input as a single line in the input file, was problematic and required a new approach. Acceptable agreement was achieved by characterizing each orifice in the multiport nozzle as a single solid cone spray with a separate line of parameters in the input file. The results again showed that accuracy of the modeled distribution is very sensitive to the resolution of the computational grid. It was concluded that if high-resolution predictions of

flux distributions are the goal, the numerical nozzle characterization requires some trial-and-error adjustments of values such as spray cone angle, spray direction, and initial drop velocity. Other recent studies have arrived at the same conclusions [105–107]. Based on these studies, it appears that fine computational grids (i.e. small cell sizes) may be required to accurately predict mist discharge characteristics in the region local to the nozzle. This may prove to be a significant limitation depending on the size of the protected space being modeled and the required resolution of the predictions.

The manner in which the spray characteristics of the nozzle affect drop transport and the transport phenomenon in general also needs additional research. Recent research has focused on both the flow of water droplets through cluttered environments [108–112] and on the effects of fire plumes and ceiling jets on the water droplets [113–119]. However, the problem lies more on a fundamental level. Drop transport and tracking are currently being performed using either Eulerian or Lagrangian formulations [120, 121]. A Eulerian formulation uses a fixed grid and assumes the drops pass through (drops and gases travel at different velocities), whereas the Lagrangian formulation considers the droplets and gases to be a single homogeneous mixture. Research has been conducted using both formulations but the information found throughout the literature is very inconclusive regarding the choice of the appropriate method [122]. The appropriate formulation may depend on the spray characteristics of the nozzle as well as on the application. For example, the transport of larger drops may be better predicted using a Eulerian formulation whereas smaller drops may be better predicted using a Lagrangian tracking model. To make matters more complicated, a specific technique may work better closer to the nozzle (near field) and lose accuracy in the far field. Additional research is needed.

With respect to extinguishment algorithms, the physics and computational issues associated with numerical modeling of fire suppression have been identified [123–125]. Studies found throughout the literature typically focus on specific fire types and scenarios. The National Institute of Standards and Technology (NIST) and the Naval Research Laboratory (NRL) have both recently developed algorithms to predict suppression of opposed flow diffusion flames [126, 127]. A recent study validated the accuracy of these algorithms [128]. Limited research has also been conducted on premixed flames [129]. On a larger scale, extinguishment algorithms have also been developed for pool fires [130–134], spray fires [135] and solid fuels [136–141]. Although these advances are promising, there is still the need to develop an all-encompassing extinguishment algorithm capable of handling a variety of fuel types and configurations to be used with CFD modeling.

With respect to the general use of CFD models to simulate the conditions during a specific application, CFD models are currently being used to evaluate full-scale test results, to assess the effects that the application and system design parameters have on the capabilities of the system (i.e., to conduct a sensitivity analysis on the system and application), to extrapolate results/capabilities to conditions outside the bounds of the approval test, and to bound the capabilities of a system in an application where there is little or no empirical data. Most of this information is proprietary with only a limited amount available to the public.

A limited number of general studies using CFD models for full-scale fire suppression research have been carried out by Hadjisophocleous [108, 142]. The research includes the extinguishment of liquid pool fires in both open and closed compartments and fire suppression in an aircraft cabin. The modeling was performed using the CFD model TASCFLOW with the water spray transport handled using a Lagrangian tracking model. During the initial study [108], water mist system parameters (the number of nozzles, nozzle locations, spray characteristics, and discharge rate) were systematically varied to determine their effect on the extinguishment process. The predicted results showed reasonably good agreement with corresponding experimental data. Recently, a sensitivity analysis on how drop size affects extinguishment was conducted using FDS

[125]. As expected, the results of the study were inconclusive due to the number of potential variables associated with the fuel and fire type, and the extinguishment process.

Studies have also been conducted using the CFD model FDS to augment full-scale fire suppression research programs [143–145]. The research includes the extinguishment of liquid pool fires in both open and closed compartments. In both cases, the water spray transport was handled using a Eulerian tracking model. During the latter study, both sprinkling and water mist systems were included in the study. The predicted results showed reasonably good agreement with corresponding experimental data.

A study was also conducted to assess the capability of the CFD model CFX to predict the suppression of hydrocarbon pool fires in an unobstructed enclosure [146]. The modeling work included a sensitivity study that looked at a number of parameters and compared the predictions to empirical data collected in a 96 m^3 enclosure. The results showed that the accuracy of the predictions was highly dependent on the grid/mesh resolution (finer resolutions produced more accurate results). This was also observed during at least three previous studies conducted with FDS [104, 145, 147].

Over the past few years, a significant amount of research has been conducted with the focus of quantifying the hazard associated with vehicle tunnels. This research includes full scale hazard quantification testing, standards development, mitigation system development and testing, modeling and validation testing [148, 149].

In a paper written by Mawhinney and Trelles [148], large scale fire tests conducted in a tunnel test facility in San Pedro de Anes, Spain were modeled using FDS. The objective was to show that the CFD simulations could be, at minimum, partially validated by demonstrating a reasonable degree of agreement with the conditions measured during the tests. The level of agreement between the fire suppression tests results and the simulated conditions was deemed to be adequate to establish confidence in applying the model to examine the conditions that would occur during an unsuppressed fire (i.e. the free-burn, baseline hazard conditions, which were not tested due to cost and potential damage to the tunnel).

In a paper written by Nilsen and Log, the results of large scale tunnel fire tests were simulated using three different models ranging in complexity from spread sheet level calculations to CDF modeling predictions using the CFD model SOLVENT [150] The results showed good agreement across the board for smaller fires but the larger fires were better simulated using CFD. Although there were deviations in the results for the larger fires, the paper concluded that all three models were acceptable tools for assessing baseline tunnel fire hazards.

The U.S. Navy has been investigating the concept of using water mist to reduce the blast overpressures produced during a weapon hit by activating the ship-board water mist system just prior to weapon impact. A series of tests were conducted to validate the concept. The results of the tests were later successfully modeled using FDS [151, 152]. To increase the accuracy of the predictions, an algorithm was developed to predict droplet breakup caused by the initial pressure wave produced by the blast.

The results obtained using CFD modeling demonstrate its potential for analyzing the complex physical and chemical phenomena of fire suppression by water mist. The primary use of CFD modeling has been to extend the understanding of the relationships between the water mist system design parameters and fire suppression (i.e., CFD modeling has been successfully used to extrapolate large-scale test results and to conduct sensitivity analyses on specific water mist system design parameters). CFD modeling not only has the potential to augment the test and evaluation process as currently being used but also shows promise for approving specific water mist system designs for actual applications in the future. The potential for CFD modeling as a research and design tool is now recognized. CFD modeling is currently being used as a research tool at NRC Canada, NRL, NIST, SP, SINTEF, and at numerous universities.

Modeling Summary

An empirical understanding of how water mist systems extinguish a fire is continuing to emerge. Although progress continues to be made, the degree of understanding is not yet at the stage where water mist systems can be designed from first principles. In order to accurately predict the conditions required for extinguishment, the combustion chemistry, combined with thermodynamics and fluid dynamics, needs to be covered in detail. These complex relations are best analyzed using computational models. The current mathematical models used to predict suppression of fires by water mist systems cover the range of approaches from zone fire modeling to computational fluid dynamics (CFD), which are often referred to as field models.

Five zone models (two steady-state and three transient) have been developed to predict the effectiveness of water mist systems against hydrocarbon fuel fires (both spray and pan fires). The models appear to make reasonably accurate first-order approximations of the extinguishment of a range of fire sizes for a given compartment configuration and set of mist system parameters/characteristics. The strength of the zone models is their ability to bound the capabilities of a water mist system for a given application. The limitation of these zone models is associated with a general lack of detail incorporated in the computation. As a result, these zone models may lose accuracy when applied to complex configurations (geometries).

CFD modeling has been shown to be a promising tool for analyzing the complex physical and chemical phenomena of fire suppression by water mist. The strength of the CFD models is their ability to expand the understanding of how the application and system design parameters affect the performance of the system. The graphical/visual nature of the output can illustrate the physical phenomena occurring during the event. The limitations are associated with the high labor costs required to develop a fine computational grid for a large-scale application and the associated long computer run-times to perform the simulation. Applying CFD modeling to a specific application can be an iterative process and requires a certain level of expertise. Additional research is required to further develop and validate techniques to model the spray characteristics of the nozzle/system, formulations to accurately predict drop transport, and an all-encompassing extinguishment algorithm capable of handling a variety of fuel types and configurations. Only limited progress has been made in these areas over the past few years due to the application specific nature of the latest research and the limited amount of validation test data. In any case, modeling still has the potential not only to augment the test and evaluation process but also to aid in approving specific designs for actual applications in the future.

Approval Testing of Equipment

Creating and delivering water mist as an effective fire suppression agent requires different types of hardware than traditional fire sprinkler equipment. The first decade of water mist development saw the introduction of innovative ideas and hardware from non-fire related industries, such as positive displacement pumps from the hydraulics (machinery) field, and the use of compressed gas as an energy source. By the end of the 1990s there were several distinct types of water mist systems on the world market: low pressure systems operating within the pressure range of conventional fire pumps and sprinkler system fittings; intermediate pressure systems requiring slightly higher pressure than conventional sprinkler systems, and high pressure systems operating at pressures much higher than conventional sprinkler systems. Some systems combined water and compressed gas as the driving force. The types of nozzles differed greatly among manufacturers, as they attempted to develop and patent atomization methods and customized valves and control equipment. Hardware, such as positive displacement pumps and pneumatically-released deluge valves, came

from industrial markets where UL Listings or FM Approvals were not common. Therefore, the only effective way to establish that a particular water mist system design based on non-listed hardware can meet performance objectives for a given application is to conduct specialized component evaluations and fire tests. Consequently, water mist approval protocols have been developed and adopted as a means to allow the introduction of non-traditional equipment to the fire protection industry.

Fire test protocols are designed to match or simulate a specific hazard. Water mist systems that meet performance criteria appropriate for that application, which are specified in a consensus test protocol, receive the approval of the approval or listing agency. Table 46.1 shows a list of formalized fire test protocols produced by approval entities recognized in North America and Europe, and that are widely accepted globally. Ideally, test protocols should test the limits of performance of systems against a realistic range of conditions, including worst-case scenarios, and establish measurable performance objectives that meet the needs of a broad range of potential end users and stakeholders.

For marine applications, consensus test protocols have been developed through the International Maritime Organization (IMO). The IMO test protocols encompass machinery room fire hazards (Class B fuels) and accommodation (sleeping rooms) and public spaces on ships (Class A fuels), where water mist systems are installed in place of marine sprinkler systems. For land-based industrial applications, the IMO test protocols have been adopted and modified by FM Global for turbine enclosures, machinery spaces, and pump rooms where liquid fuel fire hazards exist (see Table 46.1). FM Global has also developed test protocols for light and ordinary hazard classifications as referenced in traditional sprinkler system design, and wet benches in clean room environments. UL has also adopted and modified the IMO marine test protocols for machinery spaces, marine accommodation spaces, and land based ordinary and light hazard occupancy classifications.

Annex C of NFPA 750 [2] describes a number of formalized fire test protocols in detail. Note that the criteria for deciding what constitutes acceptable performance is often decided with a specific situation in mind. Successful performance may not mean extinguishment of the fire in all cases. For example, the IMO test protocols for accommodation spaces and public spaces on ships require that the fire only be controlled for a period of 10 min with a limit to the fire spread during that time period. At the end of 10 min, the fire is manually extinguished and the percentage of burned to unburned fuel is calculated. Fire damage to the test materials must be within certain limits. The fire continues to burn throughout the 10 min discharge, and when the water mist system is shut off, the fire may re-kindle. The IMO machinery space protocol, however, requires extinguishment of all fires within 15 min. To achieve extinguishment, the system designers are permitted to utilize combinations of total flooding ceiling nozzles and screening nozzles over the ventilation opening, as well as the addition of surfactants to the water supply for obstructed bilge areas.

The existence of a listing under one of the formalized test protocols does not eliminate the need for experienced judgment in applying the criteria and results of the listing evaluation to a specific application of a water mist system. It is important to confirm that the application sufficiently correlates with the conditions of the listing, and that the performance criteria used to judge pass or fail in the test protocol are consistent with the end user's needs.

Development of Additional Fire Test Protocols

The formalized fire test protocols presented in Table 46.1 do not include all potential applications for water mist systems. Where there is no existing standardized fire test protocol for an application where water mist could provide important advantages, an ad-hoc hazard-specific test protocol often needs to be developed and implemented. One possible difference between

an ad hoc test program and a formalized test protocol conducted by a listing organization is the range of expertise and opinions involved in identifying failure conditions and criteria for judging acceptability of the equipment or system being evaluated. Worldwide, many ad hoc water mist test programs have taken place and continue to be undertaken. Examples include local application systems [25], high-voltage cable tunnels [162], railway tunnels [163, 164], heritage properties [165], libraries and archival storage on fixed shelving [166, 167], electronic equipment rooms [168], computer room underfloor areas [48], aircraft cargo bays [169], and outdoor transformers [170].

Water mist standards, such as NFPA 750, provide guidance on what to include and how to develop a meaningful protocol for a specific hazard. Key factors to consider in the development of such a protocol include the following:

- The test protocols are to be based on a fire protection engineering evaluation of the fire hazard, the compartment conditions, and the performance objectives for the system.
- The test protocols are to be developed, carried out, and interpreted by recognized fire testing laboratories.

Specific to the fire test scenario of the ad-hoc protocol, the following factors should be considered:

1. Simulate the compartment conditions and fuel type and geometry (volume, height, width, and elevation of ventilation and exhaust openings).
2. Provide capability to vary the ventilation conditions to determine sensitivity of the performance to ventilation factors.
3. Select the fuel arrangement that simulates the expected combustibility and fire growth rate. This may require conducting a review of the end users' facilities to establish a realistic fuel geometry. Obtain enough fuel packages to do repeatable tests.
4. Establish meaningful and measurable performance objectives appropriate for the risk.
5. Develop an experiment plan to test the range of parameters for the water mist system design: nozzle selection, cone angle, K-factor, operating pressure (hence, flow rate), nozzle locations, spacing, and orientation.

Formalized listing protocols such as VdS 2562 [161], which is referenced in Table 46.1, describes a methodical approach to the approval of new extinguishing techniques similar in principle to that described in NFPA 750. Test protocols developed in the above manner for ad hoc testing may eventually become formalized protocols and the basis of a listing.

All details of the test must be accurately documented so that the test can be repeated (by others) in the future. The full listing process culminates in the following outputs:

- A report showing the results of the fire tests;
- A report summarizing the results of the component evaluations intended to verify the functionality, durability, corrosion, and environmental resistance of the key components; and,
- A design and installation manual explaining the correct application, installation, and maintenance of the specific equipment. The nozzle characteristics; spacing between nozzles and maximum distances from walls, ceilings, or obstructions; minimum operating pressures; and water supply requirements are all documented in the manual.

Water Mist Systems in Tunnels

One of the most active areas involving the development and application of water mist systems has been for highway road tunnels. Until recently, the European and North American standards [171–175] pertaining to fire safety in highway tunnels were opposed to the use of active water-based fire suppression systems in tunnels. To give an example, Annex D of the 2004 edition of NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways* [171], listed the objections to the use of water-based suppression systems long believed to be unassailable truths by the tunnel fire safety community. The information in NFPA 502-2004 echoed the European equivalent standards, PIARC-1999, "Fire and Smoke Control in Road Tunnels [173]." These documents included statements such as "water spray will cause explosions in petrol"; "vaporized steam can hurt people"; and "visibility is reduced due to de-stratification of the smoke layer." Appendix 4 of NFPA 502-2004 went on to recommend that sprinklers definitely not be installed in tunnels, except possibly for tunnels involving dangerous or hazardous cargo, but even for that risk the advice was to carefully consider the advantages and disadvantages of such systems.

After a series of serious highway and rail tunnel fires that occurred between 1995 and 2005, which resulted in a large number of casualties and financial losses totaling in the billions of dollars [176], road tunnel authorities have reconsidered their reluctance to use active water-based fire suppression systems in tunnels. NFPA 502-2004 and PIARC-1999 represented a different understanding of the fuel loads involved and suppression processes available, and the overall risks. Some of the conditions described the standards might be valid for a fleeting moment in a developing fire scenario, but they neither take into account the rapidity with which fire may progress from incipient to "uncontrollable", nor do they consider the catastrophic scale of the consequences of an unmitigated fire in a highway tunnel. When one considers that uncontrolled fire in the Mont Blanc tunnel burned for more than 50 h, involved hundreds of vehicles over a 500 m length of tunnel, caused catastrophic damage to the tunnel structure that cost billions in repair costs and lost revenue, and 39 fatalities [176], the concern about de-stratification of the smoke layer during the first 5 min of a fire is put into perspective.

Conventional practice for fire protection in highway and railway tunnels has been to rely on ventilation to mitigate the hazard associated with fire in a tunnel by attempting to control the flow of smoke. Refractive coverings are applied to concrete and other structural elements to protect against severe time-temperature exposures [176]. To aid in the design of such safety measures, NFPA 502 provides guidance on the expected fire size for different types of vehicles, or which "time-temperature" curve and duration to use for structural protection. For design of tunnel ventilation systems and determination of the critical velocity needed to control smoke conditions, NFPA 502-2004 indicated that a "bus" results in a heat release rate (HRR) of 20 MW; and a heavy goods vehicle (HGV) fire could achieve 20–30 MW [171]. These design-fire sizes were shown to be significant underestimates of the probable size of fires in large vehicles as a result of full-scale fire testing carried out in the Runehamar test tunnel in Norway. The Runehamar tunnel was instrumented to measure heat release rate during the fires [177, 178]. Results reported by Ingason and Lönnermark indicated that HGV's carrying standard household furniture could create fires of 150–200 MW in a tunnel fire scenario [178, 179]. This new information suggested that tunnel ventilation systems and structural fire protection based on a grossly underestimated fire size of 20–30 MW fires could prove inadequate in the event of a HGV fire in an existing tunnel.

As a result of the Runehamar tests, NFPA-502 2008 Edition [172] and PIARC-2008 [174] now indicate much larger estimated heat release rates are to be used in the design of tunnel safety systems. These influential documents have also removed the language discouraging the use of fixed fire fighting systems. Many tunnel

structural engineers now recognize that installation of fixed fire fighting systems should be (re)-considered for existing tunnels as a means to reduce fire severity so that existing ventilation systems and structural protection can survive a foreseeable fire [180].

Since 1997, a number of fire test programs have been carried out in Europe to determine design criteria for water mist systems for tunnels [181–183]. Fire tests carried out in 2003 and in 2005 in the Hagerbach test facility in Switzerland [181] involved the burning of standard passenger cars arranged to simulate an accident involving three vehicles surrounded by stationary vehicles. The tunnel outlet was instrumented to permit measurement of heat release rate of the fires. The ventilation air velocity was initially 6 m/s, but after ignition the wind velocity dropped to 3 m/s over a 2-min period. The reduction simulated the reduced piston effect as vehicles in the tunnel come to a stop on encountering the accident. Fire in the group of three vehicles typically achieved 15 MW in 7 or 8 min, then rapidly grew to 30–35 MW as the first fuel tanks ruptured. Fuel from the ruptured fuel tanks flowed downslope in the tunnel but was easily extinguished by the water mist system, primarily due to the water mist cooling the fuel as it spread into a thin layer on the roadway. Once the water mist system was activated, the fire in the three vehicles first involved was controlled to 5–7 MW, which gradually diminished as fuel inside the vehicles was consumed. The fire did not spread to adjacent vehicles. In cases where flames impinged on target vehicles about 1 m away, fire did not become established in the interiors even when the windows were breeched by heat, as illustrated in the photographs in Fig. 46.7. When the windows fell out, water mist entered the passenger compartment and soaked the plastic and fabric surfaces. Fire was limited to the three vehicles initially involved in the simulated accident.

Although fire did not propagate to the adjacent vehicles, conditions inside the vehicles shown in Fig. 46.7 photographs (a) and (b) would not have been "tenable." Claims have been made by some proponents of water mist systems that water mist provides a "scrubbing" benefit that may improve visibility and create "breathable" conditions in tunnel fires [184, 185]. If we understand tenability to be a function of temperature, soot concentrations affecting visibility, the toxicity of combustion gases such as carbon monoxide, and the duration of exposure, it is primarily the temperature component that is mitigated by the water mist. A fraction of the carbon soot may be washed out of the smoke and some of the soluble gases may be absorbed by water, but not to the extent necessary to render the environment tenable [186]. This dangerous overstatement of the effect of water mist on smoke has been disproven repeatedly in full-scale fire tests.

Fig. 46.7 Photographs showing the benefit of a water mist system in preventing fire propagation to adjacent vehicles in a passenger car tunnel [181]. With three vehicles fully involved in fire, fire did not propagate into adjacent vehicles because of the wetting and cooling effects of the water mist

Fire tests conducted in the San Pedro de Anes test facility near Oviedo in Spain in 2006 confirmed the satisfactory performance of water mist systems in mitigating fire in HGV's [182]. The fuel package consisted of European wood pallets stacked 2.5 m high, 2.5 m wide, and up to 14 m long on a platform, simulating a fully loaded trailer of a heavy goods transport vehicle. There was enough fuel in the fuel array to support a fire of 70 MW or larger if unsuppressed. The water mist system was typically activated when the fires were between 15 and 20 MW and growing. Over a total of 11 tests, the water mist system prevented the fires from growing to their full potential—reducing the peak heat release rates to 50–60 % of their maximum potential. At a distance of less than 10 m downwind of a fire with a sustained heat release rate (HRR) in the range of 20 MW, ceiling temperatures were less than 100 °C. Except in a small zone of flame impingement immediately over the fuel array, gas temperatures were too low to be a threat to the tunnel lining. Fire did not spread to targets located 5 m away from the vehicle [182]. Furthermore, the reduced temperature of the combustion gases made it possible for an air velocity of less than 2 m/s to overcome the backlayering of the smoke and heat [187]. In spite of the fact that there was a sustained 20 MW fire in the tunnel, due to the cooling provided by the mist engulfing the flames, the thermal impact on the tunnel was nothing like what would occur with an uncontrolled 20 MW fire.

The very large simulated HGV fires used in current testing are highly dynamic and rather unpredictable. Large variations in local temperature conditions may occur from one test to the next, under apparently similar conditions. In spite of some unpredictability of spot temperature readings in the near-field of the fire, the water mist consistently reduced the combustion gas temperatures to below the threshold for ignition of targets or thermal damage to concrete, within 5–10 m from the fuel array. It is important to avoid setting performance criteria based on single point measurements, such as a maximum temperature at a particular distance from the fire or elevation in the tunnel. Judgments about adequacy of the fire protection system should reflect the overall ability of the mist system to reduce fire severity [187]. The performance evaluation of a fixed fire protection system should recognize the macro-benefits of cooling and preventing fire propagation to surrounding vehicles, thus protecting the structural elements from catastrophic thermal damage. The benefits should not be viewed as limited to property protection, however. Sprinkler systems are installed in industrial buildings ostensibly for property protection objectives, yet it is widely recognized that there are very few multiple life loss fire events in sprinklered buildings including those that are industrial in nature [188]. This is because the sprinkler system provides a degree of fire control or fire suppression within the time period necessary for occupants to escape, and can prevent the fire from escalating into a life-threatening event. The same logic should apply to fixed fire fighting systems in tunnels: preventing a fire from escalating to uncontrollable intensity reduces the risk to life of persons trying to escape the fire as well as to fire fighters attempting to approach and suppress the fire.

Water mist systems in tunnels are typically open nozzle, deluge-type systems divided into approximately 30 m long zones controlled by a deluge valve. The water supply is designed so that three zones can be activated simultaneously. It is intended that a fire detection system will locate the fire source accurately and automatically activate the water mist system in the zone where the fire is located, plus one zone upstream and one zone downstream. Very seldom do the fire test protocols for water mist systems include testing the ability of the detection system to reliably locate the source of the fire within a given timeframe. In principle, the efficacy of the detection system should be evaluated as part of the performance testing of the system. There are many difficulties inherent in pinpointing the source of heat, smoke or flame in the dynamic, turbulent and dirty environment typical of roadway tunnels.

There is some debate about what the fire size could be when the water mist system is activated in a real roadway tunnel fire scenario. The fire

size will likely depend on the sensitivity of the detection system and the administrative policy regarding manual activation of the suppression system. It is this author's opinion that activating the water mist system will be beneficial at any stage, although it is obviously preferable to do so before damage to critical infrastructure occurs. The most important performance requirement of the detection system is to locate the fire so that the correct water mist zones may be activated. The benefits of the water mist system can be fully realized even if applied when the fire has reached 15 or 20 MW. HGV fires are likely to reach such intensity within 5–10 min. With 20–25 m long water mist zones and an appropriately designed and coordinated detection and releasing strategy, the fire should not activate any more than the three zones allowed for in the hydraulic design of the water supply. It should be relatively straightforward for any detection technology to detect and accurately locate a fire as large as 15 MW in a tunnel. There may be advantages in being able to detect smaller fires in order to initiate emergency response in a tunnel, such as traffic control and dispatch of emergency personnel, but there is little advantage in imposing an unnecessary requirement to detect very small fires on the detection system controlling release of the water mist system. Any gain in ability to detect smaller fires is likely to be at the cost of reduced reliability in determining the location.

A research project to evaluate fire detection technologies for highway tunnels, coordinated by the National Fire Protection Research Foundation and the National Research Council, Canada, was completed in 2007. A part of the study included monitoring four trial detection technologies over a 10-month period in the Lincoln Tunnel between New Jersey and Manhattan, NY. Detection technologies for the study were selected based only on the willingness of the manufacturers to fund their own participation in the study. One optical flame detector, two video imaging detection systems, and an air sampling detection system were evaluated. One finding of the study was that the systems were prone to generating "nuisance" alarms, or their overall reliability in being able to detect the fire source was adversely affected by the grime and other effluent that is characteristic of roadway tunnel environments. At the end of 10 months all of the systems were tested in a fire demonstration. Test fires were approximately 1–2 MW maximum HRR and were ignited inside a passenger van with windows. The two video imaging systems did not detect any of the demonstration fires, whereas the optical detection and the air aspirating systems detected most but not all of the test fires [189]. The NFPRF study did not include any linear heat detection, which is widely specified for tunnel fire detection in Europe and Japan. Linear detection is resistant to the grimy conditions of the tunnel environment. However its ability to accurately locate the fire at high ventilation air velocities can be questioned. It should further be noted that the tunnel fire testing that has been conducted in Europe has focused on the hazard presented by HGV fires, which can reach a HRR in excess of a 20 MW relatively quickly. The detection tests based on 1–2 MW fires are perhaps pertinent to fires in passenger automobiles, which do not typically result in catastrophic damage to tunnels.

More research is needed on selection and evaluation of appropriate fire detection technologies to integrate with water mist systems. However, most highway tunnels that are candidates for installation of fixed fire protection systems are equipped with closed circuit television monitors, control room and trained operators. Where CCTV monitors are present, manual activation of the water mist system by a tunnel operator can be an acceptable alternative to automatic detection.

Engineering Details of Water Mist Systems

Types of Water Mist Systems

Requirements to conduct performance-based testing of water mist systems result in an assessment of the fire fighting capabilities of the system, and promote the evaluation of new types of hardware and assemblies. This testing has

increased the rate of introduction of new equipment and fire control concepts to the generally conservative field of fire protection systems design. Hardware borrowed from non-fire industries (such as positive displacement pumps from the petroleum industry and hydraulics field), and from gaseous fire protection system hardware, can be component tested and receive the equivalent of an assembly approved for fire protection as part of the process of satisfying the testing protocol. Positive displacement pressure pumps, pressure regulating or unloading valves, compressed gas driven equipment, pneumatic and hydraulically actuated deluge valves, high pressure valves, piping and tubing, as well as tube bending and piping support methods not previously employed in fire protection systems are now available. Fire protection engineers need to understand the associated hardware in order to design, specify, test and commission new types of systems. A few of the engineering design and evaluation concepts that have been introduced as a result of water mist system research and development are described below.

Water mist systems can be categorized based on several distinguishing factors. The four most important from a systems engineering perspective are (a) the mode of application of the mist, (b) method of spray generation (c) the pressure regime, and (d) the means of providing the necessary system flow and pressure. There are several subcategories of systems, each with its own specific technical features, such as single-fluid and twin-fluid systems, and constant pressure versus decaying pressure discharges. The mode of application refers to how the system is intended to develop and deploy the mist within a given space or environment, and includes total compartment application (TCA); local application (LA), and zoned application (ZA) systems. With regard to pressure regimes, water mist systems distinguish among Low, Intermediate and High Pressure systems. The means of providing the necessary flow and pressure distinguish between the general categories of pumps either electric or gas driven, or some arrangement of compressed gas cylinders. The latter category can be further divided into systems that operate at a constant pressure, similar to a pumped system, versus those that have a declining pressure.

Mode of Application

Water mist systems can perform well in enclosed compartments where the confinement of heat, water vapor and the oxygen depletion caused by the fire can contribute to the extinguishment of even shielded fires. However, it is not the case that water mist systems only work well in enclosed compartments. They also provide fire control benefits in the open air, and in large, well-ventilated spaces such as tunnels. If the compartment is very large relative to the size of the fire, enclosure effects are diminished, and more attention must be paid to projecting water mist to the seat of the fire and wetting or cooling the flame and the surrounding fuels and surfaces.

TCA systems consist of open nozzles distributed throughout the compartment according to the manufacturer's spacing rules. Water is discharged from all open nozzles on opening of a control valve in the same manner as a deluge sprinkler or water spray system. TCA systems benefit from enclosure effects (capture of heat, confinement of water vapor, and recirculation of oxygen-depleted gases) to varying degrees, depending on the size of the compartment. However, TCA water mist systems can accomplish extinguishment with fairly large openings in the compartment, which is not the case with gaseous total-flooding agents [73]. On the other hand, it is not enough to inject a fixed quantity of mist into a compartment, close the door, and expect the fire to go out immediately. The amount of time needed to extinguish a fire varies according to the compartment volume and the size of fire [83]. Water mist must be injected continuously for a sufficient length of time to bring about control, and the fire must generate enough heat to convert water droplets into water vapor and sustain a relatively high water vapor concentration. The extinguishment time of a hydrocarbon fire can be predicted approximately on the basis of a ratio of HRR to volume

(MW/m^3) ratio, and it has been expressed that there will be a fire size that is too small to be extinguishable [83].

It is generally intended that TCA water mist systems be activated automatically by a fire detection and releasing system. In some marine or military applications, however, manual activation of the system is permitted. Some caution should be observed in the design of a system intended to be manually released. If there is a long delay in activation, the combustion gas layer in the compartment may become quite hot and deep. The empty piping may become so hot that water will boil explosively when water is introduced, potentially rupturing some types of piping systems. If the piping survives, the sudden introduction of water mist into a hot gas layer may result in a very rapid cooling, which creates a strong negative pressure in the compartment. In some experimental work a negative pressure spike of minus 1700 Pascal was measured, which resulted in violent damage to the walls of the test structure [46].

The total water discharged by a TCA system in a large space must be considered. Water mist systems require much less water than sprinkler deluge systems, but they still discharge water which must be collected and treated. On Alaska's North Slope, machinery modules up to 1500 m^3 in volume, may be protected by TCA water mist systems. State of Alaska environmental regulations require that all of the water discharged in the enclosure must be captured and removed to a waste-water treatment facility. The water cannot be simply drained into the natural environment. The retention and removal of runoff from a total compartment application system must be considered as part of the design of the system.

TCA systems may be designed for a range of objectives. The IMO machinery space systems are required in the IMO test protocol to completely extinguish most test fires in a specified period of time (15 min). On the other extreme, TCA systems have been installed in Norwegian historic wood stave churches to achieve flashover suppression [43, 165, 167] at much lower flow rates. For flashover suppression a fine mist is injected into the upper portion of the compartment to cool the fire gases and reduce thermal feedback to the objects in the compartment, which prevents flashover from occurring. The amount of water that strikes the art on the walls is minimized. Extinguishment of the source fire is achieved by installing nozzles at floor level that discharge water spray at a much higher rate than the ceiling nozzles, without damaging the treasured wall paintings. The lower nozzles are local application nozzles that work in concert with the total compartment system.

LA systems are designed to discharge directly on an object or hazard in an enclosed, partially enclosed, or open area. Since there will be no confinement of heat, water vapor, or vitiated gases, extinguishment will depend largely on gas phase cooling or wetting of the fuel. To achieve extinguishment requires projection of mist to all areas in which fire can persist. Local application systems do not necessarily need to be designed to achieve extinguishment. The discharged water mist can act as a screen to block radiant heat transfer, mitigating fire spread or limiting damage to surrounding materials. Local application systems are considered necessary compliments to a TCA system in some machinery room systems on ships [157] and in industrial process buildings. The compartment ceiling may be so high that low level equipment must be surrounded with local application mist nozzles to facilitate fire control. Local application systems may be installed around specific hazards such as diesel engines, flammable liquid or vapor compressors, or large turbines in an open floor area [190].

The IMO prepared IMO MSC/Circ. 913 test protocol for fixed water-based local application systems for marine machinery spaces [156]. FM 5560, FM Global's water mist testing standard, has test protocols for local application water mist systems for industrial food processing burners, deep-fat fryers, outdoor transformers, flammable liquid storage racks, and other special equipment [158]. VdS in Germany has test protocols for local application systems for engine test cells and electric cable tunnels (see Table 46.1) [176].

As discussed for TCA systems, choice of fire detection and system activation strategy for local application systems is an important part of the design of the system. Some systems are intended to be manually activated, whereas others incorporate special detection equipment for automatic activation. The detection system, release, and delivery equipment must be matched to the conditions dictated by the hazard.

ZA systems are designed to protect hazards in a portion of an enclosure, eliminating the need to flood the entire compartment. The concept intends that multiple zones surrounding the fire location will be activated, such that the fire area will be totally engulfed by mist in a manner similar to a deluge system. The incentive for zoning a system is to reduce the overall water flow requirement to a fraction of that required for total compartment flooding.

Recent testing conducted to develop water mist systems for highway tunnels has confirmed the satisfactory fire control performance of zoned water mist systems [181–183]. The water mist system is divided into zones up to 32 m long, each controlled by a local deluge valve. The water supply and pumping capacity are designed to support the activation of three complete zones: the zone in which the fire is located and one zone upstream and one zone downstream. Clearly it is essential that there be either a fixed fire detection system that is suitably precise to correctly locate the fire, or a CCTV system monitored by trained operators with authority to activate the system manually.

Experience with thermally activated sprinklers or nozzles in tunnels has shown that heat from a fire will travel along the ceiling and open sprinklers or nozzles faster than can be controlled by the resulting water discharge. The risk is that more sprinklers may be opened than can be supported by the water supply. For this reason, zoned deluge water mist systems are preferred because the water supply can be designed to supply a fixed, pre-determined number of nozzles, an attractive option for protecting tunnels [183]. It is essential of course that the zones that are opened completely envelope the source of the fire. Thermally activated nozzles (automatic nozzles) have been used in conjunction with a ZA system, to further reduce the amount of water required by the water mist system. Every second nozzle on a line is thermally activated and covered by a protective cap, with an open mist nozzle inbetween. Three zones of nozzle lines are activated by the detection system as for a normal zoned deluge system. There is enough water mist distributed to prevent "runaway" activation of the thermally activated nozzles as hot gases flow along the tunnel prior to activation of the mist system. Once detected and located by a separate detection system normally used in the tunnel, the appropriate zones are activated. The protective caps in the activated zones are released by water pressure, exposing the thermal elements. Then in the hottest areas directly surrounding the fire, the thermally activated nozzles activate and effectively double the mist application rate over the fire. This patented concept has been tested by Marioff Corporation and shown to be as effective at controlling temperatures as the full deluge system, with approximately 60 % of the water discharge rate.

The proper performance of a zoned application water mist system depends critically on the performance of the detection system. Testing of the ability of the detection system to determine the fire location and actuate the correct zone should be made part of the approval test protocol for such systems.

Automatic Sprinkler Alternative Water Mist Systems are a fourth category of mode of application, which is that of a water mist system with closed, thermally activated (automatic) nozzles installed throughout a building in the same manner as a conventional sprinkler system. IMO has long accepted water mist systems with automatic nozzles as equivalent to marine sprinkler systems. Such systems are installed throughout accommodation and public spaces on most passenger ships. It is not surprising that there is interest in providing similar systems in land-based applications. In a number of jurisdictions in Europe, water mist systems have been installed in hotels and office buildings in lieu of conventional sprinkler systems. The concept is

now recognized by the NFPA 750 committee. A new definition has been approved for publication in NFPA 750, 2013 Edition, which defines an "Occupancy Protection System" as "a water mist system utilizing automatic water mist nozzles installed throughout a building or portion of a building and intended to control, suppress or extinguish a fire." The question that remains to be explored is whether the building and fire regulations, which provide substantial trade-offs in building construction requirements in recognition of the benefits of automatic sprinklers, will apply those benefits to water mist systems designed and installed as an automatic sprinkler system alternative. At the present time (2012) water mist systems do not have as broad a range of approval tests as conventional sprinklers. Generic prescriptive design and installation criteria, and standardized listing evaluations exist for conventional sprinkler systems for light hazard to extra hazard applications. Such is not the case for water mist systems, which rely upon manufacturer specific design and installation criteria, and performance-based listing criteria for light and ordinary hazards (OH1 and OH2),. However, efforts are underway to expand testing of water mist systems against as many hazard scenarios in buildings as for sprinkler systems, so that the benefits associated with conventional sprinkler systems can be extended to water mist systems.

Pre-engineered versus *engineered systems*. A pre-engineered water mist system is one that has been developed for a hazard of a limited size and consistent features defining the compartment. For example, a water mist system may be tested in a test structure of a certain volume to represent a turbine or diesel engine enclosure, with specific ceiling height, obstructions, ventilation openings, and fire scenarios. The detection time and the size of fire on detection will be largely predictable. The number of nozzles, their locations, the amount of stored water required for the required duration of flow, and the diameters and maximum lengths of pipe or tubing are all determined by the test protocol. The installer need only match the nozzle spacing and stay within the limits specified for pipe diameter and length of run to install the system properly. No engineering calculations are required to ensure that nozzle pressures are adequate or that flow rates and water storage volume are sufficient for the hazard.

Pre-engineered should not be taken to mean fool-proof or "no engineering required." Pre-engineered water mist systems are sometimes improperly installed and maintained. In the international off-shore oil industry, for example, pre-engineered water mist systems are widely used to protect small turbine enclosures. The nature of the contracting environment is such that installers of the fire protection systems often work for a general piping contractor that is approved to work in the particular oil field, as opposed to a fire protection specialist familiar with the intricacies of the water mist system. Errors that can occur and have occurred, are many. The volume of the enclosure may be outside the limits of the pre-engineered system listing. Nozzles may be improperly placed or oriented; tubing diameters and lengths may be incorrect; the water storage unit may be located too far from the hazard, and specialty pneumatic releasing valves may be improperly set up. The interlocks to accomplish automatic release of the water mist and shut down the fuel pumps and ventilation may not be complete and may never have been tested. The inspecting engineers from the production sector do not have the experience necessary to inspect the systems and identify the faults. Annual maintenance may be performed by personnel unfamiliar with the system hardware, so that the installation faults never get corrected. It is not surprising that fires have occurred in which the pre-engineered system failed to operate.

Engineered systems, on the other hand, are designed in the same manner as traditional sprinkler or water spray system, based on criteria in the manufacturer's design, installation, operation and maintenance manual. The designer applies nozzle spacing rules, pipe or tubing and water flow requirements to a variety of compartment sizes and fire hazards. The pump or compressed gas supply is dimensioned to be able to satisfy

the calculated flow and pressure requirements. An engineer must perform hydraulic calculations to confirm that minimum nozzle pressures and system flow rates are achieved. Problems such as those listed above may still occur during installation, but an engineered system is likely to receive a higher level of construction supervision, acceptance testing and maintenance, than a pre-engineered system.

Methods of Spray Generation

There are numerous ways to generate atomized sprays [41]. Water mist system equipment manufacturers have staked out and filed patent applications for their preferred means of mist generation. Research in the spray and atomization literature discusses exotic technologies such as electrostatic sprays, nebulizers, and ultrasonic devices [27]. However, not all atomization processes are practical for fire protection systems. Some techniques are only suitable for mass flows of milligram/second with projection distances measured in millimeters, whereas sprays suitable for water mist fire suppression systems must have mass flow rates in the kilogram/second, with projection distances measured in meters. Suitable nozzle types include multi-orifice pressure jet nozzles, impingement nozzles, and twin-fluid nozzles. Mass flow rates are typically measured in the range of 0.033–0.667 kg/s (2–40 L/min). Cone diameters and projection distances are typically measured in meters. The atomization process must be sustained for tens of minutes in most cases. This section will highlight some of the engineering features of interest associated with different methods of generating water mist.

Twin-fluid nozzles. Twin-fluid water mist nozzles involve combining two independent streams of fluid, one of water and one of compressed gas, at a nozzle to generate finely atomized spray. By combining the energy stored in the compressed gas with a water stream, finely atomized sprays can be produced at relatively low water pressure. Twin-fluid nozzles generally have separate piping networks for water and compressed gas, which join at the nozzle. They provide a high degree of adjustability between the balance of liquid and gaseous streams—hence, they can be tuned to maximize the quality of the spray. On the small-scale twin-fluid nozzles provide excellent control and versatility in spray production. On the larger scale necessary for general fire protection, practical limits to their applicability are encountered. Designing the piping systems for both liquids involves trying to balance the air-to-liquid mass ratio (ALR) (ratio of the mass flow rate of air to the mass flow rate of water) at each nozzle throughout the discharge. Twin-fluid nozzles can utilize larger orifices than pressure jet nozzles, and are therefore somewhat less vulnerable to plugging. On the negative side, twin-fluid nozzle systems require storage and delivery of media with distinctly different engineering characteristics. Calculations must be done for both compressible and incompressible fluids in two distribution systems. A suggested approach to balancing the distribution of atomizing medium with the water flow is provided in Mawhinney [191].

The NFPA 750, 2013 Edition expands the definition of twin-fluid system to include those that combine both the water and the compressed gas in one piping system. One manufacturer has produced a reciprocating pump driven by compressed nitrogen that discharges water and nitrogen into the piping system. The friction losses in the distribution piping cannot be calculated using either incompressible liquid flow equations (normal hydraulics) or compressible flow equations. Nor is the mix a "two-phase flow" because the mix consists of two fluids, not two phases of the same fluid. The engineering of such systems, including the dimensioning of piping, confirmation of end nozzle pressures, and ensuring balanced discharge through nozzles close to the source and those far from the source, not to mention comparable discharge duration of both water and compressed gas supplies, depends almost entirely on empirical data.

Single-fluid nozzles discharge water only. Most water mist systems utilize single-fluid nozzles. The water is ejected through one or

more orifices and either disintegrates into mist due to velocity differences between the water jet and the surrounding air (pressure jet nozzles) or disintegrates into small particles on impact against an impingement surface such as a deflector plate (impingement nozzles). A more in-depth discussion of the physical mechanisms involved in atomization can be found in Lefebvre [41] and of common water mist nozzles, in Mawhinney [191].

Manufacturers of nozzles for industrial applications have catalogs filled with different nozzle designs, delivery rates, and cone shapes. They have been manufacturing a wide range of nozzles for many years. It is surprising, therefore, how much money and effort have gone into the custom design of nozzles for water mist systems by fire protection specialists. The water mist system manufacturers have developed their preferred nozzle design through in-house research and development. Some off-the-shelf commercial nozzles have been successfully applied in water mist systems, but have required customized selection of individual orifice sizes [23, 33].

Mist generation by flashing of superheated water. Evidence that water mist with sufficiently small drop sizes may quell a dust explosion is found in work conducted at the Irish agricultural research facility involving dusts of dried milk products [192–194]. The mist-generating method involves the flashing of superheated water released from a self-pressurized container [195]. Water is superheated to 175 °C in a closed container up to 70 L (18.5 gal) in volume. As steam tables indicate, this puts the closed container at a pressure of approximately 10 bar (145 psig). When released to atmospheric pressure through a fast-opening valve, a percentage of the water flashes directly to vapor phase and then condenses into fog-sized particles (<20 μm) as the cloud cools. There is a dynamic release of energy as the liquid flashes, which shatters the remainder of the mass of water into relatively fine spray ($D_v0.90$, ~300 μm) (i.e., 90 % of the volume of the spray as contained in drops less than 300 μm in diameter) [195]. The energy exchange also results in intense cooling of the spray, so that 30 cm away from the discharge orifice, the mist temperature may be 35 °C or less [193].

The flashing process does not require a nozzle—simply an open orifice—and it results in a rapid distribution of mist plus fog throughout the protected space. The condensed fog is similar in particle size to NanoMist, that is, an order of magnitude finer than can be achieved by mechanical generation of spray. The phenomenon is very dynamic and allows for the rapid distribution of "fog" and water vapor throughout a space. Full-scale fire suppression tests carried out by Mawhinney et al. [193] determined that the ultrafine mist was not more effective than other mists at extinguishing pool fires in enclosures. It was suggested, however, that its success in dust explosion mitigation may be due to the high mass fraction of very small (~20 μm), closely spaced droplets, suggested by Zalosh [40] to be a prerequisite for explosion mitigation with water mist. Further experimental work is required to validate its potential for vapor-air explosion mitigation [194].

NanoMist is an ultrafine mist with very uniform drop size distribution with a volumetric mean droplet diameter in the 10 μm range [27]. The technology combines an ultrasonic transducer assembly (nebulizer) and a process equipment for aerosolization, extraction, and transport of the mist. The capacity of the mist generator is in the range of 0.25 Lpm (0.06 gpm). The opaque cloud of low momentum mist can achieve suspended mass of water droplets in excess of 240 g/m^3. No conventional water mist nozzle approaches that level of suspended water droplets. The NanoMist is transported by fans through smooth ducts to confined areas. In a series of tests conducted for the U.S. Navy to develop a "hybrid" system (nitrogen plus water mist), NanoMist was tested in a mock computer room subfloor (false-deck) against telltale fires [26–28]. Various combinations of inert gas (nitrogen) and water mist were used to extinguish the test fires. The concentration of nitrogen needed to inert the space and extinguish the fires was first determined. Then water mist was

added to the nitrogen. A conventional fine water mist reduced the concentration of nitrogen needed to extinguish the fires by as much as 40 %. Water mist itself could not extinguish the concealed fires in the subfloor. In contrast, the NanoMist was able to extinguish the telltale fires itself without the addition of nitrogen. One of the problems encountered in trying to apply NanoMist is that of delivery. The fog itself has very little velocity or momentum; the act of trying to force it to flow and to fill spaces causes coalescence and condensation of the suspended water droplets.

Pressure Regimes

NFPA 750 distinguishes between low-, intermediate-, and high-pressure systems. Low-pressure systems operate at pressures below 12.1 bar (175 psi), the same as conventional sprinkler systems. Conventional centrifugal fire pumps can be utilized to achieve system pressures, and standard sprinkler piping and hanging methods can be used. Intermediate-pressure systems have operating pressures that lie between 12.1 and 34.5 bar (175 and 500 psi). High-pressure systems operate above 34.5 bar (500 psig). Pumps, pipe or tubing, fittings, and supports for high-pressure water mist systems require specialized knowledge to design, install and maintain.

Most pre-engineered gas-driven water mist systems require banks of high pressure compressed gas cylinders, therefore at least portions of the system require familiarity with high pressure compressed gas equipment. With twin-fluid systems, some may be high pressure and some low pressure; the extinguishing medium (water) cylinders or tanks may be at low pressure, and regulators may be used to reduce compressed gas from cylinder pressure to match the lower water pressure.

With the NanoMist technology described earlier, the water is delivered to the nebulizer under low pressure, but the mist created does not fit the conventional concept of a piping system delivering water to a nozzle under pressure. It is in effect a "no-pressure" system. A NanoMist system must incorporate a means of transporting the mist to the volume to be protected.

Low- and intermediate-pressure systems. The dividing line between "low" and "intermediate" water mist systems in NFPA 750 is 12.1 bar (175 psi). For standard sprinklers, 12.1 bar (175 psi) is the *maximum* permitted nozzle pressure, whereas many so-called low pressure water mist nozzles were developed for a *minimum* nozzle pressure of 12.1 bar (175 psi). If the minimum nozzle pressure is 12.1 bar (175 psi), basic hydraulic calculations will demonstrate that the upstream piping and the pumps required must produce pressures higher than 12.1 bar (175 psi), i.e., in the "intermediate" pressure range. For this reason, it is preferable to consider the maximum pressure in the piping system, rather than the nozzle, in distinguishing *low* from *intermediate* pressure water mist systems. By that measure, water mist systems that require pump ratings and piping pressures in excess of 12.1 bar (175 psi) but less than 34.5 bar (500 psi) are intermediate pressure water mist systems. For water mist nozzles with a minimum allowable pressure in the 5–8 bar (72.5–116 psi) range, the entire system including the fire pumps can operate at less than 12.1 bar (175 psi), therefore the system is genuinely a low pressure water mist system.

Water mist systems that require pumps rated to 17 and 20 bar (245.5 psi and 290 psi) are intermediate pressure water mist systems. Some approved fire pumps exist for this range of system pressure (20 bar, 290 psi) at least within Europe. The intermediate pressure water mist systems that this author has designed or reviewed to date, operate between 12.1 bar and 20 bar (175 psi and 290 psi).

High-pressure systems. Most high pressure water mist systems operate at pressures in the range of 60–120 bar (870 psi to 1740.5 psi), considerably higher than 34.5 bar (500 psi). Not all of the pressure is needed at the nozzles, which might be Listed with a minimum acceptable pressure of 50 bar. The surplus pressure permits the

use of relatively small diameter piping, which is an advantage for installation in some settings. For example, for heritage buildings, the ability to use small-diameter tubing reduces the impact of the fire suppression system piping on the architecture. Therefore, high pressure systems utilize electrical energy to gain some material advantage over the fire: effective at greater ceiling height; use of smaller diameter tubing and reduced water flow requirements, compared to low pressure water mist systems.

High-pressure water mist systems are installed on passenger cruise ships as an alternative to marine sprinkler systems. The ability to reduce the weight of piping in the superstructure of the ship, compared to marine sprinkler systems, was a major factor favoring the use of high pressure water mist systems. They are widely used in marine and petroleum machinery and equipment spaces on the North Slope of Alaska. Water mist systems have been installed in new highway tunnels up to 10 km in length have been high-pressure systems. They have also been installed in heritage buildings, museums, and art galleries.

High-pressure water mist systems may be gas-driven, pre-engineered systems, or pump-driven engineered systems. Gas-driven systems operate over a declining-pressure range from, for example, 100 bar at first release to 20 bar at the end of a 10 min discharge period. There is also a gas-driven pump that can extend the operation of a gas-driven high-pressure system for up to 1 h without the need for electric-motor or engine-driven pumps [196]. For high-pressure system piping, stainless steel tubing is used in conformance with the ASME/ANSI B31.1, *Power Piping Code* [197]. Good practices for tube bending, cleaning, and swabbing; supports; and makeup of compression fittings must be applied.

Opinions are sometimes expressed regarding whether high-pressure water mist systems are "better" than low-pressure water mist systems. If that were the case, one would expect that the range of successful water mist technologies would have quickly become limited to high pressure systems. The fact that both low pressure and intermediate pressure systems are actively competing with high pressure systems in the market place is because, as extensive testing has shown, acceptable fire suppression can be achieved with both high- and low-pressure water mist systems. The choice of technology for any given application is based primarily on practical matters specific to the application, such as the level of importance placed on minimizing water discharge volume, the cost of electric power, the cost of labor, and the availability of labor with the requisite skills to design, install and maintain the system. In principle, then, the engineering, environmental, and economic issues related to the different technologies will determine the best choice for a given application. However, individual vendors of water mist systems whose equipment is limited to one pressure regime will limit their recommendation for "best choice" to their own equipment.

It is highly beneficial to end users to have an independent fire protection engineer who is familiar with the technical details of all types of water mist systems, assist them in evaluating the best choice for their application. Preliminary layouts of systems with equivalent approvals can be made using different manufacturers' nozzles, and performing hydraulic calculations to determine the total water demand and pump selection. Table 46.2 is presented to illustrate this point. Nozzle and piping layouts were made following the manufacturers' spacing rules and K factors for nozzles or sprinklers. The table lists the type of nozzle or water mist system components, the minimum nozzle pressure required and its K-factor, the total number of nozzles within a design area, and the calculated total water flow rate (with 15 % overage). Hydraulic calculations were performed for each trial layout to determine the discharge pressure at the pump outlet. The pump pressure shown in Column 8 is the nominal rating of the pump that one would select, not the calculated minimum demand pressure.

Table 46.2 illustrates that there are several factors to consider when making a decision about which water mist system to use for a given application. Column 2 identifies the system by the minimum nozzle pressure. Two water mist

[b]"**Power Rank**" is the hydraulic horsepower (kW) to pump the design flow at the rated pump pressure

nozzles and the sprinkler system are shown as being in the low-pressure regime. Column 9 identifies that all of the water mist systems have system pressures greater than 12.1 bar (175 psi), and should properly be referred to as intermediate-pressure systems. Column 7 shows the calculated total water flow for each system. One water mist system requires only 338 L/min (89 gpm); another requires 832 L/min (220 gpm), while the standard sprinkler system requires a flow of 2572 L/min (680 gpm). If minimizing the total water requirement is of primary importance for the application, the "best" system will be based on Column 7. Column 10 calculates a relative energy requirement factor, referred to as "Power rank" number. This number is simply the "hydraulic horsepower," or hydraulic energy requirement in kilowatts, to move the design flow rate shown in Column 7 at the pump rated pressure shown in Column 8. The numbers shown in the table utilize Equation 46.6 presented in the following section, assuming an efficiency value of 1.0 for all pumps. The resulting number is useful for ranking the different technologies against each other according to energy requirements. The hydraulic energy requirement for the high pressure system is more than 10 times the comparative energy requirement for the water mist system with the lowest water flow and pressure requirement. By completing the preliminary designs and laying out the requirements for the candidate systems, as shown in the table, one can begin to make an informed choice. Although not shown in the table, the relative costs of the different systems will also need to be considered in selecting the best option.

Designing with Positive Displacement Pumps

High-pressure water mist systems can utilize use electric motor- or diesel engine-driven, positive displacement (PD) pumps to achieve the necessary system pressures. This is in contrast to traditional centrifugal fire pumps used in fire protection systems. Unlike centrifugal pumps, which can put out a wide range of flows (Q) at different pressures, PD pumps put out a constant Q at a specific pressure for given rotational speed. The pressure achieved is a function of the power (kilowatts) of the driver, electric motor or diesel engine, that turns the pump shaft. The pump discharges the volume of water contained in each piston chamber or gear void

with each stroke or revolution. If a PD pump operates against a closed system, i.e. no nozzles are discharging water, the pump will cause the pressure in the system to increase until the system piping fails or damage is done to the pump or the driver or both. Unlike centrifugal fire pumps, PD pumps have no "shut-off" head.

Most water-based fire protection systems, including those consisting of automatic sprinklers on a piping grid, generally have a variable demand, which depends on the number of sprinklers or nozzles expected to open in response to a fire. The hydraulic demand in terms of flow rate increases as more sprinklers activate. Thus it is essential to have a water supply with pumping ability that can accommodate the associated range of hydraulic demands of most fire protection systems [198].

There are practical limits to the pressures that can be achieved using centrifugal fire pumps, however. To provide the discharge pressures associated with high pressure water mist systems, the speed of the driver must be significantly increased, or multiple centrifugal pumps must be connected in series. Even with these arrangements though, it is unlikely that centrifugal pumps can provide the necessary pressures in the 60 bar to 120 bar (870 psi to 1740.5 psi) range that might be required for some types of water mist systems.

In order to adapt high-pressure PD pump technology to serve fire protection systems with variable demands, various innovations to traditional fire pump practice from the hydraulics industry have been incorporated. By combining the PD pump with a pressure relief valve, referred to here as an "unloader" valve, it is possible to direct the unused portion of a PD pump discharge to a bypass line, while maintaining a high pressure flow to the water mist system. Some manufacturers of high pressure pumps for water mist systems have chosen to use a single large volume PD pump, such as a gear pump, connected to a discharge header with one or two unloader valves installed to discharge any surplus flow and relieve excess pressures. Figure 46.8 illustrates the latter single-pump configuration for a PD pump with 454 L/min output at 17.2 bar (120 GPM at 250 PSIG).

The power requirement (brake horsepower) of the motor to achieve a particular flow and pressure is calculated as shown in Equation 46.6.

Designing with Positive Displacement Pumps

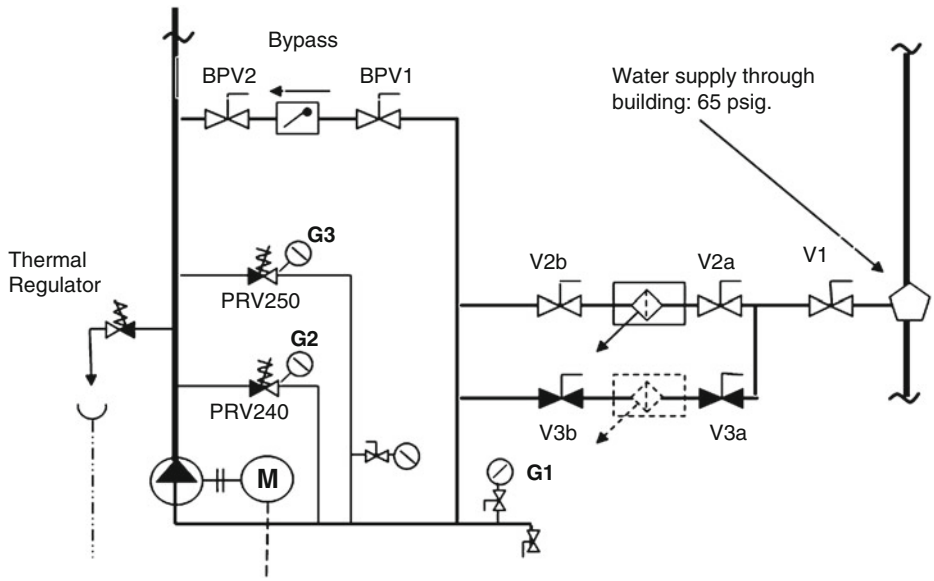

Fig. 46.8 ISO symbol diagram of a single positive-displacement pump with two pressure regulating valves discharging to the suction supply line. The thermal regulator is required by NFPA 20 for relief discharging to suction. The by-pass line is necessary to sustain a minimum standby pressure on the deluge valve manifold

$$P = Q \times H/(600 \times E) \qquad (46.6)$$

Equation 46.7 defines the maximum pressure limit (H) for a given motor-pump combination, as shown in Fig. 46.9.

$$H = (P \times 600 \times E)/Q \qquad (46.7)$$

where

P = Brake Horsepower (kW)
Q = Pump discharge (L/min)
H = Pump discharge head (bar)
E = Combined efficiency of the motor and gear drives ($\eta_d \times \eta_m$)

As a PD pump will produce the same flow at a given speed regardless of discharge pressure, a workable approach to achieving both high pressures and variable water flow rates is to combine multiple PD pumps in parallel, with each pump provided with its own unloader valve. Figure 46.9 illustrates an arrangement of one electric motor driving two PD pumps in parallel. One of the two unloader valves is set to release at a specific pressure, such as 140 bar, while the second unloader valve is set at one half of that, or 70 bar. Regarding Equation 46.6, given that the available Power (P) is constant (e.g., a 17 kW electric motor), the system is capable of discharging either Q × H, or 2Q × ½ H. That is, if each PD pump nominally delivers 50 L/min, the total output from the assembly will be 1 × 50 L/min, at the higher pressure setting of 140 bar, or 2 × 50 L/min or 100 L/min from two pumps at the lower pressure setting of 70 bar. If the system demand calls for a pressure of up to 139 bar, only 50 L/min will flow through the system as the unloader valve set at 70 bar will be discharging all of the flow from the pump it serves, through the low pressure bypass line. If the system demand pressure drops below 70 bar, 100 L/min will be flowing through the system. High-pressure pump skids are manufactured with two, four, six or more electric motors, with each motor driving two PD pumps, in a PD pump assembly. Manufacturers have obtained IMO, FM and UL approvals for such multi-motor, multi-PD pump assemblies for water mist systems.

In order to select a pump for fire protection purposes, fire protection engineers normally follow standardized hydraulic calculation practices [199, 201] to match the system demand to the water supply. NFPA 20, Standard for the Installation of Stationary Pumps for Fire Protection [200] includes a chapter on PD pumps. However, the information provided in the annex of NFPA 20 relating to the performance point for a PD pump, and the data provided by some PD pump manufacturers, is not in an ideal format for conducting conventional hydraulic analysis of

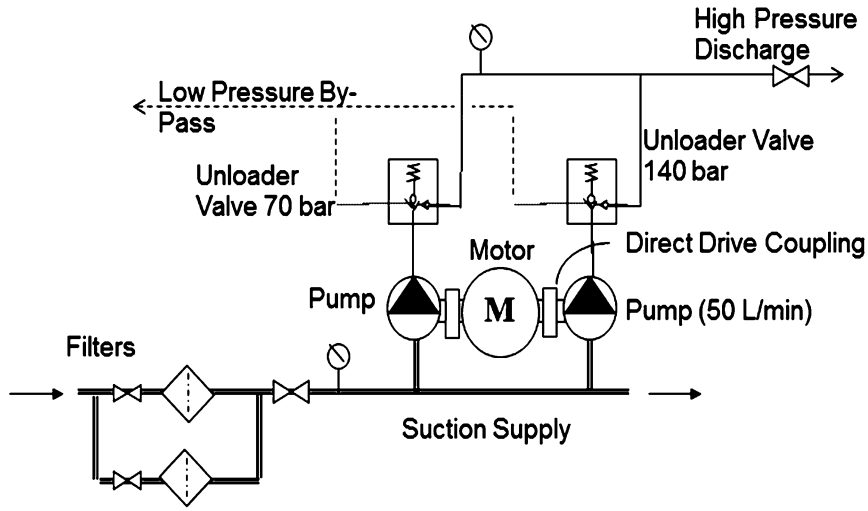

Fig. 46.9 ISO symbol diagram of a positive displacement pump assembly with two PD pumps in parallel, each with a dedicated unloader valve

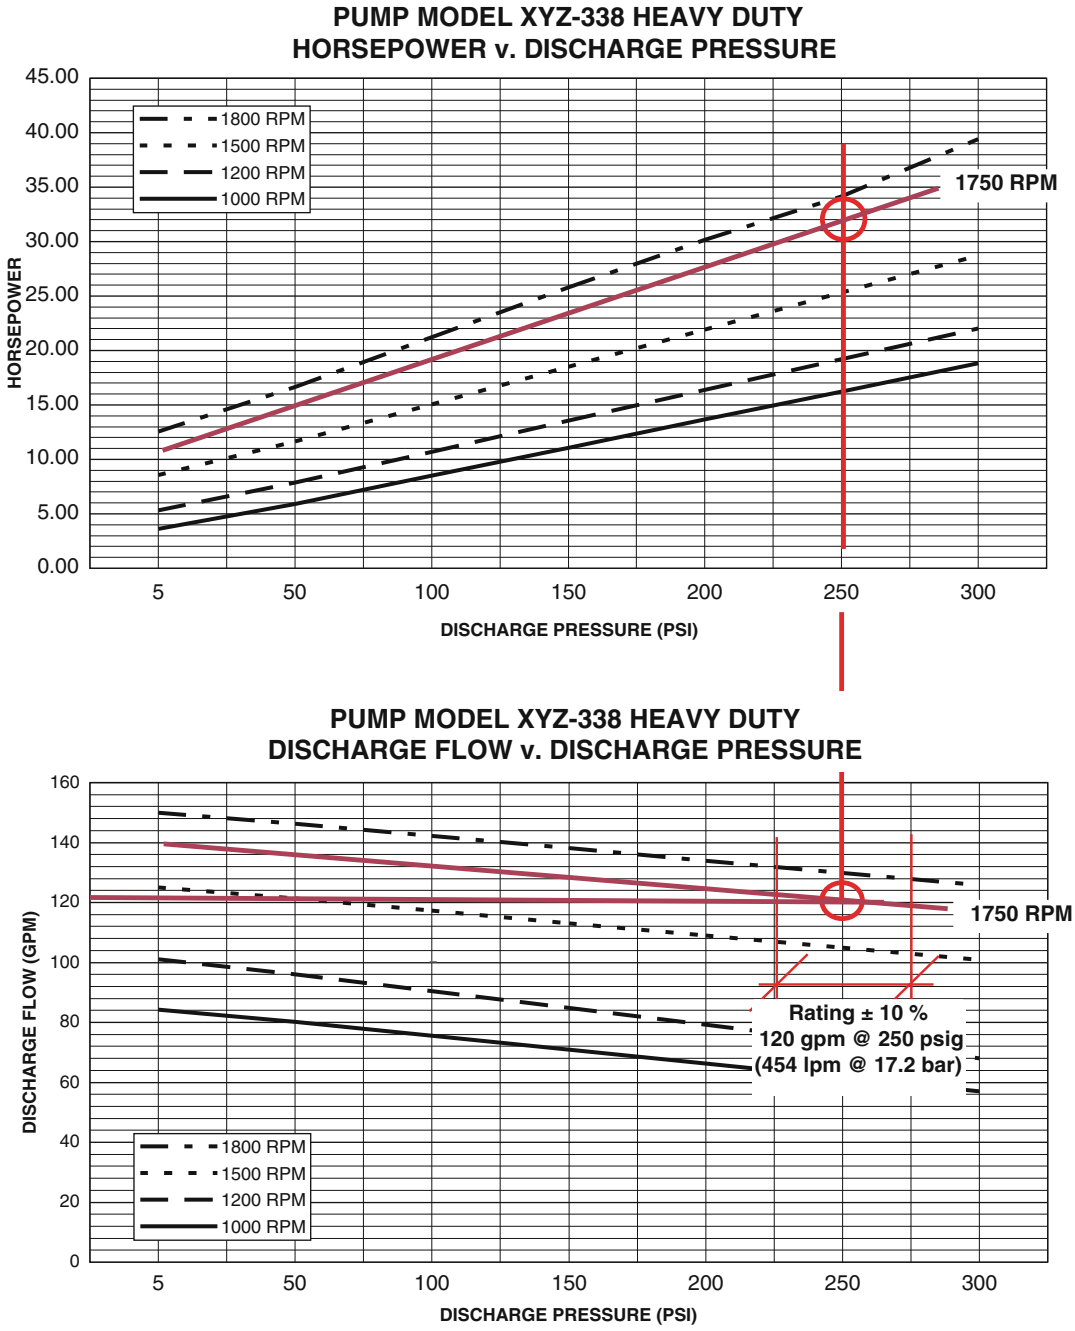

Fig. 46.10 Manufacturer's presentation of performance data for a PD pump approved for intermediate pressure water mist systems

fire protection systems as the information is not presented on a customary hydraulic (N = 1.85) graph. Figure 46.10 illustrates how to determine a specific performance point and an acceptable operating range for a given PD pump. Fluctuations in voltage to the pump motor will cause the pump to deliver slightly more or less than the nominal expected performance.

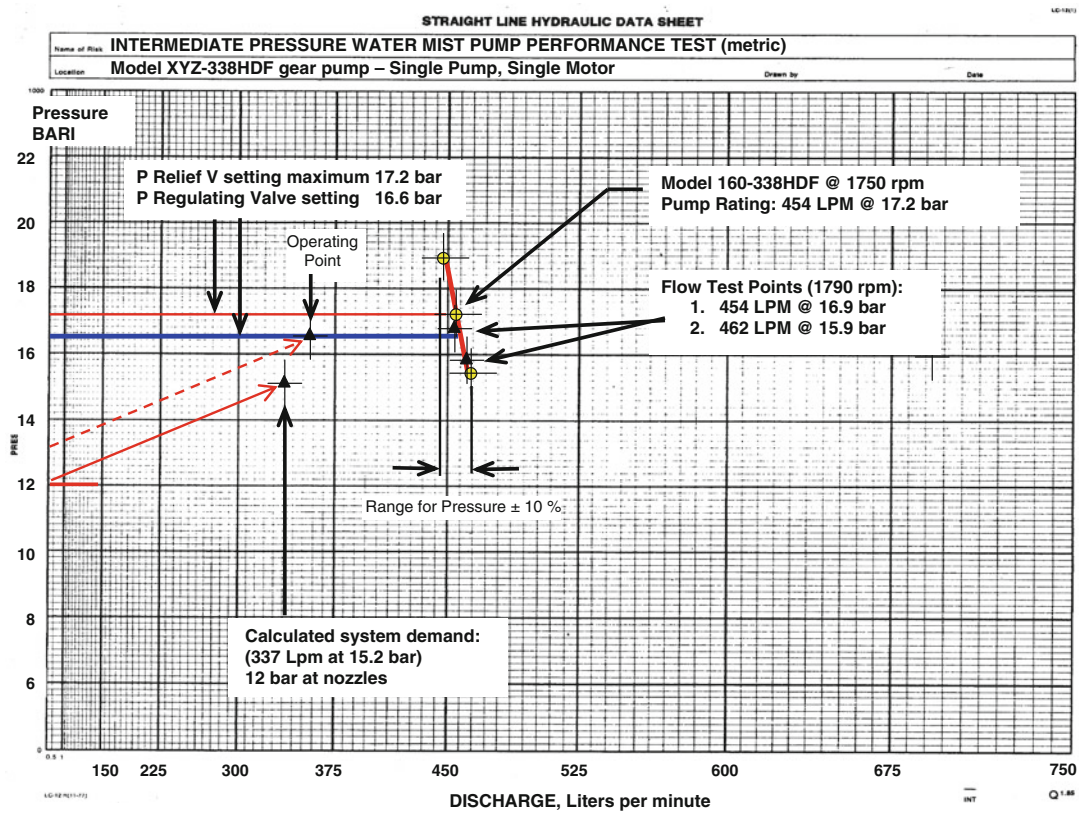

Fig. 46.11 Metric N1.85 straight line hydraulic performance plot for a single PD pump with one motor

Figure 46.10 contains two figures that indicate the available flow, pressure and horsepower for a given PD pump when it operates at different speeds. The circles indicate the necessary performance point for a pump operating at 1750 RPM to provide 454 L/min at 17.2 bar (120 gpm at 250 psi). Note that Fig. 46.10 is presented on a conventional Cartesian grid, whereas fire protection hydraulic calculations typically use N = 1.85 graph paper.

Figure 46.11 presents the information provided by the PD pump manufacturer in Fig. 46.10 on a hydraulic graph (N = 1.85) as this format better facilitates design and analysis of water supplies for fire protection systems [101]. The uppermost horizontal line at 17.2 bar represents the pump's performance "curve" for the given motor size. The pump has a nominal rating of 454 L/min at 17.2 bar (120 GPM at 250 PSI) when operating at 1750 RPM, which is shown as the point in the center of the red circle (Because of voltage fluctuations that affect motor speed, there is an acceptable operating range of approximately ± 10 % with respect to the rating value.).

When combined with an unloader or other pressure regulating valve, the PD pump's narrow performance point or output, in this case 454 L/min at 17.2 bar, can be modified to better accommodate a discharge from the nozzles that is less than the fixed output from the pump. In Fig. 46.11, the horizontal line at the unloader valve setting of 16.6 bar approximates a water supply "curve" capable of accommodating any flow between 0 and 454 L/min to a system of nozzles, while by-passing the unused portion of the pump output. The system pressure relief valve, which is required by NFPA 750 in addition to the unloader valves, is set at 17.2 bar (the upper line). The primary pressure regulating (unloader) valve set to discharge at 16.6 bar will allow a flow of about 360 L/min into the

system. The balance of the pump output, or 454–360 = 94 L/min, will be discharged either back to the suction side of the pump or to a waste line.

The minimum demand for a water mist system, as determined by hydraulic calculation starting with a minimum nozzle pressure of 12 bar, is shown in Fig. 46.11. However, the "system" will operate at the pressure point determined by the setting of the regulating valve(s), as shown in the figure. It is evident that the operating point of the pump assembly exceeds the theoretical fire protection demand, therefore the pump assembly is a satisfactory for the water mist system. The flow test points are discussed later under the Acceptance Testing section.

As noted earlier, Fig. 46.9 shows two PD pumps connected in parallel, each with its own pressure regulating or "unloader" valve. Manufacturers of high pressure water mist systems have FM approved assemblies of PD pumps and motors capable of delivering substantial flow rates at 100 bar pressure or higher. The procedure for plotting the hydraulic performance "curve" for assemblies of PD pumps is extended by summing the volumetric output of the pumps. Figure 46.12 shows a N = 1.85 straight line hydraulic graph for an assembly of six electric motors, each with 2 PD pumps, as previously illustrated in Fig. 46.9. The total flow capability with all six motors and 12 pumps operating is 585 L/min. All 12 unloader valves are nominally set to the same pressure, 100 bar. There is normally some variation in the release pressure setting of unloader valves, so that some of them will "leak" before reaching the 100 bar setting. Therefore, it is not common to achieve a flow test result during an acceptance test that is exactly at

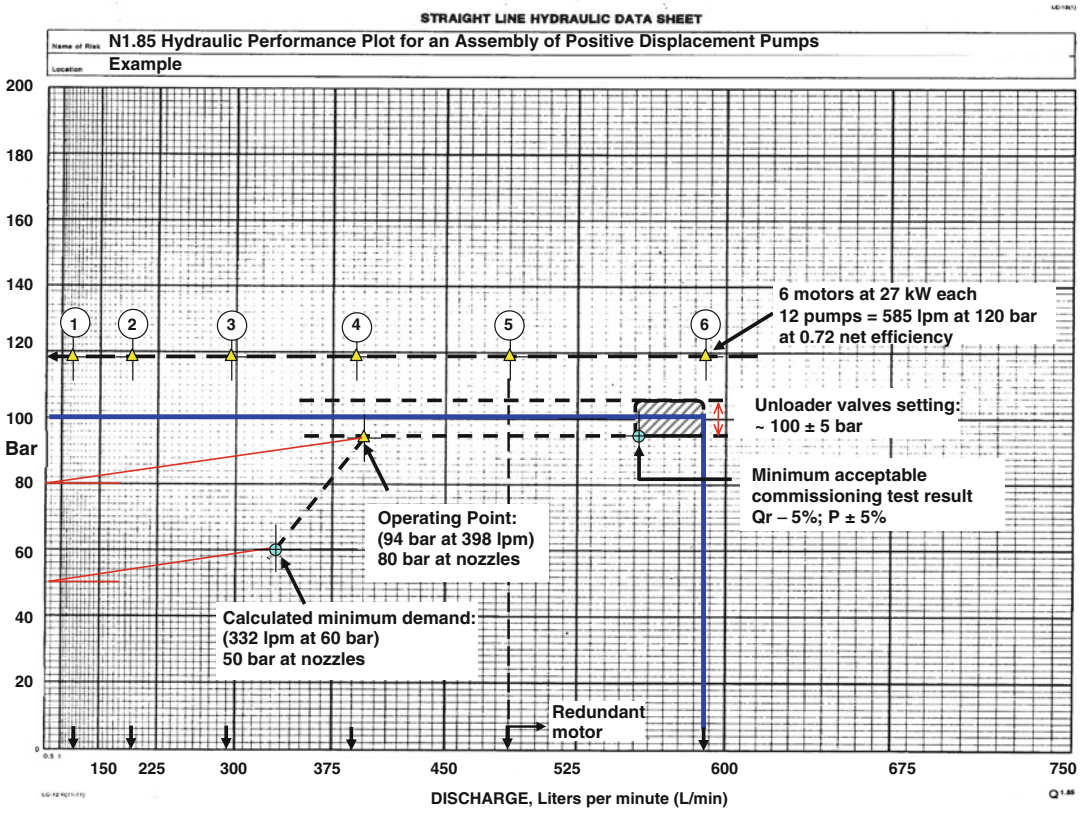

Fig. 46.12 Metric N1.85 straight line hydraulic performance plot for an assembly of six motors and 12 PD pumps connected in parallel

the nominal pressure setting of the unloader valves. For example, in Fig. 46.11 two flow test results are shown, neither of which is exactly at the nominal setting, but both of which fall nicely on the factory curve. Anticipating this, it is wise to state the pump performance at some percentage below nominal setting, so that when the pump is field tested, it delivers at least what it is specified to deliver (flow and pressure). Figure 46.12 shows a possible range within which the flow test results should lie, in order to pass the field test.

The PD pump assembly shown in Fig. 46.12 is capable of delivering 585 L/min with all six motors operating and an unloader setting of 100 bar. However, it is evident in the Figure that the assembly could deliver 487.5 L/min with only 5 motors operating, which also exceeds the system demand. For the multi-motor, multi-pump assembly shown, it is common to specify that the system design demand (Q and P) be met with only five of the six motors operating, i.e., with one of the motor/pump combinations being redundant.

Acceptance Testing of Water Mist Systems

Upon completion of an installation, NFPA 750 requires that a flow test be conducted to confirm the performance of the PD pump or pump assembly. The procedure for flow testing a PD pump or pump assembly differs from standard practice for centrifugal fire pumps as outlined in NFPA 20 [200]. For centrifugal fire pumps, the flow test data must show that the pump performance curve is equal to or better than the "factory curve" for the pump. In contrast, for PD pumps and pump assemblies, which incorporate a pressure relief/regulating or unloader valve, it is the unloader valve settings that determine the discharge pressure, not the factory rating for the pump. Furthermore, the flow test points are often less than the nominal settings of the relief valves. This is particularly the case for multi-pump assemblies, where there are many unloader valves, each with a small deviation from the nominal setting.

Figure 46.11 shows the flow test results for a single PD pump. Although the pump has a performance point of 454 L/min at 17.2 bar when operating at 1750 RPM, the two test points are at 16.9 and 15.9 bar, slightly less than the nominal setting of the regulating valves which are set at 17.2 bar and 16.6 bar. This is considered an acceptable result in spite of the fact that the test points are below 17.2 bar, the pump performance point. With only one relief valve governing the maximum pressure, the two points obtained by means of a full flow test, were very close to the nominal relief valve setting, but they are below the apparent pump rating. To be considered an acceptable test, the engineer and authority having jurisdiction must understand that the pressure regulating valves setting determines the assembly rating.

As shown in Fig. 46.12, the deviation from the nominal unloader valve setting is even greater for multi-pump assemblies than for single PD pump installations. This is because with more unloader valves, there is more "leakage" from the ones with settings slightly below the nominal setting which in Fig. 46.12 is shown as 100 bar. The pressure/flow result for an acceptable field test should be within 5 % of the sum of the output of all pumps, at a pressure not more than five percent less than the nominal setting of the unloader valves. It is important that the test engineer, the vendor and the authority having jurisdiction, be aware of these differences between testing centrifugal pumps and PD pumps, to avoid disputes over interpretation of test results.

Acceptance testing of twin-fluid, declining-pressure, and pumped high-pressure water mist systems involves engineering analysis that is not typical of traditional sprinkler and other fire protection systems. The technology involved in sizing compressed gas supplies for decaying-pressure systems, or designing PD pump assemblies, is sufficiently complicated that discharge testing is required as the final proof of functionality. NFPA 750 requires that a full system discharge test be conducted unless there is an overriding reason not to do so.

Without taking measurements of flow and pressure, it is impossible to judge by visual

indicators alone whether a system is operating properly. Visual inspection of the mist conditions during a discharge can confirm only basic aspects of the system performance, such as the opening and closing of valves, and verifying that pipes or nozzles are not plugged, and are able to produce mist. One can observe that water flows from individual nozzles, but one cannot discern that the spray quality, flow rate and projection are acceptable. Only by measuring pressures over the entire discharge duration can one be sure that the stored quantities of compressed gas and water are sufficient to meet the required discharge duration.

Figures 46.13 and 46.14 are plots of air and water pressure taken during the discharge of a twin-fluid system involving cycled flow at the hydraulically most remote nozzle and at a nozzle very close to the supply tank. The design called for six discharge cycles of 50 s each, with 40 s intervals between them. Air and water pressures at the nozzles should be between 82 and 66 psig. From visual and audio observations in the compartment, six discharges occurred. From the pressure traces, however, it was evident that the sixth discharge did not achieve the minimum nozzle pressures, particularly at the most remote nozzle. For the nozzle closest to the supply tank (Fig. 46.14), the minimum operating air and water pressures were achieved in the fifth but not the sixth discharge. The differences between pressures at the closest and most remote nozzles indicate that the nozzles closest to the source were discharging considerably more air and water than the remote nozzles.

The recorded pressures of the discharge tests demonstrated that the system exhausted the supply of atomizing medium before the end of the fifth discharge, although not the supply of stored water. Additional cylinders of compressed gas were required to achieve the desired six discharges. This test experience demonstrates that a full understanding of the performance of the system and the need for corrective action could not have been identified unless the discharge test had been instrumented so that a true measure of performance could be revealed.

Ultimately, the reliability of water mist systems depends on proper design, installation, acceptance testing and on-going maintenance. Water mist systems have less over-design capacity and more potential failure modes than standard

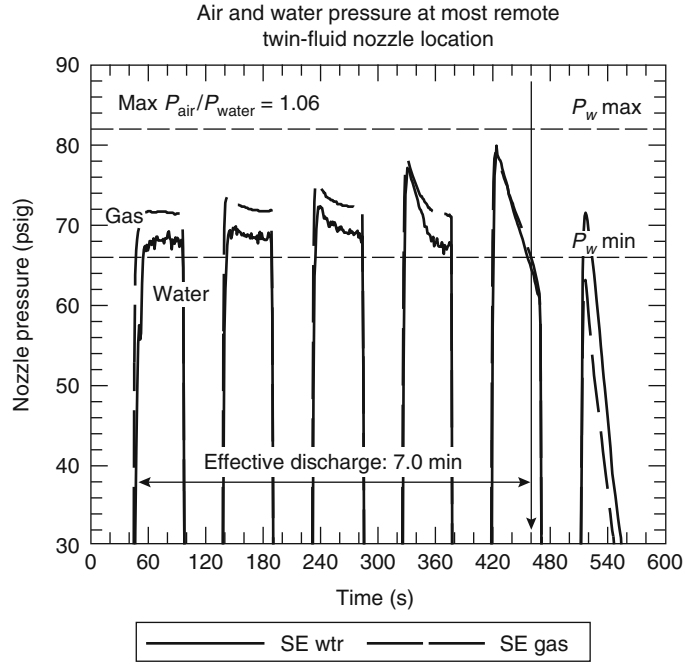

Fig. 46.13 Pressure versus time plot of compressed gas and water pressures at the most remote twin-fluid nozzle location. Acceptable operating range is between 66 and 82 psig, with compressed gas pressure required to be approximately the same as the water pressure ($P_a/P_w = 1.0$)

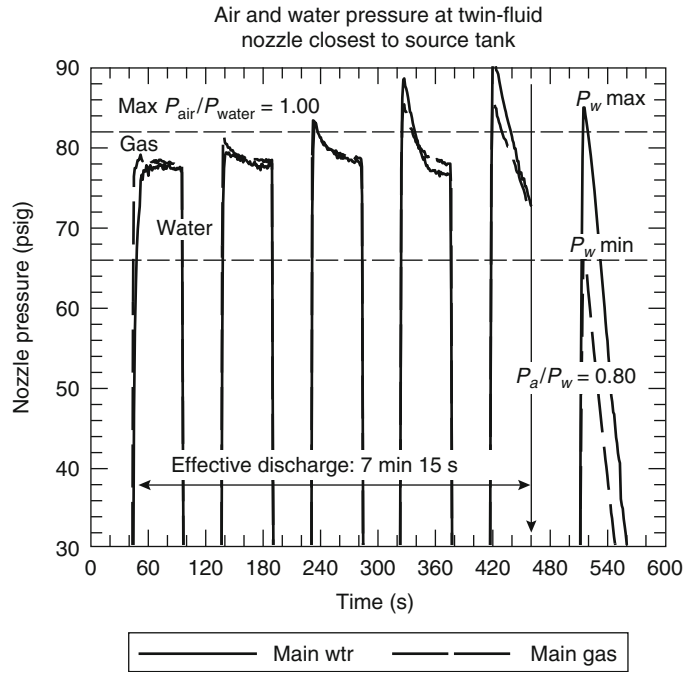

Fig. 46.14 Compressed gas and water pressures measured at a nozzle close to the source tank. Acceptable operating range is between 66 and 82 psig, with compressed gas pressure required to be approximately the same as the water pressure ($P_a/P_w = 1.0$)

sprinkler systems. The importance of applying good engineering practice, starting at the selection and design stage and continuing through the service life of the system, cannot be overstated.

Summary

This chapter provides a review of the history behind recent developments of water mist fire suppression systems. Significant studies on how finely divided water sprays improved the efficiency of fire control, suppression and extinguishment had been done years before, but it was not until the 1990s that additional incentives for considering and employing the technology became apparent. Motivated by interest in finding halon alternatives and developing lightweight suppression systems for ships, manufacturers of fire protection systems began to incorporate new ideas and new hardware into fire protection system design. Water mist emerged as a viable alternative for a number of halon applications, and the improved efficiency in use of water promised major reductions in the weight and volume of system hardware.

Currently design criteria for water mist systems must be based on full-scale fire testing for specific hazards. Interestingly, testing has revealed that the design criteria for different manufacturers' equipment, tested to a formal test protocol, may vary greatly. One water mist system could meet the performance objectives at of the test protocol at one flux density (application rate), but a second manufacturer, using a different type of nozzle or pressure regime, would also succeed, but at a lower or higher average application density. Both systems must be recognized as acceptable for the hazard, but we cannot predict what difference a change in spray characteristics might make to the suppression outcome.

CFD modeling presents a promising tool for analyzing the complex physical and chemical phenomena of fire suppression by water mist. The strength of the CFD models is their ability to expand the understanding of how the application and system design parameters affect the performance of the system. The limitations are associated with the high labor costs required to develop a fine computational grid for a large scale application and the associated long

computer run-times to perform the simulation. Applying CFD modeling to a specific application requires a certain level of expertise. Additional research is required to further develop and validate techniques to model the spray characteristics of the nozzle/system, and an all-encompassing extinguishment algorithm capable of handling a variety of fuel types and configurations. Considering the physical and chemical complexity of extinguishing multi-fuel fires, accomplishing this latter goal is rather ambitious. Only limited progress has been made in these areas over the past few years due to the application specific nature of the latest research and the limited amount of test data available for validation. In any case, modeling still has the potential not only to augment the test and evaluation process but also to aid in approving specific designs for actual applications in the future.

Water mist system technology has become a global fire protection market in the second decade of the twenty-first century. The strongest market first appeared in the international marine sector, where water mist was competitive with marine sprinkler systems on passenger ships. Satisfactory fire protection could be achieved with a fraction of the water requirements of marine sprinkler systems. Penetration of land-based markets has been restrained by a lack of suitable broad range test protocols. After a decade of full-scale fire testing and developments in computer modeling of tunnel fires, water mist systems are now recognized to be capable of preventing catastrophic fire losses in highway and rail tunnels. Water mist systems reduce the heat release rate of fires, provide thermal management to protect the tunnel structure, and prevent propagation of fire to other vehicles. More work is required to integrate the benefits of water mist systems into traditional tunnel design procedures, but water mist systems are presently being installed in many new tunnels in Europe.

Efforts are increasing in both Europe and North America to have water mist systems given the same recognition, in terms of construction trade-offs, as sprinkler systems in building codes. The largest growth potential for water mist technology is to have water mist systems installed throughout commercial and residential buildings as an alternative to standard sprinkler systems. Increasing consciousness of the need to reduce the fire protection demand on urban water systems in regions of water scarcity is one factor that is encouraging the application of water mist systems as equivalent to sprinkler systems. On the other hand, some building safety engineers express concern that the reliability of water mist systems is not equivalent to standard sprinklers, and tend to discourage the idea of treating them as equivalent to sprinkler systems. It is hoped that the water mist system manufacturers will invest in innovative approaches to increasing the reliability of water mist systems, and demonstrating their overall long term performance.

Jack R. Mawhinney was a senior engineer with Jensen Hughes, previously Hughes Associates, Inc., in Arbutus, Maryland from 1996 until his retirement in 2014. He holds a master's degree (1979) in civil engineering from the University of Alberta. He has 45 years' experience in fire protection construction and research, including 11 years with the National Research Council, Canada, Institute for Research in Construction. Mr. Mawhinney was chair of the NFPA 750, Water Mist Systems, Committee from 1992 to 2002 and a principal member of that committee until his retirement from Jensen Hughes in 2014.

Gerard G. Back III is a senior engineer with Jensen Hughes in Arbutus, Maryland. He has a bachelor's degree (1983) in mechanical engineering and a master's in fire protection engineering (1996), both from the University of Maryland. In 25 years with HAI, Mr. Back has conducted extensive fire testing and analysis of the performance of water mist systems for the U.S. Army, Navy, and Coast Guard research and development programs and for other international clients. He is a member of the NFPA 750 Committee.

Foam Agents and AFFF System Design Considerations

47

Joseph L. Scheffey

Introduction

Foams have been developed almost entirely from experimental work. Although the technologies are rather mature, no fundamental explanations of foam extinguishment performance have been developed based on first principles. As a result, foams are characterized by (1) fire tests for which there is no general international agreement and (2) physical and chemical properties that may or may not correlate with empirical results. This chapter reviews the important parameters associated with foam agents, test methods used to evaluate foams, and relevant data in the literature that can be used to evaluate foam system designs. Because of their superior performance in extinguishing certain types of hydrocarbon liquid fuel fires, the emphasis is on film-forming foams and thin pool fires (e.g., from spills). Situations involving fuels "in depth" are limited to a discussion on foam modeling and small-scale tests to assess oil and petrochemical industry hazards.

Fire-fighting foam consists of air-filled bubbles formed from aqueous solutions. The solutions are created by mixing a foam concentrate with water in the appropriate proportions (typically 1, 3, or 6 % concentrate to water). The solution is then aerated to form the bubble structure. Some foams, notably those that are protein-based, form thick, viscous foam blankets on liquid hydrocarbon fuel surfaces. Other foams, such as film-formers, are much less viscous and spread rapidly on the fuel surface. The film-formers are capable of producing a vapor-sealing film of surface-active water solution on most of the hydrocarbon fuels of interest.

Because the foam is lighter than the aqueous solution that drains from the bubble structure, and lighter than flammable or combustible liquids, it floats on the fuel surface. The floating foam produces an air-excluding layer of aqueous agent, which suppresses and prevents combustion by halting fuel vaporization at the fuel surface, and preventing air from reaching the combustion zone. If the entire surface is covered with foam, the fuel vapor will be completely separated from air, and the fire will be extinguished. Low-expansion foams (i.e., foam volume-solution volume of $\leq$10:1) are quite effective on two-dimensional (pool) flammable and combustible liquid fires, but not particularly effective on three-dimensional fuel fires. This is particularly true of three-dimensional fires involving a low flashpoint fuel. Typically, an auxiliary agent, such as dry chemical, is used with foam where a three-dimensional fire (running fuel or pressurized spray) is anticipated. In enclosed hazard areas, other extinguishing media may be used, such as water mist or high-expansion foam. These agents generally require total flooding of the hazard volume.

Description of Foam Agents

There are no universally agreed-on definitions of foam agents or terms associated with fire-fighting foam. For example, where foam is referenced in NFPA standards, definitions vary from document to document. Because foams vary in performance, in terms of application rates and quantities required for extinguishment, agent definitions can be cast to accentuate positive attributes, such as "rapid knockdown" or "superior burnback resistance." Geyer et al. have described the composition of various foam agents, paraphrased as follows [1].

1. *Protein foam.* Protein foam is a "mechanical" foam produced by combining (proportioning) foam concentrate and water and discharging the resulting solution through a mixing chamber. The mixing chamber introduces (aspirates) air, which expands the solution to create foam bubbles. The liquid concentrate consists primarily of hydrolyzed proteins in combination with iron salts. Hoof and horn meal and hydrolyzed feather meal are examples of proteinaceous materials used in protein-foam concentrates. No aqueous film is formed on the fuel surface with this type of agent.
2. *Fluoroprotein.* These agents are basically protein foams with fluorocarbon surface-active agents added. The varying degrees of performance are achieved by using different proportions of the base protein hydrolyzates and the fluorinated surfactants. Although fluoroprotein foams generally have good fuel shedding capabilities and dry chemical compatibility, the solution that drains out from the expanded foam does not form a film on hydrocarbon fuels. However, the addition of the fluorinated surfactants may act to reduce the surface tension of the solution. This reduction may, in turn, decrease the viscosity of the expanded solution, thus promoting more rapid fire control when compared to protein foams.
3. *Aqueous film-forming foam (AFFF).* These agents are synthetically formed by combining fluorine-free hydrocarbon foaming compounds with highly fluorinated surfactants. When mixed with water, the resulting solution achieves the optimum surface and interfacial tension characteristics needed to produce a film that will spread across a hydrocarbon fuel. The foam produced from this agent will extinguish in the same air-excluding fashion as other foams. Further, the solution that results from normal drainage or foam breakdown produces an aqueous "film" that spreads rapidly and is highly stable on the liquid hydrocarbon fuel surface. It is this film formation characteristic that is the significant distinguishing feature of AFFF as it actually results in a seal significantly mitigating the emission of vapors from the liquid.

These definitions are by no means all-inclusive. For example, film-forming fluoroprotein (FFFP) foam is an agent that is produced by increasing the quantity and quality of the surfactants added to a protein hydrolyzate. By doing this, the surface tension of the resulting solution, which drains from the expanded foam, is reduced to the point where it may spread across the surface of a liquid hydrocarbon fuel. An alcohol-resistant concentrate is formulated to produce a floating polymeric skin for foam buildup on water-miscible fuels. This polymeric skin protects the foam from breakdown by polar solvents, for example, acetone, methanol, and ethanol. Hybrid AFFFs are being formulated to reduce or eliminate fluorosurfactants, which may have an adverse environmental impact.

A potential new class of foams, fluorosurfactant-free foam, has been developed in response to the environmental impact of fluorosurfactants (see section on "Foam Environmental Considerations"). This is neither a film forming or protein based foam. Underwriters Laboratories (UL) classifies these foams generically as "synthetic" foams. UL defines synthetic foams as those having as its base other than a fluorinated surfactant or hydrolyzed protein.

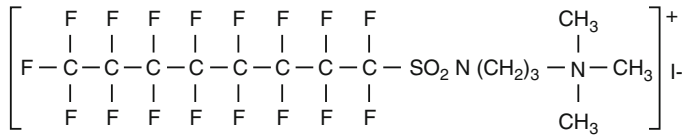

Fig. 47.1 Typical AFFF fluorosurfactant molecule [3]

The descriptions show that there are distinct chemical differences between protein-based foams and AFFF. In general, the surfactants used in aqueous foams are long-chained compounds that have a hydrophobic or hydrophilic (i.e., water repelling or water attracting, respectively) group at one end [2]. The molecular structure of a typical AFFF fluorinated surfactant is shown in Fig. 47.1 [3]. In this molecule, the perfluoroctyl group on the left is the hydrophobic group, while the propyltrimethylammonium group is the hydrophilic group. When these compounds are dissolved into solution with water, they will tend to group near the surface of the solution, aligned so that their hydrophobic ends are facing toward the air/solution interface. The advantage of this is that the perfluoroctyl group found in these compounds is also oliophobic (i.e., oil repelling) as well as hydrophobic [4].

AFFF concentrates also contain hydrocarbon surfactants. These compounds are less hydrophobic than those containing the perfluoroctyl group. However, they do provide greater stability once the solution is expanded into a foam. As a result, the surface tension of the solution is reduced below that of water; the expanded foam produced from the solution is resistive to breakdown from heat, fuels, or dry chemical extinguishing agents; and the solution that drains out from the expanded foam is able to form a film on hydrocarbon fuels.

The importance of both the film formation and foam bubble characteristics of AFFF, resulting from the combination of fluorocarbon and hydrocarbon surfactants, was evaluated in early work by Tuve et al. [5] When a highly expanded, stiff formulation of AFFF was used, these researchers found it difficult to obtain good fire extinguishment and vapor sealing characteristics. The foam resisted flow, and drainage of the aqueous solution (film) was slow. The drainage was corrected by expanding the foam to a lesser degree. This pioneering AFFF formulation, with an expansion ratio of 8:1 and 25 % drainage time of 6 min, appeared to offer the best compromise in characteristics. It provided a readily flowable foam that sealed up against obstructions, promoted the rapid formation of a surface-active film barrier on the fuel, and provided a sufficiently stable foam to resist burnback.

Fire Extinguishment and Spreading Theory

As noted in the *Fire Protection Handbook*® review of suppression theory, the fundamental mechanisms of foam fire extinguishment on two-dimensional pool fires have not been developed [6]. Usually, fire extinguishment is described simply as a factor of the cessation of fuel vaporization at the fuel surface. As the area of fuel vapor production decreases due to the spreading foam, the size of the combustion zone decreases. When the area is totally covered, sufficient amounts of air cannot reach the liquid fuel and extinguishment occurs. As the fuel is covered, cooling must also occur to bring the vapor pressure of the fuel below that of its boiling point. Once the fuel is cooled, a layer of foam must continue to be applied either manually or by spreading to terminate combustion and prevent re-ignition. Hanauska et al. have proposed fundamental extinguishment parameters [7]. A similar foam extinguishment model has been proposed by Persson and Dahlberg [8]. Bench-scale experiments have been combined with correlation/modeling techniques.

Foam Loss Mechanisms

Fire extinguishment by foams can be summarized as shown in Fig. 47.2. Foam having a temperature, T_i, and depth, h, spreads at a rate of V_s along a fuel of temperature, T_s, and vapor pressure, P_v . Fuel is volatized by the fire at a rate of $\dot{m}_{\text{fuel}}$, which is a function of the radiative feedback, $\dot{q}_{\text{rad}}$. The foam is added by the discharge application, $\dot{m}_{\text{add}}$, and lost through evaporation, $\dot{m}_{\text{vap}}$, and drop-through, $\dot{m}_{\text{drop}}$.

The total mass loss of the foam is a function of the loss due to drop-through and the mass loss due to vaporization. The mass loss due to drop-through is at least partially dependent on the drainage of liquid from the foam. Evaporation of the liquid results primarily from radiant energy from the fire. Assuming that most of the radiation results in direct evaporation of the foam, the evaporation of foam can be characterized by

$$\dot{m}''_{\text{vap}} = \frac{\dot{q}''_{\text{rad}}}{\Delta H_v} \tag{47.1}$$

where ΔH_v is the combined latent and sensible heats of vaporization. Using a rough estimate of $\dot{q}''$ from large pool fires of 45–185 kW/m^2 yields an evaporation rate of 18–72 g·m^2/s, assuming a heat of vaporization of 2563 kJ/kg. To account for reflective and absorbed losses, Persson [9] has proposed a calculation method

$$\dot{m}''_{\text{vap}} = \dot{q}''_{\text{rad}} k_e \tag{47.2}$$

where k_e is an experimentally derived constant using different fluxes from a radiant exposure. For $\dot{q}''_{\text{rad}}$ values of 45 and 185 kW/m^2, Equation 47.2 yields values for $\dot{m}''_{\text{vap}}$ of 11 and 46 g·m^2/s, respectively. Because the estimated $\dot{m}''_{\text{vap}}$ values based on Equation 47.1 at the same heat fluxes were 18 and 72 g·m^2/s, the experimental mass loss rate results are about 62 % lower than the theoretical loss. The difference between values is attributable to neglecting the reflected and absorbed losses in Equation 47.1. This indicates that about 48 % of the radiant flux to the foam surface is either reflected from or absorbed into the foam blanket. The division between these two heat transfer mechanisms is not clear and is an area for further study.

Foam loss can likewise be described theoretically, based on the downward force of gravity and the opposing forces due to surface tension and buoyancy. Alternately, a model mass loss due to drainage can be expressed as a time-averaged constant

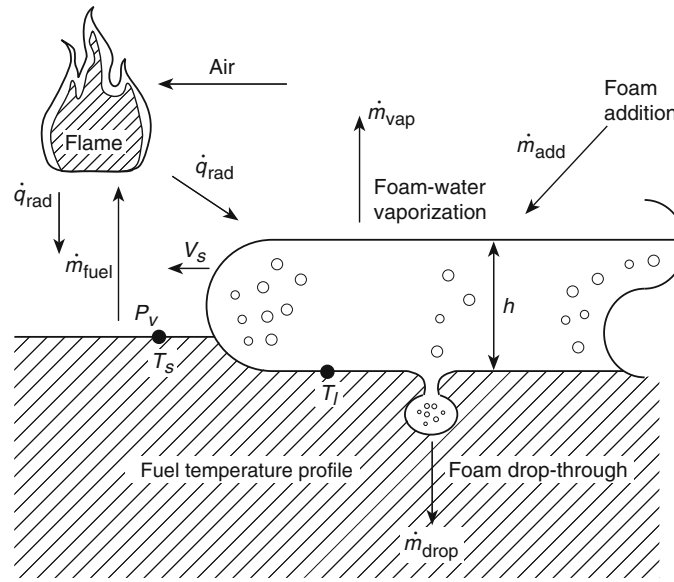

Fig. 47.2 Illustration of the significant parameters affecting a foam's hydrocarbon fuel fire extinguishment capability

$$\dot{m}_{\text{drain}} = k_d \tag{47.3}$$

where k_d is an experimentally determined drainage coefficient. From the data of Persson, the drainage coefficient can be estimated to be 17–25 g·m^2/s [9]. The drainage rate was found to be relatively independent of the radiant heat flux to the foam, but highly dependent on the expansion ratio. Foams with lower expansion ratios will drain faster. For example, decreasing the expansion ratio by about half (11.3–5.3) increased the drainage rate by a factor of about 2 (55–105 g/min). Decreasing the expansion ratio changes fundamental parameters of the foam, which allows it to drain faster.

Experimental work on the foam model, particularly with regard to the effects of incident heat flux on the foam blanket, has been performed in the United States and Europe. Lattimer et al. [10] designed a test apparatus that was used to measure the behavior of foam when exposed to irradiance levels of 0–50 kW/m^2. The apparatus provided data on evaporation rate, drainage rate, foam destruction rate, foam temperature, heat penetration, and time to fuel ignition. The performance of a single AFFF formulation was characterized.

Evaporation rates were measured primarily to be a function of irradiance, making it possible to predict evaporation using the irradiance from the fire and an effective heat of vaporization. The AFFF foam evaluated in this study was determined to have an effective heat of vaporization of 4.87 ± 0.75 MJ/kg. This result is slightly higher than that found by Ikasson and Persson [11], 4.0 MJ/kg. Different AFFF formulations may explain this difference.

Foam drainage rate was measured to be insensitive to the irradiance level or the presence of a fuel layer below the foam. This was consistent with the findings of the Swedish researchers. For foams with expansion ratios ranging from 6.0 to 9.7, drain rate was determined to be a function of foam mass per unit area. A single curve was developed to characterize the drain rate for all foams with a thickness equal to or less than 75 mm. The drainage rate was measured to be constant down to a foam mass per unit area of 3.0 kg/m^2 and decreased linearly to zero by 1.5 kg/m^2. The steady-state drain-rate level decreased from 40 g·m^2/s to 28 g·m^2/s by increasing the expansion ratios from 6.0 to 9.7, respectively.

The drainage rate of low-expansion ratio foams (3.3) was as much as 4–10 times higher than levels measured at higher expansion ratios. The high level was attributed to the fluidity of the foam, which is affected by solution density in foam, breaking and coalescing of bubbles, and solution viscosity. Measurements of foam fluidity for different AFFF foam expansion ratios and temperatures are necessary to further understand these trends in the data at low-expansion ratios.

Foam depletion rate was measured primarily to be a function of the irradiance level incident on the foam. As irradiance increased, the foam depletion rate increased. Foam depletion rate was independent of the initial foam height and expansion ratio.

Heat penetration through the foam was measured to be a function of foam height and foam mass. For all of the different tests where heat penetration was measured, the data indicate that heat begins penetrating through the foam when the foam becomes approximately 50 ± 7 mm thick and has a foam mass of 4.2 ± 1.2 kg/m^2.

Ignition time in tests with JP-5 fuel layers was measured to be a function of both irradiance and initial foam height. Increases in irradiance and decreases in initial foam height were determined to decrease the time to ignition. This result was found to be independent of expansion ratio and initial fuel temperature. At ignition, nearly all of the AFFF (less than 0.8 kg/m^2) had been lost from the fuel surface.

Additional small-scale testing needs to be performed to quantify the foam losses and foam spread characteristics of other foam concentrates. Foam loss and spread data are expected to be concentrate dependent, and these data are necessary to further validate the performance of the foam extinguishment model.

Foam drainage is a complicated phenomenon that is highly time dependent. Besides the forces associated with the bubble structure, drainage is

dependent on the continual changing geometries of the cells and other variable conditions, such as collapsing cells. Even though all aspects of this problem cannot be fully detailed, simplified models have been created that predict the drainage rate for foams. Kraynik has developed one such model that considers the drainage from a column of persistent foam [12]. The model contains no empirical parameters and assumes the foam is dry with very thin walls such that the liquid contained in the cell walls is negligible. Additional modeling has been performed as described in the following paragraphs.

The focus of the tests on the foam by Lattimer et al. [10] was to quantify the evaporation and drainage loss mechanisms, and develop methods for using these data in suppression models. Drain rates were shown to be affected by both expansion ratio and initial foam height. Evaporation rates were primarily affected by the irradiance on the foam. Additional data analysis was conducted to develop methods for expressing the data in a form that could be used in modeling the losses of foam during a fire where the foam may be exposed to a range of irradiance levels. A simple model that monitors the mass of the foam was used to evaluate the proposed methods for predicting evaporation and drainage.

Solution drain rate from foams being heated is extremely difficult to model from first principles due to the complexities that arise from bubbles expanding, coalescing, and bursting. A simple approach for predicting solution drainage was sought for use in fire suppression modeling. Persson et al. [13] found that initial foam height affected drainage rate with time for a particular type and expansion ratio of foam. Empirical relations for drain rate were developed as a function of time and foam height.

In order to avoid having to rely on accurate predictions of foam height in fire suppression calculations, an alternative approach was developed. Through analysis of the data, the mass of the foam was found to be related to the drain rate. Plotting the drain rate versus foam mass essentially collapsed the data for tests with an expansion ratio (ER) of 6 and 10. The relation between drain rate and foam mass was found to be generally unaffected by irradiance or initial foam height.

The second mechanism by which foam will lose solution is through evaporation. The evaporation of solution from the foam surface was modeled as a Lagrangian thin film of solution at a constant temperature of 100°C. The evaporation rate was simplified to

$$\dot{m}''_{\text{evap}} = \left(\frac{\alpha_{\text{foam}}}{\varepsilon_{hfg}}\right)\left(\frac{q''_{hfg}}{\Delta h_v}\right) \tag{47.4}$$

where the $\varepsilon_{hfg} = 0.96$ and the average heat flux is 97 % of the centerline heat flux, $q''_{hfg} = 0.97\ q''_{hfg,cl}$, and the heat of vaporization is that of water at 100°C ($\Delta h_v = 2257\ \text{kJ/kg}$). In the experiments, the mass evaporated was measured directly but the absorptivity of the foam was unknown. Incorporating the constants above, the absorptivity of the foam can be determined by

$$\alpha_{\text{foam}} = 2257\frac{\dot{m}''_{\text{evap}}}{q''_{hfg,cl}} \tag{47.5}$$

This pure radiation model does not account for other phenomena that may affect the evaporation rate such as bubbles bursting, foam density on the surface, and transient heating. Therefore, the absorptivity determined using experimental data would be an effective absorptivity that embodies the radiation properties of the foam and the other phenomena that affect the evaporation rate. This average effective absorptivity is shown in Table 47.1.

These methodologies were used to predict the foam mass drained and evaporated. The mass drained was predicted using a reference curve that related foam mass to drain rate. This function was developed from test data at an irradiance

Table 47.1 Test average effective absorptivity for AFFF at different expansion ratios

Expansion ratio, ER	Effective absorptivity, α foam
3	0.34 ± 0.09
6	0.42 ± 0.06
10	0.41 ± 0.04

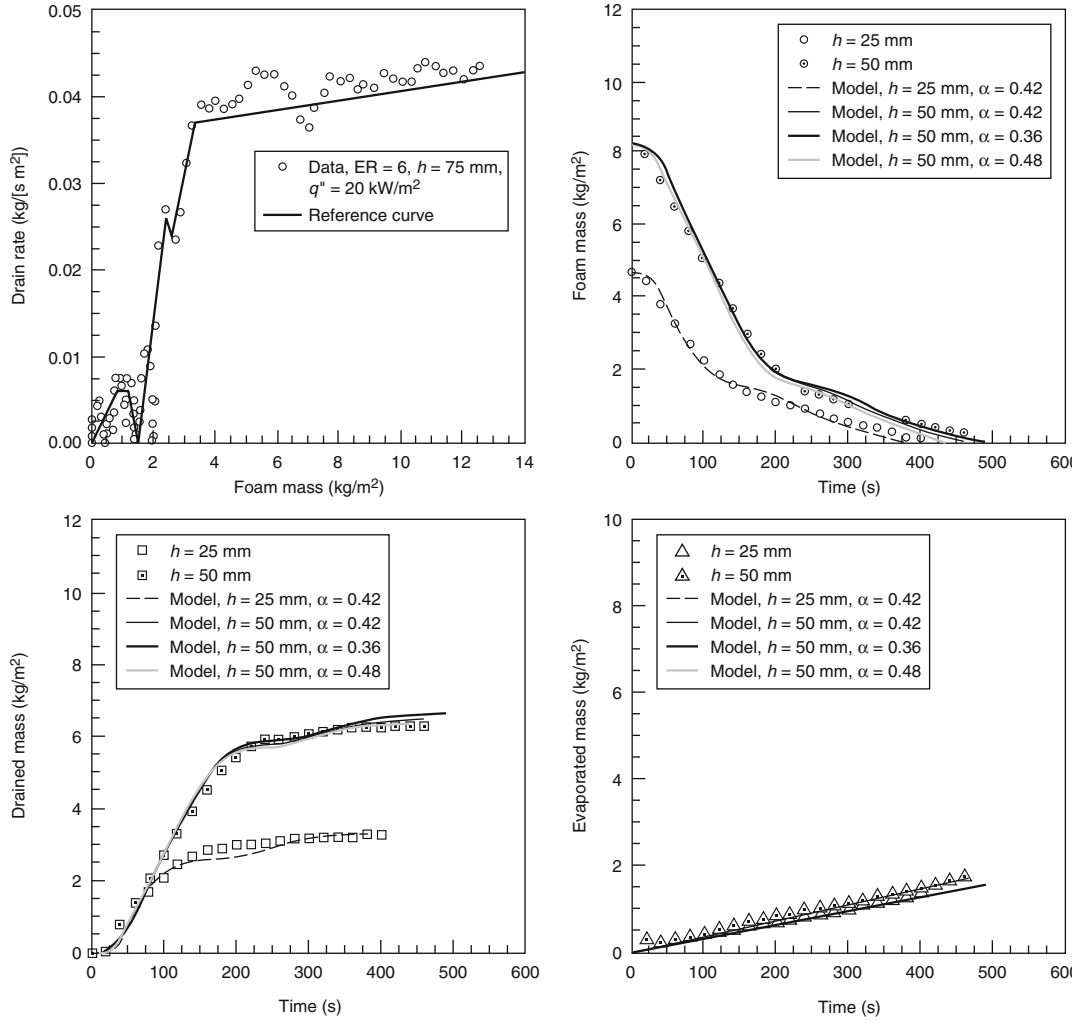

Fig. 47.3 Model predictions for foam with an ER = 6 with h = 25 and 50 mm at q″ = 20 kW/m2

of 20 kW/m^2 with a foam height of 75 mm. The mass evaporated was determined from using the effective absorptivity values provided in Table 47.1. Additional simulations were conducted to evaluate the sensitivity of the results to the range of effective absorptivity stated in Table 47.1.

Predictions of foam having an expansion ratio equal to six are shown in Figs. 47.3 and 47.4 for irradiance levels of 20 and 50 kW/m^2, respectively. Also shown is the reference curve used to predict the drainage rate. The model predicts the masses quite well, particularly near the end of the test where mass of foam on the surface could be used to predict time of fuel ignition. Data from this study indicate that the fuel beneath the foam will ignite when the foam mass per unit area is approximately 0.8 kg/m^2. With good agreement between the model and the data especially near the end of the test when ignition will occur, the model could be used to also predict fuel layer ignition. Also shown in Figs. 47.3 and 47.4 is the effect of varying the effective absorptivity. Because the evaporation represents a small portion of the mass loss, the results were not strongly

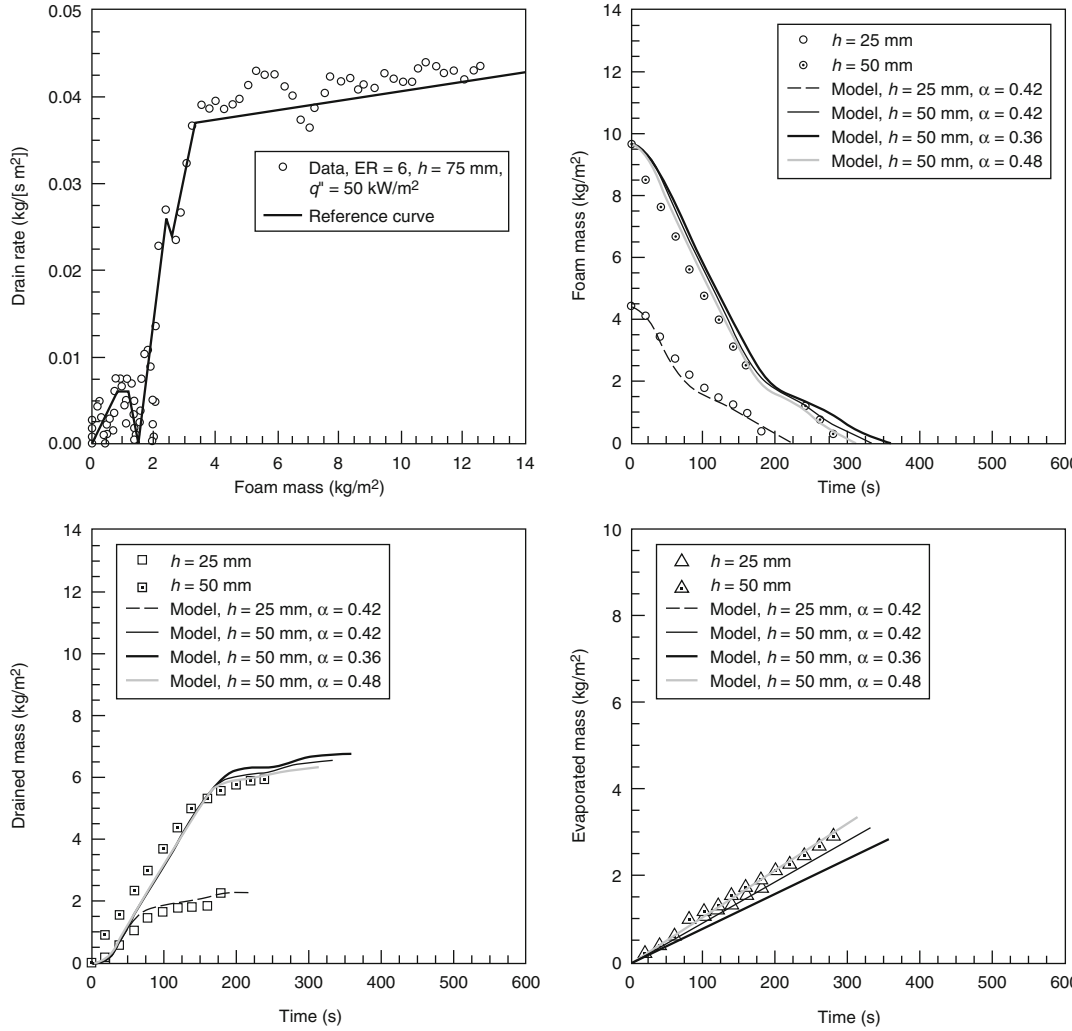

Fig. 47.4 Model predictions for foam with an ER = 6 with h = 25 and 50 mm at q″ = 50 kW/m2

affected by varying this parameter. Similar results were determined for foam at an ER = 10.

Predicted masses for foam at an ER = 3 are shown in Fig. 47.5 along with the reference curve used to predict the drainage rate. Due to the initial surge of drainage in the beginning of these tests, the model does not predict these masses as well in the initial part of the test. After approximately 150 s, the model is within 10 % of the data. Again, the predicted mass of foam near the end of the test agrees well with the data, which indicates that the time of ignition could be predicted using this model even for lower expansion foams.

Foam Spread over Liquid Fuels

In order to predict the extinguishment of a liquid pool fire by fire-fighting foam, it is necessary to describe the process of spreading the foam over the liquid fuel surface. This process of foam spread on a liquid fuel is similar to the spread of a less dense liquid (such as oil) on a more dense liquid (such as water). This

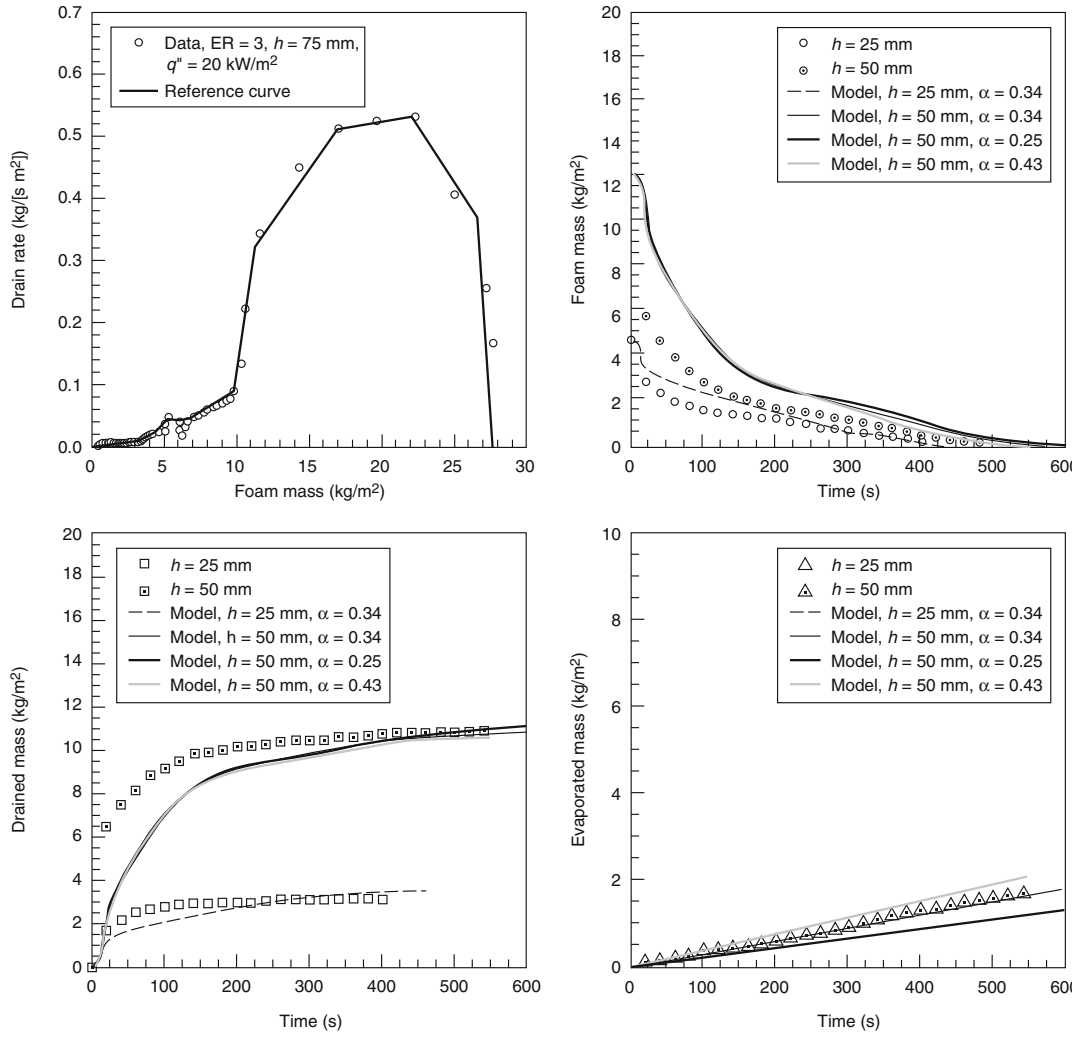

Fig. 47.5 Model predictions for foam with an ER = 3 with h = 25 and 50 mm at $q'' = 20$ kW/m2

phenomenological approach to the spread of foam on a liquid pool fire is appropriate to the extent that foam can be treated as a liquid. Kraynik characterizes foams macroscopically as being Bingham fluids with a finite shear stress and non-Newtonian viscosity [14]. That is, foam displays an infinite viscosity up to some initial shear rate above which it displays a shear-rate dependent viscosity.

Because fuels typically have low viscosities (especially compared to foam viscosities at relatively low shear rates), it may be appropriate to model foam spread across a fuel surface using models developed for oil spread on water. These models assume that the oil spreads as a fluid with a viscosity much higher than the water on which it is spreading. The process of oil spread on water has been described in detail by Fay [15], and Fay and Hoult [16]. Their phenomenologically based model describes three regimes of spread characterized by combinations of spreading forces and retarding forces. The first regime is the gravity-inertia regime, where the outward spread of the oil is driven by a gravity force and

retarded by the inertia required to accelerate the oil. The second regime is the gravity-viscous regime, where the gravity-induced spreading is retarded by viscous dissipation in the water. Because the oil is much more viscous than the water, they assume that there is slug flow in the oil and that the viscous drag force is dominated by the velocity gradient in the water. The third regime is characterized by a surface-tension spreading force opposed by the viscous retarding force. By setting the spreading and retarding forces equal in each of the regimes, they developed equations to estimate the length of the spread as a function of time.

By treating the spread of foam on fuel as similar to the spread of oil on water, the equations developed by Fay and Hoult might be used to describe the spread of a foam blanket over a fuel pool as a function of time [15]. Because foam generally has a much higher viscosity than the fuel on which it is spreading, the assumption of slug flow made for the oil by Fay and Hoult should be reasonably valid for foam spread on fuel as well [16]. The equations are

$$\begin{aligned} &\text{gravity-inertia regime:} && l = (\Delta g V t^2)^{1/4} \\ &\text{gravity-viscous regime:} && l = \left(\frac{\Delta g V^2 t^{3/2}}{\nu^{1/2}}\right)^{1/6} \\ &\text{surface-tension-viscous regime:} && l = \left(\frac{\sigma^2 t^3}{\rho^2 \nu}\right)^{1/4} \end{aligned} \tag{47.6}$$

where

l = Length of spread (cm)
$\Delta = (\rho_{\text{fuel}} - \rho_{\text{foam}})/\rho_{\text{fuel}}$
g = Acceleration of gravity (981 cm/s^2)
V = Foam volume (cm^3)
t = Time (s)
ν = Kinematic viscosity of fuel (cm^2/s)
σ = Spreading coefficient (dynes/cm)
ρ = Density of fuel or foam (g/cm^3)

Equation 47.6 represents an untested theoretical model of foam spread. The equation includes the parameters that are known or suspected to affect foam spread. They are presented here as an initial effort to understand foam flow based on first principles. They are not yet developed for engineering use. The following discussion expands on this theory.

The transition from gravity-dominated spread to surface-tension-dominated spread can be shown to occur at a critical thickness of the foam layer, h_c, given by

$$h_c = \left(\frac{\sigma}{g\Delta\rho_{\text{foam}}}\right)^{1/2} \tag{47.7}$$

The transition from inertia- to viscous-dominated retarding force occurs when the foam thickness, h, is equal to the viscous boundary layer thickness, δ, of the fuel, with

$$\begin{aligned} h &= \frac{\nu}{l^2} \\ \delta &= (\nu t)^{1/2} \end{aligned} \tag{47.8}$$

The equations for length of spread can be used to generate preliminary estimates of the spread distance and area coverage for the placement of a volume of foam on a fuel surface. The equations are only estimates because they consider a force balance between just the dominant forces for each regime. All forces are actually present in each regime. Also, the densities of both fluids are considered to be very nearly equal for the development of the equation for the gravity-viscous regime. This is the case for oil spread on water, but may not be the case for foam on fuel.

Using approximations for fuel and foam characteristics, it can be shown that a positive spreading coefficient does not begin to affect the spread of foam until the foam layer has become very thin. For the placement of a volume of foam on a fuel, this may not occur until after significant time has passed, relative to the time scale for knockdown desired in many fire protection situations.

The equations for foam spread on fuel include many of the parameters known to be important to foam spread. However, the equations are independent of the foam viscosity. Observations indicate that low-viscosity nonrigid foams, such as AFFF, spread faster than high-viscosity rigid protein foams. The inclusion in the model of a term to account for this is desirable.

The equations for spread length so far have assumed that the foam spreads over the fuel as plug flow, with no relative movement within the foam itself. It is easy to conceive that the foam has the capability to flow over itself. The relative movement within the foam is equivalent to the foam flowing over a solid surface. The total foam flow might ultimately be modeled as the combination of the foam plug over the fuel and the flow within the foam layer itself.

According to Cann et al., several regimes exist for spread of a liquid on a solid that are similar to those described for spread of a liquid on a liquid [17]. Most of this spread occurs in a gravity-viscous force regime, where the spread is given by

$$l = \frac{kt}{\mu} \tag{47.9}$$

where k is an empirically determined constant, and μ is the foam viscosity.

Thus, the spread of foam over fuel can be characterized by two scenarios: (1) high-viscosity liquid spreading over a low-viscosity liquid and (2) a liquid spreading over a "solid." The spread of foam can be described by modifying Equation 47.6, as follows:

$$\begin{aligned}
&\text{gravity-inertia regime:} \quad l = \left(\Delta g V t^2\right)^{1/4} + \frac{kt}{\mu} \\
&\text{gravity-viscous regime:} \quad l = \left(\frac{\Delta g V^2 t^{3/2}}{\nu^{1/2}}\right)^{1/6} + \frac{kt}{\mu} \\
&\text{surface-tension regime:} \quad l = \left(\frac{\sigma^2 t^3}{\rho^2 \nu}\right)^{1/4} + \frac{kt}{\mu}
\end{aligned} \tag{47.10}$$

Kraynik describes foams as being characterized by a yield stress and shear thinning viscosity [14]. Thus, the foam viscosity in the equations above is not a constant but is a function of the shear rate. The stress in the foam is a result of the gravity-induced pressure gradient. As the foam flows out and becomes thin, the stress will be reduced. When the stress falls below the yield stress, the viscosity will become infinite and the second term, kt/μ, in the spread length equations will go to zero. The foam will flow simply as plug flow. Above the yield stress, the foam will have a finite viscosity, but this viscosity will be dependent on the yield stress.

An AFFF agent that is very free flowing will have a relatively small yield stress and will retain the second term in the spread length equations until it has flowed out to a very thin layer. A protein foam that is relatively stiff will have a large yield stress, and the second term will go to zero before the foam has spread very far. Above the yield stress, the viscosity of the AFFF will be lower than that of a protein foam, and the second term will provide a greater contribution to foam spread. The rheological properties described appear to have a significant impact on foam spread; however, the properties are not a part of any current specification and are rarely measured.

Foam Extinguishment Modeling

At present, modeling of foam extinguishment cannot be performed because of the large number of remaining uncertainties. A model would have to take into account the addition of foam to the fuel surface, the spread of foam on the fuel surface, and the foam loss mechanisms of evaporation and drop-through. The foam spread length equations can be used to estimate the area of foam coverage at a specific time and for a specific quantity of foam. Modeling at this time is limited because of the lack of established values for k_e (Equation 47.2) and k_d (Equation 47.3). Also, the yield stress and viscosity relationships for fire-fighting foams have not been quantified. Experimental work is needed to complete this modeling effort. Also, the actual method of application (e.g., from a handline nozzle or fixed device such as a sprinkler) must ultimately be taken into account. Even so, preliminary calculations using this methodology are encouraging and support continued development [7].

An attempt has been made to model large tank fires [13]. This included modeling of foam spread with gentle and over-the-top application. The models were based on the assumption that a driving force caused by hydrostatic pressure differences in the foam and a resisting force due

to viscous friction between the foam and the fuel is governing the foam spread. In case of foam flow in a channel, there is also a resisting force due to friction between the foam and the sidewalls. The models take into account ordinary drainage, radiation-induced drainage, and evaporation. Friction data for the models were obtained from cold foam flow tests in laboratory scale. In general, the models for gentle application agree well with the experiments. Due to lack of data, it was not possible to incorporate the destruction of foam at the foam front when it starts to dry out. The effect of this is that the models generally predicted spreading times that were too short. A remaining uncertainty in the models is how to scale the friction data when increasing the length scale by orders of magnitude (e.g., to tank diameters 100–120 m). This is because detailed large-scale data are lacking. Obtaining better experimental observations of large tank fires was recommended.

The model was compared with a few full-scale tank fires ranging from 40 to 80 m in diameter where detailed observations were available. In general, the predicted time to cover is in the range of 10–20 min shorter than the observed time to knockdown. This is because some effects are not included in the model, such as the initial destruction of foam when the foam plunges into the burning fuel, fuel pickup, and foam destruction at the front due to drainage and evaporation. It was concluded that further work is needed to incorporate the destruction of foam at the front, quantify the initial delay phase caused by foam destruction, determine how to scale the friction data when increasing the length scale by orders of magnitude, and obtain more accurate data on foam properties generated by various types of large-capacity foam nozzles.

Surface Tension and Spreading Coefficient

Film-forming foams are defined by the ability of the aqueous solution draining from the foam to spread spontaneously across the surface of a hydrocarbon fuel. The fundamental relationship used to describe the spreading coefficient is

$$S_{a/b} = \gamma_b - \gamma_a - \gamma_l \tag{47.11}$$

where

$S_{a/b}$ = Spreading coefficient (dynes/cm)
γ_b = Surface tension of the lower liquid phase of a hydrocarbon fuel (dynes/cm)
γ_a = Surface tension of the upper layer of liquid using AFFF solution (dynes/cm)
γ_l = Interfacial tension between liquids a and b (dynes/cm)

Surface tension and interfacial tension can be measured using methods such as those described in ASTMD-1331, *Standard Test Methods for Surface and Interfacial Tension of Solutions of Surface-Active Agents*. Reagent-grade cyclohexane is typically used as a reference fuel. A du Nouy tensiometer, having a torsion balance with a 4- or 6-cm-circumference platinum-iridium ring, is lowered into the liquid and slowly pulled out until the liquid detaches from the ring's surface. The force recorded at the point where this separation occurs is the surface tension (dynes/cm) of the pure liquid. Similarly, the interfacial tension is the measurement of tension when the ring is pulled through the boundary layer between two liquids.

The Naval Research Laboratory developed some of the earliest quantitative data on the spreading coefficient of AFFF on hydrocarbons, as shown in Tables 47.2 and 47.3 [18]. As fuel temperature increases, the surface tensions of both the fuel and the solution decrease. The spreading coefficient may go to zero or go negative [18, 19].

Although it has been shown that film-forming foams are superior fire extinguishing agents compared to other foams, there are no one-to-one correlations between bench-scale surface-tension/spreading coefficient data and fire control, extinguishment, and burnback resistance times. Both Scheffey et al. [20] and Geyer [21] have demonstrated that there is no direct correlation between fire extinguishment and spreading coefficient. As such, spreading coefficient data alone

Table 47.2 Surface tension of hydrocarbon liquids and fuels [18]

Hydrocarbon liquid	Grade	Surface tension at 25 °C (dynes/cm)

[b]Sample 2

cannot be used as a relative predictor of fire performance.

Because the surface tensions of most AFFFs are approximately equal, there must be a balance between the surface tension of the fuel and the interfacial tension of the two liquids to create a positive spreading coefficient. It can be seen then that, while both the surface tension of the foam solution and the interfacial tension between the liquids have an impact on the spreading coefficient, the interfacial tension is usually the determining factor. For fuels, such as avgas or *n*-heptane, which have surface tensions in the range of 19–20 dyn/cm, either the foam surface tension or the interfacial tension, or both, must be reduced. Normally, the changes resulting from a modification of the formulation will be more significant for the interfacial-tension value than they will be for the foam surface-tension value.

Table 47.3 Interfacial tensions, spreading coefficients, and film formation observations for various surfactant solution–hydrocarbon liquid combinations [18]

Surfactant solution	Hydrocarbon liquid	Interfacial tension (dynes/cm)	Spreading coefficient (dynes/cm)	Film formed
FC-194 (lot 107) (solution surface tension of 15.5 dyn/cm at 25 °C)	Cyclohexane	4.3	4.4	Yes

	Naphtha	0.8	3.4	Yes (slow spread)

[a]Sample 1
[b]Sample 2

Still, a relationship between the two values does exist. [4] Therefore, in reducing the sum of the values to obtain a positive spreading coefficient, a delicate balance must be maintained.

Maintaining this balance and achieving a positive spreading coefficient is accomplished by controlling the amount and type of fluorinated surfactants used to formulate the agent. This at first seems beneficial, because a positive number on a low surface-tension fuel will ensure an even larger value with higher surface-tension fuels (e.g., JP-5 or motor gasoline). But, in reducing the interfacial tension, the foam may lose some of its fuel-shedding capabilities. The effects of adding too much fluorosurfactant to an aqueous solution and the result on foam bubble stability are described by Rosen [4] and Aubert et al. [2] This could be a problem that manifests itself only during actual fire testing. The type and amount of fluorosurfactants also affect the spreading coefficient [20].

Despite the lack of one-to-one correlations between surface-tension spreading coefficient data and fire control, extinguishment, and burnback results, these criteria are useful in categorizing film-forming agents. The spreading coefficient test is used internationally as a standard indicator of aqueous film-forming foams. Although undocumented, it is believed that film formation results in improved viscosity (or associated mechanisms that improve spreading), ultimately resulting in superior extinguishing performance.

Assessment of Fire Extinguishing and Burnback Performance

Standard Test Methods

Because a fundamental model of foam spreading has not been developed, performance of foams is measured using fire tests. The use of bench-scale burning fuel trays (e.g., less than 1 m diameter) results in varying fuel burning rates for the same fuel. This was observed by Chiesa and Alger when they attempted to use a 15-cm by 45-cm pan for foam performance evaluation [22]. Data from their experiments are shown in Fig. 47.6, which correlates control times observed when foam samples were tested using bench-scale apparatus (laboratory) and 4.6 m^2 (50 ft^2) fire tests (field method). Equal control times correspond to a 45° line. Because the majority of the points fall below this line, the laboratory test is more severe (about 35 %) than the field test.

Fire test methods used by regulatory authorities for certification are usually on the order of 2.6 to 9.3 m^2 (28 to 100 ft^2). Foams

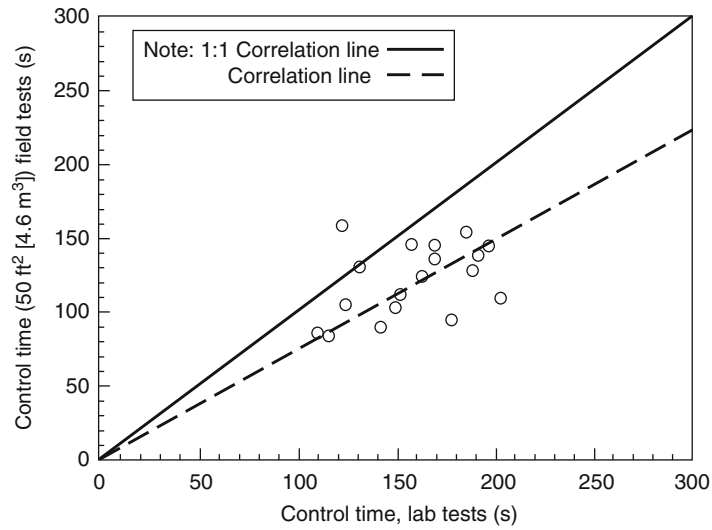

Fig. 47.6 Correlation of control times observed in laboratory and field tests of foam [22]

must also meet additional test parameters related to storage, proportioning, and equipment factors.

Underwriters Laboratories Standard 162 Underwriters Laboratories (UL) 162, *Standard for Foam Equipment and Liquid Concentrates,* is the principal test standard for the listing of foam concentrates and equipment in the United States. Test procedures outlined in this standard have been developed to evaluate specific agent/proportioner/discharge device combinations. When a foam concentrate is submitted for testing, it must be accompanied by the discharge device and proportioning equipment with which it is to be listed. Listed products, including the foam concentrate, discharge device, and proportioner, are then described in the UL *Fire Protection Equipment Directory*.

Listed with a system, foam liquid concentrates are associated with discharge devices classified as Type I, II, or III. Type I devices deliver foam gently onto the flammable liquid fuel surface, for example, a foam trough along the inside of a tank wall. These devices are no longer evaluated in UL 162. Type II discharge devices deliver foam onto the liquid surface in a manner that results in submergence of the foam below the fuel surface, and restricted agitation at the fuel surface. Examples include subsurface injection systems, tank wall–mounted foam chambers, and applications where foam is bounced off the wall of a tank. Type III discharge devices deliver foam directly onto the liquid surface and cause general agitation at the fuel surface, for example, by using handheld nozzles. The flammable liquid fire tests in UL 162 include methods for sprinklers, subsurface injection, and topside discharge devices, including nozzles.

Class B fire test requirements for Types II and III discharge devices and sprinklers are shown in Table 47.4. Commercial grade *n*-heptane is placed in a square test pan. The area of the pan is a minimum of 4.6 m^2 (50 ft^2). The application rates ("densities" in UL 162, *Standard for Foam Equipment and Liquid Concentrates*) for various concentrates are outlined in Table 47.4.

In the test fire, the fuel is ignited and allowed to burn for 60 s. Foam is then discharged for the

[d]0.16 or 1.6 times test application rate, whichever is greater

duration specified in Table 47.4. The foam blanket resulting from the foam discharge must spread over and completely cover the fuel surface, and the fire must be completely extinguished before the end of the foam discharge period.

After all the foam is discharged, the foam blanket formed on top of the fuel is left undisturbed for the period specified in Table 47.4. During the time the foam blanket is left undisturbed, a lighted torch is passed approximately 25.4 mm (1 in.) above the entire foam blanket in an attempt to reignite the fuel. The fuel must not reignite, candle, flame, or flash over while the torch is being passed over the fuel. However, candling, flaming, or flashover that self-extinguishes is acceptable, provided that the phenomenon does not remain in one area for more than 30 s.

After the attempts to reignite the fuel with the lighted torch are completed, a 305-mm (12-in.) diameter section of stovepipe is lowered into the foam blanket. The portion of the foam blanket that is enclosed by the stovepipe is removed with as little disturbance as possible to the remaining blanket outside the stovepipe. The cleared fuel area inside the stovepipe is ignited and allowed to burn for 1 min. The stovepipe is then slowly removed from the pan while the fuel continues to burn. After the stovepipe is removed, the foam blanket must either restrict the spread of fire for 5 min to an area not larger than 0.9 m^2 (10 ft^2) or flow over and reclose the burning area.

When the UL 162 test is passed, the agent, proportioning device, and discharge device become listed together. The fact that foam concentrate has a UL label does not mean it has been tested under all potential end-use conditions. The UL *Fire Protection Equipment Directory* must be referenced to determine with what equipment the concentrate has been tested and approved.

UL 162, *Standard for Foam Equipment and Liquid Concentrates,* is not an agent specification; therefore, there are no requirements for physical properties, such as film formation and sealability and corrosion resistance. Neither are there any provisions to test, on a large scale, the degree of dry chemical compatibility of an agent, or the effects of aging or mixing with agents of another manufacturer. Requirements for a positive spreading coefficient (greater than zero using cyclohexane) for film-forming foams recently have been implemented [23].

As a result of environmental issues related to AFFF, and the removal of products from the marketplace, the U.S. oil industry conducted a series of fire-fighting foam tests [24]. The purpose of the tests was to provide updated data on suitable Class B fire-fighting foam concentrates for use by the oil and petrochemical industry. The foam is used to extinguish large, in-depth flammable liquid fires in both hydrocarbon and polar solvent fuels. These tests were conducted using UL 162 as a guide. The tests were conducted using normal heptane as a baseline model, along with 93 octane gasoline, 93 octane gasoline with 10 % ethanol blend, and isopropanol anhydrous. The objective of the testing was to provide the oil industry with an updated list of foam concentrates that have passed the UL protocol with fuels more commonly found than heptane used in the test standard. This information can then be used to select foams for use at petrochemical facilities and to verify claims by different foam concentrate manufacturers regarding use of their products as suitable for all flammable liquids, including both hydrocarbons and polar solvents, found in the petrochemical industry today. The data from the Chevron Foam Concentrate Team [24] provide comparative results when the UL 162 method is used with different fuel substrates and a range of different concentrates.

U.S. Military Specification The U.S. Military Specification, MIL-F-24385, is the AFFF procurement specification for the U.S. military and federal government. The U.S. military, in all likelihood, is the largest user of foam in the world. It is important to recognize that MIL-F-24385 is a procurement specification as well as a performance specification. Hence, there are requirements for packaging, initial qualification inspection, and quality conformance inspection, in addition to fire performance criteria. Equipment designs unique to the military, in particular

U.S. Navy ships, also impact on the specification requirements (e.g., use of seawater solutions and misproportioning-related fire tests). These requirements have been developed based on research and testing at the Naval Research Laboratory and actual operational experience with protein and film-forming foams.

Table 47.5 summarizes the important fire extinguishment, burnback resistance, film formation, and foam quality requirements established by MIL-F-24385. The fire tests are conducted using 2.6 m^2 (28 ft^2) and 4.6 m^2 (50 ft^2) circular fire test pans. There are specific requirements to conduct a fire test of the agent after it has been subjected to an accelerated aging process (simulating prolonged storage) and after intentionally misproportioning the concentrate with water. In particular, the requirement to conduct a fire test of the agent at one-half of its design concentration is one of the most difficult tests. The 2.6 m^2 (28 ft^2) half-strength fire test must be extinguished in 45 s, only 15 s greater than allowed when the full-strength solution is used.

The physical and chemical properties evaluated for MIL-F-24385 agents are outlined in Table 47.6, along with the rationale for each test. These procedures have been developed based on experience and specific military requirements. For example, MIL-F-24385 requires that the agent be compatible with dry chemical agents. Dry chemical agents may be used as "secondary" agents in aviation and shipboard machinery space fires, for example, to combat three-dimensional fuel fires, where AFFF alone may have limited effectiveness. MIL-F-24385 requires that an agent's compatibility with potassium bicarbonate dry chemical agent (PKP) be demonstrated. The burnback time of the foam in the presence of the dry chemical is measured. Also, the concentrate of one manufacturer must be compatible with concentrates of the same type furnished by other manufacturers, as determined by fire tests and accelerated aging tests.

Table 47.5 Summary of the U.S. Military AFFF specification (MIL-F-24385, revision F) key performance requirements

Test parameter	Revision F
Fire extinguishment	
2.6 m2 (28 ft^2) fire test	
Application rate	2.9 L/min/m^2 (0.71 gpm/ft^2)
Maximum extinguishment time	30 s
Maximum extinguishment density	1.45 L/m^2 (0.036 gal/ft^2)
4.6 m^2 (50 ft^2) fire test[a]	
Application rate	1.6 L/min/m^2 (0.04 gpm/ft^2)
Minimum 40 s summation	320 s
Maximum extinguishment time	50 s
Maximum extinguishment density	1.34 L/m^2 (0.033 gal/ft^2)
Fire extinguishment—over- and underproportioning (2.6 m^2 [28 ft^2] test)	
One-half strength	
Maximum extinguishment time	45 s
Maximum extinguishment density	2.2 L/m^2 (0.054 gal/ft^2)
Quintuple (5 ×) strength	
Maximum extinguishment time	55 s
Maximum extinguishment density	2.7 L/m^2 (0.066 gal/ft^2)
Burnback resistance	
2.6 m^2 (28 ft^2) fire test	25 % maximum at 360 s[b]
4.6 m^2 (50 ft^2) fire test	25 % maximum at 360 s
Foam quality	
Expansion ratio	6.0:1 minimum
25 % drainage	150 s minimum
Film formation	
Spreading coefficient	
Fuel	Cyclohexane
Minimum value	3 dyn/cm
Ignition resistance test	
Fuel	Cyclohexane
Pass/fail criteria	No ignition

[a]Saltwater only
[b]300 s for one-half-strength solutions; 200 s for quintuple-strength solutions

Table 47.6 Physical/chemical properties and procurement requirements of the AFFF Mil spec

Requirement	Rationale
Refractive index	Enables use of refractometer to measure solution concentrations in field; this is most common method recommended in NFPA 412[a]
Viscosity	Ensures accurate proportioning when proportioning pumps are used; for example, balance pressure proportioner or positive displacement injection pumps
pH	Ensures concentrate will be neither excessively basic or acidic; intention is to prevent corrosion in plumbing systems
Corrosivity	Limits corrosion of, and deposit buildup on, metallic components (various metals for 28 days)
Total halides/chlorides	Limits corrosion of, and deposit buildup on, metallic components
Environmental impact	Biodegradability, fish kill, BOD/COD[b]
Accelerated aging	Film formation capabilities, fire performance, foam quality; ensures a long shelf life
Seawater compatibility	Ensures satisfactory fire performance when mixed with brackish or saltwater
Interagent compatibility	Allows premixed or storage tanks to be topped off with different manufacturers' agents, without affecting fire performance
Reduced- and over-concentration fire test	Ensures satisfactory fire performance when agents are proportioned inaccurately
Compatibility with dry chemical (PKP) agents	Ensures satisfactory fire performance when used in conjunction with supplementary agents
Torque to remove cap	Able to remove without wrench
Packaging requirements	Strength, color, size, stackable, minimum pour, and vent-opening tamperproof seal; ensures uniformity of containers and ease of handling
Initial qualification inspection	Establishes initial conformance with requirements
Quality conformance inspection (each lot)	Ensures continued conformance with requirements

[a]NFPA 412, Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment, 2003 edition
[b]BOD/COD: Biological oxygen demand/chemical oxygen demand

Standards Outside the United States The number of standards developed for foams outside the United States is quite substantial. A brief review of the literature yielded over 17 different standards and test methods [25]. Developments in the European community are reviewed here to provide examples of differences in test standards.

The International Civil Aviation Organization (ICAO) develops crash fire-fighting and rescue documents for its member bodies. The ICAO *Airport Services Guide,* Part 1, "Rescue and Firefighting," describes airport levels of protection to be provided and extinguishing agent characteristics. Minimum usable amounts of extinguishing agents are based on three levels of performance: Level A and Level B. A performance Level C has been adopted. The amounts of water specified for foam production are predicated on an application rate of 8.2 L/min/m^2 (0.20 gpm/ft^2) for Level A, and 5.5 L/min/m^2 (0.13 gpm/ft^2) for Level B. Agents that meet performance Level B require less agent for fire extinguishment. ICAO foam test criteria are described in Table 47.7. Foams meeting performance Level B have an extinguishment application density of 2.5 l/m^2 (0.061 gal/ft^2) and 1.75 l/m^2 (0.043 gal/ft^2) for Level C. There are no surface-tension, interfacial-tension, and spreading coefficient requirements.

The International Organization for Standardization (ISO) has issued a specification for low-expansion foams, EN 1568–3 [26]. The specification includes definitions for protein, fluoroprotein, synthetic, alcohol resistant, AFFF, and FFFP concentrates. A positive spreading coefficient is required for film-forming foams when cyclohexane is used as the test fuel. There are toxicity, corrosion, sedimentation, viscosity, expansion, and drainage criteria. The fire test uses a 2.4-m (8-ft) diameter circular pan with

Table 47.7 ICAO foam test requirements

Fire tests	Performance level A	Performance level B	Performance level C
1. Nozzle (air aspirated)			
(a) Branch pipe	UNI 86 foam nozzle	UNI 86 foam nozzle	UNI 86 nozzle
(b) Nozzle pressure	700 kPa (100 psi)	700 kPa (100 psi)	700 kPa (100 psi)
(c) Application rate	4.1 L/min/m^2 (0.10 gpm/ft^2)	2.5 L/min/m^2 (0.06 gpm/ft^2)	1.75 L/min/m^2 (0.043 gpm/ft^2)
(d) Discharge rate	11.4 L/min (3.0 gpm)	11.4 L/min (3.0 gpm)	11.4 L/min (3.0 gpm)
2. Fire size	≅2.8 m^2 (≅30 ft^2) (circular)	≅4.5 m^2 (≅48 ft^2) (circular)	7.3 m^2 (79 ft^2) (circular)
3. Fuel (on water surface)	Kerosene	Kerosene	Kerosene
4. Preburn time	60 s	60 s	60 s
5. Fire performance			
(a) Extinguishing time	≤60 s	≤60 s	≤60 s
(b) Total application time	120 s	120 s	120 s
(c) 25 % reignition time	≥5 min	≥5 min	≥5 min

Table 47.8 Maximum extinction times and minimum burnback times from ISO/EN specification

		Gentle application test		Forceful application test	
Extinguishing Performance class	Burnback Resistance level	Extinction time (min) Not more than	Burnback time (min) Not less than	Extinction time (min) Not more than	Burnback time (min) Not less than
I	A	—	—	3	10
	B	5	15	3	Not tested
	C	5	10	3	Not tested
	D	5	5	3	Not tested
II	A	—	—	4	10
	B	5	15	4	Not tested
	C	5	10	4	Not tested

III	B	5	15	Not tested	Not tested
	C	5	10	Not tested	Not tested
	D	5	5	Not tested	Not tested

heptane as the fuel. The UNI 86 foam nozzle is used for either a "forceful" or "gentle" application method at a flow rate of 11.4 L/min (3 gpm). The application rate is 2.4 L/min/m^2 (0.06 gpm/ft^2). For the greatest performance level, a 3 min extinguishment time is required. This extinguishment time results in an extinguishment application density of 7.6 l/m^2 (0.19 gal/ft^2).

The proposed ISO/EN requirements for extinguishing and burnback are summarized in Table 47.8. There are three levels of extinguishment performance and four levels of burnback performance. For extinguishing performance, Class I is the highest class and Class III the lowest class. For burnback resistance, Level A is the highest level and Level D is the lowest level.

Typical performance classes and levels for different concentrates are provided. Typical anticipated performance for AFFF is noted as Level IC, and Level IB for alcohol-type AFFF. For a fluoroprotein foam, performance is expected to be Level IIA for both alcohol-type and hydrocarbon-only concentrates.

Comparison of Small-Scale Tests Table 47.9 outlines the large number of variables associated with foam performance and testing. These include factors such as foam bubble stability and fluidity, actual fire test parameters (e.g., fuel, foam application method and rate), and environmental effects. Even the fundamental methods of measuring foam performance (i.e., knockdown, control, and extinguishment) vary. For example, Johnson reported that FFFP fails the proposed ISO/EN gentle application tests because small flames persist along a small area of the tray rim [27]. As a result, the foam committees have proposed redefining extinction to include flames.

Given the variations and lack of fundamental foam spreading theory, it follows that tests and specifications for various foams and international standards have different requirements. The differences are reflected in Table 47.10, which compares four key parameters of MIL-F-24385, UL 162, ICAO, and ISO/EN standards for manual application (e.g., handline or turret nozzles). There is no uniform agreement among test fuel, application rate, the allowance to move the nozzle, and the extinguishment application density for AFFF. There is a factor of six difference between the lowest permitted extinguishment application density (MIL-F-24385) and the highest (ISO/EN). This significant difference is attributed, at least in part, to the fixed nozzle requirement in the ISO/EN specification.

No study has been performed to correlate test methods; given the significant differences in performance characteristics and requirements, it is unlikely that correlation between these test methods could be established, even when considering AFFF only. An AFFF that meets the ICAO standard could not be said to meet MIL-F-24385 without actual test data. The problem of correlating differences in small-scale tests was demonstrated by UL in a comparison of UL, MIL-F-24385, O-F-555B (U.S. government protein foam specification), and U.K. test methods [28]. In those tests, differences between different classes of agents (protein vs. AFFF) and between agents within a class (e.g., AFFF) were demonstrated. No correlations between test standards could be established.

The problem of correlation is compounded when a single test method is used in an attempt to assess different classes of foam (e.g., protein and AFFF). Attempts to use a single test method are problematic because of the inherent difference between these foams. That is, protein foams require air aspiration so that the foam floats on the fuel surface. This stiff, "drier" foam is viscous and does not inherently spread well without outside forces (e.g., nozzle stream force). AFFF, because of its film-formation characteristics, does not require the degree of aspiration that protein foams require. This heavier, "wetter" foam is inherently less viscous, which contributes to improved spreading and fluidity on fuel surfaces. This is related, at least in part, to the degree of aspiration of the foam. A more exact description of foam aspiration is appropriate. Thomas has described two levels of foam aspiration: (1) primary aspirated and (2) secondary aspirated [29]. Primary aspirated foam occurs when a foam solution is applied by means of a special nozzle designed to mix air with the solution within the nozzle. The consequence is foam bubbles of general uniformity. *Air-aspirated* foam refers to this primary aspirated foam. Secondary aspirated foam results when a foam solution is applied using a nozzle that does not mix air with the solution within the nozzle. Air is, however, drawn into the solution in-flight or at impact at the fire. Secondary aspirated foam is more commonly referred to as *non-air-aspirated* foam.

The correlation between foam solution viscosity and extinguishment time has been shown by Fiala, but the entire foam spreading and extinguishment theory has yet to be demonstrated based on first principles [30]. Thus, the test standards reference bench-scale methods that measure a factor of foam fluidity (e.g., spreading coefficient), but fail to recognize the total foam spreading system, including viscous effects. Fundamental understanding of foam mechanisms would promote the development of bench- and small-scale test apparatuses that potentially have

Table 47.9 Variables associated with foam performance and testing

I. Physical/chemical properties of foam solution
- A. Bubble stability
  - 1. Measures
    - a. Expansion ratio
    - b. Drainage rate
  - 2. Variables
    - a. Water temperature
    - b. Water hardness/salinity
    - c. Water contamination
- B. Fluidity of foam
  - 1. Measures
    - a. Viscosity
    - b. Spreading rate
    - c. Film formation
  - 2. Variables
    - a. Fuel type and temperature
    - b. Foam bubble stability
- C. Compatibility with auxiliary agents
  - 1. Measures—fire and burnback test
  - 2. Variables
    - a. Other foam agents
    - b. Dry chemical agents
- D. Effects of aging
  - 1. Measures—fire and burnback test
  - 2. Variable—shelf life of agent

II. Test methods to characterize foam performance
- A. Fuel
  - 1. Measures
    - a. Vapor pressure
    - b. Flashpoint
    - c. Surface tension
    - d. Temperature
  - 2. Variables
    - a. Volatility
    - b. Depth and size
    - c. Initial temperature of air and fuel temperature
    - d. Time fuel has been burning (e.g., short versus long, and depth of hot layer)
- B. Foam application method
  - 1. Measures
    - a. Stream reach
    - b. Aspiration of foam
    - c. Foam stability (e.g., contamination by fuel)
    - d. Water content of foam
    - e. Proportioning rate
  - 2. Variables
    - a. Aspiration
      - (1) Effect on stream reach
      - (2) Degree to which foam is aspirated and the need to aspirate based on foam type
    - b. Fixed versus mobile device
    - c. Application technique
      - (1) Indirect, for example, against backboard or sidewall
      - (2) Direct
        - (a) Gentle
        - (b) Forceful
        - (c) Subsurface injection
    - d. Application location
      - (1) High—need to penetrate plume
      - (2) Low
    - e. Application rate of foam
    - f. Wind (as it affects stream reach)
      - (1) Crosswind
      - (2) With and against
    - g. Effect of reduced or increased concentration due to improper proportioning
- C. Fire configuration
  - 1. Measures
    - a. Fuel burning rate, radiation feedback to fire
    - b. Propensity for reignition
    - c. Surface tension
  - 2. Variables
    - a. Pan/containment geometry
    - b. Two-dimensional (pool) versus three-dimensional (running fuel/atomized spray)
    - c. Presence and temperature of freeboard
    - d. Wind (as it affects flame tilt and reradiation)
    - e. Surface on which there is fuel
      - (1) Rough
      - (2) Smooth
      - (3) Water substrate—"peeling" effect of fuel
- D. Measurement of results
  - 1. Measures
    - a. Time to knockdown, control, extinguish, and burnback
      - (1) Actual or estimated time by visual observations
      - (2) Summation values, that is, summation of control at 10, 20, 30, and 40 s
    - b. Heat flux during extinguishment and burnback
  - 2. Variables—qualitative and quantitative methods to determine fire knockdown, extinguishment, and burnback
    - a. 90 % control—measure of ability of foam to quickly control the fire
    - b. 99 % (virtual extinguishment)—all but the last flame or edge extinguished
    - c. Extinguishment—100 %
    - d. Burnback—25 %, 50 %

Table 47.10 Examples of extinguishment application densities of various test standards

Test standard	Fuel	Application rate ($L/min/m^2$[gpm/ft^2])	Nozzle movement permitted	Extinguishment application density (L/m^2 [gal/ft^2])
Mil SPEC	Motor gasoline	1.6 (0.04)	Yes	1.34 (0.033)
UL 162	Heptane	1.6 (0.04)	Yes	4.9 (0.12)
ICAO Level B	Kerosene	2.5 (0.06)	Yes (horizontal plane)	2.5 (0.06)
ICAO Level C	Kerosene	1.6 (0.04)	No	1.6 (0.04)
ISO/EN—Forceful	Heptane	2.5 (0.06)	No	7.6 (0.19)

greater direct correlation for predicting large-scale results.

There has been some criticism of the human element involved in many of the test methods. The human factor occurs when an operator is allowed to apply foam from a handheld nozzle onto the burning test fire. Personnel are also called on in some tests to qualitatively assess the percentage of fire involvement in the test pan during the burnback procedure. Using a fixed nozzle during a specification test eliminates the human element during extinguishment. For sprinkler applications, using a fixed nozzle is entirely appropriate and should yield results comparable to actual installations. For applications where movement is actually involved (e.g., fire-fighting handlines, crash-rescue truck turrets, and movable monitors on ships and at petrochemical facilities), the extinguishment densities in the fixed test application will generally exceed the densities found in actual applications in the field. (See Table 47.10 for differences in extinguishing densities for manual versus fixed applications.) Removal of the human element is certainly advisable from a test repeatability standpoint. However, removing the human element from approval fire tests has proved difficult. Both U.S. and Canadian military authorities have investigated the use of fixed nozzles. Both organizations concluded that tests with human operators resulted in better correlation with large fires and overall repeatability.

Quantitative methods for evaluating burnback performance have been described by Scheffey et al. [20] and been adopted in ISO/EN and Scandinavian (NORDTEST) test methods. These methods involve the use of radiometers to establish a heat flux during full test-pan involvement. After extinguishment, the radiometers measure the increasing flux as the burnback fire grows. This increasing flux due to burnback is compared against the original flux. A cutoff is established so that the maximum burnback time is the time for the burnback flux to reach some percentage (e.g., 25 %) of the original full-burning flux.

Critical Application Rates and Correlations Between Small- and Large-Scale Tests

The previous section described the application rate differences in standard test methods between AFFF, fluoroprotein, and protein foams. These application rate differences were established based on full-scale testing. For sprinklers, much of the fundamental application rate differences were established during testing conducted by Factory Mutual Research Corporation (FMRC). (See section on "Foam-Water Sprinkler Systems.") For manual applications, tests in the aviation fire protection field provide the basis for the fundamental application rates. The application rates specified in test standards are usually rates lower than those used in actual practice (see Table 47.4). There are two reasons for this: (1) a factor of safety is used when specifying rates in actual practice and (2) differences between individual foam agents are more readily apparent at critical application rates. To demonstrate how application rates are developed and how specification tests correlate with large-scale results, an example from aviation fire tests will be used.

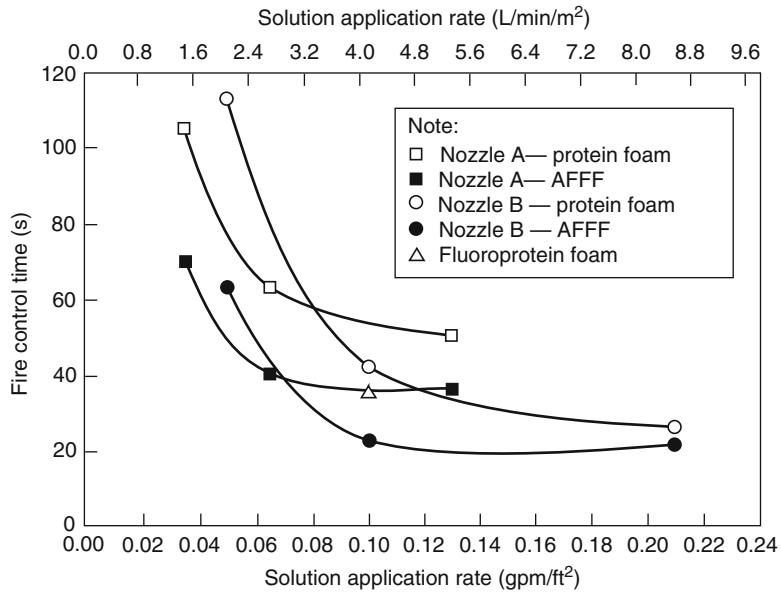

Fig. 47.7 Fire control time as a function of solution application rate using protein foam and AFFF on JP-4 pool fires [31]

This example is based on a review of foam fire test standards performed by Scheffey et al. for the Federal Aviation Administration (FAA) [25].

Tests were conducted by the FAA to determine application rates for a single-agent attack to achieve fire control (e.g., 90 % extinguishment of a fire area) within 1 min under a wide variety of simulated accident conditions. Two factors are important in addition to the application rate required for 1-min fire control: (1) the critical application rate, below which fires will not be extinguished independent of the amount of time an agent is applied; and (2) application density, which is the amount of foam per unit area to control or extinguish a fire.

Minimum application rates were originally developed by Geyer in tests of protein and AFFF agents [31]. These tests involved "modeling" tests with JP-4 pool fires of 21-, 30-, and 43-m (70-, 100-, and 140-ft) diameter. Large-scale verification tests with a B-47 aircraft and simulated shielded fires (requiring the use of secondary agents) were conducted with 34- and 43-m (110- and 140-ft) JP-4 pool fires. All tests were conducted with air-aspirating nozzles. The protein foam conformed to the U.S. government specification, O-F-555b, while the AFFFs used were in nominal conformance with MIL-F-24385 for AFFF. These tests were being performed at the time when the seawater-compatible version of MIL-F-24385 had just been adopted based on large-scale tests.

Figure 47.7 illustrates the results of the modeling experiments. The results show that, for a fire control time of 60 s, the application rate for AFFF was on the order of 1.6 to 2.4 L/min/m^2 (0.04 to 0.06 gpm/ft^2), whereas the application rate for protein foam was 3.3 to 4.1 L/min/m^2 (0.08 to 0.10 gpm/ft^2). The data indicated that the application rate curves become asymptotic at rates of 4.1 L/min/m^2 (0.1 gpm/ft^2) and 8.2 L/min/m^2 (0.2 gpm/ft^2) for AFFF and protein foam, respectively. Above these rates, fire control times are not appreciably improved. Likewise, critical application rates for fire control are indicated when control times increase dramatically. The single test with a fluoroprotein agent indicated that this agent, as expected, fell between AFFF and protein foam.

Large-scale auxiliary agent tests were conducted to identify increases in foam required when obstructed fires with an actual fuselage were added to the scenario. The results indicated that fire control times increased by a factor of 1 to 1.9 for AFFF and 1.5 to 2.9 for protein foams. It was estimated that the most effective foam

solution application rates were 4.9 to 5.7 L/min/m^2 (0.12 to 0.14 gpm/ft^2) for AFFF and 7.5 to 9 L/min/m^2 (0.18 to 0.22 gpm/ft^2) for protein foam. This is the original basis of the recommendations adopted by ICAO of 5.5 L/min/m^2 (0.13 gpm/ft^2) for AFFF and 8.2 L/min/m^2 (0.20 gpm/ft^2) for protein foam. A rate of 7.5 L/min/m^2 (0.18 gpm/ft^2) was subsequently established for fluoroprotein foam. These application rate values are still used by FAA, NFPA, and ICAO to establish minimum agent supplies at airports.

Tests of AFFF alone were conducted by Geyer [32]. These agents, selected from the U.S. Qualified Products List (MIL-F-24385 requirements), were tested on JP-4, JP-5, and aviation gasoline (avgas) fires. Air-aspirating nozzles were used with different AFFF agents. Example results are shown in Fig. 47.8. Similar data were collected by holding the JP-4 fuel fire size constant at 743 m^2 (8000 ft^2) and varying the flow rates to develop application rate comparisons. These data are shown in Fig. 47.9.

Additional tests were conducted by Geyer et al. to verify the continuation of the reduction of water when AFFF agents were substituted for protein foam in aviation situations [1]. In 25-, 31-, and 44-m- (82.4-, 101-, and 143-ft-) diameter Jet A pool fires, AFFF, fluoroprotein, and protein foams were discharged with air-aspirating and non-air-aspirating nozzles. The data, summarized in Fig. 47.10, validated the continued allowance of a 30 % reduction in water requirement at certified U.S. airports when AFFF is substituted for protein foam.

Although some test criteria in standardized methods do not necessarily correlate directly with actual fire and burnback performance, small-scale test data for AFFF formulated to the U.S. military specification (MIL-F-24385) has been shown to correlate with large-scale fire test results. This is based on a comprehensive review of small- and large-scale test data [25]. In these data, a key variable was controlled; that is, all AFFF agents were formulated to meet MIL-F-24385. Ninety percent fire control times were used as the most accurate measure of fire knockdown performance, which were reported in all tests. The use of 90 % control times eliminates the variability of total extinguishment, which

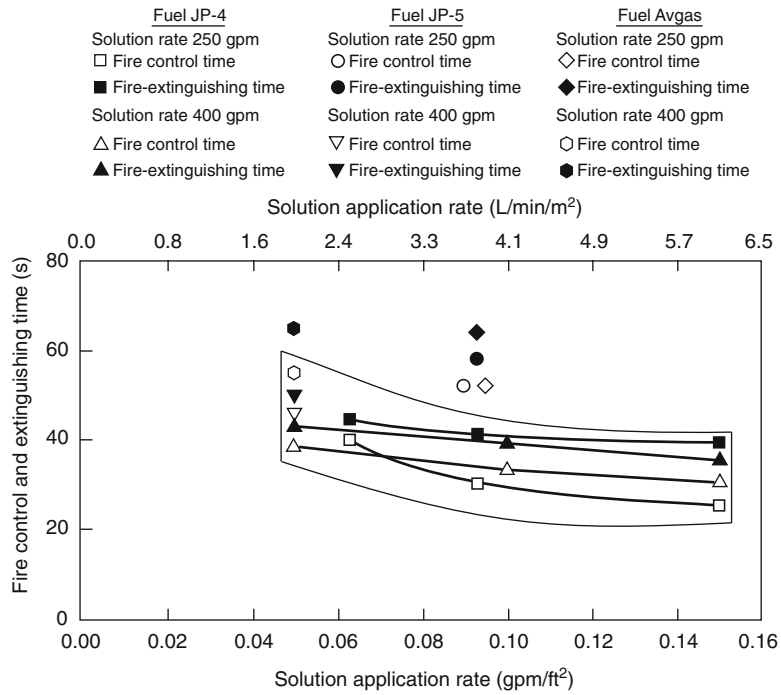

Fig. 47.8 Fire control and extinguishing times as functions of the foam solution application rate using AFFF at 250 gpm (946 L/min), 400 gpm (1514 L/min), and 800 gpm (3028 L/min) on JP-4, JP-5, and avgas fires [32]

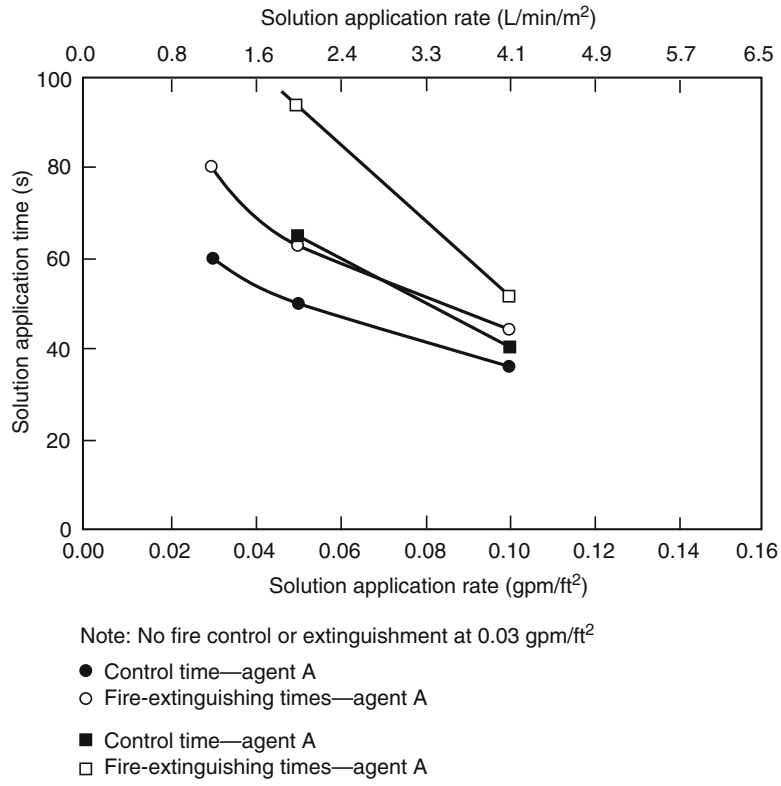

Fig. 47.9 Fire control and extinguishing times as a function of solution application rate using AFFF at 250, 400, and 800 gpm on 743-m2 (8000-ft2) JP-4 fuel fires [32]

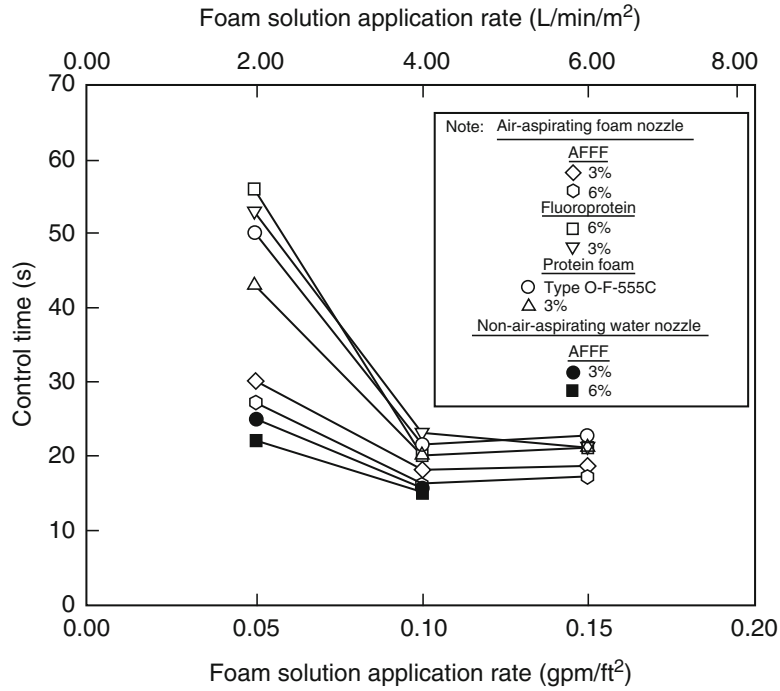

Fig. 47.10 Fire control time as a function of solution application rate for AFFF, fluoroprotein, and protein foams for Jet A pool fires [1]

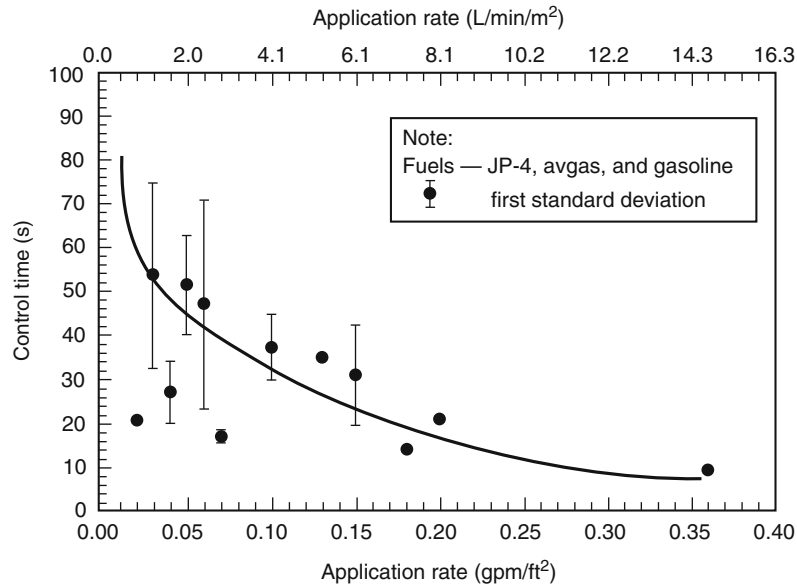

Fig. 47.11 AFFF control time as a function of application rate [25]

might be dependent on test-bed-edge effects or running fuel fire scenarios. Data for tests using air-aspirated or non-air-aspirated nozzles were combined. Low-flashpoint (less than 0°C [32°F]) fuels were evaluated. The evaluation included only tests where manual application was used, eliminating the variable of fixed versus manual application.

The effects of application rate on control and extinguishment times, as demonstrated in Figs. 47.7 through 47.10, were reconfirmed as shown in Fig. 47.11. Control time increases exponentially as application rate decreases, particularly below 4.1 L/min/m^2 (0.10 gpm/ft^2). Variability of the data is shown by the first standard deviation.

The scaling of small fires with large fires is shown in Figs. 47.12 and 47.13, which relate the time needed to control the burning fuel surface as a function of fire size. The time needed to control a unit of burning area (s/ft^2 [s/m^2]), designated as the specific control time, is plotted as a function of fire size. For low (1.2 to 2.5 L/min/m^2 [0.03 to 0.06 gpm/ft^2]) and intermediate (2.8 to 4.1 L/min/m^2 [0.07 to 0.10 gpm/ft^2]) application rates, the specific control times decrease linearly as a function of fire area. These data are in agreement with data from Fiala, which also indicate decreasing specific extinguishment control times as a function of burning area for increasing application rates of AFFF. [30] Also, Fiala showed that, for a constant application rate, AFFFs have lower specific extinguishment times as a function of burning area than those of protein and fluoroprotein foams. Obviously, this linear relationship must change at very large areas; otherwise, the specific control/extinguishment time would go to zero. This is evidenced in Fig. 47.12, where the curve flattens at the high-area end of the plot.

Figures 47.12 and 47.13 show that higher specific control times are required for MIL-F-24385 test fires (2.6 and 4.7 m^2 [50 and 20 ft^2]) compared to large fires. This is readily apparent as actual/control extinguishment times for the small fires are on the same order as results from large fires. FAA and NFPA criteria for minimum quantities of agent are also shown in Figs. 47.12 and 47.13. These criteria are expressed in terms of specific control time as a function of area by using the required control time of 60 s and the practical critical fire areas for airports serving different sizes of aircraft. The data indicate that specific control times with MIL-F-24385 agents are roughly equivalent or less than the specific control times established by NFPA and FAA

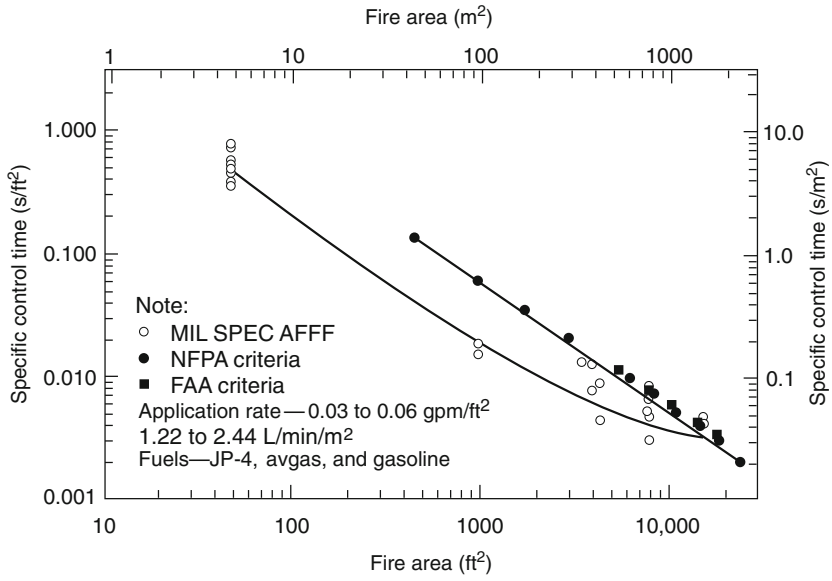

Fig. 47.12 Specific control times for AFFF at low application rates [25]

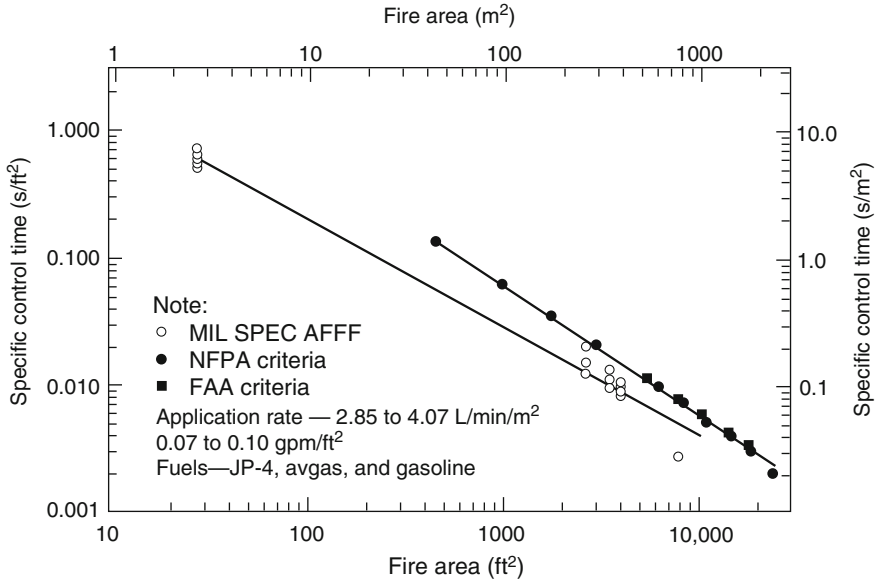

Fig. 47.13 Specific control times for AFFF at intermediate application rates [25]

requirements for large fire areas. This relationship is true even with the AFFF discharged at rates 25–75 % below the minimum NFPA/FAA discharge rate of 5.5 L/min/m^2 (0.13 gpm/ft^2). From these data, it can be concluded that a scaling relationship exists between MIL-F-24385 small-scale tests and actual large-scale crash rescue and fire-fighting applications. The MIL-F-24385 tests are more challenging than the larger tests in terms of specific control time, but

this challenging test produces an agent that can meet NFPA and FAA requirements at less than the design application rate. This factor of safety accounts for variables in actual aviation crash situations, for example, running fuel fires, debris that may shield fires, and crosswinds that may limit foam stream reach.

Aviation Fire Protection Considerations

Historical Basis for Foam Requirements

The underlying principle in aviation fire protection is to temporarily maintain the integrity of an aircraft fuselage after a mishap to allow passenger escape or rescue. When an aircraft is involved in a fuel spill fire, the aluminum skin will burn through in about 1 min. If the fuselage is intact, the sidewall insulation will maintain a survivable temperature inside the cabin until the windows melt out in approximately 3 min. At that time, the cabin temperature rapidly increases beyond survivable levels.

Aircraft rescue and fire-fighting (ARFF) vehicles are designed to reach an incident scene on the airport property in 2–3 min, depending on the standard enforced by the authority having jurisdiction (AHJ). Having reached the scene in this time frame, the agent must be applied to control a fire in 1 min or less. The 1 min critical time for fire control is recognized by FAA, NFPA, and ICAO.

Minimum agent requirements on ARFF vehicles are established using the 1-min critical control time plus the anticipated spill area for the largest aircraft using the airport. A "theoretical critical fire area" has been developed, based on tests, and is defined as the area adjacent to the fuselage, extending in all directions to the point beyond which a large fuel fire would not melt an aluminum fuselage regardless of the duration of the exposure. A function of the size of an aircraft, the theoretical critical fire area was amended to a "practical critical fire area" after evaluation of actual aircraft fire incidents. The practical critical area, two-thirds the size of the theoretical critical area, is widely recognized by the aviation fire safety community, including FAA, NFPA, and ICAO. Vehicles must be equipped with sufficient agent and discharge devices to control a fire in the practical critical area within 1 min. Vehicles must also be equipped with a secondary agent (dry chemical or Halon 1211) for use in combating three-dimensional fuel fires.

The FAA has recently reviewed the basis of airport foam requirements. They considered new large aircraft containing significantly greater jet fuel loads (e.g., Airbus A380), and aircraft containing significantly greater fuselage combustible composite materials (in place of aluminum) [33, 34]. An fire hazard approach which assumed an unlimited size aircraft spill fire was considered, along with loss history. The "critical area" concept was found to be an acceptable and appropriate approach for establishing agent quantities. Research is continuing of the impact of composite materials.

Agent Quantities and Standards

The previous text on critical application rates described the rationale used to develop design application rates used in aviation fire protection. These rates are 5.5 L/min/m^2 (0.13 gpm/ft^2) for AFFF, 7.5 L/min/m^2 (0.18 gpm/ft^2) for fluoroprotein foam, and 8.2 L/min/m^2 (0.28 gpm/ft^2) for protein foam. Using these rates, the practical critical fire area and the 60-s control time criteria, minimum agent quantities are established for airports serving different size aircraft. These criteria are contained in NFPA 403, *Standard for Aircraft Rescue and Fire-Fighting Services at Airports,* and the FAA Advisory Circular 150/5210-6C, "Aircraft Fire and Rescue Facilities and Extinguishing Agents." ICAO uses similar criteria. NFPA 403 has adopted the 4.6 m^2 (50 ft^2) fire extinguishment and burnback criteria from MIL-F-24385 for AFFF agents. UL test criteria are acceptable for protein and fluoroprotein foams. All certified airports in the United States must now use MIL SPEC AFFF when purchasing foam concentrate. Recognizing the limitations of its test methods

for aviation applications, UL has deleted references to crash rescue fire fighting from the scope of UL 162, *Standard for Foam Equipment and Liquid Concentrates*. NFPA 403 recognizes that the standards for foam that it references are widely recognized throughout North America, but may not be recognized in other areas of the world. In particular, the ICAO test method has significantly different test parameters, including test fuel, application rate, and extinguishment density. The NFPA notes that it is incumbent on the national authority having jurisdiction to determine that alternative test methods meet the level of performance established by NFPA 403 test criteria.

NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment,* provides field test methods to determine the adequacy of foam equipment on crash rescue vehicles. It includes criteria for foam expansion and drainage, and methods to determine foam solution concentration.

Expansion and Drainage Foam expansion and drainage requirements of the current version of NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment,* are shown in Table 47.11.

NFPA 412 references a 1600 mL foam sample collector, which was originally adopted by ICAO and ISO/EN. This single method is used to obtain expansion and drainage measurements for all types of foams in hope that similar success could be obtained in using a single fire test method for all foams. The multiple categories of foam test classification in Table 47.8 for the ISO/EN method show how difficult this has been to achieve. Given the different methods of foam flow over a fuel surface, it may not be practical to use a common fire test method predicated on the current means of testing. Further development of fundamental foam-extinguishing principles is recommended.

Table 47.11 Foam quality requirements from NFPA 412

Agent	Minimum expansion ratio	Minimum solution 25 % drainage time (min)
AFFF or FFFP		
Air aspirated	5:1	2.25
Non-air-aspirated	3:1	0.75
Protein	8:1	10
Fluoroprotein	6:1	10

The 1600 mL expansion and drainage test method replaced two other methods where a 1000 mL cylinder or 1400 mL pan was used as the collection device. MIL-F-24385 still uses the 1000 mL collection method. This situation, plus other different test methods, makes direct comparison of expansion and drainage data difficult. Tests performed by Underwriters Laboratories (UL) identified differences among the three test methods based on expansion and drainage results [35]. UL found that expansion ratios remained the same but that drainage was quicker using the 1600 mL method compared to the 1000 mL method for film-forming foams. Drainage time increased (i.e., doubled) for the protein foams when the 1600 mL method was used compared to the 1400 mL pan method.

No direct correlations have been established between expansion, drainage, and fire-extinguishing performance. There is a relationship between foam drainage and burnback. Longer drainage times generally result in longer burnback times. Refer back to the "Fire Extinguishment and Spreading Theory" section for quantitative relationships.

The expansion and drainage data in Table 47.11 indicate the inherent differences between air-aspirated and non-air-aspirated film-forming foams. The data in Fig. 47.10 showed that non-air-aspirated AFFF was more effective at critical application rates than was air-aspirated AFFF. This conclusion was verified by Jablonski in tests with U.S. Air Force crash trucks, as shown in Fig. 47.14 [36]. Even so, there continues to be debate over air-aspirated and non-air-aspirated foam for manual applications involving aviation fuel spills.

Under certain conditions, non-air-aspirated AFFF is not as effective as air-aspirated AFFF. The results of the foam tests in the United Kingdom [37, 38] and the results from DiMaio et al. [39] described situations where

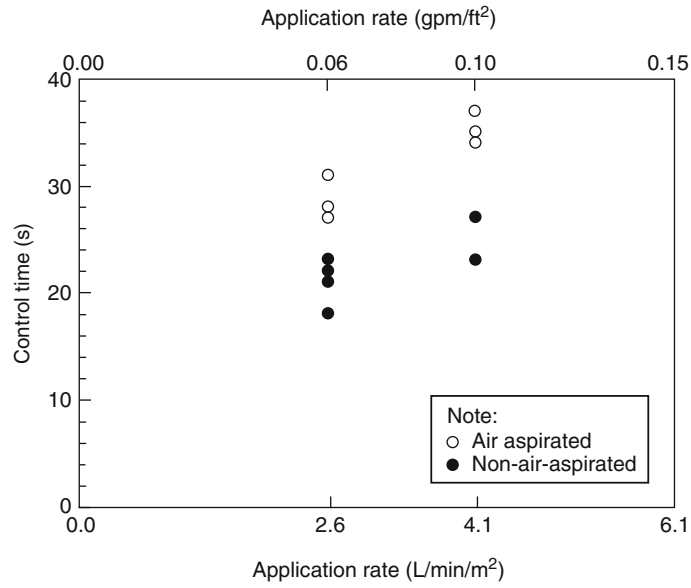

Fig. 47.14 Effects of AFFF aspiration on JP-4 pool fire control times [36]

air-aspirated AFFF resulted in better fire extinguishment performance than non-air-aspirated foam.

Given that one-to-one correlation between expansion, drainage, and fire-extinguishing performance is difficult to identify, there appears to be a lower limit where non-air-aspirated AFFF becomes ineffective. This has not been quantified, but it is speculated that poor performance occurs when the AFFF expansion ratio is less than 2.5:3.0, and drainage is difficult to measure, that is, nearly instantaneous. This is based in part on unpublished data from the Naval Research Laboratory on shipboard bilge AFFF sprinklers [40] and the results of the U.K. tests [37, 38]. The importance of this lower limit of foam aspiration is recognized in NFPA 412 criteria.

Foam Concentration Determination The most common method of determining foam concentration in the field is by use of a handheld refractometer. The refractive index, n, is defined as

$$n = \frac{\sin i}{\sin r} \tag{47.12}$$

where
$\sin i$ = Angle of incidence
$\sin r$ = Angle of refraction

Note:
Refractive index, $n = \dfrac{\sin i \text{ (angle of incidence)}}{\sin r \text{ (angle of refraction)}}$

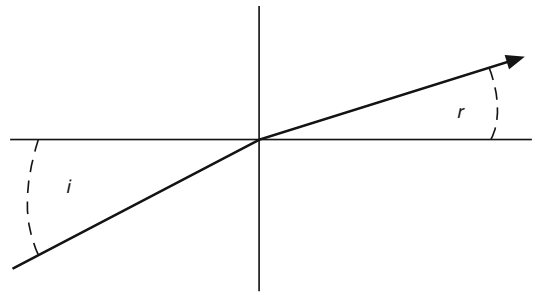

Fig. 47.15 Refractive index of solutions

This is depicted graphically in Fig. 47.15.

Manufacturers report that the glycols in AFFF formulations create the necessary refractive characteristics to determine concentration. However, they also report that glycol has a potential detrimental impact on overall agent performance. Elimination of this compound might improve (slightly) the performance of AFFF, but the glycol is also needed as a fundamental component of agent mixing.

The refractive index of water at 20°C (68°F) is 1.333 (air has a refractive index of 1.0002926). Because the refractive index of a solution is proportional to the inverse of the solution

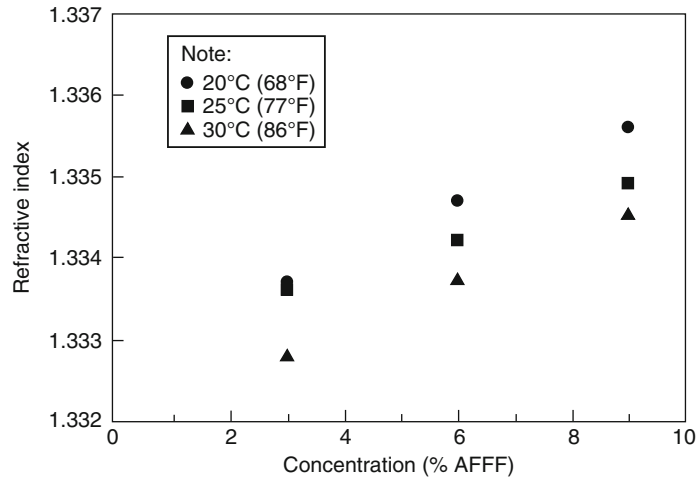

Fig. 47.16 Effects of temperature on refractive index [41]

density, and density is proportional to temperature, then

$$n \propto \frac{1}{T} \tag{47.13}$$

where T is the temperature. This relationship is illustrated in Fig. 47.16. Any refractive index measurements must be made considering temperature. Some handheld measurement devices are temperature compensated. It is good procedure to conduct concentration measurements at a constant temperature.

Other scales may be used. For example, the Brix scale is used as a measure of sucrose weight percent concentration. Units with this scale, commonly found in the food product industry, can be used to measure foam concentration. A typical range of a bench or handheld refractometer is 1.3000 to 1.7000.

NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment,* describes a method to determine foam concentration using the refractive method. In NFPA 412, the preparation of three standard solutions is recommended: one at the nominal concentration, one at one-third more than the nominal concentration, and one at one-third less than the nominal concentration. A plot of the refractive scale reading against the known foam concentration is made on graph paper. This plot establishes a "calibration" curve against which foam samples from a vehicle or system can be judged. Because refractive index is linear, a calibration curve can be created by

$$\text{AFFF}\%_{\text{sample}} = \frac{n_{\text{foam}} - n_{\text{water}}}{n_{\text{concentrate}} - n_{\text{water}}} \times 100 \tag{47.14}$$

This method is used by the U.S. Navy for checking proportioning system accuracy on board ships.

The limitations of the refractive index technique are described by Timms and Haggar [41]. The accuracy of the refractometer can become poor due to the focusing and setting of the refracted light junction on the crosshairs of the viewing window, and the reading of the graduated scale to four decimal places (where the scale is graduated to only three places). This effect is illustrated in Fig. 47.17, where a calibration curve for a 1 % AFFF concentrate was established using a straight line through the 50 % concentration point and the "water" reading by one of the experimenters. Note that the error between readings by the two experimenters at 1 % concentration exceeds 25 %. In this example, differences in the baseline water reading will create substantial error in the calibration curve. These differences are exaggerated with 1 % concentrates. At 3 % or 6 %, the experimental

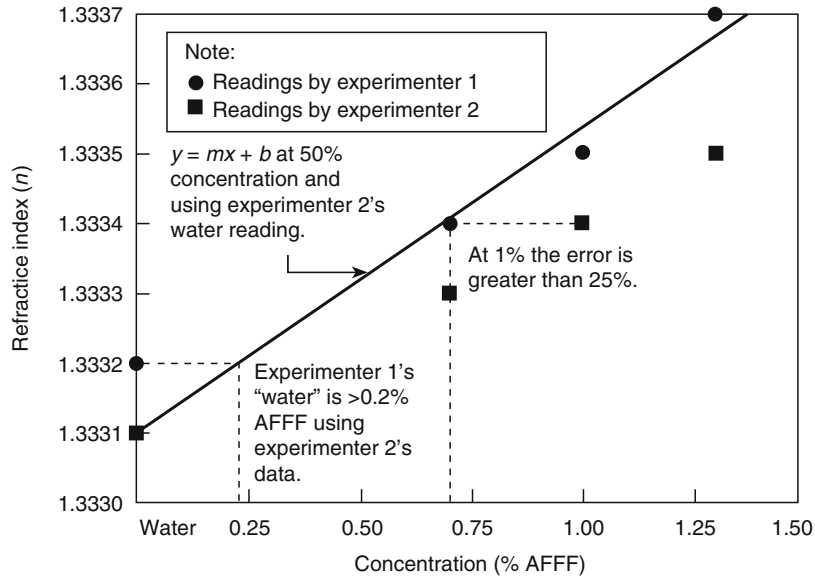

Fig. 47.17 Refractive indices of 1 % AFFF solutions in tap water

error in reading the refractometer, for field testing, is generally accepted as adequate.

Alternative methods for measuring AFFF concentration include total fluorine content, optical absorption methods, and electrical conductivity. Because neither the total fluorine content method nor the optical absorption method is suited to field use, the conductivity method has been proposed. Because foams contain electrolytes, their conductance, G, can be measured and described as

$$G = \frac{1}{R}(mhos) \qquad (47.15)$$

where R is resistance (ohms). Conductivity, σ, is conductance per unit length:

$$\begin{aligned}\sigma &= \mathrm{G/unit\ length}\\ &= \mathrm{mhos/cm}\\ &= \mathrm{siemens/cm}\end{aligned}$$

Because conductivity is directly proportional to temperature, conductivity increases with temperature (Fig. 47.18). Temperature compensation is appropriate when using this method.

Timms and Haggar showed the influence of the substrate water on both refractive index and conductivity [41] (Figs. 47.19 and 47.20). It is important to note the difference of the characteristic curve for a salt solution. AFFF actually reduces the conductivity of this highly conductive water. Note also that, although conductance may exhibit straight-line characteristics in the area of interest (0 to 10 %), the overall curves from 0 to 100 % are nonlinear.

The "sensitivity" of the two methods (i.e., refractive index and conductivity) was shown by these researchers by comparing the difference between readings for solutions of 3 % and 6 % divided by the reading at 6 %. The sensitivities for tap water show that the conductivity method is more sensitive than the refractive index measure (Table 47.12). In repeated readings of refractive index and conductivity, the foam concentration accuracy using conductivity was ±0.1 %, where the accuracy of the refractive index method was ±0.8 % (Table 47.13).

An evaluation was conducted by the U.S. FAA to comparatively test various conductivity meters and retractometers used in testing airport rescue and fire fighting (ARFF) vehicle foam-proportioning systems. [42] During the annual certification inspection of an airport fire department, refractometer and conductivity meter tests are conducted to test the foam concentrate and foam-proportioning systems of the ARFF apparatus. Historically, the refractive

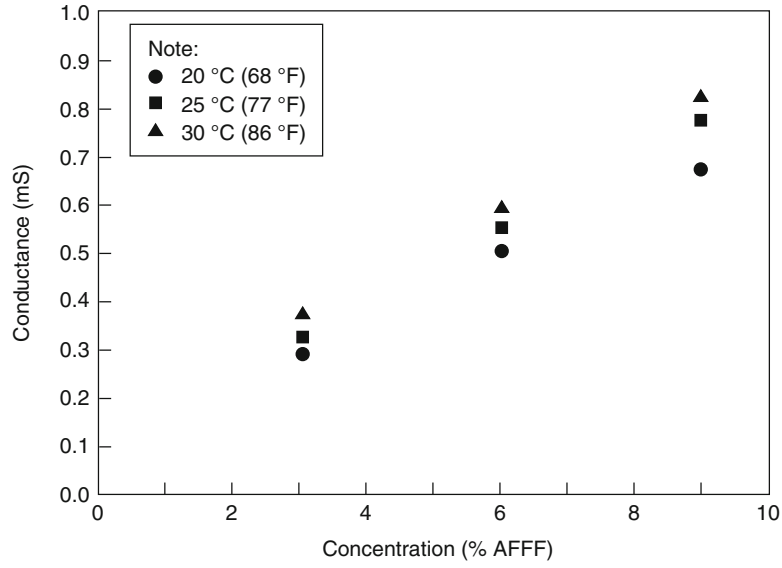

Fig. 47.18 Effects of temperature on the conductance of AFFF solutions [41]

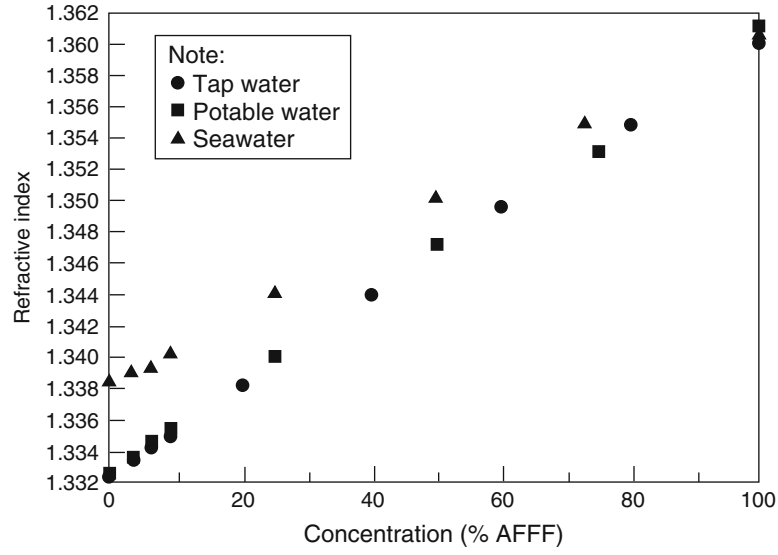

Fig. 47.19 Effect of substrate water on refractive index of AFFF solutions [41]

index method has been used to determine the proportioning of foam-generating systems. Because of the limited accuracy of the refractometer, particularly for assessing systems using 1 % and 3 % concentrates, the conductivity method is gaining more widespread use. Five conductivity meters were evaluated against a standard refractometer. A range of representative 3 % and 6 % foam concentrates were evaluated. Measured standard solutions prepared from the five conductivity meter tests show very close readings to one another. Typically, the units read within 0.2 mS. More importantly, all five conductivity meters exhibited the same trends in the readings from one foam product to the other. The refractometer data were not as consistent. A significant factor in the use of the refractometer is the fact that the readings can be interpreted differently by several evaluators during the same test. The digital readings from the conductivity

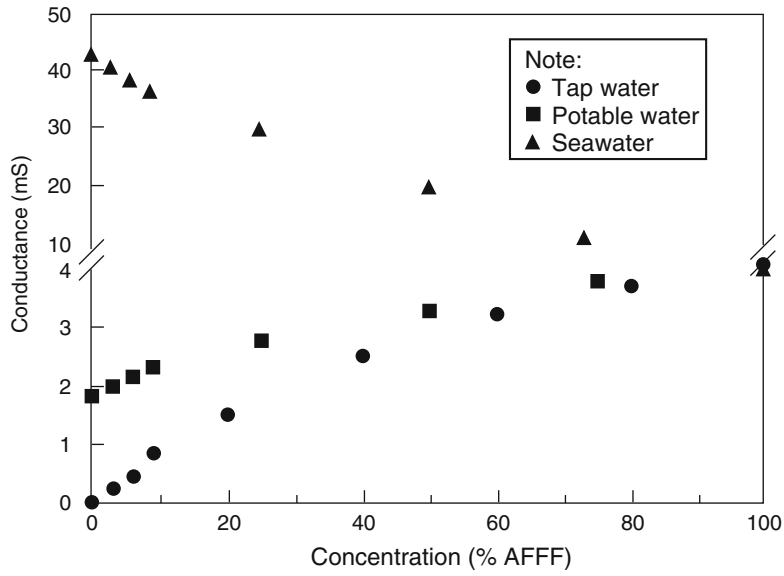

Fig. 47.20 Effect of substrate water on conductivity of AFFF solutions [41]

Table 47.12 Sensitivity of refractive index and conductivity methods for determining foam concentration [41]

	Refractive index	Conductance (mS)
3 %	1.3337	0.318
6 %	1.3343	0.558
Difference	0.0006	0.240
"Sensitivity"	0.0005 (0.5 in 1000)	0.43 (430 in 1000)

Table 47.13 Accuracy of foam test measurements [42]

Solution	Refractive index	Electrical conductance	Actual
A	4.5 % ± 0.8 %	3.5 % ± 0.1 %	3.50 ± 0.01 %
B	5.1 % ± 0.8 %	5.5 % ± 0.1 %	5.50 ± 0.01 %
C	8.7 % ± 0.8 %	8.5 % ± 0.1 %	8.50 ± 0.01 %

meters removed the interpretive errors and proved to have very good repeatability between tests.

When evaluating the various conductivity meters for usability and accuracy, it was determined in the FAA study that all five units were considered better tools for inspecting the foam-proportioning systems than were refractometers. There were some aspects of the various conductivity meters that made some meters slightly better than others. The accuracies of the conductivity meters can be greatly affected by variations between the temperature of the solution and conductivity probe; care should be taken that conductivity measurements are made when the solution and conductivity probe are at the same temperature. One of the units automatically compensated for temperature.

The electrical conductivity method is now recognized in NFPA standards including NFPA 11 and NFPA 412. NFPA 412 cautions against the use of this method for seawater applications. The electrical conductivity method, used for process control in the chemical industry, has recently been adapted for use as a proportioning controller for AFFF systems.

New Airfield Protection Approaches

The U.S. Air Force Research Laboratory (AFRL) has done extensive research and development of novel ARFF-related fire fighting techniques in an attempt to develop smaller, lightweight, air-transportable ARFF vehicles that can be easily carried on cargo aircraft, such as the USAF C-130.

AFRL research has focused on the following technologies:

Ultra High Pressure System (UHPS)—This system utilizes high-pressure positive displacement plunger pumps to deliver AFFF at a

nominal pump discharge pressure of 1500 psi. Turret residual pressures are in the 1100–1200 psi range, which in effect causes AFFF to be delivered as a foam "mist". The applied foam has the characteristics of conventional AFFF delivery. It creates a foam blanket and aqueous film formation on the fuel surface, and may have the added fire suppression feature of small droplet mist, namely cooling, flame stripping, and oxygen displacement via water vapor formation.

Compressed Air Foam System (CAFS)—In a CAFS system air is injected under pressure into AFFF solution between the pump and the nozzle, so that expanded foam discharges from the nozzle. This allows greater control over the resultant foam expansion ratio and provides a uniform, more expanded, foam delivery to the fuel surface.

Combined Agent Fire Fighting System (CAFFS)—Recent testing has focused on the patented "Hydrochem" technology where dry chemical agent, typically PKP, and AFFF are discharged through a concentric nozzle design. PKP is discharged through a central orifice while AFFF, or CAFS, is discharged through the annular opening around the central dry chemical orifice. When flowing simultaneously, the AFFF/CAFS discharge carries the PKP in the center core of the discharge stream providing greater dry chemical discharge range then if discharged separately.

Tri/Quad Agent Systems—As a refinement of the twin agent concept widely used for flammable liquid fire fighting for over 30 years, recent delivery systems have been developed to discharge three or four agents (water, AFFF, dry chemical, gaseous/Halogenated agents) either simultaneous or consecutively, often through a single nozzle. This provides the nozzle man the option of easily selecting the desired agent for the particular fire scenario.

Two recent AFRL reports [43, 44] document testing at Tyndall Air Force Base of UHPS, CAFS, and CAFFS. Testing was conducted on fuel fires on a water substrate, fuel on gravel, fuel on soil/sod, and fuel on a hard surface. Since most tests over the years have been conducted with fuel on water (previously cited Geyer and NRL testing, for example), the fuel-on-water test results are described below.

Table 47.14 USAF new technology testing [42]

Extinguishing method	Number of test fires	Mean application density (gals/ft^2)
P-19	22	0.044
UHPS	20	0.014
CAFs	27	0.028
CAFFS	27	0.027

Agent extinguishment tests were conducted against three different size JP-8 fires: 880, 3500 and 5100 ft^2. Comparative data was generated against the performance of the primary USAF crash truck, the P-19. Agent flow rates were as follows:

• P-19	250/500 gpm AFFF
• UHPS	70–100 gpm AFFF
• CAFs	250–560 gpm AFFF
• CAFFS	125 gpm AFFF/3 pps dry chem.
	220 gpm AFFF/7.5 pps dry chem.

A total of 114 fuel-on-water fire tests were conducted, with the results as shown in Table 47.14:

The UHPS delivery method produced a mean application density based on pool fire extinguishment of 0.014 gals/ft^2, compared to a mean application density with the conventional P-19 of 0.044. The UHPS provided a lower application density. The USAF, after applying an appropriate safety factor to the discharge density, is deploying this technology.

Aircraft Hangar Protection

The two objectives of aircraft hangar protection are (1) protect aircraft and (2) prevent collapse of the hangar roof structure, which is usually unprotected steel. The protection of the aircraft is the principal concern, because its value is generally many times that of the structure. This concern is particularly true for advanced military aircraft. Historically, these protection systems have been

deluge-type sprinkler systems with open-head nozzles. They are activated by rapid-response detection systems. Before the development of foam, water-deluge systems were used. The original foam-water sprinkler systems used protein foam. With the development of AFFF, research was performed to determine appropriate application rates and types of discharge devices. The research work, performed primarily by Factory Mutual Research Corporation (FMRC), provides the basis not only for current aircraft hangar protection criteria but also for other sprinkler suppression system criteria.

Overhead Sprinkler Protection Before the advent of foam, hangars were protected by conventional spray sprinklers using water. Water-deluge systems having discharge rates on the order of 10.4 L/min/m^2 (0.25 gpm/ft^2) were used in conjunction with sloped floors and drains to protect aircraft. Even with these systems, activated by detection systems, burnthrough protection of aircraft fuselages (e.g., 1 min) could not be ensured. Ceiling temperatures in an 18.3-m-(60-ft-) high space on the order of 427 to 816°C (800 to 1500°F) have been recorded for fuel spill fires where this protection was provided. For a 121 m^2 (1300 ft^2) JP-4 fuel fire, 927°C (1700°F) ceiling temperatures have been recorded within 30 s of ignition prior to deluge system discharge.

Protein foam systems, discharging at a rate of 8.2 L/min/m^2 (0.20 gpm/ft^2), were an improvement on the water systems. Air-aspirating sprinklers were required to make effective protein foam. Because of the high centerline velocities of a pool fire plume, the foam flow from the perimeter toward the center of the fire was thought to be the dominant suppression mechanism [41].

With the development of AFFF, FMRC conducted a series of tests for the U.S. military to establish appropriate design parameters. In a series of baseline comparison tests, FMRC compared AFFF with protein foam. The tests consisted of 83.6 m^2 (900 ft^2) JP-4 pool fires in an 18.3-m (60-ft) high space. Air-aspirating, standard upright, and old-style upright sprinklers were evaluated at application rates of 4.1 to 8.2 L/min/m^2 (0.10 to 0.20 gpm/ft^2). In one test, a low-level turret nozzle discharging AFFF was used in conjunction with sprinklers discharging water. Table 47.15 summarizes the results of the AFFF tests. A comparison of Tests 4 and 5 with Test 3 indicates improved results from the use of standard sprinklers compared to foam-water

Table 47.15 Hangar deluge system tests by factory mutual research corporation [45]

Test conditions	Test no. 2	Test no. 3	Test no. 4	Test no. 5	Test no. 6	Test no. 7 (turret nozzle)
Type of head	Foam-water	Foam-water	Standard	Standard	Standard	Old-style sprinkler
Spacing (m^2 $head^{-1}$ [ft^2 $head^{-1}$])	7.4 (80)	9.3 (100)	12.1 (130)	12.1 130	9.3 (100)	9.3 (100)
Application rate (L/min/m^2[gpm/ft^2])	8.2 (0.20)	6.6 (0.16)	6.6 (0.16)	6.6 (0.16)	5.2 to 4.4 (0.125 to 0.105)	6.6 (0.16) (water system)
End head pressure (kPa [psi])	193 (28)	193 (28)	97 (14)	97 (14)	35 (5)	55 (8) (water system)
25 % Drainage time (min)	2.5	2.1	0.5–0.8	1.0–1.3	0.5–0.7	No data recorded
50 % Drainage time (min)	5.0	4.4	1.3–1.8	1.8–2.3	1.2–1.6	No data recorded
Expansion ratio	4.3:1	3.4:1	2.2:1	2.3:1	2.2:1	12:1
Extinguishment time (min:s)	2:22	2:15	1:45	1:25	3:05	≈0:33

Table 47.16 Estimated particle diameter vs. terminal velocity [46]

	Terminal velocity (m/s [ft/s])			
		Foam		
Particle diameter (mm [in.])	Water	Expansion Ratio 2:1	Expansion Ratio 5:1	Expansion Ratio 10:1
12.7 (0.5)	See note[a]	10.1 (33)	6.7 (22)	4.6 (15)
6.3 (0.25)	10.4 (34)	7.3 (24)	4.6 (15)	3.4 (11)
2.5 (0.1)	6.7 (22)	4.6 (15)	2.7 (9)	—

[a]The breakup of water drops greater than about 6.3-mm (0.25-in.) diameter is highly probable due to instability

sprinklers. At application rates of 6.6 L/min/m^2 (0.16 gpm/ft^2), the standard sprinklers were 1.3 to 1.6 times as effective in achieving extinguishment compared to air-aspirating foam-water sprinklers. At an application rate of 8.2 L/min/m^2 (0.20 gpm/ft^2), the extinguishment times with AFFF from foam-water sprinklers were comparable to results from protein foam tests. Rapid suppression with the turret nozzle (at 8.3 L/min/m^2 [0.22 gpm/ft^2]) combined with an overhead water system was demonstrated in Test 7. No adverse effects were evident from the water discharged from the overhead sprinklers after the foam ran out.

The superior performance of the standard sprinklers was attributed to more effective plume penetration by higher density foam particles. The maximum centerline velocities measured were 23.2 m/s (76 ft/s), with 15.2 m/s (50 ft/s) at the centerline of the fire. The fire plumes tended to bend due to air currents within the test building. Because the terminal velocity of the foam agents was estimated to be on the order of 9.1 m/s (30 ft/s) maximum, the droplets near the centerline never reached the fire. This result supports the theory that extinguishment occurs from the outside perimeter inward. Because foam droplets from standard sprinklers are about twice as dense as air-aspirated particles, the terminal velocities are greater. Greater velocities allow greater penetration of the fire plume. The same mechanisms explain why air-aspirated AFFF provides similar performance to protein foam. When the AFFF is air aspirated, there is no longer any advantage of increased droplet terminal velocity.

Additional work by FMRC established estimates for the terminal velocity of foam, as shown in Table 47.16 [46, 47]. Plume theory was used to estimate roughly that velocity on the order of 18.3 m/s (60 ft/s) could be expected in an 18.3-m (60-ft) high space with an 83.6 m^2 (900 ft^2) JP-4 fire. This estimate was in good agreement with the experimental results. Based on an average foam particle diameter of 6.3 mm (0.25 in.), a maximum terminal velocity of 7.3 m/s (24 ft/s) could be expected. For a JP-4 pool fire, this translates into a 0.7-m^2 (8-ft^2) maximum fire size before plume penetration is not possible.

The practical significance of AFFF discharged through non-air-aspirating sprinklers was demonstrated by Breen et al. [46] Air-aspirating sprinklers require 207 kPa (30 psi) nozzle pressure to be effective. Standard sprinklers can discharge effective AFFF solution at pressures as low as 69 kPa (10 psi). This capability had important retrofit considerations where foam-proportioning system losses could be made up through reduced sprinkler pressures.

Additional tests were conducted with closed-head sprinklers in an 18.3-m (60-ft) high hangar [48]. Potential cost benefits would have resulted from reduced hardware costs and unwanted discharges from deluge systems. These tests demonstrated that this concept was not feasible for the hangar scenario because of the large number of sprinklers that opened during the 83.6 m^2 (900 ft^2) fire tests.

The superior performance of standard sprinklers compared to air-aspirating sprinklers is reflected in the criteria of NFPA 409, *Standard*

on Aircraft Hangars. If standard sprinklers are used with AFFF, the design application rate for overhead deluge systems may be reduced to 6.6 L/min/m^2 (0.16 gpm/ft^2) from 8.2 L/min/m^2 (0.20 gpm/ft^2) required for air-aspirated sprinklers. This decrease represents a 20 % reduction in foam required when standard sprinklers are used.

It should be noted that AFFF discharging from sprinklers cannot be assumed to control a three-dimensional Class B fire. In tests conducted by the U.S. Navy, AFFF sprinklers were discharged on a simulated ruptured fuel tank fire [49]. Deluge, air-aspirating sprinklers were discharged at 6.5 L/min/m^2 (0.16 gpm/ft^2) from a 8.5-m (28-ft) high simulated hangar. The three-dimensional fire consisted of 28 L/min (7.5 gpm) of marine diesel (simulating JP-5) flowing down over a shielded cascade assembly. The assembly simulated a ruptured fuel tank below a damaged aircraft wing, which prevented direct AFFF application to the running fuel fire. Although the contiguous pool fire was suppressed, the running fire was not. It was also found that delaying AFFF discharge time for this scenario had an adverse effect on suppression.

Care must be taken in designing AFFF sprinklers for both pool fire suppression and extinguishment of other hazards. In fire tests for shipboard vehicle storage areas, a fire scenario involving a Class B pool fire (marine diesel, simulating vehicle diesel fuel or JP-5) and ordinary combustibles was performed [50]. Tests were conducted in an 8.5-m (28-ft) high space with air-aspirating sprinklers discharging 6.5 L/min/m^2 (0.16 gpm/ft^2). The Class A fuel load was simulated by a 1.6 m (6 ft) stack of wood pallets. The Class B pool fire was readily controlled and extinguished, but the Class A pallet fire was not controlled or suppressed. It was concluded that a higher sprinkler application rate was required to control/suppress the Class A fire. This is consistent with NFPA 13, *Standard for the Installation of Sprinkler Systems,* requirements for a minimum application rate of 8.1 L/min/m^2 (0.2 gpm/ft^2) or greater for wooden pallets stacked 1.8 m (6 ft) high or more. Fires within actual vehicles will likely require a higher sprinkler application rate to prevent spread to adjacent vehicles [51].

Low-Level Application of AFFF With the increase in wingspan areas of large aircraft, it was recognized that significant damage could occur before extinguishment of the pool fire underneath the wing. Using overhead sprinklers only, FMRC demonstrated the times required for the foam to spread and extinguish fires (see Table 47.15). The concept of low-level application of foam, using monitors or turret nozzles, was developed to reduce extinguishment time where shielded fires may occur. This concept was later extended to include side-mounted nozzles and discharge outlets, and flush-mounted nozzles installed in a floor or deck.

These systems are effective because AFFF solution droplets do not have to penetrate the fire plume. They also typically deliver, at spot locations, high densities of foam. A high density allows the foam to gain a "bite" or toehold on the fire. Low-level AFFF systems have been used successfully for over two decades on U.S. Navy air-capable ships, protecting flight decks and special hazard areas.

Table 47.17 summarizes fire test data for low-level application of AFFF. As seen, control and extinguishment times are quite rapid. NFPA 409, *Standard on Aircraft Hangars,* criterion of 4.1 L/min/m^2 (0.10 gpm/ft^2) for low-level applications is based on a fire control time of 30 s and extinguishment in 60 s. Data indicate that a JP-5 pool fire can be 90 % controlled in 60–90 s and 99 % extinguished in 2 min when an application rate of 2.4 L/min/m^2 (0.06 gpm/ft^2) is used. The system can be effective at rates as low as 1.6 L/min/m^2 (0.04 gpm/ft^2). For low-flashpoint fuels (e.g., avgas), control time increases. Control and extinguishment times can be reduced by increasing the application rates on JP-5 fuel fires. Based on these results, the U.S. Navy adopted an AFFF application rate of 2.4 L/min/m^2 (0.06 gpm/ft^2) for protecting aircraft carrier flight decks [56].

Although they may help control a three-dimensional (spill) fire, low-level application systems cannot be assumed to suppress totally a

The contribution, if any, of the overhead deluge system toward complete extinguishment was judged to be quite small compared to the turret nozzle
[e]Wind-affected results
[f]Deck pool fire area was obstructed with simulated weapons carts

running fuel fire. Running fuel fires at a spill rate of 189 L/min (50 gpm) are typically used in U.S. Navy flight-deck suppression tests using the flush-deck system. The running fuel fire, shielded by simulated aircraft debris, requires aggressive handline attack for extinguishment [57].

Obstructions, such as parked vehicles, may block low-level nozzles. Testing for a flight-deck weapons staging area showed that a side-mounted low-level system could be effective even when nozzles were obstructed [55]. In these tests, 5 of the 12 deck-edge nozzles were obstructed to simulate vehicle tires blocking edge-mounted nozzles. Even with 40 % reduction, the fire was controlled and extinguished in less than 1 min (compared to 15–30 s when unobstructed). As with overhead sprinklers, low-level AFFF nozzles should not be relied on to extinguish three-dimensional Class B fires.

Cost of installation, maintainability, and reliability are factors when considering a low-level application system. Reliability issues with turrets/monitors have been identified by both FMRC and the U.S. Navy. The flush-deck system adopted by the U.S. Navy took considerable effort before a high degree of reliability and maintainability could be achieved. This open deluge nozzle, originally installed as a water washdown nozzle, incorporates a ball-check feature in the nozzle orifice to prevent debris from clogging the nozzle. Clean-out traps are installed in system piping for maintenance. Pop-up nozzles have been proposed as an alternative to flush-deck nozzles. These nozzles have their own reliability and maintainability issues. Unless there are very high costs associated with the loss of an aircraft, in-floor or flush-deck nozzles are generally cost-prohibitive for commercial aviation facilities. For high-risk/cost applications, in-floor nozzles may be justified. This may be the case for advanced military aircraft; for example, research has been performed on an inverted deluge system that not only can suppress a pool fire but also can cool exterior combustible components of the airframe. Initial installations have suffered from design and installation problems. [58] Lack of experience with these types of systems was the significant single cause of problems with these systems. Acceptance testing and maintenance were found to be lacking.

Side-mounted nozzles are the most reliable systems, consisting of open-pipe or -spray nozzles. The spreading rate of foam from an aspirated open-pipe system increases control and suppression time. Open-spray nozzles can be very effective, but their reach is limited.

New Hangar Fire Protection Design Concepts Issues related to asset protection, reliability of fixed systems, and environmental impact led the U.S. Navy to reevaluate its approach to hangar fire protection systems. A goal was established to install reliable and easily maintained fire protection systems that prevent damage to the hangar structure and to aircraft not directly involved in an initial spill fire ignition. This goal resulted in a multidiscipline study to address all associated technical issues.

All military service branches in North America have been plagued with false activation involving foam-water-deluge sprinkler systems over aircraft with open cockpits. These false activations have been caused by numerous sources including lightning strikes that introduced transient voltage spikes into the fire alarm system; water hammers in aging underground water distribution systems; accidental releases by maintenance personnel; deliberate acts of vandalism; accidental activation of manual pull stations; failure of pressure relief valves at pumping stations; roof-water leakage into overhead heat detection systems; and false activation of fire detection systems. This situation prompted the pursuit of alternative fire protection designs that would provide the desired level of protection.

Alternative designs included the use of closed-head AFFF overhead sprinkler systems and greater reliance on low-level monitor nozzle AFFF systems as the primary extinguishing component as described in the previous section. Low-level systems were originally designed to provide supplementary protection for the area shadowed from the overhead system by large

wing areas. In pursuing these alternative designs, technical and operational issues and limitations of both existing and proposed new systems were identified:

- Thermally activated systems may result in unacceptably high damage to assets prior to fire control/extinguishment, particularly in very high bay hangar ceilings (see Gott et al. [59]).
- Although it is readily accepted that conventional hangar fire protection systems were not designed to extinguish a three-dimensional fire, some fire protection engineers believed that AFFF extinguishing systems could be designed to control a spill fire and limit the area of the fire to only those aircraft intimate with the initial ignition source.
- Different aviation fuels are now commonly being used, for example, JP-5 and JP-8 are now the predominant fuels, compared to the lower flashpoint JP-4 previously used.
- Low-level AFFF monitor nozzle systems are
  - Relatively inefficient in terms of pattern distribution
  - Unreliable
  - Susceptible to blockage by equipment
  - Commonly found out of service in the field
- Any new AFFF low-level nozzle should be designed for minimal overspray and should not be significantly impacted by water discharge from any water-only protection system.
- Optical fire detectors are
  - Prone to false alarms
  - Currently tested, listed, and approved using fuels that are not typical in aviation
  - Subjected to few if any sources of false alarms in currently recognized approval standards

A concept was developed by the U.S. Navy to meet the desired performance goals. This concept included the following:

- Use of low-level AFFF deluge nozzles, having minimal overspray, to control/extinguish liquid fuel pool spill fires
- Operation of the low-level AFFF system using improved optical detectors designed to
  - Be highly immune to false alarms
  - Rapidly detect JP-5 fuel spill fires
- Installation of a quick-responding, closed-head, wet-pipe sprinkler system in the hangar ceiling
- Implementation of lessons learned from all military hangar design experiences in a comprehensive, new, improved design

Most of the research and development associated with the process has been completed and is described in Gott et al. [59], Szepezi et al. [60], Back et al. [61], Gottuk et al. [62], Scheffey et al. [63], and Parker [64]. Two aspects of U.S. Navy research and development are germane to the performance of AFFF. The first involves the performance of AFFF when subjected to water spray from sprinklers. The second is a developmental effort initiated to design a reliable, low-profile AFFF nozzle that could be installed in the floors of hangars.

Twenty-three full-scale fire tests were conducted to evaluate the effects of overhead water sprinklers on AFFF foam blankets [61]. One AFFF application rate (4.0 L/min/m^2 [0.1 gpm/ft^2]) and two sprinkler application rates (6.5 and 10.2 L/min/m^2 [0.16 and 0.25 gpm/ft^2]) were included in this evaluation. The tests were conducted on a range of spill fires. The spill fires were produced using either JP-5 or JP-8 aviation fuels and were evaluated on a concrete pad with similar drainage characteristics typical of navy hangars. The spill fires continued to burn (i.e., were shielded) during water/foam application. The heating effect on the burnback resistance of foam, with and without sprinkler water application, was evaluated.

The results show that the use of water sprinklers in conjunction with a low-level AFFF fire suppression system (with an application rate of 4.0 L/min/m^2 [0.1 gpm/ft^2]) had minimal effects on the ability of the system to suppress the fire and resist burnback. In all tests, the low-level AFFF system was capable of quickly

extinguishing the test fire (control ~30 s and extinguishment ~1 min) independent of the sprinkler application rate. The time required for the fire to burnback across the fuel surface was apparently a function of the drainage characteristics of the hangar and was only slightly affected by the application of water through the overhead sprinklers. The tests also show that the flashpoint of the fuel has an effect on the control, extinguishment, and burnback resistance capabilities of the system. Although the burnback times for the lower flashpoint fuels were faster than the higher flashpoint fuels, the duration of protection was not significantly altered. These tests show that overhead water sprinklers have minimal effect on AFFF foam blankets, independent of the test fuel, particular fire, and sprinkler application rate. A combined low-level AFFF extinguishing system operating in conjunction with an overhead water sprinkler system provided adequate burnback protection during AFFF discharge, but this protection may be lost shortly (a few minutes) after the end of AFFF discharge.

The new low-level fire-extinguishing system was designed to discharge AFFF adequately across a hangar floor, to be less likely to be affected by obstructions, and to reduce the likelihood of damage to exposed aircraft electronic equipment [63]. To achieve these objectives, the nozzle was designed to

- Produce a nominal AFFF application rate of 4.0 L/min/m^2 (0.1 gpm/ft^2)
- Operate at a nominal pressure of 2.8 bar (40 psi)
- Provide coverage to a distance of 7.6 m (25 ft) from a hangar floor drainage trench (centerline of two parallel trenches spaced 15.2 m [50 ft] apart)
- Spray AFFF so that the pattern height does exceed 0.3 m (1 ft) above the deck

The nominal AFFF application rate of 4.0 L/min/m^2 (0.1 gpm/ft^2) was selected based on current design practices as described in the previous two sections of the chapter. The nozzle operating pressure was selected based on standard, commercially available pump performance curves and preliminary estimates of friction loss for the system.

Over 50 nozzles were evaluated for this application [64]. Testing of these nozzles indicated that, although a limited number of commercially available nozzles could meet the design requirements, manufacturing, installation, and operation of these nozzles under normal hangar conditions were not feasible. Existing pop-up nozzles were not designed for the high flow rates or spray characteristics required of this application. As a result of these deficiencies, a prototype nozzle was developed. The prototype concept was subsequently developed into a commercially available nozzle. Foam pattern, distribution, and flow tests were conducted by Underwriters Laboratories Inc. on a nozzle with a flow coefficient of 22.6 k (gpm/psi$^{1/2}$).

There is no universal agreement on the proper approach to military hangar fire protection in North America. For example, the U.S. Air Force recognizes the use of high-expansion foam. Many of these systems have recently been installed.

The Canadian Ministry of Defense (MoD) is using compressed-air foam, or CAF. The primary advantage of CAF systems is for situations where there is an extremely limited water supply. Unlike traditional foam systems where air aspiration occurs at or near the discharge device, CAF systems inject air prior to the discharge device [65, 66]. Foam is generated by injecting air under pressure into a foam solution stream. As the solution moves through the piping system, foam is produced by the combined momentum of the foam solution and the injected-air stream in the hose or pipe. In the hangar system, AFFF is used as the foam concentrate, proportioned at 2 % compared to 3 % for traditional foam sprinklers. Also, the effective application rate (foam solution, L/min/m^2 or gpm/ft^2) is lower than similarly listed low-expansion foam sprinkler systems. NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam,* recognizes this system and provides design and installation requirements.

Additionally, the U.S. Army has evaluated the use of early suppression fast-response (ESFR) closed-head water sprinkler protection for helicopter hangars [67]. FMRC concluded that both 93 °C (200 °F) temperature-rated ESFR sprinklers discharging at 345 kPa (50 psig)

(41 L/min/m^2 [1.0 gpm/ft^2]) and 517 kPa (75 psig) (49 L/min/m^2 [1.2 gpm/ft^2]) and temperature-rated, $k = 5.6$ (gpm/psi^{½}) quick-response sprinklers at 345 kPa (50 psig) (16 L/min/m^2 [0.40 gpm/ft^2]) can provide adequate fire protection for the hangar against a 61-m^2 (200-ft^2), 473 L (125 gal) JP-4 aviation fuel-pan fire. For some tests, fuel depletion was necessary for the fire to be controlled.

New fire detection technology, potentially applicable to hangar fire protection, has become available. Video image flame detection (VIFD) is a software-based method of flame detection that can be implemented by a range of video image analysis techniques. VIFD systems can analyze images for changes in features such as brightness, contrast, edge content, loss of detail, and motion. The detection equipment can consist of cameras producing digital or analog (converted to digital) video signals and processing unit (s) that maintain the software and interface to the fire alarm control unit. The technology potentially speeds detection, while improving immunity to false alarms. *NFPA 72®, National Fire Alarm Code®,* now recognizes this technology.

Foam-Water Sprinkler Systems

This chapter has dealt with foam characteristics, foam concentrate, test standards, and manual application techniques. In particular, applications in the aviation industry were described. The text on aircraft hangar protection addressed the concept of fixed foam protection systems. Much of the foam-water sprinkler system test data was originally developed for aircraft hangars. Herein, foam-water sprinkler system design criteria for other applications are described. Again, emphasis is placed on AFFF systems because they are more effective for extinguishment than protein or fluoroprotein systems.

Codes, Standards, and Regulations

Overhead foam-water sprinkler systems, as specified in the NFPA standards, are generally designed to serve dual purposes: (1) to control and/or suppress a fuel spill fire and (2) when the foam runs out, to cool materials with water. Because the systems are designed to provide protection for flammable/combustible liquid hazards and ordinary combustibles, the specified application rates reflect this dual-protection approach. Table 47.4 shows the fundamental application rates used by Underwriters Laboratories on hydrocarbon fuel fires to evaluate sprinklers discharging foam-water. The fire must be extinguished within 5 min for AFFF discharged at 4.1 L/min/m^2 (0.10 gpm/ft^2) for standard sprinklers and 6.6 L/min/m^2 (0.16 gpm/ft^2) for agents discharged from foam-water sprinklers (air aspirating). However, because most deluge and closed-head sprinkler systems are installed in industrial occupancies for property protection concerns, they must usually meet highly protected risk (HPR) insurance requirements. As a result, the NFPA standard for deluge and closed-head AFFF systems (NFPA 16, *Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems*) requires 6.6-L/min/m^2 (0.16-gpm/ft^2) minimum water application. This water application rate also provides a safety factor over the 4.1 L/min/m^2 (0.10 gpm/ft^2) rate at which AFFF discharged from sprinklers is effective on pool fires. The safety factor is reflected in Table 47.4 under the column heading Minimum Application Rate.

Table 47.18 summarizes current requirements from NFPA standards. NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam,* is geared toward petroleum and chemical industry protection. Previous requirements from NFPA 11 allowed 4.1 L/min/m^2 (0.10 gpm/ft^2) for loading racks, for example, tank truck loading facilities. The latest requirements for NFPA 11 eliminate this design criterion and reference NFPA 16 requirements, which require 6.6 L/min/m^2 (0.16 gpm/ft^2). In special situations, 4.1 L/min/m^2 (0.10 gpm/ft^2) is permitted by NFPA 11, but only where there is low-level or manual application for a hydrocarbon fuel spill. NFPA 16 is consistent in requiring 6.6 L/min/m^2 (0.16 gpm/ft^2); it references other NFPA standards for special exceptions, for example, NFPA 409, *Standard on Aircraft Hangars,* and NFPA 30, *Flammable and Combustible Liquids Code*. NFPA 409 requirements were previously

Table 47.18 NFPA standards related to AFFF sprinkler systems

Standard*	Minimum AFFF application rate (L/min/m^2 [gpm/ft^2])	Duration (min)
NFPA 11, (2010) *Standard for Low-, Medium-, and High-Expansion Foam*	Indoor storage tank greater than 37 m^2 (400 ft^2) 6.6 (0.16)	30
	Loading rack monitors 4.1 (0.10)	15
	Diked areas	
	Fixed low level (Class II hydrocarbon) 4.1 (0.10)	20
	Monitor 6.6 (0.16)	20
	Undiked areas for AFFF handlines 4.1 (0.10)	15
NFPA 16, Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems (2015)	6.6 (0.16)	10 min; 7 min if above minimum design
NFPA 409, Standard *on Aircraft Hangars (2016)*	Overhead deluge 8.2 (0.20) for aspirated AFFF 6.6 (0.16) for non-air-aspirated AFFF	10 min; 7 min if above minimum design
	Supplemental low level (for shielded wing areas) 4.1 (0.10)	10 min

Table 47.19 Foam application rate for marine hydrocarbon hazards (NFPA 11)

Type of hazard	Calculation of rate
Deck spill	6.50 L/min/m^2 (0.16 gpm/ft^2) or 10 % of the cargo block area
Largest tank	9.78 L/min/m^2 (0.24 gpm/ft^2) of the single largest tank area
Largest monitor	3.0 L/min/m^2 (0.074 gpm/ft^2) of the area protected by the largest monitor (not less than 1250 L/min)

Table 47.20 Foam application rate for marine polar solvent hazards (NFPA 11)

Type of hazard	Calculation of rate
Deck spill	Rate for most hazardous polar solvent × 10 % of the cargo block area
Most demanding	150 % of the highest required foam tank application rate for the single largest tank
Largest monitor	45 % of the highest required foam application rate applied over the area protected by the monitor (not less than 1250 L/min)

discussed. Chapter 48 provides an example for calculating foam quantities based on design application rates and areas to be protected.

With the publication of the 1998 edition of NFPA 11, marine foam application was specifically addressed. Foam application rates are required to be not less than the greatest of that required for deck spills, the largest tank, or the largest monitor solution flow rate as shown in Table 47.19 for hydrocarbon fuels and Table 47.20 for polar solvents. For polar solvents, standardized fire tests are used to determine the minimum foam design application rate for the most difficult extinguishment case. Foam concentrates for hydrocarbon fuels must be approved using a 9.29-m^2 (100-ft^2) fire test similar to UL 162. The fixed-nozzle gasoline fire test has an extinguishment application density of 12.2 l/m^2 (0.30 gal/ft^2).

Model building and fire codes in the United States have adopted AFFF protection criteria for the storage of flammable and combustible liquids. Criteria of insurance companies are usually similar to the NFPA requirements, but this needs to be verified. Insurance authority guidelines should be referenced for specific projects, because there can be differences in protection criteria.

Protection of Stored Flammable and Combustible Liquids

Flammable and combustible liquids are stored in containers ranging in size from less than one quart to several hundred gallons. These liquids may be stored for display in a retail outlet or "superstore," stored for distribution in a general-purpose warehouse housing many different combustibles, or stored in "liquid" warehouses containing large quantities of the liquid. NFPA 30, *Flammable and Combustible Liquids Code,* addresses these situations. This code includes requirements for tank storage, piping systems, containers, and operations. Criteria for suppression system protection is addressed in the sections dealing with container storage.

The protection of flammable and combustible liquids is a function of many factors, including the liquid properties, the ignition (which can be a factor of the storage occupancy), the packaging system (e.g., stored in cardboard cartons), the container design and material (e.g., steel, plastic, glass, fiberboard), and the arrangement of storage (e.g., rack versus pallet, storage height, aisle width, and mixture of other combustibles in the array). Based on these factors, a suppression system is provided to control or suppress the anticipated fire and protect the structure. The system may be designed to (1) control a fire so that the fire department can ultimately extinguish or suppress the burning material or (2) suppress the fire. Variables in suppression system design include application rate, fire fighting agent, and sprinkler orifice size, spacing, response time index (RTI), temperature rating, and use of in-rack sprinkler protection.

The basis of protection criteria in NFPA 30 is now well documented. Fire test references and associated citations in technical literature are now included with all protection criteria [68]. The basis of the protection criteria can now be directly linked to test data or engineering extrapolations of the data. Material in Appendix E of NFPA 30 provides guidance and an example test protocol for evaluating protection of liquids stored in the containers. This includes consideration of the source of the fire, which may be a "point" ignition (i.e., small ignition) or a large spill/three-dimensional fire. Depending on other variables, such as container type and packaging material, one of these scenarios may be more difficult to protect. Annex E of NFPA 30 provides detailed guidance on this subject.

Stored liquids may be protected using water sprinklers, foam, or other approved methods. Figure 47.21 shows a conceptual grouping of water and AFFF protection methods as a function of container type and storage method for water protection of liquids. The reader should consult Nugent [68]. The basis of AFFF protection is described in the following sections.

Protection of Drum and Tank Storage Some of the earliest work using AFFF sprinklers involved the protection of 208 L (55 gal) drums. In work conducted at Factory Mutual Research Corporation, sponsored by Allendale Insurance, Factory Insurance Association (FIA), and the 3 M Company, the effectiveness of standard sprinklers supplied with AFFF for controlling drum fires was determined [69]. Five fire tests were conducted in simulated flammable liquid-drum storage using two types of storage arrangements. Three tests were conducted with two-, three-, and four-high palletized drum storage, respectively. Two tests were conducted with five-tier high-rack storage of palletized drums.

In all tests, a heptane fuel supply simulated leakage from the upper level of storage. Except for one rack-storage test that used a 57 L/min (15 gpm) spill rate, fuel spillage was 7.6 L/min (2 gpm). Ceiling protection employed high-temperature sprinklers at discharge rates of either 12.3 or 24.6 L/min/m^2 (0.30 or 0.60 gpm/ft^2). In-rack supplemental protection for the rack-storage tests was provided at three levels, with ordinary temperature sprinklers each discharging 113 L/min (30 gpm). The success of each test was based on storage stability, that is, no pile collapse, and limitation of drum pressure to 104 kPa (15 psig).

AFFF was effective in controlling spill fires on the floor. The exception was in areas not

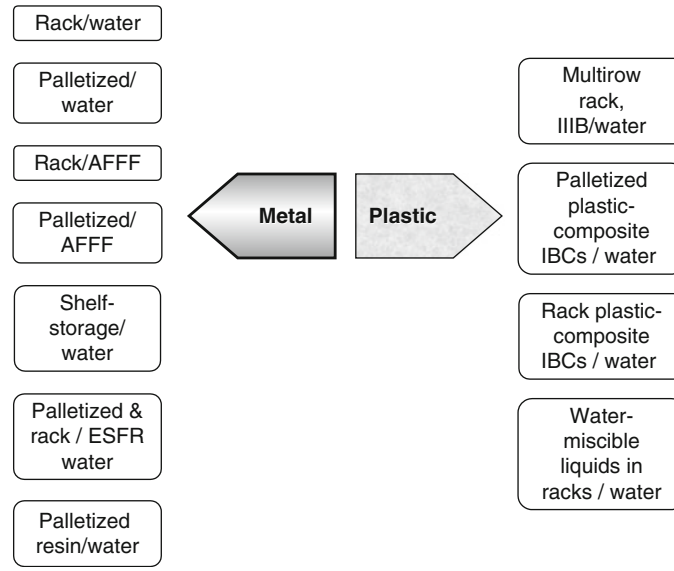

Fig. 47.21 Grouping of NFPA 30 protection criteria for liquids

reached by the discharge from operating sprinklers, where the flow of foam was blocked by pallets. Protection was not effective on the three-dimensional spill fires. Fire exposure and resultant pressure development within drums was more severe with increased clearances between storage and sprinklers due to greater delays in sprinkler operation.

Generally, results were considered good in the rack-storage tests, where in-rack sprinklers were provided in each tier. For palletized storage, the AFFF protection controlled the floor fire although pallets hindered the spread of foam. Ceiling sprinklers alone did not adequately protect palletized storage where an elevated spill resulted in a three-dimensional fire within the pile.

The results of these tests were used, along with engineering judgment, to develop AFFF protection criteria in NFPA 30, *Flammable and Combustible Liquids Code*. AFFF protection of 12.3 L/min/m^2 (0.30 gpm/ft^2) at the ceiling for rack protection of metal drum/tank storage up to 7.6 m (25 ft) high is specified. In-rack protection (e.g., sprinklers in alternating tiers or every tier) is a function of the liquid (flashpoint) container style (relieving vs. nonrelieving), and capacity of the container.

The results of the original Factory Mutual (FM) drum tests were extended in a series of tests conducted by Southwest Research Institute [70]. The objective was to test the effectiveness of relieving-style steel drums and varying degrees of overhead sprinkler protection to mitigate fire hazards associated with the storage of flammable liquids. Nylon plugs inserted in the 5.1 cm (2.0 in.) pour hole and 1.3 cm (0.5 in.) vent hole were designed to melt under fire conditions, allowing the drum to vent any built-up pressure. Heptane, a Class IB flammable liquid, was used as the stored commodity.

Tests were designed to model credible, worst-case loss scenarios involving the 208 L (55 gal) storage of the commodity. The fire modeled the accidental puncture of a full drum, and either an immediate or a delayed ignition source. Sprinkler suppression of the fire was monitored for the duration of the spill, and until flames were either under control or completely extinguished. Commodity was stacked in a 3 × 3 palletized array, to varying heights (2, 3, or 4 high), and protected with varying sprinkler types and densities.

The relieving-style closures were successful at mitigating the hazards associated with overpressurizing drums during a fire. The installed suppression systems were capable of either extinguishing or controlling the fire for the duration of the spill. A summary of the successful protection configurations for the commodity tested is provided in Table 47.21.

Table 47.21 Summary of heptane-palletized drum storage tests [70]

Test	Commodity	Protection (nominal application rates)
2 and 3	3 × 3, 2 high	3 % AFFF at 12.3 L/min/m^2 (0.30 gpm/ft^2)
5	3 × 3, 2 high	ELO water-based at 24.6 L/min/m^2 (0.60 gpm/ft^2)
7	3 × 3, 3 high	ELO, 3 % AFFF at 18.5 L/min/m^2 (0.45 gpm/ft^2)
8	3 × 3, 4 high	ELO, 3 % AFFF at 24.6 L/min/m^2 (0.60 gpm/ft^2)

The fuel spill rate (7.6 vs. 56.8 L/min) was found to have a substantial impact on the fire exposure of the drums. When taken in conjunction with the effect of the ignition scenario, the fuel spill rate had a strong influence on the number of initial heads operating and on the duration of the fire exposure. The ignition of the fuel source also played a role in the number of heads actuated during a test. The immediate ignition of fuel (simulating a spill onto an existing ignition source) resulted in a slower growing fire, actuating fewer sprinkler heads. Alternately, an ignition scenario where a 7.6 L spill was allowed to develop prior to ignition resulted in the actuation of four heads within the first minute of fire exposure. A comparable test with the immediate ignition scenario resulted in only two heads operating in a time in excess of 2 min and 30 s. The involvement of fewer sprinkler heads and the prolonged fire exposure implied that the immediate ignition provided a more challenging scenario.

The AFFF system used in the test program was successful in generating a good blanket of foam within 1 to 2 min of actuation (depending on the number of initial heads actuated). The foam quality was such that it was free to flow over drum heads, providing cooling to the tops and sides of drums, and forming a blanket at the floor to suppress pool fires. The foam system (in Tests 6 through 8) was also effective at limiting the fire at the fuel introduction point, periodically extinguishing the source. In general, by the time fuel flow to the array was complete, the foam system had suppressed all pool fires, leaving only small pallet fires for manual suppression.

An initial survey of closure obstruction versus venting phenomenon indicated that there was little or no effect on the obstruction of a plug and its ability to vent. This is indicated by the low number of drums that exhibited bulging during tests. The bulging of a drum indicates an unusual buildup of pressure. This phenomenon was not consistent, even in drums where both closures were obstructed. It was also noted that even partial venting of either opening was sufficient in reducing the pressure within the drum.

Drum deformation was recorded on a subjective basis. Typical deformation involved bulging of the head of the drum by 1.2 to 2.5 cm (0.5 to 1.0 in.). In some cases, deformations were seen on the order of 7.6 to 10.2 cm (3 to 4 in.) with some unfurling of the head chime.

It is difficult to attribute the level of deformation with a corresponding internal pressure. Several drums were deformed to a degree consistent with hydrostatic pressures of 207 to 241 kPa (30 to 35 psi); however, no pressures of this magnitude were recorded. A possible reason for higher levels of deformation at lower pressures may lie in the exposed temperatures of the drums. Several drums were subjected to uneven heating. The uneven heating phenomenon is present where a drum is located directly above a pallet containing venting drums. This scenario sets the subject drum over an isolated flame source, heating it from below.

The results of these tests have been included in the NFPA 30 protection criteria tables for palletized steel drum storage up to four high when protected using AFFF. The use of listed relieving devices is recommended; the exact details of this listing procedure are being developed.

Liquid Spill and Container Storage Table 47.22 summarizes early closed-head AFFF sprinkler testing on a flammable liquid spill [71]. In a 9.1-m (30-ft) high ceiling room, *n*-heptane was discharged in a simulated spill to create a three-dimensional spill and a two-dimensional pool fire. Fuel spill rate was varied up to 113 L/min (30 gpm). AFFF application rates were 4.5 to 12.3 L/min/m^2 (0.11 to 0.30 gpm/ft^2). The

Table 47.22 Closed-head sprinkler tests [71]

Sprinkler temperature rating (°C [°F])	Nominal application rate (L/min/m^2[gpm/ft^2])	Total heads opened	Sprinkler operation and control times (min:s)
71 (160)	4.5 (0.11)	34	First sprinkler—0:27
			Final sprinkler—1:01
			3:50 Control time
71 (160)	7.4 (0.18)	32	First sprinkler—0:22
			Final sprinkler—1:08
			1:00 to 1:20 for knockdown
			2:20 Control time
138 (280)	7.4 (0.18)	7	First sprinkler—0:33
			Final sprinkler—0:531
			1:50 Control time
138 (280)	7.4 (0.18)	15	First sprinkler—0:28
			Final sprinkler—1:44
			2:20 Control time
138 (280)	7.4 (0.18)	17 to 19	First sprinkler—0:22 to 0:24
			Final sprinkler—1:03 to 1:13
			2:00 Control time
141 (286)	12.3 (0.30)	10	First sprinkler—0:24
			Final sprinkler—1:10
			2:25 Control time

primary variables were the temperature rating of the sprinkler and the application rate. Non-air-aspirating sprinklers were used. The data show that high-temperature-rated sprinklers, activated at about the same time as ordinary temperature sprinklers, controlled the fire in comparable times (roughly 2 min control time), and resulted in significantly fewer sprinklers operating (7 versus 32). An increase in application rate when the high-temperature sprinklers were used resulted in fewer heads operating, but did not decrease overall control and extinguishment time. Fires were controlled, but not totally extinguished as a result of the three-dimensional spill fire. These tests showed the advantage of using high-temperature-rated sprinklers in AFFF closed-head suppression systems.

In response to the concerns related to flammable liquid warehouse protection, the National Fire Protection Research Foundation (NFPRF) initiated the International Foam-Water Sprinkler Research Project. The objectives were to document the performance of foam-water sprinkler systems designed for real-world storage and ignition scenarios and provide a design basis and minimum design parameters for foam-water sprinkler systems. Five tasks were performed, including a literature search, range-finding tests, and large-scale tests involving palletized and rack storage of liquids.

The literature search identified over 1100 sources of information related to flammable liquid fires and foam protection, but a dearth of data related to water and foam-water sprinkler suppression of liquid storage fires [72]. The range-finding tests indicated that the Class IB flammable liquids (heptane) provided a greater challenge than water-miscible fuels (e.g., isopropanol) [73]. Breach of steel containers exposed to a flammable liquid pool fire without sprinkler protection occurred over a range of times between 2 and 7.5 min, depending on the particular type of container. Plastic containers were quickly breached and discharged their contents to the exposing pool fire.

Large-scale tests were conducted under an 8.2-m (27-ft) high ceiling at the Underwriters Laboratories fire test facility in Northbrook, Illinois [74]. A series of 14 fire tests involving the protection of 3.8 and 18.9 L (1 and 5 gal) metal and 18.9 L (5 gal) plastic containers filled with heptane (Class IB flammable liquid) were

conducted. The use of closed-head foam-water sprinkler systems for the protection of these fuel packages was investigated. Quantities of fuel used in the fire tests varied from 605 to 7260 L (1601920 gal); fuel storage densities ranged from 160 to 1907 L/m^2 (3.9–46.5 gal/ft^2); and storage heights ranged from 4.3 to 42.7 m (1.3–13 ft). Each fire test was initiated using a 37.8 L (10 gal) flammable liquid (heptane) spill, recognizing the larger spill ignition scenarios observed in large-loss fires.

Fire tests involving palletized storage of 3.8 L (1 gal) metal F-style containers of heptane, packaged four containers in a corrugated cardboard carton, were conducted. The results indicated that the 37.8 L (10 gal) flammable liquid spill fire could be suppressed by a closed-head foam-water sprinkler system at a 16.4 L/min/m^2 (0.40 gpm/ft^2) design application rate for storage heights up to 3.3 m (10.7 ft) under the 8.2 m (27 ft) ceiling prior to any container breach or fuel loss. Fires involving 18.9 L (5 gal) metal containers of heptane could be suppressed by a closed-head foam-water sprinkler system application rate of 12.3 L/min/m^2 (0.30 gpm/ft^2) for a palletized storage height of up to 3.6 m (12 ft). Plastic pour spouts in the 18.9 L (5 gal) tight-head metal containers safely vented and prevented container breaching.

Fires involving 18.9 L (5 gal) plastic containers of heptane could not be suppressed by a preprimed, closed-head foam-water sprinkler system with an application rate of 12.3 L/min/m^2 (0.30 gpm/ft^2), where containers were stacked one high (483 mm [19 in.]), due to container breaching and flammable liquid spillage prior to foam-water discharge.

Rack-storage tests also conducted in the NFPRF International Foam-Water Sprinkler Research Project did not lead to conclusive results [75].

Based on the results of the NFPRF foam-water sprinkler testing, the FMRC original AFFF drum testing, and engineering judgment/extrapolation, the NFPA 30 Technical Committee adopted protection criteria for palletized and rack storage of liquids in metal containers when protected by AFFF. Variables that affect the specific level of protection include container size, class of liquid stored, inclusion of exterior packaging material, and storage height. Ceiling application rates are on the order of 12.3–16.4 L/min/m^2 (0.30–0.40 gpm/ft^2). Protection criteria shown in Table 47.23 are recommended for palletized storage of small containers that are nonrelieving style (i.e., do not readily vent when exposed to fire). Additional criteria are included in NFPA 30 for foam protection of palletized relieving-style containers based on extrapolation of the NFPRF data and engineering judgment. Where the hazard involves a water-miscible fuel, an alcohol-type foam should be used. The application rate should be at least as great as the rate established by foam listing requirements. AFFF solution should be discharged when four sprinklers are operating.

AFFF protection of flammable and combustible liquids should be used where large spills of low flashpoint fuels are a realistic scenario. Other protection options are available and have recently been adopted or are currently being considered by NFPA 30 and the model building/fire prevention codes. Designers of warehouse protection should have a thorough knowledge of these criteria and the available test data (including water-only protection) when considering design options for the protection of stored combustible and flammable liquids. Nugent [68] and NFPA 30 provide detailed data and guidance for water-only protection. Additional guidance for warehouse protection is available from the Center for Chemical Process Safety [76].

Foam Environmental Considerations

There has been increasing concern about the consequences of the discharge of foam in the environment. This concern affects the users of foam, the manufacturers of foam agents, the fire safety authority having jurisdiction, and environmental authorities. The issue is not a new or unique development but has received increased notice as a result of increased attention to environmental impact of fire-fighting agents.

Factors related to the impact of fire-fighting foam on the environment include

Table 47.23 AFFF sprinkler protection requirements in NFPA 30 for solid-pile and palletized storage of flammable and combustible liquids in non-relieving-style metal containers of 18.9 L (5 gal) capacity or less

Package type	Cartoned	Uncartoned
Class liquid	IB, IC, II	IB, IC, II
Application rate (L/min/m^2 [gpm/ft^2])	16.4 (0.40)	12.3 (0.30)
Area (m^2 [ft^2])	186 (2000)	186 (2000)
Temperature rating (°C [°F])	141 (286)	141 (286)
Maximum spacing (m^2/head [ft^2/head])	9.3 (100)	9.3 (100)
Orifice size (mm [in.])	13.3 (0.53)	12.5 or 13.3 (0.5 or 0.53)
Maximum height (m [ft])	3.4 (11)	3.7 (12)
Hose (L/min [gpm])	1891 (500)	1891 (500)
Water supply duration (min)	120	120
Foam supply duration (min)	15	15

1. Discharge of foam solutions and fuel-contaminated foam solutions to waterways and the potential toxicity to aquatic life
2. Effects on water treatment facilities
3. Persistence and biodegradability of chemicals in foam concentrates and solutions
4. Combustion products of fuel/foam solutions

In the United States, all fire-fighting foams are regulated at some point during their life cycle, and all have the potential to impact the environment. Fire-fighting foams have several intrinsic properties that cause environmental impacts, including foaming, oxygen demand, aquatic toxicity, biodegradability, and oil emulsification. Because of these properties, fire-fighting foams will impact surface water and groundwater if released into the environment. If sent to a wastewater treatment plant, they can cause disruption of the plant, preventing sewage from being treated and forcing the plant to discharge raw sewage.

All fire-fighting foams have these properties because they consist of ingredients that exhibit these properties. The main ingredients in fire-fighting foams are water, surfactants, solvents, and other ingredients used to make the foam work in a particular system or under specified conditions. Some of these ingredients are specifically listed in U.S. environmental laws because of their environmental impacts (e.g., butyl carbitol, dipropylene glycol methyl ether, ethylene glycol, etc.). Although it is easier to highlight these as being regulated because they are specifically named, almost all of the ingredients in fire-fighting foams are regulated due to their properties.

The properties and ingredients of fire-fighting foams make them subject to U.S. federal environmental laws that regulate their manufacture, storage, use, release, cleanup, remediation, and disposal. These laws include the Clean Water Act (CWA); Clean Air Act (CAA/CAAA-90); Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA or Superfund); the Superfund Amendments and Reauthorization Act (SARA); the Emergency Planning and Community Right-to-Know Act (EPCRA); the Resource Conservation and Recovery Act (RCRA); the Hazardous and Solid Waste Amendments of 1984 (HSWA); the Safe Drinking Water Act (SDWA); the Toxic Substances Control Act (TSCA); and the Uniform National Discharge Standard (UNDS). These laws cover the entire life cycle of fire-fighting foams from manufacture to final disposition.

Whether foams are used in fixed facility systems or on crash fire-rescue vehicles, mitigating the environmental impacts is best accomplished through careful planning and management. This forethought may include engineered systems for capture and containment, temporary containment equipment, improved standard operating procedures, and other measures. Simple substitution of one "environmentally friendly" foam for another will not eliminate environmental impacts. In order to make the final decision to use any type of system

for fire protection, it is essential to fully review the fire and environmental risks and benefits of using fire suppression chemicals and their associated systems. The review should involve both fire protection and environmental professionals to ensure a balanced approach that guarantees maximum fire protection and environmental protection at the same time.

Fluorinated Surfactants

AFFF fire fighting agents contain fluorinated surfactants (fluorosurfactants). They are key ingredients that provide AFFF with the required low surface tension and positive spreading coefficient that enables film formation on top of hydrocarbon fuels. This provides for superior fire extinguishment capability as described earlier.

Environmental regulators have investigated AFFF chemicals for their persistence, tendency to bioaccumulate, and toxicity (PTB). As part of this assessment process, the AFFF manufacturing industry has formed a coalition to represent the fire fighting foam industry's interests on all issues related to the environmental acceptability of AFFF agents. The Fire Fighting Foam Coalition (FFFC) provides periodic updates on the status and use of chemicals used to create AFFF [77]. They note that the chemicals used to produce fluorosurfactants can be manufactured by different processes and have different chemical structures. The fluorosurfactants used in AFFF have historically been produced from fluorochemicals manufactured by two methods: electrochemical fluorination and telomerization.

In 2002, the US manufacturer of fluorosurfactants using the electrochemical fluorination process voluntarily stopped production of a number of products including AFFF agents because they contain and degrade into perfluorooctane sulfonate (PFOS). PFOS is considered by environmental authorities to be PBT. Regulations in the United States, Canada, European Union, Australia, and Japan act as a ban on new production of PFOS-based products including foams. These regulations do not currently restrict the use of existing stocks of PFOS-based foam in the US, Australia, or Japan. In the EU and Canada, existing stocks of PFOS-based foam must be removed from service over a set time period. A general overview of this regulatory restriction on PFOS in the US is available in the general fire service literature [78].

Other AFFF agents contain telomer-based fluorosurfactants. Telomer-based AFFF agents do not contain or break down into PFOS. Telomer-based AFFF agents are not made with any chemicals that are currently considered by environmental authorities to be PBT. The US Environmental Protection Agency (EPA) has indicated that some telomer-based fluorochemicals can break down in the environment into perfluorooctanoic acid (PFOA) or other perfluorocarboxylic acids (PFCAs). EPA's concern is focused on long-chain perfluorinated chemicals (LCPFCs) containing eight carbons or more (C8, C10, C12). Existing data shows that shorter-chain compounds (C6 and below) have a lower potential for toxicity and bioaccumulation. Under an EPA stewardship program, fluorochemical manufacturers have voluntarily agreed to reduce both plant emissions and product content of PFOA, PFOA precursors, and related chemicals. This will result in the reformulation of many existing telomer-based AFFF agents.

The restrictions on the manufacture and use of AFFF has resulted in industry creating a new class of foams, "fluorine-free" foam. Preliminary test data show that these non-film forming foams take longer to extinguish fires compared to AFFF [79], but have better fire extinguishing performance than protein or fluoroprotein foams. This is not surprising since the fluorosurfactants used to create the "film" in AFFF have been eliminated. Users may be faced with trade-offs in selecting foams for fire performance and environmental impact. If reduced fire extinguishing performance must be accepted for lower environmental impact, priorities for protecting hazards may have to be established. An example methodology has been published by the U.S. Navy [80].

Perspective on the Use of Foam Agents

In order to assess the impact of foam on the environment, the likely scenarios under which AFFF may be discharged should be considered. Based on these scenarios, the overall impact can be assessed and, where appropriate, potential mitigation strategies can then be developed. Likely scenarios include uncontrolled fires, potential hazardous situations, fire-fighting training evolutions, and fixed or mobile vehicle suppression system discharge testing.

Uncontrolled Fires There are many fires for which foam may be used, including flammable liquid storage, process industry protection, aviation protection, and marine applications. For most fires, the elimination of foam as a suppression agent results in the potential for dramatically increased environmental impact. This impact results from the potential increase in hydrocarbon fuel effluent to the environment (due to smoke from uncontrolled burning and fuel/fire-fighting water effluent). Consider the example shown in Fig. 47.22. A 929 m^2 (10,000 ft^2) section of a warehouse containing combustible and flammable liquids may be protected using traditional water sprinklers discharging at a rate of 12.3 L/min/m^2 (0.30 gpm/ft^2). If these sprinklers fail to control a large spill fire, the fire may develop and spread past the design area of the sprinklers. The example assumes the fire is contained within the fire wall; this may not always be the case for high-challenge fires. If the fire department aggressively combats the fire, a rough estimate of fire-fighting water that may be used is 15 to 50 times the minimum anticipated agent required for suppression [6, 81, 82]. A rough estimate of the potential fuel-contaminated effluent (neglecting the actual quantities of hydrocarbon liquid) is shown in Fig. 47.22. In the alternative situation, a properly specified foam-water sprinkler system designed for a high degree of reliability can control or suppress the fire. Using application rates and discharge times based on recent tests and building code requirements, the anticipated fuel/foam-water effluent for this scenario can be estimated (see Fig. 47.22). The use of the foam-water system reduces the potential effluent by a factor of

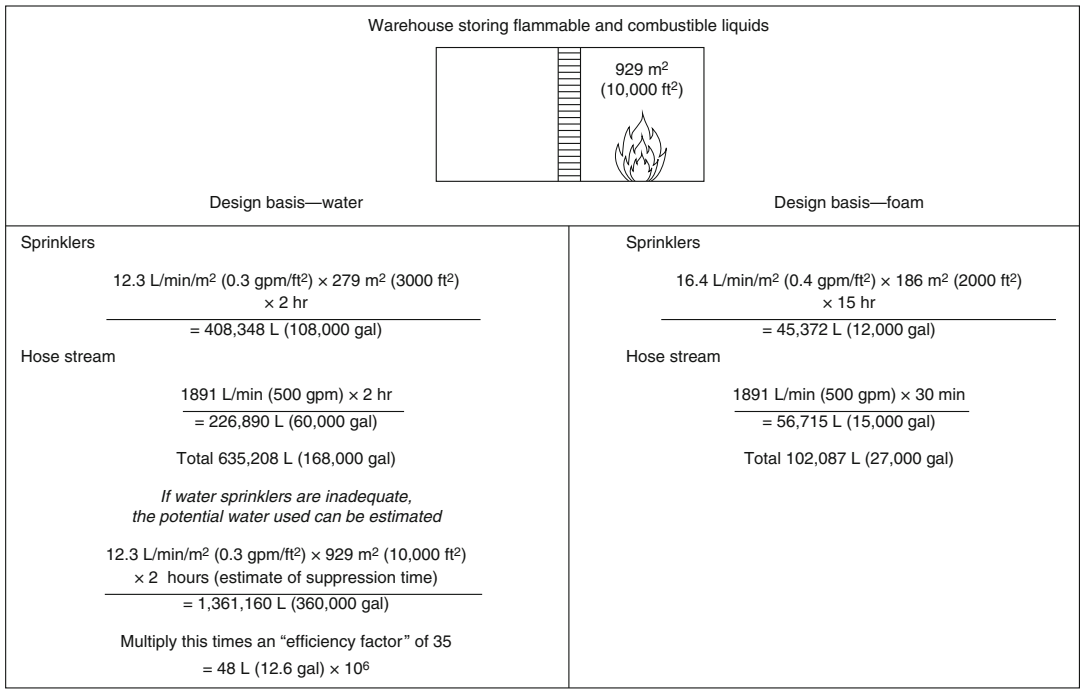

Fig. 47.22 Example of potential effluent from flammable liquid warehouse fire

nearly 500 compared to the "unsuccessful" water sprinkler scenario where handlines are used. This reduction neglects the impact of smoke discharged to the atmosphere during the uncontrolled burning in the water-only scenario.

In some cases, it may be possible to collect the effluent from an uncontrolled fire. In other situations, it may not be possible. Any foam solution that has been used in fire suppression is likely to be contaminated with fuel and diluted with water.

Potential Hazardous Situations Potential hazardous situations may result from a fuel spill where there is a likely ignition source. In this situation, foam may be applied for ignition prevention. The potential impact of ignition and resulting uncontrolled fire must be assessed against the potential additional environmental impact by discharging foam for ignition prevention. The potential environmental effects from an uncontrolled fire should be considered as described in the previous text. Another consideration is the assessment of any additional impact of foam when applied to a fuel spill. For example, would the resulting fuel with foam have any greater impact on the environment than the fuel alone? If so, how is this impact quantitatively determined?

Training Evolutions Fire-fighting training is usually conducted under conditions conducive to collection of fuel, water, and foam. A separation process might be used to recover fuel. Water/foam solution may then be treated or reused. Alternatively, simulated hydrocarbon fuel spill scenarios might be used, with a simulated foam agent. Propane-fired burners are typically used. The disadvantage of these systems is the potential loss of realism of the simulated fire/agent interaction. These techniques may potentially reduce training effectiveness. Quantitative comparisons have not been performed to assess these differences.

System Discharge Testing Facilities protected by foam systems may have containment systems that can hold effluent. Requirements for these containment systems are becoming more widespread in model building and fire codes. An alternative to discharge testing with foam is the use of a simulant that can be measured using concentration determination methods. For example, salt solutions can be used as the "concentrate" to test AFFF systems, with the simulant concentration measured using the conductivity method. Simulators may be more difficult to use for protein-based systems, where viscosity factors influence proportioning system accuracy.

Because of their persistent nature, NFPA 11 recommends that emissions of fluorochemical surfactants to the environment be minimized whenever possible using the following techniques:

1. Use training foams that do not contain fluorochemical surfactants.
2. Provide for containment, treatment, and proper disposal of foam discharges.
3. Follow applicable industry standards on the design, installation, and maintenance of foam systems and extinguishers.
4. Minimize false discharges from fixed foam systems by using approved detection, actuation, and control systems as required by industry standards.
5. When appropriate consider treating collected wastewater with granular activated carbon (GAC) or a membrane process such as reverse osmosis to remove the fluorochemical surfactants prior to disposal.

Methods of Assessment

Biodegradability The primary component of AFFF solution is water. Examples of other components are nonfluorinated surfactants, glycol ethers, and fluorinated surfactants. Freeze-resistant concentrate may contain ethylene or propylene glycol. Alcohol-type foams contain xanthan or similar gums. The fluorinated surfactants are particularly resistant to biodegradation. Further, the less-effective protein-based foams were largely assumed to be nonpolluting because of their "natural" organic base. An early review of the available literature by Factory Mutual Research Corporation indicated that both

types of agents, that is, AFFF and protein-based, present inherent environmental issues and that effluents containing either should be processed in some form of sewage treatment facility or diluted prior to discharge into a stream [47].

A conventional method used to determine the biodegradability of a material is comparison of the chemical oxygen demand (COD) of the material with its biological oxygen demand (BOD). This method is particularly important for waste treatment facilities where the stability of the treatment process may be upset. The method typically used is specified in *Standard Methods for the Examination of Water and Wastewater* [83]. BOD measures the amount of oxygen consumed by microorganisms in breaking down a hydrocarbon. COD measures the maximum amount of oxygen that could theoretically be consumed by microorganisms. Therefore, a BOD/COD ratio is representative of the ability of microorganisms to biodegrade the components in a foam. The higher the BOD/COD ratio, the more biodegradable the foam. Results reported for BOD/COD of AFFF range from 0.60 to 0.99. MIL-F-24385 requires a maximum COD of 500,000 mg/l and a minimum 20-day BOD/COD ratio of 0.65 for 6 % concentrate. AFFF agents have been reported to have higher BOD and COD values than protein foams. [47] AFFF solutions are high-BOD materials compared to the normal influent to treatment plants. Large quantities can "shock load" wastewater treatment facilities.

The fluorochemical-based surfactants in AFFF have a carbon–fluorine chain that apparently does not break down in either the BOD or the COD test. The AFFF might then appear to be completely "biodegradable," even though the carbon-fluorine chain remains.

If nonbiodegradability concerns are based on the persistence of the fluorochemical surfactants, then the environmental impact tests currently used to assess foams do not address this concern. There is speculation that the undegradable material is biologically inert, but no published data confirm this. Because the fluorinated surfactants are required to create surface-tension reduction of the solution, replacement with less persistent chemicals is problematic. There is a need for a more thorough understanding and testing related to the environmental impact of fluorosurfactants and possible alternatives.

The persistence of fluorosurfactants in soil has been quantified in a study of fire-training facilities [84]. In a study of training sites having long-term use, perfluorocarboxylates were detected using gas chromatography/mass spectrometry. These chemicals were detected at sites that were inactive for a period of 7–10 years. The results are consistent with the view that biodegradation of the long chain perfluorocarbon is unlikely. The influence of the perfluorinated compounds on the biotransformation and transport of other cocontaminants (e.g., training fuel) and other site characterization parameters (e.g., dissolved organic carbon and inorganics) is unknown.

Methods for detecting AFFF in aqueous solutions have been investigated [85]. A Fourier Transform Infrared Spectroscopy (FTIR) method and drain-time test were found to be effective in evaluating the level of AFFF contamination in wastewater and soil. The drain-time method was proposed as a simple, easy-to-use field test. Using these methods, procedures were developed to estimate AFFF contamination levels in wastewater and soil. Analysis of wastewater and soil for AFFF contamination was broken into two groups: nonbiodegraded samples and biodegraded samples. Nonbiodegraded samples were screened for AFFF, then analyzed further if deemed necessary. Samples were initially screened using the drain-time test. Samples with no drain time contain less than a 1:240 dilution of AFFF (5 ppm of fluorosurfactant). If the sample had a drain time, it was recommended that the FTIR analysis be performed on the sample. In solutions with fluorosurfactants, FTIR analysis can provide a quantitative level of AFFF in the sample if the fluorosurfactant source solution is available to develop a calibration curve. Otherwise, FTIR provides a qualitative estimate of the AFFF level in the solution.

Biodegraded wastewater samples were difficult to analyze because the hydrocarbon surfactants and a portion of the fluorosurfactant molecule were degraded. With these foam-

making constituents degraded, the drain-time test results were found to be unreliable. However, the fluorine-carbon tail of the fluorosurfactant is not biodegraded, making FTIR analysis on biodegraded samples possible. With biodegraded samples, FTIR analysis can provide a qualitative measure of AFFF levels.

Toxicity In sufficient concentrations, foams may affect aquatic life. A number of fish toxicity studies have been performed. In tests using fathead minnows, the U.S. Air Force found that these fish could live in a simulated effluent stream containing 250 ppm AFFF without fatality for up to 8 days. LC_{50} values (i.e., the concentration causing deaths of 50 % of the fish exposed) at 96 and 24 h were 398 and 650 ppm, respectively [86]. MIL-F-24385 requires AFFF toxicity testing in accordance with ASTM E729, using dynamic procedures with killifish. LC_{50} of 1000 mg/l for 6 % concentrate is permitted.

Alone, these values may be considered as having a low degree of fish toxicity using environmental regulation rating scales. Localized concentrations in ponds or streams may exceed the values cited, if there is limited water movement.

Published data do not exist for the phytotoxicity of foam solutions; however, there have been no published reports of plant kills resulting from foam solution discharges.

Manufacturers report that thermal decomposition products from AFFF do not present a health hazard during fire fighting. Again, there are no data published in the literature. Manufacturers' product environmental data for AFFF include references to a test where a layer of AFFF was burned in a pan of gasoline inside an enclosure. Two measurements of hydrogen fluoride recorded above the sample were 0.23 and 0.16 ppm [87].

Foaming and Emulsification of Fuels The surfactants in AFFF solutions can cause foaming in treatment aeration ponds. This foaming process may suspend high BOD solids in the foam. If these are carried over to the outfall of the treatment facility, nutrient loading in the outfall waterway may result. Foam aeration may also cause foam bubble backup in sewer lines.

In uncontrolled fires, spills, and live fire-training scenarios, foams may contain suspended fuels. The fuel may become emulsified in the foam-water solution.

A bench-scale study has been conducted to evaluate the potential inhibitory effects of untreated AFFF wastewater on the biological nutrient removal process [88]. In this study, bench-scale reactors simulating the nitrification process were loaded at various AFFF concentrations, and the influence on process performance was evaluated. The results indicated that AFFF in concentrations between 10 and 60 ppm did not show any inhibition to biological nitrification, and effluent did not exhibit any pass-through toxicity. These range-finding tests did indicate that nitrification inhibition did occur above 60 ppm AFFF. Some reductions in percent COD removal were observed as AFFF concentrations were increased.

Mitigation Strategies

Foam discharges are more easily handled where there is an in-place collection capability. This situation may be available at warehouses, tank farms, and fire-fighting training facilities. Where these facilities are not available, temporary diking is an alternative where time and resources permit.

Investigations have been conducted to develop foam-water separators using aeration and agitation techniques. To date, these techniques have not been optimized.

Discharge to water treatment facilities is recommended by many foam vendors when the solution is uncontaminated by fuel. Metering or dilution may be required to prevent levels of foam that will upset treatment facility reactions or cause excessive foaming. The use of defoamers to reduce aeration has been suggested.

Where fuels contaminate foam solutions, fuel-water separators might be used to skim off the hydrocarbon fuel. AFFF solutions have a tendency to form emulsions with fuels, potentially reducing the effectiveness of fuel-water separators. An alternative is to hold the solution in a pond or tank until the emulsion breaks and

the separation process can be used. Agitation should be avoided to prevent the emulsion from reforming. In some situations (e.g., training), the fuel and treated water have been reused. Many fire training facilities collect foam solution for ultimate discharge to water treatment facilities.

To ensure that unbalanced conditions do not occur in water treatment facilities, foam discharge should be carefully monitored. Different ranges of discharge rates have been suggested. This is an area requiring further investigation. Manufacturers of the foam solution should be consulted in conjunction with the wastewater treatment operator.

The entire area of environmental aspects of foam discharge requires additional evaluation and development of generally recognized guidance. Until generally recognized guidance is promulgated, users must rely on manufacturers' data and guidance. In all situations, discussions with the operator of the wastewater treatment facility and the environmental regulatory authorities are appropriate. Work is continuing in an effort to identify appropriate policy and criteria covering foam discharge for facilities having foam suppression systems. These efforts are focusing on identifying applicable codes and standards, analyzing environmental impact, and evaluating containment options.

Nomenclature

$\mathbf{AFFF\%_{sample}}$	percentage of AFFF present in the sample
$\boldsymbol{\alpha_{foam}}$	absorptivity of foam
BOD	biological oxygen demand (mg/l)
$\boldsymbol{\gamma_a}$	surface tension of liquid *a* (dynes/cm)
$\boldsymbol{\gamma_b}$	surface tension of liquid *b* (dynes/cm)
$\boldsymbol{\gamma_l}$	interfacial tension between liquids *a* and *b* (dynes/cm)
COD	chemical oxygen demand (mg/l)
ER	expansion ratio
$\boldsymbol{\Delta H_v}$	combined latent and sensible heads of vaporization (kJ/kg)
$\boldsymbol{\delta}$	viscous boundary layer thickness (cm)
$\boldsymbol{G}$	conductance (mhos)
$\boldsymbol{g}$	acceleration of gravity (cm/s^2)
$\boldsymbol{h}$	foam thickness
$\boldsymbol{h_c}$	critical thickness of the foam layer
$\boldsymbol{i}$	angle of incidence
$\boldsymbol{k}$	foam spreading coefficient, dimensionless or nozzle coefficient (L/min/kPa$^{1/2}$)
$\boldsymbol{k_d}$	foam drainage coefficient, dimensionless
$\boldsymbol{k_e}$	foam evaporation coefficient, dimensionless
$\boldsymbol{l}$	length of foam spread
$\boldsymbol{n}$	refractive index, dimensionless
$\boldsymbol{\mu}$	viscosity (cm^2/s)
$\boldsymbol{\dot{m}_{add}}$	foam addition rate
$\boldsymbol{\dot{m}_{fuel}}$	fuel mass loss rate
$\boldsymbol{\dot{m}_{drain}}$	foam mass loss due to drainage
$\boldsymbol{\dot{m}_{drop}}$	foam loss rate due to drop-out
$\boldsymbol{\dot{m}_{vap}}$	foam mass loss rate due to vaporization
mS	milli siemens
$\boldsymbol{v}$	kinetic viscosity (cm^2/s)
$\boldsymbol{n_{water}}$	refractive index of water, dimensionless
$\boldsymbol{n_{foam}}$	refractive index of foam solution, dimensionless
$\boldsymbol{n_{concentrate}}$	refractive index of foam concentrate, dimensionless
$\boldsymbol{P_v}$	vapor pressure of fuel
$\boldsymbol{\rho_{fuel}}$	fuel density (g/cm^3)
$\boldsymbol{\rho_{foam}}$	foam density (g/cm^3)
$\dot{q}''$	rate of heat transfer
$\dot{q}_{rad}$	rate of heat transfer due to radiation
$\boldsymbol{\dot{q}''_{rad}}$	radiative heat release rate from pool fire
$\boldsymbol{R}$	resistance (ohms)
$\boldsymbol{r}$	angle of refraction
$\boldsymbol{\sigma}$	spreading coefficient (dynes/cm) or conductivity (mhos)
$\boldsymbol{S_{a/b}}$	spreading coefficient between liquids *a* and *b* (dynes/cm)
$\boldsymbol{T}$	temperature (°C)
$\boldsymbol{t}$	time (s)
$\boldsymbol{T_i}$	foam temperature (°C)

T_s	fuel temperature (°C)
V	volume (cm^3 or l^3)
v_s	spreading velocity of foam (cm/s)

Subscripts

add	addition of foam
drain	drainage of foam
drop	drop-out of foam
rad	radiation
vap	vaporization

Superscripts

$\cdot$	rate of change, as in $\dot{m}$
$''$	per unit area

Foam System Calculations

48

Hamid R. Bahadori

Introduction

Foam is a stable aggregation of gas-filled bubbles formed from a homogeneous mixture of water and foam concentrate in predetermined proportions. Foam fire protection is well suited for the control and extinguishment of specific types of fires especially those involving certain arrangements of flammable and combustible liquids. Foam is generally lighter than flammable/combustible liquids; therefore it floats on the liquid surface producing a layer which has multiple advantageous effects. These effects include vapor-sealing of the liquid, cooling of the liquid surface, and limitation of oxygen to the liquid surface.

In addition to flammable and combustible liquid fires, foam can be used to address other types of fire protection problems. Building and fire regulations and standards such as those promulgated by the NFPA address the application of foam systems for an array of fire protection concerns [1].

This chapter discusses the different types of foam systems and describes the calculation procedures to properly formulate the engineering design and analysis of these systems. Although not all applications of foam systems are discussed, the procedures put forth herein will provide a fundamental overview of the steps and considerations involved.

Fire Protection Objectives for Foam Systems

Foam systems can be used to achieve the following objectives with respect to fire safety. Note that foam system can be used as a means of fire prevention as well as fire protection. Also note that the objectives are specific to certain types of fuels and their physical arrangement. The specific objective for the applicable fire scenario will drive the overall design of the foam system.

Objective 1: Secure the production of ignitable vapors from the surface of flammable or combustible liquids.

Depending upon certain physical conditions such as temperature and pressure, flammable and combustible liquids emit vapors that may form ignitable atmospheres in close proximity to the liquid surface. The presence of an ignition source can result in a fast developing fire. The production of the ignitable vapors prior to the presence of any ignition source can be mitigated and controlled by generating a foam blanket that spreads over and covers the entire liquid surface. This objective can be accomplished for stored quantities of liquids as well as for confined liquid spills.

Objective 2: Control and extinguish fires involving localized flammable and combustible liquid fuel spills inside buildings.

Flammable and combustible liquids can be stored inside buildings in drums and other types of containers such as intermediate bulk containers (IBC), subject to the limitations of the applicable codes. These stored liquids can also be used in association with other building operations such as manufacturing processes (dip tanks), industrial machinery, heating equipment, and testing activities. The rupture of a container, feed line or hydraulic line can result in the formation of a liquid pool that can release ignitable vapors. The ignition of these vapors will result in localized fires that can be controlled or extinguished by the application of foam.

Objective 3: Extinguish fires in outdoor atmospheric flammable and combustible liquid storage tanks.

Foam agent fire protection has a long track record of successfully extinguishing fires in outdoor vertical atmospheric storage tanks, and the diked areas in the vicinity of tanks to control fuel spills. This type of protection still represents one of the most common uses of foam agents. Foam agent fire protection has been successfully used to extinguish flammable and combustible liquid fires in atmospheric storage tanks with diameters up to 200 ft (61 m).

Objective 4: Extinguish fires in outdoor and indoor processing areas involving flammable liquids

A wide range of industrial processes machines utilize flammable and combustible liquids. In most processing plants, these liquids pass through pipelines and are captured in holding tanks. Foam agents, properly selected for the hazard, are suitable for controlling and extinguishing fires in process equipment by either applying the foam to the liquid fuel surface or filling the entire space containing the hazard with foam. However, foam agents are not generally suitable for protection of burning ignitable liquids flowing down vertical surfaces, or fires where the ignitable liquid is discharging from an orifice under pressure.

Objective 5: Prevent, control, and extinguish fires for fuels other than flammable and combustible liquids.

Foam systems have been found to be effective for fuels that are not in a liquid state such as rubber tire storage and rack storage of plastic commodities.

Basic Types of Foam System Protection

Foam fire protection systems can generally be classified into one of five categories. Each category is briefly described below. Conditions exist where it may be appropriate to use more than one category of foam protection for a given fire problem.

Fixed Foam Systems

These systems are complete installations piped from a central foam station, discharging through fixed delivery outlets to the hazard to be protected. Any required pumping equipment is permanently installed. For example, a fixed system for a vertical atmospheric cone roof storage tank would include the following permanently installed equipment: water supply lines, foam proportioning equipment, a foam liquid storage tank, foam concentrate and solution lines, control valves, riser pipes, and one or more topside foam chambers. Other equipment may be added based on the complexity of the problem and associated hydraulic conditions. Several calculation examples of fixed foam systems will be described within this chapter.

Semifixed Foam Systems

The semifixed foam system concept includes a system where a portion of the total system is permanently installed and the remainder of the system is provided by portable elements. In general, this includes a fire hazard equipped with fixed discharge outlets connected to piping that terminates at a safe distance. The fixed piping installation may or may not include a foam

maker. Necessary foam producing materials are transported to the scene after the incident begins and are connected to the fixed piping.

Mobile Systems

Mobile systems basically consist of a unit on wheels that transports all of the required equipment and foam liquid necessary for making finished foam. This concept includes any foam producing unit which is mounted on wheels, and which may be self-propelled or towed by a vehicle. These units may be connected to an available water supply or may use a premixed foam solution. The original concept of a mobile foam system was called a "foam house on wheels," a mobile piece of fire apparatus with a UL-rated fire pump, an integral part of the pumping network, a foam liquid tank, and fire hose. Essentially this unit can double as a structural fire suppression unit. NFPA 1901, Standard for Automotive Fire Apparatus, covers the specifications and performance criteria for mobile foam fire apparatus [1].

Portable Systems

Portable systems represent a rather economical approach to providing basic foam fire protection for small hazards. This classification considers that the foam producing equipment and materials, including the foam liquid, the proportion device(s), the discharge nozzle, the hose, and other required appliances, are transported by hand from a storage location to the incident scene. While portable systems are simple to operate, they are limited by their foam discharge rate capability; they may also be labor intensive to maintain a continuous foam supply over the required duration of discharge. Foam equipment manufacturers can provide technical information on a range of portable equipment.

Compressed Air Foam Systems

This type of foam fire protection injects pressurized air to the system to generate foam prior to the discharge device. These types of systems are limited to protection of flammable and combustible liquids and are generally not permitted for fires involving chemicals with oxidizing agents, energized unenclosed electrical equipment, water-reactive metals, hazardous water-reactive materials, or liquefied flammable gases.

Protection of Incipient Spills and Related Hazards

Portable fire extinguishers provide one method of protection for small flammable liquid storage hazards, fuel transfer hazards, and incipient spill fires. Although once classified and listed by Underwriters Laboratories (UL), chemical foam extinguishers are now considered obsolete and should not be utilized. The AFFF extinguisher closely resembles the stored pressure water extinguisher in appearance except for the special type of nozzle. NFPA 10, Standard for Portable Fire Extinguishers, should be consulted concerning the selection and placement of portable fire extinguishers [1].

Low-Expansion Foam Systems

Low expansion foam systems are well suited for protection of interior flammable/combustible liquid hazards, outdoor storage tank areas, truck loading racks, diked and non-diked spill areas. These systems may include aqueous film-forming foam (AFFF) agents, alcohol-resistant (AR) type agents, fluoroprotein (FP) agents, and film-forming fluoroprotein (FFFP) agents. This section presents several examples of design calculations.

Protection for Fixed Roof Atmospheric Storage Tanks

Fixed roof atmospheric storage tanks for the storage of flammable/combustible liquids can be protected by fire fighting foam. Several techniques are available for correctly applying foam to a fixed roof tank fire. Each technique should be carefully considered with reference to the size of the storage tank, the flammable or combustible liquid being stored in a given tank, and the foam agent classification that is suitable for the hazard. Some fundamental concepts associated with the proper protection for fixed roof atmospheric storage tanks are discussed below. Each individual topic is further developed through example design problems on cone roof atmospheric storage tanks.

Foam Monitors

One or more foam monitors may be positioned around the periphery of a fixed roof tank to project foam over the tank shell and onto the surface of a burning liquid. These monitors, or cannons, provide a large foam stream and can be fixed in position or moveable. This technique has been successfully used on numerous fires. However, NFPA 11 clearly indicates that foam monitors may not be considered the primary means of protection for fixed roof tanks when the tank is more than 60 ft in diameter. This indication represents a severe limitation on the recommended use of foam monitors for the protection of fixed roof tanks.

If foam monitors are to be utilized, the minimum foam application rate to the surface of the liquid is generally specified at 0.16 gpm/ft^2 (6.5 L/min-m^2). However, the applicable design regulations need to be consulted in this regard. The minimum application rate may need to be increased to account for flammable liquids with lower boiling points (i.e., less than 100 °F), environmental conditions such as wind, or other factors that may lead to potential foam loss. Durations of application are dependent on the fuel and generally range between 50 and 65 min.

Foam Handlines

Similar to the concept of providing protection with monitors, foam handlines may be positioned around the periphery of a fixed roof tank to project foam over the tank shell and onto the surface of a burning liquid. Foam handlines generally have a flow range from 50 gpm (190 lpm) to less than 300 gpm (1136 lpm) and are only suitable for possible protection of fixed roof tanks with a diameter of less than 30 ft (9 m) and a height not greater than 20 ft (6 m). The selection of foam handline nozzles must be carefully considered to provide the appropriate total discharge for the flammable liquid hazard to be protected. Personnel protection also needs to be sufficiently considered when this option as the primary means of protection.

Foam handlines are very important for providing supplemental fire protection. Handlines delivering a minimum of 50 gpm (190 lpm) are very useful for extinguishing small spill fires and dike fires in the vicinity of a storage tank. The number of such supplemental foam hose streams is dependent on the diameter of the largest storage tank in the facility to be protected. Again the applicable design standards and regulations needs to be consulted.

Surface Application of Foam

One common and acceptable method of applying foam to the flammable/combustible liquid surface of a single roof storage tank is through fixed discharge outlets installed on the tank shell. Two distinct types of foam discharge outlets are available based on the hazard and the type of concentrate used. Each type of device may be distinguished as follows:

Type I Outlets These approved discharge outlets deliver foam gently onto the liquid surface without submergence of the foam below the flammable liquid surface and agitation of the surface. This type of device was originally intended to apply special alcohol resistant foams to polar solvent fuels. Today, Type I discharge outlets are generally considered obsolete.

Type II Outlets These approved discharge outlets do not necessarily deliver foam gently onto the liquid surface. However, they do lessen the submergence of the foam or agitation of the surface. An air foam chamber with a Type II outlet may be attached to the top of the tank shell above the level of the liquid within. The chamber is attached to the tank shell so that the displacement of the tank roof will not subject the chamber to damage. The discharge outlet is positioned on the inside of the tank to permit discharge of the foam down the inside of the tank wall surface onto the flammable liquid surface. The number of Type II foam chambers for a given size (diameter) storage tank is presented in design standards such as NFPA 11. Discharge capacity of the chambers is calculated based on the required application rate prescribed by the applicable design, and the foam chamber manufacturer.

Procedure for Determining Foam Supply for Atmospheric Storage Tanks Protected with a Surface Application Low-Expansion System

Through a specific example, this section addresses the design and associated hydraulic calculations for surface application low-expansion foam systems protecting atmospheric storage tanks. The example addresses the topside application of foam using foam chambers for a single flammable liquid storage tank, and presents methods and techniques for computing the foam agent requirements, system hardware requirements, and the necessary hydraulic calculations to properly deliver the required rate of foam discharge onto the liquid fuel surface.

Example 1 A single fixed roof outside storage tank storing gasoline is depicted in Fig. 48.1. The tank is to be protected by a fixed foam system for the purpose of extinguishing a fire that starts on the liquid surface in the tank. A topside foam chamber arrangement is to be used. A municipal water main is the only supply of water for the foam system. The corresponding water supply curve for the municipal main is illustrated in Fig. 48.2. A foam

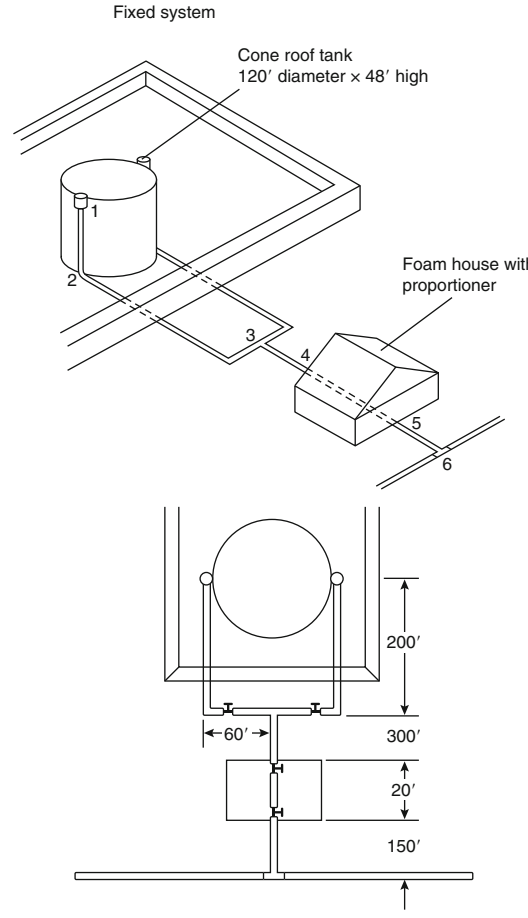

Fig. 48.1 Single storage tank with fixed foam system protection. The numbers 1 through 6 in the top portion of the drawing represent the reference points for hydraulic calculations in Example 1

system design and complete set of hydraulic calculations are to be prepared for this installation. Figure 48.3 provides a summary of the information determined in Steps 1–13 below.

Solution A systematic step-by-step process follows. Reference is made to discharge criteria presented in NFPA 11. Information on specific system components is documented in the referenced problem job sheet (Fig. 48.3) and the associated hydraulic calculation sheet (Fig. 48.4). In addition to the physical layout of the tank, information is needed on the specific type of fuel involved.

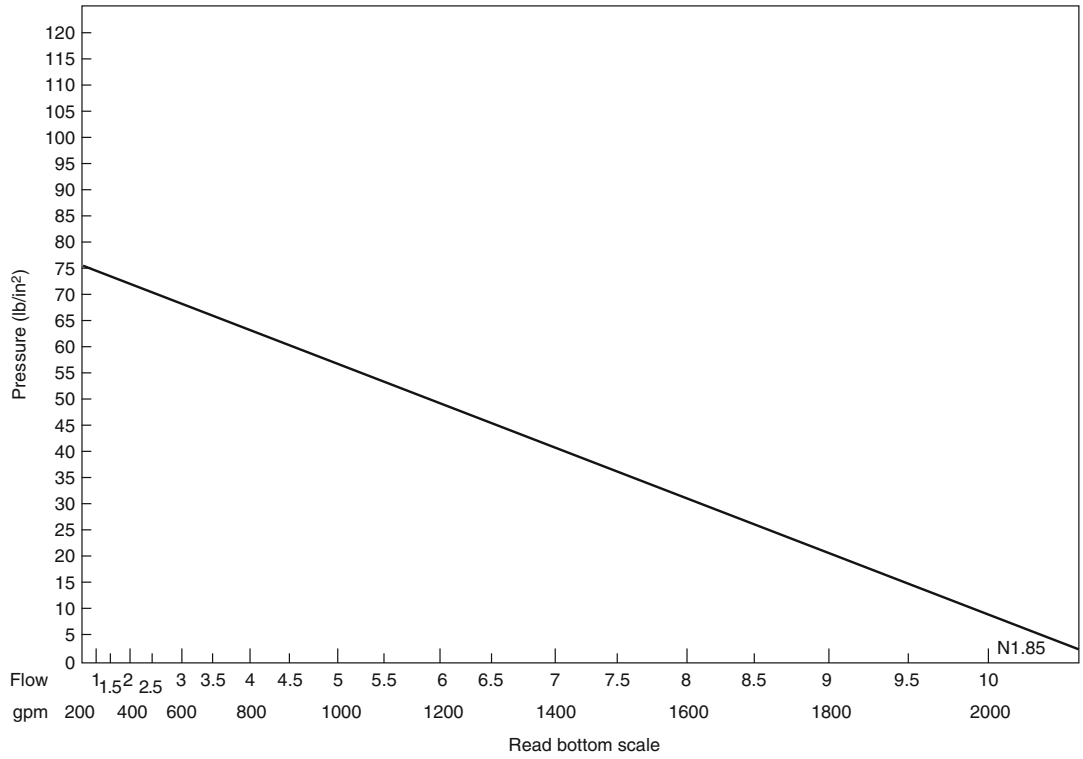

Fig. 48.2 Water supply curve for fixed foam system in Examples 1 and 2

Step 1: Installation identification.

Refer to Fig. 48.1. The evaluation must consider the site conditions of the storage tank and surrounding areas. In this example, a single vertical atmospheric storage tank is positioned in an area surrounded by a dike wall. The tank is to be protected by a fixed foam fire protection system and connected to the domestic water supply.

Step 2: Hazard classification and description.

The specific hazard and storage arrangement need to be identified. In this example, a 120-ft diameter outdoor fixed roof tank is storing a flammable liquid.

Step 3: Flammable/combustible liquid identification.

The characteristics of the stored liquid must be determined in order to select the appropriate type of foam concentrate to be used. In this example, gasoline is stored and has a specific gravity of 0.72. The fire protection engineer needs to be certain of the specific types of liquids to be stored in the tank as some facilities rotate the types of liquids stored in a given tank.

Step 4: Type of protection.

Based on the storage arrangement and contents, an appropriate protection concept must be determined. Fixed protection systems using Type II discharge outlets (foam chambers) will be used. As previously noted Type I outlets are considered obsolete.

Step 5: Surface area of liquid to be protected.

Calculate the liquid surface area to be protected. For the cylindrical storage tank, the area of protection will be equivalent to the area of the top surface:

$$\text{Area} = 1/4\pi d^2$$

$$\text{Area} = 1/4\pi(120)^2 = 11,310\,\text{ft}^2$$

FOAM SYSTEM JOB WORK SHEET

Sheet: 1 of 1

Designer: Staff Date:

Installation identification: Ourville Oil Company

Hazard classification: Flammable liquid atmospheric storage tank

Type of protection: Fixed protection system

Hazard description: 120-ft-diameter outdoor cone roof flammable liquid storage tank

Flammable or combustible liquid area to be protected: 11,310 ft^2

Flammable or combustible liquid identification: Gasoline — SG 0.72

Foam application method: Type II—fixed chambers

Description, number, and placement of foam application devices: 2—Chambers equally spaced

Foam agent selected: Fluoroprotein—3%

Foam solution application rate: 0.1 gpm per ft^2 or 1131 gpm

Foam concentration rate: 34 gpm

Water application rate: 1098 gpm

Duration of discharge: 55 min

Gallons of foam required: 1870 gallons

Gallons of water required: 60,390 gallons

Water supply information: See Figure 4-5.2

Special foam design considerations:

Fig. 48.3 Foam system job worksheet for Example 1

Step 6: Foam agent selected.

Based on the liquid being stored, an appropriate foam concentrate must be selected. Specific manufacturers will need to be consulted to determine the most appropriate foam concentrate for the hazard.

For this example, a 3 % fluoroprotein foam will be selected for the defined hazard. Note that the type of foam agent selected for a particular design will affect other variables and considerations in the foam system design.

Step 7: Description, number, and placement of foam application devices.

Several factors need to be simultaneously considered in developing this step. The selection of foam application devices will be dependent on the foam agent selected. In addition, the flow and pressure characteristics of the discharge device will be a factor or present options for the system design. Manufacturer's literature and the listing evaluation data of foam equipment should be consulted on this matter.

Fig. 48.4 Hydraulic calculation work sheet

As previously noted, foam chambers will be used and specific characteristics are associated with each type of chamber, which must be obtained from the manufacturer. For this example, the selected foam chamber is identified as ABC chamber with an operating pressure range of 40–80 psi and a flow range of 300–700 gpm.

Foam standards and manufacturer's design guides provide details on the number of foam chambers need. Referencing NFPA 11,

Table 5.2.5.2.1, a minimum of two foam chambers for a 120-ft diameter tank are required. Additional foam chambers may be used based on hydraulic considerations, or equipment costs. Individual manufacturers of foam equipment must be consulted on these options.

Placement of foam makers should consider equal spacing around the upper tank perimeter to ensure even distribution of foam. A constant and uniform flow and pressure should also be maintained during system discharge.

Step 8: Foam solution application rate.

Foam solution application rates for storage tanks containing liquid hydrocarbons are generally provided in foam standards and manufacturer's design guides. Referencing NFPA 11, Table 5.2.5.2.2, for this example an application rate of at least 0.1 gpm/ft^2 over the liquid surface area is to be provided. Specific types of foam equipment may require different application rates. Also, flammable and combustible liquids not classified as hydrocarbons may require different application rates. Appropriate references should be consulted in this regard.

The total foam solution discharge rate for Example 1 is calculated as follows:

$$\begin{aligned}\text{Rate (g pm)} &= 0.1\ \text{g pm/ft}^2 \times 11,310\ \text{ft}^2 \\ &= 1,131\ \text{g pm}\end{aligned}$$

The total discharge rate can be divided equally between the two required foam chambers. It is appropriate to specify a total foam solution discharge rate of 1132 gpm, with 566 gpm per each of the two foam chambers.

Step 9: Foam concentrate supply rate.

The foam concentrate supply rate is based on the foam agent proportioning rate. As noted in the example, a 3 % fluoroprotein foam has been selected (Step 6). In other words, 3 % of the calculated foam solution rate is the foam concentrate supply rate. This rate may be determined as follows:

$$\begin{aligned}\text{Foam concentrate rate} &= 0.03 \times 1,132\ \text{g pm} \\ &= 34\ \text{g pm}\end{aligned}$$

Therefore, a continuous supply of foam concentrate must be available at a rate of 34 gpm for the required duration of discharge (Step 11).

Step 10: Water supply rate.

The water supply rate is the foam solution rate minus the foam concentrate supply rate. The necessary water supply rate can be calculated as follows:

$$\begin{aligned}\text{Water supply rate} &= 1,132\ \text{g pm} - 34\ \text{g pm} \\ &= 1,098\ \text{g pm}\end{aligned}$$

The water supply rate can also be determined as 97 % of the foam solution rate when using a 3 % foam concentrate.

Step 11: Duration of discharge.

Foam standards and manufacturer's design guides generally specify the duration of foam discharge. Duration of discharge is dependent on the classification of the ignitable liquid stored, and the type of discharge outlet used. Gasoline has a flash point below 100 °F (37.8 °C). Referring to NFPA 11, Table 5.2.5.2.2) a minimum discharge duration of 55 min is required to control and extinguish a fire in a fixed roof storage tank containing gasoline using Type II foam chambers.

Step 12: Quantity of foam required.

The necessary foam supply for any given application should properly consider a primary supply and the availability of a reserve supply. The primary supply is calculated by multiplying the foam concentrate supply rate by the duration of discharge as follows:

$$\begin{aligned}\text{Foam agent required} &= 34\ \text{g pm} \times 55\ \text{min} \\ &= 1,870\ \text{gal}\end{aligned}$$

A risk analysis or the authority having jurisdiction may require that an equal quantity of foam be placed in reserve on site if there is a credible likelihood of a second fire occurring before the foam supply can be replenished.

Step 13: Total quantity of water required.

The basic procedure follows the concept presented in Step 12. The water requirement is the product of the water supply rate multiplied by the duration of discharge. In this case:

$$\text{Minimum Volume of water required} = 1,098\,\text{g pm} \times 55\,\text{min} = 60,390\,\text{gal}$$

Fixed foam protection systems for atmospheric storage tanks require large volumes of water. The total quantity of water must be available at the site to assure foam delivery over the entire required duration.

Step 14: Pipe size determination.

System piping can be sized to minimize friction loss between the supply and the system discharge outlets (foam chambers). Pipe can also be sized on the basis of a targeted mean velocity flow in a given section of pipe. A flow velocity of 10 ft per second is often used in the absence of other specific criteria for the determination of system piping. Hydraulic calculations need to be completed to verify pipe sizes and proper system discharge. Hydraulic calculations for the system in Example 1 are completed later in this chapter.

In addition to system piping flowing water and foam solution, piping for delivery of foam concentrate into the system also needs to be considered. Foam concentrates do not behave as Newtonian fluids, e.g. water, when flowing due primarily to their viscosity and resulting nonproportional viscous stresses. Therefore the calculation approach for foam concentrates differs from that typically used for water and foam solution, which is usually about 97–93 % water.

Step 15: Valve selection and location

Valves need to be listed for the purpose. The laterals to each foam discharge outlet on fixed roof tanks are to be separately valved outside of the dike installation. Valves are to be located where the laterals branch from the common supply line. Valves are to be located a minimum distance of at least one tank diameter from the tank. The water line to each proportioner inlet should be separated by a valve. Appropriate valves locations for the system in Example 1 are shown in Fig. 48.1.

Step 16: Foam proportioner selection.

Several different types of foam proportioners are available from equipment manufacturers. It is important to select foam proportioning equipment that meets the following requirements:

- Proper and uniform proportioning over the range of expected flows and system pressures.
- Minimum or acceptable friction loss across the proportioning device.
- Suitability for the foam concentrate selected.
- Capability of overcoming any back pressures such as might be associated with system elevation changes or subsurface foam applications.

Step 17: Pump Considerations.

To generate the necessary system flow rate and discharge, the pressure in the water supply might need to be augmented by the use of a pump. The need for a pump will be determined though hydraulic analysis. Where a pump is required, consideration must be given to the pump capacity, the pressure profile, the pump horsepower requirement, and the pump intake-discharge positions with respect to the total installation of pipe. Any pump selected for the foam system needs to be listed for the intended purpose. A foam concentrate pump might also be needed to inject the proper concentration of foam into the system. These pumps are usually different from the centrifugal pumps used for water-based system. Positive displacement pumps are usually employed for foam concentrate injection.

Hydraulic Analysis of a Surface Application Foam System Protecting a Flammable Liquids Storage Tank

The following outlines the procedure involved in calculating the hydraulic demand for a surface application foam system. The reader is assumed to posses a fundamental understanding of fire protection water supply analysis, and hydraulic calculations employing the Hazen-Williams

approach. The system in Example 1 as depicted in Fig. 48.1 is used in outlining the procedure. The design parameters and associated calculations are presented in sequential steps, which are summarized on a hydraulic calculation sheet as shown in Fig. 48.4 with reference points identified in Fig. 48.1.

Step 1: Starting point.

The design objective is to provide each of the two foam chambers in Example 1 with the required pressure to discharge the calculated quantity of foam solution. The stated problem requires each foam chamber to discharge 566 gpm of foam solution at 50 psi. An orifice plate is supplied by the foam equipment manufacturer to ensure the correct discharge at the design pressure of 50 psi. The design pressure is a function of the range of pressures that can be used with a specific manufacturer's foam chamber.

Step 2: Determination of supply riser size.

The vertical pipe supplying the foam chambers (reference points 1–2) is sized based on a maximum flow velocity of 10 ft per second. The pipe size is determined as follows:

Formula:

$$Velocity = \frac{0.40852 \times gpm}{d^2}$$

(a) Solve for d using a velocity of 10 ft per second

(b) $10 fps = \frac{0.4085 \times gpm}{d^2}$

(c) $d^2 = 23.12$ in.

(d) $d = 4.8$ in.

(e) A minimum 5-in. pipe is required.

Step 3: Determine friction loss between reference points 1 (top of tank) and 2 (bottom of tank).

1. Friction loss, FL, is determined by the Hazen-Williams formula

$$FL = \frac{4.52 \times Q^{1.85}}{C^{1.85} \times d^{4.87}}$$

Where
Q = 566 gpm
C = 100
d = 5.047 (internal diameter of 5-in Schedule 40 steel pipe)

$$FL = 0.0420 \text{ psi/ft}$$

2. Note: All friction losses and elevation losses are summed in the required pressure column.
3. The elevation loss, H_L, for 48 ft of elevation difference between reference points is computed as follows:

$$H_L = 0.433 \text{ psi/ft} \times 48 \text{ ft} = 20.8 \text{ psi}$$

4. The pipe section includes one standard elbow at reference point 2. For hydraulic calculations, fittings are treated as equivalent feet of pipe in accordance with NFPA13, Standard for the Installation of Sprinkler Systems [1].

Step 4: Determine friction loss between reference point 2 (bottom of tank) and reference point 3.

1. The flow is constant at 566 gpm so the pipe size remains the same at 5 in.
2. Pipe fittings include a gate valve outside the dike area and a standard tee at reference point 3.

Step 5: Determine friction loss between reference point 3 and reference point 4 (foam house).

1. The total foam solution flow (1132 gpm) is supplied by line 2–3.
2. Determine the pipe size based on a maximum flow velocity of 10 ft/s.

$$Velocity = \frac{0.40852 \times gpm}{d^2}$$

$$10 fps = \frac{0.4085 \times 1132 gpm}{d^2}$$

$$d = 6.8 \text{ in.}$$

3. An 8-in. pipe is recommended between the foam house and reference point 3.

4. The friction loss in the stated line includes the linear distance plus the gate valve.
5. It should be observed that the required pressure at the discharge side of the foam house is 90.0 psi.

Step 6: Determine the friction losses in the foam house piping between reference points 4 and 5.

1. The foam house will contain the proportioning equipment. The proportioner selected for this problem has a friction loss of 4 psi at a solution flow rate of 1132 gpm. This information would normally be provided by the manufacturer. The ratio controller takes up a lineal distance of 2 ft leaving 18 ft of straight run pipe within the foam house.
2. The calculations provided do not include provisions for a pump within the foam house.

Step 7: Determine the friction loss from the foam house to the water supply between reference points 5 and 6.

1. The flow rate in line 5–6 is 1098 gpm (water supply rate). Note the change in friction loss.
2. An 8-in. main is used to connect the water supply to the foam house.

Step 8: Summary.

1. The water demand requirement at reference point 6 is 1098 gpm at 97.0 psi.
2. The hydraulic demand has been calculated to provide a foam solution flow of 566 gpm at 50 psi for each designated foam chamber.
3. The water supply curve referenced as Fig. 48.2 shows a flow of 1098 gpm available at 53 psi. This water supply is not sufficient for the foam system. Therefore, a pump is required to boost the pressure from 50 psi (loss of pressure from reference points 6–5 is approximately 3 psi) to 97 psi or approximately 47 psi. A pump can be selected for this specific application.

Subsurface Application of Foam

Another method of applying foam to a fixed roof storage tank is through subsurface injection, usually near the base of the tank but above the level of any water that has accumulated in the bottom in the tank, recalling that many ignitable liquids are lighter than and not miscible with water. The subsurface application technique involves injecting expanded foam under controlled velocity conditions. The buoyancy of the foam allows the foam to slowly rise to the ignitable liquid surface and spread across the surface to effect fire control and then provide extinguishment similar to a surface application.

The subsurface application technique requires design considerations with respect to foam equipment and hydraulic calculations that differ from those of surface applications. There are three important conditions to consider in subsurface application of foam in fixed and semifixed systems.

1. Subsurface foam application is not considered suitable for the protection of Class IA hydrocarbon liquids.
2. Subsurface foam application is not currently suitable for polar solvents.
3. Subsurface and semisubsurface injection systems are not recommended for open top or covered floating roof tanks.

Procedure for Determining Foam Supply for Atmospheric Storage Tanks Protected with a Subsurface Application Low-Expansion System

Through a specific example, this section addresses the design and associated hydraulic calculations for subsurface application low-expansion foam systems protecting atmospheric storage tanks. The example presents methods and techniques for computing the foam agent requirements, system hardware requirements, and the necessary hydraulic calculations to properly deliver the required rate of foam discharge into the fuel tank. The following principles need to be understood in the design of subsurface application foam systems:

1. Foam solution is expanded outside of the dike area by a “high back pressure” foam maker.

A typical foam expansion of 4:1 is achieved at the foam maker.

2. The expanded foam flows through a carefully designed pipeline from the foam maker to an opening in the tank shell just above the water level at the bottom of the tank. In accordance with design standards such as NFPA 11, the foam velocity at the point of discharge into the tank contents is not to exceed 10 ft/s for Class IB liquids and 20 ft/s for other type liquids. An excessive input velocity to the tank can cause the foam to be saturated with fuel as it rises to the liquid surface. This phenomenon is referred to as fuel pickup.
3. Foam entering the product rises to the fuel surface by natural buoyancy.

Example 2 This example considers a 120-ft diameter storage tank storing gasoline that is to be protected with a fixed subsurface application foam system as illustrated in Fig. 48.5. A municipal water main is the only supply of water for the foam system. The water supply information shown in Fig. 48.2 also applies to this example. A foam system design and complete set of hydraulic calculations are to be prepared.

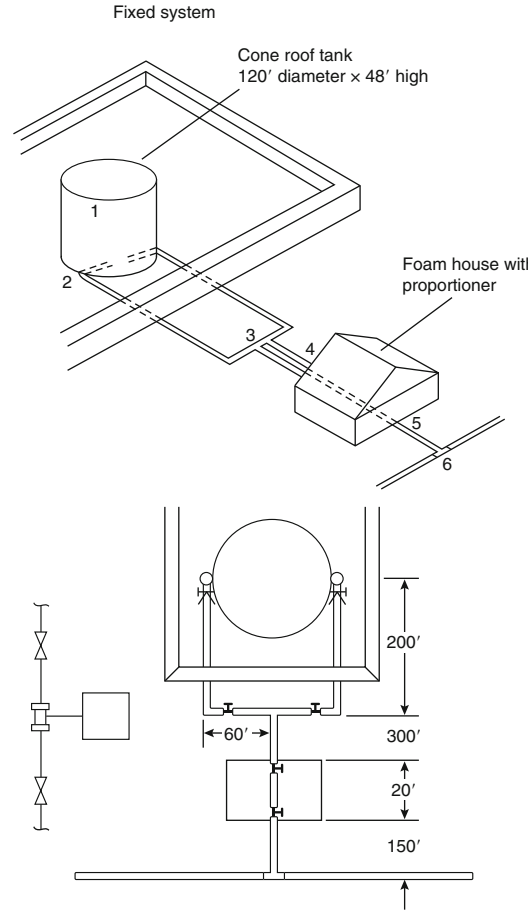

Fig. 48.5 Subsurface application foam system with reference points used in Example 2

Solution A systematic step-by-step solution follows for the design and hydraulic assessment of the associated foam system. Reference is made to provisions documented in NFPA 11 as this standard is often referenced by applicable fire regulations. Relevant information to be determined has been transferred to the work sheet in Fig. 48.6, and the associated hydraulic calculation sheet in Fig. 48.7.

In addition to the physical layout of the tank and the foam system, information about the fuel (hazard) is required as will be discussed below. Some of the steps from Example 1 on surface application are also applicable here and are identified as such.

Step 1: Installation identification.

Referring to Fig. 48.5 the site conditions of the storage tank and surrounding area are to be considered. In this example, a single vertical atmospheric storage tank is positioned in an area surrounded by a dike wall. The tank is to be protected by a fixed subsurface injection foam fire protection system supplied by a municipal water main.

Step 2: Hazard classification and description.

The specific hazard and storage arrangement need to be identified. In this example, a 120-ft diameter outdoor cone roof tank is storing gasoline, a flammable liquid.

Step 3: Flammable/combustible liquid identification.

The characteristics of the stored liquid must be determined in order to select the appropriate type of foam concentrate to be used. Again, gasoline with a specific gravity of 0.72 is stored in the tank.

FOAM SYSTEM JOB WORK SHEET

Sheet: 1 of 1

Designer: Staff Date:

Installation identification: Ourville Oil Company

Hazard classification: Flammable liquid storage tank

Type of protection: Subsurface application to fixed roof storage tank

Hazard description: 120-ft-diameter outdoor cone roof flammable liquid storage tank

Flammable or combustible liquid area to be protected: 11,310 ft^2

Flammable or combustible liquid identification: Gasoline — SG 0.72

Foam application method: Subsurface application to a liquid hydrocarbon

Description, number, and placement of foam application devices: Two subsurface injection points positioned equal and opposite on the tank shell. A PHB foam maker is used.

Foam agent selected: 3%

Foam solution application rate: 1132 gpm

Foam concentration rate: 34 gpm

Water application rate: 1098 gpm

Duration of discharge: 55 min

Gallons of foam required: 1870

Gallons of water required: 60,390

Water supply information: See Figure 4-5.2

Special foam design considerations: Foam injection piping to be sized for a maximum fluid velocity of 10 fps

Fig. 48.6 Foam system job worksheet for Example 2

Step 4: Type of protection.

Based on the hazard and the liquid, an appropriate protection scheme must be determined. Fixed protection systems using subsurface application will be used.

Step 5: Surface area of ignitable liquid in tank to be determined.

11,310 ft^2 (See Example 1 for calculation)

Step 6: Foam agent selected.

Based on the liquid being stored and the subsurface injection method, an appropriate foam must be selected. Specific manufacturers will need to be consulted to determine the most appropriate foam for the hazard.

As with the surface application example, a 3 % fluoroprotein foam is selected for the defined hazard. Note that the type of foam agent selected

for a particular design problem may affect other factors in the foam system design.

Step 7: Description, number, and placement of foam application devices.

Several equipment design factors must be considered simultaneously in this step. Again, reference must be made to a specific foam manufacturer's equipment or a comparative analysis between two or more manufacturers of suitable equipment should be conducted. The manufacturer's literature and the listing information about the foam equipment needs to be consulted in this regard.

Gasoline is a Class IB liquid, and therefore the injection velocity of the expanded foam into the product tank should not exceed 10 ft/s per NFPA 11. This does not mean that the velocity of foam between the foam maker and the injection point has to be controlled to a maximum of 10 ft/s. Rather, the foam velocity at the physical point of entry into the tank is the key consideration.

Remember that the foam is expanded at the entry point into the fuel, i.e. gasoline. Special flow curves must be examined to determine velocity characteristics with expanded foam. These curves are available in the annex of NFPA 11. Manufacturer's literature can also referenced. Figure A.5.2.6.2(a) from NFPA 11 is consulted for this example [1].

Table 5.2.6.2.8 of NFPA 11 indicates that two discharge outlets must be provided for a 120-ft-diameter tank storing gasoline. The foam solution rate for each outlet is given in Step 8 of this example and is equal to the calculations for the surface application example: 566 gpm per outlet. However, the foam is expanded at the high back pressure foam maker using a ratio of 4:1. The expanded foam flow rate at each outlet is 2264 gpm. This is the value to be used when verifying foam velocity.

A 10-in. pipe is required to maintain a foam velocity at less than 10 ft/s when the rate of expanded foam is 2264 gpm (see NFPA 11, Fig. A.5.2.6.2(a)). The pipe length upstream from the discharge point must be at least 20 times the diameter of the pipe to establish uniform velocity. Therefore, a straight run of 10-in. pipe at least 17 ft in length is necessary.

The foam outlet is not required to be at the tank shell. Note that the 10-in. pipe is actually inserted into the tank. This design approach permits economizing the pipe sizes between the tank and the high back pressure foam maker. The high back pressure foam maker is to be positioned outside of the dike area. A gate valve and a check valve are installed adjacent to the tank shell.

Step 8: Foam solution application rate.

For tanks containing liquid hydrocarbons, the foam solution rate must be at least 0.10 gpm/sq ft of liquid surface area of the tank to be protected. The maximum rate must be 0.20 gpm/sq ft. (Ref: NFPA 11, Table 5.2.6.5.1)

The foam solution application rate for this example is the same foam solution rate calculated for the surface application in Example 1, 1132 gpm.

Step 9: Foam concentrate supply rate.

The foam concentrate supply rate is determined in the same manner as set forth for the surface application in Example 1. Using a 3 % fluoroprotein foam, the requirement is 34 gpm for a total solution flow rate of 1132 gpm.

Step 10: Water supply rate.

The water supply rate is also determined in the same manner as set forth in the surface application in Example 1. The water supply rate is the foam solution rate minus the foam concentrate supply rate, which in this case is 1098 gpm.

Step 11: Duration of discharge.

The minimum discharge time for subsurface application of foam is 55 min for a tank storing gasoline (Ref: NFPA 11, Table 5.2.6.5.1)

Step 12: Quantity of foam required.

The volume of required foam is computed in the same manner as set forth in the surface application in Example 1. The primary foam supply is calculated by multiplying the determined rate of foam concentrate by the duration of flow, which indicates a quantity of 1870 gal.

Step 13: Quantity of water required.

The water requirement is the product of the water supply rate times the discharge time, or 60,390 gal.

Step 14: High-back-pressure foam maker.

A high-back-pressure foam maker is designed for the production and discharge of foam against considerable backpressure (from tank contents). The high-back-pressure foam maker selected for Example 2 is designed to operate satisfactorily at inlet pressures of 100–300 psi and produce foam of 2:4 expansion against back pressures not exceeding 40 % of the inlet pressure. With an inlet pressure of 150 psi, for example, 60 psi is available at the discharge for forcing the foam through a hose and/or piping into the storage tank and to overcome the pressure caused by the depth of fuel in the tank. Manufacturers of high-back-pressure foam equipment need to be consulted with regard to the associated flow and pressure characteristics, and back pressure limitations. Two high-back-pressure foam makers are used with this example. They are located in the foam house and are arranged for parallel operation (See Fig. 48.5.).

Step 15: Pipe size determination.

Expanded foam flowing in pipe does not follow the friction loss characteristics expressed by the Hazen-Williams approach. A set of flow curves have been developed for determining friction loss for expanded foam discharge by a high-back-pressure foam maker [1]. A set of these curves is provided in the Annex of NFPA 11.

A flow velocity of 10 ft/s is used for the determination of pipe sizes flowing foam solution and water. If necessary, water supply pipe and foam solution pipe can be sized to minimize friction loss between the water/foam supply and the discharge points.

Step 16: Valve selection and location.

For subsurface application, each foam delivery line must be provided with a valve and check valve, unless the latter is an integral part of the high-back-pressure foam maker or pressure generator to be connected at the time of use. When flammable/combustible liquid product lines are used for foam injection, product valving must be arranged to ensure foam enters only the tank to be protected. The valves need to be listed for the intended purpose.

Step 17: Foam proportioner selection.

The practices and procedures about foam proportioners outlined for the surface application in Example 1 also applies to this example. However, to accommodate the pressure requirements associated with a high-back-pressure foam maker, balanced or water-driven proportioners provide options for providing a reliable level of constant proportioning over the anticipated pressures.

Step 18: Pump Considerations.

For Example 2, the required pressure at the intake to the high-back-pressure device is approximately 150 psi. The static pressure on the water system is only 75 psi. Therefore, a pump is required to boost the water-solution pressure in the foam hose. The most efficient approach to designing a required pump installation is to select or design a pump-driver combination that will boost the available residual pressure to the required residual pressure at the demand flow. In other words, with the right capacity pump, the driver horsepower is calculated to raise the pressure over the differential range.

Hydraulic Analysis for Subsurface Application Foam System Protecting a Flammable Liquids Storage Tank

The following outlines the procedure involved in calculating the hydraulic demand for a subsurface application foam system. The reader is assumed to posses a fundamental understanding of fire protection water supply analysis, and hydraulic calculations employing the Hazen-Williams approach. The system in Example 2 as depicted in Fig. 48.5 is used in outlining the procedure. The design parameters and associated calculations are presented in sequential steps, which are summarized on a hydraulic calculation sheet as shown in Fig. 48.7 with reference points identified in Fig. 48.5.

Step 1: Pre-calculation for high-back-pressure foam maker (Reference Point?).

The hydraulic characteristics of the high-back-pressure foam maker must be considered before initiating the calculations. A high-back-pressure foam maker delivering 550 gpm at 150 psi is selected for each of the two foam lines leading to the tank.

1. Determine a K value for the foam maker:

$$Q = K\sqrt{P}$$

$$K = \frac{Q}{\sqrt{P}} = \frac{550}{\sqrt{150}} = 44.9$$

2. Required discharge per foam maker is 566 gpm.
3. Determine the required input pressure for a flow of 566 gpm:

$$566 gpm = 44.9\sqrt{P}$$

$$P = 159 psi$$

4. The pressure available to adequately account for back pressures associated with the stored fluid in the tank and associated elevation and friction losses in the system piping between the pump house and the tank is therefore 40 % of 159 psi, or 64.0 psi. Recall that from Step 14 in section 1.4.1.4 this type of foam maker was selected.

Step 2: Size foam injection pipe to tank.

Step 7 under problem assessment for Example 2—established that a 10-in. pipe is required to maintain a flow velocity under 10 ft/s.

Step 3: Determine friction loss from production storage.

Finished foam rising through the product must overcome the pressure from the product depth. Gasoline is the product for this series of problems with a specific gravity of 0.72.

$$\text{psi loss} = 48 \text{ ft} \times 0.433 \text{ psi/ft} \times 0.72 \text{ SG}$$

$$\text{psi loss} = 15$$

Step 4: Size the foam supply line from the tank shell to the foam house.

The stated pipe is selected on the basis of the allowable friction loss of 64 psi minus the pressure from the product depth (which equals 15 psi). Therefore, 49 psi (64 psi – 15 psi) can be dissipated from the tank to the foam maker through 500 ft of pipe and be used as an initial estimator; the flow rate is 2264 gpm. NFPA 11, Fig. A.5.2.6.4(a) should be consulted to determine appropriate pipe sizing. In this case, a 6-in. pipe is used. A 6-in. check valve and a 6-in. gate valve will be installed on the foam supply line adjacent to the tank in the dike area. The required friction loss calculations are presented in Fig. 48.7.

Calculation Note Subsurface foam system hydraulics actually divide into two separate calculation sets, as follows: (1) the hydraulics between the high-back-pressure foam maker and the storage tank and (2) the hydraulics between the water supply main and the high-back-pressure foam maker.

Step 5: Water supply main to fire pump calculation.

The lateral supply line will be designed at a velocity of 10 ft/s. Recall that only water is moving through this line.

$$Velocity = \frac{0.4085 \times gpm}{d^2}$$

1. Solve for d
2. $$10 ft/s = \frac{0.4085 \times 1098 gpm}{d^2}$$
3. $d^2 = 44.85$ in.
4. $d = 6.69$ in.
5. Use an 8-in. pipe

Step 6: Piping in foam hose (Reference Points).

Eight inch diameter pipe will be used in the foam house to connect between the pump, the foam proportioner, and the high-back-pressure foam maker.

Semisubsurface Injection Method

A modified form of subsurface foam injection for fixed roof tanks is used in a number of European countries. The modified technique is designated the semisubsurface injection method, based on the equipment used to insert the expanded foam into the tank shell. The semisubsurface injection method has not found any particular application in the United States and is not discussed herein.

Protection for Floating Roof Storage Tanks

Introduction

In contrast to fixed roof tanks, floating roof tanks have a cover or roof over the flammable liquid that floats on the surface of the liquid and moves vertically with the liquid level in the tank. The floating roof may be open to the atmosphere. This physical arrangement of the tank is classified as an "open-top floating roof tank." A permanently installed cover may be placed over the entire tank; this second designation is classified as a "covered floating roof tank."

The floating roof has a perimeter seal between the roof cover perimeter and the tank shell. The seal is necessary to prevent flammable vapors from escaping into the atmosphere and collecting over the floating roof. Foam system standards such as NFPA 11 address seal devices and their physical arrangement. Some devices also require the use of a foam dam when protected by fixed foam systems. The requirements for foam dams are also addressed in design and installation standards.

The fire experience with floating roof tanks is generally favorable. Consequently, fixed foam outlets are not generally called for on either open top floating roof tanks or covered floating roof tanks. When a facility operator or an owner elects to protect these types of tanks or the local fire protection authority requests protection for these types of tanks, three different application techniques are typically used for the fire protection of open top floating roof tanks. A brief description of each technique follows.

Portable Nozzle Method

The basic fire problem associated with floating roof tanks is a fire burning in the seal area between the cover and the tank shell. Typically, the surface area of this fire is quite small. One technique to extinguish this type of fire is to advance a portable hose line to the top of the tank, supply foam to this hose line, and manually apply foam to the seal area. Personnel operating this hose line should be adequately trained for these types of fire fighting operations and be aware of established safety practices.

Catenary System Method

The catenary system consists of a series of foam makers at evenly spaced points in the roof near the seal. These foam makers are connected to a common section of piping which in turn is attached to a flexible hose that rides up and down with the access stairway to the roof cover. The stairway is fixed to the top of the tank shell, and the bottom portion of the stairway rides on a set of tracks attached to the floating cover. This arrangement allows the stairway to move both horizontally and vertically as the cover moves with the flammable liquid level.

At the time of a fire, foam solution is pumped under pressure through a vertical pipe and flexible hose to the foam makers. This system can be designed to discharge foam under the seal directly onto the flammable liquid, or foam can be discharged above the seal. Foam equipment manufacturers producing this type of equipment should be consulted for engineering data on design requirements, installation techniques, and hydraulic calculations.

Fixed Foam Maker Method

The fixed foam maker method consists of installing piping around the outside wall of the tank and connecting a series of foam makers installed on special mounting shields above the storage tank rim. The circumference of the tank will determine the number of points needed for foam application. This method requires a foam dam to retain the foam over the seal or weather shield. This dam is normally 12–24 in.

(305–610 mm) in height. Construction details of the foam dam are addressed in foam system standards such as NFPA 11.

Covered floating roof tanks are generally not protected with fixed foam fire protection systems. However, there might be some cases where local regulations or practices call for protection for these types of tanks. The standards for fixed roof tanks should apply where it is required to protect covered floating roof type tanks with foam systems.

Seal Area Application of Foam

Fires that occur on floating roof tanks are generally limited to the seal between the floating roof and the tank shell. A common method of protection for this type of fire is to apply foam either above the seal or below the seal. This is the type of protection that will be examined in this section.

In certain situations, the possibility may exist that the floating roof will sink within the tank below the surface of the stored liquid. Under this scenario, the protection concept should treat the tank as a fixed roof tank as described previously.

Procedure for Determining Foam and Water Supply for Surface Application Low-Expansion Foam Systems for the Protection of Floating Roof Tank Seals

This section is concerned with the design and associated hydraulic calculations for application of foam fire protection systems protecting the seal of a floating roof storage tank. The material presented is limited to fixed protection systems using fixed discharge devices. A single flammable liquid storage tank problem is presented for developing the appropriate methods and techniques for calculating the foam agent requirements, system hardware requirements, and the necessary hydraulic calculations to properly deliver the required rate of foam to the subject hazard. The single example will be calculated using top of seal application of foam.

Example 3 A single floating roof storage tank is to be protected by a fixed foam system with similar tank characteristics as indicated in Fig. 48.1. The top of seal protection concept is to be used in this installation. A private fire service main will provide water to the foam system. The hydraulic characteristics of the main are illustrated in Fig. 48.2. For this problem, consider that the water available for the foam system is limited to the water supply characteristics shown in Fig. 48.2 (i.e., no additional water sources are available). A foam system design and complete set of hydraulic calculations are to be prepared for this installation.

Solution A systematic step-by-step process follows. Reference is made to criteria established in NFPA 11. In addition to the physical layout of the design problem, information is required on the fuel stored in the tank, i.e. the hazard. The nature of the hazard influences the system design.

Step 1: Installation identification.

The evaluation must consider the site conditions of the storage tank and surrounding areas. In this example, a single floating roof storage tank is positioned in an area surrounded by a dike wall. The seal between the floating roof and the tank shell will be a mechanical shoe seal. The tank is to be protected by a fixed foam fire protection system and connected to a private fire service main.

Step 2: Hazard classification and description.

The specific hazard and storage arrangement need to be identified. In this example, a 120-ft diameter floating roof tank is storing a flammable liquid.

Step 3: Flammable/combustible liquid identification.

The characteristics of the stored liquid must be determined in order to select the appropriate type of foam concentrate to be used. In this example, gasoline is stored in (with a specific gravity of 0.72) is stored in the tank. The designer is cautioned to carefully review the types of liquids to be stored. Facilities sometimes utilize the same tank enclosure for the storage of various types of liquids.

Step 4: Type of protection.

Based on the storage arrangement and contents, an appropriate protection concept must be determined. Fixed protection systems using Type II discharge outlets will be used.

Step 5: Surface area of liquid to be protected.

Calculate the seal surface area to be protected. For the cylindrical storage tank, the area of protection will be equivalent to the area of the tank shell minus the area of the floating roof to the foam dam:

$$\text{Area} = 1/4\pi\left(d_1{}^2 - d_2{}^2\right)$$

$$\text{Area} = 1/4\pi\left((120)^2 - (118)^2\right) = 1,500\ \text{ft}^2$$

Step 6: Foam agent selected.

Based on the liquid being stored, an appropriate foam concentrate must be selected. Specific manufacturers will need to be consulted to determine the most appropriate foam concentrate for the hazard.

For this example, a 3 % fluoroprotein foam will be selected for the defined hazard. Note that the type of foam agent selected for a particular design will affect other variables and considerations in the foam system design.

Step 7: Description, number, and placement of foam application devices.

Several factors need to be simultaneously considered in developing this step. The selection of foam application devices will be dependent on the foam agent selected. In addition, the flow and pressure characteristics of the discharge device will be a factor or present options for the system design. Manufacturer's literature and the listing evaluation data of foam equipment should be consulted on this matter.

For top-of-seal protection, foam system standards such as NFPA 11 require the discharge devices to be spaced at maximum of 40 ft intervals around the perimeter of the tank for 12-in. foam dams and at maximum of 80 ft for 24-in. foam dams. For the purposes of Example 3, a 24-in. foam dam is installed. Therefore, a 120-ft diameter tank has a circumference of approximately 380 ft and requires a minimum of 5 discharge devices spaced around the perimeter of the tank. Additional devices might be appropriate based on hydraulic considerations, or equipment costs. Individual manufacturers of foam equipment must be consulted on these options.

Placement of discharge devices should be equally spacing around the upper tank perimeter to ensure even distribution of foam. If possible, A constant and uniform flow and pressure should also be maintained during discharge.

Step 8: Foam solution application rate.

Foam solution application rates for floating roof storage tanks with a mechanical shoe seal are usually specified by foam system standards and manufacturer's design guides. Referencing NFPA 11, Table 5.3.5.3, at least 0.3 gpm/ft^2 of seal area of the tank to be protected is to be provided. It should be noted that specific types of seal protection may require different application rates. Appropriate references should be consulted in this regard.

The total foam solution discharge rate for Example 3 is calculated as follows:

$$\begin{aligned}\text{Rate (g pm)} &= 0.3\ \text{g pm/ft}^2 \times 1,500\ \text{ft}^2 \\ &= 450\ \text{g pm}\end{aligned}$$

The total discharge rate can be divided equally among the five required discharge devices. It is appropriate to specify a total rate of 450 gpm, with 90 gpm per discharge device or foam maker.

Step 9: Foam concentrate supply rate.

The foam concentrate supply rate is based on the foam agent proportioning rate. As noted in this example, 3 % fluoroprotein foam has been selected for this problem (Step 6). In other words, 3 % of the calculated foam solution rate is the foam concentrate supply rate. This rate may be determined as follows:

$$\begin{aligned}\text{Foam concentrate rate} &= 0.03 \times 450\ \text{g pm} \\ &= 13.5\ \text{g pm}\end{aligned}$$

Therefore, a continuous supply of foam concentrate must be available at a rate of 13.5 gpm for the required duration of discharge (Step 11).

Step 10: Water supply rate.

The water supply rate is the foam solution rate minus the foam concentrate supply rate. The necessary water supply rate can be calculated as follows:

$$\text{Water supply rate} = 450\,\text{g pm} - 13.5\,\text{g pm} = 436.5\,\text{g pm}$$

The water supply rate can also be determined as 97 % of the foam solution rate when using a 3 % foam concentrate.

Step 11: Duration of discharge.

Foam system standards and manufacturer's design guides generally specify the duration of foam discharge. Duration of discharge is dependent on the classification of seal protection. Per NFPA 11, Table 5.3.5.3.1, the requirement for floating roof tanks with a mechanical shoe seal and top-of-seal protection is 20 min. of continuous foam solution discharge. A minimum foam solution discharge time is specified in NFPA 11 (Table 5.3.5.3.1).

Step 12: Quantity of foam required.

The necessary foam supply for any given application should consider a primary supply and the availability of a reserve supply. The primary supply is calculated by multiplying the foam concentrate supply rate by the duration of discharge as follows:

$$\text{Foam agent required} = 13.5\,\text{g pm} \times 20\,\text{min} = 270\,\text{gal}$$

A risk analysis or the authority having jurisdiction may require that an equal quantity of foam be placed in reserve on site if there is a credible likelihood of a second fire occurring before the foam supply can be replenished.

Step 13: Total quantity of water required.

The basic procedure follows the concept presented in Step 12. The water requirement is the product of the water supply rate multiplied by the duration of discharge. In this case:

$$\text{Volume of water required} = 436.5\,\text{g pm} \times 20\,\text{min} = 8,730\,\text{gal}$$

Hydraulic Analysis of a Surface Application Low-Expansion Foam Systems for the Protection of Floating Roof Tank Seals

The hydraulic analysis for this system is similar to that provided for the surface application of foam to the fixed roof storage tank in Example 1. Therefore, the procedure is not repeated here.

Protection of Storage or High-Volume Hazards with High-Expansion Foam

High-expansion foam is an agent for the control and extinguishment of both Class A and Class B fires. The classification of foam also makes is particularly suitable as a flooding agent for use in confined spaces.

The development and application of high expansion foams for firefighting purposes started with the work of the Safety in Mines Research Establishment in England concerning the difficult problem of fires in coal mines. It was found that by expanding an aqueous surface active agent solution to a semistable foam of about 1000 times the volume of the original solution, it was possible to force the foam down relatively long corridors, thus providing a means for transporting water to a fire inaccessible to ordinary hose streams. This work was expanded upon by the United States Bureau of Mines immediately after World War II.

Developmental work in the United States on high expansion foam has led to the refinement of specialized high expansion foam generating equipment for fighting fire in confined spaces, for specific applications to fire control problems in both municipal and industrial fire fighting, and for the protection of special hazard occupancies. Medium-expansion foam was developed to cover the need for a more wind-resistant foam than high expansion foam for outdoor applications.

Concepts and Suitability for Medium and High-Expansion Foams

Medium- and high-expansion foams are aggregations of bubbles that are mechanically generated by the passage of air or other bases

through a net, screen, or other porous medium that is wetted by an aqueous solution of surface active foaming agents. Under proper conditions, fire fighting foams of expansions from 20:1 to 1000:1 can be generated. Such foams provide a unique agent for transporting water to inaccessible places, for total flooding of confined spaces such as basements, and for volumetric displacement of vapor, heat, and smoke. Extensive tests have demonstrated that under certain circumstances high expansion foam, when used in conjunction with water sprinklers, will produce more positive fire control and extinguishment than by either extinguishment system alone. This appears to be especially true with high rack storage of mixed commodities (e.g., high piled storage of paper stock and mixed storage of Class A and Class B materials). Optimum efficiency of high-expansion foam in any one type of hazard is dependent to some extent on the rate of application and also the foam expansion and stability throughout the fire event.

Personal Safety

Persons should not enter a space filled with high expansion foam without wearing full protective gear, self contained breathing apparatus, an attached lifeline, and operating in a "buddy" system. A person who is immersed in high-expansion foam can experience disorientation and other psychological and personal discomforts. Foam entering any of the body cavities may cause severe irritation and membrane swelling.

Special Considerations

The proper design and application of high-expansion foam systems are directly related to a number of unique considerations such as maximum submergence time and location of foam generating equipment.

A maximum submergence time needs to be specified for filling the enclosed space to the proper depth with expanded foam. The time, usually expressed in minutes, is a function of the type of combustible material and the arrangement of the combustible material. An important consideration in maximum submergence time is whether the materials/products to be protected remain at a constant height. Another consideration is the presence of an automatic sprinkler system. The basic objective is to control a developing fire before the fire has an opportunity to spread vertically over the face of a storage pile.

Fixed installations using high-expansion foam will probably involve the use of customized foam generating equipment to produce the necessary rate of volumetric foam discharge. The following factors should be considered in the selection and placement of high-expansion foam generating equipment:

1. Two foam generators positioned remotely from each other are more effective and efficient than a single generator.
2. Foam generating equipment should be top mounted to avoid back pressures on the foam making equipment. Foam generators are normally mounted on external towers or special roof supports.
3. Foam generating equipment should be so positioned as to avoid product-of-combustion air intake. Induced smoke into the generating equipment can significantly reduce the quality and quantity of the foam produced.
4. To effectively dampen convection currents from a developing fire in an area to be protected, the capacity of each required foam generator should be the same.

High-Expansion Foam System Calculations

Many of the fundamental hydraulic concepts presented with low-expansion foam system design problems also apply to high-expansion foam systems. Some similarities and differences between the hydraulic design for high-expansion foam systems and low-expansion foam systems are presented in Table 48.1. In this analysis, a low-expansion foam system using top-mounted

Table 48.1 Comparison of design criteria for low-expansion and high-expansion foam systems

Design/hydraulic step function	Low-expansion foam system—top chamber	High-expansion foam system—top generator
Starting point	Foam chamber(s)	Foam generator(s)
Second determination	Foam solution requirement per chamber (gpm)	Expanded foam requirement per chamber (cfm)
Third determination	Foam solution delivery rate between foam maker and foam house	Same determination
Fourth determination	Size pipe from foam maker(s) to foam house	Size pipe from foam generator (s) to foam house
Fifth determination	Determine type and size of foam proportioner	Same determination

Eighth determination	Assess requirement for pump in foam house; recalculate hydraulic requirements in foam house	Same requirement

foam chambers is compared to an elevated high-expansion foam generator installation.

The following example considers the use of a high-expansion foam system in conjunction with automatic sprinkler protection for fire control and suppression in a specified warehouse. Be careful to note the generator flow rates, foam concentrate rates, and water supply rates. One of the advantages for considering high-expansion foam for the protection of confined space hazards is the low rate of foam application and associative water rate when compared to other aqueous types of systems.

Hydraulic Calculation Procedure for High-Expansion Foam Systems

Example 4 An owner has elected to protect a number of warehouse complexes with a combination of automatic sprinklers and high-expansion foam. A typical four-bay warehouse complex is illustrated in Fig. 48.8. The storage item is crude rubber piled 12.5 ft high in 2000 ft^2 pile areas. The installed sprinkler design is 0.2 gpm/ft^2. The location of the high-expansion foam generators is illustrated on the 12-in.-wide brick fire walls. Each foam generator is equipped with a set of remote controlled baffles that permits directional flow of foam into adjacent fire areas. Custom generators are used that have a foam solution rate requirement of 1.83 gpm per 1000 ft^3 of foam production. Three percent foam proportion with listed high-expansion foam is used for this system.

Solution The key consideration in high expansion foam system design is the proper sizing of the foam-generating equipment to be used for the application. A job work sheet is provided to facilitate the system design and identify relevant requirements. (See Fig. 48.9.) Applicable information is transferred from the referenced job sheet to the associated hydraulic calculation sheet. (See Fig. 48.10.) Reference is made to criteria established in foam system standards, specifically NFPA 11. The applicable foam system standards should be referenced for the systematic evaluation of any foam system.

The fundamental considerations of the hazard to be protected against establish the basis for the system design. In the case of high-expansion foam, some subjective criteria need to be established due to the lack of specific details in some foam system standards. Subjective criteria will be specifically noted below. A systematic step-by-step process follows.

Step 1: Installation identification.

Refer to Fig. 48.8, a storage warehouse.

Step 2: Hazard classification.

High density combustibles. The actual storage material is assumed to be crude rubber provided in irregular flat sheets. This commodity is not

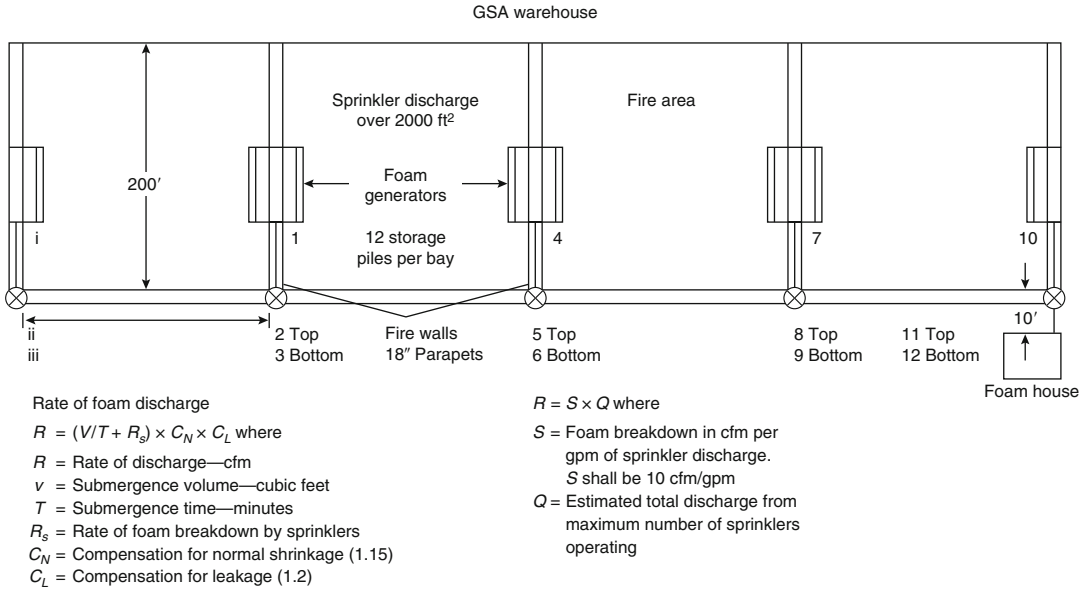

Fig. 48.8 Typical four bay warehouse complex

specifically identified in NFPA 11. Therefore, some judgment must be made when selecting foam submergence time as required for the calculations below.

Step 3: Type of protection.

The warehouse is protected by a dry-pipe automatic sprinkler system with a maximum discharge capability of 0.2 gpm/ft^2 over 2000 ft^2. This discharge density alone is not considered adequate protection for crude rubber in 2000 ft^2 piles. The automatic sprinkler protection is to be supplemented by a fixed high-expansion foam system. The foam generators are mounted on the coping section to the fire walls that divide the warehouse into fire areas. Generators positioned on the internal fire walls are arranged to discharge foam into whichever compartment, as required.

Step 4: Hazard description.

The fundamental considerations associated with the hazard are given under Step 1. It should be further noted that 12 storage piles of 2000 ft^2 each are located in the designated fire areas. Each individual pile is approximately 12.5 ft high. Due to the piling arrangement of the rubber and the burning characteristics of rubber, no deduction is made for "stock volume" in the rate discharge determination.

Step 5: Rate of discharge determination.

The basic design objective is to determine the rate of expanded foam discharge in cubic feet per minute to sub- merge the hazard in a defined period of time. This determination can be accomplished by applying a rate formula developed by the NFPA Foam Committee. The formula is given in NFPA 11, Section 6.12.8.2.3.1. The formula can be applied by first calculating and then assigning values to the formula variables.

1. *Submergence volume* (Re: NFPA 11, Section 6.12.5.2.2).

   Floor area: $200\text{ ft} \times 200\text{ ft} = 40,000\text{ ft}^2$

   Foam Depth:

   $$1.1 \times \text{height} = 1.1 \times 12.5\text{ ft} = 13.75\text{ ft}$$

   $$\text{Height} + 2\text{ ft} = 12.5\text{ ft} + 2\text{ ft} = 14.5\text{ ft}$$

   Use the larger of the two values (14.5 ft) for calculations.

HIGH-EXPANSION FOAM SYSTEM JOB WORK SHEET

Sheet: 1 of 1

Designer: Staff Date:

Installation identification: GSA Defense Materials Warehouse

Hazard classification: High density combustibles

Type of protection: Dry pipe automatic sprinkler—fixed HI-X foam

Hazard description: Crude rubber in piles

Rate of discharge determination:

1. Submergence volume (cubic feet)
   v = floor area 40,000 sq ft × foam depth 14.5 ft = 580,000 cu ft
2. Submergence time (minutes) T = 5
3. Rate of foam breakdown by automatic sprinklers: $R_s = S \times Q$ where
   S shall be 10 cfm/gpm and Q shall be total discharge from operating sprinklers
   R_s = 10 cfm × 400 gpm = 4000 cfm
4. Compensation for normal foam shrinkage—C_N: C_N = 1.15
5. Compensation for leakage—C_L; C_L range is from 1 to 1.2: C_L = 1.1
6. Rate of discharger (cfm) = $(v/T + R_s) \times C_N \times C_L$ = 151,800

Description, number, and placement of foam generators: 2—80,000 cfm foam generators per storage bay. Placement on fire walls as shown

Foam solution rate: 146 gpm/generator × 2 = 292 gpm

Foam concentration rate: 3% proportion × 292 gpm = 9 gpm

Duration of discharge: 15 minutes of full operation

Gallons of foam required: Main and reserve = 270 gals

Gallons of water required: 4,245

Water supply information: Adequate for demand curve

Special foam system design considerations: System is activated by automatic sprinkler system dry pipe trip.

Fig. 48.9 High expansion foam system job work sheet

$$\text{Volume} = \text{area} \times \text{depth}$$

$$\text{Volume} = 40{,}000\ \text{ft}^2 \times 14.5\ \text{ft}$$

$$= 580{,}000\ \text{ft}^3$$

(See Step 4—no deduction is made for stock volume)

2. *Submergence time* (Re: NFPA 11, Section 6.12.7).
   5 min for high density materials with sprinkler protection
3. Rate of foam breakdown for sprinklers (Re: NFPA 11, Section 6.12.8.2.3.2).
   Discharge from sprinklers:

Fig. 48.10 Hydraulic calculations for Example 3

$$Q = 0.2\,\text{g pm/ft}^2 \times 2{,}000\ \text{ft}^2 = 400\,\text{g pm}$$

Apply formula:

$$R_s = 10\,\text{c fm/g pm} \times 400\,\text{g pm} = 4{,}000\,\text{c fm}$$

4. *Compensation for shrinkage*. Set at 1.15 as a constant (Re: NFPA 11, Section 6.12.8.2.3.3).
5. *Compensation for leakage*. Use 1.1 to allow for some leakage around doors (Re: NFPA 11, Section 6.12.8.2.3.4).
6. Apply formula:

$$\text{Rate} = (v/T + R_s) \times C_N \times C_L$$

$$\begin{aligned}\text{Rate} &= \left(580{,}000\ \text{ft}^3/5\ \text{min} + 4{,}000\,\text{c fm}\right) \\ &\quad \times 1.15 \times 1.1 \\ &= 151{,}800\,\text{c fm}\end{aligned}$$

Note The foam breakdown from sprinklers is a relatively small value compared to the total cfm rate.

Step 6: Description, number, and placement of generators.

Custom-built foam generators will be required for this problem. Each generator will have a capacity of 80,000 cfm with a foam solution rate of 146 gpm. (See given information with problem statement.) Five generators will be required to protect the entire warehouse. Generators mounted on interior fire walls will be equipped with baffles arranged to discharge foam into either adjacent compartment; electrical controls will be operated from the foam house. Generators are actually mounted 22 ft above the finished floor.

Step 7: Foam solution rate.

The foam solution rate per generator is given in Step 6. The solution rate requirement is 1.83 gpm per 1000 ft^3 of foam production.

$$\begin{aligned}\text{Solution rate} &= 80{,}000\ \text{ft}^3/1000\,\text{ft}^3 \times 1.83\,\text{g pm} \\ &= 146\,\text{g pm}\end{aligned}$$

Two generators require 292 g pm.

Step 8: Foam concentrate rate.

The foam selected for this problem proportions at 3 %. Therefore, the concentrate rate is 3 % × 292 gpm = 9 gpm.

Step 9: Duration of discharge.

Duration of discharge for the foam systems should be checked with the authority having jurisdiction. A basic minimum discharge time is 15 min of continuous operation.

Step 10: Quantity of foam required.

It is assumed that enough foam will be placed in storage to meet both a main and a reserve requirement: 9 gpm × 15 min × 2 = 270 gal.

Step 11: Quantity of water required.

The primary water supply must provide a rate of 283 gpm for 15 min or 4245 gal. A similar quantity is required to be supplied for the secondary demand.

Step 12: The problem considers that the water supply to the foam house is adequate to meet the calculated demand for the system.

Step 13: The foam system is to be activated by the automatic sprinkler system when the dry-pipe valve trips due to a sprinkler operating. The system can also be activated manually.

Hydraulic Analysis for High-Expansion Foam System

The following outlines the procedure involved in calculating the hydraulic demand of a high expansion foam system. The reader is assumed to posses a fundamental understanding of water supply analysis and fire protection hydraulics. The system in Example 4 as depicted in Fig. 48.8 is used in outlining the calculation procedure. The design parameters and associated calculations are presented in sequential steps, which are summarized on a hydraulic calculation sheet as shown in Fig. 48.10 with reference points identified in Fig. 48.8.

Step 1: The inlet pressure requirement for the foam generator is 50 psi.

Step 2: The foam solution line supplying each foam generator and the riser pipe to the top of the fire wall are sized on the basis of a maximum flow velocity of 10 ft/s.

$$Velocity = \frac{0.4085 \times gpm}{d^2}$$

$$10 fps = \frac{0.4085 \times 146 gpm}{d^2}$$

$$10d^2 = 59.64$$

$$d^2 = 5.96$$

$$d = 2.44$$

Use a $3-$ in. pipe

Since the same size pipe is used from the foam generator to ground level, the hydraulic analysis can go from reference point 1 to reference point 3. The elevation head to be considered is 22 ft.

Step 3: The flow and pressure demand at the base of each riser supplying a foam generator is the same, since the generator sizes are equal. It is necessary to calculate a flow constant at this location so the pressure points upstream can be correctly adjusted for higher pressure values developed by friction loss between supply points. The demand constant is calculated as follows (reference point 3):

$$Q = K\sqrt{P}$$

$$146 \text{ g pm} = \text{K } (68.6)^{1/2}$$

Step 4: The ground-level cross-main connecting the foam generator risers is sized on the basis of a maximum flow velocity of 10 ft/s. The flow from two generators is used for the flow computations.

$$Velocity = \frac{0.4085 \times gpm}{d^2}$$

$$V = \frac{0.4085 \times 292 gpm}{d^2}$$

$$10d^2 = 119.282$$

$$d^2 = 11.928$$

$$d = 3.45$$

Use a $4-$ in. pipe

Step 5: Determine the actual flow characteristics for the high-expansion foam generator at reference point 4.

Use the K value (constant) determined in Step 3 to calculate the actual supply to the second foam generator at reference point 4. The new pressure at the riser base (reference point 6) is 70.7 psi from the hydraulic calculation sheet. The higher pressure is used with the K value to determine the actual flow for the second high-expansion foam unit.

$$Q = K\sqrt{P}$$

$$Q = 17.6\sqrt{70.7}$$

$$Q = 148$$

The actual flow increases by 2 gpm for the second generator.

Step 6: Determine the flow and pressure requirements at the foam house. Determine the friction loss for the total flow back to the foam hose and add in 4 psi for the foam proportioner.

Step 7: System demand.

The final system demand is 294 gpm at 90.0 psi at the foam proportioner inlet to supply the two high-expansion foam generators. The water supply to the foam house must meet this demand.

Compressed Air Foam Systems

Compressed Air Foam Systems (CAFS) are recent developments highly dependent on the manufacturer's products and the specific listing

requirements of the particular system. As such, foam system standards such as NFPA 11 do not provide comprehensive design guidance for these types of systems. Instead design standards and regulations mostly indicate that the system design must be in accordance with the manufacturer's design manual, which is required to be part of the listing.

Foam system standards such as NFPA 11 require that compressed air foam systems to provide a minimum discharge density in accordance with applicable occupancy and facility specific standards, but in no case less than 0.04 gpm/ft^2 (1.63 L/min- m^2) for hydrocarbon fuels applications and 0.06 gpm/ft^2 (2.3 L/min-m^2) for alcohol and ketone applications. The CAFS is also to be designed to provide a minimum discharge duration, 5 min for fixed spray systems and 10 min for deluge-type system per NFPA 11.

Limitations of Foam Fire Protection Systems

This section discusses both low- and high-expansion foam systems. The limitations of foam fire protection must be addressed relative to each of these two types of systems. The following factors should be reviewed during the selection and design of fire protection systems generating foam.

Limiting Factors for Low-Expansion Foam Systems

1. Low-expansion foam application is limited to the extinguishment of horizontal or two-dimensional fire problems. This type of foam application is not suitable for three-dimensional fires.
2. Low-expansion foam systems are limited by foam agent suitability for the defined flammable or combustible liquid. Basically, foam agents are suitable for either hydrocarbon fuels or polar solvents. Alcohol resistant-type foams may be approved for both hydrocarbons and polar solvents.
3. Different types and brands of foam concentrates may be incompatible and should not be mixed in storage.
4. Foam solution consists of 90 % or more water. Foam system limitations should be evaluated with respect to the proper use of aqueous based agents on flammable materials and the electrical conductivity of the application method.
5. Foam systems are limited by the equipment appliances and devices used to proportion the foam and to deliver the finished foam onto a given hazard or fire problem. Equipment limitations pertaining to flow rate, operating pressure ranges, and proportioning ranges should be carefully considered in the selection and application of foam systems.

Limiting Factors for Medium- and High-Expansion Foam Systems

1. Medium- and high-expansion foams are finding applications for a broad range of fire protection problems. However, unlike low-expansion foam systems, medium- and high-expansion foam fire protection systems should be specifically evaluated for each type of hazard condition. The fact that each system requires a feasibility study and individual design may be considered a form of limitation when contrasted to the design concepts for low-expansion foam systems.
2. NFPA 11 states that *under certain circumstances, it might be possible to utilize medium- or high-expansion foam systems for control of fires involving flammable liquids or gases issuing under pressure, but no general recommendations can be made in this standard due to the infinite variety of particular situations that can be encountered in actual practice* [1]. This statement is considered to be a design limitation.

3. Medium- and high-expansion foam systems should not be used on fires in the following hazards unless competent evaluation, including tests, indicates acceptability:
   (a) Chemicals, such as cellulose nitrate, which release sufficient oxygen or other oxidizing agents to sustain combustion
   (b) Energized unenclosed electrical equipment
   (c) Water reactive metals, such as sodium and potassium (Na, K)
   (d) Hazardous water reactive materials, such as triethylaluminum and phosphorous pentoxide
   (e) Liquefied flammable gas

The Advent of Class A Foams

Foam agent fire protection systems are also suitable for Class A fires in ordinary combustible materials in addition to Class B fires (flammable and combustible liquids). Historically, portable foam fire extinguishers provided important fire protection for both Class A and Class B problems. The dual consideration of evaluating foam fire protection systems for both Class A and Class B fire protection problems is important. This consideration is especially important for mixed occupancy storage, which may be suitably protected by foam spray systems, foam water sprinkler or spray systems, or closed head sprinkler systems using aqueous film forming foam (AFFF) type foam agents.

Class A foams have been used extensively in wildland fire suppression activities. The success of Class A foam for the confinement, control, and extinguishment of natural cover fuel fires suggests that this type of foam may be effective for structural fire protection as foam solution in fire streams. Initial research has been conducted to quantify the fire fighting efficiency of Class A foams to improve the operating efficiency of these foams when compared to plain water fire streams. The National Fire Protection Research Foundation has published research findings on Class A foam effectiveness: one in December 1993 [2] and one in November 1994 [3]. A synopsis of the findings are presented below.

The National Fire Protection Research Foundation (NFPRF) sponsored a research program with Underwriters Laboratories, Inc. (UL), to investigate the effectiveness of Class A foams by means of three discharge devices: (1) a standard spray nozzle, (2) an air-aspirated spray nozzle, and (3) by injecting compressed air into the Class A foam solution. This research investigation has two objectives: (1) to develop test data related to the fire fighting effectiveness of Class A foam solutions as compared to water only and (2) to conduct laboratory analysis of the Class A foam concentrate used in the performance tests.

Briefly, the initial fire test plan included a Class 20A wood crib fire with foam solution concentrates selected at 0.1 %, 0.3 %, and 0.5 %. Adjunct variables included nominal expansion ratios of 5 for a standard nozzle at 15 gpm, 7.5 for an air-aspirated nozzle at 15 gpm, and 7.5 for injecting compressed air into the Class A foam solution.

The wood crib fire tests were conducted at UL's test facility located in Northbrook, Illinois, and are reported in the December 1993 publication.

In summary, the initial set of fire tests provides support of the following conclusions by the Technical Advisory Committee (TAC):

- Handheld hose lines supplied with Class A foam solutions provide enhanced fire fighting performance when compared to handheld hose lines supplied with water only.
- The best foam quality, as measured by retention and exposure protection tests, was achieved with compressed air foam.
- Results of the wood crib fire tests indicated superior characteristics in terms of fire control time for Class A foams when compared to water application only.
- Fire tests conducted with the air-aspirated test nozzle had the longest reignition times, while

tests conducted with the Compressed Air Foam had the lowest crib weight losses.
- Exposure protection test results demonstrated the ability of the Class A foam to lengthen the ignition time of a combustible surface when compared to cribs protected by the same rate and duration of water.
- Retention-of-weight tests demonstrated that wood cribs exposed to Class A foam retain more weight than cribs treated with water.

The testing program outline above was very controlled in a laboratory setting. Foam applications were not subjected to many real world variables that could include wind, weather conditions, fuel geometry, pre-burn times, and human factors in the foam application. Despite such conditions, the reported testing program clearly supports a number of advantages for using Class A foam on structural type fires.

The Phase II research project report of 1994 reviews the conduct of structural fire suppression tests. These tests were also conducted at UL's test facilities in Northbrook, Illinois. A test cell measuring 30 by 36 by 30 ft was used for the Class A foam comparative analysis tests. Two fuel package scenarios were used as follows:
- The Series I UL 1626 residential fuel package consisted of a wood crib and simulated furniture positioned in one corner of the enclosure.
- The Series II fuel package consisted of a corner upholstered sofa scenario.

Fire test monitoring of the enclosure included measurements of the Class A foam solution or water flow rate; room temperature gradients at distances of 2, 9, 18, 24, 33, 48, and 72 in. below the ceiling; rate of heat release; oxygen content; smoke density; and heat flux. In each test series, observations were made of fire knockdown and damage to the walls of the enclosure and the fuel package.

Upon ignition, the fuel package was allowed to burn until flashover was achieved in the enclosure. Five seconds after flashover, a water application or a Class A foam solution was applied to suppress the fire using either a direct or indirect application method. The direct application method consisted of discharging the agent directly onto the walls of the enclosure and the fuel package. In contrast, the indirect application method consisted of discharging the agent first onto the ceiling and walls and then onto the fuel package.

The 1994 Class A Foam Study Report divides the summary information according to the Series I and II testing programs. The Series I abbreviated findings are summarized as follows:
- Class A foam using a direct application method took less time and quantity of agent to lower heat release to 500 KW than plain water.
- Class A Compressed Air Foam (CAF) using the indirect application method was more effective in reducing heat release values down to 500 KW.

The Series II abbreviated findings are limited to the following selective observations:
- The test results using Class A foam solutions generally provided for a reduced amount of total heat release from the fire and less damage to the sofa.
- Class A Compressed Air Foam applied at 7 gpm using the direct application method demonstrated the shortest time period and the lowest quantity of agent required to reduce the rate of heat released to 500 KW.
- The direct application method provides for a reduced amount of total heat release and less damage to the sofa when compared to the same tests conducted using the indirect application method.

Both reports recommend additional research on the application of Class A Foams with special attention given to hardware devices that include handheld fixed nozzles, proportioning equipment, and foam-generating equipment.

Additional research has been conducted by the National Institute of Standards and Technology [4]. The effectiveness of Class A foams on Class A and Class B fire threats were characterized. Four representative Class A foams were chosen for evaluation. A series of Class B fire suppression tests were conducted in

conformance with UL 162 *Standard for Foam Equipment and Liquid Concentrates*. These tests utilized a 4.6-m^2 (50-ft^2) heptane pool fire and consisted of the suppression of the fire and then testing for reignition and burnback resistance. Agent was applied at 2.44 and 4.88 lpm/m^2 (0.06 and 0.12 gpm/ft^2), which is one and one-half and three times the rate required by the standard for AFFF application. The higher flow rates were used because the agents could not extinguish the fire at the standard AFFF application rate. The four agents had fire knockdown (control) times similar to AFFF, but two of the agents did not completely extinguish the fire in all the tests. AFFF had a higher resistance to burnback and longer time to re-ignition than the other four agents.

Full-scale fire experiments were conducted with 92.9-m^2 (1000-ft^2) gasoline pool fires. Agent application was made with a 454 lpm (120 gpm) hose stream (i.e., 4.88 lpm/m^2 [0.12 gpm/ft^2]). Two application techniques were used with each of the four agents in the large-scale tests. One application was made with a self-aspirating tube nozzle, and one application was made with a nonaspirating adjustable fog nozzle. AFFF and water were used as benchmark agents for these tests. Plain water could not extinguish this fire. AFFF exhibited better fire control and extinguishment characteristics, and substantially better burnback resistance, than those of the Class A foams.

In tests conducted for the U.S. Air Force, the Naval Research Laboratory assessed a compressed air foam system for possible use for aircraft hangar scenarios involving JP-8 fuel [5]. The breadboard unit used AFFF as the fire extinguishing agent. It was found that a commercial off the-shelf non-air-aspirating nozzle was as effective as the air-aspirating nozzle provided with the unit. Air injection for aeration of the AFFF stream before discharge from the nozzle was found to be unnecessary.

Nomenclature

C	Hazen-Williams coefficient (constant)
C_L	Foam leakage correction factor
C_N	Normal foam shrinkage factor
D	Internal pipe diameter (in.)
FL	Friction loss (psi/ft)
K	Nozzle discharge coefficient (gpm/psi1/2)
Q	Flow (gpm)
R	Total foam generator capacity (cfm)
R_s	Total rate of foam breakdown [S × Q] (cfm/gpm)
S	Rate of foam breakdown by sprinklers per gpm of sprinkler discharge (cfm/gpm)
T	Submergence time (min)
V	Velocity (ft/s)
ν	Submergence volume (ft^3)

Considerations for Coordinating and Interfacing Fire Protection and Life Safety Systems

49

David Jacoby, David LeBlanc, Jeffrey Tubbs, and Andrew Woodward

Introduction

Fire protection and life safety strategies for modern buildings and facilities are developed to accomplish specific goals and objectives as agreed to by the relevant stakeholders. Effective implementation of such strategies requires not only sound design and installation of the relevant building systems and features, but also the proper integration and coordination of such systems and features. The overall process for properly integrating and coordinating the applicable systems often requires significant effort and focus as the various systems are often designed and installed by different engineering and contracting disciplines, and approved by different enforcement agencies. As such, it is critical that the building system integration and coordination process be appropriately considered throughout the design, installation, *commissioning* (*Cx*), and acceptance testing process, as well as during the life-cycle maintenance of the systems.

System coordination is needed for new buildings, existing building renovations, existing building additions, upgrades to existing building systems, and retrofit installations of new systems in existing buildings. Because the size, functionality and complexity of buildings continue to increase, building and fire regulations require fire protection and *life safety systems* that rely upon proper integration for effective performance. For some buildings and facilities, performance-based solutions, which are permitted by many building and fire regulations, offer the best approach because they allow greater flexibility in the design of the buildings and their supporting systems. However, these performance-based solutions may require even more sophisticated fire protection and life safety system solutions. Whether code-prescribed or performance-based approaches are used, effective integration and coordination of the associated fire protection and life safety systems requires proper attention and knowledge.

Systems and components that typically require *integrated systems* and coordination include those associated with fire detection and alarm, emergency communication, suppression and extinguishing, fire pump and water supply, security and access control, smoke control, HVAC, building management (BMS), emergency and standby power, emergency lighting, exit signage, elevators and escalators, doors, operable windows, fire shutters, and dampers.

Integration and coordination of systems can be accomplished in various ways. The following identifies a systematic approach that can be applied through various types of building design and construction procurement methods,

e.g. traditional Design Bid Build, Design Build, and Design Assist. The majority of this chapter focuses on steps three thru six below:

1. Develop the design objectives and goals with the stakeholders for the project, incorporating the *Owner's Project Requirements* (*OPR*) and establish the preliminary fire protection and life safety strategy to meet these goals and objectives during the Planning Phase.
2. Implement the strategies into the design, through the *Basis of Design* (*BOD*), fire protection and life safety strategy report, system design reports, design drawings, sequence of operation (i.e. fire alarm input/output functional matrix), specifications, and other documentation during the Design Phase.
3. Updates of the various system designs during the Design Phase, including refinements and integration of systems as described in the reports, design documents, and specifications.
4. Cross reference and verify consistency among the various systems with multiple contractor shop drawings and submittals, and field changes during the Construction Phase of the project.
5. Complete *fire and life safety commissioning* documentation for the individual fire protection and life safety systems including *pre-functional test*.
6. Complete Integrated Testing of all of the integrated fire protection and life safety systems and complete final *acceptance* testing.
7. Periodic Inspection, Testing, and Maintenance of the individual fire protection systems along with periodic integrated system testing for the life of the building.

This chapter overviews *integration*, interfacing, and coordination considerations for systems used to support comprehensive fire protection and life safety design strategies, with a focus on electronic interface among the various installed fire protection and life safety systems. These electronic or physical *interconnections* between systems comprise the interfacing between these systems. *Integration* of fire protection and life safety systems includes the physical or electronic interfaces, and also includes other items such as the trained human intervention in a defined process like a prison guard releasing egress doors in a prison during an emergency. Section "Systems Overview" provides background on fire protection and life safety design and features that may require coordination. Sections "System Integration Considerations During the Design Process", "Systems Coordination During Construction" and "Life of the Building" focus on coordination of these systems and features during design, construction, and post occupancy. The section on "Commissioning and Integrated Systems Testing" overviews commissioning for fire protection and life safety systems. Although the emphasis of the chapter is on active fire protection systems, passive systems support active systems (directly or indirectly) and, as such they are discussed where appropriate. Passive systems are an important component of the overall life safety and fire protection strategy of a building.

A general discussion is provided on considerations that may need to be addressed to ensure that the installed fire and life safety systems perform as a fully integrated and coordinated unit. A full all-inclusive list describing all possibilities is not practical. Various examples and cases are illustrated. There are numerous ways a system can be designed and configured. The specific building, fire protection systems, owner's and project's goals and objectives all impact the design and approach for coordination and integration of fire protection systems. The coordination and integration of the fire protection systems usually need to be customized for each building, and approaches will vary from project to project. Systems may be successfully integrated through other methods than those presented in the Chapter.

Fire Protection Engineers are uniquely qualified to be an integral part of the coordinating, integration, and interfacing fire protection and life safety systems, due their background, experience, and education.

Relevant Documents

Building and fire codes detail prescriptive requirements for fire protection and life safety systems and their components. For example, the International Building Code [11]; International Fire Code [12]; NFPA 101; *Life Safety Code* [17]; NFPA 5000; *Building Construction and Safety Code* [18]; and NFPA 1; *Fire Code* [19] specifically mandate various systems based upon the intended building occupancy classification, function and characteristics. Detailed design and installation provisions concerning the systems, including *acceptance testing*, are included in various reference standards and other regulations such as those published by NFPA, ASHRAE, ASME, and others. However, the general functionality of the systems is outlined in the applicable building or fire code, with specific reference made to the pertinent reference standards. In a growing number of instances, performance-based design approaches are used to develop more holistic strategies for building and infrastructure projects, and such strategies often require unique combinations of systems and their components. Insurance regulations may also mandate or recommend certain features and systems not specifically addressed by the applicable building or fire code.

Commissioning and integrated testing of fire protection and life safety systems are critical functions ideally done during the Design Phase and Construction Phase of the project. The first step in commissioning is the development of the *OPR*, the owner and user developed project requirements and performance criteria developed that describe project goals and criteria for system function, performance and maintainability. The *OPR* may then serve as direction for the *BOD*.

Fire Protection and Life Safety Commissioning is completed on an individual system basis, such that each of the individual systems are commissioned separately. *Integrated Testing* is done to integrated systems to verify the integration or interface between these systems are functioning appropriately. An independent third party owner's representative typically conducts the commissioning and integrated testing activities to verify that the systems have been properly installed, programmed and coordinated and to confirm that the installed systems function as an integrated unit as intended by their design documentation. The owner's representative ideally assists in both the Design Phase and the Construction phase of the project.

In some parts of the world, such as in several European nations, commissioning of building systems including active fire protection systems have occurred for decades and is extremely common. In the United States, commissioning of fire protection systems is a more recent growing trend.

Numerous documents addressing commissioning and integrated testing of fire protection and life safety systems have been published. The following lists specific relevant documents. Section "Commissioning and Integrated Systems Testing" discusses commissioning and the commissioning process in more detail.

NFPA 3, *Recommended Practice for Commissioning and Integrated Testing of Fire Protection and Life Safety Systems* [21], outlines a process for commissioning and integrated testing.

NFPA 4, *Standard for Integrated Testing of Fire Protection and life Safety Systems*, 2015 Edition focuses on providing the minimum requirements for integrated testing of fire protection and life safety systems as an adoptable and enforceable standard.

ASHRAE Guideline 0, *The Commissioning Process* [5] and ASHRAE Guideline 1.5, *The Commissioning Process for Smoke Control Systems* [6] outline a process and provide detail specific to commissioning of smoke control systems.

CAN/ULC-S1001-11 *Integrated Testing of Fire Protection and Life Safety Systems* [35] outlines integrated testing.

D.M.10.03.1998—Decreto Ministeriale—Criteri generali di sicurezza antincendio e per la gestione dell'emergenza nei luoghi di lavoro—Art.4 is the Law in Italy requiring Commissioning of fire protection and life safety systems

Association des Etablissements Cantonaux d'Assurance Incendie (AEAI) has released pamphlets such as NPI8:2012, *Installations techniques de protection incendie—réceptions*

et contrôles [2], which is the Switzerland common insurance requirement requiring commissioning of fire protection systems and periodic testing, with virtually every building requiring insurance.

Système de Sécurité Incendie(*SSI*)—*Fire Safety System* is the National Standard in France requiring Commissioning and Integrated Testing of fire protection systems, with other national standards that indicate what tasks may need to be performed for commissioning and integrated testing depending on the systems and their complexity.

In Australia, the commissioning requirements for fire protection systems are generally found in the individual system standards.

Terminology

When discussing systems coordination and integration, there is sometimes an inconsistency of the meanings of words. Sometimes the same terminology is viewed or understood to mean different things to different people. For example, the term commissioning has become an often used word that has very different meaning to different people, since some people inappropriately use the term *commissioning* to mean *acceptance testing*. A Glossary of Terms can be found at the end of this chapter. The authors have defined these terms to provide a common reference throughout the chapter. Readers should verify these definitions in the code, standards, and regulations in use for a specific project, as definitions may differ from those defined within this chapter.

Systems Overview

Fire protection and life safety strategies are developed to accomplish specific goals and objectives and often rely upon the effective performance and integration of various fire and *life safety systems*. While these goals and objectives guide the design of the various individual safety systems, such systems need to be interconnected and coordinated with other systems for proper implementation of the overall fire protection and life safety strategy. As stated previously, early and continuing coordination of fire protection and life safety systems throughout the design process is critical for the successful integration and performance of the individual systems and the overall approach.

The following provides a general overview of typical fire and life safety systems mandated by building and fire regulations, or otherwise recommended by fire protection strategies. More detail about these individual systems can be found in other chapters of this handbook as well as in other documents. Section "System Integration Considerations During the Design Process" of this chapter outlines integration issues that require attention during the design and construction process.

Egress

The egress strategy usually serves as the basis for the life safety strategy for a facility, and can include evacuation, relocation, or protect-in-place approaches that can be combined or phased depending upon overall goals and objectives. Evacuation plans for a building may include simultaneous full or partial phased evacuation of building occupants during emergencies. For protect-in-place strategies, occupants do not evacuate or even move from their rooms. Phasing strategies can be used to efficiently use the egress components. Evacuation plans need to consider wheel chair users and other persons with disabilities and mobility impairments [34].

Consider a typical high-rise evacuation strategy that calls for the occupant evacuation from three floors during a fire scenario—the alarm floor, one floor above and one floor below. If properly protected from the anticipated fire hazards through various active and passive systems and the fire is controlled or suppressed by the appropriate systems, occupants on other floors can remain in place for some time period and may not even need to be made aware of the fire situation. In this scenario, occupants on other floors would be directed to remain in place, or not notified of the fire situation. If necessary, a

phasing scheme can be used to evacuate the occupants on other floors depending upon the progress of fire suppression activities, or verification of the status of the alarm. Tall buildings can also incorporate specially protected and controlled elevators to efficiently and effectively evacuate occupants from upper floors.

Relocation strategies can be used to direct occupants to move away from the vicinity of the fire hazard to a safer place. This might include staff relocating patients confined to beds to an adjacent fire rated smoke zone in the event of a fire in their smoke zone. Event-based approaches allow flexibility through a selection of pre-planned scenarios, but rely upon real-time accurate information (situational awareness) provided to those in authority so that they can make effective decisions, react appropriately and relay necessary instructions. Pre-planning and training are essential. Regardless of the approach used, the means and type of occupant notification employed need to be coordinated with and appropriate for the overall life safety strategy. Egress strategies rely upon various building components and features such as doors, corridors, stairs, and exit passageways, to facilitate safe evacuation.

The specific strategy for a given facility might require more coordination and integration for certain systems. For example, coordination of fire detection and notification systems with the established evacuation protocols might be of key importance for tall buildings. Fire detection and evacuation zones need to be coordinated with fire zones or smoke compartments and their associated fire barriers. Evacuation or relocation messages need to match the evacuation strategy, and need to provide specific messages tailored to the strategy where relocation or protect-in-place strategies are used. The survivability from fire of the notification and two way communication systems should be considered so that people can continue to receive instructions during a fire regarding when and where to evacuate. Where partial or phased evacuation schemes are used, the communication systems may need to be coordinated to facilitate effective evacuation or relocation. Also, architectural and fire separation features may need to be coordinated with expected egress paths.

Compartmentation

Depending upon the overall goals, compartmentation, which is achieved through fire- and smoke-rated assemblies, and opening and penetration protection, provides necessary safeguards against the spread of fire and smoke within a building. The use of fire barriers is also used to limit or prevent the fire spread to adjacent buildings and structures. Codes and fire protection strategies require fire or fire and smoke rated barriers to separate exits and other portions of the means of egress from the effects of fire. Fire-rated and smoke-rated assemblies are also used to protect essential equipment and isolate more hazardous areas within the building. Table 49.1

Table 49.1 Typical fire-rated separations [11, 17, 18]

Protection goal	Potential protection strategies
Protect exits and limit exposure to vulnerable exit pathways	Exit stairways, exit passageways, exit discharges, horizontal exits, and corridors
Prevent or limit fire and smoke spread in buildings	Shaft enclosures, elevator lobby enclosures, atrium separations, smoke zone separations, tenant separations, storage rooms, waste and linen storage rooms, occupancy separations, floor fire ratings, edge of slab fire and smoke assemblies, hazardous use separations (control areas, paint shops, and certain furnace, boilers, and refrigerant machinery rooms)
Protect essential equipment	Fire separation for: elevator machine rooms, certain electrical transformers rooms, emergency generator rooms, fire pump rooms, fire command center, and survivability of fire alarm notification circuits or fire fighters two-way communication systems
Prevent or limit fire spread to adjacent buildings	Fire walls, party walls, sprinklers, exterior wall and opening protection, and building separation distances

identifies various fire protection goals and typical building spaces and features that require some type of fire separation or compartmentation.

Penetrations through fire-rated and smoke-rated barriers need to be protected with listed fire protection and smoke sealing products. Penetrations of rated walls can take many forms, from mechanical and electrical systems, such as ducts or conduits, to architectural openings or building features, such as lights or fire extinguisher cabinets. Duct penetrations can be protected by fire, smoke or combination dampers. Architectural openings can be protected by swing-type doors, horizontal sliding doors, or roll-downs. Doors held open by listed hold-open devices, and sliding or roll-down doors, need to close as required by the fire alarm function matrix and compartment scheme. The designer must consider the penetration protection and membrane protection for each of these breaches such that these systems do not defeat the passive system.

Detection Systems

Fire detection and supervisory devices combine to initiate critical features of most comprehensive life safety plans. Fire alarm systems are often a key system in the *interconnections* of various other fire protection and life safety systems [14].

Fire and Smoke Detection Selection of specific fire and smoke detection systems and devices should be based upon detection goals and objectives. Detection devices can include spot-type smoke and heat detectors, duct smoke detectors, linear heat detectors, radiant energy sensing devices, air sampling systems and video smoke and fire detection. Devices and systems can be integrated into the fire alarm and signaling system or can be separate, through standalone systems that integrate with the fire alarm and signaling system. Examples of standalone systems include air sampling systems in data centers, video detection systems within road tunnels, and hazardous material detection systems.

Sprinkler Water Flow Alarm-Initiation Sprinklers are heat activated devices that function well as zoned heat detectors. When the sprinklers actuate, water flows within the piping system. Water flow devices monitor sprinkler water flow through the fire alarm system, and initiate a water flow signal.

NFPA 72 allows a 90 s delay for water flow indicating devices to reduce the risk of false activation due to water pressure variations. This delay should be considered if the sprinkler system is used to initiate occupant notification [20].

Gas Detection Specialized detection devices and systems can be used to detect hazardous gases, such as general hydrocarbons, methane, carbon monoxide, chlorine gas, oxygen depletion and other hazardous gases. Detectors need to be calibrated to the specific gas, vapor or mixture expected. For flammable gases, the detector may occur at a pre-determined percentage of the Lower Flammable Level (LFL) or Lower Explosive Level (LEL), for example, 25 % or 50 % of the LFL or LEL. Once a specific gas concentration is detected, a signal is sent to the fire alarm control unit.

Manual Detection Manual fire alarm boxes (i.e. manual pull stations) allow occupants to initiate the signaling system. While these devices are important, relying only upon activation of manual devices in areas accessible to the general public should be limited and can be susceptible to nuisance activations. Consider a zoned healthcare facility with manual pull stations in each zone with an egress plan that calls for the relocation of patients to other zones. In this example, it may be possible for an untrained occupant to activate a manual pull station in a zone adjacent to the event zone. This manual system activation in the adjacent zone could initiate an incorrect sequence. A more appropriate configuration might be to locate manual pull stations at a constantly attended area (such as at

nurse stations), and in areas not accessible to the general public. With proper training, staff would then be able to appropriately and effectively activate the system through these manual devices.

Supervisory Functions A supervisory signal is activated when an off-normal condition occurs in a supervised system, or equipment. Examples include monitoring of sprinkler system control valves, low water pressure, and low and high air pressure in dry-pipe or pre-action sprinkler systems. Areas that are susceptible to freezing could be provided with low temperature alarms. If the fire suppression system is supplied through a water storage tank, the water level in the tank would be monitored.

In some facilities, the fire alarm system could be used to monitor certain aspects of a process such as the status of a pressure vessel. However, building and manufacturing processes are generally not monitored by the fire alarm system, but rather by other separate systems. Such separate systems may need to be integrated with the fire alarm system to initiate notification, means of egress activities or other functions such as the closure of doors, activation of ventilation fans, and similar devices.

Notification Systems

Occupants need to be provided with timely and accurate information so that they can understand the urgency of a particular event and make appropriate egress decisions. Emergency communication systems used for notification provide means for notifying a large group of individuals and for the fire service to communicate with occupants and other first responding personnel. As noted below, a public address system can sometimes be used for this purpose. There are one-way and two-way methods of providing communication.

One way systems include fire alarm notification, mass notification and public address systems. Fire alarm notification is commonly referred to as emergency voice/alarm communication systems and used to evacuate or relocate occupants during an emergency. NFPA 72 identifies four major categories of mass notification methods [20] that include in-building, exterior, personal and public mass notification. Public address systems would be found in airports, stadia and other large public assembly venues for general messaging and emergency notification.

Two way systems include communication between emergency responders, and emergency responders and building occupants. Communication between emergency responders can be either a wired or a wired antenna system that enhances the radio coverage within a building. Two way systems between occupants and emergency responders are used when individuals are unable to escape on their own, such as by being trapped in an elevator, or unable to use the exits.

Fire Alarm Notification Audible and visible notification of a fire situation is typically provided to occupants with horns or speakers and strobes. Alarm signals as well as pre-recorded and live instructions regarding means of egress can be announced. Alerting for hearing impaired individuals is generally provided with strobes for visible notification of an emergency. In some buildings, where a relocation evacuation strategy is used, such as hospitals and jails, chimes, bells or other signals are sometimes used to provide a coded notification to trained staff. In these cases, the audible notification provides a distinctive signal, which is usually only recognizable by staff. The selection and definition of the *Evacuation Signaling Zones* and notification zones are critical for fire alarm notification.

Mass Notification The following four major mass notification methods are available [20].

1. **In-Building Mass Notification** is obtrusive messaging within a building. These systems would not require any interaction from building occupants to receive the message and the building occupants cannot deactivate this system. This category could include a voice fire alarm system that is also used to broadcast mass notification messages, a public address system, a voice paging system that is

dedicated for mass notification, or activation of digital signage.

2. **Exterior Mass Notification** is obtrusive messaging outside the building. The system could be a tone, a voice message or a combination of both. Sirens used for warning during times of war and tornados are examples of exterior notification. High powered speaker arrays such as "Big Voice" systems used in military applications can be used to provide a voice message to broadcast specific instructions during an emergency. Outdoor notification is not intended to notify people within a building. Depending on the building construction, broadcasted messages may or may not be capable of alerting people in buildings.
3. **Public Personal Mass Notification** is personal alerting. Personal alerting messages target specific individuals. Methods of contacting an individual could be through short common message services such as text messaging, email, specific applications that display alert messages on computers or smart phones, and automatic dialing or reverse 911 to provide automated voice phone messages. Personal alerting can target a specific audience and limit the distribution. Personal alerting to a specific group such as emergency response team could provide details of an incident. Providing notification through personal alerting can be rather cost effective because individuals generally own the equipment and the organization is only providing the equipment to broadcast alerts. A challenge of personal alerting is maintenance of a current list of contact information.
4. **Public Mass Notification** is public notification. Previously, public alerts were broadcast solely through television and radio. A majority of the public alerts were weather alerts issued by the National Weather Service. In recent years, the method of transmitting public alerts has evolved. In the United States, the Commercial Mobile Alert System (CMAS) allows authorized national, state or local government officials to send text messages to a targeted geographic area. CMAS alerts are designed to be broadcast from select cellular towers in a geographic area. Systems are designed so that CMAS alerts have a higher priority over normal text messages and voice calls. Social networks allow anyone on the network to broadcast messages of events and users can follow messages from specific organizations (http://www.fcc.gov/guides/commercial-mobile-alert-system-cmas).

Public Address System Certain types of buildings containing public assembly such as airports and stadiums are generally provided with public address systems. Because of the nature of the live voice instructions and messages to be transmitted, these systems usually provide better audio quality than basic fire alarm systems. When properly designed, the public address system can be used for pre-recorded or live voice emergency messages. In addition to audible announcements, visible displays are usually also provided to relay captions of the spoken messages for hearing impaired individuals.

Two-Way Wired Emergency Communication Systems Communication between fire service responders is important during an emergency. Typically, high rise buildings were provided with fixed firefighter telephones or jacks to connect a hand-held phone to communicate with a central location or between multiple locations and the central location. Current codes require a radio enhancement system where most firefighters are equipped with a radio, rather than a wired system.

Two-Way Radio Emergency Enhancement Systems A radio emergency enhancement system is a common alternative to a two-way wired firefighter telephone system and required by model fire codes. A radio enhancement system improves the communication between the firefighters in a building, and dispatchers and command staff outside by boosting the radio signal inside of a building through a distributed antenna system throughout the building. The fire service is equipping a majority of firefighters with a handheld radio and this is their primary method for communicating during an

emergency. The building construction including steel framing and reinforcement prevents the radio signal from penetrating the interior portions of the especially large buildings such as high rise structures, hospitals, and shopping malls [10].

To provide the necessary radio coverage, a two-way radio enhancement system is provided. This system generally consists of an exterior antenna, a booster to enhance the signal and antennas strategically located throughout the building to enhance signals. An antenna system could consist of several single components, or a radiating ("leaky cable") that allows the messages to be received and transmitted through the entire cable.

Occupant Emergency Communication Systems Building occupants that are unable to use stairs can relocate to spaces such as areas of refuge where they are able to summon assistance from emergency responders. A two-way communication would need to be installed at strategic locations such as at areas of refuge to allow communication with emergency responders. Similarly, if stairway doors are arranged to prevent re-entry into the building from the stairway, a means of two way communication might need to be provided at discrete points in the stair.

Elevator Emergency Communication Systems Potential problems with elevator operations necessitate the ability for elevator occupants to communicate with others in the building to summon assistance or receive instructions. ASME A17.1 Safety Code for Elevators and Escalators [4] requires such a two-way communication system. Although not a common occurrence for most buildings, elevators specially designated and arranged for occupant evacuation might require additional features regarding means of communication.

Suppression Systems

Automatic sprinkler systems are required in many buildings as they provide an effective and reliable means of reducing fire hazards. Fire sprinkler systems are designed to suppress or control fires until the fire department arrives to extinguish the fire. Sprinkler systems can be wet pipe, dry-pipe, pre-action, or deluge.

Wet pipe sprinkler systems are connected directly to the water supply and are most common. Dry-pipe systems are used within areas subject to cold or freezing temperature. Dry-pipe systems are pressurized with air or nitrogen, rather than water. Activation of dry-pipe sprinkler systems cause the air or gas pressure to drop in the piping systems, which activates a dry pipe valve and allows water to flow through the sprinkler system.

Pre-action systems provide additional protection against false activation through interlocking the pre-action valve with a detection system. As with dry-pipe systems, the system can be pressurized with air or nitrogen. Through a releasing service fire alarm system, when a fire signature is sensed by a supplemental detection system, the fire alarm panel sends a signal that releases a pre-action valve which then allows water to enter the system piping. Deluge systems use open sprinklers with a deluge valve and a supplemental detection system similar to that for a pre-action system. As deluge systems employ open sprinklers or nozzles, water discharges from all nozzles and sprinklers once the system is activated.

Other special suppression systems, such as those that use or generate foam, carbon dioxide, clean agents, water mist, aerosols, and wet or dry chemicals can be more appropriate for specific hazards. In many cases, building and fire codes require sprinkler protection regardless of the presence of special suppression systems.

Fire detection used with pre-action, deluge, or special suppression systems are connected to releasing service fire alarm control units. These releasing systems are designed to activate the suppression systems upon detection of a certain fire signature. Such fire detection devices and systems need to be coordinated with the fire suppression zoning. The coordination of the releasing sequence is important as the suppression system relies upon the sequence for proper operation.

Table 49.2 Potential suppression systems supervision and monitoring interfaces [24, 27, 28]

System	Potential supervision and monitoring
Wet pipe system	Water flow, valve supervision, low water supply pressure
Dry-pipe system	Water flow, valve supervision, low water supply pressure, low air pressure
Pre-action, deluge, water spray, and special suppression systems	Water flow, valve supervision, low water supply pressure, low air pressure, releasing service fire alarm control unit supervision (alarm, trouble, supervisory, suppression system releasing sequence activated)
Standpipe systems	Water flow, valve supervision
Water supply tank	Low water reservoir, water reservoir empty, low water temperature, valve supervision
Diesel or electric fire pump	Pump running, controller switched to manual control, pump trouble, over speed deactivation, system overpressure, low pump room temperature, relief valve discharge, control valve closure, flow meter bypass condition, pump room intrusion
Diesel fire pump	Engine running low oil pressure, failure to start, high engine temperature, battery failure/missing battery, battery charger trouble, alternate ECM, fuel injector malfunction, low fuel, high fuel, low air pressure (air start engines), low engine temperature, fuel spill
Electric fire pump	Power phase reversal
Special suppression system	Discharge, detection, supervisory, trouble

A reliable water supply system is required for water based systems such as sprinkler, water spray and foam. The water supply can be provided through the municipal water supply with or without a fire pump, or through private fire service. Such private service might consist of private fire service mains, tanks and fire pumps. In some cases a secondary water supply is required such as might be the case for buildings located in certain seismic areas, or where the primary supply is not considered sufficiently reliable. Pressurized or gravity water tanks can provide the necessary water flow and pressure for municipal or private systems. Monitoring of water supply conditions and equipment, as well as detection of water flow and system activation need to be provided and coordinated.

System Supervision Most fire protection and life safety strategies rely upon the proper design, installation and operation of automatic sprinkler and other fire suppression systems. Approximately one-half of automatic fire sprinkler system failures are due to valves being inappropriately closed [9]. Given the reliance upon sprinklers in most fire protection and life safety strategies, control valve monitoring to ensure valves are open where required, is very important.

Generally, control and isolation valves on all sprinkler systems required for life safety purposes are required to be electronically supervised. Additionally, all standpipe supply, isolation, and control valves are normally required to be supervised. Water flow indicating devices are required to be connected to the fire alarm system and initiate an alarm. Table 49.2 lists suppression system equipment and system conditions that may require supervision and monitoring.

High-rise buildings are generally defined as buildings with occupied floors 75 f. above the lowest level of fire department access. These structures require additional reliability for the sprinkler systems, as fire service operations are hindered by the building height. Systems are provided to supervise floor control valves, and initiate supervisory signals to indicate system status. Examples of conditions that pertain to system status and which need to be monitored include valve position, low building temperatures, low water supply pressure, loss of electric fire pump power supplies, and low water tank levels.

Manual fire suppression is provided through standpipe systems and fire extinguishers. Standpipes can be standalone or combined with

sprinkler system risers. As with any water based system, valve position and water flow need to be monitored. Devices used to monitor fire extinguisher pressure and location can also be provided.

Smoke Control

Smoke from fires consists of soot, hot gases, and other products of combustion. Smoke can move through buildings and impact people or property remote from the fire zone. Smoke moves through ventilation systems running during a fire, through normal air currents like the stack effect, and through buoyancy created by the temperature difference between hot gases and ambient air. Smoke control systems are designed and installed to limit or prevent smoke spread, possibly maintain tenability, or to assist with post fire operations. The Handbook of Smoke Control Engineering [13] provides insight and information of the various types of smoke control systems.

The simplest form of smoke control is deactivation of the normal mechanical air-handling equipment through smoke detection and closing of smoke dampers to prevent smoke spread by the HVAC system and through building. Pressurization systems use pressure differences across barriers to keep smoke from moving to other areas of the building. With stair pressurization, stairs are designed as pressurization zones to limit the potential for smoke contamination into the stairs. Stair pressurization systems can incorporate pressurized vestibules, or vestibules with both supply and exhaust to purge smoke. Other pressurization methods involve floor-by-floor pressurization zones or multiple pressurization zones on each floor.

In large open spaces, smoke exhaust systems can be used to limit smoke spread within the space or to connected spaces. Exhaust systems are combined with mechanical supply or openings to provide outside air to remove smoke and limit its impact to people or property. High level vents in a large open space can be used to allow the effect of buoyancy to remove smoke.

Systems can also be provided for non-life safety post fire smoke purging. This can be achieved through manual override controls of the normal mechanical systems, switching the systems into 100 % exhaust and supply mode, or through operable windows or manual breakout windows to vent spaces post fire.

Smoke Control Components Smoke control supply and exhaust fans used to provide pressure differences or to provide the required volumetric air flow need to be controlled and monitored. Dampers may be needed to achieve intended system performance. Strategically located, automatically operated doors and vents are often used to provide make-up air for the smoke control system. Fans, dampers, and make-up air openings need to be controlled, monitored, and configured as necessary.

Mechanical Ventilation Systems Shutdown Mechanical air-handling equipment may need to be deactivated when the smoke control systems is activated. Deactivation of associated fans occurs through interruption of power to the devices or through the building management (BMS) system controls.

HVAC systems that recirculate air beyond the enclosing walls, floors, and ceiling of the room or space of concern are generally required to be deactivated to prevent the spread of smoke during a fire. Generally, a system with a capacity greater than 2000 cfm is required to be deactivated [11, 23].

Smoke Barriers Smoke barriers penetrated by ductwork require smoke dampers that close upon detection of smoke. Smoke detection is provided throughout the entire area served or a duct smoke detector located usually within 5 f. of the smoke damper. On activation of the associated smoke detector, the fire alarm system transmits a signal to close the effected smoke damper or deactivate the HVAC system that controls power for the smoke dampers and fans.

Other Ventilation Systems

Mechanical systems other than those used for smoke control may need to be controlled and monitored and be coordinated with the overall building *life safety systems* to avoid hazardous conditions. For example, mechanical systems may need to be deactivated and dampers closed within spaces using gaseous fire suppression systems, or parking garage exhaust systems that do not operate continuously to save energy may need to be activated to avoid hazardous carbon monoxide levels. Hazardous material exhaust systems are another example. Hazardous exhaust systems for laboratories, fume hoods, fabrication areas, gas storage rooms, process rooms, and similar spaces, are critical and need to remain in operation during a fire. Deactivating hazard exhaust systems during a fire could create a secondary hazard.

Emergency and Standby Power

Emergency and standby power systems are often required to provide reliable alternative power source for essential *life safety systems* during loss of primary power. Emergency power systems serve essential equipment where interruption would cause life-threatening safety or health hazards. Emergency power systems are required to transfer power within 10 s of loss of primary power [29]. Typical systems requiring emergency power include exit signs, means of egress illumination, elevator car lighting, emergency voice/alarm communications systems, automatic fire detection and gas detection systems, fire alarm systems, sprinkler alarm and supervisory system, electrically powered fire pumps, power doors and locks in certain types of occupancies, and essential hazardous material safety systems such as laboratory hoods. Emergency power may be necessary for energy saving lighting controllers and house lighting controls for dimmable arena, theater, and similar lighting to appropriately initiate the emergency lighting sequence.

Standby power is categorized within NFPA 70 as legally required and optional. Legally required standby systems mandate a 60 s transfer time after loss of primary power. The National Electrical Code notes legally required standby power is typically provided for systems that "create hazards or hamper rescue or fire-fighting operations" if interrupted [29]. Legally required standby power systems typically supply elevators, air compressors for dry-type and pre-action suppression systems, inflation systems for membrane structures, accessible means of egress elevators and lifts, evacuation elevators, horizontal sliding doors, and smoke control systems, as well as sewage disposal, critical industrial processes, and similar equipment [25, 29].

In healthcare facilities, a critical supply branch is provided as a subsystem to the emergency power system, and supplies power to critical equipment, and essential electrical systems that could cause immediate danger to patients [22].

Optional standby power is provided for systems that are not required for life safety, but are provided to continue important operations or processes. Owners may elect to supply other equipment and systems through optional standby power [25, 29].

The emergency or standby power systems can be supplied through a battery system, a generator set, an uninterrupted power source (UPS), a separate service (where approved), a fuel cell power system, or through unit equipment (i.e., batteries integral to the equipment). An automatic transfer switch senses the loss of power and switches to emergency or standby power. UPS systems are different from other emergency or standby power systems, as UPS systems provide continuous power without interruption during loss of primary power, for certain design durations. In some cases, the power source status and the automatic transfer switches are required to be monitored [26, 29].

Generator sets are required to be provided with an automatic remote start capability, a "Run-off-automatic" switch, and controls to automatically and manually shut down and lock out the prime mover. Alarms for generators include: over crank, low water temperature,

high engine temperature pre-alarm, high engine temperature, low lube oil pressure, over speed, low fuel main tank, low coolant level, emergency power system supplying load, control switch not in automatic position, high battery voltage, low cranking voltage, low voltage in battery, battery charger power failure, low starting hydraulic pressure, air shutdown damper (when used), and remote emergency stop [25].

Elevators and Escalators

In most buildings and structures, occupants are instructed to use the stairs and not use the elevators as a means of egress in an emergency. Elevators are designed to automatically recall to a lower floor, typically the level of exit discharge, upon dedicated elevator smoke detector activation. This arrangement largely prevents the elevators from being used as a component of means of egress. Elevators used for accessible egress is an exception. The intent is for the accessible egress elevators to be used for assisted rescue. Elevators are equipped with a manual over ride feature for use by the fire service to facilitate assisted rescue operations and to assist fire-fighting and emergency operations.

With the proliferation of tall buildings around the globe and the development of new elevator protection schemes [4, 11, 17], evacuation elevators now are generally permitted. These specially designed evacuation elevators allow occupants to use the elevators under certain emergency conditions. In most cases, evacuation elevators supplement rather than reduce the number and capacity of traditional means of egress components.

Elevator Emergency Recall and Emergency Operation Smoke detector actuation in an elevator lobby, elevator machine room or elevator shaft initiate Phase I emergency recall, which is designed to return elevators to a lower level and open the doors to allow occupants to exit the elevator cab during a fire emergency. Typically, elevators are not recalled by activation of any other detector in the building, but this varies in some jurisdictions. When the elevator is recalled, a special indicator in the elevator car is typically illuminated. When an elevator machine room smoke detector is activated this indicator typically flashes to warn fire fighters in the car of this situation. After recall, the elevators are available for fire service use.

Phase I recall returns all elevators to the lobby on the level of exit discharge. In most buildings, this is the first floor. If the smoke detector in the elevator lobby on the level of exit discharge activates, the elevator would return to the alternate level. Typically, the alternate recall level for the elevator is the second floor or a basement level depending on which level is most accessible to the fire service.

Phase II emergency operation is initiated manually by the fire department. A key operated switch located in the elevator lobby and in the fire command room initiates Phase II emergency operation. A second key operated switch located in the cab allows the fire service to take control of individual elevators.

Elevator Power Shunt Trip In some cases, the applicable building code requires sprinklers to be installed in the elevator machine room or shaft. Elevator equipment power is designed to be disconnected before the sprinkler actuates to prevent damage to the elevator controls, power equipment, and people.

The hoistway heat detector and water flow indicator, combined with elevator recall operations, are designed to allow elevators to be recalled and deactivated before the shaft sprinkler actuates. The flashing special indicator, such as a fireman's hat, warns that smoke has been detected in the elevator machine room, and indicates that the shunt trip may soon activate.

Emergency Evacuation Elevators Walking down many flights of stairs from upper floors of high-rise buildings and tall structures can be difficult for some and impossible for others. Even buildings of modest height pose evacuation issues for a percentage of the population, like

the elderly, injured occupants and occupants with medical conditions and mobility impairments. Emergency evacuation elevators continue to gain acceptance for providing a means of egress in tall buildings for people with mobility impairments or otherwise unable to use the stairs to exit [34].

Both the Life Safety Code [17] and the International Building Code [11] allow emergency evacuation elevators to serve as a means of evacuation with specific limitations. The Life Safety Code limits the use of emergency evacuation elevators to observation, control, operation, and signaling towers. The International Building Code allows evacuation elevators as an alternative to the required additional stair within buildings over 420 f. (128 m) tall. Emergency evacuation elevators only operate prior to Phase I emergency recall, as recall activation indicates that smoke is in the elevator lobby or that responders have determined the evacuation elevators should not be used.

Fire Service Access Elevators In the International Building Code, fire service access elevators are required for high-rise buildings with an occupied floor over 120 f. above the lowest level of fire department access. In these buildings, every floor is required to be accessed by the fire fighter elevator. The fire service access elevators recall under the same conditions and follow the same recall sequences as the other building elevators.

Escalators Deactivation Most building and life safety regulations do not allow the use of escalators as a component of a building's means of egress. There are some exceptions to this general rule such, as where they are needed to meet the objectives of the fire protection and life safety strategy or to meet local requirements. In these cases, escalators typically need to be powered down and slowed to full stop when the fire alarm actuates. NFPA 130 allows for the use of escalators as a component of the means of egress, and requires escalators operating opposite the egress direction to deactivate, slowing to a stop [15].

Access Control Systems

Access control and security system designs need to balance safety with security. Life safety needs to override security in most cases to allow occupants to escape, and access control features that are part of security systems, such as delayed egress locks, stair door locks, detention facility locks, and other security door locking arrangements, need to allow for egress during emergency conditions [11]. Components need to be carefully coordinated and tested to be sure the systems meet the appropriate design criteria and function as intended.

Electrically controlled egress doors may be required to be locked under normal building operations for security, but during an emergency the doors must be unlocked. The interface with the fire alarm system can be completed through a variety of methods. The fire alarm system can provide an output to the access control system. The access control system must be programmed to operate the required doors. For latches that are fail safe, the latches are normally powered and when the power is released, the doors unlock. In this case, the fire alarm system can intercept the power circuit to remove power to the latch. This strategy eliminates the risks associated with changes to the access control system that impact the unlocking of secure doors.

Delayed Egress Locks Delayed egress locks can be an effective means of providing a measure of security while allowing occupants a reasonable level of safety. For these systems, specific doors are normally locked but unlocked within a set amount of time, typically 15 s, after the push-bar hardware is used. Delayed egress doors unlock immediately upon loss of power, sprinkler water flow initiation, and activation of a smoke detection system. Signage is provided to alert and inform occupants of the delay [11].

Stair Door Unlocking Some arrangements require a floor level to be secure from other floors. When this is important, stair doors can be provided with hardware that prevents re-entry from the stair side, securing the floor from other floors. Stair door locking requires a means to simultaneously unlock all doors during an emergency [11].

Secure Facilities Lock-down areas in detention, correction, and healthcare facilities are of particular concern. Since detainees cannot freely exit to the exterior, detainees are moved to adjacent smoke compartments during an event. This arrangement requires smoke and fire barriers to separate compartments, along with a means for guards to quickly unlock doors and for staff control or assist movement [11].

Other Control and Monitoring Systems

The fire and life safety strategy may require interfacing with a wide range of systems, including: process control systems, explosion detection and suppression systems, CBRN (chemical, biological, radiation, and nuclear) detection, carbon monoxide or other hazardous gas detection, medical and other gas shut-down, laboratory system control, SCADA (system control and data acquisition) systems, nurse call systems, and special effects and amusement feature shut-down and control. Process controls may need to regulate and safely shutdown process, reaction vessels, or oven or other heating systems. An extreme example is the safe shutdown of a power plant. Airport baggage systems may need to be deactivated. Lighting control needs to initiate emergency lighting sequences. Explosion or hazardous gas detection systems may need to activate notification sequences, or initiate equipment de-activation, activation, or other sequences. Gas systems may need to shut down. Laboratory control systems may need to initiate exhaust sequences, or de-energize heating or other processes. SCADA systems control and integrate complex road, rail and process systems. As an example, SCADA systems can combine roadway tunnel fire detection, emergency notification, traffic signaling and control, emergency ventilation, normal ventilation, and CCTV into an integrated operator console. Nurses call systems may need to initiate a coded emergency message that without alerting patients.

Emergency (Fire) Command Center

Emergency command centers and fire command centers should be in a central location within a high-rise building that contains information on the status of all of the required fire protection and life safety features. From this location, the fire department and responding personnel can determine the status of the various building systems that could impact life safety, fire department operations, and control certain systems [11, 17]. The following list identifies the features of the emergency command center that require coordination and interfacing.

- Emergency voice/alarm communication system, which provides the ability to select specific areas of the building to be evacuated and provide the ability to broadcast live voice messages to selected areas of the building.
- Fire department communications systems, such as a firefighter telephone or radio system that allows communication within the building.
- Fire alarm system annunciation including the locations of detectors in alarm, off normal conditions with the fire suppression system, and faults with the fire alarm and other systems.
- Status indicators and controls of the air distribution system. This allows the fire department to control the air distribution system if the system is not functioning in the intended state.
- Control panel for the smoke control system in the building is required in many codes. The controls will allow the fire department to activate and deactivate the smoke control system.

The smoke control panel is required to be UL Listed to category UUKL.

- Security is a major concern; therefore, it is very common for the stairway doors to be locked to prevent unauthorized access. To facilitate access for the fire department to each of the floors, controls are necessary to automatically unlock all of the stairway doors.
- Status of the sprinkler water flow and valve equipment is required. Generally, this information would be provided through the fire alarm system, but in some cases the sprinkler system may be monitored by a separate system.
- Emergency and standby power status indicators is required. Typically this information is provided by a remote annunciator from the automatic transfer switch. An alternative is to monitor the transfer switches by the fire alarm system.
- A telephone connected to the public telephone system are required. This allows the fire department to contact responsible parties during an emergency.
- The status of the fire pump system is required. The status will inform the fire department if the fire pump system is running, impaired, or not operating due to a failure or fault.
- Generator monitoring, manual start and transfer indicators are required.
- Public address system to provide voice announcements when required. Generally, a public address system would be found in stadium facilities, conventions centers or similar public assembly facilities. Coordination and integration of the public address system with the fire alarm system and/or the emergency communication system is needed to eliminate conflicting messages.
- Elevator controls that contain recall switch(es) to initiate elevator recall is needed.
- Elevator standby power selector, for elevators provided with emergency power, is required. This allows the elevators to be transferred to emergency power manually if necessary.

Summary

Fire protection and life safety strategies may require a wide range of system coordination and interfaces to accomplish the stated goals and objectives; Table 49.3 summarizes typical system interfaces.

System Integration Considerations During the Design Process

The reliance on active systems to enhance or maintain safety has allowed designers greater flexibility to express architectural vision and meet owner and stakeholder goals. The number of active systems involved has steadily increased over the years. These systems, introduced in section "Systems Overview" above, are largely automated, which has allowed them to be integrated with other systems to better coordinate the response of the overall fire and life safety strategy, and to ensure that one system does not negate the effectiveness of another. For example, a fire alarm system has been permitted to be interconnected via an *emergency control function interface device* (relay) with a sound system for many years [20]. When the fire alarm activates, it shuts down the sound system so that the fire alarm system is audible. As technology has progressed the ability to interconnect various systems has become easier. Although the codes have not kept up with leading edge communication capabilities of these systems, they have recognized the benefits of *interconnected systems* when implemented properly and now allow for more direct communication, interfacing, and interoperability between systems.

Once the goals, and objectives, and strategies related to fire and life safety are developed and agreed to by the design team and stakeholders, the *Basis of Design* (*BOD*) can be developed to identify the concepts and approach of the design. The design team can then design the individual systems and systems integration to meet the *BOD*.

Table 49.3 Coordination and interfacing examples

Systems	Possible components and example features
Egress	Actuate security door unlock sequence, emergency lighting, emergency notification, and exit marking—audible notification,
Compartmentation	Actuate release, rolling and accordion doors release, fire/smoke shutter release, and fire/smoke damper release
Detection and notification systems	Fire and smoke detection, gas detection, actuate emergency notification, smoke control activation, SCADA (System Control and Data Acquisition) control functions, process shut-down, paging/music system shut-down, house lighting controls interface, and special suppression system release
Mass notification systems	Actuate building notification systems, initiate telephone voice messaging or text messaging, initiate textural display devices, initiate computer pop-up messaging, and interface with wide area mass notification system
Emergency communication systems	Actuate building notification systems, area-of-refuge communication systems, elevator communication systems
Fire suppression	Actuate water flow alarms, tamper switches (supervisory), low water pressure monitoring, special suppression releasing service, kitchen hood system monitoring, laboratory hood and duct system suppression monitoring and control, fire pump monitoring, and secondary water storage tank monitoring
Smoke control	System feature control (fan control, damper control, door control, fire/smoke shutter control, and other operable element control), smoke control panel overrides (manual override), and positive status indication (monitoring) of key smoke control components (such as dampers, fans, natural supply openings)
Other ventilation and conditioning systems	Fan deactivation and damper closure, parking enclosure exhaust control, hazardous exhaust and fume hood system control
Emergency and standby power	Generator monitoring and control, power status monitoring, emergency lighting control, solar and other power source shut-down, and providing operating power to various fire protection and life safety systems
Elevator and escalator	Evacuation elevator actuation, elevator recall, elevator power shunt-trip, escalator shut-down
Security systems	Access control, unlock secured doors, emergency lighting activation, emergency notification
Other systems	Building Management Systems, Security Systems, explosion suppression systems, hazardous gas detection, CBRN (Chemical Biological Radiological, and Nuclear) detection, carbon monoxide detection, medical and other gas system shut-down, process and other equipment deactivation, airport baggage system deactivation, laboratory equipment control, nurse call systems, SCADA control and monitoring functions, special effects and amusement feature deactivation and control
Emergency (fire) command centers	Voice fire alarm system panels and controls, fire department two-way telephone communication service, fire detection and fire alarm system annunciation panels, public address system controls, elevator floor location and operation annunciators, elevator fire recall switch, elevator emergency power selector switch(es), sprinkler valve and water flow annunciators, emergency generator status indicators, controls for stairway door unlocking system, fire pump status indicators, and controlled access public telephone for fire department

In large modern buildings, the designer must consider all of the systems and how these systems are intended to interact with each other. The designer must identify the intended function of each system and what, if any, *interconnection* is needed or desired. It is important to note that the system may have multiple desired functions depending on the event. As identified in Table 49.3, various types of building systems can affect fire and life safety.

Proper i*nterconnection* of all these systems requires interaction between many design professionals with the fire protection engineer often serving as the central point of contact and coordination as illustrated in Fig. 49.1. The following identifies design team members that may be involved in the design and coordination process. The degree of involvement depends upon the size and complexity of the project, owner requirements, code requirements, and project requirements:

1. Owner or Owner's Representative
2. Architect
3. Engineer of Record for each discipline
4. Fire Protection Engineer
5. Contractor
6. Sub-contractors installing the various fire protection and life safety systems
7. *Commissioning Authority* (*CxA*)
8. *Fire Commissioning Agent* (*FCxA*)
9. *Integrated Testing Agent* (*ITa*)
10. Insurance Representative
11. Third Party Testing Entity
12. Authority Having Jurisdiction (AHJ)—traditionally building and fire departments.
13. Emergency responders

Various levels of coordination are likely to be needed. The first level is typically among the architect, engineers, and owner. The *FCxA* and *ITa* may also be involved in this first level of coordination, depending on when they are incorporated into the project. The design team develops a strategy and package of information to meet the project objectives and goals. The package may include a Fire Protection and Life Safety Report, Narrative Report, Basis of Design, coordinated drawings (identifying interfaced points, locations, and methodologies), and sequences of operations of the various systems [30]. These documents will likely be updated

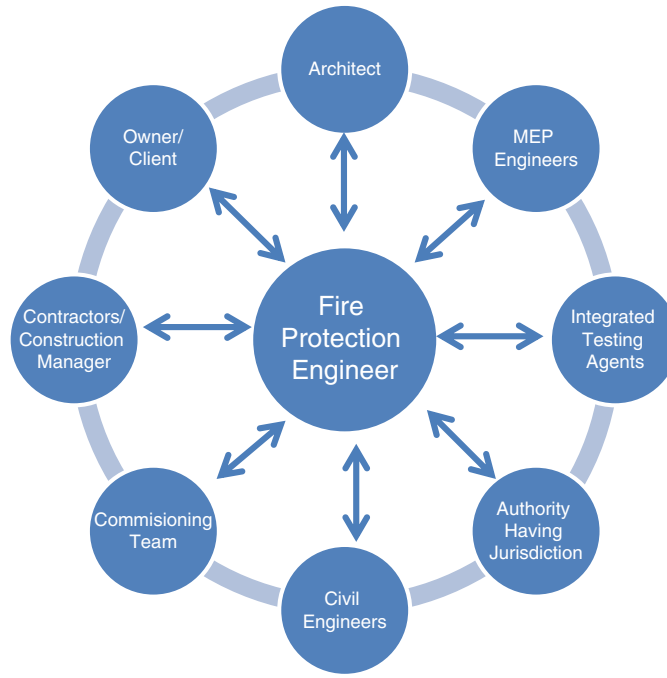

Fig. 49.1 Fire protection and life safety coordination team

throughout each phase of the design process and should incorporate modifications that have occurred in construction.

It may also be prudent at an early stage to meet with the Authorities Having Jurisdiction (AHJ), typically the building and fire official, to review the strategies and goals of the project, particularly if the approach may require a Code Variance, Modification, or Appeal. The overall project strategies, project goals, and *BOD* will eventually be reviewed by the AHJ when permit drawings are submitted. Therefore, it is advisable to meet with the AHJ and obtain their agreement and acceptance of the coordinated design as early in the process as possible. The AHJ may require a third party to support the review process.

The *FCxA* and *ITa*, if part of the project team, should be involved during the design phase of the project to participate, review, and comment on the plans and specifications during the design phase. Their review, as an owner's representative, should incorporate the project's goals and objectives. The goals and objectives should also guide the development of the *commissioning plan* of the individual systems and the integrated commissioning plan of these systems, without designing or redesigning these systems [6].

During the design phase the design documents are updated, refined, and modified based on the coordination and integration of the fire protection and life safety systems from the Engineer of Record or from comments/clarifications from the coordination team members.

Design Considerations

When designing fire protection and life safety systems, an initial step is to identify the purpose and ultimate goal of each system being installed. Identifying this purpose will assist the designer in recognizing what other systems need to be relied upon or what other systems need to be interconnected. For example, providing a total flooding gaseous suppression system in a space that is also provided with an automatic smoke control system may not allow either system to achieve the intended purpose. The smoke control system may be designed for a specific size fire that relies on the special suppression system to control the fire size. Clearly, the smoke control system would remove some of the suppression agent defeating the system's ability to control the fire and potentially overwhelming the smoke control system.

The individual system designer must be aware of the wide range of building systems that can affect the system(s) for which they are responsible and that may need to integrate with their system. To integrate these systems successfully, the designers of each of the systems need to work together to identify when and where *interconnections* will occur, priority of control for each system and shared components, fail safe conditions, *data sharing connections*, and design remediation for when system functions may conflict but cannot be addressed through system operations. One of the first items that needs to be coordinated for all of these systems are space requirements within the building. Each system must have enough space to ensure not only proper operation and function, but also so that adequate access is provided for maintenance and testing activities.

Multiple designers will provide input into the design and integration of the various systems. This information must be assembled and coordinated. Several common systems, although not necessarily integrated in all cases, still require multiple designers to be involved. Figure 49.2 provides examples of systems and the designers that would be involved with their design and integration.

A brief discussion of the decisions concerning integration and coordination of various types of systems is provided below.

Egress The egress system may have several goals ranging from relocation, to shelter in place to full evacuation. Depending on the overall goals, the designer must consider and address several systems. If the facility relies upon trained staff, individual staff responsibilities need to be identified. Coordination is needed among the fire protection engineer, architect, and owner to establish the egress goals and determine what

System \ Discipline	Fire Protection Engineer	Electrical Engineer	Mechanical Engineer	Structural Engineer	Controls Designer	Architect	Acoustician	Security Designer	IT/Comms	Plumbing Engineer	Commissioning/ Integrated Testing Agent
Smoke Control	X	X	X	X	X	X			X	X	X

Compartmentation	X			X		X	X				X
Emergency Communications	X	X					X		x		X

Fig. 49.2 Typical coordination responsibilities

active systems will need to be in place to achieve the goals. Individual systems that affect egress can include fire alarm and notification, elevators, stair pressurization, security, and compartmentation. The designers need to address the individual integration concerns for each system but also have a broader view on how each system affects egress.

Doors being held open need to be coordinated to determine if the hold-open device will be on low voltage circuits or standard building circuits. Depending on the jurisdiction, the voltage of the circuit could impact which contractor installs these circuits and equipment. *Emergency control function interface devices* (relay) from the fire alarm needs to be provided to disconnect power to the doors when they need to close. Coordination is needed to determine if each door is individually controlled or controlled through a common circuit serving multiple doors. This also needs to be coordinated with security functions such as turnstiles, gates and locked doors. Power needs to be provided to the powered doors (e.g. shutters, and sliding doors) and the need for emergency power should be considered. Latching conditions need to be considered for both normal power operation and under conditions such as power failure. If the door needs to remain latched but unlocked in the fail safe condition, this needs to be coordinated among the electrical engineer, architect, hardware consultant, fire alarm designer, security designer, and fire protection engineer.

Compartmentation Fire and smoke separations need to coordinate with the overall fire protection and life safety strategy and need to match the egress strategy. Smoke control zones boundaries, and associated fire and smoke separations, need to match the smoke control strategy. Sprinkler zones also need to match the smoke control zones if they are used to activate the smoke control system and evacuation strategies. The overall strategy needs to account for closure of opening protection components, such as doors held open with hold-open devices, roll-down or horizontal sliding doors, fire dampers, smoke dampers, and combination fire and smoke dampers.

Most buildings will have dampers located in rated walls, such as shafts. The architect or fire protection engineer will identify rated walls, and the mechanical engineer will design for dampers at locations where the ductwork penetrates a rated wall. The electrical engineer must consider how power is provided and voltage requirements for the damper circuits, and may need to coordinate with the controls designer depending upon how the damper is controlled. In some cases, placement of the damper position will need to

be coordinated with the structural engineer for cuts or notches in the building structure and the architect to provide access panels.

Generally, a fire damper is activated by a fusible element that melts releasing the fire damper. The activation of a fire damper is similar to a sprinkler. Smoke dampers are required to be powered to control the damper. Typically, a smoke damper is wired fail safe so the damper must be powered to be open.

The designer must coordinate the closure of smoke dampers with the controls for fan operation. The closure of a damper without deactivating the fan could significantly damage the ductwork. The design should deactivate the HVAC system components to prevent potential damage. Duct smoke detectors require a minimum pressure differential for air to flow through the detector sensing chamber per individual manufacturer installation instructions. Typically, when the air system is not operating the pressure differential is not within the equipment listing and the smoke dampers must be closed.

Example: HVAC Shutdown

Mechanical ventilation systems can recirculate air within spaces served by the HVAC system. In a fire, these systems could spread smoke from the room of origin to other areas of the building. The areas remote from a fire could be overwhelmed quickly by smoke. Typically, applicable codes and standards require the HVAC system to be deactivated when a system has a design capacity greater than 2000 cfm. HVAC systems with a larger design capacity and that serve multiple floors, typically 15,000 cfm, may require a smoke detector at the return for each floor.

Duct smoke detectors are necessary to determine if smoke is present in the HVAC system. Smoke detectors are typically located in the return air ducts after the last inlet, and before air is exhausted to the outside or mixed with outside air. These detectors deactivate the associated HVAC system to prevent recirculation of smoke beyond the location of the fire. If smoke dampers are present, additional smoke detectors are generally required within 5 f. of each smoke damper. Generally, all duct smoke detectors are monitored by the fire alarm system. In some instances the smoke detector may be integral with the smoke damper.

After smoke is detected, the mechanical ventilation system serving the area is to be deactivated as a minimum. Additional systems might also need to be deactivated. Depending on the size and use of the building, all of the mechanical systems could be shutdown to simplify programming and testing.

The method upon which the mechanical ventilation system is to be deactivated will depend on how the system components are controlled. The fans that are associated with the mechanical ventilation system may be controlled by a motor starter. The motor starter has a control circuit that activates a contactor that provides the higher voltage and current to a mechanical system component like a fan. The control circuits are typically 120 VAC or 24 VDC. The building management system could control the operation of the HVAC system components.

The following are some potential methods to control an HVAC system.

- An *emergency control function interface device* (relay) controlled by the fire alarm system could be located in the control circuit of the motor starter. The relay may be in series to allow control of the equipment by multiple systems. For example, the control circuit could pass through relays for fire alarm, and building management system.
- If the fans are controlled by a building management system, the fire alarm system could provide an output through an emergency control interface

(continued)

(continued)

(addressable output module or similar) to deactivate the mechanical systems. With this interfacing method, the building management must be programmed to deactivate the mechanical systems when the output is received. Changes to the building management system program could prevent the mechanical systems from deactivating in a fire condition. It is important that if the building management system program is changed, the necessary deactivations are verified similarly to the testing requirements for changes to the site specific software used by the fire alarm system.

- Newer motor starters and variable frequency drives (VFDs) are microprocessor controlled. This equipment generally has a dedicated input for fire shutdown mode. This capability might be an option and therefore must be specified by the design team.
- In older buildings, the control circuit may be required to be powered to deactivate the fan. For these systems, a power circuit is required to be provided to initiate the deactivation. The presence of power must be monitored, typically with a relay and an addressable input module. The addressable output module is typically used to deactivate the fan. This output module is required to be located close to the motor starter to reduce the possibility of wiring damage impacting the shutdown of the ventilation where this wiring is not supervised.

Detection Systems The design of the detection components of the system should consider the technical criteria and equipment selection, and should review device locations so that proper maintenance can occur after they are installed. The owners' property protection goals should be considered and may require additional detectors or types of systems with alternative alarm thresholds. For example, an atrium smoke exhaust system may require smoke detection with an alarm threshold that is lower than typical detectors. Detection zones likely need to match smoke control, egress, and notification zoning.

Gas Detection Systems Gas detection systems need to be coordinated with fire detection and alarm systems. The designer must consider how to make the notification distinct to affect the proper response from occupants. Location, color, and sound of the alarm needs to be considered with respect to other warning devices. There should be special considerations for occupant notification and off premise reporting of these hazardous conditions.

Notification Systems Fire alarm and signaling regulations, such as NFPA 72, continue to change to reflect the multiple modes for notifying occupants. In fact, the title of 2010 Edition of *NFPA 72, National Fire Alarm and Signalling* Code, has changed to represent this broader focus. Items such as Mass Notification (Emergency Communication Systems) use monitors and other text devices, as well as cellular text messaging and phone messages, as means to provide notification. Mass notification systems can take the form of integrated fire alarm systems over multiple locations or be a completely separate and independent system. The design must consider priorities and which parts of the systems will be used simultaneously [20]. For other means of notification, interface is often accomplished via a network and industry standard communication protocols. Manufacturers offer web based applications that can text and phone individuals or large groups of people to notify of an event detected by the fire alarm system. The fire alarm system can also be integrated with other systems, such as public address and public information systems. A common example of this is in sport stadia and arenas where the large display screens or "jumbo-trons" and all of the flat panel displays can be used to indicate a fire or other emergency event and provide instructions for evacuation or other actions. This requires the designer to consider what systems will be

utilized, whether appropriate redundancy and protection is provided, and which system will have priority for any shared equipment.

Interface with other systems such as general sound systems or other displays that could distract occupants from emergency instructions may also need to be deactivated or otherwise controlled. It is critical that the operation and zoning of the fire alarm system is coordinated with the emergency response plans, evacuation procedures, risk analysis, and emergency communication system strategies.

The type and mode of emergency communication needs to be coordinated with the fire and life safety consultant and the Authority Having Jurisdiction. Depending on the system chosen, the engineers and fire alarm manufacturer may need to coordinate locations, distances and number of devices operating at once for a wired system. If a radio system is used, coordination with the IT and Communications consultant will be necessary to provide the necessary infrastructure and to determine if there are conflicts with other radio systems.

The notification strategy for the fire alarm system must be coordinated with the evacuation strategy and the fire and smoke separation strategy. Public address systems require coordination with fire alarm notification systems and Emergency Communication Systems to ensure proper prioritization and avoid several audio systems being used simultaneously to make the emergency message non-intelligible. Similarly, the designer must consider the acoustics of the area being notified. In a building lobby with mostly hard surfaces, providing more, lower wattage devices will likely be necessary to achieve intelligibility. If the notification strategy provides different messages in different areas, the acoustic separation of the areas needs to be considered. In a large concourse or mall, it may be desirable to evacuate an area near to the event while only alerting areas remote from the event. If the space is open, the interface between where people receive the evacuation message and the alert message needs to be designed such that the messages can be distinct and understood.

Coordination is particularly important in high-rise buildings, where generally the fire floor, and one floor immediately above and below are initially evacuated. Emergency Voice/Alarm Communication Systems (EVACS) are required in buildings where relocation instructions are provided to the occupants.

In some cases fire alarm signals can be deactivated in the event of a higher priority mass notification event, when based upon an approved risk analysis and approved emergency response plan. The impact of an in-building mass notification system must be considered when designing a fire alarm notification system [20, 33].

To effectively communicate an emergency message, the notification scheme may need to consist of multiple alerting methods, such as voice, text, and strobes, and be coordinated with the emergency response plan. The emergency response plan should dictate when each of the alerting methods would be used. For example, in the event of an active shooter on a college campus the strategy might be discrete and provide notification through emails, automatic dialing, popups on computers, and text messages. For an immediate threat such a tornado, where individuals should quickly seek shelter, the response might consider obtrusive outdoor alert sirens, automatic dialing, weather radio alerts, and the Commercial Mobile Alert System.

Depending on the equipment configuration, other building systems such as a phone system could provide supplemental notification functions for mass notification. For example a phone system in a building can provide localized obtrusive in-building and personal alerting. Messages can be displayed on the phone if the device is equipped with a display, or each individual phone extension could be called to broadcast a message. Alternatively, current calls can be dropped during an emergency, and the speakers can activate at the maximum volume to broadcast the emergency message.

Emergency Control Functions The fire alarm system may need to provide a variety of control functions. The system may need to interface with

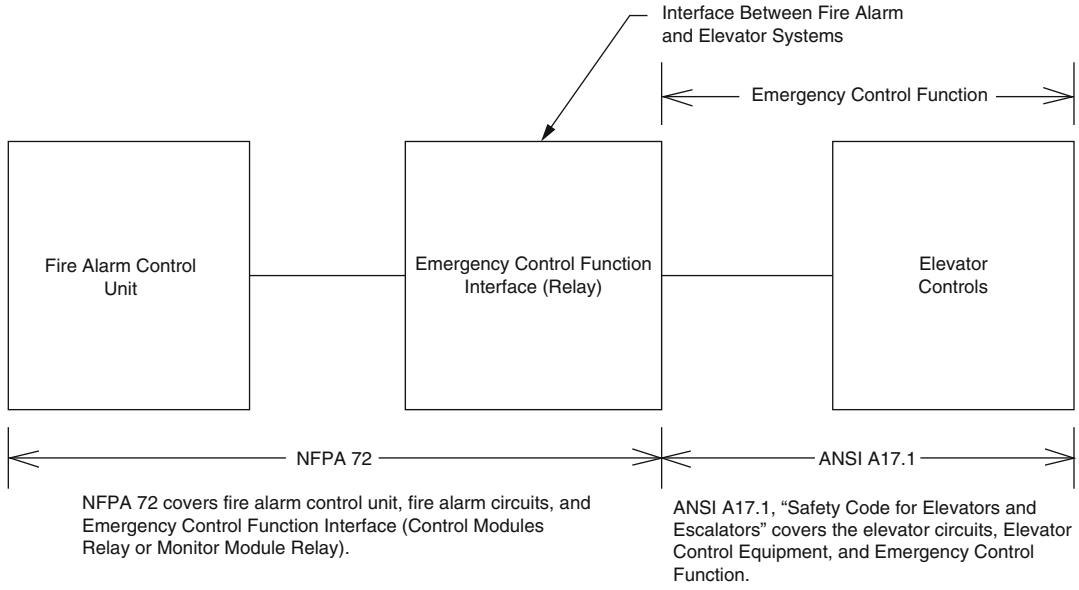

Fig. 49.3 Fire alarm system emergency control for elevator system

the elevator controls to initiate emergency elevator functions, such as elevator fire service recall, or initiate elevator shutdown. Where occupant evacuation elevators are used, the fire alarm system needs to initiate elevator evacuation mode, as well as elevator recall and shutdown. Figure 49.3 illustrates a fire alarm system *emergency control function interface device* (relay) for items such as elevator recall, shunt trip, and recall indicators. Elevator recall would be controlled by the elevator controller. The fire alarm system typically provides relays to the elevator controller. This output can be from addressable output modules or from a relay output card that is installed in the fire alarm control unit. Once elevator recall has been initiated, a key operated switch must be activated to return the elevators to normal service. Restoring the fire alarm system to normal would not automatically return the elevators to normal operation. The system may also need to initiate HVAC system shutdown, initiate door and shutter closure, and release locked doors.

An example of the division of design responsibilities during the design phase for integration of the fire alarm and elevator systems via an *emergency control function interface device* can be seen in Fig. 49.4.

The use of *emergency control function interface devices* (relay) on a fire alarm system to interface elevator controls may include initiation of the following modes:

1. Elevator evacuation sequence
2. Primary Elevator Recall
3. Alternate Elevator Recall
4. Fire service manual recall
5. Fire service notification of elevator shunt trip

Separate relays are needed for each point of information required. For example, if the only interface between the fire alarm and elevator recall was primary elevator recall and secondary elevator recall, two (2) relays would be needed to interface the fire alarm system to the elevator control equipment. Some of the inputs, such as manual fire service recall may be through the elevator control system.

The fire alarm system often needs to be interfaced either through relays or through direct communication with other systems for the sole purpose of shutting them off. As discussed above, this may include items such as lighting, door closure, and performance effects such as

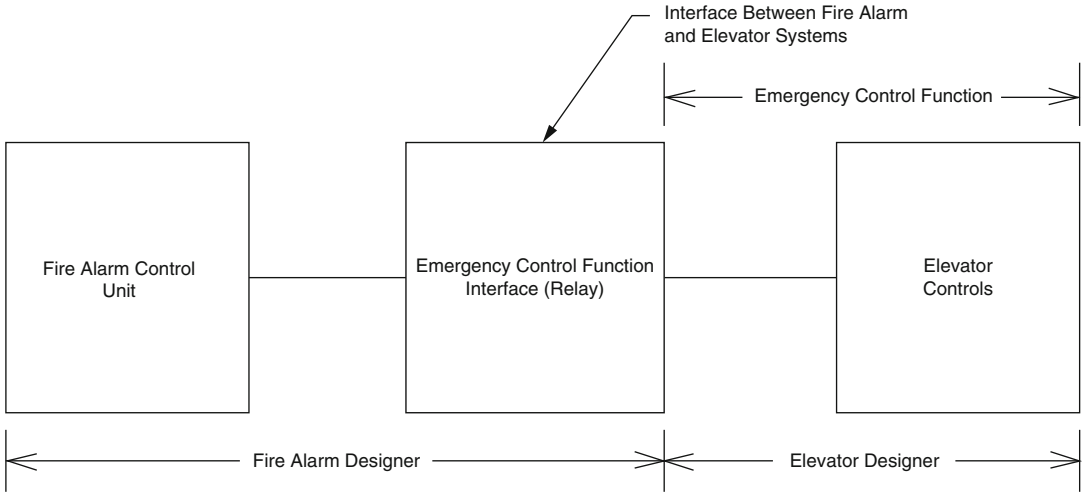

Fig. 49.4 Division of designer responsibilities example

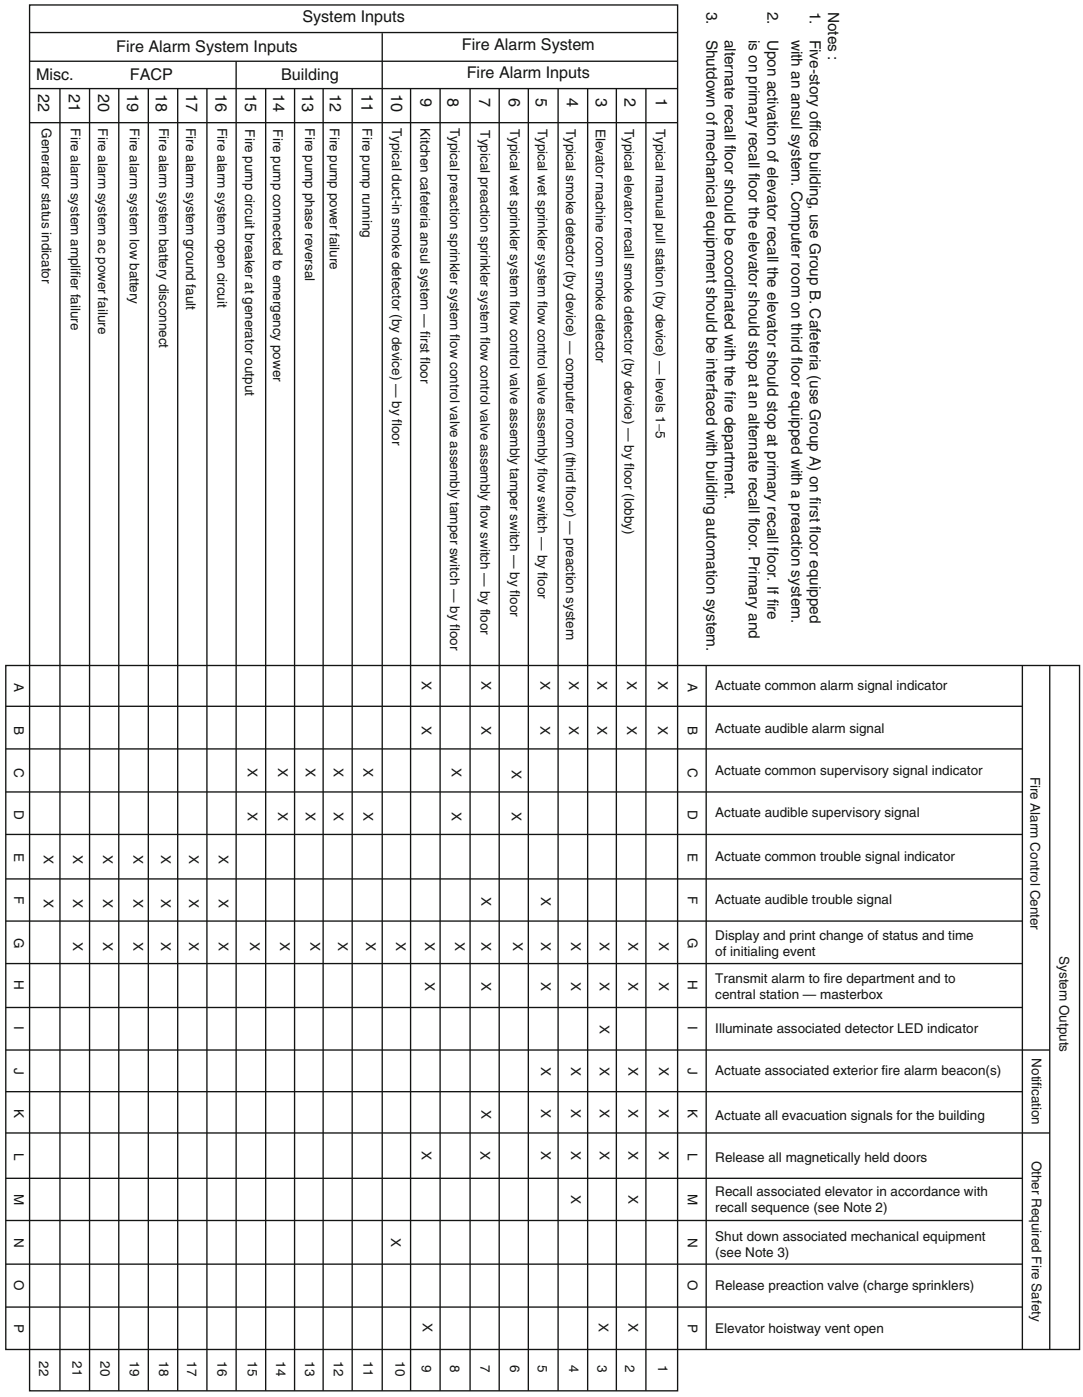
deactivating a sound system or special effects so that the fire alarm system is audible. Other systems that might need to be shutdown include gas shut-off for cooking and heating devices, medical gas systems such as oxygen, hazardous processes, and similar systems. This requires coordination between the architect, fire protection engineer, plumbing engineer and potentially a specialty piping designer. Baggage conveyor systems may also require to be deactivated. Whether in a baggage handling facility or bulk material handling, shutting down the conveyor may be necessary to maintain fire separations or to stop the flow of combustible materials to a fire.

The overall design needs to consider interfacing with other systems such as BMS to turn on a smoke control system. When dealing with hazardous chemicals it may be desirable to interface with specialized systems such as chemical hood controls. Newer systems have multiple set points to address energy saving desires, but upon alarm it may desirable for these systems to return to full operation. This may require special coordination with the mechanical engineer especially if other forms of smoke control such as an exhaust system or stairway pressurization system are present in the building.

Figure 49.5 from NFPA 3 shows a Fire Alarm System Sequence of Operations (input/output matrix), which includes fire protection systems interfaced and the intended outcome. Table 49.3 provides additional systems that may need to interface with the fire alarm system.

Suppression Systems The sprinkler designer often has to coordinate with the architect to achieve a desired function and appearance through specifying concealed or recessed sprinklers or providing a specific design to address concealing pipes or views of the sprinklers. The designer must coordinate with the fire alarm designer to connect water flow and tamper switches, and water level and pump status. If the pump is electric, emergency power must be considered. If a dry pipe or pre-action system is provided, space and power for compressors must be considered. Coordination with the mechanical engineer is necessary to determine if local space heating will be required. The sprinkler design must coordinate with the architect to identify the use of each space such that an appropriate hazard classification can be made [24].

Special suppression systems such as gaseous suppression agents require similar coordination as the sprinkler system. The fire protection engineer may specify the type of system and whether there will be any redundancies in the system.



Notes :
1. Five-story office building, use Group B, Cafeteria (use Group A) on first floor equipped with an ansul system. Computer room on third floor equipped with a preaction system.
2. Upon activation of elevator recall the elevator should stop at primary recall floor. If fire is on primary recall floor the elevator should stop at an alternate recall floor. Primary and alternate recall floor should be coordinated with the fire department.
3. Shutdown of mechanical equipment should be interfaced with building automation system.

Fig. 49.5 Fire alarm system sequence of operations (Reproduced with permission from NFPA 3–2012, *Recommended Practice for Commissioning and Integrated Testing of Fire Protection and Life Safety Systems*, Copyright 2011, National Fire Protection Association. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only in the standard in its entirety)

These systems typically involve smoke or fire detection. The dedicated detection and notification system needs to be coordinated with the overall building fire alarm system so that conflicting messages are not sent and that appropriate notification occurs when the system discharges. Controls need to be coordinated with other system functions, such as HVAC systems shutdown, damper and door closure, so that openings are sealed in order for the suppression agent to work properly. Coordination of the detailed sequencing, such as verification, interlocking, or releasing strategies are important.

In contrast, regulations might restrict the use of software in certain instances due to prior loss history. For example, NFPA 72, since the 2007 edition, does not permit fire alarm system software (programming) as a means to secure a suppression system from a discharge. These software disconnects on fire alarm systems have had previous failures due to programming changes, operating system changes, and power fluctuations, such that NFPA 72 requires a physical switch and does not allow the software disconnect for suppression systems.

Example: Special Suppression System

Special suppression systems might include clean agent, carbon dioxide, dry and wet chemical, foam systems, and interlocking and deluge water-based suppression systems. For these types of systems one or more electronic or mechanical inputs must occur for water or suppression agent to be released. Generally, special suppression systems are controlled by a dedicated fire alarm control unit. In some cases, the system can be controlled by the fire alarm system or a mechanically operated pilot actuated system. This example addresses suppression systems activated by a fire alarm system dedicated to the special suppression system.

The strategy of providing a dedicated fire alarm system for the special suppression system must consider back-up power supply requirements. Depending on the applicable regulations and design standards, and the owner's insurance company's requirements, the back-up power supply may be required to operate the system for 90 h or more. The typical duration of a building fire alarm system generally operates the system for 24 h. Therefore, it is likely that it is more cost effective to provide a dedicated control unit for the special suppression system.

Special suppression systems are likely to have a number of automatic and manual inputs. Automatic inputs may consist of points for air sampling, smoke, heat and gas detectors. The detectors may provide multiple alarm thresholds so that notification is provided at one threshold and then the agent is released when a second higher threshold is reached. Manual input could consist of manual alarm stations (pull stations) and abort switches. Depending on the suppression agent, the system may be programmed with a time delay to allow occupants to leave the area prior to agent discharge or manually preventing the agent release by continuously activating the abort switch.

Occupant notification may include horns, speakers, flashing lights and strobes. The audible notification appliance(s) may be programmed to provide multiple tones or messages. In some cases a bell or horn might pulse to notify of a pending agent discharge and then become steady once the agent has been released. Colored lights may also be used to provide notification in the protected room and at the entrances to notify of pending agent discharge.

Next, the special suppression system must be connected to a solenoid or an actuator to initiate the release of the agent. Typically the fire alarm control unit is connected to a control head that activates a master tank for certain types of systems

(continued)

(continued)

such as clean agents or carbon dioxide. For systems that require multiple tanks of agent, the master tank activates additional secondary tanks through an actuation line. The actuation line is connected from the pilot port of the master tank to each of the pneumatic actuators on the secondary tanks. This configuration allows for release of the secondary tanks only when the main tank is released. For other types of systems, such as deluge and pre-action systems, a solenoid can be operated to activate a larger valve to begin the flow of water.

As part of the commissioning process, the installation must be confirmed to the approved installation instructions. These instructions are reviewed as part of the listing and approval process. Some special suppression systems are approved to operate with a specific solenoid valves therefore the commissioning process must confirm that the appropriate equipment is being selected, designed, and installed to maintain the listing.

The special suppression system must also be interfaced with other systems, such as the mechanical system to compartment the room to maintain the agent concentration. The compartment integrity can occur through a variety of methods, such as using electrically controlled dampers or electrically actuated fusible links to release dampers to hold the agent within the space. Prior to completing the commissioning of the special suppression system, the interface with the dampers must be complete. Depending on the actuation method, replacement fusible links will need to be replaced for the system to maintain operability.

Depending on the distribution of the mechanical ventilation systems, deactivation of the fans needs to be considered to prevent damage to the mechanical systems. Failure to deactivate a fan when the damper is closed could cause high pressures in the ducts that could cause failure of the duct work.

The testing of a special suppression system must be coordinated with the construction of the building. Some authorities will require a flow test of a deluge sprinkler system, therefore this test must occur before specific items are installed and protection would need to be provided to prevent damage to surrounding areas. A discharge test of a clean agent could be cost prohibitive. It is important that the extent of testing is developed and reviewed with the AHJ during the design process. The testing must confirm that the electrically actuated equipment operates and that mechanically operated equipment is properly installed. Another critical test is the room integrity test for gaseous suppression system that is designed to hold a certain design concentration in the room.

Depending on the contractor, multiple contractors may be involved with the installation. For example, a clean agent suppression system may be installed by a separate contractor but their system might need output to the electrical, fire alarm and mechanical systems. The interfaced systems must be designed to receive these inputs and coordinated to provide the intended functionality.

The design team must coordinate the responsibilities of each of the contractors in the design documents. This coordination is necessary because it may be unclear which contractor is responsible for completing a specific activity and may result in scope gaps and delays to occupying the building. Figure 49.6 graphically depicts the various interfacing for inputs and outputs from a special suppression system and the other systems that are commonly found in buildings.

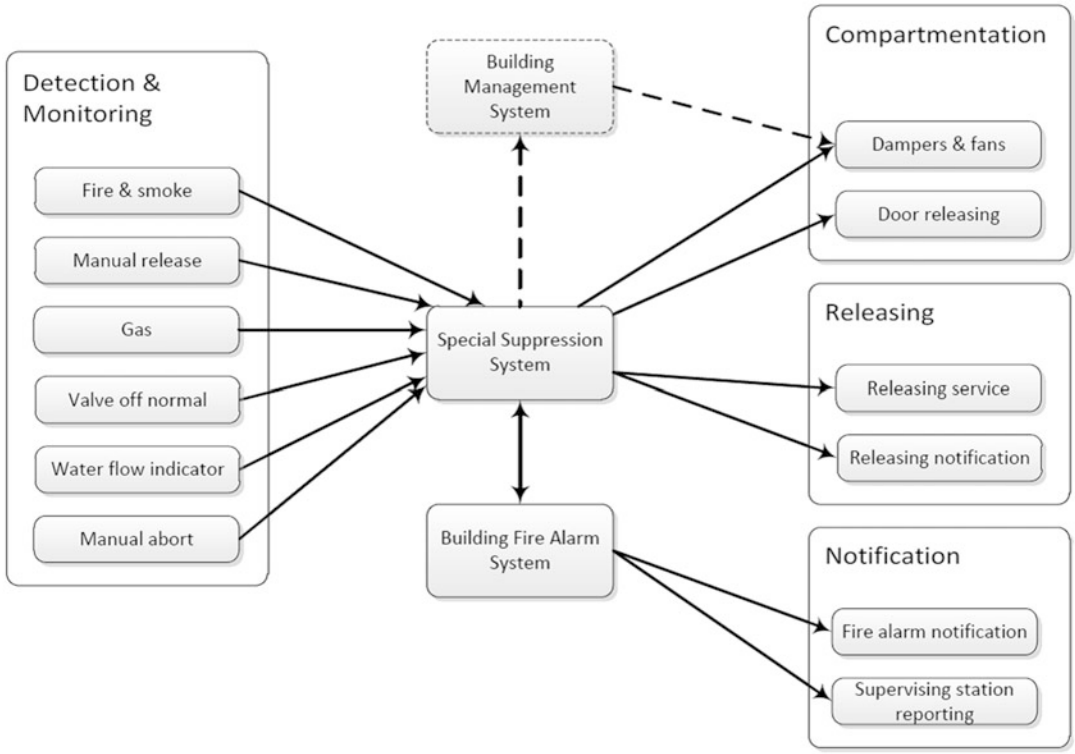


Fig. 49.6 Interconnections with special suppression systems

Smoke Control An atrium requires several systems to function correctly. A three story atrium would require smoke control, which requires coordination decisions to be made early in the process. In larger systems, the supply and exhaust locations need to be coordinated with the architecture, as the amount of louvers or openings can be quite large and getting supply air to the lowest level is often a challenge.

The smoke control system is often an *integrated system* itself, consisting of a fire detection and alarm system, mechanical systems, potentially a BMS, and the sprinkler system. Controls for the smoke control system can be through the fire alarm system, the Building Management Systems (BMS), Building Automation System (BAS), or through a dedicated controls system. The control system selected will determine interfacing and communication needed to control and supervise system components. Regardless of the control system, automatic and manual sequences need to be coordinated to achieve the system goals. Manual inputs typically override automatic smoke control functions.

Smoke control fans, dampers, and make up-air openings need to be monitored to determine if the equipment appropriately configures. Fault conditions should be reported through the control system. In some cases, dampers and make-up air openings need to be properly configured before fans are actuated, to avoid excessive duct pressures or door opening forces.

The designer must consider the activation of the smoke control system. If sprinklers are being used, then the design of the sprinkler system must include having a separate sprinkler zone for the atrium. Non-atrium sprinkler zones cannot be extended into the atrium, as this could cause an improper activation. If stairway pressurization is provided, detection for activation of the system needs to be coordinated. Where the

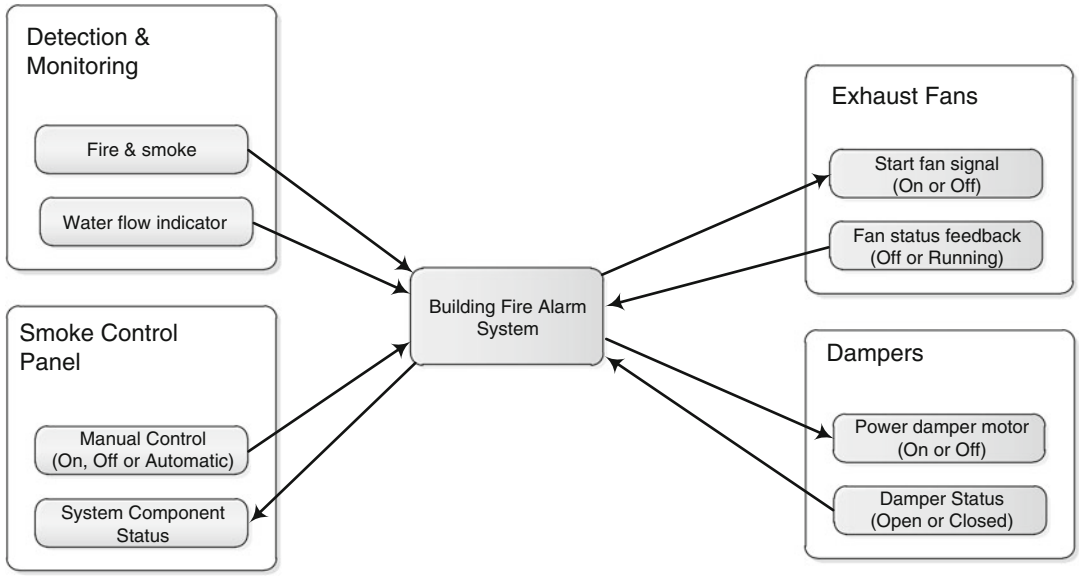

Fig. 49.7 Potential smoke control fan interfacing—option 1 (fire alarm)

smoke is being discharged, where fresh air is coming from and potential impact to surrounding buildings should be considered. The use of the BMS to control the mechanical equipment could reduce redundant wiring to equipment by the fire alarm and BMS systems. If the BMS is used, it must be appropriately listed for smoke control by an approved agency and the designer needs to understand how integrating systems may affect this listing. The interface between the fire alarm (initiating the smoke control system) and the BMS (controlling the mechanical system) also must be considered. Both Fire Alarm and BMS system manufacturers offer communication solutions such as LonWorks <www.echelon.com> or BacNet [3] for communication. These are networking platforms specifically created to address the needs of control applications. These platforms provide more information than dry contacts between the two systems would.

The location of the smoke control system components need to be coordinated with the egress plan, architecture and the computer smoke model if one were utilized. Locating exhaust points to pull smoke away from egress paths or to take advantage of a reservoir can also make the smoke control system more effective.

Figures 49.7 and 49.8 illustrate two potential options for interfacing fan control. Other options are available.

Hazardous Exhaust Systems Utilizing ventilation zones for containment, via negative pressure zones, needs to be reviewed for both construction integrity and for proper operation when a smoke control system is operating or not operating.

Exhaust systems may need to run continuously or to modulate to high-speed exhaust for hazardous atmospheres venting upon carbon monoxide gas, hazardous gas, or hazardous chemical leak detection. The exhaust systems may need to be interfaced with process controls to actuate during unwanted process conditions, such as overheating. Systems that need to run continuously may need to run during other emergency events, including loss of normal power. Exhaust and make-up air need to coordinate with smoke control and other ventilation systems, along with emergency power. These systems may need to be monitored through air flow sensors and alarms.

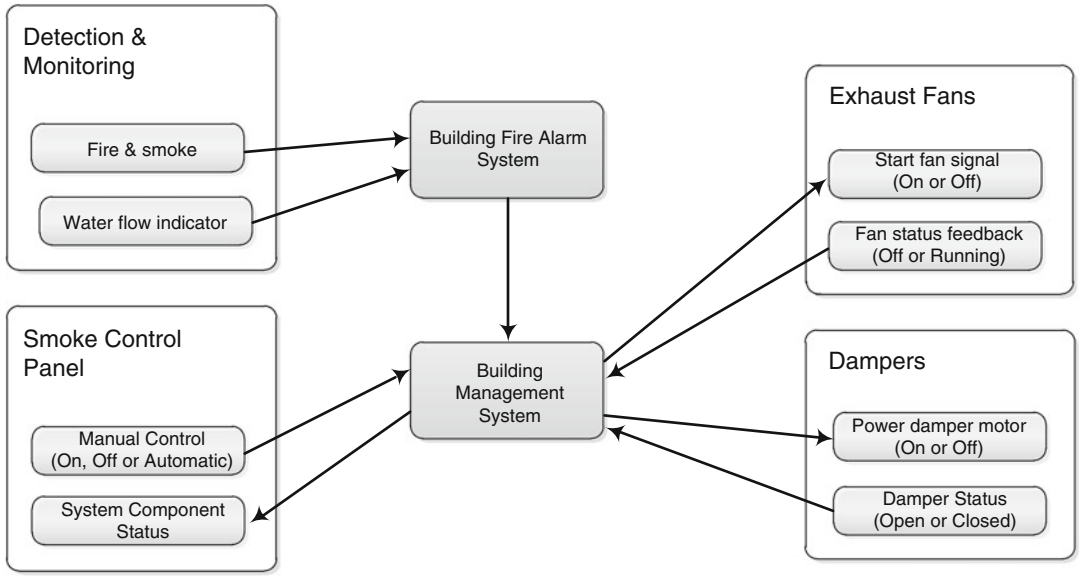

Fig. 49.8 Potential smoke control fan interfacing—option 2 (building management system)

Gas or leak detection can be through the fire alarm system, the BMS/BAS system, or standalone systems. Integrated or separate systems can be used to actuate exhaust or modulate the systems to provide additional exhaust.

Emergency and Standby Power Emergency and Standby power systems require coordination between electrical engineers providing the power system and the fire and life safety consultant in identifying the appropriate forms of emergency/standby power. This design must then be coordinated with controls and the architect to identify which systems will require power such as computer systems or medical systems. Mechanical engineers should identify which building systems will require emergency and standby power and which systems are desired to have optional standby power. In some cases the duration of fuel supply may become a concern as more and more items are added to the emergency and standby power for potentially longer and longer durations.

Required fire resistive rating of power cabling for emergency and standby power feeds to panels also requires coordination [11, 24, 25].

Elevators Interfacing with elevator controls are discussed in the Emergency Control Functions discussion above. Other considerations include building code requirements for sprinklers to be installed in the elevator machine room or shaft. To prevent damage to the elevator control equipment, the fire alarm system would be configured to initiate disconnecting of the power (shunt trip). A heat detector or a water flow switch would initiate disconnection of the power. If a heat detector is used, the device is required to located within 2 f. of each sprinkler with an activation temperature and response rate lower than the sprinkler. When a water flow switch is used, a delay is not permitted.

Generally, this would be accomplished through a shunt trip circuit breaker. The fire alarm system would activate power to initiate the disconnection of power. Most shunt trip breakers require power to initiate disconnect; therefore it is important to monitor the power source to the shunt trip breaker. Usually this is accomplished with an *emergency control function interface device* (relay) that is powered by the shunt trip source and located within 3 f. of the shunt trip breaker. The status of this relay would

be monitored by the fire alarm system and would report a supervisory signal [4, 20]. Depending on the authority, the sprinklers could be removed from these spaces eliminating the need to disconnect power.

Electronic features requiring interfacing and coordination include: elevator evacuation system status indicator in lobby (IBC only), elevator system monitoring to indicate car floor location and direction of travel, two-way communication system between elevator lobby and fire command center, elevator car occupancy status indicator (IBC only), Phase I emergency recall remote control located in fire command center, and status indicator of normal and standby power in fire command center.

Emergency elevator evacuation activation initiates through any sprinkler water flow or any smoke detector activation, other than an elevator lobby detector, and through manual activation. The system is configured to return the elevator cabs to the lobby floor to allow occupants within the cab to exit. The elevators are then prioritized to shuttle occupants from fire floor, and two floors above and below the fire floors, to the lobby floor. The highest priority is given to the fire floor. If elevator recall is initiated manually or automatically after commencing emergency evacuation sequence, the elevators return to the recall floor.

The use of evacuation elevators may be integrated with the CCTV system to detect occupants in an elevator lobby. The CCTV system could be used by an operator to determine which floors need to be evacuated first.

Access Control and Security Access control and security systems often are a challenge to the other *life safety systems* and therefore require special attention. Often a security system design is intentionally kept separate from the rest of the design process. Locking of doors, security gates and other security counter measures must be considered by the designer of the fire alarm and egress systems. Doors can be unlocked upon alarm, but the designer should consider non-fire events that do not trigger a fire alarm. As part of security plan there may be a need to evacuate and area that would normally be locked. Alternative means of egress may need to be developed. Priorities must be understood by the designer as releasing security features in places of detention may not be acceptable and alternative design solutions must be developed.

Some system integration can be done relatively simply, such as integrating a CCTV monitoring system with access control and intrusion detection. This information could also be helpful to first responders for non-security issues so integrating a video feed to a fire alarm control area may be desirable and is proposed as a requirement for high rise buildings with over 4000 occupants. Where these two systems do not conflict, as one is just "observing" the other, the integration is relatively simple. However, with new technology such as video image smoke detection, cameras can now be used for detecting a fire as well as tracking individuals or items of interest. This requires the designers to coordinate locations and view angles of cameras to address both security and fire concerns. If the cameras are being used to detect fires then redundancy, circuit integrity, and listing issues need to be addressed [8].

Lighting Lighting effects may need to be turned off and house lights may need to be brought up to an appropriate level to aid in egress. Often a theater or other performing arts venue or amusement ride has lowered lighting levels in the space. Designers need to coordinate where minimum levels of fixed lighting will be provided as well interfacing systems such that house lights are brought up and theatrical lights are turned off. Exit signs will need to be visible to occupants and their location needs to be coordinated with the architecture.

Matrix of Responsibilities

Depending upon the specific construction procurement method, systems could be installed by a different contractor and at different times. Each system connection presents a potential problem when trying to install, *pre-functional test*, and commission the individual systems and the

Table 49.4 Coordinating the design of integrated building systems

Section reference	Work	Furnish	Install	Wire	Commission
21131X	Sprinkler system	21	21	21	21 and 28
21311X	Fire pump	21	21	21	21
212200	Clean agent suppression system	21	21	26	21 and 28
233300	Fire & smoke dampers	23	23	26	23
283111	Duct smoke detector	28	23	28	23 and 28

integration of these systems. Often, these systems will be covered within different MasterSpec (e.g. standard guide specifications for building systems, equipment, and features) sections and one contractor may not even realize they need to coordinate with another. One tool to minimize these problems is for the designer to develop a responsibilities matrix, as shown in Table 49.4. This matrix identifies each trade, where the interface between systems will occur, and which trade is responsible for each system and system *interconnection* [32].

Another tool for addressing this is coordination drawings. These are drawings prepared by the contractor and reviewed by the designers. The drawings are sometimes used for physical coordination and sometimes are specifically to indicate the coordination between the different trades, and designate all of the *interconnections* and information needed for the *interconnections* [32].

Systems Interfacing Methods

Building systems are increasingly becoming more integrated, with multiple systems performing as one system. Following those trends, the number of systems integrated with the building fire alarm system is increasing, further complicating the commissioning and integrated testing process. Microprocessor based fire alarm systems are being programmed to complete more than detection and notification of occupants in the event of an emergency in a building.

The fire alarm system can be interfaced with a variety of building systems and inform trained personnel. An *Integrated System* is two or more individual systems that work together in achieving an overall fire protection or life safety objective. Figure 49.9 conceptually illustrates the difference between integrated systems and *interconnected systems*. Trained personnel can be, in certain circumstances, a critical part of the integrated fire protection system, since they may be required to evaluate the information received and take action to manually initiate other fire protection systems.

An example is trained personnel, such as a guard at a prison. A prison guard in a prison can be part of an *integrated system*, in which the guard relies on information from the fire alarm system or the emergency communication system in order to determine if manual release of door locking controls is required. This is an example on an *integrated system* that is not an interconnected system.

Wiring Methods

Various wiring methods are available to interface and connect other systems found in buildings with the fire alarm system. A device that is controlled by the fire alarm system is considered an output. The fire alarm system is interfaced with a number of building systems to activate or deactivate depending on the desired state during an emergency. Outputs are also used to initiate off premise reporting (supervising station), fire department reporting, or reporting to a constantly monitored location. Fire alarm outputs can be connected in series or parallel, and configured to be either fail safe or fail secure.

A device that reports status and is controlled by a system is a two-way interface. An example of a two way interface would be a smoke control system, when a fire alarm is initiated, the fire alarm system would activate a smoke exhaust

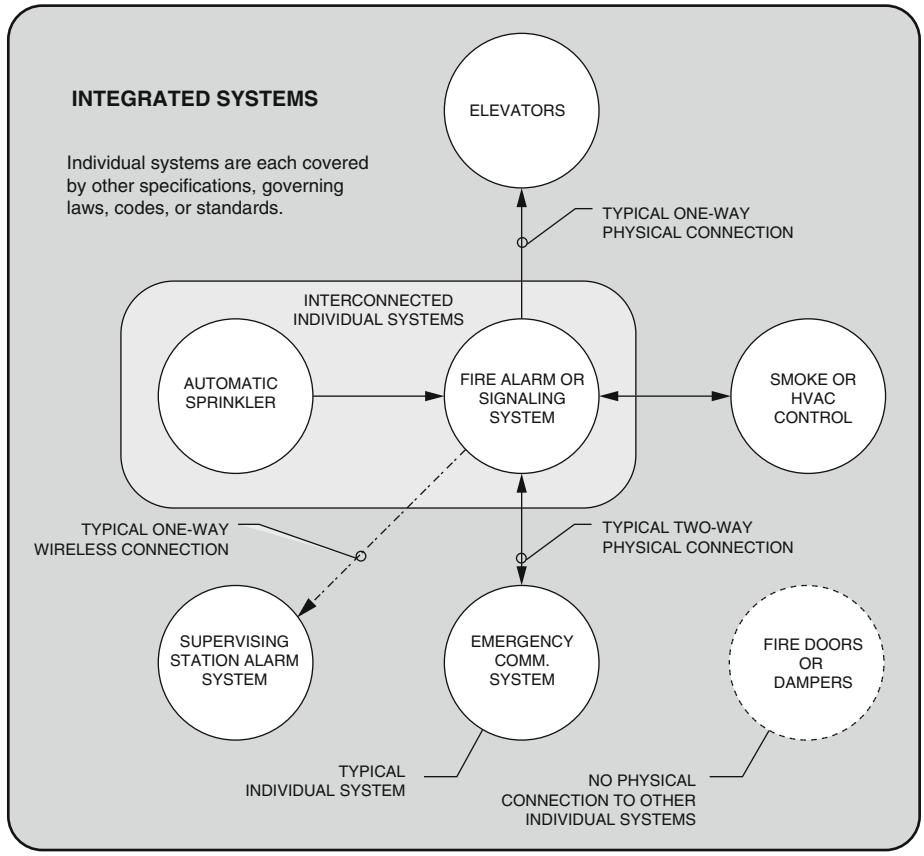

Fig. 49.9 *Integrated system* vs. *interconnected systems* (Reproduced with permission from NFPA 3–2012, *Recommended Practice for Commissioning and Integrated Testing of Fire Protection and Life Safety Systems*, Copyright 2011, National Fire Protection Association. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only the standard in its entirety)

system. The output might consist of an interface with a motor starter/controller to start a fan and open a damper. The input to the fire alarm system would be positive status indication of the system components operation, such as fan operation and damper position status. Examples of a two-way interface include data communications and building automation protocols.

Series A control circuit wired in a serial method requires all control points to be in the desired state to operate a system. For example, a control circuit for an air handler serving the building heating, ventilation and air conditioning (HVAC) system might be controlled by both the fire alarm and building management systems. In this example, if either the fire alarm controller or the building management system control shuts down the HVAC, the system will shut down. Therefore, the HVAC will not operate if the fire alarm system is in alarm, regardless of the building management system status.

Parallel A parallel circuit permits any of the control points to activate the system. An emergency lighting system that is controlled by the building automation and fire alarm system is an example of a parallel system. In this example, the building automation system includes occupancy sensors to activate lighting. Lighting would also activate when an alarm is initiated on the fire alarm system. Paralleling the control circuit would activate lighting when either system sends the command.

Fail Safe In fail safe wiring, circuit wiring may not be monitored, as the intended operation is performed in the event of circuit failure. A common example would be a motor starter circuit that controls a non-smoke control fan associated with the ventilation system. The motor starter circuit is required to be completed for the fan to operate. The fire alarm system controls the fan through a series connected *emergency control function interface device* (relay), where a control switch is required to be energized for the fan to operate. This switch can be de-energized through the fire alarm sequence or de-energized through interruption of the fire alarm circuit. If the fire alarm wiring fails, the relay would not be energized which would prevent the fan from operating. A second example would be fire or smoke doors held open by magnetic door holders, if power is lost to the electromagnet, the doors are released. Doors are also released through an alarm condition on the fire alarm.

Fail Secure An example of a fail secure component would be an electric door strike. For the door to be unlocked the circuit must be complete and power applied to unlock the door. A fail secure lock is important to maintain security of the building in the event of a power failure in the building. Fail secure locks are not permitted in the path of the means of egress.

Data Communications Complex control systems can be difficult to interface between multiple systems. In the connected world, a majority of equipment is transitioning to communication over internet protocol (IP), through a single connection that uses software to communicate utilizing a standard protocol. This strategy reduces installation and equipment, which reduces the installation and maintenance costs. The integration quickly blurs the demarcation points between multiple connections.

As more and more interfacing is completed through equipment software and firmware, commissioning and integrated testing will continue to become more complicated and involved because the control functions programed into the software of associated equipment also needs to be verified. The sequencing and control of fire alarm equipment is not usually obvious as the associated software and firmware is generally proprietary and controlled by the fire alarm system contractor. With the fire alarm system sending a fire alarm signal to the building automation system, the contractor programming the building automation system is responsible for programming items that impact the input or output from the fire alarm system. Modifications to building automation systems tend to occur more frequently than changes to the fire alarm system. These changes could impact the operation of the life safety system, and may require a partial re-test or a full re-test of the *integrated systems*. A simple software upgrade could create an incompatibility between the control units and the associated equipment they are intended to control.

Building Automation Protocols In buildings with smoke control systems, there may be a number of system components that need to be controlled that are also used for normal building HVAC systems. In some buildings, the fire alarm and building automation system are configured to require a duplication of the interfaced wiring to smoke control equipment. Building automation systems can share equipment status and control the various components through a common protocol interface, connecting to the building fire alarm system. Standard building automation protocols include BACnet, LonWorks, and MODBUS.

Each type of protocol has multiple versions. Some manufacturers customize their communication properties. When integrating the fire alarm system with a building automation protocol, it is important to confirm the type, version, and supervision of the communication, and that both systems support the necessary protocols for the intended functionality. Traditionally, most building automation systems communicated over a proprietary network that require dedicated network infrastructure. The dedicated network consisted of dedicated copper or fiber cabling between each network component. More recently, most building automation systems

support and use the shared TCP/IP network to communicate. Some manufacturers support open protocols, which allow open communication between different manufacturers.

Installation Considerations

The designer must consider the system installation methods when designing the *interconnections* of the systems. Usually a separate contractor installs each system such as fire alarm, sprinkler, HVAC, and low voltage controls. Some of these systems may be design build or fully designed by the sub-contractor. In either case, the sub-contractor often is not aware or does not fully appreciate the overall goals of the *integrated systems*, even though they completely understand their individual system. In order to address this, the designer needs to consider coordination meetings with the sub-contractors early in the process. The use of checklists can assist with coordination and integration of the various systems. In an effort to assist with plan review, many Authorities have developed internal checklists. These checklists are often made available to the designer to speed the review process and provide examples in which system interaction may be desirable. The designer may consider developing a project specific checklist for the contractors to use to verify the *interconnections* between various systems and equipment are done correctly.

Commissioning and Integrated Systems Testing

Commissioning and Integrated Systems Testing are two ongoing activities that are essential in the coordination and interfacing of fire protection and life safety systems during the design and construction phases of a building project. Many building owners recognize the benefits of a comprehensive *commissioning plan* and an *integrated test plan* initiated early in the design process for fire protection and life safety systems regardless of the complexity of their buildings. The total expense of implementing a comprehensive *commissioning* and *integrated test* plan early in the design process is usually recouped due to savings associated with reduced construction costs, delays and change orders, with efficiencies gained from optimized system performance and coordinated maintenance activities [1]. Commissioning can assist in opening a building on time [7]. Commissioning of fire protection and life safety systems is one portion of the overall building commissioning.

NFPA 3 [21] outlines a systematic commissioning process, which is completed through an owner's representative to meet the owner's goals and objectives that have been incorporated into the design and installation of the building. The commissioning process includes verification and documentation. As illustrated in Fig. 49.10 the commissioning process can include the Planning Phase, Design Phase, Construction Phase, and Occupancy Phase for a building. *Commissioning* is much more than *acceptance testing* of each individual system and can also include *integrated testing* of the interfaced systems. *Re-commissioning* (commissioning systems previously commissioned) and *Retro-commissioning* (commissioning systems never commissioned) are also part of commissioning process for existing buildings.

An early step in the commissioning process is for the relevant stakeholders to agree to use a common set of terminology. Industry terminology, which includes terms such as *Commissioning Authority* (*CxA*), Fire Commissioning Agent (*FCxA*), and *Integrated Testing Agent* (*ITa*), must be understood by all parties involved. The commissioning process and integrated testing does not replace or supersede the *acceptance testing* requirements found in individual system standards. Additionally, inspection, testing, and maintenance of the individual fire protection systems still need to be accomplished in accordance with the specific individual standards (e.g. NFPA 25 [16] for sprinkler systems). Commissioning standards and guidelines are generally more detailed in documenting the commissioning process than it is for documentation in other fire protection and

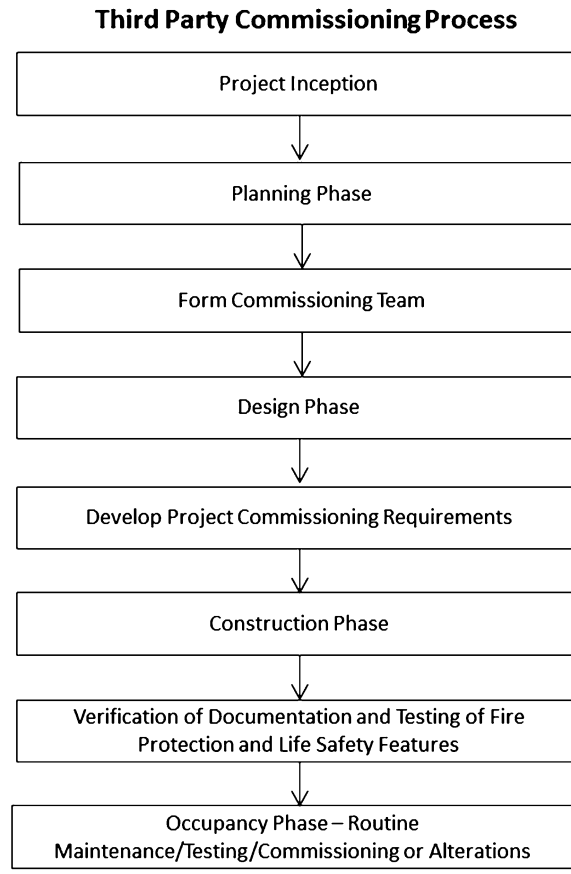

Fig. 49.10 The third party commissioning process

life safety systems codes or standards. In some cases, commissioning has become a building code requirement, for example the smoke control systems special inspector requirements included in the International Building Code (IBC) is essentially commissioning the smoke control system.

Integrated Testing is performed according to the specific *Integrated Test Plan* developed and approved for the project, which may require *end-to-end test* to verify the proper functionality of the various fire protection systems intended to operate as single unit under certain scenarios.

An important aspect of the *Integrated Test Plan* is the development of a set of test scenarios. Such test scenarios are to be agreed to prior to the commencement of any integrated testing, and are developed to articulate the adverse conditions under which the systems are expected to perform as a single unit. Ideally, these scenarios are considered and documented when the overall fire protection strategy for the facility is being developed. Part of the *Integrated Test Plan* is an *interface test*, where the integration and connectivity of the affected systems is tested, the expected performance is demonstrated and verified, and results are documented. A simple building with only a few integrated fire protection and life safety systems would have a rather simple, basic *Integrated Test Plan* with a limited number of scenarios. A larger more complex building may include numerous and expansive integrated fire protection systems, and would typically need a larger number of more complex testing scenarios. Figures 49.11 and 49.12 include excerpts from *Integrated Test Plans* for a simple scenario and a more complex scenario. The *Commissioning Plan* and the *Integrated Test*

Scenario #Y Sprinkler Water Flow Activation (SIMPLE BUILDING)

System Action

Annunciate at the fire alarm panel
Send signal to Central Station Service
Activate audible and visual alarm signals throughout building

Elevators remain in normal operation.

System Verification

Verify alarm received at fire alarm panel within 90 seconds	YES	NO
Audible and visual alarms at the fire alarm panel	YES	NO
Proper alarm annunciation at the fire alarm panel	YES	NO
Verify signal sent to Central Station Service	YES	NO
Audible/visual notification activated throughout building	YES	NO
Verify supervision in event of device failure or signal interruption.	YES	NO

Fig. 49.11 Integrated test plans excerpt– simple scenario

Scenario #X Atrium Waterflow Activation Activation on Level Y (Complex Building)

System Action

Annunciate in the Fire Command Center (F.C.C.)
Send signal to BMS system
Send signal to 24-hr remote station
Activate audible and visual alarm signals (floor of alarm, floor above, and floor below)

Elevators remain in normal operation

Activate smoke control sequence, as follows:

Atrium Exhaust Fans ON	EF-AA and EF-BB
Stair Pressurization Fans ON	SSF CCC, SSF DDD, SSF EEE, SSF FFF
Exhaust Dampers OPEN	FSD FFF and FSD-GGG
Dampers CLOSE	All others
Door Magnetic Hold Opens Release	Zone of Alarm
Release Security Stair Door Locks	All Floors

System Verification

Audible and visual alarms at Fire Command Center (F.C.C.) annunciation panel	YES	NO
Send Signal to BMS system	YES	NO
Send signal to 24-hr remote station	YES	NO
Audible/visual notification activated on floor of alarm, floor below, and floor above	YES	NO
Smoke Control Exhaust Fans ON	YES	NO
Smoke Control Supply Fans ON	YES	NO
Dampers OPEN per the Smoke Control Sequence noted above	YES	NO
Dampers CLOSE per the Smoke Control Sequence noted above	YES	NO
Stairwell Pressurization Fans operate	YES	NO
Vestibule Pressurization Fans operate	YES	NO

Verify supervision in event of device failure or signal interruption.	YES	NO
Toilet exhaust fans ON	YES	NO

Fig. 49.12 Integrated test plans excerpt—complex scenario

Plan should be developed and customized for each individual building, since each building usually has its own unique features and functions.

The contractor and subcontractors are brought in at different times of a project depending on the procurement method of the building (e.g. Design Build, Design Assist, or Design/Bid/Build). The contractor and subcontractors should be involved to some degree with the coordination process as soon as they become involved with the project. Contractor shop drawings, calculations, and equipment submittals of the fire protection and life safety systems provide more detail, including specific manufacturer's equipment proposed for installation. The contractor's shop drawings should be coordinated with all other relevant disciplines' (e.g. mechanical, electrical, plumbing, structural, and other specialists) shop drawings. The Design Team, *FCxA*, and *ITa* review of the contractor's documents needs to include verification of the *BOD*, and the project's strategies and goals. The commissioning process is not intended to alter the installation of fire protection and life safety system components from their listing requirements or the manufacturer's approved installations instructions.

Some government agencies, such as U.S. General Services Administration (GSA), have long standing requirements for a fire protection engineer (FPE) to review the overall design of the building and the various fire protection systems. Such FPE is not necessarily the engineer of record for the individual systems. With an overall understanding of the architectural design, the buildings functionality, and how the various fire protection systems and features are intended to function together, the FPE review during the design and construction phase serves to verify proper performance of the *integrated system*s. Other Agencies have also implemented commissioning requirements which include fire protection and life safety systems.

Individual fire protection and life safety systems need to undergo *acceptance testing* in accordance with the appropriate individual standards (e.g. NFPA 72 ([20]) for fire alarm systems and NFPA 13 [24] for water based suppression systems), prior to Integrated System Testing. The engineer of record for each system is required to review the progress of installation, witness *acceptance testing* of the individual systems and provide engineers approval. The Commissioning Team reviews the progress of the installation, tracks and documents deficiencies, coordinates and witnesses system testing, coordinates and witnesses, along with the *ITa*, the integrated testing of systems, and provides a complete and final fire protection and life safety commissioning team report and integrated test report recommending approval.

Final *acceptance testing* of individual fire protection and life safety systems with the Authority Having Jurisdiction (AHJ) and obtaining *acceptance testing* final approval by the AHJ may be required prior to the Integrated Testing. Discussion and coordination with the AHJ should have taken place during the design phase or early in construction phase, long before the *acceptance* testing to determine if separate individual system acceptance tests are required prior to the Integrated Test. Some AHJ's may require or desire the AHJ final *acceptance testing* to be completed after the Integrated Testing has been completed and documented, to assure the integrated systems work in a coordinated manner with each other prior to issuing a certificate of occupancy. Periodic testing, maintenance, and integrated testing of the various systems should continue to occur over the life of the building. Commissioning may continue over the life of the building for building modifications, system upgrades or major changes to the building and/or fire protection and life safety systems.

Systems Coordination During Construction

The contractor and sub-contractors are involved at different times of the project depending on the procurement method as discussed above. Contractor shop drawings, calculations, and equipment submittals of the fire protection and

life safety systems provide the next level of detail after the design phase drawings, and include specific manufacturers and equipment proposed to be installed. The contractor shop drawings need to be coordinated with the other contractors shop drawings. The Design Team, Engineer of Record, *FCxA*, and *ITa* review of the contractor's documents needs to include verification of the *BOD*, and the project's strategies and goals. All fire protection and life safety system components should be installed per their listing and written manufacturer's recommended procedures. Field changes need to be evaluated for their potential impact on individual fire protection and life safety systems and to the impact on interfaced fire protection and life safety systems. Approved field changes related to fire protection and life safety systems need to be appropriately documented and incorporated for commissioning, testing, and final *acceptance testing*.

Figure 49.13 depicts a possible contractor responsibility diagram for the fire alarm system interface device with the elevator controls via a fire alarm system *emergency control function device* (relay) for items such as elevator recall, shunt trip, fire fighter's hat, and evacuation elevators.

One of the particularly effective tools for coordination is well managed focused coordination meetings with the design team, owner, contractor, subcontractor, *CxA*, *FCxA*, and *ITa* to review interfaced or integrated points between systems, review the overall sequence of operations between the systems, review of the *Commissioning Plan*, and review development of the Integrated Systems Testing Plan. These coordination and review meetings may involve hardcopies of the drawings to review and mark-up drawings, or other times they may use Building Information Management (BIM) software [31] to electronically display the various systems on screen during the meeting.

Other coordination tools for the design team and installing contractor include:

1. Coordination Checklists
2. BIM 3D/4D Modeling
3. Responsibility Matrix (matrix outlining responsible for furnishing and installing each component)
4. Hardcopy set of redlined coordination drawings

BIM software programs, if properly implemented, allow for creation of tag layers for equipment features, such as system interface

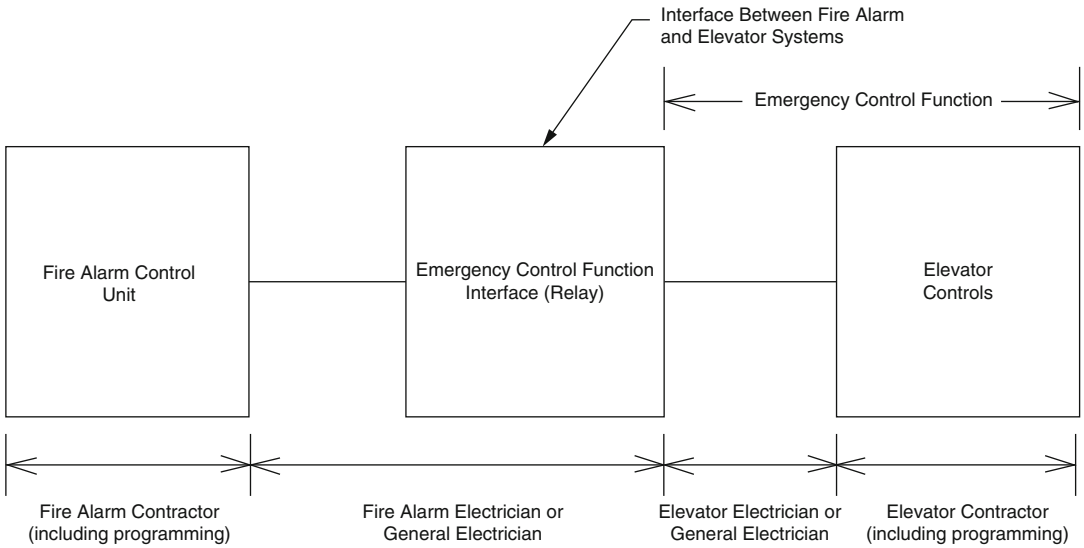

Fig. 49.13 Sample contractor responsibility diagrams

and integration locations, to be easily identified and located for identification and coordination in the future across various disciplines. This also allows reminders or notes to be added for future reference by either the person involved in that particular system, by other designers or engineers, or by other trades.

One example of the division of installation responsibilities for a combination fire/smoke damper serving a non-dedicated smoke control system controlled by a UUKL listed BMS system could be:

1. HVAC Contractor to install ductwork, and combination fire/smoke damper with integral open and closed position end switches.
2. Fire Alarm Electrical Contractor to install system duct smoke detector associated with the smoke damper, output control module to interface with the BMS system and input monitor module for monitoring of combination fire/smoke damper power.
3. BMS Contractor to install control module for the combination fire/smoke damper for initiation of the combination fire/smoke damper, monitor of the closed position switch of the smoke damper, and a monitor module interface between the fire alarm system and the BMS system.
4. Electrical Contractor to install 120 V emergency power to the combination fire/smoke damper and actuator.
5. General contractor to install shaft enclosure and access panel for combination fire/smoke damper.

Routine progress inspection of systems during the installation is required for proper oversight and coordination. Scheduled progress inspection by the Engineer of Record, *CxA*, *FCxA*, and *ITa* is critical in the commissioning and installation process. Of particular importance are specific reviews by Engineer of Record, *CxA*, *FCxA*, *ITa*, and AHJ for proper rough inspections and approvals prior to concealment of parts or all of the fire protection and life safety systems. Interim steps, such as smoke control system duct pressure tests, are critical to be performed during rough inspections, since the ducts are tested in segments as the ducts are constructed.

The Engineer of Record of the fire protection and life safety systems, fire protection engineer, and the *FCxA* review the contractor (or subcontractor) installation of these systems for conformance with the approved documents. The individual fire protection systems *pre-functional test* should be completed by the installing subcontractor, including items such as air balancing for smoke control systems. After a successful contractor *pre-functional test*, the Engineer of Record and the *FCxA* then witness the individual fire protection system *pre-functional test*. Once all the individual fire *interconnected systems* have been successfully tested, an Integrated Test, in accordance with the *Integrated Test Plan*, is conducted by the contractor and various sub-contractors, and witnessed by the Engineer of Record, the *FCxA*, and *ITa*. A final acceptance test by the AHJ would be required for final sign off. In some cases the AHJ testing may be completed at the same time as the Integrated Test. This should be discussed and agreed with the AHJ before the AHJ test.

Below are examples of integrated tests that, ideally, should be completed. Often these are not completed for various reasons:

1. Testing of emergency power on a maximum load, such as interrupting normal building power while the fire pump and smoke control system are operating.
2. *Integrated testing* of fire protection and life safety system without bypassing any of the systems (e.g. complete test without bypassing elevator recall, audio and visual notification devices, fan shutdown, or any other required sequence).
3. *End to End Test* rather than simulated events (e.g. actual sprinkler water flow rather than shorting the fire alarm sprinkler water flow monitor module).

Atrium Smoke Control Example One example, of an integrated fire protection and life safety system is an atrium smoke control system in which CFD analysis was employed to verify the design parameters of the smoke exhaust. The associated fire alarm system, sprinkler system, door operations and HVAC smoke control

equipment all need to be coordinated and integrated to meet the smoke management goals and objectives for the atrium. Improperly coordinated and integrated systems are likely to result in the spread of smoke and fire throughout the building rather than the exhaust of smoke from the space. Although the CFD computer model may have been employed with a specific design fire, it is usually not practical to simulate this design fire in the atrium during testing. However, all other conditions should be simulated during the test. A certified air balancing contractor is a critical member of the team, with responsibility for testing the performance of the smoke control system by taking various measurements, which may include airflow, velocity, and pressure differentials to demonstrate that the installed smoke control system performs as intended and meets the established design parameters.

The testing of a smoke control system is completed in four (4) primary steps.

1. Component verification
2. Component testing
3. Commissioning of and measurements of individual systems
4. *Integrated testing* of the smoke control system

Component verification is an inspection of the installed components to verify they are present and installed per the design documents, listing, and manufacture's instruction. Component testing requires testing of the components of individual systems (e.g. fire alarm, sprinklers, HVAC, dampers, and doors) to verify proper sequencing and function (e.g. smoke damper position). Commissioning tests of the individual fire alarm, sprinkler, and HVAC systems include verification of the sequence of operation, and air balance measurements of exhaust and/or supply capacities. After component verification and component testing is complete, *integrated testing* is performed to verify the proper sequence of components in accordance with the established test scenarios identified in the *Integrated Test Plan*. The *Integrated Test Plan* for a smoke control system typically incorporates test scenarios for: (1) activation an atrium sprinkler water flow (actual water flowing though inspection test connection), which is supervised by the fire alarm system, and (2) activation of an atrium smoke detector. Sequences should include initiating the atrium smoke control system in normal power and standby power. Other items that would be part of the *Integrated Test Plan* test scenarios would be to verify that the smoke control sequence does not activate from non-atrium initiation devices. For instance, tests should verify that non-atrium sprinkler water flow does not initiate the atrium smoke control system as designed.

Documentation Documentation of successful commissioning and *integrated testing* of fire protection and life safety systems should be developed and distributed, upon successful completion, and retained by the building owners.

Documentation of the individual systems and integration of the systems (e.g. shop drawings, as-built drawings, final sequence of operations, identification of location and type of interface points between systems, commissioning records, control drawings, *integrated testing* records, *integrated test plan*, and periodic testing plan) should be gathered and secured by the owner. These documents are essential for the required on-going periodic inspection and testing required by the various building, fire, and codes for the life of the building. Documentation of AHJ approval may include the signed permits, the issuance of the temporary Certificate of Occupancy, or the final Certificate of Occupancy.

Life of the Building

Once all testing is complete, approvals are complete, and occupants occupy the building, the required maintenance and testing cycles of the various fire protection and life safety systems should continue for the life of the building. Similarly, performance-based design elements, narrative basis of designs, *Integrated Test Plans*/Reports, and all critical documentation of fire protection and life safety systems need to be retained, referenced, and maintained for the building. Tenant improvement projects,

additions, alterations, system upgrades, and system replacements should be reviewed for conformance with the original fire protection and life safety documents. These critical documents may also require updates, modifications, and approvals to address changes, additions, alterations, system upgrades, new systems added, or systems being replaced over the life of the building. Periodic inspection, maintenance, and testing of all fire protection and life safety systems are required to be performed over the life of these systems. *Periodic Integrated Test* should also occur over the life of these systems per the *Integrated Test Plan*. *Re-commissioning* (*Re-Cx*) over the life of the systems may also be required due to either changes in the building or on an identified periodic basis.

Glossary[1]

Acceptance Testing Test performed with the local authorities and possibly the engineer of record or owner to show the fire protection or life safety system performs appropriately for final acceptance or approval.

Basis of Design (BOD) A report that documents the criteria of the fire protection and life safety design, which indicate the concepts and approach selected for a project, which should meet the Owner's requirements and applicable codes.

Commissioning (Cx) A formal process during the design and construction phase of a project that provides independent review and documentation that an individual system functions according to the design outlined in the project documentation, meeting the projects goals and objectives and applicable codes.

Commissioning Authority (CxA) The company or firm that is responsible and oversees the entire commissioning process for a building.

Commissioning Plan A project document that outlines the process, tasks, and procedures for implementation of *commissioning*.

Data Sharing Connection One of the methods of sharing information between interconnected fire protection systems via data streams.

End to End Test A test that replicates a real world situation that does not use simulations, such as shorting out a sprinkler water flow switch. For example, consider sprinkler system electrical supervision, the water flow indicating switch can be shorted to simulate water flow. Flowing water through the sprinkler system's inspectors test connection to verify fire alarm supervision represents an end to end test. Another example is visual verification of elevators recalling when an elevator lobby smoke detector is activated.

Emergency Control Function Interface Device The electronic interface, typically *emergency control function interface devices* (relays), between two or more fire protection and life safety systems that is a coordinated signal output to perform a particular control function (e.g. fire alarm system relay for elevator recall).

Evacuation Signaling Zone An area consisting of one or more *notification zone*s where evacuation signals are actuated throughout.

Fire and Life Safety Commissioning A formal process during the design and construction phase of a project that provides independent review and documentation that individual fire protection systems function according to the design outlined in the project documentation, meeting the *Owner's Project Requirements* and applicable codes.

Fire Commissioning Agent (FCxA) An independent company or person, acting as an owner representative, who implements and leads the *commissioning* of fire protection and *life safety systems*. Globally different terms may be

[1] The authors have defined the following terms to provide a common reference throughout the chapter. Readers should verify these definitions in the code, standards, and regulations in use for a specific project, as definitions may differ from those defined within this chapter.

utilized, for example, in France this person is referred to as the Coordonnateur SSI.

Interface Test A test that provides verification of the performance of the systems being interfaced/*interconnected* to meet the project goals and objectives. An *end to end test* or simulating event, through shorting out a *emergency control function interface devices* (relay) to simulate the input, is required.

Integrated System Two or more fire protection and life safety systems that are designed and coordinated to operate together in order to meet the *BOD*, *Owner's Project Requirements*, and applicable code requirements. A prison guard can be part of an integrated system, in which the guard relies on information from the fire alarm system or the emergency communication system in order to determine if he or she will manually release the door locking controls.

Integrated Testing Testing of integrated fire protection and life safety systems to verify the proper operation and sequence of the *integrated systems* (multiple systems) to meet the *BOD*, project goals and objectives, and applicable codes.

Integrated Testing Agent (ITa) An independent company or person selected by the owner who develops, implements, and documents the Integrated Test of the integrated fire protection and life safety systems.

Integrated Test Plan A plan on how and what tests will be performed on to confirm the proper integration of two or more fire protection system or life safety systems.

Interconnected Systems Two or more fire protection and life safety systems that have physical or electronic connections between the systems to meet the *BOD*, project goals and objectives, and applicable codes.

Interconnection The connections between two or more interconnected fire protection and life safety systems. The term interfacing is sometimes also used to describe interconnections.

Life Safety Systems A system that enhances life safety, such as evacuation, tenability (like a smoke control system) or compartmentation.

Notification Zone An area of a building that occupants would receive a common notification signal throughout an area.

Owner's Project Requirements (OPR) Owner and user developed project requirements and performance criteria developed that describe project goals and criteria for system function, performance and maintainability.

Periodic Integrated Test A test to re-verify the proper integration between multiple systems that occurs on an identified recurring period basis.

Pre-functional Testing System tests performed prior to *acceptance testing* to verify the fire protection or life safety system performs per the *BOD*, *OPR*, and applicable codes.

Re-commissioning (Re-Cx) *Commissioning* of existing fire protection and *life safety systems* that have been previously commissioned.

Retro-commissioning (RCx) *Commissioning* of existing fire protection and *life safety systems* that have never been commissioned.

Smoke Control

50

John H. Klote

Introduction

In building fires, smoke often flows to locations remote from the fire, threatening life and damaging property. Research has shown that smoke is the major killer in building fires (Harland and Woolley 1979; [37]).

NFPA 92 [29] defines a smoke control system as an engineered system that includes all methods that can be used singly or in combination to modify smoke movement. These methods are the physical mechanisms of smoke control which are discussed later in this chapter. Research in the field of smoke control has been conducted in Australia, Canada, England, France, Japan, the United States, and Germany. This research has consisted of field tests, full-scale fire tests, scale model fire tests, and computer simulations. Many buildings have been built with smoke control systems and numerous others have been retrofitted for smoke control.

The conventional approach to smoke control consists of using the physical mechanisms to prevent people from coming into contact with smoke to the extent possible. A newer approach consists of evaluating the effect of some smoke contact with the intent of providing a tenable environment for occupants. Smoke control systems based on this newer approach are referred to as *tenability systems*. This chapter focuses on the conventional approach, but tenability systems are discussed near the end of the chapter. For an exhaustive treatment of smoke control including weather design data, design fires, conventional systems, tenability systems, and method of analysis see the *Handbook of Smoke Control Engineering* [21].

In this chapter the term *smoke* is used in accordance with the NFPA 92 definition that states that smoke consists of the airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis of combustion, together with the quantity of air that is entrained or otherwise mixed into the mass. It is important for smoke control purposes that the definition of smoke includes the air that is mixed with the particulates and other gases because smoke control often involves exhausting smoke which is mostly air. Including air as a part of smoke is also important for tenability systems.

Physical Mechanisms of Smoke Control

The physical mechanisms of smoke control are (1) compartmentation, (2) dilution, (3) pressurization, (4) airflow, and (5) buoyancy. For centuries, compartmentation has been recognized as a way of controlling the spread of fire and smoke. When a person closes the door to a burning room, smoke flow from the room decreases considerably. Also, the amount of air available to the fire drops off. Today this passive

J.H. Klote (✉)
consultant specializing in fire in smoke control, Leesburg, VA

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_50, © Society of Fire Protection Engineers 2016

smoke protection is recognized in many building and fire codes even without a design analysis. Engineered smoke control systems that use only passive smoke barriers are a form of tenability systems that are discussed later in this chapter.

Dilution can occur naturally as when smoke flows away from a fire and mixes with air as it flows or be forced by fan powered flows. Naturally occurring dilution can be analyzed by the methods discussed in the section on tenability systems.

Fan powered dilution can be used to remove smoke from the fire space after a fire has been extinguished, and it can be used to remove smoke from a space connected to the fire space after the connection has been has been closed. Fan powered dilution consists of supplying air to the fire space and either exhausting air (or smoke) from the space or providing a path for a path for air (or smoke) to flow from the space. This kind of fan powered dilution can be analyzed by the methods discussed in the section on tenability systems.

The use of dilution to produce or maintain tenable conditions in the fire space is not recommended because such a system is beyond the current state of the technology. The air supplied to the fire space can increase the burning rate of the fire resulting in increased smoke production. The increased smoke production in the fire space has the potential to result in untenable conditions in the fire space. Because of this failure mode the use of dilution in the fire space is generally not recommended.

Many smoke control systems use mechanical fans to control smoke by pressurization. Pressure difference across a barrier can control smoke movement. The idea is that a pressure difference is produced across a barrier such that the smoke on the low pressure side of the barrier is prevented from migrating to the high pressure side, and this is shown in Fig. 50.1a for a relatively small amount of smoke. However, pressurization can control smoke from a

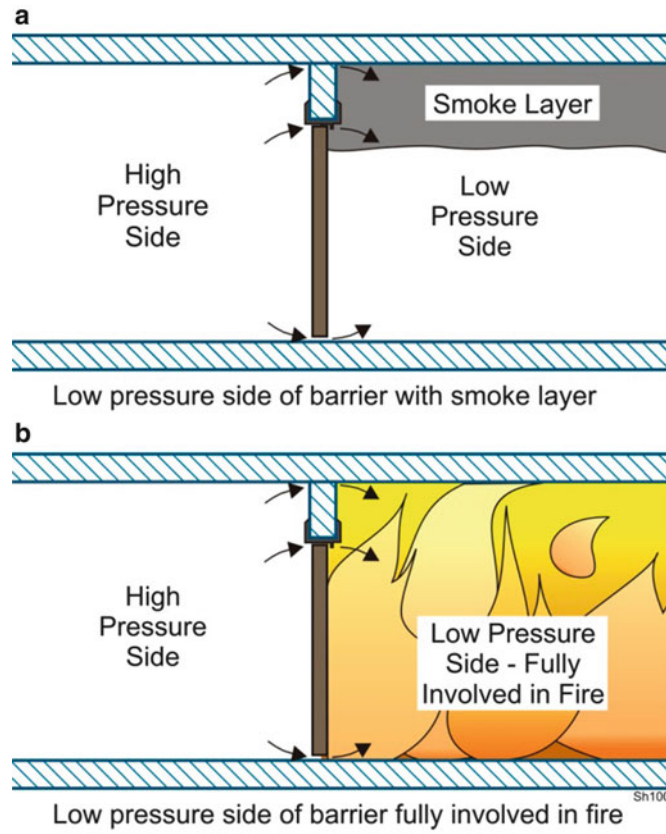

Fig. 50.1 Pressure difference across a barrier can control smoke flow

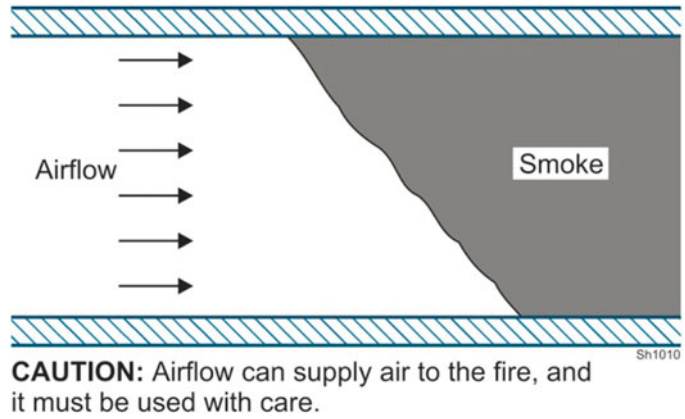

Fig. 50.2 Airflow can control the flow of smoke

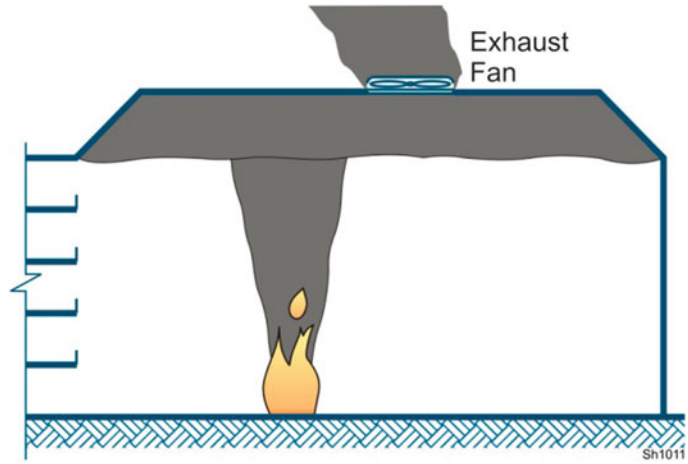

Fig. 50.3 Buoyancy can be used for smoke control as in an atrium smoke exhaust system

large fully developed fire as shown in Fig. 50.1b. In a room with a fully developed fire, everything that can burn is burning. Pressurization smoke control systems are discussed later in this chapter.

Airflow has been used extensively to control smoke flow during fires in subway, railroad and highway tunnels (Fig. 50.2). Airflow can also be used to control smoke between atria and spaces connected to atria. A number of empirical equations have been developed to calculate the air velocity needed for specific applications. Because the large amounts of air are needed for this method can supply additional oxygen to the fire, the use of airflow to control smoke needs to be done with caution.

Atria smoke exhaust systems rely on the buoyancy for a smoke plume to form above the fire and move the smoke away from occupants (Fig. 50.3). This form of smoke control is called atrium smoke management, and it is the subject of Chap. 51.

Pressurization Smoke Control Systems

Commonly used pressurization smoke control systems are (1) stairwell pressurization, (2) elevator pressurization, and (3) zoned smoke control. The concept of stairwell pressurization is to supply air to the stairwell with the intent of maintaining tenable conditions in stairwell. The idea of elevator pressurization is to supply air to the elevator shaft with the intent of preventing smoke flow through elevator shaft to locations

Table 50.1 Activation signals for pressurization smoke control systems

System	Smoke Detector	Heat Detector	Sprinkler Water Flow	Manual Pull Station
Stairwell pressurization	Yes	Yes	Yes	Yes[a]
Elevator pressurization	Yes	Yes	Yes	Yes[a]
Zoned smoke control	Yes	Yes	Yes	No

[a]Manual pull stations are not recommended for activation of stairwell or elevator pressurization systems that rely of fire floor exhaust

remote from the fire floor. The idea of zoned smoke control is to rely on pressurization or passive smoke control with the intent of preventing or minimizing smoke movement beyond the zone where the fire is located.

The primary purpose of pressurization smoke control systems is to maintain a tenable environment in the means of egress. Other purposes of these systems are to control smoke movement between fire area and adjacent spaces, provide conditions to help fire service, reduce property damage, and aid in post-fire smoke removal.

Table 50.1 lists sources of signals that can be used to activate pressurization smoke control systems. Zoned smoke control should not be activated from manual fire alarm pull stations. For proper operation of zoned smoke control needs, the location of the fire needs to be identified. A person who has seen a fire may start to leave the building and some distance away from the fire zone realize that he or she should pull the manual pull station. If zoned smoke control were activated by this manual pull station, the wrong zone would be identified as where the fire was located. Some stairwell pressurization systems and elevator pressurization systems rely on fire floor exhaust, and activation of these systems by manual pull stations can result in the wrong floor being exhausted. For this reason, manual pull stations are not recommended for activation of stairwell or elevator pressurization systems that rely of fire floor exhaust.

Network Modeling

Network models are a class of software that can simulate the flow of air or water through a complex system of paths which is called the network. Network modeling for smoke control application dates back to the 1960s, but these early models were subject to numerical difficulties and data input was extremely cumbersome and time consuming.

Network computer models such as CONTAM [36] have become widely used for analysis of pressurization smoke control systems due to their robust numerical routines and sophisticated data input. While CONTAM was developed for indoor air quality applications, care was taken to assure that it could be used for smoke control applications. Because CONTAM is a product of the US National Institute of Standards and Technology (NIST), it can be downloaded from the NIST website at no cost. In this chapter, when CONTAM is discussed, it should be noted that it may be possible that other network models could be used.

These models represent a building by a network of spaces or nodes, each at a specific pressure and temperature. The stairwells and other shafts can be modeled by a vertical series of spaces, one for each floor. Air flows through leakage paths from regions of high pressure to regions of low pressure. These leakage paths are doors and windows that may be opened or closed. Leakage can also occur through partitions, floors, and exterior walls and roofs. The airflow through a leakage path is a function of the pressure difference across the leakage path.

In network models, air from outside the building can be introduced by a pressurization system into any level of a shaft or into other building spaces. This allows simulation of stairwell pressurization, elevator shaft pressurization, stairwell vestibule pressurization, and pressurization of any other building space. In addition, any building space can be exhausted. This allows analysis of zoned smoke control systems where the fire zone is exhausted and other zones are

pressurized. The pressures and flows throughout the building are obtained by solving the conservation equations for the network. This analysis can include the driving forces of wind, the pressurization system, and inside-to-outside temperature difference.

The primary purpose of network simulations is to determine if a particular smoke control system in a particular building is capable of being balanced such that it will perform as intended. Network models are capable of simulating the pressures and flows throughout very large and complex building networks with high accuracy.

There are many flow paths in buildings including gaps around closed doors, open doors, construction cracks in walls and floors. These flow paths can be approximated for a design analysis, and the results of a network model simulation are approximations. However, these approximate results can be useful in identifying problems with specific smoke control systems. If such problems are identified, the smoke control system can be modified appropriately. A secondary purpose of these simulations is to provide information to help size the system components such as supply fans, exhaust fans, and vents.

Smoke Movement

A smoke control system must be designed so that it is not overpowered by the driving forces that cause smoke movement. For this reason, an understanding of the fundamental concepts of smoke movement is a prerequisite to intelligent smoke control design. The driving forces of air and smoke movement in building are (1) stack effect, (2) buoyancy of combustion gases, (3) expansion of combustion gases, (4) wind, (5) forced ventilation, and (6) elevator piston effect. Forced ventilation consisting of supply air is used for pressurization smoke control. Also, forced ventilation is used in heating, ventilating and air-conditioning (HVAC) systems. Generally, in a fire, smoke movement will be caused by a combination of these driving forces. The following sections discuss of each driving force as it would act in the absence of any other driving force.

Stack Effect

When it is cold outside, there is often an upward movement of air within building shafts such as stairwells, elevator shafts, dumbwaiter shafts, mechanical shafts, or mail chutes. This phenomenon is referred to as a *normal stack effect* as shown in Fig. 50.4. The air in the building has a buoyant force because it is warmer and less dense than the outside air. This buoyant force causes air to rise within the shafts of buildings, and the pressure difference due to normal stack effect is shown in Fig. 50.5. The significance of normal stack effect is greater for low outside temperatures and for tall shafts.

When the outside air is warmer than the building air, downward airflow frequently happens in shafts. This downward airflow is called *reverse stack effect* (Fig. 50.5), and the pressure difference due to reverse stack effect is shown in Fig. 50.5b. At standard atmospheric pressure, the pressure difference due to either normal or reverse stack effect is

$$\Delta p_{SO} = 7.63\left(\frac{1}{T_O + 460} - \frac{1}{T_S + 460}\right)z$$

$$\Delta p_{SO} = 3460\left(\frac{1}{T_O + 273} - \frac{1}{T_S + 273}\right)z \quad \text{for SI} \tag{50.1}$$

where

Δp_{SO} = pressure difference from a shaft to the outside, in. H_2O (Pa),
T_O = temperature outside, °F (°C),
T_S = temperature in the shaft, °F (°C),
z = distance above the neutral plane, ft (m).

The neutral plane is a horizontal plane where the pressure in the shaft is the same as that outdoors. For a shaft 200 ft (60 m) tall, with a neutral plane at the midheight, an outside temperature of 0 °F (−18 °C) and an inside temperature of 70 °F (21 °C), the maximum pressure difference due to normal stack effect would be 0.22 in. H_2O (55 Pa). This means that at the top

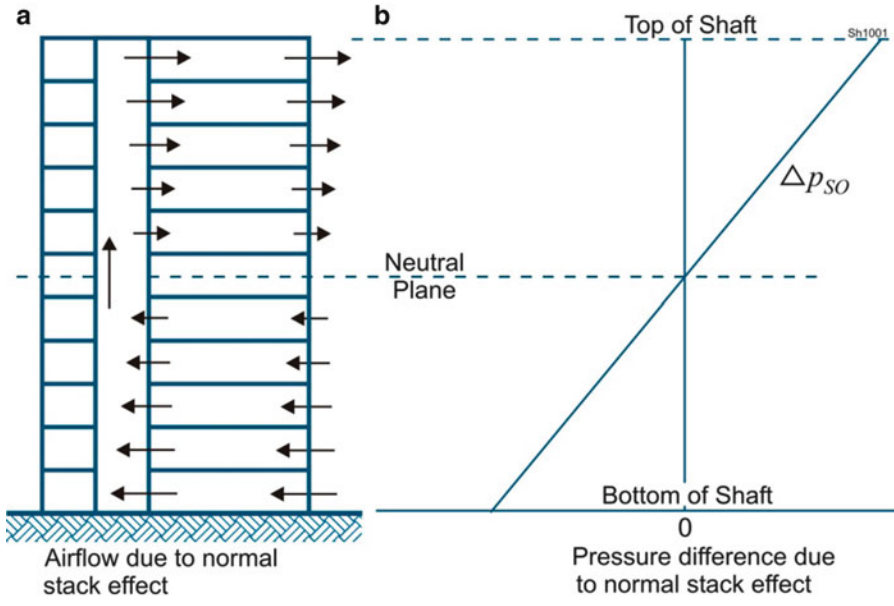

Fig. 50.4 Airflow and pressure differences of normal stack effect

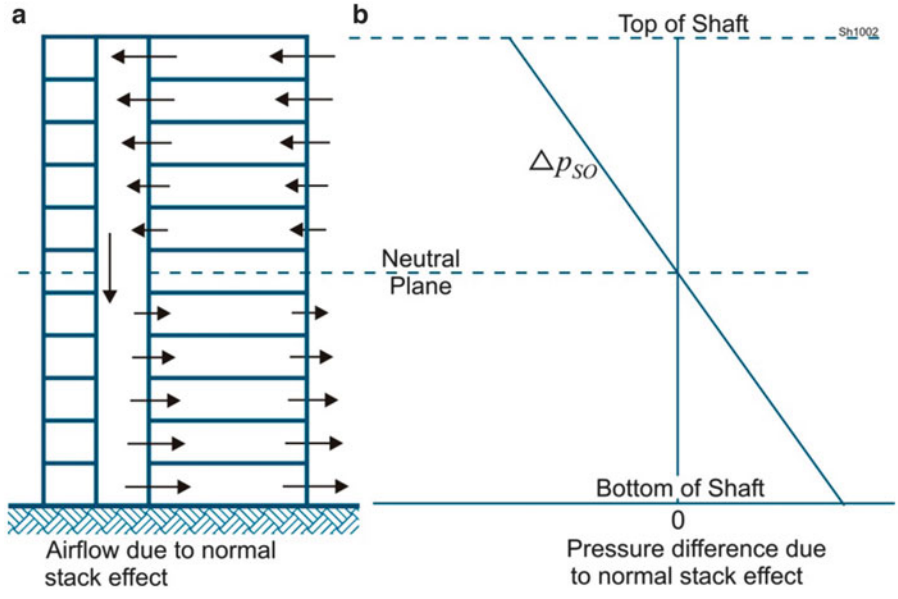

Fig. 50.5 Airflow and pressure differences of reverse stack effect

of the shaft, the shaft would have a pressure of about 0.22 in. H_2O (55 Pa) greater than that outside. At the bottom of the shaft, the shaft would have a pressure of about 0.22 in. H_2O (55 Pa) less than the outside pressure.

Stack effect can have a significant impact on smoke flow during building fires. When it is cold outdoors, the upward airflow in shafts can be enhanced by the buoyancy of the smoke. Figure 50.6 shows smoke flows in a building

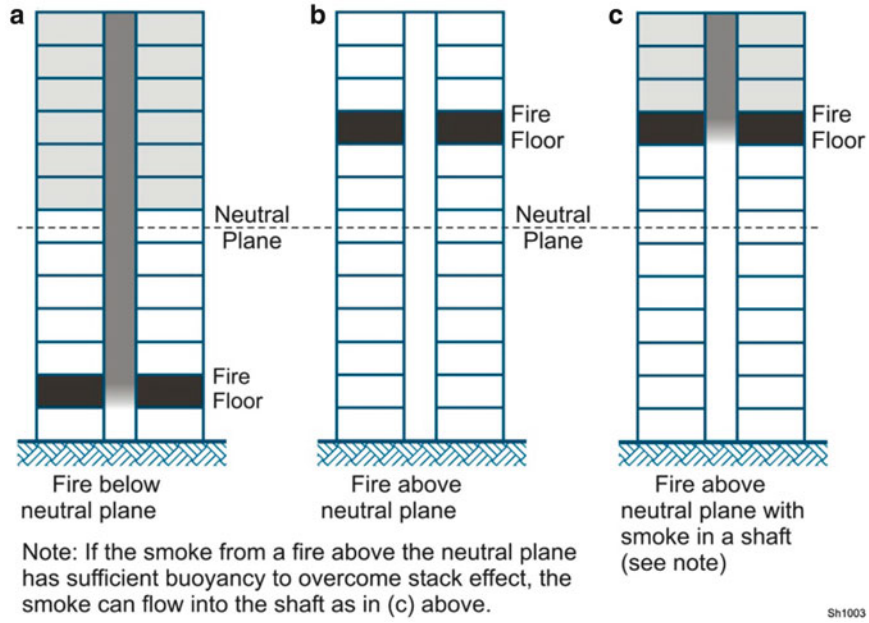

Fig. 50.6 Smoke movement in a high rise building due to normal stack effect

subjected to normal stack effect. For a fire below the neutral plane, smoke tends to enter and flow up shafts, and above the neutral plane this smoke flows from the shaft to building spaces (Fig. 50.6a). Smoke from a fire above the neutral plane can flow through cracks and gaps in the floor to the floor above the fire, but the forces of stack effect work to prevent smoke from entering shafts as shown in Fig. 50.6b. If the smoke from a fire above the neutral plane has sufficient buoyancy to overcome stack effect and flow into a shaft, it will flow up the shaft and infiltrate floors above the fire floor as can be seen in Fig. 50.6c.

For a building with shafts of various heights and different shaft temperatures, the flows can become very complicated. These flows would not look like those of either Fig. 50.4 or Fig. 50.5. Each shaft could have its own neutral plane with respect to the outside, and sometimes a shaft may have more than one neutral plane. Equation (50.1) is not applicable for such complicated buildings, but the flows and pressures in such buildings can be analyzed by CONTAM.

Myth: It is a myth that the pressure difference due to stack effect is nearly proportional to the temperature difference between the building and the outside

Fact: This pressure difference is nearly proportional to the temperature difference between a *shaft* and the outside

Another Meaning of Stack Effect

The term stack effect is often used in a different way from that discussed above. Sometimes engineers will say that a pressurized stairwell (or elevator) needs to be designed to account for the impact of stack effect. If the stairwell (or elevator) is properly pressurized, there is no neutral plane, and the flows do not look like those in Figs. 50.4 or 50.5. Strictly speaking there is no stack effect in the pressurized stairwell (or elevator). What is meant when an engineer says "that a pressurized stairwell (or elevator shaft) needs to be designed to account for the impact of stack effect" is that it needs to be

designed to account for the temperature differences that cause stack effect.

Myth: It is a myth that stack effect is the major factor impacting stairwell and elevator pressurization

Fact: Today the impact of stack effect is a minor factor for most pressurized stairwells and elevators. The pressurization air for many stairwells and elevators is untreated outside air that is not heated or cooled. The temperature of these shafts is often nearly the same as the outside temperature, and the impact of stack effect is significantly reduced as compared to shafts pressurized with air treated to the building temperature

Buoyancy of Combustion Gases

High-temperature smoke from a fire has a buoyancy force due to its reduced density. The pressure difference between a fire compartment and its surroundings can be expressed by an equation of the same form as Equation (50.1) with the variables updated as shown in Equation (50.2).

$$\Delta p_{FS} = 7.63\left(\frac{1}{T_O + 460} - \frac{1}{T_F + 460}\right)z$$

$$\Delta p_{FS} = 3460\left(\frac{1}{T_O + 273} - \frac{1}{T_F + 273}\right)z \quad \text{for SI} \tag{50.2}$$

where

Δp_{FS} = pressure difference from a fire space to the surroundings, in. H_2O (Pa),

T_O = temperature surroundings, °F (°C),

T_F = temperature in the fire space, °F (°C),

z = distance above the neutral plane, ft (m).

For a fire, the neutral plane is the horizontal plane of where the pressure in the fire space is the same as that of the surroundings. For a fire with a fire compartment temperature of 1470 °F (800 °C) and surroundings at 68 °F (20 °C), the pressure difference 5 ft (1.52 m) above the neutral plane can be calculated from Equation (50.2) to be 0.052 in. H2O (13 Pa). Fang [7] has studied pressures caused by room fires during a series of full-scale fire tests. During these tests, the maximum pressure difference reached was 0.064 in. H2O (16 Pa) across the burn room wall at the ceiling.

Expansion of Combustion Gases

In addition to buoyancy, the energy released by a fire can cause smoke movement due to expansion. In a fire compartment with only one opening to the building, building air flows into the fire compartment and hot smoke flows out of the fire compartment. Neglecting the added mass of the fuel (which is small compared to the airflow), the ratio of volumetric flows can simply be expressed as

$$\frac{V_{out}}{V_{in}} = \frac{T_{out} + 460}{T_{in} + 460}$$

$$\frac{V_{out}}{V_{in}} = \frac{T_{out} + 273}{T_{in} + 273} \quad \text{for SI} \tag{50.3}$$

where

V_{out} = volumetric flow of smoke out of the fire compartment, cfm (m^3/s),

V_{in} = volumetric flow of air into the fire compartment, cfm (m^3/s),

T_{out} = temperature of smoke leaving the fire compartment, °F (°C),

T_{in} = temperature of air entering the fire compartment, °F (°C).

For fire gas temperature of 2200 °F (1260 °C), the gas will expand to about five times its original volume. For a fire room with open doors or windows, the pressure difference across these openings due to expansion is negligible because of the large flow areas involved. However, for a fire space without open doors or windows, the pressure differences due to expansion may be important, provided there is sufficient oxygen to support combustion for a significant time.

Wind

In many instances, wind can have a pronounced impact on smoke movement within a building. The pressure that wind exerts on a wall is

$$p_w = 0.00645\, C_w \rho_o U_H^2$$
$$p_w = \frac{1}{2} C_w \rho_o U_H^2 \quad \text{for SI} \tag{50.4}$$

where
p_w = wind pressure, in H_2O (Pa),
C_w = pressure coefficient, dimensionless,
ρ_o = outside air density, lb/ft^3 (kg/m^3),
U_H = velocity at wall height H, mph (m/s).

The pressure coefficients, C_w, depends on wind direction, building geometry and local obstructions to the wind. The pressure coefficients are in range of −0.8 to 0.8, with positive values for windward walls and negative values for leeward walls.

Wind is often measured at airports, and the standard height for measuring velocity and direction is 33 ft (10 m). The Chap. 2 of the *Handbook of Smoke Control Engineering* lists design wind speeds for many locations in the US, Canada, and other countries. The local design wind can be calculated as follows

$$U_H = U_{met}\left(\frac{\delta_{met}}{H_{met}}\right)^{a_{met}}\left(\frac{H}{\delta}\right)^{a} \tag{50.5}$$

where
U_H = wind velocity at wall w/height H, mph (m/s),
U_{met} = measured velocity, mph (m/s),
H_{met} = height of wind measurement, ft (m),
δ_{met} = boundary layer height in the vicinity of the wind anemometer, ft (m),
a_{met} = wind exponent in the vicinity of the wind anemometer, dimensionless,
H = height of wall, ft (m),
δ = boundary layer height at wall, ft (m),
a = wind exponent at wall.

A number of approaches have been developed for categorizing terrain boundary layer and the wind exponent. For additional information about wind see Chap. 3 of the *Handbook of Smoke Control Engineering*, Shaw and Tamura [33], Kandola [12–14], Aynsley [3], and Klote [16]. Some civil engineering texts have useful information about wind [6, 24, 25, 35].

Forced Ventilation

The current code requirements for heating, ventilating and air conditioning (HVAC) systems started with a 1939 report by the National Board of Fire Underwriters [28]. The NBFU examined NFPA fire data from January 1936 to April 1938. Of 25 fires recorded, 19 involved combustion of parts of the air moving system. In five cases of no fire in the HVAC system, smoke was distributed by the system. Modern HVAC systems are built of materials intended to withstand fires. Also modern HVAC systems either shut down in the event of a fire or go into a smoke control mode of operation. This mode of operation is called zoned smoke control, and it is discussed later.

Elevator Piston Effect

The transient pressures and flows produced when an elevator car moves in a shaft are called *piston effect*. Figure 50.7 shows the airflows resulting from an upward-moving elevator car. Such piston effect can pull smoke into a normally pressurized elevator lobby or elevator shaft. In a

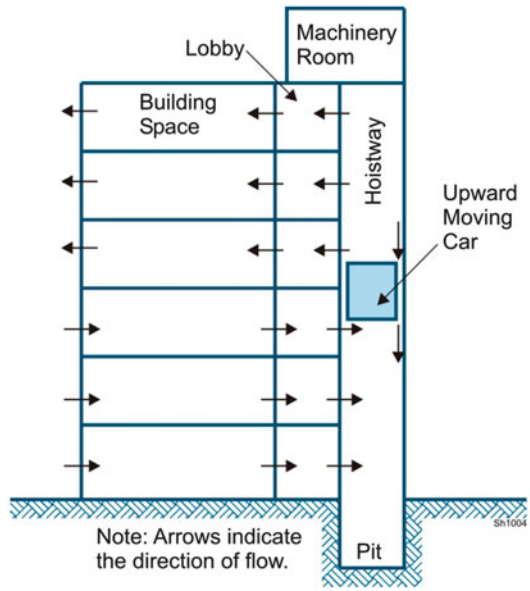

Fig. 50.7 Airflow due to an upward moving elevator car

joint US and Canadian project, an analysis of piston effect was developed and validated [15, 20, 23].

The upper limit of piston effect for an elevator with enclosed lobbies is

$$\Delta p_{u,ir} = \frac{1.66 \times 10^{-6}\rho}{2}\left(\frac{A_s A_e U}{A_a A_{ir} C_c}\right)^2 \qquad (50.6)$$

$$\Delta p_{u,ir} = \frac{\rho}{2}\left(\frac{A_s A_e U}{A_a A_{ir} C_c}\right)^2 \quad \text{for SI}$$

where

$\Delta p_{u,si}$ = upper limit pressure difference from the shaft to the building, in H_2O (Pa),
ρ = air density in hoistway, lb/ft^3 (kg/m^3),
A_s = cross-sectional area of shaft, ft^2 (m^2),
A_{ir} = leakage area between building and lobby, ft^2 (m^2),
A_a = free area around the elevator car, ft^2 (m^2),
A_e = effective area, ft^2 (m^2),
U = elevator car velocity, fpm (m/s),
C_c = flow coefficient for flow around car, dimensionless.

The flow coefficient, C_c, was determined experimentally at about 0.94 for a multiple car hoistway and 0.83 for a single car hoistway. The free area around the elevator car is the cross-sectional area of the shaft less the cross-sectional area of the car. For an elevator with enclosed lobbies, the effective area is

$$A_e = \left(\frac{1}{A_{sr}^2} + \frac{1}{A_{ir}^2} + \frac{1}{A_{io}^2}\right)^{-1/2} \qquad (50.7)$$

where

A_{sr} = leakage area between shaft and lobby, ft^2 (m^2),
A_{io} = leakage area between the building and the outside, ft^2 (m^2).

Figure 50.8 shows the upper limit of piston effect from the lobby to the building for car velocities from 100 to 1000 fpm (1 to 5 m/s). All elevator velocities are in this range with the exception of those of extremely tall buildings. The pressure differences shown in Fig. 50.8 happen for a brief time as the elevator car passes a floor.

Effective Flow Areas

Effective flow areas were essential in the early days of smoke control design to simplify flow networks. With computer network models such as CONTAM, there is much less need for network simplification. However, the effective flow area concept is still used for the following: (1) with the equation approach for analysis of pressurized stairwells, (2) with analysis of elevator piston effect, (3) to reduce data input to

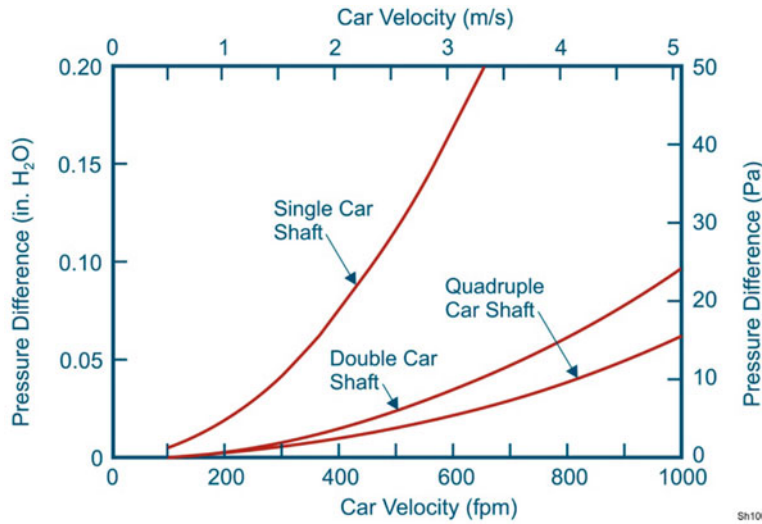

Fig. 50.8 Calculated upper limit of piston effect across elevator lobby doors

network models, and (4) to solve some problems without calculations.

The various paths of air movement in the system can be parallel with one another (Fig. 50.9a), in series with one another (Fig. 50.9b), or a combination of parallel and series paths (Fig. 50.9c). The effective flow area of a given system of flow paths is the area of a single opening that results in the same flow as the given system when subjected to the same pressure difference over the total system of flow paths. This concept is similar to an effective resistance of a system of electrical resistances.

For the three parallel flow paths in Fig. 50.9a, the effective area is

$$A_e = A_1 + A + A_3 \tag{50.8}$$

and for any number of flow paths in parallel the effective area is

$$A_e = \sum_{i=1}^{n} A_i \tag{50.8a}$$

For the three series flow paths in Fig. 50.9b, the effective area is

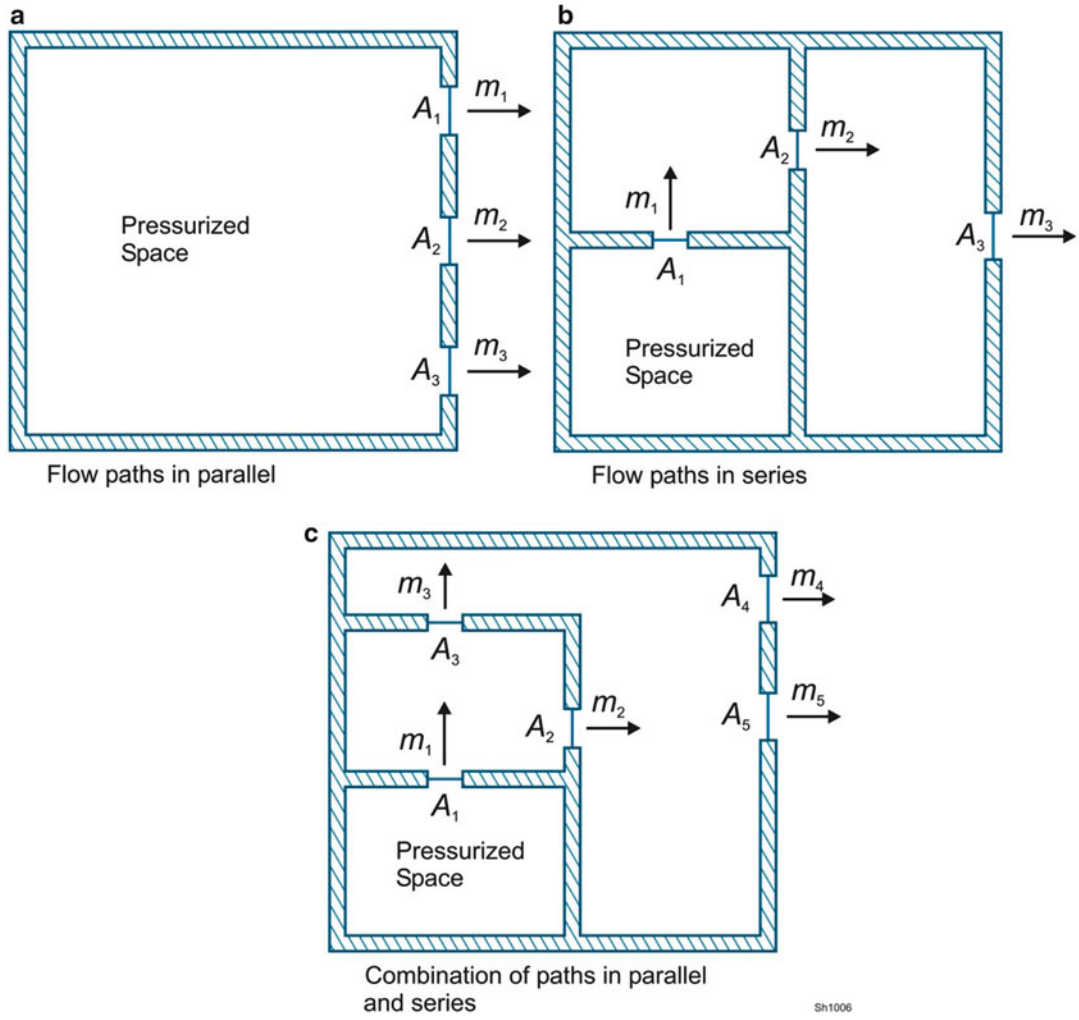

Fig. 50.9 Flow paths in parallel, in series, and a combination of both

$$A_e = \left(\frac{1}{A_1^2} + \frac{1}{A_2^2} + \frac{1}{A_3^2}\right)^{-1/2} \quad (50.9)$$

and for any number of paths in series the effective area is

$$A_e = \left(\sum_{i=1}^{n} \frac{1}{A_i^2}\right)^{-1/2} \quad (50.9a)$$

where
A_e = effective flow area, ft^2 (m^2),
A_i = flow area of path i, ft^2 (m^2).

The above equations for effective flow areas are based on having the same flow coefficients and temperatures for all the paths in the total system of flow paths. For a system with both parallel and series paths, and the method of developing an effective area for the system is to combine parallel paths first and then series paths. Example *1* illustrates calculation of effective flow areas.

Example 1. Effective Flow Areas

Part 1: In Fig. 50.9a, what is the effective flow area if A_1, A_2 and A_3 are 0.1 ft^2?

Because these areas are in parallel, $A_e = A_1 + A_2 + A_3 = 1 + 1 + 1 = 3$ ft^2

Part 2: In Fig. 50.9b, what is the effective flow area if A_1, is 0.1 ft^2 and A_2 and A_3 are both 1 ft^2?

Because these areas are in series, $A_e = \left(\frac{1}{A_1^2} + \frac{1}{A_2^2} + \frac{1}{A_3^2}\right)^{-1/2} = \left(\frac{1}{0.1^2} + \frac{1}{1^2} + \frac{1}{1^2}\right)^{-1/2} = (100 + 1 + 1)^{-1/2} = 0.099$ ft^2

This shows that for a system of flow areas in series with on area much smaller than the others, the effective flow area is slightly less than the smallest area.

Part 3: In Fig. 50.9c, what is the effective flow area if A_1, is 0.1 ft^2 and all the other flow areas are 1 ft^2?

$A_1 = 0.1$ ft^2 and $A_2 = A_3 = A_4 = A_5 = 1$ ft^2.

Because A_2 and A_3 are in parallel, the effective flow are of A_2 and A_3 is $A_{23e} = A_2 + A_3 = 1 + 1 = 2$ ft^2.

Because A_4 and A_5 are in parallel, the effective flow are of A_4 and A_5 is $A_{45e} = A_4 + A_5 = 1 + 1 = 2$ ft^2.

The effective flow area of the system of flow paths in Fig. 50.9c is $A_e = \left(\frac{1}{A_1^2} + \frac{1}{A_{23e}^2} + \frac{1}{A_{45e}^2}\right)^{-1/2} = \left(\frac{1}{0.1^2} + \frac{1}{2^2} + \frac{1}{2^2}\right)^{-1/2} = \left(100 + \frac{1}{4} + \frac{1}{4}\right)^{-1/2} = 0.0998$ ft^2

The reader can look at Fig. 50.9c and see that A_{23e} and A_{34e} are both much larger than A_1, so that for practical purposes, the effective flow area of the system is A_1.

Symmetry

As with effective areas, symmetry was essential in the early days of smoke control design to simplify flow networks, symmetry is also used with the equation approach for analysis of stairwell pressurization. Figure 50.10 illustrates the floor plan of a multistory building that can be

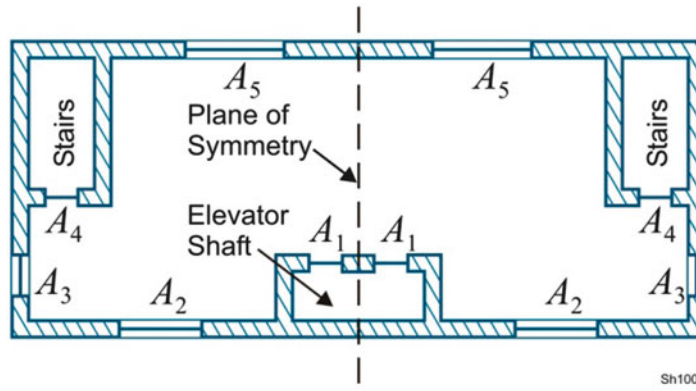

Fig. 50.10 Floor plan of building floor illustrating symmetry

divided in half by a plane of symmetry. Flow areas on one side of the plane of symmetry are equal to corresponding flow areas on the other side. For a building to be so treated, every floor of the building must be such that it can be divided in the same manner by the plane of symmetry. If wind effects are not considered in the analysis or if the wind direction is parallel to the plane of symmetry, then the airflow in only one-half of the building needs to be analyzed. It is not necessary that the building be geometrically symmetric, as shown in Fig. 50.10. A building that is not geometrically symmetric can be symmetric with respect to flow.

Flow and Pressure Difference

The primary equation used for analysis of pressurization smoke control systems is the orifice equation given in Equation (50.10).

$$\begin{aligned} m &= 12.9\, CA\sqrt{2\rho\Delta p} \\ m &= CA\sqrt{2\rho\Delta p} \quad \text{for SI} \end{aligned} \tag{50.10}$$

For mass flow at 70 °F (21 °C) and standard atmospheric pressure, the orifice equation becomes

$$\begin{aligned} m_{sv} &= 2610CA\sqrt{\Delta p} \\ m_{sv} &= 0.839CA\sqrt{\Delta p} \quad \text{for SI} \end{aligned} \tag{50.11}$$

where

m = mass flow through the path, lb/s (kg/s),
m_{sv} = mass flow through the path, scfm (standard m^3/s),
C = flow coefficient, dimensionless,
A = flow area (or leakage area), ft^2 (m^2),
Δp = pressure difference across path, in H_2O (Pa),
ρ = gas density in flow path, lb/ft^3 (kg/m^3).

One standard cubic foot per minute, scfm, equals 0.00125 lb per second, and one standard cubic meter per second (standard m^3/s) equals 1.2 kg per second at 70 °F (21 °C) and standard atmospheric pressure. Alternatively, the orifice equation can be expressed in terms of volumetric flow as shown in Equation (50.12).

$$\begin{aligned} V &= 776\, CA\sqrt{\frac{2\Delta p}{\rho}} \\ V &= CA\sqrt{\frac{2\Delta p}{\rho}} \quad \text{for SI} \end{aligned} \tag{50.12}$$

where V is volumetric flow through the path in cubic feet per minute, cfm (m^3/s).

Equations (50.10), (50.11) and (50.12) are equivalent forms of the same equation, and the label "orifice equation" applies to all of them. The orifice equation gets its name because it is used to calculate the flow through an orifice. For these flow equations, the area term is the cross-sectional area, and the flow coefficient is called the discharge coefficient. A network flow program such as CONTAM uses this flow meter terminology. Flow areas and flow coefficients for building components are discussed later, and Idelchik [10] also is a source of flow data.

Airflow paths must be identified and evaluated in the design of smoke control systems. Some leakage paths are obvious, such as cracks around closed doors, open doors, elevator doors, windows, and air transfer grilles. Construction cracks in building walls are less obvious but no less important.

The flow area of most large openings, such as open windows, can be calculated easily. However, flow areas of cracks are more difficult to evaluate. The area of these leakage paths depends on workmanship (such as how well a door is fitted or how well weatherstripping is installed). A door that is 36 in. by 7 ft (0.9 by 2.1 m) with an average crack width of $^1/_8$ in. (3.2 mm) has a leakage area of 0.21 ft^2 (0.020 m^2). However, if this door is installed with a ¾ in. (19 mm) undercut, the leakage area is 0.32 ft^2 (0.30 m^2). This is a significant difference. The leakage area of elevator doors has been measured in the range of 0.55–0.70 ft^2 (0.051–0.065 m^2) per door.

For many flow paths in buildings, a flow coefficient of 0.65 is used. The open doors of

Table 50.2 Flow areas of walls and floors of commercial buildings

Construction element	Leakage	Area ratio Leakage area per unit wall area in^2/ft^2	 ft^2/ft^2	 m^2/m^2
Exterior Building Walls (includes construction cracks, cracks around windows and doors)	Tight	7.2×10^{-3}	5.0×10^{-5}	5.0×10^{-5}
	Average	2.5×10^{-2}	1.7×10^{-4}	1.7×10^{-4}
	Loose	5.0×10^{-2}	3.5×10^{-4}	3.5×10^{-4}
	Very Loose	1.7×10^{-1}	1.2×10^{-3}	1.2×10^{-3}
Stairwell Walls (includes construction cracks but not cracks around windows or doors)	Tight	2.0×10^{-3}	1.4×10^{-5}	1.4×10^{-5}
	Average	1.6×10^{-2}	1.1×10^{-4}	1.1×10^{-4}
	Loose	5.0×10^{-2}	3.5×10^{-4}	3.5×10^{-4}
Elevator Shaft Walls (includes construction cracks but not cracks around doors)	Tight	2.6×10^{-2}	1.8×10^{-4}	1.8×10^{-4}
	Average	1.2×10^{-1}	8.4×10^{-4}	8.4×10^{-4}
	Loose	2.6×10^{-1}	1.8×10^{-3}	1.8×10^{-3}
		Leakage area per unit floor area		
Floors (includes construction cracks and gaps around penetrations)	Tight	9.5×10^{-4}	6.6×10^{-6}	6.6×10^{-6}
	Average	7.5×10^{-3}	5.2×10^{-5}	5.2×10^{-5}
	Loose[4]	2.4×10^{-2}	1.7×10^{-4}	1.7×10^{-4}

Note: The data in this table are for use with the orifice equation with a flow coefficient of $C = 0.65$. Floor leakage does not account for gaps that sometimes exist between the floor and curtain walls

pressurized stairwells commonly have stationary vortices which reduce the flow significantly [5, 19]. These vortices are thought to be caused by the asymmetric flow from the stairs, and stationary vortices can be expected at many open doors in other locations of smoke control systems. For open doors in stairwells, the geometric area of the opening should be used for the flow area along with a flow coefficient of 0.35.

Typical leakage areas for walls and floors of commercial buildings are tabulated as area ratios as shown in Table 50.2. These data are based from field tests performed by the National Research Council of Canada (Tamura and Wilson 1966; Tamura and Shaw 1976a, 1976b, 1978; [38–40]). Considerable data concerning leakage through building components are also provided in the *Handbook of Smoke Control Engineering*.

The determination of the flow area of a vent is not always straightforward especially when the vent surface is covered by a louver or screen. For vents with louvers, the flow area is referred to as the *free area*, and the free area is smaller than the geometric area (height multiplied by width) of the vent area. Because the slats in louvers are frequently slanted, calculation of the flow area is further complicated. When available, manufacturers' data regarding free are should be used. It is generally considered that the free area of a vent with a louver is about half the geometric area.

The density of air and smoke are expressed by the ideal gas law which is

$$\rho = \frac{144\,p}{R(T+460)} \qquad \rho = \frac{p}{R(T+273)} \quad \text{for SI} \tag{50.13}$$

where

ρ = density, lb/ft^3 (kg/m^3),
p = pressure, lb/in^2 (Pa),
R = gas constant, 53.34 ft lbf/lbm/°R (287 J/kg K)
T = temperature, °F (°C).

Friction Losses in Shafts

The pressure losses due to friction in ducts, stairwells and elevator shafts can be significant when flow rates are high. Tamura and Shaw (1976b) [40] and Achakji and Tamura [1] conducted tests of pressure loss in stairwells. Network computer models such as CONTAM employ algorithms that use this test data to calculate pressure losses due to friction in ducts, stairwells and other flow paths.

Door Opening Forces

The door opening forces resulting from the pressure differences produced by a smoke control system must be considered. Unreasonably high door opening forces can result in occupants having difficulty or being unable to open doors along the egress route such as into a stairwell.

The force to open a side hinged swinging door is shown in Fig. 50.11. The force required to open such a door when the smoke control system is operating can be determined using Equation (50.14).

$$F = F_{dc} + \frac{5.2WA\Delta p}{2(W-d)}$$
$$F = F_{dc} + \frac{WA\Delta p}{2(W-d)} \quad \text{for SI} \tag{50.14}$$

where:
F = total door-opening force, lb (N),
F_{dc} = door closer force, lb (N),
W = door width, ft (m),
A = door area, ft^2 (m^2),
d = distance from doorknob to knob side of door, ft (m),
Δp = pressure difference, in. H_2O (Pa).

Equation (50.14) applies when the door opening force is applied at the knob. Example 2 illustrates calculation of the door opening force.

Example 2. Door Opening Force
What is the door opening force for a side hinged swinging door 3 ft wide by 7 ft high with a door closer that requires 9 lb of force and a pressure difference across it of 0.35 in. H_2O? The knob is 3 in. (0.25 ft) from the edge of the door.

$W = 3$ ft; $F_{dc} = 9$ lb; $A = 3(7) = 21$ ft^2; $d = 0.25$ ft; $\Delta p = 0.35$ in. H_2O

The door-opening force is $F = F_{dc} + \frac{5.2WA\Delta p}{2(W-d)} = 9 + \frac{5.2(3)(21)(0.35)}{2(3-0.25)} = 30$ lb

Design Pressure Differences

Pressurization smoke control systems are designed to operate within a pressure difference range. This range is between the minimum design pressure difference and the maximum design pressure difference. A minimum design pressure difference intended to prevent smoke migration across a barrier of a smoke control system is generally stipulated by the applicable

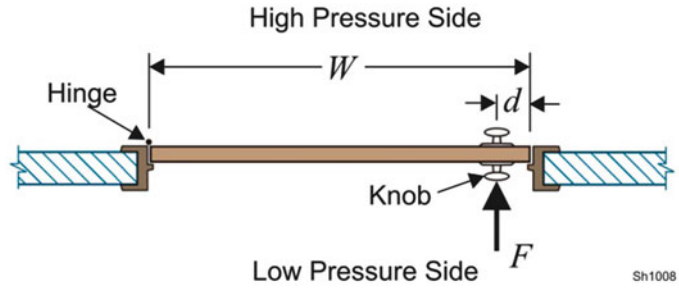

Fig. 50.11 Door-opening force for side hinged door

building and life safety regulations. A smoke control system should be designed to maintain this minimum design pressure difference under likely conditions of stack effect and wind.

The pressure difference across a barrier must not result in door-opening forces that exceed the maximum values stipulated by the applicable building and life safety regulations. For example, in NFPA 101, Life Safety Code [30], this maximum force is 30 lb (133 N). Calculation of door opening forces is discussed above. Acceptable pressurization consists of maintaining pressure differences across the barriers of a smoke control system that are between the minimum and maximum design values.

Stairwell Pressurization

Pressure differences across a stairwell tend to vary over the height of the stairwell. Figure 50.12 shows two pressure profiles for pressurized stairwells during cold winter months. One profile is for an idealized building, and the other is for a more realistic building with vertical leakage through floors and an elevator shaft. When it is cold outside, the pressure differences tend to be less at the bottom of the stairwell than at the top as can be seen in Fig. 50.12. When it is hot outside, the trend is the opposite. For both winter and summer conditions, the pressure profile for an idealized building is a straight line. An idealized building has no vertical leakage through the floors and shafts, and has leakage that is the same from floor to floor.

The pressure profiles of stairs in actual buildings depends on many factors including: (1) the leakage values of the various openings (flow paths) through building elements such as walls and floors, (2) the building floor plans, (3) the size of the elevator shaft or shafts and the number of elevator doors, (4) the presence or absence of elevator vents, and (5) the leakage through other shafts. There are many possible shapes for such pressure profiles in actual buildings.

For a building with vertical leakage, the flows through the floors and shafts act to even out to some extent the highest and lowest pressure differences across the stairwell. The profile for a building with vertical leakage is bounded by the extremes of the pressure profile of the idealized building. This means that other things being equal, the smallest pressure difference of the idealized analysis will be less than that of the actual building, and that the largest pressure difference of the idealized analysis will be more than that of the actual building. This is the reason that the algebraic equation method discussed below is conservative.

An algebraic equation method for analysis of pressurized stairwells is presented in Chap. 10 to the *Handbook of Smoke Control Engineering*. This algebraic equation method is based on

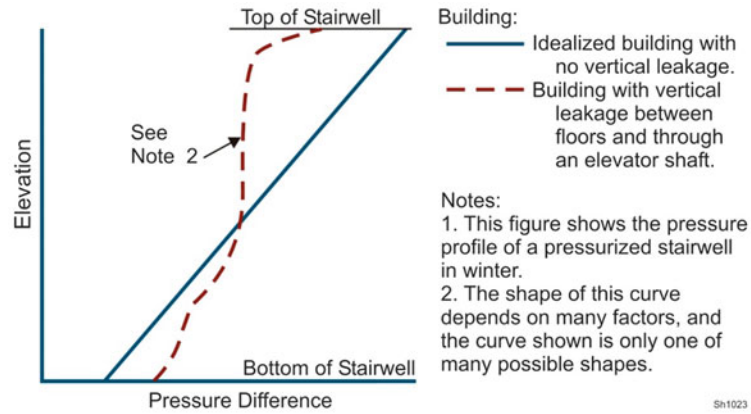

Fig. 50.12 Pressure profile of a pressurized stairwell in winter

(1) the idealized building, (2) flows calculated by the orifice equation, (3) effective flow areas, and (4) symmetry. The algebraic equation method does not account for pressure losses in the stairwell due to friction, but these losses tend to be small for stairwells when all the stair doors are closed.

Network computer models such as CONTAM are capable of analyzing pressurized stairwells much more realistically than the algebraic equation method. CONTAM can simulate the impact of a realistic building flow network based on the performance of pressurized stairwells. As already mentioned, computer network models can also simulate pressure losses in the stairwell due to friction.

Height Limit

For some tall stairwells, acceptable pressurization may not be possible because of the impact of the indoor to outdoor temperature differences. This is more likely with systems with treated supply air than those with untreated supply air.

The height limit is the height above which acceptable pressurization is not possible for an idealized building. For standard atmospheric pressure at sea level, the height limit can be determined by Equation (50.15).

$$H_m = 0.131 \frac{F_R(\Delta p_{\max} - \Delta p_{\min})}{\left| \frac{1}{T_O + 460} - \frac{1}{T_S + 460} \right|}$$

$$H_m = 2.89 \times 10^{-4} \frac{F_R(\Delta p_{\max} - \Delta p_{\min})}{\left| \frac{1}{T_O + 273} - \frac{1}{T_S + 273} \right|} \quad \text{for SI} \tag{50.15}$$

where

H_m = height limit, ft (m),

F_R = flow area factor (dimensionless),

$\Delta p_{\max}$ = maximum design pressure difference, in. H_2O (Pa),

$\Delta p_{\min}$ = minimum design pressure difference, in. H_2O (Pa).

The flow area factor is

$$F_R = 1 + \frac{A_{SB}^2 (T_B + 460)}{A_{BO}^2 (T_S + 460)}$$

$$F_R = 1 + \frac{A_{SB}^2 (T_B + 273)}{A_{BO}^2 (T_S + 273)} \quad \text{for SI} \tag{50.16}$$

where

A_{SB} = flow area between the stairwell and the building, ft^2 (m^2),

A_{BO} = flow area per stairwell between the building and the outside, ft^2 (m^2),

T_S = temperature in stairwell, °F (°C),

T_B = temperature in building, °F (°C).

The area, A_{SB}, is the total flow area between the stairwell and the building, which would typically include the gaps around all the closed doors and the leakage paths in the walls. For a stairwell with an unpressurized vestibule, A_{SB}, is the sum of the effective flow areas for all floors from the stairwell to the building.

The area, A_{BO}, is on a per stairwell basis because of symmetry considerations. For a building with an open floor plan, A_{BO} consists of the total leakage area of the exterior walls divided by the number of stairwells. For more complex floor plans, an effective flow area concept discussed above needs to be used to calculate A_{BO}.

Stairwell Temperature

Today, the supply air for most stairwells in North America is not treated so that pressurized stairwells are hot in the summer and cold in the winter. In many applications, the use of untreated supply air can be justified for the following reasons: (1) fire drills are usually held in the spring or fall when the outside temperature usually is mild, and (2) during a fire emergency being exposed to nearly outdoor temperatures seems reasonable considering occupants are often traveling to the safety of the outdoors.

When pressurization air is untreated in cold climates, there is a concern about the water freezing in sprinkler and standpipe risers in stairwells. To prevent such freezing, listed heat tracing systems can be used on the risers.. Alternately,

pressurization air can be treated to a minimum temperature in the range of 45–50 °F (7–10 °C) to prevent such freezing of water in the riser. ~~Using heat trace systems and untreated pressurization air has the advantage of minimizing the impact of stack effect, but using air treated to a minimum temperature has the advantage of minimizing the potential of freezing water on the stairwell floor during firefighting.~~

When pressurization air is untreated, the stairwell temperature can be expressed as

$$T_S = T_O + \eta(T_B - T_O) \qquad (50.17)$$

where
T_S = temperature in the stairwell, °F (°C),
T_O = temperature outdoors, °F (°C),
T_B = temperature in the building, °F (°C),
η = heat transfer factor (dimensionless).

There has been little research on the heat transfer factor. It is believed that the heat transfer factor is in the range of 0.05–0.15. In the absence of better data for a specific application, a heat transfer factor of 0.15 is suggested as being conservative regarding the impact of stack effect.

For untreated supply air, it takes a few minutes for the temperature in the stairwell to stabilize near that of the outdoors. During this stabilization, excessive pressure differences could be produced. To prevent this, supply air can gradually be increased so that when the stairwell temperature is near that of the building there is insufficient flow to cause excessive pressurization. If needed, the temperature stabilization can be evaluated by a heat transfer analysis.

Simple and Complicated Buildings

For simple stairwell pressurization systems in simple buildings, some designers may know from experience that the pressurized stairwell will work as intended, and the fans can be sized by simple calculations. A simple stairwell pressurization system is one that: (1) has air supplied at a constant (or nearly so) volumetric flow rate, (2) is intended to maintain acceptable pressurization with all the doors closed, and (3) has no features to prevent loss of pressure when stair doors are opened. As discussed later, a compensated stairwell system has features intended to prevent pressure loss when stair doors are opened, but such systems can be rather complex with regard to their design, installation and operation.

Figure 50.13a is an example of a simple building. The algebraic equation method can be used to size the supply fans for a simple building. Some engineers have developed their own rules of thumb that are appropriate for certain kinds of stairwell pressurization systems in some buildings. Rules of thumb are generally in the range of 300–550 cfm (0.14–0.26 m^3/s) per floor. Engineers determining a rule of thumb for stairwell pressurization should take into account the building specifications and the anticipated quality of construction. Of course, experienced engineers develop rules of thumb including an allowance to avoid the expense of replacing fans, motors and electrical wiring in the event that the stairwell would be somewhat more leaky than anticipated. Example *3* illustrates calculations for a simple stairwell system in a simple building.

Example 3. Simple Stairwell Pressurization in a Simple Building

The stairwells in a 20 story open plan office are to be pressurized, and the stairwells are the only pressurization smoke control systems in the building. The building has two stairwells that serve all floors. This building can be considered simple because the stairwells are all the same height and the floors are very similar from floor to floor. The winter design temperature is $T_O = 10$ °F, and the building temperature is $T_B = 70$ °F. The minimum and maximum design pressure differences are $\Delta p_{min} = 0.10$ in. H_2O and $\Delta p_{max} = 0.35$ in. H_2O. The floor-to-floor height is 10 ft, and building height is 200 ft. For a typical

(continued)

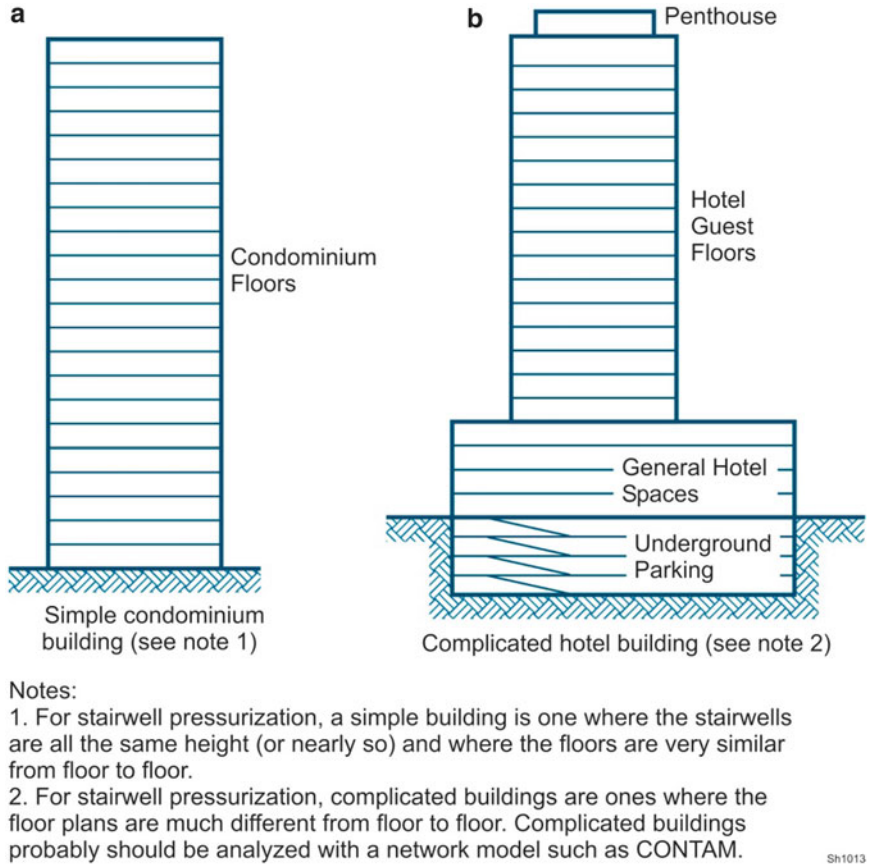

Fig. 50.13 Simple and complicated buildings with respect to stairwell pressurization

(continued)
floor, the flow area between the stairwell and the building is $A_{SB} = 0.34$ ft^2, and the flow area per stairwell between the building and the outside is $A_{BO} = 0.30$ ft^2.

Part 1: The stairwells are pressurized with untreated outside air, can this stairwell be pressurized?

Using a heat transfer factor of $\eta = 0.15$, the stairwell temperature is $T_S = T_O + \eta(T_B - T_O) = 10 + 0.15(70 - 10) = 19\,^\circ$F.

The flow area factor is $F_R = 1 + \frac{A_{SB}^2(T_B+460)}{A_{BO}^2(T_S+460)} = 1 + \frac{0.34^2(70+460)}{0.30^2(19+460)} = 2.42$.

The height limit is $H_m = 0.131 \frac{F_R(\Delta p_{\max} - \Delta p_{\min})}{\left|\frac{1}{T_O+460} - \frac{1}{T_S+460}\right|} = 0.131 \frac{2.42(0.35 - 0.10)}{\left|\frac{1}{10+460} - \frac{1}{19+460}\right|} = 1980$ ft.

Because the stairwells are in a simple building and the height limit is greater than the building height, the stairwells can be pressurized.

Part 2: The stairwells are pressurized with treated air at 70 °F, can this stairwell be pressurized?

The flow area factor is $F_R = 1 + \frac{A_{SB}^2(T_B+460)}{A_{BO}^2(T_S+460)} = 1 + \frac{0.34^2(70+460)}{0.30^2(70+460)} = 2.28$.

The height limit is $H_m = 0.131 \frac{F_R(\Delta p_{\max} - \Delta p_{\min})}{\left|\frac{1}{T_O+460} - \frac{1}{T_S+460}\right|} = 0.131 \frac{2.28(0.35 - 0.10)}{\left|\frac{1}{10+460} - \frac{1}{70+460}\right|} = 310$ ft.

This height limit is much less than that of Part 1. As with part 1, the stairwells can be pressurized, because the stairwells are in a simple building and the height limit is greater than the building height.

Part 3: Each stairwell is to be pressurized with one fan. Choose the capacity of the fan.

(continued)

(continued)

Based on experience with similar construction and buildings, the design engineer chooses 420 cfm per floor for this application. Because the stairwell is 20 stories, the fan capacity is 8400 cfm. Each stairwell needs an 8400 cfm fan.

For buildings that are relatively complicated, computer-based network analysis of the pressurized stairwells is often needed to determine if the stairwell systems are capable of being balanced to perform as intended. For stairwells pressurized with untreated air, building complexity often has more impact than stack effect. Even buildings that are not especially tall are considered complicated when the floors plans vary significantly from floor to floor.

The building indicated in Fig. 50.13b consists of underground parking levels, general hotel floors, guest room floors and a penthouse. It can be difficult to maintain acceptable pressurization of stairwells that extend from the parking levels to the penthouse, because the plans of these floors are so different. Complicated buildings should probably be analyzed with a network analysis model such as CONTAM. Wind effects add complexity to building when there are many openings to the outdoors (operable windows, balconies with doors that open, etc.). For complicated buildings with many openings to the outdoors, analysis of the pressurized stairwell systems with a computer network model is needed.

Single and Multiple Injection

A single injection system has pressurization air supplied at one location. Air can be supplied at the top of the stairwell, the bottom, or at a location in between. Figure 50.14a and b illustrate top and bottom injection systems. When roof-mounted propeller fans are used for stairwell pressurization, propeller fans should have tops that shield the fan from wind effects. Wall-mounted propeller fans should not be used because they can be adversely impacted by the wind unless a wind analysis indicates otherwise.

With a bottom injection system such as illustrated in Fig. 50.14b, some of the supply air can short circuit the system by flowing directly out of the opened exterior bottom doorway reducing system effectiveness. The bottom doorway is expected to be open as occupants egress the building through the stairwell. Simulation of such detailed fluid flow is typically beyond the capability of network models such as CONTAM, but it can be simulated with more sophisticated computations fluid dynamics, CFD, computer models. It is recommended that bottom injection systems be analyzed using CFD to determine the extent to which supply air flows out of an open exterior door. Alternatively, the air can be introduced into the stairwell at least one floor above or below the exterior doors.

For tall stairwells, single injection systems can fail when a few doors near the air injection point are open simultaneously. Much of the pressurization air can be lost through these open doors, and the system will then fail to maintain positive pressures across doors further from the injection point compromising the effectiveness of the overall stairwell pressurization system. To reduce the potential for such failure, multiple injection systems can be used. Multiple injection systems can consist of one fan supplying air through a duct located in a shaft as shown in Fig. 50.14c. Other arrangements of multiple injection systems eliminate the need for a shaft by using more than one fan as shown in Fig. 50.14d.

There has been no research on this subject, but the consensus is that single injection systems for stairwell heights more than 100 ft (30.5 m) need a design analysis using computer network models. For multiple injection systems supplying air through a duct in a shaft, injection points are usually one to three floors apart. Multiple injection systems that have a separate fan at each

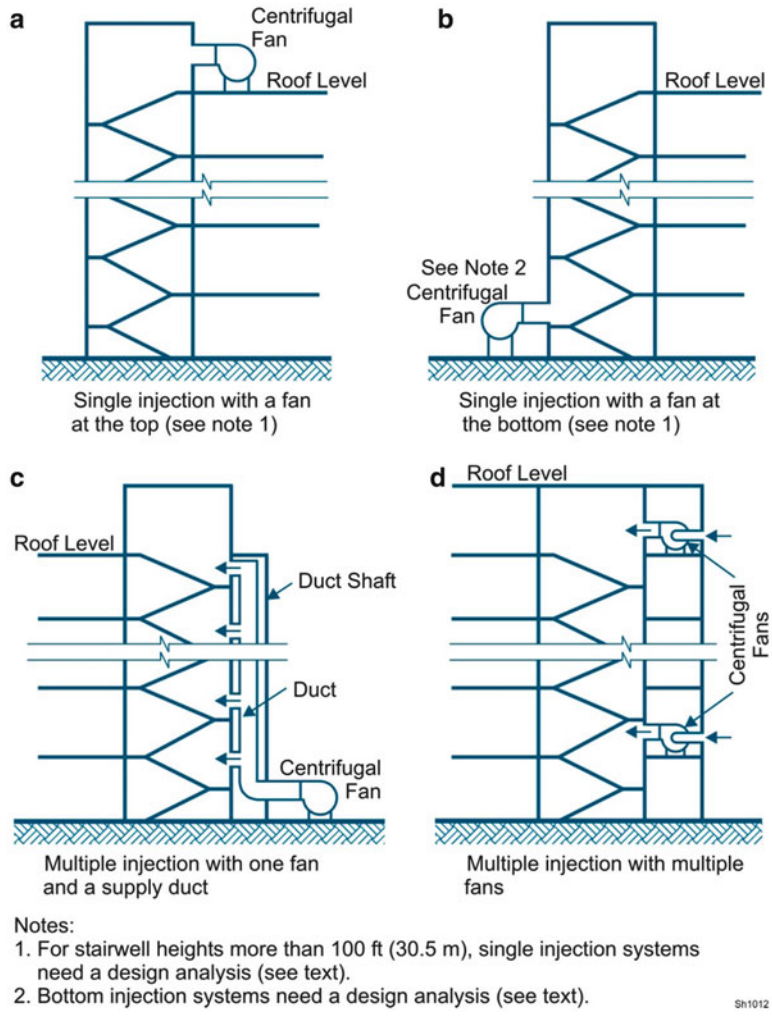

Fig. 50.14 Some single and multiple injection stairwell pressurization systems

injection point can have injection points much further apart. For systems with two injection points, one at the top and another near the bottom, a computer network model analysis is recommended for stairwell heights more than 200 ft (61 m).

Vestibules

Pressurized stairwells with vestibules are occasionally used. The vestibules can be: (1) unpressurized, (2) pressurized, (3) ventilated, or (4) a combination of pressurized and ventilated. Vestibules provide an additional barrier around a stairwell, and vestibules have the potential to reduce the probability of an open-door connection existing between the stairwell and the building.

An evacuation analysis can be performed to determine the extent to which both vestibule doors and stairway doors are likely to be opened simultaneously. For densely populated buildings, it is expected that on many floors both vestibule doors and stairway doors would be opened simultaneously. Therefore, vestibules may provide little benefit of an extra barrier for densely populated buildings.

The algebraic equation method of analysis can be used to analyze a pressurized stairwell with an

unpressurized vestibule. The pressure differences and flows of stairwell systems with any kind of vestibules can be analyzed by computer network model. It is possible to evaluate the benefits of ventilated vestibules using tenability analysis.

System with Fire Floor Exhaust

System employing fire floor exhaust can achieve acceptable pressurization of tall stairwells in very complex buildings. A relatively small amount of air is supplied to the stairs, and the fire floor is exhausted such that acceptable pressurization is maintained on the fire floor where it is needed. It is common to also exhaust one or two floors above and below the fire floor. Fire floor exhaust is a form of zoned smoke control, and stairwell pressurization with such zoned smoke control is discussed later.

Stairwells and Open Doors

When any stair door is opened in a simple stairwell pressurization system, the pressure difference drops significantly. When all doors are closed suddenly in such a simple system, the pressure difference increases significantly. A compensated stairwell pressurization system is one that adjusts for changing conditions either by modulating supply airflow or by relieving excess pressure. The intent of a compensated system is to maintain acceptable pressurization when doors are opening and closing.

In the United States, most building and life safety regulations do not require pressurized stairwells to be compensated, and such stairwells are designed to maintain pressurization only when all the stair doors are closed. Traditionally, some engineers believed that pressurized stairwells need to be compensated, but an incidental finding of a study by Klote [18] casts doubt on this opinion. For two simulations in this study with a closed stair door on the fire floor and some other stair doors open, the stairwell remained tenable. The reason the stairwell remained tenable was that the smoke that leaked into the stairwell was diluted by the large amount of air supplied to the stairwell. In light of this finding, ASHRAE is sponsoring a research project to study the need for compensated stair systems.

Many kinds of compensated stairwell pressurization systems have been used, but the most common are (1) the open exterior door system and (2) the variable air volume (VAV) system. The open exterior door system has "constant-supply" airflow, and an exterior stairwell door that opens automatically upon system activation. This system is sometimes called the Canadian system because it originated in Canada, and it has been used extensively there. The supply air rate is not actually constant, but it varies to some extent with the pressure across the fan. For centrifugal fans this variation in flow is generally small. However, the term "constant-supply" is used to differentiate this system from the systems where the supply air rate is designed to intentionally change.

By keeping the exterior stairwell door open during system operation, the Canadian system eliminates the major source of pressure fluctuations. This system is simple and relatively inexpensive, but there are many locations where opening exterior doors automatically raises issues of building security. For complex buildings, it is recommended that this system be evaluated using a computer network model to assure that it operates as intended.

With the VAV system, the flow rate of supply air to the stairwell is adjusted to account for opening and closing of doors. Tamura (1990) conducted research on VAV systems at the National Research Council of Canada. It was found that the pressure drops when doors are opened, and it took about 3–7 min for the pressure to recover to the initial value. When all the stair open doors in a VAV system are closed, there is a pressure spike. In Tamura's research, the spike had a peak of 0.728 in. H_2O (181 Pa). This spike only lasted about 30 or 40 s, but the peak was much more than any reasonable maximum design pressure difference. Such peaks are a concern. A person encountering such a peak, would probably not be able to open the stair door,

but they could open it a minute or so later provided they knew enough to try. It is possible that a person encountering such a peak would think the stair door was locked, and he or she might not try to open it again.

Wind can have a serious impact on VAV stair pressurization systems. During design analysis of some of these systems, some engineers have encountered very high pressure differences during some wind conditions. For example, when an exterior door is opened during the design wind speed, a compensated stair system may supply so much air that the pressure difference across some stair doors may exceed the maximum design value. It is possible to exceed this design value by as much as 100 %. During such an occurrence, it would be impossible or extremely difficult for occupants to enter the stairwell. For this reason, it is recommended that design analysis of VAV compensated stairwell pressurization systems include computer network model simulations under wind conditions.

Elevator Shaft Pressurization

The elevator pressurization systems discussed in this section are intended to prevent smoke from flowing from the fire floor through an elevator shaft and threatening life on floors away from the fire floor. This section does not address smoke control for elevator evacuation, but elevator evacuation is discussed in Chap. 12 of the *Handbook of Smoke Control Engineering*. Usually pressurized elevator shafts are in buildings that have pressurized stairwells, and the focus of this section is on both of these pressurization systems operating together. In the rare situation where pressurized elevator shafts are the only pressurization smoke control system in a building, the information in this section may also be useful.

The information discussed earlier about piston effect can be used to evaluate the impact of piston effect on the performance of pressurized elevator systems. The piston effect produces a pressure spike when a car passes a particular floor, and this happens for only a few seconds during the run of an elevator car. For elevators in multiple car shafts with car velocities less than 1000 fpm (5 m/s), piston effect should not adversely impact the performance of elevator pressurization. For elevators in single car shafts with car velocities less than 500 fpm (2.5 m/s), piston effect should not adversely impact the performance of elevator pressurization.

Design of pressurized elevator shafts is much more complicated than design of pressurized stairwells, but there are a number of approaches that can deal with this complexity. The reasons for this complexity are: (1) often the building envelope is not capable of effectively handling the large airflow resulting from both elevator and stairwell pressurization, and (2) open exterior doors on the ground floor can cause high pressure differences across the elevator shaft at the ground floor.

Usually a number of exterior doors on the ground floor are open during a building fire. During a fire, the fire service opens a number of exterior doors or keeps these doors open while fighting the fire. Occupants also open exterior doors during evacuation. The shaft pressurization system needs to operate as intended with these exterior doors open.

Generally a computer network model analysis is needed to determine if pressurized elevators and pressurized stairwells in a particular building are capable of being balanced to perform as intended. While it may be theoretically possible to use only a rule of thumb to design these systems, a computer network model analysis is strongly recommended.

The elevator pressurization systems discussed here are: (1) the basic system, (2) the exterior vent (EV) system, (3) the floor exhaust (FE) system, and (4) the ground floor lobby (GFL) system. As mentioned above, these systems are for use in buildings with pressurized stairwells. The results of 36 computer network model simulations using CONTAM were used to study the performance of an elevator shaft pressurization system for a 14-story building illustrated in Fig. 50.15. Further details of this analysis are presented in Chap. 11 of the *Handbook of Smoke Control Engineering*. The following discussion about elevator pressurization

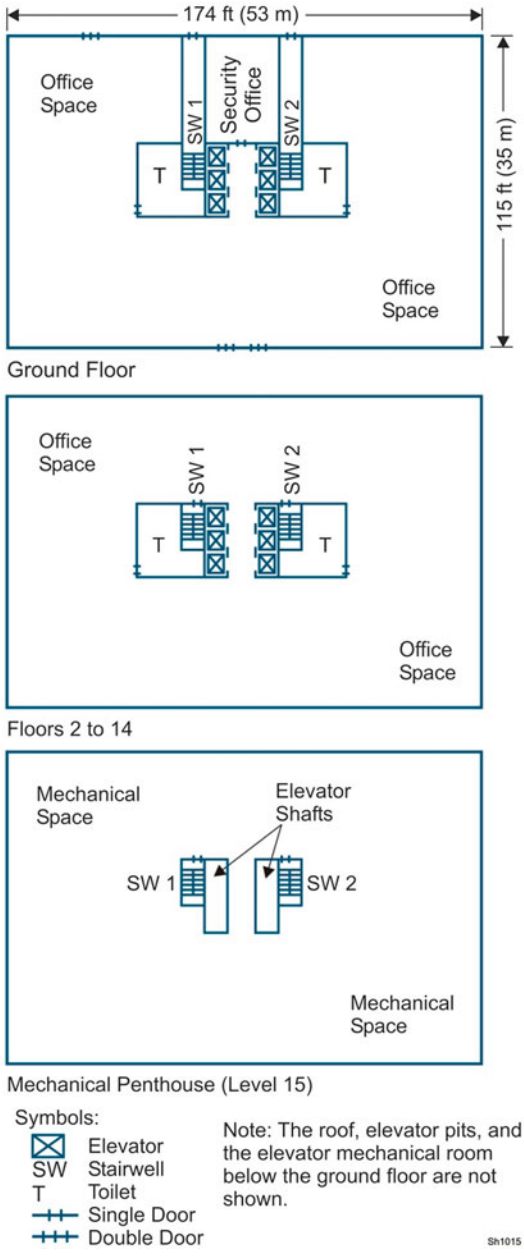

Fig. 50.15 Floor plans of the example 14 story open plan office building for elevator pressurization study

systems is based on these 36 simulations. For these simulations, the pressure difference criteria listed in Table 50.3 were used, and these criteria are consistent with pressure differences requirements in the *International Building Code* (ICC 2012). The leakage values and flow coefficients used for these simulations are listed in Tables 50.4 and 50.5. For the CONTAM simulations of the 14-story building, supply air was injected only at the top of the elevator shafts, but about half the supply air was injected at the top of the stairs and the rest at the second floor.

Table 50.3 Pressure differences criteria for elevator pressurization simulations[a]

	Minimum		Maximum	
System	in. H_2O	Pa	in. H_2O	Pa
Pressurized elevators	0.10	25	0.25	62
Pressurized stairwells	0.10	25	0.35	87

[a]The above criteria are for the elevator simulations discussed Chap. 11 of the *Handbook of Smoke Control Engineering*, and some projects may have different criteria depending on code requirements and requirements of specific applications

Table 50.4 Flow areas and flow coefficients of doors used for elevator pressurization simulations[a]

			Flow area	
Flow path	Path name[b]	Flow coefficient	ft^2	m^2
Single door (closed)	DOOR-SC	0.65	0.25	0.023
Single door (opened)	DOOR-SO	0.35	21	2.0
Double door (closed)	DOOR-DC	0.65	0.48	0.045
Double door (opened)	DOOR-DO	0.35	42	3.9
Elevator door (closed)	DOOR-EC	0.65	0.65	0.06
Elevator door (opened)	DOOR-EO	0.65	6	0.56

[a]The values in this table were chosen for the elevator simulations discussed Chap. 11 of the *Handbook of Smoke Control Engineering*. The flow areas and flow coefficients appropriate for a design analysis of a specific building may be different

[b]The path name is an identifier used in the CONTAM simulations

Basic System

In the basic system, each stairwell and elevator shaft has one or more dedicated fans that supply pressurization air. For reasons mentioned above,

Table 50.5 Flow areas and flow coefficients of leakages used for elevator pressurization simulations

Flow path	Leakage classification	Path name	Flow coefficient	Flow area	
				ft^2 per ft^2 of wall	m^2 per m^2 of wall
Exterior walls	Tight	WALL-EXT	0.65	0.50×10^{-4}	0.50×10^{-4}
	Average			0.17×10^{-3}	0.17×10^{-3}
	Loose			0.35×10^{-3}	0.35×10^{-3}
	Very loose			0.12×10^{-2}	0.12×10^{-2}
Interior walls	Loose	WALL	0.65	0.35×10^{-3}	0.35×10^{-3}
Floor (or roof)	Tight	FLOOR	0.65	0.66×10^{-5}	0.66×10^{-5}
	Average			0.52×10^{-4}	0.52×10^{-4}
	Loose			0.17×10^{-3}	0.17×10^{-3}
				ft^2 per ft of wall	m^2 per m of wall

	Loose			0.02	0.0061

See notes on Table 50.4

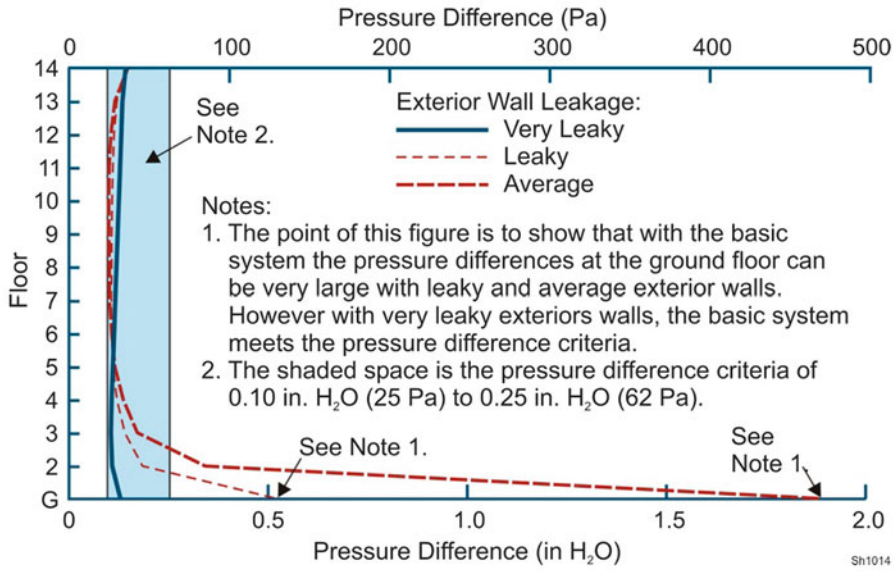

Fig. 50.16 Elevator pressure differences for basic elevator pressurization system

the basic system also includes stairwell pressurization, and the stair subsystems are not compensated systems. In most buildings the basic system does not result in successful pressurization, and the other systems discussed below consist of the basic system plus features to improve performance.

When the 14-story building contained very leaky exterior walls, the CONTAM simulations showed that the basic pressurization system would perform well, but this was not the case with less leaky exterior walls. It can be seen on Fig. 50.16 that for leaky exterior walls, the pressure difference across the elevator doors on the ground floor is about 0.5 in. H_2O (75 Pa). For exterior walls of average leakage the pressure difference across the elevator doors on floor 2 is about 0.35 in. H_2O (52 Pa), and at the ground floor it is about 1.9 in. H_2O (280 Pa). These values exceed the maximum criteria used for elevator doors, which is 0.25 in. H_2O (62 Pa) as indicated in Table 50.3. For average and leaky

exterior walls, there is insufficient leakage in the building envelope to accommodate the large amount of pressurization air supplied to the shafts.

With very leaky exteriors walls, it can be seen on Fig. 50.16 that the basic system meets the pressure difference criteria identified in Table 50.3. Air was supplied to each elevator shaft at 27,700 cfm (13.1 m^3/s), and air was supplied to each stairwell at 6560 cfm (3.09 m^3/s). With very leaky exteriors walls, there is enough wall leakage area to accommodate this large amount of pressurization air. For the few buildings that have very leaky building envelopes, the basic system can be a simple way to pressurize elevators and stairwells. For less leaky buildings, the systems discussed present other options.

Exterior Vent (EV) System

The idea of the EV system is to use vents in the exterior walls to increase the leakiness of the building envelope such that successful pressurization can be achieved. The vents are usually closed, but they open when the pressurization system is activated. The vents should be located in a manner to minimize adverse wind effects, and the supply intakes need to be located away from the vents to minimize the potential for smoke migration into the supply air. These vents may need fire dampers depending on building and fire code requirements.

Figure 50.17a shows a typical floor of the example 14-story building with vents in the exterior walls. For the example building, the vents can be sized to assure the design criteria are met. The vents were sized such that the amount of pressurization used for the basic system produce acceptable pressurization with the EV system in the example building.

The example building has open office plan. For buildings with corridors, the simple EV approach of Fig. 50.17a is not appropriate. The flow resistance of corridor walls and other walls has a negative impact on system performance

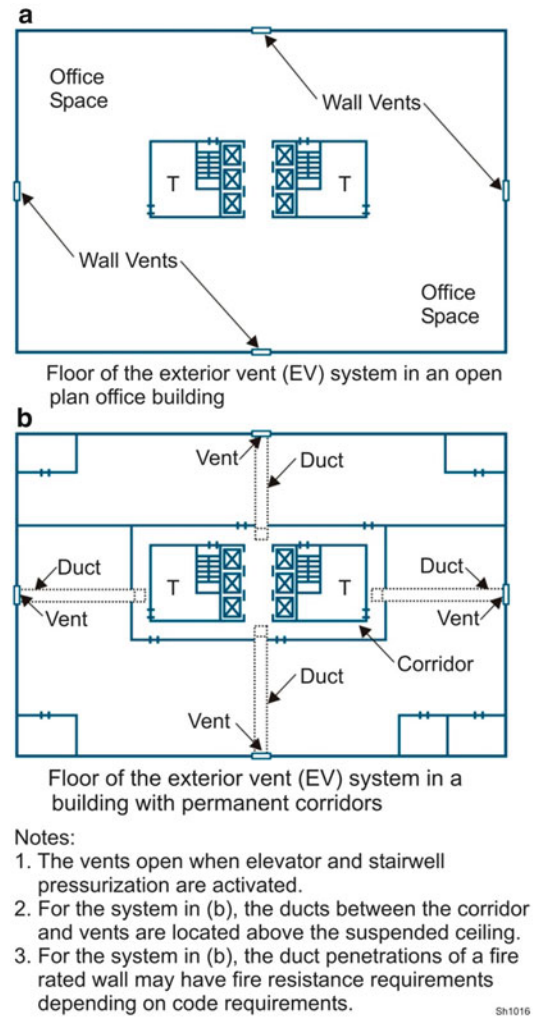

Fig. 50.17 Typical floor plans of buildings with the exterior vent (*EV*) system

when the vents are located in the exterior walls, but this can be overcome by use of ducted vents.

Figure 50.17b shows a ducted EV system that can be used for an office building with permanent corridors. The ducted EV system can be used for other occupancies such as hotels and condominiums. Any duct penetrations of a fire rated wall will need to be firestopped in accordance with applicable building and fire regulations. For a building where the floors can be either open plan or divided by tenant installed partitions, an EV system can be achieved by wall vents above a suspended ceiling and one or more

air transfer grills in the ceiling of the elevator lobby.

With open exterior doors, it is not necessary to have exterior vents on the ground floor. Because the EV system may not be able to achieve acceptable pressurization with some or all the exterior doors closed, it may be necessary to have some of the exterior doors open automatically on system activation. The number of exterior doors that need to be opened automatically can be evaluated by the use of a computer network model.

In Figure 50.17a and b, the vents are in all four exterior walls with the intent of minimizing any adverse impact of the wind. It is suggested that the vent area be proportional to the area of the exterior walls. If fewer vents are used, it is suggested that wind effects be evaluated with the use of a computer network model.

Floor Exhaust (FE) System

The FE system deals with the building envelope issue by reducing the amount of supply air used. In the FE system, a relatively small amount of air is supplied to the elevator shafts and the stairwells, and the fire floor is exhausted such that acceptable pressurization is maintained on the fire floor where it is needed. It is common to also exhaust one or two floors above and below the fire floor.

The FE system is a kind of zoned smoke control. As discussed later, exhausting air from the fire floor and some floors above and below the fire floor has a beneficial impact on shaft pressurization. Often this system can achieve successful pressurization in tall and very complex buildings.

Typically the exhaust is through a shaft with a fan located in a mechanical floor or on the roof, and dampers between the shaft and the floors are closed on all floors when the system is not operating. On system activation, the dampers open on the floors to be exhausted. The outlet of the exhaust fan needs to be located away from the inlets the supply fans to minimize the potential for smoke feedback into supply air.

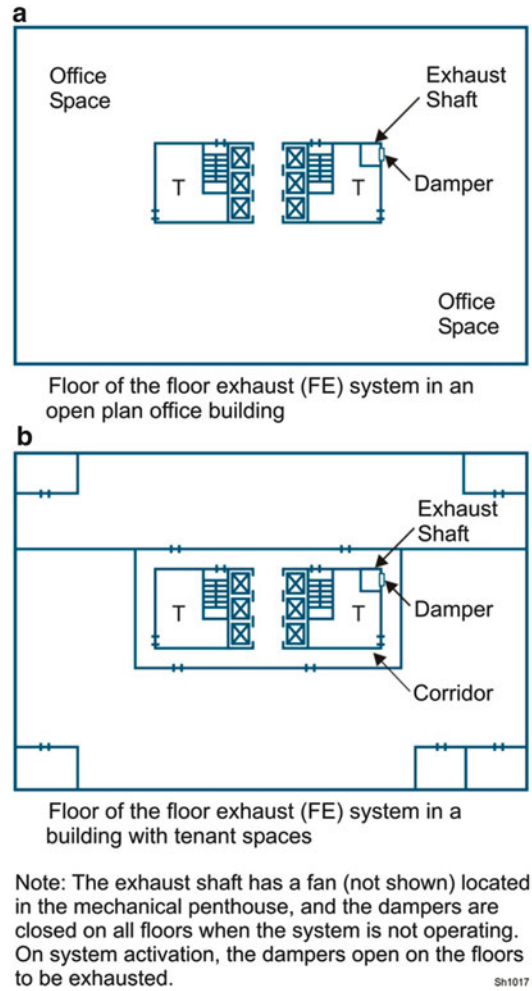

Fig. 50.18 Typical floor plans of buildings with the floor exhaust (*FE*) system

For the 14-story example building, the FE system is shown in Fig. 50.18a. For the simulations of the example building, each elevator shaft needed 15,100 cfm (7.14 m^3/s), and each stairwell needed 3800 cfm (1.79 m^3/s). The floor exhaust needed from the floors ranged from 4800 to 5400 cfm (2.28–2.55 m^3/s). For a building with many interior partitions, the exhaust can be from the corridor that the elevators and stairwells open onto, and this is shown in Fig. 50.18b.

As with the EV system, some of the exterior doors on the ground floor may need to open automatically upon system activation, and the

number of such doors needed can be determined with the use of a computer network model.

Ground Floor Lobby (GFL) System

The GFL system has an enclosed elevator lobby on the ground floor to reduce the tendency of open exterior doors to cause high pressure differences across the elevator shaft at the ground floor. The GFL system often has a vent between the enclosed lobby and the building with the intent of preventing excessive pressure differences across the lobby doors. The lobby doors are the doors between the enclosed lobby and the building.

The pressure difference across the lobby door and the elevator door depend on the area of the vent. There is no established criterion for the maximum pressure difference across the lobby doors, but the pressure should not be so high as to prevent the doors from remaining closed. This value depends on the specific doors and hardware. For discussion here, a maximum pressure difference for the lobby doors was chosen as 0.35 in H_2O (87 Pa), but this value can be much different for specific applications. The vent should have a fire damper and a control damper in series. The control damper can be used to adjust the flow area of the vent so it can be balanced during commissioning. Figure 50.19 shows the ground floor of the example building with a GFL system.

As stated above, the intent of the elevator pressurization systems discussed in this chapter is to prevent smoke from flowing from the fire floor through an elevator shaft and threatening life on floors away from the fire floor. In the GFL system, the enclosed lobby on the ground floor protects the elevator from smoke from a fire on the ground floor. For this reason, the minimum elevator pressure difference criterion of Table 50.3 does not apply to the ground floor for a GFL system. The other criteria of Table 50.3 apply. Table 50.6 identifies the criteria that were used for the GFL system simulations. For the GFL system of the simulations discussed below, successful pressurization consists of meeting the criteria identified in Table 50.6.

For fires in high-rise buildings, frequently the fire service uses the elevators for rescue and for mobilization of firefighting equipment. When ground floor lobby doors are opened, the pressure difference may exceed the maximum pressure difference. If this can happen for a particular design, the fire service should be contacted to determine if this is acceptable to them.

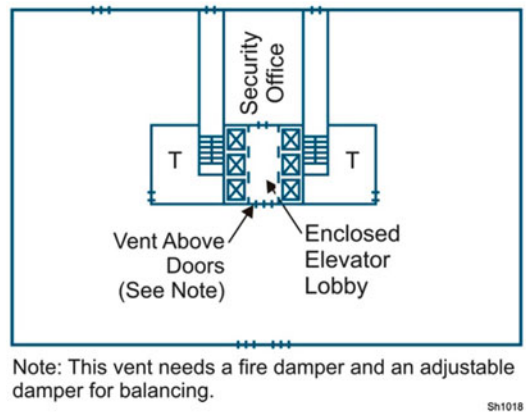

Fig. 50.19 Ground floor of a building with the ground floor lobby (*GFL*) system

Table 50.6 Pressure differences criteria for GFL elevator pressurization simulations[a]

	Criteria	Minimum		Maximum	
Location	Number	in H_2O	Pa	in H_2O	Pa
Pressurized elevators on ground floor	1	NA	NA	0.25	62
Pressurized elevators on other floors	2	0.10	25	0.25	62
Pressurized stairwells on all floors	3	0.10	25	0.35	87
Ground floor elevator lobby door	4	NA	NA	0.35	87

[a]These pressure differences are with stairwell doors closed, the elevator doors closed, and the ground floor lobby door closed. The above criteria are for the GFL simulations discussed in this chapter, and some projects may have different criteria depending on code requirements and requirements of specific applications

The floor-to-floor leakage can have a significant impact on the performance of a GFL system. This leakage consists of the leakage of the floor and that of the curtain wall gap (Table 50.5).

Zoned Smoke Control

The traditional approach for HVAC systems is to shut them down during building fires, but HVAC systems can be designed to operate in a smoke control mode during building fires. Zoned smoke control consists of exhausting the zone of the fire and possibly pressurizing the surrounding zones. For reasons discussed later in this chapter, pressurizing the surrounding zones is not recommended for zoned smoke control systems in tall buildings. For zoned smoke control systems that rely on smoke exhaust only, the zoned smoke control can complement the performance of stairwell pressurization in tall and complex buildings. In addition to using the HVAC system, dedicated equipment can be used for zoned smoke control.

In zoned smoke control, a building is divided into a number of zones each separated from the others by barriers. In the event of a fire, the zone with the fire is called the smoke zone, and the others are called the non-smoke zones. The zones that border on the smoke zone are called the surrounding zones. Passive smoke protection or pressurization smoke protection is used to limit the extent of smoke spread beyond the smoke zone. It is beyond the capability of smoke control to make conditions tenable in the smoke zone, and it is intended that occupants evacuate the smoke zone as soon as possible.

Smoke arrangements of smoke control zones are shown in Fig. 50.20. In this Figure the smoke zone is indicated by a minus sign, and the surrounding zones are indicated by a plus sign. Often the smoke zone is one floor of the building (Fig. 50.20a). A common approach is to make the smoke zone be the fire floor plus the floor directly above and below the fire floor as shown in Fig. 50.20b. In a relatively low sprawling building made of a number of wings, the smoke zone can be part of a floor as in Fig. 50.20c. A surrounding zone can be one floor as in Fig. 50.20a and b, and it can be part of a floor as in Fig. 50.20c. A surrounding zone can also be a number of floors as shown in Fig. 50.20d.

The traditional approach to zoned smoke control is to exhaust the smoke zone and to pressurize the surrounding zones, but many other approaches have been used. The methods that can be used to treat the smoke zone are: (1) fan powered exhaust, (2), passive smoke control using smoke barriers (3) exterior wall vents, or (4) smoke shafts. Fan powered smoke exhaust is the most common method, and passive smoke control using smoke barriers may be satisfactory when fan powered exhaust is not practical. Exterior wall vents and smoke shafts are not commonly used, but they are discussed in Chap. 13 of the *Handbook of Smoke Control Engineering*.

The methods that can be used for the zones surrounding the smoke zone are: (1) fan powered pressurization or (2) passive smoke control using smoke barriers. Fan powered pressurization of the surrounding zones has a negative impact on stairwell pressurization as discussed below. For the rest of this section, fan powered pressurization will be called pressurization, and fan powered exhaust will be called exhaust.

When the floors of a building are divided into many rooms with normally closed doors, these floors do not lend themselves to the traditional concept of zoned smoke control. This can also be said of wings of a building that are divided into many rooms with normally closed doors. For such applications, a form of zoned smoke control can be used that relies on a combination of corridor exhaust and passive smoke control using smoke barriers. Figure 50.21 shows a floor of a condominium building that can be considered a form of a smoke zone. The floor has corridor exhaust, and the other spaces rely on passive smoke protection of the corridor walls and ceiling floor assembly of the other spaces. This passive protection tends to minimize smoke flow through the ceiling floor assembly during a building fire.

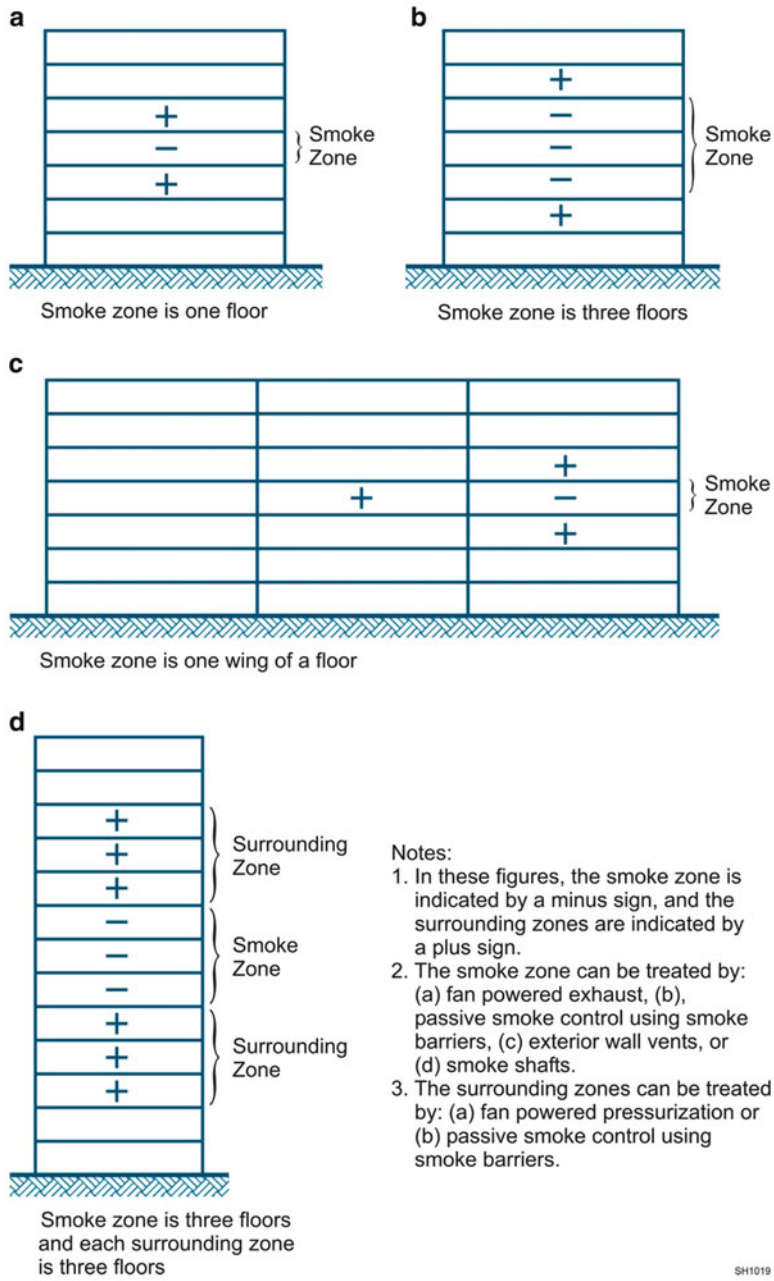

Fig. 50.20 Smoke arrangements of smoke control zones

Interaction with Pressurized Stairs

The interaction of zoned smoke control with pressurized stairwells can have a significant impact on the pressure differences across the stairwell doors. The following discussion is about smoke zones that are comprised of one floor and surrounding zones consisting of one floor above and one floor below. However, the same kind of interactions can happen with smoke zones and surrounding zones that are more than one floor.

Zoned smoke control using both exhaust and pressurization is shown in Fig. Fig. 50.22a, and pressure differences, Δp_{SB}, from the stairwell to the building are shown in Fig. 50.22b and Fig. 50.22c. Exhaust of the smoke zone increases

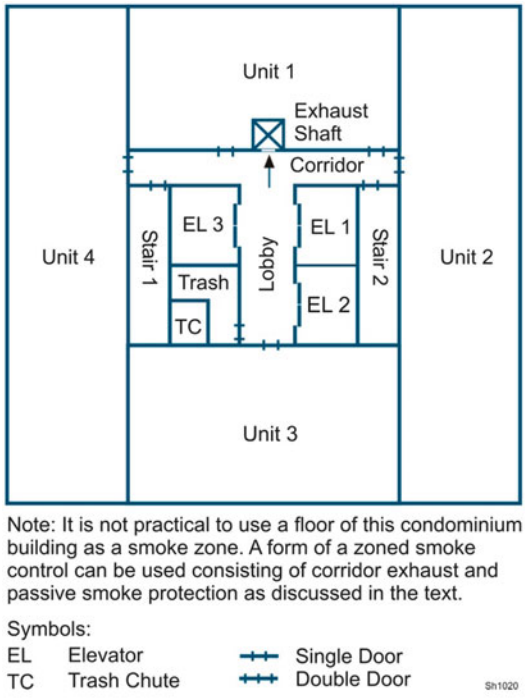

Fig. 50.21 Example of corridor exhaust and passive smoke control

the pressure difference across pressurized stairwell doors on the floor or floors of the smoke zone. Pressurization of the surrounding zones decreases the pressure difference across pressurized stairwell doors on these floors.

The pressure difference, Δp_{SB}, can be positive on all the floors as shown in Fig. 50.22b. This pressure difference can be negative on some floors as shown in Fig. 50.22c. Negative pressurization can happen on the floors that are pressurized, and this negative pressurization has the potential for the significant failure mode discussed below.

In Fig. 50.20a, smoke should be prevented from reaching the floor above the smoke zone, and negative stairwell pressurization should not compromise tenability of the stairwell. The effectiveness of this depends on proper identification of the fire floor. Properly maintained fire detection and alarm systems are very good at identifying the location of a fire, but issues can arise. In some fire scenarios, the first smoke detector to activate has been a floor or so above the fire floor. This can be attributed to any of the following: (1) smoke

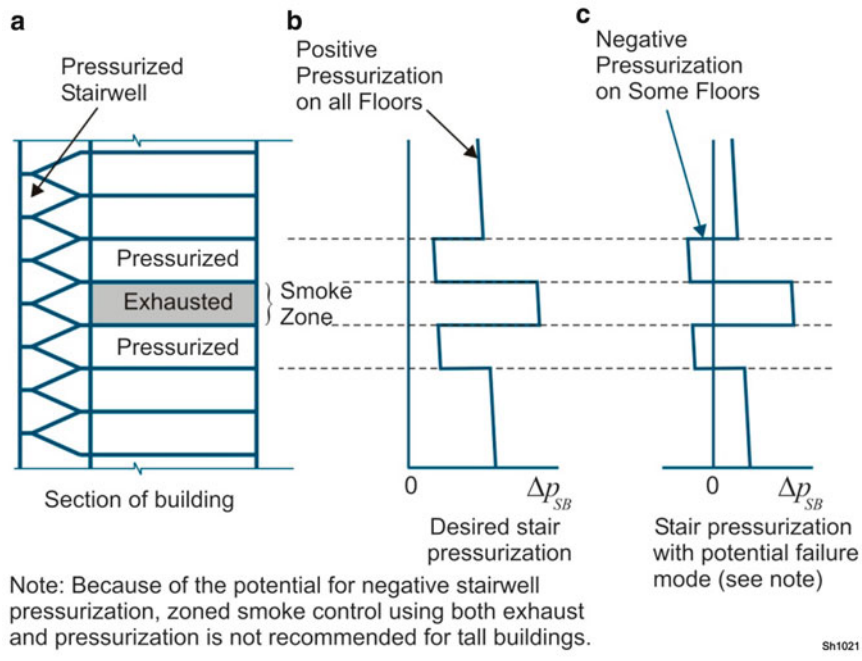

Fig. 50.22 Interaction between pressurized stairwells and zoned smoke control using both exhaust and pressurization

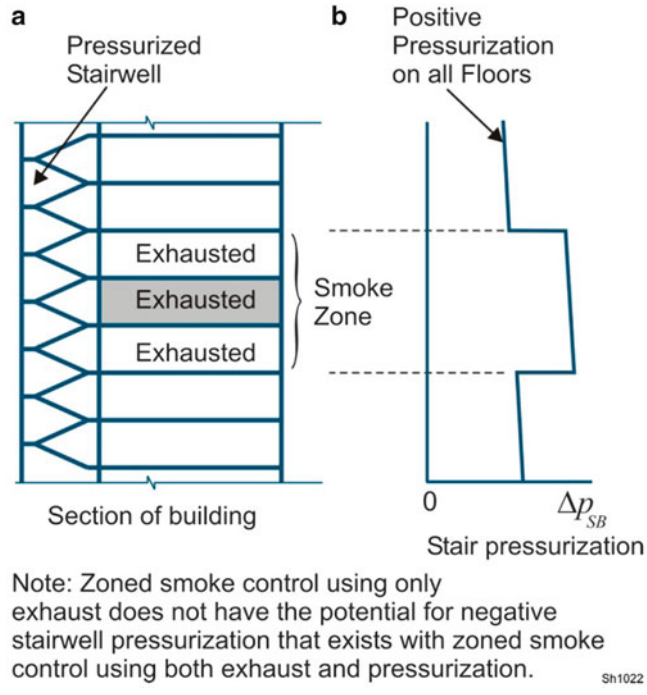

Fig. 50.23 Interaction between pressurized stairwells and zoned smoke control using only exhaust

flowing through a complex route to a floor above the fire, (2) smoke detectors not working properly on the fire floor, and (3) signals from smoke detectors being misidentified.

Regardless of the reason, when a fire floor is incorrectly identified, the smoke zone is incorrectly chosen. In this situation, the failure mode is that inadvertent pressurization of the fire floor can push smoke into the stairwells. An additional concern is that if this failure mode happens, it will probably happen to all the stairwells serving the fire floor. This failure mode is more of a concern for tall buildings because: (1) acceptable pressurization is more difficult in taller buildings than in shorter ones, and (2) stairwell smoke protection is more important in taller buildings than in shorter ones. Occupant density is another factor regarding the importance of stairwell smoke protection. In this context, a tall building might be thought of as one having a minimum of about 10 stories. Because of this failure mode, it is recommended that zoned smoke control using systems employing both exhaust and pressurization not be used for tall buildings where protection of the stairwells is especially important. Alternatively an analysis of this failure mode could be performed that includes factors such as evacuation time, emergency response time, and probability using the Firefighter's Smoke Control Station (FSCS) for corrective action.

The zoned smoke control shown in Fig. 50.23 does not have this failure mode. The zoned smoke control system of Fig. 50.23 consists of a three story smoke zone that is exhausted and the surrounding zones rely on passive smoke protection. The exhaust acts to increase Δp_{SB} for the three floors of the smoke zone (Fig. 50.23b). Because this system does not have pressurization of surrounding zones, Δp_{SB} is not reduced for surrounding zones, and this eliminates the failure mode discussed above.

In Fig. 50.23a the fire floor is shaded, and the smoke zone consists of the fire floor and the floors directly above and below. It is expected that there will be some smoke flow to the floor above the fire floor, and there may be some smoke flow to the floor below the fire floor. This smoke flow is restricted by the floor-ceiling assembly. A floor-ceiling assembly is a passive

smoke barrier that has significant resistance to smoke flow. Even a floor-ceiling assembly not constructed as a passive smoke barrier has considerable resistance to smoke flow provided that the only openings through it are construction cracks and small cracks around pipe and conduit penetrations. This means that there will be some amount of time for occupants of the floors directly above and below the fire floor to evacuate those floors. Further, the small amount of smoke on these floors should act to convince occupants of the serious nature of the fire such that pre-movement time before evacuation will be significantly reduced.

Tenability Systems

As previously stated, the conventional smoke control systems discussed above are based on the approach of preventing occupants from coming into contact with smoke. These conventional systems have some level of smoke contact with the occupant at times when stair doors open for occupant entry or due to natural fluctuations in building pressures. Provided that the contaminates are sufficiently diluted, such smoke contact is usually considered to be of little concern. Tenability systems are designed with the intent of providing a tenable environment for occupants who are exposed to some concentration of smoke.

Analysis Components

Analysis of tenability systems requires consideration of the following components: (1) fire scenario, (2) smoke transport mechanisms, and (3) tenability thresholds.

Fire Scenario A fire scenario can be thought of as the outline of events and conditions that are critical to determining the outcome of alternate designs. In addition to the fire location and heat release rate (HRR), the fire scenario includes the status of the doors, the HVAC systems, and the smoke management system, and other systems. Species (O_2, N_2, CO, CO_2, etc.) generation can be included in the fire scenario. The scenario may also include specifics about the fuel, ignition of multiple fuel packages, and the effect of an fire suppression activities. The selection of the fire scenario can be based on a combination of professional judgment, fire dynamics, historical fire data, or code requirements. An analysis of a smoke control system is likely to include the consideration of a number of fire scenarios.

Smoke Transport Smoke can flow far from a fire and threaten life. The major driving forces that cause smoke movement are naturally occurring stack effect, buoyancy of combustion gases, expansion of combustion gases, wind effect, fan powered ventilation systems, and elevator piston effect.

Tenability Tenability calculations estimate the life hazard of a scenario. Tenability calculations address one or more of the following: exposure to toxic gases, exposure to heat, exposure to thermal radiation, and visibility through smoke. The exposures are time-integrated doses of toxic gases, heat, and thermal radiation. The conservative approach generally used for tenability systems is to make the tenability calculations as if an occupant were to remain at each location under consideration throughout the duration of the fire scenario.

Smoke Transport Calculations

Smoke transport analysis can be done with network models or computational fluid dynamic (CFD) models. Network models have already been discussed. The idea of a CFD model is to divide a space of interest into a large number of volumetric cells, and to solve the governing equations to calculate the flow, temperature, and concentrations of fire products at each cell.

The CFD models are appropriate for analysis of smoke flow in large spaces such as atria, malls, and arenas; and the network models are appropriate for analysis of smoke control systems that involve all or a large part of a large building. Fire dynamics simulator (FDS) is a CFD model that is in the public domain and was developed at the National Institute of Standards and Technology

(NIST) specifically for fire applications [26, 27]. FDS is available from NIST at no cost. FDS can calculate temperatures, concentrations of gases, and visibility; this is a significant aid in the tenability analysis.

Computer network models, such as CONTAM which is available in the public domain, were previously discussed for conventional smoke control systems, but they can also be used for smoke transport calculations. CONTAM has been used to analyze a number of tenability systems ([8, 22], Ferreira 2002; [17, 18]). CONTAM can simulate the transport of contaminants, including the products of combustion. However, CONTAM cannot simulate heat transfer, so it cannot calculate the temperatures. The user needs to supply the temperatures of spaces to CONTAM, and zone fire models have been used to generate such temperature information. The zone fire model, CFAST, has been used for this purpose [11, 31, 32]. CFAST is available from NIST at no cost.

Tenability Calculations

There are a number of models that can be used to evaluate exposure to smoke. For most smoke control applications when smoke is diluted to meet visibility criteria, exposure to it is not life threatening. The fractional effective dose (FED) model is the simplest model for evaluating exposure to smoke, and it can be used to check that smoke is not life threatening.

The FED can be used to obtain an approximate of the effects of exposure to toxic gases.

$$\text{FED} = \frac{\sum_{i=1}^{n} C_i \Delta t_i}{\text{LC}t_{50}} \qquad (50.18)$$

where

FED = fractional effective dose, dimensionless,
$C_{,i}$ = mass concentration of material burned at the end of time interval i, lb/ft^3 (g/m^3),
Δt_i = time interval i, min (min),
$\text{LC}t_{50}$ = lethal exposure dose from test data, lb ft^{-3} min (g m^{-3} min).
n = number of discrete concentration time pairs.

This equation is for uniform time intervals as calculated by computer models, and it evaluates the FED for the exposure time at the end of interval i (exposure time is $n\Delta t$). An FED greater than or equal to one indicates fatality. The concentration is in units mass of the material burned per unit volume. The lethal exposure dose, $\text{LC}t_{50}$, is the product of the LC_{50} and the exposure time. The LC_{50} is the concentration of airborne combustion products that is lethal to 50 % of the subjects exposed for a specified time. The mass concentration of material burned, C_i, can be obtained from the smoke transport calculations.

For any time interval, the visibility can be calculated from

$$S_i = \frac{K}{2.303 \delta_m C_i} \qquad (50.19)$$

where

S_i = visibility, ft (m),
K = proportionality constant,
δ_m = mass optical density, ft^2/lb (m^2/g),
C_i = mass concentration of fuel burned lb/ft^3 (g/m^3).

The proportionality constant, K, is 8 for illuminated signs and 3 for non-illuminated signs. For objects in reflected light (walls, hand rails, stairs, etc.), a value of $K = 3$ is normally used. Because C_i varies from location to location in fires, the visibility calculated from the above equation is considered to be the visibility at the point for which C_i is calculated. For example, if the calculated visibility was 20 ft (6.1 m), it would mean that a person could see 20 ft (6.1 m) through smoke where C_i was uniform.

Alternatively visibility can be calculated along a path through non-uniform smoke. There are many applications where non-uniform smoke happens such as smoke on a balcony in an atrium, smoke in a tunnel, and smoke in a hotel corridor. For example, Fig. 50.24 shows a person looking at an exit sign through non-uniform smoke. The smoke near the exit sign could exceed criteria for visibility at a point, but that does not mean that the person could not see the sign. Calculation of the visibility along the path between the person and the sign can evaluate if the sign can be seen.

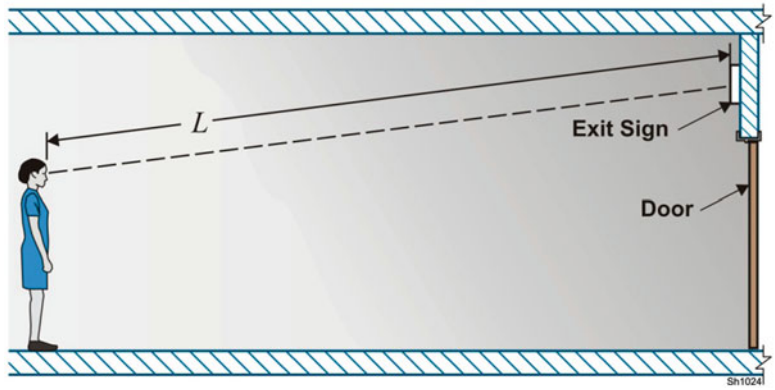

Fig. 50.24 Visibility through non-uniform smoke

Visibility along a path can also be calculated from percent obscuration as

$$S = -\frac{KL}{\log_e(1 - \lambda/100)} \tag{50.20}$$

where
S = visibility, ft (m),
K = proportionality constant,
L = length of path, ft (m),
λ = percent obscuration, dimensionless.

If the visibility is greater than or equal to the length of the path ($S > L$) an object can be seen over the path. When the path length is the same as the visibility ($L = S$), an object at the end of the path can barely be seen by a person with average eyesight. If the object were any farther away such a person could not see it. Percent obscuration, λ, can be calculated by FDS.

Generally, contact with dry air of temperatures greater than 250 °F (121 °C) can be expected to result in skin burns. Also, contact with dry air at a temperature less than approximately 250 °F (121 °C) leads to hyperthermia. For hyperthermia, heat exposure can be estimated from

$$F_{Ith} = \sum_{i=1}^{n} \frac{\Delta t}{\exp(5.67 - 0.0152T_i)}$$
$$F_{Ith} = \sum_{i=1}^{n} \frac{\Delta t}{\exp(5.185 - 0.0373T_i)} \quad \text{for SI} \tag{50.21}$$

where
F_{Ith} = total cumulative dose (dimensionless),
Δt = time interval, min (min),
T_i = temperature of air in interval i, °F (°C).

Incapacitation due to heat exposure would be expected for F_{Ith} greater than or equal to one. If contact with gases does not result in incapacitation due to heat exposure, thermal radiation from those gases would not result in incapacitation for the same exposure time. Generally, exposure to thermal radiation is not an issue for most smoke control applications.

Commissioning and Testing

Commissioning is the means to demonstrate to an owner and other project stakeholders that the installed smoke control system meets the smoke control system design for the project. Commissioning is the process for verifying and documenting that the performance of facilities, systems, and assemblies meets defined fire safety objectives and criteria. Commissioning refers to the process of examining, comparing, testing, and documenting the installation and performance of a smoke control system to ensure that it functions according to an approved design.

Special inspections are a means that an Authority Having Jurisdiction (AHJ) uses to determine that a smoke control system meets the applicable code requirements and regulations. The International Building Code (IBC) has requirements for a special inspection and describes the qualifications required for a special inspector (ICC 2012).

Commissioning Process

The commissioning process begins at the start of the project and continues throughout the project. ASHRAE Guideline 5 provides methods for verifying and documenting that the performance of smoke control systems conforms with respect to the intent of the design [2]. For smoke control systems, an AHJ such as a building official or fire marshal typically enforces a combination of building codes, fire codes, and local standards. The intent of the smoke control system commissioning testing is to determine that the system meets the Owner's Project Requirements (OPR), including code requirements and inspections by the AHJ throughout the delivery of the project

In order to achieve successful commissioning of a system, a number of different people will typically be involved in the process. In addition to the building owner and AHJ, the system designer, general contractor, subcontractors, fire protection engineering consultants, and test and balance technicians can be involved. At the end of the testing, documentation is provided that the system is working properly according to the design.

Commissioning activities can occur at multiple stages during the construction process. Duct inspections, duct leakage testing, and barrier inspections are activities that typically occur early in the construction process when the ducts and barriers are readily visible. Component testing, including air flow measurement, can occur at a mid-point in construction where power is provided to individual devices, but central monitoring and control has not yet been provided. Sequence of operations and final performance testing typically occurs when construction is nearly complete, often just before the building is intended to obtain its permits and open to the public.

Commissioning Testing

Commonly, testing and balancing is required before formal acceptance testing to achieve the expected performance of all the components. Testing and balancing refers to the process where the as-built performance of smoke control systems is tested in the field and compared to the required design conditions. Adjustments to the installed system, such as refining the supply airflow rates, are made to ensure that the smoke control system is functioning as intended in the approved design documentation.

System performance testing is the phase where the code-specified performance parameters appropriate to the smoke control design are measured. For example, building codes require that a minimum pressure difference exist between a pressurized stairwell and other zones in the building, and that door opening force must not exceed a specified amount. In this case, performance testing would focus on measuring the pressure difference across stairwell doors and door opening forces. Some common parameters measured during smoke control system performance testing are: (1) exhaust/supply airflow quantities, (2) airflow velocities at atrium or other large open space perimeters, (3) door-opening forces, and (4) pressure differences between zones.

Smoke Bomb Tests Not Recommended: Chemical smoke from smoke bombs (also called smoke candles) is not recommended for any performance testing because it lacks the buoyancy of hot smoke from a real building fire. Smoke near a flaming fire has a temperature in the range of 1000–2000 °F (540–1100 °C). Heating chemical smoke to such temperatures to emulate smoke from a real fire is not recommended unless precautions are taken to protect life and property

Periodic Testing

After a smoke control system has been commissioned, testing must still be performed periodically so that the system is in the proper operating condition in the event of a fire. Periodic testing needs to be performed over the life of a

building to determine that the installed smoke control systems are capable of operating as designed. Periodic testing includes: (1) manual testing involving ongoing inspection and maintenance and (2) automatic testing to determine that integral equipment is functional and operational. Automatic testing is often performed at a higher frequency than manual testing. Continued inspection and testing helps so that adjustments and repairs can be made to account for unforeseen changes to the building or failure of components.

Until recently, smoke control system reliability has been somewhat compromised because periodic testing was limited to manual testing. Inspections performed years after commissioning showed that some smoke control systems were inoperable, turned off, or made ineffective due to modifications to equipment or the building. It is expected that the reliability of smoke control systems will be significantly improved by the use of automatic weekly self-testing of system components, afforded by listed equipment carrying the appropriate product designations.

Nomenclature

A	Flow area, ft^2 (m^2); or door area, ft^2 (m^2),
a	Wind exponent at wall.
A_a	Free area around the elevator car, ft^2 (m^2),
A_{BO}	Flow area per stairwell between the building and the outside, ft^2 (m^2),
A_e	Effective flow area, ft^2 (m^2),
A_i	Flow area of path i, ft^2 (m^2).
A_{io}	Leakage area between the building and the outside, ft^2 (m^2).
A_{ir}	Leakage area between building and lobby, ft^2 (m^2),
a_{met}	Wind exponent in the vicinity of the wind anemometer, dimensionless,
A_s	Cross-sectional area of shaft, ft^2 (m^2),
A_{SB}	Flow area between the stairwell and the building, ft^2 (m^2),
A_{sr}	Leakage area between shaft and lobby, ft^2 (m^2),
C	Flow coefficient, dimensionless,
$C_{,i}$	Mass concentration of material burned at the end of time interval i, lb/ft^3 (g/m^3),
C_c	Flow coefficient for flow around car, dimensionless.
C_w	Pressure coefficient, dimensionless,
d	Distance from doorknob to knob side of door, ft (m),
F	Total door-opening force, lb (N),
F_{dc}	Door closer force, lb (N),
FED	Fractional effective dose, dimensionless,
F_{Ith}	Total cumulative dose (dimensionless),
F_R	Flow area factor (dimensionless),
g	Acceleration due to gravity, ft/s^2 (m/s^2),
H	Height of wall, ft (m),
H_m	Height limit, ft (m),
H_{met}	Height of wind measurement, ft (m),
K	Proportionality constant,
L	Length of path, ft (m),
LCt_{50}	Lethal exposure dose from test data, lb ft^{-3} min (g m^{-3} min).
m	Mass flow through the path, lb/s (kg/s),
m_{sv}	Mass flow through the path, scfm (standard m^3/s),
n	Number of discrete concentration time pairs.
p	Pressure, lb/in^2 (Pa),
p_{atm}	Absolute atmospheric pressure, lb/ft^2 (Pa),
p_w	Wind pressure, in H_2O (Pa),
R	Gas constant, 53.34 ft lbf/lbm/°R (287 J/kg K)
S	Visibility, ft (m),
T	Temperature, °F (°C).
T_B	Temperature in the building, °F (°C),
T_F	Temperature in the fire space, °F (°C),
T_i	Temperature of air in interval i, °F (°C).
T_{in}	Temperature of air entering the fire compartment, °F (°C).

T_O Temperature outside, °F (°C); temperature surroundings, °F (°C),
T_{out} Temperature of smoke leaving the fire compartment, °F (°C),
T_S Temperature in the shaft, °F (°C),
U Elevator car velocity, fpm (m/s),
U_H Velocity at the upwind wall of height H, mph (m/s),
U_{met} Measured velocity, mph (m/s),
V Volumetric flow through the path, cfm (m^3/s).
V_{in} Volumetric flow of air into the fire compartment, cfm (m^3/s),
V_{out} Volumetric flow of smoke out of the fire compartment, cfm (m^3/s),
W Door width, ft (m),
z Distance above the neutral plane, ft (m).
δ Boundary layer height at wall, ft (m),
ρ Density, lb/ft^3 (kg/m^3),
η Heat transfer factor (dimensionless).
λ Percent obscuration, dimensionless.
δ_m Mass optical density, ft^2/lb (m^2/g),
δ_{met} Boundary layer height in the vicinity of the wind anemometer, ft (m),
ρ_o Outside air density, lb/ft^3 (kg/m^3),
Δp Pressure difference, in. H_2O (Pa).
Δp_{max} Maximum design pressure difference, in. H_2O (Pa),
Δp_{min} Minimum design pressure difference, in. H_2O (Pa).
Δp_{SF} Pressure difference from a fire space to the surroundings, in. H_2O (Pa),
Δp_{SO} Pressure difference from a shaft to the outside, in. H_2O (Pa),
$\Delta p_{u,si}$ Upper limit pressure difference from the shaft to the building, in H_2O (Pa),
Δt Time interval, min (min),

Smoke Control by Mechanical Exhaust or Natural Venting

51

James A. Milke

Introduction

Smoke management in large-volume spaces, such as atria and covered malls, poses separate and distinct challenges from well-compartmented spaces. In particular, smoke control strategies using pressure differences and physical barriers described by Klote in Chap. 50, and NFPA 92, *Standard for Smoke-Control Systems* [1], are infeasible. Without physical barriers, smoke propagation is unimpeded, spreading easily throughout the entire space. The tall ceiling heights in many large-volume spaces pose additional challenges because of the production of substantial quantities of smoke and delayed detection times. However, on the positive side, the combination of large-volume space and tall ceiling height permit the smoke to become diluted and cooled as it spreads vertically and horizontally, thereby reducing the level of hazard posed by the smoke. Even so, there is still a need to ensure that dangerous concentrations of smoke are prevented in large-volume spaces.

In addition to atria and covered malls, there are many other examples of large-volume spaces, including convention centers, airport terminals, sports arenas, and warehouses where smoke management is of concern. The engineering principles governing the design of smoke control systems for all of these various large-volume spaces are the same. However, differences in the smoke control system designs for the variety of large-volume spaces may be found. Differences in designs are a result of differences in fire scenarios and design goals, reflecting the range of building uses and operations and the nature of who or what may be exposed to the smoke. Given the similarities in engineering principles affecting smoke control system design, the term *atrium* will be used throughout this chapter to refer to all types of large-volume spaces.

The discussion presented in this chapter is divided into two sections. First, conditions within the atrium prior to actuation of a smoke control system are discussed. As part of this discussion, the smoke filling process is described along with the time required for actuation of a smoke control system. The second part of the chapter includes a description of conditions within the atrium after actuation of the smoke control system.

As a preface to any discussion on smoke control systems, a definition of smoke must be established (NFPA 92, *Standard for Smoke Control Systems* [1], Section 3.3.13):

> The airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis or combustion, together with the quantity of air that is entrained or otherwise mixed into the mass.

Although only the combustion products are visible and potentially toxic, what is visually observed as smoke is a mixture of the combustion products and the entrained air. Air is

entrained along the entire height of the smoke plume below a smoke layer. Proportionally, the smoke is mostly entrained air. In the space between the base and tip of the flames, most of the entrained air is not consumed in the combustion process and only dilutes the combustion products. Entraining air into the smoke plume increases the mass flow in the plume to increase the quantity of smoke produced. However, the entrained air also dilutes the smoke to decrease the concentration of combustion gases and cool the smoke. In some cases, the smoke may be sufficiently diluted to mitigate the associated hazards.

Hazard Parameters

Smoke can adversely affect building occupants, fire brigade members, property (including the building structure and contents), and mission continuity. Typically, the threat to people or objects is posed when they come into contact with smoke for a sufficient period of time.

People who become exposed to smoke are generally harmed as a result of the exposure to toxic gases or elevated temperature. The toxic effects of smoke on people are described in Purser (see Chap. 63) and Klote et al. [2]. In addition, smoke may reduce visibility. A reduction of visibility may cause people to become disoriented and can in turn increase the amount of time they are exposed to the smoke [3]. A reduction of visibility may also increase the susceptibility of building occupants to trip over obstructions or even fall over balcony railings [4].

Building components can be affected by the elevated temperature due to smoke. Building components heated by smoke are considered in fire resistance analyses. In addition, building contents may be affected by exposure to the elevated temperatures, corrosive gases, or particulate matter. Contents exposed to heated smoke may be melted, distorted, or charred, depending on the temperature of the smoke and the degree of exposure. Contents that are submerged in smoke and come into contact with combustion gases and smoke particles may become stained or emit an odor of smoke. Exposure to smoke can damage electronic equipment, especially if restoration activities are not initiated promptly after the fire [5].

Following a fire, a building or portion thereof may be closed due to restoration, threatening mission continuity. This results in loss of revenue for the building owner, temporary unemployment of workers in the building, and loss of service of the facility to the community, among other outcomes.

Smoke Layer Interface Position

The smoke layer interface position is located a distance, z, above the top of the fuel, as indicated in Fig. 51.1. This parameter is used to assess the danger of people or objects being immersed in a smoke layer. Sole use of this parameter to assess hazard level is conservative by considering any concentration of smoke to be unacceptable. For people, even though the physiological effects due to being submerged in "light" smoke levels may be minor, the psychological effects and extended evacuation time may be appreciable. Being surrounded by smoke of any nature may decrease the speed of evacuation, perhaps until the smoke is no longer relatively benign. In terms of property protection issues, any smoke may be unacceptable because of smoke staining or smoke corrosivity.

Light Obscuration

As with the smoke layer depth parameter, light obscuration is not lethal by itself. Associated with an increase in light obscuration is a reduction in visibility, which is likely to yield a longer evacuation time and extend exposure to the toxins in smoke. In some documented fires, evacuation has been terminated due to a lack of sufficient visibility [6–8]. A fire fighter's injury in an atrium fire was attributed to a significant

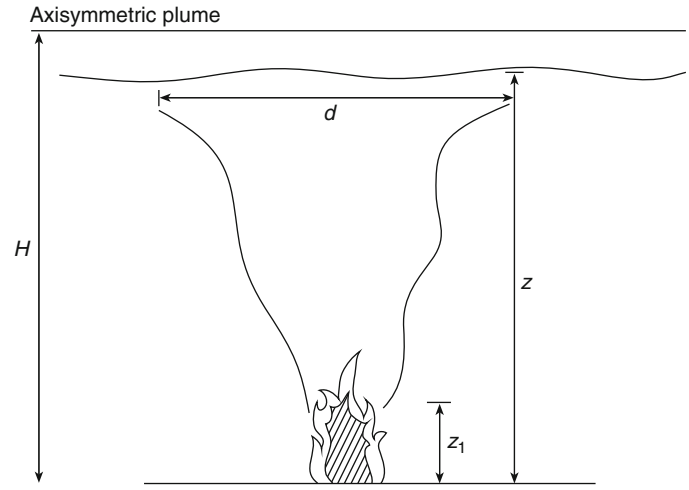

Fig. 51.1 Axisymmetric plume [1]

reduction in visibility due to light obscuration [4]. The fire fighter fell from an upper balcony because he could not see the edge.

Limiting values from 0.23 to 1.2 m^{-1} have been suggested for the extinction coefficient [6–8]. Alternatively, a critical limit may be based on a preferred minimum visibility distance to a particular target. For example, a limit of light obscuration can be suggested such that occupants can see an illuminated exit sign across a room or at the end of a corridor [3, 9].

Temperature and Gas Specie Concentration

The final two parameters, elevated temperature of the smoke layer and gas specie concentration (such as CO, CO_2, and HCN), can be directly related to the potential for harm (see Chap. 63). Critical limits for these two parameters can be suggested based on toxicity studies.

Smoke Management Approaches

The design of a smoke control system for an atrium is influenced by the following three characteristics of the atrium:

1. Geometric shape and dimensions
2. Relative location within the building
3. Separation from communicating spaces

Several approaches are available to achieve smoke management goals in an atrium (e.g., limit the fire size, provide physical barriers, and provide mechanical or natural ventilation). Selection of the best smoke management approach for a particular atrium should consider the use, size, and arrangement of the associated spaces.

Limiting the fire size can be accomplished by controlling the type, quantity, and arrangement of fuel. In addition, the fire size can be controlled through an automatic suppression system.

Physical barriers limit smoke spread to adjacent spaces. The ability of a physical barrier to limit smoke spread is dependent on the leakage of the barrier and pressure difference across the barrier. The barrier needs to withstand the exposure to smoke and an elevated temperature environment. In an atrium with a tall ceiling, the temperature of the smoke layer in the atrium may be only slightly above ambient temperatures in the space.

Mechanical or natural ventilation may be provided to remove smoke from the atrium. Removing smoke from the atrium can be intended to limit the accumulation of heat and smoke within the atrium or arrest the descent of the smoke layer. Mechanical ventilation can be provided to oppose smoke movement induced by the fire to restrict smoke spread to communicating

spaces. Gravity vents may be provided to remove smoke, though their performance can be compromised by environmental factors.

Analytical Approach

Numerous tools are available to aid in the design and evaluate the adequacy of a smoke control system. The selection of a particular tool is dependent on the accuracy needed for the analysis and the applicability of the analytical tools given the characteristics of the large space and selected fire scenarios. The principal characteristics that affect applicability are

- Geometry of the large space: variation of horizontal cross-sectional area, sloped versus flat ceiling
- Transient aspects: unsteady versus steady heat release rate, constant versus transient operation of smoke control system
- Fire development: heat release rate as a function of time (for example, constant, power-law relationship with time, t^n)
- Environmental effects: stack effect, wind
- Interacting systems: other smoke control systems, HVAC, other exhaust systems (for example in laboratories)

The range of design tools available to assess the performance of smoke control system designs can be grouped into the following categories:

- Zone model (algebraic equation based)
- Zone model (computer based)
- Field model
- Physical scale model

The intent of an engineering analysis of smoke conditions in an atrium is to express the level of hazard in terms of physically based parameters, for example, smoke layer interface position, temperature, gas concentration (such as carbon monoxide), and light obscuration. The magnitude of each of these parameters can be predicted based on engineering principles. In addition to being predictable, critical threshold values are available for the hazard parameters in order to properly assess the severity of the threat (See Chap. 63). This chapter will concentrate on the life hazards posed by smoke. The hazards smoke poses to contents, property, and mission continuity are described elsewhere [2–4, 10].

Physical Scale Models

Physical scale models provide a representation of a space, though in a reduced scale. Physical scale models are especially useful in examining atria with irregular shapes or numerous projections. A review of applying physical scale models as a design aid for atrium smoke control systems was provided by Milke and Klote [11].

Quintiere provided a review of scaling relationships based on preserving the Froude number [12]. The Froude number, Fr, is defined as v/gl.

The scaling relations are

Temperature:

$$T_m = T_F \tag{51.1}$$

Geometric position:

$$x_m = x_F \left(\frac{l_m}{l_F}\right) \tag{51.2}$$

Pressure:

$$\Delta p_m = \Delta p_F \left(\frac{l_m}{l_F}\right) \tag{51.3}$$

Velocity:

$$v_m = v_F \left(\frac{l_m}{l_F}\right)^{1/2} \tag{51.4}$$

Time:

$$t_m = t_F \left(\frac{l_m}{l_F}\right)^{1/2} \tag{51.5}$$

Convectiveheat release:

$$\dot{Q}_{c,m} = \dot{Q}_{c,f} \left(\frac{l_m}{l_F}\right)^{5/2} \tag{51.6}$$

Volumetric flow rate:

$$V_{\text{fan},m} = V_{\text{fan},F} \left(\frac{l_m}{l_F}\right)^{5/2} \tag{51.7}$$

Experiments based on Froude modeling may be done with air at atmospheric pressure. Froude modeling does not preserve the Reynolds number. However, appropriate selection of the size of the physical scale model can ensure that fully

developed flow is achieved to minimize the consequences of not preserving the Reynolds number. Because the smoke behavior in only certain areas of the scaled atrium may be of interest, fully developed flow only needs to be achieved in these particular areas. Often a physical scale model with a critical dimension of at least 0.3 m in any areas of interest will be sufficient to achieve fully developed, turbulent flow. As an example, in most shopping malls and atria, the critical dimension in question would be the floor-to-ceiling height of one of the balconies.

In addition, Froude modeling does not preserve the dimensionless parameters concerning heat transfer. Generally, this limitation has little effect because the temperature is the same for the physical scale model and the full-scale facility. Froude modeling does not apply to locations with high temperature and low Reynolds numbers (e.g., near the flame). However, Froude modeling provides useful information about smoke transport away from the fire.

Some surface effects can be preserved by scaling the thermal properties of the construction materials for the model. The thermal properties can be scaled by

Thermal properties:

$$\left(k\rho c_p\right)_{w,m} = \left(k\rho c_p\right)_{w,F}\left(\frac{l_m}{l_F}\right)^{0.9} \tag{51.8}$$

Because scaling thermal properties have only a secondary effect on fluid flow, considerations of convenient construction and flow visualization may require that some or all surface materials in the model are different from those selected based on thermal property scaling.

Example 1 A physical scale model is proposed to determine the equilibrium smoke layer position for the atrium depicted in Fig. 51.2. Because the horizontal cross-sectional area varies with height, algebraic equation and computer-based zone models are of limited value. The overall height of the atrium being studied is 30.5 m and the design fire is steady with a heat release rate of 5 MW. An exhaust fan capacity of 142 m^3/s is proposed. By applying the scaling relationships

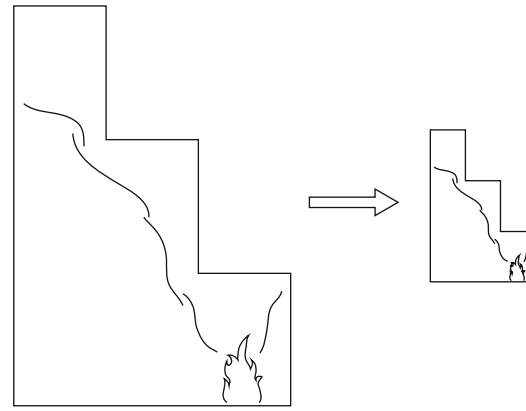

Fig. 51.2 Small-scale model of atrium

to formulate a small-scale model, the basic parameters for the scale model are

- Height: 3.8-m-tall model (1/8 scale)
- Fire size: 28 kW
- Fan capacity: 0.78 m^3/s

Analytical Models

Two categories of analytical models are zone and field models. A description of field models is outside the scope of this chapter. Zone models divide each compartment into a limited number of control volumes, typically an upper and a lower zone. Inherent in the zone approach is the assumption of uniform properties throughout each zone. In spaces with a large floor area, this assumption may be tenuous. Nonetheless, calculations associated with the zone model approach are relatively easy to perform and are often accepted for engineering purposes. Calculations following the zone model approach may be in the form of algebraic equations or a computer algorithm.

The zone model approach assumes that smoke from a fire is buoyant, rises to the ceiling, and forms a smoke layer. The buoyant nature of smoke is due to the decreased density of the heated smoke. As smoke rises in a plume, air is entrained to increase the mass flow rate in the plume. A decrease in the velocity and temperature of the smoke plume results from the increase in the plume mass flow rate, as dictated by

conservation of momentum and energy. In addition, the entrained air dilutes the combustion products in the plume. The entire smoke layer is assumed to have uniform characteristics. As smoke is supplied to the smoke layer from the plume, the interface between the smoke layer and lower clear air zone descends. The additional smoke supplied by the plume also results in an increase in the smoke layer temperature, carbon monoxide concentration, and light obscuration.

Being a simplification, the zone model approach may not be applicable in some situations. One example includes a scenario with operating sprinklers, which may cool the layer and also entrain smoke from the upper layer into the water spray pattern descending into the lower zone. Another example consists of the case where smoke does not reach the ceiling as a result of a loss of buoyancy, where the pre-fire temperature near the ceiling of the atrium is greater than that near the floor. This situation is discussed in more detail later in this chapter. A third situation involves an atrium with a large cross-sectional area where the horizontal variation in conditions from one portion of the atrium to another is important to the analyst. Where localized conditions associated with the smoke plume or smoke layer need to be assessed, field models are more appropriate than zone models.

Two categories of fire scenarios for smoke management design in atria include (1) fires located in the atrium, and (2) fires located in a space adjacent and open to the atrium. This chapter concentrates only on fires within the atrium space. Methods to estimate conditions in any of the adjacent spaces, resulting from fires originating in the atrium or from fires in other adjacent spaces, are addressed elsewhere [2].

Smoke Filling Period

A smoke layer is formed once the smoke plume reaches the ceiling and the ceiling jet spreads horizontally to reach the bounding walls of the space. Subsequently, the smoke layer starts to descend in the space. In relatively small spaces with low ceilings, the smoke layer forms almost immediately. However, in large spaces with tall ceilings, the time required to form a smoke layer may be appreciable. The delay in forming a layer is attributable to the transport lag of the smoke. The smoke filling period continues until the properly sized smoke exhaust fans are actuated.

Transport Lag

The transport lag is composed of the time for a smoke plume to reach the ceiling (plume transport lag) and the time for the ceiling jet to reach the bounding enclosure (ceiling jet transport lag). These two time periods are depicted in Fig. 51.3.

Correlations for the plume and ceiling jet transport lag are available in the literature for both steady and t^2 fires [13, 14]. Because virtually all fires have a growth period before reaching a steady phase, the transport lag correlations for steady fires have little relevance.

Correlations for the plume transport lag for steady and t^2-fires are
Steady files:

$$t_{pl} = 0.67H^{4/3}/\dot{Q}^{1/3} \tag{51.9}$$

t^2 fires:

$$t_{\mathrm{pl}} = 0.1H^{4/5}t_g^{2/5} \tag{51.10}$$

Estimates of the plume transport lag from Equations 51.9 and 51.10 are provided in Fig. 51.4. As indicated in the figure, even the shortest plume transport lag for t^2 fires, associated with the fast t^2 fire, is greater than that for a modest-size steady fire.

Comparable correlations for the ceiling jet transport lag for steady and t^2 fires are
Steady files:

$$t_{\mathrm{cj}} = \frac{r^{11/6}}{1.2\dot{Q}^{1/3}H^{1/2}} \tag{51.11}$$

t^2 fires:

$$t_{\mathrm{cj}} = \frac{0.72rt_g^{2/5}}{H^{1/5}} \tag{51.12}$$

A comparison of the ceiling jet transport lag for a modest-size steady fire and t^2 fires is

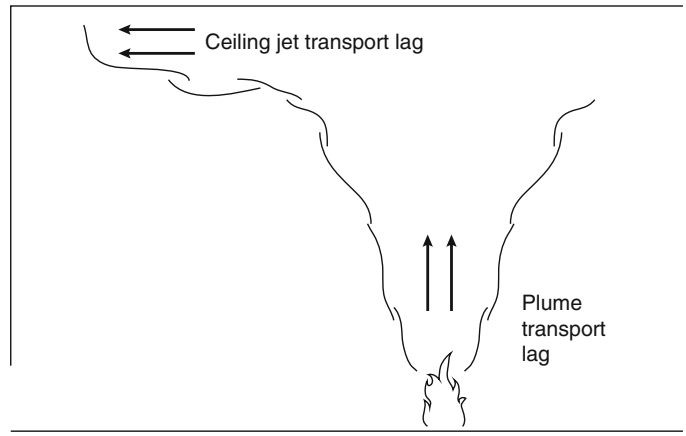

Fig. 51.3 Plume and ceiling jet transport lag

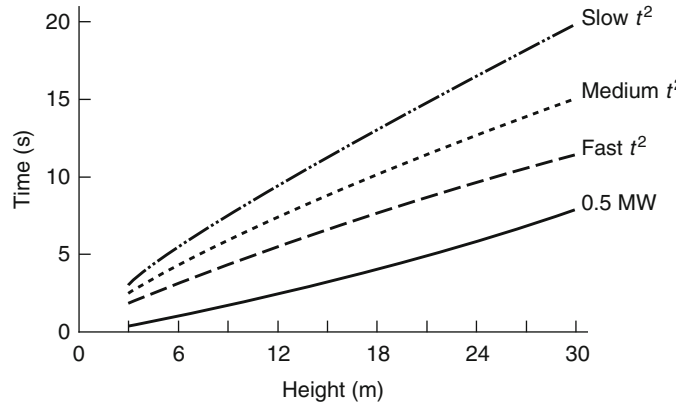

Fig. 51.4 Plume transport lag

presented in Fig. 51.5. Again, the transport lag associated with the steady fire is much less than that associated with any of the t^2 fires.

Many zone models do not account for transport lag. In low-height spaces with small compartments, this is likely to be inconsequential. In tall spaces with large cross-sectional horizontal areas, the lag may be important. In such cases, only models that incorporate transport lag are to be selected.

Smoke Layer Interface Position

Once the smoke layer has formed, the initial rate of descent of the layer is very rapid, slowing as the layer descends. This is attributable to the rate of smoke production being dependent on the height of the plume where entrainment occurs, i.e., the distance from the top of the fuel to the smoke layer.

Both empirical correlations and theoretically based methods are available to address conditions during the smoke filling period using a zone model approach [15]. Theoretically based methods use statements of conservation of mass and energy to determine the volume of the upper layer. Conservation of mass accounts for the smoke mass supplied from the plume to the smoke layer along with any smoke leaving the zone through ventilation openings. Conservation of energy is applied to address the energy being supplied by the plume along with heat losses from the layer.

Generally, the predicted smoke layer interface position determined by the two analytical

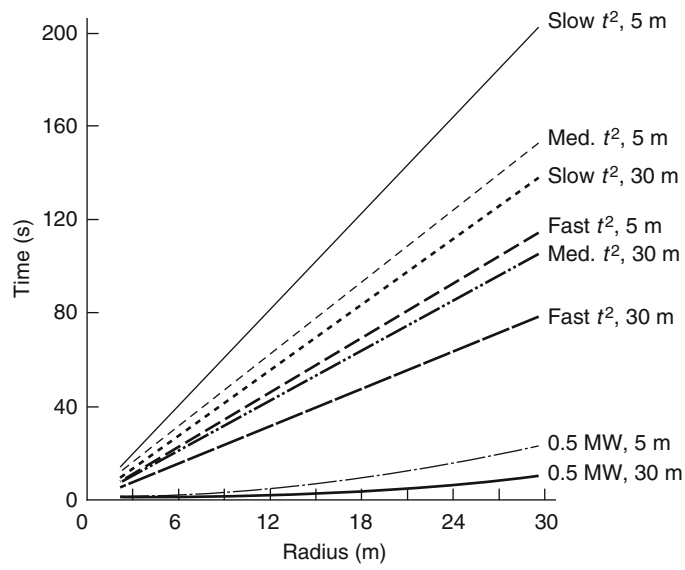

Fig. 51.5 Ceiling jet transport lag

methods differs. The smoke layer is comprised of the uppermost portion of the layer in which the conditions are relatively uniform at any elevation. Below that section is a transition zone, where the conditions decrease until they reach the bottom edge of the layer and are at their minimum value. The predictions from the empirical correlations relate to the position of the bottom edge of the transition zone as determined in an experimental program. In the theoretically based correlations, all of the smoke is considered to be in one layer with uniform properties. Combination of the transition zone and the upper portion into one uniform zone effectively results in the transition zone being compressed so as to have the same properties as the upper portion. As such, the theoretically based correlations relate to a thinner smoke layer than the empirical approach.

Empirical Correlations

Empirical correlations have been developed by Heskestad to determine the smoke layer interface position as a function of time for steady and t^2 fires. These correlations, included in NFPA 92 [1], are based on experimental data in large spaces. In the experimental efforts, the smoke layer interface position was established by a variety of means, including visual observations and measurements of temperature change, carbon dioxide concentration, or light obscuration.

The correlations are simple expressions with easily acquired input and minimal computations. The correlations provide conservative estimates of the smoke layer interface position (i.e., predicting the lower edge of the transition zone of the smoke layer which may include only 'wisps' of smoke) [16]. The correlations are applicable to simplified cases related to the fire and geometry of the space. Fire scenarios must be steady state or, if growing, follow a t^2 profile. The assumed geometrical configuration is a space of uniform cross-sectional area (i.e., rectangular or right cylindrical solids). In addition to the noted simplifications, second-order parameters such as environmental factors (e.g., stack effect, wind) and the effect of HVAC systems are neglected.

Steady Fires The position of the smoke layer interface for steady fires can be estimated using Equation 51.13 [16, 17]. Equation 51.13 is based on experimental data from fires in large-volume spaces with A/H^2 of 0.9–14 [18–20].

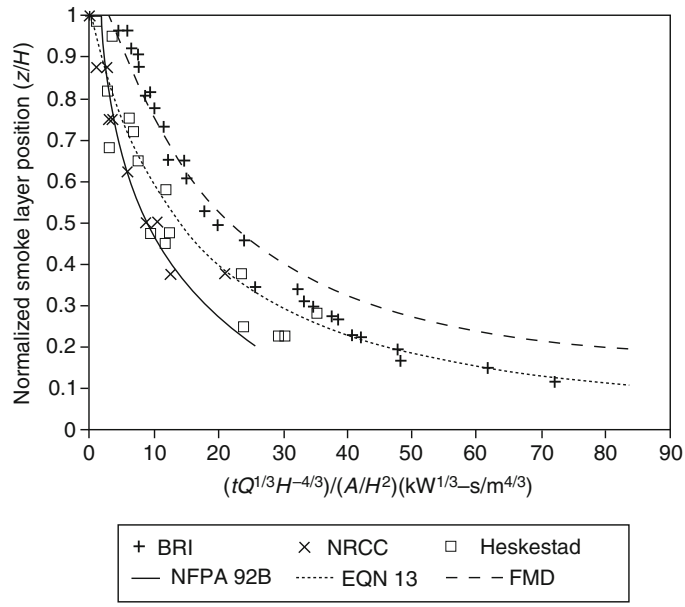

Fig. 51.6 Comparisons of smoke layer position—experimental data versus predictions

$$\frac{z}{H} = 1.11 - 0.28 \ln\left(\frac{t\dot{Q}^{1/3}H^{-4/3}}{A/H^2}\right) \qquad (51.13)$$

Where $z/H \geq 0.2$.

Equation 51.13 is presented in non-dimensional form. The quantity $t\dot{Q}^{1/3}H^{-4/3}$ represents the normalized time from ignition. The significance of the normalized time parameter is to indicate that the same relative smoke layer position occurs for a long duration, low heat release rate fire in a tall ceiling height atrium, as for a short duration, large fire in an atrium with a short ceiling height. Different atrium geometries are accounted for by the non-dimensional shape factor, (A/H^2) [18, 19].

The limits noted for A/H^2 reflect the range of shape factors for the facilities in which the experiments were performed [18, 19]. Examples of atria within the noted range include atria with a cross-sectional area of 10,000 m^2 and a height of 105 m ($A/H^2 = 0.9$) or a height of 27 m ($A/H^2 = 14$). Comparisons of the predictions from Equation 51.13 to experimental data from fires in tall spaces are provided in Fig. 51.6 [20–22].

Transport lag, or the initial time period to form a smoke layer, is implicitly included in Equation 51.13. Evidence of this characteristic is obtained for short time durations where the resulting z/H is greater than 1.0 (otherwise $z/H > 1$ would literally mean that the smoke layer interface is *above* the ceiling). The lower limit for z/H of 0.2 relates to the lowest level where data were taken in any of the referenced experiments.

t^2fires Equation 51.14 provides a correlation of the time-dependent smoke layer interface position for fires following a t^2-type profile [16]. Equation 51.14 is also based on experimental data in spaces with shape factors ranging from 0.9 to 14 [20, 23].

$$\frac{z}{H} = 0.91\left[tt_g^{-2/5}H^{-4/5}\left(A/H^2\right)^{-3/5}\right]^{-1.45} \qquad (51.14)$$

Equations 51.13 and 51.14 both assume that the fire is located near the center of the atrium floor, remote from any walls. Smoke production is greatest for the centered configuration and thereby represents the worst-case condition.

Example 2 For a fast, t^2 fire in an atrium with a cross-sectional area of 800 m^2 and height of 20 m, determine the position of the smoke layer interface after 120 s.

Solution Applying Equation 51.14 with $A/H^2 = 2.0$ and $t_g = 150$ s, z/H is 0.95 or $z = 19$ m.

Example 3 For a fast, t^2 fire in an atrium with a cross-sectional area of 800 m^2 and height of 20 m, determine the time for the smoke layer interface to reach 15 m above floor level.

Solution Re-expressing Equation 51.14 to solve for t,

$$t = 0.94 t_g^{2/5} H^{4/5} \left(A/H^2\right)^{3/5} (z/H)^{-0.69} \quad (51.15)$$

Applying Equation 51.15 with $A/H^2 = 2.0$ and $t_g = 150$ s, t is 140 s.

Reviewing the results from Examples 2 and 3, the smoke layer barely descends below the ceiling in the first 120 s. This is indicative of the lag time required for the plume to reach the ceiling and to form a layer. Then, after only another 20 s, the smoke layer descends 4 m, demonstrating the rapid initial descent rate of the smoke layer interface. The rapid descent is attributable to the significant quantity of smoke produced during the early stage of a fire in a tall ceiling space when the height available for entrainment is at its largest value. The predicted trend of rapid filling during the early stage of a fire has been reported by eye-witness accounts from four fires in atria [4, 24–26].

Theoretically Based Approach

Conservation of mass and energy can be applied to provide an estimate for the position of the theoretical smoke layer interface. Equation 51.16 expresses the conservation of mass, m_u, for the upper smoke layer, assuming no exhaust from the layer.

$$\frac{dm_u}{dt} = \dot{m} \quad (51.16)$$

Approximating the smoke as an ideal gas with properties of heated air, and assuming that the ambient pressure and specific heat are constant, the expression for conservation of energy for the smoke layer is

$$(\rho h)_u \frac{dV_u}{dt} = \dot{Q}_c + \dot{m} h_1 \quad (51.17)$$

Given the previously assumed conditions, ρh is a constant. Substituting the volumetric flow rate for the mass flow rate and simplifying,

$$\frac{dV_u}{dt} = \frac{\dot{Q}_c}{\rho h} + \dot{V} \quad (51.18)$$

The growth rate of the upper layer indicated in Equation 51.18 is dependent on two terms: (1) the volume supplied by the plume and (2) the expansion of the volume due to heating. For the case of an atrium with a constant cross-sectional area, A,

$$\frac{dV_u}{dt} = A \frac{dz_u}{dt} \quad (51.19)$$

As long as the smoke layer interface is well above the flaming region (see discussion later in this chapter), the plume mass entrainment rate can be estimated from [27].

$$\frac{dV_u}{dt} = \frac{\dot{m}}{\rho} = k_v \dot{Q}^{1/3} z^{5/3} \quad (51.20)$$

Several simplifications can be made for large clear heights (i.e., clear heights in excess of 10 m). The clear height is the distance from the top of the fuel to the bottom of the smoke layer. The magnitude of the second term is much less than the first. Generally, z is much greater than z_o. In addition, the volume increase of the upper layer supplied by the plume is appreciably greater than that due to expansion. With these simplifications and by substituting Equations 51.19 and 51.20 into Equation 51.18, an expression for dz_u/dt can be formulated

$$\frac{dz_u}{dt} = \frac{k_v \dot{Q} z^{5/3}}{A} \quad (51.21)$$

In Equation 51.21, k_v is the volumetric entrainment constant, defined as [36].

$$k_v = 0.076/\rho$$

The convective heat release fraction is the ratio of the convective heat release rate to the total heat release rate and is typically assumed

to be on the order of 0.7–0.8. Throughout this chapter, a value of 0.7 is selected for the convective heat release fraction [1]. Assuming a plume entrainment constant of 0.076 kg $kW^{-1/3} \cdot m^{-5/3} \cdot s^{-1}$ and the density of ambient air as 1.2 kg/m^3, the volumetric entrainment constant is 0.064 $m^{4/3}$ $kW^{-1/3}$ s^{-1}.

An expression for the smoke layer position resulting from a steady fire as a function of time can be obtained by integrating Equation 51.9:

$$\frac{z}{H} = \left[1 + \frac{2k_v t \dot{Q}^{1/3}}{3(A/H^2)H^{4/3}}\right]^{-3/2} \tag{51.22}$$

Alternatively, for a t^2 fire

$$\frac{z}{H} = \left[1 + \frac{4k_v t(t/t_g)^{2/3}}{(A/H^2)H^{4/3}}\right]^{-3/2} \tag{51.23}$$

A comparison of the predictions from Equations 51.13 and 51.22 is provided in Fig. 51.6. One principal difference relates to the time delay for the smoke layer to form, i.e., transport lag. Transport lag is included implicitly in Equation 51.13. Equation 51.22 assumes that a smoke layer forms immediately. The transport lag can be accounted for separately [13].

Example 4 For a fast, t^2 fire in an atrium with a cross-sectional area of 800 m^2 and height of 20 m, determine the position of the smoke layer interface after 120 s.

Solution Applying Equation 51.23 with $A/H^2 = 2.0$ and $t_g = 150$ s, z/H is 0.72 or $z = 14.4$ m.

Vented Period

If a smoke control system has the capability to exhaust smoke, the descent of the smoke layer can be arrested if the volumetric rate of smoke exhaust from the smoke layer equals the volumetric rate of smoke supplied to the layer. Neglecting the effect of expansion, the layer descent is stopped when the mass exhaust rate is equal to the mass entrainment rate by the plume. Algebraic equations are available to estimate the properties of the smoke layer, including

1. Position of smoke layer interface
2. Temperature of smoke layer
3. Light obscuration in smoke layer and
4. Gas concentration in smoke layer

Equilibrium Smoke Layer Interface Position

The exhaust rate necessary to arrest the descent of the smoke layer can be estimated based on knowledge of the mass entrainment rate into the plume. The mass entrainment rate depends on the configuration of the plume. Plume configurations reviewed in this chapter are

1. Axisymmetric plume
2. Wall plume
3. Corner plume
4. Balcony spill plume

Axisymmetric Plume Axisymmetric plumes are formed from fires involving fuel packages remote from any walls (i.e., near the center of the atrium floor). Being remote from any walls, air is entrained around all of the plume perimeter along the entire clear height of the plume. The functional relationship of the mass entrainment rate to the heat release rate and clear height is [28].

$$\dot{m} = f\left(\dot{Q}_c^{1/3} z^{5/3}\right) \tag{51.24}$$

One set of equations for the mass entrainment rate was originally derived by Heskestad [27]. One of the equations in the pair developed by Heskestad applies to estimating the entrainment in the flaming portion of the plume and another deals with the overall plume, including flaming portion and upper portion where flames are absent.

The limiting height is defined as the height of the continuous flaming region, (i.e., where flames are present 50 % of the time). The limiting height may be estimated as [27].

$$z_f = 0.166\dot{Q}_c^{2/5} \tag{51.25}$$

For clear heights less than the limiting height, i.e., where flames extend into the smoke layer, the entrainment rate is estimated using Equation 51.26

$$\dot{m} = 0.032\dot{Q}_c^{3/5} z \tag{51.26}$$

For clear heights greater than the limiting height, i.e., where the flaming region ends prior to reaching the smoke layer, the entrainment rate is estimated using Equation 51.27:

$$\dot{m} = 0.071\dot{Q}_c^{1/3} z^{5/3} + 0.0018\dot{Q}_c \tag{51.27}$$

Equation 51.27 is a simplified version of the original expression developed by Heskestad (see Chap. 13, with z_o from the original expression set equal to zero. The validity of neglecting z_o in Equation 51.27 is based on the observation that z_o is typically small, compared to z [2]. The location of the virtual origin of an assumed point source can be estimated as [27].

$$z_o = 0.083\dot{Q}^{2/5} - 1.02d_o \tag{51.28}$$

For noncircular fuels, an equivalent diameter needs to be defined. The definition of an equivalent diameter is based on a circle that has an area equal to the floor area covered by the fuel. Considering a wide range of diameters and heat release rates associated with a variety of typical fuel packages, the virtual origin ranges from 0.5 to −5 m. Negative values are obtained when the second term is greater than the first (i.e., for fuel commodities with modest heat release rates spread over a large area).

Originally, Equations 51.26 and 51.27 were developed to describe plumes from horizontal, circular flammable liquid pool fires. However, these equations have been shown to be applicable to more complex fuels, as long as the limiting height is greater than the diameter of the fuel, and the fire only involves the surface of the material (i.e., is not deep-seated) [27].

The mass rate of smoke production estimated by Equations 51.26 and 51.27 is independent of the type of materials involved in the fire, other than indirectly in terms of the heat release rate. This is due to the mass rate of entrained air being much greater than the mass rate of combustion products generated, which is true as long as sufficient air is available for combustion. As a result of the fire being approximated as a point source in the entrainment equations, the shape or form of the fuel is not of primary importance. Thus, the parameters associated with a detailed description of the fuel package are relegated to a level of secondary importance.

In both Equations 51.26 and 51.27, the mass entrainment rate is dependent on the clear height, where the mass entrainment rate increases with increasing values of the clear height. During the early stages of the fire, the clear height has its maximum value thereby providing the maximum smoke production rate. This is especially true if the flame height is well below the smoke layer, where the smoke production rate is proportional to $z^{5/3}$.

In most engineering applications, the smoke production (or exhaust) rate is expressed in terms of a volumetric rate rather than a mass rate. In order to accommodate this preference, the relationship between the volumetric rate and mass rate is expressed as Equation 51.29.

$$\dot{V} = \frac{\dot{m}}{\rho} \tag{51.29}$$

Assuming smoke to have the same properties as air, the density of smoke may be evaluated as the density of air at the temperature of the smoke layer [3]. Graphs relating the volumetric smoke production rate to the clear height for selected total heat release rates ranging from 1000 to 10,000 kW are provided in Fig. 51.7.

Example 5 A fire has a total heat release rate of 5000 kW and is located at the center of the atrium floor. The smoke layer interface is 35 m above the floor. Determine the mass and volumetric rates of smoke being supplied by the plume to the smoke layer (i.e., at the location of the smoke layer interface).

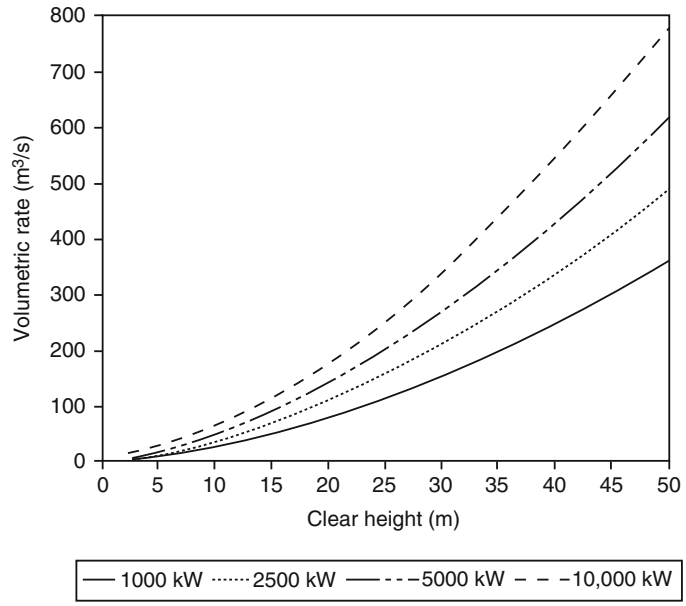

Fig. 51.7 Smoke production rate for axisymmetric plumes

Solution First, the limiting height is evaluated using Equation 51.25 to determine the applicable equation for the mass rate of entrainment, assuming the convective heat release fraction is 0.7, $z_f = 4.3$ m. Because z > z_f, Equation 51.27 is the applicable equation for determining the mass rate of smoke production. Neglecting z_o, the mass smoke production rate is 410 kg/s. The associated volumetric rate (from Equation 51.29, assuming 20 °C and 1 atm pressure) is 340 m^3/s.

Wall and Corner Plumes Fires located near walls and corners principally entrain air only along the surface of the plume away from the walls or corner. Consequently, the amount of smoke production is reduced for these locations, compared to the axisymmetric plume remotely located from the walls. Using the concept of reflection, the smoke production rate from wall and corner plumes can be estimated [29, 30].

A plume generated by a fire located against a wall only entrains air from approximately half of its perimeter, as indicated in Fig. 51.8. According to the concept of reflection, the smoke production rate is estimated as half of that from a fire that is twice as large (in terms of heat release rate) (note: having half of the entrainment does not cancel out the impact of considering twice the fire size as the entrainment is proportional to the one-third power of the heat release rate).

Similarly, a plume generated by a fire located near a corner of a room is referred to as a corner plume (see Fig. 51.8). Using the concept of a reflection, the smoke production rate from corner plumes, where the intersecting walls form a 90° angle, is estimated as one-quarter of that from a fire that is four times as large.

Example 6 A fire located on the floor of an atrium has a total heat release rate of 5000 kW. The smoke layer interface is 35 m above the floor. Compare the mass rates of smoke being supplied by the plume to the smoke layer, given an axisymmetric, wall, or corner plume configuration.

Solution In Example 5, $z_f = 4.3$ m and the smoke production rate for the axisymmetric plume using Equation 51.27 is 410 kg/s. Applying the same equation for the wall plume, the smoke production rate for a fire size of 10,000 kW is estimated as 520 kg/s. Dividing that rate by two provides the smoke production rate for the wall plume (260 kg/s). Similarly, for

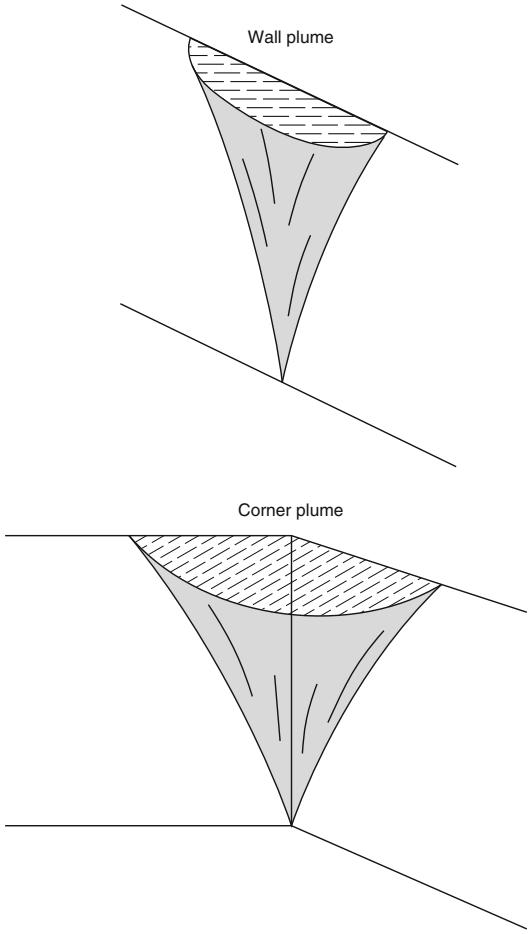

Fig. 51.8 Wall and corner plume diagrams

the case of the corner plume, the smoke production rate is 170 kg/s (considering one-quarter of the smoke production rate from a 20,000 kW fire).

Comparing the smoke production rates for the three plumes (axisymmetric, wall, and corner plumes), the smoke production rate is greatest for the axisymmetric plume (410 kg/s) compared to 260 and 170 kg/s for the wall and corner plumes, respectively. Thus, conservative hazard assessments should assume an axisymmetric plume is developed from a fire that is located away from the walls, near the center of the space.

Balcony Spill Plume A balcony spill plume is generated in cases where smoke reaches an intermediate obstruction, such as a balcony, travels horizontally under the obstruction, and then turns and rises vertically. Scenarios with balcony spill plumes involve smoke rising above a fire, reaching a ceiling, balcony, or other significant horizontal projection, then traveling horizontally toward the edge of the balcony. Characteristics of the resulting balcony spill plume depend on characteristics of the fire, width of the spill plume, and height of the ceiling above the fire. In addition, the path of horizontal travel from the plume centerline to the balcony edge is significant.

Several correlations on air entrainment into balcony spill plumes have been presented in the literature over several decades. A comprehensive review of the proposed correlations is provided by Harrison [31], Lougheed et al. [32] and Lim [33]. The correlations presented in NFPA 92 reflect the results obtained by Lougheed et al. from large-scale experiments and numerical simulations. One of the correlations in NFPA 92 has its roots back to Law's [34] interpretation of small-scale experimental data obtained by Morgan and Marshall [35]. This correlation is presented as:

$$\dot{m} = 0.36\left(\dot{Q}\dot{W}^2\right)^{1/3}(z_b + 0.25H) \qquad (51.30)$$

Lougheed et al. found that their large scale data was well described by this correlation for clear heights (z) in excess of 15 m. For lower heights, Lougheed et al. suggest the following correlation:

$$\dot{m} = 0.59\dot{Q}^{1/3}W^{1/5}(z_b + 0.17\dot{W}^{7/15}H + 10.35W^{7/15} - 15) \qquad (51.31)$$

The correlations presented in Equations 51.30 and 51.31, as well as others presented by numerous previous researchers, apply to balcony spill plumes of a specific configuration. The configuration considered is depicted in Fig. 51.9. As illustrated in the figure, the fire is located in a communicating space and the smoke flows under a soffit out from the room of fire origin, then under a short horizontal obstruction, i.e., balcony. The balcony is oriented perpendicular to the opening from the room. Any variations from

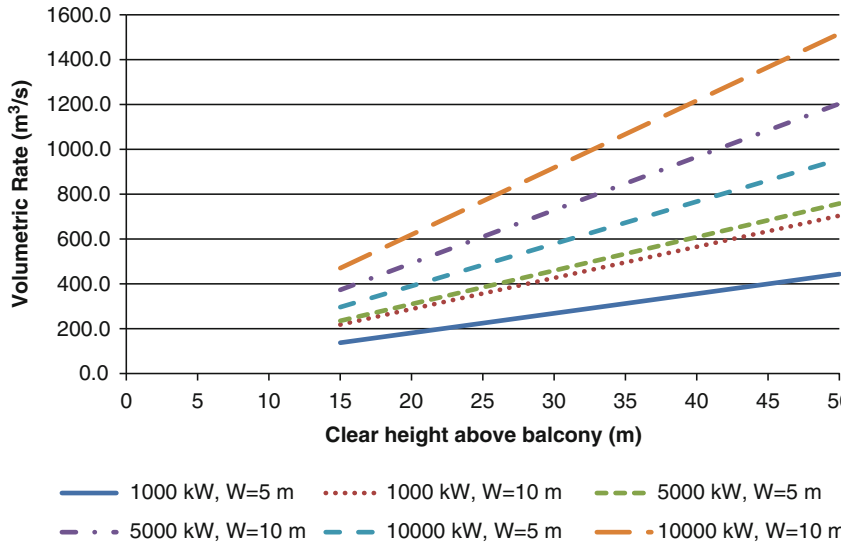

Fig. 51.9 Approximation of a balcony spill plume

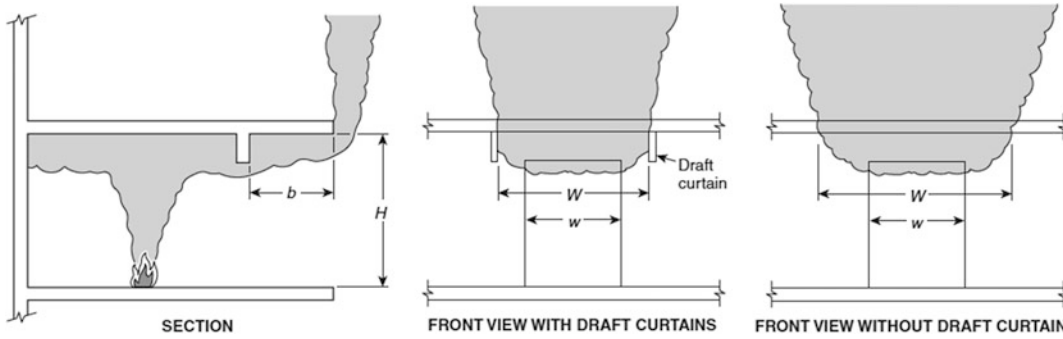

Fig. 51.10 Smoke production rate predictions for balcony spill plumes (H = 3 m)

this specific configuration have not been investigated and thus the balcony spill plume correlations presented as Equations 51.30 and 51.31 should not be applied for those situations. Instead, the application of CFD codes or small-scale models should be applied to assess those situations.

Predictions of the smoke production rate using Equation 51.30 for the balcony spill plume are included in Fig. 51.10. The calculations represented in the figure consider a 3-m height to the underside of the balcony.

A comparison of the smoke production rate for axisymmetric and balcony spill plumes is provided in Fig. 51.11. The results from both Equations 51.30 and 51.31 are depicted in Fig. 51.11 and are the reason for the points of inflection at a clear height of 15 m. The heat release rate for both fires is a steady state 5000 kW, and H is 3 m for the balcony spill plume. For short heights, the smoke production

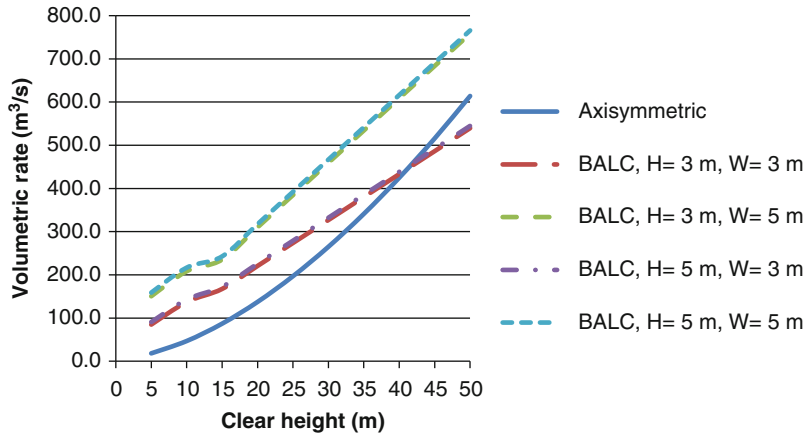

Fig. 51.11 Comparison of smoke production rate for axisymmetric and balcony spill plumes

rate for the balcony spill plume is appreciably greater than that for the axisymmetric plume. However, with increasing height, the smoke production rates from the two plumes become comparable. Eventually, the two curves intersect, suggesting that, at some height, the balcony spill plume behaves in the same manner (i.e., produces the same amount of smoke) as an axisymmetric plume. The point of intersection can be determined by setting the mass flow in Equation 51.27 equal to that in Equation 51.30.

The width of the plume, W, can be estimated by considering the presence of any physical vertical barriers attached to the balcony. The barriers act to restrict dispersion of the horizontal flow of smoke under the balcony. However, in the absence of any barriers, an equivalent width can be defined, based on results from visual observations of the width of the balcony spill plume at the balcony edge from the set of small-scale experiments by Morgan and Marshall [35]. The definition of an *equivalent confined plume width* is the width that entrains the same amount of air as an unconfined balcony spill plume. The equivalent width is evaluated using the following expression

$$L = w + b \tag{51.32}$$

Properties of Smoke Layer

Properties of the smoke layer are of interest both during the filling period of the fire and during the vented period. During the filling period, determination of the smoke layer properties is important to assess the level of hazard prior to actuation of a mechanical smoke control system. During the vented period, smoke layer properties are of interest to assess the level of hazard associated with those cases where occupants are exposed to smoke (i.e., the highest walking level is submerged in the smoke layer). The smoke layer properties of interest include temperature, light obscuration, and gas species concentration.

Temperature Rise in Smoke Layer The temperature of the smoke layer can be determined based on an energy balance for the volume of the smoke layer. Energy is supplied to the layer by the fire. Energy may be lost from the layer to the enclosure (walls, ceiling) of the space. During the filling period, the resulting expression is [1].

$$T = T_o \exp\left(\frac{(1-\chi_l)Q}{Q_o}\right) \tag{51.33}$$

Estimates for χ_l (heat loss fraction from the smoke to enclosure) vary appreciably. Some of the design guides suggest assuming that the smoke layer is adiabatic (i.e., setting $\chi_l = 0$), in order to be conservative [1]. Walton suggested values for χ_l between 0.6 and 0.9 for relatively small spaces of near cubic shape [36]. In many of the large spaces with tall ceiling heights, the temperature rise anticipated for the smoke layer is relatively modest such that convection and radiation heat transfer to an

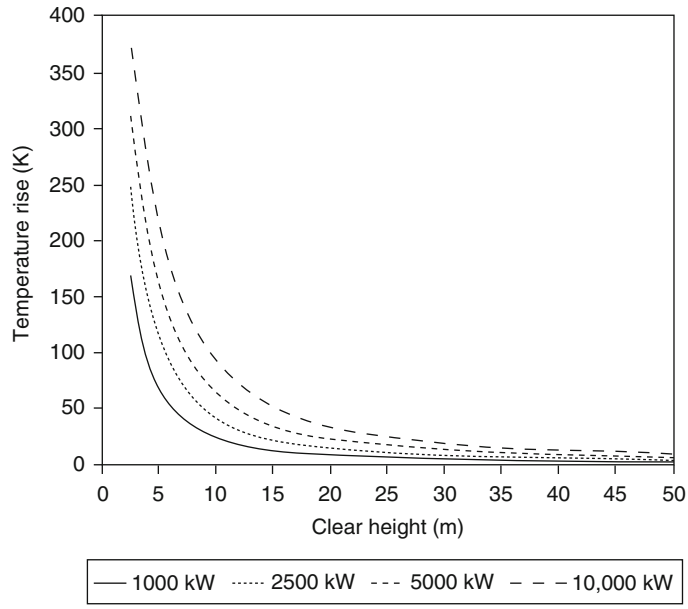

Fig. 51.12 Temperature rise of smoke layer for axisymmetric plumes

enclosure will also be modest. Consequently, in such applications, the adiabatic assumption will provide reasonable predictions of the temperature rise. However, in low ceiling spaces (under approximately 10 m) the temperature may be significantly overestimated by applying the adiabatic assumption.

Similarly, the equilibrium smoke layer temperature during venting can be approximated by applying an energy balance to the smoke layer. In this case, energy is also lost from the layer due to smoke being exhausted from the atrium. Equation 51.34 can be used to determine the temperature rise of the smoke layer under adiabatic conditions.

$$\Delta T = \frac{(1-\chi_l)\dot{Q}_c}{c_p \dot{m}} \tag{51.34}$$

If the adiabatic assumption is applied, the smoke layer temperature will be overestimated, providing a conservative estimate of the hazard. In reality, some heat is lost from the upper smoke layer to the surrounding walls and ceiling. However, no elementary method is available to estimate the overall proportion of heat that is lost to the surroundings [37, 38]. Some zone and field computer fire models account for heat losses to the boundary, thereby avoiding the need to specify the heat loss fraction [19, 39]. The adiabatic smoke layer temperature for a range of fire sizes is presented in Fig. 51.12.

The degree of overestimation can be assessed by comparing the estimated smoke layer temperature with the plume centerline temperature. For thermodynamic reasons, the smoke layer temperature cannot exceed the plume centerline temperature. The plume centerline temperature, T_c, can be evaluated using Equation 51.35 [40]

$$T_c = 0.08 T_o \dot{Q}_c^{2/3} z^{-5/3} + T_o \tag{51.35}$$

The volumetric venting rate for other heat release rates or temperature rises may be determined using Equation 51.36 considering that the specific heat is virtually constant for the expected temperature range of interest

$$\frac{\dot{Q}_{c_1}}{\dot{Q}_{c_2}} = \frac{V_1}{V_2}\frac{\Delta T_{\mathrm{ad}_1}}{T_{\mathrm{ad}_2}}\frac{T_2}{T_1} \tag{51.36}$$

As can be observed from Equation 51.36, doubling the volumetric venting rate for the same size fire reduces the temperature rise by approximately 50 % (the temperature rise is not precisely halved, since the absolute temperature of the smoke layer in both instances is not exactly the same).

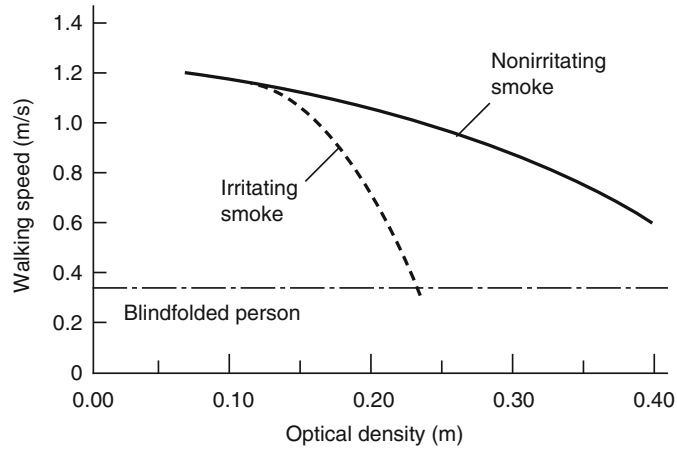

Fig. 51.13 Relationship between visibility through smoke and walking speed

Light Obscuration The visibility distance through smoke can be related to the optical density per unit pathlength via empirical correlations [41, 42]. The experimental basis for the correlations consists of tests with humans viewing objects through smoke. However, the participants were not directly exposed to the irritating effects of smoke. Consequently, the reported correlations are likely to overestimate the visibility distance.

In addition to the light obscuration quality of the smoke, the visibility of an object is dependent on the light source for the object being viewed as well as ambient lighting conditions [42, 43].

The optical density of the smoke layer can be determined considering that all of the particulates generated by the fire are transported to the layer via the plume and accumulate in the layer. Such an approach neglects any deposition of soot on enclosure surfaces, thereby overestimating the optical densities. The expressions for the smoke filling and vented periods are provided as Equations 51.37 and 51.38 [16].

$$\text{Smoke filling}: \quad D = \frac{D_m Q}{\chi_a H_c A (H - z)} \tag{51.37}$$

$$\text{Vented}: \quad D = \frac{D_m \dot{Q}}{\chi_c \Delta H_c \dot{m}/\rho} \tag{51.38}$$

The mass optical density is dependent on the fuel, burning mode, ventilation conditions, and operation of sprinklers. The mass optical density can vary by orders of magnitude for different ventilation conditions.

Although a reduction in visibility is not directly life-threatening, it does reduce the walking speed of individuals, thereby increasing the exposure time to toxic gases and elevated temperatures. In addition, the reduction in visibility may lead to an increased susceptibility to occupants tripping or falling. The relationship between visibility and movement speed is indicated in Fig. 51.13.

Carbon Monoxide Concentration The concentration of gas species contained in the smoke layer can be determined considering that all of the mass that is supplied to the layer via the plume accumulates in the layer. No absorption by the enclosure is assumed. The resulting expressions for the smoke filling and vented periods are [16].

$$\text{Smoke filling}: \quad \Upsilon_i = \frac{f_i Q}{\rho_o \chi_a H_c A (H - z)} \tag{51.39}$$

$$\text{Vented}: \quad \Upsilon_i = \frac{f_i Q}{\dot{m} \chi_a H_c} \tag{51.40}$$

In order to express the gas species concentration in units of ppm, Equation 51.41 needs to be applied

$$ppm_i = \frac{MW_{\text{air}}}{MW_i}\gamma_i \times 10^6 \qquad (51.41)$$

Input for evaluating the gas species concentration includes the yield fraction and heat of combustion, both of which are fuel dependent parameters. The yield fraction is dependent on the burning mode and oxygen concentration. Most of the information tabulated on the yield fraction, such as that by Khan (see Chap. 36), assumes well-ventilated, flaming combustion. Most of the fires of interest in large spaces will involve flaming combustion and are likely to be well ventilated. However, fires in small, connected spaces may become underventilated. Caution needs to be exercised in properly identifying ventilation conditions when predicting these parameters because the yield fraction can vary by orders of magnitude for different ventilation conditions. Also, the yield fractions noted by Tewarson are relevant only to cases where sprinklers are not operating [44].

Example 7 Estimate the steady-state smoke layer properties (temperature, visibility to an internally illuminated exit sign, and CO concentration) during the vented period, given the following situation:

1. The smoke layer interface is maintained 35 m above floor level.
2. The rate of heat release of the flaming fire is a steady state 5000 kW.
3. The fuel is comprised principally of polyurethane foam.

SOLUTION *Smoke Layer Temperature*
Equation 51.34 can be applied to determine the adiabatic smoke layer temperature rise. In Example 5, a mass rate of smoke production of 410 kg/s was determined. Thus, assuming an adiabatic smoke layer, a convective heat release rate fraction of 0.7 and specific heat of air of 1.0 kJ/kg·K, the temperature rise is 8.5 °C.

Visibility Visibility during the vented period is estimated using Equation 51.38. Fuel-related parameters are obtained in Chaps. 36, 24.

$$D_m = 260\ \text{m}^2/\text{kg}$$
$$H_c = 12,400\ \text{kJ/kg}$$

Considering smoke layer density, ρ, at the temperature of the smoke layer to be 1.17 kg/m^3, the optical density is 0.32 m^{-1} and the associated visibility is 8.5 m.

CO Concentration CO concentration for the vented period is estimated using Equations 51.40 and 51.41, with the fuel-related properties again evaluated from, Appendix C.

f_{CO} for polyurethane is ~ $0.030\text{kg}_{\text{co}}/\text{kg}_{\text{fuel}}$

The resulting CO concentration in the smoke layer is 31 ppm.

Comparison of Mechanical Exhaust and Natural Venting Designs

Design Aspects of Mechanical Venting Systems

Most smoke control systems for covered malls and atria in the United States use mechanical venting systems. Mechanical venting systems need to be designed to exhaust the amount of smoke needed to satisfy design objectives. The volumetric flow of smoke needs to be adjusted for temperature, using the methods discussed previously in this chapter.

Mechanical exhaust systems are relatively immune to environmental effects because the energy associated with the fan is able to provide a sufficient force for smoke movement and, thus, is not relying as much on the buoyancy of the smoke or stack effect. Protection from wind effects can be accommodated by hardware.

Response time is a principal limitation for mechanical exhaust systems. The response time is the sum of the time for detection and the time for the system to reach capacity (which may be up to a minute). This combined time may be longer than the time for the smoke layer to reach the critical height established by design goals. Also, because the capacity of a mechanical venting system is sized considering a particular

size of design fire (see Equations 51.26, 51.27, 51.30 and 51.31), if an actual fire has a greater heat release rate than considered in the design, the capacity of the mechanical exhaust will not be sufficient.

In addition, mechanical exhaust systems are susceptible to plugholing, a situation in which a hole is created in the smoke layer below the exhaust inlet by a high-capacity exhaust system. This results in a reduction in efficiency of the exhaust system because air from beneath the smoke layer is being extracted, thereby the desired quantity of smoke is not being extracted, causing the smoke layer to deepen. Plugholing is addressed later in this chapter.

The limitations of mechanical venting systems can be overcome in some cases by providing detection devices that minimize the time required for detection and by using several small capacity exhaust fans to avoid plugholing. However, despite these measures, it is still possible that design goals will not be able to be achieved by mechanical venting designs. Thus, the feasibility of such goals may need to be evaluated. Alternative smoke management approaches may be sought, for example, providing physical barriers at upper levels to reduce the required clear height or considering opposed airflow at openings above the design smoke layer interface position.

Design Aspects of Natural Venting Systems

Natural venting removes smoke by taking advantage of the buoyancy of the smoke. In the United States, natural venting systems are primarily found only in facilities such as industrial or warehouse structures. Outside of the United States, natural venting is often utilized in many applications.

The key advantages of natural venting systems are the self-correcting aspect of the vents in case the design fire is inappropriately defined and the simplicity of the operation of natural vents. These advantages will be described as part of the continuing discussion in this section.

The engineering principles that apply to vent operation addressed in this section consider the scenarios depicted in Fig. 51.14. Because smoke filling along the underside of the ceiling in a curtained area is similar to that in a compartment, additional information on compartment fire scenarios is presented in Chap. 33. If the draft curtains are deep enough, they can be thought of as simulating the walls of a single compartment.

The description of engineering principles of natural vents will be provided from the perspective of a two-layer zone model. The overall building compartment is assumed to have near-floor inlet vents that are large enough to maintain the area below the smoke layer at outside-ambient conditions. The upper smoke-layer thickness will change with time, but at any instant it is assumed to be uniform in space, with absolute temperature, T, and density, ρ.

Mass and energy are transferred continuously to and from the upper and lower layers. Conservation of energy and mass along with the Ideal Gas Law is applied to the layers, which leads to equations that require estimates of components of heat transfer, enthalpy flow, and mass flow to the layers. Qualitative and some key quantitative features of these phenomena are described and presented below. The reader is referred to Chap. 15, for a general discussion on the topic of flow through vents. Considering a vent in a wall or ceiling, flow is driven through such a vent mainly by cross-vent hydrostatic pressure differences from the high- to the low-pressure side of the vent. The traditional means of calculating vent-flow rates is by using an orifice-type flow calculation.

Assuming relatively quiescent conditions in the areas on both sides of the vent, the pressure in each space can be described as the hydrostatic pressure. The mass flow through a vent is derived from Bernoulli's equation, where the buoyancy pressure is related to the dynamic pressure at the vent:

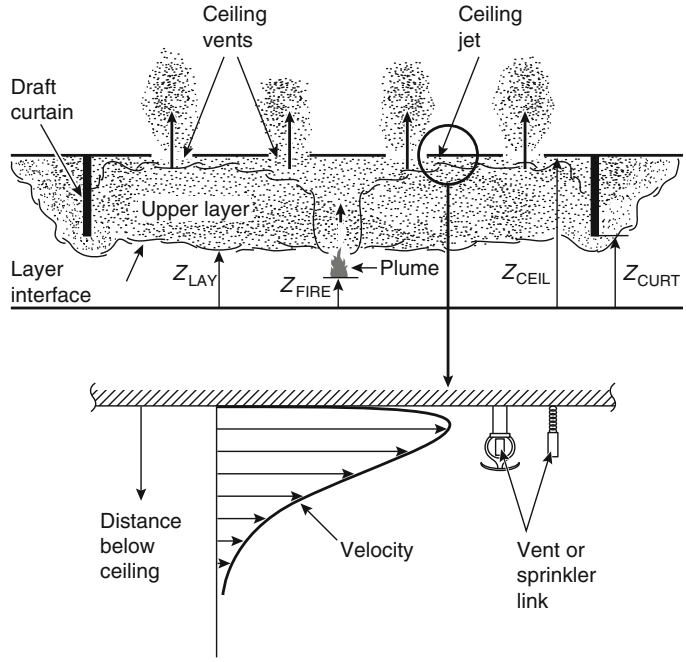

Fig. 51.14 Fire in a building space with draft curtains and ceiling vents

$$\frac{1}{2}\rho_o \mu^2 = \Delta\rho g d \qquad (51.42)$$

where
ρ = Density of smoke (kg/m^3)
ρ_o = Density of ambient air (kg/m^3)
$\Delta\rho = \rho_o - \rho$ (kg/m^3)

Relating the mass flow through the vent to the velocity of the gases

$$\dot{m} = \rho A_v u \qquad (51.43)$$

where
$\dot{m}$ = Mass flow rate through vent (kg/s)
A_v = Flow area of vent (m^2)

Replacing the densities with temperatures using the ideal gas law:

$$\dot{m} = \left(2\rho_o^2 g\right)^{1/2} \left(\frac{T_o \Delta T}{T}\right)^{1/2} A_v d^{1/2} \qquad (51.44)$$

As indicated in Equations 51.42–51.44, the capacity of natural vents is related to the pressure difference caused by the buoyancy of the smoke layer. As such, the flow rate of smoke through the vent increases with increasing smoke-layer temperature and depth.

$$\dot{m} = \left(2\rho_o^2 g\right)^{1/2} \left(\frac{T_o \Delta T}{T^2}\right)^{1/2} \frac{A_v d^{1/2}}{\sqrt{1 + \frac{C_{d,v}^2 A_v^2 T_o}{C_{d,i}^2 A_i^2 T_o}}} \qquad (51.45)$$

For vents installed in sloping roofs, the design position of the smoke layer should be at least below the bottom of the vent. To ensure that only smoke is exhausted from that vent and not any air from below the layer, the smoke layer position should be at least 10 % of the vertical distance from the top of the vent (Fig. 51.15). Then the distances d and z (recall that clear height is imbedded in the consideration of $\dot{m}$) are measured from the center of the vent.

Makeup Air Supply The effect of the inlet area on the flow rate through the vent can be assessed by recognizing that the pressure drop across the inlets associated with the inflow of replacement air must be subtracted from the buoyancy pressure causing the gases to flow through the vents. The effect of inlet pressure may be included in Equation 51.45 by replacing A_v by an effective vent area $\left(A_v^*\right)$ where

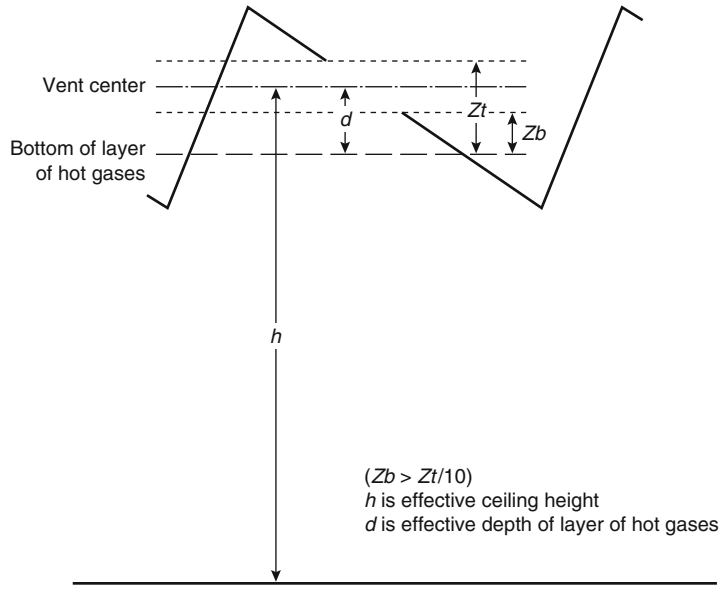

Fig. 51.15 Design position of gas layer versus vent

$$\frac{1}{A_v^{*2}} = \frac{1}{A_v^2} + \frac{1}{A_i^2}\left(\frac{T_o}{T}\right) \tag{51.46}$$

As such, the ratio of the actual vent area to the effective vent area, K, is given as

$$K = \frac{A_v}{A_v^*} = \left[1 + \left(\frac{A_v}{A_i}\right)^2 \frac{T}{T_o}\right]^{1/2} \tag{51.47}$$

The effect of vent ratio (ratio of outlet to inlet areas) on the effectiveness of natural venting is presented in Fig. 51.16 with a design fire of 2.5 MW and a ceiling height of 15 m. As indicated in the figure, with a vent ratio of 0 (having infinite inlet area), the clear height is slightly greater than when the outlet to inlet areas are equal. Thus, as with mechanical systems, the inlet area is an important consideration.

One of the principal advantages of natural venting systems is the relative insensitivity of the equilibrium smoke-layer position with the fire size, as indicated in Fig. 51.15. The graphs in Fig. 51.17 indicate that for two different ceiling heights (15 and 30 m), the equilibrium smoke-layer temperature is virtually identical for the two significantly different fire sizes. This similarity is due to the bigger fire size producing a smoke layer with a greater temperature. The hotter smoke will be more buoyant, thereby increasing the buoyancy force at the vent leading to an increase in the mass flow rate through the vent to reduce the amount of smoke accumulating under the ceiling.

The ability of a vent to perform similarly for two different fire sizes is a significant benefit of natural vents. Unlike mechanical exhaust, for natural vents if an error is made such that an actual fire is greater than the defined "design fire," the natural vents should still able to provide near-satisfactory performance.

Limitations The limitations of natural venting systems are related to the forces affecting smoke movement: principally a lack of buoyancy and wind effects. The smoke must be buoyant relative to the ambient environment in order for natural venting systems to be effective. Smoke may lose its buoyancy either due to cooling from sprinkler operation or dilution from entrained, cool air. Because the mass flow is strongly dependent on the difference in the smoke-layer temperature and outdoor temperature, if the smoke-layer temperature rise is only slightly different than the ambient temperature, then the flow from a vent will also be modest. As such, in tall spaces with relatively small fire sizes, the

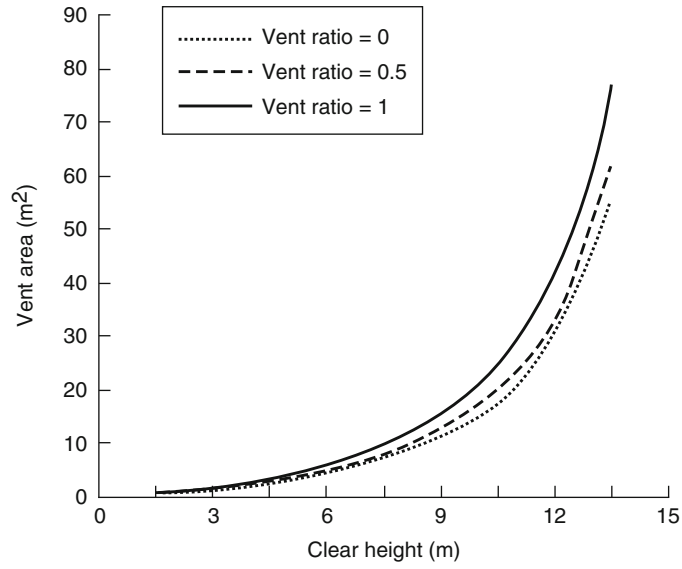

Fig. 51.16 Effect of vent ratio on natural venting

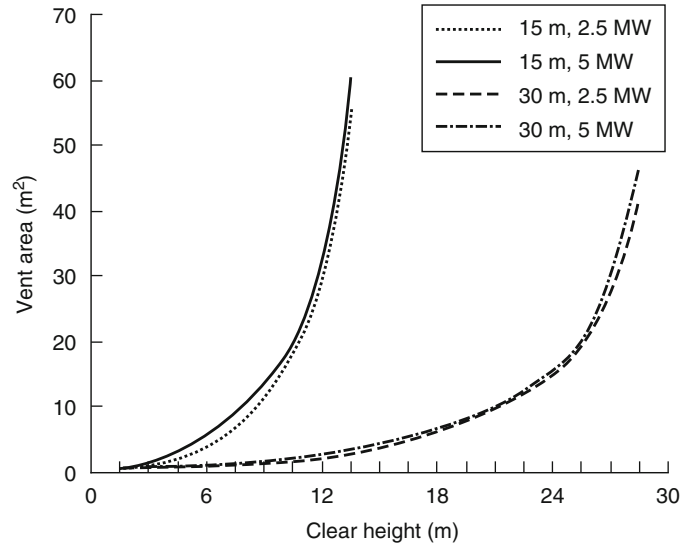

Fig. 51.17 Effect of vent ratio on natural venting for two ceiling heights (15, 30 m) and fire sizes (2.5 MW, 5 MW)

modest capacity of natural vents may constrain the ability to achieve design objectives, necessitating that mechanical ventilation be used.

To consider the effect of outside wind conditions, pressures on the outside of the building in the vicinity of the vent need to be assessed. The pressure on the building depends on the wind speed at the elevation of the vent, wind direction relative to the outside building geometry, and proximity and geometry of neighboring buildings. Wind effects on buildings are addressed in Klote et al. [2].

If the building vents are open and if vent areas are relatively small compared to the building surface area, then pressures near the vent openings will be substantially unchanged from the above-mentioned, closed-vent pressure distribution, except near any local through-vent flows that may develop. Also, although the

exterior pressures generally vary from vent to vent, they will be relatively uniform for any particular vent. Under these conditions, a determination of flow rates into and/or out of vents and through the interior of the building is based on an interior building flow analysis, with pressure-specified boundary conditions at the open vents.

A Single, Open Inlet Vent or Multiple Openings at the Same Pressure If there is only one open inlet vent on the upwind side of the building that experiences a relatively high pressure differential above the local hydrostatic pressure or if there are several open vents, all at locations on the outside surface of the building where pressures are substantially identical, then, the wind will have no effect on the inflow or outflow through the vents. Thus, if the air inside the building is uniformly at the outside air temperature and if there is no mechanical ventilation, then the effect of the wind will be simply to bring the interior hydrostatic pressure at the location of the vent(s) to the aerodynamic-flow-specified value; the interior of the building will be "pressurized" as a result of the open vent(s), but there will be no wind-induced interior flows. If there is a fire in the room with the open vent (e.g., the vent is a broken window), then, in the usual way, there will be fresh air inflow into the room toward the bottom of the vent and buoyant smoke outflow toward the top of the vent, all this taking place at an aerodynamic-flow-specified, elevated hydrostatic pressure within the room.

If the open vent is in a side of the building with a negative wind coefficient (e.g., facing downwind or on roofs near the upwind side), the pressure at the vent will be relatively low, and the local hydrostatic pressure will be *reduced* by an amount only on the order of $\rho_o u^2/2$. Again, no wind-induced flow at the vent is expected.

Two Inlet Vents, One on the Upwind Side and One on the Downwind Side of the Building If there are two inlet vents in the walls of the building, one upwind and one downwind (ignoring heating and mechanical ventilation), then there *will* be wind-induced flow through the vents and within the building. Inlet air will be provided at the high-pressure upwind vent and outlet air at the low-pressure downwind vent, with levels of through-vent flows and of interior hydrostatic pressures determined by an appropriate analysis that accounts for conservation of momentum (i.e., Bernoulli's equation) and mass at the exterior vents and at room-to-room vents within the interior of the building. The changes in hydrostatic pressures within the rooms of the building, over and above the hydrostatic pressures that would be present in a quiescent environment, would be somewhere between the wind-induced pressures at the locations of the high-pressure vent and the low-pressure vent.

Wind-Modified Pressures at Roof Surfaces and Wind-Modified Action of Ceiling Vents Roof surfaces of flat-roofed buildings tend to have negative, wind-induced pressure coefficients, unless the buildings are very long in a direction parallel with the wind direction. Sloping roofs may have pressure coefficients that can be positive or negative, depending on wind direction. Therefore, if the interior, wind-induced hydrostatic pressures are greater than those associated with a quiescent environment (e.g., the result of open vents in the upwind side of the building), then the flow of smoke through ceiling vents can be enhanced significantly by virtue of increased, favorable, cross-vent pressures. However, for reduced interior pressures (e.g., as a result of open vents on the downwind side of the building), the effect of wind conditions can substantially disrupt the desired smoke-removing action of ceiling vents, even reducing the *direction* of the cross-vent pressures and, as a result, the direction of the flow through the vents (i.e., making the flow travel from the outside to the inside).

Thermal Activation of Vents

Convective heating and thermal response of near-ceiling-deployed fusible links or other near-ceiling thermal sensor devices (including thermoplastic vent covers designed to soften

and "drop out" at specified actuation design temperatures) are determined from the local time-dependent distributions of ceiling jet velocity and temperature. These distributions will depend on vertical distance below the ceiling and radial distance from the fire-plume axis. Once the operating temperature of the thermal element is reached, the device or devices operated by the element will be actuated. Characteristics of ceiling jets are described in Chap. 14.

The mathematical fire model LAVENT (fusible-*L*ink-*A*ctuated *VENT*s) [22–24] was developed and is available to simulate most of the phenomena described above. The LAVENT model can be used to simulate on a time-dependent basis and to study parametrically a wide range of scenarios with natural vents. Full documentation for LAVENT, including its theoretical basis [22], a user guide for the computer code [23], and sample problems using the code are included in Annexes B, C, and D of NFPA 204 [45]. In its current form, LAVENT does not account for wind effects, the reduced effectiveness of vents as a result of limited-area inlet vents, or the presence of mechanical systems [22]. Input data on the thermal response characteristics of the link will be needed for such an analysis. The use of LAVENT has not been validated for estimating the response of "drop out" vents.

Sprinklers and Vents

Vents and sprinklers provide different fire safety benefits. The level of fire safety in a facility would be enhanced if both sets of benefits could be achieved systematically. However, simply providing the two technologies following design rules independent of each other will not necessarily lead to a combination of their respective benefits. Potential problems may occur as a result of the interaction of the two technologies (i.e., operation of the smoke and heat vents can modify sprinkler performance and the operation of the sprinklers can modify smoke and heat vent performance). As an example of the latter, consider the case in which water spray from a sprinkler system cools the smoke, thereby reducing the buoyancy of the smoke. The reduced buoyancy reduces the mass flow rate through a vent, thereby resulting in a deeper smoke layer. However, the sprinkler discharge can also dramatically reduce the fire size resulting in a decreased production of smoke.

Numerous research projects have been conducted to address the interaction between vents and sprinklers (see Annex A of NFPA 204 and Beyler and Cooper [46] for a thorough review of the previous research). The previous projects have sought to demonstrate the level of impact that one system has on the other's performance, either by indicating that it is always significant, always insignificant, or significant only if a particular set of conditions is provided. Projects have also attempted to identify design changes necessary if both systems are present (i.e., perhaps larger vent sizes could be installed in sprinklered buildings to counteract the reduced mass flow of cooled smoke). To date, none of the previous projects have been able to provide the conclusive results that provide definitive information illustrating the degree of influence that one system has on the other for all situations.

Past Studies of Combined Vent/Sprinkler Systems A review of 34 papers evaluated the validity of generic claims and counterclaims on the benefits of combined vent/sprinkler systems [46]. A listing of these claims and counterclaims and a summary of conclusions on their validity follow.

Claims and Counterclaims [46] In the literature, claims that have been made in favor of vent/sprinkler systems can be reduced to the following three:

1. Smoke and heat vents limit the distribution of products of combustion in the facility whether deployed sprinklers are operative or inoperative.
2. Smoke and heat vents decrease the number of activated sprinklers.

3. Smoke and heat vents assist the fire department in identifying the location of the fire within the facility and in reducing the need for manual roof venting.

In the literature, claims that have been made *against* vent/sprinkler systems can be reduced to the following four:

1. Smoke and heat vents cause enhanced burning rates.
2. Smoke and heat vents delay sprinkler activation.
3. Smoke and heat vents increase the number of activated sprinklers.
4. Smoke and heat vent flow rates are insufficient to realize any benefit.

Validity of Claims for and Against Combined Vent/Sprinkler Systems After evaluating reports of studies of combined vent/sprinkler systems, Beyler and Cooper [46] came to the following conclusions:

- Venting does not have a negative effect on sprinkler performance.
- If a fire is directly beneath a vent, activation of the first sprinklers may be delayed slightly, but there is no evidence that this delay will have a significant impact on overall sprinkler performance.
- Venting does limit the spread of smoke by removing smoke from the building near the source of the fire (within the curtained compartment of fire origin), improving visibility for building occupants while evacuating and for fire fighters during fire control operations.
- By limiting the spread of smoke and heat, venting reduces smoke and heat damage to the building.
- In the event that sprinklers do not operate, venting remains a valuable aid in controlling the fire manually.
- In many fires, current vent design practices, for example, those of NFPA 204 [45], are likely to limit the number of vents operated to one and, in successful sprinkler operations, vents may not operate at all.
- Design practices should use methods that ensure early operation of vents; vent operation should be ganged so that the benefit of roof vents is fully realized.
- When deployed with vents and draft curtains, a sprinkler design needs to take full account of draft curtains as obstructions to ceiling jet flows and sprinkler discharge.
- Draft curtains should be placed in aisles rather than over storage.

Considerations for the Design of Combined Vent/Sprinkler Systems Taking Beyler and Cooper's conclusions into account and drawing on current knowledge of basic physical phenomena involved in vent/sprinkler interactions, the design of combined sprinkler/vent systems should seek to satisfy the following general criteria:

1. A successful vent design, whether deployed with or without sprinklers, is one that leads to the benefits of improved visibility and safety during a fire by limiting the descent of the upper smoke layer to a specified height (i.e., eye level of occupants and fire fighters).
2. When draft-curtain compartmentation is included in the vent design, a significant additional possible benefit results from the smoke being contained within the curtained compartment of fire origin by action of the venting.

Interaction of Sprinkler Spray and Smoke Layer The action of sprinkler sprays on a smoke layer includes a combination of evaporative cooling and dilution of the smoke. Dilution occurs due to entrainment of the relatively cool and uncontaminated lower-layer gases and the upper layer by the spray [47–59]. Provided the sprinkler spray–reduced smoke temperature and associated loss of buoyancy are not too great, the effect of evaporative cooling of the smoke, even if accompanied by moderate sprinkler spray–driven mixing, could be offset by additional vent capacity. However, even without significant evaporative cooling, sprinkler spray–driven mixing action can be so significant that it leads to a precipitous increase in the volume of smoke and thus a deeper smoke-layer. If and when the latter vigorous mixing occurs, then even impractically large increases in vent capacity are unlikely to lead to any significant

improvement. The latter phenomenon is commonly referred to as *smoke logging*. As such, a vent design that is developed to meet the above general criteria must be based on an analysis that accounts for and avoids the phenomena of smoke logging.

There is experimental evidence that smoke logging can be controlled by venting [60], and a preliminary analysis to explain the phenomenon has been provided [47, 48]. Thus, it has been reported that "preliminary tests in [a] . . . large-scale mall . . . showed that, under some conditions, [a] . . . smoke layer could be brought down by a manually operated sprinkler spray, [and that] smoke logging then occurred rapidly, with a high smoke density at low level. However, under some conditions, the smoke layer was not disturbed by a sprinkler spray" [48].

Computer Simulations of Sprinkler Spray–Driven Cooling, Mixing, and Smoke Logging A computer model could be applied to address the issue of sprinkler spray–driven cooling, mixing, and smoke logging. However, the past experimental studies have not led to an understanding of the complex phenomena of sprinkler spray cooling and sprinkler spray–driven smoke transport and mixing that causes the temperature reduction that could be used as a basis for such a model. What is known through anecdotal accounts of visual observations is that spray-driven mixing and transport of an initially stable and growing upper smoke layer can and often does lead to onset of smoke logging, whereby the mixing actions of sprinkler sprays are so vigorous as to effectively and continuously mix any newly generated smoke from the fire plume with the smoke already present in the smoke layer to fill the entire space.

Analytic fire-modeling has been employed to assess a generic interaction of a downward-directed sprinkler spray and a two-layer fire environment can be used to resolve the above issues [59]. The model simulated the action of the sprinkler spray, including the effects of evaporative cooling and the spray-driven mixing of the elevated-temperature, upper smoke layer and the relatively cool and uncontaminated lower layer. The analysis led to the identification of six possible modes of sprinkler/layer interaction [58, 59]. The mode that prevailed at any time during the development of a particular fire was found to depend mainly on the thickness and temperature of the upper smoke layer and on the momentum, spread angle, and characteristic droplet size of the sprinkler spray. In any particular fire scenario, the action of open vents and/or draft-curtain compartmentation could provide some control of the thickness and temperature of the layer and, therefore, of sprinkler/layer interactions that prevail.

Of the six above-referenced modes of sprinkler/vent interaction, four were found to be particularly favorable in the sense that they would *maximize* the success of a combined sprinkler/vent design. Thus, with proper vent design the favorable modes could lead to the desired control of the smoke-layer depth while minimizing smoke mixing to the lower layer to the point that any smoke there is only in a highly dilute state. Thus, for a given set of sprinkler spray characteristics, if the smoke layer is kept relatively thin and/or not too buoyant (i.e., its temperature is not too high), then the rates of both mass and enthalpy flow entrained into the upper-layer part of the sprinkler's "spray cone of influence" would be relatively insignificant compared to the corresponding rates associated with the fire-plume flow to the upper layer. In the early part of a typical fire scenario and immediately subsequent to one or more rapid-response sprinkler discharges, the condition of a relatively thin and not-too-high-temperature upper smoke layer should be prevalent. As a result, the combined action of cooling and momentum exchange in the spray cone would be strong enough to transport the entrained smoke through the layer interface and well into the depth of the lower layer to be mixed eventually, with negligible consequences, into the rest of the lower-layer gases.

In contrast to the above, there were two particularly *unfavorable* modes of sprinkler/vent interaction that would *minimize* the likely success of a combined sprinkler/vent design. These configurations could lead to relatively vigorous

mixing between the smoke layer and the lower layer, leading to a rapid growth of the upper smoke layer and possibly to smoke logging.

Resolving the Problem of Sprinkler Skipping and Vent Skipping In terms of achieving vent/sprinkler design objectives, it is important to identify a possible means of resolving problems associated with the phenomena known as *sprinkler skipping* and *vent skipping*.

If ceiling jet–convected water droplets strike a sprinkler link or bulb, then, because of effects of evaporative cooling, there will be a significant reduction of its rate of heating, which can lead to a significant delay in sprinkler discharge. It is the resulting, unpredictable, and deleterious delay in sprinkler discharge that is referred to as *sprinkler skipping*.

Although research has been conducted to characterize the spray from sprinklers, a general description of all aspects of the spray is beyond the current state of knowledge. Such a description would be needed to provide a reliable model that can be used to predict the phenomenon.

Accounting for Sprinkler Skipping and Vent Skipping in Design In the design of sprinklers without vents, the effects of sprinkler skipping on the ability of a sprinkler system to control a fire are taken into account by the empirically based design standard, NFPA 204. In contrast, when vents and sprinklers are used *together,* the random and unpredictable effects of vent skipping are not accounted for in the design of automatic vent systems as outlined in NFPA 204.

In terms of combined vent/draft-curtain designs, and as an alternative to traditional automatic, fusible-link-actuated vents, which could involve the problem of vent skipping, a more controllable and reliable means of ensuring timely and effective vent action is available. One generic possibility would involve *ganging,* that is, opening together all or most vent units in the compartment of fire origin [61]. A ganging strategy that could be well integrated into a reliable, consensus sprinkler/vent design is one in which all vents of the fire compartment are ganged to open together immediately following first sprinkler discharge.

A Consensus Approach to the Design of Combined Sprinkler/Vent Systems

Using Mathematical Fire Models to Achieve Design Objectives The above discussion indicates that effective sprinkler/vent systems are feasible and that mathematical fire models with a proven capability for simulating sprinkler/smoke interactions can be used as the basis for a consensus approach to identify and establish effective sprinkler/vent system designs.

The capabilities of mathematical models to simulate sprinkler/smoke interactions have been reviewed [62, 63]. The models considered were those that are complete (i.e., they can simulate both isolated sprinkler/smoke interactions and full fire scenarios, where the latter would be used to establish the success of sprinkler/vent designs). Both zone-type and field model–type simulation approaches were found to be applicable for addressing the problem. In the usual way, the two approaches are complementary in the sense that the zone model approach is more applicable and appropriate for parametric studies and as a practical design tool and the field model approach is more applicable for simulating and studying the details of specific scenarios, for example, the discharge sequence of sprinklers and the effectiveness of a vent design where draft curtains are almost directly above the fire.

A sprinkler/vent design approach that uses zone-type fire model simulations might involve application of an advanced version of LAVENT that would include the sprinkler/smoke-interaction simulation model [59] discussed earlier. A successful preliminary implementation of this approach, with a revised prototype model called LAVENTS (fusible *L*ink-*A*ctuated *VENT*s and *S*prinklers), has already been presented [64]. Applications of the LES (*L*arge *E*ddy *S*imulation) model [65–68], the JASMINE model [69, 70], and others [71, 72] have also been reported.

One of the difficulties in applying the above for design applications is the limited availability of input data to describe the initial sprinkler spray from a wide range of sprinklers and the response characteristics of the vent.

A Set of Example Guidelines for Design of a Consensus Sprinkler/Vent System As a summary to the above discussion, the following example guidelines are provided for the design of a sprinkler/vent system.

1. Establish the sprinkler design in the traditional way; that is, develop design parameters using full-scale testing involving effective, rapid, sprinkler-activation strategies in the absence of vents (in this context, "rapid" means that the design problem involves an effectively unconfined ceiling where smoke-layer buildup is negligible and does not affect the timing or sequence of early sprinkler discharge).
2. Establish a vent design objective. In cases in which sprinkler action is expected to control the fire (i.e., the fire will not exceed a specified, maximum energy-release rate), the design objective for scenarios as shown in Fig. 51.13 might be for the vents to maintain indefinitely the smoke from spreading beyond the curtained compartment of fire origin (i.e., the smoke-layer interface does not descend below the bottom of the draft curtains). If the latter design objective is too ambitious or in cases in which sprinkler action is expected only to slow but not to stop the growth of the fire, then the design objective would be for the vents to maintain the smoke from spreading beyond the curtained compartment of fire origin for a specified time interval (e.g., the time expected for the fire department to respond and initiate an attack on the fire).
3. Adopt a practical/achievable strategy of early opening of all vents in the compartment of fire origin, e.g., ganged operation of all vents in the curtained compartment of fire origin based on and subsequent to first sprinkler activation.
4. Using a fire model with a proven capability of simulating the time-dependent interaction of sprinklers, vents, and draft curtains, develop a vent design that meets the established design objectives.

Special Conditions

There are some aspects of smoke control system design that involve special attention. These aspects, which affect actuation of active smoke control systems and the efficiency of exhaust fans, are the following:

- Intermediate stratification
- Confined flow
- Plugholing
- Makeup air supply

Intermediate Stratification

The upward movement of smoke in the plume is dependent on the smoke being buoyant relative to the surroundings. Delays in activation may be experienced where ceiling-mounted initiating devices are present if the air near the ceiling is warmer than the rising smoke [2, 73]. Dillon [74] reported measurements of the difference in ambient temperature from floor to ceiling to be on the order of 50 °C in some atria with glazed ceilings. A prefire, warm air layer may be created due to a solar load where the ceiling contains glazing materials. In such cases, the smoke will stratify below this warm air layer and not reach the ceiling. Early after ignition, the maximum height to which the smoke plume will rise depends on the convective heat release rate and the ambient temperature variation in the open space.

Algebraic correlations may be applied to address two situations (Fig. 51.18):

1. The temperature of the ambient air is assumed constant up to a height above which there is discrete increase in temperature associated with a layer of warm air. This situation may occur if the upper portion of a mall, atrium, or other large space is unoccupied so that the air in that portion is left unconditioned.
2. The ambient interior air within the large space has a constant temperature gradient

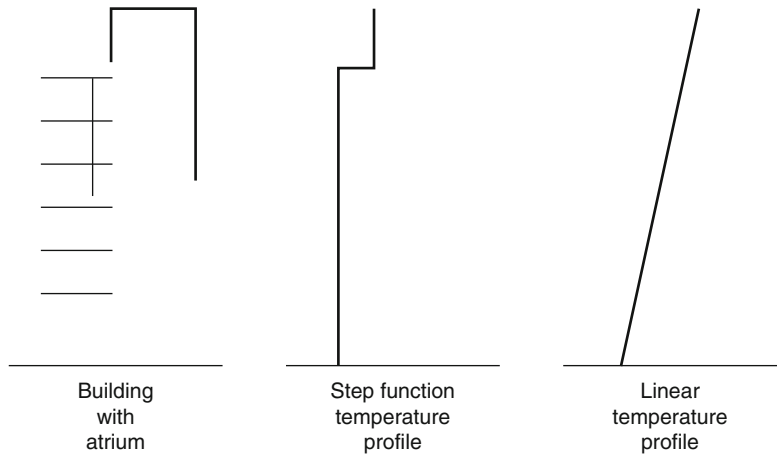

Fig. 51.18 Pre-fire temperature profiles

(temperature change per unit height) from floor level to the ceiling. This case is less likely than the first.

In the first case, where the interior air has a discrete temperature change at some elevation above floor level, then the potential for stratification can be assessed by determining the temperature of the plume at the height associated with the lower edge of the warm air layer. Where the plume centerline temperature is equal to the ambient temperature, the plume is no longer buoyant, loses its ability to rise, and stratifies at that height. One correlation for the plume centerline temperature was presented previously as Equation 51.35.

In the particular case where the ambient, pre-fire temperature increases uniformly along the entire height, the maximum plume rise can be determined from [19].

$$z_m = 3.79F^{1/4}G^{-3/8} \tag{51.48}$$

where

$$F = g\dot{Q}_c/\left(T_o\rho_o c_p\right)$$

$$G = -(g/\rho_o)d\rho_o/dz$$

Assuming standard conditions and that the smoke in the space behaves as an ideal gas, the expressions for F and G are

$$F = 0.0277\dot{Q}_c$$

$$G = 0.0335dT_o/dz$$

Because dT_o/dz is a constant, $\Delta T_o/H$ may be substituted for the derivative. Substituting the simplified expressions for F and G into Equation 51.48 yields [73].

$$z_m = 5.54\dot{Q}_c^{1/4}(\Delta T_o/H)^{-3/8} \tag{51.49}$$

By reformulating Equation 51.49 to solve for $\dot{Q}_c$, a minimum fire size can be determined that is just large enough to force the smoke to the ceiling of an atrium without prematurely stratifying due to the increasing ambient temperature.

$$\dot{Q}_c = 0.00118H^{5/2}\Delta T_o^{3/2} \tag{51.50}$$

The results of an analysis of intermediate stratification are presented in Fig. 51.19. In one case, a step function is assumed to provide a 30 °C change in temperature 15 m above the floor due to the upper portion of the atrium being unconditioned. For the other case, a temperature gradient of 1.5 °C/m is arbitrarily assumed in an atrium with a ceiling height of 20 m. Plume centerline temperatures from two size fires are graphed based on Equation 51.35. As indicated in the figure, for the case with the uniform gradient, smoke is expected to stratify

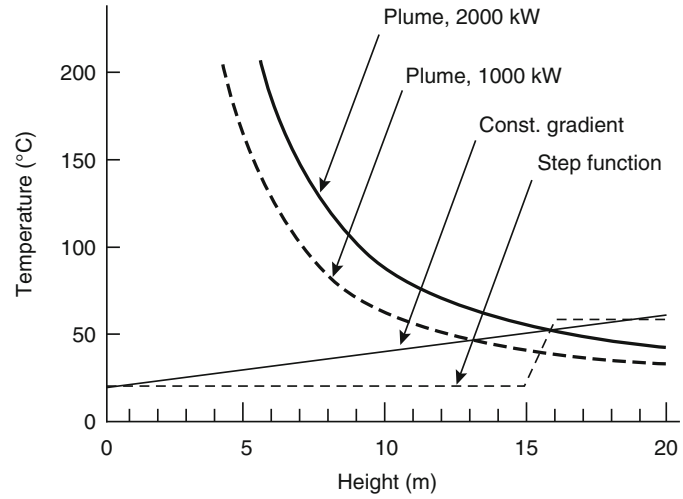

Fig. 51.19 Indoor air and plume temperature profiles with the potential for intermediate stratification

approximately 13 or 15 m above the floor, depending on the fire size. For the case involving the step function change in temperature, the smoke stratifies from both fire sizes at the height of the step change in temperature.

If the smoke is expected to stratify at an intermediate height below the ceiling, then a device other than ceiling-mounted detectors (such as projected beam detectors) needs to be considered to initiate the smoke control system. The beam detectors should be placed below the height of stratification to intercept the rising plume. In general, once the smoke control system operates, the warm air layer should be exhausted to permit the smoke to reach the ceiling.

Plume Width

As a plume rises it also widens as a result of the entrainment of additional mass into the plume. For tall, narrow spaces, the plume may fill the entire cross section of the atrium prior to reaching the ceiling. Above this position, air entrainment into the plume is greatly reduced due to the limited amount of air available. In such situations, initially the bottom of the smoke layer may be assumed to be located at this point of contact. Plume width is also important when determining the location of projected beam detectors intended to intercept the plume.

In order to determine the point of contact of the plume with the walls, the plume width must be expressed as a function of height. The width of the plume has been addressed theoretically and also experimentally.

Based on theory (see Chap. 13), the plume width is expected to be

$$d = 2.4\alpha z \tag{51.51}$$

where $\alpha \cong 0.15$

$$\text{Thus,} \quad d = 0.36z \tag{51.52}$$

Experimentally, the plume width is estimated by examining photographs [75] or the difference between the plume temperature and ambient temperature (i.e., temperature excess at various horizontal distances from the plume centerline) [30]. Using temperature measurements, the plume width is defined as the position where the temperature excess is one-half of the value at the centerline.

Handa and Sugawa [75] developed an empirical correlation of the width of the plume determined from photographs of the visual plume from wood crib fires

$$d = d_o z^{1/2} \tag{51.53}$$

Heskestad [76] noted that the visible plume diameter was greater than that determined from the temperature excess. Consequently, Heskestad

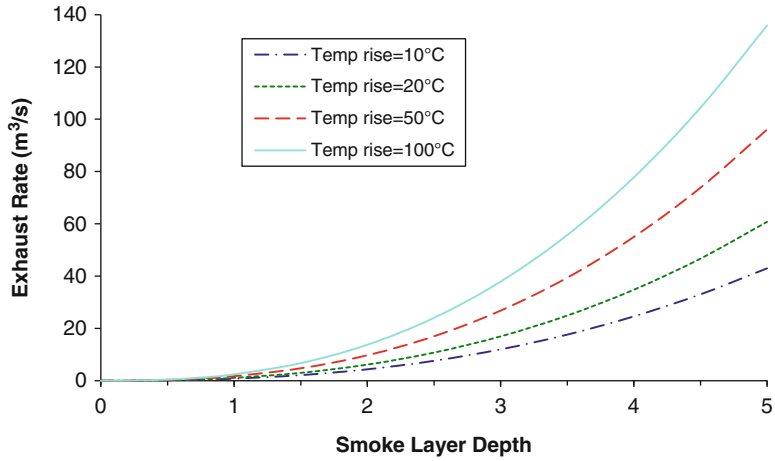

Fig. 51.20 Effect of smoke-layer depth and temperature rise on maximum exhaust capacity

estimated the visible plume diameter to be twice that determined by the excess temperature approach. Thus, the plume diameter is estimated as

$$d = 0.48\left(\frac{T_c}{T_o}\right)^{1/2} z \qquad (51.54)$$

As indicated in Equation 51.35, the plume centerline temperature decreases appreciably with increasing height. Thus, for tall spaces, the plume centerline temperature may be close to ambient. For example, at a height of 30 m with a fire size of 5000 kW and T_o of 293 K, T_c is 312 K. In this case $(T_c/T_o)^{1/2}$ in Equation 51.51 is only 1.03. Because of the rapid decline in T_c with increasing height, for engineering purposes $(T_c/T_o)^{1/2}$ can be approximated as being 1.0. Consequently, in many cases the total plume diameter may be approximated by considering the plume diameter to be approximately one-half of the height.

Considering the variety of analyses for plume width, the plume width is estimated to be 25–50 % of the height above the top of the fuel package, with the 36 % proportion from theory being near the middle of the range.

Plugholing

Plugholing occurs when the exhaust capacity at a single point is sufficiently large to draw air from the lower layer in addition to smoke. As such, less smoke is removed by the exhaust fans and a deeper layer results. Because a simple method to estimate the proportion of air drawn in from below the smoke layer by the fans is unavailable, an elementary method of estimating the smoke layer depth during plugholing is not available. As such, simple calculations can only be performed to assess the occurrence of plugholing, not the effect.

The original research on plugholing was done for natural vents. Recently, Lougheed and Hadjisophocleous demonstrated that the plugholing analysis for natural vents was also applicable to mechanical venting [77]. In order to avoid plugholing, the maximum exhaust capacity at an extract point is:

$$\dot{V}_{max} = 4.16\gamma d^{5/2}\left(\frac{\Delta T}{T_o}\right)^{1/2} \qquad (51.55)$$

Where γ is a factor relating to the location of the vent. If the vent is in the middle of the space, γ = 1 [1].

Results of applying Equation 51.56 are provided in Fig. 51.20 for a range of temperature rise values of the smoke. Where venting capacities greater than the maximum limit are needed to achieve smoke management objectives, multiple extract points need to be provided to avoid plugholing.

Assuming an axisymmetric plume, $\dot{m}$ can be replaced using Equation 51.20, and the smoke

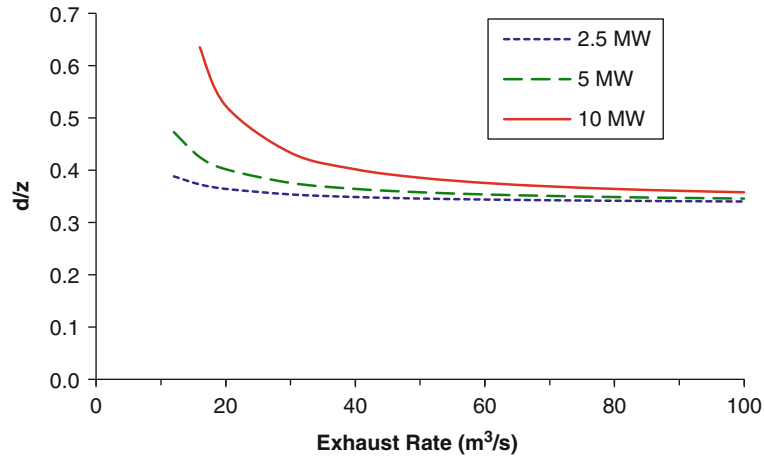

Fig. 51.21 Ratio of smoke-layer depth to clear height for single exhaust point

layer temperature can be replaced using Equation 51.34 (assuming adiabatic conditions) to express the minimum smoke layer depth in terms of the heat release rate and clear height as indicated in Fig. 51.21. For a single extract point, the minimum smoke layer depth is slightly less than 40 % of the clear height.

Makeup Air Supply

The makeup air supplied to the atrium should be

- Uncontaminated
- Introduced below the smoke layer
- Introduced at a slow velocity
- Supplied at a rate less than the required exhaust rate

Air that is not contaminated by smoke can be provided by locating intakes for the makeup air remote from the smoke exhaust discharge, preventing smoke feedback. To address the potential for smoke being introduced into the makeup air supply, a smoke detector should be provided to shut down the makeup air supply system. Selection of a smoke detector for this application should consider the operating conditions, range of temperatures, and installation within a duct.

All makeup air should be provided below the smoke layer interface. Any makeup air provided above the smoke layer interface merely adds mass to the smoke layer, which must be added to the required capacity of the smoke exhaust to prevent an increase in the smoke layer depth. If introduced near the smoke layer interface, the makeup air may increase the amount of mixing of clean air with the smoke to further add to the smoke layer.

Makeup air should be provided at a slow velocity so that the plume, fire, and smoke layer are not adversely affected. Makeup air supplied at a rapid velocity near the plume may deflect the plume to enhance the entrainment rate, thereby increasing the rate of smoke production. In addition, the burning rate of the fire may be increased by makeup air provided at an excessive velocity. Because the entrainment process induces an air velocity of approximately 1 m/s, the maximum makeup air velocity in the vicinity of the plume is often recommended to be 1 m/s. Because of the diffusion of air once past the diffuser, the makeup air velocity at the diffuser may be greater than 1 m/s.

Finally, the mass rate of makeup air supplied must be less than that being exhausted. Failure to follow this guideline may lead to the atrium being pressurized relative to the communicating spaces. Being at a positive pressure, smoke movement will be forced through any unprotected openings in physical barriers into the communicating spaces.

Limited Fuel

In some cases smoke management objectives may be fulfilled without a dedicated smoke control system due to the intrinsic qualities of the atrium. The intrinsic qualities of the atrium include parameters, such as the composition and quantity of fuel and geometry of the atrium. As an example, a limited amount of fuel may be present that is unable to sustain a fire for a sufficient period of time to create conditions beyond the allowable limits. The amount of fuel consumed during the time period of interest depends on whether the fire is steady or unsteady. In the case of a steady fire, the fuel mass consumed in a given period of time is determined as

$$\dot{m}_f = \frac{\dot{Q}_t}{H_c} \tag{51.56}$$

Alternatively, for an unsteady, t^2 profile fire, the fuel mass consumed during a given period of time is given as

$$\dot{m}_f = 333\frac{t^3}{H_c t_g^2} \tag{51.57}$$

When analyzing the inherent ability of the atrium to fulfill the smoke management design goals, the time period should relate either to the performance of a fire protection system or to the development of smoke layer conditions in excess of acceptable levels. For example, in life safety–oriented designs, the time period may be either that required for evacuation, or for untenable conditions to be generated, whichever is less.

Opposed Airflow

Opposed airflow refers to systems where airflow is provided in a direction opposite to the undesired direction of smoke movement. Opposed airflow may be used in lieu of physical barriers to prevent smoke spread from one space to another (i.e., between the communicating space and the atrium). Opposed airflow limits smoke flow by countering the momentum of the smoke attempting to enter the adjoining space. A minimum airflow velocity at all points of the opening must be provided in order to prevent smoke migration through the opening. Empirical correlations to estimate the minimum average velocity for the entire opening are available, based on limited experimental data [78]. The calculated average velocity is greater than the actual minimum velocity required at an opening to oppose smoke propagation to insure that the minimum critical velocity is achieved at all points, considering the effects of turbulence caused by the edges and corners of the opening.

The minimum average velocity to oppose smoke originating in the communicating space is evaluated using Equation 51.59.

$$v_e = 0.64\sqrt{\frac{gH(T_s - T_o)}{T_s}} \tag{51.58}$$

Alternatively, if the smoke at the opening is part of a rising plume that is rising along the side of the atrium wall, then Equation 51.60 is applicable.

$$v_e = 0.057\left(\frac{\dot{Q}}{z}\right)^{1/3} \tag{51.59}$$

The opposed airflow velocity should not exceed 1 m/s. Above that limit, the airflow velocity may deflect the plume away from the wall, making more plume surface area available for entrainment. The increased area for entrainment will enhance the smoke generation rate. Consequently, the problem of propagation to the communicating space may be solved by an excessive average velocity; however, other problems may be created by the increased smoke production rate and a possible increase in the depth of the smoke layer in the atrium. The volumetric capacity of the mechanical equipment required to deliver the necessary velocity for opposed airflow can be approximated as

$$V_{\text{oa}} = A_o v_e \tag{51.60}$$

If several openings are protected with the opposed airflow approach using the same

mechanical equipment, the cross-sectional area should be the sum of the areas for all of the openings. The opposed airflow technique may be infeasible due to the substantial amount of airflow capacity required to protect numerous openings having a large total area.

Where opposed airflow is utilized, the impact of the volume of air being introduced into the space with the fire must be assessed. For example, if the airflow is directed into the atrium and smoke exhaust equipment is also provided to maintain a constant position of the smoke layer interface in the atrium, then all of the additional air used for opposed airflow must also be exhausted. The additional air can be accounted for by increasing the required mass rate of exhaust in the atrium by the amount used for the opposed airflow. The additional air being exhausted will also affect the qualities of the smoke layer within the atrium (see Equations 51.34, 51.38, and 51.40). The smoke layer temperature, T_s(K), can be determined using Equation 51.61, based on an analysis included elsewhere [3].

$$T = 293 + \left[0.0018 + 0.072\dot{Q}_c^{-2/3} z^{5/3} + \frac{712 A_o \sqrt{H(T-293)}}{\dot{Q}_c T^{3/2}}\right]^{-1} \quad (51.61)$$

Equation 51.61 must be applied iteratively to determine the resulting smoke layer temperature. In cases with large clear heights, the temperature of the air used for the opposed airflow strategy will be virtually equal to the temperature of the smoke layer to permit the addition of volumetric rates of air rather than mass rates.

Alternatively, if airflow is directed from the atrium into a communicating space, the communicating space must also be exhausted, otherwise the communicating space will become positively pressurized.

Example 8 Considering the atrium from Example 5. There are five 5-m-wide × 2.5-m-high openings to the communicating space. The bottom of the openings is 30 m above the floor of the atrium. Considering a 5000 kW fire in the center of the floor of the atrium, determine the following:

1. Minimum airflow velocity required for opposed airflow
2. Volumetric rate of air supply for opposed airflow
3. Capacity of the exhaust fans in the atrium to maintain the smoke layer interface at an elevation 25 m above floor level and also to accommodate the additional air from the opposed airflow approach

Solution The minimum opposed airflow velocity can be determined using Equation 51.60. However, the temperature of the smoke layer, T, is unknown. Thus, Equation 51.61 must be applied first. Solving iteratively, T is approximately 305 K. The minimum airflow velocity is 0.20 m/s. The volumetric supply capacity for the opposed airflow strategy for all five openings is 12.5 m^3/s. The associated mass flow rate is 15.0 kg/s.

Without the opposed airflow, the mass rate of smoke exhaust required to maintain the smoke layer interface height in the atrium at a height of 25 m is determined using Equation 51.27 to be 236 kg/s. Thus, the combined mass exhaust rate necessary is 251 kg/s. This mass flow rate corresponds to a volumetric rate of 209 m^3/s.

As a practical issue, this exhaust rate should be compared to that required to keep the smoke layer interface above the top of the openings (i.e., 32.5 m above floor level). Based on Equations 51.27 and 51.29, the required volumetric exhaust rate is 362 kg/s. Thus, in this situation, the combined exhaust rate with the opposed airflow strategy is less than that associated with the strategy to keep the smoke layer interface above the opening.

Nomenclature

A	Cross-sectional area of the atrium (m^2)
A_o	Cross-sectional area of opening (m^2)
b	Distance from the store opening to the balcony edge (m)

C_{CO}	Volumetric concentration of carbon monoxide (ppm)
c_p	Specific heat (kJ/kg-K)
D	Optical density per unit pathlength (m^{-1})
D_m	Mass optical density (m^2/kg)
d	Plume diameter (based on excess temperature) (m)
d_o	Diameter of fire (m)
f_{CO}	Yield fraction of CO (kg_{CO}/kg_{fuel})
f_i	Yield fraction of species i (kg of species i per kg of fuel consumed)
g	Gravitational acceleration (9.8 m/s^2)
H	Height of ceiling above top of fuel surface (m)
H_b	Height of balcony above top of fuel surface (m)
H_c	Heat of combustion (kJ/kg)
$H_{c,conv}$	Convective heat of combustion (kJ/kg)
h	Enthalpy
K	Constant, depending on target being viewed (e.g., = 6 for lighted signs)[3]
k	Thermal conductivity (W/m·K)
k_v	Volumetric entrainment constant (0.065 $m^{4/3}$ kW $\cdot^{-1/3}\cdot$ s^{-1})
L	Width of balcony spill plume (m)
l	Characteristic length (m)
MW_i	Molecular weight of species i (kg)
M_{CO}	Molecular weight of carbon monoxide (28 kg)
M_{air}	Molecular weight of air (29 kg)
m_u	Mass of upper smoke layer (kg)
$\dot{m}$	Mass entrainment rate in plume (kg/s)
m_f	Mass burning rate (kg/s)
Δp	Pressure difference (Pa)
r	Radius (i.e., horizontal distance from plume centerline (m)
Q	$= \frac{1055}{t_g^2}\frac{t^3}{3}$ for t^2 fires (kJ)
Q=	$\dot{Q}\ t$ for steady fires (kJ)
Q_o=	$\rho_o c_p T_o A(H–z)$ (kJ)
$\dot{Q}$	Heat release rate of fire (kW)
$\dot{Q}_c$	Convective portion of heat release rate of fire (kW)
T_c	Temperature at plume centerline (K)
T	Temperature (K)
ΔT_{ad}	Temperature difference between smoke layer and ambient air (°C)
ΔT_o	Prefire temperature change from floor to ceiling of the ambient air (°C)
t	Time (s)
t_{cj}	Ceiling jet transport lag (s)
t_g	Growth time (s)
t_{pl}	Plume transport lag (s)
V	Volumetric flow rate (m^3/s)
V_{oa}	Volumetric capacity required for opposed air-flow (m^3/s)
V_u	Volume of upper layer (m^3)
v	Characteristic velocity (m/s)
v_e	Opposed airflow velocity (m/s)
w	Width of the balcony opening from the area of origin (m)
x	Position (m)
Y_{CO}	Mass fraction of CO (kg of species CO per kg of smoke)
Y_i	Mass fraction of gas species i (kg of species i per kg of smoke)
z	Clear height, position of smoke layer interface above the top of fuel surface (m)
z_b	position of smoke layer interface above top of balcony (m)
z_f	Limiting height above fuel (m)
z_m	Maximum rise of plume (m)
z_o	Virtual origin of plume (m)
χ_a	Combustion efficiency
χ_l	Heat loss fraction from smoke to enclosure
ρ	Density (kg/m^3)

Subscripts

F	Full-scale building
m	Small-scale model
o	Ambient air
w	Wall, ceiling, or floor of enclosure

Structural Fire Engineering of Building Assemblies and Frames

52

Jean-Marc Franssen and Nestor Iwankiw

Introduction

Use of the temperature-dependent thermophysical material properties, shape geometry, and fundamental heat transfer and structural principles, in combination with available fire test data, can enable several distinct levels of engineering/calculation methods of fire resistance. The simpler computational methods, such as those in ASCE/SFPE 29-05 [1], are semi empirically based on standard fire test results. They provide fire resistance ratings for members and assemblies that do not directly match listed assemblies to meet prescriptive code requirements. Higher-order fire simulations and structural analyses can be used as performance-based design alternatives to achieve a solution to overall fire safety.

Substantial fire-induced damage is expected after a severe (fully developed or post-flashover) fire exposure, not only to the building content and finish but also to the structural elements. It is not uncommon for well-designed, ductile, and properly functioning fire-resistive framing systems to experience visible distortions, cracking, permanent damage, and deflections that, in floors, can be on the order of 12–24 in. (300–600 mm), or more, without collapse.

In the following sections, several computational approaches to the determination of the fire resistance of building construction are summarized, independent of any requirements of a particular building code or design standard. These can be considered generally applicable to any structural material. The specific provisions of the governing building code and design standard(s) for a given project must be consulted for any engineering applications.

Limit States Design

Design for structural fire resistance and safety (i.e., for the possible strength limit states, in general) to avoid collapse requires that the structural resistance be greater than the applied load effects. This strength limit can be symbolically expressed in Equation 52.1 as

$$R_{\text{fire}} \geq L_{\text{fire}} \tag{52.1}$$

where

R_{fire} = Available structural resistance under the particular high-temperature conditions, including the effects of degraded material properties

L_{fire} = Design values of the load effects (direct effects resulting from the applied loads and indirect effects resulting from restrained thermal expansion) expected to be simultaneously acting during the fire event

For critical facilities that need to continue operations immediately after fire events, it is also possible that such an engineering approach

could be used to not only prevent collapse but to also minimize fire-induced damage. Such an objective could be accomplished through application of more stringent deflection controls in the design, to which conventionally rated fire resistive assemblies would typically not be subjected.

Because of the assumed accidental and extreme nature of this fire load and response condition, the safety/failure check should be conducted only in the ultimate limit state (ultimate strength or load and resistance factor design, LRFD) design realm, and not with the more restricted allowable or working stress design methods.

The simplest fire resistance calculations for individual structural members (beams and columns) and assemblies (walls and floor systems) are developed from best-fit, regression equations of ASTM E119 [2] fire test data and ratings. There are several shortcomings and limitations to standard fire tests and their derived fire resistance ratings, such as ASTM E119. Some are circumstantial as the cost of the tests, the time required to build specimens and do the tests and the limited number of facilities. Some others are more fundamental as the fact that only single elements can be tested as opposed to complete structures, the fact that the size of the tested elements is often smaller than the size or real elements, the fact that it is very difficult to control and have a precise idea of the boundary conditions in an experimental setup (perfect hinges and perfectly fixed supports are not easily realized in practice) and the variability inherent to experimental processes that make it nearly impossible to make controlled parametric analyses.

For a more complete assessment of structural load and response variables, Equation 52.1 provides the essential underlying criterion for strength adequacy under fire conditions, for both structural members and entire framing systems. More sophisticated analyses for members and frames rely on this basic limit state comparison of Equation 52.1 more explicitly. The degradation of the construction material properties at high temperatures; fire time-temperature values; type, thickness, and properties of the fire protection material(s); boundary conditions; connection response; and thermal strains are the key variables that should be included in this type of analysis.

Resistance

The two most important fire effects that alter a structure's resistance from that at ambient are the high-temperature degradation of its mechanical properties (strength and stiffness) and thermally induced strains. These softening, weakening, and damage to even noncombustible construction materials directly lead to a progressive reduction of load-carrying resistance at higher temperatures. Meanwhile, fire-induced thermal elongations can (1) lead to displacements so large that they influence the effects of action (a term used to designate bending moments, axial forces or shear forces) in the structure or, (2) when restrained, generate additional effects of action, typically in the form of compressive forces. These dual responses demonstrate that fire is clearly time dependent with effects on both the load and the resistance sides of Equation 52.1. Similar to the real time–history response of a structure subjected to an earthquake, load-resistance interactions exist that usually give rise to nonlinear structural behavior and permanent distortions/damage.

For example, a floor system may see the load bearing mode changing from bending at ambient temperatures to one with combined bending and axial compression; and, finally, during the large deflection and high-temperature stages of fire exposure, it may experience combined bending, axial tension and compression (catenary action in the beams and membrane action in the slab). This redistribution of the load-carrying capabilities of a typical floor system in a building from simple flexure under service conditions to catenary action at ultimate is schematically illustrated in Fig. 52.1.

The intent of the general design of Equation 52.1 is to verify the adequacy of structural

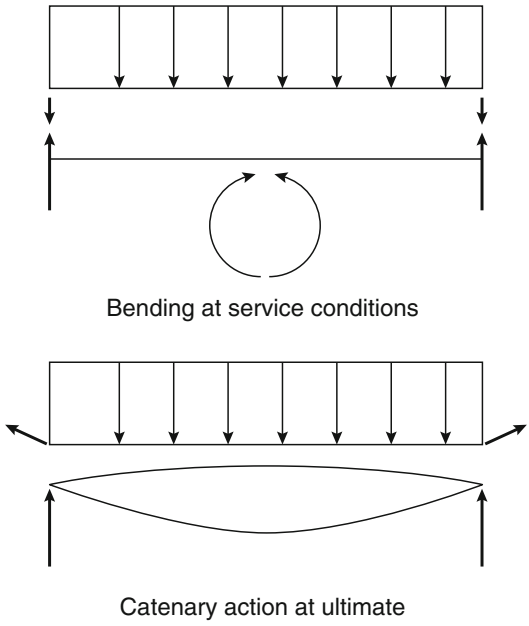

Fig. 52.1 Change in structural resistance of floor beams from bending to catenary action

resistance throughout the entire fire duration and response range or, alternatively, during a required period of performance time. The critical strength condition may not always occur at the maximum fire exposure time, especially with so-called natural design fires that have a burnout or cool-down stage. Member connections adjacent to the fire must also accordingly accommodate the forces, moments, and distortions generated by the event, with adequate ductility to avoid any failure(s); the same holds for all remote elements or parts of the structure that are not directly affected by the fire (in the sense that their temperature remains unchanged). An alternative and generally equivalent limit state formulation to that in the strength domain can be established in the time domain. Use of conventionally pre-established critical member temperatures alone does not provide a totally meaningful or comprehensive solution under fire exposure, because this is only one aspect of the structural response. It does not explicitly address whether the member will fail to support its load demands under such conditions.

Reliability

The general limit states formulation of Equation 52.1 is implicitly based on probability theory and a low, but societally acceptable, failure risk. Such a de minimis risk, or the threshold level below which an event is not of regulatory concern, is a probability of failure of approximately 10^{-6} or less per year [3]. The reliability index to sufficiently control this probability of occurrence is at least about 3.8, which could be used as the target design reliability baseline if one were not using a recognized fire design standard or code. The design reliability includes both the extreme load effects and the lower-bound expected resistance at ultimate strength, as well as the probability of occurrence of an uncontrolled, fully developed fire. The available statistics of the selected or specified load combination, design fire, and structural framing enable a rational calculation of the particular combined reliability of any such design scenario, at least in an approximate sense.

Similar to the empirical fire resistance ratings of building construction elements, fire engineering design of a compartment space is intended to control its vulnerability to localized structural member or assembly failures for a design fire exposure. The potential for fire movement beyond the compartment of origin to other areas or floors can also be duly considered and rationally evaluated, as well as effects of simultaneously occurring fires in multiple compartments and/or floors, relative to potential development of progressive (or disproportional) catastrophic failure of the framing system. For these conditions, a much more complex interaction of thermal and structural action over the affected framing takes place, with significantly greater demands placed on modeling capabilities, computational power, and convergence time for concurrent time–history solutions. The need for suitably customized finite element software, project budget allowances, and computational resources lead to the situation that these types of applications are not usually performed for smaller projects. This more advanced fire

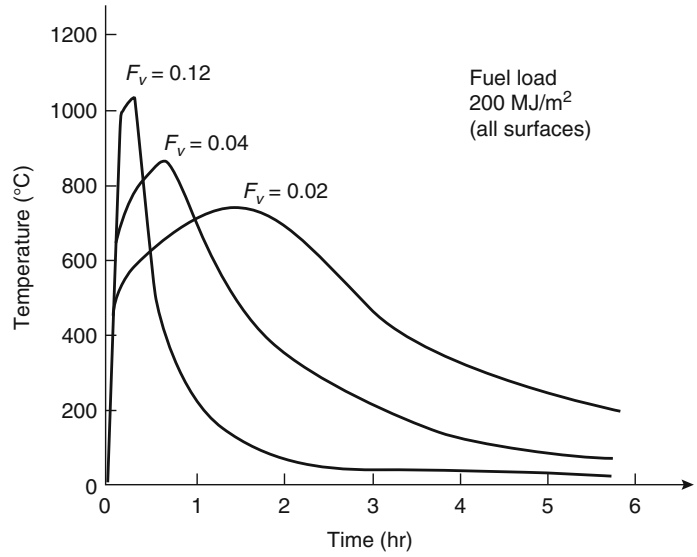

Fig. 52.2 Real time–temperature curves for different ventilation factors, F_v, with a constant fuel load [7]

engineering is essentially applied to higher importance, higher risk, high-rise and/or otherwise unique landmark buildings.

Fire Exposures

This section provides a short introduction to the information covered much more in depth in Chaps. 29, 30, 53, 54, and 55. ASTM E119, *Standard Test Method for Fire Tests of Building Construction and Materials* [2], has long provided (since 1918) the basis for the test fire used in establishing fire ratings of structural building elements in the United States. UL 263, *Fire Tests of Building Construction and Materials* [4], and NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials* [5], are similar documents, as is the international standard ISO 834 [6]. All these standard fire exposure curves can be considered essentially identical. This ASTM E119 standard fire is fast starting, hot, and rising with an equivalent burning temperature of 1000 °F (538 °C) after only 5 min.

An uncontrolled natural fire has distinct stages of growth, fully developed (flashover) burning, and finally decay. In contrast, the ASTM E119 standard fire has no decay or burnout branch but specifies ever-increasing furnace compartment temperatures with time that can reach 2300 °F (1260 °C) at 8 h, if testing were to reach this duration. Normally, ASTM E119 fire tests for listing of building construction elements are not conducted for more than 3–4 h.

A natural fire eventually consumes its combustibles in a finite time that is dependent on the initial quantity and type of fire load and the amount of ventilation in the compartment. Hence, the actual fire load and ventilation present in the room will determine the nature, intensity, and duration of a real fire. Uncontrolled, well-ventilated fires reach higher temperatures than poorly ventilated fires, but they burn faster and have a shorter duration for the same fuel. This is illustrated in Fig. 52.2 [7], in which F_v is a ventilation factor.

In Fig. 52.3, the ASTM E119 standard time-temperature curve is superimposed on several representative real fire curves for various fuel loads and a constant ventilation factor. The maximum fire temperature, its decay phase, and its fire time duration are significantly affected by the fuel content and ventilation, and are quite different from the standard time-temperature curve. As expected, higher fuel loads cause longer and hotter fires under uncontrolled conditions. The standard fire time-temperature curve between

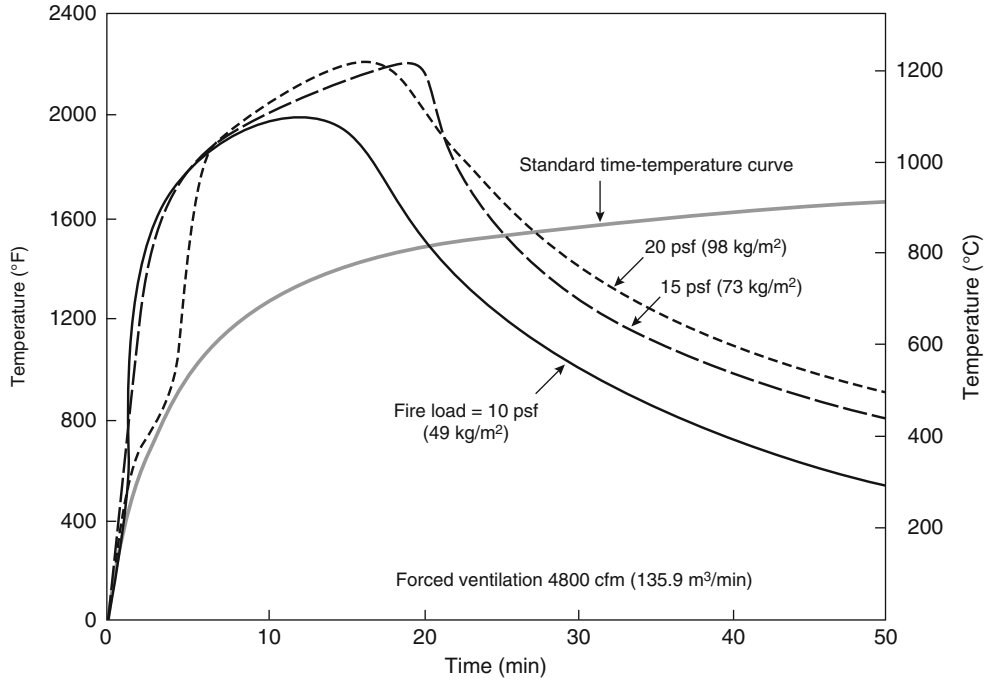

Fig. 52.3 ASTM E119 standard fire and real fire time-temperature curves

1 and 4 h provides a good order of magnitude of the room temperatures that will be encountered in a real conventional fire in many cases. However, in real uncontrolled fires, these high temperatures most likely occur over only a relatively short time interval.

For faster starting and hotter fires, such as those that occur from petrochemicals or other hazardous materials, a standard fire exposure more severe than that given in ASTM E119 may be more appropriate. ASTM E1529 (UL 1709), *Standard Test Method for Determining Effects of Large Hydrocarbon Pool Fires on Structural Members and Assemblies*, defines such a standard fire exposure that reaches and remains at about 2000 °F (1100 °C) after 5 min.

Mathematical representations of the ASTM E119 [2], other standard fire time-temperature curves, and a variety of real compartment fire time-temperature formulations can be made for analysis and design purposes. Various such fire models and parametric curves can be found in the literature, such as the *SFPE S.01 2011 Engineering Standard* [8] and Eurocode 1 [9]. Fire models usually can predict a fire temperature-time history only within a single compartment.

The simplest fire models predict the resulting evolution of the gas temperature within the fire compartment. This is the case for parametric fire models or one zone models. This gas temperature is unique at any time during the fire, which is mostly relevant for a post-flashover situation. More refined models can provide a more detailed picture of the situation in the fire compartment, which is needed if the pre-flashover phase has to be described or in the case of localized fires, such as an axisymmetric fire plume. Two zone models consider a vertical separation between a higher zone containing the hot combustion gases and a lower zone containing cold uncontaminated air. More recent travelling fire models represent the fact that, even in a post-flashover fire, the maximum combustion and maximum gas temperature do not occur simultaneously in the whole compartment [10]. Computational Fluid Dynamics

(CFD) models can also be used to give a very detailed description of the situation in terms of gas temperature, pressure, velocity, in millions of cells of the compartment.

Interior fire extensions through window openings presents another scenario category which analytical modeling can also simulate. Eurocode 1 [9] presents a standard formulation to represent such events.

In performing a structural fire resistance analysis and design, either the well-established standard fire, such as E119, or a natural design fire for the particular building and occupancy can be employed to determine both its R_{fire} and L_{fire} effects. For selection of a natural design fire, surveyed or code-specified fuel loads are an essential demand input. The fuel load can be separated into fixed and variable classifications. The fixed combustibles are those that remain essentially unchanged within the bounded compartment (i.e., interior wall, floor, and ceiling finish, structural framing), whereas the variable fuels are those combustibles that can change over time based on occupancy (furnishings and contents). The fixed fuel load should be determined from a project-specific survey or estimated for noncombustible construction. This fixed fuel load is added to the variable quantity to comprise the total fire design load. Typically, in the absence of a project-specific survey, the variable fuel load could be represented as a nominal design level for the fire demand to provide for suitable overall reliability. Adjustments to higher percentile fuel levels may be specified for selected building conditions, such as lack of automatic suppression/sprinkler systems, larger compartment sizes, occupancy, height/criticality of building, and the risk that the design fire could propagate beyond the compartment of origin to adjacent areas or floors.

As a guide for some typical variable fuel contents expressed in terms of potential heat energy release per unit floor area, Eurocode 1 [9] can provide a reasonable initial reference for common occupancies such as residential, office, commercial, and library. The expected statistical distribution parameters (mean, standard deviation) of the fuel loads are provided as well as values for certain non-exceedance percentiles. Older publications, and some current work, also cite the potential fuel in terms of a weight density per floor area, pounds per square foot (psf), or the like for equivalent amounts of wood combustibles. NFPA 557 [11] is a comparable U.S. fire load standard based on review of the literature and fuel data surveys. The particular design value for variable fire load density depends on the selected or required percentile of non-exceedance, which will vary depending on the height and criticality of the building project, presence of other fire safety measures (including active fire suppression systems), and areas of compartments. Special fuel content surveys may also be undertaken to assess this load density for particular buildings. Hence, selection of the appropriate design fire load, in the absence of a building code requirement, is subject to the responsible professional's judgment and approval by the authority having jurisdiction. For more information, refer to Chap. 35.

High hazard occupancies must be individually determined for each given project.

Overview of Heat Transfer Analysis

The structural behavior of a structure subjected to fire is directly dependent on the temperatures that are induced in this structure by the fire. The determination of the fire resistance of a structure, or of a member, by calculation thus starts with the determination of the temperatures in the structure or in the member. Once a design fire has been selected, a heat transfer analysis is thereby the next step to determine the resulting temperatures in the structure. More discussion of heat transfer is contained in Chap. 34.

Usually, lumped mass single temperature, one-dimensional or two-dimensional analyses will suffice. Most engineered structures are indeed based on linear or planar members, such as beams or columns, frames, floors or walls. If the boundary conditions imposed by the fire to such members are the same along the length of a linear element or on the surface of a planar element, the temperature does not vary along the

length or in the plane of the element. The determination of the temperature distribution is thus usually reduced to a two-dimensional problem on the section of linear elements or to a uniaxial (one-dimensional) problem across the thickness of a planar element (at least for walls and floors that have a constant thickness and are of a single material). Some slabs, like hollow core concrete slabs or composite steel-concrete floors with trapezoidal corrugated steel sheets, require a two-dimensional analysis. The problem in that case is similar to the two-dimensional problem that has to be solved for the beam sections.

Three-dimensional thermal analyses may be performed locally, for example in complex joints between linear elements such as, e.g. beam-column joints. Some walls can in fact be made of concrete blocks with internal cavities or masonry bricks that, together with the mortar joints, form a three-dimensional structure. However, thermal analyses considering the walls with such a level of details are seldom performed.

The size, nature, and type of fire protection (insulation) used for the structural member(s) are essential factors in how quickly, and to what level, the structural material's temperature will rise when subjected to the effects of a fire. Unprotected noncombustible members will heat up most rapidly to eventually reach thermal equilibrium with the fire gas temperature, whereas combustible elements will eventually ignite and be consumed as a fuel.

The heat transfer computation will determine a temperature profile for the higher-order analysis option, within a given structural member at a given fire duration. The one-dimensional heat transfer solution can produce temperature gradients in one direction, commonly through the material thickness. The further simplified, lumped mass analysis is limited to just solution of a single material temperature, hence assumed uniform member temperature. A general flowchart schematically showing the steps and options for this fire and thermal part of the engineering approach is given in Fig. 52.4. Usually, the single fire compartment scenario would govern, as assumed in the standard fire resistance tests and ratings. This scenario is repeated with the fire starting in each possible compartment and/or floor.

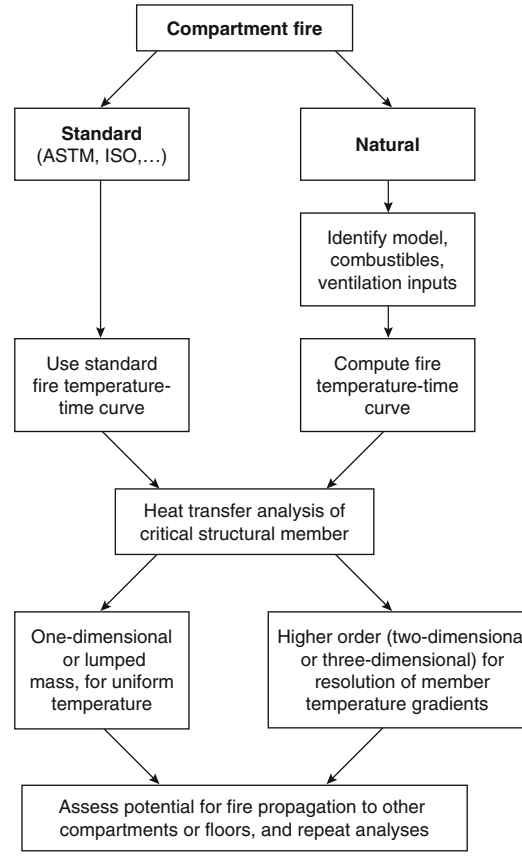

Fig. 52.4 Schematic of fire engineering process to determine maximum temperatures in individual structural members

Most often, a weak coupling is considered between the thermal and the structural analyses. This means that the effects of the temperature variation in the structure on the behavior of the structure are taken into account, whereas the effects of the structural behavior on the temperature development are neglected. One exception could be the failure of partition walls or floors that extend the fire zone.

The longitudinal heat flux that may exist along linear members or in the plane of planar members, the heat flux that may exist from members to members, and the temperature distribution in the joints are briefly discussed in the following section.

Variation of Temperatures along the Members The world in which we live is geometrically three-dimensional. The temperature distribution in construction members is thus three-dimensional in general. Even if the hypothesis of a two-dimensional temperature distribution in linear members is common and practical, longitudinal heat fluxes and temperature gradients will indeed be present in practical situations, essentially in the vicinity of the joints that connect the members and especially in the situation where some members are subjected to the heating of the fire, while some others connected to the same joint are in an adjacent compartment where the cooler ambient situation still prevails.

It is possible to determine the longitudinal heat fluxes, the temperature gradients along the length of the members, as well as the influence of these temperature variations on the mechanical behavior of the members or of the complete structure. Very often, such analyses have been performed for the idealized and somewhat academic situation of prismatic members that have, for example, one part of the length subjected to the fire and the rest surrounded by air at ambient temperature. But these members have, in most studies, the same section along their length and are themselves isolated from the rest of the building.

In reality, each joint is in general a geometrically complex object that extends in all directions (for example, two vertical elements, two horizontal elements spanning in the main direction, and two horizontal elements in the secondary direction). The joint connects members of different types and different sections. It may also be thermally influenced by the presence of nonstructural elements, such as suspended ceilings or vertical walls. Very often, the presence of stiffeners, bolts, and various connecting elements that all have an influence on the heat transfers through the joint will further complicate the situation. This explains why the determination of the true three-dimensional temperature distribution for all the joints in a real building would be an extremely long and expensive process. Performing parametric analyses on various joint typologies and deriving practical design guides about the temperature distribution to be used in everyday design is probably beyond reasonable expectations.

In fact, the information contained in the complex three-dimensional temperature distribution that could eventually be determined in a particular situation could hardly be exploited in the analysis of the adjacent elements. This is because the three-dimensional temperature distribution would be determined on the basis of three-dimensional solid elements, whereas the structural members are usually modeled by oriented elements, either linear (beams and columns) or planar (floors and walls). It would thus be challenging to map the temperature distribution determined in a 3D object into oriented 2D members.

The simplified hypothesis of a temperature distribution in the members that is uniform along the length per segment and that varies abruptly only at the joints is thus normally used. It is somehow justified by the observations made during the analysis of ideal prismatic members. Even if the thermal environment varies abruptly along the length of a prismatic member, the affected zone in terms of temperature variation is quite restricted in length [12]. There is an observable zone in the cold compartment where the temperature in the member is increased, but this temperature increase is smaller than in the adjacent heated part, and failure is not likely to appear here. There is also a short zone in the exposed part where the temperatures are reduced, but it is assumed to be on the safe side to neglect the effects of this colder zone. Typically, the affected zone is twice as long in the cold compartment as in the hot compartment.

The temperature in the joint is of crucial importance if the mechanical behavior of the joint has to be determined. For joints between steel members, the hypothesis is often made that the temperature in the joint is uniform and the mechanical behavior is determined as a function

of this temperature. This temperature can, for example, be determined on the basis of the thermal massivity of the joint as a three-dimensional object, i.e. the ratio between the exposed surface of the joint and the volume of steel. If a slightly more refined thermal model is required, it is possible to calculate the temperature in each component with its own massivity, but this amounts to neglecting the heat flux between the components, which is certainly not true in a thermally composite joint. Numerical tools can be used to derive a very detailed temperature distribution in the joint. To the authors' knowledge, joints have so far been analyzed on the hypothesis that the joint is fully exposed to the fire on all sides. The analysis of joints that are only partly subjected to the fire has yet to be done.

Thermophysical Properties of Fire Protection Materials The variation with high temperatures of key input properties such as conductivity, specific heat, and density for the various spray-on and intumescent coating products, gypsum boards, and the likes will directly affect the analytical predictions of temperatures in the structural members. There are relatively little published data on these, and they are often rather approximate, incomplete, or conflicting. A parametric sensitivity analysis would quantify the range of possible results corresponding to the input variations. Moreover, the adhesion/cohesion of these materials to the substrate and/or the integrity of their protective envelope during the fire are important response characteristics that cannot ordinarily be evaluated solely from analytical models. Experimental evidence of the materials' suitable fire protection performance in this regard is necessary to enable the analytical assumptions that the materials remain in place, as installed, throughout the exposure duration.

The relevant material properties at high temperatures are discussed in Chap. 9 in this handbook.

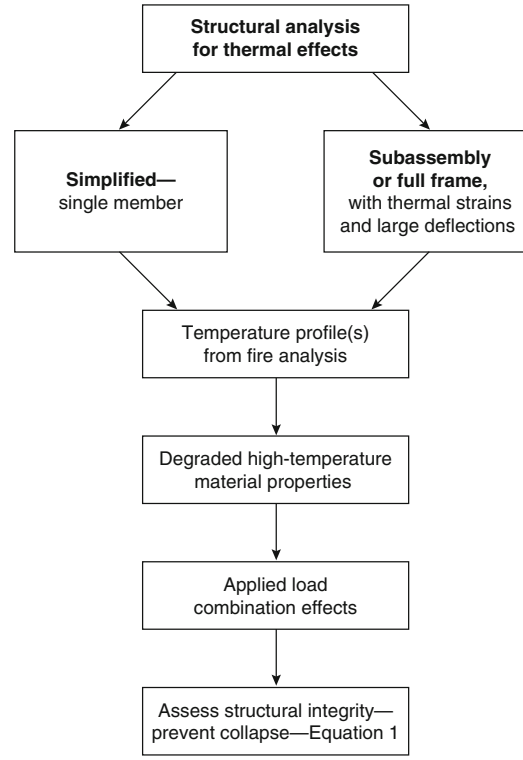

Fig. 52.5 Schematic of structural analysis for fire effects

Overview of Structural Analysis

Figure 52.5 outlines the subsequent structural analysis for loading effects that is performed once the fire-induced temperature(s) in the structural member or system have been determined. A simplified single member-by-member or a subassembly/frame structural analysis can be conducted. The fire-induced thermal expansion and structural restraints are unique features of structural-fire interaction. For the single member assumption, the member boundary conditions and load effects are taken only from the structural analysis at ambient temperatures, thereby neglecting any thermal strain effects on the selected member or the surrounding structure. A subassembly or full-frame structural analysis that includes the thermal response of the fire-exposed member(s) will offer the most complete representation of the response,

including any restraining effects on or by the adjacent framing due to the fire, which would otherwise not become manifest in the single member method. More information on structural analysis is contained in Chaps. 53–55.

Given the complex and advanced nature of the nonlinear structural response under high-temperature exposures, several unique factors that are not routinely considered for most design practice will need to be duly evaluated for analytical solution accuracy.

Local Member or Frame Instability These destabilizing effects due to slenderness of members in compression can be represented by the addition of the geometric stiffness matrix—or comparable idealizations—that accounts for the coupling of axial compressive forces on flexural stiffness. This second-order (or higher) effect can also be described as ensuring the equilibrium of the applied loads on the displaced structure, not its original geometry. The role of structural imperfections for compressively loaded elements may be important in this regard. Initial member crookedness, expected geometrical misalignments, and/or construction tolerances in the building framing or connections may need to be further assessed and studied. These initial imperfections would be reflected as input data to the model(s), in lieu of the perfectly straight original geometry. Larger compressive loads will effectively soften the member or element, which consequently leads to amplified lateral/transverse deformations and bending moments relative to linear elastic assumptions. This structural weakening can eventually progress to the final buckling limit state, when the element becomes unstable and is considered to have failed, at large distortions and with little, if any, residual stiffness. This instability is analytically signaled by the stiffness matrix becoming singular, large displacements, and/or the occurrence of non-convergent numerical solution algorithms. Local buckling instabilities can be analytically modeled and detected only if the structural member is adequately discretized into appropriate beam, plate, brick, or shell elements. If each member is discretized by one single element, only overall member and frame instabilities can be detected in a nonlinear formulation. Linear elastic solutions cannot detect any instability.

Floor Slab Effects The structural effects of the concrete and deck floor slabs on the strength and stiffness of the steel beams and girders, for bracing and composite design with shear studs, must be properly modeled; the steel beams and the concrete slab work together in a composite action.

Thermal Strains The thermal expansion, and structural restraints, must be properly included, since this is a unique feature of structure-fire interaction, as discussed later.

Tensile Membrane Action of Composite Floors [13] Composite floor systems based on profiled steel sheets (decks) are designed for the normal situation to span in one direction, the direction of the ribs. The length of the span is in the order of magnitude of 10 ft, depending on the depth and thickness of the steel deck and on the eventual presence of shoring during casting of the fresh concrete. The traditional approach for ensuring an appropriate fire resistance to such systems was, until the end of the twentieth century, based on additional steel reinforcing bars located in the ribs in order to carry the tension force when the temperature in the steel profiles has increased and their load bearing capacity has vanished. Experimental tests [14, 15] and observations in real fires such as the Broadgate fire in London in 1990 or the Churchill Plaza in Basingstoke in 1991 have shown that a different load transfer mode may develop in the fire situation. Where the load transfer capacity by bending in the slab has been lost, the slab deflects and tension develops in the central part of rectangular slab panels. These tensile forces are supported by the steel reinforcing mesh that must be present in the concrete slab and are equilibrated by a compression ring that forms in the external parts of the slab. This allows leaving some of the infill beams that support the floor unprotected on the condition that the edge beams that form the new

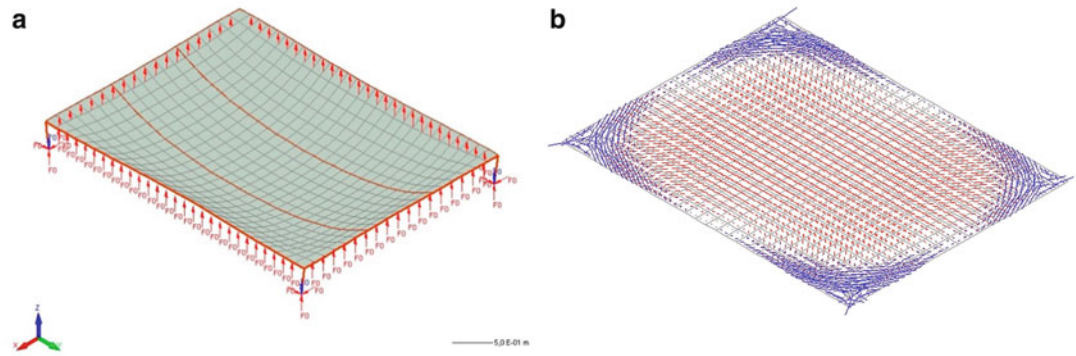

Fig. 52.6 Tensile membrane action. (**a**) Deformed shape of the floor. (**b**) Membrane forces in the floor

slab panel are able to carry the vertical reaction of the system. Figure 52.6 shows: (a) the deformed shape of the new slab panel of increased dimensions that forms during the fire when the two infill steel beams—represented by the **bold** lines—are left unprotected and (b) the distribution of membrane forces in this panel with compression near the edges and tension in the central part of the slab panel.

This mechanism is now well understood and is routinely used for designing composite steel-concrete floor systems, especially in the U.K.

Connection Moment-Rotation Behavior Building framing connections for ordinary design are usually idealized as being either fully rigid-FR (full bending moment transfer and maintain original angles between members) or simple (no bending moment capability and free rotation between members). Depending on the nature of the postulated collapse mechanism and its critical subassembly, it may become necessary to more rigorously model some of these connections with characteristic moment-rotation curves in place of the original simplifying design assumptions, in order to estimate the real joint flexibility and partial rotational restraints. Significant progress has been made in the last decade for understanding and modeling the stiffness and strength characteristics of connections in the fire situation [16]. It has been shown that not only the strength but also the ductility of the joints is essential for ensuring a satisfactory behavior, especially during the cooling phase of a fire [17].

Nonuniform Heating A temperature gradient through the member depth/thickness causes differential thermal strains between the hotter and cooler external surfaces. A temperature gradient will exist, for example, in steel beams with concrete floors under fire exposures, because the floor slab keeps the top of the steel beam cooler. Perimeter columns and truss members will also likely experience some degree of non-uniform heating in a real fire. These thermal effects will depend on whether it is assumed that the fire totally engulfs a given structural member. If so, a similarly uniform heating exposure on all sides can be expected with no temperature gradient or bowing, such as for an interior column. In simply supported members, these thermal gradients give rise to the so-called "thermal bowing." This thermal bowing/curvature will usually be toward the hotter side of the member. These induced thermal curvatures reduce the load-carrying capability of the members in compression due to P-delta effects and, hence, may influence the stability of the columns and truss. Under restrained end conditions, these displacements cannot develop and the effects of actions are modified even at first order (no need of large displacements). A beam that has both ends fixed in rotation and is subjected to a thermal gradient on its depth will experience no bowing in any direction but the bending moment diagram will be changed; if the lower part of the section is hotter than the upper part, negative moments, or hogging, will develop on the whole length of the beam.

Material Strength Limit States Strength (due to ductile yielding, crushing, or tensile rupture) will govern the response of the common construction materials such as steel, concrete, masonry and wood. Yielding, rupture, or stability will often control the ultimate strength of steel members; heavier concrete and masonry have negligible tensile resistance and rely essentially on compressive strength, with steel reinforcement providing the primary tensile capacity and supplemental shear resistance. The extent and type of reinforcing details in concrete and masonry will greatly influence the ductile or brittle nature of subsequent behavior. Plain/unreinforced concrete and masonry will generally be quite brittle and much more susceptible to early cracking failures, whereas heavily reinforced and well-detailed members can perform in a ductile manner at large deformations. Yielding marks the major departure of the structural element's behavior from linear elastic to nonlinear. This nonlinearity is manifest by reduced material stiffness below Young's elastic modulus and by strength that is governed by the constitutive properties of that particular material. Available ambient and temperature-dependent stress-strain relationships for these materials can be used in this regard. Wood structures, with loss-of-section by charring effects, can be reasonably modeled through otherwise linear elastic assumptions. Conversely, steel and concrete structures usually require a full nonlinear analysis. Cracking, potential explosive spalling, and loss of concrete cover to the interior steel reinforcement will affect the reinforced or prestressed concrete member's integrity under fire, but this response is usually well beyond the capabilities of most software.

Collapse Prevention

The primary life safety objective of structural fire resistance is either to avoid collapse during the standard, or design, fire or delay collapse, in a real fire scenario, to a time when all occupants have safely evacuated the building. Collapse can be broadly classified as either local or global. Local collapse is failure of a single member, connection, or limited frame subassembly, whereas global, progressive, or disproportionate collapse produces a major cascading series of related failures triggered by the original local collapse. The latter is the much more dangerous and destructive in terms of both public safety and property loss.

With use of the single member, subassembly, or full-frame structural/fire analyses described earlier, one can determine the source and type of any initial failure. Ordinarily, identification or avoidance of this first structural failure will suffice for compliance with the basic safety requirements of the building codes.

However, more recently with concerns after several terrorist attacks, there is an increased awareness of the risks of disproportionate collapse, particularly for taller or monumental/historical buildings. The analytical determination of whether an initial local/member failure can propagate to further global or disproportionate structural instabilities may be difficult, or impossible, for most finite element software operating in a static analysis mode. Numerical solution convergence for any subsequent catastrophic and complex global collapse mechanisms can be much more easily achieved if the nonlinear software processes the analysis (with resulting large deformations, member failures, singularities, etc.) as a dynamic, rather than static, equilibrium problem, with an appropriate time step [18].

In addition, it may be necessary to conduct such simulations in full three-dimensional space, with adequate and appropriate discretization of the potentially affected members, that is, many more model nodes and elements, to reach the best response fidelity. Such intricate simulations are likely to require extensive computing resources, time, and effort to accomplish.

Structural Load Combinations for Fire Resistance

The applied load effects, L_{fire}, for use in Equation 52.1 need to be determined from the loads

and load combinations required by the applicable building code, and these will constitute the so-called mechanical, or nonthermal, effects on the heated structure. The common building design loads are dead (D), floor live (L), roof live (L_r), roof snow (S), rain (R), wind (W), and earthquake (E), several of which may or may not act simultaneously. Maximum structural stresses or deformations, therefore, will result from the critical combination of the loads. Building codes specify various combinations that must be checked. The most critical load combination may occur when one or more of the loads are not acting. In some codes or standards, provisions for design to withstand an extraordinary, extreme, or accidental event (A_k) may also be given, such as for fire, explosion, and vehicular collisions with building.

For the fire engineering problem, the design values of the loads are based on probabilistic considerations: the probability of failure from the effect of a fire (which must meet a certain target value) is the product of the probability of having a severe uncontrolled post-flashover fire by the probability of failure when this fire occurs. As the first of these two probabilities is much lower than 1, the probability of the second event, the one that is assumed when the fire resistance is calculated, can be higher than the target value. The design value of the load will thus be less in the fire situation than the full design live load that is normally specified for ambient temperatures. In addition to the normal (ambient) design load requirements, ASCE/SEI 7-10 [19] in the United States specifies use of the following extraordinary event gravity load combination for fire design:

$$1.2D + A_k + (0.5L \text{ or } 0.2S) \qquad (52.2)$$

where A_k symbolically represents the fire effects or typically the construction material's strength and stiffness reductions caused by the fire's heating.

This load combination in Equation 52.2 for extreme exposures is intended exclusively for application in limit states design with Equation 52.1.

Other international codes and standards specify comparable reduced load combinations to be used in combination with fire exposures. This contrasts with the full gravity design live load that is used in most standard fire resistance tests, such as ASTM E119. It should be recognized that the frequency of major building fires is relatively low due to the small probability of ignition coupled with flashover, due to occupants or fire department intervention and/or automatic fire suppression system's extinguishment of the fire before it becomes fully developed [3]. However, if flashover occurs, the uncertainties of the actual fire intensity, duration, spread, and localized heat distribution effects to the affected structural members (L_{fire}) are large relative to the variability of the structural fire resistance (R_{fire}). The coefficient of variation (COV) of the fuel load contents that serve as the fire combustibles is considered to be on the order of 0.50 or more, similar to common live gravity and environmental (wind, snow, earthquake) loads [3, 20], whereas the typical structural resistance COV is in the range of 0.10–0.20.

High-Temperature Effects on Structure

The two primary high-temperature effects on structural materials that are not exhibited under typical ambient conditions are thermally induced strains and degradation of the materials' mechanical properties (strength and stiffness). Because of these two effects, deflections of structural members during the longer duration, hot fires (post-flashover) can reach many inches or even several feet. This is at least an order of magnitude greater than the small elastic deflections, usually no more than about 1–2 in. (25–50 mm) that are normally contemplated for design service. These effects are only briefly described in the following sections, as there are existing sources for this detailed information, including other chapters in this handbook. The commonly used structural fire protection materials and systems are generically addressed in the final section.

Table 52.1 Coefficients of thermal expansion for steel and concrete at high temperature [21]

Structural and reinforcing steel	7.8×10^{-6}/°F (1.4×10^{-5}/°C)
Normal-weight concrete (NWC)	1.0×10^{-5}/°F (1.8×10^{-5}/°C)
Lightweight concrete (LWC)	4.4×10^{-5}/°F (7.9×10^{-6}/°C)

Thermal Strains

Strain is defined as change in member length divided by the initial length. In general, the total strain, ε_{total}, in a structural element, can be considered to be primarily composed of mechanical and thermal parts, as given in Equation 52.3.

$$\varepsilon_{total} = \varepsilon_{mechanical} + \varepsilon_{thermal} \tag{52.3}$$

Mechanical strain is related to applied loads and stresses, whereas thermal strain results only from the material's expansion or contraction due to temperature changes. Under fire exposures, the thermal strain is elongation in proportion to the material's coefficient of thermal expansion. For constant temperatures, the total strain is only the mechanical strain, because the thermal strain is zero. However, at elevated temperatures, high mechanical strains can develop even under negligible superimposed and dead loads due to restraint of thermal expansion.

If the member is fully restrained so that no total strain occurs, all the thermal expansion effects are converted into an equal and opposite mechanical strain (compression). These mechanical strains induce internal reaction forces and moments in the structure, which may lead to either material ultimate strength or strain becoming the governing limit state. Similar to seismic design, the ultimate strain, or deformation, rather than strength may become the failure limit for the more brittle construction materials that do not have sufficient ductility. For the opposite extreme, in the case of a simply connected but effectively thermally unrestrained member, all the thermal expansion will freely occur as part of the total strain and will not directly induce any additional mechanical strain (additional mechanical strain can occur because of second-order effects linked to the large displacements that the free thermal expansion produces). Therefore, for totally unconstrained thermal expansion and unloaded elements, total strain equals the thermal strain, with thermally induced mechanical strain and stress being zero.

The real boundary conditions for thermal restraint in buildings lie between these extremes and require a more in-depth analysis for an accurate determination. For such indeterminate framing, this deformation compatibility and force/moment equilibrium analysis under heating and applied loads is the key step in assessing the structural integrity of a member or subassembly.

AISC [21] provides the following thermal elongation strains (coefficients of thermal expansion) in Table 52.1 for material temperatures above 150 °F (65 °C), which are similar to the values given in other major international standards.

Constant coefficients of expansion lead to a thermal expansion that is proportional to temperature. This simplification closely approximates more detailed representations that can be found in the literature, and it is usually both practical and sufficient for design applications of simple elements. The thermal elongation strain resulting from a temperature increase of 500 °C in the material is about 0.004 for lightweight concrete (LWC) and 0.007–0.009 for steel and normal-weight concrete (NWC), which represents an increase of about 0.5 in./10 ft (4 mm/m) for LWC or about 1.0 in./10 ft (8 mm/m) for steel or NWC. These possible levels of elongation during a severe fire are clearly significant.

Thermal Degradation of Construction Material Properties

Combustibility is one broad, and important, fire classification of building materials. Noncombustible materials will degrade under the higher

temperatures of a fire but will not burn. Combustible materials will not only degrade at higher temperatures but also ignite and burn, thereby adding to the fuel contents during a fire.

Building materials serve in the primary, load-bearing elements that are necessary to preserve the structural safety of the building in preventing partial or total collapse. The traditional building materials have been steel, concrete, masonry, and wood. Wood is the only combustible material of these four. In all cases, visible damage/distortions and degradation (potentially including cracking, dehydration, loss of section, charring, etc.) of the mechanical properties of all building materials occur under prolonged elevated temperatures.

Application of more advanced fire resistance solutions will require an explicit representation of the basic thermal and mechanical material properties at elevated temperatures, such as yield and ultimate stress, modulus of elasticity, coefficient of thermal expansion, thermal conductivity, and specific heat. The detailed material response and property variations at high temperatures of fire on concrete, masonry, and wood materials may be readily obtained from Chaps. 54 and 55 in this handbook, as well as from the published literature.

Structural Analysis

For each combination of loads that could be applied to the structure in the fire situation, the effects of actions, namely bending moments, axial and shear forces, and also the support reactions, have to be determined in the structure. This determination is the structural analysis.

Because of the indirect effects of actions, that is, those variations in the effects of actions caused by restrained thermal expansion, it may be necessary to perform the structural analysis continuously during the duration of the fire course. This has then to be made not only for every combination of loads, but also for any fire scenario that is being considered. The fact that large displacements created by unrestrained thermal expansion and the softening of materials vary constantly under increasing temperatures is another reason that may lead to the necessity to perform a structural analysis at every stage of the fire.

There are yet some simplifications that can lead to a less demanding process for the structural analysis. The conditions of these simplifications and the limitations of these simpler procedures are discussed in this section.

Structural Analysis Before the Fire

As a starting point, the effects of actions have to be determined in the structure under the design load combination in case of fire for the moment when the fire starts, a moment that is usually called $t = 0$, or time at zero.

In fact, some simplified methods used to determine the fire resistance member by member are based on the effects of actions calculated at $t = 0$. This is, of course, a gross simplification because any indirect effect of actions is then neglected. Such a simplified procedure is acceptable only when used in conjunction with a simplified representation of the fire environment, typically a nominal or standard time-temperature fire curve. It is accepted in that case because the representation of the fire is conventional and cannot pretend to reproduce or predict the real fire development that could take place. Then the structural analysis can also be done on the basis of a conventional situation for the effects of actions, namely the situation at time $t = 0$. The goal of such a simplified analysis is not to represent the behavior of a real structure in a real fire. Rather, the aim is to predict the result of a standard fire test that would be performed in a laboratory on a simple element subjected to a standardized time-temperature curve.

Even when the structural analysis will be performed in a continuous manner during the course of the fire, it is sound practice for the engineer to have a close look at the results of the structural analysis at time $t = 0$. This provides a good opportunity to verify whether the results obtained match the expected perception of the solution. Any structural engineer

should have enough experience in structural analysis at room temperature in order to judge whether the obtained bending moment diagram and the deflection shape, for example, are consistent with the boundary conditions and loads that were supposed to be applied to the structure. This also allows for checking the stress level that exist in the structure before the fire starts, which gives an idea of the load level and, hence, of the possibility for the structure to present a significant degree of fire resistance.

In practice, the structural analysis at time $t = 0$ can be performed by an elastic analysis, because it is reasonable to assume that the structure will exhibit very little, if any, nonlinear material behavior under the design load combinations in case of fire. Indeed, if the situation that prevails at the beginning of the fire is compared to the situation that has to be taken into account for the design of the structure under normal conditions, the design values of the mechanical loads are lower, as well as the partial safety factor dividing the resistance of the material. For example, a steel structure that has been designed to sustain in normal conditions a design load equal to $1.20D + 1.60\ L$ with a design value of the material strength will exhibit very little plasticity at the beginning of the fire if the load is only $1.20D + 0.50\ L$ and the actual full material strength can be mobilized, where D is the nominal dead load and L is the nominal live load. Additional discussion of limit states design principles was covered earlier in this chapter. Because the effects of actions are determined at time $t = 0$, the stiffness of the material at room temperature is, of course, taken into account. If the structure is simple, the analysis is trivial, but if the structure is complex, it is possible to use one of the numerous numerical tools developed for the analysis of structures at ambient temperature. If the structural analysis is performed continuously during the fire course and a nonlinear method is used for that, it is simpler to use the same method also at time $t = 0$.

Another good practice before performing the analysis of the structure during the fire is to load it until failure. The loads applied in the fire situation are simultaneously and proportionally increased until collapse while the temperature is maintained at ambient. The ratio between the value of the loads in the fire situation and the value of the loads at collapse is the load level. The lower the load level, the higher the fire resistance can be. Here also, the tool of choice for determining the collapse load is the tool that will be used for the analysis under elevated temperatures.

Structural Analysis During the Fire

Except when the structure is analyzed member by member, it is common practice to take into account the effects of indirect actions and of large displacements during the fire. Thus, the structural analysis has to be performed in a continuous manner during the fire exposure.

The procedure is first to apply the loads while the structure is at ambient temperature and then to let the temperature increase in the structure while the external applied loads are usually kept constant. The response of the structure is calculated until failure and, in simple structures, this time of failure may be considered as the fire resistance time for these applied loads.

If the load-bearing capacity at a prescribed fire resistance time has to be calculated, the preceding procedure has to be repeated in an iterative manner with the applied loads being modified until the obtained fire resistance time matches the prescribed resistance time. It is possible to apply a procedure that yields directly the load-bearing capacity at the prescribed fire resistance time, as is described later.

Elastic or Elastoplastic Analysis An elastic or elastoplastic analysis for the combined effects of fire and structural loads is very rarely performed due to the nonlinearities present.

Timber constructions may be an exception, because thermal expansion in wood is normally neglected and no indirect effects of actions take place in a timber structure. A structural analysis method established for the ambient temperature situation could thus be applied in the fire, simply taking into account the fact that the stiffness of

the members subjected to the action of the fire is reduced by loss of cross section, as the charring depth progresses in these members. It should be kept in mind that the effects of large displacements may increase as the fire progresses because of this reduction in stiffness of certain members, and may become crucial in the fire, whereas these could be disregarded in ambient design. The strength of the connection should be checked at every stage during the fire, as well as the decrease of the stiffness of the members and its effect on the load transfer in the structure.

One could envisage performing a thermoelastic analysis of a steel structure by one of the elastic methods normally used at ambient temperature, in which the thermal expansion and the reduction of Young's modulus would simply be introduced in order to reflect the increase of temperature. Such a procedure would have two disadvantages: that (1) the indirect effects of actions would be severely overestimated, because in reality plasticity in the members relaxes the thermal strains, and (2) any benefit from load redistribution by the formation of plastic hinges could not be accounted for.

One could also envisage performing a structural analysis of a steel structure by one of the methods established for normal ambient conditions and based on an elastic–perfectly plastic material model. This would, at least, solve the second disadvantage of the purely elastic models, namely the incapability to consider the formation of plastic hinges. The fact that the "true" nonlinear stress-strain of the material has been approximated by an elastic–perfectly plastic behavior would still lead to an overestimation of the indirect effects of action and to an underestimation of the displacements. This is why such a procedure is rarely applied. It is considered that a structural analysis based on a full nonlinear material model is not that much more complicated and is more suitable to capture the real behavior of the structure during a fire.

One practical and interesting application of elastic or elastoplastic analysis methods for the structural analysis during the fire is in very large structures that are only partially subjected to the fire. It may, in fact, prove to be an efficient procedure to limit the full nonlinear analysis to those parts of the structure that are subjected to the fire or that are in the near vicinity of the fire affected zone, and to rely on a more simple model for those zones that are far away from the fire and deemed to behave elastically. It will, nevertheless, be necessary to verify that the obtained effects of actions in the supposedly elastic part of the structure can indeed be accommodated by the assumed elastic members. Thermal elongation of rather long portions of concrete slabs subjected to the action of two burning cars has, for example, led in 2010 to the collapse in shear of a column that was 12 m away from the fire source in the "Tour d'Ivoire" building in the city of Montreux in Switzerland, see Fig. 52.7 [22].

Fig. 52.7 Concrete columns that failed in shear due to thermal elongation of the ceiling

Nonlinear Analysis The most common procedure for the structural analysis during the course of the fire is to perform a step-by-step, nonlinear analysis of the structure. The basic equations of structural mechanics are used, but most of the simplifications that were, sometimes implicitly, used for the analyses at ambient temperature cannot be used anymore. The use of a numerical program is required.

The temperature in the structure is not uniform. The level of sophistication for the representation of the temperature distribution varies from one particular method to another and from one particular software to another. Some models have a uniform temperature in the sections, with the temperature varying from one section to the other (valid only for metallic materials). Others allow a thermal gradient, linear or nonlinear, across the depth of the section, either a steel section or a concrete slab. Some others have capability for a completely non-uniform, two-dimensional temperature distribution on the sections. Still others, more rarely, may consider a full three-dimensional temperature distribution on the whole structure.

A sophisticated constitutive model represents the behavior of the material at the local level. Most of these models are based on strain decomposition. The total strain, that is, the one resulting from a spatial derivative of the displacements, is decomposed into several components accounting, for example, for elasticity, plasticity, cracking, true creep, transient creep (in concrete), and thermal expansion. All these terms are temperature dependent, most of them in a nonlinear manner. There is, for example, no such thing as a constant coefficient of thermal expansion. The thermal expansion strain is a nonlinear function of the temperature. Most of these strain terms are also stress dependent. Different material models have been developed based on different theories such as plasticity models or damage models or a combination of both [23], some in the pure local form, and some in a nonlocal form. Different models may be used simultaneously in a single analysis for a structure made of different materials. A detailed presentation of all these models is beyond the scope of this chapter.

The finite element technique is probably the most commonly used method for solving the equilibrium equations. Displacements-based elements are commonly used, although other element types are totally suitable. Here also, some care has to be taken in the development of the particular element type for the fire analysis, or in the choice of the element type taken in the library of a program that has been written for the ambient situation if it has to be used for the fire situation. The hypothesis that the neutral axis is at midlevel of a symmetrical section is not generally valid anymore, and, for example, the usual linear expression for the longitudinal displacement field in a beam element may need to be revisited.

When the structural analysis is performed in that manner continuously during the course of the fire, the numerical program tries, at every time step defined by the user or chosen automatically by the program itself, to find a displaced position of the structure that ensures equilibrium with the applied external forces. There is no separate verification of the members. The simulation will continue as long as a position of equilibrium of the structure can be found, although some members may suffer severe distortions, high level of plasticity, or cracking. The whole structure may itself exhibit very large displacements. It is the responsibility of the user to verify whether the displacements depicted by the program are still compatible with the particular serviceability limit states for the given project. A single-level single bay steel portal frame, for example, that hangs in a catenary manner such that the beam is below ground level is certainly physically not acceptable, whereas a computer program with capability for such very large deformations and highly ductile response may see no problem in that situation. Other less trivial situations may also require the attention of the engineer and an assessment decision of the analytical results.

Whereas the example of an excessively ductile result from a computer program has been depicted in the previous paragraph, the user most often faces the opposite situation, especially in complex structures. The simulation

may stop when one of the members of the structure becomes unstable, while the global stability of the structure is still maintained. Such a simulated failure produced by the inability of the software solution to converge while the global load-bearing capacity of the structure has not been exhausted is called a numerical failure. Reducing the time step used for the analysis is of no use for this problem of local failure, even though other numerical failures can be solved by the use of a shorter time step. One of the main reasons of the problems created by local instabilities has been identified in the fact that the step-by-step analysis procedure was until recently based on a series of successive, quasi-static analyses. Time was not really present in the equilibrium equations, except that it changed the material properties. A position of static equilibrium had thus to be found at any time, and such a situation of static equilibrium may not prevail during the few seconds that, for example, a member in compression buckles and its axial force suddenly drops to zero and is redistributed to adjacent members. The situation develops in a highly dynamic manner. It has been shown [18] that the numerical problems created by local failures can be significantly reduced if the dynamic behavior of the structure is taken into account in the basic equations. A significant number of the structural analyses performed in the fire situation are nowadays performed in the dynamic mode, although the final technique that would avoid all numerical failures has yet to be found.

Structural Analysis at the Required Resistance Time

It is possible to calculate directly the load-bearing capacity of a structure at the prescribed fire resistance time. This procedure may be appealing because (1) it allows expressing directly the equivalent of a safety margin in the load domain, whereas the application of the procedure described in the previous section yields a safety margin in the time domain; and (2) the numerical procedure established for the loading of structures at ambient temperature can be almost directly applied, whereas the previous procedure requires more refined theoretical developments.

The procedure is to apply from the beginning of the analysis the temperatures in the structure that prevail at the required fire resistance time. The mechanical properties of the different materials in the structure are adapted at every point of integration in order to reflect the temperature level at that point. A first loading then takes into account the thermal expansion in the materials. The external loads are then applied and increased progressively while the temperature is kept constant until equilibrium is no longer possible.

Although it may be appealing, this type of procedure is much less often applied than is nonlinear analysis during a fire. The reasons follow:

1. The step-by-step nonlinear analysis aims at reproducing the development of events in the order in which the events occur during the course of a fire, namely heating of the structure under load, whereas this procedure, which loads the structure after it has been heated, is more a numerical trick used because it may be more convenient for the designer. Yet, because the physical phenomena in play are highly nonlinear, there are no guarantees that both procedures would yield exactly the same result. In other words, if a load L yields a fire resistance time R with the first procedure, it is not certain that the load-bearing capacity will be exactly equal to L if it is calculated with the second procedure at time R.
2. If the AHJ or the engineer wants to have an idea of the safety margin in the time domain, an iterative application of calculating the load-bearing capacity at the prescribed fire resistance time is then required.
3. The complex sequence of events that ultimately leads to the global collapse of a structure can be examined and may be understood with nonlinear analysis during a fire, for example when the successive failures of

different members in the structure and the load redistribution that they generate are due to different heating rates in these members. The successive failures produced by a progressive application of the external load under isotherm conditions may be completely different and would not give any insight into the real behavior of the structure during the course of the fire.

4. This procedure is, of course, not applicable when the required fire resistance time is in the cooling phase of a real fire. If the required resistance time is sufficiently longer than the heating phase, the temperatures in the structure have significantly decreased at the required fire resistance time and the corresponding load-bearing capacity could be significantly higher than it was when the temperatures in the structure were at their maximum.

Utilization of Substructures

The structure of even a rather simple building is typically composed of tens of members linked together in a way to make a stable assembly that supports the nonstructural elements of the building, the wind, the snow loads, and the live loads. The capabilities of computers have increased tremendously in recent years, and current computer programs can analyze three-dimensional structures. It is, thus, theoretically possible to undertake the three-dimensional analysis of a complete structure; however, it has to be acknowledged that there is still a limit to the size of structures that can be practically analyzed.

For everyday practice, when time and budget constraints are important limitations, it is very rare that the entire structure is analyzed for fire effects. Instead, a substructure can be extracted from the whole system and effectively analyzed. The reason for this is to be found not only in the computer time required to run the analyses but also in the time required by the engineer to develop the computer model and interpret the results.

The quality of the results from the analysis of the substructure, defined as the similarity between the analytical results of the substructure and the total structure, highly depends on the size and on the boundary conditions imposed on the substructure, that is, at the locations where the virtual cut is made between the substructure and the rest of the structure. The decision about the model size and the boundary conditions is the responsibility of the designer. The same is also true in most structural analyses made at ordinary temperatures, but the situation is more critical for an analysis in the fire condition because of the indirect effects of actions.

The most precise results would be obtained if the rest of the structure is represented by equivalent, usually linear, springs. It may be difficult and quite time consuming to determine the stiffness of all the required springs. In most cases, the stiffness's of all the degrees of freedom that form the interface are not independent. A series of independent springs is not sufficient to represent the effect of the surrounding structure; a more or less complete stiffness matrix is required. This necessity is why it is often considered as an approximation that the variables that exist at the interface between the substructure and the rest of the structure are kept constant during the whole fire duration. These variables are—degree of freedom per degree of freedom—either a force or bending moment, or a displacement or rotation.

It is possible to define a systematic procedure that lists the different steps that have to be followed and that highlights the decisions to be taken [24].

1. The effects of actions in the whole structure must be determined at time $t = 0$ under the load combination in the case of the fire under consideration (see section "Structural Analysis Before the Fire").
2. The limits of the substructure have to be chosen. The choice is made with the contradictory objective that not only does the substructure become as simple as possible but also at the same time the hypothesis of constant variables at the boundary conditions during the fire must represent an accurate approximation of

the real situation, with respect to the thermal expansion and load paths that exist in reality. The choice of the limits of the substructure is highly dependent of the location(s) of the fire. Engineering judgment is necessary.

3. All the supports of the structure that belong to the substructure have to be taken into account as supports of the substructure.
4. All the external mechanical loads that are applied on the substructure in case of fire have to be taken into account as acting on the substructure.
5. For each degree of freedom existing at the boundary between the substructure and the rest of the structure, an appropriate choice has to be made in order to represent the situation as properly as possible. The two possibilities are:
   - The displacement (or the rotation) with respect to this degree of freedom is fixed.
   - The force (or the bending moment) deduced from the analysis of the total structure made in step 1 is applied.

   These two possibilities are exclusive because it is not possible to impose simultaneously the displacement and the corresponding force at a degree of freedom. Whatever the choice, these restrictions on the displacements and these forces applied at the boundaries will remain constant during the fire.
6. The substructure that has been defined is then considered as a new structure and a new structural analysis is performed on this new structure. Either the fire resistance is based on the effects of action at time $t = 0$ and the procedure explained in the earlier section "Structural Analysis Before the Fire" is applied, or the structural analysis is performed in a continuous manner during the fire and the procedure explained in the earlier section "Structural Analysis During the Fire" is applied, in which case the indirect actions that can develop within the substructure are taken into account. Displacements (or rotations) will appear at the degrees of freedom where the force (or moment) has been imposed whereas reactions forces (or moments) will appear at the degrees of freedom where the displacement (or rotation) has been fixed.

The necessity to perform a new structural analysis on the substructure even if the fire resistance is based on the effects of action determined at time $t = 0$ comes from the boundary conditions considered at the interface. A simple example is that of a continuous beam, uniformly loaded by p, from which one of the interior spans of length L is extracted as a very simple substructure. The bending moments determined from step 1 are approximately $pL^2/12$ at the supports, with $pL^2/24$ at mid span. If the choice made in step 5 is to consider that these moments at the supports are constant, the consequence is that the end support rotation is free and the substructure is statically determinate; it will fail as soon as the bending moment resistance on the supports decreases to $pL^2/12$ and plastic hinges are formed. If, on the contrary, the choice is to consider that no rotation can develop on the support, a new and very simple structural analysis will show that failure of the fixed-fixed beam can occur only when three plastic hinges have developed, and the bending moment resistance has decreased to $pL^2/16$ at the supports and at mid span.

Fire Resistance of Individual Members

Simple calculation models or design equations are usually able to treat the fire resistance of only individual members such as one column or one beam. Because such simple calculation models have historically been the first to be developed, it has been possible for many years to determine the fire resistance for only individual members. When complex building structures had to be evaluated with regard to their fire resistance, all constitutive members were evaluated separately, and it was traditionally considered that the fire resistance of the global structure was equal to that of the weakest member.

In fact, except for very simple structures, there is no guarantee for that conclusion. Individual members are indeed connected to each other, and there are strong interactions between their individual behaviors. As a matter of fact, these interactions are stronger in the fire than at ambient temperature because of the high levels of thermal expansion that occur at elevated temperatures. These interactions come either from additional indirect effects of actions caused by restrained thermal expansion or from large displacements caused by free thermal expansion. They can have beneficial or unfavorable effects on the fire resistance of the members and their connections and, as a consequence, on the fire resistance of the whole system (see next section, "Fire Resistance of Frames"). Therefore, this simplified member-by-member analysis and design is limited in accuracy because any changes due to the fire in load effect on the members are ignored, not only in magnitude but also in type and direction (e.g., primary bending/shear or compression load effects can change to tension [catenary action] due to thermal effects).

It is easily accepted that, because the interactions are neglected in an analysis of the fire resistance made member by member, the fire resistance of the weakest member is not exactly equal to the real fire resistance time of the whole structure. But most people think that there is at least a relationship between these two values and the correlation is positive. In other words, if the fire resistance of the weakest member is increased, the fire resistance of the whole structure is also increased. If this is true, the analysis made member by member can be used, if not to quantify exactly the time of fire resistance of a complete structure, at least to compare different systems or solutions between each other, which means that it can be used for a grading system, albeit a conventional one. A structure in which all members have a fire resistance of 2 h would necessarily be safer than a structure in which the members have only a 1 h fire resistance.

This is why more general calculation models, usually based on numerical modeling, have been developed. These allow analyzing in a more realistic manner the behavior of complete structures and determining their fire resistance as their true ability to sustain the applied loads during a certain time, and not as the minimum of otherwise independently analyzed elements.

Yet, despite its drawbacks and limitations, the analysis of structures member by member is still widely used today. It will probably continue being used for the foreseeable future and thus is worth consideration for the following three reasons.

First, the utilization of complex computer software requires a high level of education, expertise, and experience, whereas simple models for the analysis of individual members are more easily understood and applied.

Second, the costs of acquiring sophisticated numerical software, learning to use it, creating the numerical model of the structure to be analyzed, running the analysis, and interpreting the results are not always compatible with the size of the project and the resources that can be allocated to the thermal and structural analyses. An approximate conservative answer that can be obtained rapidly may be more valuable than a more precise answer that takes weeks to develop.

Finally, it has to be recognized that, for most usual structures of reasonable size and complexity, the member-by-member analysis provides a reasonable estimation of the fire resistance time of the structure. Also, in many cases, only this resistance time is to be determined, whereas the deeper understanding of the true failure mode is not required.

Most simple design equations used in the fire situation for the analysis of individual members are a direct extrapolation of the methods used for the same member at room temperature in which the stiffness and strength of the material have been adapted in order to reflect the effects of the temperature increase, although some particularities may appear in some design equations at elevated temperature. It is noted that the empirically derived correlations or tabulated data for member fire resistance based on standard fire tests are not considered to be a general structural analysis–design solution in this context and so are not addressed in this section.

Of course, the results of prescriptive fire tests for the standard fire, acceptance criteria and limited assembly conditions, together with their interpolations, can provide some validation benchmarks for the engineering methods outlined.

The design equations that give the structural resistance R_{fire} to be used in Equation 52.1 are different depending on the material type (steel, concrete, composite steel-concrete, or timber), on the type of effect of actions (tension, compression, or bending), as well as on the national building code and/or design standards to be used. The actual formulas or values for the various fire design variables, such as material strength changes with temperature, section reduction criteria, and buckling coefficients, are given by the respective design standards and building codes. Design differences among countries in this representation do exist, even though the underlying heat transfer and structural behavior are identical. The detailed equations for evaluating the fire resistance of individual linear members at elevated temperatures are given in Chaps 52–54. of this Handbook. Only floors and walls will be treated here as their design is not systematically treated in textbooks while their behavior is worth discussion.

Floors

Floor systems are usually assessed in the fire scenario where the fire is applied underneath the floor. This means that the floor evaluated is in fact the ceiling of the fire compartment. The attack from the fire that develops on that floor is usually not considered for various reasons: buoyancy that directs hot gases and diffusion flames toward the upper zone of the fire compartment, eventual presence of a mineral material that covers the floor, or presence of ashes on the floor that obstruct radiative impinging flux.

Many floor systems span in one direction only. This is the case, for example, for hollow core concrete slabs, for composite steel-concrete floors based on corrugated steel sheets, or for traditional timber floors based on simply supported timber beams. In these systems, the load-bearing capacity is assessed by the methods established for beams in bending. Additional requirements are normally imposed in order to ensure the separating function required for these horizontal elements that usually play a role in the compartmentation of the building. These requirements have to do with the thickness in concrete-based floors in order to limit the temperature increase on the upper side of the floor. In timber floors, these requirements may have to do with the thickness of the planks and also with the arrangement of the lateral joints between the planks because these joints are a weak point for the passage of hot gases.

Floor systems that span in two directions were traditionally designed in the fire situation on the basis of the bending yield-line theory, as for the ambient temperature situation. The effective yield strength of reinforcing bars in the lower zones of the slab was simply adapted as a function of their particular temperature, and the compressive zone in concrete was eventually reduced in thickness on the support lines where continuity of the slab exists. Full-scale tests performed in Great Britain [25] have demonstrated that such a design is over conservative. In reality, the load transfer system in a slab is significantly modified when the slab exhibits large deflections. In the fire, the thermal gradient on the thickness of the slab induces such high deflections already in the early course of the fire. At the later stages, when the stiffness of the slab is decreased, the applied loads also induce large deflections. In such a highly deformed position, tensile membrane forces develop in the central part of the floor, whereas a compression ring is established near the supports. If sufficient reinforcing steel is present in both directions, the loads can then be transferred to the supports more by tension in the bars than by bending.

This effect has been demonstrated in the Cardington full-scale test and has been reproduced in smaller scale but better controlled experimental laboratory tests as well as in numerical modeling. A simple method to be used by designers has been established [26], which takes that tensile membrane effect into

account. When the design is performed according to this more realistic load transfer mechanism, the floor slabs can span over wider surfaces in the fire than what the serviceability limit state allows in the ambient situation. It is thus possible to leave some intermediate supporting beams unprotected.

The tensile membrane effect can develop even in systems that are considered at room temperature as spanning in one direction (e.g., in composite floors with corrugated steel deck), provided that sufficient reinforcing is provided in the transverse direction.

Walls

Walls are vertical plane elements commonly found is most building structures. Different types of walls exist, depending on the basic material and on the way they are constructed. For example, brick walls, concrete block walls, concrete walls, steel-stud or timber-stud gypsum plasterboards, and sandwich steel panels are common construction types. Columns may be inserted in the wall in order to provide lateral stability (Fig. 52.8). Walls can also be made of a combination of masonry comprised between concrete columns and beams (Fig. 52.9).

Walls can also be classified depending on the function(s) that they have to fulfill. The main functions of walls follow:

- *Separating function in normal conditions*. A wall may be used in order to separate two rooms in a building visually, thermally, and/or acoustically. Two bedrooms in the same apartment may, for example, be separated by steel-stud gypsum plasterboard that has separating functions only in normal conditions.
- *Separating function in the fire condition*. The wall is used in order to prevent the fire from spreading from one fire compartment to the other.
- *Load-bearing function*. The wall is used in order to carry some structural loads induced in it by horizontal elements that it supports such as the floors and the roof of the building.

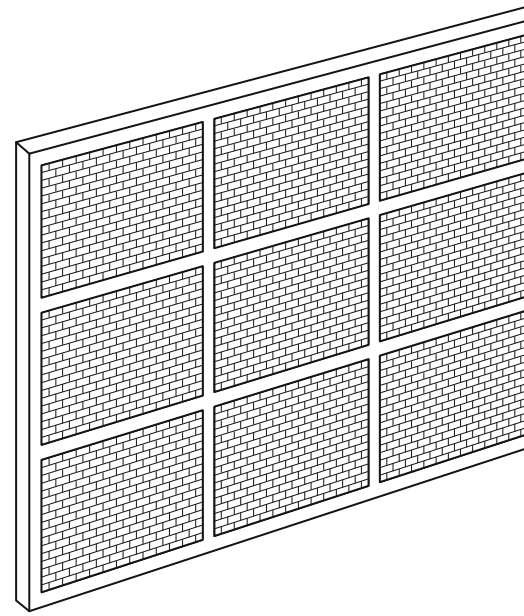

Fig. 52.9 Masonry in a reinforced concrete grid

A wall that has only a separating function in normal conditions but not in a fire is called a nonrated wall. The presence of such walls influences the development of the fire because, if only during the initial stage of the fire, the walls mark the boundaries of the room of origin

of the fire and thus deeply influence the ventilation conditions in this room. Yet, the influence of such walls is normally not considered in the design fire scenario because, first, there is no means to estimate the amount of time during which their influence will persist and, second, there is absolutely neither reliability of the influence of such walls during the fire nor reliability of the presence of the wall when the fire starts.

A wall that has a separating function in the fire is usually rated by a standardized fire test. The wall is exposed to a normalized time temperature-time curve on one side, whereas the conditions on the unexposed side are monitored and compared to defined performance criteria. The temperature is monitored on the unexposed face, and acceptance criteria are imposed on the average temperature increase as well as on the highest temperature increase at any point. Radiation emitted toward the environment by the unexposed surface can also be recorded and compared to a defined level. These criteria allow verification of the insulating property of the wall. The temperatures and the emitted flux must remain sufficiently low so that they do not pose a threat to any nearby fuel (combustibles) that may be present in the vicinity of the wall or to persons who may need to use the compartment as an escape route or as a rescue area. The characteristic of integrity is also verified continuously during the fire. In the test standard ASTM E119 [2], for example, this is done by verifying that "passage of flame or gases hot enough to ignite cotton waste" will not occur near any visible crack, fissure, or opening that appears in the wall's unexposed side. Of course, even if no external load is applied to the wall, it has to carry its own weight; any collapse of the wall from the effect of its own weight automatically leads to the failure of the two previously mentioned criteria.

A wall that has a load-bearing function must support the applied load during the prescribed fire duration. In most situations, such a wall has also a separating function and is tested as exposed to the fire on one side only. It may yet occur that a load-bearing wall is subjected to the fire on both sides. This could be the case, for example, for a shear wall of limited length located within a compartment in order to transfer horizontal loads applied in the plane of the wall. Representing such a situation in an experimental test is not easy, and walls are rarely, if ever, tested with the fire on both sides.

The insulating performance of the wall can be calculated only in very simple configurations. It is, for example, generally considered that the temperature on the unexposed side of a concrete wall can be calculated with sufficient precision by numerical methods. The temperature of masonry walls can also be estimated as long as there is no macro crack in the wall. For most separating walls, however, the insulation and the integrity criteria can only be verified by experimental tests; numerical calculation provides little help. This is because the behavior of these walls made of several components strongly depends on the relative behavior of the different components. The opening of the joints between adjacent gypsum panels in a timber-stud gypsum boards wall, the behavior of connections between a steel panel and a steel stud, the charring in horizontal joints of plane timber walls, or the settlement of fiber-insulating panels inside sandwich walls each have a direct consequence on the insulation and integrity criteria. Yet, these relative behaviors can hardly be predicted for several reasons. First, these are fully coupled phenomena; the temperature field influences the deformations, but the opening of the joints influences the temperature distribution. The scale that should be considered to model these multi-physics phenomena is so small that it is absolutely incompatible with the scale of a complete building wall. Second, these behaviors exhibit a high level of variability because of the overwhelming influence of small local details such as the size and topology of a glued connection or the fact that a mechanical fastener is perfectly perpendicular to the steel sheeting or not. Also, it has to be recognized that a comprehensive constitutive model for, say, gypsum plaster at elevated temperatures has still to be established. For similar reasons, the load-bearing capacity of walls can be calculated only in the same simple configurations.

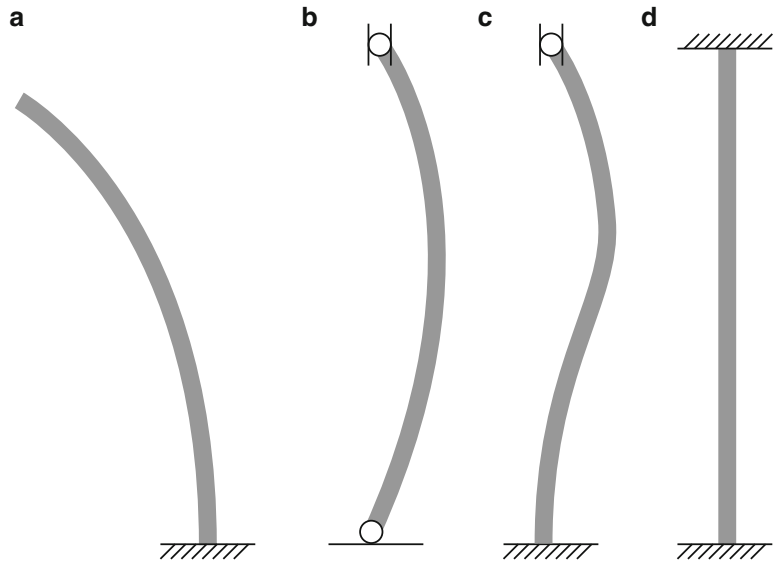

Fig. 52.10 Different lateral supports of a wall (fire on the right-hand side)

As far as the load-bearing capacity is concerned, there is no conceptual difference between a load-bearing and a non-load-bearing wall. The first one has to support an applied design load but the latter one has to support its own weight anyway. The difference is then just in the level of applied load which could affect the wall deflections, damage, integrity and stability during the fire. However, the mechanical behavior and the calculation methods for the two cases are the same.

The biggest difference between a wall and the other types of vertical elements, namely the columns, is that walls are very often heated on one side only. If a wall is heated on both sides, its behavior is similar to that of a column.
