When the wall is heated on one side only, a severe thermal gradient appears across the thickness of the wall. Because of the thermal elongation in the material, this leads to a curvature in the section and, hence, to large deformations or, if the deformations are restrained, to indirect effects of actions. Four typical behaviors can be noted, depending on the type of lateral support provided to the wall. Figure 52.10 shows schematically four possibilities with regard to the lateral supports.

The wall may be simply cantilevered from the floor with no lateral support at the top (see a in Fig. 52.10). Such a wall is statically determinate and, in a first-order theory, thermal gradients will not induce a variation of the effects of actions. Yet the lateral displacements of the wall are not restrained and large displacements will indeed occur. The displacement at the top of the wall is proportional, according to a first-order theory, to the curvature induced by the thermal gradient and to the second power of the height of the wall. The displacement at the top of significantly high walls can be very important, easily on the order of several hundreds of millimeters. This important relative displacement between the fire wall and the adjacent structure that supports the rest of the building must be accommodated. The lateral displacements lead to an increase of the bending moment, especially at the base of the wall, because of the eccentricity created for the applied load and for the dead weight. This increase of bending moment will increase the displacements, which, in turn, will increase the bending moments further. The process can converge to a position of equilibrium or can lead to the collapse of the wall. Collapse can occur either because the combined effects of actions at the base of the wall exceed the resistance of the section or because the foundation has not been foreseen to withstand this

increased eccentricity of the load and the rotation of the foundation cannot be prevented.

The wall may be simply supported at the base and at the top (see b of Fig. 52.10). In that case, the wall is still statically determinate and, in a first-order theory, thermal gradients will not induce a variation of the effects of actions. Lateral displacements will also occur but, compared to the cantilevered wall, they are four times smaller. Such walls are thus inherently more stable than the cantilevered walls and, furthermore, there is no danger of rotation of the foundation. The increase of the bending moment due to large displacements is much lower, and the maximum increase occurs at midlevel where only half of the dead weight is applied. A horizontal force will be applied to the supporting structure at the top of the wall because of the eccentricity of the dead weight, but this force should be easily accommodated by the structure that remains on the cold side of the wall. The challenge with this type of wall is that it has to be linked horizontally at the top to the structure on both sides of the wall. The fire may indeed occur on either side, and the support must be provided when the remaining cold structure is the one on either the left side or the right side. But, because the structure on either side is attached to the wall, this means that the collapse of the structure on the fire side may tear the wall down. Some developments have been made in order to disconnect the wall from the heated structure when it collapses; some are based on topological details that transmit the horizontal reaction only in the direction from the wall to the structure but not in the reverse direction, and some are based on plastic materials that are supposed to have melted when the heated structure collapses.

A wall that is fixed in rotation at the top (see d on Fig. 52.10) is not easily realized in practice. Such a wall would see an increase of the bending moment due to thermal gradients that are uniform along the height of the wall. Because of the fixity of the rotation at both ends, no lateral displacement would be induced in the wall, neither toward the fire nor away from the fire.

The wall shown as c in Fig. 52.10 can be constructed. It leads to lower lateral displacements than the simply supported wall B, but the horizontal force induced on the support at the top will be much higher. Such a configuration is not often used.

Structural Steel Design Criteria in the United States

In the United States, ASCE/SEI 7-10 [19] and ANSI/AISC 360-10 [21] are the fundamental design standards for structural steel and composite steel-concrete building construction. The former document specifies the design loads whereas the latter covers the structural design criteria. These documents should be utilized for any implementation of the pertinent design requirements.

It is noteworthy that ANSI/AISC 360-10 [21] includes an Appendix 4, "Structural Design for Fire Conditions," which contains provisions for both advanced and simple analytical methods, as well as acceptance of the traditional prescriptive methods based on standard fire testing.

The major characteristic of the AISC limit states design for fire conditions is substitution of the degraded mechanical properties (yield strength and elastic modulus) at elevated temperatures for their ambient counterparts, assuming elastic–perfectly plastic material response. Special provisions have been added to account for high temperature stability effects on compression members and laterally unbraced beams. Otherwise, the equations for design strength of steel and composite members remain identical to those specified for ambient conditions. The design basis fire may be a standard exposure or a postulated natural/real fire for the given space occupancy and use.

For example, under combined axial compression and bending loads, the AISC interaction equations for doubly and singly symmetric members at elevated temperatures would become the following:

$$\text{For } \frac{P_u}{\phi_c P_n(T)} \geq 0.2 : \frac{P_u}{\phi_c P_n(T)} + \frac{8}{9}\left[\frac{M_{ux}}{\phi_b M_{nx}(T)} + \frac{M_{uy}}{\phi_b M_{ny}(T)}\right] \leq 1.0$$

$$\text{For } \frac{P_u}{\phi_c P_n(T)} < 0.2 : \frac{P_u}{2\phi_c P_n(T)} + \frac{M_{ux}}{\phi_b M_{nx}(T)} + \frac{M_{uy}}{\phi_b M_{ny}(T)} \leq 1.0 \quad (52.4)$$

where P_u and M_u are the required factored axial and flexural strength per ASCE/SEI 7-10 [19] (see earlier section "Structural Load Combinations for Fire Resistance"), respectively; and $\phi_c P_n(T)$ and $\phi_b M_n(T)$ are the design axial compressive strength and flexural strength, respectively, per ANSI/AISC 360-10 [21], inclusive of the material property dependency on the high temperatures. The applied and resisting bending moments are referred to both the strong (x) and weak (y) principal axes of the cross section. In a similar manner, the remaining AISC provisions for ambient design can be readily converted to their corresponding design strength under fire exposure based on the predicted structural member temperature(s). Appendix 4 of ANSI/AISC 360-10 [21] permits the fire load analysis to be simply performed for the same member support and restraint boundary conditions as encountered at ambient.

Given the simplifications of the member by member approach, Appendix 4 of ANSI/AISC 360-10 [21] also allows, in general terms, for more advanced analyses and alternative design solutions that include effects of thermally induced deformations, framing restraint/continuity, and any load redistribution during the fire. Many of the methods cited earlier and in the following section are of this type, including those contained in internationally recognized design standards and in the technical literature. These advanced analysis methods for structural fire engineering will usually require use of computer models with the capability for material and geometric nonlinearities.

Fire Resistance of Frames

A frame is a structural system very often used in building construction. It is defined here as an assembly of several linear elements connected together to form a skeleton that extends vertically (columns) and horizontally (girders and beams) in one (two-dimensional frame) or two (three-dimensional frame) directions. The frame supports other components of the construction such as the floors, the roof, and the walls. In a framed building, the building and the frame are comprised in the same volume; the physical space that exists between the different elements of the frame is the usable space of the building.

Although the discussion in this section will be limited to two-dimensional frames for reasons of simplicity, most of the concepts highlighted here can be extended to a three-dimensional configuration.

Indirect effects of actions appear in a structure during the course of the fire because of thermal expansion. This is at least the case when the elements are made of metal or concrete but not so much for timber elements because this material exhibits very little thermal expansion. The indirect effects of actions come from the combined influence of two opposite sources:

1. Geometrical second-order effects, created by the change in position that the thermal expansion produces in the structure. It has been explained, for example, how severe this effect can be in a cantilevered wall (see the section "Walls" earlier in this chapter). If a high-rise building would be affected by a fire on several floors but on one side only, the situation could develop in a similar manner. Structural elements subjected to an axial force will show an increase of bending moment if lateral displacements are created in the elements by an unsymmetrical temperature distribution in the section. Similar effects are also produced if the displacements are caused by a decrease in stiffness of the elements.
2. Thermal expansion that cannot develop freely in an element will also induce variations in the

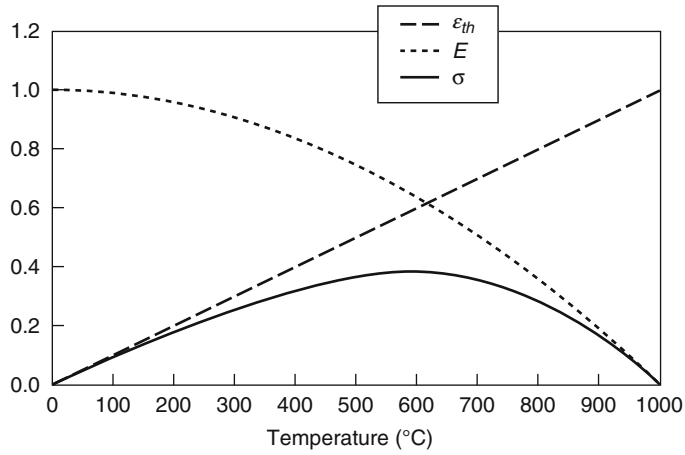

Fig. 52.11 Evolution of the restraint stress with the temperature

effects of action. When a column cannot elongate, an increase in axial force is induced in this element. Because of the variation of axial force in, say, a beam, the columns connected to that beam will consequently see an increase in bending moment. Similarly, a beam subjected to thermal gradients across the thickness will see a variation of the bending moment distribution if the transverse displacement that would be generated is prevented; this is the case, for example, of a continuous beam on more than two supports or of a beam in which the rotation is fixed at the supports.

These combined effects usually are detrimental to the fire resistance of the frame but, in some circumstances, can have a neutral or beneficial influence. This is the case, for example, when tensile forces can be mobilized to withstand the loads that bending cannot accommodate anymore.

If the design fire scenario is based on a nominal fire curve in which the temperature increases continuously, or if failure of the structure occurs during the increasing phase of a more realistic fire scenario, indirect effects of actions created by large displacements have a tendency to increase constantly during the fire. This is because the temperatures of the parts of the structure subjected to the fire increase constantly and, as a consequence, the stiffness of these parts decreases constantly, which leads to a continuous increase of the displacements.

The situation is more complex when the indirect effects of actions are due to restrained thermal expansion. This can be explained quantitatively by the model of a simple element that has a thermoelastic constitutive model and has the elongation totally restrained. The increase of stress $\Delta\sigma$ due to a thermal expansion $\Delta\varepsilon_{th}$ is equal to the amount of thermal expansion that cannot develop. For this case, it equals the whole thermal expansion (because the restraint is total) multiplied by the Young's modulus of the material E in Equation 52.5:

$$\Delta\sigma = E\varepsilon_{thermal} \tag{52.5}$$

Owing to the fact that thermal expansion is usually an increasing function of the temperature and that the Young's modulus is a decreasing function of the temperature, the product of these two variables first increases, passes through a maximum, and then decreases again. This is illustrated schematically by Fig. 52.11 in which the supposedly linear thermal strain has been normalized to 1.0 at 1000 °C and the nonlinear decrease of the modulus E has been normalized to 1.0 at 0 °C. In that hypothetical case, the so-called "thermal stress" would have a peak around 580 °C. If the restraint is not total but the restraining structure behaves elastically, the

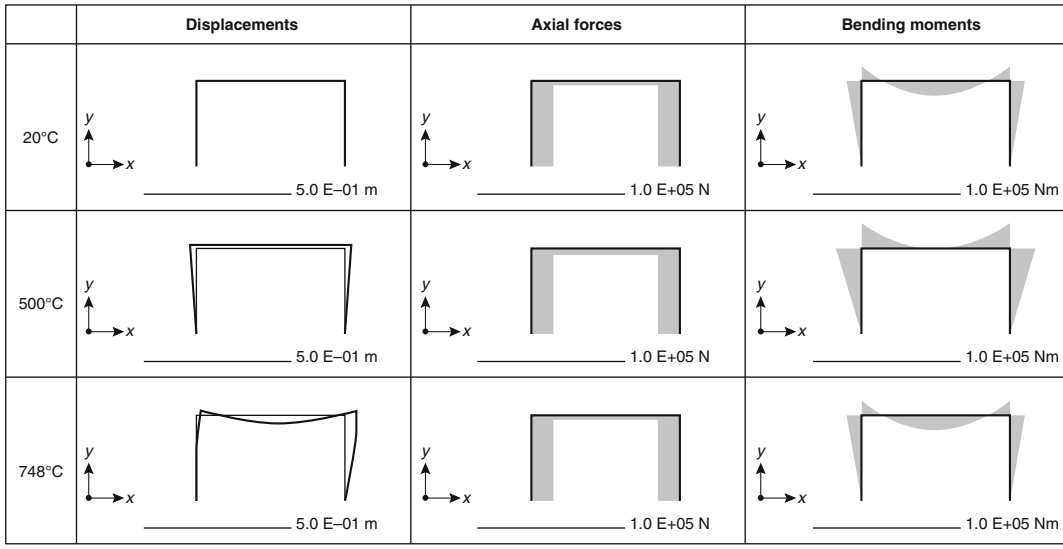

Fig. 52.12 A simple portal frame under increasing temperature

thermal stress will be lower in magnitude, but the maximum will occur for the same temperature of the heated parts.

Even if all elements of the frame are subjected to the action of the fire and in the hypothetical case that all elements have their temperature increasing at the same rate, a restraint to thermal expansion is likely to appear. This is because the supports of the structure on the ground (that is, usually, the bottom of the columns of the first floor) are normally restricted in their horizontal displacement.

Figure 52.12 shows the evolution of the displacements and the effects of actions in a small simple portal frame, 5 m wide by 3 m high, the steel members of which are heated uniformly. If the effects of creep are neglected, the situation can thus be depicted as a function of the steel temperature, independently of the fire scenario. The beam is subjected to a downward uniformly distributed load of 30 kN/m, with an associated horizontal distributed load of 30 N/m introduced as an equivalent initial imperfection. The section on the beam is an IPE400 and the section of the column is HE280B. Steel has yield strength of 235 N/mm^2. The results have been obtained by a nonlinear numerical analysis that takes large displacements, thermal expansion, and nonlinear stress-strain relationships into account.

At room temperature, the displacements can hardly be seen on the picture, although they have been amplified by a factor of 5. The axial force and bending moment diagrams are standard for this type of structure.

When the temperature of the elements increases, the thermal expansion of the columns develops freely, while the thermal expansion of the beam is restrained by the bending stiffness of the columns. The compressive axial force in the beam increases, accompanied by the same increase in horizontal reaction force directed toward the inside of the frame at the two supports. This induces a significant modification in the bending moment diagram.

The axial force in the beam increases until 500 °C and decreases thereafter. It has to be noted that, in this case, not only the stiffness of the restrained member (the beam) decreases as the temperature increases, but also the stiffness of the restraining system (the columns) does.

For temperatures beyond 500 °C and until failure at 748 °C, the indirect effects of actions decrease continuously, and at failure the effects

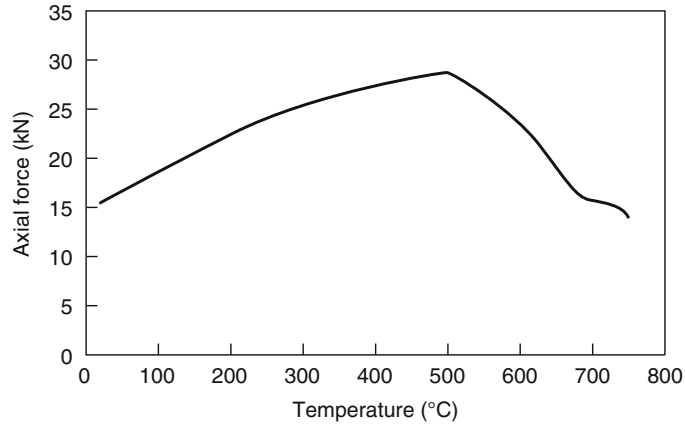

Fig. 52.13 Evolution of the axial force in the beam

of actions have nearly the same pattern as at room temperature. This behavior has been observed on many occasions, especially when the failure temperatures are rather high.

Figure 52.13 shows the evolution of the axial force in the beam as a function of the temperature in the structure. It shows that, although the force has approximately doubled at 500 °C, its value at failure is nearly identical to the value it had at room temperature.

The following example is based on a multi-story, moment-resistant frame in which only one floor is subjected to the fire. The vertical distance between the beams is 3 m; and the columns are separated by 6, 8, and 6 m. The sections and the material model are the same as for the previous example. The steel columns at floor 4 as well as the steel beam that they support are heated at a uniform temperature (Fig. 52.14).

The axial force and bending diagrams at room temperature are typical for this type of structure. The displacements can hardly be seen in Fig. 52.14, although they have been amplified by a factor of 5.

During the first phase of the fire, until a steel temperature of 405 °C, the longitudinal elongation of the heated beam is restrained not only by the bending stiffness of the heated columns that support this beam but also by the bending stiffness of the cold columns just above the beam. A compression force thus develops in that beam with, for equilibrium reasons, tensile forces in the beams directly above and below the heated beam. This is reflected in the bending moment diagram of the columns, especially the outermost ones.

From then on, the compression force in the heated beam decreases, not only because of the decrease of axial stiffness in that restrained beam and in the restraining heated columns but also because of the vertical downward deflection of the beam that provides some relief geometrically to the compression force. Whereas indirect effects of actions were mainly induced by restrained thermal expansion in the first phase of the fire, large displacements will play an increasingly prominent role.

At 633 °C, failure is imminent. A severe downward deflection in the central span of the heated beam is observed. The axial force and bending moment diagrams are not as disturbed as they were at 405 °C but are still not totally equal to the pattern displayed at room temperature.

Total collapse of the frame finally occurs at 634 °C by buckling of the two central columns. The axial force diagram shows that the compression force has nearly totally vanished in the upper part of these two central columns. This is because dynamic effects have been taken into account in this analysis (heating rate = 1 °C/s). An analysis made by a succession of static equilibrium would probably stop one or two degrees earlier, thus with only a marginal difference in critical temperature but a much less complete insight into the failure mode.

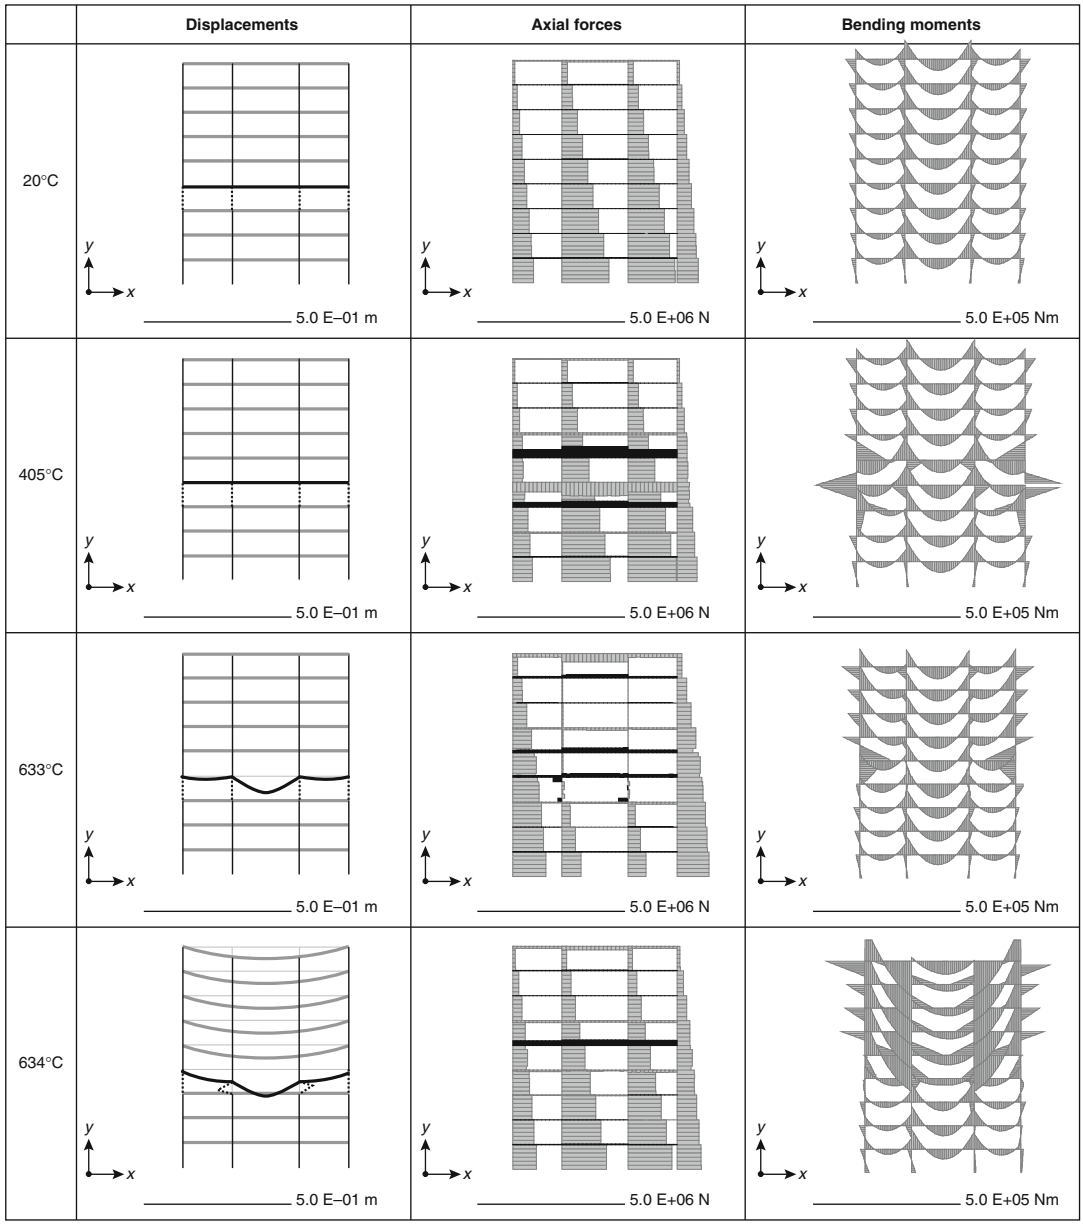

Fig. 52.14 A multistory portal frame under increasing temperature

Figure 52.15 shows the evolution of the axial force at mid length of the heated beam. It shows that, when failure is approaching, the axial force tends to decrease to the same level that it had been at room temperature, with even a sign reversal at the very end, when large displacement effects become predominant.

When the same examples are run with the thermal expansion of steel being artificially turned off, the simple frame of Fig. 52.12 fails exactly at the same critical temperature of 748 °C, whereas the multistory frame of Fig. 52.14 fails at a critical temperature of 613 °C, compared to a value of 634 °C with

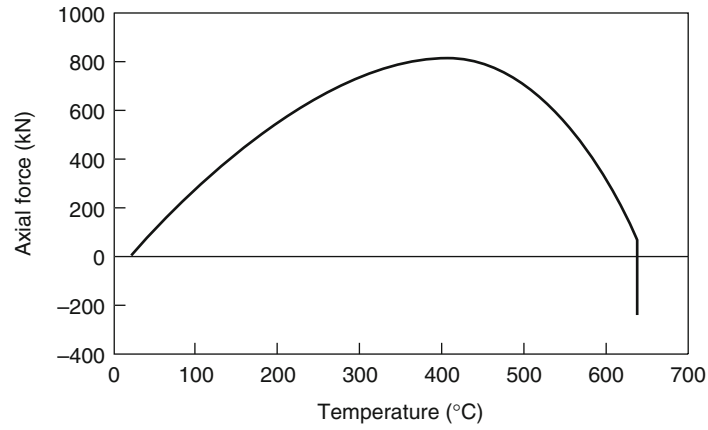

Fig. 52.15 Evolution of the axial force in the heated beam

thermal expansion being considered. This means that, in this particular example, the effects of thermal expansion are somewhat beneficial for the fire resistance.

Input and Modeling Uncertainties

Engineers and scientists are continually working with the reality of the physical world in which we are living. In particular, civil/structural engineers try to understand and quantify the different natural and materials phenomena in order to design safe structures and to protect these structures against any foreseeable loads and actions, including fire. The only way to represent the physical reality is to create analytical and experimental models that best represent it. If the models are realistic and simple enough, the engineer can vary the input of the models and see how the output varies. This allows the engineer to see the influence of different parameters on the behavior and safety of the structure.

Because the models are simplified representations of reality, they have their inherent limitations and uncertainties. Limitations are defined here as approximations that are clearly identified but accepted because of the range of input or response assumptions, or because they are considered to have a negligible influence on the results. On the other hand, uncertainties are defined as a lack of knowledge about a particular physical behavior (model uncertainty) or about the precise value of an input parameter (input uncertainties).

There are essentially two different types of model for representing reality: experimental models and analytical models. Experimental models consist of physical specimens built to represent the real structure. Very often, only a part of the structure can be represented by a specimen and tested as either a full-scale or a small-scale model. In the latter case, it is possible to represent a larger part of the structure, possibly the whole structure. Full-scale experimental models of complete structures are extremely rare in general and for structural fire response, with the one major exception and example being the series of tests performed by BRE at Cardington [25].

Analytical models are defined here as models made of equations and criteria, from the most fundamental force equilibrium, structural mechanics, and design criteria equations used in engineering office practice to the most complex numerical models (finite element), which require huge computing capabilities. A particular family of the analytical models consists of the empirical models, sometimes called the tabulated data. They are not real behavioral models, but the presentation in a simple form (data tables or statistical regression equations) of the results obtained by application of the experimental or analytical models.

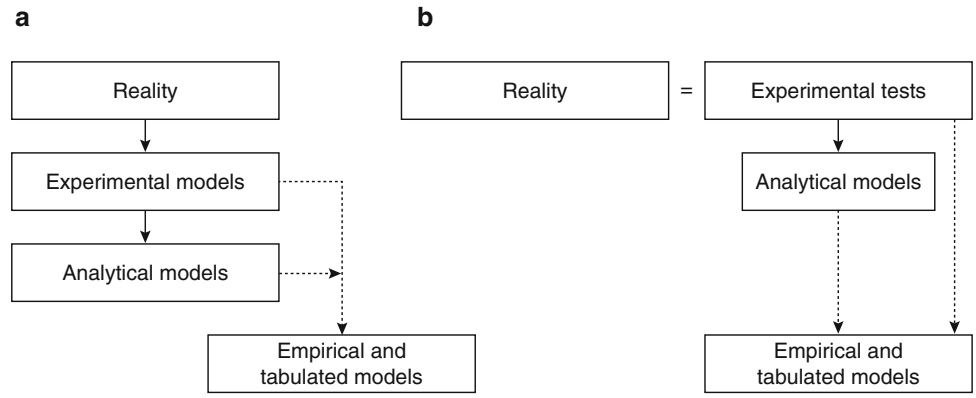

Fig. 52.16 Two common perceptions of the hierarchy in structural fire engineering

It is essential that the limitations and uncertainties of the models are fully understood by the users. If not, there is a high risk that the models may be used in an inappropriate manner or used beyond their intended scope of application. Sensitivity analyses by variation of suspect inputs can provide a more robust, bounded answer, but this is possible only if the uncertainties have been identified.

For some sciences, such as astronomy, experimental models are not feasible and only analytical models can be developed. In the field of structural fire engineering, the first experimental fire tests made on simple elements were conducted in the early 1900s before even the simplest analytical models could be created. At the end of the twentieth century, analytical models were becoming more complex due to the growth of the large historical fire test database and computational capabilities. The initial objective at the time when many of these numerical models appeared was to efficiently complement or replace fire testing of simple elements. Because of this delayed appearance of analytical models, there is a common perception that a hierarchy exists with reality at the top, the experimental models just underneath, and the analytical models at the bottom (Fig. 52.16a). For some, the experimental tests are even incorrectly considered as an exact representation of reality, not as a model of the reality (Fig. 52.16b).

The situation, that is, the relationship between the models and reality, is in fact different. First of all, it has to be realized that, when an engineer has to protect a future building against the effect of possible fires, there is no such a thing as "the reality" (Fig. 52.17).

The fires that occurred in the past provide us with some useful information but it has limited applicability. First, the historical fires may not have occurred on exactly the same structure as the one that is envisaged. Second, and above all, a building is very rarely instrumented with recording devices when a fire starts, and thus it is not easy to derive quantitative conclusions from the general observation of buildings devastated by a fire. The future fire that may occur in the building that is being designed does not belong to reality either, at least not at the time when the design is being made.

Note that one exception to this is when the case that is investigated is a real fire that occurred in a real building, in forensic investigations, for example. In that case, the text in the upper rectangle of Fig. 52.17 should be replaced by "Fire under investigation," and it belongs, indeed and unfortunately, to reality.

Second, regarding the relationship between the models and reality, if it is well accepted that analytical models, and especially the numerical models, have their own limitations, the general perception is that experimental models are a perfect representation of the real building or at least of the element under investigation. The technicians and engineers in charge of experimental fire tests know all too well this is not

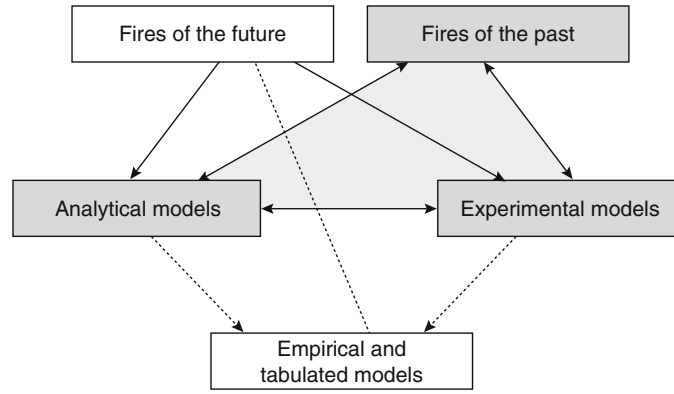

Fig. 52.17 A more correct representation of the relationships between the models

exactly the case. As it is sometimes said in a caricatured manner: "Nobody believes in the results of a numerical model, except the one who made it, but everybody believes in the results of an experimental test, except the one who made it."

Fires of the past, analytical models, and experimental models must be considered as three tools of similar utility, each with its own merits and limitations. They all should be considered on the same level, with no particular one being predominant. All three benefit from the others, as they mutually interact with each other. When analyzing a real fire, analytical models may help trying to explain what happened, and experimental reconstruction may help verifying some hypotheses made about the behavior of the building. When developing analytical models, experimental tests on simple elements are considered as the necessary point of comparison for verification, and comparison with the outcome of real fires may be considered as a good validation. Numerical models are very often used to make the predesign of experimental tests in order to ensure a higher probability of success or in a complementary manner in order to maximize the information obtained from the test.

The main limitations and uncertainties of the models will be briefly mentioned in the following sections. Most of the structures subjected to fire are designed according to the hypothesis of an uncoupling between the mechanical and the thermal problems. The temperatures in the structure are first calculated in the structure without taking the stress level into consideration, and these temperatures are then taken into account in the subsequent mechanical analysis. The limitations related to the determination of the temperature in the structure by analytical models will be discussed first, then the limitations related to the mechanical analysis by analytical models, and finally the limitations of experimental models.

Limitations and Uncertainties of Thermal Calculations

Thermal Properties In order to determine the evolution of the temperature in a structure, the thermal properties of the materials present in the structure must be known.

Generic properties are given in Appendix 2 of this Handbook for the most commonly used building materials such as structural steel, normal strength concrete, gypsum, and so forth. They can be used with a reasonable level of confidence because they have been widely validated and have been in use for several years already with no apparent significant problem. Attention must be paid when the field of application is extended to "similar" materials that may or may not have markedly different properties such as iron steel, stainless steel, high-performance concrete, bricks, mortars, and the like. The ideal situation is when the person determining the temperatures in a structure for a practical application has access

to experimental results made on elements comprising the material that will have to be taken into account in the application. It is then possible to determine by trial and error the thermal properties of the material that allow reproducing the results of the tests, and these properties can be used in subsequent analyses on structures that will not be tested but only calculated. Not only the thermal conductivity and the specific heat have to be determined but also the properties for the boundary conditions, such as the convection heat transfer coefficient and the emissivity. If this cannot be done and thermal properties of similar materials are utilized, the engineer must be aware of the inherent degree of uncertainty introduced in the final results.

For other materials, mainly the thermally insulating products, no generic properties can be given and the information must necessarily be taken from experimental tests. It must be emphasized that most of the thermal properties are highly temperature dependent and a value given for a commercial product for utilization at room temperature (e.g., insulating the walls of houses against heat loss to the outside atmosphere) cannot be used directly in a fire. The thermal conductivity, to name only one, has a tendency to increase significantly with increasing temperatures.

If a producer is able to deliver for his or her product the laws giving the evolution of the thermal properties as a function of the temperature, there is a high probability that these laws have been derived by recalculations of experimental tests by a simplified calculation method in which several hypotheses are included: a uniform temperature in the section, the temperature on the outside of the insulating layer equal to the temperature of the fire, and so on. The given laws are thus suitable for utilization in the same type of simple calculation model. If numerical calculations have to be performed, it is better first to recalculate all the available experimental tests by the use of the numerical model. Because the same simplifications are not present in the numerical analysis, the laws obtained by that method could indeed be slightly different from the laws obtained with the simplified method. It is important that the same model be used for a practical application as the one used to determine the thermal properties.

Fixed Geometry In most if not all methods used for determining the temperatures in structures exposed to fire, the geometry of the sections is given before the calculation starts, and it remains fixed during the whole simulation. Theories and numerical algorithms do exist for calculating temperature distributions in objects with a shape that is continuously changing (e.g., in the ablation process that occurs at the nose of re-entrant space vehicles), but these techniques are not commonly used for designing buildings subjected to fire.

A first situation of changing geometry is the case of intumescent painting, usually applied on steel members. Whereas the dry film has a very limited thickness in the order of some millimeters, the product exhibits an endothermic chemical reaction when heated and expands to a layer of foam-like product with a thickness of several tens of millimeters. Very few attempts have been made to model precisely this expansion (see Butler et al. [27]). The usual procedure is to model the intumescent painting as a purely conductive layer of constant thickness (e.g., the thickness of the dry film) and to determine "equivalent" thermal properties yielding the same temperature evolution for the steel section as the one observed in experimental tests. A peak can be introduced in the curve of specific heat in order to account for the endothermic chemical reaction. It has to be noted that different laws of thermal conductivity should possibly be used for different thicknesses of the dry film because it has been observed that the thermal resistance provided by these products is usually not proportional to the thickness of the dry film.

Another situation is found in timber sections that exhibit shrinkage and cracking after charring. A practical solution very often used is to also consider a constant geometry and equivalent thermal properties.

The phenomenon of concrete cracking and spalling, another situation of evolving geometry, is usually not taken into account when modeling concrete structures subjected to fire. This is acceptable only for materials that are known for not being particularly prone to spalling (e.g., normal-strength concrete with a limited level of free moisture), or if particular provisions have been made in order to prevent the occurrence of spalling (e.g., the addition of polypropylene fibers). In other cases, and especially for high-strength concrete, the behavior of the material against spalling must have been determined experimentally. In case of doubt or for critical situations, it is still possible to neglect from the very beginning of the calculation the presence of the outer layer, this one being assumed to disappear in the early stages of the fire because of spalling. The question is then to decide on the thickness of this sacrificial layer. A usual choice is to limit the spalling to the first layer of reinforcing bars, these being then directly exposed to the influence of the fire, but there is experimental evidence of cases when the spalling did progress beyond the first external layer of reinforcing bars.

Equally unpredictable by analytical models at this time are delaminations or detachment of spray-on materials or gypsum board and other fire-related damage that will accelerate thermal penetration into the structure.

Perfect Contact If two materials are in contact with each other in a section, the usual hypothesis for an analysis is that the contact at the interface between both materials is perfect. This is not always the case, and sometimes initial contact does not persist and disappears during fire tests.

For example, when a concrete slab is cast in situ on the upper flange of a steel beam in order to form a composite steel-concrete section, it is generally accepted that the contact between the concrete slab and the steel beam is nearly perfect and will remain so during the fire because of the eventual shear connectors fastening the slab to the beam. If not, simply the action of the gravity load is assumed to force the slab to follow any downward movement of the beam on which it is laid.

A situation with a similar geometry can arise if a concrete facade element is placed against the external flange of a steel column. In that case, it is not possible to be sure that no gap will be created during the course of the fire between the steel column and the wall element, with each one having its own thermal and structural bowing. If at least a reasonable amount of connectors is provided, it is reasonable to take the effect of the wall elements into account by supposing that the external flange of the steel column is not attacked by the fire. On the other hand, because of the uncertainty of the contact with the concrete element, the concrete element will not be represented in the thermal analysis of the steel column, which will inhibit in the model any heat sink effect from the column to the wall (an adiabatic boundary condition is imposed on the external flange of the column).

In composite steel-concrete slabs using unprotected thin steel decking, it has been observed in experimental tests that the steel sheet very often detaches from the concrete slab after a short duration. The research work performed by Both [28] allowed to take this effect into account in a method presented in Eurocode 4 [29], but this method is an empirical method. This effect is usually neglected in numerical analyses, with the consequences that the temperatures in the steel decking are slightly underestimated. The bare steel deck loses its strength very quickly anyway, and the temperatures in the concrete slab are somewhat overestimated, which is on the safe side.

A similar situation exists in hollow steel sections filled with concrete. The external steel tube has the highest temperatures in the section and exhibits the highest radial thermal expansion. This, plus the effect of the steam pressure from the evaporating water of the concrete, leads to a far from perfect contact, and a thermal resistance does appear at the interface between the concrete core and the steel section. As it was observed that the temperatures measured in the center of the section did not compare well with the temperatures computed on the base of a

perfect contact, it has sometimes been tried in the past to correct this effect by introducing very high levels of evaporable water in the concrete. Levels as high as 10 % in weight are reported in Eurocode 4 [29] although a more reasonable value of 4 % is recommended in the absence of data. It is by far physically more correct to include a thin layer of conductive material between the concrete core and the steel section. In Renaud [30], this contact resistance has been estimated to 0.01 m^2K/W, that is, equivalent to a 16 mm layer of concrete with a thermal conductivity of 1.6 W/mK (but it is geometrically more correct to use a 1 mm layer of a material with a conductivity of 0.1 W/mK)

Effects of Localized Fires The assumption most often used for the design fire scenario utilized for verification of a structure under the effects of fire is a uniform temperature in the compartment. The reasons are probably that, first of all, this is the situation prevailing in the standard fire tests that the numerical programs tried to mimic in the early days and, second, because it is a good approximation for fully developed fires in small compartments, which are the most challenging for the structure. Yet, more and more attention is being paid nowadays to localized fires, which include either any fire in its early stage or a fire in which the available fuel load is concentrated on a limited part of the floor area, such as a registration desk in an otherwise empty atrium or one car burning in a parking garage with no propagation to adjacent cars. These situations have to be considered because of the susceptibility of statically determinate structures to the failure of a single element that could be located just above the localized fire source, and also because this period of time when the situation is still tenable in the compartment is very critical for the evacuation of the occupants and for action of the fire brigade. With these localized fires, the temperature is far from uniform in the compartment and much more of a problem for the numerical programs. The temperature of the gas in the vicinity of the structure is by far not the most important parameter driving the heat transfer to the structure, with radiation from the fire source usually being dominant.

First, consequences are conceptual. The boundary conditions for the determination of the temperature in the structure are much more complex. They are certainly varying with the location of the boundary, and this possibility has to be taken into account in the numerical program. A steel beam located above the fire plume is not subjected to the same thermal attack as a beam located several meters away. Second, the question arises whether an uncoupled determination of the temperatures is still valid. Is it admissible to calculate the temperatures in the compartment using, for example, computational fluid dynamic (CFD) software and, afterward, the temperatures in the structure based on those calculated in the compartment? Or is it necessary to make a fully coupled determination of the temperatures, simultaneously in the compartment and in the structure, taking into account precisely the interaction between the two? The question has even been raised whether the mechanical analysis should not also be part of the same simulation. For example, the deflecting ceiling would modify the interior geometry of the compartment and this would also affect the development of the fire. Whereas the last coupling can probably be neglected in most cases, the thermal coupling from the localized fires to the structure must be considered, and this is not done easily.

A practical problem in which the interaction between the compartment and the structure has to be considered is the difference in size of the meshes used in both problems. Whereas the dimension of the cells can be in the order of 10–50 cm when modeling a compartment, the thickness of the web of a steel beam can be as low as 4 mm. It is not realistically possible to decrease the size of all cells of the compartment down to the size required for a precise determination of the temperatures in the structure. Algorithmic solutions must be derived in order to cope with this geometric discrepancy at the interface.

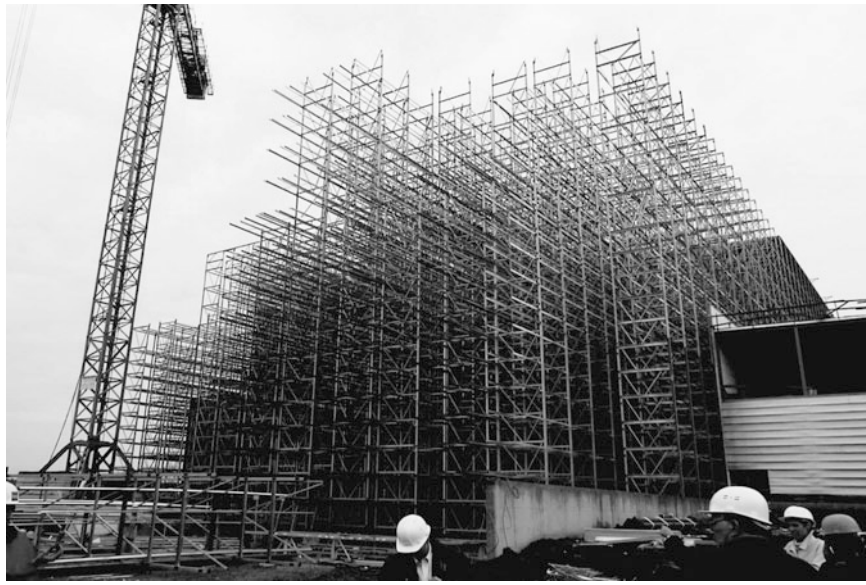

Fig. 52.18 A numerically very large structure

If the structure is subjected to the effects of a localized fire, the temperature distribution inside the structure is inherently a three-dimensional distribution. The precise determination of such a temperature distribution would normally require the utilization of a full three-dimensional model of the structure made of three-dimensional solid elements. The size of such a model would be so huge that it would not be practically feasible. Some approximations have to be made in the model, introducing some additional limitations.

Limitations and Uncertainties of Mechanical Calculations

Very Large Structures Although the geometrical dimensions of a structure are not a problem for numerical modeling, there is still a limit to everything, including the power of our processing units and the patience, schedules, or budgets of the users. Some complex steel structures may easily comprise tens of thousands of elements of different sorts, each experiencing a different temperature history (Fig. 52.18). These structures are not only geometrically big; they are above all numerically big. It is, for example, beyond any reasonable expectation to think that the whole structure of one of the WTC towers could in the foreseeable future be modeled completely in detail, with every member, every slab, and every connection represented. One possible solution in case of very large structures is to limit the analysis to substructures, that is, representative parts of the whole structure. It is also possible to represent with simple elements, possibly elastic ones, the parts of the structure that are far away from the zone affected by the fire and that are expected not to exhibit any nonlinear deterioration.

The most detailed beam finite elements used in numerical modeling allow determining the precise extent of plasticity at every point in the sections and along the members and provide a very precise shape of the deformed members; but several elements are required in order to represent each subassembly, such as a beam or a column. More simple formulations can be used, in which each subassembly is represented by a single element, for example, using the beam-column plastic hinge approach such as in Liew and Ma [31] or Landesmann [32].

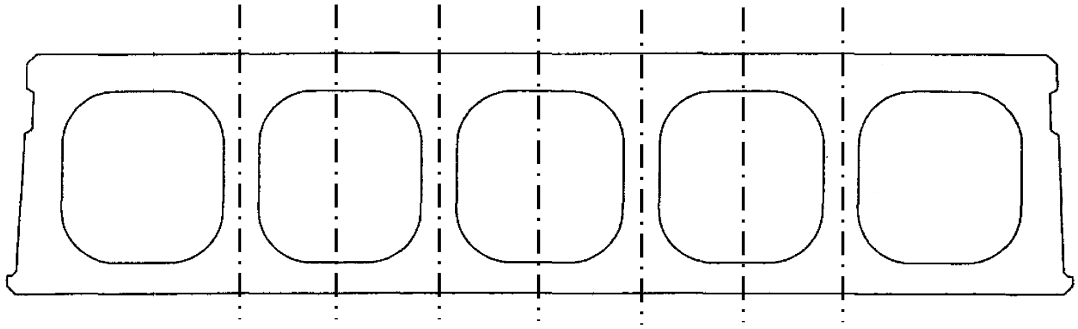

Fig. 52.19 Planes of symmetry in a hollow core slab

It has also to be realized that modeling a building structure, subjected to fire or not, using solid brick elements is far beyond our present possibilities. Only parts of the structure can be analyzed with these types of finite elements. In this case, the limitation explained in the following section will arise, namely the decision on the boundary conditions.

Boundary Conditions The boundary conditions may pose some problems in the discretizations that are particular to the fire. Some are inherent to the three-dimensional stress level in solid-type structures and they cannot be solved easily; others appear in bar-type structures when defining a substructure and selecting the appropriate boundary conditions.

Let us imagine that a simply supported flooring system made of parallel hollow core prefabricated concrete elements has to be modeled and that solid brick elements are used. If the loading is symmetric with respect to the longitudinal axis of the elements, only half of the span of the system needs be modeled. The boundary conditions along this plane of symmetry are standard and not particular to the fire. In the other direction, it is clear that a series of parallel vertical planes of geometrical symmetry do exist; for example, passing through the center of the cavities and also passing through the center of the webs between the cavities (Fig. 52.19).

If the loading is uniform on the floor, one might be tempted to discretize only a part of the structure, limited by a cavity and a web plane of symmetry. The question then arises about the boundary conditions, especially for the displacements perpendicular to the parallel planes of symmetry. If they are left free, no thermal stress will arise in this direction, and this is not correct in the fire situation. If they are completely fixed, a full restraint will be created, and this is also not correct. Even if the slab is laterally not restrained at all, a linear constraint relation between all the nodes located in a plane of symmetry would imply that a Bernoulli condition has been imposed, and this also may not correspond to reality. In fact, in order to obtain a realistic answer, it is impossible to consider all these parallel planes of symmetry. Only the one in the center of the slab can be taken into account. This means that as much as one-quarter of the whole floor has to be discretized. This can prove to create a model that is numerically very big.

In big structures made of bars, the concept of substructure is often used. In this case also, a choice has to be made for the boundary conditions at the interface between the structure and the rest of the structure (Fig. 52.20). The choice is for each degree of freedom between imposing a fixed displacement or imposing a force and leaving the displacement free. In fact, the real boundary conditions are intermediate between these two extreme solutions, dictated by the response of the surrounding structure.

Spalling The same limitations exist during the mechanical analysis as during the thermal

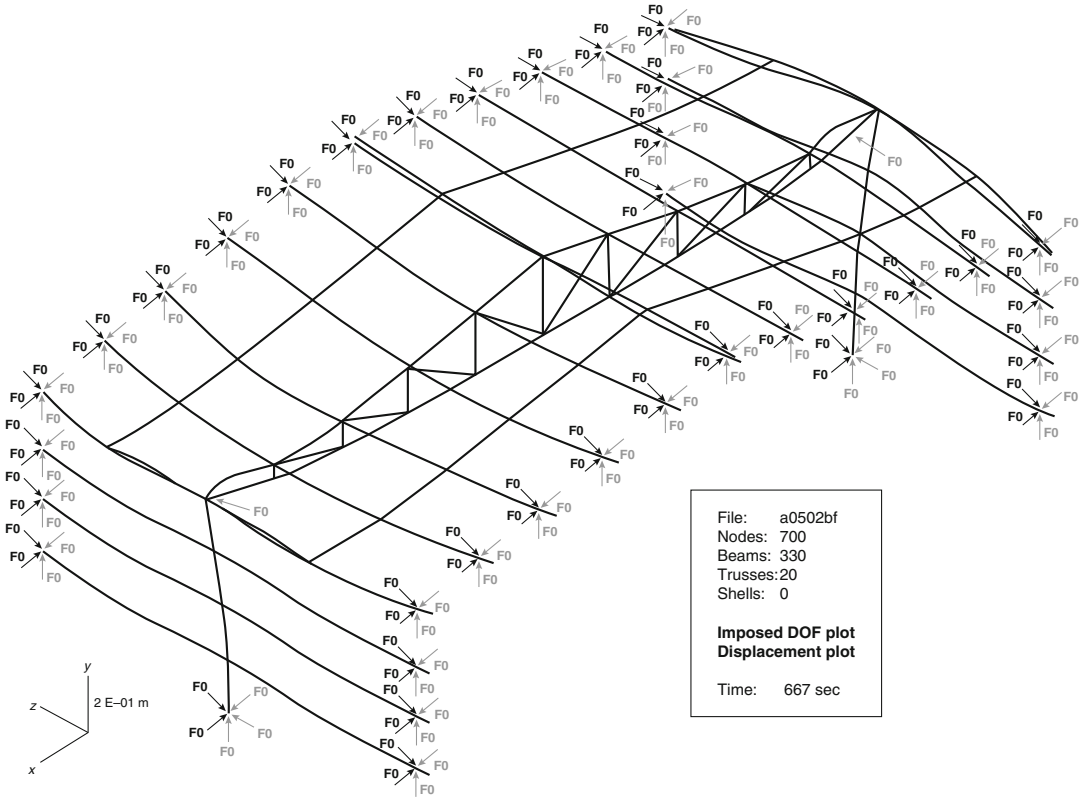

Fig. 52.20 Boundary conditions in a substructure

analysis; if the concrete spalling phenomenon is not taken into account when determining the temperatures, it is also not taken into account in the mechanical model. All comments made above in the section on fixed geometry could be repeated here.

It has to be mentioned that some efforts have indeed been made in order to predict the phenomenon of spalling. This modeling relies on highly sophisticated constitutive and numerical models taking into account the coupling between the mechanical and the thermal problems; mechanical stresses created by applied loads and by thermal restraint interaction with the water pressure. These models provide a unique insight in the phenomena that can help understand the physics and identify the relevant parameters. However, these models have to be provided with a very large number of temperature-dependent input data and the prediction cannot yet provide a complete level of confidence with respect to a phenomenon that is not really deterministic. As a consequence, in a real design situation, it is probably faster, much cheaper, and perhaps more reliable to make a simple experimental test aiming at identifying the susceptibility to spalling for a particular concrete mix/structure situation than to make all the experimental tests that are necessary to feed the model and then try to predict whether spalling is likely to occur or not.

Lack of Convergence The equations that govern the equilibrium of a structure subjected to fire are highly nonlinear, the reasons being in the geometrical as well as in the material behavior. Moreover, these equations express the equilibrium at a given time and, in order to model the evolution of the structure during the course of the fire, they have to be integrated over time. The

integration of these nonlinear equations involves an iterative procedure and experience has shown that, in structures with some level of complexity, convergence of this process is not guaranteed. Depending on the size of the time step or on the value used for the convergence criterium that is used, the simulation of the same case may stop running at different moments in the fire. The simulation may stop at an early stage, when the load-bearing capacity of the structure is not yet exhausted. These failure times produced by a lack of convergence are called *numerical failures*. In some cases, the experience of the user with nonlinear modeling in general and in the computer code used in particular allows the user to find a solution that makes the code run until the real physical time of collapse. But in the most difficult cases, all the algorithmic resources are not sufficient to solve this difficulty; the simulations stop prematurely, and this is certainly a severe limitation of the numerical models.

The biggest danger is that the user may be tempted to modify, in fact to alter, the model in order to facilitate the convergence. Modification of the constitutive models is a common way to achieve this result, with creation of numerical materials that are excessively elastic or with unlimited ductility or, for concrete, with an artificial tensile strength never encountered in reality. The model will then perhaps converge, but to a solution that has an unknown relation to the solution of the original problem. The user should perhaps have the courage to admit that the tool does not do the job that was expected, rather than draw conclusions from an altered model.

There is another problem linked to numerical modeling, which is in fact nearly at the opposite of the problem of numerical failures. In some cases, the deflections of the structure can be so high when the simulation stops that they have no possible physical existence. For example, the vertical deflection of a simply supported beam could exceed the floor to ceiling distance available under the beam. Or the horizontal displacement of a rolling support could reach several hundreds of millimeters.

Because of these two opposite problems, the moment of the last converged time step cannot be considered automatically as the fire resistance time of the structure. The displacements and the evolution of the displacements during the fire are the best indicators to decide about the fire resistance time.

If the displacements at the last converged time step are exceedingly large, it is necessary to observe the displacements at previous time steps and to decide when the fire resistance of the structure was exhausted. Conventional and sometimes arbitrary failure criteria have to be used, for example, based on deflection or deflection rate limits.

If no large displacement is found, it is necessary to judge whether this corresponds to a numerical failure or to the real loss of load-bearing capacity of the structure. Finding one degree of freedom in the structure for which the evolution of the displacement as a function on time shows a vertical asymptote near the end of the simulation is a good indication of real failure (runaway failure), at least when this movement involves a global displacement of the structure. The lateral displacement of an individual bar that buckles in a statically indeterminate structure may not be sufficient to lead to a global collapse. There are yet some cases, on the contrary, when a real failure has a particular fragile character and these are not so easily detected. The experience of the user is here a key factor.

Bernoulli Hypothesis The workhorse for modeling of building structure framing in fire is the Bernoulli beam finite element. It has yet to be understood that the hypothesis of plane sections remaining plane and perpendicular to the longitudinal axis has some consequences; some failure modes are not covered by this type of element. These are namely the shear failures, the slip between reinforcing bars or prestressing tendons and the concrete and the lack of rotational capacity due to local buckling. Any steel section, as thin as it might be, is seen by a Bernoulli beam finite element as a compact section with infinite rotational capacity. If local buckling is expected to be a crucial issue, it is still possible to rely on

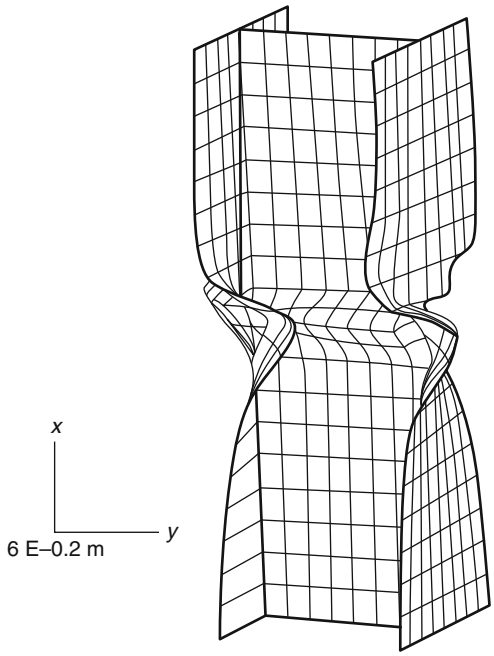

Fig. 52.21 Local buckling in a steel column

shell finite elements, see Fig. 52.21, but these are numerically more expensive elements and they will normally be used to analyze single members or subassemblies as opposed to complete structures.

Connections Connections between bar-type elements are most conveniently modeled on the basis of a simple hypothesis with respect to the relative rotation between the members: the connection is either assumed not to transmit any bending moment at all—hinged or pinned connection—or the relative rotation of the members is supposed to be null—rigid or fully fixed connection. In fact, the real behavior of any connection is between these two extreme situations. Any connection is semi rigid (or partially restrained), with some being more rigid than the others. The situation is more complex in the fire than at room temperature because of possible temperature differences between different components of the same connection and because of the presence of indirect effects of actions inducing axial forces (possibly different in sign between the heating and the cooling phase) and possible reversal in the sign of the applied bending moments. Very large displacements or thermal expansion can even totally modify the behavior of a connection. A connection that is very flexible at room temperature may become much stiffer in the fire if, for example, some gaps between different components are closed and these components enter into contact.

Significant research work has been done and is still being conducted on this topic with the aim of identifying and understanding the behavior of connections subjected to fire, especially of connections between steel, composite steel-concrete, and timber members. Valuable information has been derived, but this topic is still in the research phase and consideration of semi rigid connections in the fire situation is not yet common practice for real projects.

Limitations of Experimental Tests

Experimental tests also have their own limitations. Some are obvious, whereas others are not.

Cost is often mentioned as the first limitation. It is true that, in addition to the cost required by the fire laboratory for performing the test, other costs have to be added for the fabrication, transport, and disposal of the specimen, as well as for the time spent to define the test and assess its results.

The size of the structure is another limitation. Except under very exceptional circumstances, it is not possible to test a long span beam of, say, more than a few meters. Testing full-scale, complete structures is also seldom possible.

Time constraints may be another problem because there may be a significant amount of time between the day when the decision of a test is taken and the day when the results are available. Some time is required for buying the materials for the specimen if they are not available. The specimen has to be built and transported. Several months should be allowed for drying if concrete is involved. A time slot has to be found in the operations of a possibly busy

fire lab, and the results have to be documented and interpreted. For some problems and questions that may appear during the erection phase of a building, time may simply not be available and experimental testing is, therefore, not an option.

Experimental testing has the same problem of boundary conditions as the analytical models but in the opposite direction. Pure and perfectly identifiable boundary conditions—such as perfect hinges and totally fixed supports for a mechanical analysis or an adiabatic condition for a thermal analysis—are easily considered in an analytical model, but they seldom represent the real boundary conditions that may exist in reality. On the contrary, it is very difficult to impose well-defined boundary conditions in an experimental test. Perfectly fixed supports would require an infinitely stiff testing machine. Some precautions that may prove technically complex and financially demanding have to be taken to approach a perfect hinge. It is very difficult to test a column under a perfectly centrically loaded condition. If, and this is often the case, the supports of the specimen are outside the furnace, the longitudinal heat loss along the member is not easily quantified, but may have a significant influence on the result.

The results of experimental testing have variability. Two identical specimens tested in the same laboratory will generally not yield exactly the same result. For example, variability has been observed and documented for concrete elements in which a slight difference in the concrete cover on the reinforcing bars or a difference in spalling may have a significant influence on the results. Variability may be higher in axially loaded columns than in elements with first-order bending moments because of the bigger relative influence of accidental eccentricities in the first case. Assemblies protected with membrane ceilings likewise can exhibit substantial fire performance differences attributable to the gypsum board material and its installation details, as can other assemblies or members that are more susceptible to physical integrity failures of the protection material or system. As a consequence, it is very difficult to make a parametric or sensitivity analysis by experimental testing, because the influence of the parameter that is analyzed may be hidden by the noise produced in the results by the variability linked to other factors. This is not the case, of course, if the number of experimental tests is statistically significant—and this may require a very significant number of tests—or if the influence of the analyzed parameter is overwhelming. Because of this variability, a so-called validation of any analytical model by comparison with the result of one or even a few experimental tests may be inconclusive.

Summary

This chapter reviews the key fundamentals of structural fire engineering and introduces the more advanced analytical methods (finite element–based for computers) that are emerging. It relies on the existing background derived from decades of prescriptive fire resistance testing and design and provides an advanced framework that enables solutions for performance-based objectives. Limit states structural design principles, fire loads and resistance, reliability, heat transfer, and the basics of structural analysis are presented. Several of the important variables affecting response to severe fire exposures are described, all of which can influence potential for major damage and collapse. These include thermal strains; local, member, and frame instability; floor slab effects and catenary action; connection stiffness and strength; nonuniform heating; material properties; and limit states.

The highlight of this chapter is contained in the insights and nuances of higher-order structural fire analysis, including the nonlinear elastoplastic regime, for different types of problems, exposures, primary loads, construction materials and elements, and levels of discretization. This information draws heavily from research, international sources, and engineering experience in the field. Modeling considerations for individual structural elements, substructures, and entire frames are given and further reinforced with a realistic overview of

their advantages, limitations, uncertainties, and possible issues with numerical solution convergence. These advanced analytical methods are also juxtaposed to the typical constraints and limitations of construction fire testing to create a balanced perspective on their capabilities for prediction of actual structural behavior.

Nomenclature

A_k	Structural fire effects, typically the construction material's strength and stiffness reductions caused by the fire's heating
D	Nominal design dead load
E	Youngs modulus of a material
f_y	Minimum specified yield strength
L	Nominal design live load (gravity)
L_{fire}	Design values of the load effects (direct effects resulting from the applied loads and indirect effects resulting from restrained thermal expansion) expected to be simultaneously acting during the fire event
M_n	Nominal flexural strength
M_u	Required (factored) flexural strength
P_n	Nominal axial strength
P_u	Required (factored) axial strength
x	Strong principal axis of the cross section
y	Weak principal axis of the cross section
S	Nominal design snow load
t	Time
T	Temperature
R_{fire}	Available structural resistance under the particular high temperature conditions, including the effects of degraded material properties

Greek Letters

$\Upsilon_{M,1}$	Partial safety factor for material strength
$\Delta\sigma$	Variation of mechanical stress
$\varepsilon_{mechanical}$	Mechanical strain
$\varepsilon_{thermal}$	Thermal strain
ε_{total}	Total strain
ϕ_c	Resistance factor for compression
ϕ_b	Resistance factor for flexure

Analytical Methods for Determining Fire Resistance of Steel Members

53

James A. Milke

Introduction

Traditionally, fire resistance has been evaluated by subjecting a structural member to a standard test for a specified duration [1]. All members performing acceptably are rated and listed for the duration period of the test (e.g., 1 h, 2 h). Assemblies not listed are assumed to be unable to meet the test criteria and thus have no rating, unless proven otherwise. Providing proof of acceptable performance can be accomplished in one of three manners:

1. Conduct the standard test [1].
2. Conduct a special experiment [2].
3. Apply an analytical technique [3].

The standard test can involve an appreciable turnaround time in order to specify, schedule, and analyze the results of the test. An experimental program can require a substantial amount of effort in order to obtain accurate data. The costs involved in sponsoring a standard test or experimental program can be appreciable. In the case of archaic structural assemblies, materials may no longer be available to reconstruct the design for possible testing.

Because of these drawbacks, calculation methods have been developed to analyze structural designs for fire conditions. The calculation methods have been formulated based on analyses of data from standard tests, experimental programs, and theoretically based investigations.

J.A. Milke (✉)
Department of Fire Protection Engineering, University of Maryland, College Park, MD 20742, USA

A broad-based analytical method for fire resistance will consider three aspects:

1. Fire exposure
2. Heat transfer
3. Structural response

The fire exposing the structure must be characterized using methods described in other chapters of this handbook for the case of a real fire or by assuming the fire exposure specified in the standard test. An SFPE standard provides parameters to describe exposing fires for six fire scenarios [4]. The thermal response of the structural member can be addressed using principles of heat transfer. Heating within the member is treated by a conduction heat transfer analysis (radiation and convection heat transfer may also need to be considered if voids or porous insulation materials are present within the assembly). Typically, radiative and convective boundary conditions are applicable. Finally, the structural response is examined by comparing some or all of the following: deflections, strains, and stress levels to established limits.

The following types of calculation methods are available to assess the fire resistance of steel structural members:

1. Empirical correlations
2. Heat transfer analyses
3. Structural analyses

Empirical correlations are based on the analysis of data resulting from performing the standard test numerous times. A limitation of the empirical correlations is that they can be applied only when considering the fire exposure, loading, and span

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_53, © Society of Fire Protection Engineers 2016

provided in the standard test. If other conditions apply, then another approach is needed.

The second group of calculation methods consists of heat transfer analyses. The heat exposure conditions may be those associated with the standard test or a specified fire. The purpose of the heat transfer analysis is to determine the time required for the structural member to attain a predetermined critical temperature or to provide input to a structural analysis. The temperature endpoint criteria cited by ASTM E119 [1] are often accepted as the critical temperatures. Typically, inaccuracies of this method are related to the temperature dependence of the material properties or the description of the heating conditions.

Many of the structural analysis–based calculations are similar to those conducted for structural engineering purposes, except the material properties are evaluated at elevated temperatures and thermal expansion is considered. In higher order analyses, creep may also be accounted for. In structural analyses, the loading and end conditions must be known or assumed. Limitations result from uncertainties in characterizing the end conditions and the material properties at elevated temperatures.

This chapter provides an overview of the available calculation methods for determining the fire resistance of steel structural members. The basis of each method will be presented along with sample applications.

Standard Test for Fire Resistance of Structural Members

The standard test method in the United States for determining the fire resistance of columns, floor and roof assemblies, and walls is ASTM E119 [1].[1] Basically, the test involves subjecting the structural component to a heated furnace environment for the desired duration. If the endpoint criteria are not reached prior to the end of the test period, the assembly passes the test and is rated.

[1] Versions of the test method are also published as NFPA 251 [5] and UL 263 [6].

Gas burners are used to heat the furnace in testing laboratories throughout North America. The furnace is heated so that the temperature inside the furnace follows the time-temperature curve illustrated in Fig. 53.1. In principle, the time-temperature curve is intended to relate to a severe exposure from a room fire, though relating the standard exposure to actual fires is difficult. Thus, the applicability of the test method to examine the fire resistance of exterior structural members exposed to fires outside of the building is questionable [4].

Assemblies may be tested with or without load. If tested under load, the assembly is subjected to maximum design stress levels, based on common structural analysis procedures for ambient temperature design. Floor and roof assemblies and bearing walls are always tested under load. Columns are tested with or without a loading. Steel beams and girders may be tested without load if the design loading cannot be achieved in the laboratory.

Structural assemblies may be restrained or unrestrained against thermal expansion. The effect of restraint on the fire resistance of assemblies has been investigated by Bletzacker [7]. The degree of restraint in structural members varies with the geometry, connection method, and framing system, among other factors [6]. The descriptions presented in Table 53.1 relate actual construction conditions to the restrained and unrestrained designation noted in the ASTM E119 test method.

The minimum dimensions of the structural components for testing are specified in ASTM E119. A maximum set of dimensions is established by the size of available test furnaces. Although the test is large scale, the test cannot be considered full scale, given the stipulation of the maximum permissible dimensions. The consequence of not testing full-scale members means that continuous beams, actual floor/roof ASTM assemblies, and long columns are not tested. Consequently, given the scale of the test and furnace exposure conditions, this test is only comparative in nature and cannot be used to assess performance in actual fires.

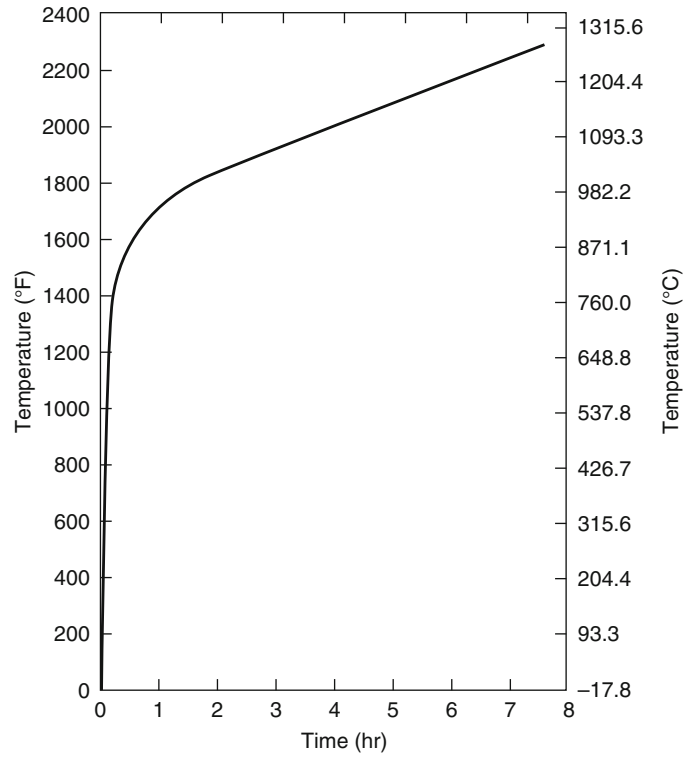

Fig. 53.1 ASTM E119 standard time-temperature curve [1]

The ASTM E119 endpoint criteria for building assemblies consider structural integrity, temperature, passage of flame, ignition of cotton waste, and, in some cases, response to the hose stream. For the tests without loading, the structural integrity endpoint criterion is relaxed to require that the component only remains in place. The structural integrity criterion addresses the need for members to remain in place (supporting self-weight of member) and to continuously support any applied loads. The ignition-of-cotton-waste endpoint addresses the ability of the structural assembly to prevent the transmission of flame and hot gases to the side not exposed to the furnace fire.

The temperature endpoint criteria are noted in Table 53.2. In principle, the endpoint temperatures are based on the maximum allowable reduction in load-bearing capacity of the structural member, considering the reduction in steel strength experienced at elevated temperature and the maximum permissible loads stipulated by structural design standards.

Fire Resistance of Steel Members

Several calculation techniques are available to determine the fire resistance of steel members, including steel columns, beams in floor and roof assemblies, and trusses [8–11]. Three types of techniques are available: empirically derived correlations, heat transfer analyses, and structural analyses.

The equations and models do not eliminate the need for all future testing. Testing is still required, at least to validate the calculation techniques and assess the interaction and mechanical behavior of the constituents of the assembly, such as the steel structural member, insulating materials, or other components. However, the calculation techniques can be used to extend the application of test results and reduce the number of required tests. In addition, experimental methods are essential in determining the material properties at elevated temperatures of the protection materials.

Table 53.1 Restrained and unrestrained construction systems (From ASTM E119 Table X3.1) [1]

Wall bearing	
Single span and simply supported end spans of multiple bays[a]	
Open-web steel joists or steel beams, supporting concrete slab, precast units, or metal decking	Unrestrained
Concrete slabs, precast units, or metal decking	Unrestrained
Interior spans of multiple bays	
Open-web steel joists, steel beams, or metal decking, supporting continuous concrete slab	Restrained
Open-web steel joists or steel beams, supporting precast units or metal decking	Unrestrained
Cast-in-place concrete slab systems	Restrained
Precast concrete where the potential thermal expansion is resisted by adjacent construction[b]	Restrained
Steel framing	
Steel beams welded, riveted, or bolted to the framing members	Restrained
All types of cast-in-place floor and roof systems (such as beam-and-slabs, flat slabs, pan joists, and waffle slabs) where the floor or roof system is secured to the framing members	Restrained
All types of prefabricated floor or roof systems where the structural members are secured to the framing members and the potential thermal expansion of the floor or roof system is resisted by the framing system or the adjoining floor or roof construction[b]	Restrained
Concrete framing	
Beams securely fastened to the framing members	Restrained
All types of cast-in-place floor or roof systems (such as beam-and-slabs, flat slabs, pan joists, and waffle slabs) where the floor system is cast with the framing members	Restrained
Interior and exterior spans of precast systems with cast-in-place joints resulting in restraint equivalent to that which would exist in condition III(1)	Restrained
All types of prefabricated floor or roof systems where the structural members are secured to such systems and the potential thermal expansion of the floor or roof systems is resisted by the framing system or the adjoining floor or roof construction[b]	Restrained
Wood construction	
All types	Unrestrained

[a]Floor and roof systems can be considered restrained when they are tied into walls with or without tie beams, the walls being designed and detailed to resist thermal thrust from the floor or roof system

[b]For example, resistance to potential thermal expansion is considered to be achieved when:

1. Continuous structural concrete topping is used
2. The space between the ends of precast units or between the ends of units and the vertical face of supports is filled with concrete or mortar, or
3. The space between the ends of precast units and the vertical faces of supports, or between the ends of solid or hollow core slab units, does not exceed 0.25 % of the length for normal-weight concrete members or 0.1 % of the length for structural lightweight concrete members

Steel Material Properties

The principal material properties of interest are yield strength, ultimate strength, modulus of elasticity, coefficient of thermal expansion, density, specific heat, and thermal conductivity. The effect of temperature on steel properties has been examined by many researchers [12]. For steel, all of the properties, except for density, are strongly influenced by temperature.

The thermal properties of ASTM A36 steel are provided in the following correlations [8, 13–15]:

$$k = \begin{cases} -0.022T + 48 & (0 \le T < 900^{\circ}\mathrm{C}) \\ 28.2 & (900^{\circ}\mathrm{C} < T) \end{cases}_{[\mathrm{W/m \cdot K}]} \quad (53.1)$$

Table 53.2 ASTM E119 temperature endpoint criteria [1]

Structural member	Location	Maximum temperature °C (°F)
Walls/partitions (bearing and nonbearing)	1. Unexposed side	
	Average	139 (250)[a]
	Single point	181 (325)[a]
Steel columns	1. Average	538 (1000)
	Single point	649 (1200)
Floor/roof assemblies and loaded beams	1. Unexposed side	
	Average	139 (250)[a]
	Single point	181 (325)[a]
	2. Steel beam	
	Average	593 (1100)
	Single point	704 (1300)
	3. Prestressing steel	426 (800)
	4. Reinforcing steel	593 (1100)
	5. Open-web steel joists	593 (1100)
Steel beams/girders (not loaded)	1. Average	538 (1000)
	Single point	649 (1200)

[a]Maximum temperature cited refers to the maximum temperature rise above initial conditions

$$c_s = \begin{cases} 0.51T + 420 & (0 \le T < 650^\circ\text{C}) \\ 8.65T + 4870 & (650^\circ\text{C} < T \le 725^\circ\text{C}) \\ -10.9T + 9340 & (725^\circ\text{C} < T \le 800^\circ\text{C}) \\ 578 & (800^\circ\text{C} < T)_{[\text{J/kg.K}]} \end{cases}$$

$$\rho = 7860 \ \text{kg/m}^3 \tag{53.2}$$

The influence of temperature on the mechanical properties of A36 steel is presented in Fig. 53.2. At 538 °C (1000 °F) the yield strength is approximately 60 % of the value at normal room temperature.

Mathematical expressions describing the relationship of the yield strength, modulus of elasticity, and coefficient of thermal expansion on temperature are [8, 17, 18]

For $0 < T \le 600$ °C,

$$\sigma_{yT} = 1 + \frac{T}{900 \ln(T/1750)}\sigma_{y0}$$
$$E_T = 1 + \frac{T}{2000 \ln(T/1100)}E_0 \tag{53.3, 53.4}$$

For $T > 600$ °C,

$$\sigma_{yT} = \frac{340 - 0.34T}{T - 240}\sigma_{y0}$$
$$E_T = \frac{690 - 0.69T}{T - 53.5}E_0 \tag{53.5, 53.6}$$

For any temperature of interest,

$$\alpha_T = (0.04T + 12) \times 10^{-6} \tag{53.7}$$

where

σ_{yT} = Yield strength at temperature T (MPa) (psi)
σ_{y0} = Yield strength at 20 °C (68 °F) (MPa) (psi)
E_T = Modulus of elasticity at temperature T (MPa) (psi)
E_0 = Modulus of elasticity at 20 °C (68 °F) (MPa) (psi)
α_T = Coefficient of thermal expansion at temperature T (m/m °C)
T = Steel temperature (°C)

Alternatively, values of the yield and tensile strength and modulus of elasticity at elevated temperature are included in Appendix 4 of the AISC Specification [19], and BSI 5950 [20]. In addition to the changes in material properties that occur at elevated temperatures, the crystalline structure of steel also changes, as noted in Fig. 53.3 [21]. However, for the low-carbon steels typically used in building construction, significant changes in crystalline structure begin to occur only at temperatures in excess of 650 °C (1200 °F) [22], above the endpoint temperature noted in the standard test.

Creep, the time-dependent deformation of a material, may be significant in structural steel at temperatures in excess of 460 °C (860 °F) [23]. The rate of creep increases approximately 300 times for ASTM A36 structural steel when the steel temperature is increased from 460 to 520 °C (860–968 °F). In-depth discussions of

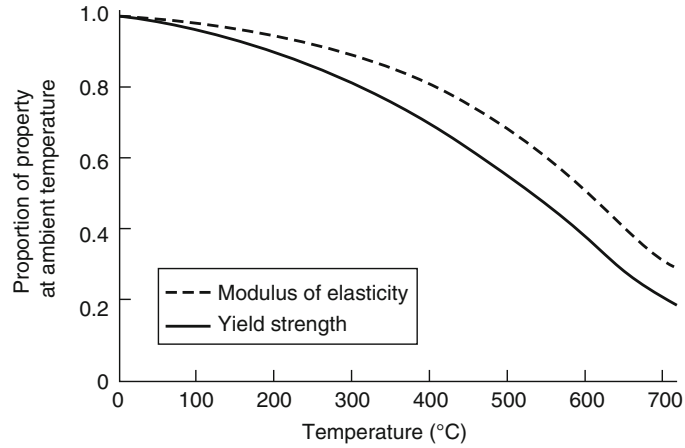

Fig. 53.2 Temperature effects on properties of ASTM A36 steel [13, 16]

creep have been prepared by Harmathy [24, 25]. Because of the complexity in addressing creep explicitly, given its dependence on the stress level, rate of heating, and other factors, often creep is included implicitly in the mechanical properties to simplify the fire resistance calculations [16, 23]. One exception to this approach was in the NIST study of the collapse of the North and South Towers of the World Trade Center. In their study, Gross and McAllister proposed that creep was a significant factor that led to the collapse of the towers [26].

Methods of Protection

The basic intent of the various methods of protection is to reduce the rate of heat transfer to the structural steel. This is accomplished by using insulation, concrete filling, membranes, flame shielding, and heat sinks.

Insulation

Insulation of the steel is achieved by surrounding the steel with materials that preferably have the following characteristics [27]:

1. Noncombustibility and the added attribute of not producing smoke or toxic gases when subjected to elevated temperatures
2. Thermal protective capability when subjected to elevated temperatures
3. Product reliability giving positive assurance of consistent uniform protection characteristics
4. Availability in a form that permits efficient and uniform application
5. Sufficient bond strength and durability to prevent either dislodgement or surface damage during normal construction operations
6. Resistance to weathering or erosion resulting from atmospheric conditions

In addition to the insulating qualities of the protection materials, chemical reactions may occur in the insulation, further reducing the rate of heat transfer. The chemical reactions include calcination, ablation, intumescence, thermal hydrogeneration, and sublimation.

Insulating methods include the use of board products, spray-applied materials, and concrete encasement. A brief review of each method is presented below.

Board Products Four types of board products are commonly used to protect structural steel: gypsum board, fiber-reinforced calcium silicate board, vermiculite-sodium silicate board, and mineral fiber board. In each case, the means of attachment of the boards surrounding the steel is a critical parameter affecting the performance of the assembly. Two commonly used methods of attachment of gypsum wallboard with and without steel covers are illustrated in Fig. 53.4. Detailed descriptions of the attachment mechanisms for the other board products are

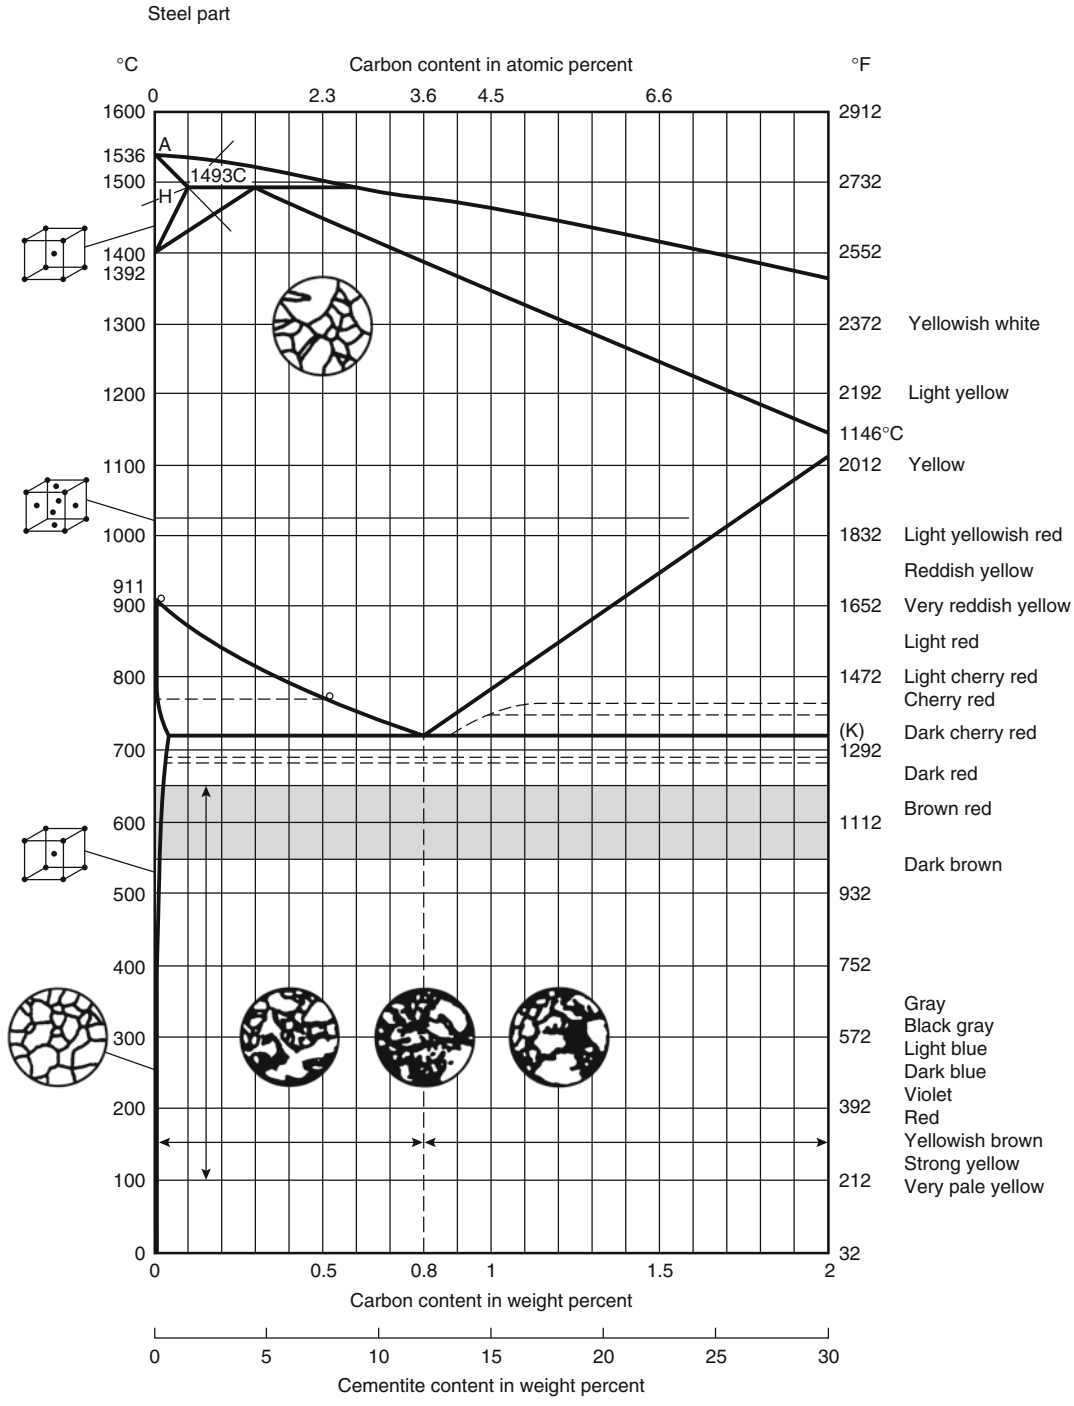

Fig. 53.3 Influence of elevated temperatures versus carbon content in steel [21]

provided elsewhere [29, 30]. Also, board products can be used in wall assemblies to provide an envelope around steel trusses.

Spray-Applied Materials Several types of spray-applied materials are commonly used. These include cementitious plasters, mineral

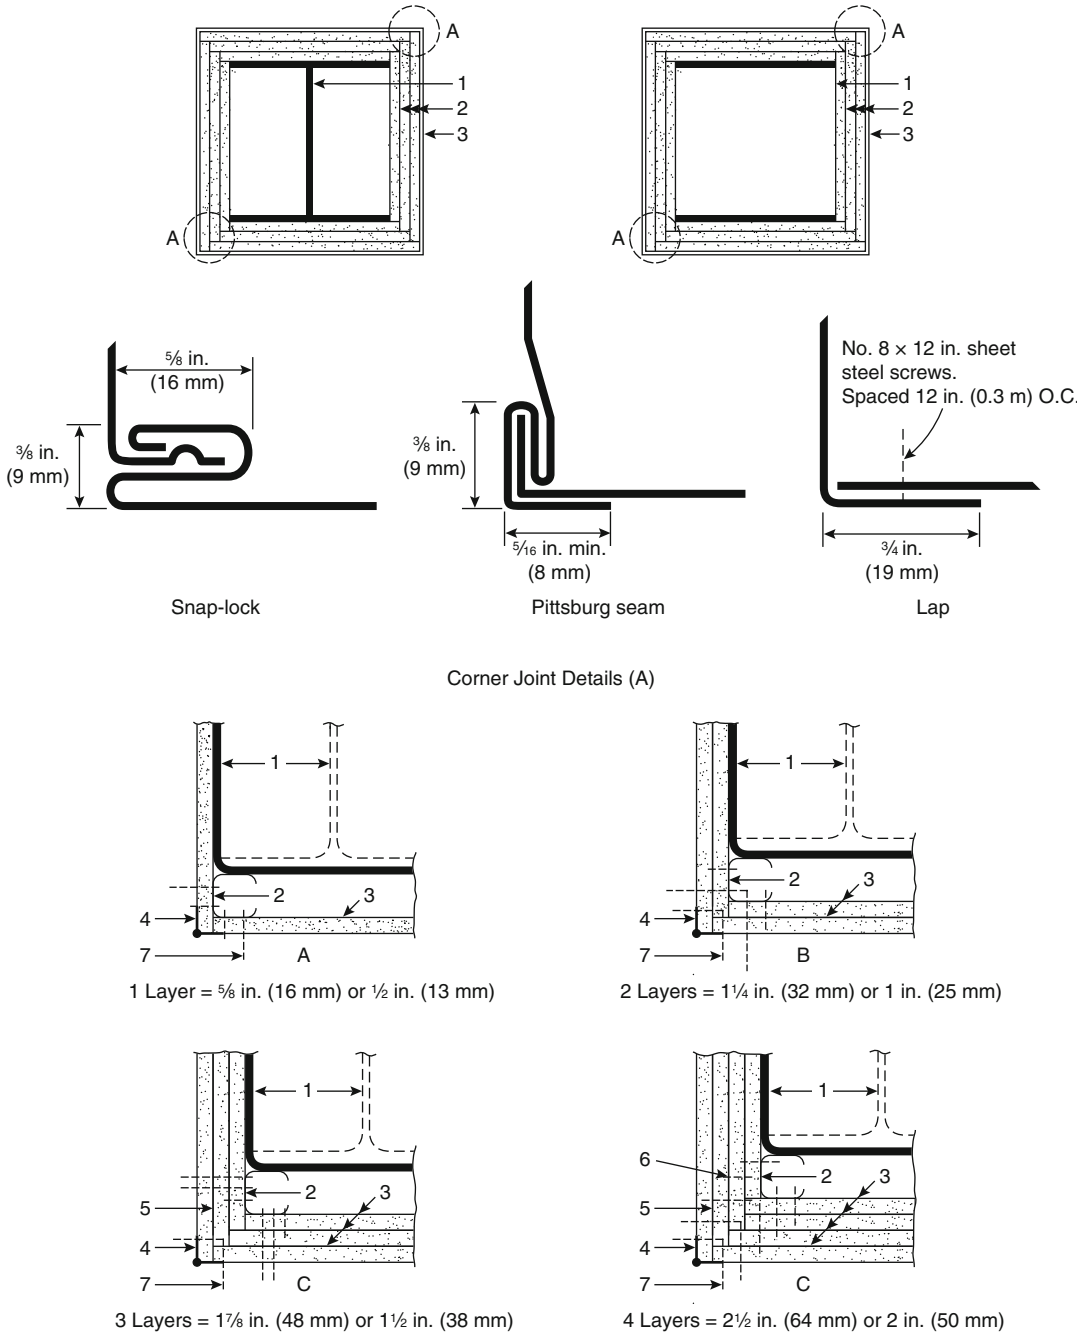

Fig. 53.4 Attachment mechanisms of gypsum wallboard to steel columns [29]

fibers, magnesium oxychloride cements, and intumescents. Sufficient data have been obtained to characterize spray-applied cementitious and mineral fiber materials for the purpose of estimating the fire endurance of structural steel protected with these materials. An illustration of a steel column protected by a spray-applied material is presented in Fig. 53.5.

Concrete Encasement Concrete encasement of steel members to surround and insulate the steel is illustrated in Fig. 53.6. As indicated in

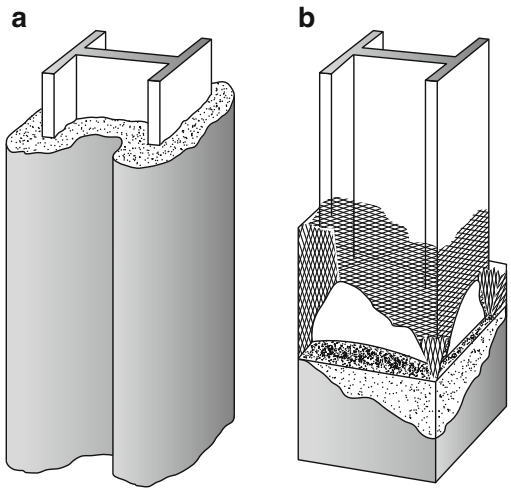

Fig. 53.5 (**a**) Sprayed insulation; (**b**) metal lath and plaster encasement [27]

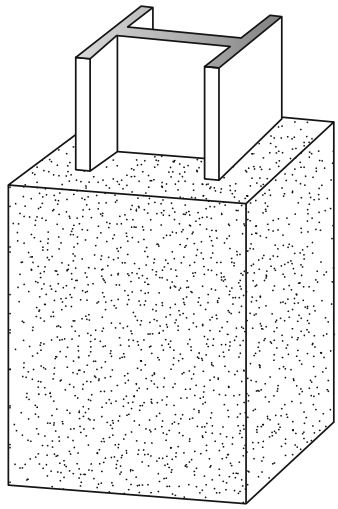

Fig. 53.6 Steel column with concrete encasement [27]

Fig. 53.6, the concrete is cast to fill in all re-entrant spaces. Alternatively, concrete column covers may be used, as illustrated in Fig. 53.7. The concrete is assumed to act only to thermally protect the steel. Some empirical correlations implicitly account for the load-bearing capacity of the concrete and possible steel-concrete composite action.

Concrete Filling

Concrete filling of hollow steel members can also be used to provide a fire-resistant assembly. The concrete may be plain concrete or reinforced concrete [31, 32].

Membrane

Suspended ceiling assemblies are used as membranes to protect structural steel in floor and roof assemblies. The ceiling panels and tiles comprising the ceiling assembly may consist of gypsum, perlite, vermiculite, or mineral fibers. Gypsum wallboard and other board products also fall into this category of protection.

The membrane method of protection is illustrated in Fig. 53.8. Heat transfer to the structural steel is reduced due to the air space above the membrane and the insulating characteristics of the membrane. Also, membranes help prevent the direct impingement of flame on the structural steel.

Flame Shield

Flame shields are intended to reduce the incident radiant heat flux on the steel by preventing direct flame impingement. The effectiveness of flame shields to protect exposed spandrel beams was first examined by Seigel [2, 33]. In this instance, 14-gauge sheet steel was used as the flame shield.

Heat Sinks

The heat sink approach delays the heating of steel by absorbing heat transferred through the steel. The heat sink approach usually involves liquid or concrete filling of the interior of hollow steel members (tubular and pipe sections). Liquid filling can be used to provide a sufficient level of protection for the columns, without any externally applied coating. The liquid used for

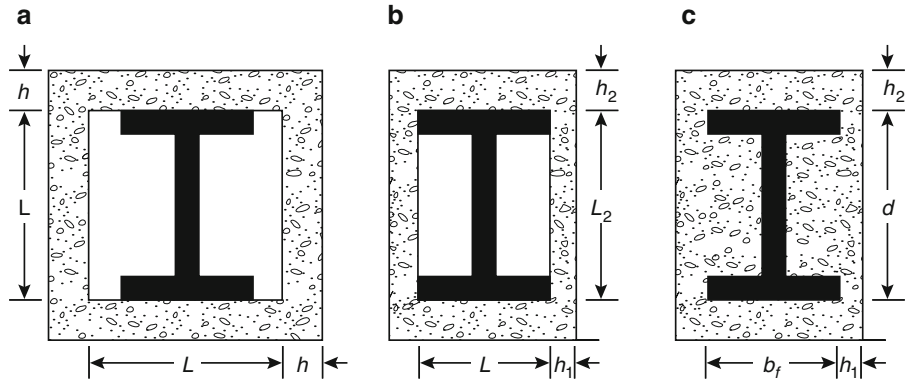

Fig. 53.7 Concrete-protected structural steel columns. (**a**) *Square* shape protection with a uniform thickness of concrete cover on all sides; (**b**) *rectangular* shape with varying thickness of concrete cover; and (**c**) encasement having all re-entrant spaces filled with concrete

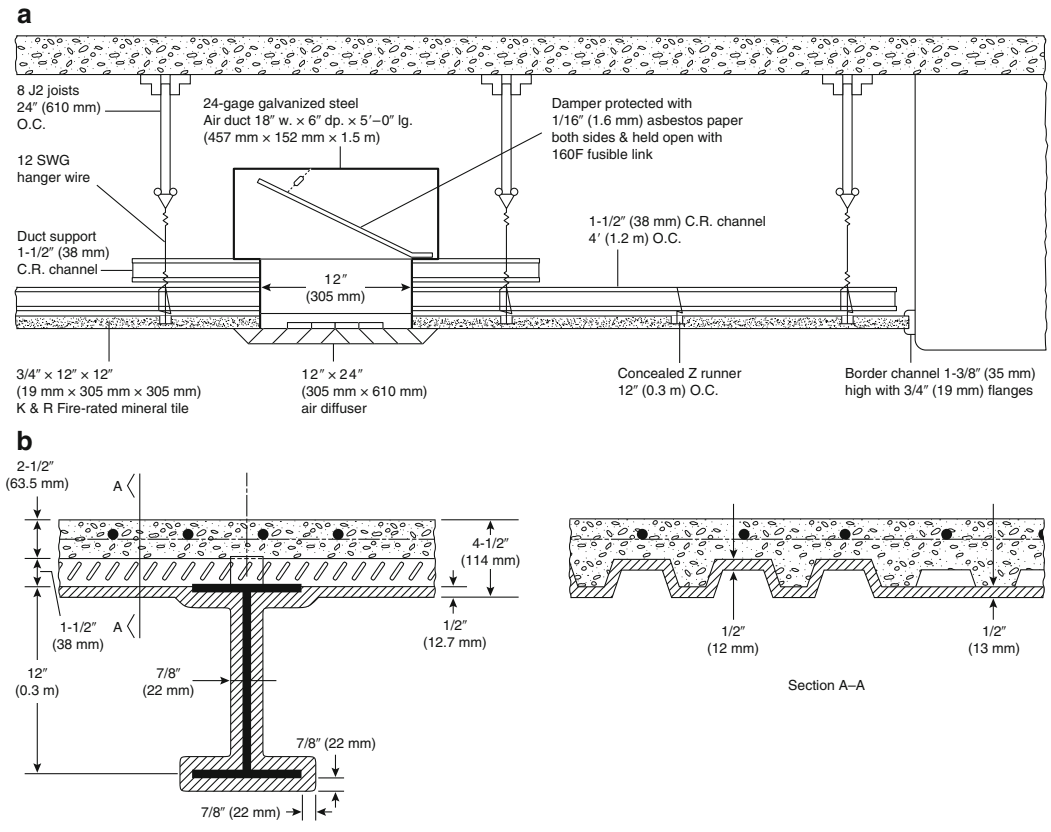

Fig. 53.8 Membrane method of protection [27]. (**a**) Cross-section of a floor-ceiling system with conventional sheet steel fusible-link damper for protecting typical ceiling outlets in galvanized sheet ducts; (**b**) sprayed contact fireproofing applied directly to the underside of formed-steel decking and to a supporting steel beam

protection is an aqueous solution. Additives are provided primarily for antifreeze, corrosion protection, and biological reasons.

A diagram of a typical design for a liquid-filled column fire protection system is presented in Fig. 53.9. The components of this system

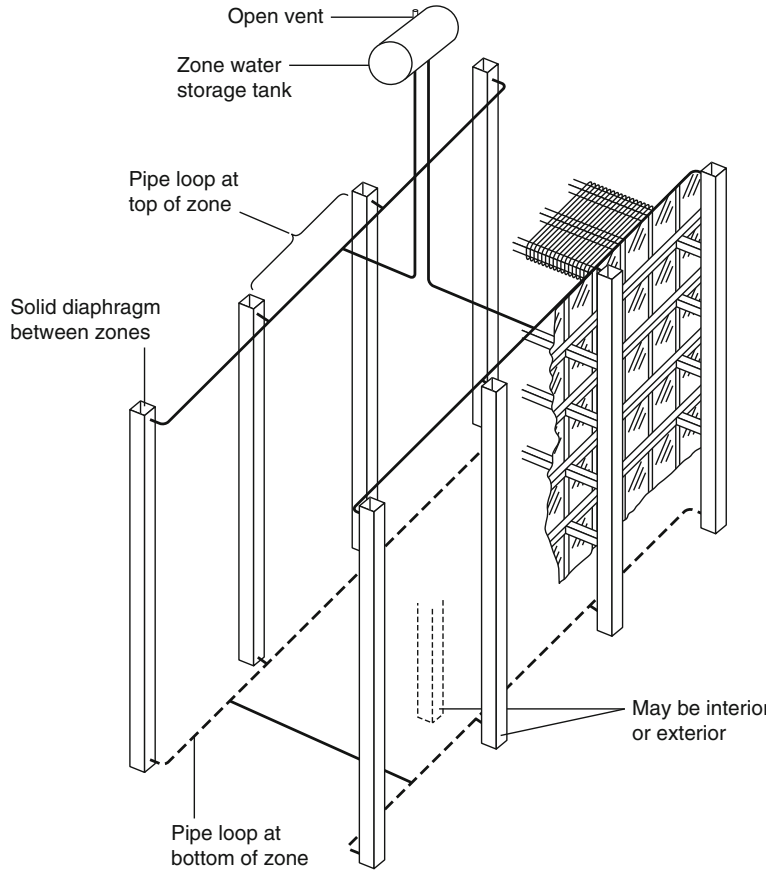

Fig. 53.9 Schematic layout of a typical piping arrangement used in a liquid-filled column fire protection system [33]

include the hollow structural steel columns, piping to connect the columns, a water storage tank, and associated valves.

The system operates on the principle that heat incident on the column is removed by circulation of the liquid. If sufficient heat is delivered to the liquid, boiling can be expected, which enhances the efficiency of the heat removal process. In many tests with liquid filling, steel temperatures have been observed to be well below those required for failure, as long as the column remains full of the liquid.

Another heat sink approach consists of filling the interior of hollow steel columns with concrete. If the concrete is reinforced, load transfer from the steel to the concrete can be expected as the steel weakens with increasing temperature. Calculation methods to determine the fire resistance of concrete-filled steel columns are available [11, 13].

Empirically Derived Correlations

Numerous easy-to-use, empirically derived correlations are available to calculate the fire resistance of steel columns, beams, and trusses. The correlations are based on data from performing the standard test numerous times on variations of a particular assembly. Curve-fitting techniques are used to establish the various correlations. In some cases, a best-fit line has been drawn for the data points, whereas in other cases, lines were placed to provide conservative estimates of the fire endurance by connecting the two lowest points [34].

Steel Columns

The correlations to estimate the fire endurance of unprotected and protected steel columns are given in Table 53.3. Present in each of the equations is *W*/*D* for wide-flange sections and *A*/*P* for hollow sections. The *W*/*D* and *A*/*P* ratios are comparable. The *W*/*D* ratio is the weight per lineal foot to the heated perimeter of the steel at the protection interface (or the perimeter of the steel if unprotected). The *A*/*P* ratio is the cross-sectional area divided by the heated perimeter. Essentially, the *W*/*D* ratio relates to the product of the density of the steel and the *A*/*P* ratio.

The relevance of the *W*/*D* and *A*/*P* ratios was first noted by Lie and Stanzak [35]. *W*/*D* ratios for commonly used wide-flange and tubular shapes for columns and beams are available elsewhere [29, 36–38]. The two factors in the *W*/*D* ratio that affect the rate of heat transfer to the steel (and consequently the rise in temperature of the steel) are (1) shape of the fire protection system, *D*, and (2) steel mass per unit of length, *W*.

The parameter that characterizes the shape of the fire protection system is *D*, the heated perimeter expressed in inches, which is defined as the inside perimeter of the steel at the fire protection material interface. Figure 53.10 illustrates the method for determining *D* in four typical cases. As indicated in the figure, the heated perimeter depends on the dimensions of the column and also on the profile of the protection system. Two different commonly used profiles are (1) contour profile, where all surfaces of the steel column are in contact with the protection material; and (2) box profile, where a rectangular box of protection material is built around the column.

A large value of *W* refers to a column with a large weight per lineal foot. A given amount of energy will raise the temperature of the massive column to a lesser degree than that of a light column. Less surface area is available for heat transfer if the heated perimeter, *D*, is small, thereby inhibiting the temperature rise in the steel. The greater the *W*/*D* ratio, the greater the inherent fire resistance of the assembly is.

Because steel elements with larger *W*/*D* ratios are inherently more fire resistant, substituting shapes with greater *W*/*D* ratios for shapes identified in the listed designs in the UL *Fire Resistance Directory* [3] is permitted while maintaining the same thickness of protection. However, such substitution yields inefficient designs, because shapes with large *W*/*D* ratios actually require less fire protection material than shapes with small *W*/*D* ratios for the same level of fire resistance.

The equation for gypsum wallboard protection is nonlinear. The weight of the gypsum wallboard is included because the heat capacity of gypsum has a considerable impact on the fire resistance of the assembly. The thickness of wallboard required to achieve a particular level of fire resistance as a function of the *W*/*D* ratio of the column is presented in Fig. 53.10.

Based on an elementary heat transfer analysis for spray-applied fire protection materials, Stanzak and Lie conducted a parametric analysis that resulted in correlations of the following form to estimate the thickness of material required to achieve a particular level of fire resistance [29, 30]:

$$R = (C_1 W/D + C_2)h \qquad (53.8)$$

where

R = Fire endurance (min., note: the version in the UL Directory expresses the equation with R in hour.)

W = Steel weight per lineal foot (lb/ft)

D = Heated perimeter of the steel at the insulation interface (in.)

h = Thickness of insulation (in.)

The constants C_1 and C_2 need to be determined for each protection material. The constants take into account the thermal conductivity and heat capacity of the insulation material. Constants for some materials are included in listings in the UL *Fire Resistance Directory* [3].

Considering the equation for the concrete cover column protection method (see Table 53.3), R_0 is the fire endurance of the assembly if the concrete has no moisture content. However, because the fire resistance of concrete cover

Table 53.3 Empirical equations for steel columns [22, 28–30]

Member/protection	Solution	Symbols
Column/unprotected	$R = 10.3(W/D)^{0.7}$, for $W/D < 10$	R = fire endurance time (min)
	$R = 8.3(W/D)^{0.8}$, for $W/D \geq 10$ (for critical temperature of 1000 °F)	W = weight of steel section per linear foot (lb/ft)
		D = heated perimeter (in.)
Column/gypsum wallboard	$R = 130\left(\frac{hW'/D}{2}\right)^{0.75}$ where $W' = W + \left(\frac{50hD}{144}\right)$	h = thickness of protection (in.)
		W' = weight of steel section and gypsum wallboard (lb/ft)
Column/spray-applied materials and some board products—wide flange shapes	$R = [C_1(W/D) + C_2]h$	C_1 and C_2 = constants for specific protection material
Column/spray-applied materials and some board products—hollow sections	$R = C_1\left(\frac{A}{P}\right)h + C_2$	C_1 and C_2 = constants for specific protection material
		The A/P ratio of a circular pipe is determined by $A/P_{\text{pipe}} = \frac{t(d-t)}{d}$ where
		d = outer diameter of the pipe (in.)
		t = wall thickness of the pipe (in.)
		The A/P ratio of a rectangular or square tube is determined by
		$A/P_{\text{tube}} = \frac{t(a+b-2t)}{a+b}$ where
		a = outer width of the tube (in.)
		b = outer length of the tube (in.)
		t = wall thickness of the tube (in.)
Column/concrete cover or encased	$R = R_0(1 + 0.03m)$ where $R_0 = 0.17(^w/_D)^{0.7} + 0.28\left(\frac{h^{1.6}}{k_c^{0.2}}\right) \times \left\{1 + 26\left[\frac{H}{\rho_c c_c h(L+h)}\right]^{0.8}\right\}$	R_0 = fire endurance at zero moisture content of concrete (min)
		m = equilibrium moisture content of concrete (% by volume)
		b_f = width of flange (in.)
		d = depth of section (in.)
		k_c = thermal conductivity of concrete at ambient temperature (Btu/hr·ft·°F)
		H = thermal capacity of steel section at ambient temperature (=0.11 W Btu/ft·°F). If encased, H is defined as: $H = 0.11W + \frac{\rho_c c_c}{144}(b_f d - A_s)$
		c_c = specific heat of concrete at ambient temperature (Btu/lb·°F)
		L = inside dimension of one side of *square* concrete box protection (in.) If encased, $L = (b_f + d)/2$
		As = cross-sectional area of steel column (in.^{2})

over steel columns is known to increase by approximately 3 % for each 1 % of moisture, R_0 is multiplied by the $(1 + 0.03m)$ factor where m is the equilibrium moisture content of concrete. The parameters h and L noted in the equation are shown in Fig. 53.7. If the protection thickness or column dimensions are not the same in the vertical and horizontal directions, average values are used for h and L.

The heat capacity of the concrete must be accounted for in the determination of H if all re-entrant spaces are filled (see Fig. 53.7).

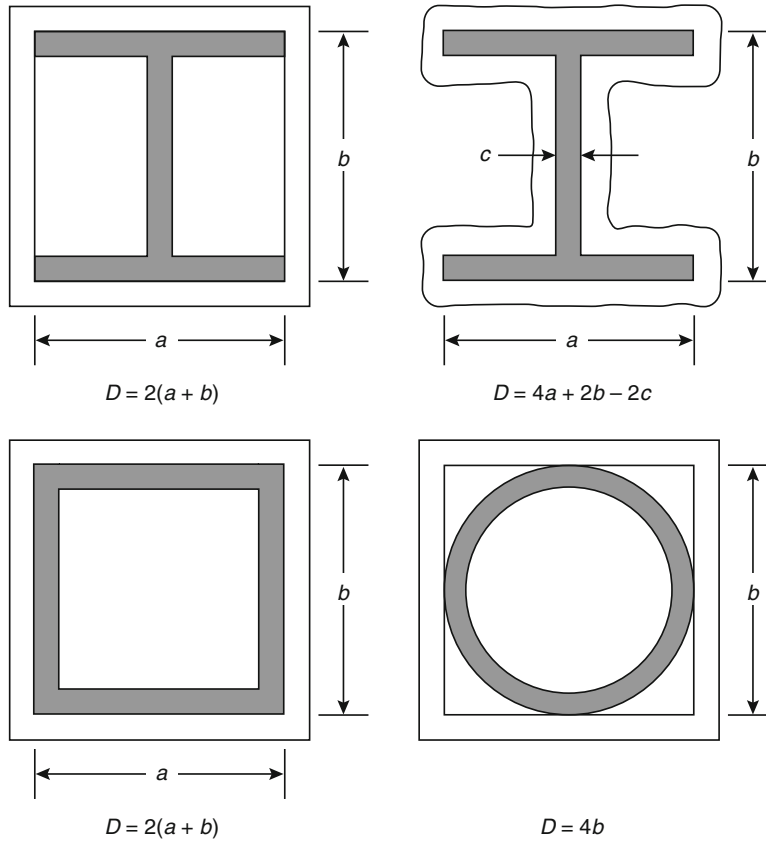

Fig. 53.10 Heated perimeter for steel columns [29]

If specific data on the concrete's thermal properties are not available, values given in Table 53.4 may be used. Typical densities for normal-weight and lightweight concrete are 145 and 110 lb/ft^3 (2320 and 1760 kg/m^3). Also, the typical equilibrium moisture content (by volume) for normal-weight concrete is 4 % and lightweight concrete is 5 %.

Many of the equations cited in Table 53.3 are limited to a range of shapes or protection thicknesses. Before applying any equation from this table, users should consult the original reference and confirm that the equation is being applied properly.

Example 1 Determine the thickness of spray-applied cementitious material to obtain a 2-h fire endurance when applied to a *W* 12 × 106 column.

Solution From UL X772, the applicable equation is

$$R = (1.05W/D + 0.6)h \tag{53.9}$$

Solving for h,

$$h = \frac{R}{1.05W/D + 0.6} \tag{53.10}$$

where

$R = 2$ h

$W/D = 1.44$ lb/ft·in. (0.0844 kg/m^2) for a *W* 12 × 106 with contour profile protection

Substituting,

$$h = \frac{2}{1.05 \times 1.44 + 0.6} = 0.95\,\text{in.} \quad (24.1\text{mm}) \tag{53.11}$$

Example 2 Determine the fire endurance of a *W* 8 × 28 column encased in lightweight concrete (density of 110 lb/ft^3 [176.2 kg/m^3]) with all re-entrant spaces filled. The concrete cover thickness is 1.25 in. (31.8 mm).

Table 53.4 Thermal properties of concrete at 70 °F

	Normal-weight Concrete	Structural Lightweight concrete
Thermal conductivity (k)[a]	0.95 Btu/h·ft·°F (1.64 W/m K)	0.35 Btu/h·ft·°F (0.61 W/m K)
Specific heat (c)[b]	0.20 Btu/lb·°F (835 J/kg K)	0.20 Btu/lb·°F (835 J/kg K)

Solution From Table 53.3, the appropriate equation is

$$R = R_0(1 + 0.03m) \tag{53.12}$$

where

$$R_0 = 10(W/D)^{0.7} + 17\left(h^{1.6}/k_c^{0.2}\right) \times \left\{1 + 26[H/\rho_c c_c h(L+h)]^{0.8}\right\} \tag{53.13}$$

Referring to Fig. 53.7,
h_2=h_1=h=1.25 in. (31.8 mm)
b_f = 6.535 in. (166.0 mm)
d = 8.060 in. (204.7 mm)
W/D = 0.67 lb/ft·in. (39.3 kg/m^2) (contour profile)
A = 8.25 in.^{2} (0.0053 m^2)
From Table 53.4,

$$k_c = 0.35\,\text{Btu/hr}\cdot\text{ft}\cdot{}^\circ\text{F}(0.605\,\text{W/m.K})$$

$$c_c = 0.20\,\text{Btu/lb}\cdot{}^\circ\,\text{F}(836\,\text{J/kg.K})$$

$$\rho_c = 100\,\text{lb/ft}^3\left(1600\,\text{kg/m}^3\right)$$

$$L = \frac{1}{2}\left(b_f + d\right) = 7.30\,\text{in.}\,(185\text{mm}) \tag{53.14}$$

$$\begin{aligned} H &= 0.11W + \frac{\rho_c c_c}{144}\left(b_f D - A_s\right) \\ &= 0.11 \times 28 + \frac{110 \times 0.20}{144} \\ &\quad \times (6.535 \times 8.060 - 8.25) \\ &= 9.87\text{in.}(251\text{mm}) \end{aligned} \tag{53.15}$$

$$R_0 = 0.17(0.67)^{0.7} + 0.28\frac{1.25^{1.6}}{0.35^{0.2}}\left\{1 + 26\left[\frac{9.87}{110 \times 0.2 \times 1.25(7.30 + 1.25)}\right]^{0.8}\right\} = 1.63\text{ hr.} \tag{53.16}$$

Assuming a moisture content of 5 % for lightweight concrete,

$$R = 1.63(1 + 0.03 \times 5) = 1.87\,\text{hours} \tag{53.17}$$

Steel Beams

As in the case of columns, the *W/D* ratio is an important parameter affecting the fire resistance of a beam. Beams with larger *W/D* ratios may be substituted for beams with lesser *W/D* ratios for an equivalent rating with no change in the protection thickness. However, as with columns, designs resulting from the direct substitution of larger beams without reducing the protection thickness may be inefficient.

In 1984, an empirically derived correlation was developed to calculate the required thickness of spray-applied material protection [37]. Correlations of the form for steel columns are not possible, given the deck's role as a heat sink. Thus, the thickness of protection for steel beams is determined based on the following scaling relationship:

$$h_1 = \left(\frac{W_2/D_2 + 0.6}{W_1/D_1 + 0.6}\right)h_2 \tag{53.18}$$

where
h = Thickness of spray-applied fire protection (in.)
W = Weight of steel beam (lb/ft)

D = Heated perimeter of the steel beam (in.) (Fig. 53.11)

and where the subscripts

1 = Substitute beam and required protection thickness

2 = The beam and protection thickness specified in the referenced tested design or tested assembly

Limitations of this equation are noted as follows:

1. $W/D \geq 0.37$ lb/ft-in (0.0217 kg/m^2)
2. $h \geq {}^3/_8$ in. (9.5 mm)
3. The unrestrained beam rating in the referenced tested design or tested assembly = at least 1 h

It should be noted that the above equation pertains only to the determination of the protection thickness for a beam in a floor or roof assembly. All other features of the assembly, including the protection thickness for the deck, must remain unaltered.

Example 3 Calculate the thickness of spray-applied fire protection required to provide a 2-h fire endurance for a W 12 × 16 beam to be substituted for a W 8 × 17 beam requiring 1.44 in. (36.6 mm) of protection for the same rating.

Solution The beam substitution correlation, presented as Equation 53.18, is used.

$$h_1 = \left(\frac{W_2/D_2 + 0.6}{W_1/D_1 + 0.6}\right) h_2 \tag{53.19}$$

Where

W_2/D_2 = 0.54 lb/ft in. (0.070 kg/m^2) for W8X17

W_1/D_1 = 0.45 lb/ft in. (0.058 kg/m^2) for W12X16

h_2 = 1.44 in. (36.6 mm)

$$h_1 = \left(\frac{0.54 + 0.6}{0.45 + 0.6}\right) \times 1.44 = 1.6 in., \tag{53.20}$$

$$h_1 = \left(\frac{0.070 + 0.036}{0.053 + 0.036}\right) 36.6 = 40.6 mm$$

Steel Trusses

There are three types of trusses used in buildings: transfer, staggered, and interstitial trusses. Because of the inherent features of each type of truss, some fire protection systems are more appropriate than others [39].

A load-transfer truss (Fig. 53.12) supports loads from more than one floor. The loads may be suspended from a transfer truss, or the transfer

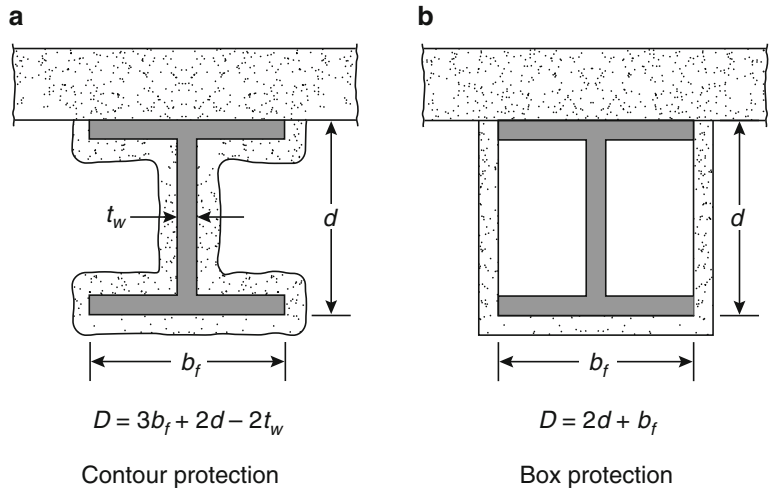

Fig. 53.11 Heated perimeter for steel beams [36]

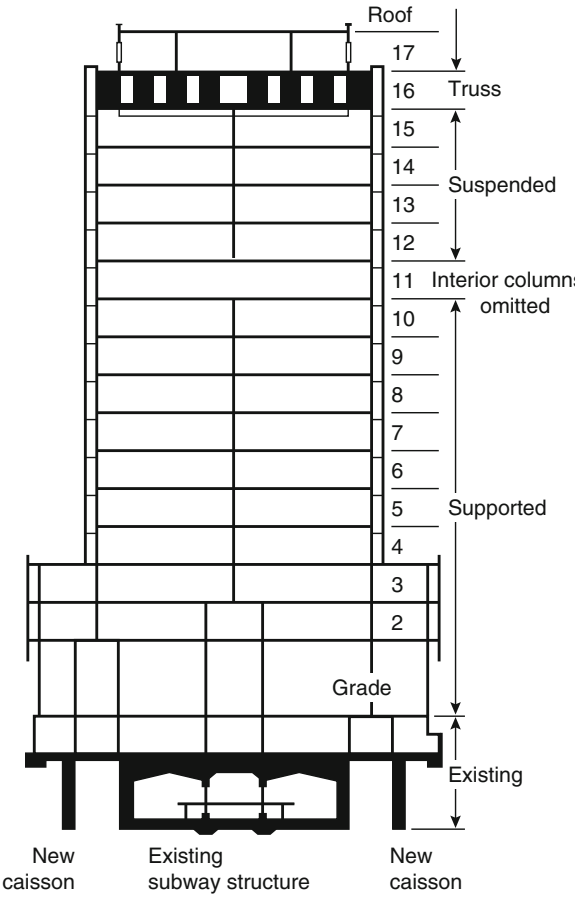

Fig. 53.12 Vierendell truss providing support from above and below [39]

truss can be used to eliminate columns on lower floors.

A staggered truss is illustrated in Fig. 53.13. Generally, staggered trusses are used in residential occupancy buildings. Staggered trusses carry loads from two floors.

Interstitial trusses are used to create deep floor/ceiling concealed spaces containing mechanical and electrical equipment, as shown in Fig. 53.14. Interstitial trusses support only those loads from the equipment enclosure and the floor above. Interstitial trusses are typically used in health care facilities with heavy mechanical equipment needs.

Three methods of fire protection are often used for trusses: membrane, envelope, and individual element protection. Some fire protection methods are more appropriate than others for the specific truss types. The fire protection methods typically used for each truss type are indicated in Table 53.5. Membrane protection is accomplished through the use of a fire-resistant ceiling assembly. Design parameters for such an assembly can be determined from listings of fire-rated designs [3, 39]. No empirical correlations are available to assess the design of membrane protection systems.

The envelope means of protection is illustrated in Fig. 53.15. The truss is enclosed in layers of a board product, with the number of layers determined by the required fire endurance. Some practical rules of thumb based on test results are noted in Table 53.6.

Individual element protection is generally accomplished using a spray-applied material. Because critical truss elements perform structurally as columns, that is, in tension or compression (as opposed to bending), the applicable equations

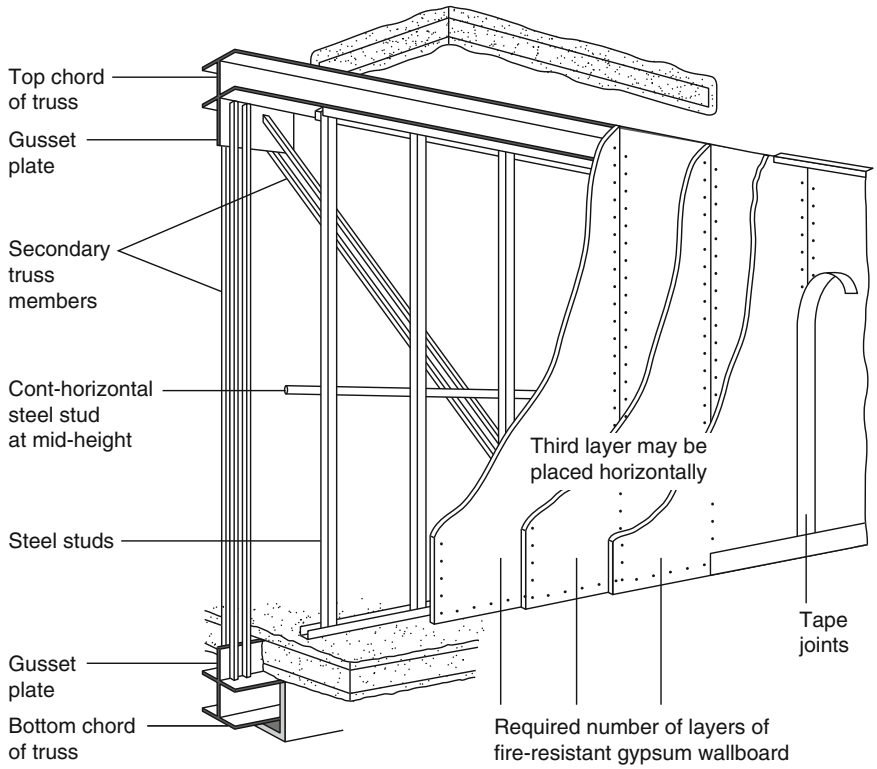

Fig. 53.15 Staggered truss protection with envelope protection [39]

for determining the thickness of spray-applied material for columns is used. In order to use these equations, the *W*/*D* ratio must be calculated for each element. Unlike columns and beams, the ratio may not be readily available. The diagrams in Fig. 53.16 are provided for assistance in calculating the heated perimeter.

Heat Transfer Analyses

Heat transfer analyses are applied to determine the time period required to heat structural members to a specified critical temperature or to provide temperature data as input to the structural analysis of the heated member. The time required to heat the member to a specified critical temperature is often defined as the fire endurance time of the member.

The critical temperature of a structural member can be determined by referring to the temperature endpoint criteria cited in ASTM E119 [1] or by a structural assessment, as is discussed later in this chapter.

The available types of heat transfer analyses can be grouped into the following categories:

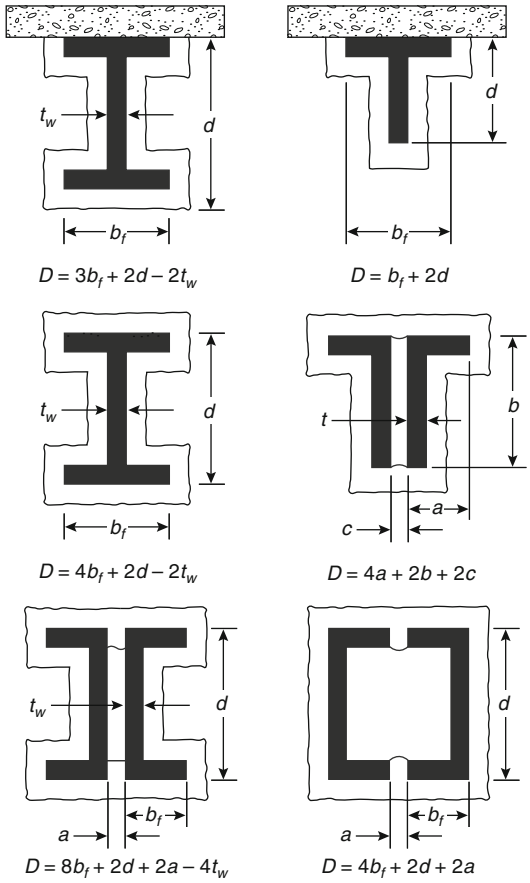

Fig. 53.16 Heated perimeter for steel truss shapes [39]

1. Numerical methods
2. Graphical solutions
3. Computer-based analyses

Numerical Methods

Many numerical methods are available to estimate the temperature rise in steel structural elements. The equations are derived from simplified heat transfer approaches.

Unprotected Steel Members The temperature in an unprotected steel member can be calculated using a quasi-steady-state, lumped heat capacity analysis. This method assumes that the steel member is at a uniform temperature. The equation for temperature rise during a short time period, Δt, is [23]

$$\Delta T_s = \frac{\alpha}{c_s(W/D)}\left(T_f - T_s\right)\Delta t \qquad (53.21)$$

where
ΔT_s = Temperature rise in steel (°F) (°C)
α = Heat transfer coefficient from exposure to steel member (Btu/ft^2·s·R) (W/m^2·K)
D = Heated perimeter (ft) (m) (see Fig. 53.16)
c_s = Steel specific heat (Btu/lb·°F)/(J/kg·°C)
W = Steel weight per lineal foot (lb/ft)/(kg/m)
T_f = Fire temperature (R) (K)
T_s = Steel temperature (R) (K)
Δt = Time step (s)
where
$\alpha = \alpha_r + \alpha_c$
α_r= radiative heat transfer coefficient
$\alpha_r = \frac{c_2 \varepsilon_f}{T_f - T_s}\left(T_f^4 - T_s^4\right)$
α_c= convective heat transfer coefficient
α_c= 9.8 × 10^{-4}–1.2 10^{-3} Btu/ft^2-s-R (20–25 W/m^{2}K)
where $C_1 = 4.76 \times 10^{-13}\text{Btu/s} \cdot \text{ft}^2 \cdot \text{R}^4 (5.67 \times 10^{-8}\,\text{W/m}^2 \cdot \text{K}^4)$ and ε_f, the effective emissivity, can be evaluated from Table 53.7.

The quasi-steady assumption dictates that the time step should be small, that is, on the order of 10 s [41]. Equation 53.21 is successively applied up to the time duration of interest. For the ISO 834 test, T_f at any time, t, can be estimated by the following expression [22]:

$$T_f = C_T \log_{10}(0.133t + 1) + T_0 \qquad (53.22)$$

Where
C_T = 620 with T_f, T_0 in °F
345 with T_f, T_0 in °C
t = time (sec)
T_0 = initial temperature °F, °C

Protected Steel Members For protected members, the thermal resistance provided by the insulating material must be considered. If the thermal capacity of the insulation layer is neglected [23],

Table 53.7 Effective emissivity [40]

Type of construction	Effective Emissivity	
1.	Column exposed to fire on all sides	0.7
2.	Column outside facade	0.3
3.	Floor girder with floor slab of concrete, only the underside of the bottom flange being directly exposed to fire	0.5
4.	Floor girder with floor slab on the top flange	
	Girder of 1 section for which the width-depth ratio is not less than 0.5	0.5
	Girder of 1 section for which the width-depth ratio is less than 0.5	0.7
	Box girder and lattice girder	0.7

$$\Delta T_s = \frac{k_i}{c_s h W/D}\left(T_f - T_s\right)\Delta t \qquad (53.23)$$

where all parameters are as defined in Equation 53.21, and

k_i = Thermal conductivity of insulation material (Btu/ft·s·°F) (W/m·°C)

h = Protection thickness (ft) (m)

Malhotra suggests that the thermal capacity of the insulation material may be neglected if the following inequality is true (see parameter definitions for Equation 53.21 [23]:

$$c_s W/D > 2c_i \rho_i h$$

If the thermal capacity must be accounted for, as in the case of gypsum and concrete insulating materials, then

$$\Delta T_s = \frac{k_i}{h}\left[\frac{T_f - T_s}{c_s(W/D) + 1/2c_i \rho_i h}\right]\Delta t \qquad (53.24)$$

where all parameters are as defined for Equation 53.21, and

c_i = Specific heat of insulating material (Btu/lb·°F) (J/kg·°C)

ρ_i = Density of insulating material (lb/ft^3) (kg/m^3)

An evaluation of the predictive capability of the lumped heat capacity approach using Equation 53.24 for protected steel sections was conducted by Berger for steel columns protected with a spray-applied cementitious material [42]. The analysis consisted of comparing predicted versus measured temperatures for steel columns exposed to the standard fire exposure. A comparison of the predicted versus measured times for the steel column to reach 538 °C is provided in Table 53.8. A comparison of the predicted temperature with that measured for one protected steel column assembly is provided in Fig. 53.17.

Predictions of temperature rise in steel beams by the lumped heat capacity approach are prone to be inherently less accurate than those for steel columns [43]. As noted previously, a steel beam in contact with a slab has only three sides exposed to a fire and also will lose heat to the slab [44]. Consequently, the temperature of a steel beam exposed to fire is likely to vary appreciably from the bottom flange to the top flange, stretching the validity of the uniform temperature assumption. Nonetheless, for many engineering applications, the lumped heat capacity approach can provide a conservative estimate of the average temperature rise of a steel beam [45]. Heat losses to the slab may be compensated for by reducing the effective flame emissivity to 0.5 [40]. However, if the temperature gradient across the beam is important, another analytical approach will need to be applied [43].

Exterior Steel Columns and Steel Spandrel Beams A design guide is available for calculating the exposure of exterior steel columns and steel spandrel beams [46]. The guide is based on research by Law and basic radiation heat transfer principles [47]. A similar calculation procedure is available in the Eurocodes [10].

Table 53.8 Comparison of predicted time from lumped heat capacity analysis and measurements for protected steel column to reach 538 °C

Shape	h (cm)	Test (min)	Calc (min)
W 6 × 16	1.9	58	56
	3.8	112	119
	7.6	210	251
W 8 × 28	3.5	122	121
	8.3	291	298
	9.5	355	352
W 10 × 49	1.9	70	62
	5.6	217	220
W 12 × 106	3.8	200	203
W 14 × 228	1.4	123	140
W 14 × 233	2.9	225	251

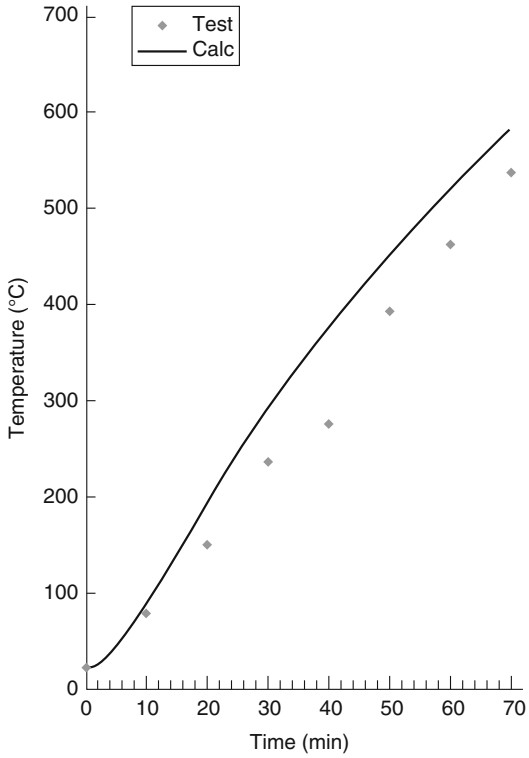

Fig. 53.17 Predicted steel column temperature [42]

The temperature of the steel member is calculated from a steady-state conduction analysis. The exposure boundary conditions consist of radiant heating from a fully developed room fire and flames emitting from windows near the steel member. For this method, a specific design is considered unacceptable if the steel temperature exceeds 1000 °F (538 °C).

Liquid-Filled Columns The design calculations for liquid-filled columns are based on the thermal capacity of the liquid. The design of a liquid-filled column fire protection system consists of three major steps:

1. Heat transfer analysis
2. Determination of volume of liquid required
3. Pipe network design

The heat transfer analysis is used to assess the impact of fire exposure on the liquid-filled column. The heat transfer analysis considers radiation and convection heat transfer from the fire to the column surface, conduction through the column wall, and convection with localized boiling into the liquid. Both temperature of the steel column and total amount of heat transferred to the liquid causing evaporation are determined as a result of this analysis.

The liquid volume calculation is important to ensure the column remains full of liquid for the entire fire exposure period. Because heat transferred to the liquid will cause some evaporation, a supplemental amount of liquid must be provided in a storage tank.

The final step in the design method is a hydraulic analysis of the tubular column and pipe network. This analysis assesses the ability of the liquid to circulate based on friction losses, elevation changes, and buoyancy of the heated liquid.

A comprehensive design aid for liquid-filled columns is available [48]. Because the procedure is rather lengthy, it will not be reviewed here.

Graphical Solutions

Because heat transfer analyses can be very tedious and may involve the use of complex computer programs, graphic solutions have been formulated to simplify the estimation of steel temperature. Graphs of the temperature of protected steel members have been developed by Malhotra [23], Jeanes [13], Lie [16], and others.

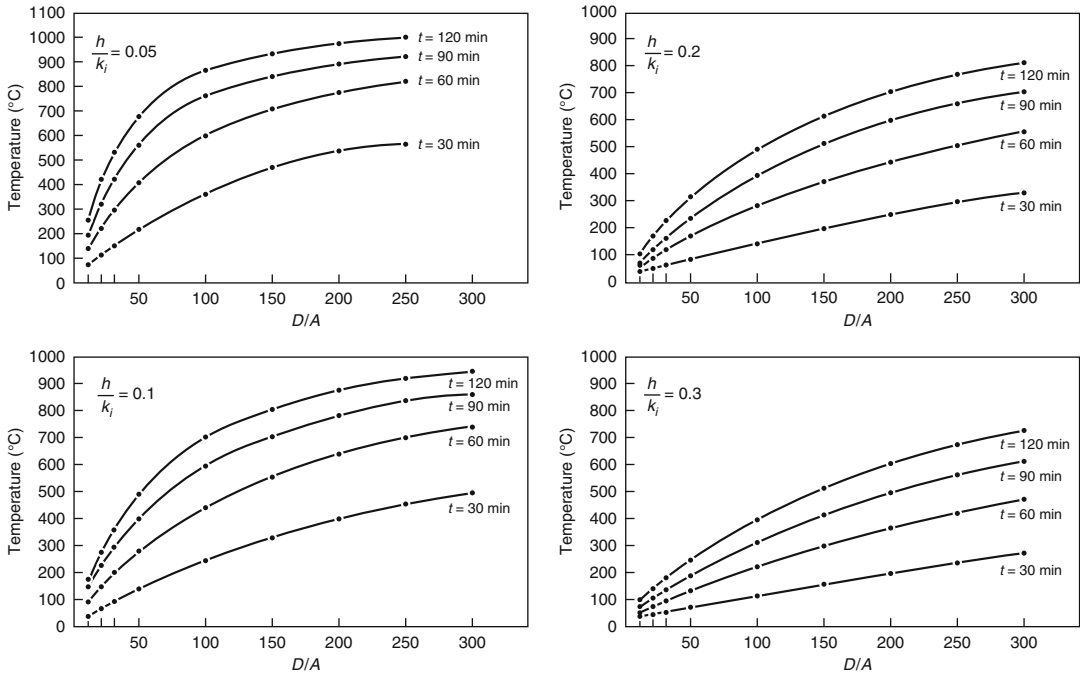

Fig. 53.18 Relationship of heated area to steel weight with temperature [23]

The series of graphs developed by Malhotra [23], presented in Fig. 53.18, for estimating the temperature of steel members exposed to the standard exposure are based on the lumped heat capacity approach described in the previous section. Steel temperatures are plotted versus the *D*/*A* ratio (analogous to the inverse of *W*/*D*) for selected time periods of exposure and thermal resistances of the insulating material. Time periods of 30–120 min are noted in the graphs. The range of thermal resistances of the insulating material covered by these graphs is 0.01–0.30 $(W/m^2 \cdot {}^\circ C)^{-1}$ (0.003–0.10) $(Btu/ft^2 \cdot h \cdot {}^\circ F)^{-1}$.

Based on the application of FIRES-T3, a heat transfer computer program that will be described in the next section, Jeanes formulated a series of time-temperature graphs of protected steel beams [13]. The steel beams are protected by a proprietary specific spray-applied cementitious material with a range of thicknesses of 0.5–1.5 in. (12.7–38.1 mm). Graphs are available for a variety of common wide-flange beam shapes [13]. Examples of these graphs are presented in Fig. 53.19 with graphs addressing the average and single-point steel temperatures relating to the maximum endpoint criteria from ASTM E119 [1]. Average and single-point steel temperatures are represented by the dashed lines. These graphs can be used to determine the thickness of protection material required to provide a desired level of fire resistance. Alternatively, the fire endurance can be estimated for a particular steel beam and insulation thickness design that has not been tested [14].

Information from numerous applications of FIRES-T3 examining the time-temperature response of steel beams protected with a spray-applied cementitious material exposed to the standard fire exposure is summarized in Fig. 53.20. Using this graph, the fire endurance of protected steel beams with a *W*/*D* ratio of 0.4–2.5 lb/ft-in. can be determined for thicknesses of the spray-applied protection between 1.3 and 3.8 cm (0.5 and 1.5 in.).

Example 4 A *W* 24 × 76 steel beam is protected with 0.50 in. (12.7 mm) of spray-applied cementitious material. Based on the temperature endpoint criteria noted in ASTM E119, determine the fire resistance of the beam by two methods:

1. Graphical approach from Jeanes [13]
2. Quasi-steady-state approach by Malhotra [23]

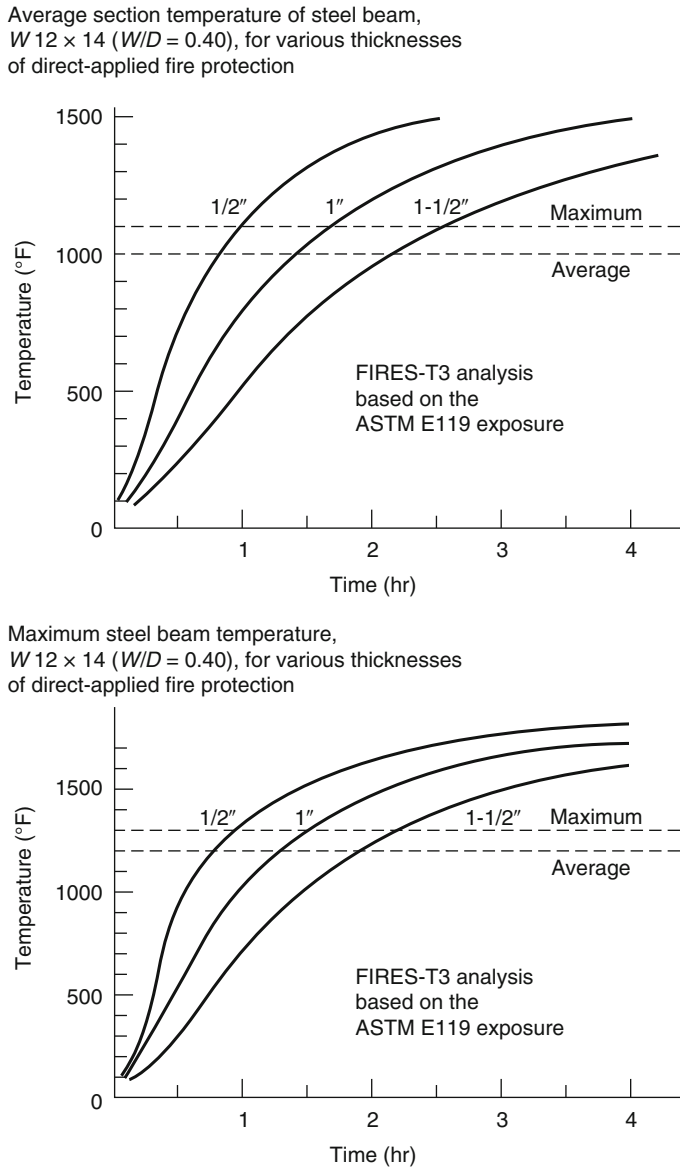

Fig. 53.19 Predicted steel beam temperature by FIRES-T3 [13]

Solution A W 24 × 76 steel beam has a W/D ratio of 1.03 lb/ft·in. or 12.36 lb/ft^2. The material properties are evaluated at mean temperatures expected during the exposure. The fire resistance can be assessed using the temperature endpoint criteria in ASTM E119. Mean temperatures of 500 °F (260 °C) and 750 °F (400 °C) are selected (arbitrarily) for the steel and insulation, respectively, to determine the thermal properties. The following material property values are assumed [13]:

	Steel	Insulation
Thermal conductivity	25.6 Btu/ft·h·°F (44.3 W/m K)	0.067 Btu/ft·h·°F (0.12 W/m K)
Specific heat	0.132 Btu/lb·°F (551 J/kg K)	0.304 Btu/lb·°F (1270 J/kg K)
Density	490 lb/ft^3 (7860 kg/m^3)	15 lb/ft^3 (240 kg/m^3)

Jeanes's Graph Using Fig. 53.21 with a W/D of 1.03 lb/ft·in. (0.060 kg/m^2) and an insulation thickness of 0.50 in. (12.7 mm), the fire endurance is estimated to be 1.33 h or 80 min.

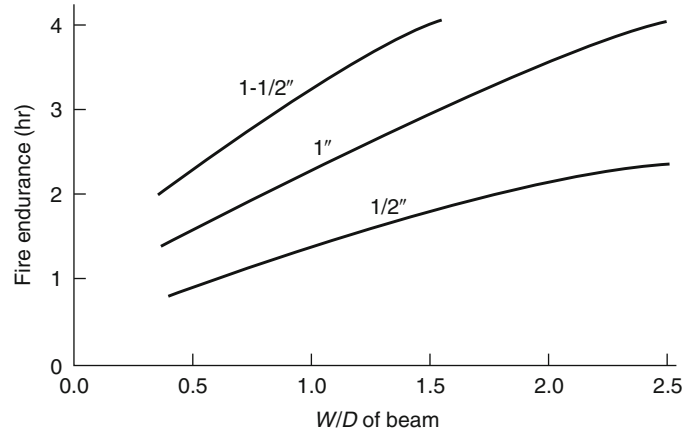

Fig. 53.20 Fire endurance of steel beams versus fire protection thickness for average section temperature of 1000 °F (538 °C) (Based on FIRES-T3 analysis of ASTM E119 fire exposure) [13]

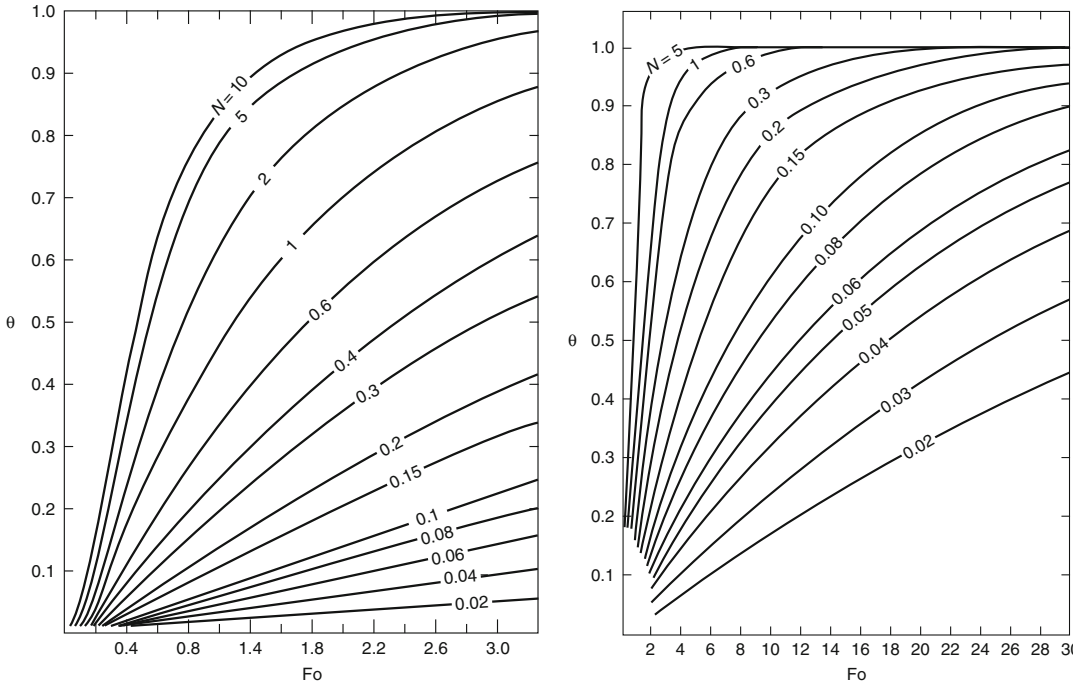

Fig. 53.21 Dimensionless steel temperature versus Fourier numbers [16]

Quasi-Steady-State Approach First, a check is performed to determine whether the thermal capacity of the insulation material must be considered.

$$c_s W/D > 2c_i \rho_i h$$
$$0.132 \times 12.36 > 2 \times 0.304 \times 15 \times 0.50/12$$
$$1.63 > 0.38 \tag{53.25}$$

Disregarding the thermal capacity of the insulation, Equation 53.23 is used to predict the steel temperature rise for each time step.

$$\Delta T_s = \frac{0.067/3600}{0.0132 \times 0.50/12 \times 12.36}\left(T_f - T_s\right)\Delta t$$
$$= 2.74 \times 10^{-4}\left(T_f - T_s\right)\Delta t \tag{53.26}$$

Time	Steel temperature (°C)	Fire temperature (°C)	Fire-steel temperature (°C)	W/m^{2}K k/h	ΔT_s (°C)
10	20.0	46	26	9.13	0.1
20	20.1	72	51	9.13	0.2
30	20.3	96	76	9.13	0.3
40	20.5	120	99	9.13	0.3
50	20.8	143	122	9.13	0.4
3220	534.2	888	353	9.13	1.2
3230	535.3	888	353	9.13	1.2
3240	536.5	888	352	9.13	1.2
3250	537.7	889	351	9.13	1.2
3260	538.9	889	350	9.13	1.2
3270	540.1	890	350	9.13	1.2
3280	541.2	890	349	9.13	1.2

Thus, the fire endurance is 54 min.

The fire endurances calculated by the two methods can be compared as follows:

Jeanes (FIRES-T3)	80 min
Quasi-steady-state	54 min

The significantly reduced fire endurance calculated using the quasi-steady-state approach is attributable to the approximate nature of the lumped heat capacity method assuming an adiabatic surface condition at the beam-slab interface.

Computer-Based Analyses

Several computer-based analyses are available to estimate the temperature rise of steel members. The analyses range from a spreadsheet procedure to perform the iterative calculations for the quasi-steady-state approach to finite element models.

Spreadsheets are one example of providing a framework to perform the iterative, quasi-steady calculations [42, 43, 49]. Typically, the spreadsheet procedures mimic the quasi-steady analysis procedure described previously, including the evaluation of material properties at a mid-range temperature for the exposure of interest. Although temperature-dependent material properties can be included within the spreadsheet framework, the accuracy implied by considering temperature-dependent properties is not consistent with the first-order nature of the quasi-steady approach.

Another framework for conducting computer-based analyses includes the numerous mathematical-equation-solver software packages. This software can be used to conduct the iterations associated with the quasi-steady approach or to solve the partial differential equations exactly.

Harmathy and Lie developed a two-dimensional finite difference model to predict the temperature rise in protected steel columns [50]. The two-dimensional network is formulated over the cross section of the insulation layer, assuming the temperature to be independent of length. The steel is assumed to be a perfect conductor (i.e., the temperature is uniform throughout the steel). Heat transfer via radiation is considered across any air spaces enclosed by the insulation and steel.

The boundary conditions included by Harmathy are those associated with the ASTM E119 test [1]. To simplify the model, convection is disregarded, because convection comprises a minor portion of the heat transfer process in the furnace test.

Pettersson et al. [40] include a finite difference formulation to predict the temperature rise of steel beams protected with a suspended ceiling exposed to a specified fire. The formulation uses a one-dimensional approximation accounting for conduction through the suspended ceiling and floor slab (above the beam), and radiation and convection in the air space between the slab and beam. The temperature of the steel is assumed to be uniform. The assembly is divided into several elements, as depicted in Fig. 53.22.

A system of simultaneous equations is derived for the temperature rise in each of the assembly elements. A numerical integration technique such as Runge-Kutta is used to obtain the solution. A comparison of the calculated versus experimentally observed temperatures for a steel beam is presented in Fig. 53.23.

General heat transfer finite-element programs have been available for many years [51]. FIRES-T3, TASEF-2, SAFIR, SUPER-TEMPCALC, and HEATING 7, among others, have been developed specifically to address the heating of assemblies with steel structural members exposed to fire conditions [52–55].

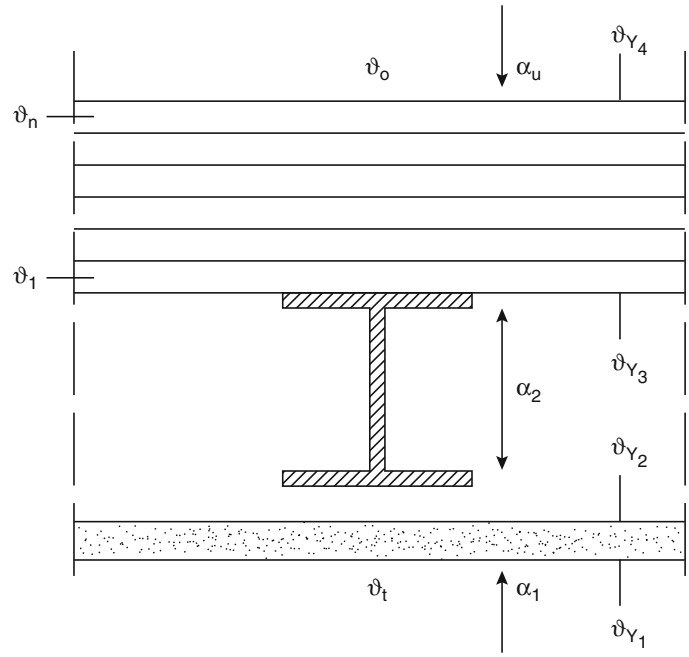

Fig. 53.22 Division of the floor slab into elements [40]

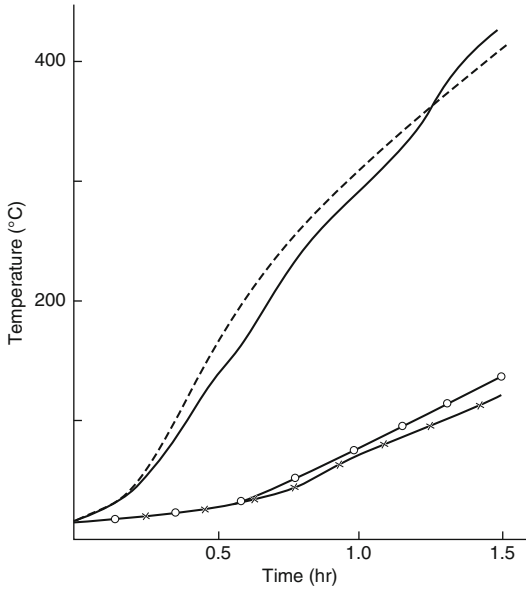

Fig. 53.23 Calculated (- -) and measured (—) steel temperature-time (θ_s – t) curve for a floor girder IPE 140 with insulation in the form of a suspended ceiling of 40-mm-thick mineral wool slabs of density $\gamma = 150$ kg/m^3. The figure also gives the calculated (–°–) and measured (–x–) temperature-time curve for the top of the 50-mm-thick concrete floor slab [40]

TASEF-2 examines the conduction heat transfer through assemblies [52]. Assemblies may include internal voids, in which convection and radiation heat transfer modes are considered. Two time-temperature curves are available: (1) the ISO 834 standard time-temperature curve and (2) a time-temperature curve from a ventilation-controlled fire.

SUPER-TEMPCALC can also be used to analyze the conduction heat transfer through assemblies with air gaps. Numerous fire curves are included within the software.

FIRES-T3 was specifically developed to examine the heating of structural members exposed to fire conditions [53]. FIRES-T3 has been applied successfully to predict the temperature rise in protected steel beams and columns [13, 56]. Almand used a finite-difference heat transfer model to estimate the protection thickness of spray-applied cementitious material required for tubular steel columns [57].

The input data requirements for the heat transfer computer models can be grouped into two categories:

1. A description of the assembly
2. A description of the fire exposure

The information necessary to describe the assembly includes geometric factors (dimensions, shape of member) and material property values (thermal conductivity, specific heat, and density). The fire exposure is characterized in terms of the temperature of the surrounding environment and appropriate heat transfer coefficients. The geometry of the assembly is established by formulating an element mesh for the assembly of interest. Required material property data consists of the density, specific heat, and thermal conductivity of the steel and insulation. Material property data are available for a limited number of insulation materials [13, 58].

For models using an explicit transient solution technique, such as FIRES-T3, caution must be exercised in selecting the time step and mesh size to obtain correct results that are numerically stable. TASEF-2 internally determines a numerically stable time step. Most heat transfer models do not address the effects of phase changes or chemical reactions that may influence the heating process. Phase changes and chemical reactions have been accounted for by altering the value of the material properties. Milke addressed the evaporization of free water in a spray-applied cementitious material by increasing the specific heat in a narrow temperature region around 100 °C (212 °F) [56].

Agreement between the predicted and experimental average steel temperatures is quite good in both applications of FIRES-T3 by Jeanes and Milke. A comparison of the temperature history for a steel column protected with a spray-applied cementitious material subjected to the ASTM E119 test is presented in Fig. 53.24. A similar comparison is presented in Fig. 53.25 for steel beams protected with the same material [13].

FIRES-T3 has also been used to conduct a preliminary analysis of the heating of partially protected steel columns (i.e., where a portion of the spray-applied protection is missing) [59, 60]. The analysis indicated that even a small portion of missing protection significantly decreased the fire resistance of the column, especially for cases involving small columns. Results of the analysis are indicated in Fig. 53.26.

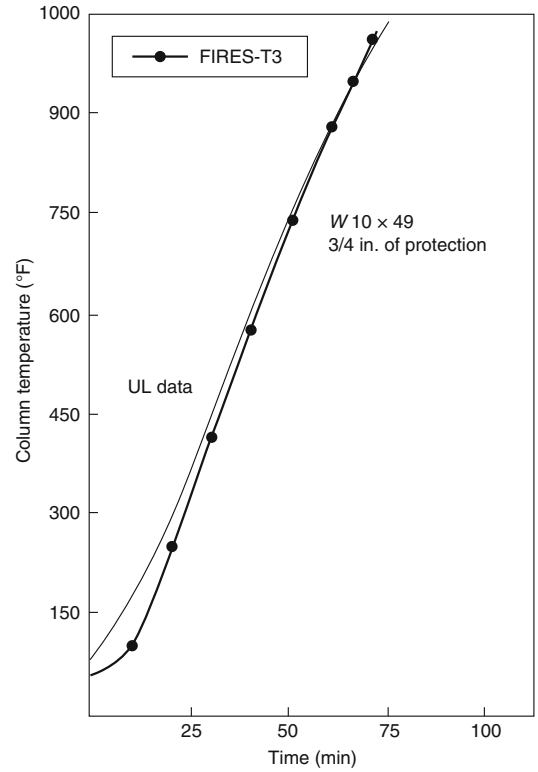

Fig. 53.24 Comparison of predicted and measured average steel column temperature [53]

Structural Analyses

Much of the previous testing and analysis has concentrated on the response of a single isolated member to fire exposure. Recent events, including the Broadgate fire, Cardington tests, and performance of buildings in or near the World Trade Center complex, have indicated that analyses need to account for interactions between structural members for more realistic assessments of behavior in fire. In the fire at the Broadgate construction site, a major fire exposed steel elements that were not yet protected. However, no collapse was observed. In the Cardington tests, no collapses were observed in any of the six tests despite steel temperatures that reached 900 °C in some tests [61].

In the many steel frame buildings involved in the World Trade Center terrorist incident on September 11, 2001, the variety of outcomes

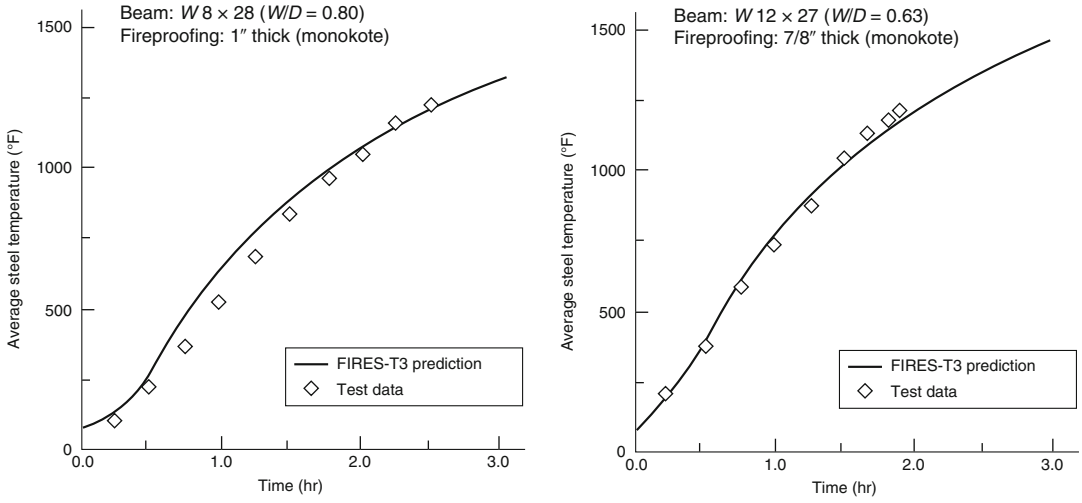

Fig. 53.25 Comparison of experimental data and FIRES-T3 analysis [13]

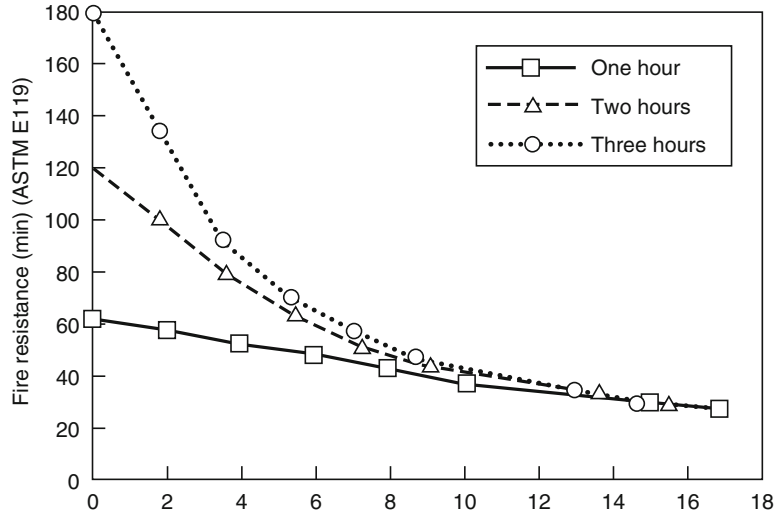

Fig. 53.26 Fire resistance versus percent protection loss for W 10 × 49 column, flange exposure

observed has been attributed to the response of subframes or the interaction of exposed structural members with adjacent structural members [62]. In the North and South Towers, the ability of the towers to remain standing for a period of time after the aircraft impact is attributed to load transfer from the severed exterior columns to core columns. In neighboring buildings, impacts by the debris from the collapsing North and South Towers were withstood because of load transfer. One of the lower buildings in the World Trade Center complex, WTC 5, withstood almost complete burnout of fuels, though beams were significantly deflected.

The interaction of structural components has been an area of increased research in recent years, as will be discussed later in this chapter relative to computer modeling efforts. Part of this interest has concentrated on joints [63]. In WTC 5, a shear plate failed, leading to a partial collapse of the building [61].

The structural analysis methods calculate one of three parameters: deflection, critical temperature, or critical load. In several of the

methods, all three of the parameters may be considered because they are interrelated. Algebraic equations, graphs, and computer programs are available to perform a structural analysis for the purpose of addressing fire resistance.

General Discussion of Three Parameters Addressed in Structural Analysis

Deflection The total deflection and rate of deflection can be calculated for loaded and heated steel beams by considering all sources of strain. The total strain comprises components of the elastic and plastic strains due to the applied loads, thermal strain (due to thermal expansion), and creep strain.

The calculated deflection and rate of deflection can be compared with established maximum limits of each. The Robertson-Ryan criteria have been widely accepted for this purpose [22, 64, 65]. However, calculation of the deflection of unheated beams is difficult except for simple loadings, geometries, and end conditions. Adding the thermal expansion and creep components further complicates the calculation, virtually requiring computer solution.

Critical Temperature As mentioned earlier in the chapter, the material properties of steel change with increasing temperature. The most important material properties for critical-temperature calculations are yield strength, ultimate strength, and modulus of elasticity. The critical temperature is defined as the temperature at which the material properties have decreased to the extent that the steel structural member is no longer capable of carrying a specified load or stress level. In this context, the factor of safety of the member is considered to be reduced if the member reaches unacceptable stress levels, buckling becomes imminent, or deflections exceed maximum limits. The critical temperature can be calculated as long as the dependence of the material properties with temperature is known. There are numerous algebraic equations to calculate the critical temperature of steel structural members [66]. Often, the critical temperature is defined based on temperature limits stated in the standard test. However, in tests steel members experienced temperatures in excess of 800 °C (1470 °F) without collapse [66].

Critical Load The critical load is defined as the minimum applied load that will result in failure if the structural member is heated to a temperature, T. The critical load can be expressed as a point load or distributed load. As with critical temperature, the critical load calculation requires the material properties at elevated temperatures. Critical load calculations can be conducted with algebraic equations or with a computer program.

Algebraic Equations: Critical Temperature

Beams

The critical temperature of Grade 250 steel beams with an allowable stress of 20,000 psi (138 Mpa) can be determined using equations by Lie and Stanzak [35]. The Lie and Stanzak equations account for creep strain and assume the beam is simply supported and thermally unrestrained.

Similar approaches have been developed by Malhotra [23], Vinnakota [65], and Kruppa [67]. Differences in the percent reduction in yield stress or modulus of elasticity are related to design method (elastic or plastic), factor of safety, and end conditions. Equations for the ratio of yield stress at elevated temperature with yield stress at ordinary room temperature are presented in Table 53.9. Typical values of Z_p/Z_e are between 1.13 and 1.15 for I sections [23], and 1.5 for rectangular sections.

Another example of the second approach is the analysis of the critical temperature of beams by European Convention for Constructional Steelwork (ECCS) [41, 68]. The ECCS guide addresses the maximum allowable reduction in yield strength by considering the applied loading, beam geometry, structural end conditions, and whether the applied loading results in stresses

Table 53.9 Critical stress equations [22]

Design basics	Critical yield stress
Elastic design	$\frac{\sigma_{yT}}{\sigma_y} = \frac{1}{F_e} \quad \frac{Z_e}{Z_p}$
Plastic design	$\frac{\sigma_{yT}}{\sigma_y} = \frac{1}{F_p}$

where
σ_{yT} = critical yield stress at elevated temperature, T
σ_y = yield stress at ordinary room temperature
F_e = factor of safety, elastic design
F_p = factor of safety, plastic design
Z_e = elastic section modulus
Z_p = plastic section modulus

in the elastic or plastic range. Critical temperature calculations based on the ECCS analysis are presented in Table 53.10.

Example 5 Determine the critical temperature of a simply supported W 12 × 26 steel beam supporting a 53-in. (1.35-m) thick rectangular slab. The applied moment is 41,750 ft·lb (15,480 N·m). The rectangular slab is 8 ft (2.4 m) wide. The section properties of the beam are

$$Z_e = 33.4\,\text{in.}^3\left(547 \times 10^3\,\text{mm}^3\right)$$
$$l = 204\,\text{in.}^4\left(84.9 \times 10^6\,\text{mm}^4\right)$$

Assume σ_y = 36,000 psi (248 MPa).

Solution Using Lie and Stanzak's equation for a beam,

$$I_d = \frac{3^3 \times 96}{12} = 216\,\text{in.}^4\left(5.19 \times 10^4\text{m}^4\right) \tag{53.27}$$

$$T_{cr} = \frac{70,000}{45.62 - 4.23(I_d/I)} - 460 = \frac{70,000}{45.62 - 4.23(216/204)} - 460 = 1240°\text{F}\ (671°\text{C}) \tag{53.28}$$

Columns

Lie and Stanzak calculated a critical temperature of 941 °F (505 °C) for slender, axially loaded columns [35]. The calculation was based on the temperature for the onset of elastic buckling for columns under maximum permissible applied stress conditions.

The Euler buckling stress at which elastic buckling is imminent is given by

$$\sigma_{cr} = \frac{\pi^2 E_T}{\lambda^2} \tag{53.29}$$

where
σ_{cr} = Euler buckling stress (MPa) (psi)
E_T = Modulus of elasticity at temperature T (MPa) (psi)
λ = Slenderness ratio = Kl/r
r = Radius of gyration (ft) (m)
Kl = Effective length of column (ft) (m)

Included in the ECCS guide [41] are dimensionless buckling curves for steel columns at elevated temperatures. These curves are presented in Fig. 53.27.

Equation 53.29 is valid only for columns that buckle in the elastic range. Generally, slender columns having a slenderness ratio in excess of approximately 90 can be expected to buckle elastically. Buckling stresses for stout columns (slenderness ratio less than 90) are in the plastic range, requiring a more complex analysis. The failure mode for columns with a slenderness ratio between 80 and 100 cannot be reliably predicted [69]. The tangent modulus can be used instead of the modulus of elasticity in Equation 53.29 for stout columns. However, predictions of the critical temperature using Equation 53.29 may not be accurate, due to residual stresses from the steel fabrication process [69]. Thus, for stout columns, a conservative estimate for the critical temperature of steel columns may be obtained by determining the temperature at which the yield stress is equal to the applied stress.

General

Malhotra has observed that critical temperatures determined from the structural analysis algebraic equations will be somewhat low when compared to experimental data [23]. Thus, the following

Table 53.10 Critical temperature of steel beams [43]

			factor $\frac{kq^*}{q_e}$ resp. $\frac{kq^*}{q_p}$				
		Static System	0.3	0.4	0.5	0.6	0.7
Base of structural design at room temperature	Theory of plasticity	Statically determinate Statically indeterminate	585	540	490	430	360
	Theory of elasticity	Statically determinate	605	565	525	475	425
		Statically indeterminate					
		Θ = 1.33 	640	605	575	545	510
		Θ = 1.0 	605	565	525	475	425
		Θ = 1.47 	650	615	590	560	535
		Θ = 1.12 	615	580	545	505	465
		Θ = 1.47 	650	615	590	560	535

q_p = Ultimate plastic load
q^* = Applied load
k = Load multiplier
Θ = Factor addressing plastic reserve of beam from redistribution of moments
q_e = elastic load limit

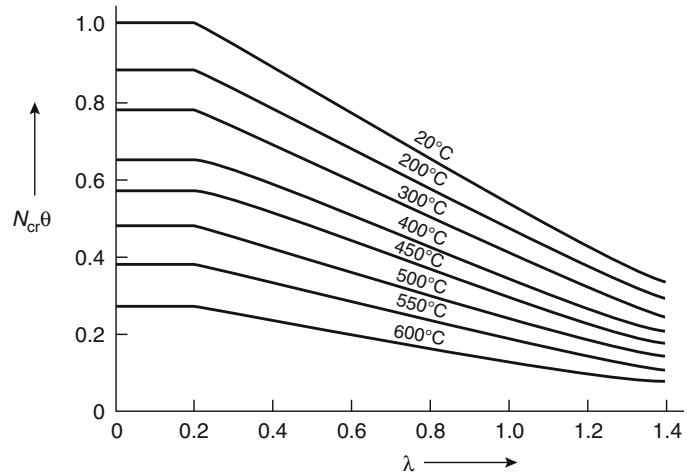

Fig. 53.27 Dimensionless buckling curves for steel columns [41]

correction factors, V, are suggested by Malhotra to improve the prediction capabilities of the approach:

1. Columns: $V = 0.85$
2. Statically determinate beams: $V = 0.77 + 0.15\frac{P_s}{P_u}$
3. Statically indeterminate beams: $V = 0.25 + 0.77\frac{P_s}{P_u}$

where

P_s = Service (applied) load (N or N/m) (lb or lb/ft)

P_u = Load to induce ultimate stress at midspan (N or N/m) (lb or lb/ft)

Example 6 Determine whether the following steel column is expected to buckle if it achieves

an average temperature of 1100 °F (593 °C). The column is simply supported, is 15 ft (4.6 m) long, and has an applied load of 12,000 psi (82.8 MPa). Assume the yield stress is 36,000 psi (248.4 MPa) and the modulus of elasticity is 30,000,000 psi (207 GPa). The characteristics of the column are

$A = 8.23$ in.^{2} (5310 mm^2)
$I = 21.6$ in.^{4} (8.99×10^6 mm^4)
$Kl = 180$ in. (4572 mm)

At 1100 °F (593 °C):

$$E_T = \left(1 + \frac{T}{2000\, ln(T/1100)}\right) E_0 = \left(1 + \frac{593}{2000 \ln(593/1100)}\right) \times 15.6 \times 10^6 = 8.11 \times 10^6 \tag{53.30}$$

Solution Calculate the slenderness ratio to determine the failure mode.

$$\lambda = \frac{Kl}{r} = \frac{180}{\sqrt{21.6/8.23}} = 113 \tag{53.31}$$

Because the slenderness ratio exceeds 90, the column is susceptible to buckling. The buckling stress at 1100 °F (595 °C) is 12,700 psi (87.6 MPa). Thus, the column does not buckle due to the applied load and elevated temperature.

Critical Stress

Columns Simple expressions for determining the critical stress for steel columns [35] are noted below.

$$P_{cr}^2 - P_{cr}\left[\sigma_{yT} + 4.8 \times 10^{-5}\pi^2 E_T + \frac{1}{\lambda^2}\right] + \sigma_{yT} A \frac{\pi^2 E_T}{\lambda^2} = 0 \tag{53.32}$$

where

P_{cr} = Critical point load (N) (lb)
σ_{yT} = Yield stress at temperature T (Pa) (psi)
E_T = Modulus of elasticity at temperature T (Pa) (psi)
$\lambda = Kl/r$

In order to improve the prediction capabilities of the critical stress approach for slender columns, the modulus of elasticity should be replaced by the reduced modulus of elasticity [16]. The reduced modulus is defined as

$$E_r = \frac{4EE_T}{\left(\sqrt{E} + \sqrt{E_t}\right)^2} \tag{53.33}$$

where

E_t = Tangent modulus

In addition, the 0.2 % proof stress may be replaced by the 0.5 % proof stress in the yield stress parameter [70].

Results of a buckling analysis on concrete-filled square hollow sections are provided in Fig. 53.28.

Beams The expressions for the critical loads for beams assume at failure that the beam is in a state of full plasticity at the location of the maximum moment [70]. Obviously, in order to calculate the critical stress, the material property–temperature relationships must be known.

The critical distributed load for a simply supported beam is [66]

$$q_{cr} = \frac{8\sigma_{yT} Z_p}{L^2} \tag{53.34}$$

where

q_{cr} = Critical distributed load (N/m) (lb/ft)
Z_p = Plastic section modulus (m^3) (in.^{3})
L = Span of beam (m) (ft)

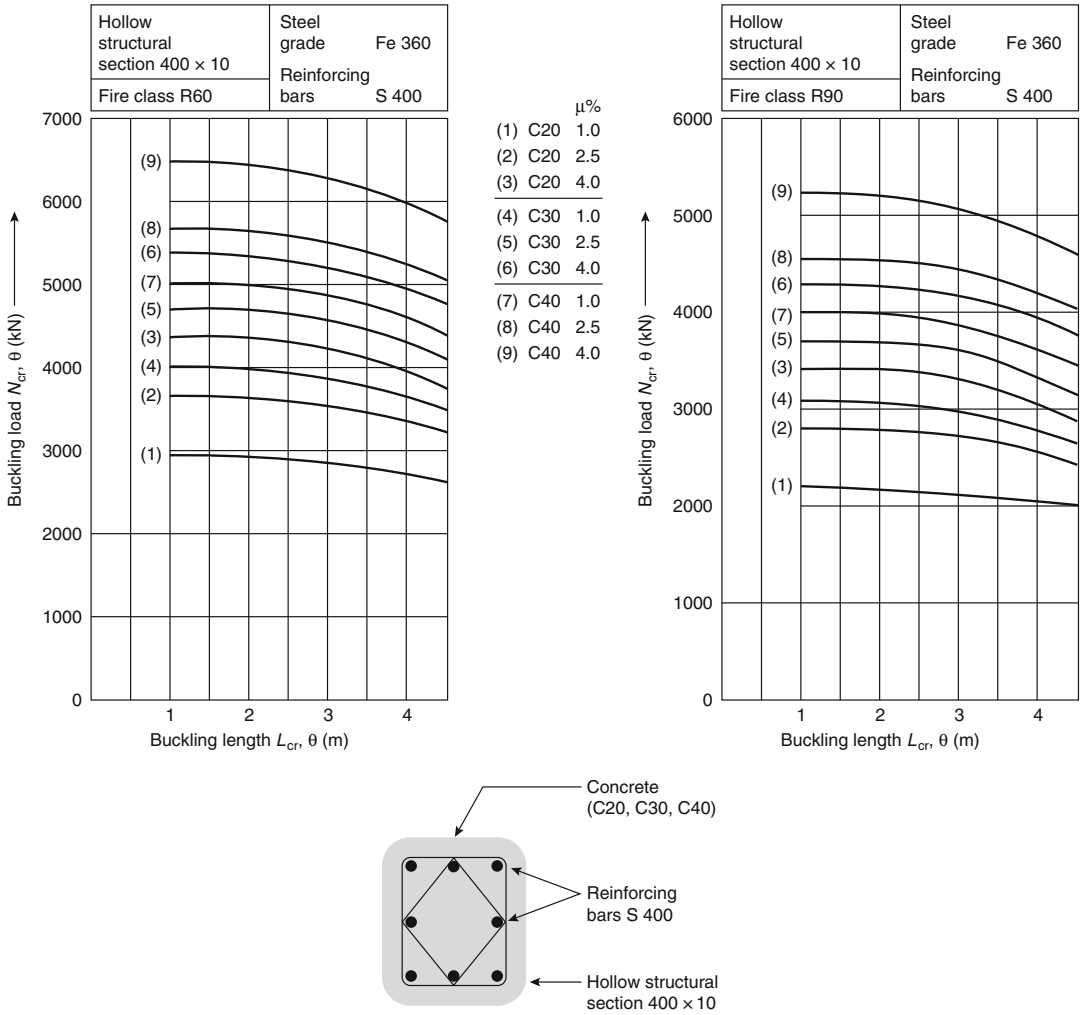

Fig. 53.28 Design graphs for ISO fire resistance requirements R60 and R90. For the concrete-filled square hollow structural section 400 × 10, the axial buckling load is a function of the buckling length, of the concrete quality, and of the percentage m of reinforcement; this design diagram is based on a simple calculation model [9]

σ_{yT} = Yield stress at elevated temperature (MPa) (psi)

Considering a cantilever beam with a point load applied one-third of the span from the fixed end, a plastic hinge can be expected at the fixed end. The critical load can be determined by

$$p_{cr} = \frac{7.5\sigma_{yT}Z}{L} \tag{53.35}$$

The above equations in this section do not account for creep strain. Based on an analysis of the deflection history of heated, loaded beams, Pettersson et al. include a load ratio, β, to determine the critical distributed stress [40].

$$q_{cr} = \beta\frac{8\sigma_z}{L^2} \tag{53.36}$$

where the yield stress is evaluated at ordinary room temperature, relaxing the need to know the yield stress–temperature relationships. β is defined as the ratio of the load causing a maximum allowable deflection under fire conditions to the load inducing stresses equal to the yield stress at ordinary room temperature. Thus, the parameter β takes into account the dependence

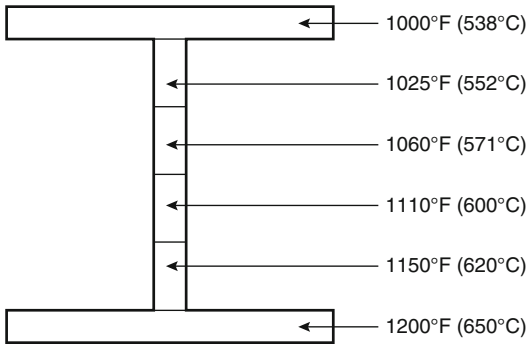

Fig. 53.29 Isothermal sections of beam

of both the yield stress and the creep on temperature. Graphs of β are available for a variety of thermal restraint and structural end conditions.

The Eurocodes include a method of analysis using algebraic equations to consider the moment capacity of steel beams that have a temperature gradient through the depth of the beam [10]. The method involves dividing the beam into small isothermal sections and treating these isothermal sections as a composite beam (Fig. 53.29). In this case, the moment capacity of the beam is given as

$$M_{\text{cap}} = \sum_{i=1}^{n} \sigma_i A_i z_i \qquad (53.37)$$

where

M_{cap} = Moment capacity (N·m) (lb·ft)

σ_i = Applied stress in isothermal element (Pa) (psi)

A_i = Area of isothermal element (m^2) (ft^2)

z_i = Distance from neutral axis to centroid of isothermal element (m) (ft)

Computer Programs

Several finite element computer models are available to assess the structural response of fire-exposed structural members or frames. Sullivan et al. indicate that most of the existing finite element models used for structural fire protection analyses were developed originally for research applications [71].

FASBUS-II is an example of a finite element model developed in the United States to evaluate the structural response of complex building assemblies such as floor assemblies consisting of a two-way concrete slab, steel deck, and steel beam [72]. Sullivan et al. and Franssen et al. provide extensive reviews and comparisons of existing finite element models for structural fire protection applications [72, 74]. At the time of the review, Sullivan et al. noted that all of the models make the following assumptions:

- Plane sections remain plane (Navier-Bernoulli hypothesis).
- Perfect composite action is assumed for steel-concrete assemblies, disregarding any slippage between the steel and concrete.
- Torsion is disregarded.
- Moisture effects are disregarded.
- Large displacements are not accurately modeled.

Traditionally, analysis of the response of the structure exposed to fire has been limited to an analysis of the response of single members. However, in structural frames comprising many members, load transfer or membrane action may occur to permit the steel member to maintain its integrity, despite achieving a temperature in excess of that typically associated with failure [73, 74].

Load transfer allows stronger members to support additional loads not capable of being carried by heated, weak members. In order to capture this phenomenon, a frame analysis is required [49]. Numerous software packages are available to conduct the frame analysis. Results of a frame analysis are presented in Figs. 53.30 and 53.31.

The frame analyses range from algebraic equation–based methods to finite element analyses. Pettersson et al. include a frame analysis via algebraic equations used to determine displacement [40]. The frames consist of beams supported by one or two columns at midspan. The analysis assumes that each beam or column has a uniform temperature (though the temperature of the beam is not required to be that of a column). A pinned connection between the structural members is assumed. The analysis considers the compatibility of the deformation of each member by requiring that the change in length of the column is equal to the beam deflection at the point of contact.

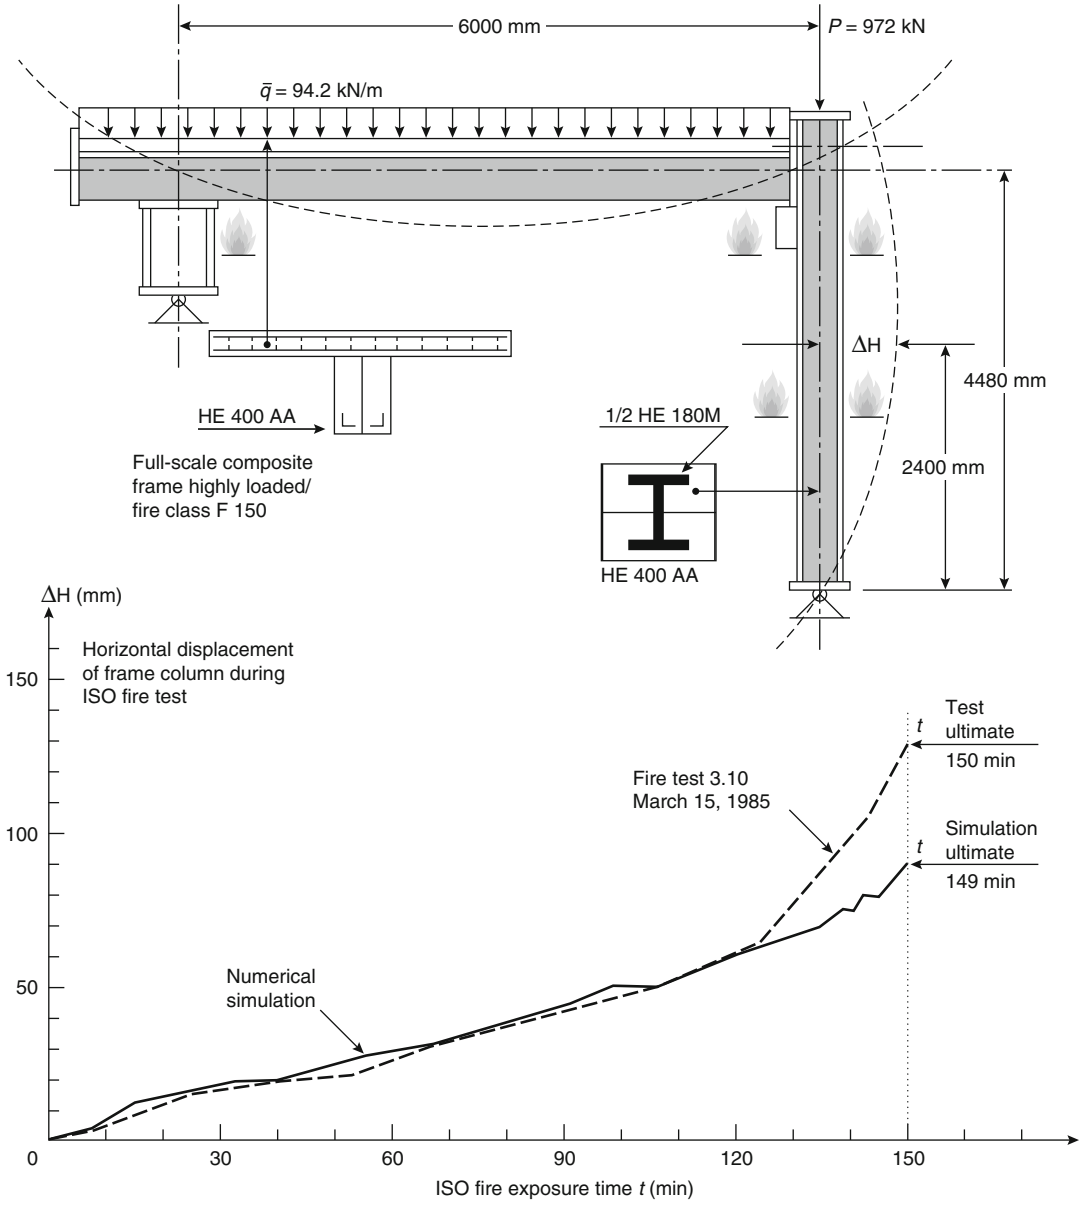

Fig. 53.30 Deformations measured and calculated by a numerical model for a composite frame [9]

Schleich et al. describe the application of CEFICOSS for a frame analysis [75, 76]. The frame consists of a single beam and column, where one end of the column is connected to an end of the beam. Reasonable agreement is indicated between predicted and measured results.

El-Rimavi et al. describe the application of another finite element model, NARR2, for the evaluation of a large building frame involving numerous beams and columns [77]. The large frame is divided into several subframes for computational ease. Good agreement is noted between predictions of deflections and force

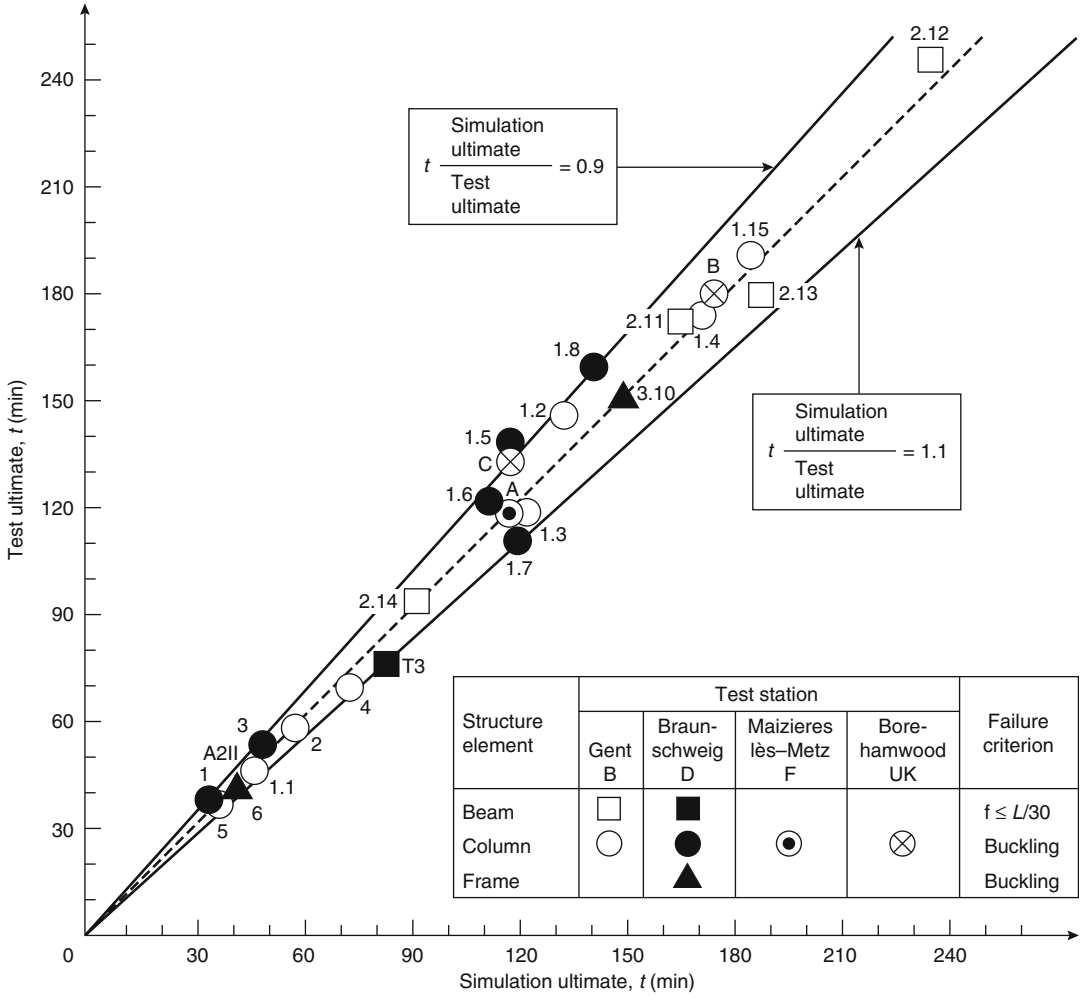

Fig. 53.31 Fire resistance times measured and calculated by a numerical model for columns, beams, or frames of any cross-section types (bare steel, protected steel, composite) [6]

resultants obtained involving simulations of the full building frame and subframes. Slightly greater failure temperatures were determined for semirigid connections as compared to rigid connections. More recently, applications of ABAQUS, SAFIR, and VULCAN to study frame behavior have been described in several references [74, 78, 79]. In contrast to the models reviewed by Sullivan et al., these models have the capability to consider nonlinear effects, large deformations, and torsion. Part of the challenge in conducting frame analyses is to model the response of a joint to fire exposure. This is a current area of research [63, 74].

Nomenclature

a	Characteristic dimension
A	Cross-section area of steel tube, steel column
A_s	Cross-section area of steel column
b	Characteristic dimension
b_f	Width of flange
c	Characteristic dimension
c_c	Specific heat of concrete
c_i	Specific heat of protection material
c_s	Specific heat of steel
C_1	Constant

C_2 Constant
d Outer diameter of steel pipe
d Depth of section
D Heated perimeter of steel section
E_0 Modulus of elasticity at ambient temperature
E_r Reduced modulus
E_t Tangent modulus
E_T Modulus of elasticity at temperature T
F Factor of safety
F_e Factor of safety, elastic design
F_p Factor of safety, plastic design
Fo Fourier number
h Thickness of protection material
H Thermal capacity of steel section at ambient temperature
I Second moment of cross sectional area
k Thermal conductivity of steel
k_c Thermal conductivity of concrete
k_i Thermal conductivity of protection material
K End condition factor
l Unsupported length of column
L Inside dimension of one side of square concrete box protection
L Span of beam
m Moisture content of concrete
M Flexural moment
N Ratio of thermal capacity of protection material to that of steel
P Perimeter of steel tube
P_{cr} Critical point load
P_s Service (applied) load
P_u Ultimate load
q_{cr} Critical distributed load
r Radius of gyration
R Fire resistance
R_0 Fire resistance with zero moisture content of concrete
t Wall thickness of steel pipe
t Time
t_w Width of web
Δt Time step
T Steel temperature
T_f Fire temperature
T_m Mean fire temperature
T_0 Ambient temperature
T_s Steel temperature
ΔT_s Change in steel temperature
V Correction factor
W Weight of steel section per unit length
Z_e Elastic section modulus
Z_p Plastic section modulus

Greek Letters

α Thermal diffusivity (when used with Fourier number)
α Heat transfer coefficient
α_c Convective heat transfer coefficient
α_r Radiative heat transfer coefficient
α_T Coefficient of thermal expansion at temperature T
β Ratio of distributed load causing maximum allowable deflection to distributed load inducing yielding
ε_f Fire emissivity
λ Slenderness ratio
θ Dimensionless temperature
ρ Density
ρ_i Density of insulation material
σ_{cr} Critical stress for buckling
σ_{y0} Yield strength at ambient temperature
σ_{yT} Yield strength at temperature T

Analytical Methods for Determining Fire Resistance of Concrete Members

54

Charles Fleischmann, Andy Buchanan, and Anthony Abu

Introduction

Concrete structures have a reputation for excellent behavior in fires. Many reinforced concrete buildings that have experienced severe fires have been repaired and put back into use. Concrete is by nature noncombustible and has a low thermal conductivity. Concrete tends to remain in place during a fire, protecting the reinforcing steel, with the cool inner core continuing to carry the load. Catastrophic failures of reinforced concrete structures in fires are rare, but some occasionally occur [1].

Analytical methods developed to predict the fire resistance of structural assemblies can be divided into two groups: (1) standard and (2) nonstandard fire exposure. For the case of the standard fire exposure, a large database exists from referenced standard tests. The analytical methods use empirically based correlations and minimum dimensions to determine fire resistance. For nonstandard fire exposure, the analysis is more complicated, requiring both heat transfer and structural analyses. Analytical methods are an alternative to conventional methods that require destructive testing of exemplar systems in accordance with standard testing procedures, for example, ASTM E119 or ISO 834.

Fire resistance calculations typically use the same acceptance criteria specified in standard test methods, that is, heat transmission and structural integrity. The analysis can be broadly divided into two parts: (1) heat transfer and (2) structural analysis. Heat transfer calculations are used to evaluate the unexposed surface temperature and the temperature distribution throughout the member, in order to evaluate material strength. The structural integrity analysis applies the strength theory [2] used to design reinforced concrete members. The reduced strength of the concrete and steel resulting from elevated temperature is taken into account by using experimental results for the compressive and yield strengths as a function of temperature. This procedure is known as the rational design method.

As the fire protection field advances into performance-based engineering, techniques like the rational design method are more likely to be used. In the rational design approach, a design time-temperature curve, based on the expected fire, is specified. The engineer then performs the heat transfer analysis to determine the temperature profile and unexposed surface temperature. Knowing the temperature distribution of the member, a structural analysis is conducted to determine the fire endurance.

This chapter presents an overview of the analytical methods for calculating the fire resistance of concrete structural members and provides a description of the mechanical properties for concrete and steel at elevated temperatures. A brief discussion of heat transfer for a concrete assembly is given, along with temperature

profiles from ASTM E119 test results. The structural calculations for simply supported and continuous members are explained. A simple example is shown to further demonstrate the basics of the design concept. Fire resistance for columns and walls is also presented. The methodology in this chapter is based largely on ACI216.1-07—*Code Requirements for Determining Fire resistance of Concrete and Masonry Construction Assemblies* [3], (ACI216) commonly used in North America.

Throughout Europe, the Eurocodes for structural design provide comprehensive chapters on fire design. For reinforced concrete, Eurocode 2: Design of concrete structures—Part 1–2: General rules—Structural fire design [4], (EN1992-1-2) gives minimum dimensions and minimum cover necessary to achieve fire resistance ratings for slabs, walls, tensile members, beams, and columns. It also provides information on thermal and mechanical properties of concrete at high temperatures, with recommended design methods. Other than using the given design solutions, Eurocode 2 allows for two overall types of design: "simplified" calculation methods and "advanced" calculation methods. The simplified calculation method is essentially the same as that described in this chapter. The advanced calculation methods include those that provide a more realistic analysis of concrete structures exposed to fire, based on fundamental physical behavior including high temperature effects. The advanced calculation methods are the only option for design of complex structures regardless of the type of fire exposure, because the interaction between different structural members is critical to the fire resistance. Design of composite steel-concrete slabs in fire conditions is given in: Eurocode 4: Design of Composite Steel and Concrete Structures, EN1994-1-2: General Rules—Structural Fire Design [5].

More comprehensive discussions of the rational design methods for calculating the fire resistance of concrete structural members can be found elsewhere [1–8]. For more detailed overview of the "State-of-Art" for fire design of concrete structures the reader is directed to bulletin 38 [9] and 46 [10] written by Task Group 4.3 of the *fib* (*fédération internationale du béton / The International Federation for Structural Concrete*).

Material Properties of Concrete and Steel

Most of the material properties for concrete and steel change significantly at elevated temperatures. In order to accurately predict the structural fire resistance of concrete members, these changes must be taken into account. Temperature-dependent values of strength and modulus of elasticity are presented in a graphical format to aid in the design process. Values have been taken from both ACI216 and EN1992-1-2. The thermophysical properties that are required for a heat transfer analysis, i.e., thermal conductivity, specific heat, and density are also functions of temperature. These values are not included in ACI216; therefore only the EN1992-1-2 values are given below.

Strength

The strength of the reinforcing steel changes significantly with temperature and must be taken into account in any structural calculation. Figure 54.1 shows the strength–temperature relationship for hot-rolled, cold-drawn, and high-strength alloy steels from both the ACI216 and EN1992-1-2. Yield strength versus temperature relationship is given for hot-rolled steel, used for reinforcing bars. Tensile strength versus temperature relationship is shown for the cold-drawn steel and high-strength alloy steel, used for prestressing bars, wire, or strands. The change from yield strength to tensile strength for the two steel types relates to the design parameters used for reinforced versus prestressed concrete assemblies.

Like steel, the strength of concrete is also diminished at elevated temperatures. Figure 54.2a–c show the strength–temperature relationship for carbonate, siliceous, and sand-lightweight aggregate concretes, respectively. The compressive strength is not only a function of temperature but is also affected by the applied load as shown in ACI216 values given in Fig. 54.2. In Fig. 54.2 the values labeled as (Stressed 0.4f'c) were obtained from specimens initially loaded to 40 % of their

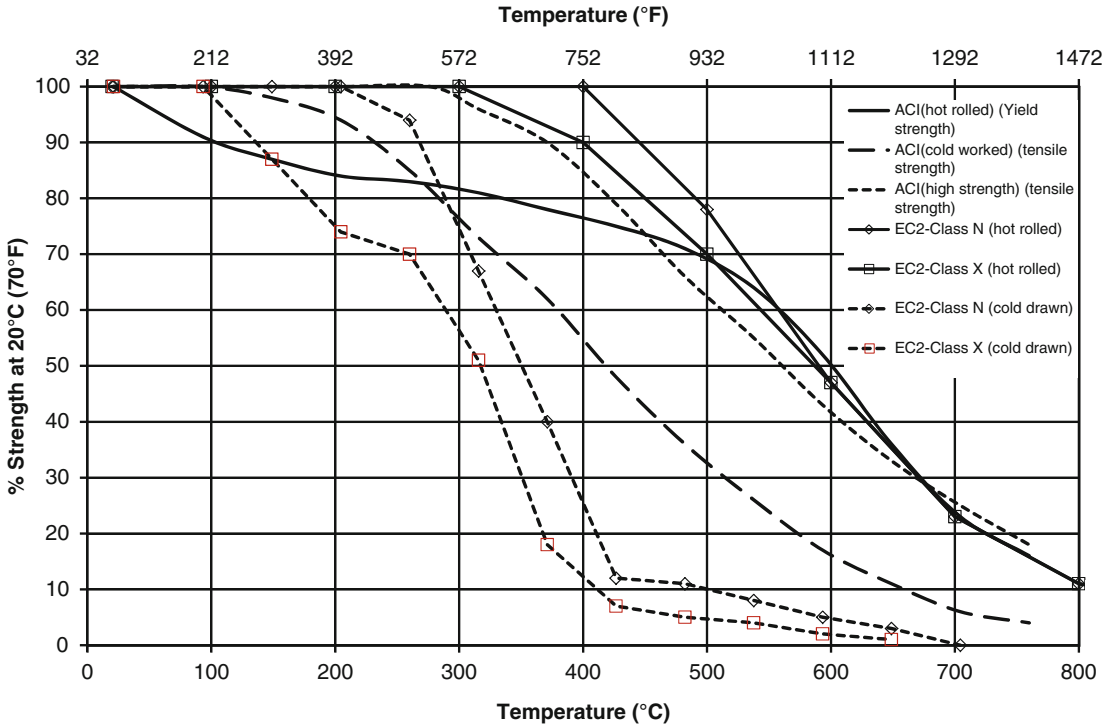

Fig. 54.1 Strength–temperature relationships for hot-rolled, cold-drawn, and high-strength alloy steels [3, 4]

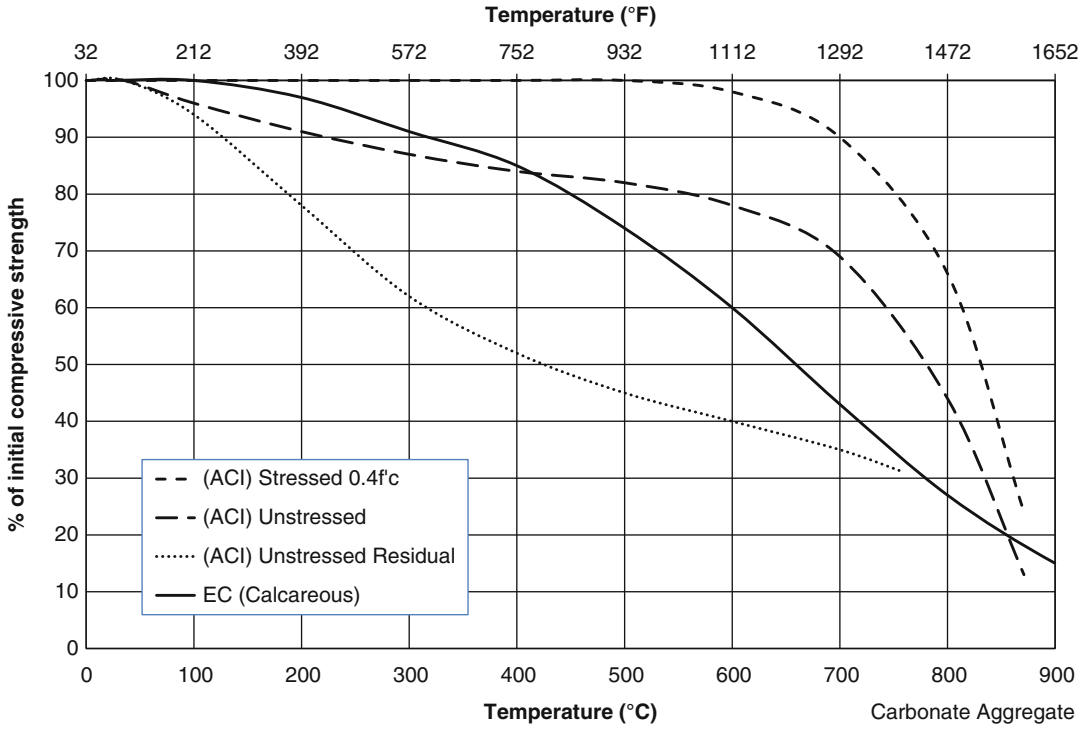
compressive strength during the heating process; when the desired temperature was reached the samples were then loaded to failure. The values labeled (Unstressed) were heated to the desired temperature and then loaded to failure. Those labeled (Unstressed Residual) were heated, allowed to cool back to ambient temperature and then loaded to failure. Figure 54.2b illustrates that for the Stressed 0.4f'c results the compressive strength of concrete remains relatively unchanged up to 500 °C (900 °F). Above 500 °C (900 °F), the compressive strength of the siliceous aggregate concrete starts to decrease rapidly and is considered ineffective at temperatures above 650 °C (1200 °F), where the compressive strength has been reduced by approximately 50 % of the value at normal temperatures. However, for (Stressed 0.4f'c) carbonate and lightweight aggregates, compressive strength remains relatively unchanged up to 650 °C (1200 °F) and is not considered to be ineffective until it reaches a temperature of 760 °C (1400 °F). The experimental method used may influence the reported compressive strength. Specimens heated without compressive loads and then loaded to failure while hot have lower compressive strengths than those heated while loaded [7]. The EN1992-1-2 results are closest to the ACI Unstressed results.

Modulus of Elasticity

The modulus of elasticity for steel decreases as the temperature increases, as shown in Fig. 54.3. Figure 54.4 shows the modulus of elasticity–temperature curve for three different concrete aggregates. In each case, the modulus of elasticity of concrete is greatly reduced at elevated temperatures. This large reduction of the elastic modulus is helpful in reducing induced thermal stresses in concrete members due to fire [7].

Thermophysical Properties

The thermophysical properties required for heat transfer calculations are also strong functions of



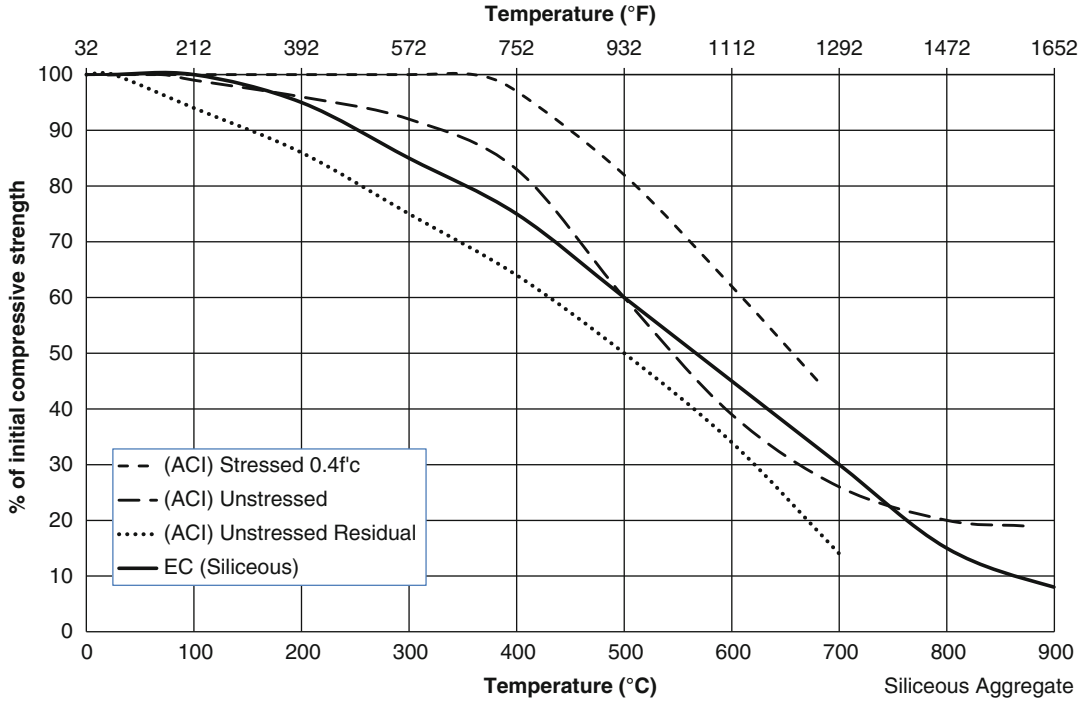


Fig. 54.2 (**a**) Strength–temperature relationship for carbonate aggregate concretes for different loading conditions [3, 4]. (**b**) Strength–temperature relationships for siliceous aggregate concretes for different loading conditions [3, 4]. (**c**) Strength–temperature relationships for sand-lightweight aggregate concretes for different loading conditions [3, 4]

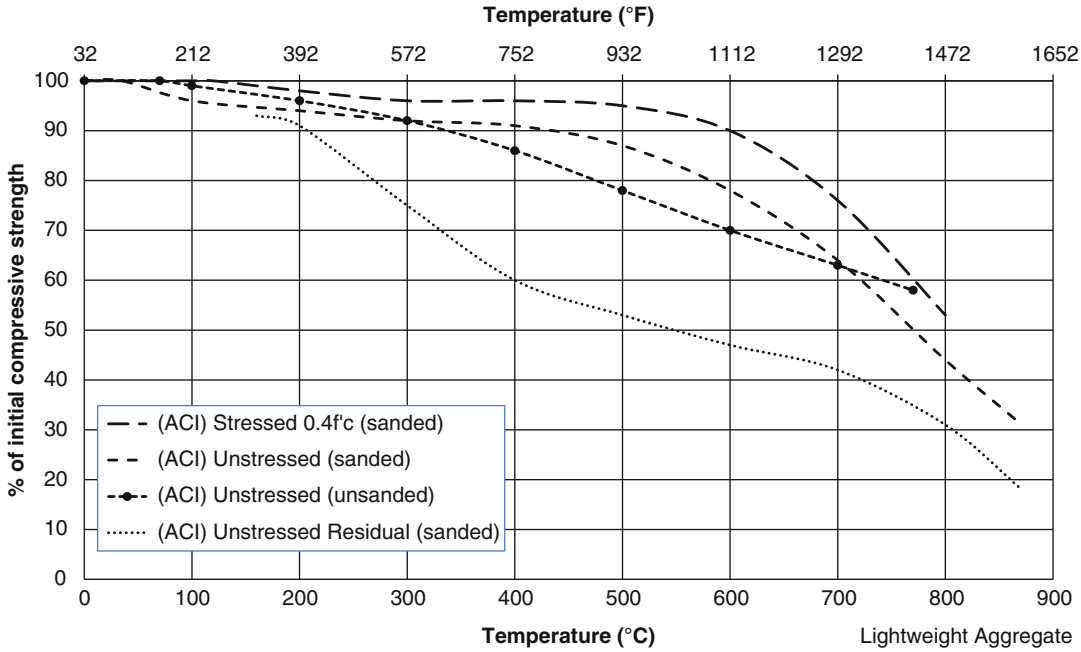

Fig. 54.2 (continued)

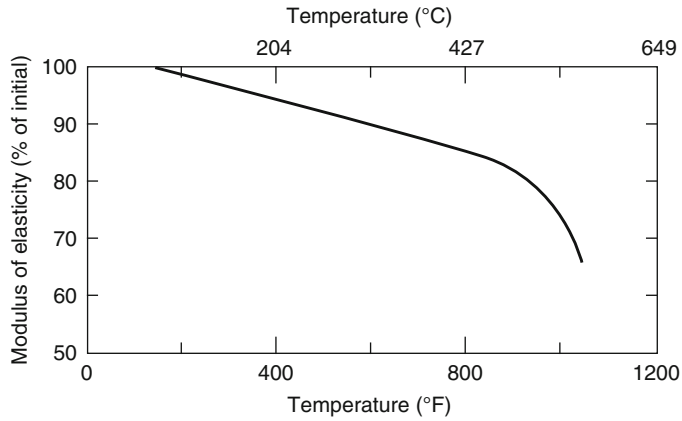

Fig. 54.3 Modulus of elasticity for hot-rolled steel at elevated temperatures [11]

temperature especially for concrete. The evaporation of water as well as changes within the cement and aggregate all play a role in the thermophysical properties.

Density. Figure 54.5 shows the percentage change in concrete density with temperature. From ambient to 1200 °C there is 12 % reduction in the density, with the greatest change occurring between 115 and 200 °C. The following relationship can be found in EC1992-1-2 [4].

$\rho(\theta) = \rho(20\ °C)$	For $20\ °C \leq \theta \leq 115\ °C$
$\rho(\theta) = \rho(20\ °C) \cdot (1-0.02(\theta-115)/85)$	For $115\ °C < \theta \leq 200\ °C$
$\rho(\theta) = \rho(20\ °C) \cdot (0.98-0.03(\theta-200)/200)$	For $200\ °C < \theta \leq 400\ °C$
$\rho(\theta) = \rho(20\ °C) \cdot (0.95-0.07(\theta-400)/800)$	For $400\ °C < \theta \leq 1200\ °C$

Specific Heat. The specific heat, $c_p(\theta)$, for both siliceous and carbonate aggregates is assumed to be identical for dry concrete with zero moisture content. Specific heat varies slightly with

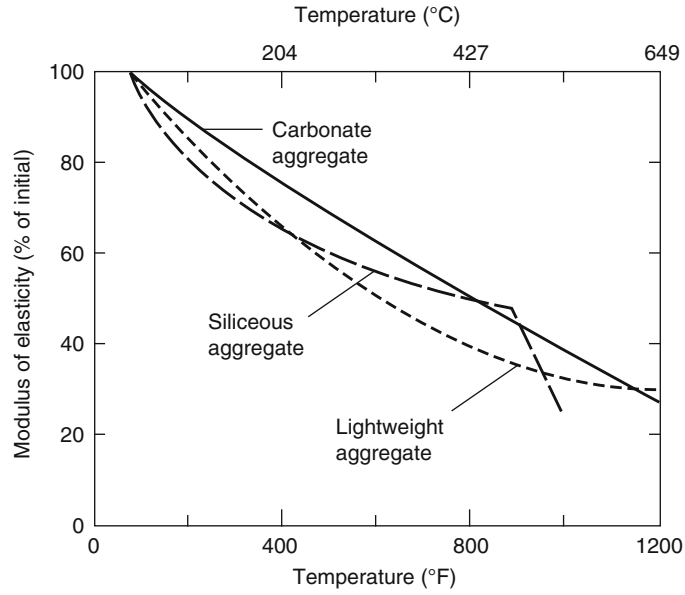

Fig. 54.4 Modulus of elasticity, at elevated temperatures, for carbonate, siliceous, and lightweight concretes [12]

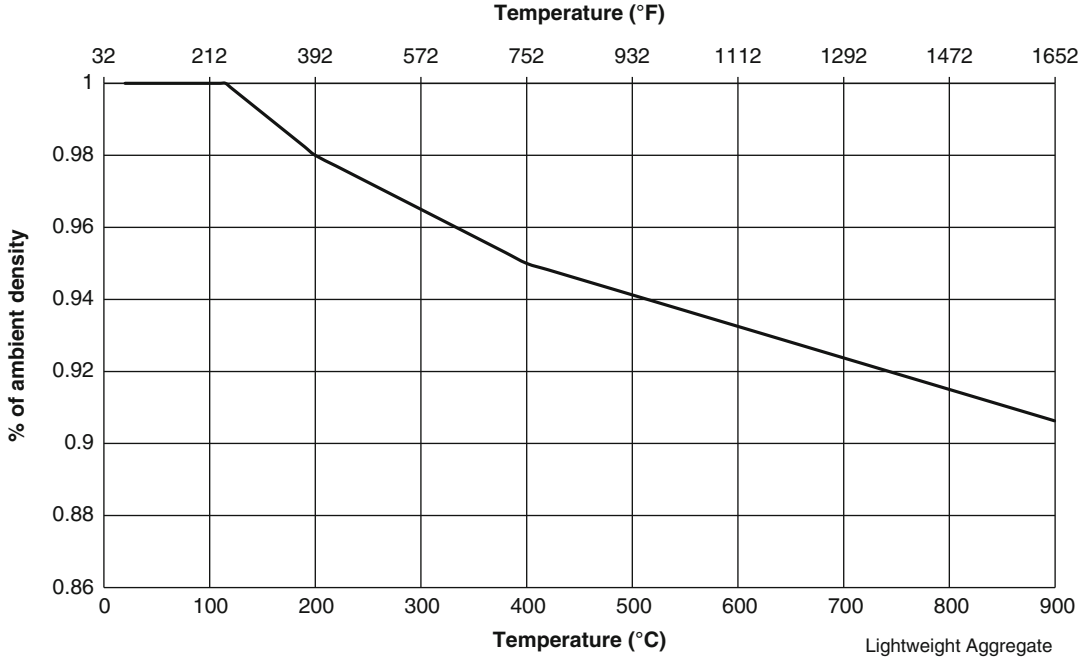

Fig. 54.5 Percentage change in concrete density as a function of temperature based on the ambient density [4]

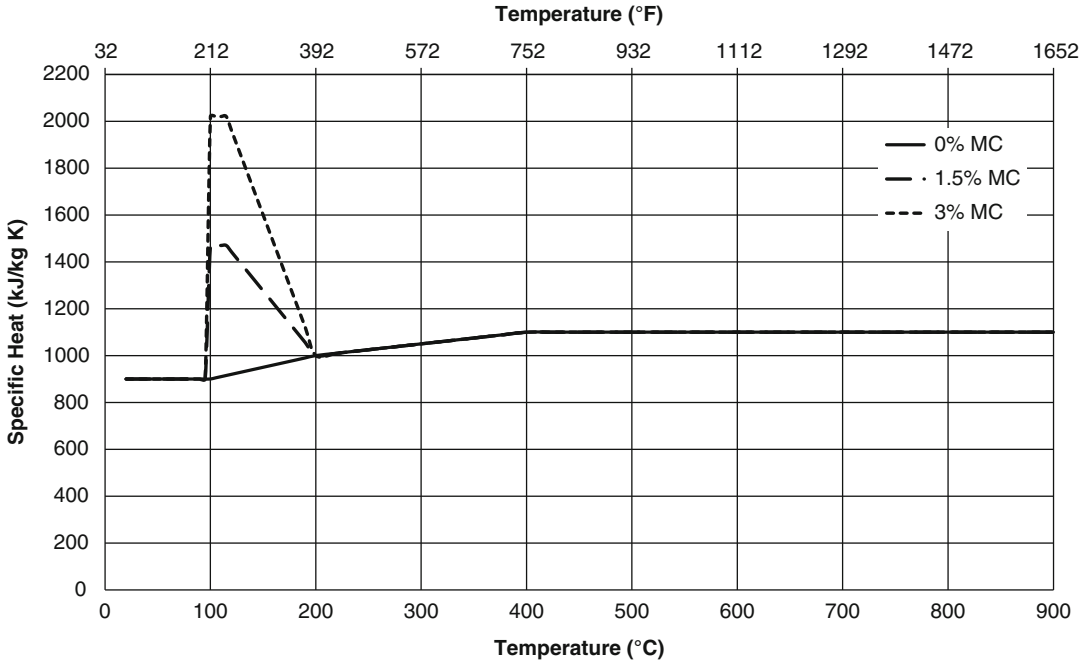

Fig. 54.6 Specific heat for siliceous and carbonate aggregate concrete as a function of temperature incorporating the moisture content [4]

temperature, ranging from 900 J/kg K at ambient to 1100 J/kg K above 400 °C. The following relationship can be found in EC1992-1-2 [4].

$c_p(\theta) = 900$ (J/kg K)	For 20 °C $\leq \theta \leq$ 100 °C
$c_p(\theta) = 900 + (\theta - 100)$ (J/kg K)	For 100 °C $< \theta \leq$ 200 °C
$c_p(\theta) = 1000 + (\theta - 200)/2$ (J/kg K)	For 200 °C $< \theta \leq$ 400 °C
$c_p(\theta) = 1100$ (J/kg K)	For 400 °C $< \theta \leq$ 1200 °C

However, when moisture is not explicitly included in the analysis and is to be included in the c_p value, the specific heat is modelled as a constant value (dependent on the moisture content) from 100 to 115 °C and a linear decline from 115 to 200 °C as shown in Fig. 54.6. The following values are given in EC1992-1-2 [4] for the constant c_p between 100 and 115 °C.

$c_{p(peak)} = 900$ J/kg K	For moisture content of 0 % of concrete weight
$c_{p(peak)} = 1470$ J/kg K	For moisture content of 1.5 % of concrete weight
$c_{p(peak)} = 2020$ J/kg K	For moisture content of 3 % of concrete weight

Conductivity. The conductivity of concrete can be modeled as a quadratic equation of temperature over the range of 20−1200 °C. Due to the variability in concrete a range is recommended for the conductivity in EC1992-1-2 [4]. Figure 54.7 shows the band between the upper and lower limits.

$$\text{Upper limit} \quad k = 2 - 0.2451\,(\theta/100) + 0.0107\,(\theta/100)^2\ \text{W/m K} \quad \text{for} \quad 20°\text{C} \leq \theta \leq 1200°\text{C}$$

$$\text{Lower limit} \quad k = 1.36 - 0136\,(\theta/100) + 0.0057\,(\theta/100)^2\ \text{W/m K} \quad \text{for} \quad 20°\text{C} \leq \theta \leq 1200°\text{C}$$

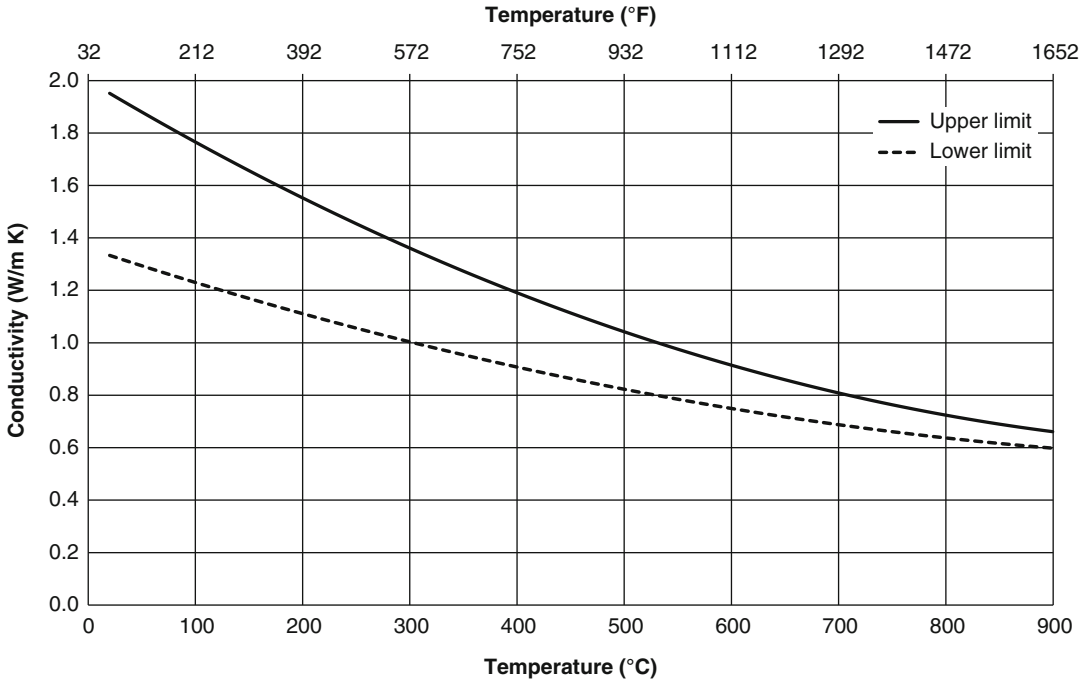

Fig. 54.7 Conductivity for siliceous and carbonate aggregate concrete as a function of temperature showing the upper and lower limit [4]

Heat Transmission

The temperature of the unexposed side of concrete floors, roofs, and walls is usually limited to prevent ignition of combustibles in contact with the unexposed surface. In ASTM E119 the criteria are 121 °C (250 °F) average and 163 °C (325 °F) single-point temperatures. These criteria often govern the fire resistance of the assembly. In addition to the unexposed surface temperature, the temperature distribution throughout the member is required in order to evaluate the material strengths in the structural calculations. Similar criteria are specified in the ISO 834.

Heat is mainly transferred through a solid concrete member by conduction. The temperature of the unexposed side of the slab is a function of the slab thickness and the type of aggregate used. The fire endurance versus slab thickness is presented in Fig. 54.8 for three types of concrete typically used in building construction. The data is based on actual fire tests of concrete slabs [7]. For the normal-weight concretes used in the fire tests, the maximum aggregate size was 20 mm (0.75 in.) and the air content was about 6 %. The maximum aggregate size for the structural lightweight concretes was slightly less than 20 mm (0.75 in.) and the air content was about 7 %. Although the slab thickness and type of aggregate are the main factors that affect heat transmission through the concrete, other factors do have some impact. These factors include moisture content, unit weight, air content, and maximum aggregate size. Within the usual range of values, water-cement ratio, strengths, and age have been shown to have insignificant effects on the heat transfer process [7].

Floor and roof slabs are often composites of materials, for example, a concrete base slab with overlays or undercoatings of either insulating materials or other types of concrete. Research has been conducted on two-course composite assemblies. An example of a composite slab

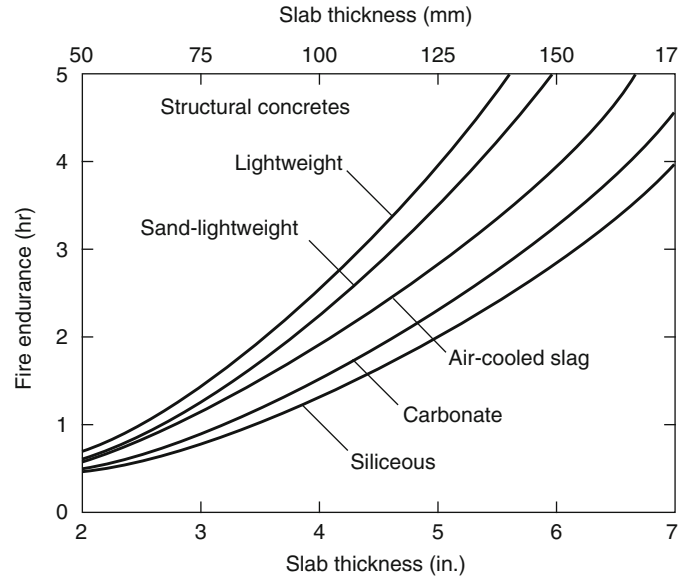

Fig. 54.8 Fire endurance of concrete slabs—effect of thickness and type of aggregate, based on heat transmission [7]

of normal and lightweight concrete is shown in Fig. 54.9. Similar plots for different composite assemblies can be found in Abrams and Gustaferro [13].

The temperature on the unexposed side is not the only temperature of concern. The temperature distribution within the member is used to determine the temperature of the reinforcing or prestressing steel. The temperature of the reinforcing bars is approximately equal to the temperature of the concrete at the level of the center of the bar; [7] that is, the presence of the steel is neglected in the heat transfer analysis. Thus, temperature distribution is primarily affected by the type of concrete, shape of the member, and exposure conditions. During fire tests, slabs and walls are typically heated on one side only; beams are heated from one, two, to three sides; and columns are heated on all four sides. Data on the temperature distribution within concrete members are available from results of fire tests. Figures 54.10, 54.11, and 54.12 show the temperatures within a slab exposed to the standard ASTM E119 time-temperature curve for carbonate, siliceous, and sand-lightweight aggregates, respectively. These data apply to any slab thickness, as long as the slab is at least 25 mm (1 in.) thicker than the point in question.

The temperature distribution within a 250 × 300 mm (10 × 12 in.) rectangular concrete beam exposed to the ASTM E119 standard time-temperature curve is illustrated in Fig. 54.13. Because the temperature distribution is a function of the beam size, it is not practical to present a complete set of figures. A procedure has been developed in which the temperature distribution can be constructed [7]. With the advent of fast, affordable computers, such empirical techniques are rapidly being replaced by complete numerical modeling of the temperature distribution. Computer models such as FIRES T3 [15], TASEF-2 [16], and SAFIR [17] can accurately predict the temperature distribution in various types of concrete members. These models are capable of handling one-, two-, or three-dimensional heat transfer, with time-dependent nonlinear boundary conditions, and temperature-dependent thermal properties. None of these models incorporate mass transfer or moisture migration, and thus require modification to the thermal properties to account for latent heat absorption of the water. All three programs use a finite-element technique to solve the energy

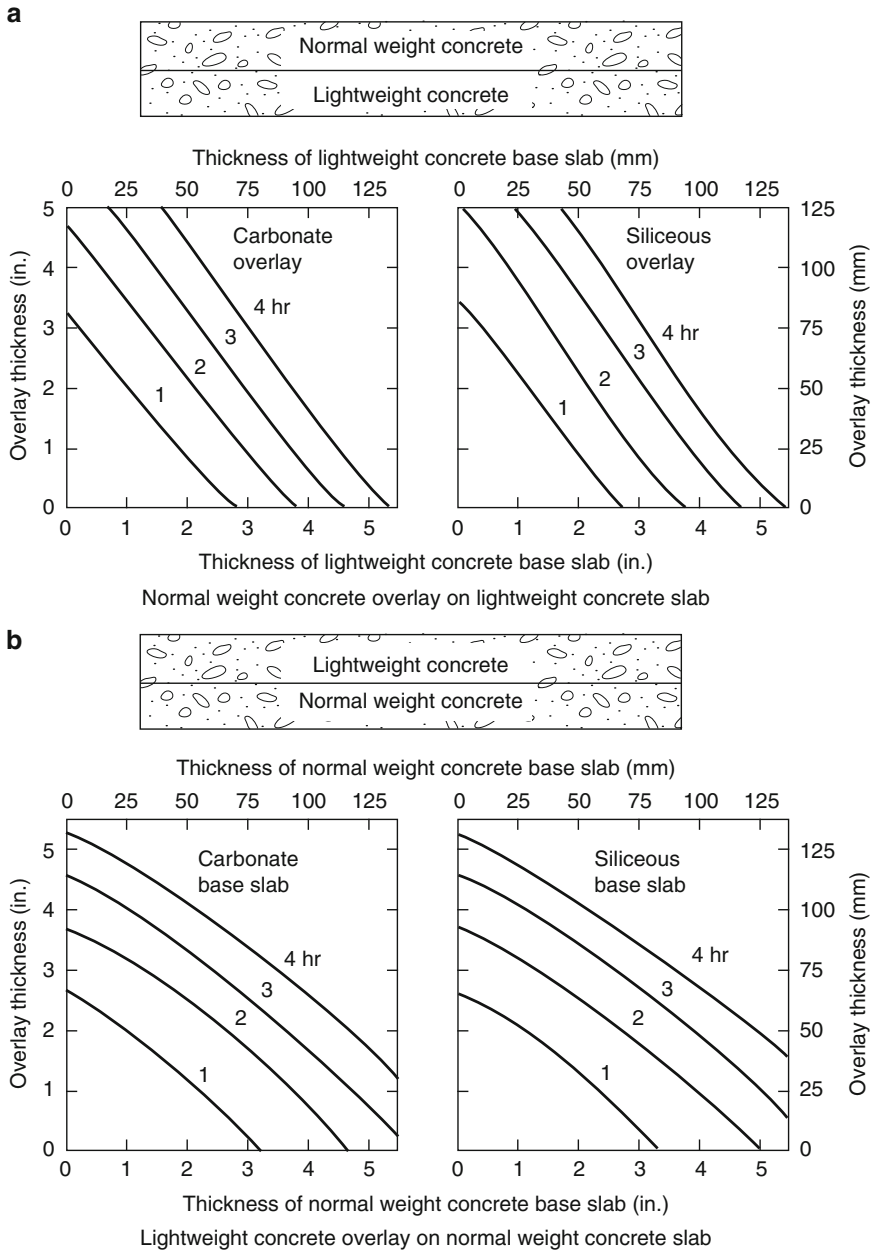

Fig. 54.9 Fire endurance of base slabs and overlays of normal weight or lightweight concretes, based on heat transmission [13]

equation and thus require a skilled operator. Recent improvements to SAFIR include element generation, significantly simplifying the input, and reducing time required. Although these models are not necessary for typical analysis assuming a standard time-temperature curve, with the increased emphasis on performance-based design and more realistic time-temperature curves, the use of such models is likely to increase in the future.

Simply Supported Slabs and Beams

Simply supported, unrestrained members are not typically cast in place. However, a discussion of simply supported members will make the discussion of continuous members easier to understand. A simply supported, reinforced concrete slab is illustrated in Fig. 54.14.

Note: The calculation methodology closely follows the procedures outlined in ACI216: 2007 [3]. A similar methodology is available in the Eurocode, EN1992-1-2 [4].

The slab is supported by a "frictionless" rollers and a "frictionless" pin, so that the slab is free to expand without resistance but should not deflect at the support. The load, w, is evenly distributed over the surface of the slab, and the reinforcing steel runs the entire length of the slab. Considering these conditions without a fire, the moment diagram for the slab is illustrated in Fig. 54.14b. The moment strength of the slab will be constant along the entire length:

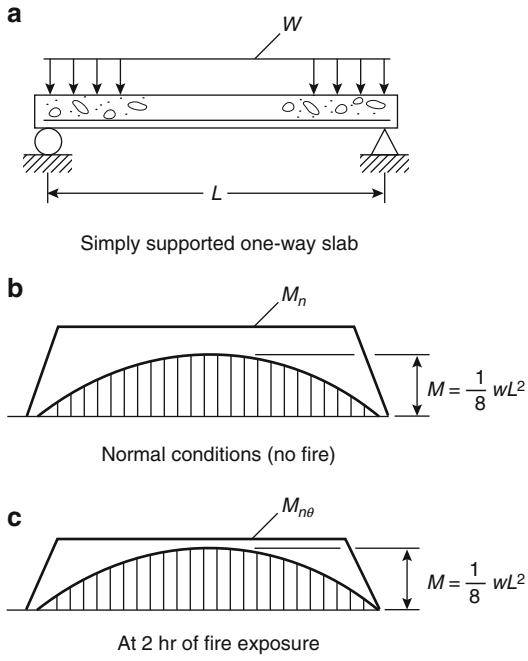

Fig. 54.14 Applied moments and reduced moment strength diagrams for simply supported one-way slab [7]

$$M_n = A_s f_y \left(d - \frac{a}{2}\right) \tag{54.1}$$

where

A_s = Area of the reinforcing steel

f_y = Yield stress of the reinforcing steel

d = Distance from the extreme compression fiber to the centroid of the reinforcing steel

a = Depth of the equivalent rectangular stress block [2]

$$a = \frac{A_s f_y}{0.85 f_c' b} \tag{54.2}$$

f_c' = Compressive strength of the concrete

b = Width of the beam or slab

During exposure to a fire, the temperature of the reinforcing steel will increase. As the temperature of the steel increases, the yield strength decreases (see Fig. 54.14c). This reduction in the steel strength causes a reduction of the moment strength of the slab [7]:

$$M_{n\theta} = A_s f_{y\theta} \left(d - \frac{a_\theta}{2}\right) \tag{54.3}$$

where θ denotes the effects of elevated temperature.

The reduced moment strength diagram is shown in Fig. 54.14c.

With a reduction in the yield stress, $f_{y\theta}$, there is a corresponding reduction in the size of the equivalent stress block, a_θ [7].

$$a_\theta = \frac{A_s f_{y\theta}}{0.85 f_c' b} \tag{54.4}$$

Typically, the temperature at the top of a slab remains relatively unchanged from normal conditions even after 2 h of fire exposure, since the concrete is a good insulating medium (see Figs. 54.10, 54.11, 54.12). Thus, the values for f_c' and d are not affected. However, if the temperatures in the compression zone exceed 480 °C (900 °F) for a siliceous aggregate or 650 °C (1200 °F) for a carbonate aggregate, the concrete compressive strength, f_c', should be reduced (see Fig. 54.2).

As previously noted, the compressive strength of concrete is reduced significantly at a critical temperature, selected here as 650 °C (1200 °F) for a siliceous aggregate or 760 °C (1400 °F) for a carbonate aggregate. To account for this substantial reduction in strength, regions of concrete in the compression zone at temperatures above the critical temperature are neglected in the design process. As a result, the depth and/or width of the compression zone are reduced by subtracting the area of the concrete, which is heated in excess of the critical temperature.

For a simply supported slab it is unlikely that the compression zone would be heated to above the critical temperature without the steel failing first, but it should be noted that, if the section of concrete is reduced, the value of d in Equation 54.3 must be adjusted accordingly.

Flexural failure occurs when the moment strength is reduced to the applied service load moment, M, at the center of the span [7]

$$M = \frac{wL^2}{8} \tag{54.5}$$

where
M = Applied service load moment
L = Length of the span
w = Applied live load plus dead load, with "factor of safety" = 1.0

The factor of safety used in fire endurance calculations is a decision for the authority having jurisdiction. In this section, the fire safety factor has been set equal to 1.0. Load combinations for structural fire design should give lower design loads than those for cold conditions. Guidance on selecting the appropriate safety factors can be found in regulatory documents such as ASCE 7-05 [18]. In North America, guidance is given by ASCE-07 with the recommended load combination for fire conditions being 1.2 dead load + 0.5 live load. Similar load combinations are specified in many other countries.

As indicated in Equation 54.3, the structural fire endurance of a simply supported one-way slab or beam is a function of the load intensity, strength–temperature characteristics of the reinforcing steel, and the depth of protection given to the reinforcement by the concrete cover. There is no benefit of continuity or restraint of thermal expansion with a simply supported slab; the total slab depth, based on heat transmission, h_t, required to obtain the desired fire rating is probably as small or smaller than the total slab thickness, h_s, required for gravity loads [7]. Therefore, there is no advantage of doing a structural fire endurance analysis for unrestrained, simply supported structural members [7].

Continuous Unrestrained Flexural Members

Continuous unrestrained members have a considerably longer fire endurance than simply supported members because of their ability to redistribute the applied moments. Figure 54.15a shows an interior span of a continuous unrestrained slab. The applied moment diagram for a normal condition, with no fire, is shown in Fig. 54.15b. The maximum positive moment occurs near the center of the span, and the maximum negative moments are located over the supports.

When the slab is exposed to fire conditions from below, the moments will be redistributed within the slab. This redistribution may be sufficient to cause the negative moment reinforcement to yield. This yielding generally occurs within the first half hour of the fire, based on observation made during standard fire tests [7]. Figure 54.15c shows the redistribution of moments after 2 h of fire exposure (2 h was selected at random). The American Concrete Institute (ACI) warns that increasing the negative reinforcement will increase the attracted negative moment, possibly leading to a compressive failure. It is important that flexural tension governs the design of concrete members. Thus, to avoid compressive failure in the negative moment region, the negative reinforcement should be small enough so that [6]:

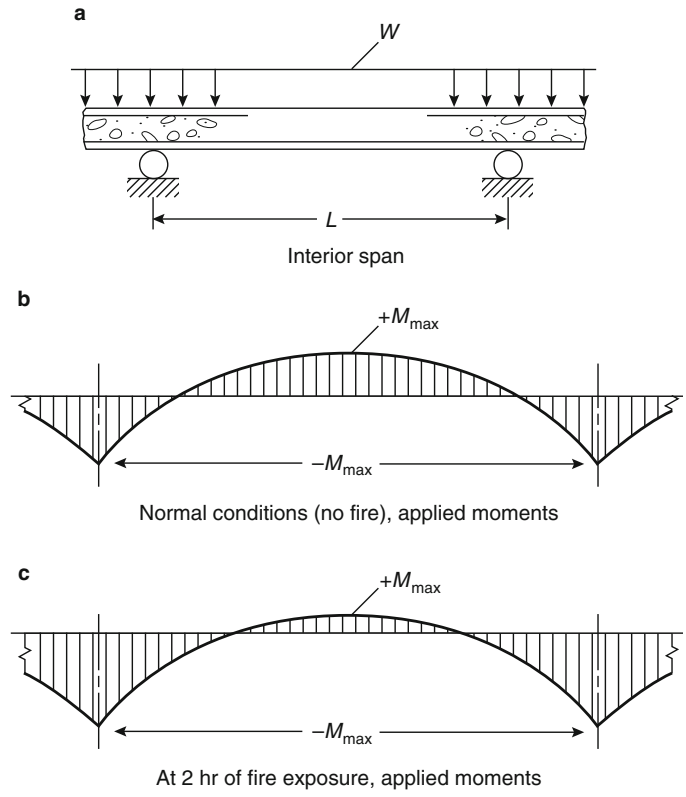

Fig. 54.15 Moment redistribution in interior span of continuous unrestrained one-way slab due to fire exposure [7]

$$\frac{A_s f_{y\theta}}{b_\theta d_\theta f'_{c\theta}} < 0.30 \tag{54.6}$$

Flexural failure of continuous members occurs when three hinges are formed within a span. One of the hinges will form near the midspan and the other two at the adjacent supports. A hinge is formed at the point where the applied moment is equal to the flexural strength at that point.

The flexural strength at any point can be calculated using Equation 54.3 for simply supported members. Figure 54.16 shows the moment diagram for a one-way span with unequal end moments, that is, when the spans are of unequal lengths. This diagram represents the general case and can be used for other conditions, that is, end spans and slabs with equal spans. The member fails when the sum of the flexural strengths is less than the applied moment, $wL^2/8$. The negative moments are calculated at the supports, and the positive flexural strength is calculated at the center of the span. The negative flexural strength is then used in the following equation for the minimum positive flexural strength [7]:

$$\text{Minimum positive flexural strength required} \quad M_{n\theta} = \frac{M^-_{n\theta_1} - M^-_{n\theta_2}}{2wL^2} - \frac{M_{n\theta_1}}{2} - \frac{M_{n\theta_2}}{2} + \frac{wL^2}{8} \tag{54.7}$$

If the minimum positive flexural strength required is less than the positive flexural strength, the member has the calculated fire endurance. The location of the maximum positive moment, X_1, is calculated from

$$X_1 = \frac{L}{2} + \frac{\left(M^-_{n\theta_1} - M^-_{n\theta_2}\right)}{wL} \tag{54.8}$$

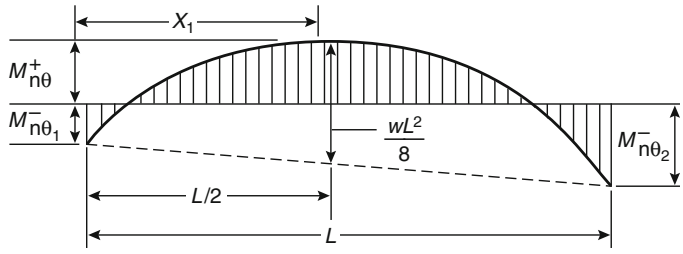

Fig. 54.16 Redistributed applied moment diagram at structural endpoint for span of a uniformly loaded continuous one-way slab or beam with unequal end moments [7]

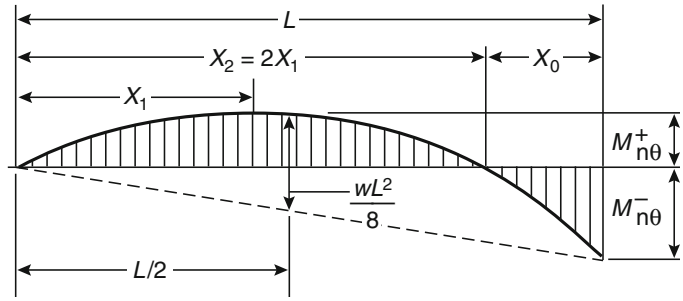

Fig. 54.17 Redistributed applied moment diagram at structural endpoint for end span of a continuous one-way slab or beam [7]

End Span

Equations 54.7 and 54.8 can be modified and used for the end span of a continuous member (Fig. 54.17). For the end span, $M_n = 0$, leaving

$$\text{Minimum required } M^+_{n\theta} = \frac{\left(M^-_{n\theta}\right)^2}{2wL^2} - \frac{M^-_{n\theta}}{2} + \frac{wL^2}{8} \tag{54.9}$$

$$X_1 = \frac{L}{2} - \frac{M^-_{n\theta}}{wL} \tag{54.10}$$

Interior Span with Equal End Moments

Equations 54.7 and 54.8 can also be modified for spans with equal end moments, as indicated in Fig. 54.18. For this case, $M^-_{n\theta_1} = M^-_{n\theta_2}$, changing Equation 54.7 to

$$\text{Minimum required } M^+_{n\theta} = \frac{wL^2}{8} - M^-_{n\theta} \tag{54.11}$$

Equation 54.8 becomes

$$X_1 = \frac{L}{2} \tag{54.12}$$

The location of the points of inflection, X_0, is dependent on the magnitude of the negative flexural strengths and can be calculated using

$$X_0 = \frac{L}{2} - \sqrt{\frac{2M^+_{n\theta}}{w}} \tag{54.13}$$

The negative moment reinforcement must be extended a sufficient distance beyond the point of inflection to allow the bar strength to become fully developed. Design criteria for the development length are outlined in the ACI *Building Code Requirements for Reinforced Concrete* [2]. It is further recommended that at least 20 % of the maximum negative moment reinforcement in the span extends throughout the entire length of the span.

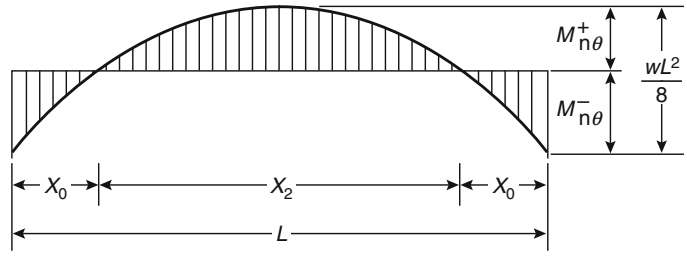

Fig. 54.18 Redistributed applied moment diagram at structural endpoint for symmetrical interior span of a uniformly loaded continuous one-way slab or beam [7]

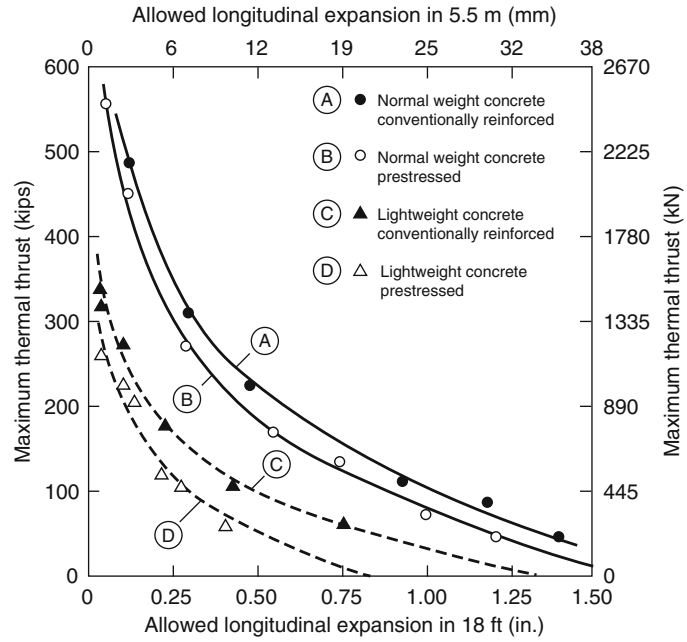

Fig. 54.19 Maximum thrust for allowed expansion of reference specimens [21]

Fire Endurance of Concrete Structural Members Restrained Against Thermal Expansion

When a fire occurs beneath an interior portion of a floor or roof slab, the heated portion of the slab tends to expand. As this portion of the slab expands, the surrounding cooler portions resist the expansion and exert a resistive force on the heated portion of the slab. This resistive force is referred to as the *thermal thrust force*.

Most U.S. fire tests of floor slabs are conducted with the specimen mounted within a restraining frame which restricts the thermal expansion [19]. The amount of restraining force provided by the restraining frame varies from one laboratory to another, based on factors such as frame design, specimen design, and specimen tightness.

Prior to 1960, no research had been conducted to measure the magnitude of the thermal thrust force. In 1960, the Portland Cement Association (PCA) began operation of its floor furnace [20]. This furnace allowed for both variable and monitored restraint during the fire test. Restraining the slab against expansion greatly affects the thermal thrust, as indicated in Fig. 54.19. Notice that with no expansion allowed, the thermal thrust force would be very high, which would cause compression failure of the concrete. However, with only a slight increase in the allowed expansion, there is a significant decrease in the thermal thrust force.

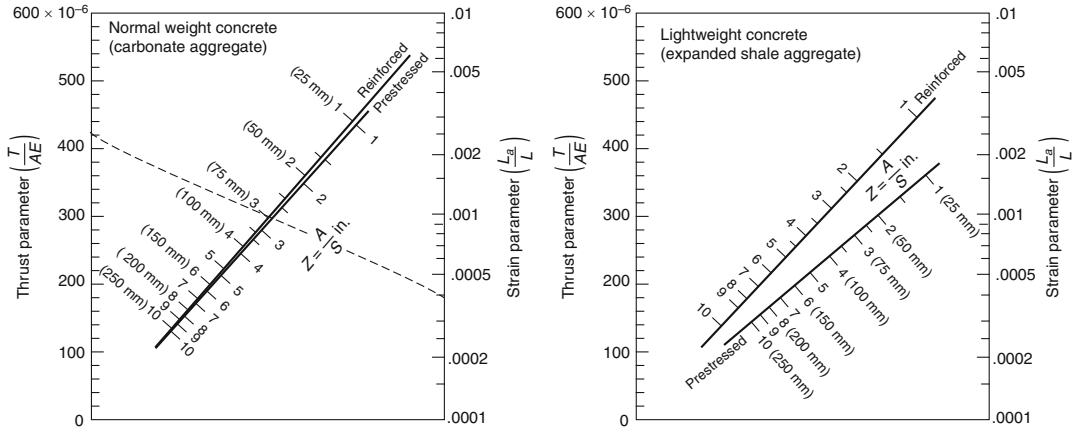

Fig. 54.20 Nomographs relating thrust parameter, strain parameter, and ratio of cross-sectional area to heated perimeter [21]

It should also be noted that the thermal thrust force developed in lightweight concrete is considerably less than is developed within normal-weight concrete. This condition is believed to be due to the lower modulus of elasticity and the lower coefficient of expansion of the lightweight concrete [7].

As a result of the fire research done at PCA, the thermal thrust force was found to vary with the initial modulus of elasticity and the heated perimeter [22]. The heated perimeter, S, is defined as that portion of the perimeter of a section of the specimen, normal to the direction of the thermal thrust, that is exposed to fire. Having assembled a large database of "reference specimens," the thermal thrust from these specimens can be used to predict the thermal thrust within a concrete member [21]:

$$\frac{T_1}{A_1 E_1} = \frac{T_0}{A_0 E_0} \frac{Z_0}{Z_1} \tag{54.14}$$

where

$Z_0 = A_0/S_0$

$Z_1 = A_1/S_1$

S_0 = Heated perimeter of the reference member

S_1 = Heated perimeter of the member in question

T_1 = Maximum thermal thrust of the member in question

T_0 = Maximum thermal thrust of the reference member

A_0 = Cross-sectional area normal to the direction of thermal thrust of the reference member

A_1 = Cross-sectional area normal to the direction of thermal thrust of the member in question

E_1 = Modulus of elasticity of the member in question

E_0 = Modulus of elasticity of the reference member

The parameter $T/(AE)$ is dimensionless, thus the units used for T, A, and E must be consistent.

Nomographs, presented in Fig. 54.20, are used to solve Equation 54.14.

For any given partially restrained expansion of a concrete member exposed to fire, there is a compatible thermal thrust developed in the fire-exposed portion. The effect of the thermal thrust on the structural behavior of a reinforced concrete slab is the same as that of a prestressing force along the line of action of the thrust. In structural fire endurance calculations, the flexural strength is the primary interest, for which case the thermal thrust can be considered a "fictitious reinforcement" along the line of an action of the thrust [23].

The moment due to the thermal thrust, referred to as the thrust moment, is equal to the thrust force multiplied by the distance between the line of action of the thermal thrust and the centroid of the compression block [21]

$$M_T = T\left(d_1 - \Delta - \frac{a_\theta^+}{2}\right) \tag{54.15}$$

where

$$a_\theta{}^+ = \frac{T + A_S^+ f_{y_0}^+}{0.85 f_{c\theta}^{'} b_\theta} \tag{54.16}$$

T = Magnitude of the thermal thrust
d_t = Distance from extreme compression fiber to the line of action of the thermal thrust, T
Δ = Deflection of the slab at the point in question
M_T = Thrust moment strength

The line of action of the thermal thrust must act below the resultant of the equivalent rectangular stress block in order to contribute to the fire endurance of the slab. Results from fire tests have shown that the line of action for the thermal thrust is near the bottom of the member throughout the fire test in most cases, particularly when the thrust is small [21]. Although the line of action acts near the bottom, the actual position changes during the fire test. The exact location of the line of action depends on the shape of the member, type of concrete, amount of reinforcement, stiffness of the restraining frame, and the amount of expansion permitted. Table 54.1 is used to locate the line of action of the thermal thrust for floor systems developing a minimal restraint to thermal expansion. The guidelines presented in Table 54.1 are based on results from standard fire tests [21].

In order to calculate the thrust moment, the deflection must be estimated. Since the deflections at the supports are assumed to be zero, the only other deflection of interest is at the midspan. The midspan deflection can be approximated using the following equation derived from the deflection equation for simply supported members [21]

$$\Delta_1 = \frac{L_1^2 \Delta_0}{3500 y_{b1}} \tag{54.17}$$

where
Δ_1 = Deflection for the member (in.)
Δ_0 = Deflection for the reference member (in.) (Fig. 54.21)
L_1 = Length of the span of the member (in.)
y_{b1} = Distance from the centroidal axis to the extreme fiber (in.)

Table 54.1 Location of thermal thrust line [6]

Type of construction	Fire exposure (h)	Location of thrust line at supports[a]
Solid slab	2	25 mm (1 in.)
	3	32 mm (1.25 in.)
	4	38 mm (1.5 in.)
Slab-and-joist	≤2	0.1 h
	2–4	0.15 h

[a]Distance above bottom of member where h = overall depth of the joist and slab

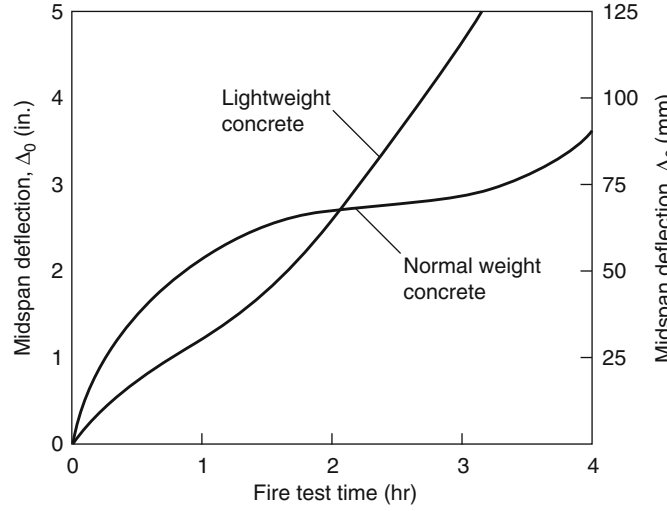

Fig. 54.21 Idealized midspan deflection, Δ_0, of reference specimens with minimal restraint [7]

In SI units, Equation 54.17 becomes

$$\Delta_1 = \frac{L_1 \Delta_0}{88{,}900 y_{b1}}$$

where Δ, L, and y_{b1} are all in mm.

Equation 54.17 is for members with minimal restraint to thermal expansion. Another equation should be used when the thrust is greater than minimal [7].

In order to summarize and illustrate how to apply this information to calculate the structural fire endurance for reinforced concrete members, a step-by-step procedure is presented. This procedure was taken from the Concrete Reinforcing Steel Institute (CRSI), *Reinforced Concrete Fire Resistance* (Table 54.2) [7].

Table 54.2 Step-by-step procedure—structural analysis for fire endurance

Step no.	Description
1	From the building code governing the project (model, municipal, state, etc.), look up the required fire ratings
2	Determine the total depths of slabs, h_t, based on heat transmission to provide the required fire ratings
3	Compare h_t vs. h_s, total slab thickness
4	If $h_t < h_s$, no further fire endurance considerations are necessary
4a	If the governing building code permits a reduced fire rating for heat transmission as long as the required structural fire rating is provided, then proceed to Step 5
5	Only if $h_t > h_s$ (or as in step 4a), compute the structural fire endurance, in hours, based on continuity and/or restraint to thermal expansion
Structural fire endurance for simply supported or continuous slabs with no axial restraint	
6	*Solid slabs*. Compute the reduced nominal positive and negative flexural strengths, $M^+_{n\theta}$ and $M^-_{n\theta}$, available at the required fire rating, for example, 3 h
7	*Interior spans*. If the absolute sum of available nominal flexural strengths is equal to or greater than the applied moment, that is, if $M^+_{n\theta} + M^-_{n\theta} \geq wL^2/8$ the fire endurance is equal to or greater than the required fire rating
7a	*Exterior spans*. Using either the reduced nominal negative or positive flexural strength available at the specified fire endurance, compute the minimum required nominal flexural strength
8	If the nominal flexural strength available is equal to or greater than the minimum required nominal flexural strength, the structural fire endurance is adequate—go to Step 9
8a	If the nominal flexural strength available is less than the required nominal flexural strength, the structural fire endurance based on continuity only is not sufficient—go to Step 10
9	If continuity only is considered in the structural fire endurance calculations, and restraint to thermal expansion is neglected, check the lengths of the top reinforcing bars to make sure the bars are long enough to develop the required nominal negative flexural strength
Note: The procedure for analyzing continuous beams and joist systems is the same as for the solid slab above, except that isothermal diagrams would be required for determining the available nominal flexural strengths	
Structural fire endurance based on restraint to thermal expansion	
10	Estimate the deflection Δ_1, of the heated slab, assuming minimal restraint occurs
11	Locate the line of action of the thermal thrust force at the supports
12	Compute the moment, M_T, that the thermal thrust force has to develop to provide the required additional nominal positive flexural
	Strength for the specified fire endurance
	$M_T = \left(\text{Min. reqd } M^+_{n\theta} - \text{Available } M^-_{n\theta}\right)$
13	Compute the thermal thrust, T_1, required to produce M_T using Equation 54.15
14	Compute the thrust parameter, T_1/A_1E_1
15	Compute the value of $z = A_1/s$
16	With T_1/A_1E_1 and z, determine the strain parameter
17	Compute the expansion ΔL, by multiplying the strain parameter by the heated length, L_h, of the member
18	Determine if the restraining elements, that is, spandrel or effective edge beams, columns, walls, and so forth, can withstand the thermal thrust, T_1, with a displacement no greater than the expansion, ΔL

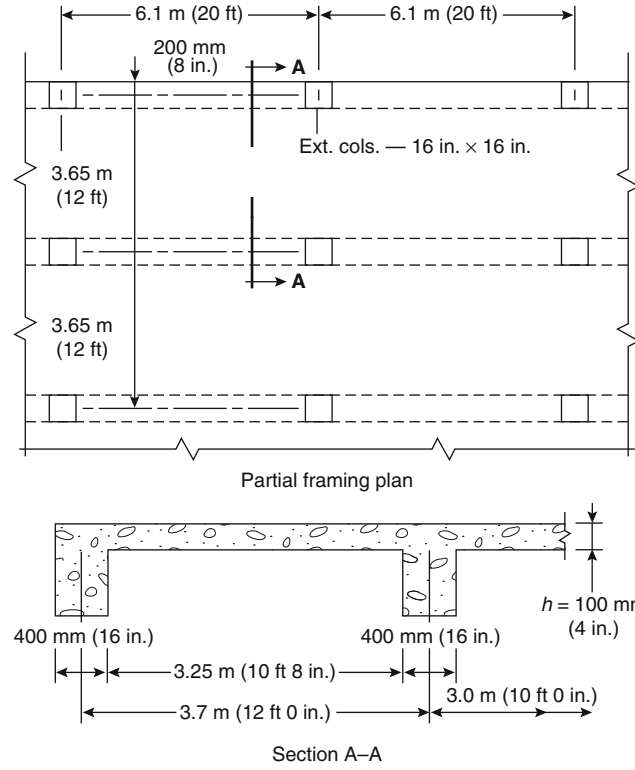

Fig. 54.22 One-way continuous slab, supported on beams [7]

Example of Continuous One-Way Span

The continuous one-way span example has been included to illustrate the step-by-step procedure for structural analysis for fire endurance that is used. The example problem is for a one-way continuous slab with no thermal restraint assumed. The slab is found to have the desired fire endurance, but the development length of the steel bars required for the negative moment strength is significantly longer than is required for standard gravity loading. The development length is then recalculated assuming minimal thermal restraint.

Given. A one-way, multispan continuous slab supported on beams as shown in Fig. 54.22. The slab is 100 mm (4 in.) thick with 3.7 m (12-ft) beam spacing. The concrete for the slab is made from siliceous aggregate with a compressive strength of 20.7 MPa (3000 psi). The slab is subjected to a 3.8 kPa (80 psf) superimposed live load and a 0.25 kPa (5 psf) dead load.

The reinforcement consists of No. 4 bars that meet the requirements of ASTM for A615 Grade 60 (415 MPa). Reinforcing bars are placed in accordance with the 1984 *CRSI Handbook* [24].

Problem: Determine if the slab has a 2 h fire endurance.

Step 1: Determine the required fire rating: 2 h, as stated in the problem.

Step 2: Determine the total depth of the slab, h_t, based on heat transmission: From Fig. 54.8, $h_t = 125$ mm (5 in.).

Step 3: Compare h_t versus h_s:$h_t = 125$ mm (5 in.) > 100 mm (4 in.) $= h_s$.

Step 4: In this example, the authority having jurisdiction has waived the requirements for heat transmission, as long as the required structural fire endurance is provided.

Step 5: Because 125 mm (5 in.) is greater than 100 mm (4 in.), the fire endurance for the end span must be computed based on continuity only.

Structural Fire Endurance Based on Continuity Only

Step 6: Compute the reduced positive and negative moment strengths, $M^{+}_{n\theta}$ and $M^{-}_{n\theta}$, respectively, available after 2 h.

Step 6a: $M^{+}_{n\theta}$ available at 2 h.

U^{+} for bottom bars, $U^{+} = 19 + 6 = 25\,\text{mm}$ (1.0 in.) (Fig. 54.23).

At 2 h, $U^{+} = 25$ mm (1.0 in.), $\theta_s{}^{+} = 360$ °C (1170 °F) (see Fig. 54.17).

$f^{+}_{y\theta} = 0.42(414) = 174\,\text{M pa}\,(25.2\,\text{ksi})$ (see Fig. 54.1).

Reinforcing is 12.5-mm bars at 215 mm (#4 bars at 9 in.)

$$A^{+}_{s} = 570\,\text{mm}^2/\text{m}\left(0.27\,\text{in.}^2/\text{ft}\right)$$

A^{+}_{s} is calculated from the rebar spacing requirements.

$$a^{+}_{\theta} = \frac{A^{+}_{s} f^{+}_{y\theta}}{0.85 f^{'}_{c} b} = \frac{570(174)}{0.85(20.7)(1000)}$$

$$= 5.6\,\text{mm}(0.22\,\text{in})\,[\text{from Equation 54.4}]$$

$$M_{n\theta}{}^{+} = A^{+}_{s} f^{+}_{y\theta}\left(d + \frac{a_{\theta}{}^{+}}{2}\right) = \frac{570(174)(75 - 5.6/2)}{1 \times 10^6}$$

$$= M^{+}_{n\theta} = 7.3\,\text{kN} \cdot \text{m/m}\,(1.64\,\text{ft} \cdot \text{kips/ft})$$

[from Equation 54.3]

Step 6b: $M^{+}_{n\theta}$ available at 2 h

The bottom 25 mm (1 in.) has been neglected, because the concrete temperature is above 650 °C (1200 °F) with a significantly reduced $f^{'}_{c}$.

Top bars, $U^{-} = 100 - (19 + 6) = 75\,\text{mm}\,(3.0\,\text{in.})$ (Fig. 54.24).

At 2 h, $U^{-} = 75\,\text{mm}\,(3.0\,\text{in.}), \theta = 270°\text{C}$ (520 °F). (see Fig. 54.11).

$f^{-}_{y\theta} = 0.83\,(414) = 344\,\text{MPa}\,(49.8\,\text{ksi})$ (see Fig. 54.1).

The $f^{-}_{y\theta}$ stress block, a^{-}_{θ}, is estimated to be about 16 mm (0.625 in.) with a temperature ranging from 650 to 480 °C (1200–900 °F).

Temperature values are estimated from Fig. 54.11. The average temperature is approximately 565 °C (1050 °F). In this example the stressed $f_{c\theta}{}^{'}$ curve was accepted by the AHJ as the appropriate strength for this design.

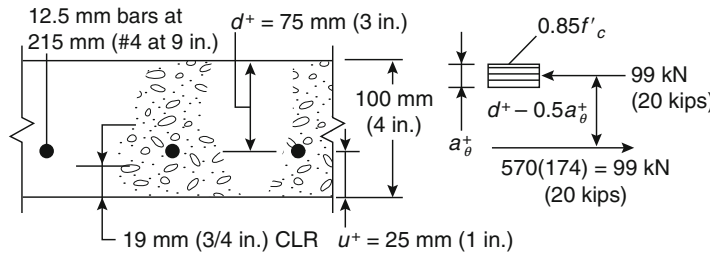

Fig. 54.23 $M^{+}_{n\theta}$ calculation for bottom bars

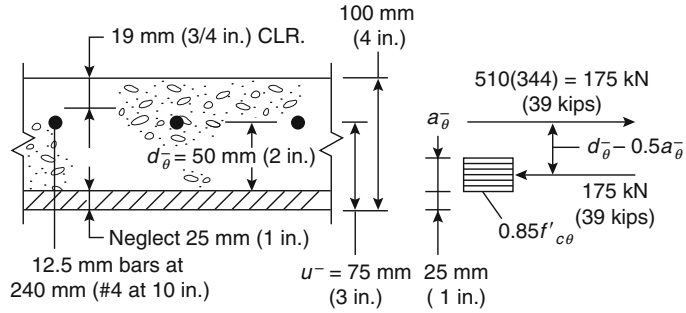

Fig. 54.24 $M^{-}_{n\theta}$ calculation for top bars

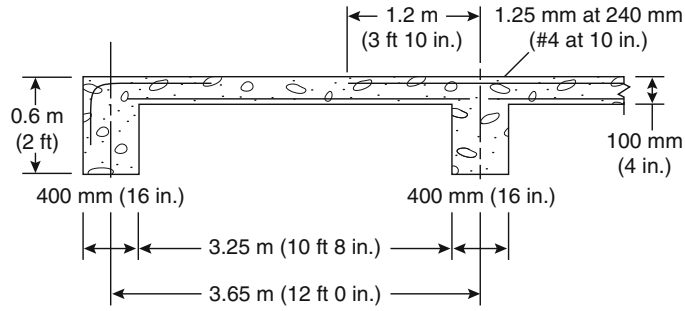

Fig. 54.25 Top bar lengths at 2 h of fire exposure

$f'_{c\theta} = 0.65\,(20.7) = 13.5\,\text{MPa}\,(1.95\,\text{ksi})$ (see Fig. 54.2).

$d^-_\theta = 100 - (19 + 6 + 25) = 50\,\text{mm}\,(2.0\,\text{in.})$.

Reinforcing is 12.5-mm bars at 240 mm (#4 at 10 in.)

$$A_s^- = 510\,\text{mm}^2/\text{m}\,\left(0.24\,\text{in.}^2/\text{ft}\right)$$

$$a_\theta^- = \frac{A_s^- f_{y\theta}^-}{0.85 f'_{c\theta} b} = \frac{510(344)}{0.85(13.5)(1000)}$$
$$= 15\,\text{mm}\,(0.60\,\text{in.})\,[\text{from Equation 54.4}]$$

$$\left\{ M_{n\theta}^- = A_s^- f_{y\theta}^- \left(d_\theta^- - \frac{a_\theta}{2}\right) = \frac{510(344)(50 - 15/2)}{1 \times 10^6} \right.$$
$$= M_{n\theta}^- = 7.5\,\text{kN} \cdot \text{m/m}$$
$$(1.69\,\text{ft} \cdot \text{kips/ft})$$
$$[\text{from Equation 54.3}]$$

Step 7: Calculate the minimum positive moment required at 2 h.

Minimum required

$$M_{n\theta}^+ = \frac{\left(M_{n\theta}^-\right)^2}{2wL^2} - \frac{M_{n\theta}^-}{2} + \frac{wL^2}{8}$$

$$w = 0.1(24) + 0.25 + 3.8$$
$$= 6.45\,\text{kN/m}\,(0.44 \cdot \text{kips/ft})$$

Minimum required

$$M_{n\theta}^+ = \frac{(7.5)^2}{2(6.45)(3.65)^2} - \frac{7.5}{2} + \frac{6.45(3.65)^2}{8}$$

Minimum required

$$M_{n\theta}^+ = 7.3\,\text{kN} \cdot \text{m/m}(1.64\,\text{ft} \cdot \text{kips/ft})$$

Step 8: If the positive moment strength available is greater than the required positive moment strength, structural fire endurance is adequate. Because the moment strength available, 7.3 kN · m/m (1.64 ft · kips/ft), is for practical purposes equal to the required moment strength, 7.3 kN · m/m (1.64 ft · kips/ft), the structural fire endurance for the end span is 2 h.

Step 9: Check the lengths of the top reinforcing bars to make sure the bars are long enough to develop the required negative moment strength. The length of the top bars under normal conditions, considering only gravity loads and no fire, is taken from the *CRSI Handbook* [24] (Fig. 54.25).

Step 9a: Top bar lengths, at first interior support, neglecting restraint to thermal expansion

The distance to the point of inflection at first interior support for structural fire endurance is calculated using

$$X_0 = \frac{2M_{n\theta}^-}{wL}$$

Because the negative reinforcement generally yields early in the fire, as discussed previously, within the first half hour, the value for the negative moment used in Equation 54.13 should be the maximum negative moment that the beam can support.

$$a = \frac{A_s f_y}{0.85 f'_c b} = \frac{510(415)}{0.85(20.7)(1000)} = 12\,\text{mm}\,(0.47\,\text{in.})$$

$$M_n^- = A_s f_y d - \left(\frac{a}{2}\right) - \frac{510(415)(75 - 12/2)}{1 \times 10^6}$$
$$= M_n^- = 14.6\,\text{kN} \cdot \text{m/m}(3.28\,\text{ft} \cdot \text{kips/ft})$$

The value used for w is left to engineering judgment based on the expected loading during a fire.

For this example, the full dead load and one-half the live load is used.

$$w = 0.1(24) + 0.25 + 1.9 = 4.55\,\text{kN/m}(0.31\,\text{kips/ft})$$

$$X_0 = \frac{2(14.6)}{4.55 \times 3.65} = 1.75\,\text{m}\,(5\,\text{ft}\,9\,\text{in.})$$

The distance the top bars have to be embedded beyond the point of inflection is given in the ACI *Building Code* [2]. At least one-third of the bars should be embedded 1/16 of the clear span, d, or $12d_b$, whichever is greater. In this example, the 1/16 of the clear span criterion governs (250 mm or 10 in.). Thus, some of the top bars must extend 2.0 m (6 ft 6 in.) into the end span. The length of the top steel, 2.0 m (6 ft 6 in.), is nearly twice the required length for the gravity load (1.2 m or 3 ft 10 in.). The maximum negative moment strength, M_n, used in Equation 54.13, represents the most severe condition for the development length. However, the assumption of frictionless roller bearing supports used in the above example neglected the restraining force in all calculations. The restraining force, or thermal thrust, T, is developed early in the fire, producing a moment opposite the support moment, which acts to reduce the magnitude of the support moment. The net support moment will then be less than the moment strength, M_n^-, used in the calculation above, thereby overestimating the development length required for the desired fire endurance [7].

The restraint criteria discussed will be used to determine if there is sufficient restraint developed in the longitudinal direction, to reduce the development lengths to that required for the gravity load.

Step 9b: Top bar lengths, at first interior support, including restraint to thermal expansion

Using $X_0 = 1.2$ m (3.83 ft), the length required for gravity loading, we can determine the net moment at the support required.

$$X_0 = \frac{2M_n^-}{wL} \tag{54.18}$$

$$M_n^- = \frac{X_0 wL}{2} = \frac{1.2(4.55)(3.65)}{2} = 10\,\text{kN}\cdot\text{m/m}(2.25\,\text{ft}\cdot\text{kips/ft})$$

The thermal thrust must produce a moment equal to

$$M_T = 14.6 - 10.0 = 4.6\,\text{kN}\cdot\text{m/m}(1.04\,\text{ft}\cdot\text{kips/ft})$$

Early in the fire, T will act at or near the bottom of the slab (see Table 54.1). T is assumed to act 12 mm (1/2 in.) above the bottom of the slab (taking the fire exposure as approximately one-half hour):

$$d_T = 100 - 12 = 88\,\text{mm}(3.5\,\text{in.})$$

$$\Delta = 0 \text{ at the support}$$

The depth of the stress block, a_θ^+, is assumed initially to be zero because the required thrust is small.

$$T = \frac{M_T}{d_T - \Delta - a_\theta^+} = \frac{4.6(1000)}{88 - 0 - 0} = 52.3\,\text{kN/m}(3.6\,\text{kips/ft})$$

Recalculating a_θ^+,

$$a_\theta^+ = \frac{T}{0.85 f_c' b} = \frac{52.2}{0.85(20.7)} = 3\,\text{mm}(0.13\,\text{in.})$$

$$T = \frac{4.6(1000)}{88 - 0 - 3/2} = 53.2\,\text{kN/m}(3.65\,\text{kips/ft})$$

Compute the expansion, L, that corresponds to

$$T = 53.2\,\text{kN/m}(3.65\,\text{kips/ft})$$

$$E_1 = 25{,}000\,\text{MPa}\left(3.6 \times 10^6\,\text{psi}\right)$$

$$A_1 = 1.0(0.1) = 0.1\,\text{m}^2/\text{m}\left(48\,\text{in.}^2/\text{ft}\right)$$

$$\frac{T_1}{A_1 E_1} = \frac{53.2}{0.1(25)} = 21 \times 10^{-6}$$

$$Z = \frac{A_1}{s} = \frac{0.1}{1} = 0.1\,\text{m} = 100\,\text{mm}(4\,\text{in.})$$

$$\frac{\Delta L}{L_h} = 0.006 \text{ (from Fig. 54.18)}$$

$$L = 0.006 \times 3652 = 22(0.86\,\text{in.})$$

In order to maintain equilibrium of the horizontal forces and compatibility of the displacements, the restraining elements must withstand $T = 53.2$ kN/m (3.65 kips/ft) and not deflect more than $\Delta L = 22$ mm (0.86 in.). The next step would be to check the strength and stiffness of the restraining elements, that is, the exterior spandrel beams and columns of the exterior support and the plane floor area of the first interior support. In this example, it is not necessary to check the strength and stiffness toward the interior of the structure, because there is considerable restraint from the large unheated floor area and many columns to provide the thrust moment at the first interior support [7]. However, the spandrel beams and columns at the exterior support should be checked to ensure that there is sufficient strength and stiffness to resist the thrust moment. Determining the strength and stiffness of the spandrel beams and columns requires a long and complex structural analysis and is not shown here. An explanation of the structural analysis of spandrel beams and columns can be found in the literature [7].

Assuming there is sufficient restraint in the spandrel beams and columns to resist the thrust moment, the required length of the top bars over the first interior support at 2 h of fire exposure must be determined. Neglecting restraint to thermal expansion,

$$X_0 = \frac{2M_{n\theta}^{-}}{wL} = \frac{2(7.5)}{(4.55)(3.65)} = 0.90\,\text{m}(2.96\,\text{ft})$$

As previously discussed, at least one-third of the top bars should be embedded 1/16 of the clear span at the point of inflection, X_0, therefore the top steel should extend 1.1 m (3 ft 8 in.) into the end span. This length is less than the top bar length required for gravity loads, so no adjustment in the length of the reinforcement steel is required to obtain the desired fire endurance.

Reinforced Concrete Columns

Throughout the history of concrete construction, reinforced concrete columns have performed well when exposed to fire. The reason for this is threefold:

1. Columns are generally large enough to prevent the center core from losing a significant amount of strength even in prolonged fire exposure.
2. Ties or spirals contain the concrete within the core.
3. The vertical reinforcing bars are generally protected by at least 48 mm (1–7/8 in.) of concrete cover, thereby insulating the steel bars [7].

Most of the building codes in the United States assign 3- and 4-h fire resistance to reinforced concrete columns larger than 300 × 300 mm (12 × 12 in.) for square shapes, or a diameter of at least 300 mm (12 in.) for round columns.

ACI recommends that columns with a specified compressive strength $f'_c \leq 82.7$ MPa (12,000 psi) should have the least dimension of the column sized in accordance with Table 54.3. In addition, minimum concrete cover thickness over the main longitudinal reinforcements should be at least 25 mm (1 in.) times the number to hours of required fire resistance to a maximum of 50 mm (2 in.). The detailing of the ties is also

Table 54.3 Minimum concrete column size

	Minimum column dimension for fire resistance rating, mm (in)				
	1 h	1.5 h	2 h	3 h	4 h
Carbonate	200 (8)	225 (9)	255 (10)	280 (11)	305 (12)
Siliceous	200 (8)	225 (9)	255 (10)	305 (12)	356 (14)
Semi-lightweight	200 (8)	216 (8.5)	225 (9)	270 (10.5)	305 (12)

quite important. ACI216.07 specifies that the ties should be formed with hooks having a six-diameter extension that engage the longitudinal reinforcements and project into the interior of the hoop. Detailed assessments of reinforced concrete columns exposed to fires have been made by Anderberg [25] and Lie and Irwin [26]. EN1992-1-2 uses a more detailed methodology for assessing fire resistance of concrete columns which accounts for the height of the column, slenderness ratio and eccentricity of the loading.

Reinforced Concrete Frames

It is not possible to use simple hand calculation methods for accurate structural design of reinforced concrete frame structures exposed to fires. Individual concrete members can be designed by the methods described above, but for moment-resisting frames, a special purpose computer program is necessary for detailed analysis and design. Available programs include FIRES-RC-II [27], CONFIRE [28], SAFIR [17], and DIANA [29].

Reinforced Concrete Walls

Typically, the fire endurance of concrete and concrete masonry walls is determined by heat transmission criteria as opposed to structural performance [6, 7]. As a result, estimating the fire resistance of walls can be accomplished using a heat transfer analysis only. For this reason, the discussion of thickness requirements presented in the heat transmission section can be used. The required thickness can be determined graphically or by applying a heat transfer computer model.

The distinction between bearing and nonbearing walls is based on building code structural requirements and not fire endurance. For example, some building codes require bearing walls to be thicker than nonbearing walls. Such a requirement has not been justified by results of a fire test. [7] ASTM E119 requires that a superimposed load be applied and maintained at a constant magnitude throughout the test of a bearing wall. When testing nonbearing walls, there is no applied load; however, the edges of the walls may be restrained against thermal expansion, in which case a thermally induced load is applied during the fire test. This thermally induced load is of much greater magnitude than the load applied to bearing walls [7].

Prestressed Concrete Assemblies

Most of this chapter refers to reinforced concrete. The same principles apply to prestressed concrete, which is often more vulnerable in fires for the following reasons: prestressing steels are much more sensitive to elevated temperatures than mild steel reinforcing bars; prestressed concrete is often manufactured in slender components with thin cover concrete; and some failure modes such as debonding, shear, and spalling are more critical in prestressed concrete.

Procedures are also available to calculate the fire resistance of prestressed concrete members. The reader is directed to *Design for Fire Resistance of Precast Prestressed Concrete* [30].

Composite Steel-Concrete Construction

Composite steel-concrete construction refers to concrete slabs cast on permanent steel-deck formwork and steel beams which act compositely with the concrete slab to resist bending moment, as shown in Fig. 54.26.

Composite steel-concrete slabs have excellent integrity in fire conditions because even if cracks occur in the concrete slab, the continuous steel deck will prevent any passage of flames or hot gases through the floor. To meet the insulation criterion, it is simply necessary to provide sufficient thickness of slab. A solid slab of uniform thickness requires the same thickness as a normal reinforced concrete slab, but for other profiles it is necessary to evaluate an effective thickness. Generic listings are given in some codes including Eurocode 4 [5], and manufacturers of steel

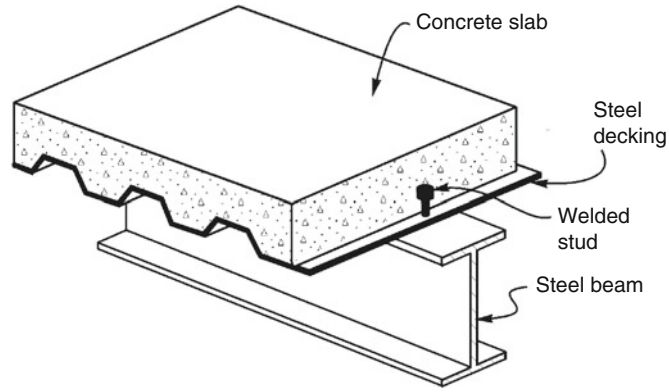

Fig. 54.26 Composite steel-concrete construction

decking have proprietary ratings for their products. It is possible to spray the underside of the steel sheeting with spray-on insulation, but this method is rarely economical.

The strength of composite steel-concrete slabs is severely influenced by fire because the steel sheeting, acting as external reinforcing, loses strength rapidly when exposed to the fire. However, composite slabs can achieve good fire resistance because of three contributing factors: axial restraint, moment redistribution, and fire emergency reinforcement.

Composite slabs often have different fire resistance ratings for restrained and unrestrained conditions [31]. During a fire test, if a composite slab is built into a rigid testing frame which allows almost no axial expansion, the slab can achieve a fire resistance rating with no reinforcing other than the steel sheeting, because of the thermal thrust developed at the supports. Some buildings are sufficiently stiff and strong to provide such restraint to a fire-exposed floor system, but because the amount of restraint is difficult to assess accurately, it is usual to rely on some reinforcing within the slab.

If the nominal reinforcing provided to control shrinkage cracking is placed near the top of the concrete and if the slab is continuous over several supports, it can develop significant negative flexural capacity through moment redistribution and hence retain sufficient load capacity during the fire. If a slab is simply supported, or if moment redistribution is insufficient to resist the applied loads, it is common practice to place *fire emergency reinforcing* in the slab, consisting of steel reinforcing bars in the troughs of the sheeting, with sufficient cover from the bottom surface to control temperatures in the bars. The flexural strength of the slab can be calculated in the usual way using the temperature of the rebars. Further design recommendations are given by ECCS [32], Lawson [33], and Eurocode 4 [5].

Recent Developments

There is continuing international research on fire performance of reinforced concrete. Several recent developments are described below.

Calculation of Temperatures

Recent publications on thermal and mechanical properties of concrete at high temperatures are given by Harmathy [34], Schneider [35], Bazant and Kaplan [36], and Neville [37]. A simple, approximate formula for calculating internal temperatures in reinforced concrete members exposed to the standard fire has been developed by Wickström [38]. Internal temperatures in concrete slabs and beams exposed to realistic fires are given by Wade [39].

Spalling

The design methods in this chapter are based on the assumption that the concrete remains intact for the duration of the fire. This assumption is invalid if the cover concrete spalls off during the fire, exposing reinforcing steel to the fire temperatures. Experiments and real fire experience have shown that most normal weight concrete members can withstand severe fires without spalling, but spalling does occur sometimes. In some cases spalling is related to the type of aggregate, but it is more often linked to the behavior of cement paste. It is generally agreed that spalling most often occurs when water vapor is driven from the cement paste during heating, with high pore pressures creating high tensile stresses in the concrete. Spalling can also occur as result of the presence of high compressive stresses [40]. Susceptibility to spalling results from high free-moisture content (such as in fresh concrete), rapid rates of heating, low water-cement ratio, large aggregate size, low tensile strength of concrete, dense reinforcement, nonuniform thickness of the member, and prestressing. Recent reviews of concrete spalling in normal weight concrete are provided by Hertz [41] and Connolly [42], and in high strength concrete by Ali [43] and Phan [44]. The most promising new development to reduce spalling is the addition of fine polypropylene fibers to the concrete mix so that the polypropylene melts during the fire exposure, leaving cavities through which the water vapor can escape [45].

High-Strength Concrete

There has been considerable recent interest in high-strength concrete as a construction material. High-strength concrete contains additives such as silica fume and water reducing admixtures, which result in compressive strength in the range 60–120 MPa (8400–18,000 psi). An extensive survey of high-strength concrete properties at elevated temperatures by Phan [44] shows that they tend to have a higher rate of strength loss than normal concrete at temperatures up to 400 °C, with explosive spalling being a problem in some cases. High-strength concrete is more susceptible to spalling since it has smaller free-pore volume (higher paste density), so that the pores become filled with high-pressure water vapor more quickly than in normal weight concrete. Fire tests on high-strength columns are reported by Aldea et al. [46] and Kodur [45], and fire tests on high-strength beams are reported by Felicetti and Gambarova [47]. Design recommendations are given by Tomasson [48], who suggests a simple method that ignores concrete above 500 °C (950 °F) for slabs and beams and above 400 °C (750 °F) for columns. A study on residual mechanical properties of high-strength concrete after exposure [49] shows that strength and stiffness of high-strength concrete decrease significantly in fire, and the recovery of strength afterwards is negligible.

Fiber-Reinforced Concrete

Thermal and mechanical properties of steel-fiber reinforced concrete at elevated temperatures are described by Lie and Kodur [50]. They show that the presence of steel fibers increases the ultimate strain and improves the ductility of the concrete during fire exposure. An extensive survey of the mechanical behavior of steel-fiber reinforced concrete at high temperatures has been conducted by Colombo [51], who expresses the flexural behavior as a thermal-mechanical damage model with consideration of irreversible thermal strains.

Hollow-Core Concrete Slabs

With the increasing popularity in recent years of precast prestressed concrete panels in construction, research is being carried out on the behavior of hollow-core concrete slabs in fire, which is more complicated than reinforced concrete because of the effect of prestressing, the small amount of reinforcing, and variable restraint from the surrounding structure. The fire behavior of composite hollow-core concrete units supported on

steel beams is described by Borgogno and Fontana [52]. Several fire tests on hollow-core concrete slabs have been carried out [53–55]. The performance of hollow-core concrete flooring systems in fire has been studied extensively by Fellinger [56] with special focus on the shear and anchorage behavior, and a simulation model of hollow-core concrete flooring systems for design purposes has been proposed by Chang [57].

Analytical Methods for Determining Fire Resistance of Timber Members

55

Robert H. White†

Introduction

The fire resistance ratings of wood members and assemblies, as with other materials, have traditionally been obtained by testing the assembly in a furnace in accordance with ASTM International (ASTM) Standard E119 "Standard test methods for fire tests of building construction and materials", International Organization for Standardization (ISO) Standard 834 "Fire-resistance tests-Elements of building construction", and similar standards. In the U.S., these ratings are published in listings, such as Underwriters Laboratories *Fire Resistance Directory*, Gypsum Association's *Fire Resistance Design Manual*, American Wood Council's *Design for Code Acceptance* publications, and those in building codes. The ratings listed are limited to the actual assembly tested and normally do not permit modifications such as adding insulation, changing member size, changing interior finish, or increasing the spacing between members. Code interpretation of test results sometimes allows the substitution of larger members, thicker or deeper assemblies, smaller member spacing, and thicker protection layers, without reducing the listed rating.

Two procedures for calculating fire resistance ratings have U.S. building code acceptance: the methodologies for calculating fire resistance ratings of exposed wood members in the American Wood Council's *National Design Specification® for Wood Construction* (NDS®) and the component additive method (CAM) for protected wood-frame walls, floors, and roofs [1]. A third methodology developed by T.T. Lie [2] is expected to be withdrawn from future editions of the U.S. codes in favor of the NDS methodology. The T.T. Lie methodology and the CAM procedures were developed in Canada and currently have both U.S. and Canadian code acceptance [3].

In Europe, the Eurocode 5 of the European Committee for Standardization (EN 1995-1-2:2004 Eurocode 5: Design of timber structures-Part 1–2: General-Structural fire design and its corrigendum EN 1995-1-2:2004/AC:2009) on design of timber structures provides calculation methods for the fire design of timber structures. A review of the development of EN 1995-1-2, improvements from the earlier ENV 1995-1-2 published in 1994, and references for the research results used to support its provisions are provided by König [4, 5]. Provisions of Eurocode 5 and more recent developments in Europe are extensively discussed in "Fire Safety in Timber Buildings—Technical guideline for Europe [6].

When attention is given to all details, the fire resistance of a wood member or assembly depends on three items:

1. Performance of its protective membranes (if any)
2. Extent of charring of the structural wood element

3. Ratio of the load-carrying capacity of the remaining uncharred portions of the structural wood elements to the applied load

Contribution of the Protective Membrane

Gypsum wallboard and wood paneling are two common types of protective membrane that provides the first line of resistance to fire in wood construction. The effects of the protective membrane on the thermal performance of an assembly are included in Harmathy's ten rules of fire endurance rating [7]. These ten rules (Fig. 55.1) provide guidelines to evaluate the relative effects of changes in materials on the fire resistance rating of an assembly. However, there are exceptions to some of these general rules. The rules apply primarily to the thermal performance of the assembly.

In the U.S., testing of assemblies often include the reporting of "finish ratings" of the protective membrane. A finish rating of a protective membrane is generally defined as the time to reach either an average temperature rise of 139 °C (250 °F) or a maximum rise of 181 °C (325 °F), as measured on the plane of the wood framing member nearest the fire. Also in the U.S., these same temperature criteria are used in the fire resistance testing of protective membranes (i.e. "thermal barriers") required for the

protection of foam plastic insulation [8]. In Europe, these same temperature increase criteria (140 K average, 180 K maximum) are used for layers in the CAM in the Eurocode 5. The contribution of the protective membrane to the fire resistance rating of a light-frame assembly is clearly illustrated in the CAM.

The North American CAM is initially discussed in the following subsection. In Europe, a new classification system for the abilities of building panels to provide fire protection has been developed [6]. The "K" classes are determined by testing for fire resistance using a temperature rise on the unexposed surface of 250 °C and horizontal orientation of the test panel.

Component Additive Method

The CAM is a calculation procedure to determine fire resistance ratings of light-frame wood floor, roof, and wall assemblies. With this procedure, as with Harmathy's rules 1 and 2, one assumes that a time can be assigned to the type and thickness of the protective membrane and that an assembly with two or more protective membranes has a fire resistance rating at least that of the sum of the times assigned for the individual layers plus the time assigned to the framing. CAM was developed by the National Research Council of Canada (NRCC) and has code approval in both the United States [1] and Canada [3]. Richardson and Batista [9] evaluated the methodology using results from tests of light-frame walls lined with gypsum board.

The times assigned to the protective membranes (Table 55.1), the framing (Table 55.2), and other factors are added together to obtain the fire resistance rating for the assembly. The times are based on empirical correlation with actual ASTM E119 tests of assemblies. The ratings obtained in these tests ranged from 20 to 90 min. The times given in Table 55.1 are based on the membrane's ability to remain in place during fire tests. In this North American CAM, the times assigned to the protective membranes in the component additive method are not the "finish ratings" of the material cited in test reports or listings.

Table 55.1 Time assigned to protective membranes

Description of finish	Time (min)
9.5 mm ($^3/_8$ in.) Douglas fir plywood, phenolic bonded	5
13 mm (½ in.) Douglas fir plywood, phenolic bonded	10
16 mm ($^5/_8$ in.) Douglas fir plywood, phenolic bonded	15
9.5 mm ($^3/_8$ in.) gypsum board	10
13 mm (½ in.) gypsum board	15
16 mm ($^5/_8$ in.) gypsum board	20
13 mm (½ in.) type X gypsum board	25
16 mm ($^5/_8$ in.) type X gypsum board	40
Double 9.5 mm ($^3/_8$ in.) gypsum board	25
13 mm + 9.5 mm (½ in. + $^3/_8$ in.) gypsum board	35
Double 13 mm (½ in.) gypsum board	40

The applicable building code should be checked for acceptance of, modification to, and limitations on the procedure. There are specific requirements for the installation of some of the membranes

Table 55.2 Time assigned for contribution of wood frame

Description of frame	Time (min)
Wood wall studs, 406 mm (16 in.) on center	20
Wood floor and roof joists, 406 mm (16 in.) on center	10
Wood floor and roof truss assemblies, 610 mm (24 in.) on center	5

Minimum size for studs is nominal 51 mm by 102 mm (2 in. by 4 in.). Wood joists must not be less than nominal 51 mm (2 in.) in thickness. The spacing between studs or joists cannot exceed 406 mm (16 in.) on center. The applicable building code should be checked for acceptance of, modification to, and limitations on the procedure

The type of fasteners and their spacing on the protective membrane can be critical factors in the performance of the membrane in a fire resistance test. Reference should be made to similar tested assemblies. The addition of insulation to a wall assembly can increase its fire resistance [10]. Adding rock wool or slag mineral wool insulation batts for additional protection to the wood stud wall generally has an assigned time of 15 min in the CAM procedure, which is added to the sum of the times for the framing and the protective membrane to obtain the rating for the

wall assembly. Assigned times for glass fiber insulation depend on the codes.

The effect of adding insulation to the fire resistance of a floor or roof assembly in a fire test depends on its location within the assembly and the method of attachment. In tests of single layer I-joists systems, the addition of insulation above the unbacked joints in the gypsum board ceiling has been beneficial. In the case of floor assemblies, adding insulation can also decrease the fire resistance of the assembly [10]. Using the results of the series of wall tests conducted in Canada, Sultan and Kodur [11] examined the effects of insulation type, insulation width between studs, resilient channel location, gypsum board thickness, number of gypsum board layers, glass fiber in the gypsum board core, gypsum board mass per unit area, and stud type. For load-bearing wood stud walls, the fire resistance is reduced when resilient channels are used to attach the gypsum boards on the fire-exposed side of the studs [12].

For asymmetrical wall assemblies, the rating in the CAM procedure is based on the side with the lesser fire resistance. For floor/ceiling assemblies, roof/ceiling assemblies, and exterior walls rated only from the interior, there are minimal requirements for the membrane on the face of the assembly not directly exposed to the fire, in order to ensure that the wall or floor/roof assembly does not fail because of fire penetration or heat transfer through the assembly. Specific alternative membranes are identified for the face of wood stud walls not exposed to fire (exterior) and for the flooring or roofing over wood joist framing. The membrane on the side not exposed to fire (the outside or top) may also be any membrane listed in Table 55.1 with an assigned time of 15 min or greater.

The application of the method in the building codes is generally limited to 60 or 90 min. Additional information can be found in publications of the American Wood Council [1] and the Canadian Wood Council [3]. When code acceptance is required, the applicable building code must be checked for acceptance of, modifications to, and limitations of the procedure. There are differences between the codes in what is accepted. CAM gives flexibility, for example, in calculations for plywood and gypsum board combined as an interior finish.

Example 1 The calculated fire resistance rating of a wood stud exterior wall (nominal 2 in. × 4 in. [51 mm × 102 mm] studs, 16 in. [406 mm] on center) with 0.625 in. (16 mm) Douglas fir phenolic-bonded plywood over 0.5-in. (13-mm) type X gypsum wallboard on the side exposed to fire is

From Table 55.1:	
16 mm (0.625 in.) Douglas fir plywood, phenolic bonded	15 min
13 mm (0.5 in.) type X gypsum board	25 min
From Table 55.2:	
Wood stud framing	20 min
Calculated rating (total)	60 min
Mineral wool insulation could be used to increase the fire rating to 75 min	

There is also a CAM in Eurocode 5 based on work in Sweden [13, 14]. In the CAM described in Eurocode 5, the fire separation function of wall and floor assemblies is calculated as the sum of the contribution to fire resistance from each layer of material:

$$t_{ins} = \sum_i t_{ins,0,i} k_{pos,i} k_{j,i} \qquad (55.1)$$

where

$t_{\mathrm{ins},0,i}$ = Basic insulation value of layer i (min)
$k_{\mathrm{pos,i}}$ = Position coefficient of layer i in relation to the fire
$k_{\mathrm{j,i}}$ = Joint coefficient of layer i

The temperature increase criteria of 140 K average or 180 K maximum are used in the determination of the basic insulation value, $t_{ins,0}$, for a single layer. Application of this CAM to address the insulation aspect of fire resistance includes consideration of the different paths for heat transfer through the assembly. The position coefficient adjusts the basic insulation value for the position of the layer within the assembly, and the joint coefficient adjusts for the configuration of any joints in the layer.

Research in Switzerland [15, 16] has resulted in improvements to the methodology. These suggested modifications to the current Eurocode 5 procedure include the impact of the adjacent

layers on the position coefficient and introduce a basic protection value. The position coefficient of Equation 55.1 is modified to be the product of two position coefficients—a position coefficient that takes into account the influence of layers on the fire exposed side of the layer and a position coefficient that takes into account the influence of layers on the non-fire exposed side of the layer. The basic protection value is used instead of the basic insulation value of Equation 55.1 for all layers except the last layer on the unexposed side. The determination of the basic protection value is based on temperature rise criteria of 250 K average or 270 K maximum. Assuming an initial temperature of 20 °C, the 270 K temperature rise corresponds to a temperature of 290 °C which is close to the 300 °C temperature criteria commonly used for the base of the char layer. Östman et al. [6] provide detailed information on this methodology, including design examples. The Eurocode 5 also includes design procedures for fire resistance of load-bearing, insulated, light-frame floors and walls that consider charring of the wood joist or stud. There are separate procedures for wall and floor assemblies with and without cavities filled with rock (mineral wool) or glass fiber insulation.

In New Zealand publications [17], an approach described as the *onset of char* method is used to determine the fire ratings of light-frame assemblies. Because the charring of wood is associated with a temperature of 300 °C (550 °F), another method is to assume that the membrane will protect any wood framing for at least the time of the finish rating of the membrane in a test involving wood framing. As with the onset of char method, the fire rating of the entire assembly with the substituted member is assumed to be at least equal to the finish rating of the protective membrane in the test with the solid-sawn wood framing.

Models for Light-Frame Construction

The protective membrane contributes to fire resistance by providing thermal protection. Numerical heat transfer methodologies are available to evaluate this thermal protection. In most cases, the models were developed for light-frame wall assemblies. An extensive literature review of efforts to model the fire resistance of light-frame construction is provided by Bénichou and Sultan [18]. In early work, Fung [19] developed a one-dimensional finite difference model and computer program for thermal analysis of walls. Gammon [20] developed a two-dimensional finite element heat transfer model for wood-stud wall assemblies. WALL2D, developed by Forintek Canada, is a two-dimensional finite-difference model for predicting heat transfer through wood stud walls exposed to fire [21, 22].

Difficulties in modeling the charring of wood, and the physical deterioration of the panel products complicate these numerical methodologies. Other research on models for light-frame construction includes activities in Canada [23, 24], Sweden [25], New Zealand [26, 27] and Australia [28, 29].

In addition to modeling heat transfer, these efforts have included the modeling of the structural capacity of the light-frame assemblies. WALL2D has been used with a simple structural model to predict structural collapse [30].

In a manner similar to the bilinear char model of Eurocode 5 for initially protected wood, Frangi et al. [31] developed a charring model for timber frame floor assemblies with void cavities. Clancy [32] used his model to examine the effects of various variables on the times for structural collapse.

As part of the development of such models, research has been done on the properties of gypsum board. Cramer et al. [33] examined mass loss and mechanical properties of gypsum board at elevated temperatures. Bénichou and Sultan [34] reported test results for thermal conductivity, specific heat, mass loss, and thermal expansion/contraction for wood, gypsum, and insulation. Craft et al. [35] developed Arrhenius rate constants for the calcinations of the gypsum. Thomas [36] reviewed thermal data for gypsum board and made modifications to obtain apparent values for the properties that were suitable for a heat transfer model.

Direct Protection of Wood Members

The steel industry improves the fire resistance of steel members by directly covering them with fire-resistive panels or coatings. Currently, the marketing of fire-resistive coatings for use on wood is almost nonexistent. The fire-retardant coatings marketed for wood are designed and recognized only for use to reduce the spread of flames over a surface (flame spread).

Depending on its thickness and durability under fire exposure, a coating may merely delay ignition of the wood for a few minutes or may provide an effective insulative layer that reduces the rate of charring. For both fire-retardant coatings and fire-resistive coatings, their performance as a fire-resistant membrane on wood has been evaluated [37–39].

In some full-scale testing of beams, those coated with an intumescent fire retardant produced improvements less than that obtained in earlier tests in a small-scale furnace [40]. Bending of the beams during the fire test resulted in adhesion problems. Tests on coated timber members were also reported in Finland and the U.S.S.R [41].

There are published data on the protection provided by directly covering a wood member with gypsum board or other nonwood panel products. Gardner and Syme [42] found that gypsum board not only delayed the onset of char formation but also reduced the subsequent rate of char formation. In their 2 h tests, 13-mm (0.5-in.) thick gypsum board on wood beams reduced the depth of char by approximately 40 %. Of the 40 %, only 17 % was credited to the initial delay in char formation.

Tsantaridis et al. [43] provided information on the charring of wood protected by gypsum board when exposed to 50 kW/m^2. Richardson and Batista [44] tested wood decks with and without gypsum board protection. A 16-mm (0.625-in.) thick Type X gypsum board increased the times for flame penetration from 4.5 to 44 min.

In a study of engineered wood rim board products, White [45] investigated the charring rates of wood composite rim boards with and without the protection of one or two layers of gypsum board when subjected to ASTM E119 exposure. Based on tests in a cone calorimeter and a series of tension tests, White [46] concluded that a single layer of U.S. 16 mm (0.625-in.) thick type X gypsum board could be used to add 30 min to the rating of an unprotected wood member and two layers could be assigned a time of 60 min. The charring of wood beneath cladding is addressed in the Eurocode 5 by adjusting the charring rate of the wood for the period before and after the failure of the different types of protective panel products [6].

Osborne et al. [47] and Dagenais et al. [48] found that using two layers of directly attached 13 mm (0.5-in.) type X gypsum boards delayed the onset of charring of cross-laminated timber (CLT) assemblies by 40 min; while a single layer of 16 mm (0.625-in.) provides 30 min. In a manner consistent with the design equations in Eurocode 5, Just et al. [49] developed specific design equations for a wide range of different types of gypsum boards.

Fire-Resistive Exposed Wood Members

As the wood member is exposed to fire, charring reduces the cross section of the member. In addition to charring of the member, the residual structural capacity is affected by the elevated temperature gradient within the uncharred wood. The fire-resistive characteristics of exposed wood members are due to the insulative characteristics of the char layer and the sharp temperature gradient beneath the base of the char layer.

As a result, even an unprotected structural wood member retains its structural stability in a fire for a period of time. In an engineering analysis of the fire resistance of an exposed wood member, information is needed on charring rate, ratio of ultimate strength to design values, and reduction in strength due to temperature gradient within the uncharred cross section.

Using such engineering analyses, Lie [2] developed simple formulas for calculating the fire resistance of large wood beams and columns that require the user to know only the dimensions of the structural element and load as a fraction of the full design load. These equations were extensively discussed in previous editions of this chapter. In terms of U.S. code acceptance, the formulas of T. T. Lie [2, 50] for beams and columns are expected to be phased out in favor of the NDS methodology.

In contrast to the more flexible NDS method, the Lie's methodology is applicable only to large wood beams and columns with common loading and bracing conditions. It also does not allow the user to adjust the charring rate. Other procedures such as the NDS method (discussed later in this chapter) and the various methods described in Eurocode 5 allow the user to specify the applicable charring rate.

Charring of Wood

Wood undergoes thermal degradation (pyrolysis) when exposed to fire (Fig. 55.2). The thermal degradation process depends on the temperatures and inorganic impurities such as fire-retardant chemicals [51]. The pyrolysis and combustion of wood have been studied extensively.

Past literature reviews include publications by Browne [52], Schaffer [53, 54], Hall et al. [55], and Hadvig [56]. Babrauskas [57] reviewed literature on wood charring and the use of charring rate of wood as a tool for fire investigations. By converting wood to char and gas, pyrolysis results in a reduction in the wood's density. The pyrolysis gas undergoes flaming combustion as it leaves the charred wood surface. Glowing combustion and mechanical disintegration of the char eventually erode or ablate the outer char layer.

Charring rate generally refers to the linear rate at which wood is converted to char. Under standard fire exposure, charring rates tend to be fairly constant after a higher initial charring rate. Establishing the charring rate is critical to evaluating fire resistance, because char has virtually no load-bearing capacity.

There is a distinct demarcation between char and uncharred wood. A temperature of 300 °C is widely used to define the base of the char layer. Early U.S. research used a temperature of 550 °F, and SI conversion from inch-pound units resulted in 288 °C, 290 °C, and 300 °C being used for 550 °F. To determine charring rate, both empirical models based on experimental data and theoretical models based on chemical and physical principles are used.

Standard ASTM E119 Fire Exposure

Expressions for charring rate in the standard ASTM E119 test are the result of many experimental studies. As given in the Eurocode 5, the normal equation for the char depth at a given time is of the form

$$d_{\text{char}} = \beta t \tag{55.2}$$

where
d_{char} = Char depth
β = Charring rate
t = Time

The design values for charring rate depend on the fire resistance methodology being used. The empirical model that is most generally used assumes a constant transverse-to-grain char rate of 0.6 mm/min. (1.5 in./h) for all woods, when subjected to the standard fire exposure. This is for one-dimensional charring in a semi-infinite slab.

There are differences among species associated with their density, chemical composition, and permeability. In addition, the moisture content of the wood affects the charring rate. Schaffer [58] reported transverse-to-grain charring rates as a function of density and moisture content for Douglas fir, southern pine, and white oak. The regression equations for C (minutes/mm, the reciprocal of charring rate β) were

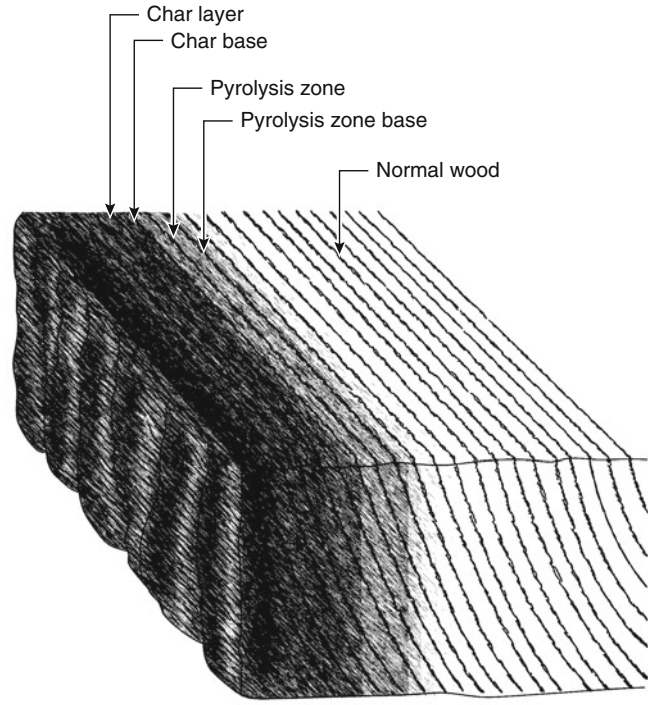

Fig. 55.2 Degradation zones in a wood section

$$C = 1/\beta = (0.002269 + 0.00457u)\rho + 0.331 \quad \text{for Douglas-fir} \tag{55.3}$$

$$C = 1/\beta = (0.000461 + 0.00095u)\rho + 1.016 \quad \text{for southern pine} \tag{55.4}$$

$$C = 1/\beta = (0.001583 + 0.00318u)\rho + 0.594 \quad \text{for white oak} \tag{55.5}$$

where
u = Moisture content (fraction of oven-dry mass)
ρ = Density (dry mass, volume at moisture content u, kg/m^3)

White and Nordheim [59] developed an empirical model based on eight species. The char rate equation was of the form

$$t = mx_c^{1.23} \tag{55.6}$$

where
t = Time (min)
m = Char rate coefficient
x_c = Char depth (mm)

This nonlinear char model is used in the NDS calculation procedure for exposed wood members. The char rate coefficients ranged from 0.42 to 0.84 mm/min$^{1.23}$ for the eight species [59]. Average values for the char rate coefficients were 0.555 for southern pine, 0.554 for western red cedar, 0.598 for redwood, 0.734 for Engelmann spruce, 0.498 for basswood, 0.653 for hard maple, 0.747 for red oak, and 0.607 for yellow poplar.

The char rate coefficient was found to be correlated to density, moisture content, and a char contraction factor, defined as the thickness of the char layer at the end of the fire exposure divided by the original thickness of the wood layer that was charred (char depth).

The application of this nonlinear model to composite wood products is discussed by White [60, 61]. Other researchers have concluded that there is not a correlation between the char rate and density [62]. Results from theoretical charring models have also shown that density has an impact on the charring rate [63]. The equation developed for the influence of density and moisture content was:

$$\beta_{\rho,w} = k_\rho k_w \beta_{450.12} \tag{55.7}$$

with

$$k_p = \sqrt{\frac{450}{\rho_{12}}} \tag{55.8}$$

and

$$k_w = \left(\frac{1.12}{1+w}\right)^{1.5} \tag{55.9}$$

where

$\beta_{450,12}$ = charring rate of wood with density of 450 kg/m^3 and 12 % moisture content, mm/min

ρ_{12} = density of wood at 12 % moisture content, kg/m^3

w = moisture content, kg/m^3

For charring in the longitudinal direction, i.e. along the grain, there is very little available data [63]. The charring rate parallel to the grain of wood has been reported as being approximately twice that transverse to the grain [55]. Based on results from a theoretical model on the impact of variations in thermal conductivity on charring rate, Cachim and Franssen [63] proposed the following relationship between a multiplication factor for thermal conductivity perpendicular to grain, k_λ, and the corresponding charring rates, parallel ($\beta_{||}$) and perpendicular to grain $\beta_\perp$.

$$k_\lambda = \left(\beta_{||}/\beta_\perp\right)^2 \tag{55.10}$$

Consistent with a doubling of charring rate, a value of 4 was suggested for k_λ. Per the Wood Handbook [64], thermal conductivity along the grain has been reported as greater than conductivity across the grain by a factor of 1.5–2.8, with an average of about 1.8. While not generally required for fire design, further work is needed on this question.

In Eurocode 5, the design charring rate, β_o, in Equation 55.2 is the rate observed in one-dimensional experiments. The listed design charring rates for timbers include 0.65 mm/min for solid-sawn or glued-laminated softwood timber (characteristic density of 290 kg/m^3 or greater), solid-sawn or glued-laminated hardwood timbers (characteristic density of 290 kg/m^3), and laminated veneer lumber (LVL) (characteristic density of 480 kg/m^3 or greater); and 0.50 mm/min for solid or glued-laminated hardwood with a characteristic density of 450 kg/m^3 or greater.

The effect of the rounding of the charred member can be taken into account by increasing the values for char rate, as is done in Eurocode 5. Eurocode 5 notional design charring rate, β_n, includes 0.7 mm/min for glued-laminated softwood and beech timbers (characteristic density of 290 kg/m^3 or greater), solid-sawn or glued-laminated hardwood except beech timbers (characteristic density of 290 kg/m^3), and LVL (characteristic density of 480 kg/m^3 or greater); 0.8 for solid softwood and beech timber (characteristic density of 290 kg/m^3 or greater); and 0.55 mm/min for solid-sawn or glued-laminated hardwood except beech (characteristic density of 450 kg/m^3 or greater).

Except for beech, the charring rates for hardwoods with characteristic densities between 290 and 450 kg/m^3 are linear interpolations of charring rates for 290 and 450 kg/m^3. The concept of notional charring rates in the Eurocode 5 is discussed by König [65]. Using results from a conductive/finite element model, Cachim and Franssen [63] suggested modifications to the Eurocode 5 values to address the effects of density, moisture content, and anisotropy on charring rates.

Assumption of a constant charring rate is reasonable when the member or panel product is thick enough to be treated as a semi-infinite slab. For smaller dimensions, the charring rate increases once the temperature has risen above the initial temperature at the center of the member or at the unexposed surface of the panel.

In tests of solid timber beams, Frangi and Fontana [62] observed an increase in the charring rate when the residual cross section was smaller than 40–60 mm. As discussed later, the elevated temperature profile beyond the base of the char layer is estimated to be about 40 mm thick.

In Eurocode 5, design charring rate listed for panels (20 mm thick and characteristic density of

450 kg/m^3) includes 0.9 mm/min for wood paneling and wood-based panels other than plywood and 1.0 mm/min for plywood. Kanury and Holve [66] suggest the model

$$\frac{\ell}{t} \approx \left(\frac{2}{a}\right)\left(1 - \frac{b\ell}{a}\right) \tag{55.11}$$

where
ℓ = Thickness of slab (mm)
t = Fire resistance time (min)
a,b = Constants

They consider the $2/a$ factor an ideal charring rate and the ratio $b\ell/a$ as a correction factor accounting for thickness and thermal diffusion effects. Noren and Östman [67] provided the equation

$$b_m = 1.128x + 0.0088x^2 \tag{55.12}$$

where
b_m = Contribution to fire resistance (min)
x = Panel thickness (mm)

The equation is based on data for various wood-based panel products.

Effect of Adhesives and Treatments

The effect of fire-retardant treatment and adhesives on the char rates depends on the type of adhesive or treatment. The charring rate of wood laminates bonded with phenol adhesives is considered to be consistent with that of solid wood. Early tests of a phenol-resorcinol adhesive and a melamine adhesive showed no delamination at the glueline in the wood beneath the char layer [68]. Delamination beneath the base of the char layer occurred at the gluelines for a polyvinyl adhesive [68].

With the introduction of Cross-Laminated-timber (CLT) construction in Europe and North America, there has been testing of more products with non-resorcinol/phenol adhesives. CLT construction panels are solid wood components built of dimension lumber in manner similar to plywood in which the grain direction of each layer is perpendicular to the adjacent layers. Frangi et al. [69] and Osborne et al. [47] observed the falling off of charred laminates during tests of CLT and the resulting increased charring rate compared with homogeneous specimens. The effect of adhesives on load capacity during a fire is discussed later in this chapter.

Fire-retardant treatments that involve the pressure impregnation of the chemicals are designed to reduce flame spread. However, few fire retardants have been found to improve charring resistance [70].

Nonstandard Fire Exposures

The above equations were stated to apply to the standard ASTM E119 or ISO 834 fire exposure. Data on charring rates for other fire exposures have been limited. Schaffer [58] provided data for constant temperatures of 538 °C (1000 °F), 815 °C (1500 °F), and 927 °C (1700 °F). Lau et al. [71] presented data for constant 500 °C and an empirical model for constant or variable temperatures.

The charring rate is a function of the external flux. For a range of 20–33 kW/m^2, Butler [72] calculated the char rate (mm/min) to be 0.022 times the irradiance (kW/m^2). Because of increased testing with heat release rate calorimeters, such as the cone calorimeter, char rate and temperature profile data as a function of external heat flux are becoming more available [73–80].

In tests of spruce, charring rates obtained were 0.56, 0.80, and 1.02 mm/min for external heat fluxes of 25, 50, and 75 kW/m^2, respectively [78]. In tests of southern pine, the linear charring rate ranged from 0.44 mm/min at 18 kW/m^2 to 0.85 mm/min at 55 kW/m^2 [73, 74]. Charring rate has been found to be proportional to the ratio of external heat flux over density [77, 78]. Eurocode 5 includes equations for parametric fire exposures in which the load-bearing function must be maintained during the complete duration of the decay phase or for a specified period of time.

Hadvig's Equations for Nonstandard Fire Exposure

Hadvig [56] developed equations for nonstandard fire exposure. The charring rate in a real fire depends on the severity of the fire to which

Table 55.3 The transfer coefficient, k [56, 81]

Type of fire compartment[a]	Geometrical opening factor, F′					
	0.02	0.04	0.06	0.08	0.10	0.12
A	1.0	1.0	1.0	1.0	1.0	1.0
B	0.85	0.85	0.85	0.85	0.85	0.85
C	3.0	3.0	3.0	3.0	3.0	2.5
D	1.35	1.35	1.35	1.50	1.55	1.65
E	1.65	1.50	1.35	1.50	1.75	2.00
F[b]	1.0–0.5	1.0–0.5	0.8–0.5	0.7–0.5	0.7–0.5	0.7–0.5
G	1.50	1.45	1.35	1.25	1.15	1.05
H	3.0	3.0	3.0	3.0	3.0	2.5

[a]A = (Standard fire compartment) The average consisting of brick, concrete, and gas concrete
B = Concrete, including concrete on the ground
C = Gas concrete (density 500 kg/m^3)
D = 50 % concrete, 50 % gas concrete (density 500 kg/m3)
E = 50 % gas concrete (density 500 kg/m3), 33 % concrete, and 17 % laminate consisting of (taken from the inside) 13 mm plasterboard (density 500 kg/m^3), 10 cm mineral wool (density 50 kg/m^3), and brick (density 1800 kg/m^3)
F = 80 % steel plate, 20 % concrete. The fire compartment is comparable to a storehouse or other building of a similar kind with an uninsulated roof, walls of steel plate, and floor of concrete
G = 20 % concrete and 80 % laminate consisting of a double plasterboard (2 × 13 mm) (density 790 kg/m^3), 10 cm air space, and another double plasterboard (2 × 13 mm) (density 790 kg/m^3)
H = Steel plate on either side of 100 mm mineral wool (density 50 kg/m^3)
[b]The higher values apply to $q < 60$ MJ/m^2; the lower values apply to $q > 500$ MJ/m^2. Intervening values are found by interpolation

the wood is exposed. The fire severity depends on such factors as available combustible material (fire load) and available air supply (design opening factor) [81]. The design fire load density is

$$q = k \cdot \frac{Q}{A_t} \tag{55.13}$$

where

q = Design fire load density (MJ/m^2)
k = Transfer coefficient (dimensionless)
Q = Sum of the products of mass and lower calorific value of materials to be found in the compartment (MJ)
A_t = Total internal area of the compartment, including floor, walls, ceiling, windows, and doors (m^2)

The transfer coefficients are given in Table 55.3 for different types of compartments and geometrical opening factors. In the case of fire compartments whose bounding structures do not come under any of the types A–H, k is usually determined by a linear interpolation in the table between appropriately chosen types of compartments.

The geometrical opening factor is

$$F' = \frac{A\sqrt{h}}{A_t} \tag{55.14}$$

where

F' = Geometrical opening factor (m^{½})
A = Total area of windows, doors, and other openings in walls (i.e., vertical openings only) (m^2)
h = Weighted mean value of the height of vertical openings, weighted against the area of the individual openings (m)

The design opening factor is

$$F = F' \cdot k \cdot f \tag{55.15}$$

where

F = Design opening factor (m$^{1/2}$)
F' = Geometrical opening factor (m$^{1/2}$)
k = Transfer coefficient of bounding structure (dimensionless)
f = Coefficient (dimensionless) to account for horizontal openings

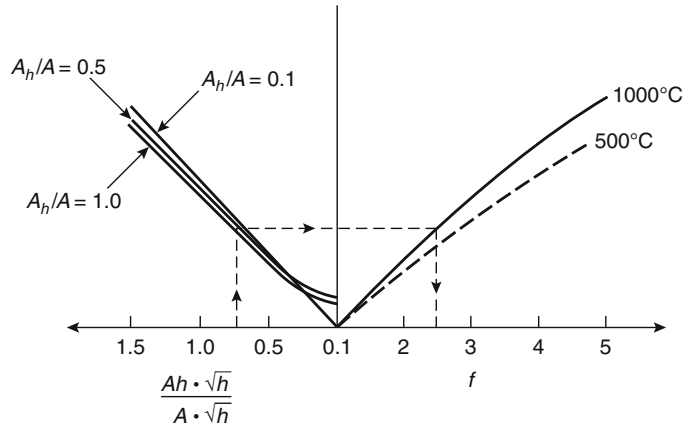

Fig. 55.3 Diagram for the determination of f for fire temperatures of 500 °C and 1000 °C [56]

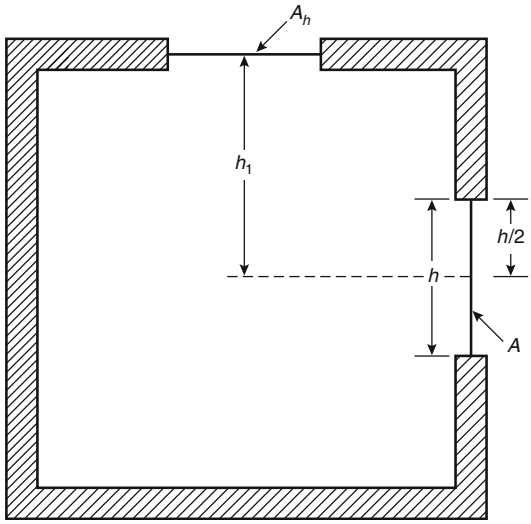

Fig. 55.4 Simplified sketch of vertical cross section of ventilated compartment with notation [56]

The dimensionless coefficient, f (Figs. 55.3 and 55.4), increases the opening factors when there are horizontal openings. For only vertical openings, f is equal to 1.

Hadvig's [56] equations are

$$\theta = 0.0175\frac{q}{F} \tag{55.16}$$

$$\beta_0 = 1.25 - \frac{0.035}{F + 0.021} \quad \text{for } 0.02 \le F \le 0.30 \tag{55.17}$$

$$X = \beta_0 \cdot \tau \quad \text{for } 0 \le \tau \le \frac{\theta}{3} \tag{55.18}$$

$$X = \beta_0 \left(-\frac{1}{12}\theta + \frac{3}{2}\tau - \frac{3}{4}\frac{\tau^2}{\theta} \right) \quad \text{for } \frac{\theta}{3} \le \tau \le \theta \tag{55.19}$$

where

θ = Time at which maximum charring is reached for the values used for F and q (min)
β_0 = Initial value of rate of charring (mm/min)
X = Charring depth (mm)
F = Design opening factor ($m^{1/2}$) (defined in Equation 55.15)
q = Design fire load density (MJ/m^2) (defined in Equation 55.13)
τ = Time (min)

These equations are valid for fire exposures less than 120 min and for a room where the combustible material is wood. Plastic burns more intensely and for a shorter time than wood. When the combustible materials in the room are plastics, Equations 55.16 and 55.17 are therefore modified for faster char rate (β_0 is 50 % higher), shorter time is allowed for maximum charring (θ is cut in half), and Equation 55.18 is applicable for τ less than θ.

Equations 55.16 through 55.19 are for glued-laminated timber with a density of 470 kg/m^3, including a moisture content of 10 % and minimum width of 80 mm or greater or square members of minimum 50 × 50 mm.

Equations 55.18 and 55.19 are valid only for $0 < X < b/4$, where b is the dimension of the narrow face of a rectangular member.

For dimensions of nonsquare cross sections between 30 and 80 mm, the ratio of the original dimensions must be equal to or greater than 1.7, the charring depth perpendicular to the wide face is X, and the charring depth perpendicular to the narrow face is determined by multiplying Equation 55.18 or 55.19 by the dimensionless quantity

$$1.35 - 0.0044(b) \qquad (55.20)$$

where b equals the dimension of the narrow face (mm).

Example 2 The room is a standard fire compartment consisting of brick, concrete, and gas concrete. The floor area is 5 × 10 m, and the height is 3 m. The openings are one window 1.5 m high and 2.0 m wide, three windows 1.5 m high and 1.0 m wide, and one skylight 1.5 × 3.0 m. The skylight is 2 m above the midheight of the windows. The fire load is 6 m^3 of wood.

Assuming a fire temperature of 1000 °C, a wood density of 500 kg/m^3, and a lower calorific value of 17 MJ/kg, describe the charring of a 38 × 250 mm wood beam exposed on three sides after 8 min of the fire. The geometrical opening factor (Equation 55.14) is

$$F' = \frac{A\sqrt{h}}{A_t} = \frac{[1(1.5 \times 2) + 3(1.5 \times 1)]\sqrt{1.5}}{[2(5 \times 10) + 2(3 \times 5) + 2(3 \times 10)]} = \frac{7.5\sqrt{1.5}}{190} = 0.048 \mathrm{m}^{1/2}$$

The design opening factor (Equation 55.15) is

$$F = F' \cdot k \cdot f$$

The k is obtained from Table 55.3 ($k = 1.0$ for type A, $F' = 0.048$). The f is obtained from Figs. 55.3 and 55.4.

$$\frac{A_1\sqrt{h_1}}{A\sqrt{h}} = \frac{(1.5 \times 3)\sqrt{2}}{7.5\sqrt{1.5}} = \frac{4.5\sqrt{2}}{7.5\sqrt{1.5}} = 0.69$$

$$\frac{A_h}{A} = \frac{4.5}{7.5} = 0.6$$

For $A_h\sqrt{h_1}/A\sqrt{h}$ of 0.69 and A_h/A of 0.6, the f from Fig. 55.3 is 2.4.

$$F = (0.048)(1.0)(2.4) = 0.115 m^{1/2}$$

The design fire load density (Equation 55.13) is

$$q = k \cdot \frac{Q}{A_t} = (1.0)\frac{(6 \times 500 \times 17)}{190} = \frac{51,000}{190} = 268 \mathrm{MJ/m}^2$$

Maximum charring rate will be reached at θ min (Equation 55.16):

$$\theta = 0.0175 \frac{268 \mathrm{MJ/m}^2}{0.115 \mathrm{m}^{1/2}} = 41 \mathrm{min}$$

The initial charring rate (Equation 55.17) will be

$$\beta_0 = 1.25 - \frac{0.035}{0.115 + 0.021} = 1 \mathrm{mm/min}$$

At 8 min, the char depth (Equation 55.18) will be

$$X = 1 \times 8 = 8 \mathrm{mm} \text{ for } 0 \le 8 \le \frac{41}{3}$$

The smaller dimension b of the beam is 38 mm. The charring depth criterion $0 < x < b/4$ is $0 < 8 < 9.5$ mm, so Equations 55.18 and 55.19 are valid. The ratio of the original dimensions is 25/3.8, or 6.6. Because 38 mm is less than 80 mm, the multiplying factor (Equation 55.20) is

$$1.35 - 0.0044(38) = 1.18$$

At 8 min, the uncharred area of the beam will be approximately

$$38 \text{ mm} - 2(8 \text{ mm}) = 22 \text{ mm wide}$$

and

$$250 \text{ mm} - (1.18 \times 8 \text{ mm}) = 240 \text{ mm high}$$

As the charring proceeds after (9.5 mm)/(1 mm/min), or 9.5 min, the $b/4$ criterion of the equations no longer holds. This is because the charring rate increases as the temperature at the center of the beam starts to increase.

Using an opening factor method and parametric time-temperature curves, equations for natural fires are provided in Eurocode 5. The approach is a simplification of Hadvig's equations. In the 1994 edition of the Eurocode

5, the equation for the parametric charring rate during the period τ_0 is

$$\beta_{par} = 1.5\beta_0 \frac{5F - 0.04}{4F + 0.08} \quad (55.21)$$

where
$F = F'$ of Equation 55.14
β_0 = Design charring rate of Eurocode 5
The time period τ_0 is

$$\tau_0 = 0.006\frac{q}{F} \quad (55.22)$$

where q is the design fire load density of Equation. 55.13.

At τ_0, the char rate decreases to zero at $3\tau_0$. The maximum charring depth during the fire exposure and the subsequent cooling period is $2\beta_0\tau_0$. Equations are valid for F between 0.02 and 0.30 $m^{1/2}$, τ_0 of 40 min or less, and char depths less than one-quarter of the dimensions.

Buchanan [82] provides a table of char rate, char time, and char depth results from the above equations for a range of opening factors. The equations in the 1994 edition were modified for the 2004 edition of the Eurocode 5. In the 2004 equations, the $5F$ and $4F$ in Equation 55.21 were modified to be a function of the thermal properties of the compartment boundaries.

Oleson and König [83] tested glued-laminated beams and found agreement with Hadvig's equations for the wide vertical side of a member. Oleson and König [83] noted that, compared with conditions at standard exposure, the mechanical behavior at natural fire exposure is different due to the changes of temperature in the residual cross section during the cooling period. The influence of elevated temperature is no longer concentrated to the outer layer of the residual cross section.

Theoretical Models

Considerable efforts have gone into developing theoretical models for wood charring, and work in this area is continuing. Janssens [84] observes that more than 50 wood pyrolysis models have been developed since World War II. Moghtaderi [85] provides a review of pyrolysis models of wood developed over the past 60 years. Theoretical models allow calculation of the charring rate for geometries other than a semi-infinite slab and for nonstandard fire exposures.

Roberts [86] reviewed problems associated with the theoretical analysis of the burning of wood, including structural effects and internal heat transfer, kinetics of the pyrolysis reactions, heat of reaction of the pyrolysis reactions, and variations of thermal properties during pyrolysis. He considered the major problems to be in the formulation of a mathematical model for the complex chemical and physical processes occurring and in the acquisition of reliable data for use in the model.

Many models for wood charring are based on the standard conservation of energy equation. The basic differential equation includes a term for each contribution to the internal energy balance. An early model for wood charring was given by Bamford et al. [87]. The basic differential equation used by Bamford was

$$c\rho\frac{\partial T}{\partial t} = K\frac{\partial^2 T}{\partial X^2} - q\frac{\partial w}{\partial t} \quad (55.23)$$

where
K = Thermal conductivity
T = Temperature
X = Location
w = Weight of volatile products per cubic centimeter of wood
t = Time
q = Heat liberated at constant pressure per gram of volatile material evolved
c = Specific heat
ρ = Density

In Equation 55.23, the term on the left side of the equal sign represents the energy stored at a given location as indicated by the increase or decrease of the temperature with time at that location. The first term on the right side of the equal sign represents the thermal conduction of energy away from or into the given location. The second term on the right side represents the energy absorbed (endothermic reaction) or the energy given off (exothermic reaction) as the wood undergoes pyrolysis or thermal degradation. Numerical solutions using computers are normally used to solve these differential equations.

In Bamford's calculations using Equation 55.23, the rate of decomposition was given by an Arrhenius equation. The heat of decomposition, q, was the difference between the heat of combustion of the wood and that of the products of decomposition. Thermal constants for wood and char were assumed to be the same, and the total thickness of char and wood was assumed to remain constant.

Thomas [88] added a convection term to Bamford's equation to obtain

$$\rho c\frac{\partial T}{\partial t} = K\frac{\partial^2 T}{\partial X^2} + Mc_g\frac{\partial T}{\partial X} - q\frac{\partial w}{\partial t} \qquad (55.24)$$

where
M = Local mass flow of pyrolysis gases
c_g = Specific heat of the gases

The convection term represents the energy transferred in or out of a location due to convection of the pyrolysis gases through a region with a temperature gradient.

The Factory Mutual Research Corporation model (SPYVAP) includes terms for internal convection of volatiles and thermal properties as functions of temperature and density. It was developed by Kung [89] and later revised by Tamanini [90]. Atreya [91] has further revised this model to include moisture absorption. His energy conservation equation is

$$\begin{aligned}\left(\rho_a C_{pa} + \rho_c C_{pc} + \rho_m C_{pm}\right)\frac{\partial T}{\partial t} &= \frac{\partial}{\partial X}\left(K\frac{\partial T}{\partial X}\right) \\ &+ i\left(1 - j\frac{\rho_c}{\rho_f}\right)M_g\frac{\partial H_g}{\partial X} \\ &- \frac{\partial \rho_s}{\partial t}\left[-Q + \left(H_a - H_c\frac{\rho_f}{\rho_w}\right)\Big/\left(1 - \frac{\rho_s}{\rho_w}\right) - H_g\right] \\ &- \frac{\partial \rho_m}{\partial t}\left(-Q_m + H_m - H_g\right)\end{aligned} \qquad (55.25)$$

where
C_p = Specific heat (J/[kgK])
K = Thermal conductivity (W/[m K])
T = Temperature (K)
t = Time (s)
X = Distance (m)
ρ = Density (kg/m^3)
M_g = Outward mass flux of volatile gases (kg/m^{2}s)
H = Thermal-sensible specific enthalpy (J/kg)
Q = Endothermic heat of decomposition of wood for a unit mass of volatiles generated (J/kg at T_x)
i,j = Parameters to simulate cracking, between 0 and 1

Subscripts:
∞ = Ambient
w = Virgin wood
c = Char
g = Volatile gases
a = Unpyrolyzed active material
m = Moisture
f = Final value
s = Solid wood

Equation 55.25 is similar to the previous equations except the material has been broken up into its components (wood, water, and char). The parameter j eliminates the convection term if the pyrolysis gases are escaping through cracks or fissures in the wood. The last term represents the heat absorbed with vaporization of the water. The conservation of mass equation is

$$\frac{\partial M_g}{\partial X} = \frac{\partial \rho_s}{\partial t} + \frac{\partial \rho_m}{\partial t} \qquad (55.26)$$

and ensures that the mass of the gases equals the mass loss due to thermal degradation of the wood and vaporization of the moisture.

As noted before, the decomposition kinetics equation for wood is the Arrhenius equation

$$\frac{\partial \rho_s}{\partial t} = -A\frac{\left(\rho_s - \rho_f\right)}{\left(1 - \rho_f/\rho_w\right)}\exp(-E/RT) \qquad (55.27)$$

where
A = Frequency factor (1/s)
E = Activation energy (J/mol)
R = Gas constant

Atreya [91] uses a moisture desorption kinetics equation for vaporization of the water in the wood, which is

$$\frac{\partial \rho_m}{\partial t} = -A_m\rho_m\exp(-E_m/RT) \qquad (55.28)$$

The CMA model [92] developed for NASA provides good results for oven-dry wood because it includes surface recession. Parker [93, 94] has taken char shrinkage parallel and normal to the surface into account in the model. Parker also includes different Arrhenius equations for each of the three major components of wood: (1) cellulose, (2) hemicelluloses, and (3) lignin.

There may be not only moisture desorption but also an increase in moisture content behind the char front caused by moisture movement away from the surface [95]. A model of Fredlund [96] includes mass transfer as well as heat transfer and provides for surface recession due to char oxidation.

In a model for wood combustion, Bryden et al. [97] modeled the wood pyrolysis kinetics, including tar decomposition, using three competing primary reactions and two secondary reactions. The surface boundary layer includes both char shrinkage and surface recession due to char combustion.

To describe the natural smoldering of logs after a forest fire, Costa and Sandberg [98] modeled the steady one-dimensional propagation of infinitesimally thin fronts of drying, pyrolysis, and char oxidation. Kanury and Holve [66] have presented dimensional, phenomenological, approximate analytical, and exact numerical solutions for wood charring. Other models include those of Havens [99], Knudson and Schniewind [100], Kansa et al. [101], Hadvig and Paulsen [102], Tinney [103], and Janssens [84]. Badders et al. [104] examined the ability of four commercial finite element analysis programs (FIRES-T3, SAFIR, TASEF, COMSOL) to model exposed wood beams.

The option of theoretical models or advanced calculations for the determination of charring rates and temperature profiles is addressed in the Eurocode 5. For purpose of such calculations, the Eurocode 5 provides values for the equivalent conductivity, specific heat capacity and the char/wood density ratio as a function of temperature.

Cachim and Franssen [63] used the finite element program SAFIR and the Eurocode property data to examine the effects of density, moisture content, and anisotropy on charring rates. Janssens [105] used the finite element software package COMSOL Multiphysics and the Eurocode 5 data to model some glued laminated beams in fire resistance test.

A major issue in the use of the more sophisticated models is the adequacy of the available data to use as input. The thermophysical properties for wood pyrolysis models are discussed by Janssens [106, 107]. Wood properties are discussed at the conclusion of this chapter. Most theoretical models for wood charring not only define the charring rate but also provide results for the temperature gradient. This temperature gradient is important in evaluating the load-carrying capacity of the wood remaining uncharred.

Load-Carrying Capacity of Uncharred Wood

In the standard ASTM E119 test of a wood member, structural failure occurs when the member is no longer capable of supporting its design load. The charring of the wood reduces the cross-sectional area of the member such that the ultimate capacity of the residual member is exceeded.

During the charring of the wood member, the temperature gradient is steep in the wood section remaining uncharred. The temperature at the innermost zone of the char layer is assumed to be 300 °C. Because of the low thermal conductivity of wood, the temperature 6 mm inward from the base of the char layer is about 180 °C once a quasi-steady-state charring rate has been obtained. Some loss of strength undoubtedly results from elevated temperatures.

The peak moisture content occurs where the temperature of the wood is about 100 °C, which is about 13 mm from the char base. Schaffer et al. [108] have combined parallel-to-grain strength and stiffness relationships with temperature and moisture content and the gradients of temperature and moisture content within a fire-exposed slab to obtain graphs of relative modulus of elasticity, compressive strength, and tensile strength as a function of distance below the char layer (Fig. 55.5).

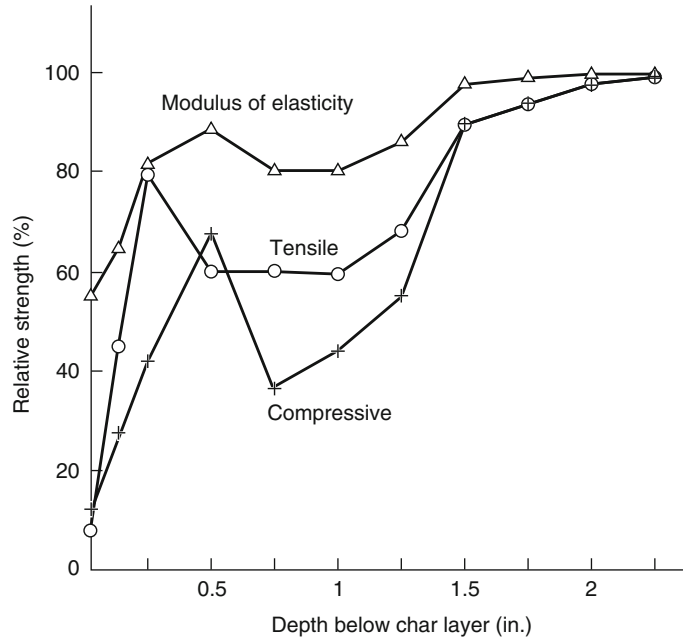

Fig. 55.5 Relative modulus of elasticity and compressive and tensile strength as a function of distance below char layer in softwood section under fire exposures (Expressed in percentage of that at 25 °C and initial moisture content of 12 %.) Duration of fire exposure should be equal to or greater than 20 min to apply results of this figure

Various equations for the temperature gradient within the charred wood slab have been developed [62, 109, 110]. An equation based on a power term is

$$T = T_i + (300 - T_i)\left(1 - \frac{x}{d}\right)^2 \qquad (55.29)$$

where
T = Temperature (°C)
T_i = Initial temperature (°C)
x = Distance from the char front (mm)
d = Thermal penetration depth (mm)

In the tests of White and Nordheim [59], an average value for the thermal penetration depth was 33 mm. Based on European tests, a more conservative value of 40 mm was recommended for the thermal penetration depth [110]. The power term does not provide for the plateau in temperatures that often occurs at 100 °C in moist wood. The power term has also been used to estimate the temperature profile in wood exposed to a constant heat flux [74]. Frangi and Fontana [62] observed that the thermal penetration depth was dependent on time and developed an alternative equation:

$$T(x) = 20 + 180\left(\frac{\beta t}{x}\right)^{\alpha} \qquad (55.30)$$

where
T = Temperature at depth x (°C)
β = Charring rate (mm/min)
t = Time (min)
x = Distance from the surface of the cross section (mm)
and

$$\alpha(t) = 0.025t + 1.75 \qquad (55.31)$$

Equation 55.30 was derived assuming the char front at 200 °C and char rate of 0.7 mm/min. Frangi and Fontana [62] also developed the following equation for a timber beam exposed to fire on three sides:

$$T(x, y) = 20 + 180(\beta t)^{\alpha} \left[\left(\frac{1}{x}\right)^{\alpha} + \left(\frac{1}{b - x}\right)^{\alpha} + \left(\frac{1}{y}\right)^{\alpha}\right] \qquad (55.32)$$

where T, t, α, and β are as defined for Equation. 55.30, and x and y are the depths from the

surfaces of the cross section in millimeters. The theoretical models discussed previously can be used to determine the temperature gradient within the wood remaining uncharred.

There are two approaches to evaluating the load-carrying capacity: to evaluate the remaining section either as a single homogeneous material or as a composite of layers or elements with different properties. In the single homogeneous material approach, one uses either reduced material properties or the room-temperature material properties. A greater reduction in cross-sectional area is calculated if the material properties are not reduced.

Reduced Properties Models

One approach in accounting for the loss in strength in the section remaining uncharred is to assume that the strength and stiffness of the entire uncharred region are fractions α of their room-temperature values. For bending rupture of a beam, an equation of this type would be

$$\frac{M}{S(t)} = \alpha\sigma_0 \tag{55.33}$$

Where
α = fraction of room-temperature values
M = Applied moment (design load)
S = Section modulus of charred member
σ_0 = Modulus of rupture at room temperature
t = Time

Assuming the residual cross section is rectangular in shape before and during fire exposure, the section modulus of charred solid rectangular bending members with the neutral axis perpendicular to depth at center is [109]

$$S(t) = \frac{1}{6}\left[(B - 2C_1 t)(D - jC_2 t)^2\right] \tag{55.34}$$

where
B = Original breadth of beam
D = Original depth of beam (depth>breath)
C_1 = Charring rate in breadth direction
C_2 = Charring rate in depth direction
j = 1 for three-sided fire exposure (top edge covered) or 2 for four-sided fire exposure (Fig. 55.6)

Alternative to Equations 55.33 and 55.34 are the following, Equations 55.35 through 55.36:

$$\left(\frac{k}{\alpha}\right)\frac{\frac{B}{D}}{\left[\frac{d}{D} - \left(1 - \frac{B}{D}\right)\right]} = \left(\frac{d}{D}\right)^2 \tag{55.35}$$

for exposure on all four sides [111], and

$$\frac{k}{\alpha}\frac{B/D}{[B/D - 2(1 - d/D)]} = \left(\frac{d}{D}\right)^2 \tag{55.36}$$

for exposure on three sides [112], [113],
where
k = Load, as fraction of room temperature ultimate load of original member
d = Critical depth of the uncharred beam

The fire resistance is equal to the time to reach the critical depth, or

$$t = (D - d)/jC \tag{55.37}$$

Proposed α values ranged from 0.5 in New Zealand to 0.83 in France [109]. The differences in α values are due to uncertainty, differences in design load, and desired level of safety. The application of the above equations is generally limited to large wood members. In light-frame members, α values would be substantially lower [114]. In Eurocode 5, this approach is called the "reduced properties method." The reduction factors are a function of the perimeter of the fire-exposed residual cross section divided by the area of the cross section.

In addition to bending rupture, the fire resistance of a beam may depend on lateral buckling of the beam [111]. Similar expressions can be developed for columns and tension members [2, 109, 113, 115]. Early reviews of fire resistance design methodologies for large wood members include those of Schaffer [109], Pettersson [116], and Barthelemy and Kruppa [117].

Kirpichenkov and Romanenkov [118] discussed the calculation procedures in the Soviet Union. The fire resistance of wood structures is also briefly discussed by Odeen [119]. In developing a model for fire-exposed

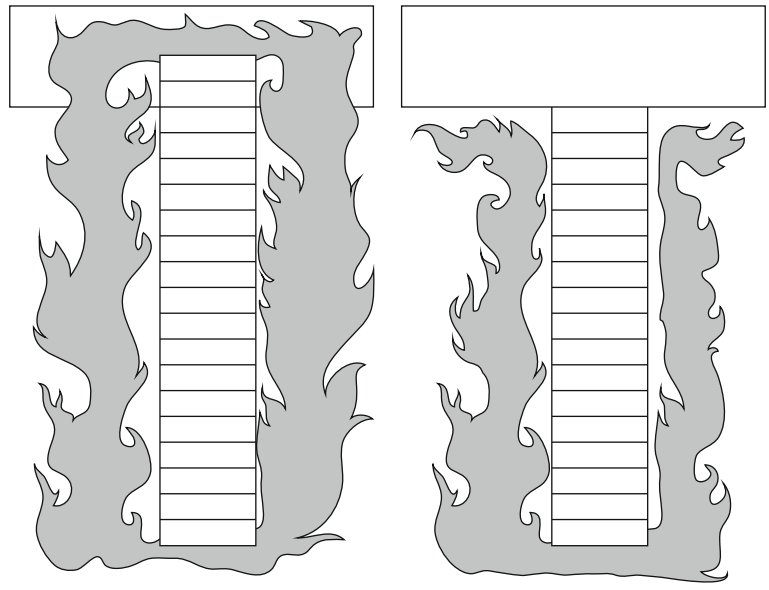

Fig. 55.6 Fire exposure of beams on three or four sides

unprotected wood joist floor assemblies, Woeste and Schaffer [120, 121] evaluated various time-dependent geometric terms that could be used to modify the strength reduction factor. The selected term was

$$\alpha = \frac{1}{1 + \left(\frac{B+2D}{BD}\right)\gamma t_f} \tag{55.38}$$

where

t_f = Failure time

γ = Empirical thermal degrade parameter

The model has been experimentally evaluated [122, 123], extended to floor-truss assemblies [121, 124] and used as part of a first-order second-moment reliability analysis of floor assemblies [120, 121]. Reliability-based design of the fire resistance of light-frame construction is also discussed by Lau and Barrett [114]. In a model for metal plate–connected wood trusses [125], the strength degradation factors for the wood are calculated as a function of the duration of exposure and the temperature profile within the wood component.

The models for load-bearing floor joist and wall studs in Annex C of Eurocode 5 incorporate the notional char depth within the calculation of the modification factor for the strength properties. König and Källsner [126, 127] developed such a modification factor for wood I-joists.

Reduced Cross-Section Area Models

A more common approach is to assume an equivalent zero-strength layer, δ, and then evaluate the rest of the member using room-temperature property values [128]. In the model of Schaffer et al. [108] for beams, the δ was estimated to be 8 mm (0.3 in.) thick. This zero-strength layer, δ, was added to the char depth, βt, to obtain the total zero-strength layer.

This zero-strength layer model was incorporated within a reliability-based model to predict the strength of glued-laminated beams with individual laminates of various grades of lumber [129]. This zero-strength layer approach is called the "reduced cross-section method" in Eurocode 5 [6]. In Eurocode 5, δ is a linear fraction of 7 mm for the initial 20 min and 7 mm after 20 min.

In the NDS method [130, 131], a 20 % increase in the charring rate is used to account for a zero-strength layer. Schmid et al. [128] presented an analysis that indicates that various

factors such as fire exposure, shape, and dimensions of the cross-section may affect the optimum thickness for the zero-strength layer. Further analysis by Klippel et al. [132] also indicated that members in compression would be better modeled using a zero layer thickness greater than the 7 mm currently specified.

For fire-damaged members, Williamson [133] recommended 6 mm (0.25 in.) for designs controlled by compression (16 mm [0.625 in.] if design is controlled by tension) and the use of 100 % of the original basic allowable stresses in calculation of load capacity.

Performance of the structural member in a fire will depend on the ratio of the applied load to the ultimate capacity of the residual member. Calculations of the structural capacity of the remaining cross section are normally made using ultimate strength values. Design or characteristic strength values are used in the Eurocode 5 calculations. In Eurocode 5, the design value of strength is the 20th percentile of the cold strength divided by a partial factor equal to one.

The design stress to member strength adjustment factors in the NDS are discussed in the next section. Design methods account for the various factors affecting performance in different manners. Care must be taken to verify that all the design values and the methodologies are compatible.

The reduced cross-section area approach is being used to predict the fire resistance ratings of walls and floors built of cross-laminated-timber (CLT) construction as described by Dagenais et al. [48]. Frangi et al. [134] developed a reduced cross-section model for calculating fire resistance of timber slabs with hollow core elements. Reduced cross-section methodologies are also used to evaluate the load capacity aspect of fire resistance for both unprotected [130] and protected light-frame assemblies [6].

NDS Method for Exposed Wood Members

The *National Design Specification for Wood Construction* (NDS®) method for the fire design of exposed wood members is a mechanics-based design method that is applicable to all wood structural members covered under the NDS. With explicit equations for the residual fire resistance of the wood members, it is possible to adjust the equations for other member types and loading conditions.

The charring rate can be modified for specific wood products. It is described in a chapter of the NDS and other articles [131]. Full documentation is provided in Technical Report 10 of the American Wood Council [130]. In the United States, code recognition is via adoption of the 2005 or later editions of the NDS. It is limited to ratings of 2 h or less.

This effective cross-section method uses the nonlinear charring model of Equation 55.6 and strength values at ambient temperatures. An increased char rate accounts for reduced strength and stiffness properties and accelerated charring at the corners. The increase in char depth is 20 % over a nominal char rate that is based on 1 h of fire exposure. Thus, the effective char rate is given by

$$\beta_{\text{eff}} = \frac{1.2\beta_n}{t^{0.187}} \tag{55.39}$$

where

β_{eff} = Effective char rate (mm or in. per hour) adjusted for exposure time, t

β_n = Nominal char rate (mm or in. per hour) linear char rate based on 1-h exposure

t = Exposure time

A nominal char rate, β_n, of 38 mm (1.5 in.) per hour is normally assumed for solid-sawn and glued-laminated softwood members. The effective char depth is β_{eff} multiplied by time. Thus, the effective char depth at 1 h is 46 mm (1.8 in.); the actual char depth is 38 mm (1.5 in.) and the equivalent zero-strength layer thickness is 7.6 mm (0.3 in.). The section properties of the members are reduced by the effective char depth for the surfaces that are exposed to the standard fire exposure.

The resisting strength or average ultimate residual strength properties are calculated by multiplying the allowable design stress values

in the NDS by design stress-to-member strength adjustment factors. Values for this adjustment factor are 2.85 for bending and tensile strength, 2.58 for compression strength, and 2.03 for beam-buckling and column-buckling strength.

As appropriate, the allowable design stress values are also multiplied by a size factor, volume factor, flat use factor, beam stability factor, and column stability factor as described in the NDS. For a fire resistance rating of time t, the induced stress of the reduced section of the charred member at time t shall not exceed the resisting strength of the member.

For glued-laminated timber bending members with tension laminations, the NDS has requirements for the substitution of core laminations with tension laminations. The specifics depend on the fire resistance rating and the details of the beam construction.

Decks

The NDS method addresses the structural requirements for fire resistance of timber decks. Decks are specified to have a thickness of at least 51 mm (2 in.). Butt-jointed decking is designed as a series of beams that have reduced charring on the partially protected sides and normal charring on the exposed bottom surface.

The char rate for the sides is one-third of the effective char rate (Equation 55.39). Single and double tongue-and-groove (T&G) decking is assumed to have charring on only the one bottom face. Janssens [135] applied a transformed section analysis of a timber deck and the Eurocode 5 effective cross-section method to develop a simplified design equation (thickness and load factor as variables) for timber decks that was similar to the T.T. Lie equations.

In addition to the requirement of structural stability, the fire resistance rating of a timber deck also depends on requirements for thermal protection. Thermal protection criteria provide for excessive temperature rise on the unexposed surface and flame penetration.

In the United States, there is no recognized procedure for solid wood floors or roofs that include the thermal failure criteria of ASTM E119. The equations for the temperature profile in a wood slab discussed previously can be used to estimate the required thickness to prevent excessive temperature rise [135, 136]. A deck is likely to have joints and gaps between the boards that become the controlling factor in the fire resistance of the deck. Joints can be a critical factor in the fire resistance of a wood barrier. Eurocode 5 provides some guidance for joints in wood-based panel products.

The estimated failure times for such panel products with a butt joint, lap joint, single T&G joint, or double T&G joint are 20, 30, 40, and 60 %, respectively, of the failure times for a solid wood barrier calculated using charring rates for wood.

The application of these adjustments developed for panel products to gaps in decks has been investigated. Based on a series of tests of timber decks, Richardson and Batista [44] concluded that the failure times for simple butt joints, single T&G joints, and double T&G boards were 10, 40, and 40 %, respectively, of the times for a solid wood member estimated using charring rates for wood. In the tests, the specification for the gaps between boards was 2 mm (0.08 in.) or less. These tests also illustrated the effect of increasing the thickness of gaps, particularly with butt joints. For gaps of $\leq$1 mm ($\leq$0.04 in.), the tests suggested that failure times for simple butt joints were 30 % of those for solid-sawn lumber instead of the 10 % for gaps of 2 mm (0.08 in.) or less.

Adding wood flooring or panel products on top of the timber deck improved the failure times in the tests of Richardson and Batista [44]. Paneling on top of the decks provided the most benefits to the fire resistance of decks when the butt joints had 4 mm (0.16 in.) gaps, compared with decks of T&G joints or narrow gaps.

Given the limited ability to control gaps between deck boards over time, the best method to address the joint issue is to provide a

multilayer deck assembly by adding panel products or other floor topping, such as gypsum concrete or lightweight or normal concrete toppings, on top of the heavy timber decks. Frangi and Fontana [62] found that the fissures between nailed-laminated timber planks did not increase the char rate but noted that the nonexposed surface must be sealed airtight to obtain such results.

Connections

Connectors and fasteners relating to support of the member must be protected for equivalent fire-resistive construction. Carling [137] summarizes work done in Europe on the fire resistance of joint details in load-bearing wood construction. Buchanan [82] also reviews the literature on the fire performance of connections. Eurocode 5 provides rules for the fire resistance of connections and protecting connections in fire-rated timber members, and the subject is discussed by König [4, 5, 138] and by Östman et al. [6].

Rules are given for connections made with nails, bolts, dowels, screws, split-ring connectors, shear-plate connectors, and toothed-plate connectors. Moss et al. [139] determined values for embedment strength as a function of temperature and predicted failure times for fire exposed bolted connections with steel and wood splice plates by applying the data to Johansen's yield equations. Racher et al. [140] used a three-dimensional finite element model to examine the thermal and mechanical behavior of dowelled timber connections exposed to fire. Peng et al. [141] reviewed recent studies on fire performance of connections and provided equations for failure times of double shear connections with either bolts or wood dowels.

Configurations for the double sheer connections included wood-wood-wood (W-W-W), wood-steel-wood (W-S-W), and steel-wood-steel (S-W-S). The equations for W-W-W and W-S-W connections incorporated char rate, load ratio, wood side member thickness, and fastener diameter. In the case of S-W-S connections, the equation of Peng et al. [141] included the load ratio and the thickness of the wood component. Peng et al. [141] reported that a single layer of 16 mm (0.625 in.) Type X gypsum board improved the fire resistance of the connections by about 33 min and reviewed results for intumescent paints.

In U.S. procedures with building code recognition, the protection of connections is addressed by prescriptive requirements. Where minimal 1 h fire resistance is required, the International Building Code (U.S.) requires connectors and fasteners must be protected from fire exposure by 38 mm (1.5 in.) of wood or other approved covering or coating for a 1 h rating. Industry publications [130] include diagrams giving typical details of such protection.

Adhesives

There have been a number of recent investigations on the potential impact of new adhesives on the fire resistance of structural wood products. These new adhesives are replacing the traditional resorcinol-formaldehyde and phenol-resorcinol-formaldehyde in structural wood products.

A note in the Eurocode 5 states that the softening temperature is considerably below the charring temperature of the wood for some adhesives. In response to concerns about the fire performance of non-phenol resorcinol adhesives in finger-jointed lumber, there were efforts in the United States to develop qualification tests for the performance of adhesives in fire-rated wood assemblies. An initial effort was a test protocol (ASTM D 7247 "Test method for evaluating the shear strength of adhesive bonds in laminated wood products at elevated temperatures") for evaluating the shear strength of adhesive bonds in laminated wood products at elevated temperatures [142].

Performance criteria based on this test were added to specifications for laminated wood products. To address the specific concerns of finger-jointed lumber, two related ASTM standards (ASTM D7374 "Practice for evaluating elevated temperature performance of

adhesives used in end-jointed lumber and D7470 "Practice for evaluating elevated temperature performance of end-jointed lumber studs" were developed as performance criteria for the "Heat Resistant Adhesives" (HRA) grade stamp on end-jointed lumber. End-jointed lumber with the HRA grade stamp was allowed to continue to be an acceptable substitution in fire-rated assemblies tested with solid-sawn lumber.

In Europe, Frangi et al. [143] tested the shear behavior of five one-component polyurethane (PUR) adhesives as well as a resorcinol-formaldehyde (RF) and an epoxy adhesive as controls at temperatures up to 170 °C. The performance of the five PUR adhesives ranged from the very good high temperature performance of the RF adhesive to the poor high temperature performance of the epoxy.

Finite element calculations using the reduced elevated temperature shear properties were consistent with an unexpected shear failure within a glued laminated beam in a fire resistance test of a timber-concrete composite slab. While generally not used in structural wood products, tests have shown that epoxy-based adhesives can have poor fire performance [82].

Källander and Lind [144] conducted a comparative study of six different adhesives before and after exposure of glulam beams to fire. König et al. [145] tested small-sized glued laminated beams in bending. The fire resistance of the beams made with the two polyurethane adhesives and the melamine urea formaldehyde adhesive were less than that for the beam made with the traditional phenolic resorcinol formaldehyde adhesive.

Frangi et al. [146] reported substantial differences in temperature dependent strength reduction and failure between several different types of adhesives, particularly when tested in tension. It is expected that concerns about the non-phenol adhesives can continued to be successfully addressed either by improvements in the formulations of the adhesives to comply with appropriate performance criteria or modifications to the fire resistance calculation methodologies to accurately reflect the performance of the structural wood composite products.

Composite Models

The most complex approach to evaluating the fire resistance of a wood member is to assume that the uncharred region consists of layers or elements at different temperatures and moisture contents. The strength and stiffness properties depend on the temperature and moisture content profiles. These are referred to as "advanced methods" in Eurocode 5.

In one model with layers, the compressive and tensile strengths and modulus of elasticity of each layer are assumed to be fractions of the room-temperature values. Using one 38 mm (1.5 in.) heated layer with reduced properties, Schaffer et al. [108] analyzed a beam using transformed section analysis. In the similar elastic transformed section model of King and Glowinski [147], the heated zone of the remaining wood section is divided into two layers at elevated temperatures. Transformed section analysis is also used by Lee-Gun Kim and Jun-Jae Lee [148] and by Janssens [135].

Finite difference and finite element methods have been used to solve the governing equations for heat and mass transfer. A finite difference model for wood beams and columns was developed by Tavakkol-Khah and Klingsch [149]. The finite element analysis software COMSOL Multiphysics was used by Janssens [105] to predict failure times of glulam beams tested with load levels of zero, 27 %, 44 % and 91 % of design load. Schnabl at al. [150] examined timber composite beams used the finite element method to solve the Luikov's equations for simultaneous heat and mass transfer. Fragiacomo et al. [151] used the general purpose finite element code Abaqus to conduct 3-D finite modeling of the thermo-structural behavior of laminated veneer lumber (LVL) loaded in tension and exposed to fire.

Do and Springer [152–154] proposed a fire resistance model for wood beams based on mass loss versus strength data. The work included a program to predict the temperatures and mass loss within the wood member. The input data came from small-scale tension,

compression, and shear tests done on specimens that had previously been heated in an oven. Examples of models that use a grid of elements to analyze the residual load capacity of the structural member include ones for wood joists [155], compression members [156], and wood studs [28].

Property Data

Proper input data are critical to the use of any model. For the models discussed in this section, property data include strength and stiffness properties and thermal properties. General property data for clear wood can be found in various chapters of *Wood Handbook*: *Wood as an Engineering Material* [64], which also includes a chapter on fire safety.

Reviews of available data on properties needed to model thermal degradation, charring, and residual load capacity of wood members can be found in the literature [82, 107]. Equations and graphs of the strength and stiffness of wood as functions of temperature and moisture content are available [157–159].

Recent research in the development of fire resistance models has provided additional data specific for application to such models. An extensive study on fire-exposed wood in tension was done by Lau and Barrett [160]. Recent efforts have been on the compression properties of wood [161, 162]. The strength reductions given in Eurocode 5 include the time-dependent effects of creep, moisture, and mechanosorption. Such effects are among the reasons for differences reported in the literature.

Preheating samples in an oven is not the same as exposing samples to simultaneous thermal and structural loads. Other methodology differences, such as rate of loading, affect the experimental results reported.

Thermal properties can also be found in the various references for charring models and Annex B of Eurocode 5 (EN 1995-1-2). As discussed by König [163], the thermal properties of EN 1995-1-2 and other sources are often effective property values that depend on the assumptions of the model and the experiments used to calibrate the input data.

Due to the complexity of wood, thermal degradation, and the heat and mass transfer within the wood element, some aspects of the complexity are accommodated by adjusting the thermal property data. Thus, such thermal property data may be applicable only to the standard fire exposure used in their development and can produce erroneous results when applied to natural fires and parametric fire curves [163]. This is particularly the case for the thermal properties of the char layer. As discussed by Hadvig [56], the "char" of the char layer is complex and its thermal characteristics are not the same as those of charcoal. Lattimer et al. [164] used inverse heat transfer analysis of fire test data for balsa wood to obtain thermal properties, physical properties and decomposition kinetics constants needed for their decomposition model.

Although assuming constant property values is often less complicated, these properties are very often a function of other properties or factors. Most wood properties are functions of density, moisture content, grain orientation, and temperature. Chemical composition may also be a factor.

Because an understanding of these factors is important to the application of property data, the factors are defined in the rest of this section. The oven-dry density of wood can range from 160 kg/m^3 (10 lb/ft^3) to over 1040 kg/m^3 (65 lb/ft^3), but most species are in the 320- to 720-kg/m^3 (20- to 45-lb/ft^3) range [64]. The density of wood relative to the density of water (i.e., specific gravity) is normally based on oven-dry weight and volume at some specified moisture content, but in some cases the oven-dry volume is used.

As the empirical equations for charring rate show, materials with higher density have slower char rate. In the Eurocode 5 discussion of advanced calculations, the suggested char/ dry wood ratios are 1.0, 1.0, 0.93, 0.76, 0.52, 0.38, 0.28, 0.26, and 0 for temperatures of 20, 200, 250, 300, 350, 400, 600, 800, and 1200 °C, respectively.

Wood is a hygroscopic material, which gains or loses moisture depending on the temperature and relative humidity of the surrounding air. Moisture content of wood is defined as the weight of water in wood divided by the weight of oven-dry wood. Green wood can have moisture content in excess of 100 %. However, air-dry wood comes to equilibrium at moisture content less than 30 %. Thirty percent moisture content is also considered the approximate moisture content at which the cell walls are saturated with water, but there is no water in the cell lumens. This condition is known as the *fiber saturation point*. At higher moisture contents, water exists in the cell lumens.

Many physical and mechanical properties of wood change with moisture content only at moisture contents below the fiber saturation point. Under the conditions stated in ASTM E119 (50 % relative humidity), the equilibrium moisture content is about 9 %. Moisture generally reduces the strength of wood but also reduces the charring rate.

Both density and moisture content affect the thermal conductivity of wood. The average thermal conductivity perpendicular to the grain is [64]

$$k = S(0.0001941 + 0.000004064M) + 0.01864 \quad (55.40)$$

where

k = Thermal conductivity (W/mK)

S = Density based on volume at current moisture content and oven-dry mass (kg/m^3)

M = Moisture content (percent)

Equation 55.40 is valid for moisture contents of 25 % or less, densities greater than 300 kg/m^3, and temperature of 24 °C. Conductivity increases about 2–3 % per 10 °C [64]. In the Eurocode 5 discussion of advanced calculations, the suggested values for "apparent thermal conductivity" of the wood/char as a function of temperature are 0.12, 0.15, 0.07, 0.09, 0.35, and 1.50 W/mK for 20. 200. 350, 500, 800, and 1200 °C, respectively.

The fiber (grain) orientation is important because wood is an orthotropic material. The longitudinal axis is parallel to the fiber or grain. The two transverse directions (perpendicular to the grain) are the radial and tangential axes. The radial axis is normal to the growth rings, and the tangential axis is tangent to the growth rings. For example, the longitudinal strength properties are usually about ten times the transverse properties, and the longitudinal thermal conductivity is 1.5–2.8 times the transverse property.

In fire resistance analysis, temperature can have a significant influence on the properties of wood. The preponderance of property data is often limited to temperatures below 100 °C. The effect of temperatures on the strength properties of wood is shown in Figs. 55.7, 55.8, and 55.9. Using data from a variety of sources, Buchanan [82] also provides graphs of the temperature effect on mechanical properties. The heat capacity, c_ρ (kJ/kg K), of dry wood is approximately related to temperature, T (in K), [64] by.

$$c_\rho = 0.1031 + 0.003867T \quad (55.41)$$

In the Eurocode 5, the suggested apparent specific heat capacity values are 1.53, 1.77, 13.60, 13.50, 2.12, 2.00, 1.62, 0.71, 0.85, 1.00, 1.40, 1.65, and 1.65 kJ/kg-K for 20, 99, 99, 120, 120, 200, 250, 300, 350, 400, 600, 800, and 1200 °C, respectively. These values results in a sharp peak between 99 and 120 °C to address water vaporization. These values are tied to the suggested char/wood ratios with the addition of the moisture content to the ratio for temperatures between 20 and 99 °C.

For moist wood below the fiber saturation point, the heat capacity is the sum of the heat capacity of dry wood and that of water and an additional adjustment factor for the wood-water bond [64]. Studies on thermal properties of wood and char continue to be active areas of research.

The major components of wood are cellulose, lignin, hemicelluloses, extractives, and inorganic materials (ash). Softwoods have lignin contents

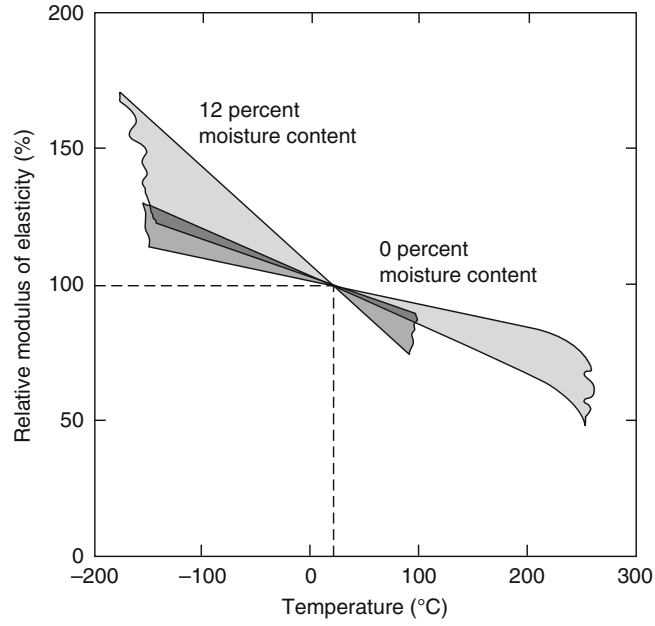

Fig. 55.7 The immediate effect of temperature on modulus of elasticity parallel to the grain at two moisture contents relative to value at 20 °C. The plot is a composite of results from several studies. Variability in reported trends is illustrated by the width of bands [64]

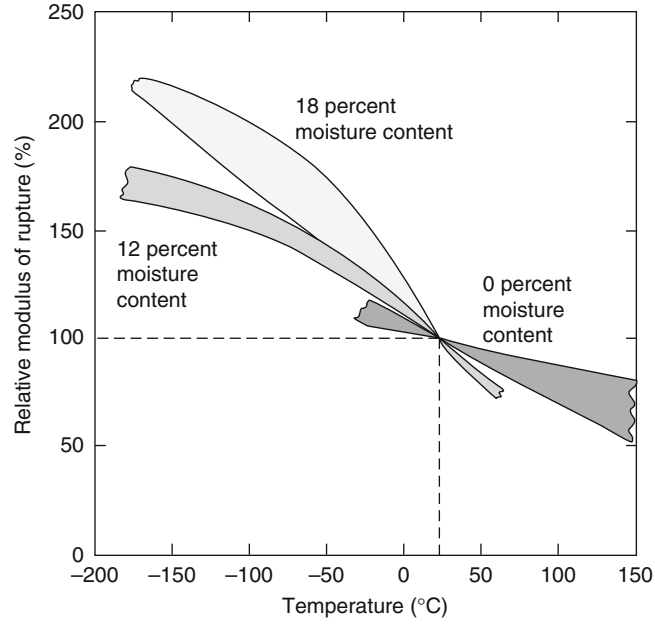

Fig. 55.8 The immediate effect of temperature on modulus of rupture in bending at three moisture contents relative to value at 20 °C [64]

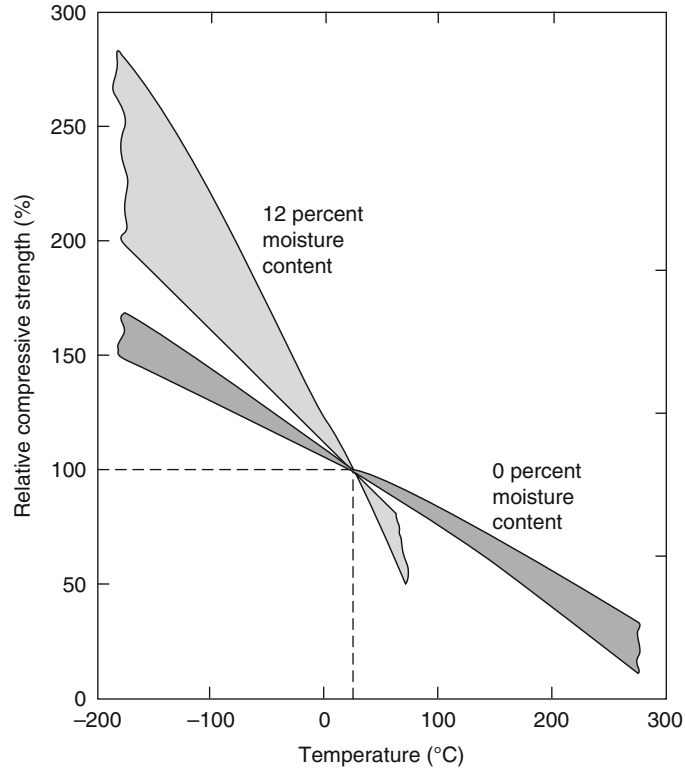

Fig. 55.9 The immediate effect of temperature on compressive strength parallel to the grain at two moisture contents relative to the value at 20 °C [64]

of 23–33 %, whereas hardwoods have only 16–25 %. The types and amounts of extractives vary. Cellulose content is generally around 50 % by weight.

The component sugars of the hemicelluloses are different for the hardwood and softwood species. Chemical composition can affect the kinetics of pyrolysis (Equation 55.27) and the percentage weight of the residual char. In the degradation of wood, higher lignin content results in greater char yield.

Egress Concepts and Design Approaches

56

Richard W. Bukowski and Jeffrey S. Tubbs

Introduction

Among the most important concepts in fire safety in buildings is to manage those potentially exposed to the fire and its effects, either by protecting them in place or by moving them to a place of safety. Protected spaces and paths of travel needed to accomplish this are the egress components, systems and procedures that are discussed in this chapter. The chapter presents an overview of considerations, concepts, methods, and strategies utilized globally for emergency egress system design. Approaches to full or partial evacuation using stairs or elevators, egress for people with disabilities, protect-in-place strategies, and alternatives to evacuation, are presented. Prescriptive and performance-based approaches are discussed and strategies for selecting specific systems are summarized.

Additional information on performance-based evacuation modeling, occupant movement simulation, human behavior during emergencies, and occupant and scenario factors is detailed in other chapters.

Chapter 57 presents methods for considering occupant factors within designs.

Chapters 61 and 63 present methods for assessing tenability and criteria for use in engineering studies.

Chapter 58 presents human behavior concepts and theory and how data is collected.

Chapter 64 presents studies of flow rate and walking speed applicable for use in engineering studies.

Chapters 59 and 60 present evacuation calculation and simulation methods and techniques.

The purpose of this chapter is to present the historical evolution of emergency egress provisions in public buildings and the varying approaches utilized to facilitate egress along with their scientific basis. By understanding the scientific basis the engineer should understand the intended performance in the context of performance based design and alternate approaches utilized to address the special needs of specific occupants or unique facilities.

The chapter begins with the history of emergency egress systems including the scientific basis for the 44 in. (1100 mm) egress stair width, the concept of exit capacity used in US Codes, flow rate, fire escapes and the 7/11 stair geometry. This should help to understand the goals and objectives of the codes and the levels of performance anticipated from the common prescriptive approaches to egress system arrangements. Next, a discussion of common strategies that address specific objectives and the expanding list of egress system components are discussed in their context of use along with related systems that notify people of the need to

take action and that provide route guidance during the action. Finally, performance-based design concepts that are frequently used to justify alternative egress system designs in unique or constrained buildings are presented.

Historical Perspective

For many years, buildings were short enough that stairs provided for access were sufficient for safe and rapid egress for most occupants in the event of fire. Until passage of the Americans with Disabilities Act (PL101-336) in 1990, buildings were rarely accessible, and emergency egress of people with disabilities was not a national priority. Even in single stair (mostly residential) buildings, experience indicated that this stair was sufficient for fire egress as long as the fire did not expose or block access to the stair. Fire resistant apartment doors shielded the stair from most fires and exterior fire escapes provided a second egress path beginning early in the Twentieth Century. The 1854 invention of the elevator safety brake enabled the passenger elevator. This system is credited with facilitating increases in building height beyond six floors and the first so-called skyscraper in Chicago in 1885 [1].

Model building regulations in the US started with the National Building Code published by the National Board of Fire Underwriters (NBFU) following the Great Fire of Boston in 1872. Property loss claims from this fire resulted in more than 70 insurance companies being driven into bankruptcy, causing insurance interests to form the NBFU and to develop building fire safety rules aimed at reducing property losses in fires. These rules became the first model building code, called the National Building Code (NBC), first published in 1905. The NBFU was able to tie compliance with their rules to their Municipal Grading Schedule on which insurance rates are based. Cities needed favorable rates to attract investment, so they were motivated to adopt regulations consistent with the National Building Code. The first edition of the NBC required exit stairs to have a minimum width of 20 in. (510 mm) [2].

Origins of the 44 in. Exit Stair in the US

In the 1913 National Fire Protection Association (NFPA) Proceedings, the Committee on Fireproof (later, Fire-Resistive) Construction reported a number of recommendations, including a minimum unobstructed width of 44 in (1100 mm) exit stairs. Handrails were permitted to intrude not more than 3.5 in. (89 mm) on each side. That same year, NFPA formed their Committee on Safety to Life. That committee's first activity was to conduct a comprehensive review of fire safety issues and regulatory approaches found in building codes and local regulations in several, geographically diverse cities. At the meeting [1], they reported that [3],

> . . . existing laws are exceedingly deficient in this very important matter of egress. A number of states report frankly that they have no real legislation upon the subject, many City Ordinances are of the most indefinite character, and in some the matter is simply left to the discretion of the fire department or other officials.

In the 1914 NFPA Proceedings section on egress, the Safety to Life Committee cites the 1913 NFPA Annual Meeting report of the Committee on Fire-Resistive Construction in which they said was presented [1].

> . . . a splendid set of specifications for the construction of a standard building. Egress received detailed attention;—specifications for smokeproof towers, for stairs, for horizontal exits, and for the capacity of vertical and horizontal exits were included.

The committee also cites the 1913 laws of the New York State Department of Labor which, ". . . as regards fundamentals appear to agree entirely with the requirements of our Committee . . .". Extracting from the referenced New York statute, they cite [1],

(a) For buildings erected in the future, a minimum of 22 in. (550 mm) of stair width shall be required for not to exceed 14 persons on any one floor.
(b) On buildings already erected this figure is reduced to 18 in. (450 mm) as a minimum.
(c) A 44-in. (1100 mm) stair in new buildings permits 28 persons to be housed on each floor above the first one.

(d) In arriving at this decision the idea has been that all of the persons on all floors shall be able to remain in the stair tower without any movement, a person requiring about 22 in. (550 mm) in width, and one person to stand on every other stair.

This committee further characterizes the New York laws' stair geometry (7.75 in. riser height by 10 in. tread) as "good", and that they recommend a minimum 44 in. wide stair for new buildings as this width is "sufficient to prevent three persons from forming an arch and blocking traffic" [4].

Exit Capacity

The above explains why the US designs exits for "capacity" and why the capacity is based on the population of a single floor. The exit is sized to "store" people, motionless within the protected exit enclosure, such that the population of one floor will fit entirely within the stair between that floor and the next floor below, with each person in a space 22 in. wide and standing on every other step.

This philosophy was recognized in the 1935 National Bureau of Standards (NBS now NIST) publication, *Design and Construction of Building Exits* [5]. Developed by the Department of Commerce Building Code Committee, this report included survey data on exit sizes and configurations drawn from eight cities chosen, "... with a view to covering places varying in size and sufficiently distributed to give a fair cross section of building construction." The survey included population counts on typical floors and compiled data on movement of people in buildings, as well as railway terminals (particularly at rush hour which was considered to be similar to emergency movement in a fire) and schools. Studies of the flow of occupants in government buildings during fire drills and of the general public exiting railway terminals at rush hour were conducted, and the data resulted in discharge rates for stairs (as a function of width and stair geometry), ramps, and doorways.

The data was used to suggest possible approaches to calculating the minimum width of exits necessary to provide for occupant safety. These included five, proposed methods (text paraphrased from the 1935 NBS report):

1. Capacity Method, which is based on the concept of storing occupants on the stairs within a protected stair enclosure, and allowing for the subsequent safe and orderly evacuation of the building. It recognized that travel down a long series of stairs in high buildings is exhausting even to normal persons. Objections of building owners over the loss of rentable space are noted as well as the comment by some authorities that people may not stand still in stairways, even in relatively taller buildings, preferring instead to proceed to the street.
2. Flow Method, which is based on the concept that people will move down the stairs at a typical flow, assumed to be 45 persons per 22 in. unit of width per minute and 60 persons per minute through doorways. It is stated that this method is usually coupled with an assumed time in which it is safe to exit the building and that this method calls for considerably less stairway width than the capacity method. However, the committee felt that it would be limited to a few occupancies and to buildings of low to moderate height since continuous movement down stairways in relatively taller buildings cannot be expected without serious effects on some occupants.
3. Combined Method suggests the flow method for lower buildings shifting to the capacity method for taller buildings also accounting for type of construction and use. Once again NBS pointed out that taller buildings would require a disproportionate amount of space devoted to stairways as compared with useable floor area.
4. Probability Method considers only the population of the six most densely populated floors since it was considered improbable that simultaneous evacuation of all floors of a large building would be needed. This is the first time that phased evacuation, as currently practiced in tall buildings, was suggested.
5. Floor Area Method relates area to units of exit width needed as a function of construction type and use. As in the probability

method, simultaneous evacuation of all floors is not considered; however, the number of floors that were considered to simultaneously evacuate varied with occupancy.

In the end, the 1935 report suggests that the needs of the vast majority of buildings can be met with the provision of two, two-unit-width (44 in. or 1100 mm) stairs. The capacity method, which includes occupants waiting within the exit enclosure, is appropriate for shorter buildings with a gradual shift to the flow method for taller buildings where people will be less comfortable waiting in the stair. For tall buildings the floor area method has some application as these are of fire resistive construction and only those near the floor of fire origin are initially at risk. NBS suggests half of the floors should be considered with the floor area method.

Early Thoughts on Elevators as a Means of Egress

Both the 1914 NFPA Proceedings [1] and the 1935 NBS report [5] discuss the possible use of elevators for egress from tall buildings. In 1914 the Committee on Safety to Life expressed the opinion that, "... elevator shafts properly enclosed and with openings adequately protected have decided value from an escape standpoint, and are absolutely necessary in high buildings." They cited as "... loss of life possibilities in many modern so-called fireproof buildings ..." the common practice of unenclosed stair and elevator shafts that might permit a fire in lower stories to, "... spread with unexpected speed ..." which "... could result in a loss of life which would stagger the civilized world." The Committee called for enclosing elevator shafts, improving the fire resisting powers of elevator doors, ensuring the integrity of the electric current applied to elevators, and "drilling" elevator operators in emergency procedures, including that persons in the upper stories "shall first be taken to the ground."

The 1935 NBS report discusses a credit for elevators against required aggregate exit width. They discount automatic elevators as unsuitable, as their "...capacity and rate of speed is not great," and "... they are not subject to a single will as in the case of an elevator operator, but to demands from many tenants." While there was a suggestion in the formulae of the flow method that five elevators might be equal to a single unit of exit stair width for some construction types and use, in the end they concluded that the uncertainties were such that no direct credit be given for elevators but to recognize their availability in high buildings.

Early Regulatory Approaches in the US

The 1914 report of the Committee on Safety to Life included detailed recommendations for the design and arrangement of egress stairs and fire escapes with the intent that this material would be incorporated by others into building regulations. No code or standard was produced by the Committee until the 1927 publication of the first edition of the NFPA Building Exits Code (NFPA 101-T) [6] which later became the Life Safety Code.

The 1927 edition of NFPA 101-T defined stairs as Class A, B, or C. Class A stairs were the main stair of a newly-constructed Assembly occupancy, and were 44 in. (1100 mm) wide (handrails could intrude not more than 3.5 in. (89 mm) on each side) with a rise of not more than 7 in. (178 mm) and a tread of not less than 10.5 in. (267 mm). Class B stairs were for new construction of all stairs not required to be Class A, and for existing construction where Class A stairs would be required if new. Class B stairs were the same width as Class A but the rise was permitted to be not more than 7.75 in. (197 mm) with a tread of not less than 9.5 in. (241 mm). Class C stairs covered existing stairs in existing buildings and were at least 36 in. (900 mm) wide (not less than 32 in. or 810 mm between handrails, but stairs less than 44 in. (1100 mm) wide only required a handrail on one side). Occupant load on a floor dictates the capacity (total width of stairs in number of

22 in. (550 mm) units) to be provided in a minimum of two stairs located "as remote as practical."

The 1935 NBS report included recommended code language in an appendix that did not follow any of the five methods for calculating minimum exit widths discussed previously. They explained that tentative requirements were drawn up and compared against the results of the field studies. Eventually a consensus of the Committee was reached and was presented in the recommended code language.

The suggested code requirements largely followed the capacity method for at least two stairs of two 22 in. (550 mm) units of exit width each, with the floor area method used, by means of occupancy load factors consistent with those found in current regulations, to determine aggregate width. No suggestions of maximum egress time, including no references to fire resistance times associated with construction types, building height, and use, that might facilitate the use of the flow method, and no mention of partial evacuation of tall buildings as discussed in the probability and floor area methods was made. These recommendations were consistent with those in the 1927 edition of NFPA 101-T, but this is not surprising since the Committee on Safety to Life was well represented on the NBS Committee. The requirements suggested in the NBS report and NFPA 101 were generally adopted in the model codes and building regulations throughout the US until the mid-1980s when the 22 in. (550 mm) unit of exit width was abandoned for assessing exit capacity in units of people per inch, but retaining the 44 in. (1100 mm) minimum width. This method provides similar results for aggregate exit width but provides more capacity credit for fractions of the 22 in. (550 mm) unit.

Early Scientific Studies of Flow Rate

The 1935 NBS report [5] included field surveys of discharge rates down exit stairs and through doors for various government buildings during drills and for subway and rail terminals at rush hours. The data collected was discussed by the Committee and a consensus reached that there was a clear correlation between width and flow. The committee agreed that "... rates of 45 persons per 22-in. unit per minute for travel down stairways, and 60 persons per 22-in. unit per minute through doorways, which had been in use on the basis of earlier observations, were sufficiently confirmed to warrant their retention in connection with the requirements under development."

Almost from the start there were issues raised with the assumed flow rate on stairs of 45 persons per minute per 22 in. (550 mm) unit of exit width. Togawa [7] in Japan conducted research in the 1940s and 1950s, that showed for densities above one person per square meter (10 ft^2), flow rates decreased significantly. His data suggested a flow rate of 26 persons per minute per (22 in.) unit of exit width.

Pauls [8] has published extensively on this topic and continues to be the scientific conscience of stair design in the US codes. Pauls [8] and Fruin [9] both discussed the concept of effective width of a stair, which is generally 0.3 m (1 ft) narrower than the actual width due to the natural tendency of people to keep a distance from walls and handrails. Fruin further spoke of the personal space (buffer) around people that increases their effective space requirement. Pauls found that for people walking on stairs, their body sways from side to side and they desire sufficient space so that they do not make contact with the person beside them. Pauls work confirmed that of Togawa, finding flow rates in stairs at typical densities to be approximately 27 persons per minute per (22 in.) unit of exit width. Extensive studies in Russia also confirmed the effects of density on flow rates and confirmed the values suggested by Pauls [8] and Togawa [10].

Chapter 64 details flow rate and walking speed studies applicable for use in engineering simulation and studies.

Early Scientific Studies of Exit Width

The current 44 in. (1100 mm) minimum exit stair width is intended to support two, 22 in. (550 mm) queues of occupants either standing still (capacity method) or moving down the stair. This also allows counterflow, which occurs when a single queue of occupants moving down are passed by firefighters or other responders moving up. The 22 in. (550 mm) dimension for the width of a person was offered in 1914, originating from soldiers standing in a line [3].

Challenges to the adequacy of the 22 in. (550 mm) dimension include the need to provide for body sway as people move down the stair [8], and the need to allow for some personal space [9,10]. Recently, the adequacy of the basic 22 in. dimension has been questioned in light of the increasing size and weight of the typical person, especially in the US. The 22 in. dimension refers to the width of a person at the shoulders, which is assumed to be the widest part. Predtechenskii and Milinskii suggest that 4 in. (100 mm) be added to each side to allow for a personal buffer except that for low obstructions (like handrails) the additional space is not needed since one's shoulders are at a higher level and will extend over the obstruction.

From anthropometric data for modern Americans, the width at the hip is approaching the width at the shoulder, and it seems that this exception may no longer be valid. Thus, with the shoulder width of the 97.5th percentile adult male reaching 20 in. (510 mm) [11] and allowing the 4 in. on each side for handrail and personal space, the new unit of exit width should be 28 in. (700 mm) and the minimum stair width 56 in. (1400 mm), see Fig. 56.1.

Arguably the most comprehensive studies of movement on stairs were conducted by Templer [12], beginning with his doctoral research [13] and including work at NBS in the 1980s. Templer observed the movement of many individuals up and down stairs of varying width and tread geometry, tabulating variables ranging from quantitative (speed, number of stumbles) to qualitative (perceived comfort). From this work Templer concluded that the minimum width of an egress stair should be 56 in. (1400 mm).

Scientific Studies of Tread Geometry

One of the earliest studies of stair geometry was conducted by a seventeenth century architect in France named Francois Blondel [14]. Blondel was primarily interested in comfort rather than safety and observed that the main stairs of classic cathedrals were comfortable to use and accommodated large numbers of people attending services. He made measurements and found that the ratio of stair height to tread depth was a constant, and he related this dimension to the length of the human gait. His formula was $2R + G = 24$ in., where R is the rise and G is the going (or run). Templer [15] adjusted Blondel's formula for the use of the old (pre French Revolution) inch and a modern gait more like 28 in. (710 mm) and arrived at the formula, $2R + G = 710\,\text{mm}$. The 7 in. rise, 11 in. run stair geometry commonly required in US codes meets the relation $2R + G = 635\,\text{mm}$.

Templer [15] summarizes a number of research studies of stair geometry and safety. Many such studies were conducted by observing people moving up or down stairs in buildings. Observations in subway or train stations at rush hours provided data for higher population densities. A few studies were conducted in laboratory settings on specially constructed stair sections where the geometries and stair angle could be varied systematically. Templer himself conducted several of these studies, including some at NBS.

Most of the studies reviewed concluded that the measure of Total Energy Cost per Meter Rise [15] is a useful metric for the evaluation of stair design for normal use and comfort; however, stair safety is more closely related to the likelihood of missteps which is a function of how the stair relates to the human gait. In both cases, the effect is different for ascent and descent, with descent being more hazardous.

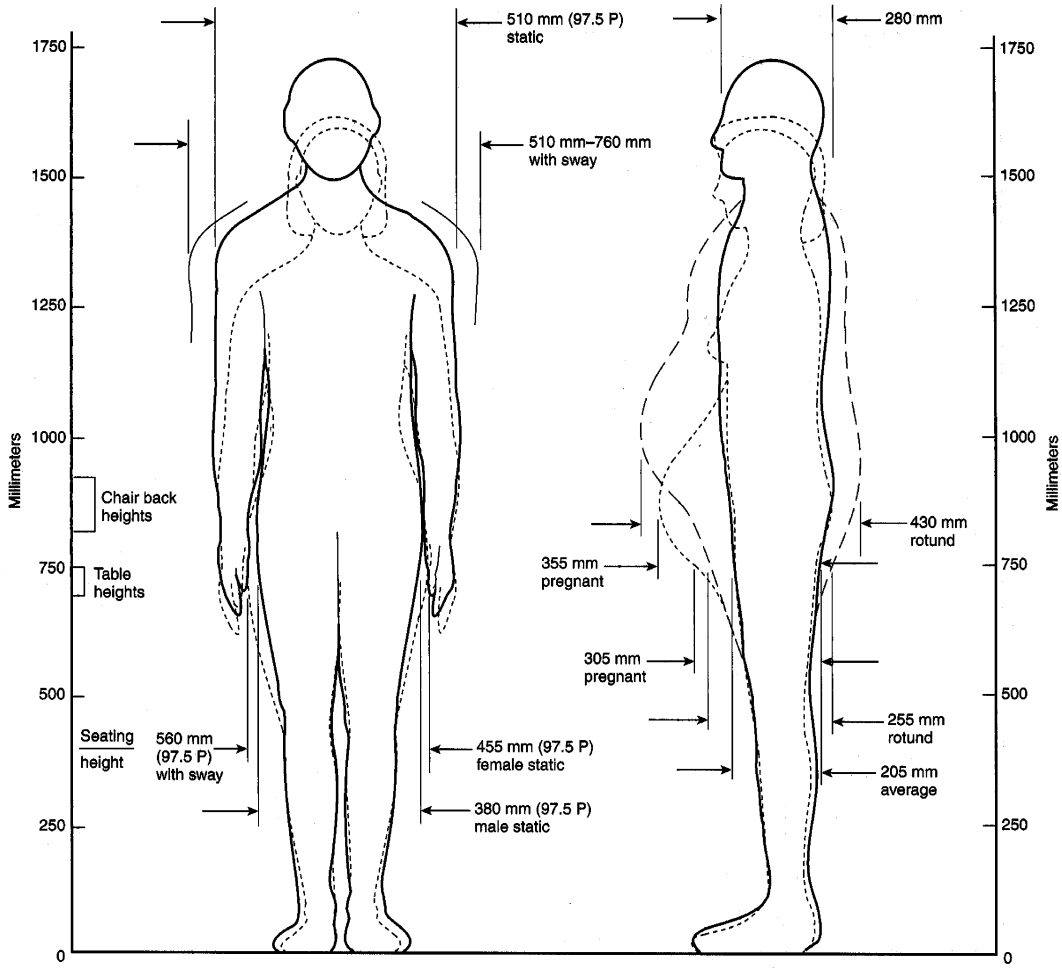

Fig. 56.1 Anthropometric data (in mm.) for adults; males and females of average, 50th percentile, size; some dimensions apply to very large, 97.5 percentile (97.5 P), adults (Reprinted with permission from NFPA 101®-2012, *Life Safety Code*®, Copyright © 2011, National Fire Protection Association, Quincy, MA). This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety

When ascending a stair, a person walks on the ball of the foot with less of the foot placed on the step. Shorter treads (goings) and higher risers produce fewer missteps. When descending a stair, the heel and most of the foot needs to be placed on the tread. Too much of the front of the foot extending over the nosing results in rotation of the foot and a fall, or a distorted gait while trying to place more of the foot on the tread. Tread depths of at least 11 in. (280 mm) are recommended to accommodate the 95th percentile foot, but considering only gait and accident history, treads (goings) of at least 9 in. (230 mm) are required. Riser heights of 6.3–7.2 in. (160–183 mm) had the fewest missteps. Other dimensions apply to curved stairs [16].

Other factors relevant to stair safety include lighting, slip resistance, single steps (most codes prohibit flights of fewer than three steps), handrails, and inability to detect the edge of the tread due to lack of visual contrast.

Fire Escapes

As with so many building code provisions relating to fire safety, requirements for exterior, non-combustible fire escapes began with tragedy. The mid-nineteenth century saw significant numbers of European immigrants settling in New York City, mostly in tenement buildings. The term generally refers to a substandard multi-family dwelling in the urban core, frequently old and occupied by the poor. These wood-frame, six-story buildings (six stories was considered the practical height limit before elevators) were crowded together in ethnic neighborhoods, generally home to several dozen families each crammed into one or two rooms with the only access and egress by a single, narrow stairway. Doors to family living rooms were usually wood panel doors with little fire resistance and the buildings often had commercial space on the ground floor. Fires starting in the commercial space or in a tenant space would quickly burn through the thin door and race up the stair, cutting off egress and trapping occupants who perished in full view of the street crowds attracted by the fire [17].

After a particularly gruesome fire that killed ten women and children in 1860 [18], New York City passed its first egress regulation, Chapter 470, Section 25 of the New York City Acts, entitled,—An Act to Provide Against Unsafe Buildings in the City of New York. This law applied to buildings housing more than eight families and required a 'fire-proof' stair attached to an exterior wall in a fire-proof building with the stair separated from all living spaces by doors. In buildings that were not fire-proof, the law required fire-proof balconies on each story of the exterior of the building connected by fire-proof stairs with all rooms communicating with the balconies and separated by doors. Since fire-proof construction was far too costly for tenement buildings, iron fire escapes became ubiquitous throughout the city.

It is interesting to note that in 1867, the Tenement House Act was enacted that required existing buildings to be furnished with fire escapes; perhaps the first example of a requirement applicable to existing buildings [17]. However, subjective provisions made enforcement difficult and many buildings were exempted or were equipped with fire escapes that collapsed, were not accessible from all rooms, or exited to narrow spaces or enclosed courtyards. Tragic losses continued in buildings without or with inadequate fire escapes, leading to several amendments to the laws, including requirements in 1871 to maintain fire escapes, transfer of responsibility from the health department to the fire department in 1882 and to the building department in 1892. The 1871 legislation extended requirements for fire escapes to hotels and other public buildings including theaters, schools, factories and hospitals.

By the beginning of the twentieth century a New York Tenement Commission surveyed tenement laws in 27 US cities and found that nearly all had some sort of egress regulation requiring fire escapes but often the details were left to the discretion of inspectors. Many disastrous fires with high death counts were attributed to occupants being trapped by the fire on upper floors or fires blocking the single exit. Fires that attracted national attention such as the Brooklyn Theater in 1876 (294 fatalities) and Chicago's Iroquois Theater in 1903 (605 fatalities), Ohio's Lake View school in 1908 (170 fatalities), and the Fifth-Avenue Hotel in St. Louis (100 fatalities) led to fire escape regulations in most major cities and to NFPA's development of the Building Exits Code in 1927. The Triangle Shirtwaist Fire in 1911 (146 fatalities) had a fire escape that collapsed under the weight of too many workers, which contributed to the high death count [19].

Egress Strategies

Egress strategies provide systems and features to allow people to safely exit structures, reach a place of safety, or safely remain in place during emergency conditions. These strategies need to be aligned with and support the overall life safety

goals and objectives, and be developed in concert with the overall fire protection and life safety program. Strategies form the basis of design for egress and other supporting features. Effective egress strategies are appropriate to the facility size and complexity, and reflect the facility, how it is used, characteristics of its occupants, fire protection and life safety systems, security features and arrangements, and hazards within the facility.

Systems are typically designed to allow occupants who are not intimate with the initial fire or emergency to escape the area of immediate hazard in order to reach a place of relative safety. The concept of protecting those "not intimate" with the incident is important. A common example of intimate with the ignition is a person involved with a fire igniting a bed, a chair or a couch while smoking [20].

Egress strategies should be based on the specific hazards expected to occur over the life of the facility. Typical egress strategies include evacuating all occupants to the exterior of the building (simultaneous full evacuation), evacuating a portion of the occupants (partial evacuation), defending occupants in place (defend or shelter in place), or relocating occupants to a safe place within the building (relocation). Partial evacuation relies on protect-in-place strategies for non-evacuating occupants. The process can be phased, initially evacuating only a portion of the occupants, or all occupants can be notified to exit simultaneously. For many structures, a single response for all events is appropriate. For others, a scalable approach that escalates from partial evacuation and protect-in-place to simultaneous full building evacuation may be necessary. Regardless of the strategy, wheelchair users, occupants with mobility impairments, or others with mobility or cognitive conditions that may hinder self-directed egress need to be considered. An overview of these strategies follows [20–23].

Simultaneous Full Building Evacuation

Simultaneous full-building evacuation has been the norm for most buildings up to six stories for many years and tends to be the most common strategy for life safety. This is usually arranged through unprotected paths of travel, with distances appropriate to the building use, to protected stairs that discharge to the public way. For tall buildings, iconic structures, large assembly buildings, or other facilities that require full-building evacuation, a performance-based engineered approach may be necessary to evaluate the impact of evacuating a large number of people simultaneously [20].

Timed egress analysis or computer-based evacuation simulation methods can help to better understand the potential impacts of specific features and strategies on evacuation times. Chapters 59 and 60 provide detail on developing timed egress analysis and computer-based evacuation simulation methods. These tasks can be completed as part of an informal qualitative process or through a formal threat and risk assessment. For tall buildings, evacuation elevators can be used to support simultaneous full-building evacuation and substantially reduce evacuation times while addressing the needs of people with disabilities.

Simultaneous full-building evacuation will require considerably longer times for many occupants to make their way out of a tall building. This leads to questions on messaging strategies and how occupants will react during the evacuation, such as "Are additional features and functionality of the life safety systems necessary to provide an appropriate level of situational awareness?" Special messaging strategies with enhanced voice communication systems and additional zoning to keep occupants informed of the situation in real-time can help to address these issues. Such situational awareness features can provide specific real-time information about an event, allowing occupants to make better decisions regarding whether to stay or leave, or more informed decisions about route choice and adapting route choice to the situation [24–27]. As noted in referenced discussion on these topics, careful planning is necessary to be sure that these systems do not become too complicated, that messages are appropriate, and that increased reliability is built into systems.

Simultaneous full building evacuation messages should be coordinated and directed by the responding local fire authorities or properly trained staff utilizing the voice communication system or the growing range of emergency communication system devices. Messages should follow established procedures defined in the emergency plan developed for the facility [11, 28–30].

When using full building evacuation strategies, attention should be given to notification messages and their effectiveness. Particular concern should be given to assumptions regarding pre-movement time, occupant characteristics, and assumptions regarding mobility and evacuation time, and building features that could restrict or impede occupant flow. Narrow doors or corridors, and other obstructions can impede flow [20].

The time required for evacuation raises concerns related to occupant and staff training. Occupants benefit from training to give people a feeling for the length of time necessary to exit the building. This would be particularly powerful if occupants understood how staff would manage the process and what process and information decision makers use during emergencies.

Consideration should be given to how occupants move and disperse once leaving the structure, particularly for tall buildings or other high occupant load structures in dense urban environments. For these examples, occupants will need a clear path for a safe distance from the structure.

Protect-in-Place

Protect-in-place strategies are also known as defend-in-place or shelter-in-place strategies. These strategies involve providing adequate safety features to allow occupants to remain in place during the event, and they are used in facilities with occupants that have a limited ability to be moved, either because they are incapacitated or they are immobile due to medical or physical restraint. Protect-in-place strategies also are used in highly compartmented structures, such as residential occupancies, where building separations provide protection and allow a portion of the population to safety use phasing strategies [20].

Designs using protect-in-place strategies use a combination of active and passive fire protection features and management procedures to provide an appropriate level of safety for occupants to remain in the initial compartment. Structures using a protect-in-place strategy are typically protected throughout with automatic sprinklers, and include fire-rated compartments to reduce smoke and fire spread.

Typical examples of facilities needing protect-in-place strategies are health care facilities, and detention and correctional occupancies. In hospital surgical suites and intensive care units, it may be difficult—if not impossible—for patients to initiate and complete escape without assistance. Some patients cannot be moved without significantly jeopardizing their safety. For these situations, a protect-in-place may even be used within the compartment of origin.

US building codes have required features for many years in high-rise buildings to allow protect-in-place strategies. In residential buildings, and similar occupancies, tenant and corridor separations compartmentalize floors, which can offer a level of safety that permits protect-in-place strategies. For example, in United Kingdom Approved Document B (Fire Safety), Provision 2.7 a single stair is permitted in sprinkler protected residential buildings regardless of height because general evacuation is not contemplated [31].

For some specific and isolated events, evacuation may not be the most appropriate action because the process of evacuation exposes occupants to higher risk. For example, consider a deadly 1988 fire within a New York City residential high-rise building—four occupants attempting to escape tragically died during this fire, while other occupants that remained in place were not injured [32]. A study of fires in hotel occupancies in the 1980s concluded that guests not in the room of origin may have been safer

sheltering in their rooms because most fatalities occurred during evacuation [33].

Other examples can be drawn from terrorist actions. Terrorists can use the fire alarm system to evacuate occupants to the street, and then detonate a car bomb. DHS [34] provides specific guidance for active shooter situations, which includes sheltering-in-place. Occupants may need to ignore evacuation alarms, as the alarms can be used by the shooter to entice potential victims out of safe locations.

Relocation

Relocating occupants from an area of potential hazard to a protected area of refuge or other safe place within a building can be a safe and effective strategy, and represents a variation on the protect-in-place strategy. The *ICC Performance Code* [35] defines a safe place as "... an interior or exterior area wherein protection from hazards is provided by construction or appropriate separation distance." As with protect-in-place strategies, relocation requires attention to management procedures and may require special detection and notification systems or other appropriate life safety features. Hospitals, nursing homes, detention and correctional facilities, and institutional facilities are examples of facilities that use relocation strategies. These facilities typically use horizontal exits, smoke barriers, protected floor separations, or other appropriate means to protect relocated occupants [22].

Relocation strategies can be used in tall buildings. Here, occupants are directed to relocate to floors below the fire and away from any fire impact. With relocation strategies, the floor and shaft fire ratings and structural fire protection are critical, as the lower floors are relied upon to provide a safe area perhaps for the duration of the incident [22].

Phased or Partial Evacuation

Phased and partial evacuation strategies combine evacuating or relocating a portion of the occupants—those in immediate danger from the incident—with allowing occupants remote from an incident to protect-in-place. In this way, phased evacuation helps to optimize the use of the available egress components. With phased evacuation, occupants remote from the fire initially remain in place, but can be evacuated later if conditions warrant evacuation of the entire building. Partial evacuation strategies require features to protect occupants remote from the incident [20].

In high-rise buildings in the US, typically the event floor and two floors above and below the event floor are evacuated [11, 36]. In theory, this allows occupants on the fire floor unobstructed use of the exit stairs, thus optimizing use of the exit components and reducing the evacuation time for the affected floor or areas. For both phased and partial strategies, occupants remote from the event floor and those in the evacuation floor zones are notified. Occupants not in the affected zone are asked to remain in place to await further instructions [20,22]. Notification of occupants outside of the affected zone is common practice in Canada.

In hospitals, phasing may be necessary for larger incidents if such incidents might compromise adjacent evacuation zones. Large assembly spaces also may allow remote occupants to remain in place, while those closer to and intimate with the incident immediately evacuate. Assembly examples include large convention centers with multiple event halls. Where convention center halls are appropriately separated, it may be possible to phase the evacuation using individual halls as evacuation zones.

Two fundamental assumptions are critical with this strategy: (1) the event will not impact occupants outside of the affected zone during the time necessary to evacuate the affected zone; and (2) occupants in the unaffected areas will remain in place.

This concept works well for 'traditional' events, such as a sprinkler-controlled fire in a high-rise building, because automatic suppression systems in high-rise buildings are designed with a degree of resilience and have proven to be generally effective and reliable in controlling or

suppressing fires. In sprinkler-controlled high-rise fire events, fire-rated floor and shaft separations minimize hazards to occupants on the unaffected floors. If it is deemed that the building will need to address events other than 'traditional' events, additional or more reliable fire safety measures may be necessary.

Changes in risk perception resulting from the September 11, 2001 attacks have impacted public acceptance of phased evacuation. Occupants may become aware of events through communication technologies, such as texting, and social media, rather than the building notification system. In the event of a disaster, occupants might ignore "standby" messages and instead decide to immediately exit the building, particularly where they are afraid that the building might collapse. This has been reported during drills in New York City high rises. Another complicating factor is that today's emergency response procedures are being developed for a broad range of potential threats, not just fires, many of which requiring significantly different actions. To accomplish this, designers need to account for occupant response to non-'traditional' events, such as wide-spread power loss, severe weather events, crowd incidents or civil disturbances, terrorisms, large scale hazardous material incidents, or transportation incidents [23].

Egress Strategies for People with Disabilities

Egress system designs need to accommodate the needs of people with disabilities. The Americans with Disabilities Act (ADA) mandates that expected disabilities be accommodated, and that structures allow for equal access.

The 2010 edition of the ADA references the IBC (2003 Edition) for requirements related to means of egress and areas of refuge. At least one accessible means of egress is required for every accessible space and at least two accessible means of egress are required where more than one means of egress is required. The technical criteria for accessible means of egress allow the use of exit stairways and evacuation elevators when provided in conjunction with horizontal exits or areas of refuge.

While typical elevators are not designed to be used during an emergency evacuation, evacuation elevators are designed with standby power and other features according to the elevator safety standard and can be used for the evacuation of individuals with disabilities. Codes typically require an elevator to serve an accessible floor that is four or more levels above the level of exit discharge [11, 36].

Evacuation elevators provide for occupant self-evacuation through elevators that are intended to be used during fire events [11, 36]. In buildings over 30 m in height, UK standards [37] require a fire service elevator that is also intended to provide egress assistance to people with disabilities.

The IBC provides requirements for areas of refuge, which are fire-rated spaces on levels above or below the exit discharge levels where people unable to use stairs can go to register a call for assistance and wait for evacuation. Individual floors within fully sprinkler protected buildings are considered to meet the requirements for area of refuge [11,20,36].

In general, codes require audible and visible notification appliances throughout public areas of all buildings and structures. Fire alarm systems are required to have capacity to add these devices in other occupancies to address the needs of persons with hearing impairments if hired.

Egress designs that serve those with disabilities need to consider the specific needs of the occupants. Emergency action plans may need to involve the disabled person to ensure that his/her needs are addressed [11,28]. People with service animals will be reluctant to leave those animals behind. Some wheelchairs are equipped with life support equipment and may weigh hundreds of pounds exclusive of the user. Plans may need to allow for these people to evacuate with the wheelchair. Stair descent devices, also known as evacuation chairs, can be provided on floors occupied by a person with a mobility limitation to help when evacuation is required. Traditional "buddy systems" that pair the disabled

with a co-worker to provide assistance are effective; however, this needs the co-worker to be available at the time of the emergency. Guidance on the development of customized plans for occupants of offices was developed after the 1993 WTC bombing [38].

Performance-Based Strategies

Prescriptive codes provide egress design guidance for a broad range of building types, occupancy, and use groups, and allow for many common arrangements. The Life Safety Code Handbook [39] and IBC Commentary [40] include helpful comments and explanations for prescriptive egress design approaches. Prescriptive approaches have been generally successful in providing safe egress from most structures. However, design flexibility is often compromised in order to create a comprehensive set of code provisions that apply to a broad range of uses and occupancies [22].

In contrast, performance-based egress approaches combine first-principles fire engineering analysis with estimates of evacuation times that assess the ability of occupants to safely exit buildings for a range of fire conditions or other events. Performance-based approaches require safety systems to be designed to meet specific life safety goals for a range of hazards and events. This can result in increased design flexibility, as it affords the opportunity to align overall building objectives with fire safety objectives. With this flexibility, however, comes an additional design burden, as analysis is needed to demonstrate that occupants can safely exit under the range of expected design scenarios. Performance-based designs are discussed later in this chapter [22].

Selecting and Evaluating Options

When selecting an appropriate egress strategy, the strategy needs to match the ability, activity and responsiveness of the occupants, the technology used, and the ability and reliability of staff or occupants to assist in the process. The selection of an appropriate egress strategy hinges upon the emergency scenarios considered, and evacuation and emergency response planning. The communication and messaging strategies need to match the evacuation strategy. Other considerations include the number of people who will need to evacuate, whether all occupants within the facility will be exposed to hazardous conditions, and the occupants' familiarity with the exits and egress routes. Egress strategies should be developed to guide the design of egress features, rather than be developed after the building is built [22].

For complex facilities, it is often necessary to develop an overall fire and life safety strategy to coordinate these features. Voice communication, suppression, and detection system zones need to match with the evacuation zones. Emergency lighting is necessary in exit pathways to allow safe movement during power outages. Exiting components will likely require appropriate fire ratings. In some cases, additional voice communication zones, two-way communication, message boards, or other communications systems may be necessary to provide occupants with an appropriate level of situational awareness and a general understanding of the incident. Zones require specific fire separations and structural fire ratings appropriate to the strategy. Other features also may be necessary: elevators may need to be protected and provided with special controls, stair door unlocking may be necessary, and life safety systems will likely need emergency power. All of these features need to coordinate with security systems [22].

A single solution may not be appropriate for complex facilities. These facilities may benefit from adaptive or event-based strategies. With adaptive or event-based evacuation, conditions dictate the specific actions and egress strategy. During an event, the situation is assessed and a strategy is selected based on that assessment. For example, consider a fire event on a single floor, a strategy including relocation through exit stairs and protecting in place those on unaffected floors may be appropriate. For the same building, a building power outage may require full building evacuation.

Adaptive evacuation concepts are particularly useful for facilities that may be exposed to a range of events, this is important when those events can involve threats both inside and outside of the building. Events occurring outside the building may require a very different response than those occurring inside. The presence of an active shooter will likely need a protect-in-place lockdown where spaces can be secured against entry by the shooter. Civil unrest or a hazardous material event outside a building may require occupants to be secured within the building. Release of a biological agent within a building may require potentially contaminated occupants to be secured within the building until it can be determined that they will not contaminate others. This strategy places a large burden on the decision makers and the decision-making process. Decision makers need relevant information and the authority to make critical decisions. While flexibility can be beneficial, simplicity creates increased reliability.

Substantial training is required to minimize confusion, particularly where differing responses are expected for different events. Appropriate systems and methods are needed for decision makers to quickly obtain credible information about the event and to empower decision makers with the appropriate authority to make egress decisions based on that information. Training can help, but the provision of real-time instructions is necessary to increase the likelihood of obtaining the correct response from a wide range of potential responses [20].

Exit Components

In the US codes, a means of egress consists of three parts; the exit access, the exit itself, and the exit discharge. The exit access is any portion of a means of egress that leads to an exit and the exit discharge is any portion of a means of egress between the termination of an exit and a public way. The exit is defined as [11],

> That portion of a means of egress that is separated from all other spaces of a building or structure by construction or equipment as required to provide a protected way of travel to the exit discharge.

Figure 56.2 illustrates the relationship between exit access, exit, and exit discharge.

A means of egress is generally considered to be a protected path of travel to the exit discharge. On floors above grade, this is typically through an exit stair. The exit stair is required to discharge on grade to a path leading to the public way. US codes generally define the public way as a street, alley, or other space open to the air that is dedicated to public use. Exit stairs need to be arranged so that once entered, occupants are not required to leave the stair until reaching the exit discharge. There are exceptions. In some cases, an exit discharge can lead to a space of sufficient

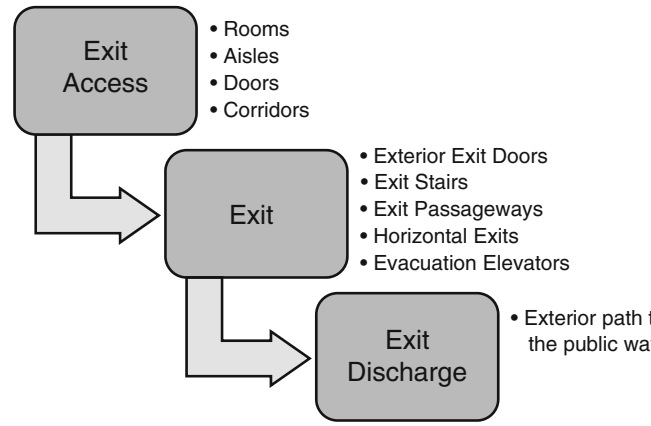

Fig. 56.2 Exit components

size to accommodate all of the occupants expected to use the exit and be located at a safe distance from the building. In other cases, exit stairs are allowed to discharge through an on-grade level floor where a direct and obvious path is provided [11, 36].

Egress systems require that at least two means of egress be provided from any point in a building. One exit can be provided for spaces that meet limits on common paths of travel. Additional exits are required based upon occupant load: three exits for spaces with 500 occupants, and four exits for spaces with 1000 or more occupants. Exits are also required to be located to meet travel distance limits. Stairs enclosed by a fire and smoke rated shaft are the most common exits. Horizontal exits can serve as a means provided that the horizontal exit passes through a rated wall that is continuous from exterior wall to exterior wall and continuous to grade. Occupants are deemed to be in a safe area after exiting through the horizontal exit.

Requirements for exit capacity, which affect the number and width of stairs and doors, are based upon the occupant load of each floor, either estimates of the actual number of occupants including visitors, or an occupant density derived from surveys of actual buildings. The load factors specified for specific occupancies are quite consistent across many international building codes. For example, the occupant load for office occupancies is 100 ft^2 (10 m^2) per person in US, Australia and Spain, 90 ft^2 (9 m^2) per person in Hong Kong and 60 ft^2 (6 m^2) per person in the UK. Some of the traditional load factors are being questioned since most of the surveys on which they are based were taken more than 50 years ago.

Egress stairs are required to be protected from the entry of smoke that could slow evacuation or harm occupants. Besides having a fire rated and smoke resistant shaft enclosure, egress stairs in high-rise buildings are typically pressurized to prevent smoke leakage through construction cracks and doors opened to provide access. Stair pressurization systems are discussed further later in this chapter.

Occupant Evacuation Elevators

Walking down many flights in tall buildings can be a difficult task for many occupants and may be impossible for some. Elderly, disabled, or injured occupants, occupants with other medical issues like heart conditions, or those with or mobility-impairing injuries may have difficulty negotiating stairs or may be incapable of evacuating using stairs. Changes in technology, an aging population, the events of September 11, 2001, and the practicalities of designing for very tall buildings, have converged to make elevators a viable option, and perhaps a necessary alternative, for emergency evacuation in tall buildings. Protected evacuation elevators can provide a safe and effective alternative to walking down many flights of stairs. With appropriate design, it may be possible to allow protected elevators use for a large segment of the building population [20,22].

The use of elevators can speed evacuation within tall buildings. This has been proven in real events. For example, reports indicate that 16 % of World Trade Center Tower Two occupants escaped through the elevators before the second airplane struck the building [41]. Utilizing elevators can result in the total evacuation of any building of any height in less than one hour, without increasing the number, size, or speed of the elevators normally provided for routine use [42].

Fire service access elevators that are also used for assisting disabled or injured occupants have been required in British codes and others following the British system since the mid-1980s [37]. No building regulation has recognized elevators for occupant evacuation in fires until the 2009 editions of the US codes, although some systems (e.g., Stratosphere Tower, Petronas Towers, Taipei 101) were approved as performance-based designs [43].

One strategy is to shuttle occupants from upper levels. Another would be to attempt to restrict elevator usage to those who simply cannot take the stairs due to health or mobility

limitations. If restricted access is planned, training of all occupants, stringent controls enforced by operators or fire wardens, and a management plan would be necessary to prioritize and discern between those that need the elevators versus those that simply choose to use the elevators. Another strategy is to allow occupants to descend stairs from the fire floor to a refuge floor, or a specially designed sky lobby, then to use the elevator from that floor or continue down the stairs [22].

In all cases, strategies need to be well-defined, well-engineered, and coordinated. Special care is necessary to help educate and train occupants in the use of such systems. Elevators must be protected, and appropriate fire and life safety features, appropriate signage and way-finding, and a well-constructed evacuation plan with training are required.

Figures 56.3a and b provide two examples of tall buildings using elevators for evacuation. In Fig. 56.3a, elevators serve the fire floor. In Fig. 56.3b, elevators only serve the sky lobbies.

Taller and taller buildings are be designed and constructed around the world. For these structures protected elevators are an important egress design component. Both the *International Building Code* [36] and the *Life Safety Code* [11] allow elevators to serve as one means of egress. The *Life Safety Code* has allowed emergency evacuation elevators to serve as the second exit within observation, control, operation, and signaling towers since its 1988 edition. These approaches potentially use all public use elevators to minimize evacuation times and to prioritize evacuation of occupants from the most threatened floors.

ASME A17.1/CSA B44 Safety Code for Elevators and Escalators [44] includes specific operational protocol and design features for elevator evacuation—Occupant Evacuation Operation. Requirements include manual elevator recall switches in the elevator lobby and in the fire command, controls to initiate "Elevator Total Building Evacuation" in the fire command center, appropriate fire alarm signs, and variable message signs to indicate elevator status and estimate time duration for the next elevator [44].

Note that in all cases, emergency evacuation elevators only operate prior to Phase I Emergency Recall Operation. This means that elevators only operate in evacuation mode until recalled to the first level by the activation of a smoke detector adjacent to the elevator opening. Phase I recall can be activated manually by the fire department to recall individual elevators while keeping others in service.

Some concerns have broad societal implications—e.g., the overall public reaction to the use of elevators is unknown. Usage of elevators during emergencies is in direct contrast to the message given for years from the life safety community: in case of fire, do not use elevators. Given this message, how will occupants react and what percentage of occupants will use elevators? These questions need to be addressed on a case-by-case basis through planning and training.

Escalators

Escalators are not generally credited to required egress capacity. NFPA 130, *Standard on Fixed Guideway Transit Systems* [45] is an exception. NFPA 130 allows non-combustible escalators to be counted for up to 50 % of required capacity from subway stations, so its acceptance in other occupancies may eventually change. Escalators are present in many buildings, are familiar to occupants through daily use, and there is no prohibition against using them for egress in fires. Thus, evacuation modeling in buildings with escalators performed as part of a performance design or a supporting egress analysis could incorporate the escalators where appropriate and acceptable to the Authority Having Jurisdiction.

NFPA 130 contains specific guidance on escalators used for egress. Escalators moving in the direction of egress travel continue to move, and those moving in the opposite direction are stopped. Note that stopping a moving escalator while people are riding must be done with extreme care to avoid falls—escalators should slow to a stop [45].

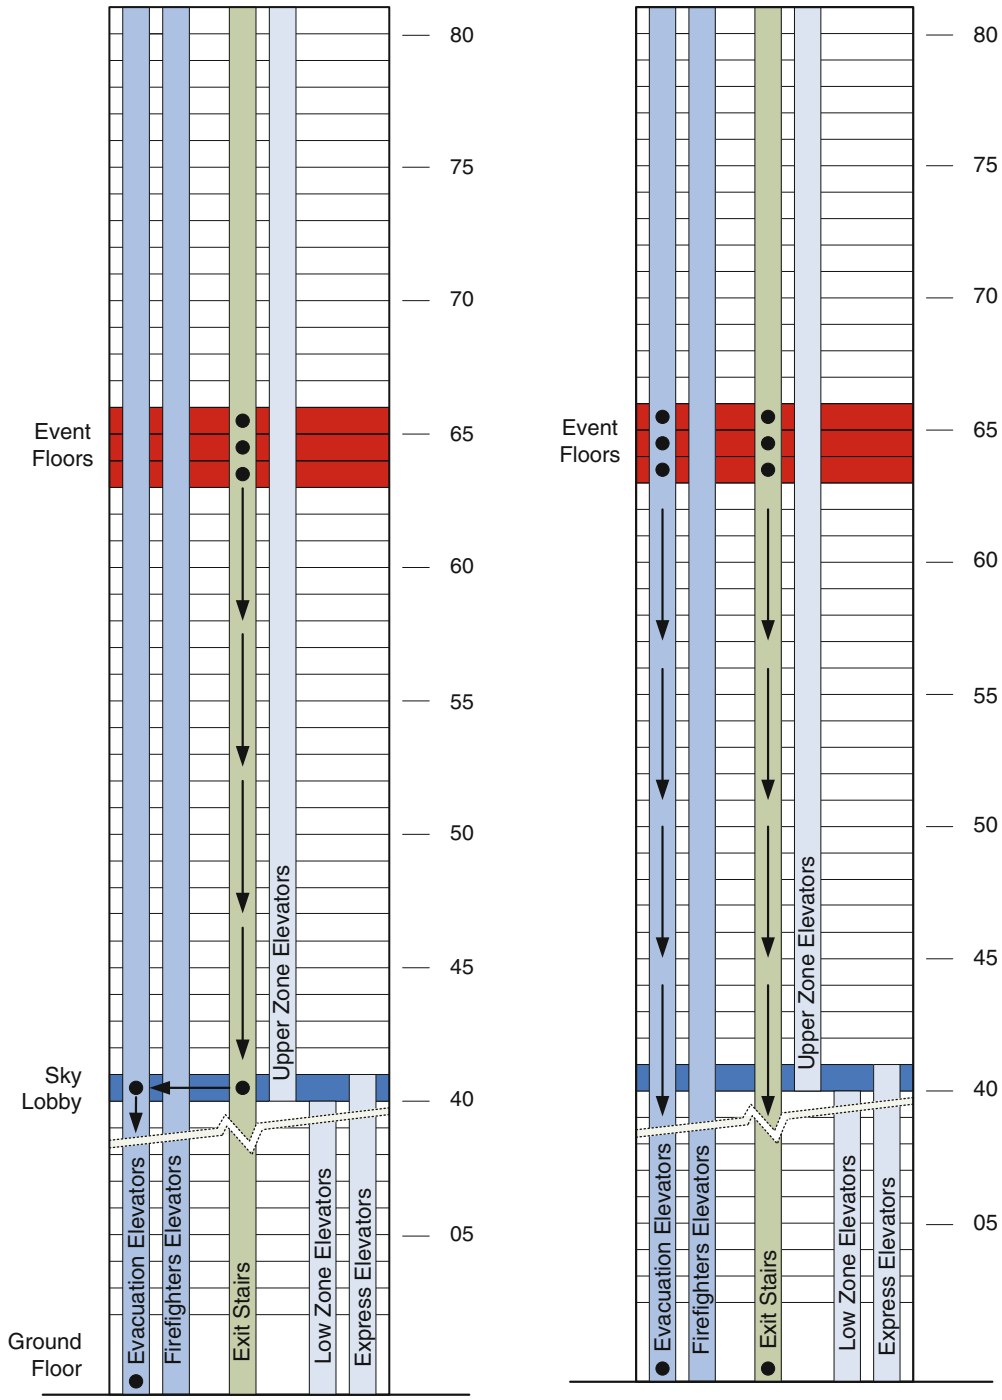

Fig. 56.3 (**a**) Elevators serving the fire floor (left) (**b**) Elevators serving sky lobbies (right) [20]

Capacity of typical escalators is credited the same as egress stairs, defined as 1.41 persons per inch-minute (0.0555 p/mm-min). Escalator speeds have been standardized by ASME A17.1 at 100 ft per minute (33 m/min), although some faster speeds can be found in special applications, especially on very long runs [44]. The egress travel speed on a stopped escalator is defined by NFPA 130 as 48 ft per minute (14.63 m/min) in the down direction and 40 ft per minute (12.19 p/mm-min) in the up direction. NFPA 130 requires that the calculation of egress time must assume at least one escalator out of service.

The main reasons that escalators are not credited as a means of egress component are their lack of a fire rated enclosure and the tread geometry does not comply with typical code requirements. Typical code compliant egress stairs are required to have a 7 in. (178 mm) rise and an 11 in. (280 mm) tread depth. Escalator steps (except at the top and bottom where they are collapsing) have a greater riser height, not more than 8.5 in. (220 mm), and a tread depth of not less than 15.75 in. (400 mm). The increased depth is not an issue since the 11 in. stair depth is a minimum. In a survey of egress stair geometry requirements in a select number of countries, Bukowski [4] found that the maximum riser height permitted for an egress stair is 7.5 in. (190 mm). Escalators do not have intermediate landings, and slopes are not more than 30° where the slope of an egress stair is 32°. In addition, the collapsing riser heights at the top and bottom can interrupt gait which slows movement and pose a potential for tripping.

Refuge Floors

Refuge floors are required in high-rise buildings in Asia and the Middle East to provide an area of temporary refuge and an ability to cross over between stairways. Refuge floors are typically provided every 15–20 floors or more, depending on occupancy, and are frequently co-located on mechanical floors. The refuge space is typically required to be at least 50 % of the floor area and separated from mechanical equipment by fire rated partitions. Exterior walls are required to be at least 50 % open to provide for natural smoke control. Perimeter deluge sprinkler systems are required to reduce the potential for smoke or fire spread into the space.

Some have expressed concerns about the practicality of refuge floors. During drills, it is reported that occupants often evacuate to the nearest refuge floor and await the call to return to their workplace. This can result in overcrowding of the refuge floor with occupants backing up into the stairs and blocking egress flow. It is unclear whether such behavior would be seen in a real emergency. Another concern is storage. Storage is not allowed in refuge areas; however, if items are stored, the area available for occupants to rest would be further reduced. Storage also introduces a fire load into the evacuation path. For these and other reasons, there is controversy over the use of refuge floors.

Pedestrian Walkways and Skybridges

Elevated pedestrian walkways are increasingly popular architectural features of urban buildings that can be found in several US cities connecting downtown buildings, usually at the second floor level. Pedestrian walkways provide a means to access portions of a downtown area protected from the outdoor weather and often connect hotels to shopping and to convention centers. Skybridges connect buildings at higher levels and are less common—the Petronas Towers skybridge is a well-known example.

Pedestrian walkways provide exit paths to adjacent buildings. This can be significant for tall buildings, as this provides an alternative evacuation path. Legal issues regarding responsibility for operating costs, maintenance, and liability must be addressed when Pedestrian walkways connect buildings under different ownership but these clearly can be addressed because such walkways are found in many cities.

Features in Codes Internationally

It is important to understand country specific requirements or cultural norms that may affect the design. The following provides some examples of egress features and design conventions used internationally.

In addition to requirements for refuge floors discussed in previously, Chinese and Korean Codes require vestibules at the entrances to egress stairs and elevators on each floor of a high-rise building. Chinese regulations permit common vestibules but Korean codes require them to be separate and integrated with an area of refuge staging floor. Korean regulations further require that a fire service access elevator be located within 30 m (98 ft) of the building exterior.

In Tokyo where buildings are crowded together and many streets are quite narrow, numerous public parks serve as protected spaces in which people who have evacuated nearby buildings can be sheltered. These parks are surrounded with trees intended to provide shielding from radiant energy from the event. The provision of parks as shelters began after the Great Kanto Earthquake (1923) where the large death toll was mostly from fires and proved its worth in the fire bombing late in WWII.

US codes allow longer travel distances, even for the reduced travel distances required for non-sprinkler protected facilities. In Hong Kong and Macau, travel to an exit must be within 40 m (130 ft). In Australia, the maximum travel distance depends on the type of building, but ranges between 20 (65 ft) and 40 m (130 ft). For comparison, the US is 61–91 m (200–300 ft) depending on the occupancy served.

Some countries utilize scissor stairs to meet code mandates for two egress stairs. In most cases these are required to have the entrance doors separated by at least 9 m (30 ft) and be fully fire separated. Other than in New York City where they are common, scissor stairs are generally not permitted to serve as separate exits due to the perceived difficulties in separating the enclosures and the resulting possibility of simultaneously contaminating both exit enclosures.

In the US, two exits are required for nearly all multi-story buildings. Single exits are common for residential high-rise buildings outside the US. This allowance is typically limited to smaller floor areas so that exits can be reached within 20 m (65 ft).

Design can include merging stairs in the International Building Code, such as basement stairs meeting and combining with tower stairs at the discharge level. In the Middle East, and China, Hong Kong, and other countries [46], designs follow an approach similar to NFPA 5000 and rising and descending flights of stairs need to be separated so that the stairs are separated and there are two independent exit discharges.

Horizontal exits are recognized in the US and Australia as a means of egress. Horizontal exiting concepts are not incorporated within Chinese Codes, but have been used in projects following the *International Building Code* or *Life Safety Code*.

Systems and Features That Support Egress

The egress strategy forms the basis for life safety and needs to be designed as part of a coordinated life safety program that integrates the fire protection and life safety features of the building. Notification, way finding, and fire and smoke protection of egress components are fundamental features that support both prescriptive and performance-based egress concepts because they support the efficient use of the egress system.

Notification

Timely evacuation begins with emergency notification. Most public buildings have a notification system initiated by automatic fire detectors or the detection of water flow in the sprinkler system.

Notification appliances in modern systems are usually voice systems since they provide the flexibility to tailor messages to a range of events. Research has shown that people are more likely to respond to voice messages because many may not understand the meaning of an audible signal or occupants may think it is a false alarm [47]. A significant improvement in voice systems can be attributed to the development of a method to make objective, quantitative measurements of the intelligibility of voice messages coupled with explicit requirements in the Notification Appliances Chapter of the National Fire Alarm Code [30]. Notification systems generally include visible appliances for the hearing impaired and may also include tactile devices. Smaller buildings are not typically required to be provided with voice communication systems.

The effectiveness of messages broadcast over voice systems can vary significantly. Effective messages are more likely to result in the desired response [48]. Attributes of an effective message including being:

- Short but informative
- Easy to understand what is expected
- Authoritative
- Provides information to support effective decisions
- Repeated but not repetitive

In some cases, such as in health care or in detention/correctional occupancies where occupants are restrained or unable to evacuate without assistance, it is unwise to directly notify people of an emergency through public mode alerting systems because of the anxiety that results in those who cannot respond to the call to evacuate. Here, notification appliances can operate in what is called private mode. Private mode signals are presented only to specific parties who then notify and assist others. In contrast, public mode alerts the general population.

Systems need to be audible and intelligible. If occupants can hear the message, it is audible. If occupants can understand the message, it is intelligible. Chapter 40 and the National Fire Alarm Code Handbook [49] describe methods for designing audible and intelligible messages.

Where people may be sleeping, notification appliances need special attention. As required by the National Fire Alarm and Signaling Code [30], audible appliances need to produce sound pressure levels of 75 dBA or more that are at least 15 dBA above the average sound pressure level of any background noises. Visible appliances need to operate at least 177 candela at the pillow to wake occupants. This is significantly higher than the 15 candela minimum at the device for visual notification of alert people. The National Fire Alarm and Signaling Code includes new requirements for low frequency alarm signals in sleeping areas to increase the ability of the waking sleeping occupants. Tactile notification provides an alternative [30].

Wayfinding

Buildings that may contain occupants who are unfamiliar with the egress system are usually required to install some features to guide wayfinding. The traditional wayfinding aid is the exit sign over exit doors and signs that direct people to these exits. Hotels usually have a floorplan map located on the back of the door in every room showing the location of the exit stairways in relation to that room.

In recent years, some regulations have been changed to move signage lower in hotels so that it is not obscured by smoke. In Europe and South America, some countries install lighted chevrons in the baseboards of exit access hallways. For the visually impaired, there are “talking signs” that transmit an audio channel that can be heard on special devices carried by the disabled person and heard as the sign is approached. Another new technology is directional sound transmitted from speakers mounted over exit doors. Even without being able to see, these sounds give the impression of direction, guiding the person to the exit.

Dynamic signage can direct occupants to specific locations, guiding evacuees away from hazards. One example is the use of dynamic signage within stairways to direct occupants to a specific exit or to direct evacuees to cross over

to another stair to avoid hazards. Some have proposed the use of messages transmitted to handheld devices including smart phones to provide way finding guidance in emergencies.

Illumination and Exit Marking

With a few exceptions, the means of egress including the exit discharge is required to be illuminated to at least 1 ft-candle when the building is occupied. Recently, illumination requirements have been supplemented by requirements for luminous egress path markings, including photoluminescent marking. Requirements in the *Life Safety Code* [11] state that, where photoluminescent markings are used, light levels sufficient to charge the material are required to be provided for at least 60 min before the building is occupied. Energy conservation systems that turn off lights when the stairs are not occupied cannot be used. Chapter 7 in Facilities Standards for the Public Buildings Service contains additional information [50].

Fire and Smoke Protection

Egress stairs typically require fire-rated shaft construction and protection from the entry of smoke. Egress stairs in high-rise or tall buildings are typically pressurized to prevent smoke leakage through construction cracks and doors opened to provide access.

Stair pressurization systems typically require pressures of at least 25 pa (0.1 in. of water) to prevent smoke infiltration but not more than 67 pa (0.25 in. of water) which could result in excessive door opening forces. Systems need to meet both limits at every door, and account for pressures resulting from stack effect and the fire itself. Shaft height, high indoor to outdoor temperature differences, and requirements for designing for open stairway doors add complexity to the design. Chapter 50 includes additional information on stair pressurization.

Simple stair pressurization systems can be designed with hand calculations. Complex arrangements such as buildings with adjacent vestibules or corridors pressurized separately from the stairs, buildings with multiple shafts, buildings with shafts taller than 75 ft, or buildings with shafts that connect to spaces that are open to the outside such as parking garages, should be addressed by use of a network model that can account for the multiple flow paths involved [51].

Before pressurization systems there were stair designs called smoke-proof towers that employ stair access through a vestibule that is naturally ventilated to the outside. Smoke-proof towers now combine mechanically vented or purged vestibules with stair pressurizations systems. Smoke-proof towers were found to be reliable and effective as long as the vestibule ventilation is not blocked.

Performance-Based Evacuation Design

The prescriptive egress provisions of the codes have been developed to provide robust evacuation features for a wide range of buildings types, uses and occupancies. While these provisions have worked well for many years, they cannot address all situations. The performance-based evacuation design process is an important tool to address situations that are either not appropriately addressed by prescriptive codes, or to address owner and designer needs that cannot be solved with traditional prescriptive code solutions.

The SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design in Buildings [52] defines a process to undertake performance-based design, which includes defining scope, developing goals and objectives, developing performance criteria, developing design fire scenarios, developing trial designs, evaluating trial designs and selecting final design, and preparing documentation. Chapters 37 and 57 provide information to help implement this process. Table 56.1 illustrates this process when applied to the evaluation of evacuation designs for fire

scenarios. The process can be applied to other non-fire emergencies as well as crowd related hazards. The following sections further discuss the process.

Design Considerations

The following list considerations related to evacuation, defend in place, and relocation designs that may be relevant for performance-based evacuation design and analysis [20].

Will occupants investigate alarm signals before deciding to leave?

Will occupants be committed to or be involved in an activity that will slow their reaction to alarm signals?

Will families or other groups attempt to find other group members before beginning to evacuate?

Will all exits be available, or will one or more exits become unusable during specific events?

Will occupants be familiar with or aware of the closest escape route?

Will occupants use the available exits uniformly, or will the main exit be more congested than others?

Will all occupants have similar abilities?

Will some of the population need special assistance?

Define Project Scope (Step 1)

The first step in the process includes gathering information about the structure and the occupants, identifying the stakeholders, and determining the level of application. The project budget and approvals process should also be determined [52].

Stakeholders should agree on the project scope, goals and objectives. The SFPE Guide [52] lists the following example stakeholders: building owner, building manager, design team, authority having jurisdiction, accreditation agencies, construction team, tenants, building operations and maintenance, emergency responders, and peer reviewer. Other stakeholders might include commissioning agents.

The project scope also defines the level of application and clearly identifies systems or components designed using prescriptive code requirements and those designed using performance methods. The scope can include individual fire protection safety components or overall systems, partial buildings, whole buildings, and multiple buildings [52].

Project Scope Examples The following provides typical examples where the performance-based process may be employed to help realize designer, or owner vision.

Performance-based assessments can include developing solutions to safely extend travel distance, extend common paths of travel, or reduce exit widths within large facilities. An integrated strategy including fire detection, smoke management, and carefully planned evacuation features can allow a safe alternative for architectural designs that differ from typical prescriptive code requirements. The process can be used to test the ability of a strategy to meet established goals and objectives, based on the expected hazards.

The process can support evacuation planning and crowd management planning assessments. For example, designs may need to optimize evacuation through the use of elevators in tall and super tall buildings. In these examples, evacuation simulations may be used to facilitate comparison of specific strategies, and elevator operations during emergencies. The process can help inform crowd management planning and can help to understand crowd movement under a range of conditions.

The process also can be used to optimize evacuation for large assembly spaces. Sime [55] notes a strong relationship between normal circulation routes and exit pathways used during emergencies. Exit paths that serve as normal circulation paths will more likely be used than other exits, even if the path of travel is further along the normal circulation route. The

assessment can evaluate strategies to minimize occupant crowding and optimize occupant flow at critical evacuation components, and allow alignment of normal circulation routes with emergency exit paths.

Define Goals and Objectives (Steps 2 and 3)

The next step is for the stakeholder team to agree on fire safety goals and objectives for the project. Chapter 37, the SFPE Engineering Guide to Performance-Based Fire Protection [52], *Life Safety Code*, *NFPA Building and Safety Code*, and the *ICC Performance Code* (ICC 2012), and *Code for Fire Protection of Historic Structures* [56] provide information and guidance on selecting goals and objectives.

Goals and objectives can relate to limiting sources of fire ignition, preventing fire ignition and growth, limiting fire impact, limiting consequences from hazardous materials, protecting people during egress and rescue operations, managing people safely, protecting responders from unreasonable risks, providing notification for emergency responders, providing access and facilities for emergency responders, and providing notification for life safety and property protection [35, 52].

The *Life Safety Code* states in part that "a structure shall be designed, constructed, and maintained to protect occupants not intimate with the initial fire development for the time needed to evacuate, relocate, or defend in place." Section 5.3 of the *Life Safety Code* refers to *Retained Prescriptive Requirements*, which are features that need to follow prescriptive methods or provide an equivalent design. Retained prescriptive requirements within the *Life Safety Code* include design details for: changes in elevation, guards, doors, stairs, ramps, fire escape ladders, alternating tread devices, capacity of means of egress, impediments to egress, illumination of means of egress, emergency lighting, and marking of egress [11].

The *ICC Performance Code* states in part that "the construction, arrangement and number of means of egress, exits, and safe places for buildings shall be appropriate to the travel distance, number of occupants, occupant characteristics, building height, and safety systems and features." The ICC Performance Code requires performance-based egress designs to address the following: exit identification, exit illumination and safety of means of egress, providing unobstructed egress paths, protecting occupants from untenable conditions, provisions to address human biometrics and expectation of consistence, maintenance of means of egress systems, maintenance of clear path, maintaining identification of exits, maintaining ease of use, and maintenance of illumination [35].

Develop Performance Criteria (Step 4)

Performance criteria are "threshold values, bounded ranges of threshold values, or distributions of expected performance," [52] and form the basis for assessment of the design. For fire evacuation events, performance criteria are typically described in terms of occupant tenability. Where performance-based assessments are used for evacuation for events other than fires, such as crowd movement events, performance criteria matching the specific hazards associated with those events is needed.

The *Life Safety Code* [11] lists four methods that provide context to tenability assessments for performance-based egress approaches for fire events. Method One accounts for designs that expose occupants to heat, smoke, or other toxic or damaging products of combustion while evacuating a structure. This method requires a tenability assessment. The Fractional Effective Dose (FED) method can be used to determine if occupants can safety exit through contaminated egress paths. Chapter 63 describes the FED method in detail. Exposures to lower doses of contaminants over a long period of time may be as severe as a higher dose over a shorter exposure. The FED method accounts for low and high exposures.

Method Two compares timed egress and smoke-movement simulation results to determine if occupants are able to evacuate before egress paths become contaminated. Method Three requires the calculated smoke layer to be maintained 6 ft or more above the floor in all egress paths throughout the required egress time. Method Four relies upon passive smoke and fire barriers, or active smoke pressurization systems to maintain pressures across barriers to keep smoke from reaching egress paths. Depending upon geometry and configurations, computer fire models may be necessary to appropriately assess smoke movement. Chapter 50 details smoke pressurization methods. Chapter 51 calculation methods for simulating smoke movement.

Tenability in fires can be quantified in terms of thermal effects, visibility through smoke, smoke toxicity, or limiting impact from falling materials. Some occupants, such those that are ill, young, or elderly can be particularly vulnerable to exposure. Criteria may need to reflect these vulnerabilities. Chapter 63 provides methods for quantifying thermal effects, visibility, and smoke toxicity. Sub-lethal effects may also be important.

Thermal Effects Thermal effects are evaluated based upon occupant exposures to heated gases or flame. Radiant and convective exposures are cumulative. The FED method allows the combined assessment of radiant and convective exposures.

Visibility Visibility estimates the distance occupants can read exit signs or distinguish exit paths through smoke. Visibility is based upon smoke density, illumination, and distance.

Smoke Toxicity Combustion products can be toxic, and can cause reduced decision-making capacity and impaired motor activity. Inhalation of toxic combustion products can lead to incapacitation or death.

Impact Falling objects, airborne building materials, or structural collapse can cause injury or death [57].

Sub-lethal Effects Sub-lethal effects can lead to severe injury and incapacitation. For example, smoke exposure can be irritating to an occupant's eyes and this physiological effect can reduce the ability to see over time. Another example would be an occupant who survives, but sustains permanent damage due to smoke inhalation. Kuligowski [58] details criteria on sub-lethal effects. Chapter 63 includes information on assessing sub-lethal effects.

Events Other Than Fire Historically, fires have been the primary incident of concern for prescriptive building codes. Earthquakes are also considered in seismic design zones. Since the September 11, 2001 attacks on the World Trade Center, there has been more consideration of planning for appropriate response to emergencies other than fire and focus has shifted to address a wider range of events. For example, the Life Safety Code states [11]:

> Life safety in buildings includes more than safety from fire. Although fire safety has been the long-standing focus of NFPA 101, its widely known title, Life Safety Code, and its technical requirements respond to a wider range of concerns, including, for example, crowd safety.

The ICC Performance Code similarly addresses a wide range of events, although the approach is different. In this code, maximum damage or outcome from event scenarios is mandated. Events are categorized as mild, moderate, and severe. For example, a mild event requires: no structural damage, fully operational non-structural systems for both normal and emergency operations, minimal damage to facility or contents, minimal hazardous material released to environment, and only minor occupant injuries with low likelihood of life loss. A moderate event would allow more severe damage. Moderate events are characterized by greater damage

requiring repair prior to reoccupation and an increased likelihood of death and injury. Severe events result in sufficient damage that re-use is unlikely and multiple deaths are likely [35].

Develop Design Scenarios (Step 5)

The next step in the process is to develop design scenarios. The SFPE Guide and Robbins, Gwynne, and Kuligowski [59] detail processes for developing fire safety scenarios, which entails identifying possible fire scenarios, paring the possible scenarios into a sub-set of design scenarios, and quantifying the design scenarios. Design scenarios include the building components and characteristics, occupant scenarios, and fire scenario(s).

There are a range of methods and analysis techniques that can be used to identify possible fire scenarios and rationalize these scenarios into the design scenarios. SFPE [52] describes probabilistic and deterministic approaches and outlines these methods. Robbins et al. [59] further describe this process. Chapter 72 and the SFPE Engineering Guide to Fire Risk Assessment [60] provide detail on fire risk assessment.

Building Characteristics Building characteristics include building height and size, occupancy and uses, architectural features, structural fire protection, egress features, fire protection and life safety systems and features, building services, functions and processes, fire department response features, environmental factors, and expected hazards and threats, criticality, and importance [20, 52, 59].

Occupant Characteristics Occupant characteristics include occupant loads, occupant ages and cognitive and physical abilities, presence of groups, and occupant response characteristics. Chapter 57 overviews occupant scenarios.

Occupant loads are determined through use classification of the spaces. Codes provide prescriptive factors for occupant loads [11,36]. In some cases, occupant loads can be determined through the expected actual use.

Occupant loads will vary based upon the event considered. In many cases, larger occupant loads will increase risk, but this may not always be the case. Consider a convention center used for lecture seating and boat shows. While lecture seating would pose a lower fire hazard, when compared to a boat show, the expected occupant loads would be significantly higher. Other uses may include exhibits with cooking or concerts with pyrotechnics. Each scenario has varying occupant loads, varying occupant conditions, varying hazards, and ultimately varying levels of safety. For these conditions, it may not be intuitive which poses a higher risk, scenarios with higher occupant loads or scenarios with higher fire hazards. The analysis would need to review a representative range of expected scenarios to appropriately characterize the level of safety [57].

Performance-based approaches require a comprehensive understanding of expected reaction times, and occupant movement. Chapter 57 and the SFPE Guide discuss factors that influence pre-movement and movement times. Factors include whether the person is alone or with others, the occupants familiarity with the building's exit paths, emergency procedures, distribution within the space or throughout the building, pre-event activities, occupant alertness, occupant physical and mental ability, social affiliation, role in the evacuation or the organization structure, location, commitment to activities or others, age, culture, occupant condition, and gender. Table 56.2 describes specific characteristics emphasized in the *Life Safety Code* [11] and *ICC Performance Code* [35].

People have a wide range of abilities, and response characteristics. Prescriptive building and safety codes traditionally use occupancy groups to imply the characteristics and typical behavior of occupants in a building. The life safety strategies and egress features required by prescriptive codes are based upon the number and location of occupants, and the building characteristics.

Table 56.2 Code mandated occupant characteristics

Life safety code	ICC performance code
Number of occupants	Number of occupants (LSC)
Length of occupancy	Sleeping characteristics
Response characteristics	Familiarity
Location	Vulnerability
Staff assistance	Relationships
Emergency response personnel	
Post-construction conditions	
Off-site conditions	
Consistency of assumptions	
Special provisions	

Most public buildings classified as Assembly, Business, and Mercantile occupancies by prescriptive building codes are assumed to contain people that are awake and generally capable of unassisted egress. Higher occupant densities associated with large crowds within Assembly buildings pose additional challenges and crowd manager requirements are included to address challenges associated with large crowds. Industrial and Storage occupancies are not typically open to the public and contain people that can be trained in the specific hazards present in the building. Residential occupancies contain occupants of all ages and may require awakening from sleep. Educational, Day Care and Ambulatory Health Care contain children or adults that may need assistance to respond appropriately. Health Care and Detention/Correctional buildings contain occupants that are restrained or incapable of response and may need to be protected in place.

Design Fire Scenarios Fire scenarios include a sequence of events that includes the fire location, source of ignition, and growth rate. If the fire continues to grow the event might reach flashover and full development, and finally decay and extinction. SFPE [52], Chaps. 26, 37, and 38 provide detail on development of design fire scenarios. The *Life Safety Code* [11] mandates use of eight (8) specific design scenarios, where applicable. Other references include the ICC Performance Code [35], NFPA 92, *Standard for Smoke Control Systems* [61], and Babrauskas and Grayson [62].

Develop Trial Designs (Step 6)

After the design scenarios are developed, the team develops trial designs. Trial designs may need to provide features to protect against hazards other than fire. Minimally, the trial design should include the development of clear intuitive egress components and features. Depending upon the level of analysis, a comprehensive and coordinated fire engineering strategy may be necessary to address structural fire protection, fire compartments, fire detection and notification fire suppression, interior finish, smoke control, and emergency power. Fire strategies can also rely upon controlling ignition and controlling the initial spread of fire. SFPE [52] provides additional detail on comprehensive fire strategies. NFPA 550, *Guide to the Fire Safety Concepts Tree* [63] can assist to identify comprehensive conceptual approaches.

Evaluate Trial Designs (Step 7)

The next step includes evaluating the trial design for compliance with the design objectives and performance criteria. For performance-based evacuation designs, this evaluation typically involves a review of Required Safe Evacuation Time (RSET) against Available Safe Evacuation Time (ASET). Required Safe Evacuation Time is the total time between notification of occupants that they need to move to a safe place and the time that the last occupant reaches that place. Available Safe Evacuation Time is the time between notification of the occupants and the onset of untenable conditions or other conditions that might impede egress or cause harm at any location that is occupied or will be traversed by occupants during egress. A timeline can be

developed to compare RSET and ASET for each design scenario.

SFPE [52] outlines a detailed process for evaluating trial designs. ASTM E1355 *Standard Guide for Evaluating the Predictive Capability of Deterministic Fire Models* [64] and "Guidelines for Substantiating a Fire Model for a Given Application," Society of Fire Protection Engineers [31] provide guidance on selecting tools for the analysis. Lord et al. [65] also provides guidance.

Analysis can follow probabilistic and deterministic approaches and outlines these methods. Refer to Chap. 37 and SFPE Engineering Guide to Fire Risk Assessment [60], for details on using fire risk assessment.

Hazard Assessment Fire growth simulation and smoke movement simulation can be used to estimate exposure to smoke, heat and thermal radiation. Other non-fire emergency and crowd related hazards can also be evaluated. Refer to Chap. 62 for information related to assessing and quantifying hazards associated with fire events.

Evacuation Overview Evacuation times consist of detection, notification, pre-movement, and movement times, and represents RSET. Figure 56.4 illustrates the evacuation process.

Detection and Notification The time between ignition of fire and the time for occupants to become aware of the situation is the detection and notification time.

Buildings with egress issues that are of particular concern typically require detection and notification systems. Detection can be through automatic systems, such as air sampling, smoke, heat, linear heat, projected beam, gas, radiant energy, video, multi-criteria, and multi-sensor detectors, sprinkler water flow devices, or through manual alarms. Chapter 40 and the National Fire Alarm Code Handbook [49] describe methods for calculating detection times.

Analysis should include transport lag time and system and detector processing times. Systems using positive alarm sequence and alarm verification should incorporate these inherent delays. The National Fire Alarm Code specifies a maximum time of 10 s for fire alarm systems to actuate alarm notification appliances or voice communication after a detection device activates. Positive alarm sequence allows a delay of up to 180 s for staff to investigate and evaluate conditions to determine if evacuation is necessary. Alarm verification allows a 60 s delay to reconfirm alarm conditions in smoke detectors and reduce unwanted alarms [30].

Audible notification can be through horns, bells, sirens, or speakers. Where a message is necessary to initiate evacuation or other action like shelter-in-place, the message needs to be audible and intelligible. Visual notification is required to alert hearing impaired occupants. Visual notification devices (strobes) are the most common. Textual and tactile appliances are also permitted. Examples of textual devices are private mode LCD devices or public mode messages in areas on large message boards. Examples of tactile appliances are bed shaking devices to wake hearing impaired occupants [30].

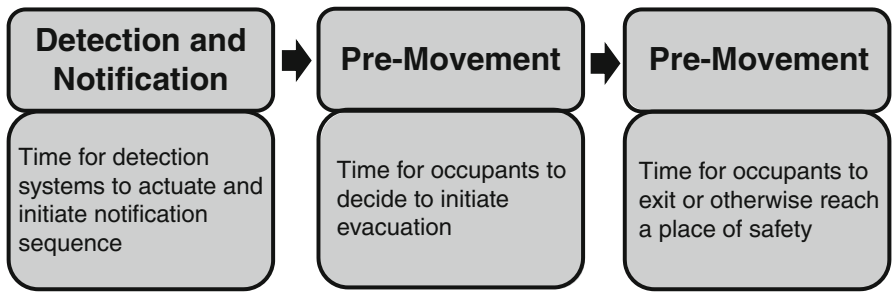

Fig. 56.4 Evacuation time

Pre-movement Time Pre-movement times, or delay times, start when occupants are notified and end when they start to evacuate or take other appropriate action that leads to evacuation. Pre-movement times are impacted by occupant activities prior to notification, method of notification, occupant training, staff assistance, and familiarity with the buildings. For example, a sleeping occupant would need to wake-up and get dressed before exiting. A mother, father, or caregiver would likely locate and assist their children before leaving.

Fahy and Proulx [66] reported actions performed by occupants after the 1993 bombing of the World Trade Center. The most frequent actions included: investigate, seek information, prepare to evacuate, alert others or report incident, assist others, seek refuge, and wait. Fahy [67] lists reasons occupants gave for not voluntarily leaving during this event: occupants "were waiting for information or instructions," occupants felt it was "better to wait or they were told to wait," occupants were not aware of the problem, occupants were "making sure others left," health reasons, "too much smoke," occupants were "waiting for better conditions," or occupants were "waiting for the fire department" as requested. Chapter 58 details pre-movement times.

Movement Time A broad range of engineering calculations are available from algebraic calculations suitable for simple egress systems to detailed models that incorporate behavior sub-models and graphically display results within the building. Regardless of the method employed, the process involves the estimation of the total evacuation time needed for all occupants to get to a safe place and the conditions to which they may be exposed during the evacuation. Models and engineering calculations are discussed in Chaps. 59 and 60; behavioral aspects of evacuation can be found in Chap. 58.

Speed of movement on horizontal egress components and stairs is well documented for non-disabled occupants. Data is available to simulate specific disabilities in Chap. 64. Movement speeds must be reduced to account for higher people densities, occupants exposed to smoke, and queuing at doors and other pinch points. While hand calculations can be used for simple systems, computer models may be necessary to account for higher occupant loads and complex designs.

Evaluate Results and Select Final Design The Required Safe Egress Time is compared with the Available Safe Egress Time to determine if sufficient time is available for occupants to escape, with appropriate safety factors. Results can also be used to determine areas of crowding, to estimate exit usage, and to input into evacuation plans and crowd management plans. When the stakeholders agree that the trial satisfies the objectives, and performance criteria, the final design is selected. To obtain a realistic yet conservative estimate of RSET, common actions and behaviors need to be explicitly included and factors of safety accounting for human variability need to be applied. The factors most often neglected in analyses are pre-movement times (or delay times) and factors of safety sufficient to account for expected variability.

Limitations Analysis of results should consider the limitations inherent with the methodologies. One limitation is that methods typically estimate the optimum egress times rather than simulate a range of expected egress times. Analysis may also need to account for non-simultaneous evacuation start times, uneven use of exits, complications associated with way finding, occupant interaction with smoke, temporary flow stoppages, merging flows, and counter flows. Chapter 64 contains additional information regarding limitations.

Safety Factors and Uncertainties Engineering models and analysis inherently contain limitations, simplifying assumptions, variability, and uncertainty. There may be variability in occupant reactions and behaviors. Models may be based

upon "best fit curves" to represent a set of data. Input data may introduce uncertainties. Assumptions may either increase or decrease the evacuation time or the time to onset of hazards. For example, doubling the fire size may result in predicting more smoke, but it may also decrease the predicted detection time. Using a single walking speed or a single flow through doors may not appropriately represent the range of expected occupant movement. The interaction and influence of these results may not be intuitive.

Safety factors provide one method of accounting for uncertainty and variability associated with limitations and simplifying assumptions inherent to engineering analysis. Safety factors are typically applied to the analysis results, as changes to specific parameters may have a non-linear effect on the results. For a discussion on addressing uncertainty with safety factors, see Frantzich [68].

Probabilistic approaches can be used to account for uncertainty and variability. Chapter 72 outlines risk informed analysis methods. Chapter 76 provides methods for understanding and accounting for uncertainty and variability.

Section 5.5.3.8 of the *Life Safety Code* [11] requires consideration of a design scenario that includes independently rendering each active or passive fire protection system ineffective. Examples include discounting a single stair, or discounting a single exhaust fan. Systematically testing scenarios with less than fully effective systems provides the designers with a better understanding of the consequences of these failures, which helps to understand the robustness and appropriateness of the selected safety factor.

Prepare Documentation (Step 8)

The final step is to document the analysis and design. SFPE [52] states that the following should minimally be included: project scope, designer's capability, goals and objectives, performance criteria, design scenarios, final design, evaluation, critical assumptions, critical design features, and references.

Design and Operational Considerations

The following outlines design and operational considerations for specific buildings and transport infrastructure.

Buildings and Transport Infrastructure

For some complex facilities, such as malls, healthcare facilities, detention and correctional facilities, following the prescriptive code can provide an acceptable and appropriate level of safety. Hospitals are among the most complex and highly regulated buildings due to the condition of most of the occupants. Since some or many patients must remain in their beds, most hospitals depend on horizontal exits to relocate occupants to a safe place on the same floor. For other buildings, a level of assessment beyond typical code compliance is warranted. The following suggests considerations for tall buildings, large assembly spaces, airports, rail stations, and rail and road tunnels. Life Safety Code Handbook [39], IBC Code and Commentary [40], NFPA 5000, Building and Safety Code [46], Appendix A of the ICC Performance Code for Buildings and Facilities [35], and Tubbs and Meacham [20] provide additional insight on a wide range of occupancies.

Systems Coordination and Integration Simple egress strategies provide safe evacuation through simple stair and exit discharge configurations, emergency notification, and emergency lighting. Complex evacuation strategies need to integrate and coordinate with the fire protection and life safety strategy. Comprehensive fire protection and life safety strategies include structural fire protection, fire-resistive compartmentation, fire detection, emergency communication and notification, fire suppression, smoke control, emergency lighting, and emergency power. These systems can have complex interactions. Based on these complexities, egress systems may need to be assessed even when the approach

does not directly relate to the egress systems [57]. Chapter 49 includes additional information on systems coordination and integration.

Tall Buildings Tall and super tall buildings pose particular challenges with respect to egress, as exiting through conventional stairway systems in tall buildings can mean walking down hundreds of flights of stairs. A portion of the population simply may not have the ability to travel down a stair system within a tall building, even with opportunities to rest along the way. Since passing in a crowded stair can be problematic, a person descending slowly due to physical limitations, injury or fatigue may delay everyone behind them.

Before the World Trade Center disaster, typical evacuation schemes for high-rise buildings included partial evacuation of only those occupants thought to be in immediate danger, by evacuating the 'fire' floor, along with one or two floors above and below the 'fire' floor. Code required stair widths have evolved to accommodate three to five floors evacuating simultaneously. If simultaneous full building evacuation from a tall building becomes necessary, it will involve a large number of people—many more than that anticipated by typical building egress designs. This inherent imbalance will result in significant delays and crowding in stairs [23].

The 2009 edition of the International Building Code introduced a requirement for buildings over 420 ft (128 m) in height to be provided with an additional stair to compensate for the high-rise fire-fighting practice of designating one of the stairs as the "attack stair" and fighting the fire from that position. The thought being that once firefighters start operations within the stair, the stair will become impassible at the level of the fire floor due to the presence of charged hose lines. These actions may contaminate the stair with smoke because the fire hoses will hold the door to the fire floor partially open. The IBC requirements further state that the required exit capacity must be met without the additional stair. Occupant additional evacuation elevators can substitute for the stair.

Large Assembly Spaces Large assembly facilities pose a range of competing challenges: airports need to balance security and continuity of operations with safety concerns, sports facilities need to balance sight-lines with providing safe steps for aisles serving seating, arenas and stadia need to provide guardrails to help prevent falls. There are many more examples.

Given the level of risk in large assembly spaces, the *Life Safety Code* [11] requires a Life Safety Evaluation when more than 6000 occupants are present, and when festival seating is used (e.g., when no seating is provided requiring patrons to stand or to provide their own seat). Both the I*nternational Building Code* [36] and *Life Safety Code* (2012a) require a Life Safety Evaluation when the reduced egress widths, increased aisle lengths, and increased travel distances allowed by smoke protected assembly seating are used. Life Safety Evaluations are required to include the following [11]:

- Nature of the events and the participants and attendees
- Access and egress movement, including crowd density problems
- Medical emergencies
- Fire hazards
- Permanent and temporary structural systems
- Severe weather conditions
- Earthquakes
- Civil or other disturbances
- Hazardous materials incidents within and near the facility

Crowd management also can be particularly important in directing the emergency actions of large crowds in assembly spaces. Fruin [69] defines crowd management as "... the systematic planning for, and supervision of, the orderly movement of people..." and provides a comprehensive discussion of crowd management. Information includes crowd communication, crowd motivation, the nature of crowds, crowd management centers, staff training, emergency response, responsibilities of performers, responsibility of staff, ticketing, owner/management duty to warn, appropriate space for occupants, occupant

metering, and ingress/egress pressure points [69]. The International Association of Venue Managers the NFPA Handbook for Fire Protection Engineering, NFPA 101, and Tubbs and Meacham [22] provide additional information on crowd management.

Rail Stations Rail stations are unique structures built to serve large transient occupant loads. In these facilities, customers tend to arrive in groups, based upon train arrival schedules. Stations can be at grade, above grade, or below grade. Underground stations pose greater challenges.

The approach described within NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems* [45] is a hybrid between prescriptive and performance-based approaches. Specific aspects are prescribed, such as the maximum platform travel distance and maximum egress times, where other aspects are based on performance concepts, such as the occupant loads, egress widths, separations to adjoining spaces, and smoke management systems [20].

Occupant loads are based on ridership, and system surge factors are used to account for variability of arrivals to the station. Egress arrangements need to result in a maximum of four minutes to clear platforms, and a maximum of six minutes to reach a point of safety [45].

Rail and Road Tunnels Rail and road tunnels can be constructed through mountains, underwater, or under urban landscapes. Air-rights structures continue to be constructed over railways and roadways to create a tunnel. NFPA 130 and NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways* address egress in rail and road tunnels. Means of egress include exits to grade at the exit portals, exit stairs discharging at grade, cross passage exit doors to adjacent tunnels, and exits to a protected exit passageway. The exiting strategy needs to be coordinated with the life safety program and specifically with the smoke management concepts [20].

Operational Concerns

Emergency Plans Emergency plans may include a wide range of events, including natural hazards such as hurricanes, tornados, tsunamis, winter storms, floods or flash floods, and earthquakes; technological events, such power outages, vehicle impacts, hazardous material releases, gas releases, and explosions; and deliberate events, such as civil disturbances, bomb threats, and acts of terrorism [70]. Depending on the facility, evacuation strategies may need to address some or all of these hazards. These considerations have led to more complex emergency plans and the need for real-time communication systems to direct occupants in the desired response. Despite this additional complexity, evacuation through protected stairways remains the primary strategy, since they provide safe, protected paths out of a structure.

Emergency planning for appropriate responses to specific threats is an active area that has evolved significantly in the past decade. When planning for events other than fire, risk assessment principles can provide guidance, in identifying and quantifying events [20].

- What threats are possible given the building location and use?
- How likely is each threat?
- What are the potential consequences?
- For each event, what strategies will limit the potential for harm to people?
- What holistic strategy provides an appropriate balance of safety?

In some cases, strategies need to balance the level of safety for differing events, as a strategy optimized for one event may not be appropriate for other events. This is particularly true for iconic buildings and spaces.

Evacuation Drills Evacuation drills are an important means of training occupants on what they are expected to do, especially where there are different responses to different threats. The US General Services Administration (GSA) is responsible for approximately 9600 federally owned or leased properties. The GSA conducts

two drills per year in every federal office building, with one a fire evacuation and the other an evacuation for some non-fire event.

In hotels, drills are important for training staff in their duties since staff are responsible for the safety of guests and it is not feasible to train guests in the procedures of the facility. Most fire codes include a requirement for regular drills, but often owners or operators terminate the drill early for fear of liability for injuring an occupant in a drill. For example, a review of high-rise drill requirements in fire codes conducted by NIST in their investigation of the September 11, 2001 WTC attacks revealed that drills conducted in New York City terminate with occupants meeting at the door to the egress stairs on their floor. In Chicago, occupants are required to enter the stairway and travel down not more than two floors. In Los Angeles occupants are required to follow the entire evacuation plan, traveling down stairs to the street level and gathering at the assembly point. This practice of following the complete plan is particularly important to familiarize the occupants with the entire egress system including any transfer corridors, and the exit discharge including assembly for accountability.

Summary

This chapter first overviewed the evolution of emergency egress provisions to provide a better understanding of current egress requirements and strategies. Next, considerations, concepts, and methods for egress strategies were outlined. Features and components that support and facilitate evacuation and protect in place methods are an essential component of building and transport infrastructure life safety strategies.

In summary, egress strategies need to be appropriate to the building design, safety features, function and use, and occupant characteristics. It is important that evacuation strategies coordinate with the overall fire and life safety strategy and specifically address occupants with disabilities or mobility impairments. Occupant evacuation elevators can be used to help occupants evacuate from tall and very tall buildings quickly and can assist those with mobility impairments. Various methods are available to assess evacuation times and are discussed in other Chapters. Evacuation times and queuing information developed as part of a timed evacuation assessment can be used to better understand the evacuation and crowd management concerns. This information can also be used as part of a performance-based evacuation design. Other chapters provide specific methodologies, data and detail to assess strategies and implement these concepts.

Selecting Scenarios for Deterministic Fire Safety Engineering Analysis: Life Safety for Occupants

57

Daniel Nilsson and Rita Fahy

Introduction

In many cases, the principle goal of a fire safety engineering (FSE) design is the life safety of the users of a structure. There are, however, other potential fire safety goals to consider, e.g., property protection, continuity of operations, protection of the environment and protection of cultural heritage [1]. Whatever the goal, users of the building, both building managers and occupants, will have a role in its achievement.

The process of evaluating an FSE design involves the development of scenarios that will test the ability of building protection and other design features to meet the fire safety goals of the analysis. The evaluation of the design involves comparing the predicted development of fire and smoke for a selected set of design fire scenarios against the time required to move any occupants to locations of safety. Little attention has been focused in the past on the combinations of occupant characteristics and other factors that would constitute '*design occupant scenarios*' analogous to design fire scenarios.

The selection of fire scenarios for fire safety engineering (FSE) analysis is outlined in Chap. 38 of this handbook. As discussed in that chapter, there are several fundamental fire safety goals for a building, one of which is to provide life safety for building occupants. This chapter will refine the fire scenario selection process for the specific fire safety goal of life safety for the occupants by showing the designer how to consider egress issues through each step. The aim of this chapter is (1) to provide the designer with a systematic method of incorporating occupants in the design fire scenario selection process, and (2) to give guidance on how, in this process, to identify specific occupant characteristics that should be included in the subsequent analysis, i.e., determine the design occupant scenarios that should be analyzed with each design fire scenario.

Chapter Outline

In the initial part of this chapter (section "Use of Deterministic Analysis in FSE Design"), a general description of the use of deterministic analysis in FSE design is given. This is followed by a section which highlights the importance of a clear definition of the context of a FSE analysis before the scenario selection process is initiated (section "Informing the Scenario Selection Process: Establishing the Context"). In this section, an example illustrating the complexity of scenario selection for the goal of providing life safety for building occupants is also presented. In subsequent sections, the scenario selection process is described in detail (section "Scenario Selection Process") and an example of the selection of scenarios for a hypothetical building is presented (section "Example"). The example is

an expanded version of a sub-set of the scenario selection example presented in Chap. 38 of this handbook.

The scenario selection process described in this chapter is based on the procedure outlined in the document ISO/TS 16733—Selection of design fire scenarios and design fires [2]. However, the procedure is only described for the specific fire safety goal of life safety for occupants, and it focuses on the appropriate incorporation of occupants in the scenario selection process.

Use of Deterministic Analysis in FSE Design

In performance-based FSE design, the designer needs to show that the proposed design delivers a sufficient level of safety. This is often done using some form of risk analysis, but these risk analyses can vary in complexity from simple qualitative reasoning to full quantitative risk analyses [3, 4]. In many cases, a deterministic analysis is chosen because it involves a manageable number of scenarios that can be handled with reasonable work effort.

In deterministic analyses, the hazards are mainly described in terms of their consequences [5], which corresponds to level 2 according to the classification by Paté-Cornell [6] of treatment of uncertainty in risk analyses. (Level 2 is defined there as 'quasi-worst case' or 'plausible upper bounds.') The deterministic analysis, sometimes also called scenario analysis, can be compared to putting the building through a severe fire test. If the proposed building design passes the test, it has also been shown that it will survive most other fires according to the deterministic analysis. Because it is imperative that the included scenarios represent the worst credible cases, it is essential that the scenario selection process is both thorough and systematic.

A deterministic analysis hence involves the selection of severe but reasonable scenarios that challenge the proposed fire safety design of the building. The fact that the scenario should challenge the design means that it must be chosen in relation to the goal of the analysis. For example, if the goal is to provide life safety for building occupants, a small and limited trash fire close to the main exit might be highly relevant as it can block the most important means of escape. However, the same fire is probably not particularly relevant, due to its limited size, if the goal is to prevent structural collapse of the building.

When the goal is to provide life safety for building occupants, the building use and users will always influence which fire scenarios are relevant. This is illustrated by the example above involving the small trash fire at the main exit. It is well-recognized that people tend to use the main exit in case of emergencies [7]. Hence, the fact that the building has a main exit (building use) and the fact that people tend to use the main exit in emergencies (behaviour of users) makes the fire scenario suitable for deterministic analysis, i.e., a credible scenario that severely challenges the fire safety design. The selection of this particular fire scenario also implies that the designer has already started to consider possible occupant scenarios. In this particular case, an occupant scenario involving building occupants initially heading towards the main exit is considered highly relevant, and it is the reason that the small trash fire is considered in the analysis.

In FSE analyses, designers often spend a lot of time and effort on the fire problem, e.g., estimating design HRR curves or simulating smoke spread, but occupant aspects may not always be incorporated appropriately in the design. As illustrated by the trash fire example above, there is always an occupant scenario paired with each fire scenario. This means that the selection of fire scenarios and occupant scenarios for deterministic analysis cannot be done independently, but it is instead a process of finding combined scenarios, i.e., coupled fire and occupant scenarios, which challenge the proposed fire safety design.

Informing the Scenario Selection Process: Establishing the Context

Before scenario selection begins, there are three elements that must be specified—the project scope, the Fire Safety Goals (FSG) and the Fire Safety Objectives (FSO)—because they dictate which scenarios are relevant for consideration in the deterministic analysis. These elements are therefore explained below, followed by a case showing that the scenario selection process is not always simple and straightforward.

Because deterministic analysis involves the identification of the worst credible cases, it is of fundamental importance to know (1) what should be protected (FSG), and (2) how this can be achieved (FSO). As previously mentioned, a deterministic analysis can be compared to putting the building through a severe fire test. This test will be different depending on what aspect is evaluated.

Project Scope

Every performance-based design process starts off with the definition of the project scope [8]. The scope is the project context, e.g., if it is an entirely new building or an existing building, if it involves the whole building or just specific components, etc. Proper definition of the project scope is important since it dictates the boundaries of the analysis. The scope is always project specific, and so for the purposes of this chapter, it will be assumed that it has been defined and will not be discussed further.

Fire Safety Goal (FSG)

The FSG, which is defined next in the performance-based design process, is often expressed in quite general terms. It describes the focus of the analysis, i.e., what is worth protecting? Examples of goals can be to protect property, the environment and/or occupants. In this chapter, only the goal to provide life safety for building occupants is treated. This definition of the FSG will inform the scenario selection process.

Fire Safety Objective (FSO)

Based on the FSG, the FSO is then defined. The FSO can be seen as a specification of how the goals will be achieved. Examples of objectives for life safety are that people should not be exposed to specified critical fire conditions, e.g., heat and smoke, or that queuing time should be within defined limits. In this chapter, only the objective to not expose people to critical fire conditions will be treated since this is an often-mentioned objective in rules and regulations [9, 10].

Specific critical fire conditions, i.e., performance criteria, are sometimes given in rules and regulations [9] and often involve limiting values (or doses) for temperature, radiation, toxic gases, visibility and/or smoke layer height [9, 11, 12]. In this chapter, however, critical fire conditions are not specified, but they are assumed to involve limiting values (or doses) related to the effects of fire.

Discussion of Scenario Relevance: A Case Study

Before presenting the steps required for selecting design scenarios, it is important to emphasize that the analysis is an integrated process, where the designer has to consider the fire, building uses and users simultaneously. The choice of scenarios is not necessarily intuitive. It is not sufficient to merely choose the biggest fire, i.e., the fire with the fastest growth rate or the highest peak heat release rate. Such a fire will not necessarily be the fire that presents the greatest challenge when the FSG is life safety for building occupants. For example, it might instead be a smaller fire close to the main entrance, e.g., in the foyer of a hotel, that presents the greatest risk of exposing evacuating occupants to critical fire conditions, i.e., that challenges the achievement of the FSO.

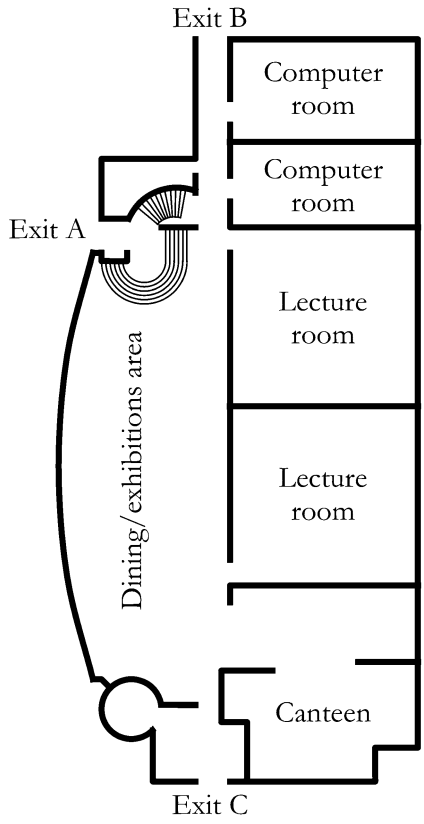

Fig. 57.1 Ground floor of the building

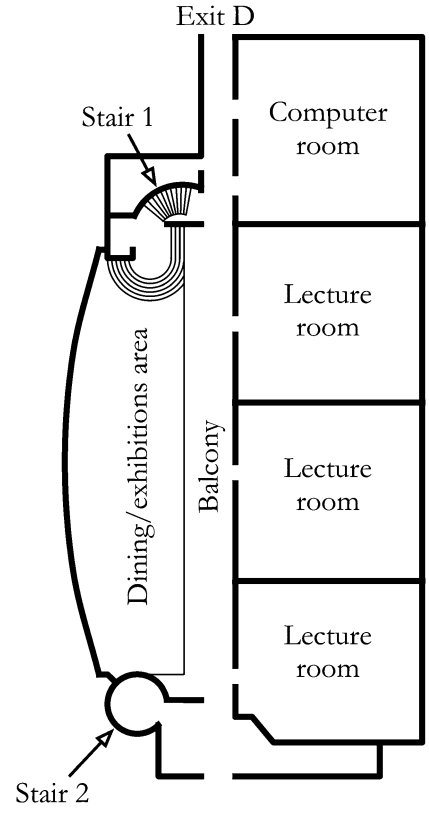

Fig. 57.2 Upper floor of the building

One example that illustrates the complexity of scenario selection is a case study involving cable fires in a university building [13]. The goal of the study was to select the fire scenario that would most severely challenge the FSG, which in this case was life safety for building occupants.

The structure is an existing four-story university building with lecture rooms, computer labs, offices, a small food service area and a combined dining/exhibition area. However, only the combined dining/exhibition area and the adjacent food service area, lecture rooms and computer labs were included in the analysis, see Figs. 57.1 and 57.2. This part of the building covers two floors, referred to as the ground floor and the upper floor. The dining/exhibition area, which has a slanted ceiling, is open from the ground floor to the balcony on the upper floor, see Fig. 57.3.

As the fire under consideration involved burning cables in a vertical cable tray, the heat release rate of the fires was prescribed. Hence, the main variable for the analysis was determining the fire location. Based on an inventory of the fire load in the building, i.e., locations where a significant amount of cable would be expected, it was clear that there were only a limited number of areas where fire could be expected to occur.

A pilot study of people's movement patterns in this building revealed that Exit A is the main exit for most people going to the food service area, lecture rooms and computer labs. People using the lecture rooms on the upper floor most often use Stair 1, which is a spiral staircase in the open area of the dining/exhibition area, near Exit A. This means that the dining/exhibition area is a location that most people pass through every day and therefore also the preferred evacuation route in emergency situations. A key feature in any building is the main exit/entrance of the building, as it is well-established that people tend to move

Fig. 57.3 View of the dining/exhibitions area of the building from the top of Stair 2

towards familiar exits in emergencies [7]. This makes a fire in the dining/exhibition, or the adjacent food service area (no fire separation), most challenging for the achievement of the FSO.

Given that most occupants would move toward Exit A, it might make intuitive sense simply to place the ignition point in the foyer at the exit. In this case study, however, a number of different specific fire locations within the dining/exhibition area and food service area were identified, and the most challenging of these was found with the help of CFD simulations.

The food service area was the first fire location that was tested, see Fire Location I in Fig. 57.4. This location was chosen since it has many possible ignition sources as well as many areas with a considerable amount of cables. CFD simulations showed that smoke spread out through the opening between the food service area and the dining/exhibition area, creating a wide plume at the balcony. Eventually, a relatively well-mixed smoke layer was created at the balcony on the upper floor. Although this smoke layer would engulf people on the balcony, the smoke would not be very dense, according to the simulations.

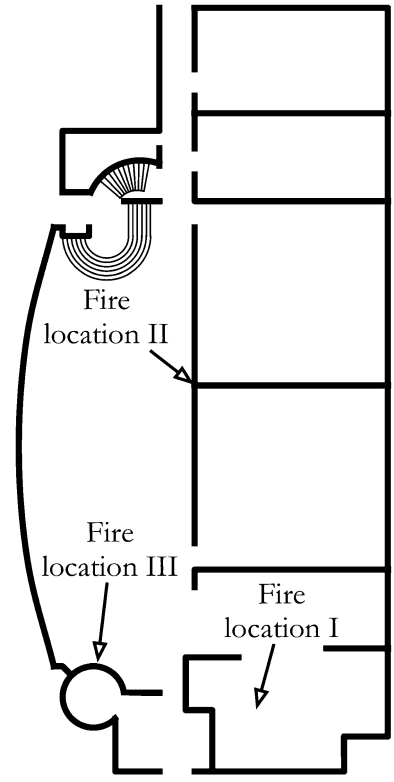

Fig. 57.4 Fire locations in the building (ground floor)

The second fire location was a cable shaft underneath the balcony at the ground floor, see Fire Location II in Fig. 57.4. This location was chosen mainly because of the considerable amount of cables in the cable shaft. CFD simulations of the smoke spread showed that a relatively wide balcony plume was generated, which eventually led to a smoke layer that covered the upper part of the balcony. The conditions in the smoke layer were considerably worse than for the fire in the canteen, which makes it a more challenging scenario in relation to the FSO.

The third and final fire location was close to the food service area but in the part of the dining/exhibition area with the slanted ceiling, see Fire Location III in Fig. 57.4. This location was chosen because cables can be expected during exhibitions and a fire occurring at that time could potentially threaten large numbers of people. CFD simulations of the smoke spread revealed that, once the plume hit the slanted ceiling, the smoke travelled along the ceiling towards the balcony. At the balcony the smoke hit a structural beam, which created a swirl that made the smoke move very rapidly along the ceiling at the balcony towards Stair 1. On hitting the wall, the smoke was pushed down quickly, creating severe conditions at the top of Stair 1.

The third fire location was deemed to be the most severe as it involves a conflict between smoke spread and evacuation. The conditions quickly became severe at the top of Stair 1, which is most likely the preferred evacuation route for people in the lecture rooms on the upper floor. Also, these people could be expected to still be moving through that area. Another important issue is that the fire is located in the far end of the dining/exhibition area, i.e., away from Stair 1, which means that people will move towards Stair 1 if they try to move away from the fire. Also, the rapid deterioration of the conditions at the top of Stair 1 means that people might be caught by the smoke. This conflict between evacuation and smoke spread makes the fire in the dining/exhibition area, under the slanted ceiling, the scenario that most severely challenges the FSO.

In this case study, simulations were used to determine the most challenging fire location, and showed that the most challenging location was not the one that conventional wisdom might have led the designer to choose. Simulations are not always necessary, and the selection process can be based on simpler and more straightforward approaches, e.g., theoretical reasoning. As illustrated by the case study, it is, however, an iterative process that considers both occupant and fire aspects simultaneously. This is necessary for finding the scenarios that challenge the achievement of the FSO. In order for the selection process to be possible, the designer hence needs to know the characteristics of the building users, which depend on the building features and building use.

Scenario Selection Process

After the FSG and FSO are defined, the scenario selection process begins. A key element in appropriate scenario selection for life safety of occupants is to carefully consider the expected *uses* of the building and the type of people who would, as a result, be the expected *users* of the building.

Selection of fire scenarios has often not tied the process as specifically to a particular building design as is necessary for the selection of scenarios for life safety. The focus on a particular design is necessary in order to assist the designer in considering the full range of users, and the variation in the types of users, who might occupy the building and need protection.

Identification of Building Uses

Specifying the building use can be simple (and almost trivial) for a single-use building. It is, however, still important to focus on the function a building is intended to fulfil, in order to fully account for the types of people who will use that building. Most buildings with engineered design will likely have multiple uses, for example, a hotel with sleeping rooms, meeting spaces,

restaurants, pool, etc., or an arena suited for various uses such as sporting events, conventions, entertainment, etc.

One illustrative example of a building with multiple uses is an arena and events centre [14]. This type of building may host a wide range of events, e.g., everything from sporting events to conferences, which in turn will influence the number and composition of occupants. It is therefore imperative for the designer to list all uses that the building is designed for. This is particularly important for structures that are inherently multi-functional, e.g., transit stations, airports, shopping malls, etc. For example, a typical transit station may contain functions such as a bus station, rail station, parking area and shops. Each of these functions or uses of the transit station might be associated with distinctly different users.

The use of a building is not only linked to the abovementioned functions, but also depends on the internal building layout. This layout influences how people move in the building during normal operation, i.e., the circulation paths, and how they usually enter and exit. There might also be specific functions that are important waypoints during everyday use, e.g., a parking garage in a shopping mall or the cash desk in a store. Since everyday physical use also influences the physical use in emergency situations, e.g., the egress paths and choice of exits [7, 15], it is imperative that the designer is familiar with the expected physical use and identifies the:

- *circulation paths*,
- *main exits/entrances*,
- *important waypoints*

Ideally, the emergency egress design of a building should be based on the everyday physical use, but for technical reasons this might not always be possible. When possible, it makes perfect sense to use the everyday exit/entrance of a building as an emergency exit, however, legislation might require a certain maximum length of egress paths, which can result in the installation of several emergency exits between a person's original position and the main exit/entrance. When these emergency exits are not used regularly during everyday building operations, they are likely to be overlooked or ignored during emergency evacuations [15, 16]. They still are an integral part of the emergency egress design, but the designer cannot assume that unfamiliar building features will always be used in an emergency. This is hence an example of why it is essential for the designer to always identify the expected physical use of the building.

Identification of Users and Their Characteristics

The *uses* of the building should provide a strong indication of the expected *users*. Once the uses of the building have been specified, the next step is to consider the types and numbers of people who will make use of the building in those ways.

Inventory of Characteristics

For the purpose of this chapter it is appropriate to divide occupant characteristics into the following categories:

- *permanent/transitory*,
- *trained/untrained*,
- *potential age ranges*,
- *cognitive*, *sensory or mobility issues*,
- *potential vulnerabilities*,
- *awake/asleep/unconscious/intoxicated*,
- *social groupings or not*,
- *role*

The number of people in any category for any characteristic will vary over time. As part of the scenario selection process, the designer must be aware of the distributions of occupant characteristics that may be present.

For example, a hospital would have permanent staff and transitory patients (in some expected proportion); the staff should be trained, the patients would not be; the staff would be working age, the patients' ages would depend on the hospital's specialities; the staff would have an expected distribution of physical disabilities, the patient vulnerabilities would depend on the hospital's speciality; the variability in the composition of the occupant groups would be limited to what would be expected for the hospital's speciality, i.e., the patients would all be sick or injured to some degree.

Similarly, a hotel would have a permanent staff and transitory guests (in some expected proportion); the staff should be trained, the guests would not be; the staff would be working age, the guests could be any age but generally mostly adults; the staff would have an expected distribution of physical disabilities, the guests could have any disabilities and the proportion of guests with disabilities could range from low to high; the hotel guests would be using sleeping rooms as well as function rooms/public spaces and would vary widely—function rooms full of children, drinkers, meetings of people with disabilities need to be considered; sleeping rooms could be filled with guests with special needs attending conferences, possibly.

Shopping centres and offices would have permanent staff and transitory customers and visitors who might have some familiarity with the space (in some expected proportion). The permanent staff may or may not be trained, but the customers and visitors would not. Again, there would be variation in the distribution of occupants with disabilities and of different age groups. All occupants would be awake. The potential for occupants to be intoxicated would have to be considered.

Why These Characteristics Are Issues

Each of the characteristics listed above are important because of the impact they can have on evacuation. These impacts can affect awareness of cues, including alarms, delay times after notification but before movement to exits, travel speeds and vulnerability to toxic exposures, etc. These effects can vary over time and the designer must take this variance into consideration in the scenario selection. A brief description of the eight characteristics is given below:

- *permanent/transitory*—Permanent staff or residents can be expected to be more familiar with a building and its systems than people who are in a building only once or occasionally. This can affect each occupant's ability to recognize alarm signals, identify alternate escape routes, or have any familiarity with a building's emergency management plan. Permanent occupants who are familiar with a building may provide guidance to transitory occupants, either proactively or simply by example, but if they are vastly outnumbered by transitory occupants, that effect may be muted.
- *trained/untrained*—Trained occupants should be familiar with a building's emergency management plan, its alarm signals, procedures and emergency exits. Designers dealing with a building with many untrained people cannot assume that their reactions and actions will be optimal.
- *potential age ranges*—Mobility, sensory and cognitive ability vary with age. Children and those with age-related cognitive issues cannot be assumed to make independent decisions that will lead to self-rescue. Young children will need assistance in evacuating a building, and they and older adults may move more slowly than others. The ages of people present in the building can vary with the current use of a building. For example, an assembly property can be used by an audience of adults or an audience of children or families, with very different ranges of cognitive abilities.
- *cognitive*, *sensory or mobility issues*—Some of the building users may have disabilities not related to age that would affect their ability to perceive or recognize fire cues and/or react to an emergency. These occupants can be either permanent or transitory users of the building.
- *potential vulnerabilities*—The effect of toxic products can vary according to the vulnerability of those exposed, so the designer must recognize that there will be some range of vulnerability among the building users, i.e., one cannot assume that all building occupants will be healthy adults who will be able to tolerate the same level of smoke or other products of combustion.
- *awake/asleep/unconscious/intoxicated*—People who are asleep are likely slow to respond to fire cues [17]. If people sleep through much of a fire incident, the evacuation conditions can be very challenging when they wake up and decide to escape. The fact that people

can be intoxicated might make the problem even worse since studies have shown that even small amounts of alcohol influence the probability of people waking up from a fire alarm [18]. Alcohol has also been shown to impair decision making abilities and increase reaction time [19].

- *social groupings or not*—family groups will assemble before evacuating and will likely move together, at the speed of the slowest member, so the presence of family groups can have an impact on evacuation [7]. This may be true of other groups as well, e.g., friends, colleagues, etc. Social influence has an impact on decision making, so the presence of groups, or of a high proportion of occupants present on their own, can affect how rapidly cues are acted upon [20].
- *role*—It has been observed in real fires that occupants may continue to function in certain roles, particularly those they fill during the normal use of the building; for example, servers in a restaurant assisting the guests at their tables, and the guests looking to the servers for guidance [21]. Similarly, students may look to teachers for guidance, employees may look to managers or supervisors, etc.

The types of people using a building, i.e., the proportion of people in those listed categories, may vary over time. For example, the guests registered in a hotel could be family groups one week and convention attendees another week. Depending on the appeal of special events, the proportion of the occupant population with certain issues or vulnerabilities can vary widely. In places such as specialized hospitals, where the characteristics of the occupants will tend to be the same over time, the number of occupants and the presence of staff might vary.

Determination of Life Safety Challenges

Because the aim of the deterministic analysis is to test the fire safety design using a selection of severe but credible scenarios, it is imperative to identify any issues or conflicts that, in combination with fire, could potentially lead to the failure of the design. These issues and conflicts are referred to here as *life safety challenges*. Such issues are often occupant characteristics that lead to non-optimal response or movement in emergency situations. Conflicts often involve a mismatch between building uses and users or between users and building layout.

An example of an issue that can result in a life safety challenge is intoxication. It has been shown in previous studies that alcohol has an effect on a person's ability to waken and respond to an alarm [18]. Intoxication can therefore pose an important life safety challenge in a hotel where guests can be expected to be asleep. Similarly, a designer will have to consider the effect of large numbers of intoxicated occupants who might be using any place of assembly, either free-standing, e.g., a concert venue, arena or nightclub, or part of a larger complex, e.g., a hotel ballroom.

One example of a life safety challenge involving the conflict between the building layout and building users may occur if people with movement impairments are forced to evacuate via the stairs. If the elevators cannot be used for evacuation, wheelchair users might not be able to leave their floor in case of a fire. Although, it is possible to wait in protected evacuation stairs, this is not an optimal situation for wheelchair users. Similar problems also apply to people who do not use wheelchairs but have other types of movement disabilities.

A typical life safety challenge involving a conflict between building uses and users is people's tendency to use familiar exits [7]. This tendency means that people will try to move towards the main entrance/exit, which is a potential major evacuation bottleneck in case of fire. A fire that quickly renders the main entrance unusable is therefore a scenario that severely challenges the fire safety design.

The case study in section "Discussion of Scenario Relevance: A Case Study" showed that uncovering the life safety challenge of a design is an iterative process that requires consideration of the building layout, fire, building use and users. In that case, the placement of the fire resulted in a choice of exits that itself resulted in a dangerous bottleneck.

Steps in Selecting Scenarios

Once the building uses and users, as well as the relevant life safety challenges, have been identified, the scenario selection process described in Chap. 38 of this handbook can be initiated. This selection is based on the 10-step procedure described in the document ISO/TS 16733. The 10 steps are listed in Table 57.1.

For deterministic analyses, the first five steps involve identification of the fire-related factors/aspects that most severely threatens the achievement of the FSO. The identification of these factors/aspects is always done in relation to the life safety challenges. In steps 6 to 10, the factors/aspects are combined into fire scenarios from which design fire scenarios are then selected.

Table 57.1 Steps in the scenario selection process according to ISO TS 16733

SCENARIO SELECTION PROCESS in ISO TS 16733
A process for selecting design fire scenarios and design fires involves 10 steps:
Step 1—Location of fire Identify the location of the fire
Step 2—Type of fire Specify the type of fire, e.g., initial intensity, rate of growth, items involved, etc.
Step 3—Potential fire hazards Consider potential fire hazards associated with the use of the property or design
Step 4—Systems and features impacting on fire Identify fire safety systems and features that can impact fire growth and smoke spread
Step 5—People response Occupant response following ignition, i.e., responses impacting on fire
Step 6—Event tree Construct an event tree that represents the sequence from ignition to outcome
Step 7—Consideration of probability Consider the probability of each event in the event tree
Step 8—Consideration of consequence Estimate the consequence of each scenario
Step 9—Risk ranking Rank the scenarios in order of risk
Step 10—Final selection and documentation Final selection of design scenarios and documentation of the reasons for selection
Steps 6 to 10 all belong to the **Scenario Selection Process**, i.e., the process in which a set of design scenarios are chosen from the range of identified scenarios

Location of Fire (Step 1)

In keeping with the FSG of life safety for occupants, fire locations most likely to threaten people will be the focus at this step. Locations are chosen in relation to identified life safety challenges. This could be due to the fire's proximity to occupied spaces, escape routes or its potential for spread of fire or toxic products into occupied spaces or escape routes and stairs.

The designer has to be sensitive to potential life safety challenges—bottlenecks in the design, critical route junctions where exit paths converge, and access to the main entrance/exit (favoured route), for example. Occupant characteristics can also impact the selection of ignition location. For example, if intoxication is an expected life safety challenge for the building, then consideration must be given to the ways that intoxication can impact an individual's ability to handle complicated way-finding tasks. Ignition locations that would require occupants to make decisions about a travel path could be a challenge for those cognitively impaired by intoxication.

Fuel packages near sensitive locations might not be involved in ignition but are vulnerable to spread. Fires in remote locations can spread smoke into escape routes. The case study in section "Discussion of Scenario Relevance: A Case Study" illustrated the situation where a fire remote from the main entrance would produce smoke in the locations where occupants would move in their efforts to reach the main entrance.

Fires that will not develop, spread into, or damage areas where occupants are located (originally or during evacuation) can be ignored for this fire safety objective.

Type of Fire (Step 2)

The issues critical to occupant movement and survivability must be considered in this step. The primary issues are visibility (due to either

smoke obscuration or irritants), heat and toxicity. Long-term effects of toxic exposure must also be considered, especially for vulnerable populations.

Visibility will be reduced by fires that generate a lot of soot, due to inefficient combustion or involvement of materials that generate soot. Lack of visibility will slow occupant movement, resulting in longer evacuation times. Exit signs will be obscured, complicating way-finding for occupants, even for those familiar with the building.

Irritants, e.g., hydrogen chloride, formaldehyde, acrolein, isocyanates, etc., can be a factor as a result of pain and discomfort, e.g., people cannot keep their eyes open, and may also be lethal. Toxic levels of irritants and asphyxiants can threaten occupants in under-ventilated fires or fires involving items such as PVC furniture. Plastics and cables, when burning, can generate compounds that are lethal in small quantities. More details on toxicity can be found in Chap. 63 of this handbook.

Slow-growing fires may create more irritants, with potential for long-term consequences in vulnerable people; fast-growing fires can expose people to heat sooner and result in entrapment. In considering the type of fire, the designer should evaluate the potential fire growth and toxicity of the involved materials. For example, for a fire involving a sofa composed of polyurethane foam and some wood, the focus should be on the foam, which will have a higher rate of burning than the wood and a smoke potential that is a factor of 5 or more higher [22] On the other hand, if a small piece of furniture is located close to a large quantity of wood, the greater threat may be presented by the wood.

Potential Fire Hazards (Step 3)

ISO/TS 16733 lists several hazards that should be considered in this step, including earthquakes and terrorist events that can result in multiple fires or disable multiple safety systems simultaneously; non-fire events that can impair structural stability; and the presence of high-hazard materials and operations that can initiate fires or complicate their suppression. Some events might also eliminate the power supply, thus knocking out the building's notification, lighting and communications systems.

Potential fire hazards should be considered in this step as they relate to occupant safety or evacuation. For example, an earthquake or terrorist attack could completely change the evacuation from what is expected. That is, the physical environment is changed and things not included in an ordinary evacuation would have to be considered, such as debris in travel paths, routes eliminated due to broken stairwells, etc. This type of change of physical environment was observed in the explosion test of the METRO project. In this test, a small explosive device not only destroyed the interior of the primary railway car, but also jammed the doors of the adjacent cars [23].

In some areas, a combination of earthquake and fire should be considered. This can be particularly dangerous as an earthquake might damage existing fire safety features or systems. This was the case in the Kobe earthquake where the sprinkler systems in some buildings were damaged by the earthquake [24]. The motion of a building in an earthquake can also distort doorframes and damage locks, affecting the passive resistance of doors and impeding evacuation [25]. This specific potential fire hazard will, however, not be relevant for all parts of the world.

Systems and Features Impacting on Fire (Step 4)

In this step, the designer must consider how the presence and functioning of passive and active protection systems in the building might affect evacuation and life safety. This should also include how the expected occupants might use or misuse the fire safety systems and features of a design, and how that might impact fire development and smoke spread from an evacuation point of view.

Among the passive systems and features that must be considered are doors, windows, structural elements, contents and furnishings and size of compartment. For example, the composition of the occupant population might influence the likelihood that a door will be closed or left open.

If a door is open, fire and smoke can spread into occupied areas and evacuation routes. If a door is closed, the scenario might not be relevant for life safety, as the closed door might afford some protection to occupants on the other side of the door. If occupants will have to move through a closed door, there could be difficulties presented by the latching mechanism or door handle, or by the opening force required by the door.

Active systems include smoke control and suppression systems; detection, warning and communication systems; fire safety management; and firefighting operations. There are various issues to consider as to how life safety can be impacted by the presence and functioning of active systems.

With smoke control systems, for example, occupants in high-rise buildings might regularly prop open the doors into pressurized stairwells. This might influence the functioning of the pressurization in a fire, hence allowing smoke to enter occupied spaces, i.e., the stairwell. A fire management plan or building maintenance program could minimize the likelihood of such a practice.

Without an operating sprinkler system, the smoke layers may be more stratified, with better visibility below the smoke layer. A sprinkler system will be expected to prevent a small fire from becoming an uncontrolled fire, but the increased mixing may result in reduced visibility in travel paths. The designer will have to factor in the effect that that will have on the evacuation or smoke exposure to vulnerable occupants.

Other systems that might influence the consequences of a specific fire scenario, such as notification and egress systems, are important to consider even if they do not directly affect fire or the smoke spread. Notification systems can alert and guide occupants in their evacuation. Determining the effectiveness of the system will have to take into consideration the abilities and disabilities of the expected occupant population. For example, how will people with different sensory impairments, e.g., hearing or vision, be alerted?

Egress systems, such as emergency elevators, will impact the evacuation, as will a fire safety management plan that will establish the likelihood of trained staff present, quality of any training provided, and overall planning and preparation for emergencies.

People Response (Step 5)

For *any* fire safety objective, the designer has to consider how the expected occupants might impact the development and spread of the fire. Under Step 4, the use or misuse of the fire safety systems and features of a design were discussed. In Step 5, consideration is given to the presence of trained occupants, who might begin warning or suppression activities. Occupants might change the conditions in ways that affect the evacuation or exposure to fire and smoke, in positive or negative ways, such as opening a manual smoke hatch (if trained to do this correctly), or inadvertently opening too many doors in a pressurized stairwell, for example. Opening too many doors might influence the functioning of the pressurization system. The mobility of the expected population will affect the likelihood of many doors being open for a long time. A fire management plan, e.g., a phased evacuation, and training could minimize the likelihood of this happening.

Scenario Selection Process (Step 6 to 10)

At this point in the process, the designer has compiled a large number of potential fire scenarios that have factored in issues related to occupant characteristics. The next series of steps (Steps 6 to 10) present a quantitative approach for the selection of design fire scenarios using an event tree. Alternatively, a more qualitative approach for selecting design fire scenarios can be followed, e.g., using a risk matrix.

In either case, at this point, the designer needs to consider the specific descriptions of expected occupants that will complement the design fire scenarios. For example, in order to develop an event tree, the likelihood of occupants attempting fire fighting or interfering in the operation of safety systems will depend on the composition and location of the occupant population.

In Step 6, an event tree is constructed describing the possible chronological sequences of

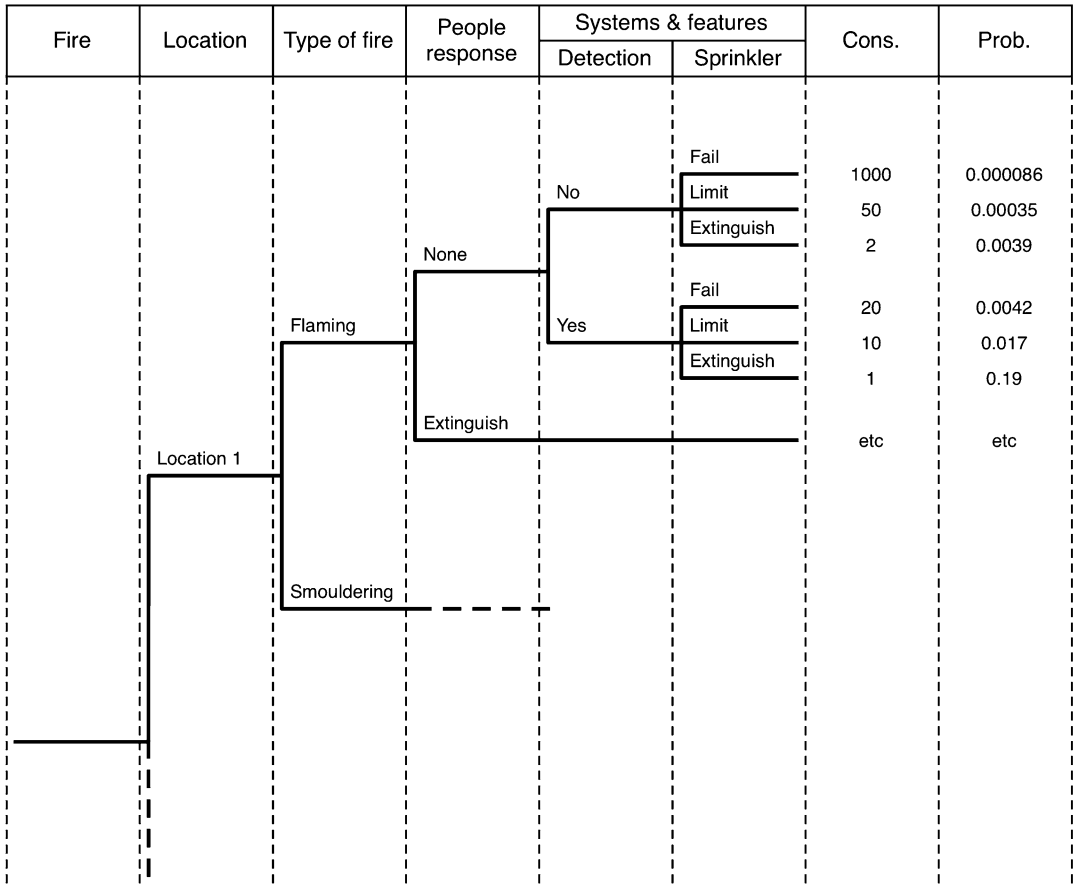

Fig. 57.5 An example of a part of an event tree that combines the aspects/factors identified in Steps 1 to 5 in a chronological order

events from the start of the fire to the final outcome for life safety. This event tree should combine the different factors/aspects identified in Steps 1 to 5, see example in Fig. 57.5. It is not necessary to combine all aspects/factors with each other as some combinations might not even be possible or might not be relevant for life safety. For example, the combination of a fire location with a specific fire safety system may be omitted simply because there is no such system in that part of the building.

In Step 7, the probability of occurrence of each event in the event tree is estimated. These estimates can be based on available statistics or, if no such statistics exist, on engineering judgement. In this step, it is important to consider how the occupant population might influence the probabilities associated with different events. For example, as mentioned in section "Systems and Features Impacting on Fire (Step 4)", the mobility of the expected population might affect the likelihood of failure of any stairwell pressurisation systems. Finally, the probabilities of events are combined to provide the probability of each branch of the event tree, i.e., the probability for each scenario.

In Step 8, the consequences for life safety of each scenario are quantified. If possible, these estimates can be based on available statistics, but in many cases engineering judgement must instead be applied. This step usually involves rough estimates of the consequences in terms of the number of people exposed to critical conditions for each scenario. During this

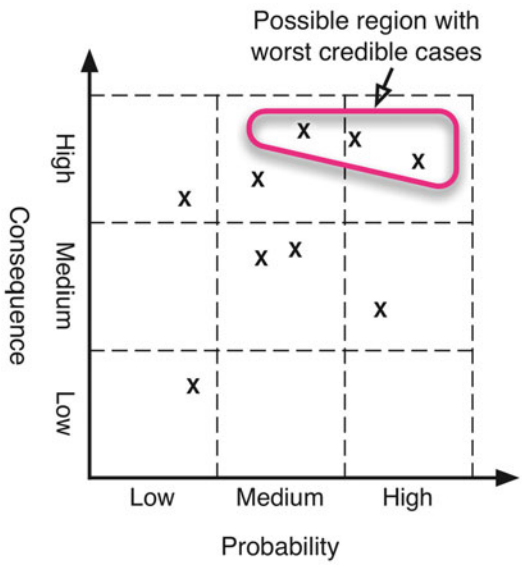

Fig. 57.6 An example of a risk matrix with scenarios (X) and a possible region with worst credible cases

estimation process, it is particularly important to recall the thought process behind the identification of aspects/factors in Steps 1 to 5. For example, a particular system might have been identified in Step 4 due to the potential high impact on life safety if it fails. Therefore, the consequence of scenarios involving failing of that system should most likely be high.

In Step 9, the probabilities and consequences of each scenario are combined into a measure of risk. According to ISO/TS 16733, the relative risk can be estimated by multiplying the probability with the consequence for each scenario. An alternative way to illustrate the risk is to insert the different scenarios in a risk matrix, see Fig. 57.6. Because the axes of the risk matrix are expressed in terms of probability and consequence, the matrix offers a more refined view of the risk associated with each scenario. It is also a useful tool for the deterministic analysis because it can be used to identify worst credible cases, e.g., scenarios with moderate or higher probability and high consequence, see Fig. 57.6.

Finally, the highest ranked scenarios in Step 9 are selected for the deterministic analysis in Step 10. These scenarios constitute the design fire scenarios. Step 10 also includes documentation of the design fire scenarios, as well as documentation of the non-selected scenarios including possible reasons for these not being chosen.

The scenario selection process and the methods/tools that can be applied are not described in great detail in this chapter. The reader is instead referred to the discussion on selection of fire scenarios in Chap. 38 of this handbook. It is, however, important to point out that the selection process for the type of deterministic analysis described in this chapter will focus on finding worst credible cases, i.e., design scenarios that challenge the achievement of the FSO.

Deriving Design Occupant Scenarios

The identification of fire-related factors/aspects that threaten the achievement of the FSO (Steps 1 to 5) and the selection of design fire scenarios (Steps 6 to 10) are linked to the fire safety challenges. Hence, each design fire scenario is linked to occupant-related issues or conflicts that, in combination with fire, could potentially lead to the failure of the design. In fact, every single design fire scenario in the deterministic analysis should have been chosen because of an expected evacuation problem or concern. For example, a fast growing fire in the main entrance of a department store in combination with a failing sprinkler system, i.e., the design fire scenario, might have been chosen because there is a conflict between building uses and users (people's tendency to use familiar exits), i.e., a specific life safety challenge. A severe fire in the main entrance of the department store would result in many people potentially being exposed to critical fire conditions.

Determination of design occupant scenarios is the process of re-examining the basis for the identification of fire-related factors/aspects (Steps 1 to 5) and selection of design fire scenarios (Steps 6 to 10). For the example above involving a severe fire at the main entrance of a department store, the design occupant scenario might involve a large number of untrained

occupants moving towards the everyday exit. Evacuees can be expected to be mainly shoppers, which for a specific combination of time and day might include a significant proportion of elderly, family groups and people with disabilities. Fire experience data can be used to determine the time of day the selected type of fire would most likely occur, and demographic data could help determine the appropriate mix of occupants at that time. In combination, these occupant-related factors/aspects make up the design occupant scenario for the design fire scenario involving the fire at the main entrance of the department store. Together, the design fire and occupant scenarios represent a severe but still credible case, which is the essence of the deterministic analysis.

The design occupant scenario is merely a qualitative description of the relevant occupant factors/aspects to be included in the deterministic analysis. Hence, the scenarios need to be expressed in quantitative terms in order to enable fire safety analysis. This involves the quantification of occupant- and evacuation-related variables for each of the chosen design occupant scenarios. These variables must include, but are not limited to:

- *number of occupants and their location*,
- *exact combination of occupant characteristics*,
- *initial response of occupants*, and
- *initial route choice of occupants*.

These variables are combined to form a qualitative description of the design occupant scenario related to each design fire scenario. The quantification of variables has to produce severe but reasonable conditions. However, much of the work related to the combination has already been considered during the identification of life safety challenges. For data and research that will assist in quantifying the occupant-related variables, the reader is referred to in Chap. 64.

Evacuation Variables for Sensitivity Analysis

Because the deterministic analysis involves a selection of a small subset of all the endless number of possible scenarios, i.e., the worst credible cases, it is important to investigate the effect of reasonable changes of different variables on the end result. If a small change of one variable, e.g., the proportion of people in wheelchairs, leads to the FSO not being achieved, the designer should question the level of safety. A sensitivity analysis, i.e., the process of changing different variables one at a time within reasonable limits [26], is one way to test the robustness of the fire safety design.

A sensitivity analysis should involve both fire- and occupant-related variables. The selection of occupant-related variables for the sensitivity analysis can be based on the occupant- and evacuation-related variables (see section "Deriving Design Occupant Scenarios"). In relation to the combination of occupant characteristics (second bullet in section "Deriving Design Occupant Scenarios"), the previously listed characteristics can be used as a starting point (see section "Inventory of Characteristics").

Example

In the following section, an example that illustrates the incorporation of human behaviour aspects in the scenario selection process is presented. The example is a subset of the example given in the chapter about fire scenarios in Chap. 38 of this handbook, but an expanded explanation of the motives behind the scenario selection is given in this presentation.

The designs used in this example are for a new building complex. This means that the plans are not final and could potentially change depending on the outcome of the analysis. In this example, however, the design is only analysed once, i.e., no modifications are considered. Ideally, the design process should be iterative in order to achieve an acceptable building design at the end of the analysis. However, in this simple example the building design is treated as if it were final.

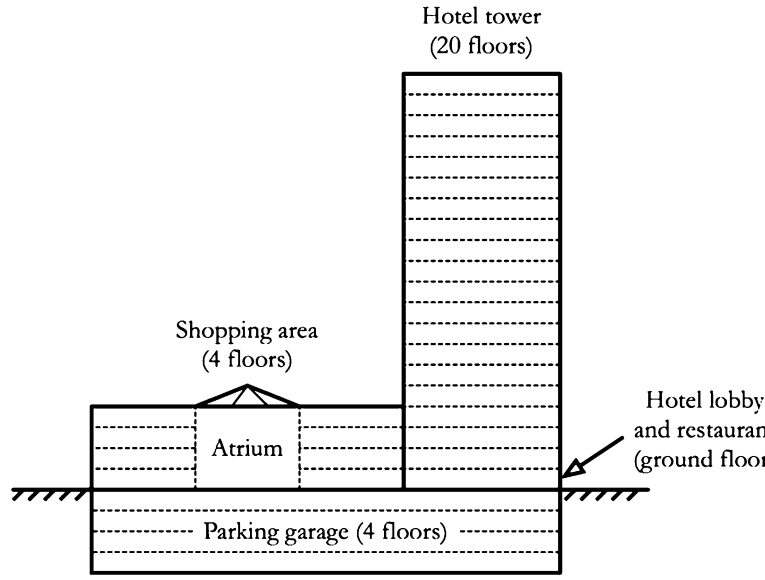

Fig. 57.7 A schematic drawing of the building complex

Description of the Building

The example is a building complex with multiple occupancies, see Fig. 57.7. The four floors underground constitute a parking garage. There is also a shopping area on the first four floors of the building, which are connected through an atrium. At one end of the building there is a 20-story hotel tower. The building is sprinklered and there is a fire alarm system. In case of emergency, people are notified by means of a voice alarm. Also, the atrium is equipped with a smoke exhaust system.

This analysis does not include the entire building complex, but instead focuses on the 20-story hotel tower. The ground floor of the hotel includes a lobby, restaurant, kitchen, three elevators and two independent evacuation stairs, see Fig. 57.8. The ground floor has an open layout, which means that there are no partitions between the lobby and the restaurant. All floors above the ground floor have a similar layout and include hotel rooms, storage rooms, three elevators and two independent evacuation stairs, see Fig. 57.9. One hotel room per floor is designed to be accessible. All accessible rooms are located close to the elevators.

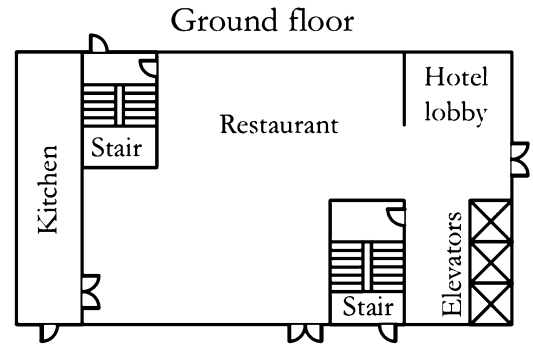

Fig. 57.8 The layout of the ground floor

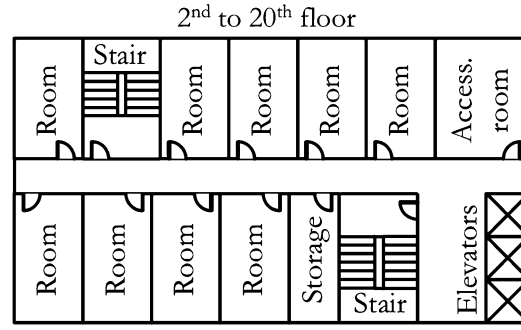

Fig. 57.9 The layout of the 2nd to 20th floor

Fire Safety Goal and Fire Safety Objectives

The only FSG used in this example is the goal to provide life safety for building occupants. This goal is assumed to be reached by achieving the FSO to not expose people to critical fire conditions. The critical conditions are not specified in this example, but include limiting values for species (CO_2, CO, O_2, HCN, etc), temperature, visibility and radiation.

Identification of Building Uses

This building has several uses. It is mainly used as a hotel, i.e., a temporary place of accommodation. As can be seen in Fig. 57.9, there are both regular rooms and accessible rooms on each hotel floor. On the ground floor of the building there is also a restaurant. All types of meals might be served in the restaurant, e.g., breakfast, lunch and dinner, but it might also host other types of events, e.g., private parties or receptions. However, the restaurant is not intended to be used as a nightclub or bar. Finally, the hotel is also the workplace of the hotel/restaurant staff. For example, people will be working in the restaurant, kitchen, hotel lobby, hotel floors, etc.

The most important aspects of physical use of the building are linked to the main exit/entrance and important waypoints. For the 20-story hotel tower, the main exit/entrance of the complex is the entrance door near the hotel lobby. It is expected that this is the main way in and out from the building during everyday use. Two major waypoints for the hotel guests are (1) the hotel lobby, where people can get information or assistance, and (2) the elevator lobby (or elevators), which people usually pass on their way to or from their room. For restaurant guests, one major waypoint is the entrance to the restaurant where the coatroom is also located. As the movement patterns are relatively simple for the 20-story hotel tower, e.g., occupants moving to and from their hotel room or to and from the restaurant, there are no complicated circulation paths.

Identification of Users and Their Characteristics

The uses of the building are each associated with a number of different users. The main users in the example are the hotel guests. Most guests are likely unfamiliar with the building as it is only temporary accommodation (*transitory* and *untrained*). However, other characteristics of the guests may vary widely. It can be expected that the hotel is used by people on, for example, business trips, romantic getaway weekends and family holidays, which implies that the users can be single persons, couples and families (*social groupings*). Both adults and children can be expected (*age range*). It is also expected that people with disabilities will use the hotel, and the types of disabilities can include everything from a hearing impairment to a movement disability (*vulnerabilities*). More specifically, it can be expected that some guests use wheelchairs as the hotel offers accessible rooms (*vulnerabilities*). Another user characteristic that might be relevant for the scenario selection is the level of intoxication (*unconscious/intoxicated*). Finally, guests might be awake or asleep (*awake/asleep*).

The restaurant guests constitute another important group of users in the example. Many of the restaurant guests might also be hotel guests, but others might be people who are just visiting the 20-story hotel tower for a meal (*transitory*). Guests might visit the restaurant in a variety of different combinations, such as families, groups of friends, couples and single individuals (*social groupings*). As the restaurant is not a place that most guests visit frequently, they are expected to be relatively unfamiliar with the environment (*untrained*). Also, a restaurant is a setting in which people's roles and associated rules can be very important, i.e., guest versus server (*role*). This relationship is associated with rules that dictate people's behaviour, and it is, for example, likely that the guests will display more passive behaviour compared to that of servers [27]. Also, since guests have often invested in the situation, e.g., waited for a long time for their food, they might be unwilling to

Table 57.2 Occupant characteristics

Characteristic	Hotel guests	Restaurant patrons	Hotel employees
Familiarity	Transitory	Transitory	Permanent
Training	None	None	Yes
Ages	Adults and children	Adults; children possible	Adults
Disabilities	Wide range possible	Wide range possible	Small range possible
Vulnerabilities	Possible	Possible	Possible
Level of intoxication	Intoxication possible	Intoxication possible	Conscious
Awake	Awake or asleep	Awake	Awake
Social groupings	Individuals, couples, families	Individuals, couples, families, groups	Individuals, co-workers
Role	Guest (expects assistance)	Guest (expects assistance)	Manager/subordinate

evacuate [28]. Level of intoxication is also a very important characteristic to consider as guests might be consuming alcoholic beverages (*intoxicated*). Finally, the restaurant is presumably accessible and different types of disabilities are therefore always relevant (*vulnerabilities*).

Hotel staff are typically familiar with the building since they spend a lot of their time there (*permanent* and *trained*). The staff represent a range of different occupations, and some examples include server, cook, hotel receptionist, hotel manager, housekeeper and security guard. These different occupations are associated with different roles and associated rules, which will govern how they behave in fire emergencies (*role*). For example, the role of *manager* versus the role of *receptionist* may significantly impact how willing the receptionist is to activate a fire alarm without confirmation or permission from his/her boss. As mentioned previously, the different roles of guests and staff may make staff more responsive and staff may also take on more of the responsibility in emergencies. These varying characteristics are shown in Table 57.2.

Determination of Life Safety Challenges

One potential life safety challenge is that guests might be asleep in their hotel rooms, which can lead to slow response in case of a fire emergency. Also, guests with movement disabilities will experience difficulties during evacuation because there are no evacuation elevators.

Another life safety challenge is the fact that the entrance door near the hotel lobby is the everyday main exit for both the people in the hotel rooms and the restaurant. In case of an evacuation, there is hence a risk that people will try to head through the lobby on their way out, which is a severe potential challenge.

Location of Fire (Step 1)

In the example given in Chap. 38 of this handbook, a number of different fire locations were identified, but only the following two are relevant for the 20-story hotel tower:

- *Fire in a hotel room*
- *Fire in the restaurant of the hotel adjacent to the hotel lobby*

These two locations are both identified since they are possible fire locations that severely threaten the achievement of the FSO. As previously mentioned, the fact that hotel guests can be asleep in their room and that some guests can have movement disabilities makes the evacuation situation especially challenging. A fire in close vicinity of hotel rooms is therefore highly relevant.

On the 2nd to 20th floors of the hotel tower there are a number of possible fire locations, but a fire in a hotel room is estimated to be one of the most relevant. The number of fuel packages in the evacuation stairs, hotel corridor, elevators and elevator lobby can be expected to be very limited, and fires at these locations are thus both unlikely and relatively minor. Hotel rooms on the

other hand have a significantly higher fuel load. Also, rooms are occupied by guests who engage in activities that might result in fires, e.g., smoking and ironing, and rooms have electronic equipment that might malfunction, e.g., TVs and refrigerators. This makes a hotel room a credible fire location. Storage rooms are similar to hotel rooms as they contain a large amount of combustible material, but they are typically locked and only accessed by staff. This makes a fire in a storage room much less likely than a fire in a hotel room. Given the reasoning above, a hotel room appears to be a credible location that threatens the achievement of the FSO.

The hotel lobby was identified as a major waypoint, i.e., a potential life safety challenge, and a fire in the adjacent restaurant is therefore considered most relevant. The lobby of the hotel is most likely sparsely furnished and has limited possible ignition sources. A fire in the lobby would therefore be unlikely and relatively minor. However, in the adjacent restaurant there are likely an abundance of possible sources of ignition, e.g., candles on tables or hot surfaces in the kitchen. Also, the restaurant has many fuel sources, e.g., furniture in the dining area or frying oil in the kitchen. Due to the open plan of the ground floor, smoke from a fire in the restaurant can easily spread to the hotel lobby. The restaurant, either the seating area or the kitchen, is therefore a credible location that severely threatens the achievement of the FSO.

Type of Fire (Step 2)

A rapidly growing flaming fire with a high heat release rate is considered the most relevant type of fire for the hotel room since it most severely threatens the achievement of the FSO. Many types of hotel room fires are possible. Firstly, the ignition source might relate to activities that the guests engage in, e.g., smoking or ironing, as well as malfunction of electronic equipment, e.g., TVs and refrigerators. The resulting fire growth characteristics might also vary and include anything from a slowly developing smouldering fire to a rapidly growing flaming fire. For the hotel room example, a rapidly growing flaming fire with a high peak heat release rate is deemed most relevant since it has the potential to make the evacuation situation unacceptable before people have responded to the initial fire cues, which relates to the previously mentioned life safety challenge. This type of fire might be ignited with a cigarette that is thrown in a garbage bin that ignites curtains and subsequently spreads to large fuel items, e.g., a bed and/or a sofa.

For the restaurant location, a rapidly growing flaming fire with a high heat release rate is also considered most relevant since it has the potential to generate a lot of toxic and hot smoke that may quickly fill the hotel lobby, thereby threatening the achievement of the FSO. One example could be a candle that falls over and ignites a tablecloth and then a large fuel item, e.g., a sofa or table/chairs. Alternatively, a fire might start at a deep fryer in the kitchen and subsequently spread to uncleaned and greasy parts of the duct system. Both of these fires have the potential to create and uphold difficult evacuation conditions in the hotel lobby.

Potential Fire Hazards (Step 3)

In this example, one potential fire hazard that could severely threaten the achievement of the FSO is an arson attack. This type of attack may involve combustible liquid, e.g., gasoline, which is carried into the building complex and ignited. Although unlikely, this type of attack has been known to occur, see for example the PUB incident in Stockholm [29]. The liquid might be ignited in the lobby as it is a public area and hence easily accessible. Also, this is a location that relates to one of the previously mentioned fire safety challenges.

In an area susceptible to serious earthquake damage, consideration should be given to the impact of a possible post-quake fire, where occupants might have to deal with damage to components of the egress system, such as doors jammed in distorted doorframes that could result in entrapments.

Systems and Features Impacting on Fire (Step 4)

Some of the systems that are used in the 20-story hotel tower to mitigate the fire effects on people are the automatic sprinkler system, the fire alarm system and the fire barriers. A failing or compromised barrier, i.e., a hotel room door that does not close properly or a stairwell door that is propped open, would make conditions outside the room of origin unacceptable quickly. Similarly, a failing sprinkler system, or a sprinkler system unable to control a shielded fire, could allow a fire to grow bigger more rapidly and a failing fire alarm or voice messaging system would potentially delay people's response. Failure of any of these systems would hence severely threaten the achievement of the FSO for both the fire in a hotel room and a fire in the restaurant.

People Response (Step 5)

The building users may engage in activities that can make conditions either better or worse. In this example, manual suppression is an activity that can improve the chances of achieving the FSO. This occupant response is deemed more likely for the restaurant fire due to the presence of trained staff that is familiar with the building. One activity that threatens the achievement of the FSO is if occupants do not close doors, e.g., a hotel room door, which would make fire barriers ineffective, or if opening too many doors in a pressurized stairwell affects its proper functioning.

Scenario Selection Process (Step 6 to 10)

Steps 6 to 10 of the example, i.e., the compilation of scenarios, the scenario selection process and the documentation, are not described in this chapter and the interested reader is referred to the description in Chap. 38 of this handbook. It should, however, be pointed out that each scenario is evaluated in relation to the achievement of the FSO. The evaluation in the example resulted in the selection of the following design scenario involving a fire in a hotel room in the 20-story hotel tower:

> *Fire started in a garbage container and spread to the curtain and mattress. Nobody was in the room of fire origin. The sprinkler system did not activate because the water supply was turned off for repairs. The fire spread from the room door to the corridor of the hotel. For life safety calculations, assume that occupants were asleep when the fire started.* (Chap. 38)

It is important to note that a number of scenarios believed to challenge the system must be selected in order to adequately test the design. This example will follow only one—a fire in a hotel room.

Deriving Design Occupant Scenarios

No details about the occupants were included in the example in Chap. 38, other than that the occupants outside the room of origin were asleep. In order to do the evaluation of the design, assumptions must be made about the characteristics of the occupants so as to formulate a scenario that will challenge the fire safety design. A suitable design occupant scenario in this example is therefore that all guests are asleep in their rooms and that one accessible room per floor is occupied. All rooms are assumed occupied to their maximum capacity. As hotel guests are transitory occupants, it will also be assumed that they are unfamiliar with the layout of the building and they are not trained in evacuation. As a result, there will be delays in evacuation as they assess the situation after waking, prepare for evacuation and attempt to find the exits. These conditions are believed to represent a worst credible case.

Evacuation Variables for Sensitivity Analysis

In previous sections, a number of occupant characteristics for hotel guests were highlighted in relation to the hotel use of the building. These characteristics are also the evacuation variables that should be the variables included in a

sensitivity analysis. For this example, the evacuation variables for the sensitivity analysis include:

- *transitory*—familiarity with the building
- *social groupings*—alone, couples, families
- *age ranges*—adults, children
- *vulnerabilities*—types of disabilities
- *intoxicated*—level of intoxication

These characteristics are mainly concerned with the ability of building occupants to mitigate or cope with a fire event. All these variables can be varied with regards to their magnitude, e.g., the degree of familiarity with the building, and frequency, e.g., the number of guests who are very unfamiliar with the building. It might also be relevant to vary the initial behaviour and the initial route choice in the sensitivity analysis.

For example, in the baseline scenario, the hotel guests were asleep, but not intoxicated. The sensitivity analysis would assume some percentage of occupants were intoxicated, with the resulting additional delays in waking, and possibly more difficulty in decision making and way-finding. Similarly, the sensitivity analysis can test the effect of varying the ages of the occupants.

The sensitivity analysis will test the robustness of the safety design, which could result in changes to the design or refinements to the fire safety management plan for the building.

Summary

The intent of this chapter has been to extend the discussion on the selection of scenarios for deterministic fire safety engineering analysis according to ISO/TS 16733 when the Fire Safety Goal is life safety. In this case, the fire, building and occupants all play an important role in determining scenario relevance.

Before the scenario selection process can be initiated, the designer must first define the project context by setting the scope, Fire Safety Goal (life safety for building occupants in this chapter), Fire Safety Objectives and critical fire conditions. The subsequent step involves identification of possible building uses, as well as the subsequent users and their characteristics. In this chapter, characteristics are divided into eight categories commonly used in the identification process.

Once the uses and users are known, the designer needs to determine the life safety challenges, which are any issues or conflicts that, in combination with fire, could potentially lead to the failure of the design. These life safety challenges are essential for the scenario selection process because it is in relation to them that the severe but credible scenarios, i.e., the worst credible cases, are chosen in the deterministic analysis.

In the first five steps of the fire scenario selection process of ISO/TS 16733, fire-related factors/aspects, e.g., fire locations and types of fire, that severely threaten the achievement of the FSO are identified. This identification is always done in relation to the life safety challenges as described in this chapter. In Steps 6 to 10 of ISO/TS 16733, design fire scenarios are then chosen for the deterministic analysis from the multitude of possible fire scenarios.

Because the entire fire scenario selection process is linked to the fire safety challenges, each design fire scenario is also linked to occupant-related issues or conflicts. This means that for every design fire scenario there is already a design occupant scenario. The process of determining these design occupant scenarios involves re-examination of the basis for the identification of fire-related factors/aspects (Steps 1 to 5) and selection of design fire scenarios (Steps 6 to 10).

Scenario selection is an iterative process as occupants can impact the fire, the fire can impact the occupants, and the building and its features impact both the fire and the occupants. A failing design might be addressed by changing, for example, the building layout, which in turn might influence both potential fires and occupants. This means that the described process might need to be repeated several times before an acceptable design is found.

The evaluation of the safety of a design involves comparing the expected growth and spread of challenging fires (the design fire scenarios) against the ability of occupants to avoid or survive the effects of those fires. There is a great deal of interaction between the

occupants of a building and the likelihood of fire ignitions and fire spread. While this chapter has focused on life safety, parts of the process could be applied to the consideration of other fire safety objectives, where the number and type of occupants could impact fire ignition, growth, spread and suppression.

Human Behavior in Fire

58

Erica D. Kuligowski

Introduction

Human behavior in fire is at the core of all life safety projects completed by fire safety or fire protection engineers. A better understanding of how people respond to building emergencies can aid in safer building design; improved use or development of calculation tools used to ensure the level of safety afforded by these designs; and more effective emergency procedures, emergency communication systems, and pre-event emergency training for buildings and communities. The purpose of this chapter is to provide a basic understanding of human behavior in fire concepts and theory for use by engineers. The chapter contains the following aspects of human behavior in fire and other emergencies: a definition of human behavior in fire, including a discussion of the types of disciplines employed in the study of people in fires; a presentation on what human behavior in fire is not, including examples of disaster myths; an overview of the disaster-based decision-making process in fires and other emergencies; a discussion relating theory to practice (highlighting studies from fire events that support the decision-making theory); the identification of important factors that influence the decision-making process; and a conclusion highlighting what is missing in the field of human behavior in fire. Each section of this chapter will include an implications section that outlines the reasons why these ideas or theories are important for engineers to understand and incorporate.

Definition of Human Behavior in Fire

Human behavior in fire is the study of human response, including people's awareness, beliefs, attitudes, motivations, decisions, behaviors, and coping strategies in exposure to fire and other similar emergencies in buildings, structures and transportation systems. The study of human behavior in fire is highly multidisciplinary, involving practitioners from the fields of engineering, architecture, computer science, mathematics, law, sociology, psychology, human factors, communications and ergonomics, to mention just a few. The primary focus of human behavior research and its translation into practice is to minimize the risk to people from fire. This is achieved by generating and collecting quantitative and qualitative data on human responses which can be used to develop human fire response theory.[1] A comprehensive theory of human response is key to improve current fire safety engineering design, performance based regulatory systems, egress-

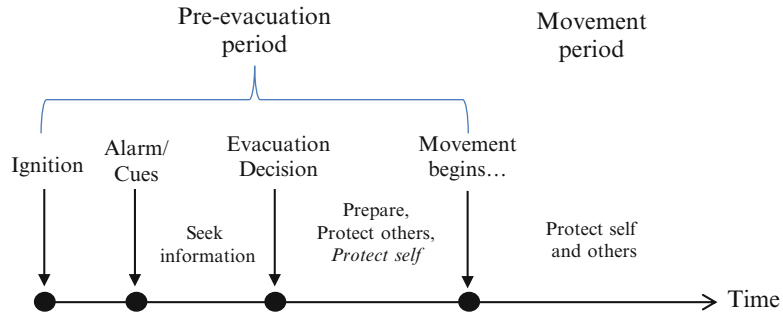

Fig. 58.1 Timeline of a human response to a building fire emergency

related computational models and fire safety management.

The ultimate goal of improving life safety analyses in performance-based design is to develop a comprehensive theory of human fire response. Human behavior is complex and there is more work to be done to achieve this goal. A focus on case studies of specific building fires [1–3], and research on particular aspects of a fire evacuation has left the field of human behavior in fire with a series of partial-theories, rather than a comprehensive theory of human behavior in fire. As a result, human response to fires is often crudely categorized into two main periods: the pre-evacuation period[2] and the movement period, with little understanding of the behavioral processes that take place within each one. The pre-evacuation period estimates the time when ignition begins until the point when an individual or group begins purposive evacuation movement to a place of safety. The time period in which purposive movement to safety occurs is then considered the evacuation or movement period.

As shown in Fig. 58.1, and as will be presented throughout this chapter, the pre-evacuation and movement periods consist of additional sub-phases that the engineer should understand. For example, within the pre-evacuation period, at least three sub-phases can exist:

- The pre-alarm phase, which is the time from the point when fire ignition begins until the point when the building alarm initiates and/or building occupants are exposed to cues from the fire event (i.e., seeing smoke or being told about the fire event by a staff member)
- The evacuation decision-making phase, where building occupants are exposed to or seek out cues/information from the fire event and others in the building, and after processing this information, must decide whether or not it is necessary to protect themselves (e.g., evacuate)
- The protective action phase, whereby individuals engage in certain actions, e.g., gathering personal belongings or assisting others to prepare for evacuation that allows them to protect themselves or others before beginning evacuation.

These phases are important to understand, because in certain types of buildings or emergencies within a building, the pre-evacuation period can be significantly longer than the movement period in a building evacuation.

Additionally, the same types of decisions and actions can take place during the movement period, especially when people are faced with additional environmental cues.

The purpose of this chapter is to aid the engineer in understanding the current state of knowledge regarding the entire process of human behavior in fire emergencies. This process is important to understand because it is often the goal of fire safety or fire protection engineers (as well as fire marshals, authorities having jurisdiction, and other emergency responder personnel) to ensure that a particular structure or transportation system provides the appropriate

[2] Other terms have been used to express the pre-evacuation period, including pre-movement or pre-response.

level of life safety to its users. With this goal in mind, it becomes an almost impossible task to assess life safety (credibly or reliably) without understanding how the structure or transportation system will be used during a fire emergency. In a building, for example, an engineer must understand how the building occupants will respond to a fire in order to assess whether the building and the fire safety features provide an adequate level of safety during a fire emergency event. Therefore, this chapter focuses on communicating current understanding of human behavior in fire, including all phases of the human response, for use in fire safety and life safety analyses of structures and other systems.

Discarded Theories in Human Behavior in Fire

Before we can achieve an understanding of human behavior in fire, we must first discuss what human behavior in fire *is not*. This is critical since our understanding of human behavior in fire has direct implications to the engineering design process. Since behavior in fires has been studied since the 1950s (and for other disasters, earlier than that), certain claims have been made and then subsequently refuted as explanations of human behavior in fires. In this chapter, and elsewhere [4], these claims are labeled as disaster myths. In some cases, these disaster myths are true for a small minority of the population, but have become overgeneralized to hold for the entire population. In other cases, the disaster myth is completely invalid [5]. Three disaster myths will be discussed in this section: panic, disaster shock, and group mind. All three myths have been overgeneralized by society and the media to account for negative situations in some disaster scenarios, but, in reality, are very rare. These are chosen as discussion points in this section, since they have been used in the past to characterize occupant response to building fire disasters. These are not the only disaster myths promulgated by past events, nor the only disaster myths that may be promoted by future events.

Panic Behavior

The concept of panic is often used to explain the occurrence of multiple fatalities in fires. Representatives of the media and public officials often label various types of fire incident behavioral responses as panic [6, 7], often going so far as specifically asking about the presence of the behavior when interviewing disaster survivors [8].

According to most definitions, panic is a flight or fleeing type of behavioral response that also involves extravagant and injudicious effort. Panic is not necessarily limited to a single individual, and may be mimicked and adopted by a body of persons (i.e., mass panic or collective flight). Johnson describes panic as the following: "...selfish competition uncontrolled by social and cultural constraints—i.e., unregulated" and the breakdown of social order [9, 10]. Wenger et al. [11] includes a definition for "panic flight" as "the competitive mass behavior of individuals involved in fleeing from an imminent threat that results in increasing the danger to themselves and others". Quarantelli [7] characterizes panic not only as withdraw (or flight) behavior, but also as a behavior that encompasses a lack of consideration for others (i.e., competition).

Often, however, the concept of self-destructive or animalistic panic-type behavioral responses to fire incident stimuli, such as the presence of flames or smoke, has not been supported by the research on human behavior in fire incidents. As indicated by Sime [12], Quarantelli [13], and others [14–17], panic behavior in which the flight response is characterized by actual physical competition between the participants and personal injuries is rare. For example, Best studied extensive interviews with survivors of the Beverly Hills Supper Club fire (1977) to find that the staff and patrons of the club did not exhibit panic behavior, despite media accounts attributing the large loss of life to the phenomenon [18]. Also, several studies have been conducted on the 2001 World Trade Center Disaster (WTC), allowing researchers to assess the accuracy of the headline of a BBC News Online article, entitled: "Panic on

the stairs" [8, 19]. Studies of both media accounts [20, 21] and survivor interviews [1, 22, 23] of this deadly terrorist attack revealed overall trends of calm and altruism. While there were reported situations of emotion, i.e., crying or being anxious or nervous about the situation, the majority of stories reported rational, orderly, and often times, delayed responses to the disaster event.

Therefore, the use of the concept of panic must be separated from the use of the terms *anxiety* or *fear*. These are natural emotions in emergency situations that do not necessarily lead to competitive, injudicious flight behavior (i.e., panic). Additionally, research has shown that survivors of fire emergencies (or other disasters) may mistakenly categorize their own behavior or the behavior of others as panic, whereas further description of actual actions barely reflect panic behavior [12, 24]. Ramachandran [25], in his review of studies on human behavior in fires in the United Kingdom, has developed the following conclusion relative to nonadaptive behavior:

> In the stress of a fire, people often act inappropriately but rarely panic or behave irrationally. Such behavior, to a large extent, is due to the fact that information initially available to people regarding the possible existence of a fire and its size and location is often ambiguous or inadequate.

In reality, and in stark contrast to panic behavior, engineers should be aware that people's first assumption in many disasters, regardless of the intensity of the information perceived, is that nothing unusual is happening, and thus, no response is required. This phenomenon is known as normalcy bias [26–29]. It is our challenge, as engineers, to ensure that disaster victims (i.e., those who are in danger) become aware that a dangerous situation is taking place, and that they perceive personal risk. If not, they are unlikely to take actions to protect themselves from harm. Even in an event as large and intense at the 2001 WTC disaster, building occupants had to be convinced of the danger to which they were exposed, sometimes taking several minutes, before evacuating the building [30]. Additionally, in reference to the assumption of competition, engineers should acknowledge that altruistic behavior is more likely to occur. Researchers have found that even though disasters can cause shifts in the pre-existing situation, the breakdown of social order is rare [31, 32]. Many of the societal norms and social roles evident before the disaster carry over into the new, evolving situation. Therefore, occupants are likely to engage in pro-social behaviors, including helping others rather than competing with others, as they would do in non-disaster situations. Engineers should also be aware of these types of pro-social behavior, since they could lead to delays in the evacuation process, among other issues. The delays associated with altruist behavior, such as helping, should be accounted for in fire protection and emergency procedural design for buildings in the event of fire emergencies.

Disaster Shock

An additional disaster myth suggests that individuals who do not act irrationally (i.e., panic) are often immobilized by fear in emergency events [4, 33]. This myth creates an image of large numbers of individuals dazed or shocked; i.e., unable to cope with the new disaster-created situation at hand. This myth also extends into the disaster recovery stage, suggesting that the paralyzing shock created by the situation is followed by longer-term personal effects, often labeled as post-traumatic stress disorder, or PTSD. Although this may at first seem irrelevant to fire emergencies, since much of the research on disaster shock is reported in response to the natural or technological disasters, the myth of disaster shock is directly applicable to fire emergencies. In a building fire, the fire ignites and continues to grow as building occupants are made aware of the event and are encouraged to take protection (e.g., evacuate). In fires, different from a tornado event, for example, building occupants are warned about the event after it has already started to cause destruction. Thus, it is possible to assume in building fire events that individuals

will go into shock in response to the fire, and thus rendering themselves incapable of evacuating on their own.

Researchers have found that following disasters, documented reports of disaster shock are rare. Melick [34], after reviewing disaster studies conducted between 1943 and 1983, found the following three conclusions regarding disaster shock: (1) Disaster shock occurs more frequently in sudden onset disaster events that are accompanied by little forewarning and extensive physical and social destruction; (2) Disaster shock affects a relatively small proportion of the population in any one event [7, 35]; and (3) Disaster shock usually occurs within the immediate postimpact period of a disaster, lasting no longer than a few hours or days [5]. Other researchers have shown that this phenomenon is rare and the state is usually short-lived [36].

Disaster researchers attempt to dispel this myth by explaining that disaster response behavior is often performed in an active manner [7]. Instead of waiting for assistance, in a dazed or disoriented manner, disaster victims are more likely to show considerable personal initiative, performing search and rescue activities, casualty care, and restoration of essential services even before emergency responders arrive on scene [11]. This kind of response was observed in the 2001 WTC disaster [30], where survivors were often the first individuals to respond to the needs of their coworkers, assisting them to reach safety before first responders could reach the upper floors. Belief in this assumption could cause engineers to focus more on emergency response officials and their role in evacuation. However, it is important for engineers to understand that building occupants will react in an emergency and proactively engage in their own (and others') safety. In turn, engineers must ensure sufficient and efficient evacuation routes and strategies to ensure safety for all occupants in the building.

One note that should be made here regarding this myth is the inability to interview those who perish from building fires, and the effect that this gap may have on our overall understanding of disaster shock. The fires and disaster fields may not fully understand the role of disaster shock in consequences (i.e., injuries and deaths), and therefore future research should focus on obtaining a better understanding of the circumstances of fatalities from fires (when possible). One way to obtain this type of data is to interview individuals who were physically with (or in contact with) the deceased during the fire emergency.

Group Mind

A third disaster myth is the oversimplification that the group is something other than the sum of individuals responses; i.e., that the group has a "mind" of its own when making decisions in a disaster [37]. Another way of thinking about group mind is the assumption that when a disaster occurs, individuals become a part of a group and the group (as a whole or as one entity) acts in response to the disaster. This assumption can also be characterized as mob behavior or herd behavior.

However, sociologists have stated that thinking that the group acts or thinks in a certain way is "often a serious oversimplification" [37]. Making this assumption can cause the engineer or researcher to be blinded by any diversity associated with the group, including individual characteristics, experiences, decision-making or behavior. If we make this assumption, we may then assign attributes to the group, including a mind, a sense of responsibility, a conscience, or even a lack of self-control (related to mass panic described above).

What is more likely, and what has been seen in actual disaster events, is that groups consist of a variety of different individuals. During disasters, it is more likely that groups engage in what is called "a division of labor" in that certain individuals take on particular roles based upon their experiences and/or relationships with others in the group, which complement each other and allow the group to function [37]. It is therefore important to understand the division of labor within the groups and the characteristics,

experience, decision-making and behavior of the individuals within the group to truly understand human behavior in fire.

It should be noted; however, that there is extensive research in group dynamics and how groups "act" in disasters and building fires. This research will be described later in this chapter. Overall, it is neither the description of the group (only) nor the description of the individual (only) that is sufficient in understanding human behavior in fire. Instead, identifying both his/her attitudes toward the object (or issue at hand, in this case, the fire cue or cues) [38] and attitudes toward the group and others in the building (i.e., the processes of group dynamics) leads to the true understanding of human response in emergencies [37].

Engineering Implications of Disaster Myths or Why Should the Engineer Care?

Unfortunately, these disaster myths can have negative implications on fire safety in our society. Images of human behavior during disasters are often the basis for critical decisions made by engineers and other fire protection designers on building design requirements, emergency communications systems design and guidance, as well as emergency response procedures for fire events. The assumptions of irrationality or human frailty can inappropriately shape the way that engineers and emergency officials plan for response to fires in their buildings, as well as how evacuation models represent evacuation behavior during fires. Instead, it is important for engineers to understand the true needs of building occupants so that engineering and emergency procedural designs and methods more accurately reflect realistic occupant behavior during building fire events.

One example of how a disaster myth has had negative implications on fire safety is the influence of panic on emergency communication during fires [33]. The view that people would panic in response to an incident (and specifically to information describing the incident) has influenced both the notification procedures employed and the language used (by survivors) to report the exhibited behavior [39]. This assumption influenced a difficult and harmful cycle consisting of the following steps: people report that they panicked, emergency officials continue to believe that panic is a normal response, emergency information is withheld in the next disaster so that people do not panic, human response is delayed and inefficient, and the situation becomes more dire. Over the last 25 years, this point of view has been slowly replaced with the recognition that people need detailed and credible information as early as possible in order to initiate and inform their response. The availability of this information encourages people to accept the emergency procedures and to improve their familiarity with the required response, and later informs the decision-making process that determines their response. People need information in order to act. Detailed information by no means guarantees the desired response; however, without this information, an uninformed approach (ignorant of the conditions and the options available) is much more likely. It is now broadly accepted that depriving evacuees of information is more likely to lead to an inefficient and inappropriate response; e.g., misinterpreting the incident and the threat it poses, delaying response, engaging in an inappropriate response, and ignoring safe egress routes. During an incident, people will seek information regarding the nature of the incident and what they should do in response to it. Unfortunately, this information may not always be easy to find, reliable, consistent or accurate. It is critical that an information vacuum is avoided and that accurate, credible information is provided.

The previous section discussed the factors and theories that do not accurately describe human behavior during building fires and other events. Therefore, the following section will focus on describing the theory of human behavior in fires and the foundation upon which this and other related theories were built. This understanding of human behavior focuses on decision-making at the level of the individual, independent of whether the individual is on his/her own, a

member of a group, or a member of a larger crowd during the emergency. Social psychological theories of decision-making during emergencies will be presented in the following section.

Social Psychological Theories of Human Behavior in Emergencies

Everyday, individuals go about their normal lives—attending meetings at work, watching movies at the local cinema, and shopping at the mall or the grocery store for all of their necessities. These are activities in which individuals have engaged so often that they have become routine in nature. When an emergency occurs, these activities may suddenly seem irrelevant. When an alarm is sounding or smoke is billowing into a room from an air conditioning duct, individuals are faced with a potentially new and unique situation where previous actions may no longer apply.

Under these new conditions, individuals are required to make a concerted effort to create meaning out of new and unfamiliar situations, often under time pressure. From this meaning, a set of actions, different from those that have become routine, must be created. Emergent norm theory (ENT), explains the process of meaning-making in the face of uncertain conditions [37], stating that in situations where an event occurs that creates a normative crisis (i.e., an event where the institutionalized norms [e.g., sitting at a desk and working] no longer apply), such as a building fire, individuals interact collectively to create an emergent situationally-specific set of norms to guide their future behavior. In other words, individuals must work together to redefine the situation and propose a new set of actions, which is the product of processes labeled "milling" and "keynoting".

Milling is a communication process whereby individuals come together in an attempt to define the situation, propose and adopt new appropriate norms for behavior, and seek coordinated action to find a solution to the shared problem at hand [40]. The group engages in both physical and verbal communication in order to ask the three following questions: (1) what happened? (2) what should we do? and (3) who should act first? (known as leadership selection) [41, 42]. Leaders emerge as keynoters, or those who advance suggested interpretations of the event or suggestions on what do to next [37, 43]. The consequences of the milling process are that individuals become sensitized to one another, that a common mood develops, and that a collective definition of the situation is decided upon that minimizes initial ambiguity [44]. Overall, in the face of new and uncertain situations, milling and the keynoting processes allow the group to define the situation and to propose next steps for alternative schemes of social action [40, 43, 44].

The new situation and next steps developed do not emerge in a social vacuum, however. Rather, individuals within a group bring with them certain aspects of the "normal" or non-emergency situation that influence decisions made in the new situation. First, individuals bring their "social stock of knowledge" to the situation. The social stock of knowledge consists of an individual's internal set of knowledge about the disaster (or disasters in general), experiences from previous disasters or building evacuations, and his/her relationships and roles within the building, especially those related to building fires and other types of disasters [45]. Second, individuals bring conventional norms, i.e., previous ways of acting within the building and/or society as whole, which are likely to influence the newly developed "next steps for action" during the current disaster situation [31].

Protective Action Decision Model—A Background

A decision-making model has been developed that extends and applies ENT's explanation of the meaning-making process in crises to disaster situations. The Protective Action Decision Model (PADM), which is based on over 50 years of empirical studies of hazards and disasters [28, 38, 46–49], provides a framework that describes the information flow and decision-

making that influences protective actions taken in response to natural and technological disasters [50]. The model posits that cues from the physical environment (e.g., the sight of smoke) as well as information from the social environment (i.e., emergency messages or warnings), if perceived as indicating the existence of a threat, can interrupt normal activities of the recipient. Depending upon the perceived characteristics of the threat (e.g., what is going on and how dangerous is it?), indicative of the milling and keynoting processes described above, individuals will either seek additional information, engage in actions to protect people or property, perform actions to reduce psychological stresses, or resume normal activities [50]. In addition to perceptions of the threat, responses are also determined by the perceived feasibility of protective actions.

Before describing the stages of the PADM in detail, it is necessary to introduce the additional research and social models that it draws upon. Studies of social influence provide insight on the types of cues and information that affect behavior. Research and studies on the decision-making process shed light on the steps in which people engage to make decisions on their next course of action. Additionally, the PADM is based upon other theories and conceptual models that link together cues, cognitive processes and subsequent protection actions.

First, since people perceive information from both the physical and social environment, the PADM incorporates insights from social influence research. Theories of social influence posit that the actions of others and the risk communication process can influence human response in disasters. In ambiguous situations, the presence or actions of others helps to define what behavior is appropriate in a particular situation. If people are seen to be taking protective action, for example, moving to the same stair, others are likely to follow suit [51, 52]. Conversely, if people are not taking emergency action, others are also less likely to engage in emergency actions. Additionally, research has shown the influence of information (for example, warnings provided via emergency communication systems), on a person's beliefs, attitudes, and subsequent behavior [53, 54]. Aspects of the risk communication process, e.g., the source, the message, the channels, and the receiver characteristics (i.e., the receiver's perceptions of the credibility of the message, message comprehension, and channel preferences), can ultimately predict whether or not protective action is taken before or during crisis [38, 50].

As a decision-making model, the PADM also relies on behavioral decision theory. In a perfect world, in which those at risk behave like rational actors, decisions would be made based upon all of the necessary information available to the individual, which would be weighed based on costs and benefits of the various outcomes, leading ultimately to an optimal decision on the best course of action. More often, however, people lack the necessary information needed to make decisions, and they do not always search for additional information. Instead, they make decisions based on their beliefs about the situation, and many times, these beliefs can reflect poor understandings of the situation [55]. For example, in the Beverly Hills Supper Club fire when an employee took the stage and announced the presence of a fire, some of the patrons thought that the announcement was part of the evening's entertainment and in turn, remained in place rather than moving to the exits [18]. Decision scientists argue that people are often poor judges both of the likelihood of a disaster event and of the range and severity of impacts disasters can produce. This is because people use a variety of "quick and dirty" heuristics, which are simple rules or "cognitive short cuts" through which they judge a situation or event [56, 57]. One example of a heuristic that people employ is the availability heuristic, or judging the likelihood of an event based on the ease of recalling similar instances from memory [57, 58]. For example, people often think that deaths due to plane incidents are more frequent than deaths due to car accidents because they can recall more easily dramatic media coverage of large-scale plane crashes [59]. Another short cut, similar to social influence research, is an over-reliance on the actions of others [60]. In cases of procedural uncertainty, where individuals have little

experience dealing with high-stakes decisions, individuals are likely to adopt the decision strategies of others and follow their behavior [60]. Unfortunately, the individuals who are followed may also be using cognitive short-cuts and taking inappropriate action. Heuristics can result in biased understandings of the situation, which may then be used to make sub-optimal decisions during a disaster.

Research in the area of judgment and decision-making under uncertainty also provides insights into the ways in which people make decisions on their next course of action based on their beliefs. "Rational-actor"-based research claims that individuals will optimize decision-making by weighing all options and choosing the best one [61, 62]. In situations of uncertainty or crisis, however, individuals or groups are unlikely to search for a large number of options due to significant time pressures [63–66]; limited mental resources (e.g., when they are under stress) [67–69]; or if they perceive themselves as experienced in or knowledgeable concerning recommended protective procedures [56, 70]. In situations with greater time pressure, dynamic conditions, and ill-defined goals [56], all of which are likely to characterize building emergencies, people are likely to *satisfice*. Satisficing [67, 69, 71] is a method in which an individual chooses what s/he sees as a sufficient rather than optimal option, "not to find the best [option] but to find the first one that works" [56]. For highly trained and experienced individuals, for example, fire fighters, satisficing may in fact lead to quicker, more effective and appropriate decisions for the task at hand. The decision-making technique may be detrimental, however, for occupants who are less experienced in building fires, increasing their delay to safety or even leading to more severe consequences, like injury or death.

Finally, the PADM is based upon theories that link cues, cognitive (internal) processes, and subsequent protective action. Much of that research seeks to establish links between the perception of risk and the performance of protective action. Janis and Mann [72] developed the conflict model to describe the process of emergency decision-making. An individual's response to a warning is based upon his/her perception of the severity and immediacy of the threat, the perceived effectiveness of the possible protective action, and the possibility of gaining more information about the event and possible actions.

Mileti and Sorensen [38] developed a model that describes the influence of cognition on warning response. Whereas the PADM focuses on responses of people to various types of cues before or during a disaster, this model summarizes the determinants and consequences of public responses to disaster warnings. The warning response model outlines a process in which the receiver must hear, understand, believe, and personalize the warning message in order to respond in an appropriate way. The first stage of the process is perceptually receiving the alert or warning; Mileti and Sorensen [38] note that before anyone can respond to a message, they must receive it first. Once the warning is received, it must be understood, and in this instance, "understanding does not refer to correct interpretation of what is heard, but rather to the personal attachment of meaning to the message" [38]. For example, what does a flood warning mean to one person, versus another? The next stage involves whether the person believes the warning or not—involving whether they believe that the warning is authentic and the contents of the message are accurate. Finally, the last stage in the process before response is personalization. This is the stage in which people think of the warning in personal terms, in that they begin to consider the implications of the risk for themselves and others around them. If the individual has heard, understood, believed, and personalized the warning, s/he will then decide what to do about the risk. Mileti and Sorensen [38] do not discuss the decision-making process and subsequent actions in depth, but generally state that people do next what they think is best for them. An important part of this process is confirmation. In threat situations, people are constantly seeking new information to confirm prior information, whether from family, friends, neighbors, and co-workers, or from various media sources and authorities. Confirmation

affects each stage of the warning process, in that it helps people to better understand warnings, believe them, personalize the risk, and make decisions.

Protective Action Decision Model—The Stages of Decision-Making

Although the PADM is similar to the Mileti and Sorensen warning response model, the PADM provides a more general framework that describes information flow and decision-making specifically in response to various types of cues that originate from natural and technological disasters [50, 73]. The PADM asserts that the process of decision-making begins when people witness cues from the disaster event. Individuals can encounter only one type of cue (for example, seeing smoke) or may be presented with a variety of different cues, for example, environmental cues, the behavior of others, and warning messages. Warning messages can consist of both official and unofficial messages; i.e., official messages are those that come from official warning providers (e.g., emergency managers in a building fire) and unofficial messages are those that come from unofficial sources, such as others in the building.

The introduction of these cues initiates a series of pre-decisional processes that must occur in order for the individual to perform protective actions. First, the individual must perceive or receive the cue(s). Then, s/he must pay attention to the cue(s). Finally, the individual must comprehend the cue(s). Comprehension means understanding the information that is being conveyed. If the message uses a different language or highly technical terms, comprehension will be difficult. Comprehension also refers to the development of an accurate understanding of environmental cues. For example, will the individual understand that the smoke s/he smells is coming from a building fire rather than from burnt toast in the kitchen?

People go into any disaster with widely varying pre-event perceptions or beliefs about the elements that go into a disaster—the event itself, the actions that they have taken (or should take) before the disaster occurs, and the individuals involved in the response to a disaster. The differences in these perceptions are important to understand because they often are predictors of the individuals' response behaviors when the disaster occurs. The PADM labels these pre-event perceptions as core perceptions or schemas and highlights as important three main core perceptions: perceptions of threat, perceptions of protective actions, and perceptions of stakeholders [73].

First, perceptions of environmental threats include people's beliefs about the probability and consequences of certain types of disasters as well as their expectations about personal impacts, including death, injury, property damage, and disruption of daily activities (i.e., work, school, shopping, etc.). These can vary from individuals' beliefs that they are very unlikely to be involved in any type of disaster to individuals' severe worry or dread that the next disaster is coming specifically for them. Also associated with perceptions of environmental threats is what Lindell and Perry call "the degree of hazard intrusiveness" [73]. This refers to how often individuals are personally concerned with disaster consequences, the time they spend talking about disasters, and the amount of information they receive (passively) about hazards and disasters.

The second pre-event perception includes people's perceptions of protective actions; i.e., the actions that they can take to prepare for a disaster. Essentially, this perception captures individuals' attitudes about engaging in preparatory actions before a disaster occurs. This can also vary widely, from individuals taking no preparatory action at all and believing that these types of actions are not necessary to individuals taking extensive preparation in their homes and/or work places.

The third pre-event perception consists of individuals' perceptions toward stakeholders in a disaster. Stakeholders in a disaster can be authorities (i.e., federal, state or local government), evaluators (e.g., scientists, universities, medical professionals), watchdogs (e.g., news

media), industry/employers, and individuals themselves (i.e., in their homes or places of work). Here, it is important to understand the ways in which people perceive stakeholders in terms of three factors: their expertise about disasters (in this case, fires), trustworthiness, and responsibility when a disaster or building fire takes place. This pre-event perception is more applicable to community-based disasters, such as hurricanes or tornadoes, but could be applied to fires in instances where, for example, building occupants do not trust warning information provided by a building manager.

All three of these perceptions have been shown in research to vary from individual to individual involved in the disaster situation. More importantly, these factors (among others) have been linked to the decisions that individuals make in disasters, and in turn, their protective actions (discussed below).

After the three pre-decisional processes are completed and the three core perceptions are activated (i.e., it is understood that there are differences among individuals in these three areas), the decision-making model consists of a series of five questions [50]:

- Is there a real threat that I need to pay attention to? [If yes, then the individual believes the threat]
- Do I need to take protective action? [If yes, then the individual decides that s/he needs to take protective action]
- What can be done to achieve protection? [The individual begins searching for possible protective action strategies]
- What is the best method of protection? [The individual chooses one of the action strategies developed in the previous stage and develops a protective action strategy or plan]
- Does protective action need to be taken now? [If yes, the individual follows the plan developed in the previous stage]

Individuals must "answer" each question in order to proceed through the perceptual-behavioral sequence, in which the outcome of the process is the performance of a behavioral action. A graphic of the process is shown in Fig. 58.2.

The first stage of the decision model involves the issue of risk or threat identification. If the individual perceives, pays attention to, and comprehends cues associated with an event, s/he first asks "Is there a real threat that I should pay attention to?" In this stage, according to Lindell and Perry, the individual decides if there is actually something occurring that may require her action, sometimes referred to as warning belief [74], "but this term unnecessarily excludes people's reactions to environmental cues so the term *threat belief* is generally more appropriate" [50]. This stage corresponds to the phase in ENT in which members of a population realize that the norms and behaviors for "stable times" no longer apply [37]. If the individual's answer is yes, then s/he is said to believe the threat, and s/he subsequently moves on to consider the next question in the process.

The second stage of the decision model is referred to as risk assessment. Research has shown that a person's perception of personal risk, or "the individual's expectation of personal exposure to death, injury, or property damage" is highly correlated with disaster response [50]. In this stage, also known as personalizing risk [38], the individual determines the likelihood of personal consequences that could result from the threat and asks oneself the following: "Do I need to take protective action?" At this point, which is also discussed in human factors research as "situation awareness" [75], the individual tries to gain insight on the potential outcomes of the disaster and what those potential outcomes mean for his safety. The internal dialogue that takes place at this stage can be thought of as mental simulation or mental modeling [56], in which the individual develops a mental model of what is going on in his environment, based on perceived cues, and then expands the mental model to predict the personal consequences of the event. The more certain, severe, and immediate the risk is perceived to be, the more likely the individual is to perform protective actions [76].

In the third and fourth stages, the individual engages in a decision-making process to identify (1) what can be done to achieve protection; and (2) the best available method of achieving this

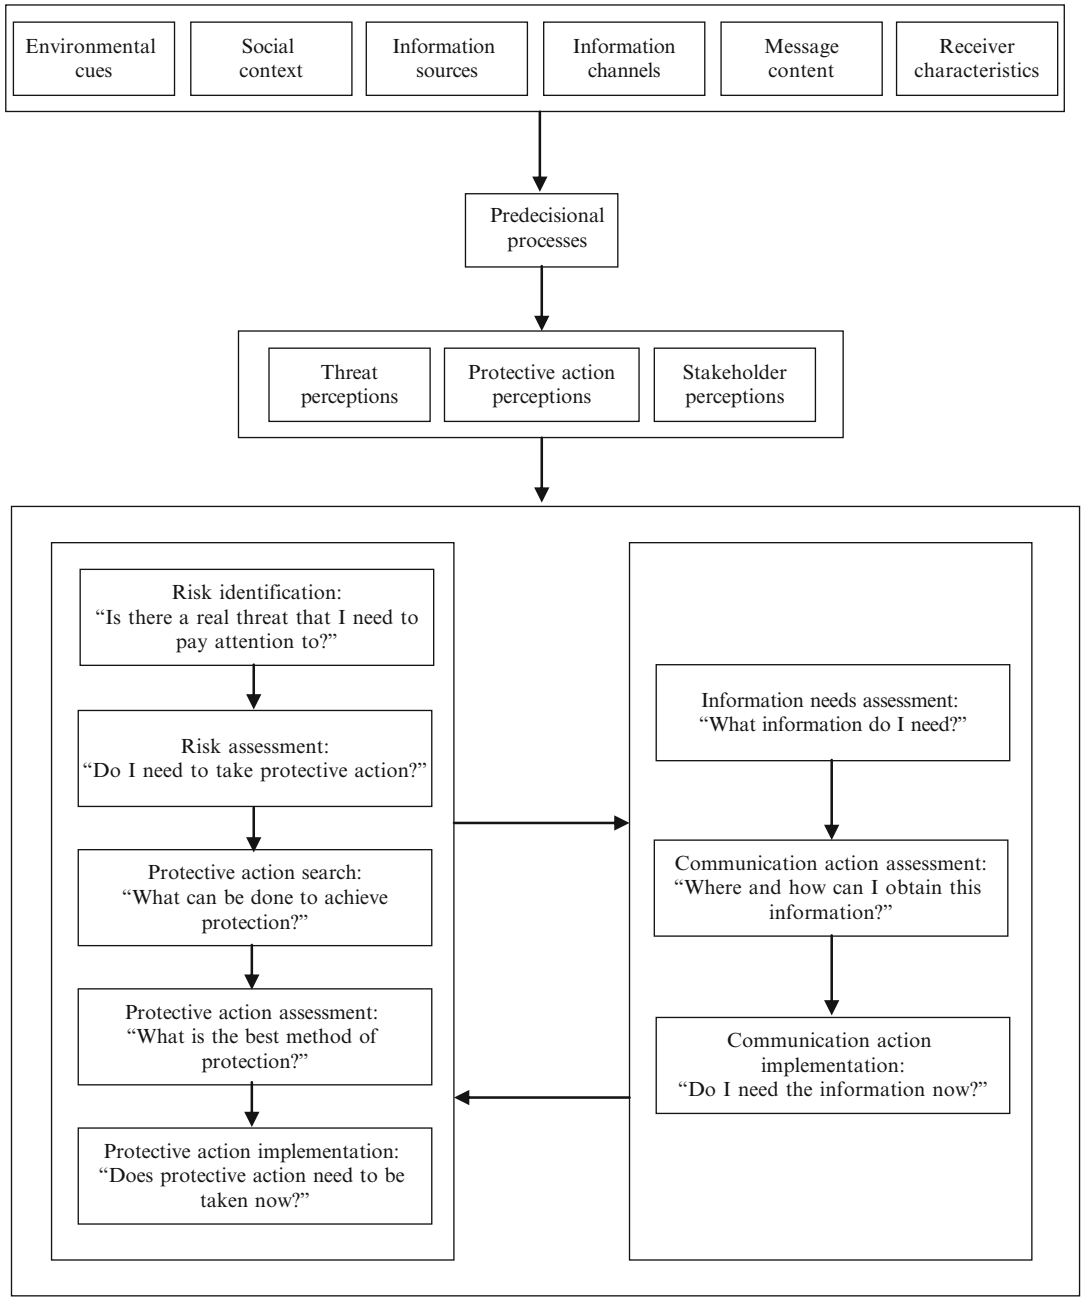

Fig. 58.2 The protective action decision model [73]

protection. The outcome of the third stage is a set of possible protective actions from which to choose. After establishing at least one protective action option, individuals engage in the fourth stage of the PADM: protective action assessment. This stage involves assessment of the potential option(s), evaluating the option(s) in comparison with taking no action and continuing with normal activities, and then selecting the best method of protective action (e.g., evacuating, sheltering in place). Once an action is chosen, the end result of stage 4 is an adaptive plan,

which can vary in its specificity. For example, for households under threat conditions,

> [a]t a minimum, a specific evacuation plan includes a destination, a route of travel, and a means of transportation. More detailed plans include a procedure for reuniting families if members are separated, advance contact to confirm that the destination is available, consideration of alternative routes if the primary route is unsafe or too crowded, and alternative methods of transportation is [sic] the primary one is not available [50].

After a protective action is chosen and the adaptive plan is developed, the final step in the decision process involves the implementation of the protective action plan or strategy. Here, the individual asks whether the protective action needs to be taken now. If the answer is yes, then s/he engages in that action. However, Lindell and Perry [50] note and other studies confirm [18, 77, 78] that individuals are still likely to delay the performance of protective action, even when the threat is perceived as imminent.

Passage through these stages is often problematic. If at any stage the individual is uncertain about the answer to a question, s/he engages in additional information-seeking actions. Information seeking is especially likely to occur when individuals think that time is available to gain additional insight on the question at hand. If information seeking is successful, in that the person at risk judges s/he has obtained enough information to answer the question, then the individual moves on to the next stage or question in the decision-making process. However, if the information-seeking action is unsuccessful, there will be additional searching for information as long as s/he is optimistic that other sources or channels can help [50]. If s/he is pessimistic regarding future information seeking success, s/he is likely to attempt to decide on a protective action based solely on whatever information is available.

This description is not meant to imply that decision processes are linear and straightforward. For example, information feedback loops allow for the receipt of new environmental and social cues after initial engagement in information-seeking actions. An individual who gains additional information is likely to carry on with the decision-making process until s/he is ready to implement a protective action. Additionally, individuals do not have to go through each stage or question in the decision flow chart [50]. For example, if an individual is presented with information about the event from a credible source or if s/he is ordered to evacuate, s/he may move on to later stages in the decision process rather than going through each one in succession.

This decision-making framework describes the process of how individuals respond to disasters. Even though the focus of the models discussed so far is on community-wide disasters, it is clear that the models also apply to decision-making during more localized types of events, such as building fires.

Engineering Implications of the Protective Action Decision Model

Engineers must understand that response to fires and other disasters is the result of a process. Individuals or groups of individuals engage in a decision-making process (i.e., a series of steps) before they respond, based upon the cues presented from their environment (including information), the social context, personal characteristics, past experience [23, 76, 79–81] and hazard knowledge [82]. With this understanding, the engineer should recognize that occupants of a building are unlikely to evacuate immediately, and simultaneously, and instead, recognize that occupants are required to receive and process information on an individual- (or -group-) basis. Also important is that if, at any time in the process, the answer to a decision-making question is unclear (See Fig. 58.2), then the individual will engage in information-seeking actions. Information-seeking actions take time to complete and delay the occupant from reaching safety.

Additionally, just because cues or information are provided to building occupants does not necessarily mean that they will act appropriately.

The cues or information must be perceived (e.g., heard or seen), paid attention to, and then comprehended first before any actions take place. Therefore, engineers must ensure that any information meant for building occupants must be provided in such a way to ensure that these three processes take place. One example of this is to ensure that the public address announcements disseminated in a building fire are set to an appropriate volume level such that all occupants in the buildings can hear them; and if not and in order to reach occupants with hearing disabilities, other means of disseminating the information are used (e.g., visual signage) [83].

Engineers should also acknowledge that occupants must perceive a credible threat and personalize the risk before taking action. Research has shown that individuals are more likely to identify and personalize the risk if they perceive a larger number of cues [43, 84, 85] that are intense or extreme in nature [86, 87]. In building fires, for example, occupants who witness heavy, thick, black smoke that decreases visibility and irritates the eyes are more likely than those noting less intense cues to realize that a serious event has taken place that puts them in danger [88]. However, it is always the responsibility of the engineer to protect building occupants, which includes limiting their exposure to fire effluent.

The main way to prompt safe, effective, and appropriate action from building occupants is to disseminate warning messages during fire emergencies that will positively influence risk identification and assessment. Research has shown that a ***successful warning message*** contains the following factors or qualities:

- Specific about the threat and the risk involved [89–91],
- Repetitive [50],
- Consistent [92],
- Disseminated via multiple channels [93],
- Provided by a credible source [49, 76, 81, 94].

Source credibility is defined in terms of the source's expertise, including access to special skills or information, and trustworthiness, or the perceived ability to communicate information about the disaster without bias [50, 54]. Source credibility can differ depending upon a number of factors, including the type of disaster, characteristics of the source, such as social role and believability, and characteristics of the warning receiver, such as past experience in disasters and social location [95–100]. For some warning receivers, credible sources may be friends and relatives, and for others, credible sources may be disaster authorities, such as government officials [101, 102] or fire fighters [38].

As far as content, a warning message should contain five important topics to ensure that building occupants have sufficient information to respond with little or no additional delay and information seeking [38, 103]. These five topics, labeled here as the five W's of any effective warning message, are as follows:

1. Who is providing the message? (i.e., the source of the message, which should be perceived as credible by the building occupants)
2. What should people do? (i.e., what actions occupants should take in response to the emergency and if necessary, how to take these actions)
3. When do people need to act? (i.e., in rapid-onset events, the "when" is likely to be "immediately")
4. Where is the emergency taking place? (i.e., who needs to act and who does not)
5. Why do people need to act? (including a description of the hazard and its dangers/consequences).

Another way to prompt safe, effective, and appropriate action from building occupants is through training. An individual's past experiences in emergencies, specifically the actions that s/he has performed previously, can influence the actions that s/he considers as options during the current emergency [50, 56, 104]. The individual uses memories of the protective actions s/he performed in the past as options for actions to perform in the current emergency. Similarly, an individual's emergency-based training and knowledge, for example, knowledge about evacuation procedures, can influence the options that s/he develops during an emergency [78, 105–108].

Relating Theory to Practice—Protective Actions in Fires

As shown in the earlier section, research has established the theoretical process through which community residents or building occupants make decisions in response to fires and other disasters [50]. However, these theories do not provide sufficient information on the specifics or the *types* of protective actions in which occupants engage and why they engage in these types of actions during fire emergencies.

Research has been performed that identifies the types of actions that people perform during a building fire evacuation, with a focus on the pre-evacuation period. Both summary research [77, 87, 109] and research on specific incidents [1, 3, 18] highlight certain actions in which occupants are likely to engage. These actions, depending upon the situation, can include seeking information, waiting, investigating the incident, alerting others, preparing for evacuation (or deciding not to evacuate), assisting others, fighting the fire, and searching for or rescuing others. One factor that has been used to differentiate one set of actions from another set of actions is the type of building in which the emergency occurs. For example, individuals who are at home (especially at night) may engage in a different set of preparatory actions than individuals who are awake in their offices when the alarm sounds, for example. Therefore, in this section, studies that have been performed on different types of structures will be presented to identify the actions in which individuals most frequently engaged.

U.S. and UK Residential Studies

One of the first studies of behaviors performed during residential fire evacuations was by Wood [15]. The study involved 2193 fire-department conducted interviews with residents from 952 residential fire incidents in Great Britain. Within the same decade, Bryan [14] also studied residential fire incidents by analyzing on-scene interviews conducted by fire service personnel with 584 participants from 335 fire incidents in the United States.

Both researchers found that behavioral responses to fires could be categorized into the following actions: notifying others, searching for the fire, fighting the fire, calling the fire department, getting dressed, getting the family, asking others to call the fire department, gathering personal property, closing the door to the fire area, turning off appliances, doing nothing, attempting to evacuate, and evacuating; among other more specific actions. The most frequent behavioral responses to fire in both the UK and US studies were identified as evacuating the building, fighting or containing the fire, and notifying other individuals or the fire brigade.

Bryan and Wood also organized these actions into first, second, and third actions in an attempt to begin to order the actions taken during the residential evacuation process. In both studies, it was found that investigation actions, such as searching for the fire; notification actions, such as notifying others, pulling the fire alarm or getting family; and preparation actions, such as fighting the fire, turning off appliances, and getting dressed; were performed. In the U.S. study, Bryan [14] indicated that the action of "investigate" was very common as a first action by 45 % of occupants in the sample and as a second action by 23 %. These authors also report that actions such as "mitigate the fire," "help others," and "call for help" were in the middle of the actions sequence, and "escape" or "go for help" were at the end of the usual sequence of four to five actions. "Call the fire brigade" was generally a fourth action, and "fight the fire" usually occurred between the second and sixth actions.

Bryan [14] and Wood [15] also identified actions that were specifically linked to engagement with the fire and/or subsequent toxic products produced by the fire during these residential evacuations. Some percentage of occupants in both studies engaged in fire-fighting behavior, re-entry behavior (i.e., they returned to the structure after leaving), moved some distance through smoke, and/or turned back (i.e., stopped their movement to or into smoke and redirected

based on environmental conditions) [77]. These results show that individuals were likely to engage in potentially risky behavior, such as fire-fighting or re-entry behavior, during the fire incident.

For more information on the psychophysical effects of smoke on individual movement and actions, including the visibility distances in which people moved through smoke or turned back, please see Chaps. 61, 63, and 64.

MGM Grand Hotel Fire

Analysis was also performed on the behaviors engaged in during the MGM Grand Hotel fire in Clark County, Nevada, on November 21, 1980 [110]. This hotel fire involved both injuries and fatalities among the guests. The management of the MGM Grand Hotel, and the Clark County Fire Department, in cooperation with the National Fire Protection Association (NFPA) [111], conducted an intensive study of the guests registered in the hotel for the evening of November 20 to 21, 1980, to determine how the occupants became aware of the fire incident and their behavioral responses.

The MGM Grand Hotel fire was discovered by an employee of the hotel who entered the deli-restaurant located on the casino level of the hotel at approximately 7:10 a.m. on November 21, 1980. The fire reached a flashover condition in the deli area, immediately spread from east to west through the main casino area, and extended out the west portico doors on the casino level immediately following the arrival of the initial fire department personnel. The heat and smoke extended from the casino area through seismic joints, elevator shafts, and stairways throughout the 21 residence floors of the hotel. The heat was intense enough on the 26th (top) floor to activate automatic sprinkler heads located in the lobby area adjacent to the elevator shafts.

Due to the rapid early evacuation of the telephone staff, guests in their rooms were not alerted by the hotel public address system nor the local fire alarm system. Guests who were alerted early in the fire incident, or guests already awake and dressed, were able to escape prior to the smoke conditions becoming untenable on the residential floors. Guests alerted later in the progression of the fire incident remained in their rooms or moved to other rooms, often with other occupants. The flame propagation did not extend above the casino level, with the exception of very minor extension into two guests' rooms on the 5th floor. The fire resulted in 85 fatalities to guests and hotel employees in the following areas of the hotel [110]: 14 persons were found on the casino level, 29 persons were found in guest rooms, 21 persons were found in corridors and lobbies, 9 persons were found in the stairways, and 5 persons were found in elevators. The victims were located on the casino level, and the 16th through 25th floors, with the majority of fatalities found between the 20th and the 25th floors. Various estimates have been provided of the number of guests and fire department personnel that suffered injuries at the MGM Grand Hotel fire. Morris [112] indicated that 619 persons were transported to hospitals from the fire scene, and another 150 guests were treated at the Las Vegas Convention Center, where the survivors had been transported.

Behavioral responses from survivors of this fire were elicited from 554 returned mail-surveys. Similar to the residential studies, one topic of interest was to collect information on the types of behaviors in which survivors engaged. The initial five behavioral responses of the 554 guests as elicited from the NFPA questionnaire study are presented in Table 58.1. The five most frequent first behavioral responses were "dressed," "opened door," "notified roommates," "dressed partially," and "looked out window." The guests involved in the first responses were predominantly engaged in attempting to define and structure the fire cues relative to the severity of the threat to themselves. Only a small percentage, approximately 8 % of the study population, initiated or attempted to initiate their evacuation behavior as the first response.

Examination of Table 58.1 indicates the five most frequent behavioral responses reported by guests as second actions were "opened door,"

Table 58.1 Compilation of the initial five actions of guests in the MGM grand hotel fire incident [111]

	Percent of population				
Actions	First	Second	Third	Fourth	Fifth
Dressed	16.8	11.6	6.5	–	–
Opened door	15.9	11.7	6.7	3.4	–
Notified roommates	11.6	3.0	–	–	–
Dressed partially	10.1	7.5	4.5	–	–
Looked out window	9.7	5.7	–	–	–
Got out of bed	4.5	–	–	–	–
Left room	4.3	5.4	8.1	2.4	2.0
Attempted to phone	3.4	3.6	–	2.8	–
Went to exit	2.5	10.3	9.5	16.1	6.7
Put towels around door	1.6	2.5	3.0	6.8	7.7
Felt door for heat	1.3	2.3	–	–	–
Wet towels for face	1.3	3.7	6.3	4.6	7.9
Got out of bath	1.1	–	–	–	–
Attempted to exit	1.1	3.0	5.8	4.3	–
Secured valuables	–	6.8	4.3	–	–
Notified other room	–	3.4	2.2	–	–
Returned to room	–	–	3.9	8.4	4.1
Went down stairs	–	–	3.9	5.4	21.3
Left hotel	–	–	3.4	2.6	2.0
Notified occupants	–	–	3.0	–	–
Went to another exit	–	–	–	3.6	4.8
Went to other room	–	–	–	3.6	3.6
Went to other room/others	–	–	–	3.4	8.7
Looked for exit	–	–	–	2.4	–
Broke window	–	–	–	–	4.3
Offered refuge in room	–	–	–	–	1.8
Went upstairs to roof	–	–	–	–	2.9
Went to balcony	–	–	–	–	1.8
Other	14.8	19.5	28.9	30.2	20.4
Total (percent)	100.0	99.1	96.9	90.4	79.6
Number of guests	554	549	537	501	441

"dressed," "went to exit," "dressed partially," and "secured valuables." Whereas approximately 40 % of the population was engaged in evacuation or sheltering actions by the second act, others were engaged in protective actions. Approximately 19 % of the study population reported they were involved in the dressing actions, 10 % were involved in notification activities, and 7 % were gathering valuables prior to initiating evacuation or seeking refuge.

Examination of the third behavioral responses of the 537 guests in the study population indicated the responses of the guests generally progressed to evacuation, attempted evacuation, and notification responses. Thus, approximately 25 % of the MGM Grand Hotel fire incident study population was involved in evacuation-related behavioral responses, and approximately 10 % of the guests were involved in attempted evacuations as identified by their third responses of "attempted to exit" and "returned to room." The alerting and notification actions of the guests were involved with the third behavioral responses of "notified occupants" and "notified other room."

The fourth behavioral responses of the guests in the study population indicated a progression of the guests to evacuation, attempted evacuation,

Table 58.2 Activities prior to evacuation reported in telephone survey by survivors of WTC 1 and WTC 2 [1]

Activities before evacuation	Percent reporting the activity (n = 440 in WTC 1) (%)	Percent reporting the activity (n = 363 in WTC 2) (%)
Talked to others	70	75
Gathered personal items	46	57
Helped others	30	34
Searched for others	23	32
Talked on telephone	16	16
Moved between floors	8	8
Shut down computers	6	7
Continued working	3	6
Fought fire or smoke	6	1
Other activities	25	20

Source: NIST WTC Telephone Survey Data
Note: Total does not add up to 100 % because respondents may have taken multiple actions

and self-protection or room refuge procedural responses. Additionally, the fifth behavioral responses of the guests were primarily for self-protection, including the improvement of the room as an area of refuge, and evacuation behavior.

Overall, in this hotel fire, hotel guests were more likely to take initial actions investigating, notifying others, and preparing for evacuation, which in this case involved getting dressed. This is similar to the residential studies, likely because a hotel and a residence involve similar living circumstances. In both cases, individuals may be alerted to a fire when they are sleeping—meaning that they will require additional time to prepare for evacuation; i.e., getting dressed themselves or getting other family members dressed. Then, after initial investigation, preparation and warning activities ended, and hotel guests engaged in protective actions and evacuation.

2001 World Trade Center Disaster (Office Buildings)

Different from a residential or hotel fire, studies were performed on the 2001 World Trade Center (WTC) evacuation of the two office towers [1, 22, 30]. On September 11, 2001, two commercial airplanes flew into World Trade Center (WTC) Towers 1 and 2 and initiated full building evacuations from both 110-story office buildings. At 8:46 am, Flight 11 slammed into the north face of WTC 1, disconnecting the entire population above the 91st floor from any way out of the building. It was at this moment that the largest full-scale building evacuation in history began for occupants who had the opportunity to evacuate from both WTC 1 and 2. None of them knew, however, that another commercial jet was on its way—one that was heading straight for WTC 2. Sixteen minutes after WTC 1 was struck and after one-third of WTC occupants had already evacuated,[3] Flight 175 sliced into floors 78 to 84 of WTC 2 leaving only one of the three stairs available for evacuees above the 78th floor. Occupants who could evacuate continued to pour from the structures until the towers eventually succumbed to structural collapse (WTC 2 collapsed at 9:58:59 am and WTC 1 collapsed at 10:28:22 am).

The frequency of actions performed in the 2001 WTC disaster by occupants evacuating Towers 1 and 2 was reported by Averill et al. [1] and Day, Hulse and Galea [113], shown in Tables 58.2, 58.3 and 58.4 below. The focus here is an understanding of the actions taken before evacuation movement in the stairs began. As part of the NIST WTC study [1],

[3] 21 % from WTC 1 and 41 % from WTC 2.

803 interviews were conducted via telephone using a computer program that allowed the interviewers to collect data electronically, also known as computer-assisted telephone interviewing (CATI). Quantitative data was captured via an interview schedule designed to measure the following five primary areas: preparedness and training, initial September 11 experience, interim September 11 experience, evacuation experience on September 11, and respondent demographics. The two populations selected for study were all of the people who worked in WTC Tower 1 and WTC 2 who were in the buildings between 8:46 am and the time at which their respective Tower collapsed on September 11, 2001. In the UK, the WTC evacuation was also studied as part of an in-depth research project carried out by the Project High-rise Evacuation Evaluation Database (HEED) research team [22]. Project HEED was a 3-year project to explore human behavior associated with the evacuation of high-rise buildings. The basis for this project was an analysis of the 2001 WTC disaster through both face-to-face interviews with survivors and computer simulation of the evacuation. The project resulted in over 250 face-to-face or telephone interviews with survivors from the 2001 WTC disaster, collected to both inform the development of future building regulations and evacuation computer models and to make data available to bona fide building safety researchers in countries around the world. In both cases, the studies' presentation of actions taken was not ordered in any way (i.e., first, second, and third actions); however, both studies provide an understanding of the actions that were most frequently performed from one tower to another.

Averill et al. [1] presented a list of the "general" pre-evacuation actions performed in both towers, shown in Table 58.2, below, acknowledging that not all actions were covered by these categories by including the "other" category at the end of the list. The majority of individuals in both towers engaged in actions that involved talking to others (70 % in WTC 1 and 75 % in WTC 2) and gathering personal items (46 % in WTC 1 and 57 % in WTC 2). Additionally, about a third of occupants in both towers engaged in helping others and searching for others.

Day, Hulse and Galea [113], on the other hand, grouped pre-evacuation actions into two different categories: information tasks and actions tasks (shown in Tables 58.3 and 58.4). Information tasks, which involved action taken to obtain or receive information, were further divided into three different areas: seeking

Table 58.3 Comparisons of information tasks by tower [113]

	WTC1		WTC2	
Information tasks	% PPTs	Freq	% PPTs	Freq
Seek information tasks				
Environmental (e.g., window)	53	66	83	142
WTC colleagues/friends	36	44	27	46
Waited for further info	13	17	8	11
People outside WTC (e.g., called family, friends)	8	17	3	4
TV/internet/radio	2	2	6	7
Professional bodies (e.g., port authority, security, police, fire)	2	2	5	6
Communication tasks				
Instruct others to evacuate	34	51	40	89
Inform others of my situation	17	25	30	63
Debate/challenge	3	5	11	15
Receive information tasks				
Non-professionals (e.g., managers, family)	12	16	23	35
Professionals (e.g., PA announcements, security, police, fire)	8	9	19	31

WTC1: N = 119, WTC2: N = 121, PPTs participants

Table 58.4 Comparisons of action tasks by tower [113]

	WTC1		WTC2	
Action tasks	% PPTs	Freq	% PPTs	Freq
Personal tasks				
Collected personal items (e.g., wallet)	60	141	63	145
Went to toilet/comfort break	3	3	2	2
Changed footwear/glasses	3	3	1	1
Emergency tasks				
Evacuation facilitation (e.g., searched office/floor, forced exit open)	19	25	26	47
Waited for others so evacuate together	7	8	14	17
Gave others physical assistance (e.g., carried/gave first aid)	6	7	3	4
Protective action (e.g., took refuge, blocked/sealed cracks, got under smoke, made masks)	7	8	3	4
Distributed useful items (e.g., mobiles, masks, bottled water)	0	0	1	1
Work tasks				
Secured items/areas (e.g., locked files, bank vaults)	7	10	3	4
Tidied desk	3	5	8	14
Latent tasks				
Denial/Froze/continued working	2	2	13	17
Travelled to another area/floor/stairwell (reason unknown)	4	5	3	4

WTC1: N = 119, WTC2: N = 121, PPTs participants

information, communicating with others, and receiving information. The action tasks, a term which was not specifically described by the authors, was subdivided into additional categories: personal, emergency, work and latent actions. According to this study, and similar to Averill et al. [1], the majority of tasks undertaken by the participants were "Information tasks" (54 % in WTC 1 and 63 % in WTC 2)—specifically the action termed as "seeking information". Additionally, the most common "Action Tasks" performed by occupants in each tower were "Personal Tasks"—accounting for 68 % of the "Action Tasks" in WTC 1 and 57 % in WTC 2. Personal tasks involved occupants collecting or packing up their personal possessions before evacuating the building. Day, Hulse and Galea [113] also tracked the number of tasks completed by each participant in the study. The range of tasks completed was between 0 and 13 in WTC 1 and 2 and 21 in WTC 2; with an average number of tasks completed in WTC 1 of 3.96 and an average number of tasks completed in WTC 2 of 5.86.

Table 58.5 Range of times associated with WTC pre-evacuation actions [30]

Action	Range of timing (minutes)
Preparation (Action task, personal)	0.5–5
Communicating with others (Information task)	3
Looking out the window (Information task)	1–5
Helping, by authorities (Action task, emergency)	4–10

While most empirical studies of actual incidents [114–116] and evacuation drills [117–119] provide overall timing estimates for activities in the pre-evacuation period, very few researchers discuss times associated with specific pre-evacuation actions. From analysis performed by this author on the Project HEED database [30], pre-evacuation action times were reported by some WTC occupants and are presented in Table 58.5 as a range of times (minutes) for each action type.

University Library Building in the Czech Republic

From a study of an unannounced evacuation drill in a university library in the Czech Republic, Galea et al. [120] collected data on the number, type and duration of pre-evacuation actions. To begin the evacuation, the alarm system, consisting of a combination of tones, recorded voice and live voice messages, was activated. The recorded voice message began by stating the word "attention" multiple times, followed by a declaration that an emergency situation was taking place. The message also instructed people to prepare for evacuation and wait for further instruction. Two live messages were also disseminated during the drill. The message made it clear that the evacuation instruction was directed at occupants in the library building only and then gave instructions on the routes to take, depending upon where the individual was located within the library building. The live messages also warned individuals not to use the elevators, and to only use the stairs to evacuate. On the day of the trial, the alarm system failed to operate in certain parts of the library building. Some individuals heard the alarm tone and announcements and some did not. In the places where the alarm failed to function, the evacuation was initiated by staff intervention.

Video observation and analysis of the evacuation drill allowed for the collection of pre-evacuation action (or task) type and duration. In this study, similar to the WTC study presented above, pre-evacuation actions were categorized in two different ways: information tasks (or actions that involve the occupant seeking, providing or exchanging information regarding the incident) and action tasks (or all other types of pre-evacuation actions, e.g., preparation, fighting the fire, helping others, etc.). Throughout the evacuation, 235 information tasks and 268 action tasks were completed; the average number of information tasks (per person) was 3.7 and the average number of action tasks (per person) was 4.3. On average, an evacuee in this study engaged in a total of 8.0 tasks prior to beginning evacuation movement (e.g., into the stairs).

There were differences in task numbers between evacuees who received staff intervention and those who were alerted by the alarm system. For those who were alerted via staff intervention, the average number of information tasks was 2.0 and the average number of action tasks was 3.6; for an average number of total tasks performed prior to beginning evacuation movement of 5.6. For those alerted via the alarm system, the average number of information tasks was 7.4 and the average number of action tasks was 5.7; for an average number of total tasks of 13.1. The authors of this study noted that individuals alerted by the alarm engaged in twice as many tasks during pre-evacuation than individuals notified by a member of staff.

Work was also performed to measure the time to undertake each individual task from the video footage [120]. The analysis showed that the average duration of a single action task was 6.4 s and the average duration of an information task was 9.7 s (independent of how an evacuee was alerted to the incident). The authors concluded that, in this study, an information task took 1.5 times as long as an action task. Analysis of task timing was also performed by comparing the two groups alerted to the drill via different means. For the population alerted by staff intervention, the average time for an action task was 6.5 s and for an information task was 6.7 s. On the other hand, for the population alerted by the alarm system, the average time for an action task was 6.4 s and for an information task was 9.9 s. The authors of this research noted that there was a considerable difference in the average time to complete information tasks among the two populations—showing that the population alerted by the alarm system took a longer time (on average) to complete information tasks in comparison to the population alerted by staff intervention. This highlights the greater influence of in-person, official communication/instruction on a faster response time when compared with an alarm system.

University of Greenwich Dreadnought Building (Educational and Library Services Building)

A study was performed on an evacuation of a university building known as the Dreadnought building, located on the University of Greenwich campus in London, UK [121]. The Dreadnought building is a three-story structure used for a variety of purposes, including library services, student computing facilities, and a small cafeteria. Data were collected by research staff located at 15 key locations throughout the building via handheld video and manual observations. Additionally, questionnaires were handed out to all evacuees to collect information about their experience during evacuation. Last, 62 closed-circuit cameras were used to gather data on the starting locations of evacuees, their behaviors/actions, and response times. Because of camera locations, initial responses and times could only be captured for 247 evacuees of this building: 228 students and 19 members of staff. In this building, once the alarm sounded, nominated members of staff swept each room, "forcing students to leave their work and belongings, and informing them of the routes they should adopt" [121].

During analysis, a dictionary of potential actions was created based upon examination of the video evidence from the evacuation. The list of actions comprised of the following:

- Evacuate immediately
- Perform a computer shutdown
- Disengage socially
- Collect items, including bags, coats, paperwork, etc.
- Investigate the incident.

Additionally, it was found that 27 % of the participants of this study completed one or no actions prior to beginning evacuation, 55 % completed two actions, and 18 % completed three or more.

Engineering Implications of Actions Taken During Evacuation

Engineers should understand that actions, both information-related actions and protective actions, are performed during fire evacuation. Depending upon the circumstances, these actions can take a considerably long time to complete and will contribute to the time to reach safety. First, engineers must account for these actions in some way when calculating evacuation timing in a proposed design building fire. Actions and delay times associated with these actions can be especially important in certain types of buildings, where individuals are likely to engage in certain types of lengthy actions; i.e., those in which people may be asleep or located on upper floors of uniquely tall buildings. Many times, when performing an evacuation calculation, engineers are asked to provide a specific pre-evacuation time period or distribution as input. Engineers should choose a time that is based upon specific scenarios and resulting occupant actions (and action timing). Additionally, to improve occupant response, engineers should account for evacuation actions when developing fire evacuation plans for buildings. As stated earlier, research has shown that providing specific warning information in certain ways or providing leadership to prompt evacuation response could reduce the need for information seeking, and even the performance of certain protective actions. If engineers understand which evacuation actions they should anticipate in a specific building or fire scenario, they can formulate plans that are successful in decreasing delays caused by evacuation actions. Therefore, it is important to first understand that types of actions that individuals have engaged in previous fires and how these actions can vary from building to building, and from fire event to fire event.

Relating Theory to Practice—The Sequence of Protective Actions in Fires

Beyond identifying the types and percentages of actions, including the percentage of actions that were performed first, second, and third, research has been performed to identify the sequence of actions taken in different types of fires. Canter, Breaux, and Sime [78] developed decomposition diagrams for various types of fire events that

identify the sequence of actions. The study was conducted in the United Kingdom on domestic fires (14 domestic fires and the acts of 41 persons), multiple-occupancy fires (eight multiple-occupancy fires and the acts of 96 persons), and hospital fires (6 hospital fires and the acts of 61 persons). All persons in this study were interviewed about their experiences in the fire; first asking them to give a detailed account of everything that happened starting from the time at which they considered that something out of the ordinary might be occurring. Once individuals had given full accounts, interviewers questioned respondents on certain issues, including recognition of the fire event, location of the occupant, ongoing behavior, sequence of actions, perception of the situation, past experiences, and background information.

The results of this analysis were the development of decomposition diagrams. These diagrams are provided here, as Figures 58.3, 58.4, and 58.5. Dashed circles indicate the acts which occurred with a lower frequency. The relationships between acts are indicated by arrows; and if actions are repeated, the circle (representing the action) would have a looped arrow coming back on itself. The numbers next to an arrow refer to the strength of the association. The higher the association number, the greater the association is; i.e., the more likely it is that given the performance of one act, the next action (specified) will follow.

The decomposition diagram for domestic fires is shown in Fig. 58.3. The domestic diagram summarizes 1189 acts which occurred in 14 domestic fires. It outlines departure from pre-event activities, such as sleeping, to a range of other investigative, notification, and preparation activities. In these domestic fires, individuals tended to perform actions related to investigating which involved encountering or engaging with the fire in some way, and then evacuating; or discuss the situation, notify or warn others, preparing to evacuate, and then leaving the house.

The decomposition diagram for multiple occupancy fires is shown in Fig. 58.4. The multiple occupancy diagram summarizes 1714 acts which occurred in all eight multiple-occupancy fires [78]. All fires occurred in the United Kingdom in hotel occupancies. Similar to the domestic fires, occupants went to investigate the receipt of strange noises, which led to them encountering the fire environment and/or warnings about the emergency. If direct contact with the fire environment ensued, the characteristic sequence that followed involved the occupant going to the window, shouting for help, and then being rescued. Also similar to domestic fires, occupants engaged in activities such as warning others, gathering personal items, and closing or opening windows.

The decomposition diagram for hospital fires is shown in Fig. 58.5. The hospital diagram summarizes 1104 acts which occurred in all six multiple-occupancy fires [78]. The case studies covered a variety of hospital types, i.e., geriatric, psychiatric and general medicine; however, patterns were still revealed among the entire population, as a whole. Detection and investigation actions are performed relatively early in these fires, possibly because the higher spread of people in the building. Also, the sequence of actions is different in this diagram, when compared with others, due to the nature of the organizational hierarchy of the hospital. Senior nursing staff, whose job it was to investigate the fire, relay information to junior colleagues, who then had a series of actions that they performed in response.

The reader should note the inclusion of process-related factors (first described in the PADM) into these action-based diagrams. For example, Figures 58.3, 58.4, and 58.5 contain circles for the receipt of cues, i.e., “hear strange noises” or “encounter difficulties in smoke”, which are not actions. Instead, these are processes in which individuals engage in order to act in a building fire. Also, all three diagrams contains circles for the interpretation of cues, i.e., “misinterpret (ignore)”. The domestic diagram even contains an entry for “feel concern”. These entries also are not actions, but interpretations about the situation and personal risk (first described in the PADM) as direct

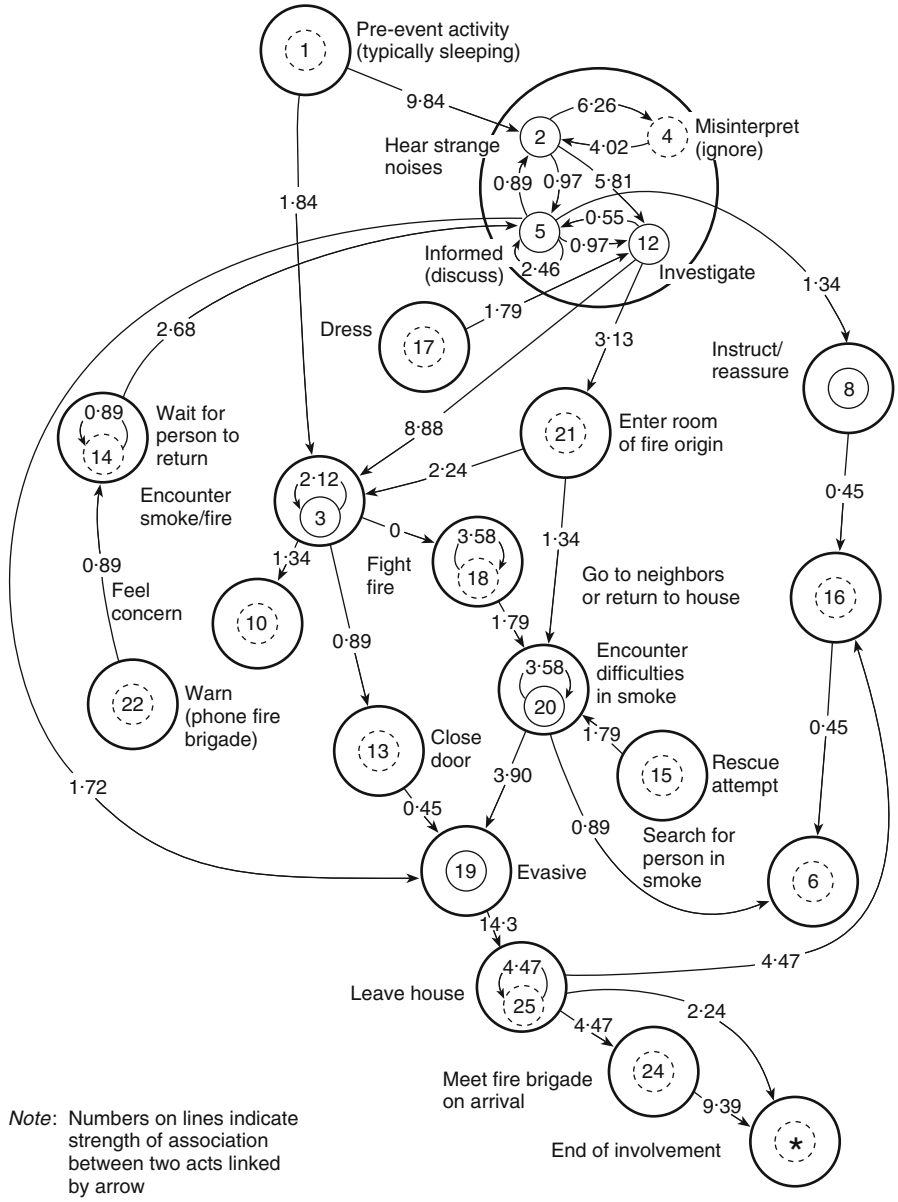

Fig. 58.3 Decomposition diagram—domestic fires [78]

influences of actions. These diagrams truly represent the first attempt at developing an inclusive conceptual model of evacuation actions—that identify not only the action, but also the processes of receiving cues and processing information in order to act in an emergency.

Patterns of behavior exist across all three diagrams (of varying occupancy type). What is important to note here is that certain actions take place in specific locations within the evacuation sequence. First, immediately after the receipt of initial cues, individuals were more likely to

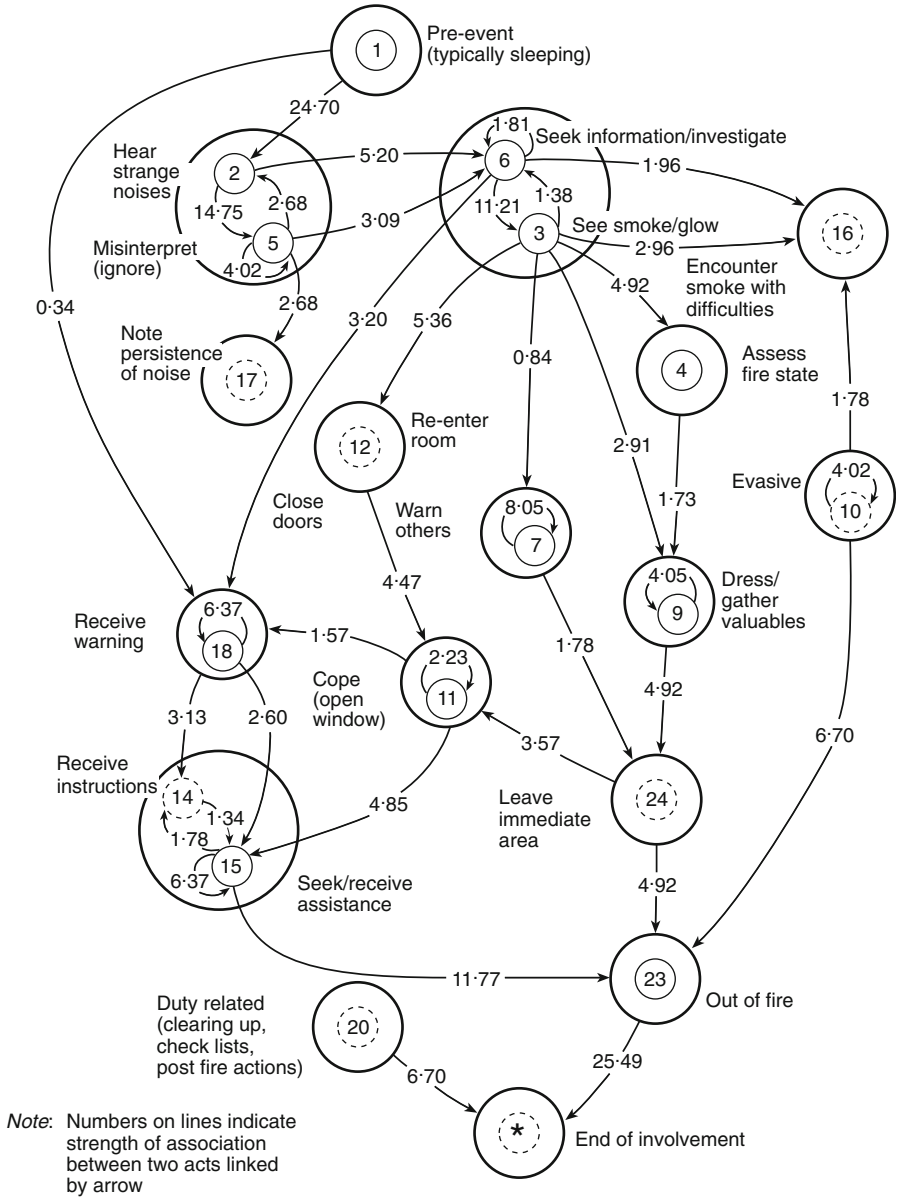

Fig. 58.4 Decomposition diagram—multiple-occupancy fires [78]

'investigate' the situation and/or 'misinterpret' (or ignore) cues that they received early on in the event. Then, after seeing smoke, one of three 'prepare' sequences were more likely to be performed, including 'instruct', 'explore', or 'withdraw'. Finally, depending upon the particular preparation action chosen, occupants were more likely to engage in the following actions: 'wait', 'warn', 'fight' or 'evacuate'.

Engineering Implications of the Linkage of Actions Taken During Evacuation

Actions follow a specific pattern across all types of building fires, and an understanding of the patterns of behavior is important when attempting to accurately model an evacuation scenario (i.e., the methods outlined in Chap. 57). Take for example, an office building

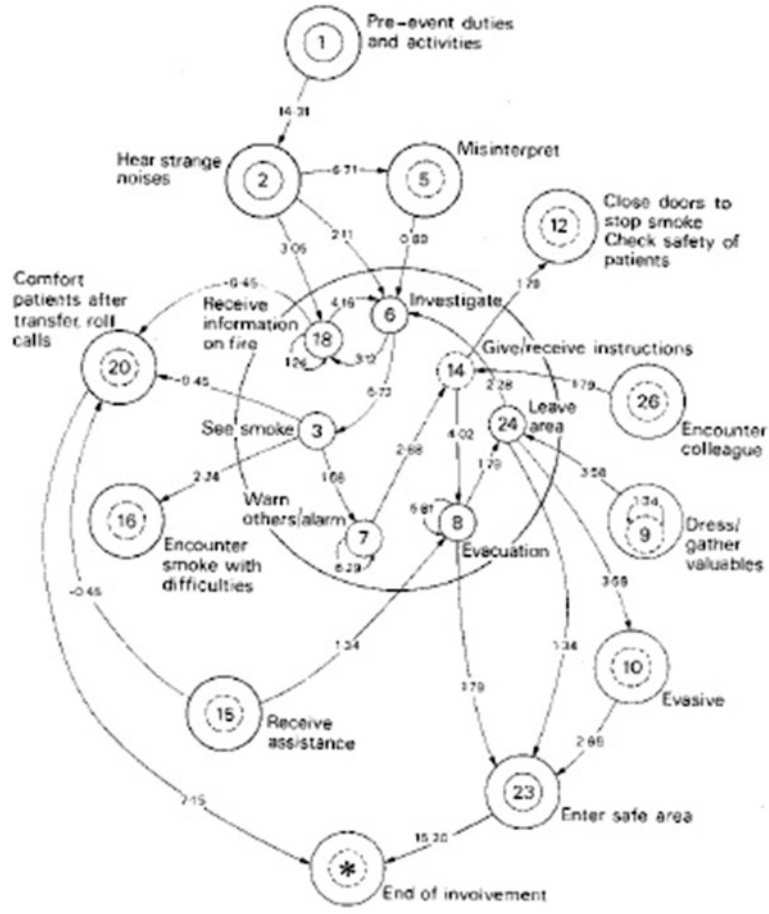

Fig. 58.5 Decomposition diagram—hospital fires [78]

that houses a child daycare for its employees on the 10th floor of a 20-story building. It will be important for engineers to understand that occupants will spend some period of time on their floors investigating the situation and making decisions as to what needs to be done; i.e., if evacuation is necessary or not. Therefore, a determination of the fire and smoke conditions on any occupied floor is important immediately after the fire begins. Next, the engineer should understand that some proportion of occupants may travel to the 10th floor to rescue their children from the daycare center, requiring an assessment of the environmental conditions on that floor for some time period after investigation is complete (i.e., the protective action phase).

An understanding of the behavioral process is important also for the design of evacuation procedures for a building. For example, the presence of staff as well as a building alarm for alerting the population of a building fire may decrease time spent investigating and deciding to evacuate. If staff members instruct building occupants to evacuate, especially if they represent a credible source to the population, then building occupants may be more likely to begin evacuation sooner than if left to their own decisions [30].

Relating Theory to Practice—Group Behavior

Research also exists to explain observations from numerous fire studies that people tend to travel or converge into groups during emergencies. There are theories that support the idea that individuals come together and form a group before evacuating, and then continue their evacuation together until they reach safety. This behavior, labeled as affiliative behavior [107], is described first in this section. Individuals also come together in groups to help one another. Helping behavior is found in almost every disaster, and an overview of this behavior will also be provided in this section. Finally, individuals have been found to converge together in groups during emergencies in order to take refuge from the fire conditions. Convergence groups, or clusters as termed by Bryan [77], were found in situations whereby individuals attempted evacuation and decided that is was not possible at the time.

Affiliative Behavior

According to Sime, who developed the Affiliative model, there is a relationship between people and their physical settings [107]. This model assumes that individuals with close psychological ties will attempt to escape with other group members during an emergency evacuation. Through his study of the Summerland fire, he found that nucleus family members were more likely than others to maintain group ties during travel to and through exits. Mixed groups, on the other hand, including friends and/or relations, did appear to have been less concerned with maintaining group ties during evacuation than they might have under normal circumstances.

Proulx also found this trend in group behavior while studying evacuation timing in apartment building evacuations [122]. Through the analysis of video tapes, it became apparent that people traveled in groups during evacuation: families with children would typically evacuate in a close group with an adult carrying the smallest child. However, family groups would split slightly when traveling with children who were a bit older in age. Additionally, seniors also traveled in groups of two or three; noting that they would exit their apartment and gather to discuss the drill, finally proceeding to evacuate together. Overall, Proulx found that 62 % of the occupants (in the four buildings studied) evacuated in groups. One important aspect to note is that Proulx also monitored the speed of movement of building occupants and found that groups tended to assume the speed of the slowest person, which in many cases in the apartment buildings studied were young children or older adults. Also, people tended to stop to converse during evacuation, rather than maintain the same speed throughout the entire evacuation.

Helping Others

Occupants also help one another during building emergencies, bringing people together in groups at one time or another. Analysis of building fires [77, 78, 108] and community-wide disasters, such as tornadoes [123, 124] and hurricanes [125, 126], provide many examples of instances where evacuees are often the first responders in any emergency. For example, Johnson, Feinberg and Johnston's study [127] of the Beverly Hills Supper club event (where a fire broke out in a nightclub in Kentucky in 1977, causing 165 deaths and over 200 injuries) showed that people put themselves in what they categorized as "grave danger" while assisting others in their group—"at times, returning to the burning building to search for loved ones; staff performing heroic acts while trying to save their clients". Aguirre et al. [128] through their study of another nightclub fire (i.e., The Station Nightclub Fire), which occurred at approximately 11:09 p.m., on February 20, 2003, in West Warwick, Rhode Island [129], found evidence that people cooperated and took care of one another in their group during and after the evacuation, which was a key aspect of their survival.

Drury, Cocking, and Reicher [32] discuss the reasons why helping behavior occurs in

emergencies. They claim that people help others in moments of crisis not only because they know and care about each other, but also because individuals have "internal cognitive categories" that allow identifications with others in certain contexts. In other words, an emergency requires individuals to redefine the situation collectively (as discussed in an earlier section of this chapter), and through this redefinition, individuals can form a sense of 'we-ness'. In emergencies, the redefinition of most situations, especially building fires, can be one where the evacuees are 'all in this together' or 'all in the same boat'—i.e., in need of protection or in search of survival. This redefinition of 'we-ness' then lends itself to the associated behavior of helping others.

Convergence Clusters (for Refuge)

The phenomenon of occupant convergence cluster formation in a fire incident was initially noticed in a study of occupant behavior in a 1979 high-rise apartment building fire [130]. Convergence clusters appear to involve the convergence of the occupants of the building in specific rooms selected as being areas of refuge, when evacuation was perceived as not possible. In the MGM Grand Hotel fire, for example, guests tended to select rooms on the north side of the east and west wings, and rooms on the east side of the south wing, due to the prevailing atmospheric conditions and the external smoke migration. In addition, guests reported that people had converged in rooms that had balconies and doors leading to the balconies because of the ease of ventilation, the reduced smoke exposure, improved visibility, and the communication advantages the balconies offered. The guests who reported their participation in convergence behavior in rooms provided either numerical estimates of the persons occupying the room or suite, or indicated only that "others" or "other persons" were present. Bryan also recorded the numbers of individuals in each convergence cluster, noting that the smallest number of people identified as a single cluster involved three persons and the largest was 35 persons.

Convergence clusters may serve as an anxiety and tension-reducing mechanism for individuals confronted with a fire incident perceived as life threatening. In addition to the detailed human behavior study of the MGM Grand Hotel fire [131], the NFPA conducted a similar questionnaire study of the guests' behavior in the Westchase Hilton Hotel fire [132] and also found the presence of convergence clusters.

Implications of Describing Behavior in Terms of the Group

The main reason for understanding group behavior, especially these three examples provided above, is because groups take time to form and move together as a unit, with decisions made according to the attributes of the group and movement speeds converging to the slowest member of the group to ensure group cohesion. People have been found to delay their own safety in order to help others. Depending upon where others are located in the building, these actions can take a significant amount of time, delaying movement to safety.

However, the previous sections on actions taken during an evacuation, action sequences, or a description of group processes do not yet tell the entire story of human behavior in fire. Not included are the *causes* of the decisions made and actions performed during fires. The studies of convergence clusters did begin to show that individuals reduce stress and anxiety in emergencies when they meet with members of their social circles; more insight is needed here. Therefore, the following section focuses specifically on the factors that affect decisions made or actions taken during a fire evacuation.

Factors that Influence Behavior in Fire

People in fires very rarely act in similar manners throughout the fire event. Instead, based on various environmental and individual factors, they internalize and process the information, and then act in kind.

Research into community disasters and building fires identifies individual and process-related factors that influence behavior [133]. There are some research that identifies the factors that influence various stages of the emergency decision-making process and others that identify factors that they claim directly influences behavior (however, it is more likely that these factors influence some stage in the decision-making process, that then influences behavior). These factors include social influence (or the influence of others in the building), stress, the built environment, leadership, and demographics (notably gender). Each factor will be described in further detail below and supported by appropriate research studies. It is important to identify these factors so that engineers can identify circumstances within fire scenarios in which certain types of behaviors (resulting in times delays) are likely to occur.

Factor 1: The Influence of Other Occupants on Behavior (Social Influence)

Research has been performed on the influence of others in the building on an individual's response to fire cues. This phenomenon is labeled here as social influence. This section will begin by describing psychological experiments performed by Latane and Darley [52] to test the influence of others on behaviors. Then, the section will describe research findings on the effect of groups (i.e., others who have formed a group tie) on the timing of actions during evacuation.

Latane and Darley [52] created an experimental situation involving college students. While the students were completing a written questionnaire, the experimenters would introduce smoke into the room through a small vent in the wall. If the subject left the room and reported the smoke, the experiment was terminated. If the subject had not reported the presence of the smoke within a 6-min interval from the time the smoke was first noticed, the experiment was considered completed. In some cases, subjects were alone in the room. In other cases, subjects were accompanied by "actors" that were told to remain in the room for as long as the subject did, no matter what. Finally, there were cases where subjects were accompanied by other subjects (or participants) who were unaware of the purpose of the experiment.

Subjects alone in the room reported the smoke in 75 % of the cases. When two "actors" were introduced in the room with each subject, only 10 % of the groups reported the smoke. When the total experimental group consisted of three unknowing subjects, one of the individuals reported the smoke in only 38 % of the groups. Of the 24 persons involved in the eight unknowing subject groups, only 1 person reported the smoke within the first 4 min of the experiment. In the situations involving subjects alone in a room, 55% of the subjects had reported the smoke within 2 min and 75 % reported smoke in 4 min.

Latane and Darley reported that noticing the smoke was apparently delayed by the presence of other persons, with the median delay of 5 s for single subjects and 20 s for both of the group conditions. These results would appear to indicate the inhibiting influences that may be imposed on individuals in public places. Latane and Darley reported the behavioral response of nine of the unknowing subjects in the ten passive research situations as follows [52]:

> The other nine stayed in the waiting room as it filled up with smoke, doggedly working on their questionnaire, and waving the fumes away from their faces. They coughed, rubbed their eyes, and opened the window but did not report the smoke.

Latane and Darley suggest that, while trying to interpret ambiguous threat cues as to whether a situation requires a unique response, the individual is influenced by the behavioral response of others who are exposed to identical cues. If these other individuals remain passive and appear to interpret the situation as a nonemergency, this inhibiting social influence may reinforce this nonemergency interpretation for an individual. This behavioral experiment may help explain the reported tendency of persons (1) to disregard initial ambiguous fire incident cues or (2) to interpret the cues as a nonemergency condition when the fire incident occurs with a social

audience of other persons, as in a restaurant, theater, or department store. This experimental study may also be helpful in understanding the incidents reported to fire departments that have been delayed by occupants for periods of minutes or even hours. In the report of the Arundel Park fire [32], several of the residents indicated that when they re-entered the hall after observing the fire from outside the building, they warned other residents and suggested they leave, but they were laughed at and the warning was disregarded.

Latane and Darley indicated that social inhibition, diffusion of responsibility, and mimicking appear to be primarily responsible for the inhibition of adaptive and assistance behavior responses by participants in emergency situations. It would appear that the inhibition of behavioral responses in the early stages of a fire incident (when the fire incident cues are relatively ambiguous) may predispose participants to a nonadaptive type of flight behavior, since the available evacuation time has been expended. In some fire incidents it appears to be difficult to get occupants of a building to evacuate because of the variables of social inhibition and diffused responsibility. The tendency to mimic the interpretation of cues and the behavior responses of others (as established by Latane and Darley) appears to be a frequent occurrence in fire incidents in restaurants, hotels, and other places of public assembly.

Similar to the studies that showed occupants were less likely to react if others were not reacting, studies have found that individuals are likely to follow others (i.e., begin their evacuation) if they witness others acting/reacting in emergencies. Occupants in the 2001 WTC disaster were likely to begin evacuation if they saw others evacuating as well, and this was especially the case if they viewed this individual (or individuals) as a credible decision-maker [30]. Even more interesting is the choice between stairs and elevators in WTC 2. As discussed earlier in this chapter, there were 16 min between the time that WTC 1 was hit and when WTC 2 was subsequently struck by the second plane. Therefore, occupants of WTC 2 who decided to evacuate before their own building was hit had access to both stairs and elevators. There were individuals in WTC 2 who decided to use the elevators for evacuation. One of the factors that influenced their decision was the presence of other individuals also using elevators for evacuation that day. In addition, similar to elevators, a stair route was not considered an option if no one was using it or if people encountered barriers, such as toxic conditions, that inhibited use.

Research has also been performed on the effect of groups on evacuation timing, or the timing to initiate evacuation behavior. First, Aguirre, Wenger and Vigo [40] performed a quantitative study of the 1993 bombing of the World Trade Center Tower 1 (the north tower). After the bombing occurred, researchers sent 690 mail surveys to management representatives to distribute to the 776 occupants selected using a stratified random sampling technique. Overall, the total sample included 415 respondents (161 from WTC 1 and 254 from WTC 2), for an overall response rate of 53.4 %. In this analysis, the dependent variable was the length of time (in minutes) that respondents took to join the evacuation, with the independent variables of interest being group size (large group of 20 or more people [1] or not [0]) and social interaction (a scale starting with: the respondent did not know anyone in group [0] and ending with the respondent knew everyone very well [11]). Results of this analysis showed that the more people whom respondents knew in their evacuating group, and the better that they knew each one, the longer it took them to initiate their evacuation. Further, respondents in large groups took 6.7 min longer to initiate their evacuation than others. Also of interest was the influence of perceived risk on time to evacuate. The study showed that people who perceived more danger tended to initiate evacuation earlier; however, the opposite was true if they were people in large groups who knew people more thoroughly. In other words, people who perceived risk, but were in larger groups of people whom they knew well, took longer to initiate evacuation. According to the researchers, this finding is

likely due to the importance of interacting within the group pro-socially; i.e., spending time trying to help friends or known others to decide to evacuate or prepare themselves before beginning evacuation movement.

Much of the focus of this chapter has been on the behavioral actions taken during evacuation, since other chapters in the handbook focus primarily on movement (e.g., Chap. 59). However, research on social influence has also found that group formation can delay the speed at which the group moves throughout the building during an emergency [122]. This finding is a direct result of the members of the group moving at the speed of the slowest member, so as to keep together during the emergency. Other movement aspects of an evacuation are outside of the scope of this chapter and more information on these can be found in Chap. 59.

Engineering Implications of Social Influence on Behavior

It is important to understand the effects of others on evacuees, especially in highly occupied buildings. In many buildings, occupants are surrounded by others, some of whom they find credible and others they may not. Social influence is especially important to remember when using current evacuation modeling or simulation tools to assess life safety of a structure. Many times, evacuation models simulate each individual (or agent) as if they are not behaviorally influenced by anyone else around them. For example, some models will randomly distribute pre-evacuation times throughout the simulated population, and, when one simulated agent in a room leaves, all other agents remain in place until their assigned pre-evacuation time has expired. This example does not represent a realistic scenario and engineers should be aware of social influence when running simulation tools.

Additionally, a proper understanding of social influence can aid engineers in developing new and more effective evacuation procedures. For example, if a building manager or engineer is aware that designated fire wardens are more likely than anyone else in the building to respond quickly during a fire evacuation, one potential evacuation scenario might be to strategically place these "quick responders" throughout the building (rather than all in one place) to promote faster response from other building occupants. This is simply one example of many for how an understanding of social influence can also help improve occupant response through smarter emergency procedure development.

Factor 2: The Influence of Stress on Behavior (Perception)

Research has also been performed to understand the effect of stress on emergency or evacuation behavior. Stress can be brought on in an emergency via several different complex conditions or states. Other than the obvious threat from physical harm due to the fire, fires can cause other conditions or states, including uncertainty/ambiguity, information overload, and time pressure. *Uncertainty* for building occupants [56, 134] can occur due to missing information, unreliable information (actual or perceived), ambiguous or conflicting information (more than one way to interpret the information) [87, 135], and/or overly complex information. *Information overload* occurs when the individual or group perceives that there is too much information to filter though in the time available, and it is posited that time pressure is necessary to produce the perception of information overload [136]. Last, with *time pressure*, occupants may perceive their situation as urgent and that they only have a limited amount of time to perform certain actions [137]. All of these conditions mentioned above can be considered as stressors for the building occupant [56, 134, 138, 139], leading the occupant to experience a physical state of stress and/or anxiety. In order for the individual to experience acute stress, some of the stressors must be present and the individual must be aware of the presence of stress, motivated to resolve the situation and uncertain of the outcome [138].

One of the main ways in which stress affects evacuation decision-making is through the narrowing of an individual's perceptive field. In this instance, stress makes it more difficult to perceive cues from the event [56, 137], and in turn, individuals may only pay attention to a select number of cues from their physical environment. Because of this, they could very well miss important pieces of information about the event which they would need to make safer or more effective decisions. Additionally, the ability to process information is skewed in three major ways under stress [140]:

- They process information at a faster rate, without carefully connecting the appropriate pieces of information together into an coherent story
- They can engage in the avoidance of optimal decision-making, i.e., making random choices
- Subjectively, the important data are chosen for consideration in the decisions

Another effect of stress on behavior and decision-making is that individuals are more likely to make choices that are less risky, thus, for example, providing additional support for the use of more familiar exits rather than unknown exits during evacuation [66].

Engineering Implications of Stress on Behavior

It is important for engineers to understand the implications of stress because this understanding can help improve the way we design buildings as well as emergency communications systems for fire safety. If individuals are more likely, in stressful situations, to pay attention to a lower number of cues, for example, engineers should design more noticeable signage or warning cues that easily grab people's attention. One example of this is providing information via luminous materials, like visual signage, that are central to people's perception field. Signage should be designed to capture people's attention and keep their attention during a building fire in as many ways as they can (see Kuligowski and Omori [83] for further information on better communication of emergency information during building emergencies).

Factor 3: The Influence of the Built Environment on Behavior

Research has also been performed on the influence of the built environment, i.e., the building, on evacuation behavior. Much of this work has been performed by Jonathan Sime, and refers back to the Affiliative Model [107] presented in an earlier section of this chapter. Similar to how individuals are likely to move toward individuals who are familiar to them before (or during) evacuation movement, people will attempt to use (or evacuate by) the exits or exits routes that are most familiar to them [107]. In general, in the Summerland fire that took place on the Isle of Man in Great Britain in 1973, Sime found that people attempted to leave via the exit route with which they were familiar; often, that was the exit that they had used to gain entry into the building. The Affiliative model also predicts that because a fire route (or exit) is not in regular use, and thus likely unfamiliar to the population, it is less likely to be used in a fire evacuation. People will prefer to use the most familiar exits, and this is exacerbated in emergencies [107].

Nilsson, building upon Sime's findings on familiarity, performed several studies on the features of exits that could increase the attractiveness of one exit over another [141]. He based his analysis of exit design on the theory of affordances [142], which states that people perceive objects in terms of what they can offer or afford. Based upon Gibson's work, Hartson [143] introduces four types of affordances and the types of activities they support:

- Sensory affordance—sensing or seeing
- Cognitive affordance—understanding
- Physical affordance—physically activity (doing or using)
- Functional affordance—fulfillment of an individual's goals

Nilsson [141] provides examples of how the theory of affordances can be used to analyze the design of an emergency exit. The first, or sensory affordance, suggests that the exit must be designed such that it is easy to sense. Nilsson provides specific examples of how to increase an

exit's sensory affordance in the following ways: clearly distinguish the door from other elements in the space (e.g., by using color or pattern) and equipping them with flashing lights, as long as sufficient contrast is provided by the environment. Cognitive affordance suggests that people understand that the exit should be used in emergencies and that it can lead them to a safer place. Examples of increasing cognitive affordance include providing an emergency exit sign above the door, placing flashing lights next to the exit sign (which would cover both sensory and cognitive affordances), and providing green flashing lights that is associative with safety or emergency exits (especially in countries where the exit signs are green). Physical affordance suggests that the user should be easily able to open and operate the door in an emergency. An example of increasing physical affordance is providing a door that is easy to open (i.e., no large force is required to open the door). Finally functional affordance suggests that the exit aids the user in obtaining their goal—to escape as quickly as possible. The difficulty, according to Nilsson, with functional affordance is that individuals during a building evacuation may have a multitude of goals; i.e., to not be the only one using an exit (for fear of looking foolish) or to avoid unpleasant environments in the building. Therefore, it is difficult to identify specific examples of increasing functional affordance in a building evacuation.

Finally, studies have shown that the individual's definition (or perception) of their environment can influence behavior during a fire evacuation. Donald and Canter's study of the King's Cross Disaster [144], where a fire began in the escalators of London, UK's King's Cross underground metro station, showed instances of the influence of place. Individuals located in the underground station were told by police officials to evacuate the underground station; however, the location to which they actually traveled depended upon their definition of the underground station. Some were unsure whether "the station" included the ticket hall area or the concourse or both, causing confusion about where they should actually travel to reach a safer location.

Engineering Implications of the Built Environment on Behavior

In all three studies, individuals' perceptions of the built environment, including familiarity, exit affordances, and the location of safety, influenced their decisions on and actions toward exit routes during the emergency event. It is important for engineers to understand the factors that influence exit choice for two reasons. First, buildings or emergency procedures can be designed to account for this type of behavior—e.g., increasing the size of the main exit for certain type of buildings. Similarly, evacuation procedures can institute a plan whereby staff members direct individuals to exits that are less familiar or are unknown to many of the population. Second, an understanding of exit choice can aid the engineer in designing more efficient emergency communication systems. This may include specifically telling certain individuals which exits to use in the building or equipping potentially unfamiliar exits with flashing lights (see Kuligowski [83] for further information on better communication of emergency information during building emergencies).

Factor 4: The Influence of Leadership (or Role) on Behavior

This section focuses on the influence of leadership (or role) on evacuation behavior. Depending upon the building, leadership may already be in place before an emergency event begins. For example, in office buildings, there usually exist individuals in management positions throughout the building. Similarly, mercantile buildings often consist of customers and employees, some of whom are in management roles. However, in emergencies, leadership has been known to emerge as well [31]. In emergent cases, the individual (or individuals) did not hold a pre-emergency leadership role, but engaged in actions (i.e., helping behavior or the provision

of instructions) that reflect a certain level of responsibility for others.

Jones and Hewitt, for example, studied group formation and leadership during the evacuation of a high-rise office building due to a fire [145]. Overall, a person's role in the organized hierarchy (pre-event leaders) had an influence on the group actions; i.e., in some cases, the leader's group listened, relinquished decision-making to this individual, and followed directions. The same type of scenarios were found in Kuligowski's study of the 2001 WTC evacuation [30] where individuals, more times than not, followed the instructions provided by their management of when and how to evacuate the towers. Jones and Hewitt did find exceptions to this trend, however, noting that when leadership failed to retain influence, new leadership emerged (i.e., even from those who were not previously in leadership roles).

Individuals also followed leadership in the King's Cross Disaster (discussed in the previous section) [144]. Individuals modified their action when they received instructions from people who appeared to hold official authoritative roles, i.e., police officers. In this disaster, even though the police did not have any additional official information and actually gave out incorrect information at times, they felt some responsibility for dealing with the situation and the public looked to them for instructions and guidance. In this particular instance, the reactions of the public to transportation staff was to ignore them, unless their instructions were backed by the police or fire department; showing that the people's confidence in the transportation staff was fairly low.

Engineering Implications of Leadership on Behavior

Leadership studies show the engineer that there are certain people in the building who are more likely than others to assume a leadership position during a fire emergency. These individuals are likely to provide suggestions on what to do, and in turn, influence others' actions. The more credible these individuals are, the more influence they will have on the rest of the population. For example, if the engineer is aware that managers are already more likely to respond and take leadership roles, another possibility is to assign fire safety leadership roles to people who are not already predisposed to help; i.e., empowering other types of occupants, in addition to managers, to enroll in key fire safety roles. Based on previous research, people with previous experiences in disasters or individuals with emergency-related occupations may already hold credibility as emergency experts with the larger population, and as an extension of this research, may be more likely to take interest in fire safety roles. Additionally, if the engineer understands that managers, for example, are already more likely to take leadership roles during a fire event, then managers should receive special fire safety training to ensure that they are providing accurate information and performing appropriate actions during building fires.

Factor 5: The Influence of Demographics (Gender) on Behavior

Demographics refer to the characteristics of a population, notably those characteristics that are genetic to the individual. Examples of genetic-based demographics are provided here: gender, age, physical fitness, physical abilities or disabilities, race, and culture. However, demographics can also include other social factors that can define or label an individual in some way, including socio-economic status, location (i.e., where s/he lives), marital status, occupation, etc. In this section, studies are presented that have been performed on one type of demographic (i.e., gender), and its effects on evacuation or emergency decision-making.

Bryan [14] and Wood [15] studied the influence of gender on certain residential evacuation behaviors. These researchers tested their respective datasets to see if gender had an influence on the first action taken, the action of fire fighting, and the act of notifying others in the building before evacuating.

First, with respect to initial actions taken, Bryan [14] studied the impact of gender. He found statistically significant differences

between males and females in the categories of "searched for fire," "called fire department," "got family," and "got extinguishers." Male participants were predominant in fire-fighting activities: 14.9 % of the males participated in the behavioral response of "searched for fire" as opposed to 6.3 % of the females, and 6.9 % of the males were involved in the action of "got extinguishers" as opposed to 2.8 % of the females. In the U.S. population, females differed significantly from the males in the warning and evacuation activities—11.4 % of the females "called fire department" as their initial behavioral response action as opposed to 6.1 % of the males. In relation to the evacuation behavior, 10.4 % of the females "left building" as the first behavioral response action, contrasted with 4.2 % of the males.

Bryan [77] stated that the cultural influence of gender on female participants is probably explicitly indicated in the concern for other family members, with the finding that 11 % of the females "got the family" as the first behavioral response, whereas only 3.4 % of the males engaged in this behavioral response. It should be noted that the male actions of "searched for fire" or "fought fire" were matched by the female actions of "called fire department" and "got family." This identical pattern of behavioral responses has also been observed in fire incidents in health care and educational occupancies. However, considering the fact that these studies took place in the late 1970s and early 1980s, additional and updated research should be performed on these gender roles to test their current applicability.

In contrast, studies have been performed on building fires where gender was not identified as a predictor of behavior. For example, Proulx et al. [146] studied the 2 Forest Laneway fire in 1995, a high-rise apartment fire that killed 6 people in Canada. Researchers inquired about behaviors by distributing behavioral surveys to survivors, and found no significant differences between the actions taken by males and females.

Horasen and Bruck performed studies of response behavior of students in secondary (junior and senior high) schools [147]. Behavioral intention questionnaires; i.e., questionnaires that ask individuals what they would do if a particular situation were to occur, were completed by 170 students across grades 7 to 12. The first section of the questionnaire contained questions on student demographics, the second section presented students with six scenarios to collect information on the most probable actions taken under the given conditions, and the third section asked about students' previous experiences with evacuation drills and actual fire incidents. Overall, the study found no significant differences in likely behavioral responses of males versus females. However, when asked about scenarios in which they would be alone and with smoke cues, females were more likely to 'leave the building immediately', whereas males were more likely to 'find an extinguisher'. Saunders [148] studied an office building fire, also using behavioral intention questionnaires and found support for gender differences with respect to evacuation actions. Females were more likely than males to report that they would investigate, warn, and evacuate in response to various types of cues. However, neither males nor females wanted to fire fight. These studies may support research showing that women have a higher perception of risk in emergencies, and therefore, are more likely to respond in emergencies.

However, there are limitations associated with the use of behavioral intention questionnaires as a means to understand future behavior. In both studies described above, participants were asked to provide insight on what they would do in a series of hypothetical situations. Here, the participant is asked to mentally picture the scenario without physically being a part of the situation. If the scenario is not described in sufficient detail to the participant of the study, he/she will likely be unable to mentally picture the scenario accurately and make estimates of potential response behavior. Also, even if extensive detail is provided on the scenario description, behavioral intention questionnaires deprive participants from experiencing, first-hand, the cues from the physical (i.e., the fire) and social environments. The inability to experience the environment in the hypothetical scenario can cause difficulty in

determining behaviors that would be performed, since it is the physical and social environments that prompt internal cognitions, decision-making and action in a fire emergency. Additionally, a participant's prediction of future behavior in a particular scenario may be influenced by previous experiences in building fires or other disasters. Thus, participants who have not experienced an actual building fire emergency may be less inclined to accurately predict response behaviors in future fire emergencies.

Engineering Implications of the Influence of Demographics (Gender) on Behavior

As mentioned earlier in this section, there are several demographic factors that could be considered as influential to behavioral actions during emergencies. Gender is simply one demographic factor that is highlighted here in this chapter. While it is important for engineers to understand that demographics can play a role in behavioral response during building fires, engineers must also understand that the relationship between demographics and behavior is complex [133]. Engineers should be aware that individual factors are more likely to be predictors of internal cognitions (such as risk perception), which then influence action, rather than direct influences of action. Rather than stating that all women warn others during fire emergencies, what is more likely to be the case is that situational or emergency-related variables, such as environmental cues and demographics, lead to risk identification and assessment, which then leads to action. Therefore, engineers should inquire how gender and other individual-based factors influence perceptions of the threat and risk, which then directly influence actions performed in response to a fire.

Summary—Behavioral Facts

A great deal of information has been provided on human behavior in fire in this chapter. Following each section, engineering implications were discussed, providing the "so what?" to readers. The engineering implications were provided after each section so that a reader might be able to see the application of these findings to actual engineering projects. In addition, examples of "behavioral facts," first introduced by Kuligowski and Gwynne [149] and extended by Gwynne [150], are listed below to summarize the major findings captured by this chapter, which link to the section in which each fact is discussed. A total of 11 behavioral facts are listed here:

Behavioral fact #1: *Rather than panic, people's first instinct is to feel (sometimes inappropriately) safe in their environment* (*Sections "Discarded Theories of Human Behavior in Fire" and "Panic Behavior"*).

Behavioral fact #2: *Just because information is provided in a fire emergency does not mean that appropriate occupant response will take place. Perception of, attention to, and comprehension of information (in a fire event) is a critical part of occupant response* (*Section "Social Psychological Theories of Human Behavior in Emergencies"*).

Behavioral fact #3: *Occupants must perceive a credible threat and personalize the risk before protective action is taken* (*Section "Social Psychological Theories of Human Behavior in Emergencies"*).

Behavioral fact #4: *People will engage in information seeking actions, especially when cues are ambiguous and/or inconsistent* (*Sections "Social Psychological Theories of Human Behavior in Emergencies"* and *"Relating Theory to Practice—Protective Actions in Fires"*).

Behavioral fact #5: *People are likely to engage in preparation activities before beginning evacuation response. Preparation activities will likely delay their response* (*Section "Relating Theory to Practice—Protective Actions in Fires"*).

Behavioral fact #6: *Generally, people act rationally and altruistically during building fires* (*Section "Relating Theory to Practice—Group Behavior"*).

Behavioral fact #7: *The surrounding population will influence the individual's decision-making process* (*Section "Factor 1: The Influence of Other Occupants on Behavior [Social Influence]"*).

Behavioral fact#8: *Stress can narrow a person's field of perception, causing individuals to miss or ignore certain cues or information* (*Section "Factor 2: The Influence of Stress on Behavior [Perception]*)".

Behavioral fact #9: *People move to the familiar. The relationships with the structure and people that existed prior to the incident influence response during the incident* (*Sections "Relating Theory to Practice—Group Behavior"* and *"Factor 3: The Influence of the Built Environment on Behavior"*).

Behavioral fact #10: *People do not instantaneously switch to a different set of roles in a building fire event. The rules and roles prior to the event form the basis of those employed during the event* (*Section "Factor 4: The Influence of Leadership [or Role] on Behavior"*).

Behavioral fact#11: *People are heterogeneous and these individual differences in characteristics* (*or demographics*) *can influence behavior* (*Section "Factor 5: The Influence of Demographics [Gender] on Behavior"*).

What Is Missing in Human Behavior in Fires?

This chapter first presented an overarching theory of human behavior in disasters; i.e., the period of time in which individuals make decisions on whether protective action is necessary and then which actions they will take in response to the threat (the PADM). However, this theory is more general in nature and does not actually identify the factors that would predict the performance of particular actions, such as helping others or taking a particular route in the building. Next, this chapter presented studies from the field of human behavior in fire to support the larger, general theory. These studies identified the actions that people take in response to fires, the approximate timing of action types, as well as began to identify the factors that influenced these types of actions. Most studies focused on the pre-evacuation period of a building fire.

What is missing in the field of human behavior in fires is a comprehensive theory that brings all of the theory and data from studies together to predict, rather than to simply determine based upon user input, human behavior during evacuations. With a larger comprehensive theory, engineers could perform more accurate calculations for performance-based design (i.e., see Chaps. 57, 59, and 60) and model developers could create more accurate evacuation models that rely less on user input and more on fundamental theory (see Gwynne [150]).

One step in the process of reaching this comprehensive theory is to develop models that can predict *the actions that people take in response to fires*—both before they decide to evacuate (pre-evacuation) and during the evacuation (or movement) time period. Canter, Breaux and Sime's [78] decomposition diagrams begin to tie various sub-theories together, but focus primarily on the linking of evacuation actions together, and often neglect to identify the interpretations and levels of risk perception that are influential to occupant's actions.

One example is provided here of a qualitative model that predicts the pre-evacuation actions of survivors of the 2001 World Trade Center (WTC) Disaster [30, 151]. Through analyses of transcripts from 245 face-to-face interviews with survivors from both WTC towers, collected by Project HEED [22], this model is the first inductively-developed, individually- (or -evacuee-) based model explaining the actions taken during the pre-evacuation period of a building fire/evacuation event. The goal of this research was to describe evacuation decision processes in greater detail than either research on building fires or studies on community-wide evacuation, focusing on how people perceive and interpret environmental cues and warnings, how they seek confirmation during sensemaking and milling processes, and what they do before moving to safety.

There are five main findings that can be highlighted from this research. The findings are as follows:

- The WTC pre-evacuation period was divided into two main phases: the milling/sensemaking phase and the protective action phase. In the milling/sensemaking phase, WTC occupants engaged in two different actions—continuing to work or seeking additional information. In the protective actions phase, on the other hand, occupants engaged in actions that were focused specifically on protecting themselves or others (i.e., helping others, preparing to evacuate, or defending in place). Both phases took place before moving to the stairs or elevators.
- Risk perception, or the feeling of personal danger, was the main predictor of when individuals decided to evacuate—i.e., the transition from the milling/sensemaking phase to the protective action phase. Both individual and environmental factors were identified as influential of risk perception development.
- Some individuals made their decisions to evacuate before others on their floor. These "early responders", as labeled by Kuligowski [30], were primarily higher-level managers, fire wardens, military personnel, or individuals with experiences or occupations in emergency situations. These individuals still required the receipt of information that increased their level of perceived risk, but were also more inclined to act first (before others) because they felt responsibility for others and/or had previously experienced/witnessed negative consequences associated with fire or building evacuations.
- Certain factors, such as personal responsibility, social connections, and the actions of others, influenced which protective actions people engaged.

See Kuligowski [30] for further explanation on the conceptual model.

Kuligowski's model is not without limitations, however. The model focuses specifically on the pre-evacuation period of one building event. Additionally, the model does not incorporate any decisions or actions of the decedents. While the findings in the model were verified with theory from other events, the factors that influenced each action performed were specific to an office building fire and subsequent evacuation, thus making it difficult to generalize the findings. This is a first start to developing a model to predict actions taken during building fires; however, this effort should be expanded upon to include findings from analysis of other building fires, including fires in different types of structures and with different populations, as well as from analysis of other types of disasters, not limited to building fires.

An additional step in the process of reaching this comprehensive theory is to develop models that can predict *the timing associated with the performance of certain actions*—both before they decide to take protection (e.g., evacuate) and during the evacuation (or movement) time period. First, there are a few studies that attempt to predict how long people delay before evacuating [1, 40, 84, 152] as well as the time it takes individuals to evacuate via stairs [1]. For example, NIST's federal investigation of the 2001 WTC disaster performed multiple regression analysis to predict pre-evacuation delay and normalized stairwell evacuation time—identifying factors such as action type, floor number, the number of environmental cues and level of perceived risk as predictors of pre-evacuation delay time and factors such as the presence of counterflow, the presence of crowding, the number of environmental cues, floor number, pre-evacuation delay, and evacuation interruption as predictors of normalized stairwell evacuation time [1].

Other research efforts have attempted to quantify human behavior in the form of an empirical model. One such model was developed by NIST [153] based upon the WTC conceptual model [30], presented earlier in this section. A first-order quantitative model, labeled as the Evacuation Decision Model (EDM), was developed to predict the time when a simulated occupant, or agent, decides to evacuate (i.e., the decision that protective action is necessary). In the EDM, the prediction of the evacuation decision is based upon the agent's perceptions of risk during the

pre-evacuation period. In its simplicity, the EDM model attempts only to simulate the evacuation decision, without additional simulation of protective action behaviors.

At present, these qualitative and quantitative models scratch only the surface of the development of a larger, comprehensive model of human behavior in fire. These models provide a path forward on the methods that could be used in its eventual development. However, there is much work still to be done to improve our understanding of human behavior in fire, and without this understanding, a comprehensive model is near impossible. Listed here are just a few examples of areas in the field that require further study:

- The influence of fire's toxic products and heat on decision-making and behavior (before incapacitation or death occur) in a building fire
- An identification of all of the factors that influence risk perception and how they interact to increase or decrease risk perception levels.
- The types of protective actions that are performed in building fire evacuations
- The factors that influence the various types of protective actions performed in building fire evacuations
- The factors that influence the receipt of cues, the ways in which people pay attention to cues, and the comprehension of cues
- The ways in which individual factors, such as gender, disability, age, body size, culture, marital status, past experiences, training and social role, influence decision-making during building fires
- The timing associated with the performance of behavior during building fires, and the factors that influence this timing
- The influence of urgency or other types of dissemination techniques on the response of building occupants during fires
- The influence of group dynamics on individual decision-making and group decision-making during fires
- The role of place (including building type or building characteristics) on decision-making during fires
- The role of psychological states, including stress or anxiety, on decision-making during building fires.

For the field to reach its goal and develop a larger understanding of human behavior in fire, accurate, rigorous, and comprehensive research must continue. There is still much left to understand, but the ultimate goal of a comprehensive model is in our future.

Chapter Summary

Human behavior in fire is a key aspect of understanding and designing for life safety in building fires. However, the treatment of human behavior in performance-based design analyses often times falls short by ignoring, oversimplifying, or inaccurately accounting for it. Relationships in human response are complex; though, these relationships are not impossible to describe or even predict. The chapter began with a description of three disaster myths, which, if accurate, would make it easier for the field to surrender and admit defeat against the task of predicting human behavior in fire. However, the occurrence of panic, disaster shock, and group mind are rare in fire emergencies; and with this realization, comes an understanding that real patterns of behavior should be identified when studying human response to fires. These patterns are clearly displayed in the PADM, also introduced in this chapter, which describes the process by which individuals make decisions and respond to disaster situations. Patterns are also identified by the studies weaved throughout this chapter—identifying the role of group dynamics, social influence, stress, the built environment, leadership/status, and demographics on behaviors performed by occupants in response to a fire emergency.

Following each section, the author presented the "so what?" or the "who cares?" to the reader. The purpose here was to make clear why this information is important and what influence these various aspects of human behavior in fire have on life safety and building design. All of the information presented in this chapter should be

considered by an engineer performing a life safety analysis and/or developing evacuation procedures for building occupants in fire emergencies. In some cases, data are available that makes this consideration easier, and in other cases, the engineer must use appropriate and technically-sound judgment and decision-making.

The fire field recognizes the need for a comprehensive theory of human behavior in fire, and researchers around the world are working on various aspects of the problem to make this a reality. This theory would then be incorporated into standard engineering tools, so that human behavior in fire can no longer be ignored or discounted in performance-based analyses. Until this occurs, the onus is placed upon engineers and review authorities to ensure that building occupants are accounted for and protected. It is the hope that the results of performance-based analyses are significantly enhanced by the information included in this chapter as well as the suite of egress-related chapters available in this edition of the handbook: design strategies (Chap. 61), egress data (Chap. 64), the design of egress scenarios (Chap. 57), hydraulic modeling (Chap. 59), evacuation modeling (Chap. 60), toxicity (Chaps. 63 and 62), and smoke effects (Chap. 61).

Acknowledgements This chapter is dedicated to the late Dr. John L. Bryan (Prof), who authored this chapter in the previous four editions of the handbook. Dr. Bryan provided mentorship and guidance to so many in the field, including the author of this chapter. He is deeply missed. Dr. Kuligowski would like to thank all of the reviewers of this handbook chapter, including Paul Reneke, Jason Averill, Thomas Cleary, Anthony Hamins, Howard Harary, and Steven Gwynne, all of whom provided insightful comments. Also, special thanks to Elizabeth Landry for help with chapter editing and formatting.

Erica D. Kuligowski is a Fire Protection Engineer and Sociologist in the Engineering Laboratory at the National Institute of Standards and Technology. Her major research interest is human behavior in fires and other emergencies, including preparedness, response and recovery decision-making and behavior. The chapter represents research performed by Dr. Kuligowski both as part of her official duties at the National Institute of Standards and Technology and as part of her doctoral research at the University of Colorado at Boulder, under Dr. Kathleen Tierney.

Employing the Hydraulic Model in Assessing Emergency Movement

59

Steven M.V. Gwynne and Eric R. Rosenbaum

Introduction

This chapter provides the engineer with a model to quantify egress performance. This model is formed from a set of numerical tools that vary in their scope and sophistication. Guidance is provided on the capabilities of these tools and on when they should be employed, making reference to the data on which these tools are based. Detailed examples are presented to clarify the application of these tools, along with a description of how the use of these tools fits in with other fire engineering calculations. This chapter will, therefore, allow the engineer to assess egress performance in a responsible and informed manner.

Prediction of evacuee movement is an essential component of performance-based fire safety analysis. Safe egress from fire is assumed to be achieved if the required safe egress time (RSET) is sufficiently shorter than the available safe egress time (ASET), where ASET is defined as the time until fire-induced conditions within a building become untenable. Methods to evaluate the development of fire-induced conditions and tenability criteria are addressed elsewhere in this handbook.

The model discussed in this chapter provides the engineer with a means to establish RSET (i.e., the time taken to reach safety) and therefore complete this component of a performance-based assessment. This model, albeit imperfect, quantifies the egress performance of a design and, importantly, enables comparisons to be made between different design variants to be made.

The hydraulic model is presented as a means of quantifying egress performance that can support an engineering approach and expert analysis. Hydraulic models are based on a simplification of egress behavior where the evacuating population is described by a set of equations. This population moves from egress component to egress component (e.g., from a corridor to a stairwell), with the speed of their movement dictated by the equations that form the model. Guidance is provided on how best to employ these equations, on the scenarios to which this model can be applied, and on the limitations of the approach.

The inherent structure of the hydraulic model described in this chapter tends to an optimistic estimate of evacuation time. It assumes that the exit paths will be continually used at maximum capacity from the moment of alarm to total evacuation. The model should be considered as a baseline calculation to be extended as appropriate to account for delays caused by human decisions, notifications, and other factors (see Chaps. 58 and 64).

For each evacuee the RSET can be subdivided into a number of discrete time intervals, the sum of which constitute the total RSET:

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_59, © Society of Fire Protection Engineers 2016

$$\text{RSET} = t_d + t_n + t_{p-e} + t_e \quad (59.1)$$

where

t_d = Time from fire ignition to detection; that is, the detection phase

t_n = Time from detection to notification of occupants of a fire emergency; that is, the notification phase

t_{p-e} = Time from notification (or cue reception) until evacuation commences; that is, the pre-evacuation phase

t_e = Time from the start of purposive evacuation movement until safety is reached; that is, the evacuation phase

The components described are considered the core elements of egress analysis (see Chap. 64 for further discussion), although it is recognized that other components will certainly contribute to evacuee performance (e.g. the Pre-Warning delay incurred through staff actions and their decision-making which may prolong notification of the general population).

The RSET elements t_d and t_n typically involve a technical solution and human interaction, including fire detection devices and fire alarm equipment, and also human intervention, such as the discovery of a fire by a staff member and notification of the population. The theory and design of detection systems are covered elsewhere in this handbook (see Chap. 40).

The element t_{p-e} relates to the individual and collective responses of the occupants; that is, the time between them being notified of the incident and the time to commence their evacuation. This can be prolonged by a number of complex activities (see Chaps. 58 and 64). These include receiving a cue; interpreting the cue; validating the cue; performing pre-evacuation activities; and determining an appropriate response (see Chap. 58). All of these contribute to the time spent in the pre-evacuation phase, prior to commencing purposive evacuation movement to a place of safety.

The element t_e is the time from when an individual initiates evacuation movement up to the point that he or she reaches safety. For an individual evacuee, t_{p-e} and t_e are basically sequential. Crudely speaking, it is typically assumed that for an individual evacuee, t_{p-e} and t_e are basically sequential. There is a period before the individual has determined that an evacuation response is required (through the perception of sufficient risk levels and the subsequent completion of preparatory actions) and a period where this response is conducted (i.e. where protective actions are taken). That is not to say that the individual need be static in either time period or that the performance of actions are not iterative or cyclical—only that at a certain point in time, the individual decides that the situation requires them to take protective actions and their subsequent actions broadly reflect an attempt to disengage from the current actions and take protective actions.

However, across a population, t_{p-e} and t_e are neither independent of each other nor mutually exclusive [1]. There may be significant overlap between these components given the varying conditions evident at different locations within the structure, the different levels of information available, and the differences in the abilities of the population [2].

RSET can be reduced into two sets of components: the phase prior to evacuee involvement, made up of t_d and t_n, and the escape phase (t_{esc}) where

$$t_{\text{esc}} = t_{p-e} + t_e \quad (59.2)$$

It should be noted that, in reality, the evacuation phase can be interrupted through behavioral actions and developments in the incident scenario [3].

This chapter describes the basic hydraulic model enabling t_e to be calculated. It also describes the extension of the hydraulic model to also include t_{p-e} in the calculation and therefore allow an estimation of t_{esc} to be produced. A methodology is presented to enable the engineer to determine the RSET value as part of a performance-based assessment. It provides sufficient information for the engineer to calculate RSET under a number of different incident scenarios, while also making the engineer aware of the limitations and assumptions of the hydraulic model (Fig. 59.1).

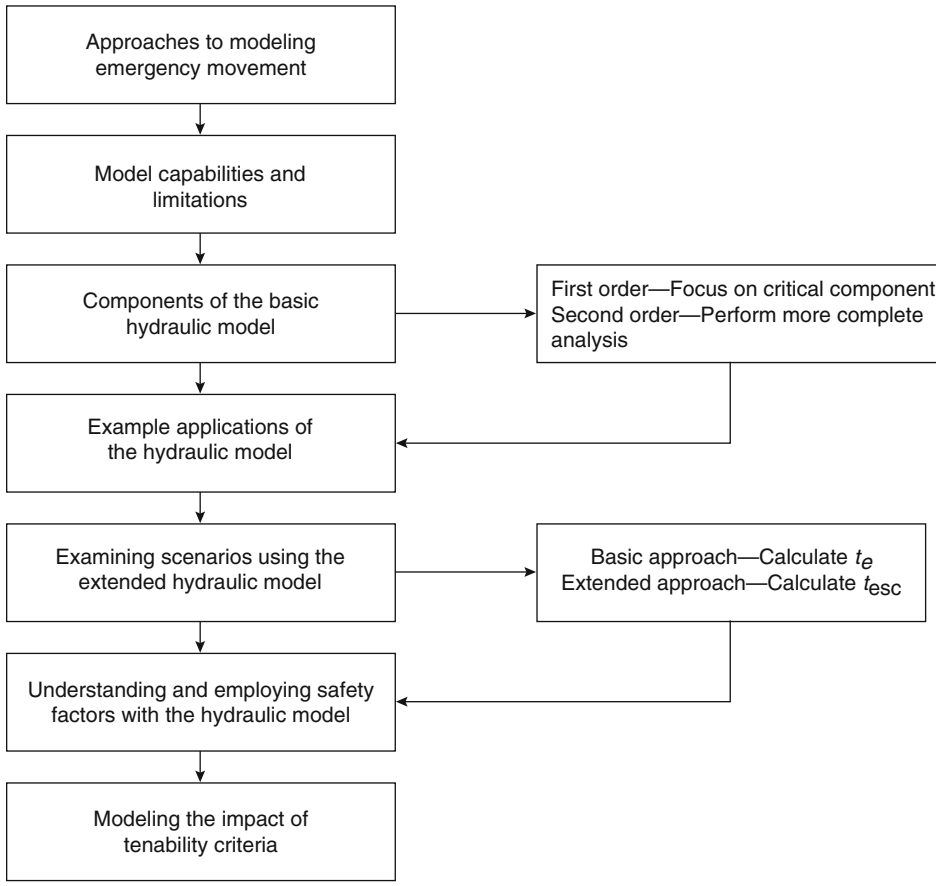

Fig. 59.1 Structure of this chapter

Establishing Egress Performance

Over the last few decades an increasing effort has been made into investigating human behavior in response to fire. This research has provided a clearer understanding of egress behavior and the factors that influence egress performance. As a consequence, human behavior can be taken into consideration when designing emergency procedures and modeling human performance. Prior to this time, human behavior was disregarded altogether, seen as immeasurable, and/or drastically simplified according to a few basic assumptions. The former understanding of human behavior was based on a number of assumptions: people's behavior would likely be panic based [4]; it would likely be selfish and competitive; and it would involve immediate and direct movement once the incident was discovered. Although some of these assumptions are contradictory, they have had a direct impact on the engineering calculations made for a long period of time and continue to exert some degree of influence on egress design decisions to this day [3].

In recent times, a more detailed and comprehensive understanding of human behavior in fire has been established (see Chaps. 58 and 64). This understanding has been derived from the examination of actual incidents, the collection of empirical evidence, and the development of behavioral theories. All of this has, to a large degree, refuted the assumptions that had previously dominated. This realization has allowed engineers (as well as behavioral researchers,

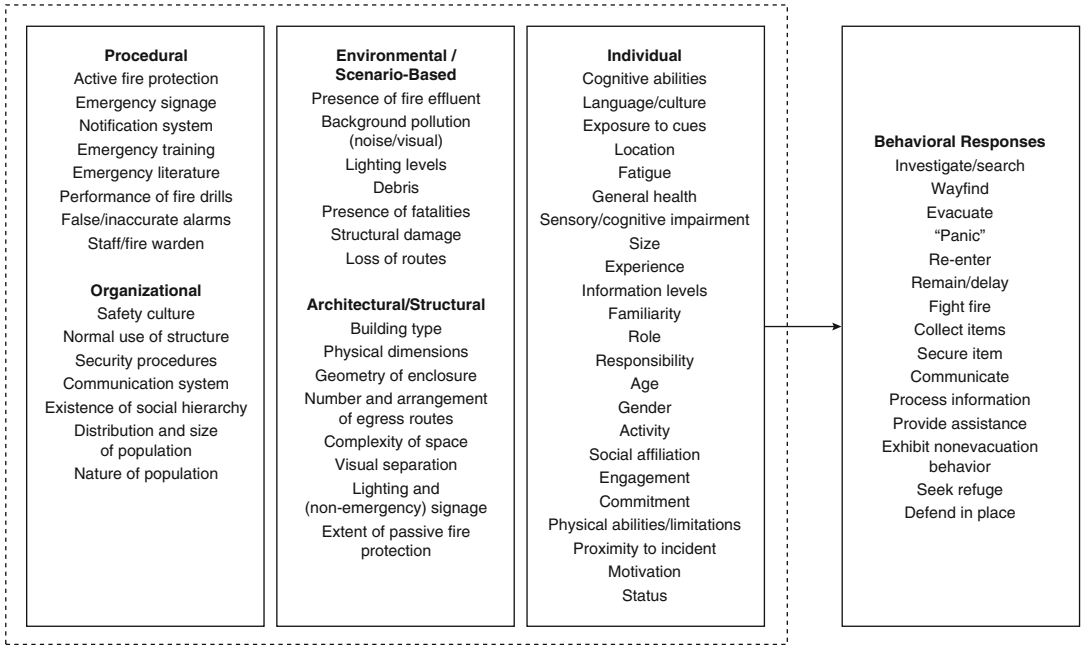

Fig. 59.2 Factors that can influence egress performance

procedural designers, and evacuation modelers) to take human behavior into account, albeit imperfectly, when trying to establish evacuation performance.

It is now felt that the evacuation process is not simply a matter of initiating an evacuation and then controlling the ensuing hysterical crowd response; instead, it is now viewed as a more multifaceted event in which people's responses are sensitive to the incident scenario, the information available, and the local conditions (among other things). The problem of understanding human behavior in fire is not the simple process previously assumed. Instead, it relies on a number of factors that can interact and can influence the outcome in different ways (Fig. 59.2). These factors also influence the engineering methods required to assess performance. Ideally these factors should be considered in any assessment of egress performance; however, the methods employed in this assessment are limited and, to different degrees, exclude many of the key factors influencing egress performance. It is critical that these limitations are understood by an engineer prior to the application of such methods.

Models

Several approaches are available to the engineer to establish egress performance; that is, estimate t_{esc}. Each of these approaches requires the application of a model: a simplified version of reality used as an indicator of actual egress performance. All of these approaches are limited. One or more of the following four model approaches are usually applied:

- *Model Approach A*: *The application of prescriptive codes*. The expertise embedded within the regulations is assumed to satisfactorily represent (or at least account for) the performance of the evacuating population. Generally, these codes focus on the physical constraints imposed by the structure and exclude behavioral and procedural factors.
- *Model Approach B*: *The performance of an egress trial*. An (un)announced trial is

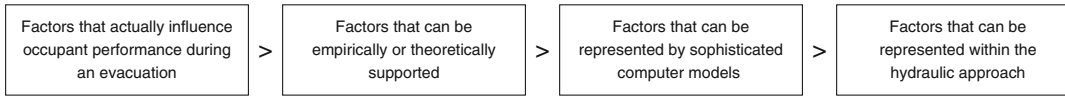

Fig. 59.3 Difference between the actual and modeled evacuation

conducted in order to assess the outcome of a simulated incident using the population of interest. This approach has a number of limitations: it is expensive; there are ethical issues in achieving realism in such an event; the trial produces only a single data point; and the structure has to be in place already [5].

- *Model Approach C*: *The application of a* (*computer-based*) *simulation model*. An attempt is made to incorporate our understanding of human behavior in fire within a computer-based model. This is then applied to a representative set of scenarios in order to establish egress performance. The quality of the results is highly dependent on a number of factors: the sophistication and validity of the model used, the expertise of the user, and the scenarios examined and their appropriateness [6].
- *Model Approach D*: *The application of an engineering calculation*. Here, empirical data are distilled into a representative set of equations. These equations are deemed to represent a simplified version of evacuation movement (instead of behavior), where the results are largely determined by the physical attributes of the components involved; for example, the people, the structure, and so on. As such, they largely overlook many of the complexities apparent in the human response to fire. These calculations can be applied at the level of the structure (see Chap. 64) or the level of the structural component. For instance, details of the structure can be included in an equation that generates an overall egress time; for example, the number of floors, the population size, and the egress width available.

  Alternatively, the attributes of a particular structural component (e.g., staircase, section of corridor, etc.) can be used. These describe the performance of the population when traversing the component in question. These results are then pieced together to form a network representation of a structure to describe the performance of the population when traversing an egress route.

In reality, none of these approaches include all of the factors that influence the outcome of an evacuation; that is, they represent only a subset of those factors mentioned in Fig. 59.2. Indeed, given the relatively immature state of the study of human behavior in fire, it would be not be possible for the models to include all of the factors affecting egress. It is vital to understand the limitations of these models in order to more reliably interpret and assess the results produced. There is a difference between the number of factors that actually affect an evacuation and the number that can be modeled. The gap between this prediction and reality is outlined in Fig. 59.3. The hydraulic model discussed here is an engineering calculation, that is, model approach D.

Model Limitations

Many factors influence the outcome of an evacuation; models have the potential to incorporate a subset of these factors. This potential influence is based on the assumption that (1) sufficient theoretical support exists (i.e., that the factors have been identified and formalized); (2) there are data that can be incorporated into the model (i.e., that the factors can be quantified in some way); and (3) there are no limitations in the technology used to apply the model (e.g., hardware or software).

The hydraulic model is limited in the factors it can represent. Several aspects of the model should be noted:

- Behaviors that detract from movement are not explicitly considered.
- The numbers of people in a structural component are considered rather than their identity and their individual attributes.
- Movement between egress components is considered (e.g., from room to room), rather than within them.
- The results are deterministic and will therefore remain the same unless changes are made to the scenario or the assumptions employed.

The expert user can, to some degree, compensate for these limitations, but these limitations are inherent in the hydraulic model. Therefore, given the nature of the hydraulic model, it is able to represent only a small subset of behavioral factors (primarily related to those that influence movement).

Some time has been spent outlining the limitations of the hydraulic model along with the other modeling approaches available. As with any model, it is critical that the engineer is aware of these limitations prior to its use. When the hydraulic (or any other) model is employed, a brief description of these limitations should be presented along with the results produced and the conclusions drawn. However, despite these limitations, it is possible to employ the hydraulic model to establish egress performance in a consistent and informative manner. A hydraulic model can assess t_e by quantifying egress performance, and therefore provide insight into the effectiveness of a design. In a similar manner, the extended version of the model, described later in this chapter, is able to estimate t_{esc}.

In many cases, the hydraulic model is an acceptable method to model egress. Examples include where only a general estimate of egress time is required and where the hydraulic model is the most sophisticated model available to the engineer: the prescriptive codes may be too restrictive and not allow dedicated data to be incorporated; the resources available may not extend to the use of a complex simulation model; and egress trials may be precluded as the structure may not yet have been built. Where these other models are available, the engineer may want to apply several simultaneously (e.g., the hydraulic model and a computer simulation model) in order to have a stronger basis for the results [1]. Care should be shown in the application of the hydraulic model and the presentation of the results produced. With responsible use, it is able to produce reasonable results in many situations. In some situations a more sophisticated model should, ideally, be employed; for example, where complicated procedures are in place, where complex flows are expected, and where the population is heterogeneous (see Chap. 60).

In the next sections the use of the basic hydraulic model to estimate t_e (the evacuation time) is discussed. The empirical evidence supporting the hydraulic model is outlined, and the calculations involved are described. Two different versions of the basic hydraulic model are described: a simplified approach (first order) and the full approach (second order). Both act at the level of the structural component but do so to different degrees of computational rigor. The engineer must select one of these versions based on the project, his or her expertise, and the time available. Several examples are provided demonstrating how the hydraulic model can be applied. Finally, guidance is provided on how these calculations can be employed and, by extending the model, the types of scenarios that should be examined. An engineer should consider all of these issues when determining t_e (and then eventually t_{esc}).

Estimating t_e Using the Basic Hydraulic Model

This section describes the fundamental components of egress movement that form the basic elements of the hydraulic model; that is, the equations used in calculating the t_e component in Equation 59.1.

Research-based engineering calculations for predicting emergency population flow have emerged over the past few decades. The major contributors include Predtechenskii and

Milinskii [7], Fruin [8], and Pauls [9, 10]. A number of other contributions have been made to the field in recent years; [11–25] however, the methods presented here (originally developed by Nelson and MacLennan [26]) were based primarily on the major contributors highlighted above. A more complete list of the research performed relating to human behavior and movement is presented in Chaps. 58 and 64, as well as elsewhere [4, 27–37].

It should be noted that at the time of writing there is some discussion regarding the validity of several of the data-sets on which these models are based. This has led to data-sets being withdrawn from the SFPE handbook and from other publications (see Chap. 64). However, their contribution to the model described here is not removed given that the data-sets are broadly comparable, that they form a core component to the original model derived by Nelson et al. [26], that they have not yet been proven invalid (in an available, peer-reviewed publication), and that, perhaps more importantly, there is a lack of other equivalently comprehensive data-sets available.

As mentioned, the sources included here are, in most cases, compatible and supportive of each other. All are based on the relationship between the speed of movement and population density of the evacuating population stream. The equations derived from these sources are based on the following assumptions:

1. All persons start to evacuate at the same time.
2. Occupant flow does not involve interruptions caused by evacuee decisions.
3. The evacuees are free of impairments/disabilities that impede their movement.

Given the discussion presented in Chaps. 58 and 64 and from Fig. 59.2, these assumptions exclude a number of factors and behaviors that might detract from egress performance. These assumptions also have the effect of separating the egress components (presented in Equation 59.1) into distinct activities that are then treated separately during the calculations; in reality, these components would be coupled.

When representing an actual event, Equation 59.1 can be rewritten as

$$\mathrm{RSET} = t_d + t_n + t_{p-e} + (t_{\mathrm{trav}} + t_{\mathrm{flow}} + t_{n-e}) \tag{59.3}$$

where t_e is broken down in three constituent parts: t_{trav} is the time spent moving toward a place of safety, t_{flow} is the time spent in congestion controlled by flow characteristics, and t_{n-e} is the time spent in nonevacuation activities that do not directly contribute to the population moving to a place of safety. Even this equation is a simplification, although it does demonstrate that in the evacuation phase there is likely to be an amount of time spent in activities other than moving directly to an exit. Given the assumptions associated with hydraulic models, the RSET calculation using the basic hydraulic model produces the following equation:

$$\mathrm{RSET} = t_d + t_n + t_{p-e} + (t_{\mathrm{trav}} + t_{\mathrm{flow}}) \tag{59.4}$$

The behaviors that do not directly contribute to the evacuation are not modeled (t_{n-e}). Calculations based on these assumptions require compensatory actions in order to account for the factors not included. These actions are discussed later in this chapter.

Fundamental Movement Calculations

The modeled evacuation time (i.e., the time predicted by the hydraulic model) utilizes a series of expressions that relate data acquired from tests and observations to a hydraulic model of human flow. These primarily relate to the following considerations: effective width, population density, speed, flow characteristics, time for passage through a component, and transitions between components. Each of these considerations is discussed in detail by Proulx [38]. By taking these considerations into account, egress movement can be quantified using the hydraulic model. Figure 59.4, shows a typical relationship between the source data and the derived equation. Although the expressions indicate absolute relationships, there is considerable

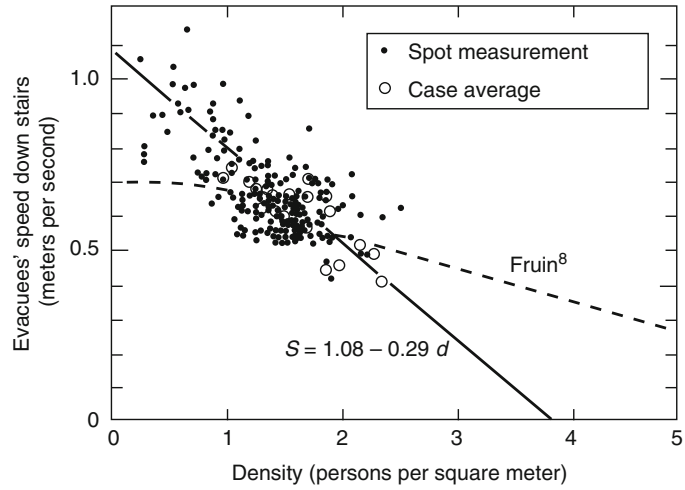

Fig. 59.4 Relation between speed and density on stairs in uncontrolled total evacuations (Dashed line from Fruin [8])

variability in the data. The engineer may wish to take this into account during the calculation process.

The equations and relationships presented in the following paragraphs can be used independently or collected together to solve more complex egress problems. Several examples outlining the use of these equations are presented later in this chapter.

Effective width, W_e The effective width is the usable width of the component, or W_e. Persons moving through the exit routes of a building maintain a boundary layer clearance (i.e., maintain a distance between themselves and the object in question) from walls and other stationary obstacles they pass (see Fruin [8], Pauls [9, 10], and Habicht and Braaksma [39]). This clearance is needed to accommodate lateral body sway and assure balance. Personal preference dictates that people attempt to maintain space around themselves assuming that the population density is sufficiently low.

Discussion of this crowd movement phenomenon is found in the works of Pauls [9, 10], Fruin [8], and Habicht and Braaksma [39]. The useful (effective) width of an exit path is the clear width of the path less the width of the boundary layers. Figures 59.5 and 59.6 depict effective width and boundary layers. Table 59.1 is a listing of boundary layer widths. The effective width of any portion of an exit route is the clear width of that portion of an exit route less the sum of the boundary layers. Clear width is measured

1. From wall to wall in corridors or hallways
2. As the width of the treads in stairways
3. As the actual passage width of a door in its open position
4. As the space between the seats along the aisles of assembly arrangement
5. As the space between the most intruding portions of the seats (when unoccupied) in a row of seats in an assembly arrangement

The intrusion of handrails is considered by comparing the effective width without the handrails and the effective width using a clear width from the centerline of the handrail. The smaller of the two effective widths then applies. Using the values in Table 59.1, only handrails that protrude more than 2.5 in. need be considered; that is, if the handrail protrudes less than 2.5 in. into the stair width, then the overall calculated width will still be less than the 6 in. reduction produced by the stairwell. Minor midbody height or lower intrusions such as panic hardware are treated in the same manner as handrails.

Population Density, D Population density, D, is the measurement of the degree of crowdedness in an evacuation route. The calculations in this

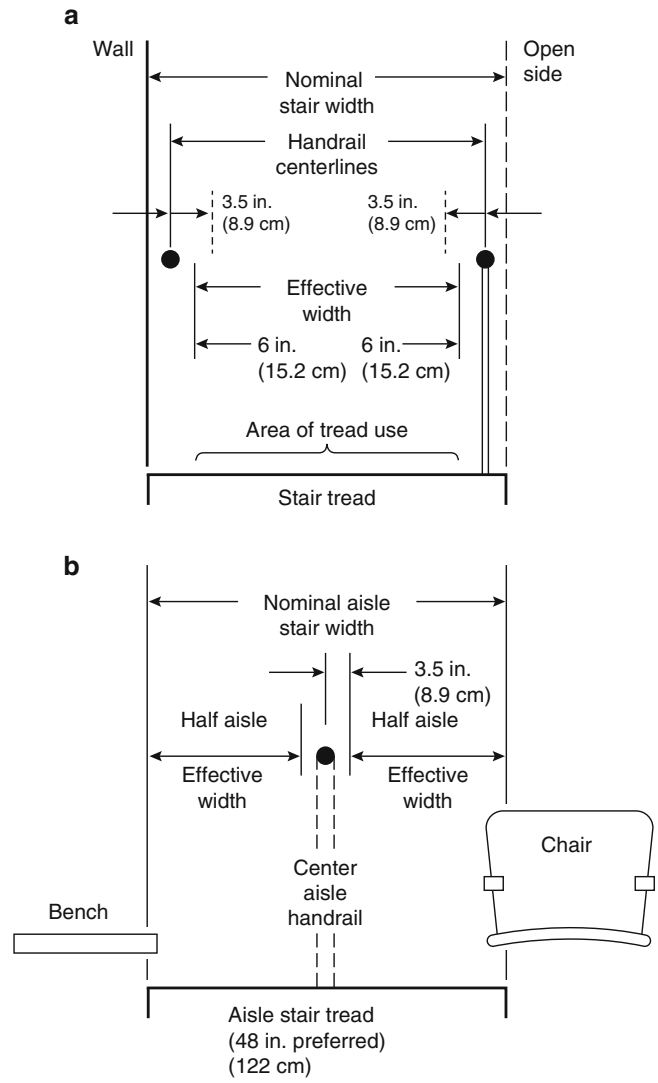

Fig. 59.5 Measurements of effective width of stairs in relation to walls, handrails, and seating

chapter are based on population density expressed in persons per square foot (or persons per square meter). It should be noted that researchers employ several different units when describing population density. These units include the number of people per unit of space, the space available per person, and the proportion of floor space occupied [7]. In reality, the population density will be dependent on the size of the individuals present. These sizes may vary greatly. Here, the sizes are assumed to be uniform or averaged across the population.

Unless specifically stated, the entire population of the first egress component (i.e., the component from which the egress movement starts) is included in any flow calculation. This will demonstrate the capacity limits of the route element. If the evacuating population is widely dispersed within an egress component (i.e., it would take them significantly different times to reach connected egress components), the calculation is based on an appropriate time step that reflects the time of their arrival. At each time increment, the population density of the exit route is based on

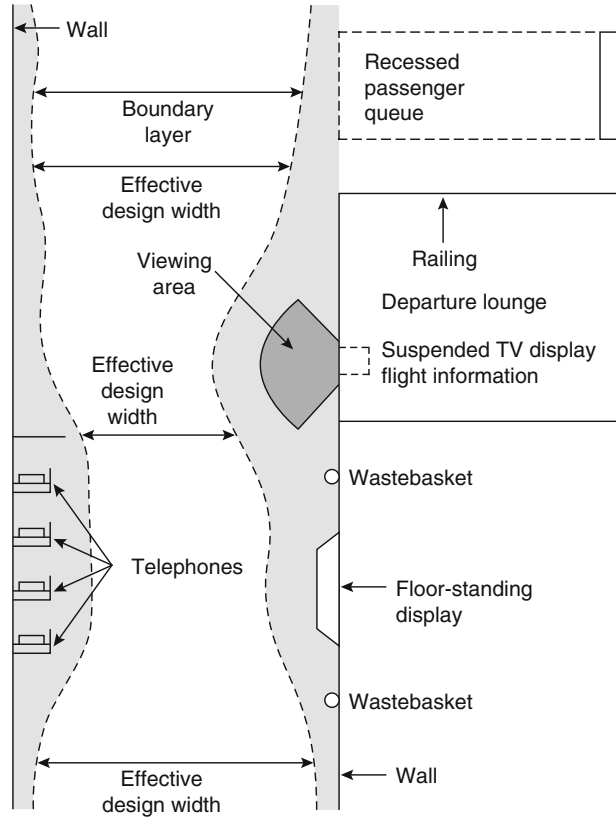

Fig. 59.6 Public corridor effective width

Table 59.1 Boundary layer widths

Exit route element	Boundary layer (in.)	(cm)
Stairways—wall or side of tread	6	15
Railings, handrails[a]	3.5	9
Theater chairs, stadium benches	0	0
Corridor, ramp walls	8	20
Obstacles	4	10
Wide concourses, passageways	<18	46
Door, archways	6	15

[a]Where handrails are present, use the value if it results in a lesser effective width

those that have entered the route minus those that have passed from it. In such situations the engineer may wish to separate the components into subcomponents; for example, a corridor could be broken into several components reflecting the different performances of the population. In this case, the density calculations would then be based on the entire population of each of the new components.

The population density factors in subsequent portions of the egress system are determined by calculation. The calculation methods involved are contained in the section of this chapter titled "Transitions."

Speed, *S* Speed is defined as the movement velocity of exiting individuals, or *S*. Observations and experiments have shown that the speed of a group or an individual in a group is a function of the population density. The relationships presented in this chapter have been derived from the work of Fruin [8], Pauls [9, 10], and Predtechenskii and Milinskii [7]. If the population density is less than approximately 0.05 persons/ft^2 (0.54 persons/m^2) of exit route, individuals will move at their own pace, independent of the speed of others. If the population density exceeds about 0.35 persons/ft^2 (3.8 persons/m^2), it is assumed that no movement will take place until enough of the crowd has passed from the crowded area to reduce the

population density. Between the population density limits of 0.05 and 0.35 persons/ft^2 (0.54 and 3.8 persons/m^2), the relationship between speed and population density is assumed to be represented by a linear function. The equation of this function is

$$S = \mathrm{k} - \mathrm{ak}D \tag{59.5}$$

where
S = Speed along the line of travel
D = Population density in persons per unit area
k = Constant, as shown in Table 59.2
= k_1; and a = 2.86 for speed in ft/min and density in persons/ft^2
= k_2; and a = 0.266 for speed in m/s and density in persons/m^2

Table 59.2 Constants for Equation 59.5, evacuation speed

6.5	12	229	1.16
6.5	13	242	1.23

1 in. = 25.4 mm

Figure 59.7 is a graphic representation of the relationship between speed and population density. The speeds determined from Equation 59.5 are along the line of movement; that is, for stairs the speeds are along the line of the treads. Table 59.3 provides convenient multipliers for converting vertical rise of a stairway to a distance along the line of movement. The travel on landings must be added to the values derived from Table 59.3. To be conservative, it should be assumed that the population does not increase velocity when traversing a landing between stairs but continues on at the same reduced rate associated with stair movement.

Although, in reality, population densities of greater than 0.175 persons/ft^2 (1.9 persons/m^2) can be achieved, it is suggested that these densities should not be assumed in an engineering design [3]. This density produces the maximum achievable flow rate; beyond this density, the flow rate falls rapidly. If the population density increases significantly beyond 0.37 persons/ft^2 (4 persons/m^2), then crush conditions might develop [9, 10, 40]. This suggested maximum compares to the occupancy levels suggested in NFPA *101®*, *Life Safety Code®*, of 0.142 persons/ft^2 (1.54 persons/m^2) to 0.003 persons/ft^2 (0.022 persons/m^2) depending on the type of occupancy [41]. The suggested maximum

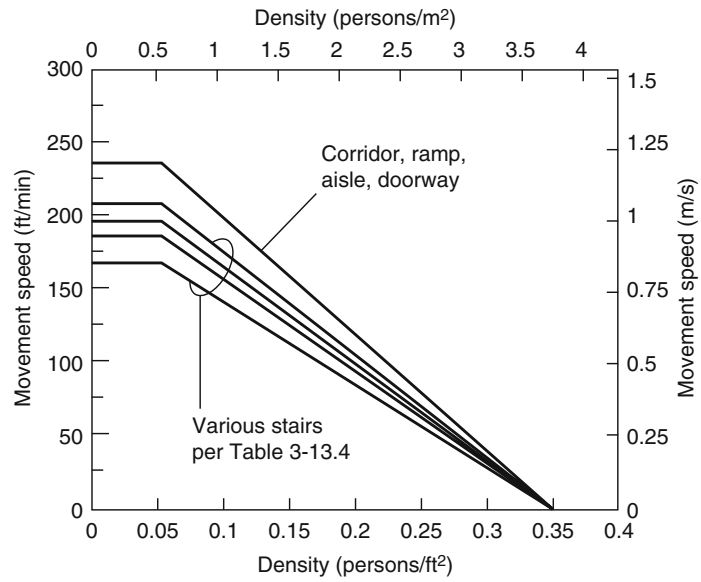

Fig. 59.7 Evacuation speed as a function of density. S = k − akD, where D = density in persons/ft^2 and k is given in Table 59.2. Note that speed is along line of travel

Table 59.3 Conversion factors for relating line of travel distance to vertical travel for various stair configurations

Stairs riser (in.)	Tread (in.)	Conversion factor
7.5	10.0	1.66
7.0	11.0	1.85
6.5	12.0	2.08
6.5	13.0	2.22

1 in. = 25.4 mm

density is therefore beyond the heaviest occupant load suggestion in the *Life Safety Code* and should therefore be adequate for all occupancy types.

A conservative approach is therefore adopted regarding the population densities that might be achieved during the movement of the population. As can be seen in Fig. 59.7, a maximum population density of 3.76 persons/m^2 is assumed. This limit constrains the movement of the population. The relationship between speed/flow and density is similarly affected by this constraint, with achievable population densities below those that might be expected in reality and curtailed earlier than might be expected.

The maximum speed is possible, but not inevitable, when the density is less than 0.05 persons/ft^2 (0.54 persons/m^2). These maximum speeds are listed in Table 59.4.

Within the range of dimensions listed in Tables 59.2, 59.3, and 59.4, the evacuation speed on stairs varies approximately as the square root of the ratio of tread width to tread height. There is not sufficient data to appraise the likelihood that this relationship holds outside this range.

Specific flow, F_s Specific flow, F_s, is the flow of evacuating persons past a point in the exit route per unit of time per unit of effective width, W_e, of the route involved. Specific flow is expressed in persons/min/ft of effective width (if the value of $k = k_1$ from Table 59.2), or persons/s/m of effective width (if the value of $k = k_2$ from Table 59.2). The equation for specific flow is

$$F_s = SD \tag{59.6}$$

Table 59.4 Maximum (unimpeded) exit flow speeds

Exit route element		Speed (along line of travel) (ft/min)	(m/s)
Corridor, aisle, ramp, doorway		235	1.19
Stairs			
Riser	Tread (in.)		
7.5	10	167	0.85
7.0	11	187	0.95
6.5	12	196	1.00
6.5	13	207	1.05

1 in. = 25.4 mm

where
F_s = Specific flow
D = Population density
S = Speed of movement

The flow rate unit is often referred to in persons/ft/minute or persons/m/second. This change in units will have no impact on the results.

F_s is in persons/min/ft when density is in persons/ft^2 and speed in ft/min; F_s is in persons/s/m when density is in persons/m^2 and speed in m/s.

Combining Equations 59.5 and 59.6 produces

$$F_s = (1 - aD)kD \tag{59.7}$$

where k is as listed in Table 59.2.

The relationship of specific flow to population density is shown in Fig. 59.8. In each case the maximum specific flow occurs when the density is 0.175 persons/ft^2 (1.9 persons/m^2) of exit route space. It is possible to establish F_s from Equation 59.7 and solve for D. There is a maximum specific flow associated with each type of exit route element; these are listed in Table 59.5.

Special Consideration for Door Mechanism In Table 59.5 and Fig. 59.8 the maximum achievable specific flow rates for corridors and doorways are considered equivalent. This is based on the original calculations made by Nelson and MacLennan [26]. However, this is based on the assumption that the entire effective width

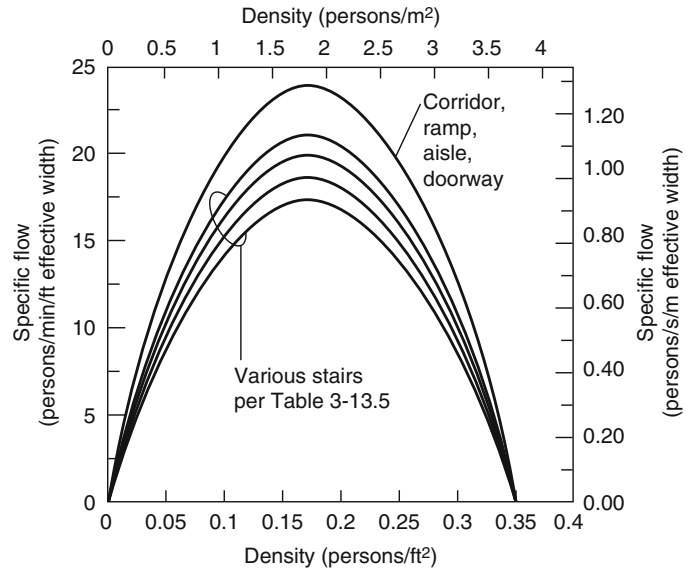

Fig. 59.8 Specific flow as a function of population density

Table 59.5 Maximum specific flow, Fsm

Exit route element		Maximum specific flow	
		Persons/min/ft of effective width	Persons/s/m of effective width
Corridor, aisle, ramp, doorway		24.0	1.3
Stairs			
Riser	Tread		
(in.)	(in.)		
7.5	10	17.1	0.94
7.0	11	18.5	1.01
6.5	12	20.0	1.09
6.5	13	21.2	1.16

of the doorway is available and that the passage of the population through the doorway is not influenced by the door mechanism itself. If the door leaf is not mechanically held open, then the traversing population may be forced to hold it open, delaying their passage. These actions have the potential for slowing the evacuees' movement through the opening, producing a reduced flow rate. It may also reduce the width available to the width of a single person (i.e., the width required for the person holding the door and passing through the exit), rather than the full available width of the exit leaf. In this case, the exit width available may be dynamic and reduced even from the calculated effective width.

These factors may act to limit the flow through the doorway. When doors on an egress route are not mechanically held open, these factors should be considered. In such circumstances, where the interaction with the door leaf influences performance, it may be more conservative to assume a maximum achievable flow rate based on the number of door leaves available rather than the actual width (effective or otherwise) of each door leaf; that is, increasing the door leaf size may not produce a linear increase in the achievable flow, given the need to hold the leaf open and the reduction in the available door width due to the position of the closing leaf. A *maximum* flow rate of 50 persons/min/door leaf is suggested for doors that are not mechanically held open [3, 8]. Fruin originally noted flow rates between 40 and 60 persons/min through exits with door leaves; however, the lower flow rate of 40 persons/min was produced during observations involving slow-moving occupants and so is discounted [3].

The data used to support the flow rate through doors are several decades old and may not accurately reflect the movement and shape characteristics of current populations; for example, the impact that the increasing levels of obesity in some parts of the world might have on the capacity of egress routes and on movement rates

[42]. In addition, the data from which these relationships were derived were collected from nonemergency pedestrian movement and/or egress drills. The functions described should not be assumed to necessarily provide conservative predictions; the engineer should therefore factor this into the design recommendations made.

Calculated flow, F_c The calculated flow, F_c, is the predicted flow rate of persons passing a particular point in an exit route. The equation for calculated flow is

$$F_c = F_s W_e \tag{59.8}$$

where
F_c = Calculated flow
F_s = Specific flow
W_e = Effective width of the component being traversed

Equation 59.8 is based on the assumption that the achievable flow rate through a component is directly proportional to its width.

Combining Equations 59.7 and 59.8 produces

$$F_c = (1 - \mathrm{a}D)\mathrm{k}DW_e \tag{59.9}$$

F_c is in persons/min when k = k_1 (from Table 59.2), D is in persons/ft^2, and W_e is in ft. F_c is in persons/s when k = k_2 (from Table 59.2), D is persons/m^2, and W_e is m.

Time for passage, t_p The time for passage, t_p, is the time for a group of persons to pass a point in an exit route and is expressed as

$$t_p = P/F_c \tag{59.10}$$

where t_p is time for passage (t_p is in minutes where F_c is in persons/min; t_p is in seconds where F_c is persons/s). P is the population size in persons.

Combining Equations 59.9 and 59.10 yields

$$t_p = P/[(1 - \mathrm{a}D)\mathrm{k}DW_e] \tag{59.11}$$

There are several transition configurations that may arise during an engineering calculation that involve the interaction between flows of people. These transitions need to be identified, as they require a different approach and have an impact on the overall calculation produced. The transitions can be categorized into merging or branching flows.

Transitions Transitions are any points in the exit system where the character or dimension of a route changes or where routes merge or branch. Typical examples of points of transition include the following:

1. Any point where an exit route becomes wider or narrower. For example, a corridor may be narrowed for a short distance by a structural change, an intruding service counter, or a similar element. The calculated density, D, and specific flow, F_s, differ before reaching, while passing, and after passing the intrusion.
2. A point where the terrain changes; that is, the point where a corridor enters a stairway. There are actually two transitions: one occurs as the egress flow passes through the doorway, the other as the flow leaves the doorway and proceeds onto the stairs.
3. The point where two or more exit flows merge; for example, the meeting of the flow from a cross aisle into a main aisle that serves other sources of exiting population. It is also the point of entrance into a stairway serving other floors.
4. Where a flow branches into several other flows. A decision has to be made regarding the proportion of the incoming flow that uses each of the outgoing flows, that is, into several other egress components. The proportion of the flows will be influenced by a number of different behavioral and procedural issues (refer to Chaps. 58 and 64, and also to Predtechenskii and Milinskii [7]). The proportion of flow using each of the egress components may be apportioned evenly, according to the capacity of the components, or according to behavioral/procedural issues, such as familiarity. Once this apportionment has been established, then each of the flow calculations proceed as before and can be conducted independently of each other.

The following rules apply when determining the densities and flow rates following the passage of a transition point:

1. The flow after a transition point is a function, within limits, of the flow(s) entering the transition point.
2. During the transition between two components, it will be necessary to establish the density in the new component; that is, it is assumed that sufficient information is available on the previous component to enable this calculation to be made. The density in the new component will be calculated by solving for D in Equation 59.9; this will produce a quadratic in D. In order to do this, the flow rate into the component will need to be known. Unless the maximum value is achieved, there will normally be two solutions of D produced: one above and one below $D_{\max}$ (where $D_{\max}$ is the density value that produces the maximum flow). Nelson and MacLennan [26], and Predtechenskii and Milinskii [7], and Milke [40] state that the smaller of the D values should be employed; that is, less than or equal to $D_{\max}$. If the larger D value (greater than $D_{\max}$) is used, it implies that the flow rate between the two components both rises and falls during a single transition. This is not considered to be reasonable.
3. The calculated flow, F_c, following a transition point cannot exceed the maximum specific flow, F_{sm}, for the route element involved multiplied by the effective width, W_e, of that element.
4. Within the limits of rule 2, the specific flow, F_s, of the route departing from a transition point is determined by the following equations:
   (a) For cases involving one flow into and one flow out of a transition point,

$$F_{s(\text{out})} = \frac{F_{s(\text{in})} W_{e(\text{in})}}{W_{e(\text{out})}} \tag{59.12}$$

   where
   $F_{s(\text{out})}$ = Specific flow departing from transition point
   $F_{s(\text{in})}$ = Specific flow arriving at transition point
   $W_{e(\text{in})}$ = Effective width prior to transition point
   $W_{e(\text{out})}$ = Effective width after passing transition point

   (b) For cases involving two incoming flows and one outflow from a transition point, such as that which occurs with the merger of a flow down a stair and the entering flow at a floor,

$$F_{s(\text{out})} = \frac{F_{s(\text{in}-1)} W_{e(\text{in}-1)} + F_{s(\text{in}-2)} W_{e(\text{in}-2)}}{W_{e(\text{out})}} \tag{59.13}$$

   where the subscripts (in-1) and (in-2) indicate the values for the two incoming flows.

   (c) For cases involving other geometry formations merging together, the following general relationship applies:

$$\left(F_{s(\text{in}-1)} W_{e(\text{in}-1)}\right) + \cdots + \left(F_{s(\text{in}-n)} W_{e(\text{in}-n)}\right) = \left(F_{s(\text{out}-1)} W_{e(\text{out}-1)}\right) + \cdots + \left(F_{s(\text{out}-n)} W_{e(\text{out}-n)}\right) \tag{59.14}$$

   where the letter n in the subscripts (in-n) and (out-n) is a number equal to the total number of routes entering (in-n) or leaving (out-n) the transition point.
5. Where the calculated specific flow, F_s, for the route(s) leaving a transition point, as derived from the equations in rule 4, exceeds the maximum specific flow, F_{sm}, a queue will form at the incoming side of the transition point. The number of persons in the queue will grow at a rate equal to the calculated flow, F_c, in the arriving route minus the calculated flow leaving the route through the transition point.
6. Where the calculated outgoing specific flow, $F_{s(\text{out})}$, is less than the maximum specific flow, F_{sm}, for that route(s), there is no way to predetermine how the incoming routes will merge. The routes may share access through the transition point equally, or there may be total dominance of one route over the other. For conservative calculations, assume that the

route of interest is dominated by the other route(s).

A simple example is presented in order to clarify the required calculations [40]. This simple example is followed by a more comprehensive example illustrating the two different hydraulic models: first- and second-order hydraulic models.

Example 1 A 1.8 m (approximately 6 ft) wide (descending) 7/11 stair has 10 risers and leads to a 10 m long (approximately 33 ft), 1.8 m wide corridor (approximately 6 ft). At the end of the corridor, there is a 1.3 m (approximately 4 ft 3 in.) wide door (Fig. 59.9). This door is mechanically held open. How long does it take for 50 people starting at the top of the stairs with an initial density of 1.5 p/m^2 (p = persons) to exit from the door at the end of the corridor?

Solution The velocity can be calculated according to Equation 59.5:

$$S = \mathrm{k} - \mathrm{ak}D$$

For 7/11 stair, k = 1.08:

$$1.08 - (0.266)(1.08)(1.5)$$
$$\therefore S = 0.65 \text{ m/s} (128 \text{ ft/min})$$

The time to traverse the stair can then be calculated. The distance to be covered is

$$10 \text{ risers} = 70 \text{ in.} = 1.78 \text{ m}; 10 \text{ treads} = 110 \text{ in.} = 2.79 \text{ m}$$
$$\text{diagonal length} = 3.31 \text{ m} (\text{approximately } 10 \text{ ft } 10 \text{ in.})$$

Therefore, the time to cover the stairs is 3.31/0.65 = 5.1 s.

The width of the stair can be calculated using Table 59.1 (1.8–0.3 m). Given that the density (1.5 p/m^2) and the velocity (0.65 m/s) are known, the flow rate on the stair using Equation 59.9 can now be determined:

$$F_c = F_s W_e = (\mathrm{k} - \mathrm{ak}D) D W_e$$
$$F_c = 1.46 \text{ p/s}$$

This value produces a specific flow rate less than the maximum value and so it can therefore be used during the calculation.

Fig. 59.9 Geometry used in Example [1]

The time delay for the last person to start on the stair can be calculated as follows. With a flow rate of 1.46 p/s on the stair (and thus of the queue entering the stair), the time for the queue to dissipate is calculated using Equation 59.10:

$$t_p = P/F_c$$

The time for the population at the top of the stairs to enter the stairs is then

$$50/1.46 = 34.2 \text{ s}$$

The time for the entire population to enter the staircase and the time to traverse the staircase are now known. Given this, the time taken for the last person to enter and traverse the staircase can be determined. The time to traverse the corridor now needs to be calculated.

The flow rate into the corridor is 1.46 p/s; that is, that produced on the staircase. Equation 59.9 states that

$$F_c = F_s W_e = (\mathrm{k} - \mathrm{ak}D) D W_e$$

where F_c can be set to 1.46; this equation can now be solved for D.

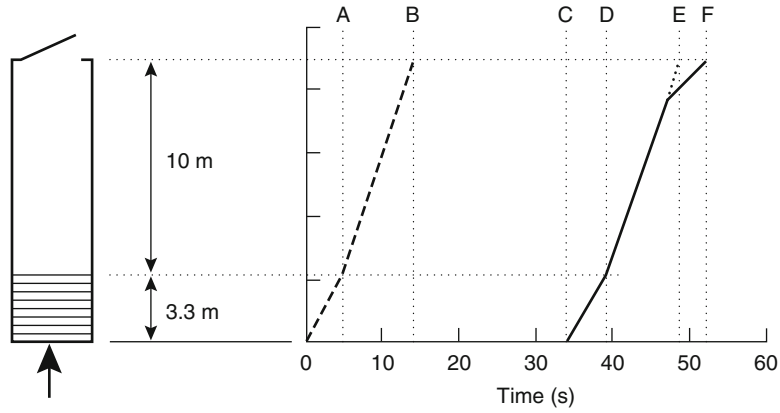

Fig. 59.10 Movement of people through the components

For a corridor, k is set to 1.40. Given the corridor is 1.8 m in width, the effective width is $W_e = 1.4$ m (4 ft 7 in).

Therefore, solving for D

$$0.266D^2 - D + (1.46/1.4 \times 1.4) = 0$$
$$0.266D^2 - D + 0.744 = 0$$

Solving for D, it is therefore either 1.03 or 2.72 p/m^2.

$$\therefore D = 1.03 \text{ or } 2.72 \text{ p/m}^2 \left(0.1 \text{ or } 0.25 \text{ p/ft}^2\right)$$

From the previous discussion regarding selecting D values, a value of 1.03 p/m^2 (0.1 p/ft^2) should be chosen.

Given that the density is known and the relationship between density and velocity is expressed in Equation 59.5:

$$S = \mathrm{k} - \mathrm{ak}D$$

the velocity, S, can be calculated as being 1.02 m/s (201 ft/min). The time to traverse the corridor is therefore 10/1.02 = 9.8 s. The flow through the doorway at the end of the series of components can now be determined. Given the narrowing at the door, the formation of the queue should be examined. The specific flow rate at the door is calculated using Equation 59.8:

$$F_s = F_c/W_e = 1.46/1.0$$

$F_s = 1.46$ p/s/m (27 p/min/ft) $> F_{sm}$, where the value of F_{sm} is 1.3 p/s/m (24 p/min/ft). The time for the population to flow through the doorway is then calculated using Equation 59.10:

$$t_p = N/F_sW_e = 50/(1.3/1.0) = 38.5 \text{ s}$$

The final solution is not simply formed from adding these values together, as some of them occur simultaneously. The final result is better explained by referring to Fig. 59.10.

The dashed line indicates the movement of the first person. This person is not influenced by queuing at any point and is therefore constrained only by the velocity values derived from the densities calculated on the different components. This person therefore spends 5.1 s traversing the stairs and 9.8 s traversing the corridor, reaching the final exit after 14.9 s (marked A and B in Fig. 59.10). The entire population entered the staircase after 34.2 s (marked C in Fig. 59.10) and has reached the end of the stairs after 34.2 + 5.1 = 39.3 s (marked D in Fig. 59.10). The last person from this group will have reached the exit at 49.1 s, assuming that person did not encounter any congestion approaching the door (marked E in Fig. 59.10). Given that the first person has reached the exit after 14.9 s and that the congestion at the final exit lasted for 38.5 s, this congestion is not clear until 53.4 s (marked F in Fig. 59.10, indicating the end of the solid curve). Therefore, the last person to arrive interacts with the congestion at some point prior to reaching the door; that is, the congestion still exists when that person arrives. The evacuation

time is then determined by the time taken for the congestion to clear at the final exit (e.g., 53.4 s).

First- and Second-Order Hydraulic Models

The various calculations discussed in the previous section can be combined in order to assess the movement component of the evacuation process; that is, to calculate t_e. By applying these calculations, the necessary movement components (e.g., flow rates, velocities, population densities, and travel speeds) can be established enabling the overall movement time to be found.

First-Order Hydraulic Model

There are several ways in which these movement calculations can be used; two are described here. The first-order hydraulic model represents a simplified approach: instead of calculating the flow of people between individual components, this method focuses on the component that places the most severe constraint on the flow of people around the structure and then uses this constraint to determine the movement time. The engineer is required to establish the time to reach the controlling component; the time for the population to traverse this component; the time for the last person to leave the controlling component; and the time for the last person to reach safety from the controlling component [43]. This process is outlined in Fig. 59.11a. This approach makes greater use of the maximum flow rates and densities allowed, given the reduced level of calculation required. The controlling component will depend on the nature of the structure; for example, the controlling component could be a stair, an exit from the stair, an exit from a room, and so on.

Second-Order Hydraulic Model

The second-order hydraulic model requires that the flow of people between each of the structural components (i.e., between areas where the physical constraints affecting egress performance change) is calculated. This is more labor intensive than the first-order approach, requiring a larger number of calculations to be made; however, it does require fewer assumptions and provides information on the movement between each of the structural components in the egress route rather than a subset of them. A second-order analysis is by no means a trivial task and requires judgment based on the structure examined and the incident scenario. This process is outlined in Fig. 59.11b.

Example Applications

The first- and second-order hydraulic models can be better understood through the description of two example applications. (More examples can be found elsewhere [43].) A relatively simple example is presented, although even in this case the difference between the effort required in applying the two versions of the model is apparent.

Example 2 Consider an office building (Fig. 59.12) with the following features:

1. There are nine floors, 300 ft by 80 ft (91 m by 24 m).
2. Floor-to-floor height is 12 ft (3.7 m).
3. Two stairways are located at the ends of the building (there are no dead ends).
4. Each stair is 44 in. (1.12 m) wide (tread width) with handrails protruding 2.5 in. (0.063 m).
5. Stair risers are 7 in. (0.178 m) wide and treads are 11 in. (0.279 m) high.
6. There are two 4 ft by 8 ft (1.2 m by 2.4 m) landings per floor of stairway travel.
7. There is one 36-in. (0.91-m) clear width door at each stairway entrance and exit. These are assumed not to be mechanically held open.
8. The first floor does not exit through stairways.
9. Each floor has a single 8-ft (2.4-m) wide corridor extending the full length of each floor. Corridors terminate at stairway entrance doors.

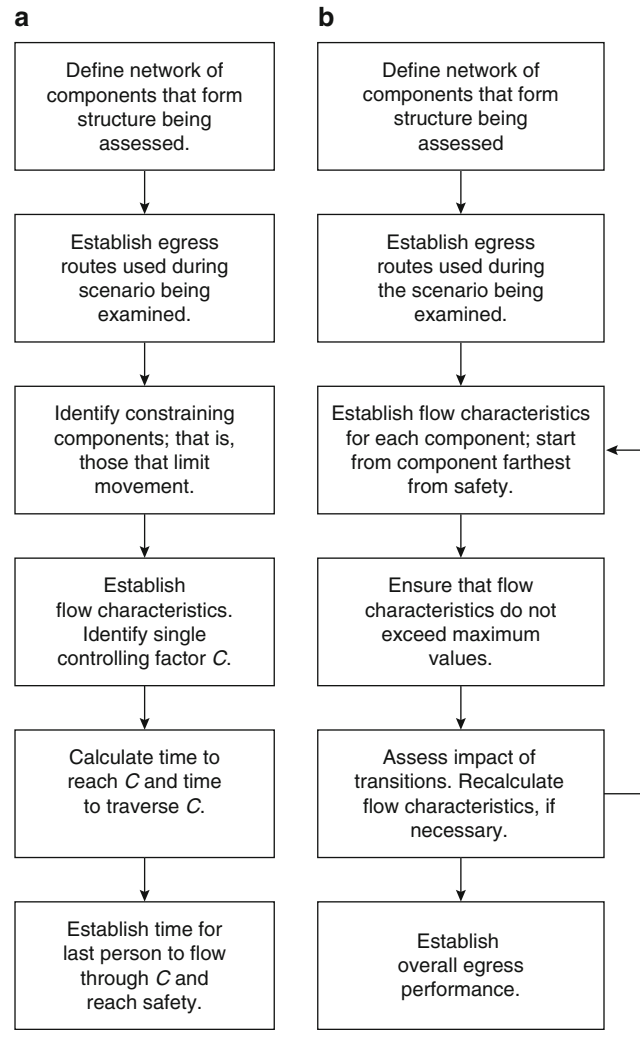

Fig. 59.11 (**a**) First-order hydraulic model; (**b**) second-order hydraulic model

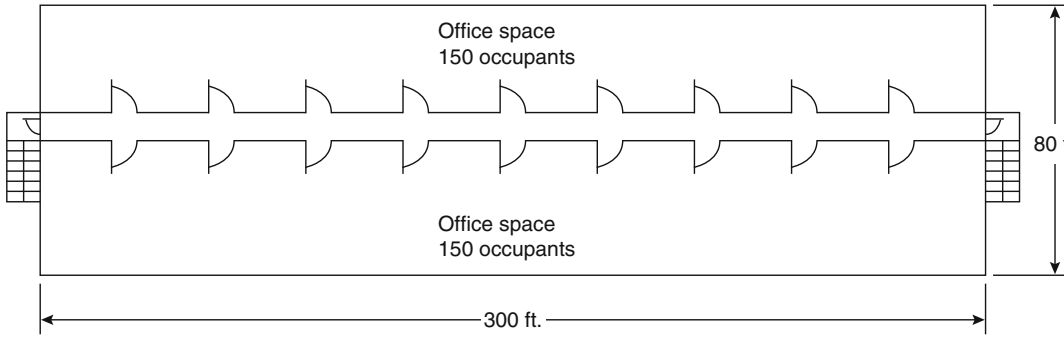

Fig. 59.12 Floor plan for example

10. There is a population of 300 persons/floor.

Solution A First-Order Approximation.

1. Assumptions.

   The prime controlling factor will be either the stairways or the door discharging from them. Queuing will occur; therefore, the specific flow, F_s, will be set to the maximum specific flow, F_{sm}. All occupants start evacuating at the same time. The population will use all facilities in the optimum balance.
2. Estimate flow capability of a stairway.

   From Table 59.1, the effective width, W_e, of each stairway is $44 - 12 = 32$ in. (2.66 ft) (813 mm [0.81 m]). The maximum specific flow, F_{sm}, for the stairway (from Table 59.5) is 18.5 persons/min/ft (1.01 persons/s/m) of effective width. Specific flow, F_s, equals maximum specific flow, F_{sm}. Therefore, using Equation 59.6, the flow from each stairway is limited to $18.5 \times 2.66 = 49.2$ persons/min.
3. Estimate flow capacity through a door.

   Again from Table 59.5, the maximum specific flow through a 36-in. (0.9 m) door is 24 persons/min/ft (1.31 persons/s/m) of effective width. Also, the effective width, W_e, of each door is $36 - 12 = 24$ in. (2 ft) (609 mm [0.61 m]). Therefore, using Equation 59.8, the flow through the door is limited to $24 \times 2 = 48$ persons/min. This is less than the maximum flow rate through an exit that is not mechanically held open (50 p/min). Because the flow capacity of the doors is less than the flow capacity of the stairway served, the flow is controlled by the stairway exit doors (48 persons/stairway exit door/min).
4. Estimate the speed of movement for estimated stairway flow.

   From Equation 59.5 the speed of movement down the stairs is $212 - (2.86 \times 212 \times 0.175) = 105$ ft/min(0.53 m/s). The travel distance between floors (using the conversion factor from Table 59.3) is $12 \times 1.85 = 22.2$ ft (6.8 m) on the stair slope plus 8 ft (2.4 m) travel on each of the two landings, for a total floor-to-floor travel distance of $22.2 + (2 \times 8) = 38.2$ ft(11.6 m). The travel time for a person moving with the flow is $38.2/105 = 0.36$ min/floor.
5. Estimate building evacuation time.

   If all of the occupants in the building start evacuation at the same time, each stairway can discharge 48 persons/min. The population of 2400 persons above the first floor will require approximately 25 min to pass through both exits. An additional 0.36-min travel time is required for the movement from the second floor to the exit. (A more conservative estimate of the travel time might also include the time for the first person to move from within the second floor to the stair.) The total minimum evacuation time for the 2400 persons located on floors 2 through 9 is estimated at 25.4 min.

Solution B Second-Order Approximation.

1. Assumptions.

   The population will use all exit facilities optimally; all occupants start egress at the same time. All persons are assumed to start to evacuate at time zero.
2. Estimate flow density (D), speed (S), specific flow (F_s), effective width (W_e), and initial calculated flow (F_c) typical for each floor.
3. Divide each floor in half to produce two exit calculation zones, each 150 ft (45.7 m) long. To determine the density, D, and speed, S, if all occupants try to move through the corridor at the same time, that is, 150 persons moving through 150 ft of an 8-ft (2.4-m) wide corridor:

$$D = 150 \text{ persons}/1200 \text{ ft}^2\text{corridor area} = 0.125 \text{ persons/ft}^2$$

From Equation 59.5, $S = \mathrm{k} - \mathrm{ak}D$.
From Table 59.2, $\mathrm{k} = 275$.

$$S = 275 - (2.86 \times 275 \times 0.125) = 177 \text{ ft/min } (54 \text{ m/min})$$

From Equation 59.7, $Fs = (1 - \mathrm{a}D)\mathrm{k}D$.
$\mathrm{F_s} = [1 - (2.86 \times 0.125)] \times 275 \times 0.125 = 22$ persons/min/ft(1.2 persons/s/m) effective width

From Table 59.5, F_s is less than the maximum specific flow, F_{sm}; therefore, F_s is used for the calculation of calculated flow.
From Table 59.1, the effective width of the corridor is

$$8 - (2 \times 0.5) = 7 \text{ ft}(2.13 \text{ m})$$

From Equation 59.9, calculated flow, $F_c = (1 - aD)kDW_e$.

$$F_c = [1 - (2.86 \times 0.125)] \times 275 \times 0.125 \times 7$$
$$= 154 \text{ persons/min}$$

At this stage in the calculation, calculated flow, F_c, is termed initial calculated flow for the exit route element (i.e., corridors) being evaluated. This term is used because the calculated flow rate can be sustained only if the discharge (transition point) from the route can also accommodate the indicated flow rate.

4. Estimate impact of stairway entry doors on exit flow.
Each door has a 36-in. (0.91-m) clear width. From Table 59.1, effective width is

$$W_e = 36 - 12 = 24 \text{ in. } (2 \text{ ft})(0.61 \text{ m})$$

From Table 59.5, the maximum specific flow, F_{sm}, is 24 persons/min/ft effective width.
From Equation 59.12,

$$F_{s(\text{door})} = \left(F_{s(\text{corridor})}W_{s(\text{corridor})}\right)/W_{e(\text{door})}$$
$$= (22 \times 7)/2 = 77 \text{ persons/min/ft}$$
$$(4.2 \text{ persons/s/m}) \text{ effective width}$$

Since F_{sm} is less than the calculated F_s, the value of F_{sm} is used. Therefore, the effective value for specific flow is 24 p/min/ft.
From Equation 59.8, the initial calculated flow,

$$F_c = F_s W_e = 24 \times 2 = 48 \text{ persons/min}$$

through a 36-in. (0.91-m) door. Since F_c for the corridor is 154 p/min while F_c for the single exit door is 48 p/min, queuing is expected. The calculated rate of queue buildup will be

$$154 - 48 = 106 \text{ persons/min}$$

5. Estimate impact of stairway on exit flow.
From Table 59.1, effective width, W_e, of the stairway is

$$44 - 12 = 32 \text{ in.}(2.66 \text{ ft}) \quad (0.81 \text{ m})$$

From Table 59.5, the maximum specific flow, F_{sm}, is 18.5 persons/min/ft (1.01 persons/s/m) effective width. From Equation 59.12, the specific flow for the stairway,

$$F_{s(\text{stairway})} = 24 \times 2/2.66 = 18.0 \text{ persons/min/ft}$$
$$(0.98 \text{ persons/s/m}) \text{effective width}$$

In this case, F_s is less than F_{sm} and F_s is used.

The value of 18.0 p/min/ft for F_s applies until the flow down the stairway merges with the flow entering from another floor.

Using Fig. 59.8 or Equation 59.7 and Table 59.2, the density of the initial stairway flow is approximately 0.146 persons/ft^2 (1.6 person/m^2) of stairway exit route. From Equation 59.5 the speed of movement during the initial stairway travel is

$$212 - (2.86 \times 212 \times 0.146)$$
$$= 123 \text{ ft/min}(0.628 \text{ m/s})$$

This value differs from that produced in the first-order, which is based on the maximum achievable density rather than a calculated density.

From the first-order solution, the floor-to-floor travel distance is 38.2 ft (11.6 m). The time required for the flow to travel one floor level is

$$38.2/123 = 0.31 \text{ min}(19 \text{ s})$$

Using Equation 59.8, the calculated flow is

$$F_c = 18.0 \times 2.66 = 48 \text{ persons/min}$$

After 0.31 min, 15 (i.e., 48 × 0.31) persons will be in the stairway from each floor feeding to it. If floors 2 through 9 exit all at once, there will be

$15 \times 8 = 120$ persons in the stairway

After this time the merging of flows between the flow in the stairway and the incoming flows at stairway entrances will control the rate of movement.

6. Estimate impact of merging of stairway flow and stairway entry flow on exit flow.
From Equation 59.13,

$$\begin{aligned} F_{s(\text{out-stairway})} &= \left[\left(F_{s(\text{door})} \times W_{e(\text{door})}\right) + \left(F_{s(\text{in-stairway})} \times W_{e(\text{in-stairway})}\right)\right] / W_{e(\text{in-stairway})} \\ &= [(24 \times 2) + (18 \times 2.66)]/2.66 \\ &= 36 \text{ persons/min/ft}(1.97 \text{ prsons/s/m}) \\ &\quad \text{effective width} \end{aligned}$$

From Table 59.5, F_{sm} for the stairway is 18.5 persons/min/ft (1.01 persons/m/s) effective width. Since F_{sm} is less than the calculated F_s, the value of F_{sm} is used.

7. Track egress flow.

Assume all persons start to evacuate at time zero. Initial flow speed is 177 ft/min (0.9 m/s). Assume that congested flow will reach the stairway in approximately 0.5 min. This conservative assumption is based on the population having to travel a distance of between 50 ft and 150 ft (15.2 m and 45.7 m) to the exit traveling at 177 ft/min (0.9 m/s); that is, the derived travel speed in the corridor. At 0.5 min, flow starts through stairway doors. F_c through doors is 48 persons/min for the next 19 s (0.31 min). At 49 s, 120 persons are in each stairway and 135 are waiting in a queue at each stairway entrance.

How the evacuation progresses from this point on depends on which of the floors take precedence in entering the stairways. Any sequence of entry may occur [1]. To set a boundary, this example estimates the result of a situation where dominance proceeds from the highest to the lowest floor.

The remaining 135 persons waiting at each stairway entrance on the ninth floor enter through the door at the rate of 48 persons/min. The rate of flow through the stairway is regulated by the 48 persons/min rate of flow of the discharge exit doors. The descent rate of the flow is 19 s/floor.

Therefore, referring to Equations 59.8, 59.10, and 59.11, at

$$(135/48) \times 60 + 49 = 218 \text{ s}(3.6 \text{ min})$$

all persons have evacuated the ninth floor.

At

$$[(135/48) \times 60 + 49] + 19 = 237 \text{ s } (4.0 \text{ min})$$

the end of the flow reaches the eighth floor.

At

$$237 + \{[(135/(2.66 \times 18.5)] \times 60\} = 401 \text{ s}(6.7 \text{ min})$$

all persons have evacuated the eighth floor.

At

$$(401 + 19) = 420 \text{ s } (7.0 \text{ min})$$

the end of the flow reaches the seventh floor.

At

$$420 + \{[135/(2.66 \times 18.5)] \times 60\} = 584 \text{ s}(9.7 \text{ min})$$

all persons have evacuated the seventh floor.

At 603 s (10.1 min)	The end of the flow reaches the 6th floor
At 767 s (12.8 min)	All persons have evacuated the 6th floor
At 786 s (13.1 min)	The end of the flow reaches the 5th floor
At 950 s (15.8 min)	All persons have evacuated the 5th floor
At 969 s (16.2 min)	The end of the flow reaches the 4th floor

(continued)

At 1133 s (18.9 min)	All persons have evacuated the 4th floor
At 1152 s (19.2 min)	The end of the flow reaches the 3rd floor
At 1316 s (21.9 min)	All persons have evacuated the 3rd floor
At 1335 s (22.3 min)	The end of the flow reaches the 2nd floor
At 1499 s (25.0 min)	All persons have evacuated the 2nd floor
At 1518 s (25.3 min)	All persons have evacuated the building

From this example it is clear that in some situations little difference exists in the results produced by the use of the two basic hydraulic models (first and second order). This may be expected in simple geometries and simple movement scenarios. However, as the scenarios and geometries become more complex, the results produced by the two versions of the model may differ significantly, especially if there are difficulties in establishing the controlling element in the first-order approximation.

The second-order hydraulic model produces a larger set of information (e.g., the time to clear components, the time to clear floors, the movement conditions between all structural components, etc.). However, it is sensitive to which of the components have precedence (e.g., in merging flows) and in the proportion of the population using particular routes. This may require several calculations to establish the most conservative result. The first-order hydraulic model produces only the overall evacuation time and the results relating to the constraining component. It should also be noted that in complex geometries identifying the constraining component is not a trivial task, and it can be extremely time consuming.

Given that an assessment of a structure is necessary, it is important to identify the scenarios involved in this assessment. It may not be possible to definitively establish the worst-case scenario prior to the calculation. It is therefore essential to examine several representative scenarios that form a set of predictions. This will offer insight into the scenarios examined and more reliably provide an estimate of the longest RSET value to be expected, as compared with the assessment of a single scenario.

Employing Extended Hydraulic Model to Calculate t_{esc}

Factors Influencing an Evacuation

The extended hydraulic model provides a foundation to evaluate evacuation performance, that is, escape time (t_{esc}) as opposed to evacuation movement time (t_e). Figure 59.3 indicates that there are more factors that actually influence an evacuation than can currently be modeled. The factors that can be included are dependent on our understanding of real-life phenomena, on the data available, and on the limitations of the model adopted. As has already been stated, the hydraulic model outlined here can be employed in the examination of different egress scenarios. This is critical in generating a robust and representative solution.

A number of behaviors can influence the performance of the population. It is possible to *implicitly* represent some of these behaviors (i.e., the consequences of these behaviors) by manipulating parameters associated with the hydraulic model and then examining a range of scenarios.

In order to increase the information obtained in any egress analysis and the confidence in this information, a representative set of egress scenarios could be examined. Producing one "definitive" result is insufficient, given the many scenarios that can actually develop and also given the limitations of the modeling approach. Presenting a single answer may produce overconfidence in the accuracy and validity of the result.

Basic Variables

Given the scope of the extended hydraulic approach, the scenarios that can be examined

are limited and require the manipulation of a few basic variables:

- The routes available during the evacuation
- The evacuee's use of the routes available during the evacuation
- The movement attributes of the evacuating population and the presence of impairments and disabilities
- The time taken to respond to the call to evacuate—the pre-evacuation time (t_{p-e})

When using the extended hydraulic model, these variables can be manipulated to produce a number of different scenarios and therefore an envelope of results. By manipulating these variables, at least a small subset of the behaviors that might detract from egress performance can be accounted for, albeit in an implicit way. The manner in which this is performed will be dependent on the nature of the occupancy being examined and the scenarios that are considered as realistic. The scenarios examined (and omitted) by the engineer should be justified through a detailed explanation accompanying the reported results. In addition, the scope of the results can be extended to represent t_{esc} rather than just t_e.

Routes Available During the Evacuation In some scenarios it is possible that routes will be lost due to the nature of the incident or given the use of the space available; for example, a route might not be protected. This loss can be considered.

Some existing codes require such forms of analysis. For instance, in the British Standard BS5588 [44], the largest exit is discounted, assumed blocked by the incident. In NFPA *101* one scenario requires the evaluation of the impact of a fire located in the primary means of egress [41].

The hydraulic model can be manipulated to represent the loss of available egress routes. In the example shown in Fig. 59.12, an entire staircase could be presumed lost due to the nature of the incident. This would have a profound impact on the results produced. Instead of an overall evacuation time of 25.4 min, it instead required 50.4 min, when applying the first-order approximation. The calculation may also involve the loss of individual components, rather than the entire egress route.

Evacuee's Use of the Routes Available During the Evacuation In reality, egress routes are rarely used according to their design capacity (i.e., efficiently). Instead, routes are used according to occupant familiarity, visual access, the procedure in place, and the evolution of the incident itself. [4, 45] This reality can be represented within the hydraulic model by modifying the proportion of the population using a particular route. Although it might be difficult to gather accurate data on the use of the routes available, engineering judgment could still be used to assess the potential impact of the unbalanced use of the egress routes available. For instance, in the example shown in Fig. 59.12 it was assumed that the population used the egress routes in an optimal manner; that is, that they split evenly between the staircases. It may be the case that one route is more familiar to the population than another (through normal use, proximity to elevators, connectivity to nearby car park, etc.). This inefficient use can then be reflected in the calculations by more people using one of the routes available. If it is assumed that 75 % of the population make use of one of the staircases, then applying the first-order model produces an overall egress time of approximately 37.9 min (1800/48 + 0.36). As a consequence, the other staircase would clear more quickly.

Movement Attributes of the Evacuating Population The makeup of the population can vary over time. Variations in the population's capabilities can be represented through the modification of the maximum velocities that can be attained. The range of the population's capabilities can be extended to include the presence of the mobility impaired. Although the reduction of velocities represents only one aspect of impairment (e.g., it does not represent behavioral issues, pre-evacuation issues, the impact that the presence of the mobility impaired might have on population densities, etc.), it is still an important consideration. This may be of

particular importance where the egress performance is not dominated by congestion and flow constraints, but by travel distances. Looking at the example presented above, in the first-order model, the presence of the impaired may increase the 0.36 min to travel between the floors on stairs. In the second-order model, it may have a more complex effect. It could also be taken into consideration when determining the t_{p-e} component, with a population with impairments extending the preparation required.

Time Taken to Respond Part of the RSET calculation (see Equation 59.1) requires the assessment of a pre-evacuation phase, t_{p-e}; this phase is the time between notification and the time for the population to evacuate. It can be varied given the scenario being represented, the notification system in place, the procedures employed, and so on. This time may then allow limited comparisons to be made between different procedural measures, notification systems, and the like. Pre-evacuation time may be particularly important where scenarios are not dominated by flow and the egress route capacities [1]. However, it should be recognized that the potential benefits of distributing the response of the population cannot be represented in the hydraulic approach given its fundamental assumptions.

In reality, the relationship between the pre-evacuation phase and the evacuation phase is complex. It is not simply a case of adding the times of the two phases together. Given the scenario, the extent of the pre-evacuation time distribution may increase or reduce the level of congestion produced. This complex relationship is difficult to represent unless the evacuees are simulated on an individual basis (see Chap. 60).

Data are required in order to include these factors in the calculation. These data, particularly regarding the pre-evacuation phase, are scarce and not always reliable (see Chap. 64). Although this limitation should be acknowledged, it does not preclude further engineering analysis. Even where engineering judgment is required, it is still critical to assess the robustness of the results by trying to account for these factors. Where it is not relevant or possible, then it should be clearly stated allowing the exclusion of the factors from the assessment to be judged.

Developing Escape Scenarios

As mentioned previously, when assessing the egress performance of a structure, it is vital to produce results that cover a range of scenarios. This process adds to the robustness of the results and the credibility; that is, it is not credible that the use of a hydraulic model (or any other model) would produce a definitive, single result. This is discussed in more detail in Chap. 57 and has been discussed and developed elsewhere (e.g. in PD 7975-6:2004) [46]. Ideally, a number of scenarios should be examined. A viable set of scenarios can be produced by varying factors within the hydraulic model (including those identified in the previous section) in a logical manner. Given that several factors are represented (e.g., speed, flow, route availability/usage, pre-evacuation times), each of these factors can be modified to implicitly represent different scenarios. Using this approach, a range of viable scenarios can be examined that produce different RSET values. Once complete, the longest RSET value generated would then be used for comparison against the ASET value produced.

Purser identified two base scenarios that can then be modified through the manipulation of model variables in order to produce sets of scenarios for analysis (Fig. 59.13) [1]. This is just one suggested approach at gaining a broader insight into the evacuation performance of a structure and establishing RSET using an engineering calculation; however, it is indicative of the different scenarios that can be examined.

Purser identified that in sparsely populated spaces, the overall egress time produced (t_{esc}) is more sensitive to the time taken to traverse the distance to a place of safety and the time taken to respond, than to the time for congestion to evaporate. In such situations, it is unlikely that egress

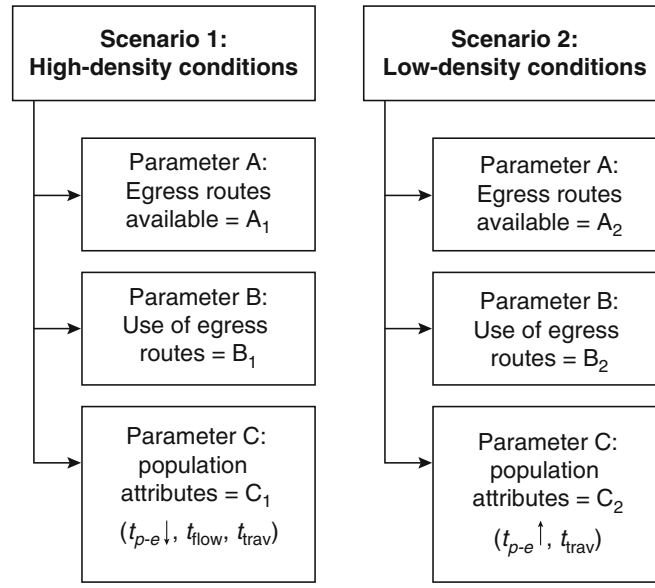

Fig. 59.13 Generation of scenarios by manipulating parameters

components will be overloaded and generate queues that dominate the egress performance.

In densely populated spaces, Purser identified that it is more likely that congestion will be produced. In such situations, the response of individuals may be influenced by observing the activities of other evacuees [45, 47]. This is likely to reduce the distribution of pre-evacuation times produced. This implies that the population will arrive at structural components within a smaller range of times. Therefore, the time to reach a point of safety is likely to be highly sensitive to the clearance of congestion along the egress routes.

When applying a sophisticated simulation model, the factors that determine the outcome of a scenario (e.g., whether it is determined by flow, travel, etc.) will be a *result* of the analysis (see Chap. 60). Given the limitations of the hydraulic model, the engineer has to *impose* these conditions prior to the calculation being conducted (e.g., whether congestion or travel distance determines the time to reach safety) and then assess their impact; the critical behavioral/movement components are determined prior to the calculations being made. The Purser approach can be applied in order to establish what underlying factors determine the overall evacuation time, by examining scenarios where the results are determined by different factors; for example, flow and/or travel and response. For a single structure the impact of these different scenarios can be assessed to establish which of them produces the most prolonged egress time.

When using the Purser approach to establish the evacuation time from a particular structure, it is assumed that the engineer cannot be sure which of these scenarios will produce the longer escape time, prior to the calculation being conducted. Both scenarios are therefore examined. Each of the scenarios includes an assessment of the population movement (i.e., t_e) and the pre-evacuation phase (i.e., t_{p-e}). The combined result of these two phases is termed t_{esc} (see Equation 59.2). Where other new terms are used below, they are described.

Purser identified two situations (labeled Scenarios 1 and 2 in Fig. 59.13). In Scenario 1 it is assumed that congestion dominates the results produced (t_{flow}). In such situations the time required for the evacuation of an enclosure depends on the pre-evacuation time and unrestricted walking time of the first few occupants to start to leave; these determine the time for congestion to develop. Once queues have formed at the "constraining" component, the time to

clear the building becomes a function of the number of occupants and the evacuation flow rate capacity of these components. The evacuation time for an enclosure is estimated to be

$$t_{esc} = t_{p-e1} + t_{trav} + t_{flow} \quad (59.15)$$

where t_{p-e1} is the pre-evacuation time associated with the first people to respond. Purser uses the first percentile of a representative pre-evacuation distribution to estimate this value [1]. If this is not available, then the average pre-evacuation time associated with the occupancy (which is more likely to be available; see Chap. 64) should be used as a conservative estimate. t_{flow} is the time of total occupant population to flow through the most restrictive components. t_{trav} is the time taken to traverse the average distance to a place of safety. (The maximum distance should be employed in this calculation for a more conservative approach.)

It is apparent that either the first- or second-order hydraulic model can be used to generate t_{flow} and t_{trav}; indeed the combination of these two parameters approximates the t_e term previously described (see Equation 59.4).

In Scenario 2 it is assumed that congestion does not dominate the results; the results are primarily influenced by the time taken to reach safety (t_{trav}) and the time to respond (t_{p-e}). This scenario is not necessarily based on the assumption that congestion does not develop; only that the impact of the congestion is dominated by the extensive pre-evacuation phase and the distances that need to be traversed, and is not a factor in the calculation. The egress time for an enclosure is given by

$$t_{esc} = t_{p-e1} + t_{p-e99} + t_{trav} \quad (59.16)$$

where t_{p-e99} is the pre-evacuation time for the last few occupants to respond (i.e. the 99th percentile). Purser uses the 99th percentile of a representative pre-evacuation distribution to estimate this value [1]. If this is not available, then a multiple of the mean pre-evacuation time should be employed; it is not appropriate to use the average pre-evacuation time. The pre-evacuation times usually form a log-normal distribution [1, 47]. Given the limited data currently available it appears that the 99th percentile can be reasonably approximated by a value of four to five times the mean pre-evacuation time [25, 30, 47–50].

Again the example shown in Fig. 59.12 can be used to illustrate the two different scenarios. Let us assume that the structure represents an office space as indicated. In the first analysis, it is assumed that the evacuation is dependent on flow characteristics (i.e., Purser's Scenario 1) and will therefore make use of the flow calculations already made. In addition, pre-evacuation times will be extracted from the work conducted by Fahy and Proulx to support these calculations [25]. Given that it is an office space, pre-evacuation times ranging from 1 to 6 min will be assumed. These times are employed as conservative estimates of the 1st and 99th percentiles.

Given the results already produced, the evacuation time for Scenario 1 can be estimated as being

$$t_{esc} = 1 + 25.3 = 26.3 \text{ min}$$

This time is based on the assumption that t_{trav} and t_{flow} is approximated by the results produced in the second-order model.

If instead it is assumed that, for some reason, this scenario was not determined by flow (i.e., Purser's Scenario 2), then the following calculation can be made:

$$t_{esc} = 1 + 6 + (0.5) + (8 \times 38.2)/187 = 9.2 \text{ min}$$

Here, t_{p-e1} is again assumed to be 1 min, while t_{p-e99} is assumed to be 6 min, with both values being derived from Fahy and Proulx [25]. The distance calculations generated by the first-order model are used here. In this case Scenario 1 produces the most prolonged evacuation times and would therefore be used in the estimation of the RSET value.

If it is now assumed that the space is instead a mid-rise apartment building, rather than an office space, then different pre-evacuation times are suggested by the data [25]. In this case,

pre-evacuation values of 1–24 min are used (again derived from Fahy and Proulx [25]). In this case the calculations become

$$\text{Scenario } 1 : t_{\text{esc}} = 1 + 25.3 = 26.3 \text{ min}$$

and

$$\text{Scenario } 2 : t_{\text{esc}} = 1 + 24 + (0.5) + (8 \times 38.2)/187 = 27.1 \text{ min}$$

Once the set of scenarios have been examined, the longest t_{esc} value produced should then be employed to generate the RSET calculation. In this case Scenario 2 produces the most extended evacuation time and would therefore be used in any RSET calculations.

This is certainly not the only approach for producing a range of scenarios (or at understanding what factors should be taken into consideration [51]). However, it does demonstrate how several different scenarios can be considered using the hydraulic approach allowing comparisons to be made between the results produced. This approach can be taken further by incorporating the other parameters deemed to be amenable to the hydraulic approach; for example, manipulating the routes available, familiarity, mobility impairments, and so on.

The results will always be limited by the sophistication and fidelity of the model employed. However, the examination of different scenarios is critical in providing a reasonable understanding of the conditions that might arise. Inevitably, there may be cases where data are not available to support these calculations. These situations will require engineering judgment. These cases should be documented and based on the most reliable and appropriate information available.

Addressing Modeling Error

The hydraulic model, whether it is the standard or extended version, produces only *modeled* predictions. The actual egress time will exceed the modeled time by an unknown amount. This is due to the exclusion from the model of many of the factors that might inhibit evacuation performance (e.g., t_{n-e}) and also to limitations in the data available (see Chap. 60). The difference between modeled evacuation movement time and actual evacuation movement time can be expressed in the following terms:

$$t_e^{\text{act}} = t_e^{\text{mod}} e \tag{59.17}$$

where

t_e^{act} = Actual time from when purposive evacuation movement commenced to when safety was reached

t_e^{mod} = Modeled estimate from when purposive evacuation movement commenced to when safety was reached

e = Modeling error

It is assumed here that the relationship is multiplicative; however, the relationship could also be additive.

The modeling error, e, is a function of elements that interfere with the model prediction. In the case of a hydraulic model, this includes

- Delays caused by the egress management activities of wardens or others directing the evacuation
- Time delays involved in the stopping and restarting of flows at merging points and conflicting flows
- Evacuee behaviors that detract from their movement to safety

Similar inaccuracies exist in the modeled pre-evacuation phase.

From Fig. 59.2 there are many factors that can interfere with an evacuation, but that cannot be explicitly represented by a hydraulic model. It should be noted that many of these factors are also beyond the most sophisticated simulation models currently available (see Chap. 60).

All of these factors can increase the discrepancy between the modeled and actual results. The first step in appraising emergency movement is usually to calculate the modeled evacuation time, t_e^{mod}. The use of model calculations provides a reproducible base of reference in appraising the impact of overall systems, individual components, or changes in systems. If, however, the results of the modeled evacuation time

are to represent a realistic evacuation time (or are to be compared against expected fire development), then the engineer should understand that the modeled movement time is seldom achieved in reality; that is, that e is greater than 1 in Equation 59.17. A conservative estimate of the movement time requires the modeled time and an appraisal of modeling error (see Equation 59.17). This will allow t_e^{act} to be approximated (or at least surpassed) by the modeled time, which is achieved through the application of a safety factor. The employment of a safety factor is a recognition that the hydraulic model omits some factors that may prolong the time to reach safety and/or represents other factors in a simplistic manner.

For the design of a structure to be acceptable, a sufficient margin of safety is required between ASET and RSET. In order for the engineer to have confidence in the RSET calculations, a safety factor, e', is employed that approximates e (i.e., the discrepancy between the modeled and actual movement time):

$$\text{Safety margin} = \text{ASET} - \left[t_d + t_a + t_{p-e} + e'\left(t_e^{\text{mod}}\right)\right] \tag{59.18}$$

The application of the safety factor described in Equation 59.18 is based on the assumption that the inaccuracies are found in the evacuation movement component and that these inaccuracies need to be addressed (see Chap. 64 and the SFPE Task Group document [43]). In this case, the engineer would need to be confident in the accuracy of the other components in the calculation. A more conservative estimate would be to apply the safety factor, e', to all of the behavioral components (i.e., both the pre-evacuation and evacuation phases):

$$\text{Safety margin} = \text{ASET} - \left[t_d + t_a + e'\left(t_{p-e} + t_e^{\text{mod}}\right)\right] \tag{59.19}$$

Although this is more conservative, it does require the assumption that the error levels in the pre-evacuation and evacuation movement components are comparable and can be addressed by the same safety factor.

The most conservative approach requires the application of the safety factor to the entire RSET calculation:

$$\text{Safety margin} = \text{ASET} - \left[e'\left(t_d + t_a + t_{p-e} + t_e^{\text{mod}}\right)\right] \tag{59.20}$$

This is the approach adopted by Tubbs and Meacham [29]. If the same values are assumed throughout, this approach will generate the largest RSET value of the three methods (shown in Equations 59.18 through 59.20). This approach does assume that the errors that exist are comparable between the behavioral and technical components. Alternatively, separate error factors might be applied to these components, such that

$$\text{Safety margin} = \text{ASET} - \left[e_1'(t_d + t_a) + e_2'\left(t_{p-e} + t_e^{\text{mod}}\right)\right] \tag{59.21}$$

where e_1' may be based on information provided by the manufacturer of the technology involved; and e_2' is based on the research literature available. Given the method adopted, the safety margin needs to be acceptable, even after the RSET value has had a safety factor applied. Guidance on the values to employ in order to estimate the modeling error (particularly relating to the behavioral components) can be established (see Chap. 64). The basis for the safety factors employed should be clearly stated and supported.

Using the Hydraulic Model in Conjunction with Other Models

The hydraulic model can be used in a number of different ways, depending on the resources and expertise available. Currently the expertise in the use of hydraulic models far outweighs the expertise in applying simulation models, that is, computer-based models that attempt to represent the evacuation by simulating the activities of individual agents. However, it is anticipated that this will change in the coming years especially as larger and more complex spaces are examined. Indeed, the hydraulic model is often calculated using a computer. It should also be

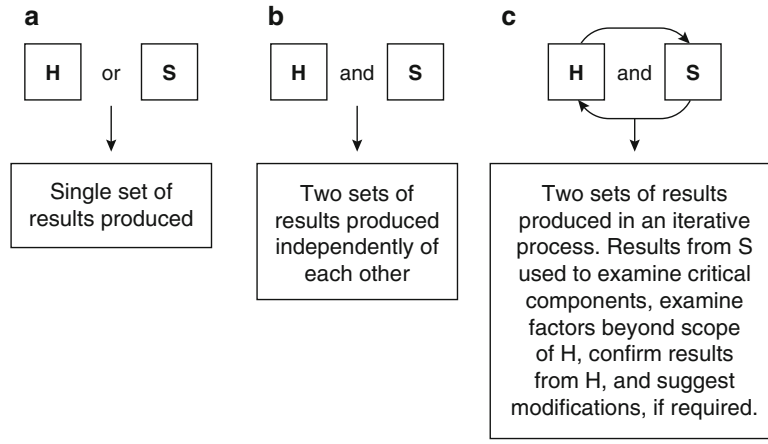

Fig. 59.14 The three uses of the hydraulic and simulation models (**a**) Used on their own; (**b**) used in parallel; (**c**) used in conjunction with each other [1]

recognized that several current computer models are little more than the hydraulic model coded into computer software (see Chap. 60). Therefore, as engineers become more familiar with the computer models available and the results that they can produce, the following points will become increasingly apparent:

- Engineers will gain expertise in a number of modeling approaches.
- Engineers will become more familiar with the capabilities of a number of different modeling approaches.
- Several models will be applied to the same problem.

These points will have an impact not only on how hydraulic models are used but also on the nature of the hydraulic analysis and the expectations of the results produced. Any discrepancy between the results produced by simulation and hydraulic models (in their format and their content) will therefore become more apparent to the engineer. Therefore, when the hydraulic model is applied:

- A number of scenarios should be examined.
- The assumptions and limitations should be identified.
- A detailed set of results should be presented.

The difference between the typical results produced when employing simulation and hydraulic models becomes all the more evident if these models are used together on the same project. It is suggested that the hydraulic model can be employed in three distinct ways (Fig. 59.14) [1]. The manner in which it is employed will be dependent on a number of factors including the expertise and the resources available.

The hydraulic model (identified as H in Fig. 59.14a) is commonly used on its own to determine the evacuation time. Computer simulation models (indicated as S in Fig. 59.14a) are also now routinely employed on their own. Alternatively, more than one model can be employed (Fig. 59.14b). The hydraulic and simulation models may be employed independently of each other and then the final results compared. This would allow comparisons to be made between the results, the strengths of the different models to be exploited, and the level of confidence in the findings to be increased.

The application of more than one model provides benefit but also results in additional efforts since results have to be calculated more than once requiring additional time, expertise and analysis. However, using multiple models may provide some engineering benefits (see Table 59.6). A typical analysis may include both a simple, computationally inexpensive model (e.g., hydraulic approach) and a more refined representation of evacuee response (e.g., simulation tool). This then allows some additional confidence in the overall results produced.

Table 59.6 Engineering benefits of the use of multiple models

Benefit	Description
Triangulation	Given that there is no absolute confidence in any one model being employed, the results of several models may be compared to determine whether the conclusions reached are consistent between different approaches.
Refinement	The scenario may require examination of elements of the evacuation process not represented in the underlying model employed.
Scope	The project may be of such a scale (e.g. WTC) that the most refined models cannot be employed to the whole task. In such projects it may pay for the engineer to employ the most refined models in critical areas, which have the greatest influence over the conclusions drawn. These would then be used in conjunction with the underlying model to assess performance at key spatial or temporal locations.

This would allow comparisons to be made between the results, the strengths of the different models to be exploited, and the level of confidence in the findings to be increased based on the assumption that consistent model results improve confidence.

Finally, models can be run in an iterative manner (or even in a coupled manner), with the results of one influencing the scenarios examined by another. For instance, in a project involving extremely large structures, the hydraulic model can be employed to provide an overview of the results produced, possibly suggesting areas for further analysis (Fig. 59.14c). A more "sophisticated" simulation model could then be used to confirm the key assumptions and findings produced by the hydraulic model (e.g., areas of congestion) and suggest remedies. The simulation tool can confirm the results by examining sections of the structure or events of particular interest to provide detailed analysis. By using the simulation model in a more focused way, fewer computational resources will be required and the results produced by the hydraulic model, especially in critical locations, can be validated (Fig. 59.15). A hybrid approach of hydraulic and simulation analysis may allow for detailed analysis to be conducted, where previously the cost of a full-scale computational analysis was prohibitive. This hybrid approach may also be useful when resources are scarce or the scale of the project is beyond the capabilities of a sophisticated model; for instance, where an evacuation involves a business district or complex, rather than a single building.

Some simulation tools are currently under development that would allow such coupling of simple and more complex tools within the same environment. In this instance, the computational resources available could be targeted at the areas deemed to be most critical within the same computational environment [52]. Currently, users need to define in advance which areas of the geometry are represented in a refined manner, while others are represented in a cruder manner. This distinction requires an understanding of the importance of particular routes, the computational impact of design decisions and the impact that these decisions might have on the results produced. In the future, these decisions may be conducted dynamically, where the models allocate locations to one or other of the various levels of representation, precluding the need for the user to make this judgment in advance.

Impact of Tenability on ASET and RSET

As part of a performance-based assessment, a decision has to be made regarding tenability; that is, the point at which the conditions preclude the evacuation to "safely" continue [3]. The tenability limits will then be used to determine the ASET value: calculations are made to determine when the environmental conditions reach the tenability criteria stated. The ASET value produced will then be the benchmark against which the RSET results will be compared.

In reality, environmental conditions can have a behavioral and a physical (physiological)

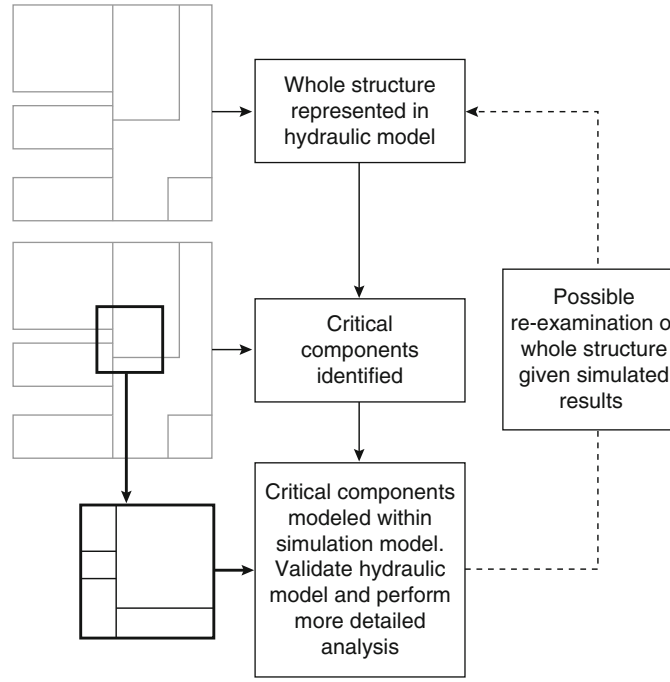

Fig. 59.15 Example application of both hydraulic and simulation models

impact on the performance of the evacuating population (see Chaps. 58, 61, and 63). Ideally, the impact of the tenability criteria should be reflected in the model scenarios employed; that is, if the environmental conditions reach a point at which they are expected to influence physical or behavioral performance, then this should be reflected in the model employed. The assumed occupant performance will have an impact on the validity of tenability criteria selected and on the credibility of the results produced.

There may be a temptation for engineers to select tenability criteria that artificially prolong the ASET time; that is, that the environmental conditions are allowed to develop to a relatively severe level before the tenability limits are reached, allowing a longer RSET calculation to be acceptable. This situation might include severely reduced visibility, elevated temperatures, and smoke layers descending close to the floor. By coupling the assumed tenability limits with the movement calculations made, there will at least be some counterbalance to these assumptions (Fig. 59.16), possibly encouraging a more conservative approach to be adopted throughout. *The adoption of tenability criteria that represent severe environmental conditions will then have a direct impact on the modeled performance of the evacuees.*

Suggested values are available for tenability limits (refer to Chaps. 61 and 63). These values, or similarly derived empirical values, should be used to inform the selection of reasonable and informed tenability criteria. This critical component in the performance-based assessment should be clearly supported in any results reported; effectively these values determine the amount of time available to complete the evacuation.

Given that these tenability criteria are established, their impact can be reflected within the hydraulic model. Some data (albeit, in some instances, supported by engineering judgment) are available to reflect the impact that a deteriorating environment can have upon egress performance (see Chaps. 58, 61, and 63). Data relating to physical performance are provided by Jin, who indicates the possible effect that deteriorating visibility has on travel speeds (see Chap. 61), specifically in relation to smoke. Other physical and behavioral data are also available (see Chaps. 58 and 63). Data on the impact of smoke are particularly important given that in

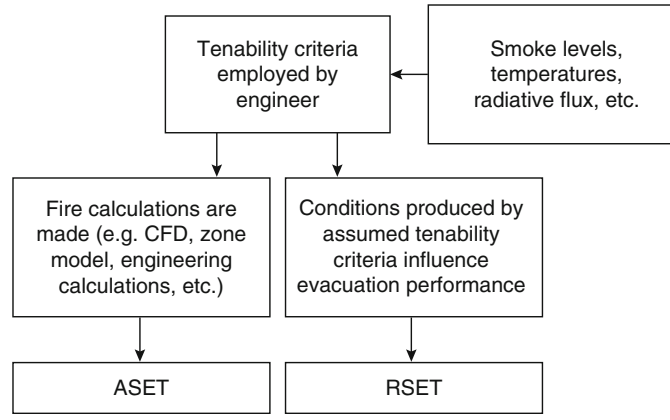

Fig. 59.16 Coupling tenability criteria to egress performance

many instances evacuees will be more likely to interact with smoke than with the fire itself.

Although there may be many ways in which the environment influences evacuee performance, it can be simplified especially given that the evacuating population is typically moving to minimize their exposure. This will produce several scenarios to be considered (in addition to those mentioned in the previous sections) when the hydraulic model is employed. These scenarios relate to the attainable travel speeds and the routes available.

The conditions produced (e.g., specific smoke visibility levels are reached, see Chap. 63) might block off certain routes. For instance, it could be assumed that when smoke reaches a certain level, a proportion of the population might not proceed through the smoke. The tenability criteria reached (e.g., smoke level) could also be deemed to influence attainable travel speeds in the affected areas. This can be modeled by reducing the maximum achievable travel speed; for instance, in Chap. 61 data are provided relating smoke level to visibility and travel speed. A conservative approach might be to assume the impact at the level of the tenability criteria in the affected spaces (i.e., where the environment is deteriorating) throughout the entire evacuation; that is, that whenever tenability criteria are reached the related impact on travel speed is assumed to be present throughout the evacuation. An example of the way in which the two effects of smoke can be included into the hydraulic model is shown in Fig. 59.17.

In Fig. 59.17a, route selection is not influenced by the presence of smoke. Within the hydraulic model the maximum travel speed within this component can be reduced to simulate the impact on the evacuees traveling through this component when filled with smoke (e.g. at or below the tenability threshold). In Fig. 59.17b, it is assumed that the smoke-filled corridor is not used; this is reflected in the hydraulic model by assuming that a larger population uses the East corridor. The potential impact of the two different behavioral scenarios can then be compared.

Attempting to match the development of the fire with the progress of the population in the hydraulic approach is cumbersome and would require numerous additional assumptions. To assess the maximum impact, a scenario could be examined where the entire population refused to pass through the smoke; similarly a scenario could be examined where the entire population is assumed to pass through the affected area at reduced speeds.

It may be impractical to employ these factors within all egress calculations. There is certainly a lack of supporting data. However, even if these additional scenarios are not considered, the impact that the deteriorating environment can have on egress performance should at least be acknowledged and explained in the presentation of any results. Otherwise, it is assumed that the

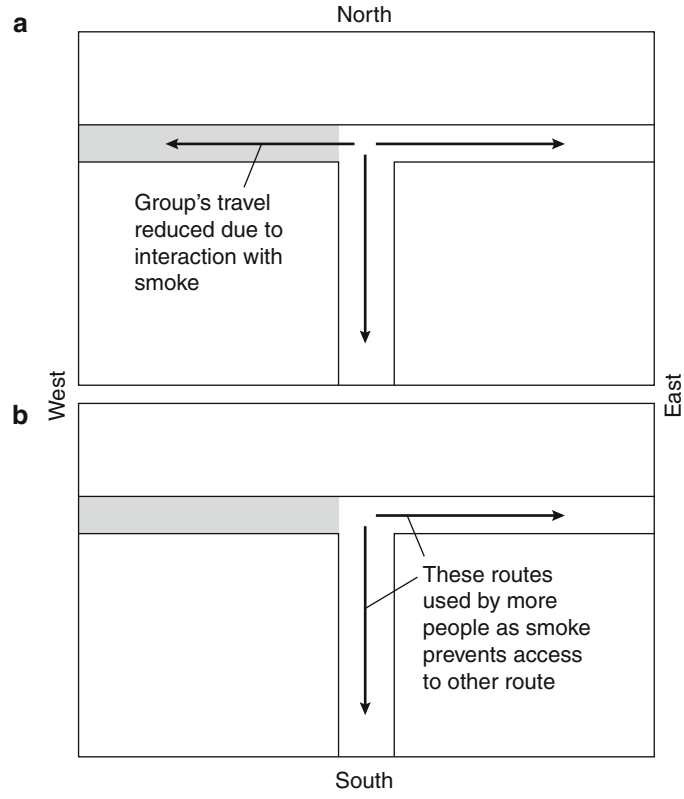

Fig. 59.17 Example of the impact of smoke on the hydraulic model

environmental conditions have no impact upon the performance of the evacuating population prior to tenability conditions being reached. This may be credible; however, it should be acknowledged.

In most designs, there would ideally be no physical interaction at all between the evacuating population and the deteriorating environmental conditions. That does not preclude the population seeing the developing conditions, which might influence their behavior. Even here the untenable conditions could be modeled in the hydraulic model through the loss of available egress routes.

Summary

This chapter described the application of the hydraulic model and its capabilities in assessing emergency movement. The model is able to provide a reliable means of assessing RSET and therefore in conducting performance-based analyses. When employing the model, it should be remembered that the results produced will be optimistic, and therefore remedial measures should be employed to compensate for this.

The limitations associated with the model do not prevent its being used to examine different egress scenarios; neither do they excuse the oversimplistic use of this model or presentation of the results. Those employing this model need to provide sufficient information on the approach adopted, the assumptions made, the scenarios examined, and the results produced.

When using the hydraulic model, it is still possible to examine a number of evacuation scenarios and incorporate the effect of various factors on the performance achieved. Given the potential for hydraulic and simulation models to be employed together, it becomes even more important to provide comparable levels of detail and confidence in the results produced.

Acknowledgment The authors acknowledge that this work includes substantial sections from the original chapter written by Harold "Bud" Nelson in partnership with Hamish MacLennan and then Fred Mowrer.

Nomenclature

ASET	Available safe egress time
RSET	Required safe egress time
t_d	Time from fire ignition to detection
t_n	Time from detection to notification of occupants of a fire emergency
t_{p-e}	Time from notification (or receipt of cues) until evacuation commences
t_e	Time from start of purposive evacuation movement until safety is reached
t_{esc}	Escape phase, being the sum of the pre-evacuation ($t_{p\text{-}e}$) and evacuation (t_e) phases
t_{trav}	Time spent moving toward a place of safety
t_{flow}	Time spent in congestion controlled by flow characteristics
t_{n-e}	Time spent in nonevacuation activities that do not directly contribute to the population moving to a place of safety
W_e	Effective width
D	Population density
S	Travel speed
k	Constant used to calculate travel speed
a	Constant used to calculate travel speed
F_s	Specific flow
F_{sm}	Maximum specific flow
F_c	Calculation flow through a component
t_p	Time for a group of persons to pass a point in an exit route
P	Population size in persons
$F_{s()}$	Specific flow and associated direction of movement
$W_{e()}$	Effective width of a particular component given its location
t_{p-e1}	Pre-evacuation time of the first people to respond
$t_{\text{p-e99}}$	Pre-evacuation time of the last people to respond
t_e^{act}	Actual time from when purposive evacuation movement commenced to when safety was reached
t_e^{mod}	Modeled estimate from when purposive evacuation movement to when safety was reached
e	Modeling error
e'	Approximation of e employed within calculation

Steven M.V. Gwynne, PhD is a senior research officer at the National Research Council Canada. He specializes in pedestrian and evacuation dynamics. His work includes the collection of data, the development of behavioral theories, and the application of models to assess people movement under emergency and nonemergency scenarios.

Eric R. Rosenbaum, P.E., is Vice-President of Jensen Hughes, Inc. a fire protection engineering, code consulting, and research and development firm. He has been actively involved in the evaluation of egress facilities for structures throughout the world.

Computer Evacuation Models for Buildings

60

Erica D. Kuligowski

Introduction

With the rapid increase in computer capability and the increase in egress model development, there is a need for guidance on evacuation modeling, specifically the process involved and the models available. This chapter provides general guidance to users on the first three steps of the evacuation modeling process, namely, (1) identifying project requirements, (2) selecting the appropriate model (including a review of 26 current building evacuation models), and (3) configuring the model scenarios. In addition, an example of evacuation modeling configuration is provided to identify the factors to consider when configuring the building, the population, and the procedures. The chapter briefly reviews the final three steps of the evacuation modeling process, which are applying the model, obtaining output, and analyzing results. These final steps are important but only briefly mentioned due to the fact that these are often specific to the evacuation model chosen and the goals of the project. Overall, this chapter aims to provide necessary guidance that is general enough to be model independent and specific enough to be valuable to the model user.

Overview of Computer Evacuation Models

The rapid increase in computer capability and decrease in cost have expanded the use of computer models in all fields of engineering, particularly for evacuation models. This chapter introduces a framework for deciding which model or models are appropriate for a particular life safety analysis, presents a review of 26 current evacuation models, and provides an example of an evacuation model configuration that identifies important factors to consider involving the building, population, and procedures.

An engineer performing a life safety analysis on a structure is presented with a number of alternative tools from which to choose to complete this task. Depending on the type of building and the time allotted for the analysis, the engineer may choose to employ a variety of techniques, including empirical calculations [1], manual engineering calculations [2], and/or evacuation modeling.

The empirical engineering approach compares the structure in question to data collected from a comparable structure. The user can then extrapolate from those data in order to make a

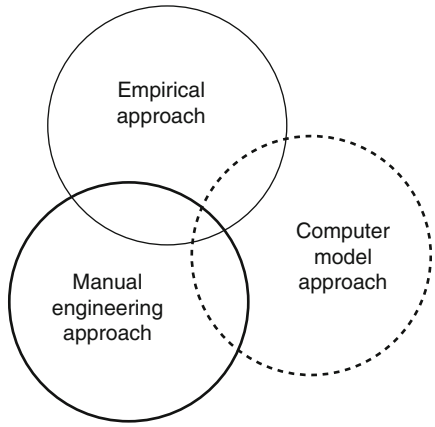

Fig. 60.1 Overlap between computational, empirical, and manual approaches to modeling

prediction of the egress performance of the structure [1]. The manual engineering approach applies empirical data at the component level (doorways, stairs, etc.) in order to ascertain the egress performance across the structure. This is done by predicting the performance of the evacuees on the components in question along predefined routes within the structure [2]. Finally, computer evacuation models represent a diverse set of methods and sophistication, ranging from a relatively crude account of homogeneous occupant flow to autonomous agents moving throughout three-dimensional space. The diversity of this sophistication is such that some models simply incorporate the methods of the empirical and manual engineering approaches (Fig. 60.1), effectively automating the process. Since the *SFPE Handbook of Fire Protection Engineering* [1, 2] describes a life safety analysis using both empirical and manual engineering approaches, this chapter will focus on the use of evacuation models.

In the recent past, both computer evacuation model development and use have expanded due to technological developments as well as the demand for flexible techniques that can cope with complex designs. In addition, the needs of the fire protection community to address problems other than building fires have been apparent. Computer evacuation models can evaluate evacuation results from a variety of structures, such as marine vessels, aircraft, buildings, and cities. In addition to diversity in structure, evacuation models can be used to simulate different types of scenarios, such as evacuation from fires, bomb threats, terrorist events, weather, riots, and even relocation (instead of evacuation) within the building. Acknowledging the different types of computer models and emergency events, this chapter will focus on computer evacuation modeling of fire emergencies in buildings, specifically the process of evacuation modeling.

Figure 60.2 displays a simplified version of the egress modeling process. The steps of the process are the following: [3]

1. Project requirements are provided to the user.
2. The user selects a model based on the project and other requirements.
3. The user constructs detailed model scenarios, which involves obtaining data and configuring the model.
4. The user applies the model.
5. The user obtains outputs from the application.
6. The user analyzes results and formats these results for the client.

The rest of this chapter focuses on providing guidance for Steps 1–3 of the modeling process displayed in Fig. 60.2: obtaining project requirements, selecting a model, and constructing model scenarios. The chapter begins by describing the project requirements that help guide model selection. Next, the features of evacuation models will be described to aid the user in model selection. The features of 26 evacuation models will be presented for comparison. Finally, the chapter will focus on model scenarios and provide an example to illustrate the issues that may arise in model configuration. Although Steps 4–6 are also important to the modeling process, these are often specific to the evacuation model chosen for the project (see Kuligowski and Milke [4] as an example).

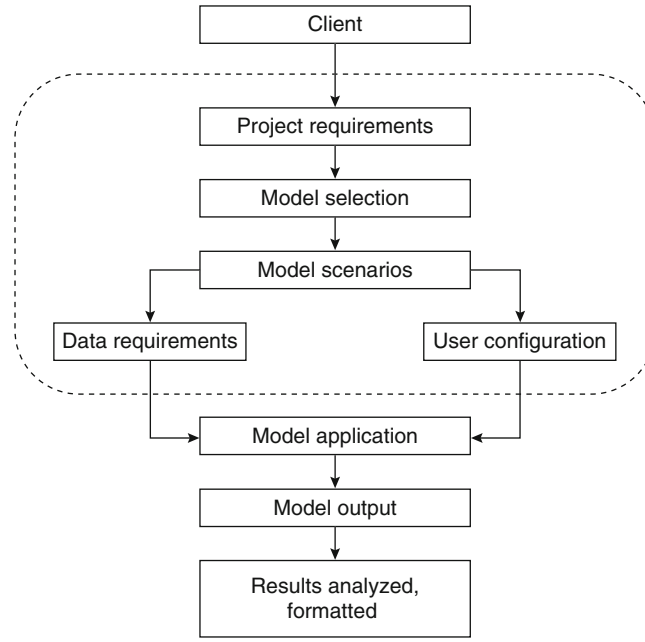

Fig. 60.2 The computer modeling process

Step 1: Project Requirements

Before selecting a model, the user should consider the following key questions relating the suitability of the model to the specific project [3]:

- What information is needed within the project to frame the egress analysis and configure the computer model?
  - What information is available?
- How much time and funding are available to complete the project?
  - What effort is required to configure and execute the model?
- What is the nature and scope of the project?
  - What are the technical resources required?
  - What additional human resources (training, expertise, etc.) are required?
  - What are the conditions that need to be represented?
- What are the deliverables of the project?
  - What output needs to be produced by the model?

This list is not an exhaustive list of the questions that need to be asked, nor are the questions necessarily mutually exclusive; however, by answering these four questions, the user should be able to ascertain whether the model is able to support the project requirements and whether it is appropriate to be used for the project at all.

Project Information Availability

The amount of project information available to the user may influence the model selection. The model may require a number of inputs in order to take advantage of its functionality or to function at all. However, the information that the user has during the project may be limited (e.g., a vague description of the building floor plan rather than a detailed architectural diagram, limited information on the population distribution, etc.). In some instances, this information may be collected/acquired during the life-time of the project. However, typically this will not be the case. If the required information is not available, the user may select a less sophisticated model with a limited number of inputs; i.e., the functionality of a sophisticated model cannot be employed given gaps in the data available.

Nature and Scope of the Project

It is important to examine the nature and scope of the project in order to determine whether the model is able to cope with the requirements of that particular application area. The user may need to establish whether certain factors are represented at all or, if they are, whether they are represented in a sufficiently refined way. For instance, if modeling a building evacuation, the user may need to represent stair movement. However, given the procedure, the user may also require stair counter-flow to be represented—i.e., people simultaneously moving up and down a stairway. The user should then ask whether stair movement is represented, and, if so, whether this representation is sophisticated enough to answer the counter-flow questions being posed within the project.

Deliverables of the Project

Typically, model output can be produced in a number of forms (e.g., numerical, tabular, plot, 2D, 3D, animated, or descriptive) and may represent different levels of refinement (e.g., individual object/agent, a specified set of objects/agents, or the entire collection of objects/agents). Depending on the combination of form and refinement, the user will be able to deduce different information from the results generated— ranging from understanding possible causal factors to examining the conditions that were produced.

The completion of any project involving modeling will require the production of a set of deliverables that will support the desired outcomes. The user should be aware of both the model output that can be produced and whether it provides sufficient detail to satisfy the project deliverables. It may not be feasible to make use of a model when, for instance, a detailed understanding of the experiences of the simulated evacuees is required but only the final arrival time can be produced by the model. In addition, the techniques used within the model (e.g., artificial intelligence techniques, flow calculations, cognitive models, etc.) may not be capable of producing the output required by the project. For instance, a cognitive model may provide information on the decision-making process; however, it might not be able to provide a quantitative assessment of the overall evacuation time.

Project Timing and Funding

Finally, it is important for the user to understand the amount of time and funding allocated to the egress analysis of the project that may influence the selection of the model, potentially precluding those models from selection that are financially and/or computationally expensive and that then cannot be employed given the resources available.

Step 2: Model Selection

The next step in the modeling process, as identified in Fig. 60.2, is model selection. This section will highlight the key factors involved in choosing an appropriate computer evacuation model [3]. This task is often governed by matters of availability, expediency, and economics rather than based on selecting the model best suited for the task at hand. Of primary importance in the selection process is an understanding of the background of the models and their current characteristics (capabilities and limitations). By understanding these aspects of the model, the user can differentiate among the models available and make a more educated choice.

Background Research on Origin of Model

Understanding the background of the model is important in the selection process because it establishes the model development and model validation criteria.

Model Development The user should be aware of the group or individual who developed the model. For many models, information can

be found on the developer/developing institution from the model users' guide. The background of the development team may affect the abilities of the model to capture some of the more complex behaviors or actions of the occupants during an evacuation.

Model Validation An important aspect of model selection is determining the level to which the model has been subjected to validation. It is vital that the user obtain documentation from the developer and other agencies that have performed any type of validation to make his or her own judgments on the validity of the results produced and whether the validation is sufficiently detailed, reliable, and in an area comparable to that involved in the project. For instance, if the model has been validated using scenarios and/or data extracted from a small-scale building, would the validation performed be sufficient to warrant the use of the model in a tall building application? Validation studies help to identify the capabilities of the model as well as its limitations. These validation studies can investigate a number of different aspects of the model: quantitative performance, qualitative performance, functional performance, component-based performance, efficiency, speed, and scope [5]. The availability of the supporting data required to perform such comparisons can limit these vital evaluations. The user should develop his/her own suite of tests to provide a level of confidence in the validation process and an understanding of the use of the model.

Current computer evacuation models are validated using a variety of techniques including validation against code requirements, validation against fire drills or other people movement experiments/trials, validation against literature on past evacuation experiments (flow rates, etc.), validation against other models (see Weckman et al. [6] and Lord et al. [7]), and third-party validation. However, some current computer evacuation models provide no indication of validation of the model in the references available. It should also be recognized that validation is a challenging process constrained by the data available, and the complexity of the processes represented. It is critically important for users that validation efforts are documented in detail allowing them to make an informed choice; understanding (amongst other things),

- What validation activities have been undertaken?
- How these activities have been conducted?
- What aspects of the model have been validated?
- How relevant the validation is to the project at hand?

Model Characteristics

In addition to assessing the project requirements and model's developmental background, it is important to understand the current modeling capabilities and characteristics, thus enabling a comparison between the models currently available. By identifying and understanding the key capabilities and characteristics of the current evacuation models, the user will be able to make a more informed choice of the most appropriate model for the specific project. The key characteristics deemed to define the current evacuation models are displayed in Fig. 60.3.

Modeling Method The modeling method [8] is a feature of computer evacuation models that describes the level of sophistication used to calculate evacuation times for buildings. The modeling method can be broadly categorized as one of the following:

- *Movement models*. Those models that concentrate on the simulation of occupant movement and that do not have a behavioral component. These models demonstrate congestion areas, queuing, or bottlenecks within the simulated building. Also, within the movement category, there are some models that are specifically optimization models, meaning that they aim to optimize time in an evacuation through the exclusion of nonoptimal behaviors.
- *Partial behavior models*. Those models that primarily calculate occupant movement but also simulate evacuee behavior to some degree. Possible behaviors could be implicitly

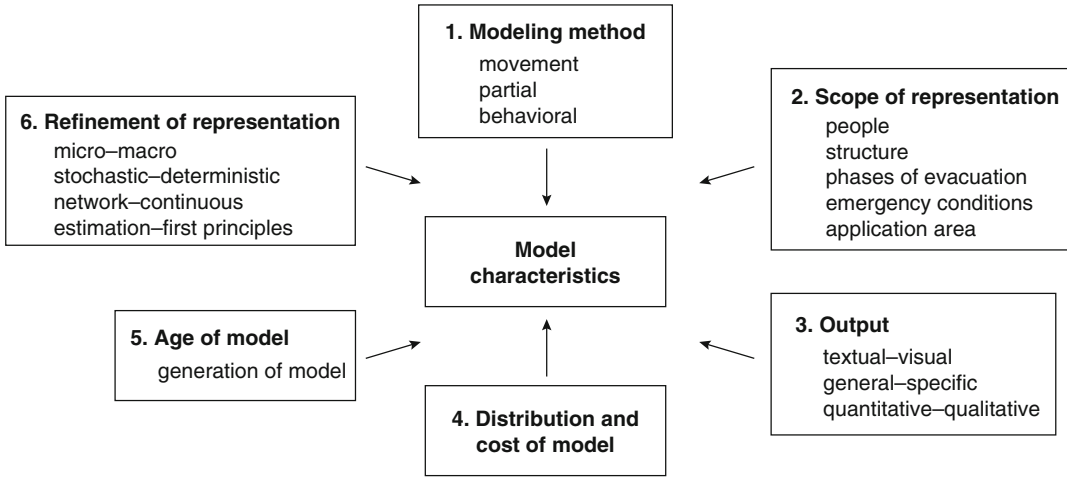

Fig. 60.3 Current characteristics of evacuation models [3]

represented by pre-evacuation time distributions among the occupants, unique occupant characteristics, overtaking behavior, and the introduction of smoke and its effects on the occupants.

- *Behavioral models*. Those models that incorporate occupants performing actions in addition to movement toward a specified goal (exit). These models can also incorporate decision making by occupants and/or actions that are performed due to conditions in the building. The behaviors simulated may detract from the evacuation performance of the individual or the population as a whole. Within this category, there are some models that have the capability of performing a risk assessment of the evacuation.

Scope of Representation Users should also be familiar with the differences in the scope or flexibility of how the models represent aspects of the evacuation, including the occupants, the structure, emergency conditions, the expected evacuee behavior, the procedures present (e.g., whether there are safety, operational and security procedures in place that may affect each other), and so on. Examples of the scope of representation include the simulation of the impact of occupants with disabilities, the inclusion of certain aspects of the structure (e.g., doorways, signage) via engineering plans, the number of phases of the event simulated (e.g., whether ingress, circulation and egress need to be considered), the procedural elements included (e.g., security, operational, safety, etc.) and the simulation of fire conditions and their impact on evacuees against their performance under non-emergency conditions. It is important to understand how a particular model represents/simulates certain aspects of an evacuation, especially if they are a key component of the scenarios required for the project in question. For example, if the project requires the simulation of a population that includes people with differences in age, gender, mobility impairments, and size, the user should ensure that the model has this capability.

Output The output is an important characteristic to consider when selecting a model. Many times, the interested parties will require more information from the simulation than simply the total evacuation time. Current models can provide a variety of output, including textual output (qualitative and quantitative), two-dimensional graphical output, and three dimensional/virtual reality interface. In addition, several models are able to have the nature of their output modified in order to fit the project requirements. Data formats are briefly discussed in Chap. 64.

Distribution and Cost of Model Model availability and cost are considered to be of primary importance, as the initial concern of the users will be to gain access to the model. Some models are distributed for local application, whereas other models are employed by their developers centrally with the results then distributed. In the former case, the model user is actually developing the input, running the simulations, and then analyzing the output; and in the latter, the user is working with the developing company and will have access to the output only. In reality, the model may be distributed in a number of different ways: the software is free of charge; available on a consultative basis; available via a flat rate fee; available under license control, or some combination of these methods.

Age and Generation of the Model In addition to availability, it is important for the model user to be aware of the age of the model and the developments/advancements since its release. In some cases, older models become dated, cease to advance in accordance with technology progress, and therefore become obsolete. Conversely, if it is seen that the developing organization of an older model continually updates and maintains the software, the user may be interested in using a more established model that has been continuously developed and has been involved in a variety of projects over the years. In the case of newly developed models, the user should be cognizant of its validation efforts, specifically if the model has been used for practical purposes and projects since its release.

Level of Refinement The level of refinement of an evacuation model describes to what level of detail the aspects of an evacuation, such as the population and structure, are simulated. The refinement of a structure reflects the method employed to represent the configuration of the building within the model and will also have an impact on how the movement of the occupant is represented. The user should be aware that an increase in refinement may require an increase in the effort needed of the user and an increase in the computer time needed to run the simulation. Computer evacuation models can differ regarding the refinement of the structure, the population, and the behavior of the occupants (if behavior is simulated at all).

The refinement of a structure can be categorized in the following way: a coarse network, a fine network, and a continuous network. A defining attribute of a coarse network is that the nodes do not need to be uniform, representing the actual shapes and sizes of rooms in a building. A coarse network divides the floor plan into rooms, corridors, stair sections, and so on, and the occupants move from one structural component to another (e.g., room to corridor). The fine network, on the other hand, produces a series of small, uniform nodes (in both shape and size). Each can be occupied typically by one person at a time. A fine network divides a floor plan into a number of small grid cells between which the occupants move. The defining attribute of a continuous network is that, instead of nodes, the structure is overlaid with x-y coordinate points, allowing occupants to travel through all possible space in a building. The continuous network applies a two-dimensional (continuous) space to the floor plans of the structure, allowing the occupants to walk from one coordinate to another throughout the building. Fine and continuous networks have the ability to simulate the presence of obstacles and barriers in building spaces that influence individual path route choice, whereas the coarse networks "move" occupants only from one portion of a building to another.

The refinement of a population refers to the method employed by the model to represent the population as either individuals (a microscopic level) or a homogeneous population (a macroscopic level). The refinement of behaviors refers to the method employed by the model to simulate behaviors of the occupants during an evacuation. These behaviors can be defined by the user or model (deterministic) or based on probabilities specified by the user (stochastic).

Given the rapid development of current computer evacuation models, any review attempting to categorize the models currently available may present data that are out-of-date. The categorization presented in the next section attempts to avoid this problem by limiting itself to the fundamental aspects of the models.

Review of Current Computer Evacuation Models

Currently, several evacuation model reviews exist [8–21] that attempt to explain and categorize the computer evacuation models. This section briefly reviews each computer evacuation model,[1] identifying fundamental characteristics of the models currently available. For a more detailed analysis of the models, the reader should refer to the reviews referenced above.

This section covers a total of 26 computer models that simulate emergency egress within the built environment, categorized by the model features outlined in the previous section [16]. Many of the models reviewed can also simulate evacuation from other types of structures; however, evacuation from buildings is the main focus of this review. The model features that will be highlighted involve the model's background and characteristics including the following categories:

- Developer information
- Validation
- Availability
- Modeling method
- Refinement of the population
- Refinement of the structure
- Refinement of the behavior (where behavior is simulated)
- Output

Specific information on each of the 26 models is provided in Table **60.1**. Accompanying references and links for each model can be found in the following references: Kuligowski and Peacock 2010 [16] and the Evacmod.net website [22]. To clarify the abbreviations provided in Table **60.1**, a key is provided.

[1] Certain commercial entities, equipment, or materials may be identified in this document in order to describe an experimental procedure or concept adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the entities, materials, or equipment are necessarily the best available for the purpose.

Once a computer evacuation model is chosen, it is often the case that the user has little guidance on possible model scenarios. Even the referenced material may omit information on how the model was configured and simply discuss in detail the results of the particular study. The next section is written from a user's perspective in order to present the key considerations in the creation of model scenarios, specifically focusing on the building, the population, and the procedures during an evacuation [9].

Step 3: Model Scenarios

Once the user is familiar with the project specifications, model features, and specifics on current models, the user should begin developing possible scenarios for model configuration. The purpose of this section is to outline the choices a user will have to consider and offer guidance on how to make the decisions that will eventually lead to application of the model.

In the following sections, the four aspects of scenario configuration will be introduced: the building, the population, the procedures, and environmental conditions. Within each category, the model user will be provided with descriptions of different methods of configuration within the scenario(s) for a project. Following this section on scenarios, the methods within each category will be displayed in an example.

Building Configuration

When using a computer evacuation model, it is up to the user to describe the building characteristics in a manner consistent with the method used by the model to represent the geometry of the building. This description includes the location of open spaces and walls, information on the stairs, and the location of the final destination of safety. The user may be required to provide these data in a number of different ways, according to the model features available. As described previously, the modeling method being employed to represent the structure will

- *F* Fine network
- *Co* Continuous

Refinement of the Behavior:
- *D* Deterministic
- *S* Stochastic

Output:
- *T* Textual output
- *V* Visual output

directly influence the results produced; therefore, the user should seek information within the user's guide and additional model reviews relating to the specific method being applied. The following sections describe the methods used in current models to configure the building:

- Structure generation
- Structure representation
- Additional building information

Structure Generation The first stage in this process is for the user to determine the format for incorporating the building geometry (known as grid or structure) into the model, which is dependent on the assumptions of the model. Broadly speaking there are three means by which a user can generate the structure and three means by which the models represent the geometry of the building.

There are three main ways that the user can generate the structure within the model. These ways are through computer-aided design (CAD) drawings, manual drawings, and text files. Although these methods can produce an accurate depiction of the structure, it is by no means a trivial activity; indeed the preparation of the engineering diagram can represent a significant proportion of the modeling process when dealing with complex structures. In addition, methods are now becoming available that reflect additional aspects of the building (e.g., BIM), the building as a three dimensional structure (e.g., Google Sketch-Up) and/or other aspects of the structure that might influence evacuee performance.

Alternatively, if an engineering diagram cannot be directly imported, the user is required to manually specify the building geometry, either by drawing it within the model or importing a text file that links building segmented areas to other areas on a floor plan. Several models provide users with the ability to select exactly how they wish to re-create the geometry of the structure within the model.

Structure Representation Irrespective of the means by which the user generates the structure within the model, there are methods by which the model represents the structure. If a coarse network is employed within the model, the model represents the floor plans of the structure as a segmented version of the building. This will normally relate to the connectedness and capacity of each of the structural components (i.e., rooms, corridors, hallways, and stairs) without specifying a detailed geometrical representation of the structure. This segmented version of the building would usually be in the form of a text file, manually or automatically produced from the architectural diagrams. This file identifies certain areas of the building and describes how they are linked together within the building. Many models that use a coarse grid structure do not accept CAD drawings and do not have a visual representation of the structure. This is an important consideration as it usually implies that the user will be expected to manually reproduce the geometry of the structure in some form without making reference to a visual representation of the geometry. Given the sensitivity of the results to this structure, the level of work required here and the likelihood of error in this process should be recognized.

When employing a fine grid structure, the model (via the user) overlays a mesh of small nodes throughout the occupiable space within the entire floor area. These nodes connect to each other to form the paths that occupants might use to travel between and within the structural components. The fine nodes are usually given a uniform default area that corresponds to the space normally occupied by one individual, unlike the coarse representation where the area of the nodes is governed by the configuration and by the user. Many of these models allow the importation of CAD drawings to make this procedure easier. The majority of the models that employ a fine node network are then based on the assumption that a node will only be occupied by one person at a time. Nodes are then generated automatically or manually to cover the occupiable space within the plan. These nodes are generally square, although other shapes have been used (e.g., hexagons). The choice of node size may affect the final evacuation time significantly, especially in the cases where an occupant can occupy only one node at a time. The user needs to understand how varying the node size impacts the results from a particular model [7].

Finally, there are several models that are categorized as continuous models. These incorporate the engineering (e.g., CAD) diagrams of the building and produce a continuous plane to represent both the occupiable space and the potential movement of the simulated occupants using a coordinate-based system. Consequently, simulated occupants move from coordinate to coordinate within the continuous space. Theoretically, this method should involve the least amount of user judgment and adaptation of the building representation.

Additional Building Information In addition to providing network linkages throughout the building, the user is sometimes required to enter additional building information into the model for each scenario. This information consists of areas, lengths, and widths of certain spaces (specifically with the coarse network models) and information about the stairs connecting floors. The stair information is not usually imported with the CAD drawing, since stairs are not strictly part of one floor plan, but rather a linkage between floors. Depending on the sophistication of the building representation, the model user may have to supply the following information: stair width, diagonal length between stories (discussed later in the chapter), riser and tread dimensions, and handrail information.

Summary of User Configuration of the Building When using a computer evacuation model, it is up to the user to describe the building characteristics in a manner consistent with the scenario and the methods used by the model to represent the building. This includes the location of open spaces and walls, information about the stairs, and the location of the final destination of safety. Each provides a different level of time and effort from the user, and the decisions made by the user affect the results produced by the model. Irrespective of the approach adopted, great care has to be shown to ensure that any simplifications made relating to the spatial representation are justified (and justifiable) and that the geometry modeled actually reflects these simplifications as stated.

Population Configuration

Once the structure has been produced, it needs to be populated before the simulation can proceed. In order to do this, the following information from the scenario needs to be supplied to the model:

- The number of occupants and their distribution throughout the building
- Occupant characteristics (e.g., age, gender, knowledge level, impairment, etc.)
- Movement data (e.g. achievable speeds, flow/density relationship, etc.)
- Pre-evacuation delays
- Specified behaviors and associated delays

It should be noted that within the model, the impact of these factors might not be completely independent of each other. For instance, occupant characteristics and pre-evacuation time might influence the time for an evacuee to commence movement; movement data and specified behaviors might influence the time to reach safety, etc.

As the model's sophistication increases, so the number of behavioral variables considered may also increase, potentially increasing the number of possible input parameters. It is then up to the user to select input parameters that specify the entire population, subpopulations, or individuals throughout the building. Often the models provide default values; however, the user should be informed about these defaults and make decisions about whether they pertain to the population involved in the project at hand. Default data sets are not necessarily appropriate for a particular scenario and it is not safe to assume that they necessarily are so.

As discussed earlier in the chapter, there are two fundamental methods to represent the evacuating population within the structure during the simulation. The simulated population can be represented at the micro level as individuals (shown by multiple arrows in Fig. 60.4) or at the macro level, as a homogeneous group given population-wide characteristics (as shown by one large arrow in Fig. 60.5). The method used by the model affects the decisions made by the user when implementing a specific scenario. For

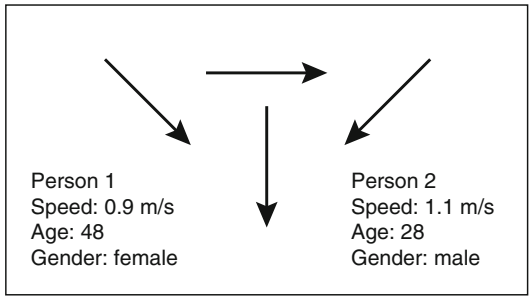

Fig. 60.4 The population represented at the micro level

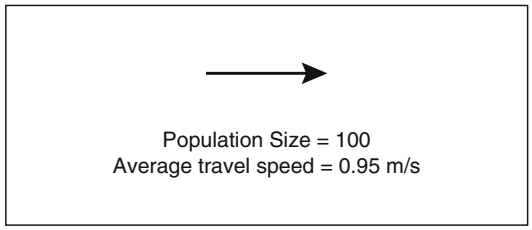

Fig. 60.5 The population represented at the macro level

instance, when the individual evacuee is modeled, there is the potential to simulate a range of personal characteristics for that individual. At the population level, the same attributes may also be included; however, these are assigned to the entire population as a whole.

Number of Occupants in the Building The first thing that a user will have to specify about the population inside the building is the number of occupants and their distribution throughout the structure. This calculation can depend on a variety of factors within a scenario, such as the building type, the locations of facilities/services located inside and outside of the structure, the floor space within the structure devoted to occupants, the date, and the time of day. Depending on the building type and simulation scenario, a particular season of the year and especially a particular day and time of day may warrant more occupants than another season, day, or time of day. For example, if a university building is being simulated, the number of people in the building increases during the months when school is in session and typically peaks between 9:00 a.m. and 3:00 p.m. on school days. The number of occupants influences the interaction between occupants, which therefore directly influences the following performance elements.

Occupant Characteristics Many factors need to be considered when choosing movement data because, in much of the existing evidence available, unimpeded speeds are influenced by gender, age, ability, and other occupant characteristics. If the model represented the population as homogeneous (on a macro level), the user would then need to provide the model with a higher-level representation of data (e.g., an average initial unimpeded movement speed for the occupants of the building) rather than including the details. Resources for movement data can be found in Chap. 64.

It should be noted that there is no correlation between increased sophistication in the refinement of the representation and accuracy. A high modeling sophistication does not necessarily indicate that the evacuation model uses and/or provides the appropriate data to model such behaviors. The user should be aware of the validation methods and associated limitations of each model used.

In addition to physical characteristics, some models allow for the knowledge levels of evacuees and other non-physical factors to be set; e.g., exit awareness, level of motivation, etc. These may influence the actions performed and the manner in which they are performed, depending on the model in question.

Pre-evacuation Times In addition to movement data, the user is confronted with the decision of selecting and applying a pre-evacuation time (i.e., the time between ignition and purposive response safety) for either the entire population or subpopulation (macro level) or for individual occupants throughout the building (micro level). The user will be faced with the following choices:

- No pre-evacuation times (i.e., no delay), where the pre-evacuation component is not

modeled or the response is assumed to be instantaneous (i.e., a best-case scenario)
- A specific time delay that is applied to the entire population
- A specific time delay for particular individuals throughout the building (for instance, with a particular trait or at a specific location)
- A distribution over the population of pre-evacuation times

Enormous care should be taken when importing pre-evacuation times into the model. The results produced and conditions within the scenario are likely to be sensitive to the extent and range of the pre-evacuation times provided. The pre-evacuation phase is often the most extensive phase of the evacuation and is always critical [1].

The nature of the pre-evacuation times employed will depend on a number of factors including the time of day of the event (e.g., was it nighttime when the evacuees initially would be asleep?), the type of alarm system in the building (e.g., was there a traditional bell alarm system or were more advanced techniques employed?), the expected exposure of the individuals to external social/physical cues, the activities of the occupants in the building (e.g., were they committed to an activity?), and the presence of staff. Although these factors should be considered, it is not suggested that the models currently available could explicitly simulate these factors. These factors may need to be implicitly simulated through the provision of suitable data to the model, placing a greater onus on the user.

Movement of Occupants Depending on the level of refinement utilized by the model, the user will need to make certain decisions regarding the movement data supplied for the simulated occupants. For the majority of evacuation models, the user is tasked with providing initial unimpeded movement speeds for the entire population. This may be a single value or be selected from a distribution of values.

The initial travel speed attribute is usually then modified according to the density of the surrounding population. The effect of speed versus density is usually either derived directly from the available density correlations (see Gwynne and Rosenbaum [2], Fruin [23], and Predtechenskii and Milinskii [24]) or calculated according to the position, route choices, trajectory, and/or separation distances of those around the individual in question. However, in some models, the user must provide the model with speed, flow, and density values for each space within the building. Again, whether the evacuees are represented as individuals or as a uniform entity will influence the detail in which the user may have to provide the data. At the individual level, movement speeds might take into consideration the range of abilities and mobility within a population and how these may interact, whereas at the population level, this effect would be averaged out across the population in question.

Behavioral Actions of Occupants In most real situations, there is a diverse set of actions that would be expected of the occupants in response to the incident. Similarly, there is a range of methods employed to simulate these actions—in terms of their nature, their impact and any associated delays that might be incurred when they are performed. In turn, the number of assumptions and the amount of data required by the models will vary greatly.

In order to represent the specific behavioral response of a population, the user may have to select and apply an expected behavioral response for a section of the population. In doing so, the user needs to understand the expected behavior of the population in the scenario, when and where this behavior occurs, and the expected consequences. An example might be that the user is aware of a daycare center in the middle of an office building. Given that this facility is provided to cater for the children of staff, the user might wish to simulate some office workers first traveling to the daycare before evacuating the building. (Refer to the case of the Summerland incident, where just such behavior was evident [25, 26].) As with the previous considerations, the level of refinement of the behavior is dependent on the representation of the population

(e.g., can the performance of individuals be tracked?) and the detail to which their movement is simulated (e.g., can the model assign itineraries?). This is just one example of a possible decision that the user may want to simulate involving behavior.

Models simulate behavior in different ways, including the following methods:

- Neglect to simulate behavior at all (response is then imposed and constant through the population)
- Simulate only occupant characteristics that affect movement
- Simulate behavior conditionally (individuals are affected by conditions within the building)
- Allow behavior to emerge adaptively such that behaviors are constructed according the conditions faced, the internal information available and some analysis of the situational picture available (attempting to simulate the decision-making process)

It is relatively common within those models that include a conditional representation that the user can specify certain behavioral actions for individuals or sometimes distribute certain probabilities of behaviors over a segment of the population. In such circumstances, the user is directly determining the actions performed by the evacuees. Therefore, the conditions under which the actions are performed, the likelihood of their performance (potentially 100 %) and the consequences of their performance (e.g., a delay of between 20 and 60 s or a change in the state of an object or person) should be based on empirical data and guidance wherever possible. Unfortunately, there is not a great deal of information or data on occupant behaviors during evacuations that can then be categorized according to the nature of the structure.

Summary of User Configuration of Resident Population Once the structure has been configured, information needs to be supplied to the model by the user including the number of occupants in the building, movement data, personal characteristics (e.g., age), pre-evacuation delays, and even specified behaviors. The level of detail and sophistication of the resident population simulated depends on the type of evacuation model chosen. See Chap. 57 for additional information on the design of occupant scenarios.

Procedural Configuration

The third area of the evacuation simulation that would need to be addressed is the procedures that are expected to be applied during an evacuation. These relate to credible situations within the scope of the project at hand to be simulated within the model. These may have been defined and presented to the user or arrived at by the user alone.

As the scenarios vary for the building, the user has to make a variety of choices on whether to include certain evacuation procedures and situations (assuming that the model is capable of representing the scenario in question). Considerations involving the configuration of the procedures include the following:

- The route choice of the occupants
- The existence of counterflow (i.e., the occupants and/or fire fighters)
- The inclusion and activity of human and technological resources

Many of these features are only included in the more sophisticated models. Also, since many of these features are specific to the evacuation models themselves, the user should consult model references and/or evacuation model reviews to find out the current information on the procedural capabilities.

Route Choice When simulating fire evacuation scenarios, a user should be cognizant of the occupant route choice. Several evacuation models offer choices as to the route that the population or portion of the population would adopt when evacuating the building. These choices might include the evacuees adopting the shortest route, optimally using exits according to their familiarity and experience, being assigned a predefined route, or configuring a conditional route. Many times, the default choice for the model will be the shortest route available; however, the user should be aware that this choice may not always represent the paths that

occupants will *actually* choose in a fire evacuation. A few models also provide the option of evacuating occupants via elevators and stairs. The route selection of the individual evacuees (if they are simulated individually within the model) will not only directly influence the outcome for the individual but will also influence the overall outcome for the structure. As such, this is a key component of the configuration process.

Representing Emergency Responders Another consideration for alternative evacuation scenarios is the presence of emergency responders in the building. This is primarily of interest in the interaction that they might have with the evacuees and the changes that they may bring to the availability of routes and the environmental conditions. Some of these aspects would be beyond the models currently available and would, therefore, require implicit modeling.

If the user is interested in simulating this type of counterflow situation, then there are several models that have this capability, which is achieved in a variety of different ways. For instance, it might require the provision of the percentage of stair space taken up by the counterflow at certain times, providing a general delay caused by counterflow (i.e., implicitly representing the counterflow) or assigning an itinerary to a group of occupants (e.g., the fire department), so that the group travels to a designated area of the building that causes them to interact with the evacuees (i.e., explicitly modeling the counterflow generated). This would depend on having a relatively detailed understanding of the procedures employed by the fire department and might be sensitive to a range of issues including the body size of this emergency group.

Representing Human and Technological Resources The simulation of a scenario with the explicit inclusion of a human or technological procedural measure that directly affects evacuee performance (e.g., the impact of alarm type or the presence of staff on pre-evacuation time) is a relatively rare capability in the existing set of evacuation models. Most of the models currently available do not have the capability of explicitly simulating this effect. Instead, the impact is more typically represented indirectly or implicitly with numerical values (i.e., timing) assigned to represent the impact [9].

Summary of User Configuration of Procedural Actions The third area of the evacuation simulation involves the procedures that are expected to develop during an evacuation. These relate to credible situations within the structure that need to be addressed within the scope of the project and simulated within the model. These may have been defined and presented to the user or arrived at by the user alone. Specific examples of the decisions made by the user include the route choice of the occupants, the provision of countermeasures (i.e., the counterflow of occupants and/or fire fighters), and the inclusion and activity of staff.

Incident information

When modeling a fire event, the user has to consider the initial location(s) of the fire, depending upon the number of different scenarios simulated. Along with this decision, the user should decide how to coordinate any information about the fire event with the simulation of the occupants in the building (i.e., how closely coupled is the simulation process with the development of the fire?). Depending on the nature of the model, the effect of the fire might be supplied by the user or represented within the simulated environment.

Evacuation models have different means of incorporating fire information with the evacuation process, including no fire representation, input of fire information manually, importation of calculated fire information, and coupling with a fire model. Several models have no representation of the fire conditions. Within these models, the user would have to manually determine when the conditions reached a level that would influence the behavior and well-being of the

evacuees. This would require assumptions to be made on behalf of the user that would directly influence the results produced. Some models allow the user to input fire information manually, requiring the user to either derive a description of a fire suitable for the scenario in question or apply empirical data. Other evacuation models allow fire model results to be imported in order to inform the calculations of how the environmental conditions change during the simulation. In this case, the user would need to be able to configure the fire model appropriately and ensure that the conditions produced within the fire model reflected the same scenario conditions that were being represented within the evacuation model (e.g., position and status of doors). A few of the evacuation models have a fire model built into the program. It is up to the user to decide which method is best to use for the specific project.

Summary of User Configuration of Incident Information The fourth area of the evacuation simulation involves the location and impact of the incident. Examples include the location of the fire and the inclusion of toxicity or fire data.

Summary of Model Scenarios

The examples presented in this section are meant to provide users with guidance when examining and designing scenarios for a project. This section has been designed to provide guidance on the factors that should be considered when using an evacuation model.

Grid size, as well as other user inputs that are occupant-focused (e.g., occupant numbers, occupant size, and occupant speed) may affect the results of the evacuation model. For more information on how inputs can affect evacuation model results, see Lord et al. [7].

Example of Evacuation Model Scenario Configuration

The total evacuation from a high-rise building will illustrate the types of concerns relating to the use and configuration of an evacuation model. This will provide the user with an example of the configuration process to use as a reference. (See Chap. 57 for additional information on the design of occupant scenario's for life safety analyses.) The following paragraphs will describe the building and the scenario.

Although this example does not incorporate results from any specific model, research has been done to highlight differences in results when multiple models are used on the same building [4, 6, 7, 27–29].

Scenario Information

Only one scenario will be discussed in this section to provide an example of the kinds of decisions that users will make when configuring an evacuation model. In this scenario, a fire initiates in a guest room on the 5th floor at 2 a.m. The reason for choosing a fire initiating at 2 a.m. is to provide an example of a worst-case scenario for a hotel building due to the fact that most guests will be in their rooms sleeping. In this scenario, the fire event will trigger a full-building evacuation.

As mentioned previously, the user is faced with decisions on how to configure the building, the population, and the environment. The following discussion provides examples of decisions made for this specific scenario in each category of configuration.

The building used for the example is a hypothetical office/hotel building. The office/hotel building has 20 stories, with each floor occupying an area of approximately 1200 m^2. The distance measured between floors (floor height) is approximately 3 m. The first 10 floors (floors 1–10) consist of a segmented floor plan typical of hotel rooms and the top portion of the building (floors 11–20) consists of an open floor plan used for office space. There are two 1.11 m (44 in.) stairs located on either side of the floor plan that serve all floors in the office/hotel building. It is assumed that the user has been given this design to evaluate for life safety purposes. In reality, the design may be far more complex. However, this design should be sufficient to illustrate the processes at hand.

The following additional information is provided to the user for this scenario:

- The hotel portion of the building is occupied by people on business and leisure travel.
- The hotel has a limited 24-h staff.
- The fire department is located across the street from the hotel.
- Once an alarm sounds in an area of the building, a staff member will investigate. The staff member then decides whether to sound the main building alarm.

The plans for the hotel space on each of the 10 floors (floors 1–10) are identical and the floor plans for the office spaces (floors 11–20) are assumed to also be identical. The floor plans for floors 1–10 and 11–20 are displayed in Figs. 60.6 and 60.7, respectively. In this example, the ground floor is not considered. Therefore, in order to reach an area of safety as part of this life safety analysis, all occupants in the building will move past floor 1, down two flights of steps, and out the final exit.

Building Configuration

The model user is faced with a variety of decisions when configuring the building. Depending on the type of grid/structure method employed by the model, the user will have to construct a coarse network, fine network, or continuous network within the floor plan of the building. Examples are provided here for each type of network. In addition, the user must also make decisions about adding extraneous building information, such as stairs and exits.

Coarse Network When using a coarse network, the network does not explicitly represent all of the occupiable space. Therefore, the user is required to artificially segment the structure in order to produce components that will appear in the network. It is not always apparent how best to segregate the structure and, therefore, represent the structure within a coarse network model.

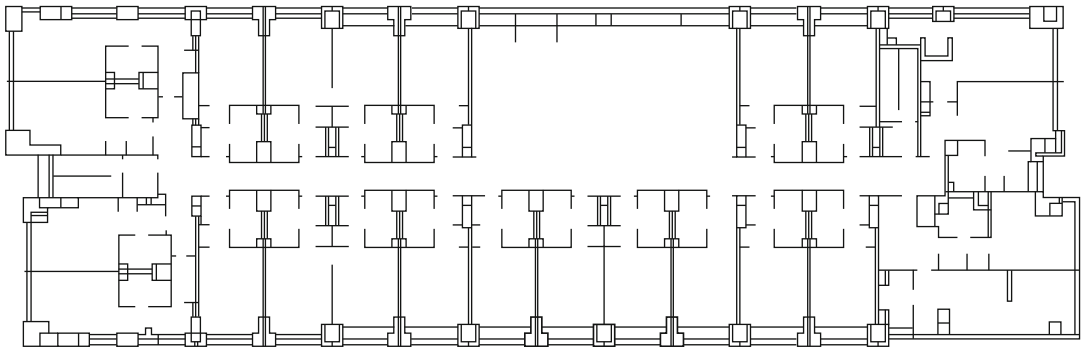

Fig. 60.6 Floor plan of floors 1–10 (the hotel space)

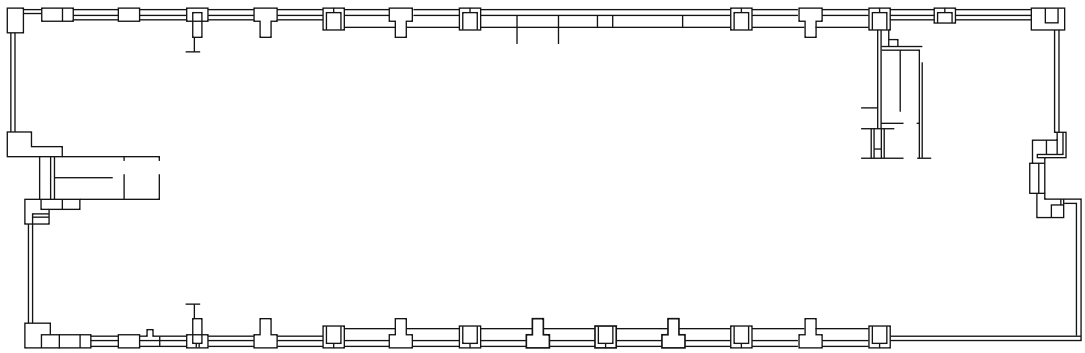

Fig. 60.7 Floor plan of floors 11–20 (the office space)

As mentioned previously, this segmentation will have a direct impact on the results produced. Figures 60.8 and 60.9 are used to demonstrate the different (and equally viable) ways to segment the building for a coarse network. Figure 60.8 shows the open office floor plan that is divided into 12 "user-derived" sections (derived in that they are not immediately apparent from the architectural description of the structure) with each connecting arc. This derived design leaves a longer rectangular box for the hallways and finally two sections for the stairs on either side of the floor plan. In a coarse network, the model simulates that the occupants will move from the middle of one segmented area to the middle of another (with which it is linked). The segmentation of the structure will, therefore, directly influence the movement of the occupants and the routes that may be adopted. Often open floor plans are difficult to segment because users are not privy to the eventual segmentation that each company will employ when the building is in use. Therefore, it is up to the user to provide segmented areas that are representative of how occupants might move throughout this space to safety as shown in Fig. 60.8.

In contrast, Fig. 60.9 provides a different example of larger segmented spaces of the same structure. This space is segmented into fewer office sections than in Fig. 60.8 (eight in total) and two staircase sections. Although this example requires less time to produce, it might not accurately represent occupant movement through this space. When segmenting out any space in a building, the user might want to run sample simulations of each floor plan to analyze the simulated occupant movement to determine whether the movement path and times are representative.

Figure 60.10 shows a segmentation of one of the hotel floors of the example building. The majority of the segmented areas relate to the hotel guest rooms. Therefore, there is less scope for flexibility in the association of nodes

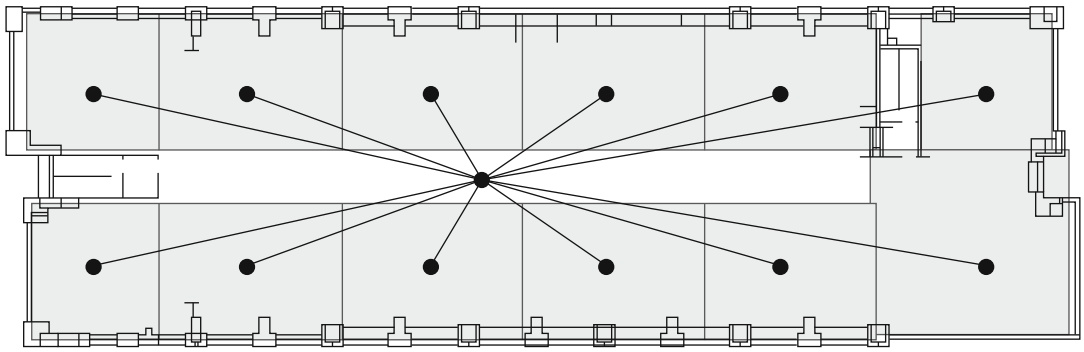

Fig. 60.8 First example of the segmented office floor plan

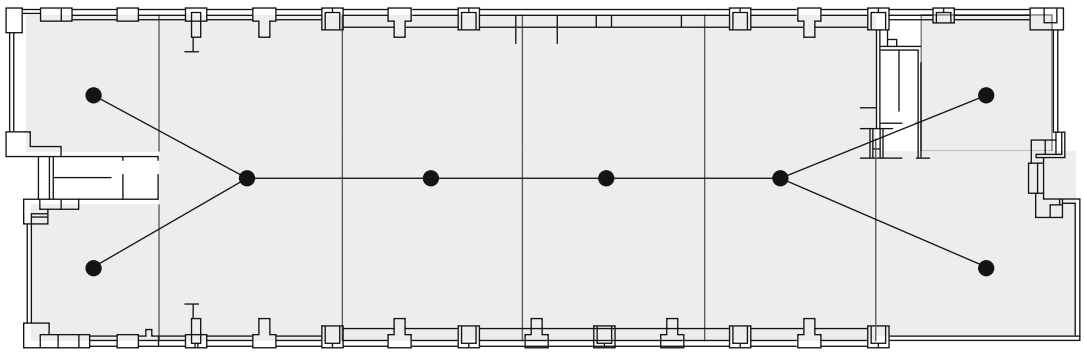

Fig. 60.9 Second example of the segmented office floor plan

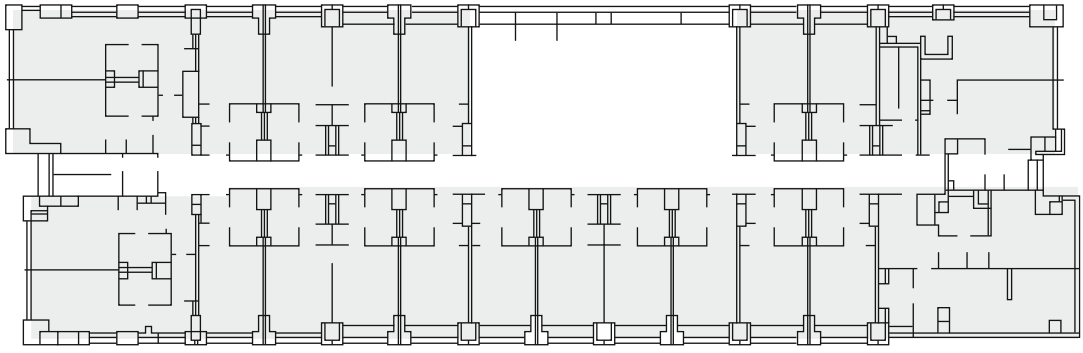

Fig. 60.10 Physical segmentation of hotel design providing a more apparent coarse node network

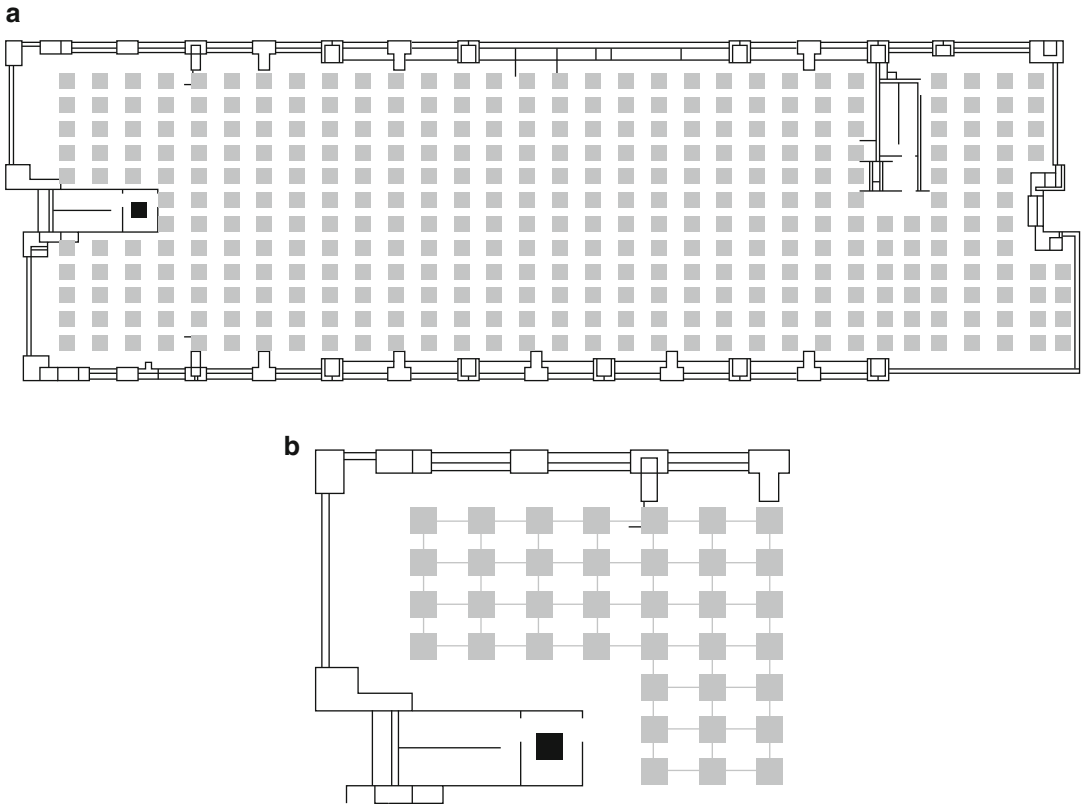

Fig. 60.11 (**a**) Fine nodal mesh; (**b**) horizontal and vertical connections between nodes

with compartments. In this floor plan, the physical structure adequately defines the separate spaces required. The main area of flexibility in the association of the design to a coarse network is the large hallway. Depending on the length of the hallway, the space might require multiple segmented areas rather than representing it as a single node.

Fine Network Grid Figure 60.11a shows a meshed open floor plan for a fine network grid. In comparison to the coarse network, the fine network requires a larger number of small nodes to mesh the geometry. Also the fine network grid is performed at a different level of refinement with the mesh relating directly to occupiable space rather than compartments.

Instead of describing the passage of individuals between components, the nodes are describing the movement of evacuees at a much higher resolution. In Fig. 60.11b the initial steps in this process are shown where the nodes displayed are connected horizontally and vertically. Normally this process would continue to also include diagonal connections to provide the occupants with a greater degree of freedom in their movement.

Figure 60.12a shows the hotel floor plan partially meshed with a fine nodal grid. This is a time-consuming and error-prone procedure if performed manually, given the number of nodes that need to be produced and the precision with which they would need to be positioned. Normally this process would be automatic or semi-automatic, with the mesh being calculated and imposed by the model. Even so, the user would need to check and modify the mesh to determine whether the algorithm in question had represented the occupied space with sufficient accuracy. Figure 60.12b is color coded (shown in different shades of gray here) to show that the connectivity of the rooms should reflect the ability of the simulated occupants to move from space (or component) to space. In other words, the simulated occupant would not be able to pass through a physical barrier (e.g., a wall) that might be present in the actual structure.

Continuous Network Figure 60.13 shows the occupied space within the hotel structure as depicted by a continuous network. As previously described, a continuous network model represents the building floor plan as a continuous plane that simulates the occupants' movement on a coordinate-based system over all occupiable space. Instead of occupants occupying blocks of

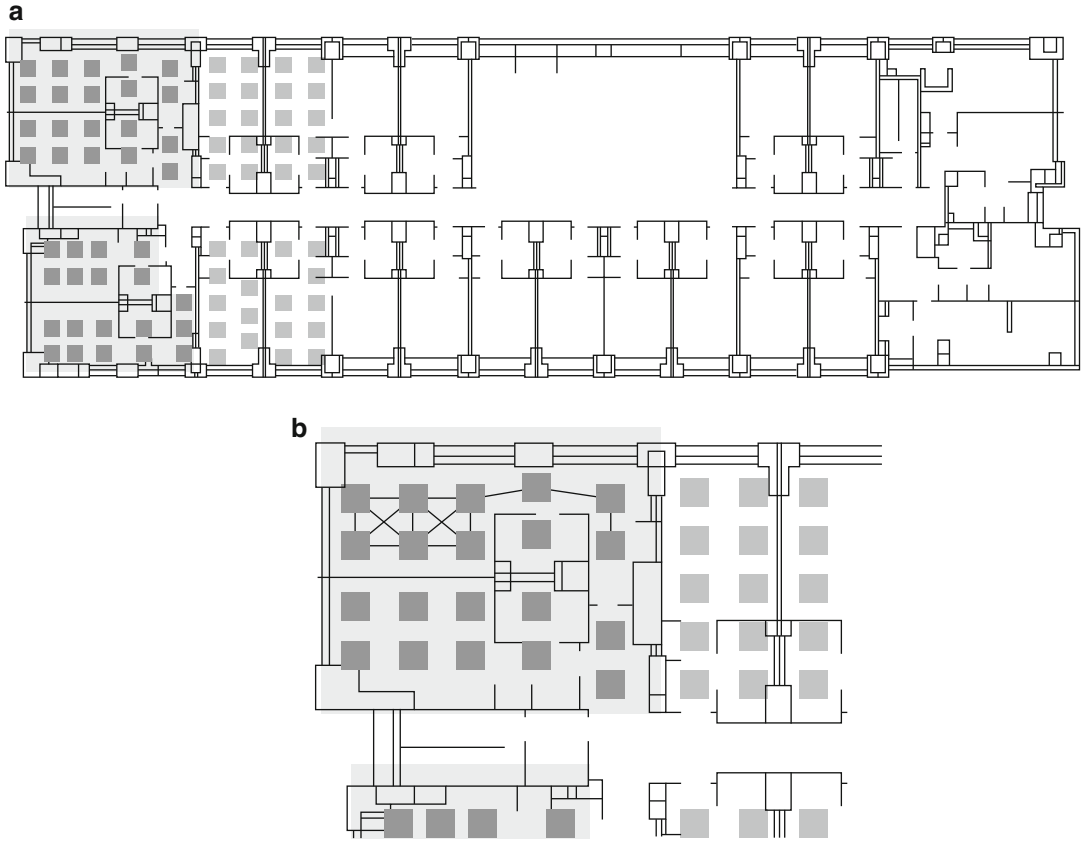

Fig. 60.12 (**a**) Example of fine mesh applied to hotel geometry; (**b**) connectivity of a section of this geometry

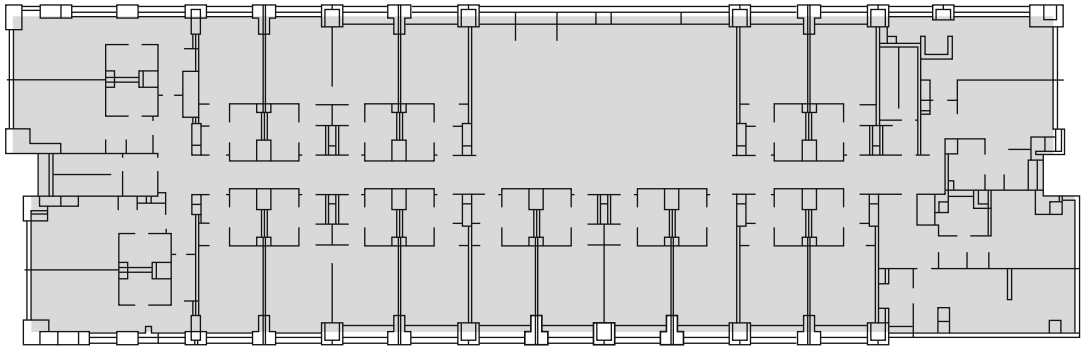

Fig. 60.13 Occupiable space within the hotel structure, represented by a continuous plane

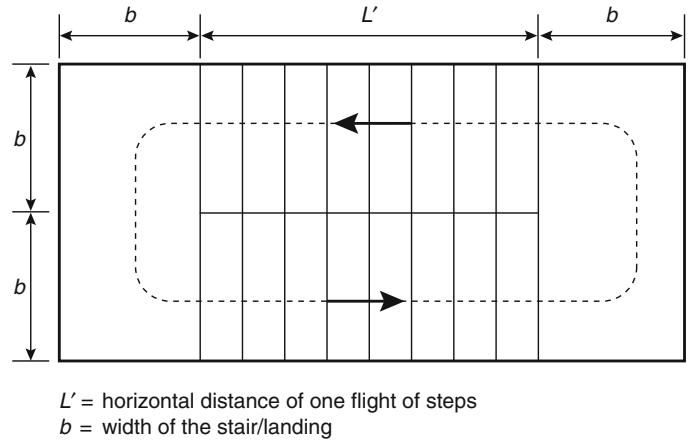

Fig. 60.14 Graphic drawn to explain the stair calculation (Predtechenskii and Milinskii [24], p. 28)

space (coarse network) or square nodes (fine grid), a continuous model simulates occupant movement on a flowing *x*-*y* (and *z* for multiple stories) coordinate system. In most instances, this provides a more accurate representation of the floor plan of a building.

Additional Building Information

In addition to the method with which sections of the building are represented and connected, the model also requires the user to identify information about the stairs and exits (location, width, etc.). In this example, there are two 1.1 m (3.6 ft) wide staircases, one at each end of every floor in the building. Depending on the model, the user may be required to provide the distance along the staircase between floors, either the diagonal distance or the horizontal distance. In both cases, the distance along the landings should be taken into account within the distance calculation. In addition, some models allow the user to incorporate certain distances that the simulated agents will remain away from the walls of the stairwell (e.g., to represent a handrail inside the staircase).

An example of a method used to calculate the diagonal distance along a two-flight staircase measuring 1.1 m (3.6 ft) in width, wall to wall, is provided here. For this example, a staircase flight is the portion of the stair that extends half the distance between floors (Fig. 60.14). Following the development of Predtechenskii and Milinskii [24], Equation 60.1 is used to calculate the diagonal distance of one of the stairs located in the hotel/office building.

$$L = \left[2L^{'} / \cos\ (\theta)\right] + 4b \qquad (60.1)$$

where
L = the total diagonal distance of two flights
L' = the horizontal distance of one flight of steps
θ = the inclination of the stair at each flight
b = the width of the stair/landing

In the case of the example, b is equal to 1.1 m (3.6 ft), L' is equal to 2.0 m (6.56 ft), and the angle of the stairs is 37°, which corresponds to 3 m (10 ft) between floors with 8 steps at 19 cm by 25 cm (7.5 in. by 10 in.) riser and tread for each flight. With these values inserted into Equation 60.1, the diagonal distance of the stairs is calculated to be 9.5 m (31 ft).

Evacuation models also require the user to identify the location of the exits within the building. In this example, the exits are placed at the bottom of the staircase directly below floor 1. The occupants reach the exit once they have traveled down the final staircase and out of the 0.9 m (36 in.) door present.

Population Configuration

All evacuation models require the user to specify characteristics about the population in the building. These characteristics, depending on model sophistication, can include the number of people in the building, movement speeds/flows, pre-evacuation times, and specific behaviors. Macroscopic models, for example, require the user to provide only the number of occupants located in the building and/or in specific sections throughout the building and characteristics representative of the entire population instead of individuals. Therefore, the user need not identify specific information about the occupants other than the number and a representative speed and flow for the population. Identifying the number of occupants in the building, which is required by all models, will be described in the following paragraphs.

Number of People Most building evacuation computer models require the user to specify the number of people in the simulated building evacuation. If the project does not specify the number of people, the user can use information on the building type and available floor space to calculate the number of people using occupant load factors [30]. The occupant load factors provided by NFPA *101*®, *Life Safety Code*®, are estimations of the maximum probable number of occupants present in the building type at any time. (Studies have been done [31] showing that the design loads in NFPA *101* may grossly overestimate the number of people expected to be in particular types of buildings.) For a day-time scenario, the NFPA occupant load factors would be used to estimate a conservative number of occupants on each floor of the office space. The maximum occupancy of the hotel rooms will be used as an example to estimate the occupancy of the hotel floor plans.

For a fire initiating at 2 a.m. on the fifth floor of the office/hotel building, it is expected that there will be more people located in the hotel portion of the building compared with the office floors. Using the maximum occupancy figures for each hotel room, 100 occupants per floor are estimated for the hotel room floors. However, due to the time of the scenario (2 a.m.), only 10 people per floor are assumed for the office floors. These people are included to simulate cleaning staff and the possibility of overnight workers.

Overall, the population of the building is estimated to be 1100 people in the entire 20-story building. This number includes 100 people per floor on the hotel floors and 10 people per floor on the office floors.

Movement Another occupant characteristic provided by the user is unimpeded movement speeds of the population and/or individual occupants in the simulated building. For macroscopic models, the user is required to provide an average or overall speed (unimpeded) for the entire population. On the other hand, microscopic models require the user to provide specific information on characteristics of groups within the simulation in addition to the number of occupants in the building. These can include individual speeds (unimpeded), body sizes, and disabilities.

For the hotel/office building example, there are certain factors that can affect the movement speed of individuals in a building. The following list includes factors to consider when choosing unimpeded movement speeds for members of the population:

- The distribution of men/women within the structure
- The age of the occupants simulated
- The body size of the occupants simulated
- The presence of occupants with disabilities

In the case of the 2 a.m. fire scenario, it is of particular interest that the user understands the characteristics of the hotel population expected in the building at the time of the fire. As discussed earlier, some evacuation models require the user to supply only movement speeds for the entire population. For this type of information, please see Chap. 64. However, there are evacuation models that require the user to specify information about the individuals in the simulated building. Since the majority of the people in the building at the time of the fire will be located in the hotel floors, the majority of the research on individual characteristics for this scenario will be made on the hotel population.

Occupant Characteristics Although difficult, the user can obtain information about the gender and the age of the occupants expected to be in the hotel portion of the building at the time of the fire. The scenario information provided in this example specifies that the hotel is expected to house individuals on both leisure and business travel at any time throughout the year. References such as D.K. Shifflet's DIRECTIONS Travel Information System [32] and the American Hotel and Lodging Association [33] contain a wide variety of information from U.S. hotels such as the percentages of male and female guests, a distribution of the ages staying at hotels for all types of stays (e.g., business or leisure stay), and the additional percentage of children present during leisure trips.

With this type of information, the user can identify the type of occupants in the building, according to the requirement of the evacuation model used. Once an occupant population is determined, information on movement speeds of individuals or groups of individuals based on occupant characteristics can be found in Chap. 64. An example of how hotel distribution information has been used to identify the probability of certain occupant sets has been completed by Stiefel et al. [34].

In addition, if the user and/or the project require the simulation of occupants with disabilities, it is important to understand the number of occupants with disabilities expected to frequent this hotel or, in general, hotels within the United States. With that number in mind, there are sources that provide information on unimpeded speeds of occupants with disabilities [35–37].

Pre-evacuation Time Depending on the model, the user may have the opportunity to provide information on pre-evacuation time for the overall population or individual/groups within the building. In the case of the hotel/office building, the literature provides some guidance on data that could be used to represent the pre-evacuation times for an office building and for a hotel building, depending on the factors just mentioned (see Chap. 64).

If the model allows for the assignment of pre-evacuation times to individuals, the office occupants should be assigned a separate distribution from the hotel guests, thereby implicitly simulating the different responses that may be expected given the role and activity of those involved. However, if the model views the population from a macro level, as with the movement data, an average can be assigned to the entire population, being less sensitive to the differences within the populations in question.

When simulating pre-evacuation times, the hotel population should be assigned a pre-evacuation time that takes into account the time of day that the fire will occur. Since the fire in this example occurs at 2 a.m., it is very likely that the hotel population will be sleeping. Before evacuating their room, the occupants will likely need time to wake up to the sound of the alarm,

dress, retrieve needed items (i.e., glasses, wallet, purse, etc.), and wake any other occupants sleeping in their room or in other rooms nearby. When assigning pre-evacuation times to hotel buildings, because there isn't a large amount of recent information [35], it might be more useful to research pre-evacuation times for apartment buildings as well [38].

Behavior/Actions Finally, the user may wish to assign behavior itineraries or actions to certain individuals during the simulated fire evacuation. Many of the evacuation models available do not provide this option to the user; however, for those models that do, the user should be aware of the lack of data in this area. There have been studies done on behaviors performed by occupants in certain building fire evacuations (e.g., see Chap. 58), which can be used to simulate specific behaviors during an evacuation.

For the example with the hotel/office building evacuation, the user can specify that certain hotel occupants, before evacuating, "visit" other hotel rooms to awaken occupants for evacuation. Or, if there are sufficient data available on turn-back behavior in smoke, the user can simulate that certain occupants turn back when/if the smoke becomes too hazardous to travel through. These are only examples of behaviors that can be simulated. Any behaviors that users do simulate, however, should be accompanied by the appropriate data to support such simulations.

Procedural Configuration

Route Choice In the case of the hotel/office building, even though the choice of exits might appear obvious, it would be beneficial to run several different scenarios where the routes adopted by the occupants differ to determine the sensitivity of the results to the choice of route and the robustness of the structural and procedural design. If alternative scenarios are run such as simulating a predefined route as well as a shortest-route option, the user can compare the results and then make suggestions for improvement. If the user is interested in simulating occupants traveling first to a daycare center or other points located in the building and then evacuating, the user would have to make sure that the model had the capability of a predefined route choice.

Representation of Emergency Responders Another procedural choice of the user is to decide whether it is necessary to include the simulation of emergency responders during the evacuation. In the case of the hotel/office building example, the local fire station is located directly across the street from the simulated building. Since the response time of the fire department is expected to be less than 2 min, it is important to consider the simulation of counterflow of the fire department in the stairs, as long as the evacuation model is capable of simulating such activity. Because the response time of the fire department is expected to be short and the response time of the occupants to evacuate is expected to be higher (greater than 10 min), the simulation of the interaction of fire fighters and occupants in the stairways should be considered.

Representation of Technological and Human Resources Last, although many evacuation models do not have the capability of simulating the presence of staff or alarms, the user should consider whether this is an important part of the evacuation to simulate. With the hotel/office building example, staff is available 24 h per day; however, the nighttime staff is limited. Similarly, the same hotel may have a voice alarm system that is present in each of the guest rooms. The user might consider whether these factors will have an effect on the pre-evacuation time of the occupants if they are active during the incident. There are limited data on this feature of an evacuation scenario, but they should be

kept in mind when running scenarios of a fire evacuation and should certainly be discussed when presenting the assumptions on which the simulated scenarios are based.

Incident information

When performing a life safety analysis of a building, the user should simulate a number of different scenarios. In each fire scenario, the user has to decide the location of the fire source. In the hotel/office building example, there are many different locations where a fire could be assumed to begin. Statistics on fires in offices and/or hotels can be consulted to obtain probable places of origin [39]. These statistics depend on the type of building, the time of day, the type of facilities in the building (e.g., hotel kitchen, laundry area, office space, main lobby, etc.), and the possible activities of the occupants (e.g., can occupants smoke in their hotel rooms?). Information can be obtained from NFPA statistics, including the top causes of civilian deaths, causes of injuries, causes of property damage, and frequent areas of origin. The guest room was chosen as the area of origin for this example because even though only 12 % of hotel and motel fires began in bedrooms, these fires caused a majority of the deaths and injuries [39]. Potential causes of this scenario's fire, based on NFPA data, could be intentional, cooking equipment (in the room), and even heating equipment [39]. Scenarios should be run with guestroom doors held open and closed along with fires beginning in other areas/rooms throughout the building.

User Checklist

The discussion in the previous section outlines the types of factors that need to be examined when configuring and applying computational tools. In many cases, it may not be possible to represent all of the factors in the detail desired. This might be due to issues of time, cost, data available and/or modeling limitations. However, irrespective of whether these factors are addressed, the engineer should be mindful of them when configuring the tool, describing what is (and what is not) addressed in the scenarios examined, and in presenting the results.

Figure 60.15 provides a brief checklist of the types of factors and issues that the user should address when selecting and configuring an evacuation model ready for application within a project specification. This list is by no means exhaustive but should at least prompt the user to address the issues that have been discussed in this chapter. Reference should also be made to Chap. 57, where matters of scenario design are discussed in more detail.

Summary

This chapter has provided an overview of 26 current egress models and developed a checklist to be applied when using a new model. Guidance for applying many of the features found in these egress models has been provided. It is not suggested that the guidance provided in this chapter is sufficient for the user to perform the analysis required. However, it is contended that for many, especially those who are relatively inexperienced in egress modeling techniques, the guidance provided is necessary. This chapter could then act as a companion chapter to those provided within this volume to outline the process of egress analysis from the initial identification to the delivery of the end product.

All modeling is a result of compromise and represents a simplification. The guidance provided in this chapter should highlight the decisions that need to be made, the information that is required to make these decisions, and the tools needed to complete the simulation and analytical process. In effect, it acknowledges that compromises have to made, but such compromises must be informed so that they can be defended.

Erica D. Kuligowski is a fire protection engineer and sociologist in the Engineering Laboratory at the National Institute of Standards and Technology (NIST). Her research interests include human behavior in fires, and other emergencies, including preparedness, responses, and recovery behaviors, behavioral modeling of response and recovery; and emergency communications.

Visibility and Human Behavior in Fire Smoke

61

Tokiyoshi Yamada and Yuki Akizuki

Introduction

This chapter presents the scientific basis for establishing effective safety evacuation countermeasures, that is, evacuation plans, escape signs, and so forth in case of fire. The data were obtained in Japan, but should provide more general guidance internationally. In particular, issues of physical and physiological effects of fire smoke on evacuees are addressed. The chapter consists of three sections: (1) visibility, (2) characteristics of human behavior, and (3) development of an intensive system for escape guidance in fire smoke.

In Japan, since the 1960s, an increasing number of people have been killed by smoke in fire-resistant buildings. Toxic gases and/or depletion of oxygen in fire smoke are the final causes of death of those victims. However, many evacuees are trapped in an early stage of fire by relatively thin smoke, and loss of visibility is an indirect but fatal cause of death. For this reason, the relations between the visibility and optical density of fire smoke were examined experimentally, and practical equations were proposed.

For further understanding of inability of human behavior in fire smoke, many investigations were conducted by interviewing evacuees and analyzing questionnaires. Also, experimental research was carried out with subjects under limited fire smoke conditions and the threshold of fire smoke density for safe evacuation was examined.

Through many field investigations of fires, it is found that an effective guidance sign system is required for safe evacuation in fire smoke. Improvements of conspicuous exit signs have been conducted under various conditions i.e., size, shape, luminance and/or adding flashing light sources. Also, special types of escape guidance instruments were developed. One involves a continuously traveling flashing light source system, the effectiveness of which was examined in a smoke-filled corridor with reduced visibility. The other is a directional sound escape guidance system; its effectiveness was also examined in a smoke-free corridor. These innovative technologies for safe evacuation are now in practical use in Japan in a large underground shopping mall and in facilities used by people with impaired sight and hearing. The former technique is already found in floor lighting of passenger aircraft cabins.

Visibility

Introduction

Generally speaking, three factors are closely related to visibility: environmental conditions, object's conditions and human visual ability. The former two factors define visual stimulus,

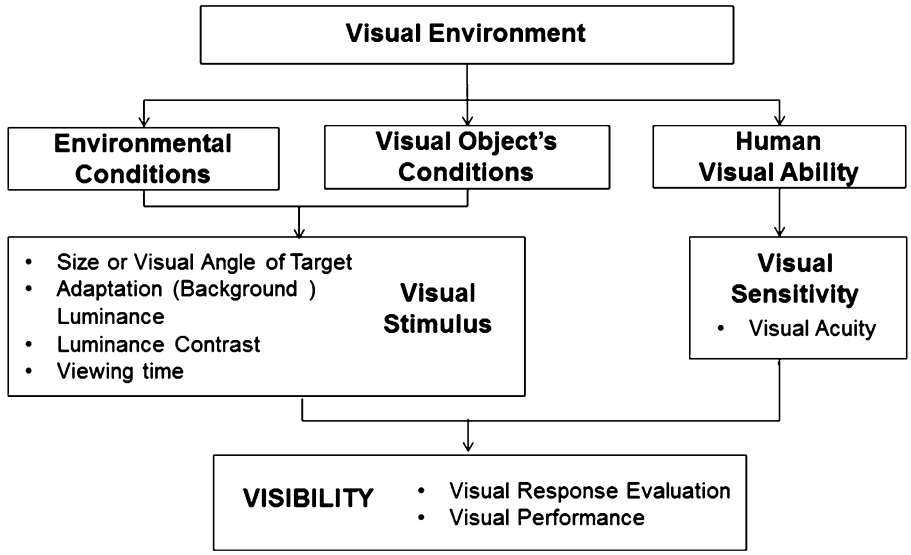

Fig. 61.1 Evaluation system for visibility

and the latter one defines visual sensitivity. Visual response evaluation, namely visibility depends on both visual stimulus and visual sensitivity. Visual stimulus is represented by four elements, namely size [m] or visual angle [minutes] of a visual target, adaptation (background) luminance L_b [cd/m^2], luminance contrast between the visual target luminance and background luminance, and viewing time. If the viewing time is more than 100 ms, the visibility becomes stable regardless of time [1]. The evaluation system of visibility is shown in Fig. 61.1. We can treat visual response evaluation and visual performance, like visible distance or threshold value, as the visibility. Human visual ability consists of many functions like field of view and color sensitivity and so on, but usually the most important is visual acuity (VA).

Visual Acuity

Visual acuity (VA) shows clearness of vision, which is dependent on the sharpness of the retinal focus within the eye. VA can be defined the spatial resolution of the visual processing system, and measured by identifying the direction of characters like letters and numbers on a test chart from a set distance. Normally VA refers to the ability to resolve two separated points or lines, but there are other measures of the ability of the visual system to discern spatial differences. The chart characters are represented as black symbols against a white background for maximum contrast more than 0.9. The distance between the observer's eyes and the test chart is set at a sufficient distance to approximate infinity in the way the lens attempts to focus.

Visual acuity is often measured according to the size of letters viewed on a Landolt ring chart or the size of other symbols, such as Snellen chart or Tumbling E.

The Landolt C (see Fig. 61.2) consists of a ring that has a gap, thus looking similar to the letter C. This is identical to the letter C from a Snellen chart. It was developed by the French ophthalmologist Edmund Landolt, and this optotypes was adopted in 1909 at the 11th International congress of Ophthalmology. The Landolt C is the standard optotypes for visual acuity measurement in most European countries and Japan. It was standardized, together with measurement procedures, by ISO 8596–2009; ophthalmic optics -visual acuity testing—standard optotypes and its presentation [2]. The ISO specifies a range of Landolt C optotypes and describes a method for measuring distance visual acuity under daylight conditions for the purposes

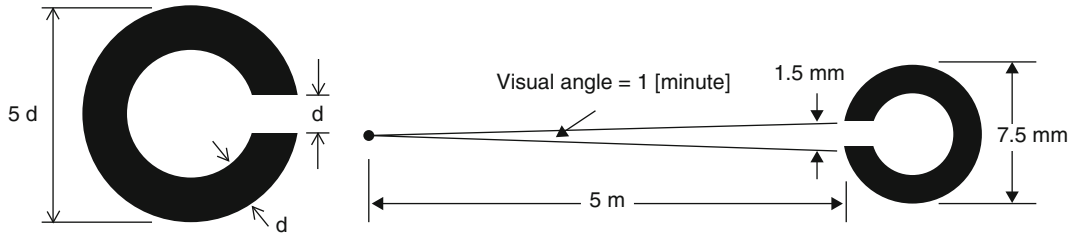

Fig. 61.2 Landolt C as the standard optotypes for visual acuity test

of certification or licensing. The stroke width is one-fifth of the diameter, and the gap width is the same. The height and width of the optotypes (letter) is five times the thickness of the line. The gap can be at various positions (usually left, right, bottom, top and the 45° positions in between) and the task of the tested person is to decide on which side the gap is. The size of the C and its gap are reduced until the subject makes a specified rate of errors. The minimum perceivable angle of the gap is taken as measure of the visual acuity. In the decimal system, the visual acuity is defined as the reciprocal value of the size of the gap (measured in arc minutes) of the smallest Landolt ring that can be reliably identified. Normal visual acuity is frequently considered to be what was defined by Landolt C as the ability to recognize an optotypes when it subtended 1 min of arc (1.00 decimal) or Snellen's chart 20/20 ft (6/6 m). For example a person who can correctly identify Landolt C on the 1.45 mm gap from 5 m distance, i.e. he can discern the gap that are separated by a visual angle of 1 arc minute, his visual acuity is described as 1.0. There is no unit of visual acuity value by Landolt C.

The charts usually display several rows of optotypes (test symbols), each row in a different size (see Fig. 61.3).

A Snellen chart (see Fig. 61.4) is an eye chart used by eye care professionals and others to measure visual acuity. Snellen charts are named after the Dutch ophthalmologist Herman Snellen who developed the chart in 1862. The traditional Snellen chart is printed with 11 lines of block letters. The first line consists of one very large letter, which may be one of several letters, for example E. When printed out at this size, the E on line one will be 88.7 mm (3.5 in.) tall and

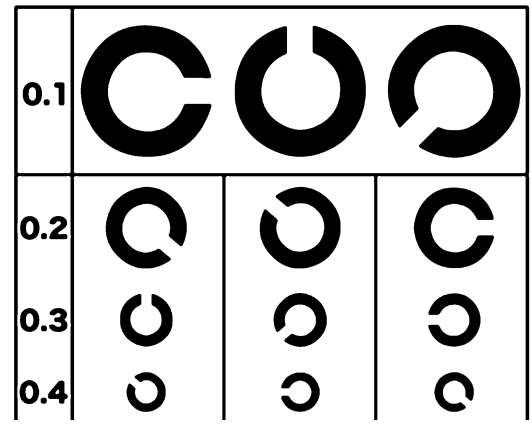

Fig. 61.3 Landolt C optotypes

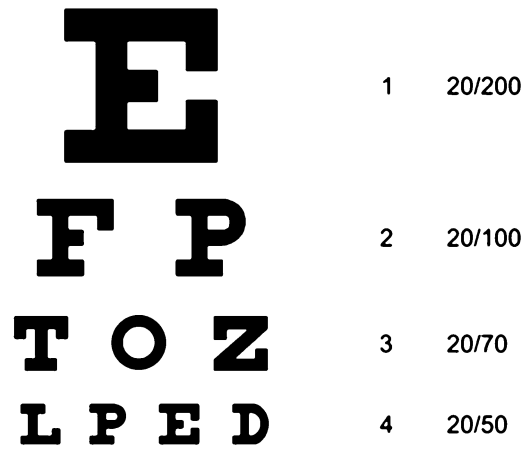

Fig. 61.4 Snellen optotypes

when viewed at a distance of 20 ft, you can estimate your eyesight based on the smallest line you can read. At 20 ft, the letters on the 20/20 line should subtend 5 min of arc. Outside of the US, the standard chart distance is 6 m,

normal acuity is designated 6/6, and other acuities are expressed as ratios with a numerator of 6. If the room don't have 6 m available, and either a half-size chart subtending the same angles at 3 m, or a reversed chart projected and viewed by a mirror is used. By Snellen's normal visual acuity is commonly referred to as 20/20 vision, the metric equivalent of which is 6/6 vision. At 20 ft or 6 m, a human eye with nominal performance is able to separate lines that are 1 arc minute apart a value of 1.0 is equal to 20/20.

Effect of Age on Visual Acuity

There is a significant difference of visual acuity not only among age groups (young/aged) but also among individuals [3]. Figure 61.5 shows the relationship between age and visual acuity by Landolt C chart at near point.

Visual acuity is much better in bright light than dim light. Figure 61.6 shows the relationship between visual acuity and background luminance of Landolt C Chart (the contrast is 0.94) for different age groups [4]. Visual acuity was enhanced with higher luminance. In Fig. 61.6, there are large variations among individual results, but positive correlations were confirmed between visual acuity and background luminance. Equation 61.1 shows the relationship between luminance and visual acuity in the two age groups.

$$VA = \gamma \times (\log_{10} L_b + 1.85)$$
$$\because \gamma_{\text{aged}} = 0.17, \gamma_{young} = 0.34 \quad (61.1)$$

where visual acuity is VA[-], the background luminance of Landolt C chart is L_b [cd/m^2], and age-related constant number is γ[-]. Equation 61.1 shows that the visual acuity of the aged group consistently was about one half of that of the young group under any luminance levels. Therefore, representing visibility under light conditions meant considering age differences by visual acuity.

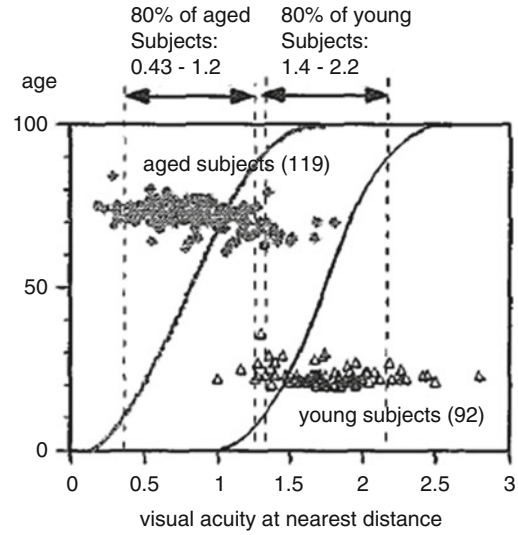

Fig. 61.5 Relationship between age and visual acuity at near point by Landolt C chart [3]

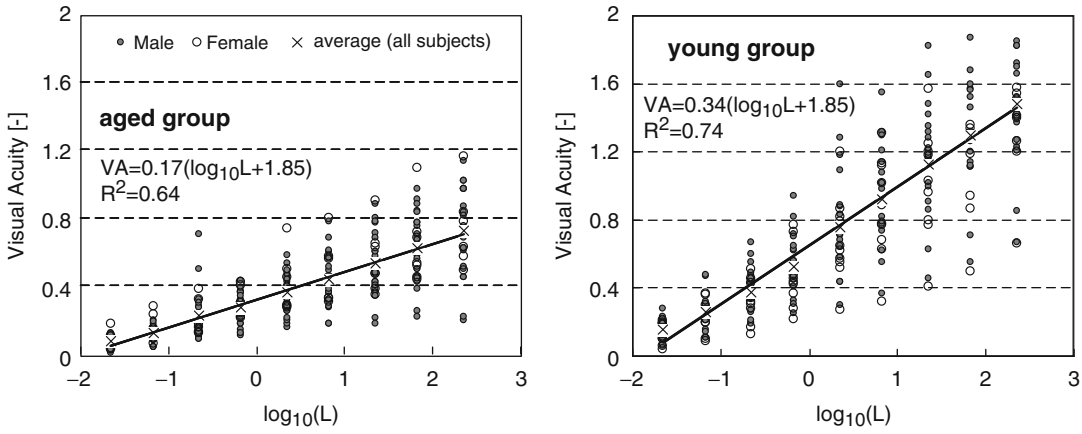

Fig. 61.6 Relationship between background luminance and visual acuity [4]

Visibility in Fire Smoke

Introduction

There has been much research on visibility in fog in the past, whereas relatively little research has been carried out on visibility in fire smoke. This difference is due mainly to the physical characteristics of these composite particles. Fog is composed of water mist and the individual particles are spherical. The particle size is also relatively stable in time and space. These simple characteristics enable a visibility model in fog to be developed. On the other hand, the characteristics of fire smoke, that is, composition, shape, and size of the particles, depend on the combustible materials involved and the conditions of combustion. These characteristics are also highly dependent on surrounding flow and temperature fields and vary with time.

Figure 61.7 shows the result of measuring the relationship between visibility and smoke density on the extinction coefficient obtained from experiments performed in Japan [5]. Data vary under different smoke conditions although the correlation is roughly linear. There are two reasons for the decrease in visibility through smoke: (1) luminous fluxes from a sign and its background are interrupted by smoke particles and reduce its intensity when reaching the eyes of a subject, and (2) luminous flux scattered from the general lighting of corridors or rooms by smoke particles in the direction of a subject's eyes is superimposed on the reduced flux mentioned in (1).

The human eye can distinguish a sign from the background in smoke only when the difference between the luminance of the sign and the background luminance is larger than some threshold value of luminance contrast, that is, when the following Equation 61.2 can be established between the sign's luminance L_t[cd/m^2], the background luminance L_b[cd/m^2], and the threshold value of luminance contrast, δ_c:

$$\left|\frac{L_t - L_b}{L_b}\right| \geq \delta_c \qquad (61.2)$$

The value (the threshold contrast of signs) varies depending on the intensity of luminous flux from the background and the properties of smoke, but particularly when discussing the visibility in a meteorological fog, a constant value $\delta_c = 0.02$ is normally employed for both day and night.

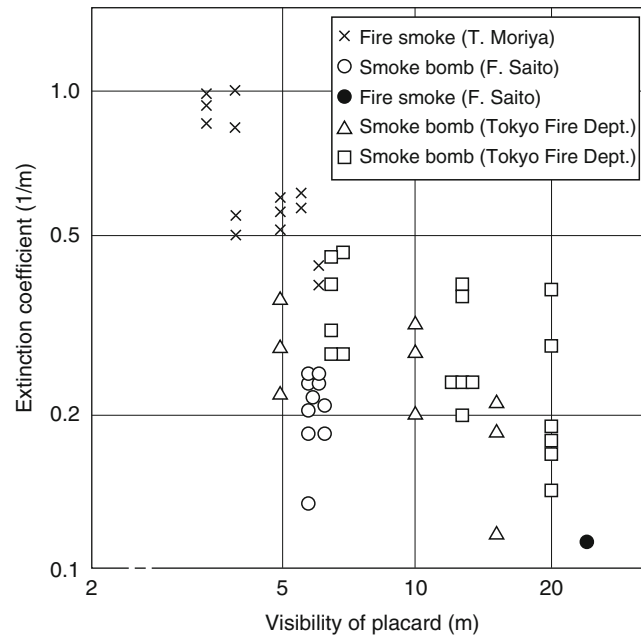

Fig. 61.7 Relation between visibility of the placard-type signs and extinction coefficient by the experiments performed in Japan [5]

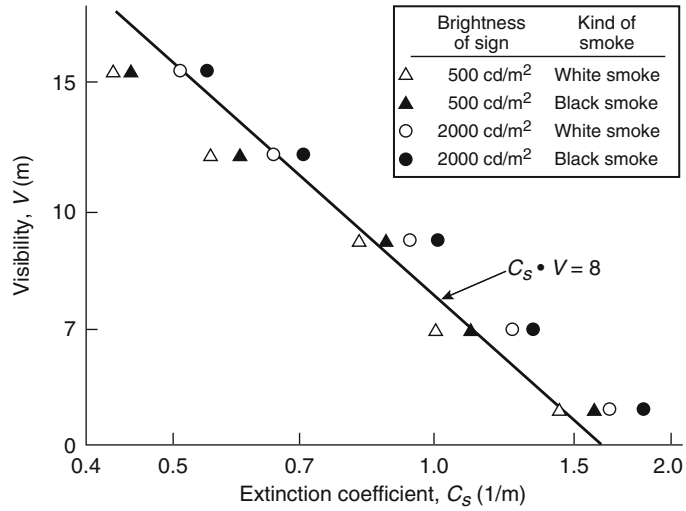

Fig. 61.8 Relation between the visibility of self-illuminated signs at the obscurity threshold and smoke density (extinction coefficient)

Smoke Density and Visibility

Development of a mathematical visibility model based on physical parameters has attracted some researchers, but it is very complicated and tends to be of little practical use. A simple visibility model for signs seen through fire smoke is proposed by Jin as Equation 61.3 [6]:

$$V = \frac{1}{C_s}\log_e\left(\frac{L_t}{\delta_c \alpha E/\pi}\right) \qquad (61.3)$$

where

V = Visibility of signs at the obscuration threshold [m]

C_s = Smoke density expressed by the extinction coefficient [1/m] (hereafter, smoke density will be expressed by the extinction coefficient in 1/m[1])

L_t = Brightness of signs [cd/m^2]

δ_c = Contrast threshold of signs in smoke at the obscuration threshold (0.01 ~ 0.05)

$a = \sigma_s/C_s (0.4 \sim 1.0)$ and $C_s = \sigma_s + \sigma_{ab}$ (σ_s: scattering coefficient; σ_{ab}: absorption coefficient)

E = mean illuminance of illuminating light from all directions in smoke [lm/m^2] or [lx]

The signs in a smoke-filled chamber were observed from outside through a glass window. The results are shown in Fig. 61.8. This shows the relation between the visibility of self-illuminated signs at the obscuration threshold and the density of smoldering smoke (white) or flaming smoke (black). In the range of the visibility of 5–15 m, the product, k, of the visibility, V, at the obscuration threshold and the smoke density, C_s, is almost constant as expressed in Equation 61.4.

$$V = k\frac{1}{C_s} \qquad (61.4)$$

The visibility in black smoke is somewhat better than in white smoke of the same density; this remarkable difference in visibility is not recognized among smokes from various materials. For reflecting signs, the product of the visibility and smoke density is almost constant as well. The product depends mainly on the reflectance of the sign and the brightness of illuminating light. The visibility, V, at the obscuration threshold of signs is found to be

[1] Note that the extinction coefficient C_s can be obtained by the following equation:

$$C_s = -\frac{1}{D}\log_e\left(\frac{I}{I_o}\right)$$

where

I_o = The intensity of the incident light [cd]

I = The intensity of light through smoke [cd]

D = Light path length [m]

$$V = \frac{5}{C_s} \sim V = \frac{10}{C_s} \quad \text{for a light-emitting sign} \tag{61.5}$$

and

$$V = \frac{2}{C_s} \sim V = \frac{4}{C_s} \quad \text{for a reflecting sign} \tag{61.6}$$

The visibility of other objects such as walls, floors, doors, stairways, and so forth in an underground shopping mall or a long corridor varies depending on the interior and its contrast condition; however, the minimum value for reflecting signs may be applicable.

Visibility of Signs Through Smoke

Visibility of exit signs: Additional experiments on visibility of various signs in nonirritant white smoke have been conducted [7] under similar conditions to obtain empirical formulae. There are two types of exit sign currently used in Japan. One is rectangular and the other is square type. The technical standard of the latter was newly prescribed in 2000 by the Fire and Disaster Management Agency [8]. The ordinary type has a light box with an internal light source and a pictograph is lit from behind. As for the new type exit sign, a pictograph is lit from the side section at the top of the pictogram plate by using an inner scattering effect. There are three sizes, i.e. "Small" or "C-class", "Medium" or "B-class" and "Large" or "A-class" with different light sources respectively. The visibility of three exit signs as listed in Table 61.1 was examined.

The data describe above [6] were somewhat scattered, however the correlation expressed by Equation 61.4 in additional experiments [7] is more precise and suitable to the data as shown in Fig. 61.9.

The obscurity threshold is about 10 m for ordinary light-emitting exit sign and 13 m for new small exit sign under 1.0 [1/m] smoke density condition respectively, whereas the B-class exit sign is twice as visible as others due to size effect.

It should be noted that the constant k in Equation 61.4 tends to be larger than the previous data indicated by Jin [6, 9]. Therefore these experimental data were obtained under nonirritant white smoke without background light source condition.

Collins showed other results of visibility of exit signs through smoke [10]. Twelve exit signs of different design were evaluated. Results indicated the importance of sign luminance in determining the visibility through smoke. Signs with mean luminance above 70 [cd/m^2] required substantially greater optical density value for obscuration and longer time to disappearance. The optical density required to obscure these signs was between 0.07 and 0.16 [1/m], in line with the densities

Table 61.1 List of test exit signs and visibility in smoke

No.	Type	Appearance	Size (cm) height × width	Light source	Average luminance (cd/m^2)
1	Ordinary type exit sign (small)		12.5 × 36.0	One fluorescent light tube of 10 W	700
2	New type exit sign (B class)		22.5 × 22.5	One CCFL (cold cathode fluorescent lamp) of 3 W	800
3	New type exit sign (C class)		14.0 × 14.0	One CCFL of 2 W	250

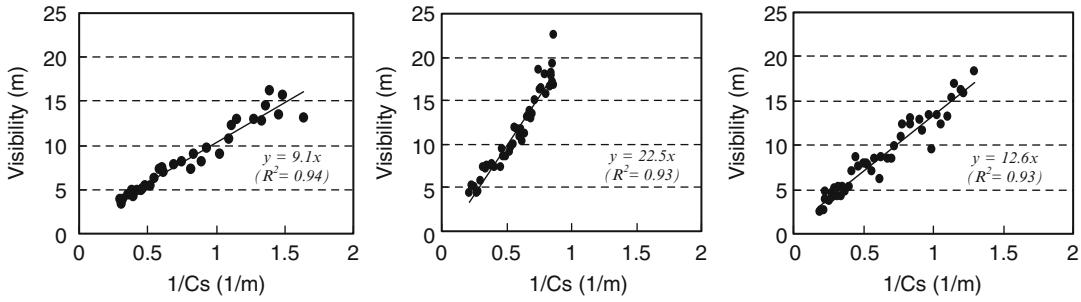

Fig. 61.9 Relation between the visibility of ordinary exit sign at the obscurity threshold and inverse of smoke density through nonirritant white smoke (*left*: Small, *middle*: B-class, *right*: C-class)

observed by Rea [11]. Also Jin [9] determined that exit signs with higher luminance were more visible through smoke.

Visibility of Emergency Lights

There are various types of emergency lights in different installation locations such as buildings and ships The main purpose of the lights is to preserve light in case of power failure. And it is also expected to work for aiding evacuation where no exit signs are equipped such as stairwells in buildings or engine rooms in ships etc. The configuration of the emergency light, i.e. size, color and luminance etc., is different from those of the exit sign as above, and the visibility and the conspicuousness through smoke is different as shown in Table 61.2. Visibility of such emergency lights depends on luminance intensity and distribution of light. General types of emergency lights can be seen at about 10 m under 1.0 [1/m] smoke density condition as mentioned above. In general, narrow light distribution giving high luminance intensity like halogen lamp #1 type improves visibility, however it should be noted that the narrow light beam is too directive to recognize it as a light source from outside of luminous area under thick smoke condition. It is not conspicuous once evacuees stay away from the light axis.

Visibility of Colored Signs

Figure 61.10 shows the change of the relative spectral extinction coefficient (ratio of spectral extinction coefficient to that at a wavelength of 700 nm) with time for smoldering wood smoke. It indicated that reduction of the longer wavelength (red light) is small compared with the shorter wavelength (blue light) in fire smoke. And the reduction (gradients of the curve in the figure) changes with time due to change in the size of smoke particles. In practical aspect, the result supports common knowledge, i.e. "red colored signs are more visible and stable compared with blue colored signs in fire smoke".

The figure shows that the visibilities of red-lighted signs are 20–40 % larger for smoldering smoke. This fact indicates that visibility varies by only a few tens of percent at the most by changing the color while keeping the brightness constant. If we need to double the visibility of a conventional sign, there is no other way but to increase the brightness by a significant factor (see Equation 61.3).

Decrease of Visibility in Irritant Smoke

A 20-m-long corridor was filled with smoke corresponding to an early stage of fire; a highly irritant white smoke was produced by burning wood cribs with narrow spacing between the sticks,

Table 61.2 Lists of test emergency lights and visibility in smoke

No.	Type	Purpose of utilization	Light source area		Max-luminance (cd/m^2)[a]	Illuminance (tx)[b]	Regression linear function	
			Appearance	Size (cm)			Slope (k_1_)	Intercept (k_2_)
1.	Ordinary emergency light	Emergency light and exit sign used for ship		9.5	10,000	7	4.5	3.4
2.	Hanging lamp	Emergency light		13.0	1000	3	9.2	2.1
3.	Halogen lamp #1	General purpose, (unidirectional)		5.5	10,000	690	47.6	−6.3
4.	Halogen lamp #2	General purpose (wide-directional)		5.5	60,000	34	32.9	−3.9
5.	MIL standard emergency lamp	Emergency light based on US military specification		10.0	16,230	103	8.9	2.0

[a]"Max luminance" was the highest luminance of light source surface
[b]"Illuminance" was the vertical illuminance from 1m against the light source center

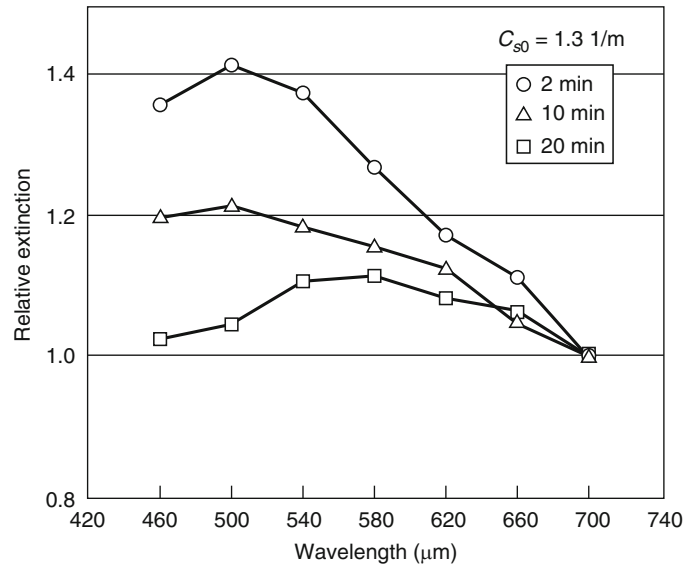

Fig. 61.10 The change of the relative spectral extinction coefficient with time for smoldering smoke from wood. C_{s0} = Initial smoke density

and a less irritant black smoke was produced by burning kerosene. The subjects were instructed to walk into the corridor from one end, or to record the places where they saw a lighted FIRE EXIT sign (signs of the type used before 1982) at another end, or to read the words on the signs [6, 9].

For the obscuration threshold of the sign, the following relation can be found: $C_sV \cong$ constant.

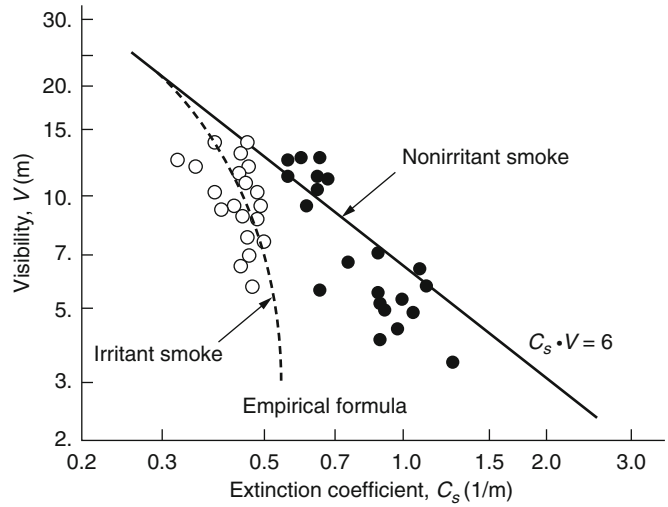

Fig. 61.11 Visibility of the FIRE EXIT sign (signs of the type used before 1982) at the legible threshold of the words in irritant and nonirritant smoke

However, for visibility at the legible threshold of words, this relation can only apply to nonirritant smoke, as shown in Fig. 61.11.

The visibility in irritant smoke decreases sharply at a smoke density exceeding a certain level. In thick irritant smoke under 0.5 [1/m], the subjects could only keep their eyes open for a short time and tears ran so heavily that they could not see the words on the signs. However, in this case when the exit signs are very simple or sufficiently familiar to the occupants to be recognized at a glance, this irritant effect of smoke may not cause so much trouble in locating the exits. Whereas evacuees cannot keep their eyes open in thicker irritant smoke over 0.5 [1/m]. The smoke irritation reduces the visibility and gives physical annoyance such as sneezing for evacuees and consequently there will be a possibility of needless unrest or lose countenance [12, 13]. The smoke hazards of concern are found not only in such psychological reactions, but also in evacuees' actions, especially walking speed as mentioned in the following section.

Decrease of Visibility Due to Smoke Adhesion on Signs

Under a fire, we have to treat the effects of absorption and scattering of smoke on luminous stimuli: the background luminance, target luminance and luminance contrast. Another factor to

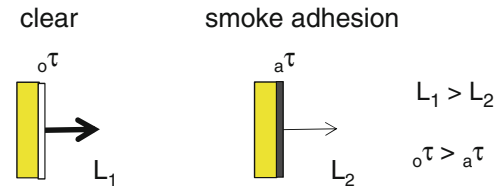

Fig. 61.12 Concept of effect of smoke adhesion on sign's luminance

be considered is that smoke emitted by the fire adheres to the sign surface, light sources, and surrounding walls, causing deterioration of transmission ratio and insufficient light. Therefore, all of them need to be incorporated into the calculation of sign's visibility (see Fig. 61.12). This section proposes a calculation model of target luminance in fire-smoke taking into account of smoke adhesion [14]. The luminance reduction rate due to smoke adhesion ζ is obtained as Equation 61.7 respectively,

$$\zeta = \frac{L_1 - L_2}{L_1} = 1 - \frac{L_2}{L_1} = 1 - \frac{a^\tau}{0^\tau} \qquad (61.7)$$

where L_0 is the initial luminance [cd/m^2], and L_1 and L_2 are the transmitting luminance through glass/acrylic panels [cd/m^2]. $_a\tau$ ($_a\tau \leq {}_0\tau$) is the smoke-adhered transmittance of smoke-adhered glass/acrylic panels, and the initial transmittance of glass/acrylic panels is $_0\tau$ ($0 < {}_0\tau \leq 1$).

Considering the emergency signs, we examined two materials, i.e.: glass (for light sources)

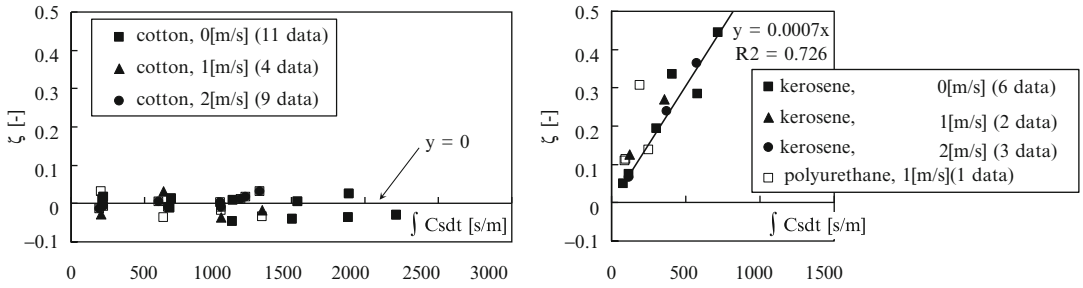

Fig. 61.13 Relationship between e and C_s [14]

and acrylic plate (for emergency signs). It can be concluded that it is not necessary to concern about the effects of the material on smoke adhesion. Rather, fire source affects much more the value of ζ.

As ζ obtained from ${}_a\tau$ is a cumulative result after the transient exposure to smoke in the experiment, we perform the integration of C_s for total exposure time ($\int C_s dt$). In Fig. 61.13, the values of ζ of two kind of smoke (smoldering and flaming smoke) are plotted to versus $\int C_s dt$ for each ventilation velocity. Both kerosene and soft-polyurethane of flaming smoke show linear correlation between ζ and $\int C_s dt$ with similar values of regression coefficient, while in the case of cotton ζ remains around 0 irrespective of $\int C_s dt$. The ventilation velocity may affect the relationship but the difference among the ventilation velocity is not so significant, as long as the present experiments are concerned. We obtained a common regression line for kerosene and soft-polyurethane because they tend to show similar correlations.

Therefore, the relation between ζ and $\int C_s dt$ is represented by

$$\zeta = \eta \int C_s dt \tag{61.8}$$

where the regression coefficient η [m/s] is adhesion coefficient. Adhesion coefficients of three fire sources are obtained from the above data irrespective of ventilation velocity as follows:

$$\eta = const. = \begin{cases} 0.0007 & (Flaming\ Kerosene\ and\ Polyurethane) \\ 0 & (Smoldering\ Cotton) \end{cases} \tag{61.9}$$

The adhered transmittance ${}_a\tau_e$ can be interpreted as the ratio of the non-adhered area to the total area of the object panel. It is considered that area with no smoke adhesion maintains the initial transmittance τ_e. Subscript "a" at the left of transmittance and reflectance means smoke adhesion. ${}_a\tau_e$ can be estimated by

$${}_a\tau_e = \tau_e(1-\zeta) = \tau_e\left(1 - \int \eta C_s dt\right) \tag{61.10}$$

Letting the initial reflectance ρ_e be the reflectance of adhered smoke (virtually no reflection), reflectance decreased by smoke adhesion ${}_a\rho_e$ can be estimated by

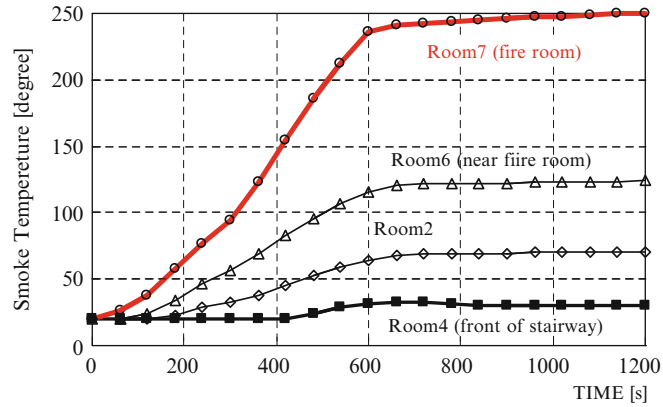
$$\begin{aligned} {}_a\rho_e &= \rho_{smoke}\zeta + \rho_e(1-\zeta) \\ &= \rho_e - \int \eta C_s dt(\rho_e - \rho_{smoke}) \end{aligned} \tag{61.11}$$

Light Attenuation by Destructive Hot Smoke

Emergency lights are designed only for an electric blackout, which is caused by damage due to high temperature smoke or flames as shown in Fig. 61.14. Evacuation sign and light are not

Fig. 61.14 Damaged emergency light in Daegu subway fire

Fig. 61.15 Smoke temperature



always secured to work, especially in fire smoke, but this tends to be forgotten. Therefore emergency lighting (or illuminating signage) cannot ensure the sufficient light intensity for evacuation visibility against fire smoke.

In JIL55017 [15] (a standard of Japan Luminaries Association), the emergency light is required to work for 30 min in the ambient temperature of 413 [K]. Figures 61.15 and 61.16 show an example of prediction results [16]. The luminous flux in the hot smoke layer was set to 0 [lm] due to its damage when the smoke temperature is over 413 [K]. Smoke temperature was shown in Fig. 61.15, and it related damage of emergency lights. In Fig. 61.16, the floor illuminance of fire room changed drastically, as lighting equipments were broken and the floor illuminance was reduced to almost zero at 420 s after fire ignition. Needless to say smoke height and optical smoke density affected luminous flux attenuation with smoke adhesion. By fire smoke, engineers should consider that the visibility of escape routes decrease due to broken lightings by high temperature, attenuation of initial luminous intensity by smoke adhesion on the surface of lightings (and light sources), and attenuation of ambient light intensity by smoke adhesion on the surface of escape routes and reduction in surface reflectance of the escape routes.

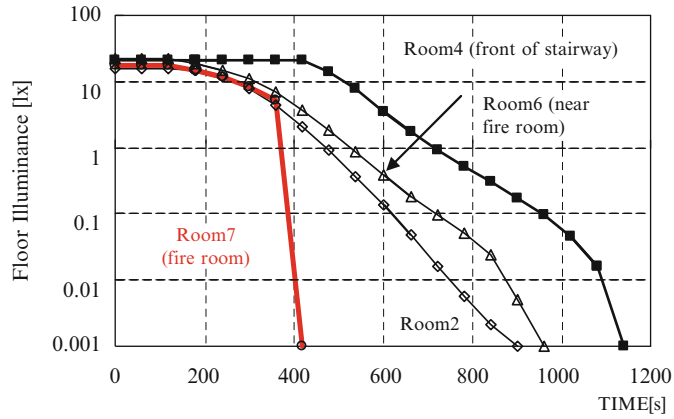


Fig. 61.16 Floor illuminance

Human Behavior in Fire Smoke and Related Environment

Travel Speed in Escape Routes Considering Luminous Condition, Smoke Density and Evacuee's Visual Acuity

There are some important previous studies on evacuation performance. Simmons [17] studied the relationship between illuminance and travel speed of evacuees. The result was referenced by CIE/ISO standards of Emergency lighting [18], which set the standard value 1.0 [lx] of floor illuminance for 1.0 [m/s] of travel speed. Jaschinski [19] compared the travel speed of young and elderly subjects. In his results, the elderly group walked slower than the young group. Webber [20] converted these results from travel time to travel speed versus floor illuminance as shown in Fig. 61.17.

In this section, we dealt with floor luminance of the walking space as the visual stimulus of the space under various lighting/smoke conditions, and elucidate the age-related difference of travel speed in previous studies using subjects' visual acuities [4]. Figure 61.18 shows the relationship between travel speed and floor illuminance for the two age groups. At 1.0 [lx] of floor illuminance and lower, the average speed of the young group was higher than the aged group, which supports the findings of the previous study [19]. If the floor illuminance was higher than 3.0 [lx], the travel speed was similar for both age groups. The relationship between visual acuity and travel speed by age groups is shown in Fig. 61.19. By converting the floor illuminance of the travel space into luminance by using Equation 61.12, it predicted levels of visual acuity under any experimental condition. ρ is reflectance of the floor. E is the horizontal illuminance of the walking space.

$$L = \frac{E\rho}{\pi} \tag{61.12}$$

The age difference is not seen, which implied that travel speed was does not vary by visual acuity regardless of age.

From the relationship shown in Fig. 61.19, the travel speed v_o [m/s] of an observer who adapts completely to the luminous intensity of the walking space (i.e. under complete adaptation) could be correlated with visual acuity VA as expressed by Equation 61.13 ($R^2 = 0.80$ and 0.86). If we can predict visual acuity under a disaster situation's light conditions, we can further predict performance, i.e. travel speed of evacuees by this equation.

$$v_o = \begin{cases} 1.56 \times VA^{0.12} & (VA < 0.25) \\ 1.32 & (VA \geq 0.25) \end{cases} \tag{61.13}$$

Figure 61.20 shows the comparisons between the results in smoke and the results without smoke (Cs = 0.68[1/m]). The result showed the large degradation of travel speed in smoke. Under the

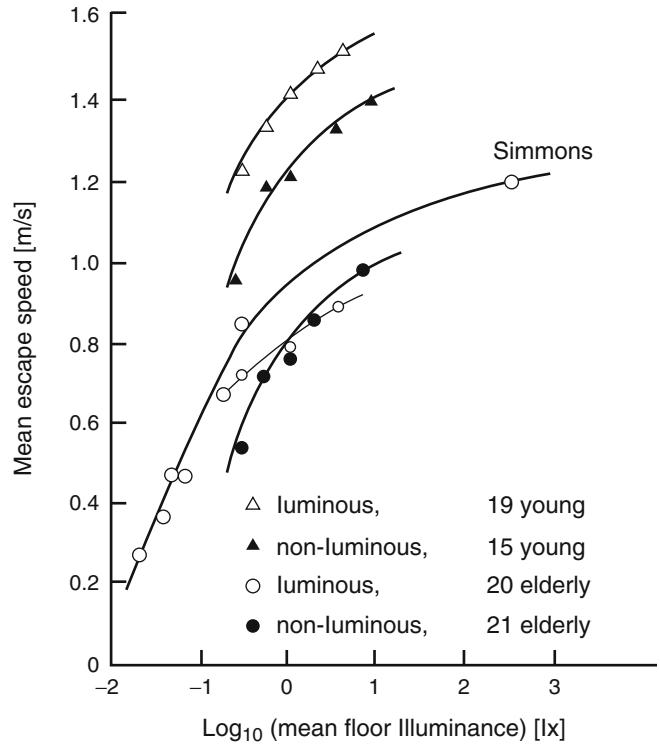

Fig. 61.17 Relationship between ζ and C_s [20]

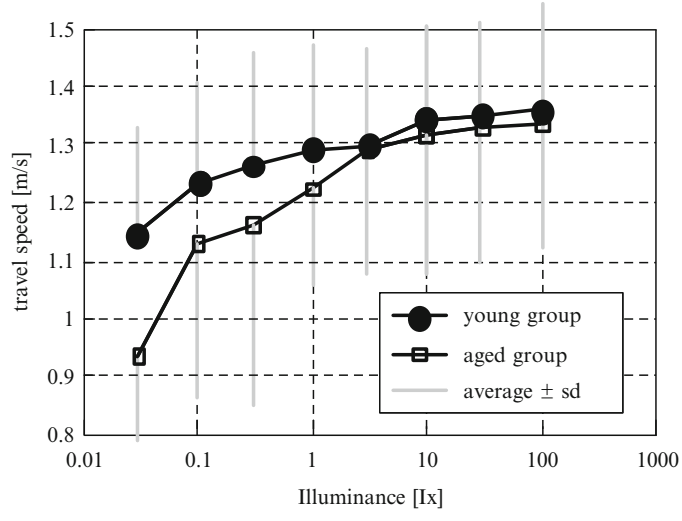

Fig. 61.18 Illuminance and travel speed [4]

same illuminance conditions, subjects walked more slowly in smoke than without smoke. In the above-mentioned Fig. 61.18, there was little difference between travel speed of the young and aged groups, and both travel speeds were constant under the illuminance condition 3.0 [lx] or more. However, under the conditions more than 3.0[lx] in smoke as shown in Fig. 61.20, the travel speeds of both groups increased as illuminance increased. The travel

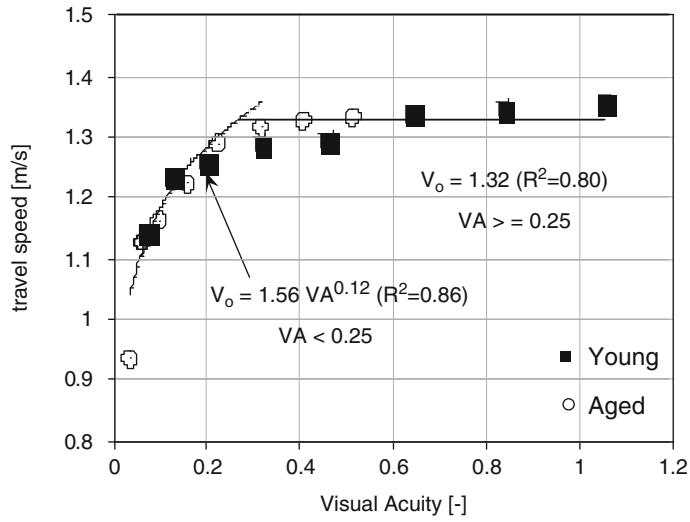

Fig. 61.19 Travel speed and visual acuity [4]

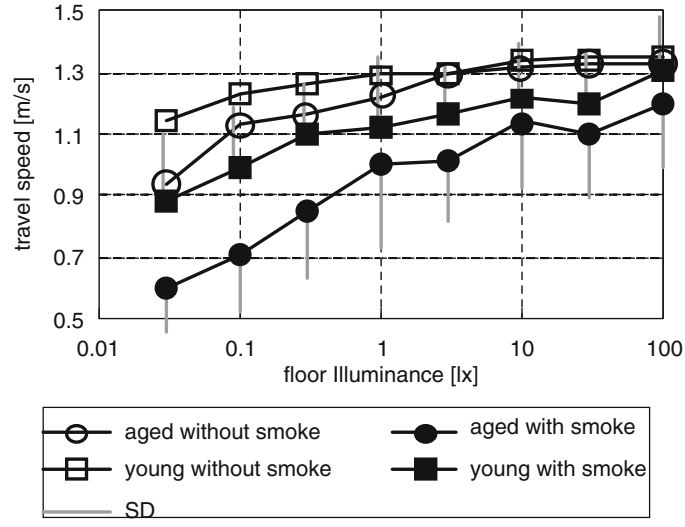

Fig. 61.20 Illuminance and travel speed in smoke

speed of the young group was consistently higher than that of the aged group.

Even under the same illuminance conditions, subjects walked more slowly with smoke than without. Therefore the ratio of travel speed in smoke (Rv_{smoke}) regarding the effect of smoke was defined by Equation 61.14.

$$Rv_{smoke} = \frac{v_{smoke}}{v_o} \tag{61.14}$$

where v_o [m/s] is the travel speed under complete adaptation without smoke, and v_{smoke} [m/s] is the travel speed under complete adaptation in smoke.

The relationship between Rv_{smoke} and visual acuity by age groups are shown in Fig. 61.21. The mean value of Rv_{smoke} is based on each subject's result. The age difference was not seen in Fig. 61.21, which implied that the effect of smoke on travel speed could be explained by visual acuity regardless of age. Equation 61.13 showed convergence with VA ≧ 0.25, but the results in Fig. 61.21 suggested smoke affects travel speed at higher levels of visibility.

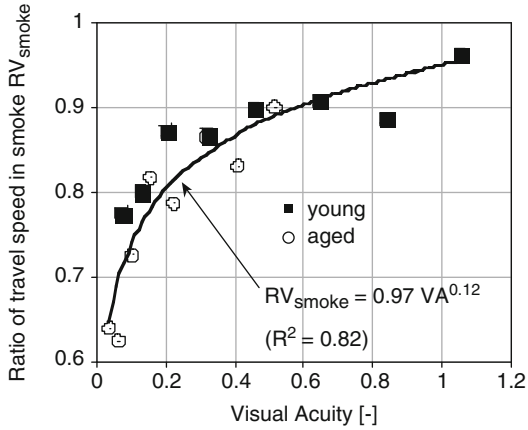

Fig. 61.21 Relative travel speed and visual acuity [4]

Finally the relationship between the travel speeds under complete adaptations with smoke v_{smoke} [m/s] and visual acuity are shown in Equation 61.15.

$$v_{smoke} = \begin{cases} 1.51 \times VA^{0.24} & (VA < 0.25) \\ 1.28 \times VA^{0.12} & (VA \geq 0.25) \end{cases} \quad (61.15)$$

At a fire situation, the power often fails in escape routes, and the light intensity rapidly decreases. Due to the rapidly change of the adaptation state of evacuees, the visibility will decrease too. When the illuminance in the adaptation space E_a [lx] and in the travel space E_t [lx] was significantly different, the travel speed increased to the level of complete adaptation's speed as subjects travel farther. The relationship between the ratio of adapting illuminance change $RE_{adaptation}$ ($=E_a/E_t$) and the ratio of travel speed $RV_{adaptation}$ were examined. Large value of $RE_{adaptation}$ raises deterioration of visibility by adaptation transition and physiological load. Under the condition that $RE_{adaptation}$ value was 10 (i.e., the illuminance of the adapting space is ten times that of the travel space), $RV_{adaptation}$ was nearly 1. Regression equations were established when $RE_{adaptation}$ was more than 100. The regression relationship between visual acuity and v_i [m/s] of the travel speed under incomplete adaptation were given by Equation 61.16.

$$v_i = \begin{cases} 1.56 \times 1.12^{f\left(RE_{adaptation}\right)} \times VA^{\left\{0.08 f\left(RE_{adaptation}\right)+0.12\right\}} & \left(RE_{adaptation} \geq 100, VA < 0.25\right) \\ 1.56 \times VA^{0.12} & \left(RE_{adaptation} < 100, VA < 0.25\right) \\ 1.32 & \left(VA \geq 0.25\right) \end{cases} \quad (61.16)$$

Effect of Irritant Smoke on Travel Speed

Along with the experiment of effect of irritant smoke on visibility, walking speed in the smoke was examined as shown in Fig. 61.22. Both smoke density and irritation appear to affect the walking speed. This figure shows that the walking speed in nonirritant smoke decreases gradually as the smoke density increases. However, in the irritant smoke, the speed decreases very rapidly in the same range of smoke density levels. From this observation, the sharp drop in walking speed is explained by the subjects' movements: they could not keep their eyes open and they inevitably walked zigzag or step by step along the side wall.

Emotional State in Fire Smoke

An attempt was made to monitor the subjects' emotional state of mind when exposed to fire smoke (white smoke by wood chips) using a steadiness tester that is often employed in psychological studies [5]. The subject's task is to hold a metal-tipped stylus in various progressively smaller hole sizes without touching the sides of the steadiness tester under limited time. Figure 61.23 is the result of an attempt to determine the subjects' emotional variations on the basis of the number of stylus contacts on the steadiness tester. Curves with two peaks as shown were obtained for both groups of subjects. These peaks seem to attest to the following facts:

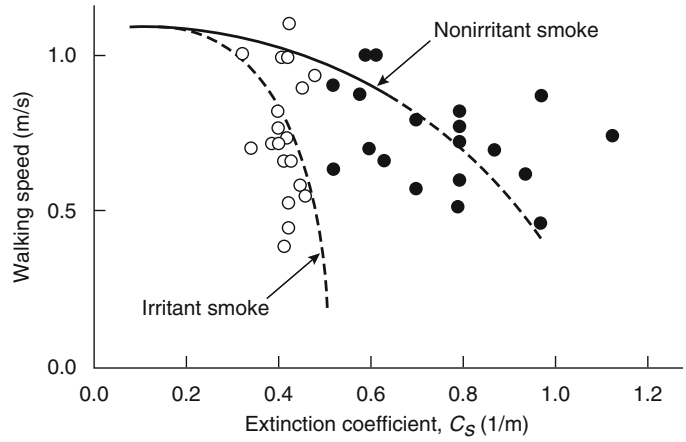

Fig. 61.22 Walking speed in fire smoke

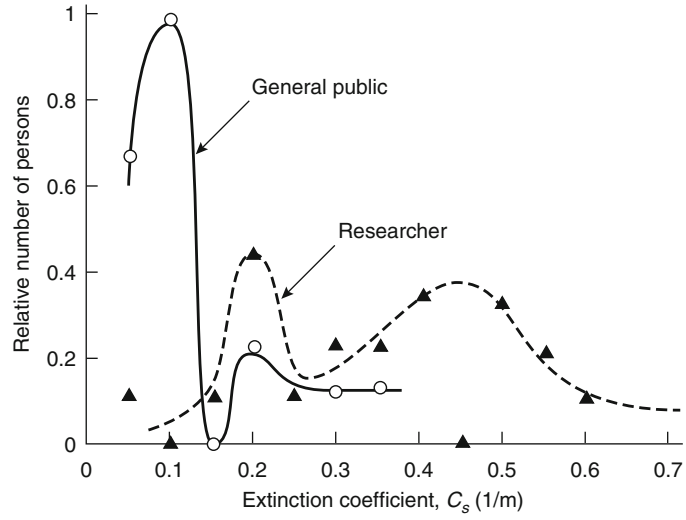

Fig. 61.23 Number of emotionally affected subjects versus smoke density at the point of rapid increase in the number of contacts in the steadiness tester

other than the Institute researchers, most subjects began to be emotionally affected when the smoke density reached 0.1 [1/m], but in a few others, emotional fluctuations did not begin to be pronounced until the smoke reached an extinction coefficient of 0.2–0.4 [1/m]. In contrast, most researchers began to show emotional fluctuations only when the smoke density reached 0.35–0.55 [1/m] although a small number of them responded at the lower smoke density of 0.2 [1/m].

Interviews with some subjects were held after the experiment. Comments by many of the subjects representing the general public could be generalized like this: "Smoke itself didn't scare me much when it was thin, but irritation to my eyes and throat made me nervous. When I thought of the smoke still getting thicker and thicker, I was suddenly scared of what was going to happen next." In other words, these subjects were more afraid of what was going to happen next than they were physiologically unable to withstand the smoke. They were not well informed about the geometry of the test room and smoke in the pre-test briefing not like for the Institute researches as mentioned below.

Hence, the author believes that the data obtained from these subjects could reasonably be treated as equivalent to those that would be

obtained from a group of unselected people who are unfamiliar with the internal geometry of a building on fire. The smoke density of 0.15 [1/m], at which most of the subjects analyzed in Fig. 61.23 began to feel uneasy, could be determined as the maximum smoke density for safe evacuation of a building to which the public have access.

In contrast, the Institute researchers who served as subjects said in the interview, "Irritation to my eyes was rather acute but the smoke didn't scare me because I had heard in the pretest briefing that it was harmless. But as the smoke grew denser, I began to feel more acute irritation in my eyes and throat, and when I got the signal to end the test (smoke extinction coefficient 0.5–0.7 [1/m]), irritation and suffocation were near the limit I could physiologically withstand. Toward the end of the test, visibility in the test room was so limited that I saw only a small floor area around my feet, and this made me a little nervous when I walked through the smoke."

Even though these researchers had some knowledge of smoke from the pretest briefing and were well informed of the geometry of the test room, most of them began to be emotionally affected when the smoke density exceeded 0.5 [1/m]. It could be reasoned that emotional instability of these subjects during the test resulted from physiological rather than psychological reasons.

These facts led the author to believe that the results of this experiment using Institute researchers as the subjects can be treated as data relevant to people who are well informed of the inside geometry of a building on fire. This means that the smoke density of 0.5 [1/m], at which Fig. 61.23 indicates most of the researchers began to lose steadiness, can be determined as the threshold where escape becomes difficult even for persons who are well familiar with the escape route in the building.

Visibility at these smoke densities is listed in Table 61.3, which indicates that those who know the inside geometry of the building on fire need a visibility of 4 m for safe escape while those who do not need a visibility of 13 m.

In Table 61.4, a comparison is made between some of the values of acceptable visibility or allowable smoke density proposed by researchers who have conducted many experiments on escape through fire smoke [2]. Wide variations in the proposed values are probably due to differences in the geometry of the places and the composition of the group escaping from fire.

Table 61.3 Allowable smoke densities and visibility that permits safe escape

Degree of familiarity with inside of building	Smoke density (extinction coefficient)	Visibility
Unfamiliar	0.15 1/m	13 m
Familiar	0.5 1/m	4 m

Table 61.4 Visibility and/or allowable smoke density for fire safe escape proposed by fire researchers

Proposer	Visibility	Smoke density (extinction coefficient)
Kawagoe [21]	20 m	0.1 1/m
Togawa [22]	–	0.4 1/m
Kingman [23]	4 ft (1.2 m)	–
Rasbash [24]	15 ft (4.5 m)	–
Los Angeles Fire Department [25]	45 ft (13.5 m)	–
Shern [26]	–	0.2 1/m
Rasbash [27]	10 m	0.2 1/m

Intensive System for Escape Guidance

Improvement of Conspicuousness of Exit Sign by Flashing Light Source

An emergency exit sign, which indicates a location and/or direction of emergency exit and leads evacuees to a safe place swiftly, is important in case of fire or other emergencies. In Japan, three sizes of emergency exit sign were ordinarily used (h[cm] × w[cm] are 40 × 1200, 20 × 60, and 12 × 36). However, the conspicuousness of an exit sign in a location where there are many other light sources was not known. In the first experiments, the conspicuousness of an "ordinary" exit sign in an underground shopping mall was measured during business hours. The

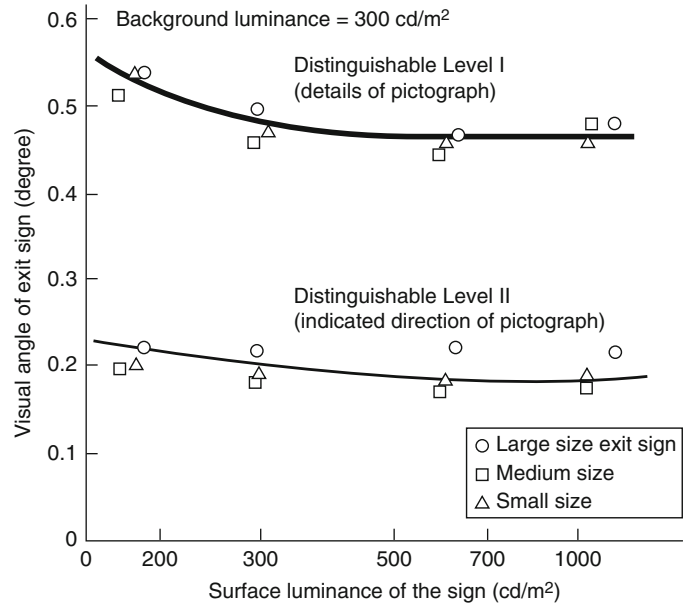

Fig. 61.24 Relation between surface luminance of exit sign and visual angle associated with visibility

experimental variables were the observation distance, size, and luminance of the sign. In the second series of experiments, the conspicuousness of a self-flashing type exit sign (flashing the lamp in the sign) was compared with that of an ordinary exit sign [28].

Visibility and Conspicuousness of Exit Source

Prior to this study, another experimental study on visibility of exit signs had been carried out. In that experiment, the original type of exit sign was observed in a background without other light sources. Figure 61.24 shows one of the results concerned with the relation between visibility expressed by visual angle (defined by the height of the pictograph) and surface luminance. In this figure, visibility is represented on two discrimination levels; one is the level at which a person can distinguish the details of the pictograph and the other is the level at which only the direction of the running person in the pictograph is distinguishable. This result indicates that visibility is almost constant when the luminance of the white part of the exit sign is more than 300 [cd/m^2]. This observation is true for every size of the exit sign. It is independent of the size of the sign when visibility is expressed in terms of the visual angle.

Figure 61.25 shows the relation between conspicuousness of ordinary exit signs and the visual angle according to the evaluation categories given in Table 61.5 [29]. The conspicuousness increases with visual angle. However the same visual angle doesn't give same conspicuousness level especially when the visual angle is larger. The larger-size exit sign is more conspicuous than the smaller one when the visual angle is the same. As above indicated, surface luminance doesn't give much effects on the distinguish level when the visual angle is similar. And lower surface luminance sign needs large visual angle to keep the same distinguishable level. This indicates that conspicuousness depends on the relative scale and brightness of exit sign against those of surrounding light sources.

Improvement of Conspicuousness by Flashing the Light Sources

Figure 61.26 shows the relation between conspicuousness of an ordinary exit sign and that of the self-flashing type exit sign using the

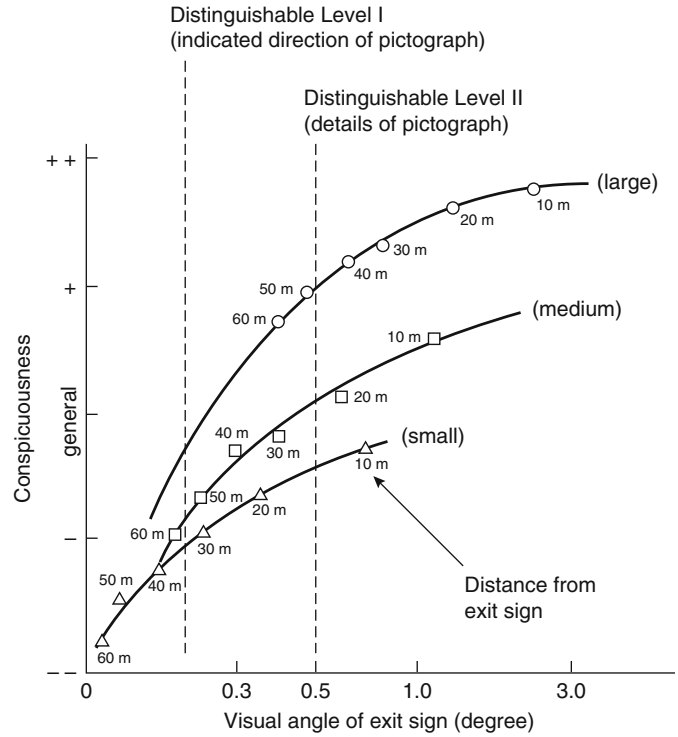

Fig. 61.25 Relation between conspicuousness of ordinary type exit sign and visual angle

Table 61.5 Categories for evaluating conspicuousness of ordinary-type exit sign

Evaluation categories	(Marks in Fig. 61.25)
1. The exit sign is fairly conspicuous	(+ +)
2. The exit sign is slightly conspicuous	(+)
3. The exit sign is similar to the general level	(General)
4. The exit sign is less conspicuous	(−)
5. The exit sign is not conspicuous at all	(− −)

categories for evaluation given in Table 61.6. In this figure the vertical interval between the dash-dotted line and the curves corresponds to the improvement of conspicuousness by the flashing light in the sign. For the medium-size exit sign, a self-flashing type sign is more effective to improve conspicuousness. However, the small-size exit sign of the self-flashing type is not conspicuous enough when observed from a distance more than 20 m in the background with many other lights, because the exit sign is too small to be recognized as an exit sign, even though the flashing was expected to be much more conspicuous. The large exit sign is big enough to have sufficient conspicuousness without flashing even in the background with many competing light sources. Conspicuousness of the sign could also be improved by adding a flashing light source the same as a flashing-type sign.

In addition to the improvement achieved by adding a flashing light, the author has suggested the development of an acoustic guiding exit sign. Adding a speaker and voice recorded IC chip to the flashing exit sign can provide an announcement such as “Here is an emergency exit” when fire is detected by, for example, smoke detectors [30].

Development of Intensive Escape Guidance System

Escape guidance system by traveling flashing light sources: An escape guidance system has been developed for safe evacuation. This system indicates the appropriate escape directions by

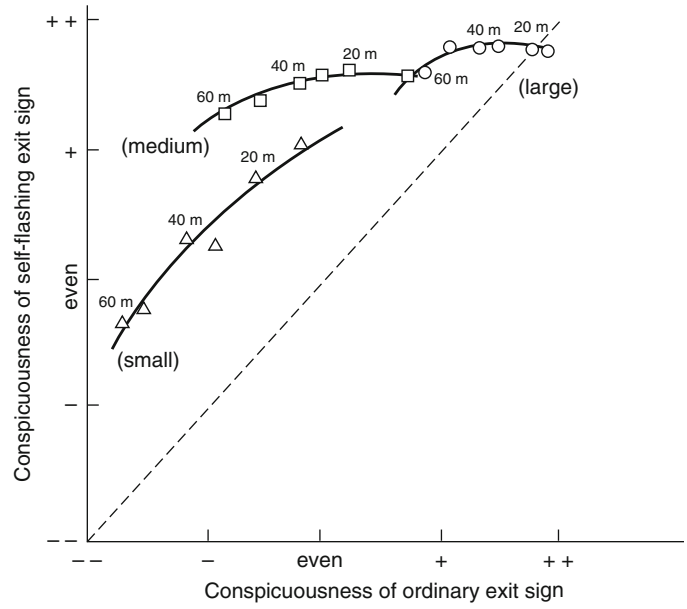

Fig. 61.26 Relation between the conspicuousness of a self-flashing exit sign and that of an ordinary one

Table 61.6 Categories for evaluating conspicuousness of self-flashing exit signs

Evaluation categories (as compared with the ordinary-type exit sign)	(Marks in Fig. 61.26)
1. The flashing exit sign is fairly conspicuous	(++)
2. The flashing exit sign is slightly conspicuous	(+)
3. The flashing exit sign has similar conspicuousness	(General)
4. The flashing exit sign is less conspicuous	(−)
5. The flashing exit sign is not conspicuous	(− −)

creating a row of flashing lights leading away from a hazardous area such as a fire in a building (see Fig. 61.27). A form of this is already found in the floor lighting of passenger aircraft cabins.

An experiment was carried out to evaluate this system using a portion of passageway (1.4 m width, 6.3 m length, and 2.5 m height) filled with smoke. As lighting for the passageway, fluorescent lamps are provided under the ceiling, giving about 200 [lx] at the center of the passage in the absence of smoke. The flashing light unit boxes are set on the floor along the side of the right-hand wall at intervals of 0.5 m, 1.0 m, and 2.0 m as a test guidance system [31].

Table 61.7 Categories for effectiveness of the escape guidance

Score	Effectiveness
7 points	Very effective for escape guiding
5 points	Fairly effective
3 points	A little effective
1 point	Not effective

The effectiveness of the escape guidance was evaluated by 12 subjects under various conditions that is, changing the spacing and the traveling speed of flashing lights and smoke concentration. Under each condition, subjects walk along the system successively with free walking speed.

The degree of effectiveness of escape guidance is classified into seven steps as follows, and the evaluations are made by filling one score from 7 points into an observation sheet directly after each test run by subjects respectively. These categories are adopted as a semantic differential scale and the relative evaluation for escape guidance effectiveness is determined as subjective grading in each test run. (Points 2, 4, and 6 correspond to the middle point between 1 and 3, 3 and 5, and 5 and 7 respectively.) In general, the effectiveness decreases with increasing smoke.

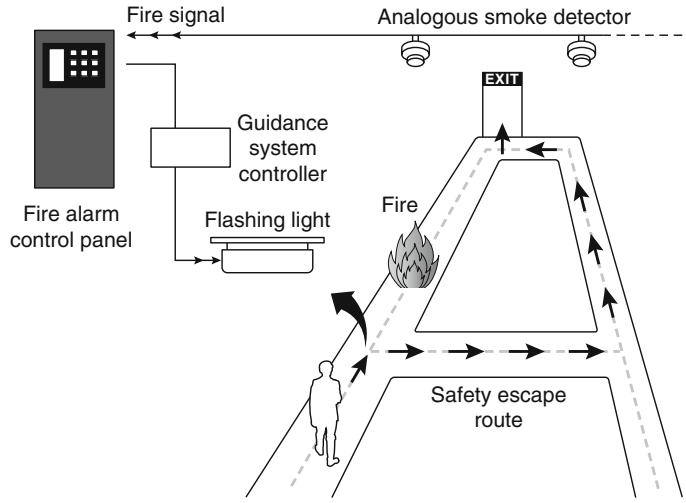

Fig. 61.27 Illustration of the traveling flashing light sources system

The evaluation value of 4 points stands for less effective than fairly effective and more effective than a little effective, so we consider the value a threshold where practical effectiveness of escape guidance is secured.

The correlation between smoke concentration and the effect of escape guidance is shown in Fig. 61.28. This indicates that this system is useful for evacuees to escape in thick smoke (up to an extinction coefficient of 1.0 [1/m]er) when the spacing length is 0.5 m and the flashing speed is 4 [m/s]. When the spacing length is set to be 1.0 m, the effectiveness decreases but it is still useful in smoke under 0.8 [1/m]. However, when the spacing is greater than 2.0 m, less effectiveness is expected even under a no-smoke condition. The evaluation values in the meshed area to the left in Fig. 61.28 were obtained under no smoke conditions.

The effectiveness of flashing traveling signs in an ambient atmosphere is maintained up to smoke density of 0.4 [1/m]. This result is very important for evaluating the escape guidance system from the viewpoint of safe evacuation. Visibility (observable distance) of normal exit signs drops rapidly from more than 10–5 m as shown in Fig. 61.8, and the guidance effectiveness is also lost over the same range of smoke densities [6].

However compared with the decrease in visibility of ordinary exit signs, the decrease in the effectiveness of the guidance system with increasing obscuration seems to be small, so that the new system is expected to maintain high and stable effectiveness of guidance escape, even in relatively dense smoke. Clearly, the spacing between flashing light sources is a very important factor to maintain effectiveness. High effectiveness is expected, especially, when the spacing is less than 1.0 m. The relation between effectiveness and flashing light conditions in the presence of smoke is found to be almost the same as the relation under non-smoke conditions.

Effectiveness of a Directional Sound Escape Guidance System Using the Haas Effect

Directional sound escape guidance systems are expected under smoke filled conditions where visibility is lost. One of methods to create directive sound is to utilize the Haas effect, which is used in a large hall so that a voice can be heard from each speaker where many speakers are installed on the sidewalls with respect to the direction of the lecturer.

In Japan, the system is used in combination with the traveling flashing light sources and it has

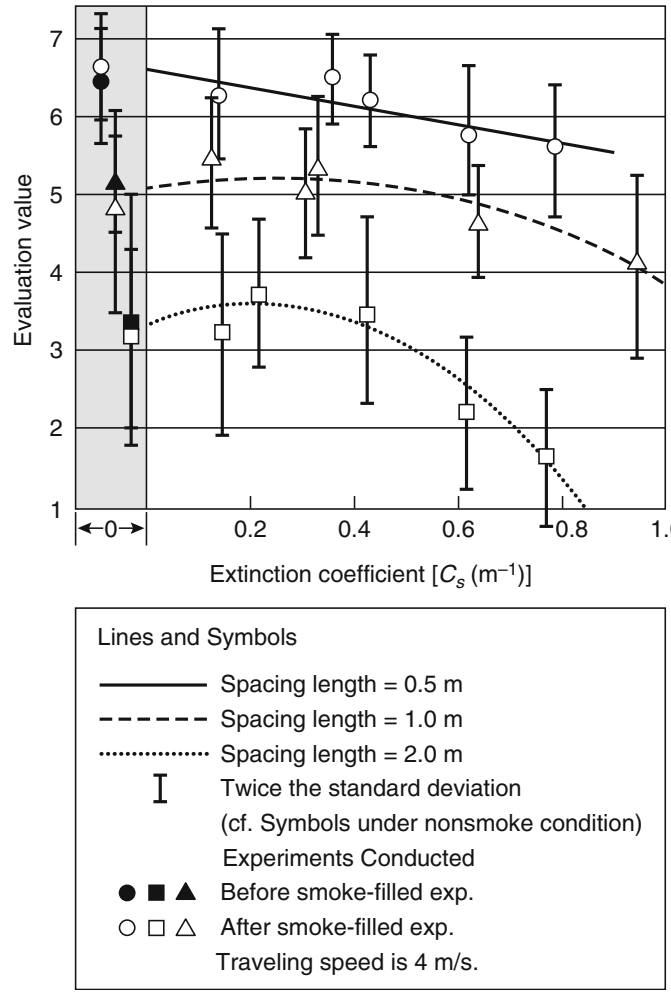

Fig. 61.28 Relation between smoke density and the effect of escape guidance with variation of flashing light sources under a smoke condition

been installed for a large-scale underground shopping mall and in facilities used by people with impaired vision and hearing. The directional sound escape guidance system using the Haas effect has two separate speakers that are located on the ceiling above the emergency exit within a distance of 10 m in a corridor. They are next to each other, but there is a time delay between them. When a fire occurs, a warning message (a chime sound plus an announcement: "Here is the emergency exit") is given from each speaker. The message is heard only from that emergency exit as a result of the Haas effect (also called precedence effect) [32, 33]. Its effectiveness was also examined in a smoke-free corridor.

Table 61.8 Categories for confidential of the escape direction

7	They were very confident that the sound came 968 from the right direction.
5	They were quite confident that the sound came 970 from the right direction.
3	They could identify a direction but were not 972 confident that it was the correct one.

A guidance effect experiment was carried out in the passageway of an assembly area approximately 130 m length, 4.8 m width, and 2.5 m height. Subjects moved strait forward to the end exit with a distance of 2 m between them, and they evaluated their perception of the direction of

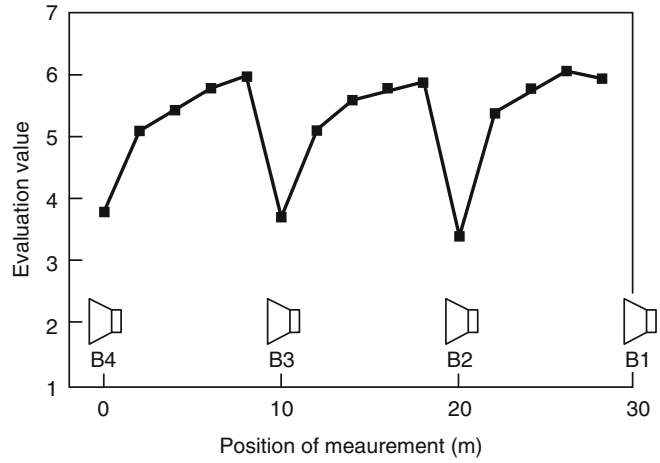

Fig. 61.29 Evaluation of the sound escape guidance system

the sound in relation to the direction in which they were walking. The evaluation was based on the following subjective ranking:

The example shown in Fig. 61.29 is the result of such an evaluation experiment of the direction from various positions. A ranking value above five indicates that the individual has a good feeling of the direction for various locations, although when directly under the speaker it falls to 3.5. As for the distance between speakers, it is desirable to install them less than 10 m apart because the evaluation value close to the speakers is difficult if the separation of the speakers is wide.

As for the direction in which the speaker is pointing, it is better to have it pointing horizontally along the length of the passageway. The worst situation is to have the speaker pointing vertically downwards (90° to the horizontal). The limiting case for a good response is 45° downwards from the horizontal.

The delay time T_d [s] between the speakers is given by

$$T_d = D/v_{sound} + (35 \pm 10) \times 10^{-3} \quad (61.17)$$

Where

D = Distance between the speakers [m]

v_{sound} = Speed of sound in air [m/s]

$(35 \pm 10) \times 10^{-3}$ = A constant that must be adjusted for the building structure

Summary

The following are the major conclusions derived from these research activities:

1. The relationship between smoke density and visibility in fire smoke was examined under various kinds of smoke, and simple equations were proposed for practical use.
2. The visibility in fire smoke depends on its irritating nature as well as the optical density of the smoke. Increasing irritating effect causes a rapid drop of visual acuity. A modification due to irritating effect was made for the visibility versus smoke density equation.
3. There are various indirect effects of smoke on visibility, i.e. light attenuation due to smoke adhesion and/or destructive hot smoke. Empirical equations to evaluate such effects are introduced. Also effects of luminous conditions on travel speed in smoke are examined and correlated with visual acuity depletion.
4. Evacuees' performance could be predicted by visual conditions such as the luminous environment and evacuee's visual acuity. Travel speed was determined by visual acuity regardless of age, whether with or without smoke.

Under complete adaptation or incomplete adaptation, travel speed decreased if the evacuee's visual acuity was less than 0.25. Smoke caused the degradation of travel speed even with sufficient illumination.

5. Evacuees begin to feel emotional instability in relatively thin smoke; however the threshold of smoke density varies with the subject. Ability of evacuees to think clearly when exposed to fire smoke decreases with increasing smoke density. Generally, this is caused by both psychological and physiological effects on evacuees.
6. Conspicuousness of the ordinary exit sign was improved by a flashing light source sign or by adding a flashing light source in conditions where there were many other light noises.
7. Two new types of escape guidance systems have been tested. One is the continuously traveling flashing light source system, the effectiveness of which has been examined in a smoke-filled corridor with reduced visibility. The other is a directional sound escape guidance system that makes use of the Haas effect. Its effectiveness has also been examined in a smoke-free corridor. These innovative technologies for safe evacuation are now in practical use in Japan in a large underground shopping mall and in facilities used by people with impaired vision and hearing.

Tokiyoshi Yamada was born in 1954 in Japan. He received his doctor of engineering degree from Tokyo University in 1983. He joined the Fire Research Institute in 1983 and has worked in the field of visibility and human behavior in fire smoke with Dr. Jin. Major research background is fire physics. In 2011, he joined the University of Tokyo as a project professor.

Yuki Akizuki was born in 1970 in Japan. After spending 5 years in the lighting research and development laboratory of Matsushita Electric Works (now Panasonic), she received her Ph.D. degree from Nara Women's University in 2003. She joined Disaster Prevention Research Institute of Kyoto University in 2003 and studied with Prof. T. Tanaka. She got the second doctoral degree of engineering from Kyoto University in 2012. She has been an associate professor at University of Toyama since 2007.

Combustion Toxicity

62

David A. Purser

Introduction

The purpose of this chapter is to review experimental studies, especially those involving combustion chemistry and toxicity test methods, in order to establish the basis and validation for material toxicity and toxic hazard calculations and to obtain yield data for input to fire dynamics and toxicity calculations. The review covers several major topics, including the following:

- How combinations of fire investigation studies, experimental studies of the composition of fire effluent mixtures and studies of their effects on exposed human and animal subjects, have been used to identify the variety of toxic substances produced during combustion of a wide range of materials, and the extent to which these toxic effects can be attributed to a small number of key toxic chemical substances.
- Another related topic, is the extent to which unusual or "super-toxic" substances or effects have been identified from certain materials, which cannot be explained in terms of common toxic combustion products.
- A third topic describes how the yields of key toxic effluents vary with different combustion conditions in fires and how specially designed bench-scale combustion tests have been used to replicate these combustion conditions and measure toxic product yields from a range of materials for application to fire dynamics calculations, toxic potency estimations and environmental contamination assessments.
- Also discussed are the limitations of some simplistic bench-scale "combustion toxicity" tests sometimes used for product specification purposes.

The toxicity of combustion products from materials involved in fires was subject of considerable interest in the 1970s and 1980s. This was stimulated by findings at the time of a fourfold increase in deaths and from exposure to toxic smoke in fires (as opposed to burns) in the UK during the post-war period and a high incidence of smoke deaths in fires in the United States and other countries. During this period there were marked changes in the materials used in construction and contents of buildings and transport vehicles, with the widespread introduction and use of a range of modern synthetic polymeric materials which differed chemically from the traditional (mostly natural) materials used previously. The high incidence of smoke-related injuries and deaths gave rise to concerns that, when they were burned, some of these materials might be producing unknown "supertoxic" substances with a high toxic potency (so that exposure to small amounts could produce severe incapacitation or death) and unusual specific toxicity (so that the nature of the toxic effects might be different from those caused by effluents from traditional materials). Another possibility was that the range of important toxic chemical

substances produced by modern materials was similar to those from traditional materials such as wood and that the increased toxic hazards in fires were more related to the burning behavior of modern materials and products. According to this hypothesis, fires at that time involving modern materials (especially fires in domestic dwellings involving upholstered furniture and bedding), were easier to ignite and produced more rapidly growing fires. The yields of common toxic products including smoke, irritants and asphyxiant were also higher, so that the mass production rates of toxic effluents were greater than previously.

During this period a variety of bench-scale combustion devices were used to generate thermal decomposition product atmospheres. These were used with animal exposures to measure toxic effects and potencies, combined with efforts to measure the detailed chemical composition of effluent mixtures from a wide range of materials. There was also a concept that some form of bench-scale "toxicity test" method might be developed which might be used to screen novel materials for the production of super toxicants and also to measure and to rank the toxic potencies of the effluent mixtures from different materials or products.

The findings from this work were the combustion chemistry of materials was indeed very complex so that combustion products from all materials contain many hundreds of toxic compounds with a range of toxic effects and toxic potencies. The chemical composition and in particular the yields of different components of the effluent mixtures vary considerably for any individual material depending on the combustion conditions. Also, when different materials are decomposed there tends to be a set of basic organic and inorganic substances produced that are common to most materials, plus an additional set of substances related to the specific chemistry of the material and sometimes unique to that material or class of materials. In addition to the chemical identity of effluents, the physical form varies in ways that are of toxicological importance. Fire effluents contain a mixture of gases, liquid droplets and solid smoke particles. The aqueous solubility of the gases and the size-range of the droplets and particles determine where they are deposited in the respiratory tract during inhalation, which in turn partly determines their toxic effects.

Despite these detailed complexities only two specific examples have been found of unusual toxic effects. One was for a particular caged biphosphorus ester (TMPP) formed during thermal decomposition of trimethylol polyols in the presence of phosphate additives. The other was a highly toxic nanoparticle mist formed from per-fluorinated materials under specific non-flaming thermal decomposition conditions. Apart from these two cases it was found that in terms of effects on escape and survival during and immediately after fires, the incapacitating physiological effects on fire victims were relatively simple, consisting of irritancy and asphyxia, which could be explained in terms of a small set of toxic gases and smoke particulates common in effluents from most burning fuels.

Combining the results from these studies with detailed studies of full-scale fire experiments and fire incident investigations, it has also become evident that "toxicity" or more correctly "toxic hazard" in fires is a system property of full-scale fires. This involves a series of different physiological effects occurring at different timescales during a fire and caused by different effluent components. The effluent composition also varies during fire development depending upon the combustion conditions, resulting in the varying time-concentration curves for the smoke, irritants and asphyxiant gases. It also became evident that the different forms of bench-scale decomposition apparatus had been chosen mainly for convenience of use rather than in an attempt to replicate any specific combustion conditions occurring in full-scale compartment fires. In practice most studies involved oxidative pyrolysis in a furnace rather than flaming combustion, and for the few cases where flaming conditions were established no consideration was given to the considerable effect that the fuel-air equivalence ratio has on the yields of toxic products at different stages of compartment fires.

Table 62.1 ASET parameters

The time-concentration (or time-intensity) curves for the major toxic products, smoke and heat in the fire at the breathing zone of the occupants, which in turn depend upon
Fire growth curve (mass loss rate of the burning fuel [kg/s] and its dispersal volume [kg/m^3] with time)
The yields of the major toxic products (kg/kg) and heat (kj/kg) (for example kg CO per kg of material burned)
These terms can be measured directly in full-scale tests or calculated using appropriate fire dynamics computations with appropriate input data including reaction-to-fire properties and data on product yields under a range of fire conditions. Guidance on calculation methods for these terms is given in other chapters of this handbook. Some information is provided in this chapter on toxic product yields under a range of fire conditions and also in Chap. 16, [1] and Chap. 36, [2]. Data on toxic product yields can be be obtained using the ISO TS19700 tube furnace or the ASTM E2058 flammability apparatus. A guide to the general characteristics of fires and examples of full-scale fire profiles are presented in Chap. 63 [3]
The concentration/time/physiological effect relationships of these products in terms of the physiological/toxic potency of the products and heat (the exposure concentration [kg/m^3]), or exposure dose (kg·m^{-3}·min or ppm·min) causing toxic effects (and the equivalent effects for heat and smoke obscuration). The important endpoints are:
Concentrations, doses (or heat intensity) likely to impair escape efficiency due to behavioural and/or physiological effects
Exposure concentrations or doses likely to cause incapacitation or prevent escape due to behavioural and/or physiological effects
Lethal exposure concentrations or doses
These terms can be calculated by the application of appropriate physiological methods (Fractional Effective Dose methods [FED equations]) presented in Chap. 63 [3] and in ISO 13571 [4]

Since it is not possible in any bench-scale test to re-create the sequence of fuel combustion and decomposition conditions occurring in a full-scale fire, and since "toxicity" is a sequence of different physiological effects that cannot be represented by a single quantity, it is considered that bench-scale toxicity tests are of limited value for direct application to either toxic hazard assessment or product specification. Toxic hazard in fires is best evaluated using the approach shown in Table 62.1 and described in detail in Chap. 63 [3]. For this method the time-concentration curves for the small range of key toxic products known to be important are measured in full-scale tests or calculated using computer models with appropriate input data on parameters including fuel-composition, heat release rate and toxic product yields as a function of fire type and fuel-air equivalence ratio. These data are then used with the human FED expressions detailed in Chap. 63 to calculate time to impairment of escape capability from smoke and irritants, and time to incapacitation from asphyxiant gases, This is then used to estimate ASET for any specific fire scenario.

Despite the limitations of bench-scale toxicity tests for toxic hazard assessment or product specification a set of published data exists from the animal exposure and chemical analysis studies, and several bench scale test methods are still used for different purposes, with new methods under development. This chapter consists of a review of useful information obtained by past and current test methods in the following areas:

- **Key products and effects**: Where fire effluent mixtures have been generated for animal exposures and chemical analysis it has been possible to measure the toxic effects and establish the extent to which these can be explained in terms of the measured effects of individual toxic substances and interactions between known mixtures of individual substances. Although concentrations and ratios of different substances in the effluent mixtures generated in these bench scale tests may differ somewhat from those occurring in compartment fires, tests carried out under non-flaming decomposition conditions are rich in a wide range of toxic substances so are useful for estimating the extent of toxic

interactions between different atmosphere components and the extent to which key products are responsible. Flaming decomposition tends to produce simpler mixtures containing a few irritant and asphyxiant gases which and have been useful for evaluating the effects of these components and their interactions. The results of these studies form the basis for the development of the human FED calculation methods described in Chap. 63 [3].

- **Measurement of toxic substance yields from materials under different fire conditions**: As set out in Table 62.1, if time-concentration curves for toxic substances in full-scale fire scenarios are to be calculated using computer fire dynamics models, essential inputs are the yields of each key toxic product from each burning fuel as a function of the combustion conditions. Although bench-scale tests cannot produce the dynamics of full-scale fires, it is possible to use some test bench-scale methods to reproduce the chemical decomposition conditions to which fuel pyrolysis products are exposed in terms of flaming/non-flaming behavior, decomposition temperatures and fuel/air ratios, in order to measure smoke particulate and toxic substance yields. Data from a number of test methods are presented in this chapter.
- **Identification of super-toxicants**: Bench-scale animal and chemical measurement tests have been useful to confirm that the majority of polymers have not produced unusual or "super-toxic" substances relevant to acute fire hazards, and in identifying the two cases where such substances have been produced. These are described
- **Measurement and calculation of lethal toxic potency ranges for materials**: Bench-scale chemical measurement tests are also useful in combination with rat lethality FED calculations to establish the range of toxic potencies of effluent mixtures from different materials, and how these vary with combustion conditions. Examples for a range of polymers decomposed under different defined conditions are presented.
- **Simple toxic hazard calculations using material toxic potency data**: Material toxic potency data cannot be used directly to rank toxic hazard, but they can be used as input to a simple form of toxic hazard analysis as an alternative to the human FED methods in Chap. 63 For this simple hazard analysis the calculated toxic potency for a material decomposed in a bench-scale test is combined with fuel mass loss rate and dispersal calculations for a compartment fire. This can then be used to generate a time-FED curve to calculate the time at which a lethal exposure is predicted. Some data and examples of this method are presented.
- **Limitations of bench-scale test methods**: As stated, a number of bench-scale methods have been used to produce toxic yield and potency data, and for product specification purposes, but have severe limitations in terms of the test conditions, form of data and applications to which they are put. A number of test methods are discussed.
- **Generation and yield measurements for environmental toxins**: Bench-scale tests can be used for the generation and detailed measurement of the yields of the wide range of environmental toxins from different materials. This can be very valuable in relation to workplace health and safety and environmental contamination evaluation. For these applications a wide range of systemically toxic and carcinogenic substances, such as halogenated dioxins, furans, volatile organic chemicals and polycyclic aromatic hydrocarbons may be important. When materials are decomposed under defined non-flaming and flaming combustion conditions relevant to different full-scale fire conditions the yields of these substances can be measured. This area is beyond the scope of this chapter on acute fire hazards.

Material-Based and System-Based Approaches to Toxic Hazard Assessment

Materials-Based and Combustion Product–Based Approaches to Toxicity Assessment

There have been two main views as to why smoke toxicity appears to be an increasing problem, which in turn have led to two rather different approaches to the evaluation of toxicity.

1. One view held that smoke from modern synthetic materials contained new toxic products that were not present previously, and that in some cases these products (the so-called "supertoxicants") might be very potent, exerting novel toxic effects at very low doses. Such effects could therefore be detected by means of simple, small-scale toxicity tests that could be used for regulatory purposes [5–7]. To some extent this approach followed the discovery that two materials, a flexible polyurethane foam containing a phosphorus-based fire retardant and polytetrafluoroethylene (PTFE), could under certain laboratory conditions evolve products with a very high toxic potency [5, 6]. This led to the use of rather simplistic materials-based toxicity tests, where the toxicity of materials is ranked in terms of the rodent LC_{50} (the concentration of combustion products expressed in terms of mg of material per liter of air causing the deaths of 50 % of animals exposed) [7, 8]. This approach implies that the engineer should design by using those materials with the better performance in toxicity tests and that are consistent with good performance in other types of small-scale fire tests.
2. The other main view was that the basic toxic products of fires were much the same as always, but that in many modern fires the rate of fire growth and the rate of evolution of the common toxic products were much greater than they had been previously. Therefore, the best way to mitigate toxic hazard in fires was to control such factors as ignition, flame spread, and rate of smoke evolution rather than the qualitative nature of toxic products. For this approach, which is favored in the United Kingdom, there is more interest in estimating toxic hazard by measuring or modeling the yields and time-concentration curves for the main toxic products given off by materials during fires. This can be achieved by carrying out large-scale fire tests. Alternatively, data on the yields of the main toxic products can be obtained from suitable small-scale tests described in this chapter and used as input to calculation of full-scale fire behavior using engineering calculation models such as those described in Chap. 16 [1] and Chap. 36 [2]. These data are then used to estimate time to incapacitation and death. In this context the main function of small-scale toxic potency tests (other than to provide data on yields of the main toxic gases) would be to confirm that the toxicity associated with particular burning materials was indeed due to the common toxic fire products via chemical atmosphere analysis in conjunction with animal exposures and to identify those cases where unusual toxic effects occurred. This approach enables a fire safety engineer to design to a set of fire scenarios in a system (for example, a hotel bedroom or an aircraft cabin) and, by a simple chemical analysis of atmospheres produced during appropriate small- and large-scale fire tests, predict likely toxic hazard. This is the basis of the FED hazard assessment methods presented in Chap. 63. Of course the quality of such assessments is only as good as that of that of the input data and calculation methods.

Another approach, based upon the view that toxicity results from a small number of common toxic products, make use of simple bench-scale "toxicity" tests in which a small sample of a material or product is exposed to a heating regime and the concentrations of a defined set of evolved decomposition products are measured using chemical analysis. The data are then input into a calculation

method to obtain a "toxicity index" for the product, which is then used as the basis for a prescriptive product classification. This approach not considered realistic, because, as described, it is considered that toxic hazard is a time-related emergent property of the full-scale fire scenario, and cannot be measured directly by any bench-scale test. Also, such tests do not replicate the decomposition conditions occurring in full-scale fires, so that the concentrations and yields of toxic gases are very different from those occurring in compartment fires.

In practice there is a need for both appropriate small-scale materials-based toxicity tests and for fire profile modeling based on a few major toxic fire products. Existing information is often inadequate and misleading, and a better standard of research and testing is needed if data are to be produced for practical use. This chapter will give the reader an understanding of what is known about combustion product toxicity, the extent to which effects can be predicted from knowledge of common fire products, and how small-scale tests should be performed and the results interpreted and used.

Use of Small-Scale Tests to Represent Toxicity and Toxic Product Yields

Historically bench-scale tests have been used to measure the "toxicity" of materials or products in terms of single numbers for ranking and specification purposes. A test specimen is decomposed, usually in an enclosed chamber, and either animals (usually rats or mice) are exposed to the effluent atmosphere produced to measure toxicity directly, or measurements of toxic gas concentrations are made and used to calculate the predicted toxicity of the effluent mixture. Results are expressed in terms of lethal concentration for 30-min exposures (LC_{50} concentration) expressed in terms of the mass charge or mass loss of the material tested (for example lethal toxicity of wood g/m^3). Alternatively the results may be expressed in terms of an index value based on 30-min IDLH values (Immediately dangerous to life or health after 30-min exposure).

These methods are considered to be of limited value for hazard assessments because:

- Toxic hazard is a property of a full-scale system depending upon the time-varying dynamics of fire growth and effluent spread in specific fire scenarios
- Yields of toxic species and hence toxicity from any material or products are variables which depend upon the changing combustion conditions during fires. The decomposition conditions in existing toxicity test methods are uncharacterized and give a poor representation of any specific stage of any full-scale compartment fire, let alone a representation of the changing combustion conditions
- Toxicity involves a time varying set of different physiological effects

One area where bench-scale animal exposure tests combined with chemical effluent analysis have been valuable is in establishing that the toxic effects can be understood in terms of a small number of key gases and the interactions between them, despite the fact that fire effluents are known to contain many hundreds of toxic substances [9, 10]. This has enabled validation of the Fractional Effective Dose models based on this small number of key toxic products, with essentially additive effects among the different components.

Another important use of specific bench-scale tests is for measurement of the yields of key toxic products under the different combustion conditions occurring in compartment fires. Two test methods capable of providing these data are the ASTM E2058 flammability apparatus [2] and the ISO TS19700 steady state tube furnace [11–13], which has been developed specifically for this purpose (see this Chapter "The Use of Small-Scale Combustion Product Toxicity Tests for Estimating Toxic Potency and Toxic Hazard in Fires"). The steady state tube furnace has been designed to reproduce the decomposition conditions in all six stages of fires defined in ISO 19706 [14] (including pyrolysis under nitrogen, non-flaming and smoldering oxidative

decomposition, well ventilated flaming, under-ventilated pre- and post-flashover flaming).

The Significance of Toxicity as Part of Total Fire Hazard

For scenarios involving the escape of occupants from a fire, survival depends on the outcome of two parallel processes.

1. *The developing hazard from the fire*. This process incorporates ignition, fire growth, and the spread of fire and fire effluent. These depend on a range of variables, such as the nature and disposition of the fire load, potential ignition sources, the reaction to fire properties of the lining materials and contents, the height and ventilation of the compartment, and the nature of the fire effluent. The actions of occupants and the provision of passive containment and active smoke extraction or suppression systems also affect the rate of development and extent of the hazard from a fire.

   Assessment of these processes for any particular scenario is aimed at calculating the time from ignition to the time when occupants would receive an incapacitating exposure to fire effluent (sufficient to seriously impair their ability to escape). This represents the available safe escape time (ASET).
2. *The process by which occupants escape*. This depends on detection, the provision of warnings, response to warnings (pre-movement time), occupant profile (such as age and physical and mental ability, sleeping or waking, and population density), subsequent pre-egress behavior (such as seeking information, collecting belongings, choosing an exit, and other activities), egress (including way finding, movement toward an exit, crowd flow, and other factors), design of escape routes, exit numbers and widths, and the psychological and physiological influence of exposure to heat and smoke on escape behavior.

   Assessment of these processes for any particular fire scenario is aimed at calculating the time from ignition to the time when occupants have evacuated or reached a place of safety. This represents the required safe escape time (RSET).

Toxic smoke products and heat affect calculations of time available for escape in that they determine the ASET tenability endpoint. They may also affect RSET calculations by effects on exit choice and speed of movement through smoke-filled escape routes.

Once a fire has started, the outcome of the situation depends on the outcome of these two processes. If the occupants have escaped before the fire becomes hazardous, with a reasonable margin of safety, then the design can be considered to have succeeded, but if the fire growth processes result in the fire becoming hazardous before the occupants have escaped, or within a narrow margin of safety, the design may be considered to have failed.

It is evident from this list of parameters that when all the needs of building occupants are considered, there is no single answer to fire safety or fire hazard and that any practical system involves some compromise between all of these parameters. Fire safety can be improved or compromised in a number of different ways, while the occupants are involved in a number of ways, both in terms of their physiology and their behavior.

It is possible to consider the effects of fires on occupants in three phases.

1. The first phase consists of the period when the fire is growing but before occupants are affected by heat or smoke. During this phase the important factors influencing escape and ultimate survival are largely psycho behavioral or logistical factors, such as how occupants are alerted to the fire and react to that knowledge, whether they respond to alarms, attempt to leave or stay to fight the fire, how they interact with other individuals, and how they respond to the geography of the fire environment in effecting an escape.
2. The middle phase is the period when occupants are exposed to smoke, heat, and toxic products, and where physiological factors such as irritancy and asphyxiation affect their escape capability. During this

phase such factors as the toxic nature of fire products and the dynamics of their production become critically important to escape.
3. The third phase is death in the fire, which may be caused by the major factors of toxicity and burns or a number of other factors.

The toxic effects of fire products are, therefore, most important during the second and third phases of fire growth. Most studies of fire toxicity have been confined to aspects of lethality. The ultimate causes of death in fires have been studied through pathological investigations of fire fatalities such as the Strathclyde study in the United Kingdom [15]. Also, the majority of combustion toxicity studies on laboratory animals have been used to measure lethality, principally in terms of the LC_{50} for individual fire products such as carbon monoxide (CO) or hydrogen chloride (HCl), or mixtures of thermal decomposition products from individual materials [16].

The middle phase of incapacitation in fires can be studied either by animal experimentation or by investigations of the circumstances surrounding real fire casualties, particularly survivors of serious smoke exposure. However, this crucial area of toxicity has been largely neglected.

One particular series of studies has been carried out on the sublethal effects of combustion atmospheres on animals, mainly primates, to examine the mechanisms whereby people become incapacitated in fires [17]. Incapacitation rather than death has been studied because most fires are potentially lethal due to heat or CO if occupants are exposed to these for sufficient time. The two major determinants of whether a potential victim escapes are (1) the point at which incapacitation by toxic products is reached, and (2) how these products affect escape capability during the window of time available for escape between ignition and the development of lethal conditions.

In addition to direct physiological effects, behavioral effects can inhibit escape. The effects of seeing smoke or flames or the exposure to irritant smoke may result in some occupants being unwilling to use a particular escape route or turning back. These effects of smoke are discussed later.

The behavioral and physiological effects of exposure to toxic smoke and heat in fires result in varying degrees of incapacitation, which also may lead to death or permanent injury. These incapacitating effects include the following:
1. Behavior-modifying effect of smoke and irritants on willingness to use escape routes
2. Impaired vision resulting from the optical opacity of smoke and from the painful effects of irritant smoke products and heat on the eyes
3. Respiratory tract pain and breathing difficulties or even respiratory tract injury resulting from the inhalation of irritant smoke, which may be very hot. In extreme cases this effect can lead to collapse within a few minutes from asphyxia due to laryngeal spasm and/or bronchoconstriction. Lung inflammation may also occur, usually after some hours, which can also lead to varying degrees of respiratory distress
4. Asphyxia from the inhalation of toxic gases, resulting in confusion and loss of consciousness
5. Pain to exposed skin and the upper respiratory tract followed by burns, or hyperthermia, due to the effects of heat preventing escape, which can lead to collapse

All of these effects can lead to permanent injury, and all except the first two effects can be fatal if the degree of exposure is sufficient.

With regard to hazard assessment the major considerations are the following:
1. The time when partially incapacitating effects are likely to occur that might delay escape
2. The time when incapacitating effects are likely to occur that might prevent escape, compared with the time required for escape
3. Whether exposure is likely to result in permanent injury or death

Up to a certain level of severity, the hazards listed in items 1 through 5 under incapacitating effects cause a partial incapacitation by reducing the efficiency and speed of escape. These effects lie on a continuum from little or no effect at low levels to relatively severe incapacitation at high levels with a variable response from different individuals. It is important to make some estimate of effects that are likely to delay escape, which may result in fewer occupants being able to escape during the short time before conditions

become so bad that escape is no longer possible. Most important in this context is exposure to optically dense and irritant smoke, which tends to be the first hazard confronting fire victims. For more severe exposures a moment may be reached when incapacitation is predicted to be sufficiently bad as to prevent escape. For some forms of incapacitation, such as when asphyxia leads to a rapid change from near normality to loss of consciousness, this moment is relatively easy to define. For other effects a defining moment is less easily characterized; for example, when smoke becomes so irritant that pain and breathing difficulties lead to the cessation of effective escape attempts, or when pain and burns prevent movement. Nevertheless it is considered important to attempt some estimate of the moment when conditions become so severe in terms of these hazards that effective escape attempts are likely to cease and when occupants are likely to suffer severe incapacitation or injuries. In the following text the mechanisms whereby these various factors cause incapacitation and death, and how they are likely to produce partial incapacitation and affect escape capability, are examined in detail. Toxicological and physiological data and models are presented are presented here and in Chap. 63 to enable calculations (or exposure dose) to incapacitation and death.

Basic Toxicity Patterns of Fire Products

As a result of chemical studies of large- and small-scale experimental fires [18] and animal exposures to the thermal decomposition products from a wide range of materials [16, 17], two important basic points have emerged concerning the nature of fire product toxicity.

1. Atmospheres of thermal decomposition products, even from single materials, contained large numbers of potentially toxic products. The chemical composition of the products could vary considerably depending on the different conditions of temperature and oxygen supply under which they were decomposed [17]. When animals were exposed to these atmospheres, similar variations in toxicity were observed. In many cases, however, similar basic ranges of products were evolved from quite different materials [18].
2. Despite the great complexity in chemical composition of smoke atmospheres, the basic toxic effects were relatively simple. For each individual smoke atmosphere the toxicity was dominated either by an asphyxiant gas (CO or HCN) or by irritants. Also, interactions between individual asphyxiant gases or between asphyxiants and irritants were found to be approximately additive, so that a reasonably good predictive model for incapacitation could be developed by summing the effects of each individual toxic component [17].

This work and that done using rodents [16] seem to indicate that the theory that smoke casualties have increased because new, highly toxic products are formed from modern materials is unlikely to be correct. Also, the finding that a small number of basic products are particularly important leads to the possibility of predicting toxic effects from a relatively simple chemical analysis of fire products. (This is not to say that unusual, highly toxic products cannot occur, as at least two examples have been discovered in the laboratory [5, 6, 8, 9], which is one important reason that the toxicity of thermal decomposition products from materials should be submitted to an animal screen.)

Environmental and Health Issues with Regard to Fire Retardants and Combustion Products

Although escape and survival from fires have been found to involve a small number of key toxic gases, combustion product mixtures contain a very large number of systemically toxic and carcinogenic organic compounds produced at low yields. Although not acutely life-threatening, exposure to such compounds in the workplace, home or outside environment can present potential health hazards, especially following repeated exposures over time-scales of

years. In addition, some fire retardant chemicals used as additives to materials can be released into the environment during use and, where these are bioaccumulative, they may present potential environmental and health issues. Some of these fire-retardant treatments, especially those containing halogens, lead to the production of environmental toxicants including polychlorinated biphenyls and halogenated dioxins and dibenzofurans. Concerns regarding potential adverse health implications from environmental release of such compounds have resulted in a recent increase in interest in both releases of pedigree compounds from treated materials and in the release of toxic compounds in combustion products. Ultimately the use of any flame-retardant treatment needs to be justified on the basis of the societal benefits in terms of reduced fire incidence, improved survivability during fires that do occur, and reduced fire effluent releases from fewer fires, compared with any potential environmental hazards from the fire-retardant systems or their combustion products.

Another issue of recent concern has been exposures to the atmospheric release of mineral dusts and fibers during fires such as the World Trade Center fire and aircraft fires, and the subsequent adverse health effects of these releases, especially to fire fighters.

These environmental toxicity aspects are considered beyond the scope of this chapter, which is restricted to consideration of fire-safety design.

Dose/Response Relationships in Relation to Material Toxic Potency

In order to determine the toxic effects of individual toxic fire products and effluent mixtures it is necessary to determine the basic parameters required to quantify exposure. These are described in detail in Chap. 63. For application to bench-scale toxicity tests the main criteria measured are the exposure concentration and exposure dose. For smoke obscuration and sensory irritancy, effects occur immediately or almost immediately on exposure, with the severity proportional to the exposure concentration. For evaluating the effects of animal exposures during a test the important parameters is the concentration (expressed as a volume ratio in ppm or mass concentration (g. m^{-3}). The effects of asphyxiant gases and lung irritants depend upon a dose accumulated over a period of time so that the main parameter is the exposure dose (expressed as ppm·minutes or g·min·m^{-3}). This is a simplification often used by toxicologists assuming toxic effects obey Haber's rule, which states that the toxicity depends on the dose accumulated, and that the product of time and concentration is a constant [19], so that

$$W = C \times t \tag{62.1}$$

where W is a constant dose, specific for any given effect. In practice, dose in inhalation toxicology is often expressed in terms of Ct product. In the case of the LC_{50}, the effect is death of 50 % of the animals and

$$W = LC \cdot t_{50} \tag{62.2}$$

In practice there can be significant deviations from this ideal behavior. The standard exposure period for most bench-scale toxicity tests is usually 30 min.

The Nominal Atmosphere Concentration

There are occasions in combustion toxicology when it may be desirable to relate the toxic effects of an exposure to the material being decomposed rather than to its individual toxic products. This applies particularly to small-scale test results, where, for example, the LC_{50} of wood when decomposed in a particular way might be considered. This is a somewhat unsatisfactory approach, since any material evolves different products at differing yields in compartment fires as the combustion conditions change, so that the toxicity also changes. However, this parameter does have some value when the small-scale test decomposition conditions have been validated against the full-scale fire conditions of

interest, and also when calculated in conjunction with measurements of the actual toxic products. This approach is related to another concept used in inhalation toxicology, that of the nominal atmosphere concentration (NAC). This theoretical concentration of test material in the test atmosphere is calculated from the amount of material produced from the atmosphere generation system each minute, divided by the diluent airflow rate. This concept is not strictly applicable in combustion toxicology since the test material is decomposed in the fire or furnace system, but two analogous concepts are useful with regard to small-scale test methods since they enable some relationship to be established between the test material and the degree of toxicity. These are the nominal atmosphere concentration in terms of mass charged into the furnace and the nominal atmosphere concentration in terms of mass decomposed, as follows:

1. Nominal atmosphere concentration (mass charge) equals mass of material placed in the furnace system divided by volume of air into into which the combustion products are.
2. Nominal atmosphere concentration (mass loss) equals mass lost by material during decomposition divided by volume of air into into which the combustion products are.

In practice the calculation of these parameters depends on the particular decomposition system used (see the section of this chapter "Examples of Small-Scale Test Methods") and a shortcoming of some systems is that these parameters cannot easily be estimated.

If predictions of toxicity are to be made from large-scale fire test atmospheres, or if toxicity data from animals are to be interpreted, the following data should be available:

1. The nominal atmosphere concentration(s) of the test material(s) mass charge ($g \cdot m^{-3}$) (NAC mass charge)
2. The nominal atmosphere concentration of the test material mass loss ($g \cdot m^{-3}$) (NAC mass loss)
3. The concentration of each major toxic product in the atmosphere and the anticipated duration of exposure, that is, the concentration/time profile
4. The rate of uptake of the atmosphere, or V_E
5. Measurement of the blood concentration of certain toxicants
6. Particle size range. This is also important in determining the respirability and site of deposition of atmospheric products. However, smoke from nonflaming decomposition in small-scale tests is usually highly respirable
7. The nature of the effects of toxic products and the time/concentration relationships of these effects

Basis and Validation of Human FED Hazard Models from Human and Animal Exposure Studies

In order to evaluate toxic, smoke and heat hazards to people in fires, it is necessary to determine the main physiological and pathological effects of exposure to toxic fire effluents and the mechanisms whereby they impair escape, cause incapacitation and death. It is, then, necessary to identify the main toxic species responsible for these effects amongst the hundreds of chemical species known to occur in fire effluents and the relationships between exposure concentration (or heat intensity), dose, and severity for each toxic species individually, and in the combinations occurring in fire effluents. One source of relevant information is from fire incidents, associated fire tests and pathology studies. These data are obtained directly for exposed human subjects, survivors and deceased, from real fire scenarios, but there is often limited information regarding the exact fire conditions, the fuel materials involved and the composition of the fire effluent atmospheres. Detailed incident investigation can supply some of these data, especially if large or full-scale incident recreation tests are performed, or by using computer fire modeling to determine the fire conditions. Since fire victims are exposed to the full fire effluent mixtures, it is possible to determine the importance and effects of different symptoms such as irritancy and asphyxiation, and the extent to which these can be understood in terms of the known effluent composition (see Chap. 63).

Another approach has been to expose animals (rodents or primates) to combustion atmospheres generated by thermal decomposition of different materials in bench-scale tests (and in a few cases exposure of rodents to effluents from large-scale fire experiments). A limitation in most cases has been a limited correspondence between the combustion conditions in the test apparatus and those in different stages of full-scale compartment fires, but the test conditions used have generated a general mix of the effluent species occurring in fires. Another limitation has been that most of the experiments were directed at measuring lethality, while the key aspect of fire exposures is the extent to which they are incapacitating and prevent escape—since most fires are eventually lethal due to carbon monoxide or burns. Where such experiments combined detailed chemical analysis of the effluent atmosphere with measurements of toxicity endpoints, this provided an opportunity to determine a number of important aspects:

- The extent to which the overall toxic effects can be understood in terms of a small number of key toxic species.
- The extent to which there were interactions between the toxic effects of different individual toxic species in providing the overall toxicity (whether individual toxic species were acting independently, were additive or synergistic [i.e. multiplicative or more than additive—all variations commonly encountered in toxicology].
- Whether any unexpected or high potency "supertoxic" effects on exposed animals occurred that could not be predicted from the known effects of the chemical effluent components (especially from the range of novel polymeric materials coming into use at around this time).
- The extent to which smoke particulates and organic components contributed to toxicity.
- Where detailed physiological measurements were made, mostly using primates, it was possible to measure incapacitating effects and the toxic species responsible

In addition to these animal studies of mixed effluents from different polymeric materials, experimental studies were carried out on individual fire gases and interactions between specific gas mixtures. Some of these measurements (for example uptake and effects of carbon monoxide, carbon dioxide and low oxygen) and exposure to optically dense smoke, convected and radiant heat, have been carried out directly in human subjects, but mostly at sub-incapacitating levels. For ethical reasons, it is not possible to expose humans to incapacitating levels of toxicants; so non-human primates have been used to supplement the human data at these levels. Additional human data are also available from sources such as industrial exposures and accidents involving individual chemical species, but these are often limited by a lack of data on the exact exposure concentrations.

Rodent data are useful for understanding toxicity mechanisms and effects for different chemicals, but while these have the advantage that comprehensive data sets can be generated, with means and statistical distributions of endpoints, there always remains the difficulty and uncertainties of extrapolating from animal data to predicted effects in humans. The most important difference between animals and humans, which is often ignored, is the scaling effect of body side. In general terms, respiration in mammals (liters of air inhaled each minute/kg body mass) is proportional to the body surface area/volume ratio. The result is that the rate of uptake of a toxic gas such as CO by a mouse is much more rapid than in a human, so that for exposure to a given CO concentration, the time to reach an incapacitating or lethal dose is much shorter. This is illustrated in Fig. 62.1 comparing rate of uptake of CO in terms of increasing blood %COHb in resting rats, macaque monkeys, and humans at inhaled CO concentrations of 1200 ppm and 3000 ppm. For rats, uptake is rapid, reaching high equilibrium levels within 15–20 min, while for humans uptake is much slower, equilibrium being approached only after 100 min or more. Humans and monkeys are incapacitated at 40 %COHb, while the rats were more resistant to the toxic effects and were unaffected until %COHb levels of 66–75 % had been achieved [20].

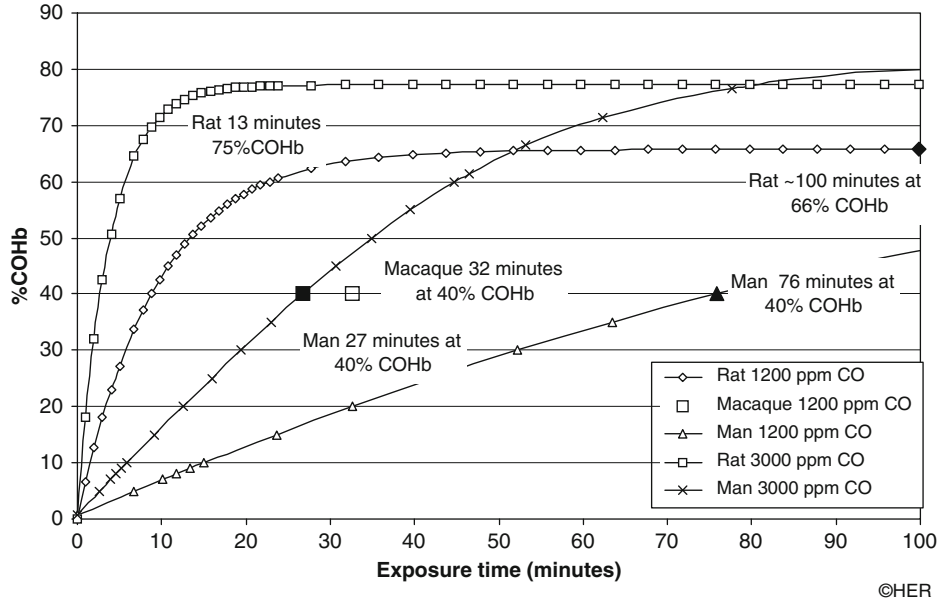

Fig. 62.1 Rate of uptake of CO as %COHb, time to and %COHb at incapacitation for rats, humans and macaque monkey at 1200 and 3000 ppm CO exposure concentrations

Other important differences between rodent and humans are basically allometric. Rodents have very large nasal cavities with a large surface area relative to their body size compared with humans. They are also unable to breathe through their mouths as primates often do. These aspects and other scaling factors result in differences in the uptake, deposition and effects of irritant acid gases and particulates. Rodents also appear to be somewhat more resistant to asphyxia than primates. Although the basic physiological and toxicological effects are very similar in rodents and humans, it is important to understand and take into account the differences when predicting effects in humans. For humans it is also important to take into consideration variations in susceptibility and the effects of aspects such as body size, activity level, age and health status.

The overall position is that since it is not possible to expose human subjects directly to fire effluent atmospheres to measure the effects, it is not possible to produce precise calculation expressions to predict effects of exposure, or to quantify probability distributions for different endpoints. But by taking account of the full set of data available from all the sources described, it has been possible to derive a set of predictive expressions for calculating times to different toxicity, smoke, and heat endpoints during fires with a reasonable level of confidence. Some aspects can be predicted with more confidence than others, and attempts have been made to reflect this as they are discussed.

Recently, it has become possible to validate the predictions of FED and FEC calculations against the conditions occurring in specific incidents, where these have been re-created in some detail using experiments and fire computer simulations (see Chap. 63).

Fire Incident Investigations, Associated Tests and Pathology Studies

Smoke Irritants

An important source of information on toxicity and toxic hazards in fires has been fire incident investigation combined with clinical and pathological studies of fire survivors and fatalities. With regard to conditions during fire incidents, survivors surveyed in a number of studies have reported difficulty or unwillingness to enter and

move through smoke, and that both smoke obscuration and irritancy are factors. Smoke from electrical fires (likely to be high in HCl) is reported as being particularly irritating, and very low smoke levels in minor incidents have resulted in buildings being evacuated due to eye and respiratory tract irritation.

The presence of a significant content of irritants in fire effluent smoke, and its tendency to penetrate deep into the lungs, is also confirmed by the occurrence of chemical pneumonitis in some fire survivors. A typical pattern in a proportion of fire survivors is a transient hypoxic crisis with low arterial blood oxygen concentrations developing several hours after rescue due to pulmonary edema and inflammation. This can be fatal, or can resolve after around 24 h. It may, then, progress to bronchopneumonia, which can also be fatal. If infection is avoided recovery can be rapid, so that while most people report a slight hoarseness and productive cough for a few days after the incident, after 3 months, they are generally free of respiratory symptoms [21].

Irritants are therefore known to be present, and both sensory irritation and lung inflammation are know to occur as result of exposures to fire effluents, but fire incidents do not really enable the identification of important irritant species or provide a method for predicting the severity of effects.

Asphyxiant Gases

CO is always present, often at high concentrations (0.5–1 %CO), in fires and remains in the blood during and after exposure as carboxyhemoglobin. The presence of high %COHb levels in the blood of fire survivors and fatalities is therefore strong evidence that they have inhaled significant quantities of a toxic smoke mixture during a fire, since all fire gases tend to be present simultaneously. Also, studies of fire fatalities and human victims of accidental and deliberate CO poisoning show similar %COHb distributions (See Chap. 63, Fig. 63.15), leading to the suggestion that CO is likely to be the major ultimate cause of death in most fires where serious burns are not present. In fact the %COHb levels in many fire victims are somewhat lower than those from CO deaths, indicating the presence of other asphyxiants [22]. Post-mortem studies also show elevated blood cyanide concentrations in a proportion of fire victims, but elevated blood cyanide levels are always accompanied by elevated %COHb levels [23]. Because cyanide is much less stable in blood than CO [24], and due to the dynamics of uptake and dispersal of cyanide in the blood, it is difficult to determine its importance in producing incapacitation at the fire scenes from post-mortem studies [20, 25, 26]. However, measurements taken during experimental house fires involving typical domestic furnishings showed HCN concentrations exceeding 1000 ppm which is likely to be a major factor in causing incapacitation (loss of consciousness) and thereby limiting time available for escape in many fire incidents [27, 28]. This is supported by a study in which fresh blood samples were taken from fire survivors at the time of rescue from the fire scene, in which high blood cyanide concentrations were measured [29], and also in samples taken from the Manchester Airtours fire victims [30].

Carbon dioxide and low oxygen hypoxia do not leave any obvious traces in fire survivors or fatalities once removed from the fire scene. Carbon dioxide is always present at high concentrations during fire experiments, and in fire victims its main effect is to cause hyperventilation, thereby increasing the rate of uptake of other fire gases. With regard to low oxygen hypoxia the effects are more difficult to predict. During enclosure fire experiments (such as that shown in Chap. 63 Fig. 63.8) it is generally found that oxygen depletion at head height is relatively minor by the time victims are predicted to be severely affected by CO and HCN [27]. However, oxygen concentration in upper layer fire effluent plumes can be as low as 1 %O_2 as well as being at temperatures of several hundred degrees centigrade. If a fire victim were to be exposed to, and inhale, an atmosphere such as this (for example when opening a door on a fire enclosure), they would be expected to collapse unconscious within seconds. A small number of reports do

exist of observations that could be consistent with this effect, in which victims in fire incidents have been observed to collapse or almost collapse following inhalation of a single breath of smoke.

Other potential asphyxiant gases present in fire effluents are oxides of nitrogen (NOx), but concentrations measured have not been high enough to make a significant contribution to asphyxia, except in specific incidents such as fires involving nitrate film [31].

The general indications from fire incident studies and full-scale fire experiments are that a short list of asphyxiant gases is important in most fires, including CO, HCN, CO_2 and low O_2. Of these, CO is present in all fires and almost always found at high concentrations in the blood of fire survivors and fatalities that have received serious smoke exposure in fires. CO is also likely to be the major ultimate cause of deaths during fires, but it is likely that both HCN and CO are important as causes of incapacitation, while their uptake is enhanced by the presence of CO_2. Irritants and simple hypoxia may be important in some fires as additional causes of hypoxia, and all may be additive with CO as ultimate causes of deaths from asphyxia during fires. Based upon the %COHb levels in fire fatalities it is possible to estimate the fatal exposure doses of CO for human fire victims. By comparing clinical status with measured %COHb concentrations in fires survivors it is possible to make some estimates of CO exposure doses and %COHb concentrations causing incapacitation during fires, however wide variations are reported in practice, as described in the section on CO in Chap. 63.

Findings from Primate Exposure Studies

Experiments involving sub-lethal exposures of macaque monkeys to individual asphyxiant fire gases (CO, CO_2, HCN and low oxygen hypoxia) and a set of mixed fire effluent atmospheres generated from a range of polymeric materials [17, 32–35] were used to investigate the physiological mechanisms by which fire effluents impede escape and cause incapacitation. Detailed physiological parameters were measured before, during and after 30-min exposures under dynamic steady-state exposure conditions. Effluent atmospheres were generated using an early version of the ISO19700 tube furnace [11], whereby strips of material were introduced at a constant rate into a tube furnace under a stream of air, and the effluents expelled into a mixing chamber where they were diluted with secondary air, forming an effluent atmosphere to which the animals were exposed (via a face mask or in a whole-body shuttle box chamber). Continuous measurements were made of physiological parameters indicating respiratory, cardiovascular and neurophysiological status, including respiratory flow, tidal volume and frequency, heart rate and electrocardiogram, electrocorticogram, nerve-conduction velocity and auditory-evoked potentials. Clinical signs and status of body reflexes were also monitored, and blood samples were taken at intervals for measurement of carboxyhemoglobin and blood cyanide concentrations. Observations were continued for 14 days post- exposure and some lung pathology investigations were also carried out.

For fire effluent exposures different materials were decomposed in two sets of experiments. For the first set wood (*Pinus sylvestris*), polyacrylonitrile and flexible polyurethane foam were pyrolysed under nitrogen at 300 °C, 600 °C and 900 °C. For the second set of experiments a rigid polyurethane foam, nylon 6, polystyrene and polypropylene were decomposed under non-flaming oxidative decomposition conditions at 440–500 °C. Polypropylene was also decomposed under flaming and pyrolytic decomposition conditions and polystyrene under pyrolysis. The fire effluent atmospheres were monitored continuously for CO, HCN, CO_2, O_2 smoke optical density and total particulates. Based upon these and more detailed investigations of decomposition chemistry by Woolley and Fardell [18], the different effluent atmospheres were found to contain significant concentrations of asphyxiant gases (CO and HCN), and varying concentrations of smoke particulates. GC-MS investigations showed a rich mix of aliphatic and aromatic hydrocarbons generated under pyrolysis, with an additional significant content of partially oxidized species (acrolein, formaldehyde,

crotonaldehyde, acetaldehyde, phenol, aliphatic acids etc.) being formed under non-flaming oxidative decomposition conditions. Under flaming combustion conditions the organic content was mostly consumed in the combustion process. Flexible polyurethane foam decomposed into isocyanate derived "yellow smoke". In addition to these experiments on resting primates two sets of experiments involved animals conditioned to carry out a behavioral task in a chamber. For these experiments the animals were conditioned to press a lever when an audible signal was sounded, after which they had a few seconds to reach the other end of the chamber where a food reward was presented for a brief period. The task was repeated at 3–5 min intervals throughout a 30-min exposure and post-exposure period [33]. The purpose was to test the animal's performance abilities during exposure and to maintain them in an active state. These behavioral experiments were carried out with exposure to different concentrations of carbon monoxide and also to fire effluent atmospheres generated from polypropylene under pyrolytic and non-flaming oxidative thermal decomposition conditions.

Kaplan et al. [36] used a condition escape paradigm to examine effects of 5-min exposures of baboons to different concentrations of acrolein or HCl gas. After 5 min exposure, the animals were conditioned to press a lever to release the door catch and escape from the exposure chamber.

The findings from the individual gas exposure experiments are summarized as follows:

- During exposure to carbon monoxide, no physiological or behavioral effects occurred until the blood carboxyhemoglobin concentration reached approximately 30 %COHb (for active animals) or 40 %COHb (for animals at rest). Free moving animals were unaffected until they suddenly became lethargic and over a period of seconds passed through a brief episode of apparent intoxication to collapse and loss of consciousness. Resting animals were unaffected until a time when their consciousness became suddenly impaired. At this point, there was a decrease in heart rate with occasional arrhythmias, a large increase in slow-wave brain activity, a decrease in respiration and failure of withdrawal reflexes as the animals became unconscious. Loss of consciousness from CO occurred at a threshold exposure dose of around 27,000 ppm·minutes for free moving animals and 36,000 ppm·minutes for resting animals. Inactive baboons became incapacitated at 35,000 ppm·minutes.
- During exposure to hydrogen cyanide there were also no immediate effects, but after a period of a few minutes (depending upon the exposure concentration) the animals started to hyperventilate. This induced a positive feedback in that the increased ventilation increased the rate of uptake of HCN, which further stimulated respiration until the animals lost consciousness, showing similar signs to those exposed to CO. At this point, there was a large decrease in respiration, so that the rate of HCN uptake decreased and the blood cyanide concentration leveled off. Some animals showed signs of recovery during this period, then passed slowly deeper into unconsciousness. Recovery was rapid within a few minutes of the end of the exposure, although whole blood cyanide concentrations showed little decrease over periods of up to an hour [25, 26]. Short exposures to high HCN concentrations (150–200 ppm) produced incapacitation within a few minutes (C·t exposure dose 270 ppm·minutes) while lower concentration of 80–100 ppm required approximately 30 min to cause incapacitation (C·t exposure dose 2610 ppm·minutes).
- Exposure to 10 % oxygen also resulted in signs of cerebral depression and lethargy throughout most of a 30-min exposure, but signs were short of loss of consciousness.
- Exposure to 5 % carbon dioxide produced some minor cerebral effects, but mainly an approximate threefold increase in V_E.
- The findings from the baboon studies were that the animals were able to perform the escape behavior efficiently up to very high concentrations of 15,000 ppm HCl and 2780 ppm acrolein, although post exposure signs or severe irritancy were observed at HCl concentrations above 1000 ppm.

The findings from the studies involving exposure to fire effluent atmospheres were as follows:

- The physiological effects measured were the same as those of the dominant toxic gases present in the effluent atmosphere and where either:
- Dominated by and identical with the effects of CO alone (e.g. wood pyrolysed at 900 °C, flaming polypropylene)
- Dominated by and identical with the effects of HCN (e.g. pyrolysed polyacrylonitrile, 900 °C, rigid polyurethane foam non-flaming oxidative decomposition)
- Dominated by signs of sensory irritancy during exposure and lung inflammation after exposure (polyurethane foam pyrolysed at 300 °C and 600 °C, wood pyrolysed at 300 °C
- In one case where significant concentrations of both CO and HCN were present, the effects were consistent with the toxicity of the two gases being additive.
- Where both CO and irritants were present, although there was some hyperventilation resulting from stimulation of lung irritancy receptors, the uptake of CO was not increased. It was considered that although V_E was increased, it was likely that ventilation-perfusion ratio changes prevented increased CO uptake.
- When polypropylene was pyrolysed, the resultant atmosphere contained a hydrocarbon mist and a wide range of aliphatic and aromatic pyrolysis products, but the atmosphere was innocuous, producing no signs of irritancy or other toxic effects in the animals, and no disruption of the behavioural task performance. When polypropylene was decomposed under non-flaming oxidative conditions, the resultant atmosphere also contained a smoke, and was highly irritant to the animals, producing a distinctive respiratory pattern with hyperventilation, and signs of lung edema and inflammation some hours after exposure. Behavioral task performance was inhibited at 1.85 mg/L mass loss concentration.
- When flexible polyurethane foam was pyrolized the particulate isocyanate-derived "yellow smoke" was highly irritant, producing respiratory changes during exposure and lung inflammation and edema some hours later.

The overall results of these primate studies basically confirmed and quantified the effects reported in fire fatalities and survivors, that the only important effects of exposure to fire effluents from common polymeric materials were asphyxia from the mixed asphyxiant gases present (CO, HCN, CO_2 and low oxygen hypoxia) and irritant effects consisting mainly of sensory irritancy at the time of exposure and lung inflammation and edema after exposure. The effects of CO and HCN were found to be additive as later confirmed in experiments with rats.

The irritant effects were as predicted in general terms from the chemical composition of the effluents, in that atmospheres rich in partially oxidized organic species such as unsaturated aldehydes of isocyanate-derived compounds were found to be highly irritant, while atmospheres low in organic content, or lacking partially oxidized organic species were relatively non-irritant. Polypropylene provides a good example of this finding. When polypropylene was decomposed under nitrogen, the atmosphere formed was rich in organics, but contained no organic species containing oxygen and was non-irritant. Under non-flaming oxidative decomposition condition in air there was a high organic content to the atmosphere produced, consisting of a mixture of products, including both oxygen-containing and non-oxygen containing species. The resultant atmosphere was highly irritant. When the furnace temperature was increased to 700 °C so that flaming combustion occurred, a "cleaner" atmosphere was formed with a lower smoke and organic content and most of the fuel carbon released as oxides of carbon. The resulting atmosphere was of low irritancy but caused asphyxia due to the carbon monoxide content. Irritant atmospheres were produced by both wood and flexible polyurethane foam when decomposed under nitrogen, since both materials contained sufficient molecular oxygen to release significant yields of irritant compounds.

These results confirm that for all materials, the highest irritancy atmospheres, rich in a wide range of organic species at relatively high yields, are obtained under non-flaming oxidative decomposition conditions. For non flame-retarded materials, well-ventilated flaming results in efficient combustion, so that organic species are oxidized to form carbon oxides and irritants are absent or present at low yields. Under vitiated (under-ventilated) combustion conditions the organic content increases, so that atmospheres produced are predicted to be somewhat irritant, but almost certainly less irritant than atmospheres produced under non-flaming conditions, since both the number of species present and the yields are lower than under non-flaming oxidative decomposition conditions [18, 37]. Also, if any exotic acute toxic effects are likely to occur from organic chemical species in fire effluents, they are almost certain to be found in the organic-rich effluents from non-flaming oxidative decomposition, while under flaming combustion conditions, the main toxic effects can be predicted to be those of the major asphyxiant gases, plus a degree of irritancy especially from products of vitiated combustion, or from acid gases. Although none of the materials used in the primate studies were flame-retardant, increased irritancy is to be predicted from flame-retardant materials, mainly from the acid gases released (halogen halides, sulfur oxides and phosphoric acid) under all decomposition conditions, and also because flame retardants acting in the gas phase (especially halogen flame retardants) reduce the efficiency of combustion under flaming conditions, thereby also increasing the content of potential organic irritants [38, 39].

The work involving sublethal exposures of primates to individual fire gases and fire effluent mixtures has therefore provided useful information on the mechanisms of incapacitation of human fire victims. It has also provided important quantitative information on the uptake and effects of toxic fire gases, which have been used to develop predictive methods for calculating time to incapacitation in human fire victims. However, the range of materials studied was limited to a small number typically used in domestic furnishings. In order to study the toxic effects of fire effluents from a wide of variety materials it has been necessary to use rodent animal models.

Sensory Irritancy

Sensory irritancy occurs in all mammals when irritant chemicals are deposited in the eyes and upper respiratory tract, especially the nose and throat. The symptoms occur immediately upon exposure (at least at painfully irritant concentrations), consisting of a burning pain, followed by a characteristic breathing pattern consisting of a pause at the end of each inspiration resulting in reduction in breathing rate. This reflex decrease in breathing rate is well developed and stable in mice, the extent of the rate decrease being proportional to the logarithm of the inhaled concentration of the irritant substance. The mouse respiratory rate depression (RD_{50}) test is used to measure the concentration of an inhaled irritant causing a 50 % decrease in breathing rate and has been used to measure the irritant potencies of a wide range of individual irritant compounds and combustion product mixtures from different materials generated in small-scale combustion toxicity tests. The use of data such as these is discussed in more detail in the irritancy section of this chapter, but an important issue is the interaction of individual irritants in mixtures. Few data are available on this issue but the following points are relevant:

- Certain irritants are chemically similar and stimulate irritant nerve receptors in the same way, so they can be predicted to be additive in their effects. An example would be a mixture of hydrogen chloride and hydrogen bromide.
- Chemically different irritants, such as aldehydes and inorganic acid gases, stimulate irritant nerve receptors by a variety of different mechanisms, but below the saturation level (maximum response level), the effects are considered likely to be additive.
- In experiments in which mice have been exposed to mixed combustion product atmospheres, the observed irritant potency of the mixture was always considerably higher

than that of the individual or summed irritant potencies of the measured known chemical components. This indicates not only that additive effects are likely to be present, but that unknown irritant chemical species of high irritant potency are present in combustion product mixtures.
- The default (conservative) assumption used for assessing the hazards from mixtures for industrial hygiene applications is that they are likely to be additive.

For these reasons, in predicting the effects of mixed irritants in combustion product mixtures it is assumed both in this chapter and in ISO 13571[4] that the effects of individual irritants are additive.

Estimates of Lethal Toxic Potency for Natural and Synthetic Polymers Under Different Fire Conditions Using Rodents, and Contribution to Overall Toxic Potency from Major Toxic Gases

Multi-gas FED Models for Lethality (LC_{50} Concentrations) in Rats Following a 30-min Exposure

There is an extensive database of the lethal toxic potencies to rats (30-min LC_{50} concentrations) for a range of individual common fire gases, and some data on the effects of combinations, which have been used as inputs to rodent lethality FED calculation models. The main concepts in these models are similar, but they differ somewhat in terms of which factors are considered and in the ways the various interactions are handled. The models estimate the FED for lethality for rats in terms of the concentration of each toxic gas present, expressed as a fraction of the LC_{50} concentration for a 30-min exposure period. The basic concept is that fractions of lethal doses of almost all gases are directly additive. Thus, if half the lethal 30-min concentration of CO is present with half the 30-min lethal concentration of HCN, then exposure of rats to this mixture for 30-min will, on average, result in the deaths of half the animals. Deaths are considered both during exposure and over a post-exposure observation period of up to 14 days, which is important for gases causing lung inflammation. It is considered that in terms of overall lethality, the effects of all gases, including asphyxiants and irritants are additive, but it is recognized that CO_2 modifies the toxicity of other gases and this is treated differently in different models. It is also recognized that NO_2 has some protective effect against HCN toxicity due to methemoglobin formation.

The FED calculation models can be used to calculate predicted LC_{50} concentrations for mixed combustion product atmospheres in which these gases have been measured, and the results compared to the measured LC_{50} concentration in exposed rats in the same tests [10].

A number of different combustion toxicity test methods have been used with rats, mostly in the 1970s and 1980s to estimate the lethal toxic potency of the effluents from a range of different natural and synthetic polymeric materials. Unfortunately, few of these have involved LC_{50} concentration measurements in combination with comprehensive measurement of the chemical composition of the atmospheres or the mass loss concentrations of the materials tested. Also, few have been conducted under conditions that can be readily correlated with those in full-scale fires, and for most methods the composition of the test atmosphere and the decomposition conditions change continuously during a test run, so that it is difficult to determine the relationship between the test atmosphere composition and effects. Three methods used have provided some data that can be used to determine LC_{50} concentrations under reasonably constant and well-defined combustion conditions coupled with measurements of the concentrations of at least a few of the major toxic gases.

The most useful data sets are the results obtained by Levin et al. [6] using the then National Bureau of Standards cup furnace method. This method involved decomposing samples of different mass in a crucible furnace under non-flaming oxidative thermal decomposition conditions at a temperature 25 °C below the autoignition temperature of the specimen and

also under flaming conditions at 25 °C above the autoignition temperature. The effluent generated from the crucible passed directly into an enclosed 200-l volume chamber to which groups of six rats were exposed nose-only. Exposure began as the sample was dropped into the crucible furnace, so in practice the composition of the test atmosphere to which the rats were exposed was not constant but increased in concentration for a period as the specimen was decomposed. For flaming exposures there was also a period during which products of non-flaming decomposition were generated before ignition occurred, but this was usually quite short. Exposure concentrations of the major asphyxiant gases (CO, CO_2, O_2 and HCN) were measured and the stated exposure concentrations were averaged over the 30-min exposure period. Animal deaths were scored during the exposure period plus a 30-min post-exposure period (scored as within exposure deaths) and also for the exposure period plus a 14-day post exposure period. The test material exposure concentrations are reported on a mass charge basis.

For a more recent set of experiments, the crucible furnace was replaced by a radiant furnace, which is the basis for the current NIST toxicity test method [40]. For this method the specimen, in the form of a flat strip, is irradiated from above by two angled radiant heaters. The effluent rises through a slit between the heaters into the enclosed 200 l chamber, while replacement air circulates back into the air space between the sample and the heater via two slits at each end of the heated area. The main decomposition mode is flaming combustion, and as with the crucible furnace method the initial decomposition is under non-flaming conditions until the specimen ignites, followed by a period of flaming until the specimen is extinguished, and a subsequent period during which off-gassing may occur from any residue. The basic exposure procedure is the same as for the cup furnace method, involving a total 30-min exposure period over which the gas concentrations are averaged. The mass loss rate of the specimen is also measured and the exposure concentrations are reported on both a mass charge and mass loss basis.

Another method for which some useful rat lethality data have been generated is the DIN 53436 tube furnace method [41, 42]. This method represents an early version of the concept used for the ISO19700 test method, in which the sample in the form of a strip is decomposed continuously in a stream of air, producing a dynamic steady state decomposition condition with a constant atmosphere composition to which the rats are exposed nose-only over a 30-min period (plus 14-day post-exposure observation period). This method has mostly been used for non-flaming decomposition, although some flaming decomposition experiments have been performed [43]. Unfortunately, the test atmosphere composition measurements made were somewhat limited. Table 62.2 shows a compilation of these data to which a rat LC_{50} FED calculation model has been applied. The rat lethality model [10, 44, 45] makes use of the rat LC_{50} data for individual gases and gas interactions obtained by mainly by Levin et al. [46] and Hartzell et al. [47].

The key precepts of the model are:

- Fractions of lethal doses of all gases except CO_2 are directly additive.
- The main effect of CO_2 is considered to be a multiplicative effect on the rate of uptake of other gases depending upon the extent of CO_2 driven hyperventilation. In addition it is considered that once animals are incapacitated, CO_2 induced respiratory acidosis enhances the metabolic acidosis already present, providing an additive toxicity factor.
- Low oxygen hypoxia is usually a minor factor in small-scale rodent toxicity experiments and can be ignored unless oxygen concentrations are allowed to decrease below 12 %. At low levels, a non-linear additive term can be used. An exponential function has been developed to allow for the effects of oxygen at low concentrations.
- A correction for the protective effect of NO and NO_2 on HCN toxicity due to methemoglobin formation can be made if necessary and for the additive effect of other nitriles present.

Table 62.2 LC_{50} concentrations (exposure plus 14-days, mass charge) for materials tested in the NBS cup furnace, NIST radiant furnace and DIN53436 tube furnace apparatus

[a]Depletion

[b]Calculated as mass loss concentration of organic polymer material × fraction of mass loss carbon as organic carbon/35. If data unavailable: non-flaming 0.35, flaming 0.035, vitiated flaming 0.105

- It is considered important to make allowance for the effect of all inorganic acid gases present and for organic irritants.

The estimated FED for lethality in rats for a 30-min exposure and a defined set of toxic gas concentrations is calculated as follows:

$$FED = \left(\frac{[CO]}{LC_{50}CO} + \frac{[CN] - [NOx]}{LC_{50}CN} + \sum_{i=1}^{n} \frac{[I_A]_i}{LC_{50}I_{Ai}} + \sum_{i=1}^{n} \frac{[I_O]_i}{LC_{50}I_{Oi}} \right) \times VCO_2 + A + \frac{1}{H} \qquad (62.3)$$

where:

I_{Ai} represents each irritant acid gas present (summed for 0 to n acid gases)

I_{0i} represents each irritant organic substance present (summed for 0 to n organics)

VCO_2 is a multiplication factor for CO_2 driven hyperventilation $= 1 + (exp\,(0.14 \times [CO_2]) - 1)/2$

A is an acidosis factor $= ([CO_2] \times 0.05) - 0.02$

H is a hypoxia function $= exp\,(8.13 - 0.54 \times [21 - O_2])$. This can be omitted if $[O_2]$ is not less than 12 %.

$[CN]$ represents the concentration of cyanide

$[NOx]$ represents the summed concentration of NO and NO_2

Where data on organic irritant concentrations are absent, it is recommended that a contribution to the overall FED should be derived from an estimate of the total yield of organic products. The FED component for organic irritants (FED_{org}) is then estimated as:

FED_{org} = mass loss concentration of organic material x fraction of mass loss carbon present as organic carbon, divided by 35. FED_{org} is then substituted for the organic irritant term in Equation 3. This term is empirically derived from the contribution to overall lethal toxicity attributable to the organic fraction during rat exposure to non-flaming wood and non-flaming flexible polyurethane foam.

If these data are unavailable, an FED_{org} of 0.35 is used for non-flaming decomposition, 0.105 for vitiated or inefficient combustion, and 0.035 for well ventilated, flaming combustion at the LC_{50} mass loss concentration.

If the concentrations of the irritants present and their lethal exposure doses are known, then the equation can be solved fully. Where unknown irritants are present the equation enables the maximum LC_{50} to be predicted based upon the asphyxiant gases and a generic expression for overall irritants.

The LC_{50} concentration values used for the Purser LC_{50} FED model are (Equation 3) shown in Table 62.3.

The VCO_2 exponential function is derived from the measured increase in the rate of uptake of CO and other inhaled toxic gases in humans and rats to increased CO_2. This is an exponential function of the inhaled CO_2 concentration, as shown from experiments in humans. In rats, inhalation of 5.25 % CO_2 produced a 1.54 times increase in the rate of CO uptake, so an exponential function has been derived intersecting this point. In situations where a 30-min exposure is lethal, animals become comatose after approximately 15 min so that hyperventilation ceases. For this reason the increased rate of uptake is applied for half the exposure time. In addition to the hyperventilation effects, CO_2 is known to cause acidosis and this respiratory acidosis, combined with hypoxia-induced metabolic acidosis, results in an additive toxic component which has been estimated according to the function shown. The data on which the deviation of these functions was based were obtained from references [46, 48].

Table 62.3 LC_{50} concentrations for gases used in the Purser LC_{50} FED—model

Gas	LC_{50} concentrations for 30 min exposures plus 14 day post-exposure period (ppm)
CO	5705
HCN	165
HCl	3800
HF	2900
HBr	3000
SO_2	400
NO_2	170
NO	1000
Acrolein	150
Formaldehyde	750
Hypoxia (using function)	21−5.4 = 15.6 % depletion

The hypoxia function is also based upon experimental data from humans and rats. From human data, it is known that there is an exponential function between percentage oxygen depletion and time to and severity of effects, with minimal effects down to 12 % O_2. In rats, the measured LC_{50} concentration for a 30-min exposure is 5.4 % oxygen (15.6 % oxygen depletion) [46, 49]. For the hypoxia term an exponential function has therefore been derived providing a

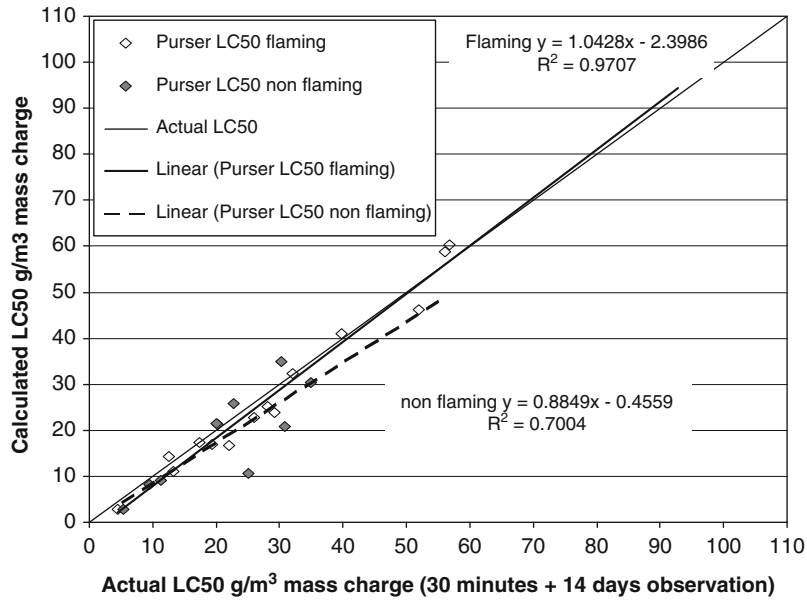

Fig. 62.2 LC_{50} concentrations calculated using the Purser rat LC_{50} model compared with measured rat LC_{50} concentrations for different materials decomposed under non-flaming and flaming combustion conditions

minimal FED at concentrations above 12 % O_2, an FED of 1 at 5.4 % O_2, and increasing FED values at lower concentrations.

The derivation of these terms for the lethal FED contribution effects of mixed organics, carbon dioxide, and low oxygen hypoxia are of necessity estimations, intended to provide a toxicologically and physiologically based approach to the calculation of lethal toxic potency for complex fire effluent mixtures. The extent to which the modified equation including these terms may provide an improved model for the calculation of lethal toxic potency from polymer effluent mixtures is tested here by application to the experimentally derived rat lethal toxicity database.

Figure 62.2 shows the measured rat LC_{50} concentrations plotted against those calculated using the LC_{50} calculation method. Linear regression lines have been fitted for the non-flaming and for the flaming data. The extent to which the regression lines overlay the 45° actual LC_{50} line gives an indication of the predictive power of the FED calculation method. Where the calculated line lies to the left of the 45° line this indicates that the calculation method underestimates the toxic potency of the combustion products mixtures, while a line laying to the right indicates that the calculation method overestimates the toxic potency.

The results show a good fit for the flaming data ($R^2 = 0.9707$) and a reasonably good fit for the non-flaming data ($R^2 = 0.7004$). The models are intended to be general, and therefore applicable to all forms of combustion atmosphere (both flaming and non-flaming). Pooling the non-flaming and flaming data gives the following linear fit equation:

$$\text{Calculated } LC_{50} = 1.026 \times \text{Measured } LC_{50} - 2.498 \qquad R^2 = 0.919 \tag{62.4}$$

The overall findings from the application of the model is that it provides good predictions of actual rat LC_{50} concentrations using measured concentrations of a small number of key toxic gases for a range of common polymeric materials, with a variety of chemical compositions. This is especially true for flaming decomposition, for which the composition of the

atmospheres is much less complex than under non-flaming conditions, consisting mainly of the common asphyxiant gases (for polymers containing C, H, O and N), with the addition of some irritant acid gases (for polymers containing N, F, Cl, Br, P or S), but low concentrations of organic species. Since the model is based primarily on an additive fractional effective dose concept, it also demonstrates that the toxic effects of these gases can legitimately be considered as primarily additive, and in particular that the lethal effects of the asphyxiant gases during exposure can be considered approximately additive with the lethal effects of irritants on the lung, to some extent during exposure, and particularly during the post exposure period up to 14 days (but mainly during the first 48 h after exposure). This is consistent with the findings of Pauluhn of a reasonable agreement between LC_{50} N-gas calculations and experimental data obtained using the DIN43536 apparatus [50].

This is important, because it demonstrates that for a range of common of materials (with the exception of per-fluorinated polymers and particular phosphorus-containing polymers), the toxic effects of fire effluent mixtures can be predicted from this small set of gases using relatively simple additive models, and that (especially for flaming combustion conditions) there is no evidence for any major unknown acute toxic effects other than the asphyxiant and irritant effects predicted from these few mixed gases.

The application of the model also shows the importance of CO_2 as a multiplicative term increasing the uptake of other toxic gases. In practice in these small-scale tests the highest chamber CO_2 in these experiments was only 4.4 % while levels of up to or exceeding 10 % have been measured in full-scale compartment fires. The model also demonstrates the importance of organic irritants. Based upon both observed effects in humans and primates, and the results in the rats and mice (particularly the post-exposure deaths) it is evident that the mixed organic irritants produced, particularly under non-flaming oxidative thermal decomposition conditions, (but also to some extent under vitiated flaming combustion conditions), make an important contribution to overall lethal toxicity. This is particularly the case where the organic atmosphere component is high in relation to that of the asphyxiant gases. Unfortunately, it is difficult to obtain fully quantitative measurements of the concentrations of all the potentially irritant organic compounds in fire effluent mixtures, Such GC-MS studies as have been performed have shown that the mix of compounds formed under specific decomposition conditions are often relatively similar for different materials, containing a range of species common to most materials, with the addition of a number of species more specifically related to the molecular structure of the material [37, 39]. On this basis, the approach taken for the LC_{50} FED model is to use a generic term for the total organic content of the atmosphere, calculated from the organic fuel mass loss multiplied by the fraction of fuel carbon present in the form of organic carbon in the fire effluent.

Fractional Effective Dose Hazard Assessments and Toxic Potency

In the context of fire safety, toxicity information is useful only to the extent that it can be used to assess toxic hazard in a full-scale fire scenario. There are a number of reasons for carrying out such an assessment. It may be needed in order to carry out a fire safety engineering assessment of a building design. In this context a particular set of fire scenarios may be run in order to assess probable outcomes in terms of the relationship between time available for escape compared to time required for escape. Time available for escape depends on the fire dynamics and time to incapacitation for building occupants exposed to toxic smoke. Time required for escape may also depend partly on the effect of toxic smoke on escape behavior. Another reason for modeling time to incapacitation may be the investigation of fire incidents in order to evaluate effects on fire

victims. Another reason may be for a manufacturer to evaluate and compare potential toxic fire hazards from different materials of products or for specifiers to determine the applicability of particular materials or products to particular design applications. In this situation a range of full-scale fire scenarios can be considered in order to evaluate product performance.

A difficulty with carrying out toxic-hazard assessments is that toxic substances exert a range of different effects on building occupants, and toxicity information may be presented in a number of different forms. Confusion also often arises in relation to toxic potency data and their application to toxic-hazard assessment.

The toxic potency of a substance depends on how much is required for a given toxic effect. The smaller the amount needed, the more potent the toxic substance. For example, in fires, hydrogen cyanide is about 20–40 times more potent than carbon monoxide because the amount needed to be inhaled to cause collapse is a much smaller exposure dose for hydrogen cyanide than for carbon monoxide.

Toxic hazard in a fire depends on the extent to which toxic products in that fire scenario present a danger to building occupants. Put simply it depends on how quickly and how much toxic products are produced and how potent the products are.

Toxic Potency

Toxic potency can be considered in terms of

- An individual toxic gas such as carbon monoxide or hydrogen chloride
- A mixture of toxic substances occurring in a fire (for example, the asphyxiant toxic potency of a CO and HCN mixture, or the irritant potency of a mixture of acid gases)
- The mixture of toxic substances evolved from the thermal decomposition under defined conditions of a particular material or product (such as wood, polyethylene, or a length of electrical cable)

The Toxic Potency of Individual Fire Gases and Gas Mixtures

In fires three major toxic effects are important.

1. The concentrations of irritant gases likely to impair escape efficiency or cause incapacitation (sensory irritation)
2. The exposure doses (Ct product doses) of asphyxiant gases likely to cause incapacitation through confusion and loss of consciousness (or to cause death)
3. The exposure doses of irritants likely to cause death through lung edema and inflammation after the fire

For sensory irritants the main criteria are the time during the course of a fire when the concentrations of irritants are sufficient to impair escape efficiency and the time when they are likely to cause incapacitation through pain and respiratory distress. This is evaluated using the concept of fractional irritant concentration (FIC), by which the fractions of an irritant concentration for each irritant present are summed. When FIC = 1, a tenability endpoint (escape impairment) is predicted. Incapacitation is predicted at higher concentrations (FIC ~ 3–5). The sensory irritant potencies of different individual irritants occurring in fire atmospheres cover an enormous range spanning six orders of magnitude. More than 20 irritant compounds are considered to contribute to the overall sensory irritancy of fire atmospheres. The most important irritants identified are acid gases (hydrogen fluoride, hydrogen chloride, hydrogen bromide, nitrogen oxides, phosphoric acid, and sulfur dioxide) and organic irritants (such as acrolein, formaldehyde, and crotonaldehyde). Evaluation of the effects of individual irritant substances and irritant fire effluent mixtures from different materials depends heavily upon data obtained from animal exposure studies together with limited human exposure data. The derivation of methods for the assessment of the effects of irritants and the derivation of tenability limits for human exposures is described in this Chapter in the section "Irritant Fire Products." Detailed

guidance on the assessment of sensory irritancy of fire effluents is presented, and used for the deviation of the Fractional Incapacitating Concentration (FIC). The application to human hazard assessments is then described in Chap. 63 in the section on smoke and irritants.

For asphyxiant gases the main criterion is the time during the course of a fire when a sufficient exposure dose (*Ct* product dose) of asphyxiants has been inhaled to cause incapacitation through confusion and loss of consciousness. This is evaluated using the FED concept, incapacitation being predicted at FED = 1. The gases important in causing asphyxiation are carbon monoxide, hydrogen cyanide, and reduced oxygen concentration. Carbon dioxide is important mainly because it increases the rate of uptake of CO and HCN. The toxic potencies of asphyxiant gases are less simple to define because for cyanide (and reduced oxygen concentration) the incapacitating exposure dose is not a constant. However, the exposure doses lethal to rats over a 30-min exposure period are approximately 5700 ppm for CO and 164 ppm for HCN. For asphyxiant gases, although the results descried in this chapter which have been obtained form primate and rodent experiments provide important information, considerable detailed physiological data are available from human experimental exposures. The evaluation of asphyxiants and derivation of hazard calculation methods has therefore been described in detail in the section "Asphyxiant Fire Products" In Chap. 63.

Another important aspect of irritants that needs to be considered is the time during the course of a fire when a sufficient exposure dose of mixed irritants had been inhaled to cause potentially lethal lung inflammation. The toxic potencies of different lung irritants occurring in fire effluent cover a very wide range of approximately 5 orders of magnitude (Table 62.4). For hazard assessments lung irritancy is calculated in terms of the Fractional Lethal Dose (FLD_{irr}), the exposure dose calculated to cause death after exposure of half an exposed population. Detailed guidance on the evaluation of lethal lung irritation is also given in the section "Irritant Fire Products." Application of the method to human fire hazard calculations is presented in Chap. 63 in the section on smoke and irritants.

Toxic Potencies of Individual Materials

When individual materials are decomposed in full-scale fires or small-scale combustion toxicity tests, they produce a range of individual irritant and asphyxiant toxic products. The overall toxic potency of the resultant effluent mixture will depend on the yields of individual toxic products and their toxic potencies. For any particular material the yields of individual toxic products depend on the thermal decomposition conditions (nonflaming oxidative, well-ventilated flaming, or vitiated flaming). In general, materials produce high yields of toxic products under nonflaming oxidative and vitiated flaming conditions, and lower yields under well-ventilated flaming conditions. This result is described in detail in Chap. 63 [3] in the section "Chemical Composition and Toxicity of Combustion Product Atmospheres" and the section "Fire Scenarios and Victim Incapacitation."

For any individual material decomposed under a particular decomposition condition in a small-scale test, it is possible to evaluate the toxic potency of the effluent mixture in terms of sensory irritation, asphyxiation, or potential for lung inflammation. The toxic potency is then expressed in terms of the nominal concentration of the decomposed material rather than in terms of individual toxic products. Table 62.5 shows examples of the sensory irritant potency of fire effluent from materials, expressed in terms of the mouse RD_{50} concentration of the material decomposed (expressed as the mass loss concentration). The RD_{50} is the concentration causing a 50 % decrease in respiration rate in mice during a short exposure, which is a measure of sensory irritant potency. A reasonably good relationship has been found between the mouse RD_{50} concentrations for a range of irritant vapors and the concentrations reported as being painfully irritant to humans [33] (see section on "Irritant Fire Products"). Table 62.5 shows the mouse RD_{50} for a number of materials, some of which

Note: The potential for causing sensory irritation spans 6 orders of magnitude, whereas that for causing death spans approximately 3 orders of magnitude. For substances down to NO_2 death is likely to be due to lung irritation, whereas for the remainder from styrene to acetone death is likely to be due to asphyxiation

[a]Substances not detected in combustion atmospheres

[b]RD_{50} from Alarie [61] where no data exist substances have been ranked according to their reported irritancy in humans

[c]LC_{50} concentrations have been normalized to a 30-min exposure time according to Haber's rule

occur in aircraft, when decomposed under the thermal decomposition conditions indicated, using the BRE tube furnace method [62]. The majority of experiments were conducted under nonflaming oxidative decomposition conditions, but a small number of experiments were conducted under flaming decomposition conditions. The results show that the majority of materials have RD_{50} values lying between 0.05 and 0.5 g/m^3 under nonflaming oxidative decomposition conditions, which means that if the products of decomposition of between 0.05 and 0.5 g of material are dispersed into each cubic meter of air, then the resultant atmosphere is predicted to be painfully irritant to the eyes and respiratory tract. However, under flaming decomposition conditions the smoke irritancy decreases by a factor of 10 or more. For use in a hazard analysis for humans the RD_{50} mass loss concentration should be regarded as producing a total FIC_{irr} of approximately 1 for the effluent from the material in question.

Although it is, therefore, possible to measure or calculate the sensory irritant toxic potency of

the fire effluent from materials decomposed under specific decomposition conditions, traditionally, toxic potencies for materials have been expressed in terms of overall lethal toxic potency to rats. This information was originally obtained by exposing groups of rats to thermal decomposition atmospheres from materials in small-scale tests and establishing the exposure concentrations causing the deaths of half the exposed animals (LC_{50} concentrations) during or within 14 days after a 30-min exposure period. These data can also be expressed in terms of an exposure dose (Ct product dose) by multiplying the LC_{50} concentration by 30 to give an LCt_{50} exposure dose. Animal experiments of this kind have now largely been replaced by chemical measurements used in conjunction with appropriate calculation models as a method for estimating the rat LC_{50}. For this method the same small-scale tests may be used and the composition of the fire effluent is measured in terms of the major toxic fire gases. The data are then used as input to the special type of FED calculation designed to predict lethal toxic potency in rats as described. (This should not be confused with the FED calculation methods used to predict incapacitation and death of humans exposed to full-scale fire atmospheres.) Details of these FED calculations for rat lethality are presented in the section on "Multi-gas FED Models for Lethality (LC_{50} Concentrations) in Rats Following a 30-min Exposure". This calculation method

[10, 44] has been published as a Standard method in British [63] and International [45] standards.

The lethal exposure concentrations or exposure doses expressed in this way represent the overall lethal toxic potency of the effluent from both asphyxia and lung irritation. Sensory irritation is not considered. The lethal toxic potency to rats is considered to be similar to that expected to occur in humans. It can therefore be used to represent an exposure dose of effluent from a material under defined fire conditions predicted to be lethal to humans. Incapacitation would be predicted at around a third of this exposure dose. In this context the toxic potency is expressed in terms of the nominal atmosphere concentration of the material (e.g., $g \cdot m^{-3} \cdot min$ mass loss of wood). This obviously provides a very crude estimate of the toxic potency of effluent to humans, since it does not take into account different toxic endpoints such as sensory irritancy and asphyxiation, it does not allow for deviations from Haber's rule known to be important with asphyxiant gases, it does not differentiate between effects occurring at different times during exposure and afterwards, and it does not allow for differences between rodents and humans or the range of different sensitivities occurring within the human population.

The lethal toxic potencies of materials tend to be dominated by toxic gases evolved at high yields such as carbon monoxide, hydrogen cyanide, and acid gases when the relevant anions are present as a significant part of the elemental composition of the material. Under some conditions organic irritants or other compounds, including irritant ultrafine particulates, can be important. Figure 62.3 illustrates the range of lethal toxic potencies from individual compounds occurring in fire atmospheres and for individual materials decomposed under different combustion conditions [64, 65]. The acute lethal toxic potencies of individual toxic products occurring in fire atmospheres range over more than 5 orders of magnitude. The most acutely toxic substance so far identified in the thermal decomposition product atmosphere is the ultrafine fluoropolymer particulate evolved when perfluorinated polymers such as polytetrafluoroethylene (PTFE) are decomposed under nonflaming conditions at temperatures of 400–350 °C [65]. The LC_{50} of this particulate is <0.017 $g \cdot m^{-3}$. This toxic particulate has a short half-life and is unlikely to present a hazard in most fire scenarios. It is not formed at high temperatures or when the fluoropolymer is flaming. Other compounds with a high acute lethal toxic potency evolved during fires are perfluoroisobutylene, carbonyl fluoride, and carbonyl chloride. Hydrogen cyanide and nitrogen dioxide and some low molecular weight carbonyl compounds are also highly toxic in the 0.1– ~1 g/m^3 range. Carbon monoxide and common acid gases such as hydrogen chloride lie in the 1.0–10 g/m^3 range, whereas a range of organic products with varying toxic potencies occupies higher ranges up to some with very low acute toxic potencies such as methane and other aliphatic compounds.

When the range of toxic potencies of these individual toxic products is compared with the acute lethal toxic potencies of effluent mixtures from particular materials or classes of materials expressed in terms of NAC mass loss (g/m^3), then a similar range of approximately 4–5 orders of magnitude occurs, ranging from fluoropolymers decomposed in such a way as to evolve ultrafine particulate (~0.017 g/m^3) to cellulosic materials decomposed under well-ventilated conditions in such a way that very low yields of toxic products are formed (>100 g/m^3). In practice, the lethal toxic potency of perfluorinated polymers covers a very wide range from approximately 0.017 to 8.6 g/m^3, depending on the decomposition conditions [65]. For most materials, the worst-case conditions for producing high toxic potencies are nonflaming or vitiated (under-ventilated) flaming conditions, particularly for materials containing nitrogen or halogens. Many materials show toxic potencies in the range 1–10 g/m^3 under these conditions. Well-ventilated flaming tends to destroy toxic products such as CO, HCN, and organic irritants, so that for polymers containing carbon, hydrogen, and oxygen the toxic potencies are low, with LC_{50} in the 10–100 g/m^3 range (Tables 62.6 and 62.7).

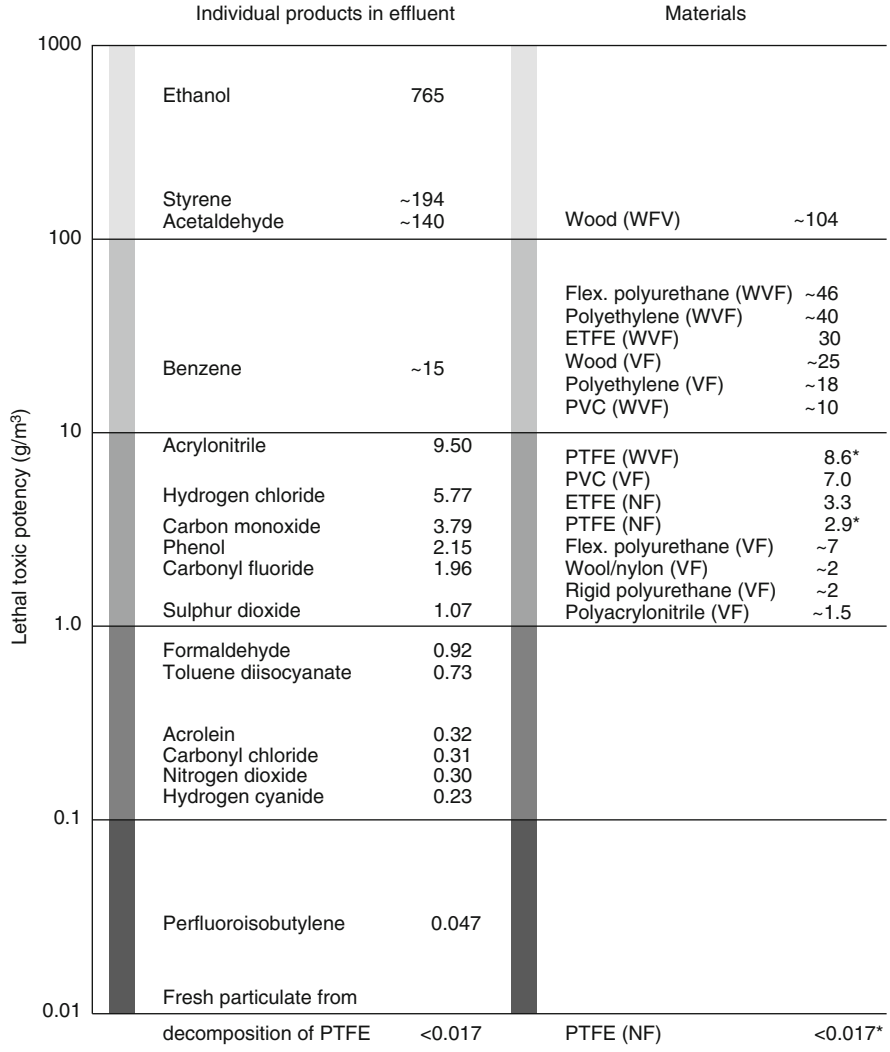

Fig. 62.3 Lethal toxic potencies (g/m^3) of individual compounds and the combustion products from various materials. *NF* Nonflaming, *WVF* well-ventilated flaming, *VF* vitiated flaming. *The toxic potency of particulates evolved from fluoropolymers (and therefore the toxic potency of fluoropolymers themselves) varies considerably with the decomposition conditions and the age of the particulates. Extreme toxic potencies have not been observed for fluoropolymers under full-scale fire conditions

Approximate rat LC_{50} concentrations and LEDs (Lethal Exposure Doses) for 30 min exposure plus 14 days observation

For most materials under most fire conditions (including fluoropolymers) the lethal toxic potencies (30-min LC_{50}) fall within a range of approximately 2 orders of magnitude. These aspects are discussed in more detail in later sections.

Contribution of Different Toxic Gases to Overall Lethal Toxic Potency from Different Materials

Figures 62.4, 62.5, 62.6, and 62.7 illustrate the extent to which different toxic species contribute to the overall toxic potency of different materials for the main different fire types described in ISO 19706 [14]. The contributions from different chemical species are calculated using the Purser LC_{50} FED model. The chemical atmosphere composition data are from the NBS cup furnace, NIST radiant and mainly from ISO19700 tube furnace [31, 66]. Figure 62.4 shows the results for non-flaming oxidative thermal decomposition (mostly NBS cup furnace data). The data are plotted as toxic potency ($1/LC_{50}$), so that the higher the bar the greater the toxicity. The shading then illustrates the contribution to the overall toxic potency from each atmosphere component.

Under non-flaming oxidative thermal decomposition conditions (Fig. 62.4) toxic potencies are relatively high, ranging from 0.029 to 0.37 (LC_{50} 34.8–3.8 g/m^3). The main toxic components are HCN, with a small contribution from NO_2 (for nitrogen-containing polymers), CO, organic irritants for most materials, and HCl (for PVC).

For well-ventilated flaming (Fig. 62.5) the yields of toxic products are low, so that toxic potencies are generally low. The results are therefore plotted at a scale five times expanded than that for non-flaming decomposition. The overall potencies range from around 0.008 to 0.13 (LC_{50} 118–7.9 g/m^3). A variety of different components contribute to the overall potencies, but for well-ventilated combustion CO_2 is always important as a cause of hyperventilation. In this sense, it is not directly toxic itself, but magnifies the toxicity of the other components by increasing their rate of uptake. It also makes a direct toxic effect at high concentrations due to acidosis. For nitrogen-containing materials HCN is important, but NO_2 also makes a contribution, since the yields of nitrogen oxides are highest under well-ventilated combustion conditions. CO is also important for some materials, and for materials containing chlorine; both CO and HCl are significant components of the overall toxicity (due to inefficient combustion resulting from the gas phase effect of chlorine). Hypoxia and organic irritants also make a contribution at high mass loss concentrations.

As fires in buildings grow and become under-ventilated (Fig. 62.6), the yields of toxic gases and overall toxic potencies are considerably

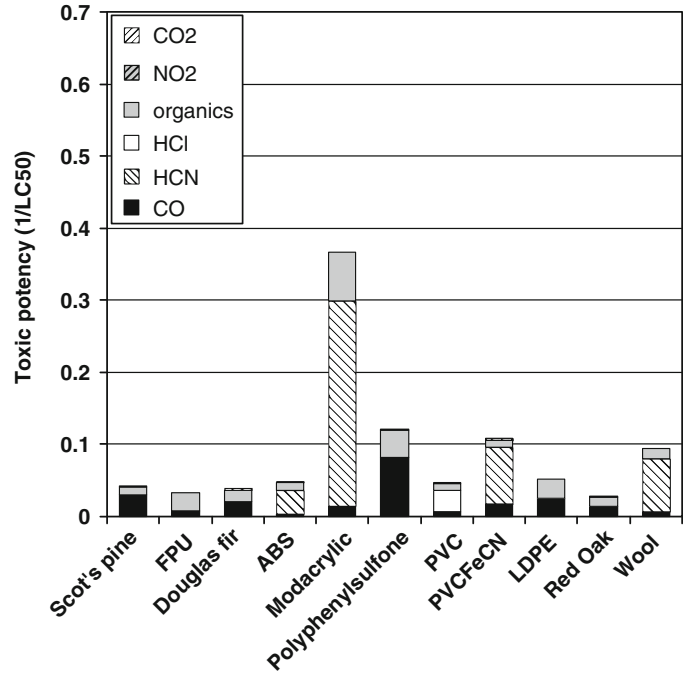

Fig. 62.4 Toxic potencies ($1/LC_{50}$) for non-flaming oxidative decomposition conditions

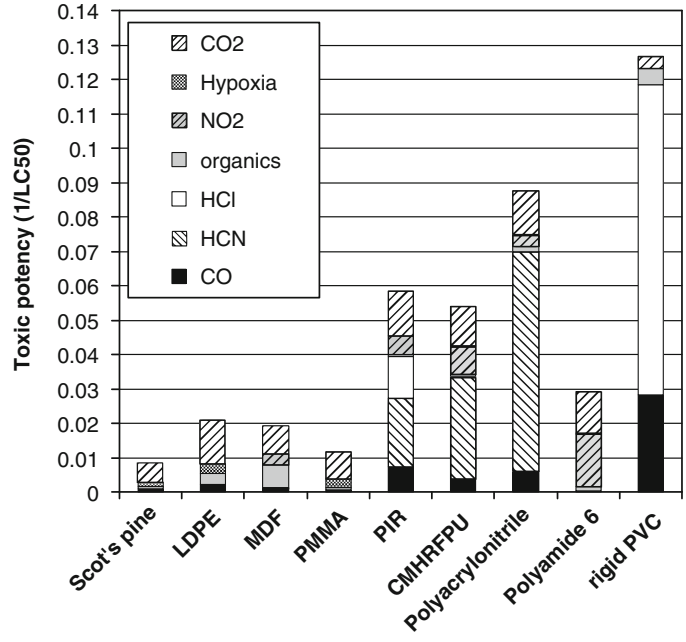

Fig. 62.5 Toxic potencies ($1/LC_{50}$) for well-ventilated flaming conditions

higher than for well-ventilated combustion conditions (0.03–0.09), (LC_{50} 30.8–3.1). Carbon monoxide is a significant toxic component in all cases, with a contribution from CO_2 and organic irritants. For nitrogen-containing materials the toxicity is dominated by HCN, with a small contribution from NO_2, and for PVC, HCl and CO are the main toxic components with a small contribution

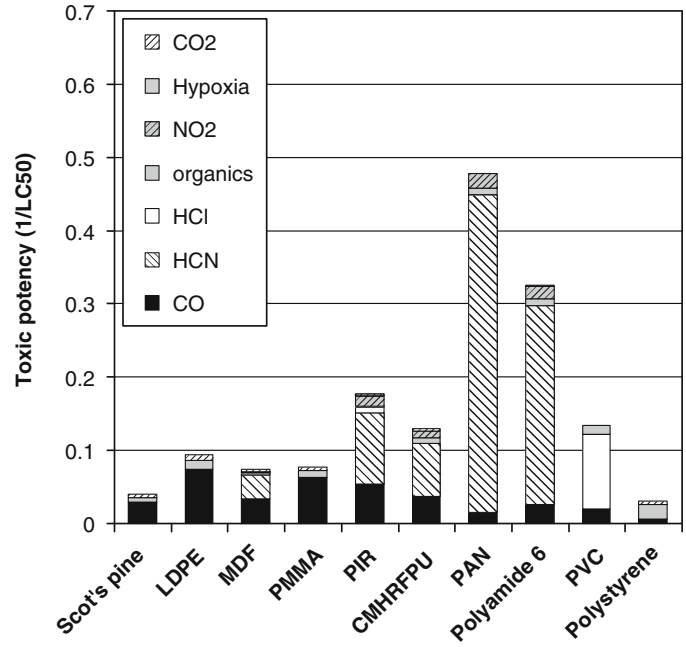

Fig. 62.6 Toxic potencies ($1/LC_{50}$) for under-ventilated flaming conditions

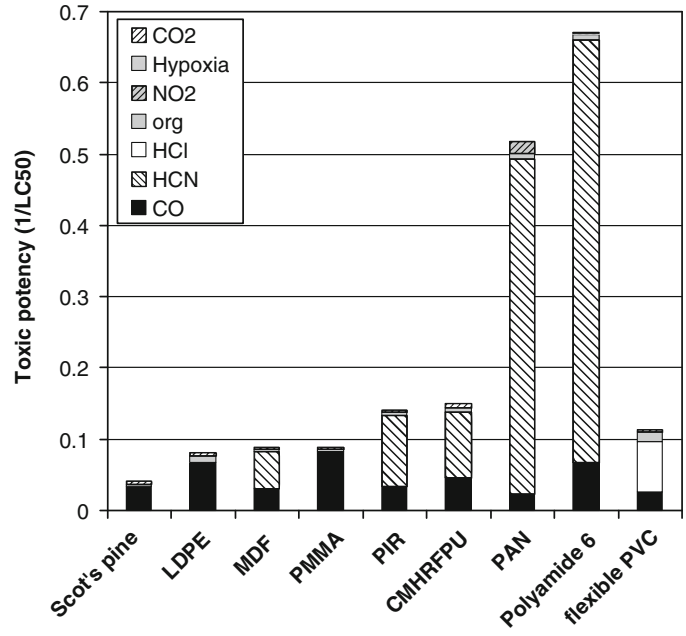

Fig. 62.7 Toxic potencies ($1/LC_{50}$) for post-flashover under-ventilated flaming conditions

from organic irritants. Polystyrene toxicity is heavily influenced by irritant organic particulates.

At higher temperatures representing post-flashover, under-ventilated combustion conditions (Fig. 62.7), the toxic potencies and patterns are similar to those under pre-flashover, under-ventilated combustion conditions, but yields of CO and HCN can be somewhat higher, so that toxic potencies for this set of materials range from 0.04 to 0.67 (LC_{50} 23.9–2 g/m^3).

In this set of materials only one (the fluoropolymer polytetrafluoroethylene), showed toxic effects under certain specific non-flaming conditions not accounted for in terms of simple asphyxiant gases and organic irritants.

Excluding fluoropolymers, the lethal toxic potency (mass loss LC_{50} concentrations of fire effluent mixtures from different materials) ranges from polyamide 6 decomposed under post-flashover, vitiated flaming conditions (LC_{50} 1.51 g/m^3), to Scot's pine and similar cellulosic materials decomposed under well-ventilated, flaming conditions at low equivalence ratios (0.5–0.8), giving an LC_{50} concentration of 119 g/m^3. In practice the lowest possible mass loss toxic potency (highest possible LC_{50} concentration) for any flammable material is limited to somewhere in the 120–150 g/m^3 range, because at these loadings CO_2 and oxygen depletion are in the lethal range, giving a total toxic potency range of approximately 2 orders of magnitude (factor of 79) between the most toxic and least toxic effluent atmospheres for common materials. In general, the toxic potencies are lower under well-ventilated combustion conditions, and higher under non-flaming, and under-ventilated conditions as illustrated in Figs. 62.4, 62.5, 62.6, and 62.7. Table 62.6 shows some historical rodent lethality from three bench-scale test methods while Table 62.7 shows approximate LC_{50} concentrations and approximate lethal exposure doses (calculated as lethal mass loss exposure concentration multiplied by exposure time) for common classes of materials under the four main fire conditions from a wider data set including animal data and LC_{50} estimates calculated using the FED equation applied to ISO TS19700 tube furnace data. Note that strictly speaking an LCt_{50} g·m^{-3}·min represents a value for a lethal dose calculated statistically from a set of animal exposure data. An "LED" represents an estimate of the lethal dose derived from a mixed set of data. For the purposes of the application described here "LCt_{50}" and "LED" both expressed in g·m^{-3}·min may be regarded as the same.

Flaming combustion conditions in compartment fires begin by being well-ventilated and then gradually become more vitiated as the fire grows and the ventilation becomes limiting. Individual materials in fires are therefore first decomposed in well-ventilated conditions at low equivalence ratios, and the equivalence ratio increases as combustion becomes under-ventilated. The effect of this on lethal toxic potency is illustrated in Fig. 62.8, which shows plots of calculated LC_{50} against equivalence ratios for a set of materials combusted in the ISO TS19700 tube furnace (the lower the LC_{50} the greater the toxicity). Most materials show a considerable increase in toxic product yields and overall toxic potency as the equivalence ratio increases. Thermal decomposition and combustion products from fluoropolymers show a great range of toxic potencies, depending upon the precise thermal decomposition or combustion conditions. A detailed account is given in Purser [65, 67].

Despite the limitations of lethal toxic potency data for individual materials, they can be used for simple estimations of toxic hazard in full-scale fires. This method represents one of a number of different approaches that can be used for the assessment of toxic hazard in full-scale fires, with varying degrees of sophistication and validity. The different methods are summarized in the next section.

Basic Requirements for Toxic Hazard Assessments of Full-Scale Fires

A key step in the process of toxic hazard assessment is to describe the growth of the fire, the production of toxic effluent, and its spread. A number of methods can be used to achieve this, but the main elements are as follows:

1. Obtain the mass loss curve for the fire and the dispersal volume of the effluent, either by conducting a simple large-scale test (measuring mass loss or heat release), by using a design fire, or by modeling
2. Determine the time-concentration curves for the main toxic fire gases, smoke optical density, and temperature of the fire either by
   (a) Direct measurement in a full-scale fire test

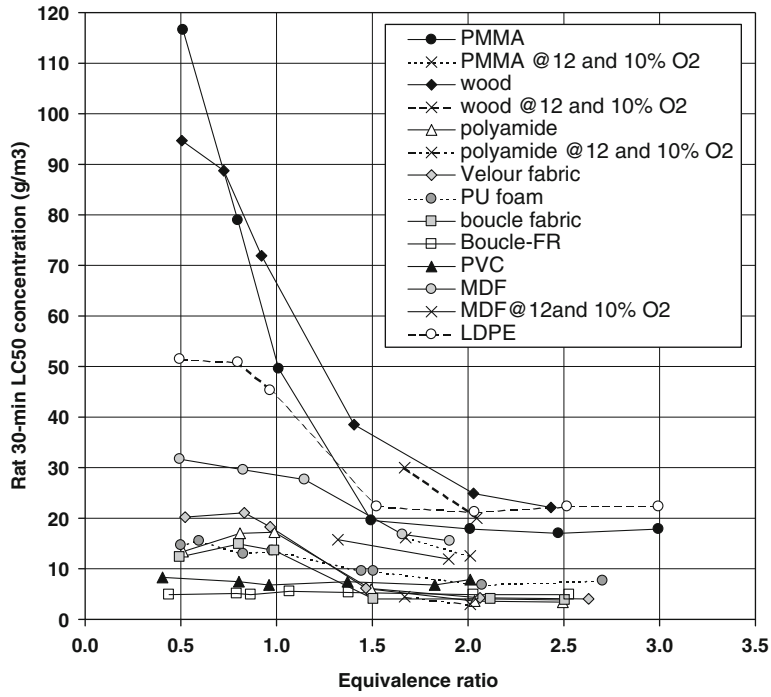

Fig. 62.8 Variations in lethal toxicity (LC_{50}) concentrations with combustion conditions (ISO TS19700 tube furnace)

(b) Calculation from the yields of toxic products, smoke and heat from the materials involved in item (1), measured in small-scale tests performed under appropriate fire conditions
(c) Calculation from a knowledge of the composition of the materials involved in item (1) and fire decomposition chemistry

3. As an alternative to item (2), calculate the mass loss concentrations and mass loss exposure doses for materials involved in the fire

Once the growth of the fire and the spread of the fire and effluent have been described it is possible to proceed to quantify hazardous effects and estimate time to incapacitation and death. This estimate can be done in two main ways.

1. Time to incapacitation and death can be estimated using physiological FIC and FED calculation models for smoke, irritant, and asphyxiant fire gases in conjunction with time-concentration curves for toxic fire gases as input data. This method is described in detail in Chap. 63 and calculates the following:
   (a) Time at which concentrations of smoke and sensory irritants are likely to impair or reduce the efficiency of egress due to psychological or physiological effects
   (b) Time at which exposure concentrations or doses are likely to cause incapacitation or prevent egress due to psychological or physiological effects
   (c) Time at which a lethal exposure dose has been inhaled
2. Alternatively, lethal toxic potency data for the materials involved in the fire can be obtained from small-scale combustion toxicity test atmospheres using animal exposures or using chemical analysis of the key toxic gases measured in such tests in conjunction with rat lethality FED calculations. These data can then be used with mass loss exposure dose curves from method (3) to estimate time to death (i.e. time to inhale a lethal exposure dose). An incapacitating dose can be estimated as approximately 0.3× the lethal dose,

The Application of Small-Scale Tests for the Determination of Toxic Product Yields, and Time-Concentration Curves, to Toxic Hazard Assessment

Where time-concentration curve data are obtained from full-scale fire tests it is possible to proceed directly to an assessment of time to incapacitation using the physiological FED algorithms. The main calculation expressions and a worked example are presented in Chap. 63 Appendix 3. Where full-scale fire data are unavailable, it is necessary to use modeling and small-scale test data obtained from performance-based tests to estimate the full-scale fire and the time-concentration curves of the main fire gases. In order to do this, it is necessary to use some form of fire growth curves (such as a t^2 fire growth curve or curves derived from heat release rate data) and a zone or computational fluid dynamics model to calculate the distribution and concentration of fire effluent (expressed in terms of fuel mass loss concentration) with time within the building enclosures. It is then necessary to obtain data for the yields of toxic fire products per unit mass of fuel decomposed, from which the concentrations of smoke and toxic gases in the fire can be calculated. As described in Chap. 16 and Chap. 36, and as presented in this chapter, for particular fuels, the yields of CO and other toxic gases are dependent on the equivalence ratio (ϕ) and particular characteristics of the fuels (such as the organic structure and the presence of oxygen or fire-retardant additives [such as nitrogen, halogens, or phosphorus]).

As with all fire parameters the yields of toxic gases in full-scale fires can be variable and difficult to measure, while the equivalence ratio can be expressed in several different ways on a global or local basis within a fire enclosure. In practice, it is not practical to carry out full-scale tests to evaluate most hazard scenarios, so it is necessary to rely on modeling using reaction to fire data from small-scale tests or standardized fire curves, although these represent a further abstraction from the full-scale scenario, and need to be used with caution. One way of obtaining data on the relationship between ϕ and the yields of toxic products is to decompose the material in a small-scale toxicity test designed to combust materials under defined equivalence ratios. If the mass loss and product dispersal curve for the full-scale fire and the full-scale equivalence ratios are calculated, it is then possible to estimate the concentrations of toxic products by reference to the small-scale data. One example of such a small-scale test is the ASTM E2058 fire propagation apparatus developed by Factory Mutual Research, data from which are shown in Chap. 36 [2]. Another is ISO TS19700 tube furnace method [10–13, 68, 69]. These methods have been used to examine the relationship between ϕ and toxic products yields, and the results obtained are close to those obtained in full-scale tests [1, 70]. The apparatus is described in the section "Second-Generation Test Methods." The following section gives a simple theoretical example of the application of this method. In addition to measurement of chemical product yields as a function of ϕ the ISO TS19700 method also measures the effective heat of combustion. This also varies as a function of ϕ, so that when using a t^2 heat release rate (HRR) curve to calculate fuel mass loss rate the heat of combustion can be entered as a variable term. At a ϕ of 2 the heat of combustion is approximately halved for most fuels, so that the mass loss rate increases more steeply than the HRR. Of course the HRR curve from a given fuel load inside a fire enclosure will depend not only upon the combustion characteristics of the fuel but also upon the boundary conditions for the enclosure in terms of ventilation and heat exchange. Secondary combustion may also occur beyond the fire enclosure where a fuel rich plume entrains secondary air, so that the changing combustion conditions and product yields beyond the fire enclosure may need to be considered if these areas are also occupied.

Using Small-Scale Toxic Product Yield Data in Toxic Hazard Assessments Figure 62.9 shows the relationship between ϕ and CO yield for two fuels comprised of carbon and hydrogen only. Large-scale data using hexane and fuel are reproduced from Gottuk and Lattimer [1, 70].

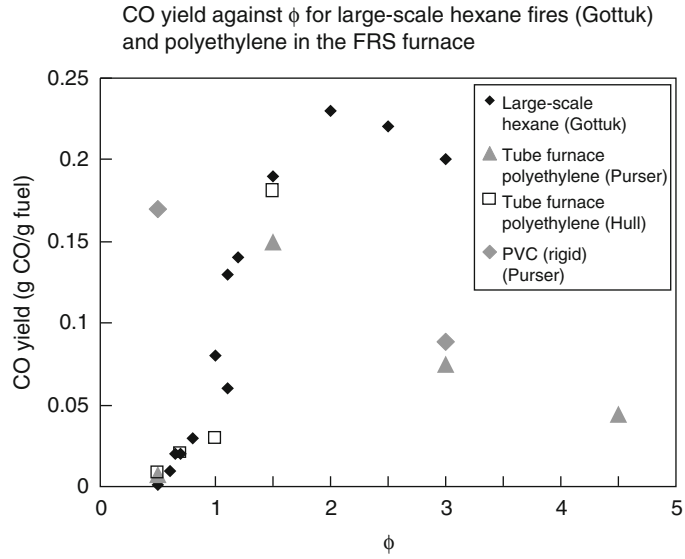

Fig. 62.9 CO yield against ϕ

The small-scale data are taken from Hull et al. [51] and Purser [50] for polyethylene and PVC using the ISO TS19700 tube furnace. As the figure shows, CO yield is very low for these fuels at ϕ values >1 and peaks at ϕ values of around 2 at approximately 0.2 g/g. Similar relationships occur for other toxic products and an inverse relationship for CO_2 (see Tewarson [2]). As a simple example, a full-scale fire is estimated as a medium growth rate t^2 fire, with a theoretical fuel decomposing with the same CO and CO_2 yields as were obtained from the tube furnace tests at ϕ values of 0.5 (well ventilated) and 1.5 (vitiated). The fire is in an enclosed room (2.44 × 3 × 2.44 m) with a 1 × 0.3 m vent at floor level. The fire growth rate, heat release rate, and upper-zone filling rate are modeled using CFAST. The mass loss rate is calculated from the heat release rate. The CO yield and CO_2 yields are taken from the tube furnace experiments as

Well ventilated :	0.007 CO	2.54 CO_2	g/g fuel mass loss
Vitiated :	0.149 CO	1.57 CO_2	g/g fuel mass loss

The FED for human incapacitation from CO and CO_2 is calculated, using Chap.63 Equations 63.15 and 63.35 (Fig. 62.10). Three cases were calculated. For one it was assumed that the CO and CO_2 yields remained fixed at the well-ventilated levels. For the second it was assumed that the yields changed linearly with time from the start to the peak of the fire, and for the third it was assumed that the yields remained constant throughout at those obtained under vitiated conditions. In reality, the yields would be expected to change with ϕ, which could be calculated for the full-scale fire case. The results of the exercise for the variable yields illustrate that the yields of CO and CO_2 during the early, well-ventilated phase of the fire produce only a small increase in FED for asphyxiation. This is partly because the smoke layer is above the occupant's head for some of the time, but mainly because the fire is small and producing only small amounts of effluent. During the later parts of the simulation the fire is larger, producing effluent at a much greater rate. It is also becoming vitiated so that both the mass and yield of CO are increasing. After 200 s the FED is predicted to reach 1 and incapacitation is predicted to occur. If the CO and CO_2 yields are assumed to remain constant at the well-ventilated levels throughout, then the

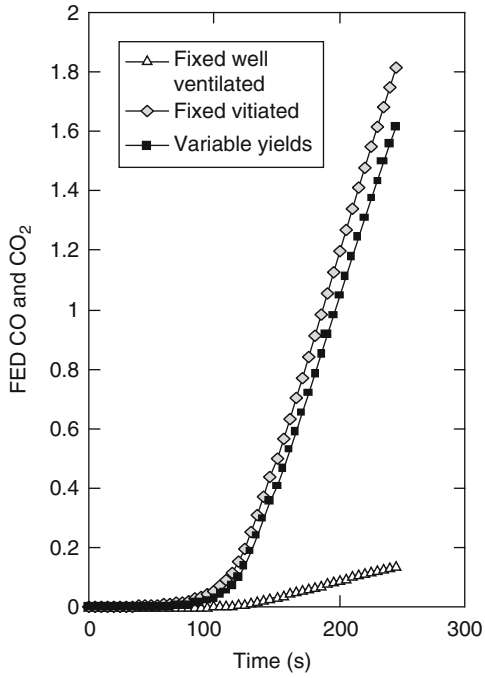

Fig. 62.10 FED for human incapacitation due to CO and CO_2 during a theoretical enclosed room fire involving a polymeric material such as polyethylene. CO and CO_2 yields obtained using the FRS tube furnace, fire modeled using CFAST [68]

increasing toxic hazard is seriously underestimated, reaching an FED value of only 0.1 after 200 s. When the CO and CO_2 yields are assumed to remain constant at the vitiated yield values, then the increasing FED is slightly earlier than, but very similar to, that obtained when continuously varying yields were assumed. This result illustrates the importance of obtaining toxic product yield data under the correct fire conditions and the extent to which the toxic hazard is driven by the later stages when the fire is larger and the CO yields greater. In this example the error obtained by assuming a constant high yield of CO throughout is small.

It is then possible to consider what outcome might have occurred if the polyethylene was substituted by a polymer treated with a fire retardant such as phosphorus or halogen additives. When these materials burn, they tend to produce high yields of CO even under well-ventilated conditions, and so might be considered to present a toxic hazard in some fires. For the example shown here, it is possible to examine the potential toxic hazard from CO and CO_2 if a halogenated polymer such as PVC was burned and the yields were as obtained in the tube furnace. Assuming that initially the fire growth rate of PVC was the same as for polyethylene (while in practice it is likely to be much slower) and the yields of CO were as obtained in the tube furnace, then it is possible to consider the effects on FED development for asphyxiant gases. As Fig. 62.9 shows, the yield of CO from PVC under both well-ventilated and vitiated conditions was very similar to that obtained from polyethylene under vitiated combustion conditions. It can therefore be estimated that the FED for PVC would follow the case calculated for a constant high CO yield. If the toxic potency of PVC (in terms of asphyxiants) under well-ventilated combustion conditions was the only item considered, then it might be estimated that PVC was a much more hazardous material than polyethylene, because the CO yield under these conditions is more than 20 times greater than for polyethylene. However, as the hazard modeling shows, the differences in CO yield during the well-ventilated phase of the fire have very little influence on the hazard development, so that, at least for this example, very little difference in time to incapacitation from asphyxiation would be expected between either fuel. In practice it would be expected that the fire growth curve for the PVC would be much slower than for polyethylene (assuming flaming ignition occurred) with a consequently slower growing FED curve. However, an additional hazard from a PVC fire would be the evolution of hydrogen chloride and other irritants, which would also need to be considered in the model. For all such hazard analysis it must be remembered that it is the concentration of toxic products at the breathing zone of a building occupant that is important. Depending on the positions of the occupants and the time during the fire development, it is likely that concentrations of acid gases in particular will be diluted relative to those near the fire and further reduced by losses to building surfaces.

Using Mass Loss Lethal Toxic Potency Data for a Simple Toxic Hazard Assessment

Another approach to carrying out a simplified toxic hazard assessment is to make use of mass loss lethal toxic potency data. The simplest approach is to use a single generic lethal exposure dose figure for all general mixed fuels under different basic combustion conditions. A slightly more sophisticated method is to take account of generic lethal exposure doses for different categories of fuels. These approaches are described in the following sections and a simple worked example is presented.

Using a Single Generic Lethal Exposure Dose for All Mixed Fuels

A simple hazard assessment can be made using lethal toxic potency data for materials obtained from a small-scale toxicity test. One way of performing a preliminary simple hazard analysis for a fire is to consider what exposure in terms of a single criterion, the mass loss concentration profile of products in a fire, is likely to be lethal to a victim. For such a calculation use can be made of mass loss lethality data from small-scale rodent toxicity test data for the material or materials involved in the fire. The assumption is that the lethal concentration to a human would be similar to that in a rat. This is standard practice in toxicology for making approximate classifications of hazard for the acute effects of industrial chemicals, however it is then usual to apply safety factors to allow for uncertainties relating to the differences between animal species and humans and to allow for variations in sensitivity in the human population. It is also necessary to make the assumption that mass loss lethality data follow Haber's rule. The three items of data needed for such an assessment are the following:

1. The basic fire condition (smoldering, early flaming, pre-flashover underventilated or postflashover)
2. The mass loss/dispersal volume-time curve for the fire
3. The rodent LCt_{50} or LED exposure doses for the materials involved in the fire in terms of the mass loss concentration for a quoted exposure time, determined under the same conditions as those in the fire

As discussed LCt_{50} data for common materials have been derived using a number of small-scale test methods under a variety of decomposition conditions. Most published data relate to nonflaming oxidative decomposition conditions, well-ventilated flaming, or mixed flaming and nonflaming conditions. Very few data are available for underventilated or postflashover fire decomposition conditions. Table 62.6 shows examples of data sets obtained using three well-known test methods. The range of LC_{50} for the references quoted (shown in Table 62.6) was approximately 5–60 $g{\cdot}m^{-3}$ mass loss for a 30-min exposure, which is equivalent to an LCt_{50} dose range of approximately 150–1800 $g{\cdot}m^{-3}{\cdot}min$, with an average value of 23 $g{\cdot}m^{-3}$ (690 $g{\cdot}m^{-3}{\cdot}min$). Allowing for a small margin of safety, it has been suggested within British standards that, for a simple hazard assessment, a single figure of 500 $g{\cdot}m^{-3}{\cdot}min$ might be considered as a single average figure for the approximate toxic potency of the thermal decomposition products from common materials. For the purpose of carrying out hazard calculations, the toxic potency of any individual material can then be expressed in terms of a potency factor relating the actual LCt_{50} to 500, as follows:

$$\text{Toxic potency factor for a material under a defined fire condition} = 500/LCt_{50}\ \ g \cdot m^3 \cdot min$$

Using Toxic Potency Data for Different Common Material Classes Under Four Fire Conditions

Using a wider database than that for Table 62.6, a survey of the toxic potency data for common materials in nonflaming, early well-ventilated flaming, pre-flashover underventilated flaming

and postflashover fire conditions was possible to derive approximate LCt_{50} (LEDs) for common materials [10, 39, 64]. Excluding fluoropolymers, the results for individual materials range over approximately 2 orders of magnitude from 20 to 3750 g·m^{-3}·min; but when the data are reduced to basic types of materials under each decomposition condition, a relatively simple pattern can be described, as presented in Table 62.7. The table shows the approximate average lethal exposure doses (LCt_{50} or LED) for classes of materials, (i.e. the LC_{50} for 30-min exposures). The findings are as follows.

- Under nonflaming oxidative decomposition conditions at >400 °C most materials have a similar potency close to 500 g·m^{-3}·min, due mainly to the effects of carbon monoxide and irritants. The main exceptions are nitrogen-containing materials releasing significant HCN at low temperatures (e.g., polyacrylonitrile, modacrylic, and rigid polyurethane foam).
- Under early well-ventilated flaming conditions most nonfire-retarded materials are substantially less toxic than under nonflaming conditions. Cellulosics (wood and cotton) are the least toxic with an LCt_{50} of >3000 g·m^{-3}·min. Plastics containing carbon, hydrogen, or oxygen are somewhat more toxic (LCt_{50} ~ 1200), and those containing low percentages of nitrogen (e.g., flexible polyurethanes, wool, and nylon) also fall into this area. PVC and fire-retarded materials have a similar toxic potency to that under nonflaming conditions. Rigid polyurethanes and nitrogen-containing acrylics have high potencies similar to those under nonflaming conditions.
- Under postflashover conditions (and preflashover vitiated combustion conditions), the potency of all materials increases due to the increased yields of HCN and CO. More smoke and irritants are also present than under early flaming conditions, which may add somewhat to the potency, particularly of the non-nitrogen-containing materials. For cellulosic materials and hydrocarbon plastics, the potency is similar to that under nonflaming conditions. For all nitrogen-containing materials, the toxic potency is high. PVC has an LED of approximately 270 under these conditions.

It is suggested that the data in Table 62.7 provide a method whereby small-scale toxicity test data, obtained under appropriate decomposition conditions, can be applied in fire engineering calculations. A simple, first estimate could be based on a single lethal toxic potency figure of 500 g·m^{-3}·min for all materials, using total fire load or heat release as the source of the mass term. In order to assess an incapacitating exposure dose (and to allow for possible greater sensitivities between rats and average humans) this should be multiplied by 0.3 to give an incapacitating dose of 150 g·m^{-3}. A further factor of 0.3 could then be applied to allow for the range of sensitivities in the human population, giving a figure of 45 g·m^{-3}·min to allow for escape of the majority of the occupant population. When more detailed information on the nature of the materials likely to be involved in a fire is known, the calculations for particular fire scenarios can be based on the predicted mass loss rate for each material, adjusted by the appropriate toxic potencies. The range of toxic potencies of common materials decomposed under conditions occurring in flaming fires is approximately two orders of magnitude. Difficulties in making estimates of the specific toxicities and toxic potencies of common materials arise from the very poor database of both small- and large-scale tests conducted under appropriate conditions. This is particularly true of the vitiated pre- and post- flashover condition, although ISO TS 19700 data are now available for a range of materials [13].

Theoretical Example of the Application of the Mass Loss Lethal Toxic Potency Data for a Simple Toxic Hazard Assessment [63]

Consideration is being given to replacing the floor covering material in a hotel bedroom. There is a concern that if the material is ignited by a small ignition source the rate of

development of a toxic hazard from the new material (material B) should not be worse than that from the old material (material A). It is considered that the most likely scenario would involve a closed room, so that rapid smoke filling would occur and the effluent can be considered as evenly mixed throughout the room volume (i.e., layering effects can be considered very transient and can be ignored). A problem is that the toxic potency of material B is twice that of material A, although it burns more slowly once ignited.

Information Available The volume of the room is 40 m^3. The floor covering materials are 1 cm thick with an area density of 1 kg/m^2. Horizontal burning tests have shown that both materials burn through rapidly so that a front of complete combustion spreads from the point of ignition. For material A the rate of flame spread is 10 cm/min whereas for material B the rate of flame spread is only 5 cm/min. However, small-scale toxicity tests have shown that, under well-ventilated flaming conditions, the toxic potency of material B (LC_{50} 10 $g{\cdot}m^{-3}$, lethal exposure dose 300 $g{\cdot}m^{-3}{\cdot}min$) is twice that of material A (LC_{50} 20 $g{\cdot}m^{-3}$, lethal exposure dose 600 $g{\cdot}m^{-3}{\cdot}min$).

Hazard Analysis Assuming a small point ignition source, both materials will burn through, and a circle of burned area will spread out from the point of ignition (Fig. 62.11). Since material A burns twice as quickly as material B, the area of material A consumed will be four times that of material B at any time during the early stages of the fire.

Table 62.8 shows how the FED calculations are made using material A as an example. The FED for each point in time is the exposure dose divided by the lethal exposure dose for that material. The FEDs for each time interval are then summed throughout the fire until the FED reaches unity, at which point the toxicological endpoint, in this case lethality, is predicted.

Figure 62.12 shows the results of the FED calculations for materials A and B in the 40-m^3 room. The analysis shows that lethal conditions are attained after approximately 6 min for material A, and approximately 1.5 min later for material B. It can, therefore, be concluded that material B presents less of a toxic hazard than material A in this scenario, despite the fact that material B has twice the toxic potency of material A.

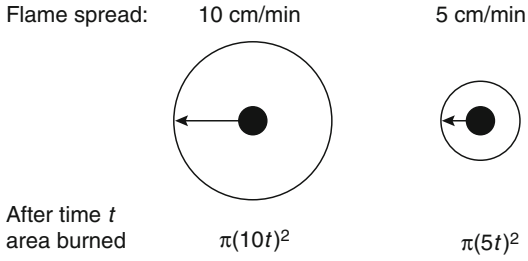

Fig. 62.11 Flame spread rate for two materials

Incapacitation

This rather crude method could be used to give an approximate indication of when conditions in a fire are likely to be lethal, but in practice the effects of fires on exposed victims are not so simple. In many cases death is not due to the immediate toxic effects of exposure but results from the victim being trapped in the fire, either because irritant and optically obscuring smoke prevents escape or because asphyxiant gases cause incapacitation, so that the victim remains in the fire to die either from a fatal dose of toxic products acquired during the prolonged exposure or from burns. One way of taking these factors into account would be to determine the *Ct* product dose at which effects such as incapacitation due to asphyxia occur in small-scale toxicity tests. These could then be applied to the fire hazard analysis to estimate the fractional incapacitating dose rather than the fractional lethal dose. However, because of differences in generating small-scale fire test atmospheres similar to those occurring in large-scale fires, a potentially much more effective way of predicting toxic hazard would be to measure the concentration/time profiles of the important toxic products in the fire and to determine their effects from toxicity data derived from experiments in humans and primates (and to a lesser extent also from rodents) as described in Chap. 63.

Table 62.8 Example FED calculation data for materials A and B

Time (min)	Area burned (cm^2)	Mass consumed (g)	Mass loss concentration (averaged for each time interval) ($g \cdot cm^{-3}$)	Exposure dose ($g \cdot cm^{-3} \cdot min$)	FED
Material A	(LC_{50} 20 $g \cdot m^{-3}$; LCt_{50} 600 $g \cdot m^{-3} \cdot min$)				
0	0	0	0	0	0
0.5	79	79	1.0	0.5	0.001
1.0	314	314	4.9	2.9	0.005

Material B	(LC_{50} 10 $g \cdot m^{-3}$; LCt_{50} 300 $g \cdot m^{-3} \cdot min$)				
0	0	0	0	0	0
0.5	20	20	0.25	0.12	0.000
1.0	79	79	1.2	0.74	0.002
At 5 min	1963	1963	44.4	82.2	0.274

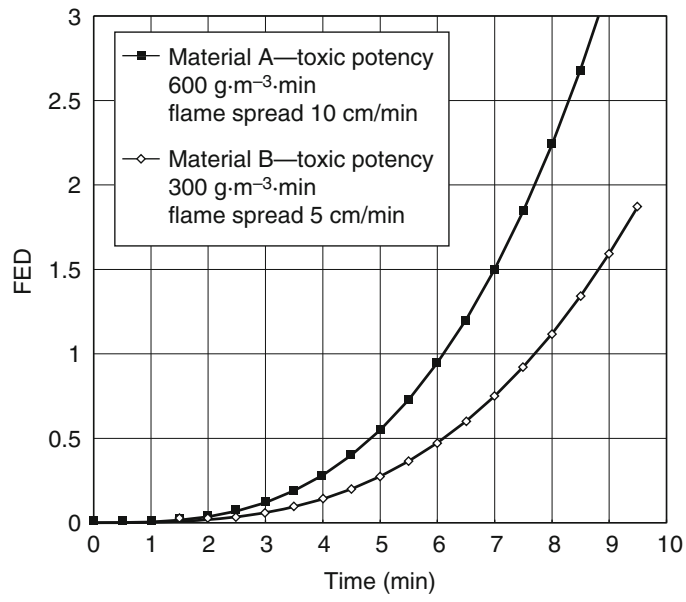

Fig. 62.12 Relative toxic hazard from two materials calculated according to the mass loss lethal exposure dose method (time to lethality when FED = 1) [63]

Assessment of Irritancy and Derivation of Irritancy Calculations for Humans

Chapter 63 shows some data for the effects of exposure to smoke during fire incidents on occupant behavior and willingness to enter and move through smoke. Also presented are data on the experimentally determined relationships between smoke density and walking speed for non-irritant smoke (from kerosene) and somewhat irritant smoke (from smoldering wood chips) or slightly irritant theatrical smoke containing a low concentration of acetic acid. In practice smoke from different burning materials contains a wide range of irritant chemicals the identities and yields of which vary with the materials composition and the combustion conditions. Although data and calculation methods presented for generic "averagely irritant" smoke may be applicable to some design cases, a more complete analysis of the hazards to

escape and survival from exposure to irritants is preferable, especially when the presence of significant yields of the more potent organic irritants and acid gases are considered likely to occur. The following sections consider the nature of irritant fire products and the derivation of method to measure irritancy and derive FEC and FED methods for calculating time to irritancy endpoints in humans, and for estimation of walking speeds in atmospheres of irritant composition. The calculation methods derived from this information for effects of sensory irritant on escape capability and movement speed, and for calculation of lethal lung inflammation are presented in Chap. 63. The basis for the calculation methods is described in the following section.

Irritant Fire Products

Unlike the incapacitating effects of asphyxiants, which are clear-cut and well understood, the incapacitating effects of irritants are much more difficult to determine. Reviews of combustion product irritancy and effects are presented in Purser [71, 72]. Irritant fire products produce incapacitation during and after exposure in two distinct ways. During exposure the most important form of incapacitation is sensory irritation, which causes painful effects to the eyes and upper respiratory tract and to some extent also the lungs. Although exposure may be painful and thus incapacitating, it is unlikely to be directly lethal during exposure unless exceptionally high concentrations of irritants are present. However, the second effect of irritants penetrating into the lungs is an acute pulmonary irritant response, consisting of edema and inflammation, which can cause respiratory difficulties and may lead to death 6–24 h after exposure [32, 73]. The effects do not show the sharp cut-off of asphyxiation but lie on a continuum from mild eye irritation to severe pain, depending on the concentration of the irritant and its potency [52, 56, 74]. For sensory irritation the effects do not depend on an accumulated dose but occur immediately on exposure and usually lessen somewhat if exposure continues [17, 52]. For the later inflammatory reaction the effect does depend on an accumulated dose, approximately following Haber's rule and there seems to be a threshold below which the consequences are minor, but when this dose is exceeded severe respiratory difficulties and often death occur, usually 6–24 h after exposure. However, for most sensory irritants the ratio between the concentration producing severe irritation and the dose causing death is usually large (15–500 times) [57, 58] for 30-min exposure times (see Table 62.4).

The effects of low concentrations of irritants can best be considered as adding to the obscurational effects of smoke by producing mild eye and upper respiratory tract irritation. In this situation irritants may have some effect by impairing the speed of an individual's movement through a building (as would simple visual obscuration), but the combined effects of eye irritation and direct visual obscuration may be more serious, and it has been shown that human volunteers moved more slowly through irritant smoke than through nonirritant smoke [75]. The limitation of escape capability may not be simply restricted to direct physiological effects but also to psychological and behavioral effects such as the willingness of an individual to enter a smoke-filled corridor [76].

At the other end of the scale, when irritants are present at high concentrations, there is some disagreement about the likely degree of incapacitation. Some investigators believe that the painful effects on the eyes and upper respiratory tract would be severely incapacitating, so that, for example, escape from a building would be rendered extremely difficult [77]. Others believe that the effects peak at moderate concentrations, and that although the effects may be very unpleasant they would not significantly impair the ability to escape from a building and would provide a strong stimulus to escape that might almost be beneficial [44].

One of the main difficulties in attempting to predict the consequences of exposure to irritants is the poor quality of data available on humans. Obviously, very few controlled studies have been made of the effects of severe irritancy in humans, so that most data are anecdotal, derived from

accidental industrial exposures, with only a vague knowledge of exposure concentrations. Reports of the severity of the effects also tend to be very subjective, so that the term *severe irritation* could cover a wide range of sensations with varying degrees of actual incapacitation. Another problem is that since sensory irritation covers a continuous range from mild eye and upper respiratory tract irritation to severe pain, there are no simple objective endpoints or thresholds. The most extensive studies of the effects of severe irritancy in humans have been performed on volunteers exposed to riot-control agents such as CS (o-chlorobenzylidene malonitrile) or CN (α-chloroacetophenone). Even these studies do not really show how the ability to escape from a building might be affected, but they do to some extent convey the severity of the effects.

The effects of CS, which are probably similar to those of any severe sensory irritant, have been described by Beswick et al. [52]. They consist of an almost instantaneous severe inflammation of the eyes accompanied by pain, excessive activation (tearing), and blepharospasm (spasm of the eyelids). There is irritation and running of the nose with a burning sensation in the nose, mouth, and throat, and a feeling of intense discomfort during which the subjects cough, often violently. If the exposure continues, the discomfort spreads to the chest and there is difficulty in breathing. Many subjects describe a tightness of the chest or chest pain as the worst symptom of CS exposure. The respiration pattern is irregular and the breath is held for short periods. Attempts to avoid the irritation by breath-holding, followed eventually by fairly deep breaths, are reported as being extremely unpleasant. At this stage most individuals are acutely apprehensive and highly motivated to escape from the smoke. However, if exposure continues there is some remission of signs and symptoms. When subjects were exposed to 0.08 ppm CS, they found the immediate effects very unpleasant but after 4–5 min were able to play cards. Another finding with CS, perhaps related to the development of tolerance, was that subjects could endure a relatively high concentration (~0.8 ppm CS) if it was achieved gradually even over as short a period as 10 min (as is likely to occur in fires) while they were totally unable to bear an immediate exposure to the same concentration [52, 53].

Reports are conflicting among fire victims. Some persons say they went through dense smoke without experiencing any great discomfort, whereas others say that respiratory difficulties prevented them from entering smoke-filled areas [78]. This seems to depend on the type of fire. For example, the smoke from some well-ventilated fires involving primarily cellulosic materials has been reported as irritant but not seriously incapacitating, whereas that from some plastic materials (e.g., the interior of a burning car) was found to cause severe effects when only a small amount of smoke was inhaled. Anyone who has had bonfire smoke in their eyes will know the pain of the experience. However, the effects can be mitigated by blinking or shutting the eyes, and the effects on the nose can be mitigated by mouth breathing and breath-holding. Also, it is known that people in emergency situations are often unaware of painful stimuli [79]. It is, therefore, likely that irritant smoke products do have some severe effects on the escape capability of fire victims, but it is difficult at present to predict accurately the likely degree of incapacitation.

Animal Models for the Assessment of Irritancy and Their Extrapolation to Humans

Having established that irritancy is likely to be a major cause of incapacitation in fires, it is important to find some way of assessing the potential of fire atmospheres for causing irritancy. The basic effects, consisting of an acute inflammatory reaction of the tissues accompanied by stimulation of pain receptors, are common to all mammals, so that animals can realistically be used to assess the potential for irritancy in humans.

The characteristic response to eye irritation is stimulation of trigeminal nerve endings in the cornea leading to pain, blepharospasm (reflex, or more or less involuntary closure of the

eyelids), and lacrimation. Severe damage may also lead to corneal opacity.

The effects of irritants on the upper respiratory tract have been studied in a number of species, including humans, for a wide range of airborne irritants including atmospheres of combustion products [80, 81]. The characteristic physiological response (also due to trigeminal nerve stimulation), is a reflex decrease in respiratory rate accompanied by a prickling or burning sensation in the nose, mouth, and throat, often accompanied by mucus secretion. At very high concentrations rapidly developing inflammatory reactions in the upper respiratory tract and laryngeal spasm may cause death during or soon after exposure, but in humans the lung is likely to be the more seriously affected target organ.

In contrast to these effects, the characteristic response to irritants penetrating into the lung is an increase in respiratory rate, generally accompanied by coughing and a slight decrease in tidal volume. There may also be bronchial constriction and increased pulmonary flow resistance, particularly if the victim is hypersensitive to the irritant [58, 80]. This is accompanied by tissue inflammation and edema, which at very high concentrations can cause death during, or more often after, exposure [15, 32].

The effect (upper respiratory tract or lung irritancy) that predominates depends on a number of factors such as the physical characteristics of the aerosol, the aqueous solubility of the irritant, the animal species, and the duration of the insult. An important difference between mice and rats (which are often used to measure irritancy) and primates, including humans, is that in rodents the nasal passages are complex in structure and have a large surface area, so that soluble gases are readily taken up and particulates are readily deposited. A decrease in respiratory rate in the upper respiratory tract is the major response in rodents, which tends to protect them from exposure. Their great tolerance to hypoxia (and possible circulatory adaptations similar to the diving reflex) also enables them to maintain greatly reduced breathing for long periods. In humans and other primates the nasal passages are simply structured with a relatively small surface area, and in humans particularly, mouth breathing is common. Thus, although upper respiratory tract irritation occurs initially and is accompanied by some respiratory rate decrease, a greater proportion of the inhaled irritant is carried into the lungs, so that lung irritation is generally a more pronounced effect. In primates, including humans, a transient respiratory rate depression is followed rapidly by the increased respiratory rate characteristic of lung irritation [17, 32] (Figs. 62.13 and 62.14).

Rodent Respiratory Rate Depression Test

The method most commonly used to quantify upper respiratory tract irritancy both for pedigree chemicals and combustion products is the mouse respiratory rate depression test [81, 82]. The basic method involves measurement of the percentage decrease in respiratory rate during exposure over a range of different atmosphere concentrations. From this measurement the RD_{50} (the concentration required to produce a 50 % decrease in respiratory rate) is calculated. Since the basic irritant mechanisms are the same in all mammals, it is certainly possible to identify an individual substance, or mixture (such as a combustion atmosphere), that is likely to be irritant to humans; however, it may also be possible to predict the degree of irritation in humans. As a result of comparisons of data from humans with results from mice, Alarie [33, 61], has demonstrated a relationship between the potency of known sensory irritants in humans and a derivative of the mouse RD_{50}. When the log of the TLV (often based on symptoms of irritancy in man) is plotted against the log of 0.03 multiplied by the RD_{50} in ppm, most chemicals known to be sensory irritants in humans fall into a linear relationship with the respiratory effects in mice. Chemicals that are highly irritant in humans such as acrolein or chlorine have low RD_{50} measures in mice whereas mild irritants such as ethanol have a high mouse RD_{50} [33, 61] (see Table 62.4).

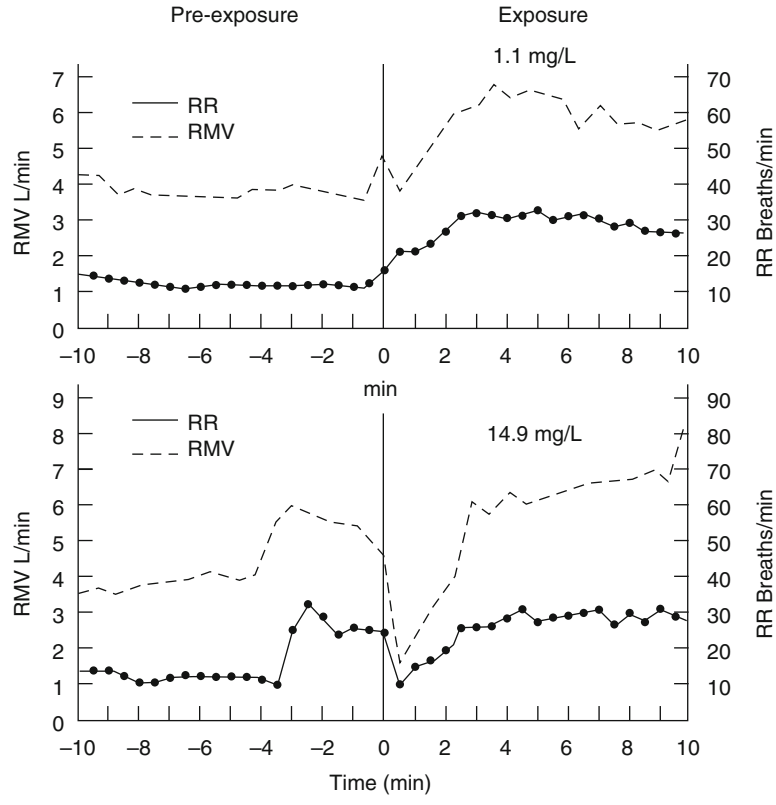

Fig. 62.13 Respiratory effects of polypropylene decomposed under nonflaming oxidative conditions—cynomolgus monkey

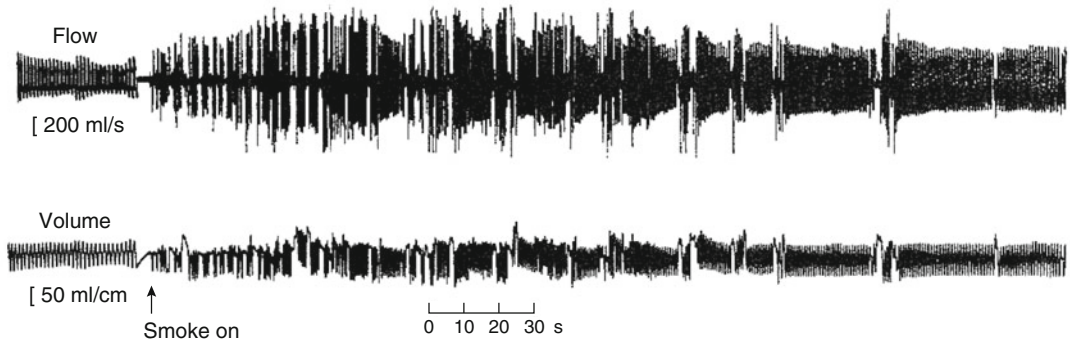

Fig. 62.14 Effects upon respiration of exposure to an irritant smoke atmosphere; wood pyrolyzed at 300 °C. When the smoke reaches the primate there is an initial sensory irritant response consisting of a decrease in respiratory rate with pauses between breaths. This rapidly gives way to a pulmonary irritant response consisting of an increase in respiratory rate and volume, which is maintained for the duration of the exposure [16]

Such methods appear to give good predictions of irritancy at low levels that are suitable for fixing hygiene standards, but for the high concentrations occurring in fires it is necessary to predict which concentrations will produce sufficient incapacitation to cause serious impairment of escape capability and also which concentrations will cause serious lung damage after exposure. As stated previously, such predictions of incapacitation in humans are difficult because of the variable and subjective nature of irritancy. However, Alarie states that a human

exposed at the mouse RD_{50} concentration of any substance would find the atmosphere severely irritating and would be seriously incapacitated within 3 min [61], which certainly seems to be justified in terms of some individual chemicals. For example, the work with CS [52, 53] shows that, although it is very difficult to measure intolerable irritancy in humans, there does seem to be a reasonable agreement between the human and mouse data. Thus the mouse RD_{50} (4 mg/m^3, 0.52 ppm) is very close to the concentration found to be immediately intolerable when humans were exposed for up to 12 min (5 mg/m^3, 0.6 ppm), and the list of RD_{50} levels and concentrations reported as highly irritant in humans [51] given in Table 62.4 shows a reasonable correspondence, particularly for the irritants commonly found in fires.

However, these apparent irritancy correlations between rodents and humans still do not enable the exact prediction of the degree of incapacitation likely in humans, and in some cases there is evidence that the mouse model does not even give a good prediction of the degree of sensory irritation, although it can be used to demonstrate when sensory irritation is likely to occur in humans.

Three experiments, two involving nonhuman primates and the other involving humans, may illustrate the difficulties of extrapolating from the RD_{50} and physiological effects in mice to the degree of irritancy, incapacitation, and physiological effects in primates. In a series of experiments the irritant effects of smoke produced by the nonflaming oxidative decomposition of polypropylene were evaluated in cynomolgus monkeys [17, 32]. The effects of breathing smoke through a face mask were mild at concentrations (NAC mass charge) of up to 4 mg polypropylene/L, consisting of a transient decrease in respiratory rate lasting approximately 30 s (a sensory irritant response), followed by an increased respiratory rate (lung irritant response) with a slight increase in RMV (see Fig. 62.13). The respiratory response pattern is illustrated in Fig. 62.14, where similar effects occurred during exposure to pyrolysis products from wood. For polypropylene the lung irritant response was the most sensitive effect with a threshold of 1 mg polypropylene/L. At concentrations above 6 mg/L the irritant effects were more marked, and although recovery appeared complete immediately after exposure, signs of nasal and pulmonary inflammation occurred some hours later. One animal died following an exposure of 30 min at 8 mg polypropylene/L. When free-moving monkeys trained to perform a behavioral task were exposed, there was evidence of some eye irritation and mild disruption of behavioral performance at a concentration of 1.85 mg polypropylene/L, the effects of exposure at 0.92 mg/L being very slight. However, the mouse RD_{50} for the same polypropylene atmosphere was found to be 0.1 mg/L. According to the model this concentration should have been highly irritant to the monkey, and yet in practice only the mildest of signs occurred at concentrations more than an order of magnitude higher.

Similarly, in another study Potts and Lederer [83] exposed mice and humans simultaneously to smoke from the pyrolysis of red oak (mouse RD_{50} 0.37 mg/L). At this concentration the smoke was barely visible and all human subjects stated that although the smoke was unpleasant and irritating, in no sense were they physically incapacitated, and they were quite capable of performing tasks such as threading nuts and bolts of various sizes.

The third experiment was performed on two pedigree substances, hydrogen chloride and acrolein, often regarded as important irritants in smoke. In these experiments baboons were trained to press a lever in order to escape from a chamber after a 5-min exposure [57]. It was found that the animals could perform this task efficiently even at the incredibly high concentrations of 2780 ppm acrolein or 16,570 ppm HCl, although in both cases the animals died from lung inflammation after exposure. These concentrations compare with mouse RD_{50}s of 1.68 ppm for acrolein and 309 ppm for HCl, and at these concentrations both substances are highly irritant in humans (Table 62.9).

As a result of this work on irritants in rodents, nonhuman primates, and humans, it would seem that the rodent models are good methods for

Table 62.9 Irritancy data

Acrolein[a]
Mouse RD_{50} = 1.68 ppm [77]
Marked irritation of eyes and nose in humans—1 ppm [51]
Severe irritation of eyes and nose in humans—5.5 ppm [51]
Henderson and Haggard [51] state that 10+ ppm is lethal in humans within a short time due to pulmonary irritation. However, 10 ppm for 3.5 h in cats was nonlethal [51]
Kaplan [57] has reported that baboons can escape from a chamber after 5 min exposure at up to 2780 ppm. One animal died due to pulmonary effects following exposure at 1025 ppm, and another following 2780 ppm. No signs of pulmonary effects were observed following exposure at 505 ppm and below
A case has been reported of a man dying following exposure to 153 ppm for 10 min [56]
The 6-h mouse LC_{50} is 66 ppm [55]
The 30-min rat LC_{50} is 135 ppm [55]
Hydrogen chloride[b]
Mouse RD_{50} = 309 ppm [77]
Strongly irritant to humans at 50–100 ppm for 1 h [51]
Brief exposure at 1000–2000 ppm is regarded as dangerous to lethal in humans [56]
Humans LCLO 1300 ppm for 30 min [55]
Kaplan exposed baboons for 5 min to concentrations of up to 16,570 ppm and found that they were able to perform escape maneuvers. One animal suffered permanent lung damage at 11,400 ppm and two died at approximately 17,000 ppm (~2830 ppm for 30 min)

[a]From these rather variable data the concentration lethal to humans following a 20-min exposure would be 80–260 ppm. A severe irritant effect on the upper respiratory tract would be expected at around 5 ppm, but from Kaplan's work [38] this may not be unbearable, even up to several hundred ppm

[b]Therefore, anything over 100 ppm is likely to be highly irritant and over a 20-min period approximately ten times this concentration may cause permanent lung damage or endanger life

identifying smoke atmospheres or individual substances likely to be irritant to humans and even for ranking irritants in order of potency and setting hygiene standards. However, when predicting concentrations of smoke atmospheres that would seriously impair the ability to escape from a fire, there is a need for more work to establish the effects of known irritants in humans and to establish the relationship between the rodent response and human incapacitation.

Lung Inflammatory Reactions

Just as it is difficult to predict the degree of incapacitation from sensory irritation likely to occur in victims during fire exposure, it is also difficult to predict concentrations likely to cause death in humans from lung inflammatory reactions, although experiments in rodents should enable some estimates to be made from postexposure LC_{50} data. When rodents are exposed to smoke atmospheres in small-scale combustion toxicity experiments, death occurs principally either during exposure due to asphyxiant gases (CO, HCN) or some time after exposure, due to lung irritation. In cases where the majority of deaths occur after exposure and are accompanied by signs of lung irritation, measurements of the concentration causing postexposure deaths give some indication of concentrations likely to be hazardous to humans.

Since the effects of asphyxiant gases can be predicted without animal exposure, whereas the potential for causing sensory irritation and lung inflammation cannot, measurements of sensory irritancy by the respiratory depression test (RD_{50}) and measurements of the concentrations causing postexposure deaths (LC_{50}) are important uses for small-scale toxicity tests. It is also important to stress that whereas sensory irritation occurs immediately upon exposure, and is concentration related, the inflammatory reactions resulting from lung irritancy are dose related and depend approximately on the product of exposure concentration and duration (Ct product). When an LC_{50} concentration is quoted, it is also important to quote the exposure duration.

For combustion toxicity experiments exposure times are usually 10 or 30 min, and the 30-min LC_{50} should be approximately one-third of the 10-min LC_{50} when postexposure irritancy is the cause of death. It is also important to know the time over which the deaths were scored. Thus some studies quote LC_{50} levels only in terms of animals dying during exposure (which will be due to asphyxia or very high concentrations of irritants). Other studies include deaths occurring both during or up to 24 h after exposure, whereas other studies use the standard method for inhalation toxicology studies that includes deaths during exposure and for up to 14 days after. For the assessment of toxic hazard in possible fire scenarios, it is important to take all these factors into account when considering different building designs or applications of materials.

Irritant Components of Thermal Decomposition Product Atmospheres

If mathematical models are to be constructed to predict the potential for sensory irritancy and later lung inflammation of exposures in fires, it is important to attempt to identify the main irritant chemical species occurring in fires and to measure their potency individually and in combination. This is an area where knowledge is still inadequate, but large numbers of known irritant chemicals have been found to occur in fire atmospheres [17, 18] (see Table 62.4). The irritant chemicals released in fires are formed during the pyrolysis and partial oxidation of materials, and the combinations of products from different materials are often remarkably similar [18]. Some materials release irritant components simply upon pyrolysis, such as HCL from PVC, isocyanates from flexible polyurethanes, and various substances from natural materials such as wood. However, for all organic materials and particularly for simple hydrocarbon polymers such as polypropylene or polyethylene, the main pyrolysis products, which consist of various hydrocarbon fragments, are innocuous. Thus when polypropylene is pyrolyzed in nitrogen the products listed in Table 62.10 are produced,

Table 62.10 Pyrolytic and oxidative decomposition products of polypropylene at 500 °C showing percentage yields of major irritants as indicated, and Threshold Limit Values (TLVs) where available [51]

[b]Oxygen-containing products

and such an atmosphere was found to have no effect on primates [17, 32, 62, 64]. However, when these products are oxidized during nonflaming decomposition in air, some are converted to highly irritant products as shown in the table, and such atmospheres were indeed found to be highly irritant to both mice and primates [16, 42, 84].

These atmospheres produced by the nonflaming oxidative decomposition of materials are always the "worst case" for any material in terms of irritant potency. Both the chemical profile and the irritant potency as determined by the mouse RD_{50} test are often similar for different materials, the majority lying within a range of approximately 1 order of magnitude [62]. However, when materials flame, these organic irritants are destroyed in the flame to produce CO_2 and water, so that the irritancy of the atmosphere depends on how much irritant escapes the actual flame zone and the efficiency of combustion. Thus "clean," smoke-free flames, involving efficient combustion, such as those that occur in a gas burner or well-ventilated fire, are relatively nonirritant, whereas "dirty," smoky flames resulting from inefficient combustion may contain high concentrations of irritants, and produce these irritants at a greater rate than under smoldering or nonflaming conditions. In primates the atmosphere produced by flaming polypropylene was found to retain some irritancy, although considerably less than under nonflaming conditions [17]. In mouse experiments, some fire-retardant materials, which could be induced to flame only intermittently, with considerable smoke production, were found to produce atmospheres up to 300 times more irritant than the same polymer in its non-fire-retardant state, which burned cleanly [85].

The picture is again confused regarding the role of specific chemical products in smoke. Table 62.4 shows some irritants identified in smoke atmospheres in order of their sensory irritancy and includes data on the LC_{50}, due principally to lung inflammation, where these were obtainable from the literature. In some cases there was a considerable range of estimates for both sensory irritancy and lethality, and these are indicated. The lethality data are mostly for rodents, and have been normalized to a 30-min exposure period assuming that lethality is dose related according to Haber's rule. Table 62.9 gives more detailed data for the effects in humans and animals of the best-known fire irritants, hydrogen chloride and acrolein. One point to note from Table 62.4 is that irritants vary enormously in their potency, over 5 orders of magnitude. The most important irritants are probably the ones near the top of the list, including isocyanates (from polyurethanes), the unsaturated aldehydes acrolein and crotonaldehyde, and the first of the saturated aldehyde series—formaldehyde (which is produced by nearly all materials when decomposed). Irritants with a moderate potency, such as phenol and the halogen acid gases HCl, HF, HBr may be important in some fires if they are present in high concentrations, while it is difficult to conceive of any product with an RD_{50} of more than 1000 ppm, such as acetaldehyde, methanol, or any hydrocarbon, being of significance as a smoke irritant.

A difficulty in predicting the irritancy potential of fire atmospheres is that it is not known exactly how the various irritant components of an atmosphere interact, although there are indications that some degree of additive effect occurs. However, a more serious problem is that where comparisons have been made between the mouse RD_{50} of combustion atmospheres and their chemical composition as revealed by GC-MS analysis, the atmospheres in most cases turn out to be much more irritant than can be accounted for by a knowledge of their components. It is possible that small amounts of short-lived reactive chemical species with a very high irritant potency ($RD_{50} < 1$ ppm) are responsible, and more work is needed in this area [86].

Prediction of Incapacitation Due to Sensory and Lung Irritation

In Chap. 63 a model for the prediction of asphyxia in fires has been presented. This model is realistic because it is based on the following facts:

1. Asphyxiation in fires gives two well-defined endpoints, loss of consciousness and death, both of which are likely to occur during the fire exposure.
2. Time and dose to these endpoints can be predicted from established data.
3. Asphyxiation in fires can be shown to depend on a few known toxic gases.
4. The effects of each toxic gas are well known, and so their interactions, so that predictions of asphyxia based on gas profile measurements show a good agreement with observations of animal exposures.

However, it is difficult to develop a predictive model for irritancy for the following reasons:

1. Sensory irritation does not have a clear endpoint but lies instead on a continuum of increasing eye and respiratory tract pain. Although this pain may be considered incapacitating, sensory irritation does not cause obvious incapacitative effects such as loss of consciousness, and it is not lethal, except under extreme conditions. Lung inflammation appears to cause relatively minor effects until near lethal levels of exposure are reached, so the main predictable endpoint is death, although this does not usually occur until several hours after exposure.
2. The identity and number of only a few of the irritant substances important in fires are known. There is also a poor correlation between the composition of experimental fire atmospheres in terms of known irritants and their actual irritant effects on animals, indicating that important unknown irritant remain to be identified.
3. The concentration/time/dose effects of irritants and the degree of interaction between different irritants are also only partly understood
4. The subjective sensation of pain and effects on escape behavior are only partly related to the severity of the irritant stimulus. In emergency situations (for example during military combat situations) individuals may be less affected than at other times.

For these reasons it is currently possible only to develop an approximate mathematical model to predict irritant effects from a knowledge of fire profiles in terms of known irritant products. An alternative is to base a model empirically on the effects on animals of smoke atmospheres produced in small-scale tests (which are described in a later section of this chapter).

To use small-scale test data, it is first necessary to ensure that the test fire model reasonably represents the decomposition conditions in the type of fire of interest (smoldering, early flaming, or postflashover). The concentration of irritants may then be represented in terms of mass charge or mass loss of the test material per liter of diluent air.

Sensory irritation may then be measured in terms of the mouse RD_{50} test. Although this test relates primarily to upper respiratory tract irritation, the results also show some correlation with eye irritation [61]. Sensory irritation may also be assessed directly if required in terms of the severity of eye lesions occurring in the mice (ranging from lacrimation through chromodacryorrhoea to ocular opacity).

Lung edema and inflammation may be measured in terms of the mouse or rat LC_{50} where deaths occur principally after exposure and are accompanied by signs of inflammation such as increased lung weights or histopathological lung lesions.

Attempts may then be made to relate the RD_{50} and LC_{50} to possible effects in humans, but as described there are difficulties with these extrapolations. Fortunately, for most different materials the rodent RD_{50} and LC_{50} levels cover relatively narrow ranges (approximately one order of magnitude) under some given thermal decomposition conditions. For these reasons it is difficult with current knowledge to give guidance on irritancy for hazard modeling. Guideline tenability limits can be presented, based on observations of the sensory and lethal lung irritant effects of exposures of rodents and primates (and humans) to combustion product atmospheres from a range of materials decomposed under a range of conditions. It is, therefore, suggested that irritancy should be treated as follows:

1. Sensory irritation occurs immediately on exposure and is primarily concentration related, not increasing with exposure duration.
2. All fire atmospheres are likely to be highly irritant, and at low concentrations the irritant effects should be regarded as adding to the obscurational effects of smoke through eye irritation, and possibly causing mild behavioral disruption by effects on the respiratory tract. At higher concentrations the disruptive effects of severe sensory irritation on vision and breathing may seriously limit escape capability, and as an approximation non-flaming atmospheres are likely to cause severe sensory irritation at a nominal atmosphere concentration (mass loss) of around 1 mg material/L air. This may occur when the optical density of the smoke is very low (<0.01/m) or even where there is no detectable smoke. It is therefore proposed that an NAC (mass loss) of 1 mg/L should be used as a tenability limit for non-flaming fires, although this may be modified in the light of RD_{50} or other data on the particular material and fire condition of interest.
3. Lung edema and inflammation are most likely to occur some hours after fire exposure, and severity of these is basically dose related, approximately following Haber's rule.
4. Dangerous lung edema and inflammation are likely to occur following a 30-min exposure to an NAC (mass loss) of approximately 10 mg material/L, representing a Ct product of approximately 300 mg/L min. This figure may be replaced by LCt_{50} data on the materials involved in individual fires.
5. These exposure limits for sensory and lung irritation are based largely on exposures to nonflaming atmospheres. Flaming atmospheres may be somewhat less of an irritant, depending on the efficiency of combustion and the severity of the fire. For flaming fires somewhat higher limits such as 5 mg/L might be applied for sensory irritancy and 200 $g{\cdot}m^{-3}{\cdot}min$ for increased risk of lung inflammation.
6. Data for some common fire irritants are shown in Tables 62.4 and 62.9.

Setting Tenability Criteria for Sensory/Upper Respiratory Tract and Lung Irritancy

The work by Jin and others on human behavior in smoke does provide some possibility to determine the effects of smoke obscuration on escape speed and efficiency (see Chap. 63), but a problem remains in determining the likely irritancy of the smoke and the likely severity of the effects of the irritants. It seems from the experience of people exposed in fires that there is a considerable variation in irritant severity between different types of fire effluent. Some fires produce large amounts of sooty smoke that are optically obscuring but relatively nonirritant. Other fires produce smoke that is both optically obscuring and irritant, while in some cases a highly irritant fire atmosphere has been reported when there was little or no visible smoke. From work at BRE Ltd., Fire Research Station (FRS), it has been found that smoke irritants consist of inorganic acid gases (such as hydrogen chloride) and organic compounds, particularly low molecular weight aldehydes (formaldehyde and acrolein). More than 20 irritant substances have been detected in smoke and it is considered that others remain to be identified (see section "Irritant Fire Products"). The yields of inorganic acid gases in fires depend mainly on the elemental composition of the materials being burned, whereas the yields of smoke and organic irritants depend mainly on the decomposition conditions in the fire. In general, smoldering or vitiated flaming fires (fires burning inefficiently) tend to produce irritant smoke whereas well-ventilated flaming fires, if burning efficiently, tend to produce nonirritant smoke.

The first effect of exposure to smoke irritants is sensory irritation, which consists of painful stimulation of the eyes, nose, throat, and lungs. Sensory irritation depends on the immediate concentration of irritants to which the subject is exposed, rather than a dose acquired over a period of time, with the effects lying on a continuum from mild eye irritation to severe eye and respiratory tract pain. Most people are familiar with the effects of smoke with a high-irritant

potency from exposure to bonfire smoke in the garden. The effects can be temporarily incapacitating with severe eye pain, closure of the eyes, and tears. If the smoke is inhaled, coughing and breathing difficulties occur. It is easy to imagine how difficult it must be to find one's way through the escape routes in a building under such conditions. One of the best scientific descriptions of the effects of exposure to a sensory irritant is in a paper on the effects of experimental exposures of human volunteers to a substance designed to cause incapacitation due to sensory irritation, CS riot control gas [52]. The effects described consisted of an almost instantaneous severe inflammation of the eyes, accompanied by pain, excessive lacrimation (tearing), and blepharospasm (involuntary closure of the eyes due to spasm of the eyelids). There is irritation and running of the nose with a burning sensation in the nose, mouth, and throat, and a feeling of intense discomfort during which the subjects cough, often violently. If the exposure continues, the discomfort spreads to the chest and there is difficulty in breathing. Many subjects describe a tightness of the chest or chest pain as the worst symptom. The breathing is irregular and the breath is held for short periods. Attempts to avoid the irritation by breath-holding, followed eventually by fairly deep breaths, are reported as being extremely unpleasant. At this stage most individuals are acutely apprehensive and highly motivated to escape from the smoke.

In evaluating this aspect of irritancy in fires, the aim is to predict what concentration of mixed irritant products is likely to cause such pain and difficulty in breathing that escape attempts would be slowed or rendered less efficient, and what concentration is likely to seriously disrupt or prevent escape (a degree of incapacitation approximately equivalent to that at the point of collapse resulting from exposure to asphyxiant). For example, with regard to hydrogen chloride it is considered that concentrations from approximately 100–500 ppm would be painfully irritant, producing effects similar to those described for the CS experiments, and that the effects may slow escape but probably would not prevent it.

Table 62.11 Example of the effects of exposure to an acid gas irritant—hydrogen chloride

No odor ppm	
<5	Minor nasal irritation can be detected below 5 ppm (the OEL)
10–50	Perceived as irritant, but work is possible at up to approximately 50 ppm
50–100	Strongly irritant, and some people report exposure to 100 ppm as being excruciatingly painful to the eyes and respiratory tract
309	Mouse RD50
1000–2000	Brief exposure regarded as being dangerous to lethal to humans
3800	Lethal exposure dose to rats for a 30-min exposure, representing an exposure dose of 114,000 ppm·min
15,000	5-min lethal exposure concentration in rats and baboons is around 15,000 ppm

However, at approximately 1000 ppm and above it is suggested that the effects might be so severe as to prevent escape [87]. The effects of exposure to different concentrations of an acid gas irritant (HCl), detailed in Table 62.9, are shown in Table 62.11. Figure 62.15 shows the respiratory depression response of mice to exposure to a sensory irritant atmosphere from PVC decomposed under nonflaming oxidative conditions. Figure 62.16 shows the logarithmic concentration—effect relationship. In the absence of detailed information on irritant mixtures it is assumed that all irritants would be additive in their effects, since they are all capable of causing damage to lung tissue. In large-scale fire tests it is possible to measure inorganic irritants directly, but it is difficult to assess the degree of irritancy from organic products, which form a very important component. In general, the effects of organic irritants depend on the concentration of partially oxidized organic species in the smoke. For example, smoke from smoldering wood or polyolefines decomposed under smoldering or vitiated flaming conditions has a high organic content, is highly irritant, and is characterized by low CO_2/CO ratios and high smoke yields. Under well-ventilated flaming conditions, the organic content of the effluent is low, and irritancy is low. In general, it is predicted that smoke from a mixed fuel source with an optical density/meter of 0.5 would be strongly

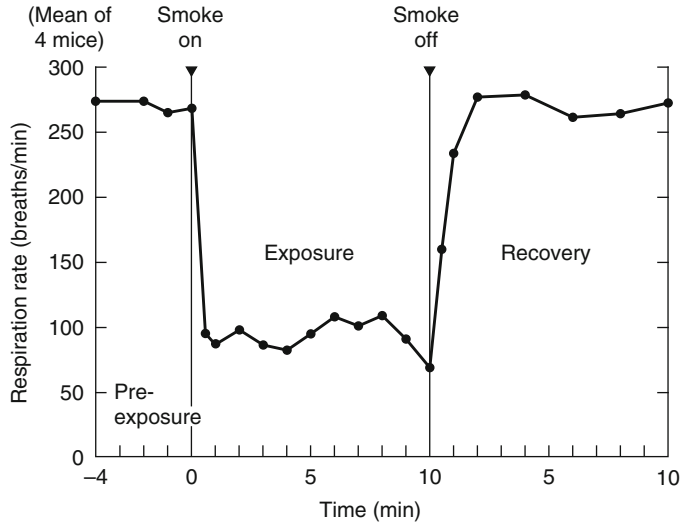

Fig. 62.15 Concentration—effect relationships for sensory irritants: effect of exposure on mouse breathing rate of thermal decomposition products from PVC-J (0.72 g•m^{-3}) [86]

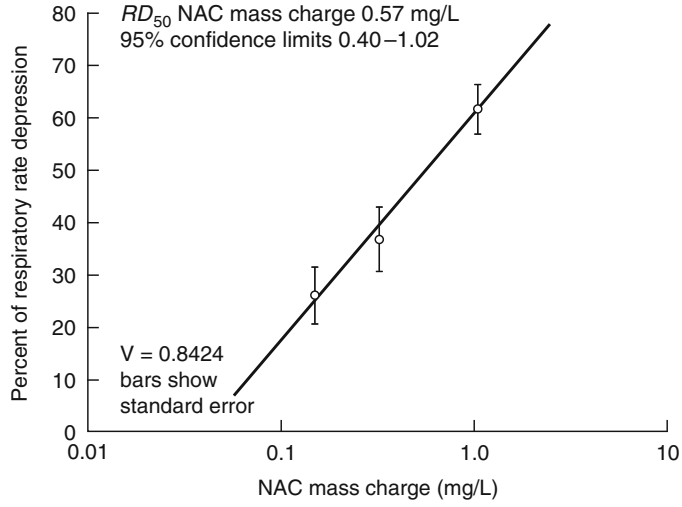

Fig. 62.16 Concentration—effect relationships for sensory irritants percent breathing rate depression in mice is proportional to log concentration [86] RD_{50} PVC-I 0.57 g•m^{-3}

irritant to the eyes and respiratory tract. However, for a given smoke density, there are differences between different types of fires.

It is difficult to quantify these irritant effects exactly because the database on the effects of individual irritants or irritant mixtures on escape behavior in humans is poor, and, because the effects lie on a continuum of severity, there are no precise endpoints. Assessment has to be based on a small number of human experimental exposures, usually at relatively low concentrations, accidental exposures, and the results of bioassay studies. For ethical reasons it is never going to be possible to obtain direct data for effects on humans so that estimates of this important parameter must be based on existing data and the judgment of physiologists. Further details of data from human and animal exposure

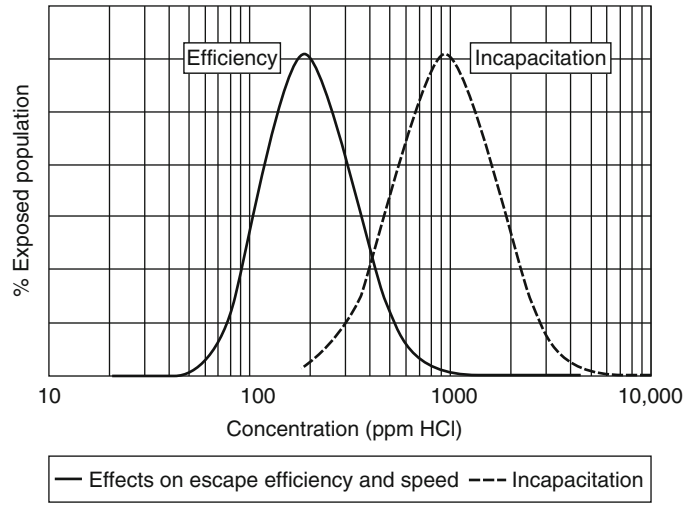

Fig. 62.17 Estimated sensitivity distribution for human population to HCl exposure [27]

to HCl and other irritants are given in Purser [72, 87].

Another concern is the range of susceptibility in the human population. Some individuals, particularly those with respiratory diseases, are likely to be more susceptible than others, whereas particularly fit individuals or those used to working in irritant environments are likely to be more resistant. It is also likely that the subjective irritancy of an exposure is on a log scale of sensitivity for humans, as it is in rodents. Figure 62.17 shows a suggested likely distribution of sensitivity for a human population for HCl, in terms of the proportion of the population likely to suffer severe irritancy, to have impaired escape efficiency at different concentrations and to suffer incapacitation. This is based on existing human and animal data and the judgment of the author. Whereas most individuals are considered likely to be affected at around 200 ppm, some may be affected by low concentrations of around 100 ppm, but some may be able to tolerate exposure to very high concentrations of over 500 ppm without suffering serious effects on escape capability.

In order to assess the combined effects of irritants, a concept of fractional irritant concentration (FIC) has been developed, whereby the concentration of each irritant present is expressed as a fraction of the concentration considered to be severely irritant. The FICs for each irritant are then summed to give a total FIC. If the total FIC reaches unity, then it is predicted that the smoke atmosphere would be highly irritant, sufficient to slow escape attempts. If the total exceeds unity by a factor of approximately four or more, then it is likely that escape would be prevented and possible that collapse might occur due to static hypoxia from bronchoconstriction or laryngeal spasm. On the basis of available data, current estimates of the concentrations of each gas likely to be highly irritant are as shown in Table 62.12.

It is predicted that each gas at the above concentrations is likely to be sufficiently irritant to affect escape efficiency in the majority of subjects and may cause incapacitation in susceptible individuals. A factor of 0.3 FEC for escape impairment should allow for safe escape of nearly all exposed individuals.

On the basis of the somewhat limited evidence that all irritants capable of causing sensory irritancy are additive in their effects, the overall irritant concentration FIC is then given by Equation 62.5:

$$\mathrm{FIC} = \mathrm{FIC}_{\mathrm{HCl}} + \mathrm{FIC}_{\mathrm{HBr}} + \mathrm{FIC}_{\mathrm{HF}} + \mathrm{FIC}_{\mathrm{SO_2}} + \mathrm{FIC}_{\mathrm{NO_2}} + \mathrm{FIC}_{\mathrm{CH_2CHO}} + \mathrm{FIC}_{\mathrm{CH_2O}} + \sum \mathrm{FIC}_x \quad (62.5)$$

where $\sum FIC_x = FICs$ for any other irritants present.

A considerable degree of variability is likely in individual susceptibility within the population and there is a degree of uncertainty as to which tenability thresholds should be recommended. In the recently published international standard for the estimation of time available for escape (ISO 13571[4]) the chosen tenability endpoint has been that of predicted incapacitation (rather than escape impairment), defined as sublethal effects that would render persons of average susceptibility incapable of effecting their own escape. The endpoint and predicted endpoint concentrations are very similar to those in the right-hand column of Table 62.12 with a suggestion that design tenability limits might be set at 0.3 times these concentrations to allow for more sensitive subpopulations. Although these levels may be set rather high, since it is considered that the symptoms of irritancy increase with the logarithm of the concentration, the difference between the levels is not large. The choice of limits also depends on the degree of effect considered acceptable for building occupants attempting to escape. Since the suggested figures for escape impairment in the left-hand column of Table 62.12 represent average susceptibility, the extent of escape impairment might be expected to be greater for sensitive subpopulations, so a factor of 0.3 might also be considered for this endpoint for design applications. The application of this model to fire hazard calculation for human exposure is presented in Chap. 63.

Table 62.12 Irritant concentrations of common fire gases

Gas	Concentration predicted to impair escape in half the population (ppm)	Concentration predicted to cause incapacitation in half the population (ppm)
HCl	200	900
HBr	200	900
HF	200	900
SO_2	24	120
NO_2	70	350
CH_2CHO (acrolein)[a]	4	20
HCHO (formaldehyde)[a]	6	30

[a]Where the concentrations of acrolein and formaldehyde (or other important irritants) are unknown, a term derived from smoke density 0.5 OD/m may be used as an indication of irritancy likely to impair escape efficiency

Current Concerns Regarding Effects of Sensory Irritants

In the preceding sections, the background data and considerations from which guidance on the effects of irritants have been derived have been presented in some detail. The proposed tenability limits can never be precisely verified since the human experiments needed cannot be performed, but by the same token it is not possible to determine accurate lower safety limits. For this reason the best guidance can only be given by toxicologists familiar with the background human and animal data. The figures presented have been derived in this way and are very similar to those proposed by an expert panel of toxicologists in the International Standards Committee (ISO/TC92/SC3), which was responsible for the ISO 13571 standard.

Concerns have been expressed from some quarters that the proposed limits are too low for application to practical fire safety engineering and provide too wide a limit of safety. An important point to consider in this context is that the proposed tenability limits are designed to be applied at the breathing zone of a potential building occupant and not at the fire source. In a fire scenario, it is likely that some time will elapse from ignition to the time these tenability limits are breached in the breathing zone of a building occupant some distance from the fire source. With regard to the actual limits used, these have been chosen in the context of escape and survival in an emergency situation and are considerably in excess of hygiene levels. Even with regard to emergency situations, other expert groups of toxicologists have proposed similar or even lower tenability limits. One set of limits developed for dangerous acute exposures in an industrial context by the American Industrial Hygiene Association is the Emergency Response Planning

Table 62.13 Emergency response planning guidelines for common fire irritants

Definition	HCN	HCl	HF	Acrolein	Formaldehyde
ERPG-3 (ppm)					
The maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 h without experiencing or developing life-threatening health effects	25	100	50	3	25
ERPG-2 (ppm)					
The maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protective action	10	20	20	0.5	10
ERPG-1 (ppm)					
The maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 h without experiencing other than mild, transient adverse health effects or without perceiving a clearly defined objectionable odor	na	3	5	0.1	1

Guidelines (ERPG). These are expressed in terms of three limit levels, two of which are relevant to survival in emergencies such as fires:

ERPG-3: maximum levels designed to prevent death

ERPG-2: maximum levels below which nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protective action

For irritant gases, there are two issues: concentrations at which individuals are likely to experience serious health effects or symptoms likely to impair escape or ability to take protective action, and exposure doses that might cause life-threatening health effects. For example, with respect to hydrogen chloride:

ERPG-2 set at 20 ppm on the basis that $>20 < 100$ ppm would be expected to cause serious eye and respiratory tract irritation (which might impair an individual's ability to take protective action). This reflects the immediate effect of exposure concentration.

ERPG-3 set at 100 ppm on the basis that exposure exceeding this level for 1 h may be expected to produce severe health effects such as pulmonary edema and possibly death in a heterogeneous human population. This reflects the effect of an exposure dose. The same principle applies to the other irritant gases.

In the context of ability to escape from a fire, the ERPG-2 level would, therefore, represent the appropriate tenability limit. This limit is, in fact, an order of magnitude more stringent than the design tenability limit proposed here for fire engineering design. Although 20 ppm HCl would be sufficiently irritant to adversely affect most people, it is unlikely that such low concentrations would seriously inhibit the ability of most people to perform the actions necessary to escape from a fire. On this basis, the higher concentration of 200 ppm is proposed as a tenability limit for the average person, although it is likely that a proportion of the population might suffer some degree of impairment at lower concentrations as indicated in Fig. 62.17. Table 62.13 shows the ERPG levels for some sensory irritants commonly occurring in fire atmospheres [88].

A more recent set of emergency guidelines has been published between 2004 and 2006 by the U.S. Environmental Protection Agency under the AEGL scheme (Acute Exposure Guideline Levels of Hazardous Substances) [89]. The Acute Exposures Guidelines (AEGL) provide guidance for the assessment of likely acute effects of human exposures a range of individual substances likely to be released during industrial accidents, including a range of irritant gases occurring in combustion product mixtures. These are very useful because the documentation

Table 62.14 Acute Exposure Guideline Levels of hazardous substances (AEGL)

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure
AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape
AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening adverse health effects or death

Table 62.15 AEGL2 limit concentrations for different exposure periods

Exposure period (hours)/	0.167	0.5	1	4	8
Substance					
HCl	100	43	22	11	11
HBr	100	43	22	11	11
HF	95	34	24	12	12
NO_2	20	15	12	8.2	6.7
SO_2	0.75	0.75	0.75	0.75	0.75
Formaldehyde	14	14	14	14	14
Acrolein	0.44	0.18	0.1	0.1	0.1

includes detailed review of available toxicity data from both human and animal studies, with carefully justified opinion on extrapolation between and within species and application to the choice of guideline ceiling levels for exposure periods from 10 min to 8 h. The AEGL guideline levels (Table 62.14) are for three endpoints in exposed humans as follows:

For application to combustion product exposures all three levels are relevant for different exposure assessment situations For relation to potential lethal levels the AEGL1 values are most relevant, while for effects on escape capability the AEGL2 levels are most applicable. The AEGL 3 values may be relevant to assessment of minor health effects from acute exposures. The AEGL2 levels for some irritant fire gases are shown in Table 62.15.

AEG-1 and AEGL-2 make use of low level human exposure physiological signs and animal toxicity data, especially histopathological changes to the respiratory tract. For sensory irritancy use is made of human experience and mouse RD_{50} data, on the basis that such effects are not dose-related, but concentration-related and maintained. The concentration predicted to cause significant sensory irritancy therefore sets a ceiling on the exposure levels over the entire range of exposure periods from 0 min to 8 h. Where significant pathological effects are reported at lower exposure concentrations (or exposure doses) for different exposure periods these are applied to reduce the ceiling exposure concentrations for longer exposure periods.

For the AEGL-1 levels some form of $C^n t$ relationship is the main basis for setting the ceiling concentrations for the different exposure times. The most reliable animal data are usually obtained using 4-h exposure periods, although this is rather long for most fire incidents, for which the 10 and 30 min exposure periods are most relevant.

The AEGL-2 levels (the level above which irreversible health effects and impaired escape ability are predicted) for irritant gases for an exposure time of up to 10 min (a time period considered more relevant to escape from fires) are somewhat higher than the ERPG-2 levels but are more stringent than the levels proposed in the left-hand column of Table 62.12 (except for formaldehyde).

For smoke atmospheres containing significant concentrations of the acid gases and organic irritants it is also important in the application of egress calculations to consider the effects on the walking speed of escaping occupants at concentrations below those in the right-hand column of Table 62.12. Between zero and the concentration causing incapacitation there will be a relationship between the irritancy of the smoke and walking speed (as demonstrated by Jin [84]). In order to provide some indication of possible effects on walking speed between these limits, an expression has been developed for any irritant based on the concentration estimated to be very painfully irritant [90]. Details of the derivation and application of this expression to walking speed calculations for occupants escaping in irritant smoke is presented in Chap. 63.

The other important effect of irritants is that a proportion of those inhaled penetrate into the deep lung. If a sufficient dose is inhaled over a period of time, a lung inflammatory response can occur, usually some hours after exposure. The deep-lung effects of irritants may be increased by the presence of smoke particulates, which may cause respiratory failure and death or permanent lung damage in survivors. The 30-min exposure doses (30-min exposure LC_{50} concentrations multiplied by 30) likely to be lethal for each irritant gas are as shown in Table 62.16.

The effects depend on the exposure dose, which can be quantified approximately in terms of the product of concentration (c) and exposure time (t) to give the ct product exposure dose (ppm·min). During a fire, when the concentrations of the toxic products vary with time, it is possible to predict when an incapacitating or lethal dose has been received by using the FED method. For this method the ct product doses for small periods of time during the fire are expressed as a fraction of the dose causing a toxic effect, and these FEDs are summed until the fraction reaches unity, when the toxic effect is predicted. The fraction of a lethal dose (FLD) for each irritant is calculated as the ct product exposure dose during a period in the fire (e.g., in ppm·min) expressed as a fraction of the lethal exposure dose. The lethal effects of the different irritants are assumed to be additive on the same basis as the irritant effects, so that the total FLD_{irr} for each time period is given by Equation 62.6:

Table 62.16 Lethal exposure doses of irritants contributing to asphyxia and lung damage [27]

Gas	Exposure doses predicted to be lethal to half the population (ppm·min)
HCl	114,000
HBr	114,000
HF	87,000
SO_2	12,000
NO_2	1900
CH_2CHO (acrolein)[a]	4500
HCHO (formaldehyde)[a]	22,500

[a]Where the concentrations of acrolein and formaldehyde (or other important irritants) are unknown, a term derived from smoke density and time of 90 OD/m·min may be used as an indication of lethal organic irritant exposure dose

$$FLD_{irr} = FLD_{HCl} + FLD_{HBr} + FLD_{HF} + FLD_{SO_2} + FLD_{NO_2} + FLD_{CH_2CHO} + FLD_{HCHO} + \sum FLD_x \quad (62.6)$$

where $\Sigma FLD_x = FLDS$ for any other irritants present.

The FLD_{irr} for short periods of time during the fire are summed until the FLD_{irr} reaches unity, when it is predicted that a lethal dose has been inhaled.

The application of this expression to calculation of lung inflammation hazards to humans for fire hazard analysis is presented in Chap. 63.

Incapacitating and Lethal Effects of Asphyxiant Fire Gases

The effects of asphyxiant fire gases are not instantaneous as with sensory irritant, but develop when a sufficient dose has been inhaled. The main asphyxiant gases in fire effluents are

CO and HCN. The effects of these gases, consisting of tissue hypoxia are additive, and combine to some extent with direct low oxygen hypoxia. Carbon dioxide increases the rate of uptake of CO and HCN, and itself causes narcosis after a few minutes inhalation at concentrations above approximately 7 $\%CO_2$. The combined effect of exposure to these gases is to cause incapacitation (loss of consciousness) during exposure above a critical dose threshold. After a further few minutes as inhalation continues this is followed by death from respiratory and cardiac arrest. The effects of exposure to these gases individually and in fire effluent mixtures on exposed humans and animals has been described earlier in this chapter, with details of the derivation of an FED hazard assessment calculation method for application to humans described in Chap. 63.

The derivation and validation of lethality FED calculation methods for application to small-scale toxicity test data has been described in a previous section of this chapter. These include terms for the lethal toxic exposure doses (30-min exposure period) for CO and HCN, which are added to the lethal exposure doses of the irritant substances present. For lethal mass loss concentrations of fire effluents in small scale tests the asphyxiant gases are found to cause incapacitation and death mostly during or within a hour after the end of an exposure. The irritants mainly cause death by lung inflammation some hours or days after the end of the exposure. As described earlier in this chapter, a lethality expression treating the lethal effects of asphyxiants and irritants as directly additive provides a good prediction of measure rat lethality. This raises the question of the extent to which asphyxiants and irritants are acting independently and sequentially to provide the overall measure lethality, or the extent to which their effects are overall interactive both during and after exposure. Experiments in which deaths are only during and immediately after exposure (as opposed to during exposure and up to 14 days after), show a somewhat reduced effect from the irritants, but still more than would be predicted from the effects of the asphyxiants alone. Further information on rodent lethality interactions and calculation models can be obtained from the following references [6, 10, 40, 44–46, 72].

The Use of Small-Scale Combustion Product Toxicity Tests for Estimating Toxic Potency and Toxic Hazard in Fires

Applications of Small-Scale Toxicity Test Data

Small-scale toxicity tests of different kinds are used for the following main applications:

1. For the development of FED expressions such as those presented in Chap. 63, for application to time to incapacitation (ASET) engineering calculations using full-scale fire data
2. For application to simplified mass loss FED lethal toxicity ASET calculations
3. For measurement of yield data for the main toxic fire gases from burning fuels for application to ASET engineering calculations (for calculating time-concentration curves for each toxic gas during compartment fires)
4. For product specification purposes—particularly for transport applications

Development of FED Expressions Historically, a number of bench-scale combustion furnaces have been used to generate thermal decomposition and combustion product atmospheres from a range of materials and products. Using a combination of chemical measurements of atmosphere composition with animal exposures, it has been possible to establish that the main incapacitating and lethal effects of exposure to fire atmospheres are due to a limited set of toxic gases and to determine their combined effects in fire effluent mixtures [10, 17]. These and other data from human and animal exposures to individual toxic gases and gas mixtures have been used to develop the FED (Fractional Effective Dose) expressions presented in this chapter and in ISO 13571[4] The expressions are used with time-

concentration curve data for full-scale fires (obtained from fire modeling calculations or full-scale fire tests) in order to calculate time to incapacitation (ASET) or time to lethal exposures. The animal experiments have also been useful to identify cases in which unusual toxic effects are present and for the development of methods for handling such effects in performance-based applications. These aspects have been discussed as appropriate throughout this chapter and Chap. 63.

Mass Loss FED A method whereby small-scale toxicity test data can be applied directly to FSE calculations, as an alternative to the use of the individual gas FED expressions, is the mass loss toxicity method. For this method a toxicity endpoint is expressed in terms of a lethal or incapacitating mass loss exposure dose for combustion products from a particular material or product. The mass loss exposure dose with time during a modeled fire or full-scale fire test is then calculated. This method is described here and in ISO 13344,[45] but this approach is rarely used, the individual gas FED method being more widely used for engineering calculations.

Measurement of Toxic Gas Yield Data In order to model the time-concentration curves for toxic gases in full-scale fires it is necessary to establish the yields of the main toxic gases under a range of combustion conditions. Although it is not possible in small-scale tests to reproduce the dynamics of fire growth in full-scale compartment fires or the detailed temporal and spatial variations in fuel exposure and combustion conditions, small-scale methods in combination with large-scale experiments are proving increasingly useful in establishing the relationship between combustion conditions and toxic product yields [13, 38, 39, 66, 69, 90–92]. In particular, it has been established that the yields of key toxic products (especially carbon monoxide, hydrogen cyanide, smoke particulates, and organic irritants) vary considerably with combustion conditions and particularly in the following:

- Flaming or nonflaming decomposition
- For flaming fires the fuel/air equivalence ratio (or mixture fraction)
- Temperature in the combustion zone and upper layer and to some extent oxygen concentration
- Presence of flame-retardant elements active in the gas phase, especially halogenated flame-retardants

Full-scale fires can be classified into four main types or stages in terms of the combustion conditions, which can be replicated in small-scale apparatus. The main types are non-flaming fires, well-ventilated flaming fires, and ventilation-controlled (underventilated) pre-flashover or post-flashover fires with vitiated combustion conditions (see Table 62.23). Two small-scale test methods have been developed that can test materials or products under a range of fuel-air equivalence ratios for the measurement of toxic gas yields. These are the ASTM flammability apparatus, which is described in detail in Tewarson [2], and the BRE tube furnace method [12, 93], which is a British Standard [94] and an ISO Technical Specification [11] and is described later in this section. The tube furnace method has been developed specifically to measure toxic product yield data for application to FSE calculations. It is capable of addressing the combustion conditions in all four fire stages and for flaming fires to generate toxic product yield data as a function of equivalence ratio and temperature. Yield data for a variety of materials over a range of combustion conditions (expressed as a function of equivalence ratio) have shown a good agreement with data from the ASTM flammability apparatus and from large-scale compartment fires [66, 90]. Data obtained using the ASTM flammability apparatus for different materials are presented in Khan Chap. 36 [2] and some tube furnace data are presented later in this section.

Product Specification A number of small-scale toxicity test methods are in use to produce toxicity data for product specification purposes (mainly for transport applications). These test methods generally use small-scale combustion devices for the generation of thermal-decomposition products, with measurement of the concentrations of a specified list of toxic gases. The toxic gas data are input to a specified calculation method in order to generate a toxicity index, usually based on immediately dangerous

to life or health (IDLH) limits for individual toxic gases. The use of materials or products for specific applications is then based on a specified toxicity index score.

The most commonly used methods are the French tube furnace method (NFX 70-100-1) [95] and the E662 smoke box method [96] using the cone heater (in ISO 5659-2) [97] and IMO or Airbus Industries smoke toxicity test procedure [98, 99]. This smoke box is an area-based method designed to generate smoke optical density and toxic gas concentration data for qualification of materials. These methods are considered of limited use for application to FSE calculations because they are generally based on primitive combustion scenarios in which the combustion conditions are undefined and cannot be readily related to those in full-scale fires. Similarly, the toxicity indices consist of simplistic endpoints using additive models that may not be predictive of incapacitation during fires. (See BS 6853 [100] for applications of the NFX and E662 methods to railway passenger trains.)

Essential Criteria for Test Methods

The evolution of toxic products in large-scale fires is determined essentially by two sets of parameters.

One set of parameters relates to the large-scale structure and development of fire scenarios that determine the growth and spread of the fire, the decomposition conditions under which products are formed, and their rate of evolution. It is not possible to replicate ("model") these features in a single physical small-scale test, although they are the most important factors determining the toxic hazard in a fire. This is the main reason why it has not been possible for experts to agree on standard bench or intermediate scale test methods suitable for regulatory control of materials or products in terms of "toxicity" or "toxic hazard". These parameters need to be measured directly in a full-scale compartment fire test with appropriate boundary conditions, or calculated using a computational fire dynamics model using appropriate input data for the necessary combustion properties of the fuel and compartment.

The other set of parameters that contributes to the determination of toxic hazard and that can be replicated using small-scale fire tests (albeit only in a general way) is the set of thermal decomposition conditions encountered by materials at different stages, in different locations or in different types of fires. Basically, the thermal decomposition products given off by any material depend on the temperature and oxygen supply to which it is subjected and whether it is flaming or nonflaming. Although it is possible to identify a number of subsets, there are three basic thermal decomposition conditions, namely:

1. Nonflaming oxidative/smoldering decomposition at midrange temperatures
2. Flaming decomposition in a local environment at midrange temperatures, ranging from well-ventilated flaming (equivalence ratio <1) to vitiated flaming (equivalence ratio >1)
3. High-temperature/low-oxygen vitiated conditions encountered in fully developed or post-flashover fires (equivalence ratio >1)

If it can be demonstrated that a particular small-scale test method can replicate one or more of these conditions, then it has the potential, if used with a suitable bioassay procedure and/or measurements of chemical product yields, to produce toxicity information that can be used as one item in a toxic hazard evaluation. To produce such information, a number of essential test criteria must be fulfilled.

1. The most important criterion for any small-scale fire model is that it should be capable of producing atmospheres with broadly similar compositions to those formed in one or more of the basic stages of a full-scale fire.
2. Following from this, it is essential that measurements should be made of the temperature and/or radiant flux to which the sample is subjected, the air-fuel ratio, the smoke optical density, and whether the sample is flaming or nonflaming. The chemical composition of the atmosphere must also be characterized as fully as possible, the minimum being in terms of CO, CO_2 (with calculation of the CO_2 to CO ratio), O_2, and HCN (if the material

contains nitrogen), or hydrogen halides (if F, Cl, or Br is present) and the effective heat of combustion. These measurements are important for two reasons: first, because they define whether one of the basic fire conditions is being adequately simulated; and second, because they should enable the key products responsible for the animal toxicity to be identified, or at least make it possible to decide if unusual toxic products are present.

The time/concentration profiles of the key toxic products can then be measured in large-scale fire tests, or predicted by mathematical fire modeling. Estimates of likely toxic hazard in realistic fire scenarios can then be attempted.

If possible, a fuller product analysis including GC-MS measurements of the profiles of organic products should be made for more accurate correlations with the observed toxicity. In addition, comprehensive measurements of product composition in small-scale tests enable comparisons to be made with product profiles in large-scale fire tests and a judgment of how well the small-scale decompositions are able to reproduce the chemical "cocktails" present in different large-scale fire conditions [18].

3. The bioassay method must be capable of detecting and measuring the particular types of toxic effects experienced by human fire victims. It must also be possible to make a reasonable extrapolation from the toxic effects in the animal model to those likely to occur in humans. It is, therefore, essential to determine both the qualitative and quantitative aspects of toxicity and the time during or after exposure when they occur. People in fires experience incapacitating effects that may crucially impair their ability to escape, causing them to remain in the fire to be killed later by heat or CO, so a simple body count (LC_{50}) animal test without any description of pre-terminal toxicity is of very limited usefulness for input to toxic hazard models.
4. Some estimate of dose must be made. This estimate should be reported in terms of concentration and duration of exposure as mass charged and mass consumed of material per liter of diluent air and concentrations of basic toxic products as described previously. By carrying out tests at different concentrations, estimates should then be made of dose/time/response relationships.

Practical Methods for Toxic Hazard Assessment

There are essentially two ways in which toxic hazard in fire can be assessed.

1. From large-scale fire tests (or computer fire models) that include measurements (or predictions) of the concentration/time profiles of the major toxic gases and existing knowledge of the toxic effects of these gases
2. From a battery of small-scale tests and mathematical models or simple large-scale tests. The essential components are the following:
   (a) The toxic potency data for materials (lethal mass loss exposure dose [$g \cdot m^{-3} \cdot min$]) obtained from small-scale tests using animal exposures or analytical methods
   (b) The mass loss/concentration curve for the fire

Of these, full-scale simulations and large-scale tests are the most valuable, since they enable the first two major parameters (fire growth and product yield) to be measured directly. For the third parameter (toxicity), an algorithm for calculating times to incapacitation and death for humans from toxic gases, heat, and smoke obscuration from large-scale fire data has been developed and presented in Chap. 63, while simplified versions are presented in ISO/IEC TR 9122-5 [101], 1357 [1, 4] and 13344 [45]. Full-scale tests are already in use for a number of purposes (such as the furniture calorimeter and room calorimeter used for heat release measurements). With the addition of a few simple gas measurements, they can be extended to provide the data for full-scale hazard assessment of compartment fire scenarios with similar boundary conditions. Although the use of full-scale tests for regulating

fire performance has been criticized on grounds of cost, this approach has been used successfully in California.

The other notable method is to make use mainly of small-scale test data. Small-scale tests suffer from the difficulty that they are several steps removed from a full-scale fire, so it is important to determine the validity of the parameters measured with respect to real fire conditions.

It has been claimed that some small-scale tests can be used to give a direct indication of the toxic hazard presented by a material in a full-scale fire, including elements of ignitability, fire growth, and toxic potency. The UPITT test and the NIBS test are claimed to be usable in this way to produce hazard rankings for materials. However, small-scale tests cannot successfully model the complex growth and development of a full-scale fire, so such methods are considered invalid. It may, however, be possible to extract a number of characteristics of the fire behavior of a material from a single test protocol and use these as inputs to mathematical models for making hazard assessments. An example is the use of the cone calorimeter for measurement of both heat release and toxic gas yield from a material in early well-ventilated fire scenarios.

Nevertheless, the main job of small-scale toxicity tests is to provide data on yields and toxic *potency* of the combustion products from materials so that the data can be used as input to toxic hazard analysis in conjunction with fire growth data obtained from other sources.

The lethal toxic potency of combustion products from materials can be measured in small-scale tests in terms of the LCt_{50}, the lethal exposure dose to rodents. This is expressed in terms of the mass loss concentration of products (the mass of material decomposed in the test) divided by the volume of air into which they are dispersed (g/m^3) and multiplied by the time for which the animals were exposed to give the exposure dose ($g \cdot m^{-3} \cdot min$). It is possible to quote the toxic potencies of materials in these terms for most small-scale test protocols, so that the results from different tests can be compared directly and so that the data can be used in conjunction with mass loss data from full-scale fire tests or model calculations to make toxic hazard assessments. The toxic hazard presented by the materials in full-scale fires can then be estimated in terms of the time during a fire when a victim will have received a lethal exposure dose, provided that the decomposition conditions in the small-scale test are the same as those in the full-scale fire. This is done by the fractional effective dose (FED) method, in which the mass loss exposure dose generated each minute during the full-scale fire (either measured or calculated) is expressed as a fraction of the lethal mass loss exposure dose for the material, obtained from the small-scale toxicity tests. When the integrated fractions during the fire reach unity, death is predicted. This method has been developed for use in toxic hazard assessments in British Standards [102] and in ISO/IEC standards [4, 101].

Examples of Small-Scale Test Methods

A variety of different methods have been used to generate combustion product atmospheres and evaluate their toxicity using animal exposures, and it is not possible here to describe these methods or the results obtained from them in detail. There are, however, three test methods that were in relatively wide use in the United States and in Europe during the 1970s and 1980—the NBS test method [6, 83], the DIN test method [41, 42, 103] and the University of Pittsburgh test method [82, 98]. An excellent description of these and other methods, and of the results obtained from them, is given in Kaplan et al. [16]. The value of the published results from these methods is that they provide an animal toxicity database for thermal decomposition and combustion products from a wide range of materials, enabling the main mechanisms of fire effluent toxicity to be established and the toxic potencies of effluents from different materials to be quantified. The main limitations of these and other small-scale test methods have been the extent to which the test decomposition conditions replicate those occurring during different types and stages of full-scale fires. A brief description of the principles of these three

methods and their validity in predicting effects of exposure to large-scale fire environments follows. The methods are illustrated diagrammatically in Fig. 62.18.

National Bureau of Standards (NBS) Test Method

The NBS test method [6, 83] is the simplest of the three. The test apparatus consists of a sealed rectangular polymethylmethacrylate chamber (200-L volume) containing a cup furnace set into the floor at one end. The animals (rats) are exposed nose only and placed in restraining tubes that are plugged into the sides of the chamber. Exposures are carried out under nonflaming conditions 25 °C below the ignition temperature of the sample and under flaming conditions 25 °C above the ignition temperature. The sample is placed into the preheated cup with the animals already in position, and they are exposed to the atmosphere in the chamber for 30 min. For this test there is thus an initial period when the concentration of decomposition products in the box increases as the sample decomposes, followed by a period when the atmospheric composition remains relatively constant for the remainder of the exposure. The concentration of products in the chamber is varied by placing different amounts of sample in the cup. This type of method is referred to as a "static" method, since there is no forced airflow over the sample and no ventilation of the chamber. It is possible to characterize the atmosphere approximately in terms of mass charge per liter of air by assuming a constant composition for the duration of the test. The atmosphere also can be characterized in terms of mass loss by weighing the residue after the test or by placing the cup on a load cell. Measurements are also made of the chemical composition of the atmosphere in terms of the principle products. The animal toxicity is usually quoted in terms of the LC_{50} concentration of mass charge/L, but it is also common to monitor the asphyxiant effects on the animals by means of the leg flexion test. Effects on respiration (such as irritant effects) could be monitored if desired.

The main advantage of this method is its simplicity, but it has the disadvantage that there is little control over the decomposition conditions. Another disadvantage is that the composition of the atmosphere does not remain constant, since there is a variable period during which the sample is decomposing, followed by a period when the smoke is aging and some products may condense onto the chamber walls. In tests where the decomposition product atmosphere has been compared to that produced in large-scale tests [18], it has been found that the method gives a reasonably good simulation of the products from a smoldering or nonflaming fire and also of the conditions during the early stages of a flaming fire. However, it was not possible to model the decomposition conditions of a high-temperature, fully developed fire, since when the cup is heated to high temperatures the pyrolysis products tend to escape from the cup before they are fully decomposed. In general, it should therefore be possible to use data from this method as one item in a toxic hazard assessment for nonflaming or early flaming fires.

University of Pittsburgh Test Method

In this method [98] the sample is also heated statically in a cylindrical furnace (early versions of the test used a tube furnace). However, in this case a flow of air is maintained over the sample and then mixed with diluent air before being passed through the animal (mouse) exposure chamber. In this way fresh products are continually passed to the animals under dynamic airflow conditions as they are generated over a 30-min exposure period. The unique feature of this method is that the sample is not maintained at a constant temperature but is heated by means of a ramped temperature profile, the temperature increasing at 20 °C/min. The animal exposure starts when the sample begins to decompose and lose weight as indicated by a load cell. The mice are exposed in the head-only configuration, as with the NBS method. In the University of Pittsburgh method the composition of the atmosphere changes continuously throughout the

DIN53436 apparatus.[166]

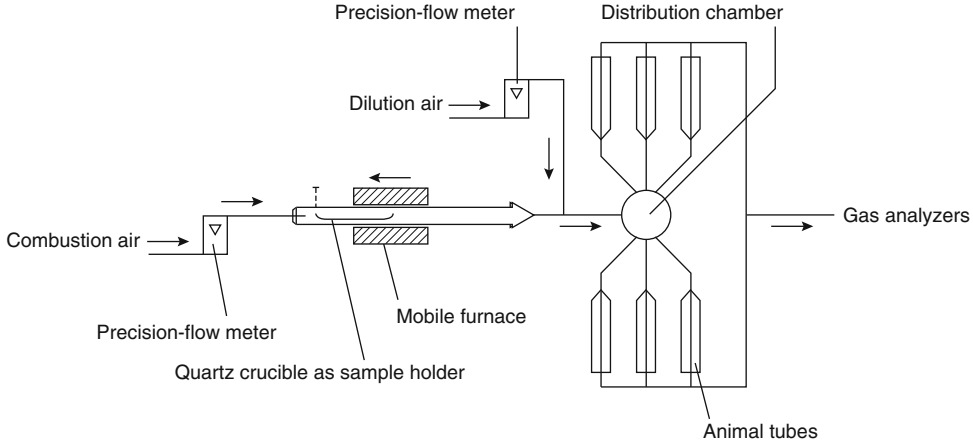

Fig. 62.18 Laboratory-scale combustion toxicity test methods

30-min animal exposure, and the atmosphere usually changes from nonflaming to flaming at some stage. The concentration of the decomposition products can be varied by changing the mass of material placed in the furnace (although presumably this could also be achieved by altering the flow of diluent air). It is possible to measure the changing profile of products to which the animals are exposed throughout the test and also to monitor toxic effects such as asphyxia or irritancy, mainly from recordings of respiratory pattern. However, in its more recent application, the results of the test are usually expressed in terms of the LC_{50} in grams of material charged, which is used to rank different materials.

The main advantage of this method is that it theoretically covers a number of different decomposition conditions within a single test run, ranging from low-temperature nonflaming to high-temperature flaming. It is also said that this situation mimics the conditions in a real fire where materials begin by being cold and are then heated up until they pyrolize and eventually flame. A feature of the test is that the time-temperature increase taken from the start of the decomposition run to the occurrence of the evolution of smoke, toxic effects, and flaming may be used as criteria for judging materials. Thus a material that flames early or produces smoke early may be judged more hazardous than one that does not start to decompose until a high temperature is attained.

Although ramped heating of a sample may provide a useful model for the specific situation where a material is subjected to a slowly rising temperature, it cannot be said to mimic the changing conditions in a fire. In a fire, a material or its immediate pyrolysis products may be subjected to any of a variety of conditions of temperature or oxygen supply under nonflaming or flaming conditions, and the way in which these conditions change is governed by the nature of the large-scale fire scenario. In order to model these various conditions, it is necessary to subject separate samples of test material to a range of different temperatures (or radiant fluxes) and oxygen supplies. The main problem with ramped heating of a sample is that it does not submit the whole material to the necessary range of conditions, since it causes fractional decomposition of the material. Products evolved at relatively low temperatures will not, therefore, be present at a later stage to be involved in flame; neither will they be subjected to high temperatures, since they will have left the furnace before higher temperatures are achieved. This may have a profound effect on the kind of products evolved and, hence, the toxicity.

Another disadvantage of this test method is the difficulty of characterizing dose, since the composition of the atmosphere changes throughout the test. For comparison with other methods, it would be possible to calculate a very approximate nominal atmospheric concentration in terms of mass charged/L if it is assumed that the decomposition averages out over the duration of the test. A better estimate may be made of the atmosphere concentration in terms of mass loss/L if the mass loss as measured by a load cell is integrated over the exposure period. This might give a reasonable measure of dose to enable an LC_{50} to be calculated, but other estimates of toxicity are complicated by the changing nature of the atmosphere. Thus, if death or asphyxia were to occur at 30 min, for example, it is not possible to determine whether this would be due to the delayed effect of a product evolved at 5 min or an immediate effect of a product from 29 min.

There are thus some difficulties with this method, both as a fire model and as a toxicity assay. But, if the method is backed by a full profile of material mass loss and product concentrations, plus qualitative and quantitative estimates of toxic effects throughout and after the exposure, it may be possible to apply the data in certain special situations.

German DIN 53 436 Test Method

This method [41, 42, 103] was used in both the United States and in Europe. It is still in occasional use, although usually in analytical mode only (without animal exposures). It employs a fully dynamic system in that fresh material is decomposed at a constant rate throughout the

test and fresh atmosphere is supplied continuously to the animals. The method has been used with rats, mice, and primates, rats being the principal test animals. The principle of the method is that a strip of test material is placed in a silica tube under a current of air (or nitrogen for studies of pyrolysis) and a traveling annular furnace is moved along the outside of the tube at a constant rate, thereby continuously decomposing the sample. The products are expelled from the silica tube, whereupon they are mixed with diluent air and passed through the animal exposure chamber for 30 min. The rats are exposed in the head-only manner as with the other methods. The sample weight and volume, the primary air supply to the sample, the diluent air, the decomposition temperature, and the concentrations of products in the exposure chamber are measured. The test may be repeated over a range of temperatures under nonflaming or flaming conditions, and the concentration of the products is varied principally by changing the diluent airflow. This has the advantage that the decomposition conditions remain constant as the product concentration is changed, which is not necessarily the case with the other two methods. However, it is also possible to change the product concentration by altering the furnace load, if necessary. The animal toxicity is usually reported in terms of the LC_{50}, which is expressed in terms of mass charged (mass entering the furnace/min)/L diluent air. It is also possible to calculate the concentration in terms of mass loss from the mass of residue remaining after the test run, since the rate of decomposition is constant. Sometimes the results are expressed in terms of the volume of material consumed. In addition, it is possible to monitor the toxic effects on the animals during and after the test as with the other methods.

The great advantage of this method is its versatility, and in theory it the apparatus could be used to model any of the four basic fire conditions: nonflaming, well-ventilated flaming, underventilated-flaming and high temperature post-flashover, as well as variations on them. It is also possible to carry out static ramped temperature decompositions similar to the Pittsburgh method, if required. In practice the method has been found to provide a good correlation with large-scale nonflaming decomposition conditions, and at high temperatures it provides a reasonable model for the conditions of a fully developed flaming or nonflaming fire (high temperature—low oxygen) [18]. However, under standard conditions it does not provide a good model for an early flaming fire (which is reasonably modeled by the NBS method) as the oxygen concentration in the furnace tube tends to be low. Another problem is that the flame tends to travel along the sample more rapidly than the furnace, giving an uneven decomposition. These problems can be overcome by varying the fuel-to-air ratio in the furnace tube and by altering the rate of travel of the furnace.

On balance, the DIN method is reasonably good, and the data obtained could be applied to a number of stages of a fire as one item in a hazard assessment. However, like all small-scale tests it cannot mimic the changing and developing conditions of a large-scale fire; neither can it test materials or objects in their end-use configuration, all of which can have an enormous impact on a developing toxic hazard.

Second-Generation Test Methods

Since these small-scale test methods were developed, there has been considerable progress in understanding of how toxic hazard develops in fires and in particular that hazard depends to a large extent on the general fire properties of materials (in terms of ignitibility, flame spread, rate of fire growth, and smoke evolution), as well as the specific toxicity of the combustion products. Also, critical examination of the fire models used for toxicity test methods (and for small-scale tests for other fire properties such as smoke) has led to the recognition that the models are somewhat inadequate, particularly for the main fire condition of flaming. Another difficulty is that toxicity data are of little value unless they can be related to a range of physical and chemical parameters necessary to characterize the thermal decomposition process, as described in the previous section of this chapter.

There is, therefore, a case for arguing that for many material-based fire properties, a good small-scale test method depends on a decomposition model that can be convincingly related to the essential features of large-scale decomposition conditions. If such a model could be developed, it could be used to measure simultaneously a number of material-based fire performance parameters ranging from ease of ignition, through growth and heat release characteristics, to smoke and toxicity.

A second generation of small-scale fire test methods is being developed, incorporating, hopefully, some of the best features of existing methods and designed to measure a range of parameters.

Cone Calorimeter A second-generation small-scale test method is the NIST cone calorimeter, [104] which has been developed primarily as a heat release apparatus but which also offers the possibility of measuring ignitibility, smoke evolution, and toxicity. This not only enables a range of parameters to be measured simultaneously but also enables the separate parameters to be related, hopefully providing a more comprehensive data set for comparison with, and inputs for modeling of, large-scale fire conditions.

In practice, although useful for measuring reaction-to-fire properties such as ignitability and heat release rate. the cone calorimeter has not proved to be very suitable for measuring toxic potency. It is capable only of reproducing the decomposition conditions in very well-ventilated fires, and the products are subjected to a very large dilution, so that measurement of toxic species is difficult. Attempts are being made to enlarge the range of fire types and stages addressed by modification of the apparatus (vitiated cone), but so far with limited success.

NIST Radiant Method A second-generation version of the NABS cup furnace method has been developed in which the cup furnace was replaced by a radiant panel heater unit. This method has been developed to address the conditions in postflashover fires, but as with the cup furnace version and the cone calorimeter, the combustion process tends to be too well ventilated to reproduce the conditions typical of these fires, which are usually rather vitiated. For further details see Babrauskas et al. [40].

ISO TS19700 Tube Furnace Method [12, 13] The most recently developed method intended to address some of the deficiencies of older methods is a tube furnace method based on the same concept as the DIN tube furnace method. The method employs a strip of sample being advanced through a standard tube furnace under a stream of air (Fig. 62.19). The products are expelled into a

chamber where they are diluted with secondary air, and analytical measurements are made or animals can be exposed nose-only. By using a range of different temperatures and airflow rates it is possible to reproduce all the different fire stages and types defined by ISO (and others), including low-temperature nonflaming oxidative decomposition, well-ventilated flaming, under-ventilated flaming high-temperature under-ventilated (postflashover) flaming decomposition conditions. The method also provides stable flaming conditions, solving the problem of mixed, intermittent periods of flaming and nonflaming common with the original DIN method.

The ISO TS19700 tube furnace method [11–13, 66, 90–94] has been developed specifically to measure the yields of toxic products over the full range of non-flaming thermal decomposition and flaming combustion conditions occurring in fires in order to provide data for input to toxic hazard calculations for full-scale fires [11, 13, 66, 90–94]. Detailed data have been obtained for a range of common polymers [66], for which the polymer types and elemental compositions are shown in Table 62.17. The yields of key toxic gases from a number of polymers measured over a range of combustion conditions (defined in terms of equivalence ratio and temperature) have been have been validated against yield data from the same polymers in large-scale compartment fires. The repeatability and reproducibility of the method have been validated in an international "round robin" study including participating laboratories from the United States, Canada, Sweden and the United Kingdom [13].

For these materials the yields of key toxic products such as CO and HCN (kg product/kg material mass loss) depend on the efficiency of conversion of the fuel carbon to CO and fuel nitrogen to HCN (the recovery fraction) and the proportion of these elements in the base material. Table 62.17 shows the mass percentages of each element in materials tested at the UK Building Research Establishment (BRE) [66]. For combustion conditions under which the materials burned with a flame throughout the test the pattern of yields for all toxic products is illustrated by Fig. 62.20. This shows the relationship between equivalence ratio and CO yield (g/g)

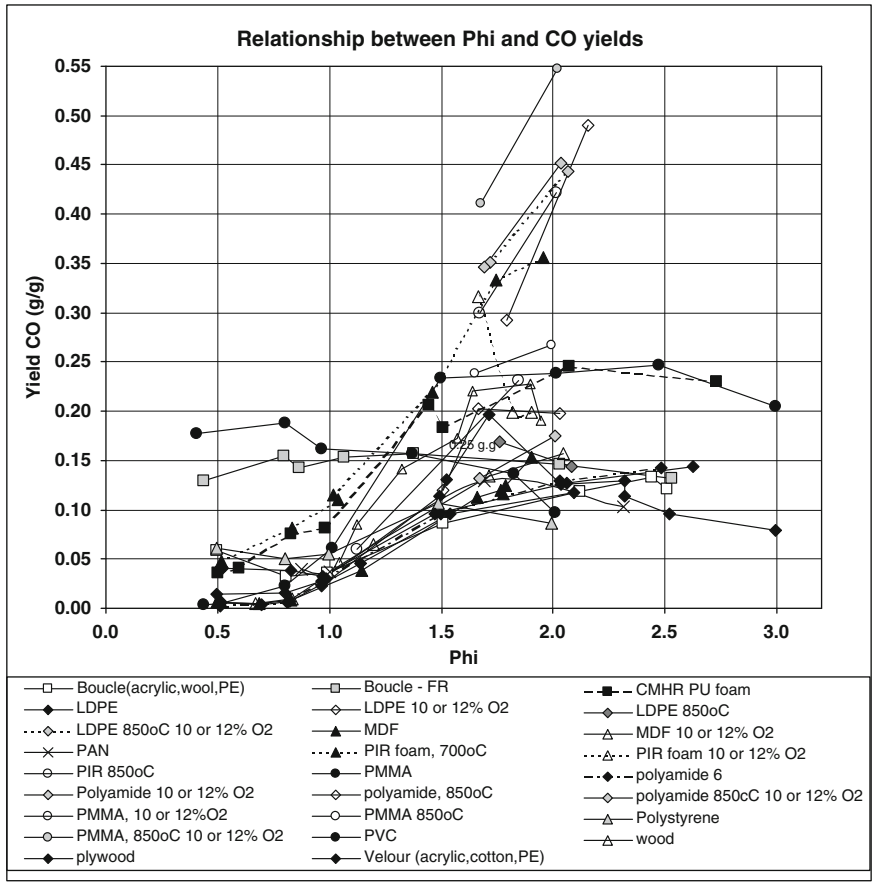

Fig. 62.20 CO yield (g/g) under flaming combustion conditions as a function of equivalence ratio for a range of different polymer types measured using the ISO 19700 tube furnace

for all the materials tested. The basic pattern and yield values are similar to those reported by Khan [2] (See Chap. 36). Under well-ventilated combustion conditions at phi values $< \sim 0.8$ the yields of CO (and other toxic products including particulates, hydrocarbons and HCN) are very low, except for materials containing halogenated fire retardants. There is a sigmoid relationship between equivalence ratio and CO yield in that at around phi values of 1 and above there is a steep increase in CO yield, reaching a plateau at phi values of around 1.5–2.0. Flaming combustion was difficult to sustain at phi levels above approximately 3.0. Most of the results shown in Fig. 62.20 are for a moderate furnace temperature (650 °C) considered to represent the conditions in pre-flashover compartment fires. Under fuel-rich combustion conditions the CO yield depends upon the carbon content of the fuel and the efficiency of conversion of fuel carbon to CO. For aromatic materials (polystyrene) with less efficient combustion, and cellulosic materials (with carbon contents of around 50 %), the yield under fuel rich conditions levels out at around 0.15 g/g, while for aliphatic hydrocarbons and materials such as PMMA somewhat higher yields of around 0.25 g/g fuel mass loss were obtained. For the majority of tests combustion was carried out under a stream of air, but for some tests the same equivalence ratios were obtained at higher flow rates of nitrogen air mixtures (containing 10 % or 12 % oxygen). Under these conditions it was found that some materials produced significantly increased CO

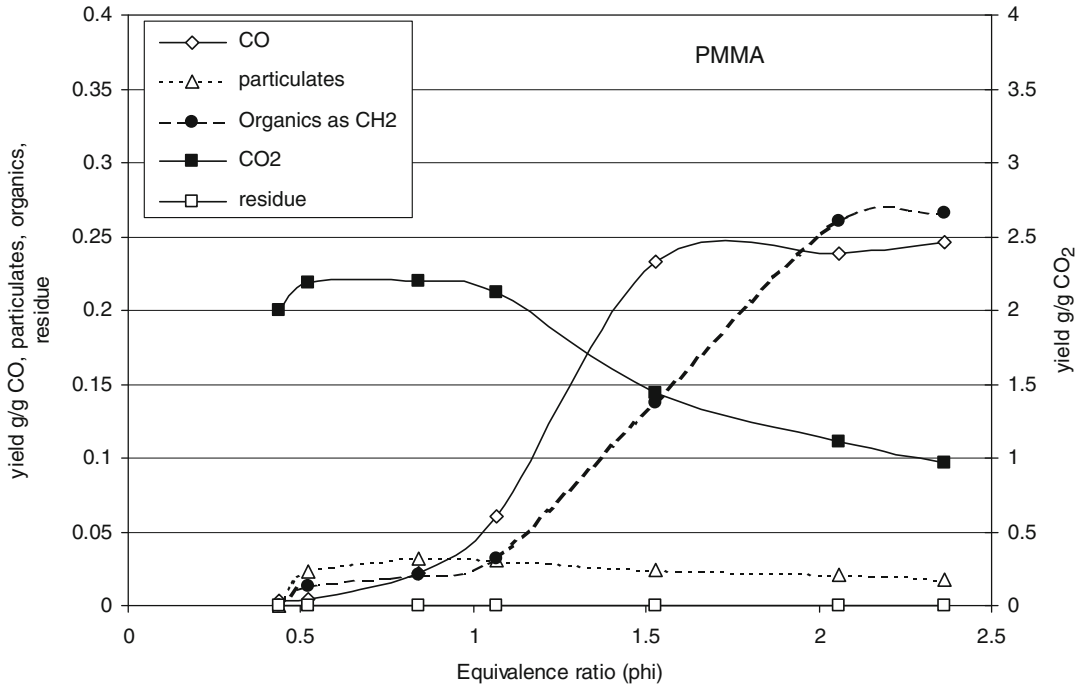

Fig. 62.21 Toxic product yields from a C,H,O polymer (PMMA) under flaming combustion conditions as a function of equivalence ratio (phi) in the ISO TS19700 tube furnace

yields. Higher temperatures (800 °C), also produced somewhat higher CO yields for some materials. Similar variations in CO yields with different oxygen mixtures and temperatures have been observed in compartment fire experiments [1, 27, 31, 70]. For materials with a high halogen content such as PVC, the CO yield remains approximately constant, with inefficient combustion throughout the range of equivalence ratios typical of well-ventilated and under-ventilated fires, and the CO yield tends to be proportional to the halogen content of the fuel [39].

The range of toxic products evolved during flaming combustion fall into three main categories with respect to the relationship between equivalence ratio and yield:

- Products are evolved at approximately constant yields independent of the combustion conditions (mostly halogen acid gases [HF, HCl and HBr]),
- Products for which there is an inverse sigmoid relationship, with yield decreasing as a function of phi are the products of efficient oxidation, comprising mainly CO_2 and water, but also nitrogen oxides (NO and NO_2),
- Products of inefficient combustion with yields increasing as a sigmoid function of equivalence ratio (smoke particulates, partly decomposed organic compounds, CO and HCN)

Figures 62.21, 62.22, and 62.23 illustrate these relationships for thee common polymers: an aliphatic hydrocarbon-based polymer PMMA, a nitrogen-containing polymer polyamide-6 and a polymer with a high halogen content (PVC).

PMMA provides an example of a simple, non-charforming, aliphatic polymer comprised of carbon, hydrogen and oxygen. Under well-ventilated flaming combustion conditions there is no residue and a high yield of CO_2, but at phi values above 1 a large increase in yields of CO, volatile organics and smoke particulates occurs.

For the nitrogen-containing polymer polyamide 6, combustion is also efficient under well-ventilated combustion conditions. A small fraction of the fuel nitrogen is released as NO,

a very small fraction of which is oxidized further to NO_2. At phi levels above 1 the yield of CO_2 and these nitrogen oxides decrease (to very low levels for the nitrogen oxides), while there is a large increase in the yields of CO, HCN, smoke particulates and organics.

The heavily halogenated material PVC shows relatively high yields of all products, both under well-ventilated combustion conditions and throughout the phi range. The HCl yield is constant under all combustion conditions.

Table 62.18 presents the data from all these polymers considered most important for input into fire engineering calculations, which are the toxic product yields under well-ventilated combustion conditions (phi <0.8) and under fuel rich (under-ventilated) combustion conditions (including pre- and post-flashover fires) (phi 1.5–2.0).

Although it is useful to present the yield data directly for each individual polymer, another method is to normalize the data in terms of the

Table 62.19 Generic CO recovery fraction expressions for all materials

Boucle FR (acrylic, cotton, polyester)	Slope:	0.017	Intercept:	0.0827	

content of the key element present in the toxic product. The normalized yield then represents the efficiency with which the fuel element is released as the same element in the toxic product (for example the mass fraction of fuel carbon released as carbon in the form of CO or the fraction of fuel nitrogen released in the form of HCN). When expressed in this way the yield curves for different materials collapse into a closer range, so that it becomes more feasible to consider the generic relationship between combustion conditions and toxic product yields for any material (or at least for groups of materials).

For any specific material the yield of any specific toxic product can then be calculated by multiplying the recovery fraction function (or any individual recovery fraction value) by the mass fraction of carbon, nitrogen or other element in the fuel (from the carbon and nitrogen percentages shown in Table 62.17) and a constant representing the mass of the element in the product. For example, the yield of HCN is calculated as:

$$Y_{HCN} = 1.928\, f_{Nfuel} Y_{Nnorm} \tag{62.7}$$

where:

Y_{HCN} = g HCN/g fuel mass loss

f_{Nfuel} = mass fraction of nitrogen in fuel

Y_{Nnorm} = normalized yield: mass of fuel nitrogen recovered as nitrogen in cyanide

1.928 = molar mass HCN/atomic mass N

Table 62.21 Generic organic carbon recovery fraction expressions for all materials

Organic carbon recovery expression	α	β	k_1	k_2	k_3

is then = 0.02 × 28.01/12.01 = 0.047 g CO/g fuel mass loss.

Although the fuel/air equivalence ratio was the main variable affecting the recovery fraction, it was found that for a given ϕ value the conversion efficiency was somewhat higher when materials were decomposed in 10–12 % nitrogen/air mixtures than when decomposed in air. Comparison with large-scale fire tests showed that this condition was likely to be more typical of combustion conditions in more enclosed compartment fires with mixing and recirculation of effluent at low levels, whereas the lower conversion efficiency was more typical of vented fires with fresh air entrainment at low levels in the enclosure but a vitiated upper layer.

Although there were some differences in behavior among individual materials, in terms of the CO recovery fraction, it was possible to classify materials into two main groups:

Low recovery group. Polymers containing only carbon and hydrogen (polystyrene and polyethylene), and some polymers containing some oxygen and nitrogen (boucle and velour fabrics, polyacrylonitrile, and polyamide). These showed low CO recovery fractions under well-ventilated combustion conditions ($\phi < 0.8$) between around 0.01–0.05, increasing to a recovery fraction around 0.08 under vitiated combustion conditions ($\phi > 1.5$). At ϕ values less than 1.5 in 10–12 % oxygen (in air/N_2 mixtures) the recovery fraction increased to 0.15.

High recovery group. Oxygen-containing polymers such as cellulosics, PMMA (polymethylmethacrylate), PU (flexible polyurethane foam), and PIR (polyisocyanurate foam). These also show low CO recovery fractions under well-ventilated combustion conditions ($\phi < 0.8$) between around 0.01–0.05, with the maximum recovery fraction increasing to between 0.16 in air and 0.25 in air/N_2 mixtures.

A third type is the quasi-constant recovery group (materials with a high content of fire-retardant additives acting in the gas phase, such as halogens). Carbon monoxide recoveries from boucle FR, expressed in terms of recovery fraction, were relatively constant at 0.10 across the entire range of ϕ studied. For PVC the recovery fraction was high at low ϕ values and decreased somewhat at higher ϕ values. At low ϕ values (<0.8), for all materials, the CO yield was proportional to the halogen content of the material. For materials containing small amounts of halogen additive the CO recovery increased from less than 0.01 to 0.05 depending on the additive content.

The different expressions for the different recovery behaviors are obtained by using values for the constants shown in Table 62.19 for input to Equation 62.8. For boucle FR a linear expression has been fitted. The slope and intercept are shown in Table 62.19. For PVC the slope is negative, so the plus sign in Equation 49 after k_1 becomes a minus sign.

For nitrogen-containing polymers, the HCN yield depends on the nitrogen content and the recovery fraction of fuel nitrogen as nitrogen in HCN. HCN recovery showed a similar sigmoid relationship with ϕ, being low under well-ventilated conditions. On average the recovery of carbon as CO and nitrogen as HCN was similar at any given ϕ value. In practice some materials gave higher HCN recoveries than others. Table 62.20 gives values for input into Equation 62.8.

Other toxic species produced by combustion of nitrogen-containing materials are oxides of nitrogen. The relationship between ϕ and NO_x

production is the inverse of that for HCN production, in that NO_x yields and recoveries are maximal under well-ventilated conditions and minimal under vitiated conditions. The main component of NO_x recovered in fresh fire effluent was NO and the yields were generally very low at 0.001–0.003 g/g (grams NO/g fuel mass loss) at a ϕ of 0.5, decreasing to 0.005–0.002 g/g at a ϕ of 2. Somewhat higher yields at low ϕ values were obtained for polyamide 6 and the boucle fabric (0.008–0.011 g/g).

For heteroelements such as halogens in fuels, the main combustion product is the equivalent acid gas. Recovery fractions were generally high, so that for PVC and PIR 90–100 % of fuel chlorine was released as HCl. For the boucle fabric 50–70 % of fuel chlorine was released as HCl, and approximately 50 % of fuel bromine and fuel sulfur as bromide and sulfur oxides. Recoveries of chlorine from the PU foam were lower at around 17 %. High fractional releases of these acid gases are, therefore, considered likely to occur into fresh effluent in compartment fires, except where fuels contain additives such as calcium carbonate. Once released into building compartments, acid gases are gradually lost from the effluent over a time scale of some minutes by deposition and reaction with linings and metal surfaces. The recovery of fuel carbon as carbon in the form of organic products followed a sigmoid relationship with equivalence ratio similar to those for CO and HCN ratio. The following groups could be identified:

Low organic recovery group: The cellulosic (wood-based) products and PIR (due to char formation)

Medium organic recovery group: Most synthetic polymers

High organic recovery: LDPE

Table 62.21 gives values for input to Equation 62.8.

The recovery of fuel carbon as carbonaceous particulates also increased with the equivalence ratio. The following groups were identified:

Low particulate recovery fraction: Cellulosic (wood-based) products and PMMA. The maximum recovery fraction was around 0.09.

Medium-low particulate recovery fraction: Polyurethane foam, LDPE, and polyamide. The maximum particulate recovery fraction was around 0.09.

Medium-high particulate recovery fraction: Boucle and velour fabrics, PAN (all three materials containing polyacrylonitrile), and also the PIR foam. The maximum recovery fraction was around 0.16.

High particulate recovery fraction: Polystyrene with a maximum recovery fraction of 0.2, demonstrating the well-known propensity of compounds with a high aromatic content for the formation of soot in flames.

Quasi-constant recovery group (fire-retarded materials): The two fire-retarded materials (PVC and boucle FR) showed high particulate recovery fractions throughout the ϕ range, with a gradual increase to a maximum of 0.2.

Table 62.22 gives values for input to Equation 62.8.

As stated, smoke optical density and smoke yields are proportional to the particulate concentration.

Relationship Between Toxic Potencies of Materials in Small-Scale Tests and Full-Scale Fires

When the toxic potency of the combustion products from a material are expressed empirically in mass loss terms, the data relate to the toxic effects of the total mixed combustion product evolved. This depends on the type of toxic products evolved and their yields. The most difficult problem in estimating the toxic potency of a material in a fire is that the yields of toxic products depend very much on the decomposition conditions, which vary considerably at different stages and between different types of fires [38, 39]. If small-scale test data are to be used as estimates of the likely toxic potency of products evolved in full-scale fires, it is essential that the decomposition conditions in the test be shown to be the same as those in the type or stage of

Table 62.23 Revised classification of fire types [64]

Fire stage or type	Temperature (°C)		Oxygen to fire (%)	Fire effluents	
	Hot	Layer fire		Oxygen from fire (%)	CO_2/CO (v/v)
1. Nonflaming					
(a) Self-sustaining	450–600	RT	21	>20	1–5
(b) Oxidative pyrolysis from externally applied radiation	300–600	<50	21	>20	1–5
(c) Nonoxidative pyrolysis from externally applied radiation	300–600	<50	0	0	<5
2. Well-ventilated flaming where the fire size is small in relation to the size of the compartment, the flames are below the base of the hot layer, and fire size is fuel controlled	>700	RT to 500	>15	5–21	>20[a]
3. Less well-ventilated flaming where the fire size may be large in relation to the size of the compartment, the flames are partly above the base of the hot layer, and fire size is ventilation controlled:					
(a) Small vitiated fires in closed compartments	>700	RT to 500	<15	0–12	2–20
(b) Postflashover fires in large or open compartments	>700	500–1000	<15	0–12	2–20

[a]May be lower if the burning materials contain fire retardants. In order to determine whether flaming decomposition conditions in a particular apparatus fall into category 2 or category 3, it is necessary to use a nonfire-retarded reference material capable of efficient combustion

full-scale fire being modeled; otherwise the small-scale test data are not valid.

The decomposition conditions and yields of toxic products evolved from materials in full-scale fires depend mainly on whether or not the fuel is flaming, the fuel-air ratio (equivalence ratio), and the upper-layer temperature. In ISO/IEC TR 9122-4 [105], and ISO 19706 [14], an attempt has been made to define the major categories of fire in these terms, the type of decomposition for flaming fires being expressed in terms of the CO_2/CO ratio. A revised scheme is shown in Table 62.23. The six fire types shown in the table contain three major categories: (1) nonflaming, (2) well-ventilated flaming, where the fire size is small in relation to the size of the compartment, the flames are below the base of the hot layer, and fire size is fuel controlled, and (3) less well-ventilated flaming ("underventilated" or "vitiated" flaming, where the fire size may be large in relation to the size of the compartment, the flames are partly above the base of the hot layer, and fire size is ventilation controlled. The third case includes small, vitiated fires in enclosed or poorly ventilated compartments and postflashover fires in large or well-ventilated compartments. In ISO/IEC TR 9122-4 small-scale toxicity test protocols are judged by the extent to which the test conditions are relatable to one of these categories in terms of temperature or radiant heat flux, oxygen concentration, and CO_2/CO ratio. If they are to be considered useful to measure the toxic potency of the combustion products from materials, the decomposition conditions must relate to one of these fire stages or types, and the results of any small-scale test are then only valid for the particular category being modeled. Based on the results of full-scale fire tests and fire death statistics, it is suggested here that the most important toxic hazard situations that should be assessed for all materials are the following:

1. Nonflaming oxidative/smoldering decomposition at low/midrange temperatures where the potential hazard relates mainly to victims in the enclosure of fire origin

2. Early/well-ventilated flaming conditions at midrange temperatures, and later small vitiated fires in closed compartments, where the potential hazard relates mainly to victims both in the enclosure of fire origin and remote from the fire
3. postflashover/postflashover, vitiated decomposition at high temperatures, where the potential hazard relates mainly to victims remote from the fire (since occupants of the fire enclosure are likely to have died already during stages 1 and 2)

In the United Kingdom just over half of all fire deaths in buildings occur in the room of fire origin and most result from exposure to toxic smoke evolved from small fires (which may involve periods of nonflaming and both early well-ventilated and later underventilated flaming decomposition). The other major category, particularly related to deaths from smoke exposure, consists of victims in remote locations. These result from pre-flashover underventilated fires and in some cases following fully developed fires. It is this second category that has been identified as the major problem in the United States, particularly in relation to fires in multioccupation buildings.

Unfortunately, many existing small-scale test protocols do not cover the necessary range of decomposition conditions found in full-scale fires, especially pre-flashover underventilated and fully developed, high-temperature, oxygen-vitiated fires. However, a new technique is presented here whereby certain predictions about the toxicity of combustion product atmosphere can be made based entirely on analytical data. This technique enables use of data both from small-scale experiments and full-scale fire tests.

As stated, in the section of this chapter on Multi-gas FED models, it is considered that the major toxic effects of fire effluents can be explained in terms of a small number of well-known fire gases, so that the effects of fire gases on human fire victims can be predicted to a large extent if the concentrations of these gases during a fire are known. In a similar way, it is now possible to a large extent to predict the exposure dose of combustion products generated in small-scale tests that would be lethal to rodents if the concentrations of the major toxic gases are measured. If necessary, it is then possible to verify the prediction by carrying out the animal exposures.

Experiments of this kind, have shown that toxic gases are basically additive in their effects, so that, for example, an exposure to an atmosphere containing half a lethal dose of carbon monoxide mixed with half a lethal dose of hydrogen cyanide constitutes a lethal mixed atmosphere [9, 49, 106].

The toxic effects of combustion products result mainly from asphyxia and irritancy. Asphyxiation is caused by carbon monoxide, hydrogen cyanide, low-oxygen hypoxia, and carbon dioxide, and so can be quite well predicted if the concentrations of these gases are known. Irritancy is somewhat harder to predict because many irritant organic products and inorganic acid gases occur in fire atmospheres. Where acid gases are present the concentrations can be measured and their effects added to those of the asphyxiant gases. In small-scale tests where both chemical analysis and animal exposures are used it is possible to calculate the contribution to the overall toxicity made by the measured asphyxiant gases and acid gas irritants. Any residual lethal toxicity can then be reasonably considered to be due to the effects of organic irritants, except in very rare cases where unusual toxic effects occur. For small-scale tests, or even large-scale fires, where analytical data only are available it is possible to calculate a theoretical LCt_{50} in terms of the main asphyxiant fire gases and acid gases. This calculation then represents the highest estimate of what constitutes a lethal dose for that atmosphere (i.e., the smoke atmosphere must be at least as toxic as this estimate and could be somewhat more toxic if substantial amounts of organic irritants are present or if unusual toxic effects are present). In small-scale tests there is little oxygen vitiation, so low oxygen hypoxia has little effect. On this basis Equation 62.3 was developed to predict the lethal FED to rats of a combustion product atmosphere. Equation 62.3 has been validated by demonstrating a good

agreement between predicted and actual rat LC_{50} results for a wide range of materials as shown in Fig. 62.2 [9, 45].

Currently generally accepted 30-min LC_{50} concentrations for exposure of rats to common fire effluent gases are given in Table 62.3. A difficulty with estimating the toxicity of oxides of nitrogen is that while the main gas generated in fires is NO, with a relatively low lethal toxic potency due to the formation of methemoglobin (30-min LC_{50} approximately 1000 ppm), in fire effluent atmospheres and in animal gas atmosphere exposures some degree of oxidation to the much more toxic lung irritant NO_2 occurs. For more detailed data on the acute toxicity of nitrogen oxides and the other gases listed in Table 62.3 the series of AEGL reports [89] is recommended.

Where data on organic irritant concentrations are unavailable, it is recommended that a contribution to the overall FED should be derived from an estimate of the total yield of organic products. The FED component for organic irritants (FED_{org}) is then estimated as the mass loss concentration of organic fuel material × percent carbon present as organic carbon, divided by 25. FED_{org} is then substituted for the organic irritant term in Equation 62.3 [10, 45].

When the FED for the concentrations of a set of gases entered into this equation equals unity, then death is predicted, and the mass loss exposure dose for the material producing these gas concentrations is then equal to the LCt_{50} for that material decomposed under the conditions of the test. The equation is designed to be applied iteratively. If the calculated FED from a set of gas concentrations is >1 or <1, then it a new set of gas concentrations is calculated for a lower or higher fuel mass loss concentration and the FED is recalculated for different gas concentration set until a set providing FED $= 1$ is found. If the concentrations of the irritants present and their lethal exposure doses are known, then the equation can be solved fully (e.g., the LCt_{50} for HCl is 112,980 ppm·min) [47, 107]. Where unknown irritants are present, the equation enables the maximum LCt_{50} to be predicted based on the asphyxiant gases and any known irritants.

This is a powerful technique because it enables a number of things to be done, as follows:

1. Where a material is tested in a small-scale test using only chemical atmosphere analysis, it enables an estimate to be made of the likely approximate toxic potency of the combustion products from the material, without the use of animal exposures.
2. Where a material is tested in a small-scale test using both chemical atmosphere analysis and animal exposures, then it is possible to determine the extent to which the toxicity of the combustion products can be accounted for in terms of the common toxic gases, or if additional toxicants are present.
3. If the toxic effects are almost entirely accountable in terms of the common toxic gases (as is often the case), then it enables the toxic effects of full-scale test atmospheres to be predicted with confidence, without animal exposures, if these gases are measured.
4. Where the LCt_{50} in a small-scale test is estimated from analytical data, or where it is measured using animals, it enables estimates of toxic potency of full-scale fires to be made simply from the mass loss rate and dispersal of products in the fire, provided the full-scale fire is of the same type (has the same combustion conditions) as the small-scale test decomposition.
5. Where analytical data are available from full-scale tests, they enable some estimates to be made of the toxic potencies of the materials involved.

The following examples show how this technique can be applied, using data from experiments with wood. When samples of Douglas fir were decomposed under flaming conditions in the NBS cup furnace, the LCt_{50} for a 30-min exposure of rats was 1194 $g \cdot m^{-3} \cdot min$. In the test, the CO concentration was 3400 ppm and the CO_2 concentration was 3.71 %, a CO_2/CO ratio of 11/1. According to the FED equation given above, this represents a FED of 1.0. It can therefore be concluded that in this test the observed toxic potency can be fully accounted for in terms of CO and CO_2,

and that there was little or no contribution from irritants or other toxic products on lethality. This result is to be expected, since the NBS cup furnace method generally simulates reasonably well-ventilated early flaming conditions where combustion is usually efficient, so that the yield of organic irritants would be expected to be low. However, in this test it is surprising that the CO_2/CO ratio is so low and more representative of somewhat vitiated burning conditions.

It is now possible to examine some full-scale test data on wood fires of this type, in the knowledge that CO and CO_2 are the main toxic products to consider. Such a test was performed at the U.K. Fire Research Station, where a 5-kg wood crib (Scotch pine) was burned in a closed 26 m^3 room. At 6 min into this fire the CO_2/CO ratio in the smoke was 60/1. Based on a 44 % carbon content for wood, and assuming that all carbon in the mass lost was converted to carbon oxides (CO_2 + CO), it is now possible to calculate what mass loss of wood in a small-scale test would be required for a 50 % rodent lethality at a CO_2/CO ratio of 60/1. It is to be expected that under these conditions the wood smoke would be less toxic than in the reported NBS test, since the major toxicant is the CO, and the CO yield is low at this moment in the fire. This is indeed likely to be the case, since the FED equation predicts an LCt_{50} of 3750 g·m^{-3}·min under these decomposition conditions, approximately three times less toxic than in the small-scale test.

Major Determinants of Toxicity in Fires and Small-Scale Tests

The toxicity of the combustion products from individual materials in fires, in terms of the type and yields of the major asphyxiant, irritant, and other toxic products depends principally on three factors.

1. The elemental composition of the material
2. The organic composition of the material
3. The decomposition conditions

The most important toxic products from fires are usually carbon monoxide and hydrogen cyanide, so that the most important elemental determinants of toxic potency are normally the carbon and nitrogen content of the fuel, with the halogen content being important to a lesser extent in some cases, and organic irritants in others. Figure 62.3 Illustrates the range of toxic potencies of individual compounds and combustion product mixtures, while Figs. 62.4, 62.5, 62.6, and 62.7 illustrate the extent to which different toxic species contribute to the overall toxic potency of different materials for the main different fire types described in ISO 19706 [9, 14].

Nonflaming Oxidative/Smoldering Fires

Nonflaming decomposition is slow, so that a long time is required for the development of hazardous conditions. However, of the small masses of materials decomposed during nonflaming oxidative decomposition, the yield of CO can be quite high, and these conditions generally provide the highest yields or organic products, including irritants, the identity of which is often unknown. In small-scale tests conducted under these conditions, only a small proportion of the observed toxic potency can be accounted for in terms of the common toxic gases [38, 39]. Table 62.24 shows two examples of this type, from experiments using the NBS cup furnace method to decompose Douglas fir and a flexible polyurethane foam under nonflaming oxidative conditions. The results show that at the LCt_{50} of wood to rats of 684 g·m^{-3}·min, only 0.47 of the observed toxicity could be accounted for in terms of common toxic gases, and for the flexible polyurethane foam only 0.29 of the observed toxicity could be accounted for. This result means that for these (and many other) materials decomposed under nonflaming oxidative conditions, a large part of the toxic potency is due to products other than those normally measured, almost certainly organic irritants, so that the FED method tends to underestimate the toxicity, unless allowance is made for irritants (in this case organic irritants) as in the Purser FED equation (Equation 62.3). From experiments such as that shown in Table 62.24 it can be estimated that approximately half of the

Table 62.24 Toxic potency analysis of materials decomposed under nonflaming oxidative conditions in the NBS cup furnace

	Douglas Fir 440 °C		Flexible polyurethane foam 400 °C	
	Concentration	FED	Concentration	FED
Carbon monoxide	2700 ppm	0.47	1261 ppm	0.22
Hydrogen cyanide	0 ppm	0.00	11 ppm	0.07
Carbon dioxide	0.69 %	$\times VCO_2$ 1.0	0.4 %	$\times VCO_2$ 1.0
Total FED asphyxiants		0.47		0.29
FED presumed due to irritants		0.53		0.71
LCt_{50} calculated	1455 g·m^{-3}·min		3621 g·m^{-3}·min	
LCt_{50} observed	684 g·m^{-3}·min		1050 g·m^{-3}·min	

toxic potency is likely to be due to organic irritants for most common materials under these decomposition conditions).

The nonflaming condition is adequately replicated by a number of small-scale test methods, and there is a large toxicity database available for many materials, since by far the greatest amount of published test results are obtained under these conditions.

From reviews of published toxic potency data from common materials and appropriate FED calculations [9, 10, 64] including data from a number of small- and large-scale test methods it is possible to make some general observations regarding the toxic potencies of the decomposition products from materials under a range of fire conditions. For nonflaming oxidative decomposition conditions, the range of LCt_{50} for individual materials covers approximately a factor of 12 from 63 to 767 g·m^{-3}·min (see Table 62.7) and Fig. 62.3.

Early or Well-Ventilated Flaming Fires

In flaming fires, the yields of carbon oxides and nitrogen compounds depend mostly on the decomposition conditions, particularly the air/fuel ratio. With regard to carbon, a key indication is the CO_2/CO ratio, which not only determines the toxic potency of the smoke, since CO is approximately 20 times more toxic than CO_2, but to a large extent defines the fire type. In early, well-ventilated fires combustion is usually efficient, and the CO_2/CO ratio may be as high as 200/1, although in practice somewhat lower ratios around 60/1 are more typical. Under these conditions the yield of organic irritants is usually low, since combustion is efficient, and the yield of CO is so low that the overall toxic potency of materials containing principally hydrogen and carbon can be expected to be low. The exceptions tend to be flame-retardant materials acting in the gas phase, "naturally" fire-retardant materials such as PVC, and some largely aromatic materials such as polystyrene, all of which tend to burn inefficiently and give low CO_2/CO ratios even under well-ventilated conditions. This results in high yields of CO and usually of irritants, and somewhat higher toxic potencies than for more easily and cleanly burning materials.

With nitrogen-containing materials, the situation is somewhat analogous to that with carbon, since in well-ventilated, early flaming fires, most nitrogen in materials is oxidized to nitrogen oxides and N_2. The yield of HCN is generally low (with the exception of acrylic materials, and to some extent rigid polyurethanes). Although NO_2, which is a potent lung irritant, can be expected to be present but at low yields under these conditions, the general effects seems to be that, since the HCN yield is low, toxic potency tends to be low. With materials like PVC, almost all the chloride is released as HCl under almost all decomposition conditions, including flaming conditions.

The general picture then is that the toxic potency of combustion products from most materials is lowest under early, well-ventilated

flaming conditions. Materials that tend to perform comparatively less well under these conditions are FR materials, and materials like PVC, where the halogen acid gases cannot be destroyed by the flames (Fig. 62.5).

Small-Scale Tests Replicating Well-Ventilated Flaming Conditions

To study the toxic potencies of materials under the decomposition conditions similar to those during the early stages of flaming fires it is necessary to use a test method that provides flaming combustion throughout the test until the material is fully decomposed. The test method must also provide good ventilation of non-vitiated air to the specimen and have a general temperature environment of around 400–700 °C (or equivalent radiant flux). Most important, however, it must produce high CO_2/CO ratios (in the range approximately 200/1 to 50/1) from normally combustible (i.e., non-FR) materials.

NBS Cup Furnace Test Of the small-scale test methods commonly used, a number perform well in this area. The one for which the most animal toxicity data are available for well-ventilated flaming is the (now discontinued) NBS cup furnace test. In this test the material specimen is decomposed in a crucible furnace, and the products are evolved into a 200-L box. The key feature of this test is that it is normally used with quite small specimens, so that the oxygen concentration in the box is not significantly lowered during the test, and studies of the combustion process have shown that air circulates rapidly down into the cup furnace during decomposition, so that combustion tends to be reasonably efficient. The CO_2/CO ratios typically produced in tests are in the 40/1 to 60/1 region, so that, although perhaps not representing the most efficient combustion, they are generally a reasonable model for the results obtained in small, well-ventilated, full-scale fire tests.

NIST US. Radiant (NIBS) Test A more recent development of the NBS cup furnace test is the NIBS test or NIST radiant test. The two versions of the test use the same apparatus, but somewhat different test protocols. For this test a radiant heating unit is placed in a cavity under the NBS chamber and connected to it by a slit-shaped chimney. Investigations of the combustion mode of this test [21] have also shown that under flaming combustion conditions the circulation of air is such that the specimen is very well ventilated, so that CO_2/CO ratios are generally reasonably high. Data from this test method suggest that it may best represent the decomposition conditions in a well-ventilated fire. However, in its present form it does not appear to generate the very low CO_2/CO ratios and high CO and HCN yields found in typical underventilated pre- and post-flashover fires in compartments.

A particular issue with all closed-box methods such as these is ageing if the effluents and losses resulting from deposition to the walls of the fraction of the atmosphere consisting of smoke particulates, organic products and acid gases. Also, since the enclosed atmosphere is continuously circulated trough the furnace, changes to the effluent composition can result from secondary decomposition processes.

Cone Calorimeter The cone calorimeter has not been used very successfully with animal exposures, but using the FED model presented in this chapter, it is possible to make some useful estimates of likely toxic potency based on the toxic gas yields and the mass loss of the specimen. The cone calorimeter gives the most efficient combustion conditions of any test method, typically producing CO_2/CO ratios in the 200/1 to 100/1 range for non-FR materials. It can also, therefore, be used as representative of the decomposition conditions during very early and very well-ventilated fires. So far, attempts to modify the combustion process and decrease the combustion efficiency to model other stages of fire have not proved very successful.

DIN 53 436 and ISO19700 Tube Furnace Methods For these methods, decomposition occurs in a tube furnace, the furnace passing over a strip of the sample (DIN) or the sample

passing into the furnace (ISO19700), with decomposition achieved by passing a stream of air through the furnace and over the sample. The products from the tube furnace may then be diluted with secondary air for animal exposures, if required. The atmosphere produced is in a "dynamic steady state," in that the concentrations of decomposition products remain constant because the test material is decomposed at a constant rate throughout the test. The epithet "DIN" has come to represent a number of tube furnace methods based on the same principle, generally accepted as DIN test results, the important point being to demonstrate that the decomposition atmosphere generated is relatable to real fire conditions, rather than that the apparatus design is standard.

The important feature of this design is its versatility, since the decomposition conditions can be varied over a wide range by varying the sample load, air supply, and furnace temperature. This contrasts with the other methods described, which are very restricted in the range of conditions that can be modeled. The improved tube furnace method, originally recently developed at the UK Building Research Establishment, Fire Research Station (FRS) [12], is based on the DIN method concept, and is the only one developed so far that can simulate the decomposition conditions for all fire types, including nonflaming, early flaming, and fully developed fires with restricted ventilation, particularly postflashover fires (see Fig. 62.19). A limitation with the official DIN method, in regard to flaming combustion, is that the decomposition conditions tend to be rather vitiated, giving low CO_2/CO ratios, and flaming is unstable. However, this is remedied in the ISOTS19700, by increasing the air-fuel ratio in the furnace tube and the rate of sample advance, so that it has been possible to increase the ratios to those occurring in early, well-ventilated, full-scale fires, while achieving stable flaming conditions [39].

UPITT Method The University of Pittsburgh method is considered to give a poor representation of actual fire conditions, and it is considered that it is not possible to relate it to any of the fire conditions shown in Table 62.23. For this reason (and others), UPITT data are considered unsuitable for the assessment of toxic potency of materials involved in fires, except in very special cases where the conditions can be shown to be similar to the sequence of events occurring in the UPITT apparatus.

Toxic Potency Data Obtained from Tests Under Early, Well-Ventilated Flaming Conditions

Because well-ventilated flaming conditions tend to destroy compounds such as organic irritants, it is to be expected that the toxic potency will be more completely due to the common toxic gases than for the nonflaming fires shown in Table 62.24. Table 62.25 illustrates this fact with some examples taken from NBS cup furnace test data. The data for Douglas fir show that, unlike the nonflaming situation illustrated in

Table 62.25 Toxic potency analysis of materials decomposed under early, well-ventilated flaming conditions in the NBS cup furnace

	Douglas Fir 485 °C		Flexible polyurethane foam and polyester 525 °C	
	Concentration	FED	Concentration	FED
Carbon monoxide	3400 ppm	0.60	2270 ppm	0.40
Hydrogen cyanide	0 ppm	0.00	63 ppm	0.38
Carbon dioxide	3.71 %	× VCO_2 1.4 + 0.2	3.36 %	× VCO_2 1.25 + 0.1
Total FED asphyxiants		1.04		1.08
FED presumed due to irritants		0		0
LCt_{50} calculated	1148 g·m^{-3}·min		1038 g·m^{-3}·min	
LCt_{50} observed	1194 g·m^{-3}·min		1170 g·m^{-3}·min	

Table 62.26 Toxic potency analysis of materials decomposed less efficiently under early, well-ventilated flaming conditions in the NBS cup furnace

	PVC 625 °C		FR flexible polyurethane foam 425 °C	
	Concentration	FED	Concentration	FED

LCt_{50} observed	519 g·m^{-3}·min		810 g·m^{-3}·min	

[a]HCl (hydrogen chloride) for PVC or HCN (hydrogen cyanide) for FR flexible polyurethane foam

Table 62.24, the toxic potency can be fully accounted for in terms of carbon oxides, and an LCt_{50} for wood calculated on this basis would be very close to the observed value. For flexible polyurethane (FPU) foam it was not possible to obtain a lethal concentration in the cup furnace under flaming conditions due to limits on the capacity of the apparatus for the size of sample required, but in other experiments a mixture of polyester and FPU was tested. With this mixture of materials it was possible to obtain lethal exposure conditions, and the data are also shown in Table 62.25. As with the wood, it was possible to account fully for the observed toxic potency on the basis of carbon oxides and hydrogen cyanide.

For materials that burn less efficiently under these conditions or that produce inorganic acid gases, the data analyses indicate contributions to lethality from irritants. For example, Table 62.26 shows data on PVC and an FR polyurethane foam obtained using the NBS cup furnace method. For the PVC test, the contribution to the total FED from carbon oxides was only 0.19, so that the major cause of death had to be some other factor. Unfortunately the HCl concentration was not measured, but from the mass of PVC decomposed, it can be estimated at approximately 5000 ppm. As the analysis shows this would have been more than enough to account for the observed lethality. With regard to the FR FPU, the yield of common toxic gases was significantly greater than that from the untreated foam, so that it was possible to obtain an LCt_{50} using the cup furnace. The concentrations of carbon oxides and hydrogen cyanide were sufficient to account for approximately 0.7 of the observed toxic potency, but it is possible that the remaining 0.3 represents the effects of unidentified irritants evolved due to the less efficient combustion occurring from this foam compared to an untreated foam.

Based on available published small- and large-scale test data, it is possible to make some general observations regarding the early, well-ventilated flaming condition. The basic finding is that the published database involving animal exposures is very poor, there being only a few tests or none on quite common materials. The only materials for which a reasonable number of tests have been performed under flaming conditions are wood, flexible polyurethanes, and PVC. Needless to say, these involve a variety of wood species and polymer formulations. Based on this inadequate database, the pattern that emerges is that the range of toxic potencies of common materials covers approximately a factor of 50, with LCt_{50} exposure doses of from approximately 75–3750 g·m^{-3}·min. As could be predicted, the least toxic materials are the cellulosics and simple hydrocarbon polymers, such as polypropylene. Flexible polyurethanes are of low to intermediate toxic potency within this range. The most toxic materials are the acrylonitriles, which release quite large amounts of HCN even under well-ventilated flaming conditions. PVCs are generally somewhat more toxic than the cellulosic materials under these conditions, due to their relatively low combustion efficiency and high HCl yield.

Small-Scale Tests Replicating Fully Developed Fire Conditions—Especially Postflashover Fires

The decomposition conditions in fully developed fires depend very heavily on the conditions in fire compartments and in particular the ventilation. A general principle would be that in the common situation of a fire in a building, which would typically contain large amounts of combustible fuel, the fire growth will depend on the rate of involvement of the fuel in the early stages with efficient combustion and high CO_2/CO ratios (100/1 to 200/1). Then as the fire grows, combustion becomes increasingly ventilation controlled, so that later and fully developed fires tend to be oxygen vitiated with low CO_2/CO ratios (<10/1). However, it is possible to have fully developed, well-ventilated (fuel controlled) fires with high CO_2/CO ratios (up to 100/1), as indicated in Table 62.23. These conditions can commonly occur during some stages of test fires in large-scale test rigs. Such large-scale tests usually have a relatively small amount of fuel (such as a single chair) and have a rig with an open side or doorway or window openings, which are, in turn, supplied freely with air from outside or from a large test facility building. Another factor that may provide high CO_2/CO ratios in the effluents from a primarily vitiated postflashover fire is secondary combustion outside the fire compartment where the products mix with air and are sufficiently hot to support further combustion. This effect has been observed at the DIN furnace outlet when attempting to simulate postflashover decomposition conditions.

Accidental fires in real occupied buildings often have access to a much larger amount of fuel than test fires and often have access to a more restricted air supply (such as air from inside the building). Thus in the Boston Fire Department study of accidental fires [108], 50 % had CO_2/CO ratios of less than 10/1 and a further 22 % had ratios of approximately 10 to 20/1. Only 17 % fell into the well-ventilated category with ratios above 40/1. When full-scale tests are more closely related to real buildings or contents, then low ratios occur. For example, a simulation of a fire in a fully furnished hotel bedroom, opening on an open corridor with a side room attached, gave CO_2/CO ratios of 2/1 in the burn room and 3/1 in the side room at the fire peak [109].

Once a fire has passed beyond the very early, well-ventilated stage, there are basically two paths for continued development, depending largely on the boundary conditions, especially the dimensions of the fire enclosure, its thermal properties and ventilation.

Where a flaming fire occurs in a domestic room-sized compartment and the room doors and windows are shut, an oxygen depleted upper layer fills down rapidly, so that within a minute or so the combustion becomes vitiated as the flames penetrate the upper layer. Once the upper layer descends to the base of the fire, the fire becomes very small and may self-extinguish. A typical enclosed domestic room will not support complete combustion of more than a few kg of fuel before the oxygen concentration in the room is reduced to approximately 10–15 % and the fire extinguishes or dies down. Fires of this type, involved in many deaths, tend not to develop beyond a small size as long as the compartment is closed, but the CO_2/CO ratio decreases from a very early stage. An example is a burning 5 kg wood crib in a closed room. Table 62.27 shows the gas concentrations in the room during this fire, the atmosphere becoming progressively more vitiated and the CO_2/CO ratio decreasing as the fire progresses. The last column shows the influence this process has on the toxic potency of wood, assuming that carbon oxides are the only important toxic products (and also ignoring any toxic effects of low-oxygen hypoxia). The data show that, if a sample of wood was decomposed in a number of runs of a small-scale test under conditions giving the range of CO_2/CO ratios recorded at different stages of the full-scale fire, then the toxic potency of the wood would increase from very low levels as shown.

A further variant of this situation occurs when exterior doors and windows in a dwelling remain closed, but the fire-room door is open to the hallway. Under situations such as this the

Table 62.27 Toxic gas concentrations and calculated toxic potencies during full-scale wood fires in a room-corridor test rig

1. Fire of 5 kg wood in a closed room—total mass loss 3.5 kg; room temperature approximately 200 °C					
Time (min)	CO ppm	CO_2 ppm	CO_2/CO ratio	O_2%	LCt_{50}[a] for CO_x g·m^{-3}·min
6	750	45,000	60	18	3750
8	1500	75,000	50	13.5	3461
10	2500	88,500	35	11	2857
12	4000	95,000	24	10	2222
20	9000	75,000	8.3	11.5	1034
2. Fires of 44 kg wood in open room with high and low ventilation; room temperature approximately 800 °C					
High vent.	10,000	150,000	15	9	1800
Low vent.	50,000	150,000	3–1.5[b]	4	750

[a]LCt_{50} calculated in terms of mass loss concentration of wood, assuming carbon oxides to be the only toxic products of importance

[b]Second figure shows ratio in corridor, all other figures in room

original enclosure fire also becomes vitiated, and the fire size restricted, at an early stage as the upper layer descends below the flame height. But as the upper layer descends below the doorway soffit, effluent flows out into the hallway and open areas, while fresh air enters new floor level. The resulting fires can then grow somewhat larger than those in a single enclosed room (depending upon the dimensions), and burn in a vitiated manner for longer, filling all open areas with a lethal effluent (see fire scenario descriptions in Chap. 63). After a few minutes such fires die down as the whole system becomes oxygen depleted, and may self extinguish unless exterior windows fail or exterior doors and windows are opened. Pre-flashover underventilated fires such as this are major causes of smoke injuries and deaths for occupants both in and beyond the enclosure of fire origin.

Another other common situation is where a window and door (or door only) is open, or where the compartment has a large area compared to its height, so that there is sufficient ventilation to support a much bigger fire before the air supply becomes the controlling factor. Such fires, also typically a cause of smoke deaths in locations remote from the fire, become both hot and vitiated, and may progress to postflashover. This combustion condition can be simulated in small-scale tests, with a temperature of 800 °C or more, and CO_2/CO ratios of less than 10/1, and as low as 2/1. The lower part of Table 62.27 illustrates this with data from the developed stage of larger (44 kg) wood fires run in the same rig as the 5 kg test. These fires were run with high and low ventilation from the corridor, to simulate well-ventilated and oxygen-vitiated, fully developed (postflashover) fires. The results show that both fires become vitiated when fully developed, the poorly ventilated fire giving very low CO_2/CO ratios of 3/1 in the room and 1.5/1 in the corridor.

If the typical postflashover fire is hot, and oxygen vitiated, with low CO_2/CO ratios, the next consideration is what effects these decomposition conditions have on the toxic potency of the products. The most obvious effect is that the toxic potency is increased compared to well-ventilated fires due to the higher concentrations of CO produced as the CO_2/CO ratio falls. The series of room-corridor fires performed at the Fire Research Station using 44 kg wood cribs provides a good example. When these were burned with restricted ventilation, the CO_2/CO ratio fell to the low values mentioned, of 3/1 in the room and 1.5/1 in the corridor after 3.5 min, with very high concentrations of CO (5 %) in the room. Assuming as before that toxicity would be due solely to carbon oxides, then the theoretical LCt_{50} would be 750 g·m^{-3}·min, which is approximately five times more toxic than that in the well-ventilated, early flaming fire, and is similar to results obtained for pine and sipo wood in the DIN apparatus at 850 °C. Table 62.28 shows the toxic potency analysis for this fire.

Table 62.28 Toxic potency analysis of materials decomposed under high-temperature, vitiated conditions in large-scale fires and in the DIN apparatus

	Scotch Pine 850 °C room corridor low ventilation		Wool 700 °C DIN	
	Concentration	FED	Concentration	FED
Carbon monoxide	5515 ppm	0.97	379 ppm	0.07
Hydrogen cyanide	0 ppm	0	153 ppm	0.93
Carbon dioxide	1.7 %	$\times VCO_2$	0.17 %	$\times VCO_2$
		1		1
Total FED asphyxiants		0.97		1
FED presumed due to irritants		0		0
LCt_{50} calculated	750 g·m^{-3}·min		81 g·m^{-3}·min	
LCt_{50} observed (DIN test under similar conditions)	876 g·m^{-3}·min		No data	

A very important aspect of postflashover fire conditions is the fate of nitrogen in materials. Under hot, vitiated conditions the yield of HCN from all nitrogen-containing materials increases dramatically. Hydrogen cyanide can, therefore, be an important toxic product in postflashover fires where the fuel has a high nitrogen content. Another problem with such fires is the yield of organic irritants. Vitiated postflashover fires produce large quantities of smoke, and experiments with some common materials decomposed under these conditions in a DIN-style tube furnace have shown that the dense smoke is rich in organic products, which are irritant to mice. With regard to inorganic irritants, such as HCl, these are produced at the same high yield as with early flaming fires, except that their effects are less prominent in the fully developed fire in comparison with the high yields of other toxic products.

Results from DIN and Other Tube Furnace Methods and Full-Scale Tests

If the database of small-scale animal toxicity test results on materials tested under early flaming conditions is poor, that on materials tested under postflashover conditions is even smaller. The only small-scale apparatus that can be used to replicate these conditions is the DIN and ISO19700 tube furnace when it is run at high temperatures. A small amount of rodent lethality data is available from tests run using the DIN method at temperatures above 800 °C. Apart from this, other data are from a number of small-scale and large-scale tests where analytical measurements were made. From these which it is possible to make toxic potency assessments, assuming that toxic effects were due only to carbon oxides, HCN, acid gases, and generic organics (such as measured using the ISO19700 tube furnace [11, 13, 66, 69, 91, 92]. In such vitiated postflashover conditions, it is found that carbon monoxide and hydrogen cyanide are dominant toxic species, since carbon monoxide is be present at high yields in all fires and hydrogen cyanide can also be expected at high yields if the materials being burned contain nitrogen. Added to this is a contribution from organic irritants, and a contribution from inorganic irritants if these are present. Although recent work suggests that organic irritants may be more important under these conditions than was thought previously, it is considered likely that they are less important than under nonflaming conditions and are unlikely to be the dominant factor in the toxic potency.

Table 62.28 shows some examples of toxic potency analyses for this fire condition. The table shows analytical data from a large-scale wood fire, compared with animal data from a DIN test on wood for which no analytical data are available, and data from a small-scale (DIN) furnace test on a nitrogen-containing material (i.e., wool). Rats were exposed in the test at an exposure dose of 18 g·m^{-3}·min, and all died. The data shown are projected gas concentrations at the calculated LCt_{50}. For the wood data, the point

illustrated is that, based on the measured carbon oxide concentrations, the toxic potency is likely to be dominated by CO, and on this basis the potency of wood is greater than under well-ventilated flaming conditions. That this projection is reasonable is supported by the results of DIN work on Scotch pine, carried out under nominally similar conditions. This work gave a rat LCt_{50} of 875 $g{\cdot}m^{-3}{\cdot}min$, which is similar to the predicted figure for wood decomposed under these general conditions. Unfortunately, no analytical data were published for the DIN test results. For the wool data, the main point illustrated is that even at 700 °C which is somewhat below what would be considered a postflashover temperature, the toxicity is likely to be dominated by the high HCN yield, and this is also considered to be true for most other nitrogen-containing materials. The other point made strongly by these examples is the paucity of available data for this type of fire.

Based on the available data it is estimated that the toxic potency range for common materials decomposed under vitiated postflashover conditions covers an LCt_{50} range from approximately 21 $g{\cdot}m^{-3}{\cdot}min$ for materials with a high nitrogen content decomposed at temperatures around 1000 °C up to 3000 $g{\cdot}m^{-3}{\cdot}min$ for certain cellulosic or hydrocarbon-based polymers, a range of more than 2 orders of magnitude for the small sample of published data.

Adaptation of Data from Other Small-Scale Tests

It has been recognized that tests other than the DIN, such as the cone calorimeter and the U.S. radiant method, are incapable of simulating postflashover decomposition conditions, producing the wrong yields of CO and the wrong CO_2/CO ratios. However, since it is also considered in the United States that this fire condition is the most important to study, suggestions have been made that a calculation method can be applied to cone and U.S. radiant data toxicity data to allow for the low CO yield in the tests, relative to those in postflashover fires. This is obviously not a realistic suggestion, since even if a calculation factor could be used to correct the CO data, the result would still be wrong if no factor were used to correct for the differences in the yields of HCN and other nitrogen-containing products, and for the yields of the many other organic irritants. Rather, if it is wished to study the behavior of materials under vitiated, high-temperature postflashover conditions, small-scale tests should be used that create such decomposition conditions, so that the chemistry and toxicity of all the decomposition products evolved under these conditions can be studied. Since tube-furnace methods similar to the ISO TS19700 method are cheap and very effective means of simulating this fire condition, it is recommended that this method be used, under appropriate conditions of temperature and airflow, for this purpose. Where calculation methods are to be used, it is better to base them on the elemental composition of the material and knowledge of full-scale fire conditions rather than on small-scale tests conducted under inappropriate conditions.

General Pattern of Toxic Potency for Common Materials Under Three Fire Conditions

The survey of the toxic potency data for common materials under four fire conditions, (1) nonflaming, (2) early flaming, (3) underventilated pre-flashover and (4) underventilated post-flashover, has revealed an inadequate database, but it has been possible to derive approximate LCt_{50} for common materials. The results for individual materials range over approximately 2 orders of magnitude from 20 to 3750 $g{\cdot}m^{-3}{\cdot}min$, but when the data are reduced to basic types of materials under each decomposition condition a relatively simple pattern can be described (Table 62.7). The table shows the approximate average lethal exposure doses (LED $= LCt_{50}$) for classes of materials, the LC_{50} for 30-min exposures. The findings are as follows:

Under nonflaming oxidative decomposition conditions at >400 °C most materials have a

similar potency close to 500 $g \cdot m^{-3} \cdot min$ due mainly to the effects of carbon monoxide and irritants. The main exceptions are nitrogen-containing materials releasing significant HCN at low temperatures (e.g., polyacrylonitrile, modacrylic, and rigid polyurethane foam), which have LED values of 150–1200.

Under early flaming conditions most non-fire-retardant materials are substantially less toxic than under nonflaming conditions. Cellulosics (e.g., wood and cotton) are the least toxic with LCt_{50} of >3000 $g \cdot m^{-3} \cdot min$. Plastics containing carbon, hydrogen, or oxygen are somewhat more toxic with a potency factor of LED ~2100). and those containing nitrogen (e.g., flexible polyurethanes, wool, and nylon) range from 240 to 510. Both PVC and fire-retardant materials have LED values similar to those under nonflaming conditions of approximately 1.

When equivalence ratios in pre-flashover fires exceed 1 the toxicity increases, so that LEDs are similar to or lower than under non-flaming conditions.

Under postflashover conditions the potency of all materials are similar to or slightly greater than for pre-flashover underventilated conditions with high yields of HCN or CO. More smoke and irritants are also present than under early flaming conditions, which may add somewhat to the potency, particularly of the non-nitrogen-containing materials. For cellulosic materials and hydrocarbon plastics, the potency is similar to that under nonflaming conditions or greater. For all nitrogen-containing materials the toxic potency is high, with LED values ranging from approximately 54 for polyamide to 210 for flexible polyurethane foam. It is suggested that rigid PVC would have a potency of approximately 8 under these conditions.

The Conduct and Application of Small-Scale Tests in the Assessment of Toxicity and Toxic Hazard

Small, laboratory-scale toxicity tests are of necessity capable only of investigating materials. Investigation of toxic fire hazard associated with actual items such as furnishings can be investigated only in large-scale tests, although it may be possible to a limited extent to study some composite materials using small-scale tests. The potential usefulness of these tests is then to examine the toxicity of the decomposition products from materials. This information can be used in conjunction with other small-scale test data on such characteristics of materials as ease of ignition, rate of flame spread, heat release, and smoke production to judge the suitability of one material versus another for a particular application, and ideally as a prelude to large-scale fire tests. From these it should be possible to draw some conclusions as to likely fire scenarios as well as the toxic and general fire hazards involved. A sensible approach to the use and application of such toxicity tests should involve the following steps:

1. Decide what kinds of fire scenarios are of interest and likely to involve the material under investigation, and what types of fire conditions it may be subjected to—smoldering/overheat, small flaming fire, or fully developed/postflashover.
2. Choose a small-scale test method or methods capable of simulating these conditions.
3. Run the test without animals and measure as many as possible of the common fire products important with respect to toxicity. A minimum that should be measured include CO, CO_2, O_2, HCN (if nitrogen present in material), HCl (or other appropriate acid gases if likely to be present), smoke optical density, and particulate concentration. All tests should be characterized in terms of NAC mass charge, NAC mass loss, decomposition temperature, and whether the decomposition is flaming or nonflaming. Calculate an approximate LCt_{50} at this point for use in hazard modeling. If there is any reason to suspect from the chemical and physical composition of the material that more exotic toxic chemical products or physical entities such as nanoparticles or fibers may be released into the effluent so that more information is required, proceed to carry out animal experiments.

4. Set up a test atmosphere at a concentration that should be just sublethal for the known toxic atmosphere constituents (in most cases the determining factor will be the CO concentration). Then expose a group of animals and measure the toxic effects in terms of type (asphyxiant or irritant), time of onset, severity, and duration, noting in particular the degree of incapacitation and the occurrence of any deaths. In the first instance this should involve a 30-min exposure followed by a 14-day observation period.
5. Decide from this whether the observed effects are consistent with the toxicity due to common fire products or whether there were any unusual or severe toxic effects. If the toxicity can be interpreted in terms of the common asphyxiant products CO and HCN, then it should be possible to attempt modeling of toxic hazard on a large scale. However, if the products are irritant, as in most cases they will be, or if some unexpected toxic effect should occur, then further investigations are indicated.
6. If some unexpected toxic effect should occur, attempt to identify the toxic product or products responsible, and the conditions under which they are likely to be formed. The minimum necessary is to establish the 30-min exposure LC_{50} concentration to give some indication of the possible toxic potency of the material when decomposed in a fire. However, if the identity of the toxic product and the conditions of its formation are not understood, it is unwise to assume that small-scale tests will adequately predict what might happen in a large-scale fire. A good example is PTFE (Teflon). In one small-scale test method (the NBS method), PTFE decomposes to form a highly toxic lung irritant that causes death at concentrations of 2 to 3 orders of magnitude less than that of other polymeric materials [6]. In the Pittsburgh method the material is approximately 20 % less toxic [110], and in a tube furnace method similar to the DIN method a further three times less toxic [111] although still somewhat more toxic than most other materials. However, when decomposed in a way different from any of these tests, the high toxic potency is lost [112] and it is possible that under real fire conditions the products may not be significantly more toxic than those of other materials, although this is yet to be established.
7. Assess the irritancy potential of a material by measuring the effects of its thermal decomposition and combustion products in animals. With regard to the assessment of irritancy, although many known irritants have been identified in combustion product atmospheres, it is still not possible to predict the irritancy of an atmosphere from an analysis of its composition. The potential for causing upper respiratory tract and eye irritation (sensory irritancy) should be assessed by measuring the mouse RD_{50} concentration of the material. The potential for causing lung irritation with serious or lethal lung inflammation should be assessed by examining postexposure lethality in rats or mice. Thus if carbon monoxide concentrations are relatively low in relation to irritant products, a concentration of decomposition products may occur when the animals die either during, or in most cases after, exposure due to lung inflammation. An LC_{50} concentration for these nonasphyxiant deaths should then be determined to indicate the potency of the material in terms of causing lung inflammation under specific decomposition conditions. If it is not possible to identify the product or products responsible for these irritant effects, it will be necessary to use the material RD_{50} and LC_{50} data in an attempt to predict likely large-scale toxic hazard. Although this measurement is only approximate, there are indications that both the RD_{50} and LC_{50} levels of most materials fall into relatively narrow bands, each effect spanning approximately one order of magnitude, with 1–2 orders of magnitude between the effects, at least under nonflaming conditions. Under nonflaming conditions it is likely that most materials may cause potentially serious lung

inflammation following a 30-min exposure at an NAC mass loss of approximately 10 mg/L, and severe sensory irritation at somewhat lower concentrations, possibly around 1 mg/L, although tenability limits for humans are difficult to estimate. Under flaming conditions the degree of irritancy is likely to be less, sometimes considerably so, depending on the efficiency of combustion.

8. Having evaluated the toxicity of the combustion products from the material in this way, it should be possible to use the data in conjunction with other information from small- and large-scale fire tests, or mathematical models, to assess potential toxic hazard for the material or materials in question in their end use configuration.

Tenability limits for some 5- and 30-min exposures to common toxic fire products in terms of time to incapacitation and death are shown in Appendix 3 of Chap. 63.

Misuse of Toxicity Test Data

Another way of using toxicity test results is to rank materials in order of toxicity and choose the least "toxic" material, as if toxic hazard were an inherent property of the material. This is not a realistic approach, since the toxic hazard is not a single property but a sequence of different toxic effects developing over different time-scales during a fire. The mix of toxic substances in a fire effluent associated with any material is also not an inherent property of a material or product, but a system property of a full-scale fire scenario. The yields and concentrations of toxic substances in fire effluents change continuously during a fire as the fire develops and the combustion conditions change. Indeed, it is very easy to alter the toxic substance yields and "toxicity" of a material in a small-scale fire test simply by altering the test conditions, particularly with respect to CO and HCN yields. Thus, when wood or most other hydrocarbon polymers are decomposed under flaming conditions with restricted oxygen, the CO_2 to CO ratio in the products can be lowered (to around a value of 4) [17, 18] and the toxic potency is high. However, under well-oxygenated efficient combustion conditions, the CO_2 to CO ratios in a fire may be as high as 1000, and under such conditions the toxic potency of the products is very low. Although such anomalies can be overcome to some extent by careful control of the small-scale decomposition conditions and by relating them to conditions known to occur in large-scale fires, it is still difficult to predict the CO concentration-time profile and, hence, the toxic hazard development for a large-scale fire from the small-scale fire model in a toxicity test. For this reason, ranking materials in order of their performance in small-scale toxicity tests does not have much meaning or usefulness.

The best use of small-scale toxicity tests is to identify the products responsible for the major toxic effects and measure their yields under defined combustion conditions validated against full-scale fires. The concentration/time profiles of these products in large-scale fires can then be measured or modeled, and the likely toxic hazard can be assessed.

Appendix

Glossary of Terms

Acidosis: A condition in which the pH of the blood is lowered (i.e., becomes more acidic). Respiratory acidosis in fire exposures results from excess carbon dioxide uptake. Metabolic acidosis results from impaired tissue respiration (due to tissue hypoxia) caused by burns or asphyxia. (See alkalosis.)

Addition: Two or more toxic substances are considered to exert an additive effect when they act in concert, such that the effect in combination is greater than the effect of either substance acting alone but not greater than the sum of the effects of either substance acting alone (when they may be said to be directly additive). (See also synergism.)

Aerodynamic diameter: The aerodynamic diameter of a particle is an expression of particle size, and represents the diameter of a spherical particle of unit density with the

same aerodynamic properties as the particle under consideration.

Aerosol: Solid or liquid particles dispersed in air.

Alkalosis: Respiratory alkalosis occurs when the pH of the blood is increased (i.e., becomes more alkaline). It is caused by excess removal of carbon dioxide from the blood via the lungs during hyperventilation and may cause a loss of consciousness.

Available Safe Escape Time (ASET): ISO Definition: Time available for escape for an individual occupant, the calculated time interval between the time of **ignition** and the time at which conditions become such that the occupant is estimated to be incapacitated, i.e., unable to take effective action to **escape** to a **safe refuge** or **place of safety**

NOTE 1 The time of **ignition** can be known, e.g., in the case of a **fire model** or a **fire test** or it may be assumed, e.g., it may be based upon an estimate working back from the time of detection. The basis on which the time of ignition is determined is always stated.

NOTE 2 This definition equates **incapacitation** with failure to escape. Other criteria for **ASET** are possible. If an alternate criterion is selected, it is necessary that it be stated.

NOTE 3 Each occupant can have a different value of ASET, depending on that occupant's personal characteristics.

Asphyxia: Suffocation; a decrease in the oxygen content, and increase in the carbon dioxide content of the blood that may occur due to laryngeal spasm caused by burns or irritant gases or to impairment of breathing or gas exchange in the lung. The term has been extended to include all causes of tissue hypoxia, including exposure to asphyxiant gases (low oxygen concentration due to the excess of any other gas, or exposure to the asphyxiant gases carbon monoxide and hydrogen cyanide, which produce asphyxia chemically).

Atmosphere (fire atmosphere or test atmosphere): The total airborne medium to which a victim or experimental animal is exposed, consisting of solid and liquid particles and vapors dispersed in air.

Behavioral effects/incapacitation: The extent to which exposure to fire products affects the ability or willingness of a subject or experimental animal to perform coordinated movements or tasks, particularly movements or tasks similar to those required to escape from a fire. (See incapacitation.)

Bioassay: Originally a term reserved for the use of a biological system to detect or measure the amount of a biologically active material. In the fire context, it refers to the use of animal exposures rather than chemical analysis to determine the toxicity of a combustion product atmosphere.

Blepharospasm: Involuntary and sustained closure (spasm) of the eyelids. In fires it is due to the painful stimulation of the cornea by combustion products that are sensory irritants.

Bronchoconstriction: Constriction of the conducting airways in the lung due to the contraction of smooth muscle in the airway walls in response to an agonist or to stimulation of irritant receptors acting through the vagus nerve.

Burn: Tissue lesion caused by heat or chemicals. For description of burn types and degrees, see text.

Carboxyhemoglobin (COHb): Combination of carbon monoxide with hemoglobin in the blood, which limits the combination of hemoglobin with oxygen (oxyhemoglobin), and therefore the carriage of oxygen in the blood.

Cerebral depression: Condition in which the electrical activity of the cerebral cortex as revealed in the electroencephalogram consists mainly of slow wave (or delta wave) activity that is typical of a semiconscious or unconscious state.

Combustion products: Strictly speaking, this term means the products of flaming decomposition and is used in this sense when contrasted with thermal decomposition products. However, in general usage, the term may be taken to include all fire products,

whether produced by flaming or nonflaming thermal decomposition.

Concentration: The amount of a contaminant in the atmosphere per unit volume of the atmosphere, usually quoted as mass/volume (mg/L or mg/m^3) or volume/ volume (ppm or percent). (See nominal atmosphere concentration.)

Dose: The amount of a toxicant to which a fire victim or test animal is exposed. The simplest estimation of dose for inhalation toxicology is to multiply the atmosphere concentration by the duration of exposure (*Ct* product). A lethal dose may be expressed in terms of the LCt_{50}. However, other factors may affect the amount of toxicant actually entering the body, and for fires it may be necessary to express dose in terms of the material in the fire. (See nominal atmosphere concentration.)

Edema: Accumulation of an excessive amount of fluid in cells, tissues, or body cavities. Pulmonary edema occurs when a fluid exudate leaks out of blood vessels as a result of inflammation or circulatory insufficiency, and the lung tissues become swollen and waterlogged. Further development results in a fluid exuded within the alveolar spaces. This fluid accumulation seriously affects gas exchange in the lung and may be fatal.

Electroencephalogram: Waves of electrical activity in the cerebral cortex recorded from the surface of the head, which give an indication of the physiological state of the brain and the degree of alertness of the subject. A preponderance of fast (beta and alpha) activity indicates a conscious and normal state, whereas a preponderance of slow (theta and delta) activity signifies a physiologically depressed or unconscious state.

Erythema: Reddening of the skin in response to heat. This change coincides with pain and just precedes a skin burn.

Fire profile: Record of the changes with time of the concentrations of important fire products and intensities of physical parameters during the course of a fire.

Flaming fire: In the context of this chapter, this term refers to the early stages of fire growth (preflashover), when the fire is still confined to burning items within a well-defined area.

Flashover: Point in growth of a flaming fire where the flames are no longer confined to burning items but also occur within the fire effluent, remote from the seat of the fire.

Fractional incapacitating dose: The dose of a toxic product acquired during a short period of time, expressed as a fraction of the dose required to cause incapacitation at the average exposure concentration during that time interval. The fractional incapacitating doses acquired during each short time period are summed throughout the exposure, incapacitation occurring when the fraction reaches unity.

Fully developed fire: A fire that has reached its maximum extent of growth, usually extending throughout the fire compartment.

Haber's rule: Principle that toxicity in inhalation toxicology depends on the dose available and that the product of concentration and exposure time is a constant.

Hazard: A toxic fire hazard exists when a toxic product is present at a sufficient concentration and over a sufficient period of time to cause a toxic effect. A physical fire hazard exists when a physical fire parameter (heat or smoke) is present at an intensity and over a period sufficient to cause injury or seriously inhibit the ability to escape from a fire.

Hypercapnia: Increased blood carbon dioxide concentration.

Hyperthermia (heat stroke): An increase in body temperature above 37 °C. Hyperthermia is life-threatening if the body core temperature, or temperature of the blood entering the heart, exceeds 42.5 °C.

Hyperventilation: Increased rate and depth of breathing (increased respiratory minute volume, or RMV), in response to increased carbon dioxide, hypoxic hypoxia, hydrogen cyanide, exercise, heat, or stimulation of pulmonary irritant receptors.

Hypoxia: A reduction in the amount of oxygen available for tissue respiration, which can occur in the following four ways:

- **Anemic hypoxia**: The arterial PO_2 is normal, but the amount of hemoglobin available to carry oxygen is reduced and the ability to release oxygen to the tissues is impaired. For fire exposures this results mainly from the formation of carboxyhemoglobin following exposure to CO, but an anemic subject would be at increased risk.
- **Histotoxic hypoxia**: The amount of oxygen delivered to the tissues is adequate, but due to the action of a toxic agent such as HCN, the tissue cells cannot make use of the oxygen supplied to them.
- **Hypoxic hypoxia (low-oxygen hypoxia)**: The PO_2 of the arterial blood is reduced as a result of a low atmospheric oxygen concentration or impairment of gas exchange in the lung, due to bronchoconstriction or respiratory tract damage or disease.
- **Ischemic hypoxia**: Blood flow to a tissue is so low that adequate oxygen is not delivered to it despite a normal PO_2 and hemoglobin concentration. This occurs during shock following burns and in cerebral tissue due to alkalosis or briefly during postural hypotension.

Incapacitation: An inability to perform a task (related to escape from a fire) caused by exposure to a toxic substance or physical agent in a fire. A distinction is sometimes made between severe physiological incapacitation, in which the subject is unable to move normally, such as might occur in an unconscious or badly burned victim, and the more behavioral incapacitation, such as that caused by visual obscuration or eye irritation from smoke, in which the victim is more or less intact, but still unable to escape from the fire.

Inflammation: A complex of reactions occurring in blood vessels and adjacent tissues around the site of an injury. The initial reaction is congestion (engorgement of local blood vessels), exudation of fluid into the tissues (edema), and pain followed by a phase of destruction and removal of injured tissue by inflammatory cells and then a phase of repair.

Intensity: Level of a harmful physical fire parameter (such as radiant heat flux, air temperature, or smoke optical density).

Intoxication: A state in which a subject is adversely affected by a toxic substance. Specifically, the time at which a subject has taken up a sufficient amount of an asphyxiant (narcotic) gas that he or she behaves like someone severely affected by alcohol.

Irritation and irritancy: Irritation is the action of an irritant substance, irritancy is the response. This response takes the following two forms:

- **Pulmonary (lung) irritant**: Response occurs when an irritant penetrates into the lower respiratory tract and may result in breathing discomfort (dyspnea), bronchoconstriction, and an increase in respiratory rate during the fire exposure. In severe cases it is followed after a period (usually of a few hours) by pulmonary inflammation and edema, which may be fatal.
- **Sensory irritant**: Response occurs when an irritant substance comes in contact with the eyes and upper respiratory tract (and sometimes the skin), causing a painful sensation accompanied by inflammation with lacrimation or mucus secretion. At low concentrations, this effect adds to the visual obscuration caused by smoke, but at high concentrations the severe effects may cause behavioral, and to some extent physiological, incapacitation. Sensory irritation causes a decrease in respiratory rate that is transient in humans but continuous in rodents.

Lacrimation: The production of tears in response to sensory irritation of the eyes.

LC_{50}: Lethal concentration—50 %. The concentration statistically calculated to cause the deaths of one-half of the animals exposed to a toxicant for a specified time. It may be

expressed as volume/volume (ppm, percent) or mass/volume (mg/L). Care must be taken in comparing LC_{50}s of both the exposure duration and the postexposure period over which deaths were scored. In combustion toxicology, the LC_{50} may be related to the test material rather than its products and expressed in terms of the nominal atmosphere concentration of material either of mass charge or mass loss. (See nominal atmosphere concentration.)

***LCt*$_{50}$**: The product of exposure concentration and duration causing the deaths of 50 % of animals.

Narcosis: Literally "sleep induction" but used in combustion toxicology to describe central nervous system depression causing reduced awareness, intoxication, and reduced escape capability, leading to loss of consciousness and death in extreme cases. The asphyxiant gases CO, HCN, and CO_2 cause asphyxia, as does lack of oxygen due to the inhalation of an atmosphere low in oxygen, an impairment of breathing, or an impairment of gas exchange in the lung. The terms *narcosis* and *narcotic gases* are used synonymously with the terms *asphxia* and *asphyxiant gases*.

Nominal Atmosphere Concentration (NAC): The theoretical concentration of test substance in a test atmosphere, calculated from the mass of test substance produced from the atmosphere generation system each minute divided by the air volume into which it is generated. This concept is not directly applicable to combustion toxicology since the test material is decomposed in the fire or furnace system, but two derivative concepts are used to relate the test material to the degree of toxicity as follows:

Nominal Atmosphere Concentration mass charge (NAC mass charge): The mass of material placed in the furnace system per volume of air into which it is dispersed (mg material/liter).

Nominal Atmosphere Concentration mass loss (NAC mass loss): The mass loss of material during decomposition per volume of air into which it is dispersed (mg material/liter).

Physiological effects: Effects of chemical fire products or physical fire parameters on the functioning of the body, as opposed to parameters affecting the mind. Thus, a physiological effect of smoke is that it obscures vision, which might have a psychological effect on the willingness of a victim to enter a smoke-filled corridor.

Pneumonia (Pneumonitis): Inflammation of the lungs, in fire victims due to the direct effects of inhaled chemicals or hot gases, or secondarily to skin burns. The initial inflammatory phase may be followed by infection. As it passes through different phases, pneumonia may be life-threatening at any time from 1 h after exposure in a fire to several weeks after exposure.

Potency: The toxic potency is a measure of the amount of a toxic substance required to elicit a specific toxic effect—the smaller the amount required, the greater the potency.

Psychological effects: Psychological effects of exposure to fire scenarios are on the mind of the victim and may result in a variety of behavioral effects. These are distinct from physiological effects on body function (see above). A fire victim is likely to suffer both types of effects at various stages of a fire, and interactions between psychological and physiological effects are likely.

Psychomotor: Psychomotor skills are required to perform behavioral tasks involving a series of coordinated movements of the type required to escape from a fire in a compartment (such as a building).

Pyrolysis: In this chapter, the term *pyrolysis* is restricted to the thermal decomposition of materials without oxidation. In small-scale tests pyrolysis may be achieved by heating the material in a stream of nitrogen.

***RD*$_{50}$**: Respiratory depression 50 %—statistically calculated concentration of a sensory irritant required to reduce the breathing rate of laboratory rodents (usually mice) by 50%.

Respiratory Minute Volume (RMV): Volume of air breathed each minute (liters/minute). RMV = TV × RR.

Respiratory Rate (RR): Respiratory frequency (i.e., number of breaths per minute).

Respiratory tract: The nose, pharynx, larynx, trachea, and large bronchi are termed the upper respiratory tract, and the bronchiole, alveolar ducts, and alveoli are termed the lower respiratory tract.

Required Safe Escape Time (RSET) ISO definition: Time required for escape. Calculated time period required for an individual occupant to travel from their location at the time of **ignition** to a **safe refuge** or **place of safety** cf. **available safe escape time** and **evacuation time**.

Shock: A reduction in the circulating blood volume with a fall in blood pressure.

Smoke: Total fire effluents, consisting of solid and liquid particles and vapors.

Smoldering/nonflaming oxidative decomposition: Thermal decomposition in which there is partial oxidation of the pyrolysis products but no flame. This may result from overheating of materials by means of an external heat source or from self-sustained smoldering.

Specific toxicity: A particular adverse effect caused by a toxicant (e.g., asphyxia, irritancy).

Supertoxicant: A term used to describe a toxicant with an unusual specific toxicity not usually associated with fire effluents, often with a high potency.

Synergism: Situation where the toxic potency of two or more substances acting in concert is greater than the sum of the potencies of each substance acting alone.

Tenability limit: Maximum concentration of a toxic fire product or intensity of a physical fire parameter that can be tolerated without causing incapacitation.

Thermal decomposition: Chemical breakdown of a material induced by the application of heat.

Tidal Volume (TV): Volume of air exhaled in each breath.

Toxicity: The nature and extent of adverse effects of a substance on a living organism.

Ventilation (lung): The volume of air breathed each minute (synonymous with respiratory minute volume).

David A. Purser has a PhD in neurophysiology and a diploma in toxicology from the Royal College of Pathologists. As former director of combustion toxicology research at Huntingdon Research Centre, England, and subsequently as associate director of the Fire Safety Engineering Centre in the Fire and Risk Sciences Division at BRE Ltd., Watford, England, he has worked on fire chemistry, combustion toxicology, fire assessment, fire incident investigation, building code development and human behavior in fires for over 35 years. Since retiring from BRE in 2006, he continues with consultancy and academic work, as adjunct faculty at the University of Maryland (until 2014) and visiting professor at the Universities of Greenwich and Central Lancashire UK. He was a member of the Scientific Advisory Committee of the US National Association of State Fire Marshals (until 2014). He chaired the British Standards Committee on fire hazards until 2011 and serves as an expert on the International Organization for Standardization (ISO) fire hazard and fire safety engineering subcommittees and working groups.

Assessment of Hazards to Occupants from Smoke, Toxic Gases, and Heat

63

David A. Purser and Jamie L. McAllister

Introduction

The aims of this chapter are to provide methods for the assessment of life safety hazards in fires and an understanding of the effects of smoke, heat, and toxic fire effluents on occupants of buildings and other enclosures. Detailed discussions of the physiology and derivation of expressions suitable for a range of applications are presented in the main sections of the chapter. The assessment of toxic products from materials and the findings from studies of the toxicity of fire effluents in humans and animals from fire incident investigations, large and bench-scale fire tests and animal exposures is presented in Chap. 62 [1].

To aid the reader wishing to apply the methods to engineering hazard calculations, a summary of all the principal calculation expressions required for ASET design calculations, is presented in Appendix 1 with an example of an application in Table 63.22 and associated explanations. Full descriptions of the derivation of the different expressions, with more detail variations for specific applications, and further examples are presented in the later sections of this chapter. The summary section expressions are fully cross-referenced to the main text.

Fire effluents consist of a highly complex mixture of liquid and solid smoke particulates and vapors containing many hundreds of substances many of which are toxic. The range of toxic substances evolved in fires and their yields depends on the composition of the burning fuel and the decomposition conditions. The toxic effects of exposure, the potency of the different toxic substances (concentration or dose required to produce a toxic effect) and the interactions between different components are also complex, ranging from incapacitating effects on escape capability and survival to increased risk of developing cancer after many years of exposure. The toxic hazards considered in this chapter are limited to those considered important in relation to escape and survival during and immediately after exposure in fires. A major simplifying principle is that the main incapacitating effects on fire victims are caused by a small number of key irritant and asphyxiant substances and that the main interactions between the individual substances are essentially additive. The justification for these assumptions, based upon the results of fire incident investigations and experimental studies of the toxicity and physiological effects of individual fire gases and combustion product mixture using animals, is examined in Chap. 62. Chapter 62 also considers the use of small-scale toxicity test data. This includes consideration of methods for the calculation of toxic potency from chemical yield data obtained from small-scale tests and their application to full-scale fire scenario calculations. Toxic hazards in different

DOI 10.1007/978-1-4939-2565-0_63, © Society of Fire Protection Engineers 2016

types of full-scale fire scenarios are discussed here in Chap. 63.

The development of fire hazards is time based, and the endpoint of an ASET (Available Safe Escape Time) design calculation is the time when conditions in each building enclosure are considered untenable. Untenable conditions occur when it is predicted that occupants inside or entering an enclosure are likely to be unable to save themselves due to the effects of exposure to smoke, heat, and/or toxic effluent, or when occupants of refuge areas are exposed to conditions capable of causing injury or death. Exposure to fire effluents also affects escape behavior and travel speeds, thereby influencing the time required for escape (RSET—Required Safe Escape Time).

The effects on occupants of exposure to any particular set of conditions and the probability that they will be able to escape depend on a variety of factors including the fire conditions, the physiological and behavioral susceptibilities of the individuals or groups of occupants exposed, the nature of the occupancy, and the fire scenario. There are also some degrees of uncertainty in the predictability of effects of toxic gases, smoke, and heat on the average person, and also uncertainties related to variations in susceptibility within the population. The margin of safety designated as acceptable for a design therefore needs to be determined by the designer and regulatory authority in the context of any particular application. The different sections in this chapter describe the effects of exposure to different fire hazards and calculation methods that may assist with decisions on acceptable design limits. Information is also presented on lethal and post-exposure health effects, which may also be relevant to these considerations, as well as to probabilistic fire safety engineering design and forensic fire incident investigation.

Fundamental Aspects of Toxicity and Toxic Hazard Assessment

Life Safety Objectives of Design Codes

The main objective of life safety design is to provide building occupants with an acceptable level of safety from fire. What constitutes "acceptable" depends upon the objectives of the local building and life safety codes. In the United States and the United Kingdom, the basic objectives are performance-based. For example, the scope of the NFPA Life Safety code [2] is to prevent danger to life through "construction, protection, and occupancy features" and to provide egress facilities capable of supporting the "prompt escape of occupants" in the event of a fire. The document further states that the goals are to protect occupants not intimate with the fire and improve survivability of those occupants who are intimate with the fire.

For the United Kingdom (England and Wales), the performance-based requirement for means of warning and escape (Requirement of part B1 of the Building Regulations (England and Wales) 2006) [3] states that the design shall provide occupants with" .....early warning of fire, and appropriate means of escape in case of fire from the building to a place of safety outside the building capable of being safely and effectively used at all material times".

Both the U.S. and U.K. requirements can be met by following prescriptive design guidance or by a performance-based design.

On a global level, In the International Organization for Standardization (ISO) publication ISO/TR 13387 Fire safety engineering Part 8: Life Safety—Occupant behaviour, location and condition [4], the life safety objectives of a design are stated as:" Should a fire occur in which occupants are exposed to fire effluent and/or heat, the objective of the fire safety engineering strategy is to ensure that such exposure does not significantly impede or prevent the safe escape (if required) of essentially all occupants, without their experiencing or developing serious health effects".

Hence, the general objective is the same, the design should limit or prevent exposure of most occupants during the majority of envisaged scenarios; This is achieved either by evacuating occupants to the outside of the building (or intermediate area of temporary refuge) via protected escape routes or by using a "defend in place" strategy which relies on the prevention of fire and fire effluent spread into the occupied areas.

Although these design strategies have been effective (e.g., the risk of injuries and death in fire is low compared with other risks), the annual rates of injury and death from fire still remain considerable.

From an engineering design perspective, it is possible to work to a variety of life-safety endpoints depending upon the system being designed and the possible fire scenarios envisaged. For example, the designer may:

- Design for no exposure to heat or smoke for worst-case fire scenarios.
- Accept that for a few envisaged scenarios certain occupants may experience some degree of exposure, but demonstrate that such exposure would be insufficient to significantly impair escape or result in significant injury, long-term health effects, or death.
- Accept that for a few envisaged scenarios there is a risk of deaths but that the risk is acceptable or comparable with those from a code-compliant, prescriptive design (using a probabilistic risk assessment).

The first scenario, where no exposure to occupants occurs, may be possible for some design cases. For example, a shopping mall may be designed with passive or active smoke extraction assuming a worst-case fire scenario. The smoke extraction system may be designed such that the smoke layer never descends lower than a given level above an average walking height and the upper layer temperature never exceeds 200 °C. This would allow occupants to escape without exposure to smoke and without experiencing pain from downward heat radiation.

This strategy relies on all smoke from the fire being sufficiently buoyant such that no smoke that none cools and mixes near the floor. Similarly, evacuation from multi-compartment buildings relies on the passive and active systems completely preventing smoke contamination of escape routes and occupied enclosures. In practice, this ideal situation, often, does not occur and it is not possible to ensure that there is no smoke exposure. When fire occurs within an occupied enclosure, especially small (domestic sized) enclosures and ones with a relatively low ceiling height, then it is difficult to prevent some exposure of occupants, especially those more intimate with the initial fire (as recognized by the NFPA life safety code). Some smoke exposure is also likely in sprinkelered enclosures due to downdrag and loss of smoke buoyancy. Additionally, there is always the potential that a system may be rendered inoperable (e.g., human interaction, mechanical failure, etc.) or fail to operate effectively. For all these situations occupants are likely to suffer some exposure to toxic fire effluents and/or heat.

An example of the second scenario, where some exposures occur but are not expected to be life threatening, might be for an atrium space with high-level balconies near the roof level. For any fire at a lower level, a buoyant smoke plume will rise and mix to form a dilute layer, which may extend down to engulf the upper balconies, or stratify at a certain height. Since the smoke is so dilute, this may be considered a minor hazard to occupants needing to move through it (e.g., to reach protected stairs). In this scenario, it is therefore necessary to determine the highest acceptable concentration of smoke and toxic gases to which occupants may be exposed without significant impairment of escape capability or injury.

The third type of scenario, where there is a risk of death is for serious fires—such as in the Station Nightclub, or domestic dwelling fires. For such fires, conditions are benign for a minute or so after ignition, but then rapidly become life threatening. The rapidly deteriorating conditions result in occupant exposure to hot, dense, irritant smoke impairing escape capability and leading to incapacitation and death. Analysis of such a scenario is aimed at estimating the probability that occupants will be able to escape prior to untenability. It is also aimed at estimating the risk of injury and death throughout the life of the building, either for specific scenarios or for a range of scenarios with varying probabilities. Solutions to preventing or minimizing such outcomes are likely to involve a variety of interventions other than modification of the toxic product yields from the fuels involved, included modifications to the reaction-to-fire properties of fuels, improved warning systems, modified structural

design or installation of active systems. Assessment of the hazards to occupants in different potential fire scenarios can be regarded as the ultimate test of the safety performance of the system. Analysis of hazards during serious fires is also important in relation to incident investigations.

The methods described in this chapter are intended for application to all these kinds of situations

Injuries and Deaths in Fire: Extent to Which Life Safety Objectives Are Achieved

Although exposure to toxic smoke has always been one of the hazards confronting people in fires, there was a considerable increase in concern in this area during the 1970s and 1980s. In the United States, attention was focused on the toxicity of furnishings and building materials and finishes due to a number of large fire disasters where victims died from exposure to toxic smoke products [5]. Although this is also true to some extent for the United Kingdom, the major impetus for work in this area resulted from statistical surveys of fire casualties carried out in the mid-1970s. These surveys of casualties from all fires, and particularly from fires in domestic dwellings, revealed that not only was a large proportion of fatal and non-fatal fire casualties being reported in the category "overcome by smoke and toxic gases" rather than "heat and burns," but also that there was a fourfold increase in the former category between 1955 and 1971 [6] (Figs. 63.1 and 63.2). This increasing trend continued into the 1980s, so that approximately half of all fatal casualties and a third of all non-fatal casualties of dwelling fires (the majority caused by fires in furniture and bedding) were reported as being "overcome by smoke and toxic gases", while burns caused around 40 % of deaths and 20 % of injuries [7]. This increase occurred despite the fact that the total number of fires remained approximately constant.

During the 1990s, there was some reduction in the total annual number of fire deaths in the United Kingdom (and in the United States), but smoke deaths in the United Kingdom were still approximately four times the levels reported in the 1950s. Also, injuries from smoke and toxic

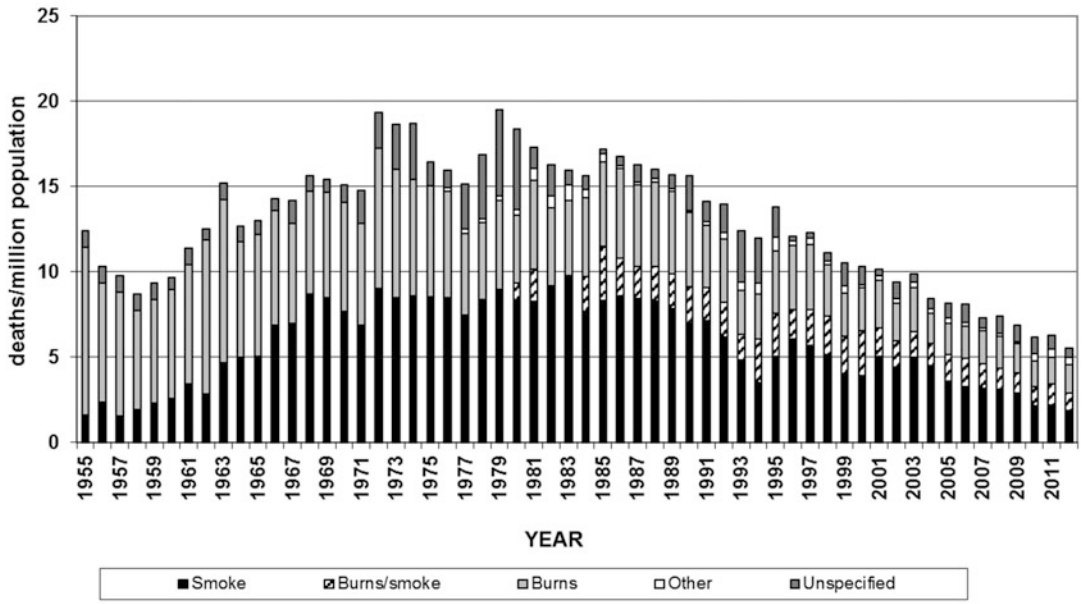

Fig. 63.1 U.K. fire deaths per million population [6, 7]

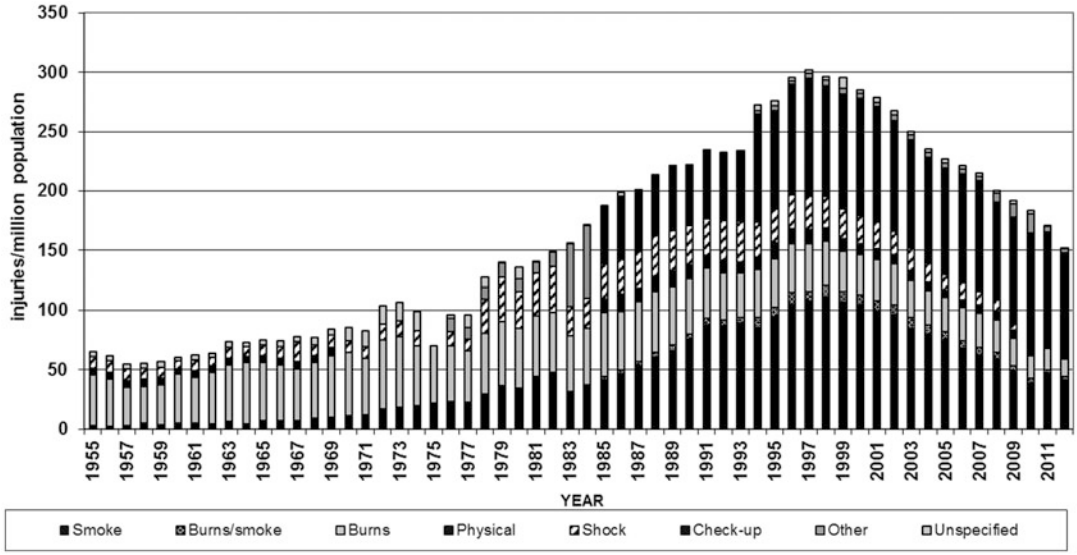

Fig. 63.2 U.K. nonfatal fire injuries per million population [6, 7]

fumes had increased continuously from an annual rate of approximately 170 in the 1950s, to 2600 during the 1980s and more than 6000, during the late 1990s. In the United Kingdom the decrease in fire deaths occurring during the 1990s improved further during the next decade from a total of 613 in 2000 to 388 (7.64/million) in 2010. The total injuries also decreased over this period from 16,183 to 11,134 (219/million of which 74.1/million were due to burns or smoke). Injuries from smoke decreased from 123/million in 2000 to 47/million in 2010.

These improvements may be related to changes in heating and cooking appliances, improved fire performance of upholstered furniture and bedding, reduced tobacco use and/or increased use of smoke detectors.

A number of possible reasons have been suggested for the earlier increase in smoke-related casualties. They have been linked with the increased use of modern synthetic materials in furnishings. Another view is that the increase may not have been directly related to modern materials but to changes in living styles over the period that have led to more furnishing and upholstery material being used in the average British home and, therefore, a greater fire load. Epidemiological data are, often, difficult to interpret, but many of those working in this area are convinced that the earlier increase in smoke-related casualties was real. The situation in the United States is more difficult to interpret, since it contains a larger and more diverse population, and statistics may not have been collected to reveal such a trend.

The U.S. fire death rates were around twice those in the United Kingdom, Western Europe (in general), and Japan 30 years ago but have improved steadily since; they are currently closer to the U.K. and European death rates at approximately 10.5 per million inhabitants [8, 9]. Figure 63.3 compares deaths per million inhabitants in the United Kingdom and United States over the period 1977–2010. The US data are plotted from both the NFPA and NFIRS data sets [10, 11]. The United States data shows a considerable variation between States, ranging from New Hampshire (4.6 deaths per million population) to West Virginia (38.7 deaths per million population [NFIRS 2006]).

In the United States and the United Kingdom, toxic smoke products are recognized as being the major cause of death in fires [12]. A possible difference between the pattern of fire deaths in the United Kingdom and the United States is that in the United Kingdom, the majority of fatalities

occur in the room of fire origin (mainly in domestic dwellings) for fires that have not spread beyond the room of fire origin (65 % of deaths). For 50 % of deaths, the fire spread is restricted to less than one-third of the room area [7] In the United States more than 50 % of deaths are reported to be remote from the room of origin, from fires that have spread beyond the room of origin [13]. Although deaths remote from the room of origin are also common in the United Kingdom, these disparities indicate that cultural differences and variations in building styles can be important. Houses in the United Kingdom are commonly constructed with masonry compared to the combustible timber construction that is more common in the United States. U.S. homes also tend to have open-floor plans, less compartmentation, and larger rooms. As in the UK, in the US by far the greatest numbers of fire deaths (76 % in 2007) and injuries occur in residences (dwellings), with only 9 % in non-residential properties.

For fire deaths, the "dose" of carbon monoxide in the blood expressed as percentage carboxyhemoglobin (%COHb) provides a good indication of the cause of death and how long a victim survived exposure before death. This is for two reasons. Firstly, as carbon monoxide is inhaled in a fire, some minutes are required for the dose to reach fatal levels (>approximately 40–50 %COHb). Secondly, during the early stages of most flaming fires combustion is efficient, so the yields and concentrations of CO in the fire enclosure are low. As compartment fires develop, they become ventilation-controlled and fuel rich, with high yields of CO and other toxic products. Fire deaths with burns and low % COHb levels are therefore indicative that the victim was intimate with the fire and that burns were the most likely cause of death, while high % COHb levels, especially in the absence of burns, are indicative that the victim was remote from the fire and overcome by exposure to toxic smoke after a period of exposure. Figures 63.4 and 63.5 show data from fatal fires in London between 2002 and 2006 [14]. Figure 63.4 is for 109 victims dying in the room of fire origin and shows a wide range of %COHb levels from 0 % to 90 %. The majority of victims have sub-lethal %COHb levels (<~40 %COHb). Almost all of these were recorded as having suffered burns, while "serious burns" indicates that burns were

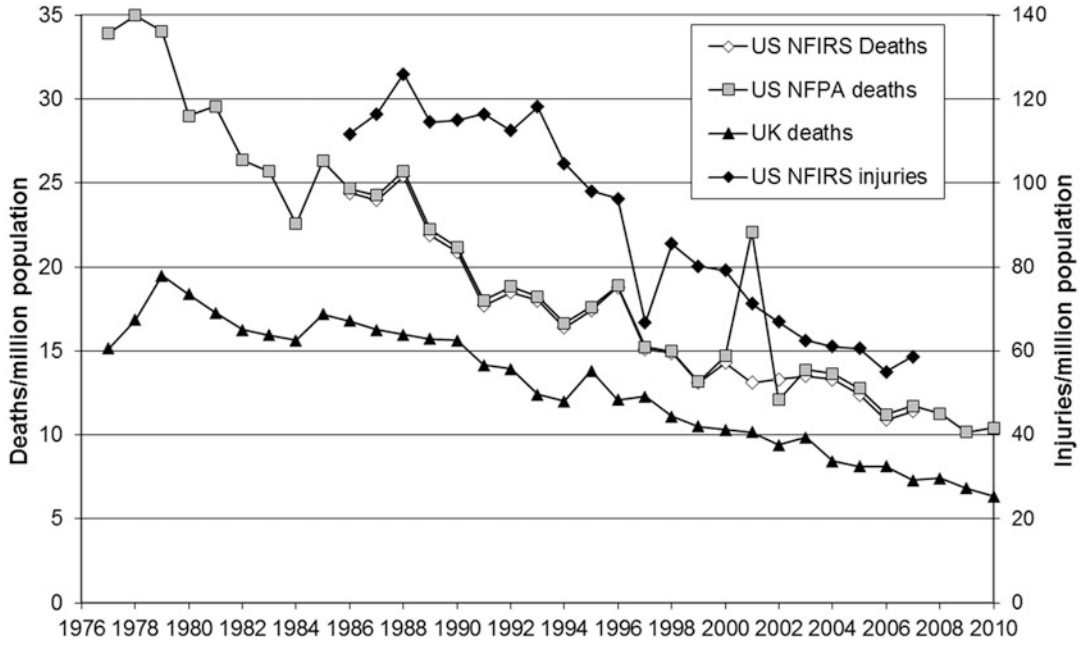

Fig. 63.3 US and UK deaths, US injuries per million population (UK: Communities and Local Government [7], US: National Fire Protection Association and National Fire Incident Reporting System) [10]

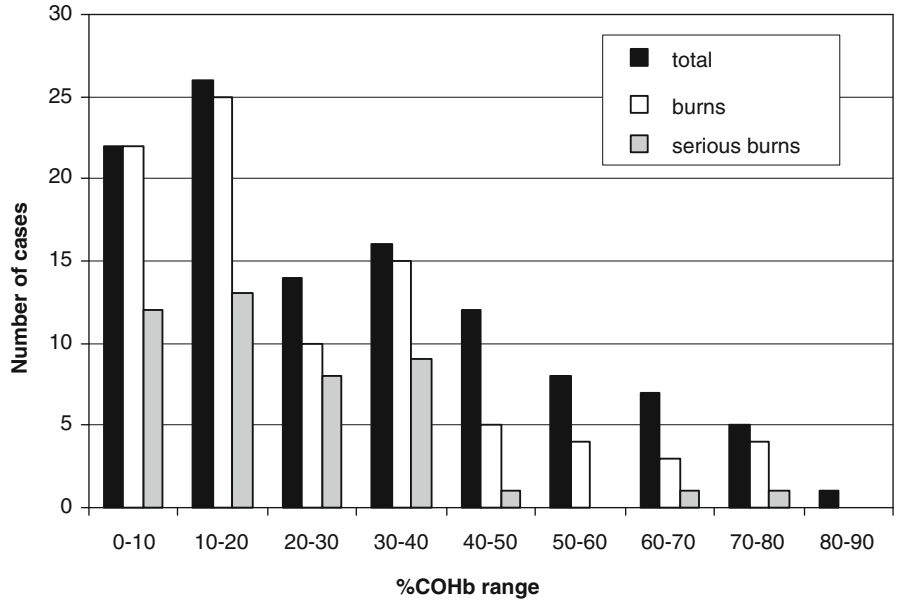

Fig. 63.4 Distributions of %COHb, burns and serious burns in 109 fire fatalities dying in enclosure of fire origin in London 2002–2006 [14]

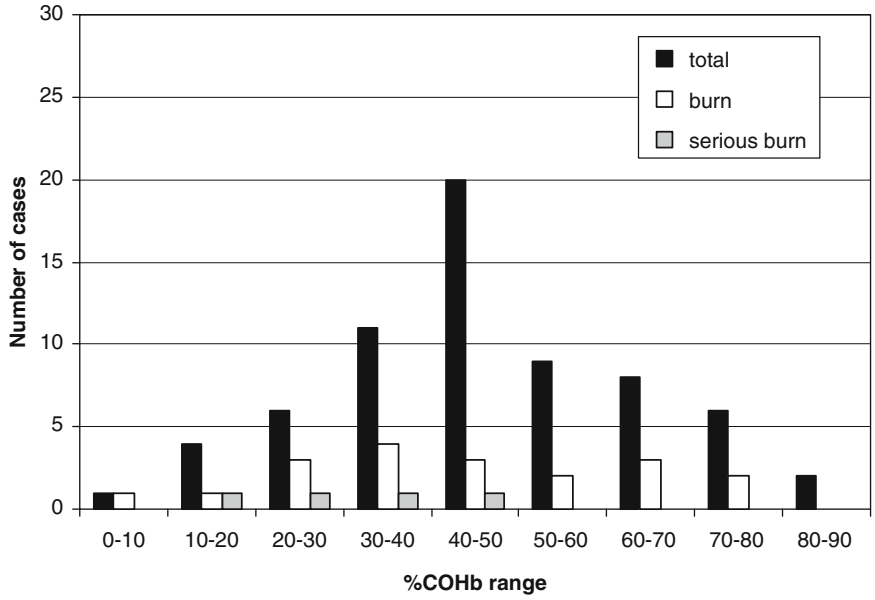

Fig. 63.5 Distributions of %COHb, burns and serious burns in 67 fire fatalities dying in enclosure remote from that of fire origin (Data from London 2002–2006 and a multi-fatality nursing home fire in Scotland) [14]

entered as a contributory cause of death on the death certificate. A smaller subset have lethal % COHb levels and a much lower incidence of burns, and of those recorded as having been more remote from the fire itself the average % COHb was 58 %, indicating that they died from the effects of toxic gases rather than burns, despite being in the same room as the fire.

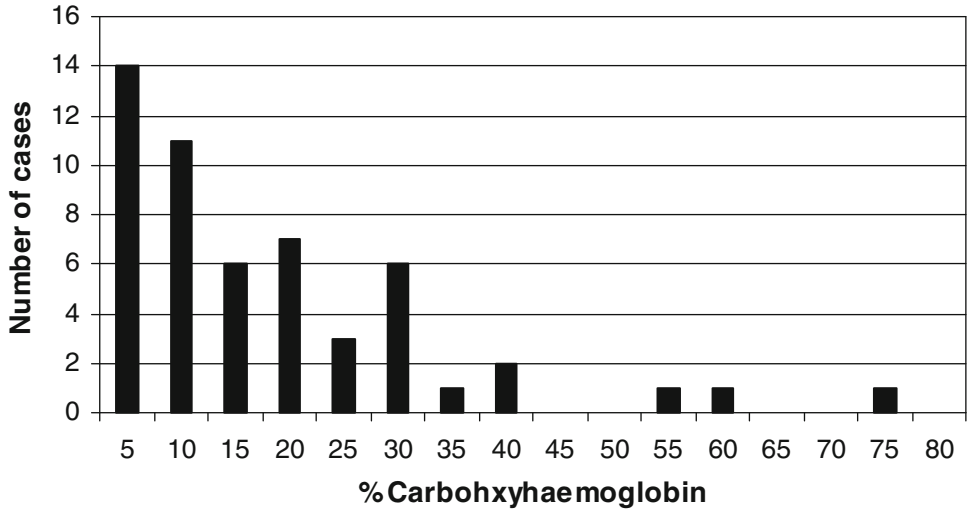

Fig. 63.6 Distributions of %carboxyhemoglobin in 53 fire fatalities in post-crash vehicle fires in Texas for which fire could be identified as contributing to the causes of death [15]

For victims dying beyond the room of fire origin (Fig. 63.5) the incidence of burns is much lower and the majority have %COHb levels in the lethal range, indicating that most people dying beyond the room of fire origin die from toxic smoke rather than from burns.

The distinction is even clearer for post-crash vehicle fires, which often involve rapid conflagrations in the passenger cabin. As Fig. 63.6 for vehicle fire deaths in Texas shows, few victims survive long enough to reach life-threatening %COHb levels [15].

Hazards in fire incidents in general result from an inadequate control of combustible contents leading to rapid fire growth and spread, especially for victims in the fire enclosure, and from failure of construction or design, so that fire or fire effluents penetrate and spread between enclosures and fire compartments. Failure of safe escape by occupants results from failure to understand the extent of fire risk and the needs of occupants, late detection, failure to provide timely and adequate warning and fire safety management, and failure to provide adequate structural containment to protect escape routes or refuge areas.

Life safety hazard from fires in buildings (or other enclosures) depends upon the performance of a dynamic system involving interactions between the building, the fire and the occupants. Since fire hazards are essentially time-based phenomena, the objective is to ensure as far as possible that should a fire occur, the occupants are warned and have time to escape before conditions become untenable. Once a fire occurs in a building the outcome in terms of fire safety and hazard depends on two parallel time-based processes, the growing fire hazard and the escape performance of the occupants.

In fire safety engineering terms it is necessary to ensure that available safe escape time (ASET) is greater than required safe escape time (RSET) by an acceptable margin of safety [16, 17].

- ASET is the time from ignition to that when conditions become untenable to occupants such that they are no longer able to escape without assistance.
- RSET is the time for ignition to that when affected occupants are able to reach a place of safety

In situations designed such that occupants are not expected to escape (defend in place strategy), then conditions in occupied enclosures should not develop so as to threaten safety.

The hazards from toxicity and heat are therefore the main determinants of ASET, but they also affect escape time, mainly in terms of the

Table 63.1 Acute survival hazards during fires

Impaired vision from smoke obscuration
Impaired vision, pain and breathing difficulties from effects of smoke irritants on eyes and respiratory tract.
Asphyxiation from toxic gases leading to confusion and loss consciousness
Pain to exposed skin and respiratory tract followed by burns from exposure to radiant and convected heat leading to collapse

effects of exposure to smoke on occupant behaviour in terms of deciding to enter and continue through smoke or turn back and seek refuge, and on walking speed and wayfinding ability.

Toxicity, or more realistically toxic hazard, in fires is a system property of the full-scale fire scenario. It consists of a sequence of time-varying effects depending upon the changing combustion conditions and the varying rates of development of a sequence of different toxic effects, caused by different toxic fire effluent components. For this reason it is not possible to make meaningful measurements of "toxicity" for any material or product in any small or even large scale fire "toxicity" test. Rather it is necessary to determine toxic hazard in terms of calculated time to incapacitation or death for specified full-scale fire scenarios.

The time required for occupants to escape depends upon a set of parameters related to fire detection and warning times, the behaviour of occupants in response to alarms in terms of starting (pre-movement) times and exit choice, and the time required to travel through escape routes and out of the building. In situations where evacuating occupants see or are exposed to smoke, their exit choice and movement speed (and hence their travel time) can be affected. These effects need to be considered in evacuation calculations, and calculation methods for these parameters are presented in this Chapter in the section on smoke.

The main tenability limits for ASET are conditions that cause incapacitation of occupants such that they are unable to escape.

For the toxic effects of exposure to combustion products in fire effluent, particularly in relation to the survival, injury or death of fire victims, it is mainly the more immediate physiological effects that dominate at the fire scene; This is because physiological effects occur rapidly, often within a few seconds, while pathological changes tend to occur over time scales of hours to years. Physiological effects also occur in response to heat and smoke exposure in fires, interacting to some extent with the effects of toxic products.

Table 63.1 lists the acute physiological fire hazards affecting escape capability. These tend to be encountered more or less in the order shown, with exposure first to smoke, which is likely to be irritant, followed by asphyxia or burns, depending upon the type of fire scenario and the proximity of the person to the fire. Once a victim has become trapped or incapacitated in a fire, then conditions usually become lethal within a further few seconds or minutes. This is because flaming fires grow exponentially, so concentrations of smoke and toxic gases, and the heat intensity, increase rapidly, resulting in death either from asphyxiation or heat exposure. The key determinant of survival is therefore incapacitation so that the lethal potency of fire effluent is of limited relevance.

Figure 63.7 illustrates the sequence and time scales over which physiological and pathological toxic effects occur during and after a fire. A common scenario is for a fire involving room contents such as an upholstered armchair on the lower floor of an enclosed two-story house with the bedroom door closed but the lounge door left open. In experiments re-creating this scenario [18] the fire self-extinguished after approximately 10 min due to oxygen depletion and the effluents then mixed evenly throughout the open volume, giving the maintained toxic gas concentrations and temperature listed in the figure. Consider the sequence of hazards faced by a bedroom occupant if they awoke and opened the

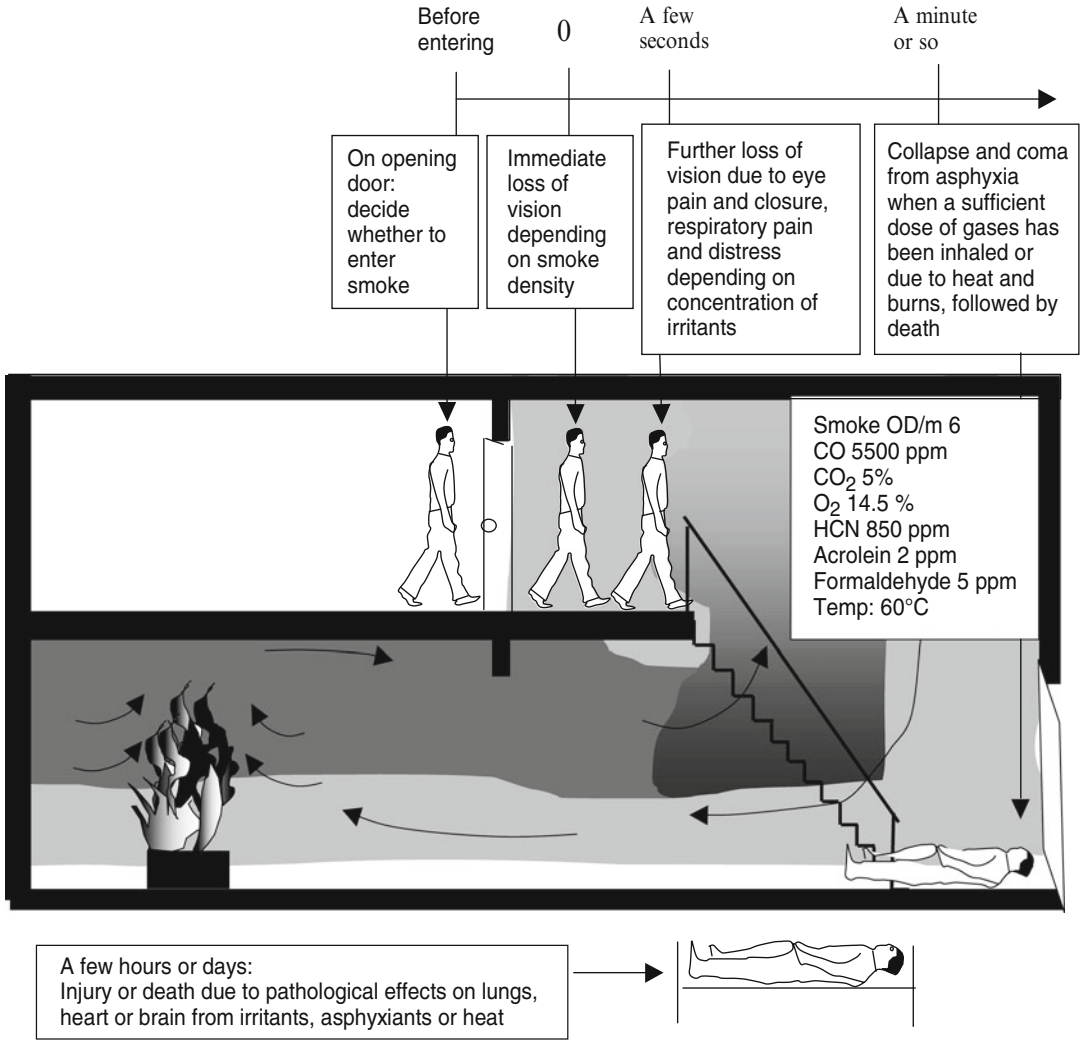

Fig. 63.7 Sequence of hazards affecting a subject escaping from a bedroom of an enclosed two-storey dwelling with a fire on the floor below

bedroom door at this time. On opening the bedroom door an occupant attempting to escape must first decide whether to enter the dense smoke, or close the door and remain in the bedroom. If they step out onto the landing the first physiological effect is immediate loss of vision, which is followed within a few seconds by further visual impairment and eye pain from the effects of smoke irritants, and pain to the nose and chest with breathing difficulties. As the subject inhales asphxyiant gases, especially CO and HCN, a dose builds up in the body. There are no immediate effects but when the inhaled dose reaches a critical level (after a few seconds or minutes) it leads to collapse and coma, followed by death within a further few minutes. In this scenario the smoke is hot (60 °C), but not sufficiently to cause pain or distress within a few minutes. If the victim is rescued alive after collapse, then they may recover, or may suffer a further set of health problems, including brain damage, heart attack or lung inflammation over a period of a few hours to a few days, all of which can be fatal.

Not only do the different physiological effects occur over a time sequence as in this example,

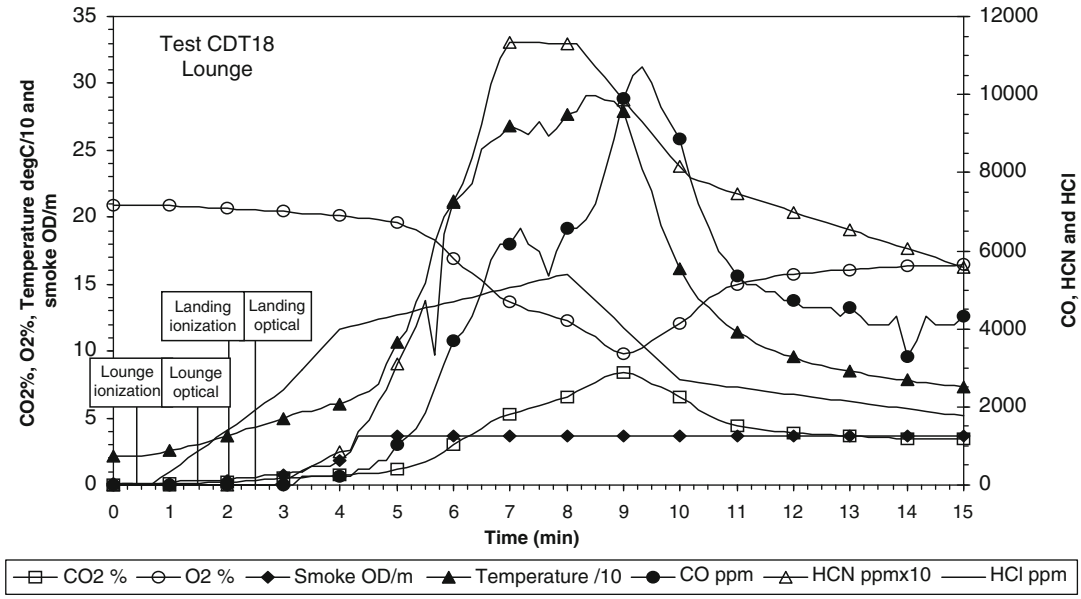

Fig. 63.8 Example of time-concentration curves for smoke, toxic gases and temperature at head height in the domestic lounge of a house during an armchair fire. The doorway to the hall is open but the house is otherwise enclosed. The time for triggering of smoke detectors is shown [18]

but in most cases the fire conditions also change rapidly as the hazards develop. Figure 63.8 shows the time concentration curves of the main fire gases, smoke, and heat in the lower floor fire room during the early stages of the same fire. In order to determine the developing hazard and time to incapacitation, it is therefore necessary to evaluate these time-dependent processes.

Fractional Effective Dose Methods and Application to Fire Hazard Analysis

ASET for any system is determined by the parameters in Table 63.2 [16]:

For application to toxic hazard calculations the concept of Fractional Effective Concentration or Dose (FEC or FED) is used whereby the exposure concentration or dose at any point during a fire is expressed as a fraction of the exposure concentration or dose predicted for a given endpoint. For example, the concentration of smoke present at any time during a fire can be expressed as a fraction of the concentration required to seriously impair escape capability. The accumulated dose of carbon monoxide at any time during a fire can be expressed as a fraction of the dose required to cause collapse and loss of consciousness, or the dose of heat can be expressed as a fraction of the dose of heat required to cause severe pain or burns. Time to loss of tenability from the effects of smoke, or toxic gases of heat is then calculated as the time at which each endpoint reaches a FEC or FED of 1.

The hazard assessment is therefore based on a "step-through" approach whereby the extent of the hazard is calculated for each successive minute (or other appropriate time interval) during the fire until the point is reached where different hazard endpoints are predicted. The behavioral and physiological effects of exposure to toxic smoke and heat in fires combine to cause varying effects on escape capability, which can lead to physical incapacitation and permanent injury or death.

The fire profile should be characterized in terms of the following range of parameters, measured over successive short periods

Table 63.2 ASET parameters

The time-concentration (or time-intensity) curves for the major toxic products, smoke and heat in the fire at the breathing zone of the occupants, which in turn depend upon:
Fire growth curve (mass loss rate of the burning fuel [kg/s] and its dispersal volume [kg/m^3] with time)
The yields of the major toxic products (kg/kg) and heat (kJ/kg) (for example kg CO per kg of material burned).
These terms can be measured directly in full-scale tests or calculated using appropriate fire dynamics computations with appropriate input data including reaction-to-fire properties and data on product yields under a range of fire conditions. Guidance on calculation methods for these terms is given in other chapters in this handbook. Some information is provided in this chapter and Chap. 62 on toxic product on toxic product yields under a range of fire conditions and also in Chaps. 16 [19] and 36 [20]. Data on toxic product yields can be obtained using the ISO TS19700 tube furnace or the ASTM E2058 flammability apparatus. A guide to the general characteristics of fires is shown in Table 63.3 and an example of a fire profile in Fig. 63.8.
The concentration/time/physiological effect relationships of these products in terms of the physiological/toxic potency of the products and heat (the exposure concentration [kg/m^3]), or exposure dose ($kg \cdot m^{-3} \cdot min$ or $ppm \cdot min$) causing toxic effects (and the equivalent effects for heat and smoke obscuration). The important endpoints are:
Concentrations, doses (or heat intensity) likely to impair escape efficiency due to behavioural and/or physiological effects
Exposure concentrations or doses likely to cause incapacitation or prevent escape due to behavioural and/or physiological effects
Lethal exposure concentrations or doses
These terms can be calculated by the application of appropriate physiological methods (Fractional Effective Dose methods [FED equations]) presented in this chapter and in ISO 13571 [21]

(<1 min) at the breathing zone of a potential victim:

1. Mass loss of material decomposed divided by the volume of air into which the material is dispersed in (mass loss concentration)
2. Carbon monoxide concentration
3. Hydrogen cyanide concentration (if materials containing >1 % by mass nitrogen are present)
4. Carbon dioxide concentration
5. Oxygen concentration
6. Incident radiant heat flux to subject
7. Air temperature
8. Smoke optical density (and particulate concentration)
9. Irritant acid gas concentrations (HF, HCl, HBr, SO_2, NO and NO_x)
   Note: If the total content of halogens in the fuel is less than approximately 5 % of the burning fuel mass, the total sulfur content less than 2 %, and the nitrogen content less than 5 %, the contribution to irritancy from acid gases can be considered minor as a first approximation.
10. Concentrations of organic irritant species (especially acrolein, formaldehyde, and crotonaldehyde)
    Note: In practice the relevant yield data for the key irritant organic species are seldom available, and not all the important species have been identified. In general it can be assumed that all smoke from compartment fires involving mixed fuels will contain concentrations of irritant organic species in proportion to the smoke optical density. Overall irritancy can then be expressed in terms of smoke optical density (or particulate concentration) plus the contribution from irritant acid gases if present in significant concentrations (see 9 above).

These data may be obtained from large-scale fire tests or calculated using fire dynamics models with appropriate data on toxic product yields under a variety of fire conditions as in Table 63.3: specifically, smoldering/nonflaming, early (well-ventilated) flaming, developed small vitiated (underventilated) flaming, and fully developed/postflashover underventilated fires.

For a basic fire engineering design there are two main considerations:

1. The time at which the concentration of smoke reaches a level such that safe escape is compromised due to

Table 63.3 Classification of toxic hazards in fires as revealed by large-scale fire simulation tests

Fire	Rate of growth	CO_2/CO	Toxic hazard	Time to incapacitation	Escape time available
1. Smoldering/non-flaming: victim in room of origin or remote	Slow	~1	CO 0–1500 ppm low O_2 15–21 % irritants, smoke	Hours	Ample if alerted
2. Well ventilated Flaming: victim in room of origin	Rapid	1000 decreasing toward 50	CO 0–0.2 % CO_2 0–10 % low O_2 10–21 % irritants, heat, smoke	A few minutes	A few minutes
3. Small vitiated flaming: victim in room of origin or remote	Rapid, then slow	<10	CO 0.2–4 % CO_2 1–10 % O2 < 12 % HCN to 1000 ppm irritants, heat, smoke	A few minutes	A few minutes
4. Fully developed: (postflashover) victim remote	Rapid	<10	O2 0–3 % in upper layer flowing from fire CO 0–3 %[a] HCN 0–1000 ppm some irritants, smoke, and possibly heat	<1 min near fire, elsewhere depends on degree of smoke dilution	Escape may be impossible or time very restricted. More time at remote locations

[a]Concentrations depend on position relative to fire compartment

(a) Behavioral and physiological effects due to exposure to heat and toxic smoke on escape behavior and ability
(b) In the absence of direct exposure, behavioral effects caused by seeing fire effluents

The effects of exposure to smoke result from impaired vision due to the optical opacity of smoke and from the painful effects of irritant smoke products on the eyes and respiratory tract. Occupant movement speed and wayfinding ability is impaired. Behavioral effects of seeing or being immersed in smoke result in a proportion of occupants being unwilling to approach smoke or heat-logged areas or escape routes.

2. The time at which the exposure dose of asphyxiant toxic gases or heat reaches a level at which occupants are likely to become incapacitated, such that they cannot save themselves and are likely to die within a minute or so unless rescued.

In a regulatory or design evaluation context, it is possible to consider several different approaches:

1. *Simple criteria for tenability based on zero exposure*. Where a design fire calculation is based on a descending upper layer of hot smoke filling an enclosure or escape route, engineering tenability criteria are often based on a minimum clear layer height of 2.5 m above the floor and a maximum upper-layer temperature of 200 °C. Occupants are considered to be willing and able to escape in clear air under such a layer and the downward heat radiation is considered tolerable.
2. *Tenability criteria accepting some degree of exposure to smoke, toxic gases and heat in relation to willingness to enter or ability to move through effluent*. In situations where smoke is mixed down to near floor level, some building occupants might move through dense smoke in some situations, but in other situations people might be unwilling to enter smoke logged escape routes, turn back, or be

unable to find an exit. Where heat is not an issue, the immediate effects of smoke depend on the visibility distance and the sensory irritancy of the smoke if people are exposed directly. For such situations, it is necessary to set tenability criteria for design purposes, depending on the level of adverse effects on occupants considered acceptable or unacceptable.

This chapter contains all the different FED and FEC expressions used for calculating time to the different toxicity and heat hazard endpoints and illustrates their use by application to sets of smoke and toxic gas data measured during full-scale experimental fires. Expressions are also presented for the effects of smoke on travel speed and on the probability that exposed subjects will attempt escape through smoke.

An FED Hazard Calculation Model for Time and Dose to Incapacitation and Lethality

From the physiological effects of exposure to the different individual irritant and aspxhyiant gases described, it has been possible to develop a comprehensive set of fractional effective dose calculation models for the assessment of human fire hazards. These models are designed to be applied to time-concentration curves for smoke and toxic gases in full-scale fires for which the data have been obtained either from full-scale fire experiments or from data derived using fire engineering zone or computational fluid dynamics (CFD) models. Complementary models have also been developed for calculating the effect of convected and radiant heat on exposed subjects.

The use of full-scale fire tests is limited by time and expense, leaving fire dynamics modeling as the often-preferred option. Although current models provide good representations of some aspects of full-scale fire scenarios, they are often limited by the extent to which they are able to represent the pyrolysis rates, effective heats of combustion, and yields of major toxic species (such as CO, HCN and acid gases) as they change with changing combustion conditions. The predictability of physiological effects in humans from exposure to toxic gases and mixtures is also affected by variations in susceptibility within the human population and uncertainties related to the need to rely on animal models. Also, while FED models are limited to consideration of a small number of key toxic products, fire effluents are known to contain many hundreds of toxic substances. This is one area where bench-scale animal exposure tests combined with chemical effluent analysis have been valuable in establishing the importance of key gases in complex mixtures and the extent of interactions between them [22, 23], as described in Chap. 62 [1].

Figure 63.8 shows an example of typical data set of fire time-concentration curves to which the FED models can be applied. The models are used to calculate time and dose to incapacitation and lethality for human exposures to fire effluents. Figures 63.9 and 63.10 show examples of FED curves calculated from time-concentration curve data. Figure 63.9 is for the static conditions in the upstairs landing of the fire illustrated in Figs. 63.7 and 63.10 is for the changing fire conditions in the lounge illustrated in Fig. 63.8. The FED models may be used for fire engineering design or product evaluation purposes by calculating ASET. This time may then be compared with an absolute requirement or in a performance-based analysis with RSET. Toxic fire effluents are the main determinants of ASET, but they can also affect RSET in that exposure to fire effluent may affect escape behavior, and movement speed is reduced in smoke, so that methods have also been developed to calculate these effects, which can be applied to evacuation models.

In addition to effects on escape capability, these methods can also be used to evaluate the probability of long-term survival and health consequences in subjects who survive immediate exposure at the fire scene.

In a forensic context, the models are used to establish causes of injury and death in fires in conjunction with full-scale incident re-creation experiments or calculations. In this context, the

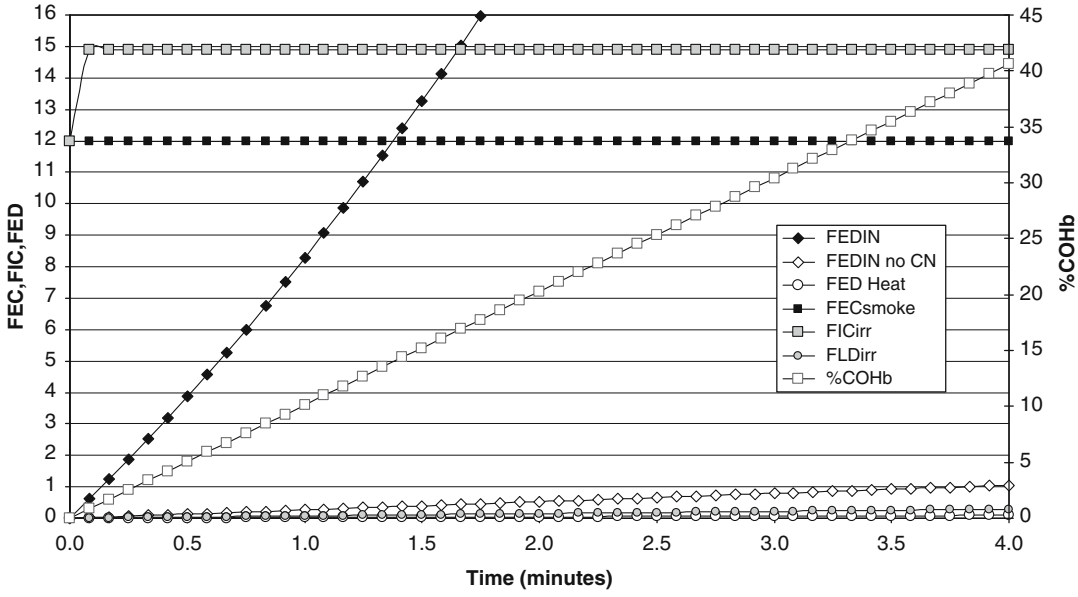

Fig. 63.9 Fractional Effective Dose plots for the static fire hazard condition in Fig. 63.7

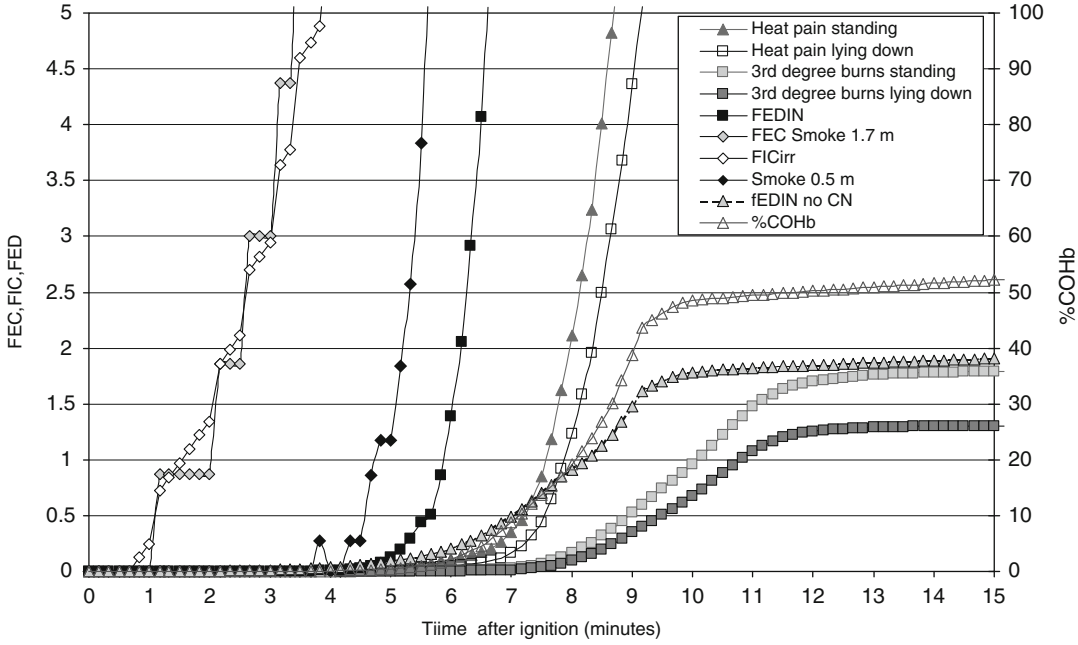

Fig. 63.10 Fractional Effective Dose plots for the changing fire hazard conditions in Fig. 63.8

application of FED modeling can also be valuable as a validation of such re-creation experiments or calculations, in that predicted effects on occupants obtained using the models can be compared to estimates of the conditions to which the actual occupants were exposed, back-calculated from the carboxyhemoglobin and blood cyanide concentrations in decedents and survivors. If the

results of the two approaches agree, this provides good evidence that the actual fire conditions were similar to those in the tests or simulations (see application to the Mont Blanc Tunnel fire [24] and Rosepark Nursing Home fire [25]).

For a hazard analysis of fires such as those shown in Figs. 63.9 and 63.10 it is possible to calculate a number of different, endpoints in relation to ASET as follows:

- Time when optically obscure smoke and irritants are predicted to significantly impair the escape efficiency.
- Time when irritancy is predicted to be so severe as to effectively prevent escape.
- Time to incapacitation (loss of consciousness) from the effects of asphyxiant gases.
- Time to incapacitation due to heat exposure.
- Time at which a lethal exposure dose of asphyxiants has been inhaled.
- Time at which heat exposure and burns are predicted to be lethal.
- Time at which an exposure dose of lung irritant sufficient to cause severe injury or death some hours after exposure has been inhaled.

Each endpoint is predicted when the level of the relevant term exceeds 1 on the y-axis. Thus for Fig. 63.9, the terms of visual smoke density and sensory irritancy (FECsmoke and FICirr) are well in excess of the concentrations predicted to impair escape as soon as the occupant opens the bedroom door, collapse from asphyxia (FED_{IN}) is predicted after 12 s, while the doses of convected heat and lung irritants (FED Heat and FLD_{irr}) are still well below threatening levels after 4 min. Figure 63.10 shows that concentrations of smoke and irritants in the lounge at head height are predicted to impair escape after 2 min, but at 0.5 m height these endpoints are not exceeded until after 5 min, due to the delayed descent of the upper smoke layer to this level. Collapse from asphyxia is predicted after 6 min and pain from heat after 7.5 min (standing) and 8 min (for a subject lying down). Also shown are the calculated times to potentially fatal 3rd degree burns for standing and lying subjects, and the calculated %COHb.

The way the calculations for these different endpoints are applied may depend to some extent on the purpose of the analysis. For a deterministic design application, it may be considered that the design has failed alternatively, if there is any predicted smoke exposure, or exposure to smoke of sufficient density to impair escape efficiency. For a probabilistic design, or for a forensic application, it may be important to consider the further consequences of different exposure scenarios, requiring calculation of time to incapacitation or to a lethal exposure.

For all these calculations, the exposure and effects are calculated for the breathing zone or at the head level of an occupant. For a simple deterministic analysis it is therefore possible to consider the tenability in a specific enclosure during a fire, assuming an occupant is either standing or sitting in the same position throughout. The ASET time then depends on the time-concentration curves for the toxic gases and heat at approximately 1 or 1.5 m height. Depending on the complexity of the fire model, it may be possible to differentiate between effluent concentrations and heat exposure at different locations. For a more sophisticated analysis, using evacuation calculation models in conjunction with a fire model, it is possible to calculate FEDs for a moving subject. ASET for each subject then depends upon their breathing zone exposure throughout the escape process as they move through a building, either walking or crawling. It is therefore possible to perform generic ASET calculations for the conditions inside any specified enclosure, or specific ASET calculations for individuals moving within and through different enclosures.

A summary of all the calculation expressions required for ASET design calculations, is presented in Appendix 1 with an example of an application in Table 63.22 and associated text. Full descriptions of the derivation of the different expressions, with more detailed variations for specific applications, and further examples are presented in the later sections of this chapter. A simplified set of methods is presented in ISO 13571 [21].

Basis of Fractional Effective Dose Methodology

As stated, some toxic or physical effects of exposure to combustion products occur almost immediately on exposure, and the severity of the effect is proportional to the concentration of the substance and its potency. This applies to visual smoke obscuration and to the painful effects of exposure to irritants. For example, irritant smoke in the eyes or nose immediately causes pain (sensory irritation), reflex closure of the eyes, and breathing difficulties.

For other substances, such as asphyxiant gases, the effect depends upon the dose inhaled. The effects therefore take some time to develop and depend upon the concentration inhaled and the time over which it is inhaled. The effects tend to be more persistent that those of sensory irritants, since it takes some time for the toxic material inhaled to be metabolized and excreted (for example carbon monoxide or hydrogen cyanide). An example of a dose-dependent effect is collapse from asphyxia resulting from exposure to carbon monoxide.

In practice, for asphyxiant substances (and to some extent also for heat) a distinct threshold concentration or exposure dose can be identified at which serious effects are predicted, and there is a sudden transition from minor effects to severe effects. Examples include the dose of CO at which a transition from a headache to collapsing unconscious occurs, or the dose of heat to the skin at which a sensation of heat becomes one of severe skin pain. For application to toxic hazard calculations, the concept of Fractional Effective Concentration or Dose is used whereby the exposure concentration or dose at any point during a fire is expressed as a fraction of the exposure concentration or dose predicted to produce a given effect. For example, the concentration of smoke present at any time during a fire can be expressed as a fraction of the concentration required to seriously impair escape capability.

Thus FEC_{smoke} (Fractional Effective Concentration of smoke) = 1 represents a smoke concentration considered capable of seriously limiting escape capability. Where FEC_{smoke} = Concentration (of smoke) present in a fire at any time divided by the concentration considered to significantly affect escape efficiency

A form of Fractional Effective Dose for CO can be expressed as a fraction of the exposure dose predicted to cause incapacitation.

Thus for example F_{Ico} (fraction of an incapacitating dose of carbon monoxide) can be expressed as:

$$F_{Ico} = \frac{\text{conc. gas present} \times \text{time}}{\text{conc.} \times \text{time for incapacitation}} \quad (63.1)$$

$$F_{Ico} = \frac{1000\text{ppm CO} \times 20\,\text{min}}{35,000\,\text{ppm.min}} = 0.57 \quad (63.2)$$

Although the FED calculations for different asphyxiant gases are based upon this simple concept, they are in practice more complex for a variety of physiological reasons, but the user is required to know only the concentration and exposure duration to perform the FED exposure dose calculation.

One reason for expressing the concentration or dose as a fraction of an effective concentration or dose for each toxic product is that fire atmosphere contains a mixture of toxic products of differing potencies. In order to sum the effects of the different effluent components, it is necessary to normalize them in terms of the effective dose. Furthermore, since concentrations of toxic products change with time during a fire, for constituents whose effects are dose-related, it is necessary to calculate the effective doses received, based upon the concentrations averaged over short periods of time, and then integrate these over successive periods. The aim is to calculate the time at which the summed effective doses reach unity, at which point the endpoint (such as incapacitation) is predicted to occur. The general FED equation is therefore:

$$FED = \int_{t1}^{t2} \sum_{i=1}^{n} \frac{C_i}{(Ct)_i} \Delta t \quad (63.3)$$

Where:

C_i is the average concentration, of a dose related toxicant such as an asphyxiant gas "*i*" over the chosen time increment;

Δt is the chosen time increment, expressed in minutes (min)

$(Ct)_i$ is the specific exposure dose expressed as concentration × minutes, that would constitute an effective dose (i.e., an exposure dose producing a defined endpoint such as preventing an occupant's safe escape)

Effective concentrations and exposure doses for defined endpoints for smoke, heat and toxic effluent mixtures are presented in the following sections.

Application of FEC and FED to Full-Scale Compartment Fire Data

In order to carry out and an FEC and FED analysis of compartment fires, such as those depicted in Figs. 63.9 and 63.10, the time-concentration curves for smoke density, toxic gases, temperature and radiation are used to calculate the FEC and FED fractions for the following terms as a function of time during the fire:

- FEC_{smoke}—Fractional effective smoke concentration where FEC = 1 represents a smoke concentration likely to significantly impair escape efficiency.
- FIC_{irr} Fractional irritant concentration: where FIC = 1 represents a concentration of organic irritants and/or acid gases likely to significantly impair escape efficiency. FIC = 5 represents an approximate incapacitating dose predicted to cause collapse.
- F_{IN} Fraction of a dose of asphxyiant gases F_{IN} = 1 represents a dose predicted to cause collapse and loss of consciousness due to asphyxia (F_{IN} = 2 represent an approximate lethal dose).
- FED_{heat} Fraction of an exposure (dose) of radiant and convected heat where FED_{heat} = 1 represents a "dose" sufficient to cause severe pain to unprotected skin (head and hands), (FED_{heat} ~8 represent second degree burns and FED 12 severe third degree burns which may be lethal.
- FLD_{irr} Fraction of a lethal dose of irritants: where FLDirr = 1 represents an inhaled exposure dose of lung irritant sufficient to cause severe injury or death some hours after exposure.

Expressions for the calculation of each of these terms are presented in later sections and summarized in Appendix 1.

Figures 63.9 and 63.10 illustrate the application of this method for the two fire cases in Figs. 63.7 and 63.8. Figure 63.9 shows the effects of exposure to fire effluent on when the upper floor bedroom occupant steps out onto the landing 10 min after ignition of the armchair fire in the open lounge on the floor below. Upon opening the door the occupant is confronted by smoke with an FEC of 12, which means that the smoke density is 12 × the concentration predicted to seriously impair escape attempts. Within a few seconds exposure to this smoke causes severe irritant pain to the eyes, resulting in reflex eye closure (blehparospasm), further impairing and inhibiting escape movement onto the landing. The smoke is also quite hot (60°C), which may further deter escape, but not hot enough to cause distress. The result at this stage is that the occupant is likely to decide that escape is too hazardous, to shut the bedroom door and take refuge in the bedroom. If the subject decides to attempt to descend the stairs, the speed of descent will be slow, and the next occurrence depends on the subjects breathing pattern. If the subject holds their breath before being exposed to the smoke, then there is no intake of toxic gases until they are forced to take a breath. At this point, the inhaled breath will be a deep one, with immediate incapacitation due to the irritancy and asphyxiant gases.

The analysis in Fig. 63.9 assumes the subject is breathing normally throughout, at a rate associated with a moderate level of activity. This results in uptake of asphyxiant gases (HCN, CO. CO_2 and low oxygen) from the time the subject steps onto the landing. Incapacitation (collapse and loss of consciousness) is predicted when the F_{IN} exceeds unity, which occurs after 0.2 min (12 s). This is mainly due to the effects of inhaling hydrogen cyanide, which was present at the high concentration of 850 ppm in this

experiment fire. Also considered in the analysis is the calculated time to incapacitation assuming there was no nitrogen in the burning fuel (armchair), in which case the most important asphyxiant gas is carbon monoxide. Uptake of carbon monoxide (increased by the presence of CO_2) results in accumulation of a dose producing an incapacitating level of carboxyhemoglobin (approximately 40 %COHb) after 4 min exposure, which represents an F_{IN} (no CN) of 1. The accumulating %COHb is calculated as part of the analysis and is shown in Fig. 63.9.

Also shown in Fig. 63.9 are the accumulating doses of heat (FED_{heat}) and of lung irritants, both of which hardly rise above the baseline up to 4 min. Since the smoke temperature is only 60 °C only minor discomfort is predicted over this timescale.

The predicted results from this analysis are then that if a subject attempted to escape through these conditions:

- They would find the effects of the smoke exposure to be painful and distressing and be likely to turn back and take refuge in the bedroom.
- If they were familiar with the building, the distance to the main exit on the lower floor was short, and the door easy to open, they might be able to hold their breath long enough to reach the exit and escape before being overcome.
- If they took a breath at anytime they are likely to collapse more or less immediately from the effects of the high concentrations of asphyxiant gases, especially hydrogen cyanide.
- If they collapsed on the stairs or near the door, they would die within a further few minutes, mainly from the effects of carbon monoxide, with a blood carboxyhemoglobin concentration of around 40–60 %COHb.
- If they were rescued at 4 min and treated with oxygen, they would be likely to make a rapid recovery (depending on their pre-existing health status). They may suffer some eye and throat irritation the next day, and develop a minor productive cough, but would be unlikely to suffer significant lung injury. There would be a possibility of suffering a heart attack or stroke due to the inhalation of fine smoke particles and CO. There would be a possibility of suffering long-term brain damage due to cerebral hypoxia.

During these experiments measurements of smoke and toxic gases were also made in a closed bedroom. It was found that although minor smoke penetration occurred around the bedroom door (no smoke seals), the conditions remained tenable for up to approximately 30–60 min, especially if the bedroom window was opened.

Figure 63.10 shows an FED analysis for an occupant of the lower floor fire room from the data in Fig. 63.8. This differs from the analysis in Fig. 63.9 in that the exposure period starts with ignition of the fire, after which the conditions change rapidly. For a person in the fire room but on the opposite side of the room from the fire, there is no initial exposure to either heat or smoke as the effluent from the early flaming fire collects under the room ceiling. Once the upper layer descends below the soffit of the door to the hall, the smoke starts to flow out into the hall and landing, further reducing the rate of descent of the upper layer in the fire room. For a person standing in the room the first exposure to smoke is predicted from 1 min after ignition, when the upper layer descended to head height (1.7 m). An FEC = 1 for smoke density and FICirr = 1 for the effects of the irritant gases present in the smoke is predicted at 1 min, from which time a subject would be predicted to suffer an impaired escape capability due to the optical obscuration from the smoke and the smoke irritancy, derived from a significant content of both organic irritants and acid gases including HCl, HBr, HF and SO_2, which were measured using ion chromatography. However, if the subject got down to near floor level (0.5 m), then they would be beneath the smoke layer until 4 min. Conditions deteriorated very rapidly from around 4 min, so that at 5.5 min an FED exceeding 1 is calculated simultaneously for both asphyxia and heat. At this time, it is predicted that a standing exposed subject would suffer severe pain to exposed areas

of skin, especially the head and hands, and would collapse unconscious due to the effects of inhaled asphyxiant gases, and in particular hydrogen cyanide. The kink in the F_{IN} curve at this point reflects the reduction in breathing, and thus in the rate of uptake of asphyxiant gases, as a person becomes unconscious. For a person sitting or crouching below the smoke layer up to this time the exposure to hot gases would be somewhat less, so that time to severe pain from heat is predicted at just before 6 min. As the exposure to heat continues an exposed subject would begin to suffer from burns (both to clothed and unclothed areas depending upon the thickness of the clothing), so that for a standing person fatal extensive full thickness (3rd degree) burns are predicted after 8 min and for a sitting person after 9 min. The FED heat curves then level off because by now the fire has self-extinguished and the temperatures in the room are dropping.

The other two curves in Figure 63.10 have been included to consider the situation with regard to asphyxiant gases in the absence of hydrogen cyanide. For these upholstered furniture fires the hydrogen cyanide concentrations increased rapidly to well in excess of those observed to result in loss of consciousness in exposed primates within 2 min. Cyanide is therefore the main driver of collapse from asphyxiation in these fires. If the fuels had not contained nitrogen (or <1 % Nitrogen by mass), then the main asphyxiant gases present would have been carbon monoxide, carbon dioxide and reduced oxygen hypoxia. Another factor would have been the high concentration of irritants smoke gases and particulates. It is considered that these would have made breathing difficult for exposed occupants, thereby adding to some extent to the asphyxiant effects of the inhaled gases. For the full form of the F_{IN} model for asphyxia, the fraction of a lethal dose of irritants (FLD_{irr}) is included as an additive term. When this is done for this fire the main drivers of asphyxia are the inhaled doses of CO and these irritants, increased by the presence of high CO_2 concentrations and with a small contribution for the lowered oxygen concentrations. For this model, the calculated time to FED_{IN} asphyxia (excluding HCN) is 7 min. At this time it is calculated that the overall degree of incapacitation is likely to be sufficient to cause collapse and prevent escape. Since the extent of additive effects from the irritants are somewhat uncertain, the final curve shows the situation with this term removed from the analysis. The result shows loss of consciousness after 8.5 min as the blood CO level reaches 40 % COHb, which happens to coincide with the time by which a person sitting or lying on the floor is likely to receive life threatening burns.

After 10 min the FLD for lung irritants is 0.25, indicating that post-exposure lung inflammation is unlikely if rescued at this time, although elderly subjects in particular have been found to be vulnerable to the development of fatal pneumonia from lung infection.

The predicted results for a subject exposed to these conditions depend very much upon their condition at the time of ignition and their subsequent behavior:

- A subject awake and ambulant at the time of ignition, and aware of the fire from ignition should be able to escape without difficulty, suffering no or minimal exposure.
- A waking subject may get into difficulties if they remain at or enter the scene to carry out activities such as getting dressed, attempting to retrieve belongings or to fight the fire, or if they are unable to escape due to incapacity (for example due to physical or mental disability, alcohol or drugs). Due to the rapid deterioration in conditions after 4 min they may become disorientated and overcome by toxic smoke and heat, collapsing and dying at the fire scene.
- For a sleeping subject the outcome depends upon when they become aware of the fire and their subsequent behavior. Figure 63.8 shows the activation times for smoke detectors placed on the lounge and upper floor landing ceilings for this experiment. The optical detector placed on the landing ceiling activated 2.5 min after ignition, by which time there was already dense smoke at head height in the lounge. Whether or not a subject would escape before being overcome would then depend upon how rapidly they awoke, took in

the situation and when they decided to leave the room. Although escape via the hallway and main exit would be possible following a rapid response, any delay would be likely to result in the occupant being overcome and collapsing, either in the lounge or hall.

- Unlike the bedroom case it is considered that many occupants in this situation would attempt to escape through the smoke even at high density, since they would be motivated by the need to move away from the source of the fire and effluent.
- A similar analysis has been carried out for the conditions faced by an occupant of an open upper floor bedroom during this fire experiment, both for a situation with the fire room door opened and closed. Once smoke from a fires in an open lounge such as these begins to enter an open bedroom on the floor above, the time available for response and escape is very short (around 1–2 min) before incapacitation is predicted.

Case Examples

It is common for occupants of upper floor bedrooms to decide not to attempt escape through landing smoke from a fire involving a single item on the floor below [26]. In some cases victims have closed the bedroom door and escaped through a window or waited for rescue. In other cases they have failed to close the bedroom door, allowing smoke to flow into the open bedroom and either been overcome or survived by hanging out of an open bedroom window until rescued. Others have succeeded in escaping via the stairs past the fire room, especially in cases where the fire room door was closed. As stated in the previous section, most fatalities from such situations are found to have minimal burns but potentially lethal blood %COHb concentrations. In one such case bedroom occupants died half out of bed with high %COHb concentrations before they were able to begin to evacuate. In two other cases, occupants opened the door onto a smoke-logged landing in situations involving an active vitiated fire on the floor below, then failed to close the door and attempted to escape, in one case along a corridor towards an exit and in the other via a window. In the first case, two occupants collapsed and died after traveling approximately 10 m and one was rescued after taking refuge in a closed room. In the other case, one person escaped via the window while the second was overcome and died in the room. In two cases, occupants collapsed unconscious on the floor of a room containing an underventilated fire but survived after rescue. For one case the fire was of a medium size and confined to corner of the open room, providing conditions considered to be similar to those in Fig. 63.10. The occupant collapsed away from the fire area and when rescued after about 15 min had approximately 40 %COHb and potentially lethal 80 % full thickness burns (despite being clothed with the clothes undamaged). This and similar cases are considered to provide some validation of the FED smoke, toxicity and heat models described.

In other cases occupants have taken refuge in closed rooms, but subsequently been overcome over periods of up to an hour or more before they were rescued (but died in hospital) [27]. This kind of incident is important from the perspective of a defend-in-place strategy. The engineering design analysis must be able to demonstrate that conditions in such refuge enclosures remain tenable for as long as necessary.

Fire room occupants commonly become aware of a fire before conditions become life threatening, even in the absence of automatic smoke detection (alerted by noise, heat or smoke), but a significant number remain in the fire room and become incapacitated without escaping. Some are intimate with the fire and suffer severe burns, while others may be away from the immediate fire and be overcome by toxic smoke, either with or without burns.

Despite the fact that in some situations people will take refuge rather than attempting to escape through dense smoke, in other situations people have been shown to travel considerable distances through dense smoke, subsequently escaping or being overcome at the scene. During the Mont Blanc tunnel fire a number of victims escaped from their vehicles and walked several hundred

meters through dense smoke in the tunnel before being overcome. Victims closer to the fire were overcome by a combination of heat and toxic gases, while others 407 m from the fire were overcome by toxic gases having traveled 525 m through smoke[24]. During the Dupont Plaza fire a witness described holding her breath and deliberately entering the lobby, which was filled with dense smoke. There she joined a crowd of people moving some tens of meters along a heavily smoke-filled corridor and escaped from the main entrance. She described walking in the crowd holding her breath, but then being forced to take a breath and immediately almost collapsing, but was able to keep moving and was prevented from falling by contact with the crowd. In a store fire in the UK, a large number of persons were trapped in dense smoke on a sales floor while there was a large queue at the storey exit to the stair. A number of persons subsequently traveled through dense smoke to escape via windows or down the smoke-logged stair. Two deaths resulted from CO intoxication of two persons disorientated and remaining on the floor in a restaurant area [28]. The Station Nightclub provides an example of a situation in which large numbers of persons attempted to escape through dense hot smoke, some of whom succeeded while others were overcome before they could escape [29]. In other cases victims have entered smoke filled corridors and stairwells and been overcome as they attempted to descend.

These descriptions of occupant behaviors and outcomes in different incidents highlight the difficulty of specifying what constitutes an acceptable level of exposure from a design perspective, in situations where some degree of exposure to fire effluent is predicted. The main FEC and FED expressions presented in this chapter are intended to represent exposure conditions likely to seriously impair escape attempts (smoke and irritants) or cause incapacitation (loss of consciousness or severe pain) for asphyxiants or smoke for average adults. Designing to these limits would therefore be predicted to involve failure to escape by a large proportion of an exposed population. Consideration of aspects relating to choice of design limits is discussed in a later section.

Dose/Response Relationships and Dose Estimation in the Evaluation of Toxicity

Before considering the particular effects of individual toxic fire products it is necessary to determine the basic parameters required to quantify exposure. Ultimately, the degree of toxicity is determined by such factors as the concentration of toxic product in the target organ of the body and the time period for which a toxic concentration is maintained. For an asphyxiant product, the most important criterion is the concentration in the cerebral blood supply or inside the brain cells, whereas for an irritant product the most important factor is the concentration in the linings of the nose, throat, or lung. In some cases it is important and feasible to measure such parameters directly. For CO it is not the concentration in the smoke that directly determines how someone will be affected but rather the concentration that has accumulated in the blood in the form of carboxyhemoglobin, which can be determined relatively simply from a drop of blood [30, 31].

In practice, however, it is often not feasible to measure the amount of toxic product directly accumulated in the subject. Also, relating observed toxic effects to measurements of toxic products in the smoke itself is preferable, since it enables predictions of toxicity to be made based on chemical measurements of fire atmospheres without necessarily exposing animals. A series of useful secondary measurements can, therefore, be made that can be related to toxic effects in animals, but it must be remembered that these indirect measurements of exposure always involve some degree of error or uncertainty.

The Relationships Between Concentration Inhaled, Duration of Exposure, and Toxicity

In inhalation toxicology two parameters that are always measured and reported are the actual analyzed concentration of the test material per unit volume of air in the animals' exposure chamber and the duration of exposure. For

droplet aerosols or dusts the particle size range in the atmosphere is also measured so the respirable fraction (the part capable of entering the body) can be calculated. Where toxic effects can occur rapidly, as with the asphyxiant gases, it is also important to measure the rate of uptake of the toxicant. This can be estimated by measuring the volume of air breathed by the animal per minute (the respiratory minute volume (RMV), usually expressed as V_E (the volume of air exhaled per minute), although for accurate calculation of uptake and dose, further measurements, such as of blood levels, must be made. Variations in V_E can have dramatic effects on toxicity as will be described in the following section.

Although such parameters as respiration and particle size of aerosols are important, the most basic parameters reported are the concentration of the toxicant and the duration of exposure, which enables a rudimentary estimation of the dose. Thus, the product of concentration and time (*Ct* product) gives an estimate of the dose available to the animal. In general safety evaluation of novel chemicals for an acute exposure, a standard single 4-h exposure time is used and toxicity is expressed in terms of the concentration of test material causing the death of 50 % of the animals during exposure or within 14 days after exposure. This is known as the 4-h LC_{50} concentration.

In practice, however, it may be necessary to predict what will happen to a subject exposed to a higher concentration for a shorter period of time or a lower concentration for longer time. Although this can be done by carrying out more LC_{50} experiments using different exposure durations, as an approximation toxicologists often resort to Haber's rule, which states that the toxicity depends on the dose accumulated, and that the product of time and concentration is a constant [32], so that

$$W = C \times t \tag{63.4}$$

Where W is a constant dose, specific for any given effect. In practice, dose in inhalation toxicology is often expressed in terms of *Ct* product. In the case of the LC_{50}, the effect is death of 50 % of the animals and

$$W = LC \cdot t_{50} \tag{63.5}$$

expressed in mg · min/L (i.e., the product of the concentration and the duration of exposure causing lethality). This relationship implies a linear uptake of the toxic substance with time (Fig. 63.11). It holds true for some substances where the primary target organ is the lung. In the context of combustion toxicology, this relationship can be applied to estimates of the dose of a lung irritant likely to cause post-exposure fire deaths from lung inflammatory responses. An example of such an irritant is carbonyl fluoride, a highly toxic lung irritant produced during the thermal decomposition of PTFE, which has a 1-h LC_{50} of 0.990 mg/L, which is exactly four times the 4-h LC_{50} of 0.248 mg/L [33].

Unfortunately, this simple principle does not always hold true. In particular, some volatile substances (such as CO) are both taken up and excreted via the lungs. In this case the rate of uptake depends on the difference between the concentration inhaled and that in the body, giving an exponential uptake so that:

$$W = C\left(1 - e^{-tk}\right) \tag{63.6}$$

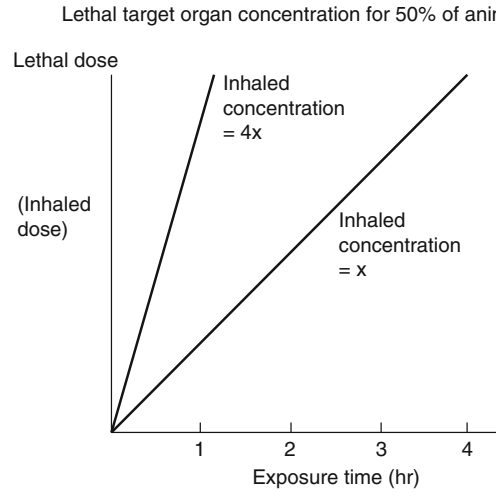

Fig. 63.11 Uptake of a substance obeying Haber's rule (i.e., with a long half-life of detoxification or excretion), where the rate of uptake is directly proportional to the inhaled concentration, so that 1-h LC_{50} is four times the 4-h LC_{50}. The lethal dose represents a lethal target organ concentration for 50 % of the animals

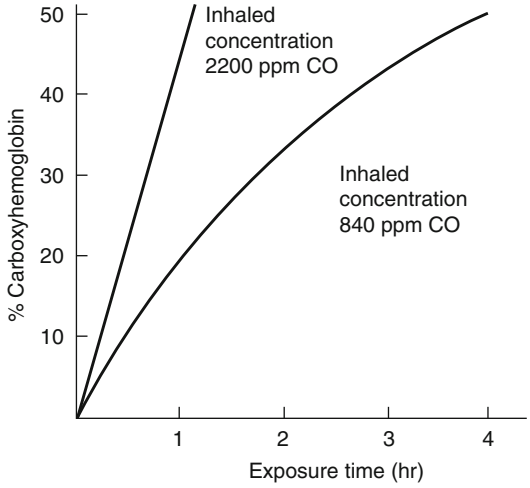

Fig. 63.12 Uptake of a substance (carbon monoxide), which is both absorbed and excreted via the lungs, and where the rate of uptake depends on the difference between the concentration inhaled and that in the body. For short exposures at high concentrations, uptake to a lethal dose is almost linear, obeying Haber's rule. For longer exposure times, uptake follows a curve so that the inhaled concentration necessary to achieve a lethal dose (50 % carboxyhemoglobin) at 4 h (840 ppm) is 0.38 times that required for deaths at 1 h, as opposed to 0.25 times (550 ppm) as predicted by Haber's rule. Uptake was calculated for a 70 kg human at rest (RMV 8.5 L/min) using the CFK equation

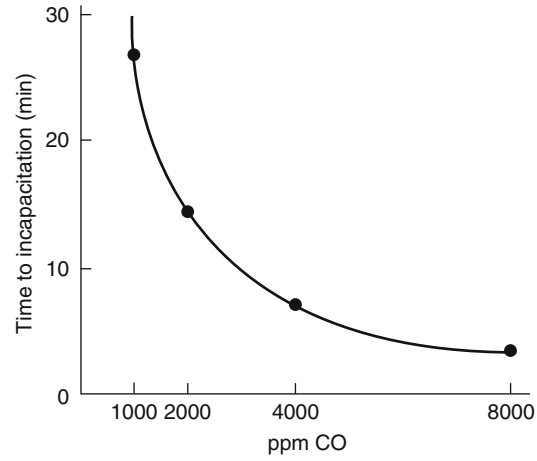

Fig. 63.13 Relationship between time to incapacitation and carbon monoxide concentration in active monkeys. 1000 ppm Ct = 26,600 ppm · min; 2000 ppm Ct = 28,097 ppm · min; 4000 ppm Ct = 26,868 ppm · min; 8000 ppm Ct = 26,086 ppm · min

This is the basis for the Coburn-Forster-Kane (CFK) equation [34, 35] describing the uptake of CO in humans. This relationship approaches the linear Haber's rule (Equation 63.4) when the concentration, C, in the atmosphere is high with respect to the concentration in the body required to cause incapacitation or death (Fig. 63.12), and for short exposures to high CO concentrations, uptake is approximately linear. This effect is illustrated by the results from CO exposure experiments in primates. At a constant level of activity, and thus of respiration, the animals became unconscious when exposed to approximately 27,000 ppm · min of CO at concentrations between 1000 and 8000 ppm (Fig. 63.13). For such situations it is, therefore, possible to use linear models for CO uptake without serious error.

Some toxic effects, however, are not dependent on a dose acquired over a period of time but are concentration related. Thus, the irritant effects of smoke products on the eyes and upper respiratory tract (sensory irritation) occur immediately on exposure with the severity depending on the exposure concentration. In fact, far from increasing as exposure continues, the effects usually lessen, as the subject adapts to the painful stimulus even though the dose is increasing [24, 36].

Other cases where concentration is an important determinant of toxicity as well as duration of exposure are the asphyxiant effects of hypoxic hypoxia (oxygen lack) and hypercapnia (high CO_2 concentrations). If a subject is exposed suddenly to a low oxygen concentration, a finite time is required for the air in the lungs and gases in the blood to equilibrate to the new conditions, so to some extent a "dose" of hypoxia is acquired over a period of time. Once equilibrium is established, usually within a few minutes, the severity of the effects depend on the oxygen concentration and do not then change appreciably with time [37, 38]. This also applies to high CO_2 concentrations. Equilibrium is established within a few minutes and concentration-related effects then determine the pattern of toxicity [25, 37].

For the other main asphyxiant gas in smoke, hydrogen cyanide (HCN), although

accumulation of a dose is one factor, the most important determinant of toxicity appears to be the rate of uptake, which in turn depends on the concentration. Thus, as shown in Fig. 63.14, incapacitation occurs rapidly (after 2 min) at the high concentration of 180 ppm (*Ct* product 400 ppm · min), but at the lower concentration of 100 ppm, incapacitation occurs only after approximately 20 min, requiring a much higher *Ct* product dose (2000 ppm · min). This effect leads to the unusual kinked HCN time/concentration curve shown in Fig. 63.14 compared to the smooth curve for CO.

In attempting to predict what will happen to a subject exposed to a smoke atmosphere containing all these products it is, therefore, important to allow for these different concentration/time/effect relationships.

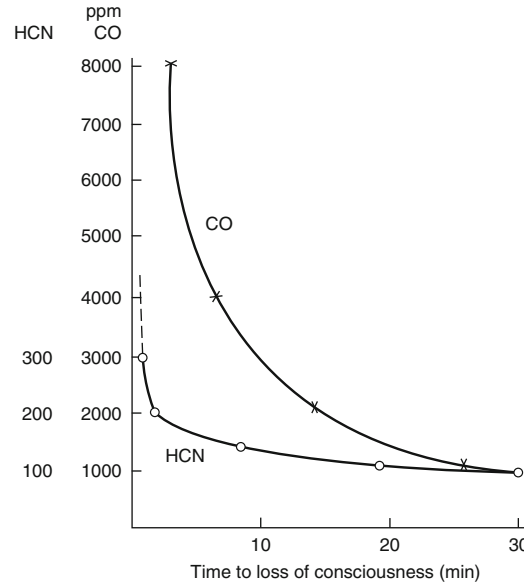

Fig. 63.14 Comparison of the relationship between time to incapacitation and concentration for HCN and CO exposures in primates. Time and concentration are equivalent for CO; for HCN, a small increase in concentration causes a large decrease in time to incapacitation

Ct Product and Fractional Effective Dose

The basic concept established in the previous section is that for the majority of toxic products in a fire atmosphere a given toxic endpoint such as incapacitation or death occurs when the victim has inhaled a particular *Ct* product dose of toxicant. In order to make some estimate of the likely toxic hazard in a particular fire it is, therefore, necessary to determine at what point in time during the course of the fire exposure the victim will have inhaled a toxic dose. This can be achieved by integrating the area under the fire profile curve for the toxicant under consideration. When the integral is equal to the toxic dose, the victim can be assumed to have received a dose capable of producing that toxic effect.

A practical method for making this calculation is the concept of *fractional effective dose* (FED) [39]. The *Ct* product doses for small periods of time during the fire are divided by the *Ct* product dose causing the toxic effect. These fractional effective doses are then summed during the exposure until the fraction reaches unity, when the toxic effect is predicted to occur. Thus, the FED equation can be represented as:

$$\mathrm{FED} = \frac{\text{Dose received at time } t(Ct)}{\text{Effective } Ct \text{ dose to cause incapacitation or death}} \tag{63.7}$$

For substances obeying Haber's rule, the denominator of the equation is a constant for any particular toxic effect. For substances deviating from Haber's rule, the denominator for each time segment during the fire is the *Ct* product dose at which incapacitation or death would occur at the concentration during that time segment. For the hazard model presented in this chapter, the denominator is presented in the form of equations giving the required *Ct* product doses predicted for humans, which have been derived for each toxic gas and are presented in the following sections. Special cases of the fractional effective dose are referred to as the *fractional incapacitating dose* (FID) and the *fractional lethal dose* (FLD).

For sensory irritation—a toxic effect that depends on the immediate concentration of an irritant to which a subject is exposed rather than the dose—a concept of *fractional irritant concentration* (FIC) has been developed, where

$$\mathrm{FIC} = \frac{\text{Concentration of irritant to which subject is exposed at time } (t)}{\text{Concentration of irritant required to cause impairment of escape efficiency}} \tag{63.8}$$

Allowance for Margins of Safety and Variations in Susceptibility of Human Populations

The methods for assessing the effects of toxic gases were originally developed to predict the exposure concentrations or exposure doses that would be expected to cause serious effects such as impairment of escape capability, incapacitation, or death of a building occupant. When they are used for design purposes, the main consideration is not to predict a serious effect level but a maximum safe level. When used in this context, it is necessary to use some degree of conservatism in applying tenability endpoints for two reasons. One reason is to allow for uncertainties in the predictability of the endpoints, which is mainly because the endpoints cannot be fully quantified within narrow limits without performing experimental human exposures to a variety of complex and dangerous toxic effluent mixtures. These tests obviously cannot be done for ethical reasons. Another reason is the wide range of sensitivities to toxic effects in a heterogeneous human population.

The physiological algorithms are based partly on experimental data and reported effects in humans and partly on animal studies. These methods involve either the exposure dose or concentration predicted to produce a given effect on humans exposed to fire effluent. However, the effects are based on data for healthy young adult animals or humans. The exposure dose or concentration, therefore, represents the average in a statistical distribution of subjects' responses surrounding that exposure dose or concentration. This is the mode, or most frequently expected exposure dose for an exposed population. Individual exposure doses or concentrations for the response would, in practice, be statistically distributed around the mode in a probability curve. The overall human population contains a number of subpopulations, which exhibit greater sensitivity to various fire effluent toxicants, principally due to compromised cardiovascular and pulmonary systems.

Two of the largest such subpopulations are the elderly and the approximately 15 % of children and 5 % of adults who are asthmatic [40]. The elderly, and particularly those with impaired cardiac perfusion, are particularly susceptible to asphyxiant gases. Thus the average lethal carboxyhemoglobin (COHb) concentration in adults dying in fires or from accidental CO exposure is lower in the elderly [41]. Figure 63.15 shows the distribution of postmortem carboxyhemoglobin concentrations in human fire and nonfire CO fatalities in the United States [29]. The results show that some individuals died at COHb concentrations below 30 % while others survived long enough to obtain blood concentrations above 90 %COHb. Many fire fatalities occur at lower COHb concentrations than for cases of CO poisoning alone. This may partly reflect the influence of other toxic gases in addition to CO in fire atmospheres. Also it has been shown in experimental studies that as little as 2 %COHb significantly reduces the time to the onset of pain in an exercise test of angina sufferers [42]. This could be very important when attempting to escape from a fire.

A further complication with the CO lethality data illustrated in Fig. 63.15 is that in practice few people survive an exposure of more than 50 %COHb if rescued and treated, even though much higher levels are found in the bodies of decedents. This result is because uptake continues in comatose people until the point where respiration ceases, which is illustrated in data from a study by Pach [43] (Table 63.4). This study shows the proportions of survivors and

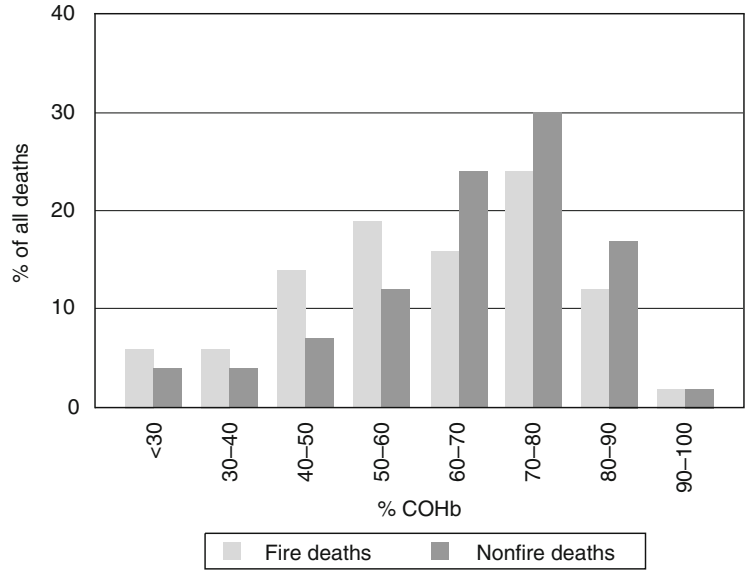

Fig. 63.15 Range of lethal sensitivity to carbon monoxide in humans [41]

Table 63.4 Proportions of survivors and fatalities in different COHb ranges [43]

Percent COHb range	Survival rate	Fatality rate	Number of cases
>30	1.0	0.00	65
30–40	0.9	0.10	29
40–50	0.67	0.33	20
50–60	0.14	0.86	29
60–70	0.02	0.98	43
70–80	0.05	0.95	22
80–90	0.0	1.00	3

fatalities from a sample of 260 CO poisoning cases. The data show that survival is rare above 50 %COHb, that around 67 % of people survive in the 40–50 %COHb range, and that most people survive below 40 %COHb.

Asthmatics and sufferers of other lung conditions, such as chronic bronchitis and reactive airways dysfunction syndrome, are particularly susceptible to bronchoconstriction on even brief exposure to very low concentrations of irritants, with distress, severely reduced aerobic work capacity, collapse, and death resulting, depending on the sensitivity of the individual and the severity of the exposure.

It is the objective of fire safety engineering to ensure that essentially all occupants, including sensitive subpopulations, should be able to escape safely without experiencing or developing serious health effects. Thus, safe levels for exposure of the human population to fire effluent toxicants must be significantly lower than those determined from experiments with uniformly healthy animal or even human surrogates.

The toxicity endpoints from the functions presented in this chapter are all predicted to represent the median of the distribution of exposure doses or concentrations resulting in a given toxicity endpoint. Since individual susceptibility varies in the population, it is considered that approximately 11.3 % of the population is considered likely to be susceptible below an FED of 0.3 (see ISO 13571 [21]). Approximately 90 % of the population is considered to be susceptible below an FED of 1.3. For this reason, it will be necessary for the user to select an FED value to protect an acceptable proportion of vulnerable subpopulations (for example, an FED of 0.3 or some other value). Note: Due to the rapid (t^2) rate of increase of smoke and asphyxiant gas concentrations in most flaming fires, variations in individual susceptibility and uncertainties in prediction of incapacitating doses tend to have relatively minor effects on predicted times to incapacitation.

Application of FED Methodology to Deterministic and Probabilistic Hazard Modeling

The FED endpoints discussed in the previous section may be applied directly to deterministic design in order to set design limits for ASET for a particular design fire scenario. They can also be used for a more probabilistic design by determination of acceptable ASET endpoints for a variety of possible fire scenarios.

Such an application can be to probabilistic scenario modeling cases for one or more specified design fire scenarios. An example could be to estimate the numbers of occupants likely to escape uninjured from a specific fire scenario and the extent of injury and survival rate for other occupants. Gridflow [44] and Exodus [45] are examples of computer evacuation models that can be used in this way. In Gridflow, the time-concentration curves of toxic hazard conditions in any occupied enclosure in a building can be introduced as a smoke-irritancy concentration term and an asphyxiant gas (or heat) dose term. The model is then populated with escaping agents (i.e., people) who are exposed to the concentration term (affecting their walking speed) and also progressively inhaling the exposure dose. When the concentration or dose terms reach critical values, an agent is considered to be incapacitated and ceases to escape. By varying the severity of the levels of the hazard parameters used as endpoints for these terms, it is possible to set conservative criteria: determination of time for safe escape of all occupants, or less conservative criteria: determination of the number of occupants suffering severe incapacitation or full-thickness burns.

In order to reflect the varying sensitivity of individual subjects to a given level of insult, Gridlow has a "FED susceptibility" parameter that can be assigned a mean and standard deviation from which each individual agent can be randomly assigned with a susceptibility level. For a population escaping under identical conditions, this can then result in a proportion escaping while others fail to escape.

A difficulty in carrying out such probabilistic simulations is the limited data available on the behavioral and physiological susceptibility of people in a population to the different hazard parameters. In this Chapter, some data on the variability in susceptibility within the population have been provided. Some guidance has also been given on the proportion of people willing to enter and continue to escape through smoke as a function of smoke density, and a suggested standard distribution for the variations of walking speed around a function relating average walking speed to smoke density. Additionally, in the section on sensory irritation, information is provided on the possible range of susceptibilities of an exposed population as a function of the logarithm of the exposure concentration. This is also complicated by the uncertainty of the available data.

For asphyxiant gas exposures, especially CO, some guidance on variations in susceptibility to collapse has been presented in the previous section. For any exposed individual, it is considered that the degree of impairment is generally minor until a critical dose has been inhaled, at which point severe incapacitation (collapse) occurs after a brief period of intoxication. The variation in sensitivity in the population (variation in the dose required to cause collapse for different individuals) is more difficult to specify. Problems with susceptibility of angina patients at very low CO levels have been described, and cases of syncope (fainting collapse) can occur in mildly hypoxia situations such as aircraft cabins or at moderate altitude in mountains in susceptible individuals. It, therefore, seems likely that some people will succumb to quite low levels of asphyxiant gas exposures during escape from fires. As shown in Figure 63.5, approximately 5 % of fire fatalities exposed to smoke remote from a fire and with no burns had blood CO concentrations <30 %COHb. Based on fire

fatality and experimental data it is considered that, depending upon their activity level, by far the majority of exposed people would not be overcome or seriously affected until they achieved 30–40 %COHb, and few would remain unaffected by 45 %COHb. In terms of overall F_{IN} for asphyxiant gases this would mean that relatively few individuals would be likely to be overcome at F_{IN} levels below 0.5, while few would remain able to function at levels above 1.125.

For heat exposure, individual tolerance endpoints are also difficult to specify. As with smoke, the effects on escape behavior are likely to be affected by the context, in that occupants in or near a place of relative safety may be unwilling to enter hot smoke in an escape route, or turn back if they find the heat intensity painful. For such situations, the relatively conservative endpoints to time to pain may be correct, or in some situations not conservative enough in that an individual may be unwilling to enter areas of significant heat even if the areas are at a level below the pain threshold. In other situations, especially when occupants find themselves immersed in a hot smoke environment, they have been found to continue to move and in some cases succeed in escaping through extreme conditions resulting in serious burns. At some point, a heat exposure results in collapse and death. From case histories, this is considered likely to happen at the point where serious 2nd degree or full-thickness (3rd degree) burns occur. It is considered that although light indoor clothing provides some protection to clothed areas of the body, this is likely to result in only a small increase in tolerance time or time to burns, and of course does not apply to sensitive areas such as the hands and head. For this reason it is considered that the tolerance and time to burns expressions presented in this Chapter are most relevant rather than expressions for clothed subjects, except in situations where protective clothing is in use.

Derivation of a Model for the Prediction of the Effects of Optically Dense, Irritant Smoke on the Eyes and Respiratory Tract

Although it is difficult to make precise predictions of the effects exposure to irritant smoke has on escape behavior, the degree of incapacitation, and the post-exposure effects on lungs, it is important to consider these effects in engineering design, and to be able to make some estimates of the likely effects of exposure. Herein is presented a current "best estimate" model for likely effects.

Smoke presents three hazards affecting escape capability. The first two relate to simple impairment of visibility. Firstly, the presence of smoke in an occupied enclosure obscures illumination from windows and other light sources (especially high level lighting), so that escaping occupants can find themselves in dimly lit conditions, and secondly the smoke directly impairs the ability of the subject to see through it to surrounding objects and signage. The attenuation of general illumination can be modeled to provide an indication of the brightness and contrast of the surroundings of a subject taking the smoke density and distribution into consideration. The effects of smoke obscuration (visibility distance in non-irritant smoke) on escape behavior has been studied (see Chap. 61 [46]), but the sensory irritant effects of smoke, both on the eyes and respiratory tract are also important, affecting both behavior and walking speed. The next section provides a simple method for the evaluation of the effects on escape capability of "averagely irritant" smoke. This represents a default for smoke of an irritant potency likely to occur from flaming fires in most normal occupied enclosures such as domestic dwellings, offices, assembly or sleeping accommodation, in which any combustible fuels are considered to have a low content of elements producing acid gases and organic irritants. The section following this considers in more detail the evaluation of sensory

irritancy for fuels of known composition likely to produce more irritant smoke, such as smoldering fires, flaming fires involving electrical equipment or consumer products (in any building), store fires (e.g., especially supermarkets and DIY stores) and fires involving transport (tunnels, motor vehicles, aircraft and ships).

Evaluation of the Effects of Smoke on Escape Capability

Smoke affects both available safe escape time and the time required for escape. The time available for escape is often limited by the development of smoke conditions that occupants are unwilling to enter or turn back after entering. When occupants do attempt to escape through smoke the time required can be increased by effects on exit choice and wayfinding as well as walking speed through smoke.

Where occupants of a relatively uncontaminated enclosure find their escape route smoke-logged their willingness to enter the smoke and continue through it depends on a range of behavioral parameters related to their individual characteristics, their knowledge of the building and escape routes and their appraisal of the relative risks of seeking refuge or attempting escape. Once exposed to smoke, their willingness and ability to continue also depends upon the optical density, irritancy and temperature of the smoke, the ambient lighting and exit lighting and features of the built environment such as the enclosure size, complexity, presence of obstacles or other hazards.

When occupants are in the fire enclosure and exposed to smoke, or are threatened by rapidly deteriorating fire conditions in their vicinity, then they are more likely to attempt to escape through it than when they have the choice of entering or remaining in a refuge. Studies of occupant behavior during different fire incidents show examples of situations where occupants have turned back or remained in place even when smoke contamination of escape routes is light, and other cases where occupants have successfully or unsuccessfully attempted to escape though conditions of extremely dense hot and irritant smoke. Experimental studies of movement through smoke are useful for measuring movement behavior and speed, but they differ from real incidents in that the participants know they are safe and may therefore move with more confidence than they otherwise would. Even within experimental studies movement behavior and speeds appear to depend to some extent on the nature of the occupants and the physical characteristics of the experimental enclosure. For these reasons it is difficult to provide precise guidance on the relationship between smoke conditions and predicted occupant behavior and walking speeds.

Deciding Whether to Enter a Smoke Contaminated Escape Route, Seek Refuge or Find an Alternative Escape Route

The effects of smoke density on escape behavior during actual fire incidents is reviewed in Chap. 58 [47]. Two studies (in the US and UK) [47–49] report occupant behavior in terms of distance traveled through smoke of different densities (expressed as visibility distance) and numbers turning back or seeking refuge. Although the irritancy and temperature of the smoke is not mentioned it can be assumed that the smoke was in most cases somewhat irritant and hot. Both studies showed remarkably similar results. In the UK study 91 % of those turning back having entered smoke did so when visibility was less than approximately 4 m, representing 62 % of those exposed to smoke at this visibility or lower, while only 11 % of those exposed to smoke with a visibility >4 m turned back (5 % for visibility >9 m). For individual cases the authors have examined or investigated [26] several cases of dwellings fires have been encountered in which occupants on an upper floor have been confronted with dense, hot, smoke from a fire on the floor below when opening a bedroom door. In almost all cases the occupants have decided to close the door and remain in the bedroom or attempt escape via a window rather than to attempt to proceed through the smoke-filled escape route, citing the density,

irritancy and temperature of the smoke as deterrents. In two incidents, five occupants attempted to escape away from a location where they had opened a landing door and enabled a smoke plume to enter from a fire on the floor below. Three were overcome and died while attempting to escape, while one escaped through a window and one was rescued having taken refuge in a closed room.

During the Dupont Plaza hotel incident some witnesses reported occupants being trapped or overcome by smoke, while others successfully traveled a considerable distance and escaped along a long smoke-filled corridor. During the Mont Blanc road tunnel fire most occupants remained (and died) in their vehicles rather than entering the smoke-filled tunnel, while a small number traveled a considerable distance along the tunnel before being overcome by toxic gases or heat [24]. Other cases are described in Chap. 58. The general pattern from these incident investigations is that occupants will generally be unwilling to enter smoke with a visibility of more than approximately 3 m (0.33 OD/m, extinction coefficient 0.76), especially if they have an option of turning back or seeking refuge, and women were more likely to turn back than men. These effects are summarized in Table 63.5. When occupant attempt to move significant distances through dense smoke from enclosed compartment fires, the concentrations of asphxyxiant gases are often sufficient to result in collapse within a few minutes while attempting to escape. On the other hand there have been incidents in which occupants have succeeded in traveling through dense smoke for distances exceeding 10 m and survived. Behavior may also depend on whether layering permits occupants to crouch down to levels where the smoke density is lower and if low-level lighting is used to improve visibility. Behavior also depends on features of the built environment. In corridors or tunnels subjects' behavior changes from walking in the open to feeling their way along a wall at a critical density. Infrared video shows subjects waking slowly forward in a crouching position as if to feel their way with their hands and to minimize trip hazards. Personal experience of attempting to walk along a unfamiliar landing in theatrical smoke was of moving forward slowly, affected by fear of tripping over or walking into unseen objects, or falling down an unknown step or level change. For this reason it is considered that in a setting where obstacles are less likely to occur, such as walking along a tunnel walkway holding a railing, then subjects may progress somewhat more rapidly.

Based on considerations such as those described above for the optical density and irritancy of the smoke it is possible to set tenability limits for smoke density appropriate to particular fire scenarios, in relation to the physiological effects on the ability of occupants to see sufficiently well to escape efficiently, and possible psychological effects on their escape behavior. Appropriate limits will depend on the building and occupant characteristics. For example, for small spaces with short travel distances to exits, it may be possible to set less stringent tenability criteria if occupants are familiar with the building. For large spaces it may be necessary to set more stringent tenability limits, particularly if occupants are likely to be unfamiliar with the building and need to be able to see much farther in order to orient themselves to find exits. With regard to the effects of irritancy on the ability to see, it may be necessary to use more stringent smoke density tenability criteria for scenarios where the smoke evolved is likely to be highly irritant to the eyes. Other factors to be taken into consideration would be the complexity of the space, the lighting, and the visibility of the signage. Suggested tenability limits are presented in Table 63.5. Jin [50] suggests tenability limits of extinction coefficient 0.15/m (OD/m = 0.06) for subjects familiar with an escape route or 0.5/m (OD/m = 0.2) for subjects unfamiliar with the escape route. Rasbash [51] suggested a 10-m visibility limit (equivalent to OD/m = 0.08), whereas Babrauskas [52] suggested a tenability limit of extinction coefficient 1.2/m (OD/m = 0.5) in the context of domestic fires. In order to assess the visual obscuration effects of smoke, a concept of fractional effective concentration (FEC) has been developed, whereby the smoke

Table 63.5 Reported effects of smoke on visibility and behavior

Smoke density and irritancy OD/m (extinction coefficient)		Approximate visibility (diffuse illumination)	Reported effects
None		Unaffected	Walking speed 1.2 m/s
0.5 (1.15)	Nonirritant	2 m	Walking speed 0.3 m/s
0.2 (0.5)	Irritant	Reduced	Walking speed 0.3 m/s
0.33 (0.76)	Mixed	3 m approx.	30 % people turn back rather than enter
Suggested tenability limits for buildings with:			
Small enclosures and travel distances:		OD/m 0.2 (visibility 5 m)	
Large enclosures and travel distances:		OD/m 0.08 (visibility 10 m)	

concentration is expressed as a fraction of the concentration considered to significantly affect escape efficiency. If the total FEC_{smoke} reaches unity, then it is predicted that the level of visual obscuration would be sufficient to seriously affect escape attempts. The default limit levels proposed for design purposes are OD/m 0.2 (α_k 0.5) for small enclosures and OD/m 0..08 α_k 0.5 (α_k 0.18 for large enclosures).

$$FEC_{smoke} = (OD/m)/0.2 \text{ for small enclosures or } (OD/m)/0.08 \text{ for large enclosures} \quad (63.9)$$

Movement Speed in Smoke

Fundamental work on movement speed in smoke was carried out by Professor Jin in Japan (See Chap. 61). In experiments where people were asked to walk down a 20 m smoke-logged corridor, Jin found that for nonirritant black smoke (from burning kerosene), walking speed decreased with smoke density and that at an extinction coefficient of 1.15 (optical density of 0.55/m visibility 2.1 m) walking speed decreased from approximately 1.2 m/s (no smoke) to approximately 0.3 m/s [53]. Under these conditions people behaved as if they were in total darkness, feeling their way along the walls or weaving from side to side rather than walking in a straight line.

When people were exposed to irritant smoke, made by heating wood chippings, movement speed was reduced to that in darkness at a much lower smoke density (extinction coefficient 0.5, optical density 0.2 OD/m), and the experience was found to be more distressing. The visibility in irritant smoke decreased sharply at a smoke density exceeding a certain level. "The subjects could only keep their eyes open of a short time and tears ran so heavily that they could not see the words on the signs". Both density and irritancy were found to affect walking speeds, the speed decreasing very rapidly in the same range of smoke density levels. The subjects could not keep their eyes open and they walked with a zigzag pattern or along the wall.

Figure 63.16 shows plots of Jin's results and those from two tunnel experiments, one from a study by Franzich and Nilsson [54] and another by Fridorf et al. [55]. The Figure shows that although it is possible to suggest a relationship between smoke density and walking speed for both non-irritant and irritant smoke from Jin's data, and walking speed was definitely slower in dense smoke, there is a considerable scatter in the data. Also, although the walking speed in the absence of smoke was stated to be approximately 1.2 m/s, there is no indication of the scatter of individual speeds in clear and low smoke density conditions. The results do appear to show a relationship between smoke density and walking speed for non-irritant smoke over a range of k from 0.2 to 1.13, a linear fit to the data being shown in the Figure. For non-irritant smoke with an average density of $\alpha_k = 0.73$ the average walking speed was 0.74 m/s (standard deviation 0.17). For irritant smoke, although it is possible to obtain a linear fit showing a decrease in speed with smoke density, the data are over a very short density range $\alpha_k = 0.32$–0.5 and there is a large scatter of walking speeds. For example

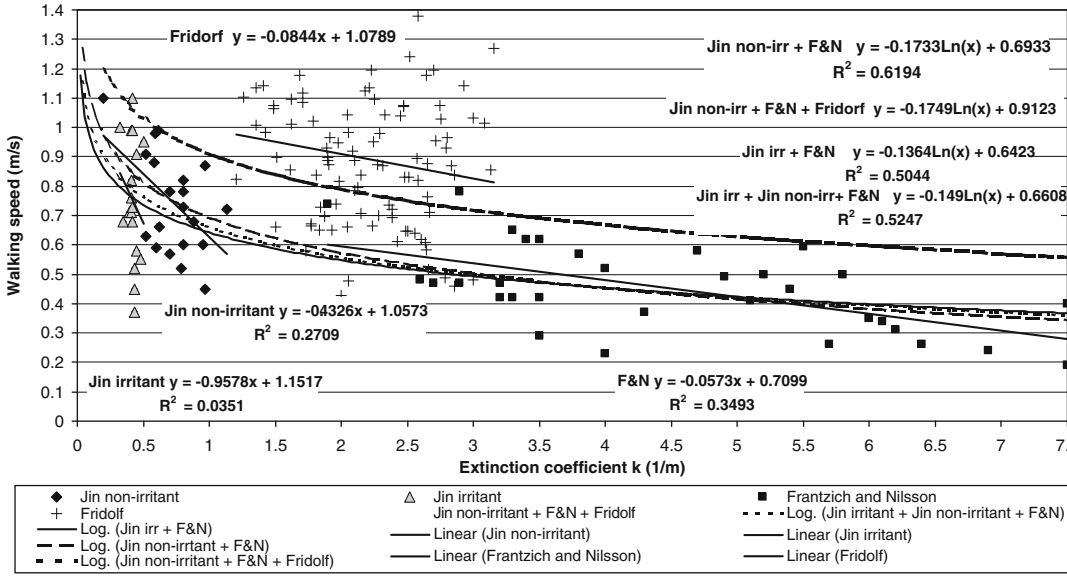

Fig. 63.16 Scatter of data and relationship between smoke density (extinction coefficient α_k (1/m) and walking speed (m/s). Data show Jin (non-irritant smoke), Jin (irritant smoke) in a corridor, Frantzich and Nilsson (mildly irritant smoke) in a tunnel mock up and Fridolf et al. (mildly irritant smoke) in a long tunnel

at $\alpha_k = 0.42$ speeds range between 0.37 and 1.1 m/s. For an average density of $\alpha_k = 0.42$ the average speed is 0.75 m/s (standard deviation 0.21). This is very similar to the average speed in non-irritant smoke, but at a lower density. Taking these data in conjunction with Jin's description of subjects' behavior, it does seem that a person's ability to walk through irritant smoke is more severely impaired than for non-irritant smoke, but it is less obvious that there is a clear relationship between density and speed. Rather it seems that some subjects are severely affects at a low smoke density of around $\alpha_k = 0.42$ (optical density 0.18, visibility approximately 5 m), which is close to the suggested design limit for small enclosure of OD/m 0.2 (See Table 63.5)

The two more recent data set for movement in smoke were those obtained by Frantzich and Nilsson [54] and by Fridolf et al [55]. The scenarios were somewhat different from that of Jin's work in that subjects were asked to walk through a smoke-logged simulated road tunnel. For the Frantzich and Nilsson experiments the "tunnel" contained parked vehicles and had a walkway down the right-hand side from the point at which the subjects were introduced. There was general lighting (on or off in different tests) and an illuminated sign over an exit near the far end on the left side, the subjects being required at some point to cross the tunnel to reach the exit. Smoke was theatrical smoke made slightly irritant by the addition of some acetic acid vapor. The Fridorlf tunnel was a long narrow tunnel without obstacles with wall mounted emergency lighting every 8 m along the sides at waist height at intervals and an illuminated exit sign over an exit 160 m from the start point.

The results for the Frantzich and Nilsson case with general lighting are shown in Fig. 63.16. Apart from differences in the test scenario, a major difference from Jin's experiments are that much higher smoke densities were used varying from α_k 1.9–7.5. The whole data set therefore sits beyond the density at which Jin found that subjects behaved as if in darkness and walked feeling their way along the wall with their hands. A linear fit to Frantzich and Nilsson's results does show a shallow slope of slower speed with increasing smoke density, but another way of looking at the data is to consider it all as constituting dense smoke and consider the average walking speed compared to Jin's figure of a

speed of 0.3 m/s (although the slowest measured speed was 0.37 m/s). For Frantzich and Nilsson's study, the mean walking speed was 0.45 (Standard deviation 0.21), which is quite close to that obtained by Jin in dense smoke. It was also noted in this study that most subjects moved for part of the distance by feeling their way along the walls, and that those subjects doing this for more than 2/3 the total distance had a greater average speed. As with Jin's work, there was a considerable variation in walking speeds between subjects at all smoke densities.

Fridolf et al's data are also shown in Fig. 63.16. These cover a range of smoke densities intermediate between those of Jin and Frantzich and Nilsson. The general pattern from this study again shows a scatter in walking speeds, but the average speeds are rather faster than those from the other two studies. On reason for the relatively rapid walking speeds may be that the tunnel was long and simple, without obstacles. The participants could feel their way along the sides and see the lights every few meters, so that they may have gradually developed a more confident walking pattern as they progressed, in contrast to the short corridor and tunnel used in the other experiments.

In order to derive calculation expressions for the relationship between smoke density and walking speed for non-irritant or irritant smoke, it is possible to perform a variety of fits to these data sets. Figure 63.16 shows logarithmic curves fitted to four data sets: Jin non-irritant plus Frantzich and Nilsson, Jin non-irritant plus Frantzich and Nilsson plus Fridolf, Jin non-irritant plus Jin irritant plus Frantzich and Nilsson, and Jin irritant plus Frantzich and Nilsson. The three fitted curves not including the Fridolf data are quite similar. For a simple deterministic and most conservative calculation an expression fitted to Jin's irritant data and the Frantizich and Nilsson data is suggested as follows:

$$\mathrm{Wsmoke(m/s)} = -0.1364 \times \mathrm{Ln}\,\alpha_k + 0.6423 \qquad (63.10)$$

Where Wsmoke = walking speed in moderately irritant smoke

The standard deviation is 0.157

A logarithmic fit to the "non-irritant" data set (Jin non-irritant, plus Frantzich and Nilsson plus Fridolf) gives a significantly shallower curve. The general impression from these data sets is that, apart from the obvious variation between individual subjects, there do appear to be inverse relationships between smoke density and walking speed, but both individual and average speeds are highly dependent upon the detailed exposure scenario.

For modeling the unrestricted walking speed in smoke of each subject of a population, a speed could be randomly generated from a normal distribution with a mean from Equation 63.12 and standard deviation of 0.125. A difficulty when considering individuals starting to walk in clear air and then entering smoke is that it is not known whether speed in smoke is a fraction of the unrestricted speed (so that fast walkers in clear air walk fast in smoke). A suggested approach is to take the unrestricted starting speed in clear conditions as a mean of 1.2 m/s with a standard deviation of +/- 0.15 m/s then reduce the speed of each person according to Equation 63.12. The Mont Blanc tunnel incident study provides some validation of the predicted effects of smoke density on walking speed [24], and a further study has examined these issues regarding walking speed in smoke and its variability as applied in evacuation models [56].

Composition and Toxic Effects of Smoke

Smoke comprises the total effluents from a fire and consists of two parts: the invisible vapor phase and the visible particulate phase. From a toxicological standpoint, all of the asphyxiant fire products occur in the vapor phase, whereas irritant products may occur in both phases. The particulate phase consists of solid and liquid particles covering a wide range of particle sizes, depending on the nature and age of the smoke. These particles may contain condensed liquid or solid irritant products; or irritant products including gaseous ones may be dissolved in liquid particles (as in acid mists) or be absorbed onto the surface of solid, carbonaceous particles. Particle size is of

great toxicological importance, since it determines how "deeply" particles penetrate into the respiratory tract and the patterns of subsequent deposition. Particles with a mean aerodynamic diameter of less than 5 μm are capable of penetrating deep into the lung, whereas larger particles tend to deposit in the nasal passages and upper airways. Generally speaking, the smoke from smoldering or nonflaming decomposition tends to consist mainly of small particles (less than 1 μm mean aerodynamic diameter, as in cigarette smoke) that are highly respirable. Smoke from flaming fires contains larger particles, particularly as it ages and the particles agglomerate; however, reports on fire victims usually record smoke penetration well into the lung. At very high concentrations, smoke deposits may physically clog the airways. This result could occur even with biologically inert particles at concentrations in excess of 5 mg/L and is more probable with irritant smoke particles that are likely to acutely inflame tissues. Apart from the toxic effects of these particles on the lung, they may also be important in increasing the thermal capacity of the smoke and increasing the likelihood of lung burns.

Tenability Limits and Fractional Irritant Concentrations for Sensory Irritants

The previous section considered assessment of the effects on escape capability and walking speed of exposure to non-irritant and generic "averagely irritant" smoke evolved from typical compartment fires involving mixed fuels. Where the composition of the fire effluents in terms of individual irritant substances is known, and especially when they are know or estimated to contain significantly high concentrations of particularly irritant substances, such as acid gases, then it can be important to assess the effects in terms of the Fractional Irritant Concentration (FIC) for sensory irritants.

$$\mathrm{FIC} = \mathrm{FIC}_{\mathrm{HCl}} + \mathrm{FIC}_{\mathrm{HBr}} + \mathrm{FIC}_{\mathrm{HF}} + \mathrm{FIC}_{\mathrm{SO_2}} + \mathrm{FIC}_{\mathrm{NO_2}} + \mathrm{FIC}_{\mathrm{CH_2CHO}} + \mathrm{FIC}_{\mathrm{CH_2O}} + \sum \mathrm{FIC}_x \quad (63.11)$$

As described in Chap. 62, the immediate effects of exposure to sensory irritants occur over a range of increasing severity from mild eye and respiratory tract irritation to severe pain and breathing difficulties with no obvious threshold levels for different effects. The severity of signs and symptoms is approximately proportional to the logarithm of the exposure concentration. A model relating rate of uptake at the epithelial surface with a concentration-related rate of removal or detoxification has been found to provide a good prediction of the development time and severity of effects on the upper respiratory tract [57]. For humans the eye and upper respiratory tract effects are almost instantaneous and maximal within a few seconds of exposure at painfully irritant exposure concentrations, followed within a short period by lacrimation, mucus secretion and large airway effects including bronchoconstriction and chest pain.

Although there is no specific threshold, for practical application to ASET calculations, two threshold concentration endpoints may be calculated for sensory irritants:

- A concentration capable of seriously impairing escape capability and movement speed.
- A concentration capable of causing incapacitation, such that the subject effectively cannot move.

Table 63.6 shows proposed threshold concentrations for use in ASET calculations (SFPE escape impairment and SFPE incapacitation), compared to threshold concentrations for different endpoints proposed for ISO 13571 and the US EPA Acute Exposure Guidelines. The threshold concentrations proposed here for and in BS7899-2 [58] for design application have been suggested by the authors as concentrations of common fire irritants likely to severely affect escape capability in most humans (escape impairment), while it is proposed that exposure to the higher concentrations shown in the second column is likely to be so painful and cause such severe breathing problems as to effectively incapacitate exposed subjects. As described in Chap. 62, it is difficult to determine threshold levels of human subjects because direct

measurements cannot be made for ethical reasons, and most experimental work has been carried out using animals, mostly rodents. There are, therefore, uncertainties in extrapolating from the existing data to predict the concentrations likely to affect average human subjects. There are also further uncertainties relating to the distribution of sensitivities in the human population. Taking into account the existing data and the fact that effects are on a logarithmic scale of severity, it is considered that a significant proportion of the population are likely to suffer impairment of escape capability at concentrations down to approximately 0.3 × of those affecting the average person, but also that a significant proportion may be able to tolerate twice or even three times that concentration. Thus for HCl, the proposed concentration for escape impairment of the average person (i.e., half the population) is 200 ppm, but some people may be impaired at 60 ppm and others may be able to escape through approximately 400–600 ppm.

For the ISO 13571 guidance documents on assessment of toxic fire hazards [21], a considerably less conservative endpoint of incapacitation for the average person is proposed (which is 1000 ppm for HCl). However, for both here (SFPE) and in ISO13571 more conservative design limits are recommended to allow for sensitive members of the exposed population, such as a design FED of 0.3 for the general population or even 0.1 for particularly sensitive groups (such as for those in health-care premises). For the proposed (SFPE) guidance this would result in a limiting HCl concentration of 60 ppm to avoid escape impairment in the majority of the exposed population. The Acute Exposure Guidelines limits [59] for immediate impaired escape capability and long-lasting adverse health effects (AEGL-2) for exposures of up to 10 min already include provision for sensitive sub-populations, so that for example the proposed limit for HCl of 100 ppm is close to the adjusted SFPE guidance concentration but somewhat more conservative than the ISO 13571 level, which is closer to the AEGL-3 "life threatening concentrations" for 30-min exposures.

Since fire effluents contain a mixture of irritants, it is necessary to consider how they interact in combination. Based on the data reviewed in Chap. 62 and Reference [57], it is currently recommended that they should be considered additive. The overall FIC for an irritant mixture is then as follows:

$$\begin{aligned} \mathrm{FIC} = {} & \mathrm{FIC_{HCl}} + \mathrm{FIC_{HBr}} + \mathrm{FIC_{HF}} \\ & + \mathrm{FIC_{SO2}} + \mathrm{FIC_{NO2}} \\ & + \mathrm{FIC_{CH2CHO}} + \mathrm{FIC_{CH2O}} \\ & + \Sigma \mathrm{FIC_x} \end{aligned} \tag{63.12}$$

Where $\Sigma \mathrm{FIC_X}$ = FICs for any other irritants present.

For each term the numerator is the exposure concentration of an irritant present at any time during an exposure, and the numerator is the concentration predicted to cause impaired escape capability (with use of the SFPE values recommended with an FED factor of × 0.3 to allow for sensitive individuals). Since these are intended to represent immediate sensory effects, they would be expected to ameliorate if the exposure concentrations decreased (for example if, a subject moved out of a contaminated area).

For smoke atmospheres containing significant concentrations of the acid gases and organic irritants, it is also important in the application of egress calculations to consider the effects on the walking speed of escaping occupants at concentrations below those in the SFPE Incapacitation column of Table 63.6. Between zero and the concentration causing incapacitation, there will be a relationship between the irritancy of the smoke and walking speed (as demonstrated by Jin [53]). In order to provide some indication of possible effects on walking speed between these limits, an expression has been developed for any irritant based on the concentration estimated to be very painful [16]. The model is based on a concept that at low concentrations an increase in irritancy will have a relatively minor effect as does smoke (e.g., walking speed in 10 m visibility smoke should be the same as in 100 m visibility smoke). There is, then, a middle range over which an increase in irritancy is likely to have a large effect on walking speed. Then a point occurs where walking is slow and further increases in irritant concentration have less incremental effect. This concept is illustrated in

Table 63.6 SFPE/BS7899-2, ISO13571 and AEGL, guidelines for escape impairment and incapacitation

	SFPE escape impaired	SFPE Incapacitation	ISO 13571 Incapacitation	SFPE 30-min lethal	AEGL-2 10 min escape impairment	AEGL-3 30 min life threatening
HCl	200	900	1000	3800	100	210
HBr	200	900	1000	3800	100	250
HF	200	900	500	2900	95	62
SO_2	24	120	150	400–1400	0.75	30
NO_2	70	350	250	63	20	25
NO	–	>1000	–	~1000	–	–
CH_2CHO (acrolein)[a]	4	20	30	150	0.44	2.5
HCHO (formaldehyde)[a]	6	30	250	750	14	70

[a]where the concentrations of acrolein and formaldehyde (or other important irritants) are unknown, a term derived from smoke density 0.5 OD/m may be used as an indication of irritancy likely to impair escape efficiency

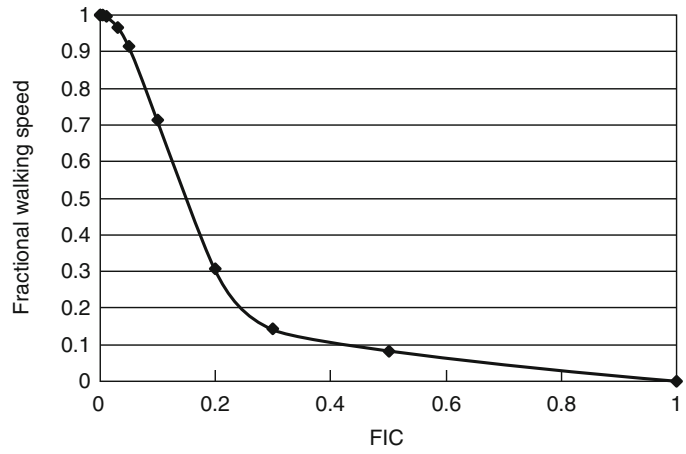

Fig. 63.17 Estimated relationship between fractional walking speed and FIC for a sensory irritant

Fig. 63.17, which shows a general case for the effect of exposure to any irritant gas or mixture of irritant gases on fractional walking speed. The *x*-axis show the fractional irritant concentration (FIC) where FIC = 1 represents incapacitation (e.g., 1000 ppm HCl).

Unlike the situation for nonirritant smoke, the curve reaches a fractional speed of zero when FIC is 1.0 because painful effects on vision and breathing are predicted to be of sufficient severity to cause incapacitation and cessation of effective escape movements. The expression for the curve shown in Fig. 63.17, which can be applied to any individual irritant compound, or to the fractional irritant concentrations for a mixture of compounds, is given by

$$F_{wvirr} = \frac{\left(e^{-(1000x/b)^2}\right) + (-0.2x + 0.2)}{1.2} \quad (63.13)$$

where

F_{wvirr} = Fractional walking speed (1 = normal walking speed of 1.2 m/s)

$b = 160$

x = FIC

The overall effect of exposure to an irritant smoke on walking speed (F_{wv}) would then be given by

$$F_{wv} = 1 - (1 - F_{wvsmoke}) - (1 - F_{wvirr}) \quad (63.14)$$

where

F_{wv} = Overall fractional walking speed (1 = normal walking speed of 1.2 m/s)

$F_{wvsmoke}$ = Fractional walking speed due to smoke effects on visibility

F_{wvirr} = Fractional walking speed due to irritant effects for irritant compounds 1 to n

Post-Exposure Lung Inflammation and Survival

In addition to incapacitating effects of sensory irritation, affecting escape capability, a proportion of inhaled irritant gases and particulates penetrates to the deep lung, and when a sufficient exposure dose is accumulated this can lead to inflammatory processes which can be fatal over periods of several hours to several days after exposure (see Chap. 62 and References [57, 60]). The exposure dose considered likely to cause death in an average exposed human subject is estimated as the rat LCt_{50} exposure for a 30-min exposure and 14-day post-exposure observation period. A guide to exposure doses of common irritant gases likely to cause incapacitation at the scene or death following exposure is given in Table 63.7 (SFPE exposure doses) These are not intended as design limits but for estimates of the extent to which post-exposure deaths from lung edema and inflammation are likely to occur. The 30-min AEGL-3 values shown in Table 63.6 are for concentrations above which it is predicted that the general population, including susceptible individuals, could experience life-threatening adverse health effects or death. When these are expressed as exposure doses and compared with the SFPE levels in Table 63.7 it is evident that the AEGL-3 exposure dose limits for this endpoint are much more conservative. The appropriate choice of limits to use would depend upon the application. Following exposures of primates and rodents to fire effluents, signs of post-exposure inflammatory effects on the lung were minor up an apparent threshold above which effects were severe [60].

Table 63.7 Exposure concentrations and exposure doses for incapacitation and lethal lung damage

Gas	SFPE exposure doses predicted to be lethal to half the population (ppm · min)	AEGL-3 30-min life-threatening exposure doses (ppm · min)
HCl	114,000	6300
HBr	114,000	7500
HF	87,000	1860
SO_2	12,000	900
NO_2	1900	750
NO	~30,000	75
CH_2CHO (acrolein)[a]	4500	2100
HCHO (formaldehyde)[a]	22,500	

[a]where the concentrations of acrolein and formaldehyde (or other important irritants) are unknown, a term derived from smoke density 90 OD/m.min may be used as an indication of lethal organic irritant exposure dose

The fraction of a lethal dose (FLD) for each irritant is calculated as the ct product exposure dose during a period in the fire (e.g., in ppm · min) expressed as a fraction of the lethal exposure dose. The lethal effects of the different irritants are assumed to be additive on the same basis as the irritant effects, so that the total FLD_{irr} for each time period is given by Equation 63.15:

$$FLD_{irr} = FLD_{HCl} + FLD_{HBr} + FLD_{HF} + FLD_{SO_2} + FLD_{NO_2} + FLD_{CH_2CHO} + FLD_{HCHO} + \Sigma FLD_x \quad (63.15)$$

where ΣFLD_x = FLDS for any other irritants present.

The FLD_{irr} for short periods of time during the fire are summed until the FLD_{irr} reaches unity, when it is predicted that a lethal dose has been inhaled.

Asphyxiation by Fire Gases and Prediction of Time to Incapacitation

Asphyxiant gases cause incapacitation mainly by effects on the central nervous system and, to some extent, the cardiovascular system [37].

In general, time to incapacitation and its severity are predictable in that signs are minimal until a critical dose has been inhaled, when a few seconds of intoxication is followed by a sharp decline into loss of consciousness [61, 62]. Most asphyxiant gases produce their effects by causing brain tissue hypoxia [37, 38]. Since the body possesses powerful adaptive mechanisms designed to maximize oxygen delivery to the brain, it is usually possible to maintain normal body function up to a certain dose of asphyxiant, and the victim is often unaware of the impending intoxication. Once a point is reached where normal function can no longer be maintained, deterioration is rapid and severe—beginning with signs similar to the effects of severe alcohol intoxication, consisting of lethargy or euphoria with poor physical coordination, and followed rapidly by unconsciousness and death if exposure continues [38, 62].

Asphyxiant Fire Products

The two major asphyxiant gases in fires are (1) carbon monoxide (CO) and (2) hydrogen cyanide (HCN). Carbon monoxide is always present to some extent in all fires, irrespective of the materials involved or the stage (or type) of fire, so that there is almost always some degree of risk of asphyxia from CO exposure [63]. Hydrogen cyanide is always present to some extent when nitrogen-containing materials are involved in fires. These include materials such as acrylics, polyurethane foams, melamine, polyamide, and wool, which are likely to be involved to some extent in most fires in buildings. Hydrogen cyanide is likely to be present at high concentrations in underventilated (vitiated) fires and especially in large postflashover fires. Unlike carboxyhemoglobin, which is routinely measured in the blood of fire victims, blood cyanide is often not measured. However, it has been detected at high concentrations in the blood of some fire victims, particularly when blood samples have been taken immediately after exposure [64]. In addition, low concentrations of oxygen (less than 15 %) [65] and very high concentrations of carbon dioxide, CO_2 (greater than 5 %), can have asphyxiant effects [66].

Carbon Monoxide

Carbon monoxide combines with hemoglobin in the blood to form carboxyhemoglobin (COHb), which results in a toxic asphyxia because it reduces the amount of oxygen supplied to the tissues of the body, particularly brain tissue. Tissue oxygen supply is reduced because the amount of hemoglobin available for the carriage of oxygen (in the form of oxyhemoglobin) is reduced and also because the ability of the remaining oxyhemoglobin to release oxygen to the tissues is impaired (due to a leftward shift of the oxygen dissociation curve). Carbon monoxide also replaces oxygen in the myoglobin in muscle, and CO entering cells has some inhibitory effect on cellular oxygen metabolism. The effects of CO in fires is reviewed in Purser [67].

The affinity of hemoglobin for CO is extremely high, so that the proportion of hemoglobin in the form of carboxyhemoglobin increases steadily as CO is inhaled. The acute toxicity of CO, therefore, depends mainly on the accumulated dose of carboxyhemoglobin, which is expressed in terms of the percentage of total hemoglobin in the form of carboxyhemoglobin (percent COHb)[31].

There is little doubt that CO is the most important asphyxiant agent formed in fires. In the Strathclyde pathology study [64] lethal levels (>50 %COHb) were found in 54 % of all fatalities, while some 69 % of fatalities had carboxyhemoglobin levels capable of causing incapacitation (>30 %COHb). Incapacitating levels of carboxyhemoglobin are also common in victims surviving immediate fire exposure. Carbon monoxide is, therefore, particularly important because of the following reasons:

1. It is always present in fires, often at high concentrations.
2. It causes confusion and loss of consciousness, thereby impairing or preventing escape.
3. It is the major ultimate cause of death in fires.

To understand the effects of CO exposure on fire victims and to predict the likely consequences of a particular exposure, it is essential to know a number of features of CO intoxication. (To some extent these apply to an evaluation of the toxicity of any fire product.) It is necessary to take the following steps:

1. Determine which types of toxic effects occur at different dose levels.
2. Determine the concentration/time relationships of these toxic effects, whether they occur immediately or some time after exposure, and whether the effects of a short high-concentration exposure are the same as those of a longer, low-concentration exposure.
3. Quantify the parameters that determine the rate of uptake and removal of CO from the body.

Some information on these points is available from accidental exposures and low-level experimental exposures in humans [31], and data are available on the symptoms experienced in humans at various carboxyhemoglobin concentrations at rest [31, 65, 68]. Loss of consciousness is predicted at approximately 40 %COHb, but can occur at lower levels (~30 %COHb) in physically active subjects or more susceptible resting subjects, and lower levels can be dangerous for subjects with compromised cardiac function [31]. Death is predicted at COHb concentrations of 50–70 %COHb, [54, 57, 58, 65, 69]. Survival is rare in subjects with blood levels exceeding 50–60 %COHb (see Table 63.4) and 50 %COHb is usually considered as an average lethal level. It has been suggested that death can occur at lower concentrations in susceptible subjects [31, 70]. The severe incapacitation caused by high-level exposures, such as those encountered in fires, has been studied experimentally in animals [37, 62]. The effects of experimental exposures on cynomolgus monkeys are shown in Fig. 63.18 in terms of physiological parameters (respiration, cardiovascular parameters, and brain electroencephalogram or EEG) monitored in sedentary animals sitting in chairs, and in Fig. 63.13, where free-moving animals were trained to perform a behavioral task designed to simulate some aspects of the escape maneuvers of human fire victims (i.e., tasks involving bodily movements with a certain amount of exercise, requiring the use of coordinated movements and the application of psychomotor skills).

Table 63.8 summarizes findings on the relationship between inhaled CO dose expressed as %COHb and symptoms in humans and primates.

The first important characteristic of CO poisoning illustrated by these experiments is that CO uptake and intoxication are extremely insidious. During the early stages as the carboxyhemoglobin concentration builds up gradually in the blood the effects are minimal. Thus Fig. 63.18 shows no detectible changes in physiological parameters until the end of the exposure when the COHb concentration approached 40 %. In active animals the first minor signs of behavioral performance deficits did not occur until concentrations of 15–20 %COHb were achieved. Similar results have been obtained in humans, where O'Donnel et al. [72] could find no effects on psychomotor performance at levels of up to 12 %COHb, and Stewart et al. [68] reported the first symptoms (consisting of a headache) to occur at 15–20 %COHb, while objective tests at these levels showed only minor deficits in behavioral performance.

Another major characteristic of asphyxia shown clearly by the animal experiments is that when significant effects do occur, their onset is sudden and the degree of incapacitation rapidly becomes severe, so that by the time a victim is aware that he or she is affected effective action is probably not possible. Thus, Fig. 63.18 shows the physiology of a monkey passing from a normal state to unconsciousness within a few minutes after 25 min of exposure, with decreased respiration, a severe decrease in heart rate, and greatly increased slow-wave EEG activity (indicative of cerebral depression). For active animals there was a sudden rapid decline in behavioral task performance accompanied briefly by signs similar to severe alcohol intoxication, which led rapidly to a state of deep coma.

These findings may explain why deaths from CO derived from defective heating appliances are so common. Survivors of such situations often report that they, or other victims who died, experienced headaches or nausea, but had

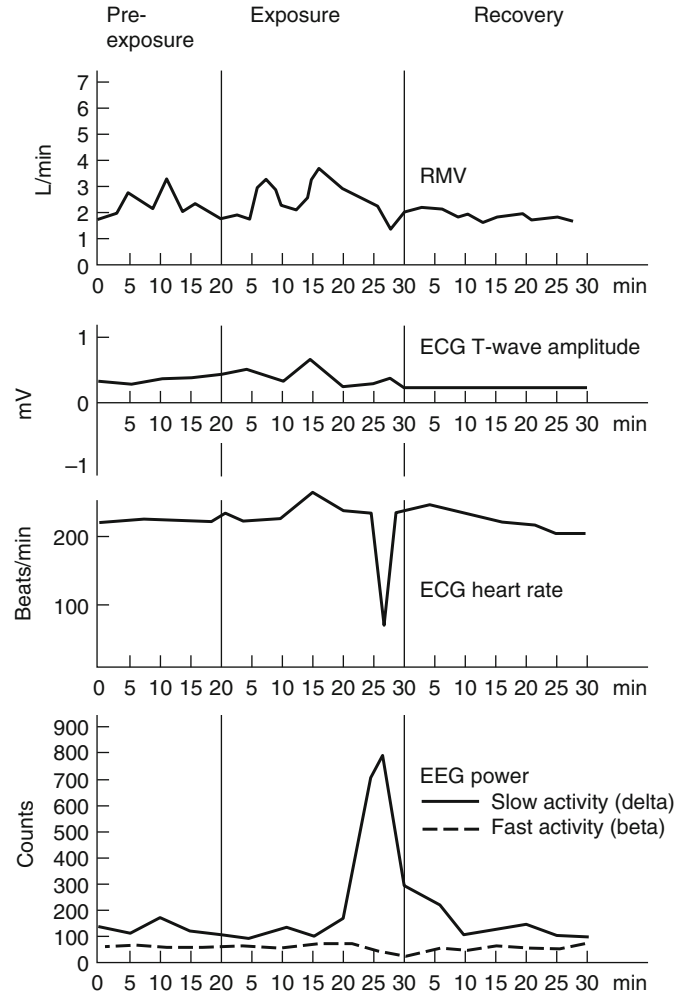

Fig. 63.18 Physiological effects of an atmosphere containing CO (1850 ppm)—wood pyrolyzed at 900 °C [61]

no idea of the cause, so they did not attempt to leave the area until overcome by fumes [73].

During the early stages of incapacitation the main effects appear to be on motivation and psychomotor ability, with a tendency for the victim to sleep if left undisturbed [62]. Under these conditions one might expect a subject, if alerted by a sudden noise such as of breaking glass (often reported by fire survivors), to "sober up" and awake sufficiently to make an escape attempt. However, such a victim is likely to fail for three reasons.

1. This stage is rapidly followed by unconsciousness and coma.
2. Active subjects are seriously affected by carboxyhemoglobin concentrations that have only minor effects on sedentary subjects. Thus, while sedentary primates were often unaffected at carboxyhemoglobin levels of up to 40 %, those engaged in light activity were seriously affected at carboxyhemoglobin levels in the 25–35 % range [62]. Similarly, in one study of humans, although a sedentary subject could perform such tasks as writing, even at the exceptionally high level of 55 % carboxyhemoglobin, the subject collapsed and became unconscious immediately when attempting to rise and walk [74]. Therefore, a victim in a bed or chair attempting to escape not only would be in danger of a rapid collapse due to continued CO uptake, but also even if no further uptake occurred, the ability

Table 63.8 Classical relationship between carboxyhemoglobin concentration and signs exhibited in humans and non-human primates

Blood saturation %COHb	After Stewart [31]	After Sayers and Davenport [71]	After Purser [61, 62, 67] (non-human primates)
0.3–0.7	Normal range due to endogenous production		
1–5	Increase in cardiac output to compensate for reduction in oxygen carrying capacity of blood (heart patient may lack sufficient cardiac reserve		
5–9	Exercise tolerance reduced, visual light threshold increased, less exercise required to induce chest pains in angina patients	Minimal symptoms <10 %	
16–20	Headache, abnormal visual evoked response, may be lethal for patients with compromised cardiac function	Tightness across forehead and headache experienced 10–20 %	
20–30	Throbbing headache; nausea; abnormal fine manual dexterity	Throbbing headache	
30–40	Severe headache; nausea and vomiting; syncope (fainting)	Severe headache; generalized weakness, visual changes; dizziness, nausea, vomiting, and ultimate collapse	30 % caused confusion, collapse and coma in active animals during 30 min exposures with nausea after
40–50		Syncope, tachycardia (rapid heartbeat) and tachypnoea (rapid breathing)	40 % caused coma, bradycardia (slow heartbeat), arrhythmias, EEG changes, in resting animals during 30-min exposures
50+	Coma; convulsions	Coma and convulsions	
60–70	Lethal if not treated	Death from cardiac depression and respiratory failure	

to perform even light work or exercise would be severely impaired. Even the simple act of rising from a horizontal to an upright position may precipitate loss of consciousness.

3. The rate of uptake of CO depends on the respiration (respiratory minute volume) and, hence, the activity of the subject. When the subject becomes active, the blood carboxyhemoglobin is, therefore, likely to increase rapidly to an incapacitating level.

Another issue is the distribution of sensitivities to collapse from CO intoxication in the exposed population during escape from a fire. The range of 30–40 %COHb for collapse in Table 63.8 is for average healthy adults. Some individuals are known to be more sensitive and a proportion of the population may be able to tolerate somewhat higher exposures. Although there are not definitive studies of sensitivity distributions, based upon the information available, the distribution of sensitivity to collapse at different inhaled %COHb ranges is considered likely to resemble that suggested in Fig. 63.19. The shape of the distribution reflects the finding that a small fraction of the population is likely to be at risk from collapse at low %COHb concentrations in the 5–20 %COHb range, while most subjects are likely to collapse at between 30 and 40 %COHb, but very few are likely to even survive exposure above 50 % COHb.

A Model for the Prediction of Time to Incapacitation by CO in Fires

Incapacitation by CO depends on a dose accumulated over a period of time until a

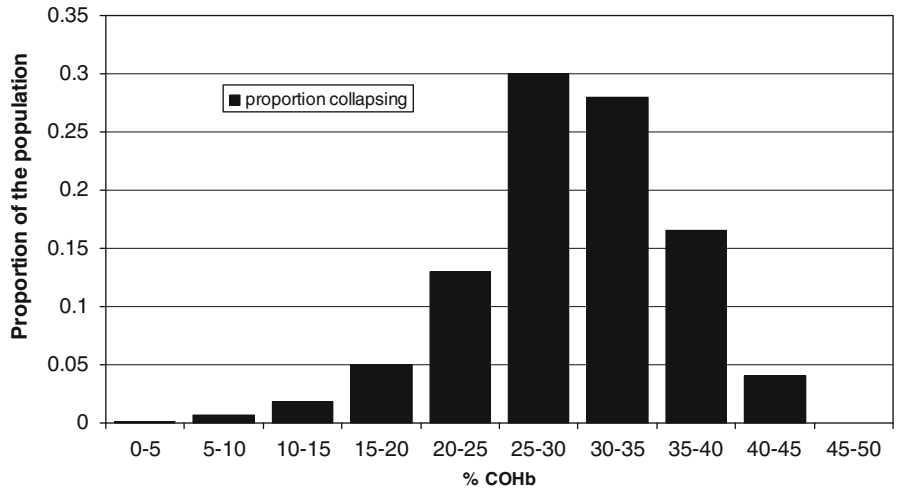

Fig. 63.19 Suggested population distribution of sensitivities to collapse from CO intoxication

carboxyhemoglobin concentration is reached where compensatory mechanisms fail and collapse occurs. To predict time to incapacitation of fire victims due to CO it is necessary to know the carboxyhemoglobin concentrations at which incapacitation is likely to occur and the rate of uptake of CO so that the time to achieve this concentration can be calculated. The carboxyhemoglobin concentrations likely to cause incapacitation depend on the activity of the victim and should be similar to the concentrations causing incapacitation in primates at similar levels of activity [62].

Since CO is both inhaled and excreted via the lungs, the rate of uptake depends on the difference between the CO concentration in the blood, W, and that in the inhaled air, C, and is an exponential function described by the general equation (Equation 63.6):

$$W = C\left(1 - e^{-tk}\right) \qquad (63.6)$$

where t is the time exposed and k is a constant determined by a number of factors, so that uptake is rapid initially but gradually levels off as uptake and removal from the blood reach equilibrium. This relationship is described fully by the Coburn-Forster-Kane (CFK) equation [34, 35], which takes into account a whole range of variables, including respiratory minute volume (V_E), body size, exposure duration, and parameters related to lung and blood physiology (see Appendix 2). When all these various factors are known, this equation enables accurate predictions of CO uptake to be made that agree well with experimental data [35, 75]. The uptake pattern for CO is illustrated in Fig. 63.12, which predicts time to achieve a potentially lethal blood CO concentration (50 %COHb) for a 70 kg human at rest (RMV 8.5 L/min) at two CO concentrations, 2200 and 840 ppm.

When the inhaled concentration is high compared to that in the blood as during short duration, high concentration exposures such as those that occur in flaming fires, the departure from linear uptake is not great as shown in Figs. 63.11 and 63.12 the deviation from Haber's rule ($W = C \times t$) is small. However, over long periods at lower concentrations, as equilibrium is approached, uptake deviates considerably from linearity. This effect is also illustrated in Chap. 62, Fig. 62.1, comparing uptake in rats, monkeys and humans. For the rats, which have a very high respiration rate in relation to their body size, CO uptake reaches non-linear, near saturation levels within a few minutes, whereas for resting humans with a lower respiration rate in

relation to body size, the near-linear phase of uptake is much longer.

Simple C · t Exposure Dose Method

The simplest method for estimating time to incapacitation for an exposure to CO is the C · t product exposure dose method. This method is derived from experimental animal exposure data and then applied to calculation models on the assumption that incapacitation or death occurs at fixed C · t product exposure doses, for any combination of concentration and exposure time. As illustrated in Fig. 63.12, this method works reasonably well for short exposures to high CO concentrations under specific exposure conditions, but makes no allowance for the effects of any physiological variables and especially respiration. For active macaque monkeys (approximately 4 kg bodyweight) the exposure dose for incapacitation was approximately 27,000 CO ppm · min [62]. For sedentary animals of the same body size (but at rest with a lower respiratory minute volume [the volume of air inhaled each minute: V_E]) the exposure dose to incapacitation was higher at approximately 48,000 ppm · min [61]. For moderately active juvenile baboons (approximately 7–10 kg bodyweight), the exposure dose to incapacitation was 34,250 ppm · min and for rats 33,900 ppm · min (both for 5 min exposure periods [76]). The apparent similarity between rats and baboons is coincidental, resulting from a combination of more rapid uptake approaching equilibrium in rats (as illustrated in Chap. 62, Fig. 62.1) and a higher tolerance to hypoxia than in primates. In practice, even over relatively short exposure periods, C · t ≠ K due to the non-linearity of the uptake curve, so that C · t for incapacitation was found to vary experimentally between 37,000 ppm · min at 10,000 ppm CO and 126,750 ppm · min at 1300 ppm CO. The C · t exposure doses for incapacitation and death in different species including humans at different levels of activity are shown in Table 63.9.

Basically, the C · t exposure dose for incapacitation in humans engaged in light-moderate activity (fast waking) while escaping from a building is predicted to be approximately 30,000–35,000 ppm · min, which is similar to that of lightly active baboons and macaques.

This C · t product exposure dose method is proposed for application to fire hazard calculations in ISO 13571 [21], with the proposed C · t exposure dose for incapacitation of 35,000 ppm · min intended to represent humans engaged in moderate physical activity with a V_E of 20 L/min. The advantage of this method is that it is extremely simple to use in a fire hazard modeling context, and it is considered to be valid for moderately active adult humans under the high CO concentrations and short exposure time scales usually occurring during fires (often a few minutes critical exposure period during flaming fires and seldom more than 60 min). A caveat is that for applications outside these limitations (such as application to children, resting adults, long exposure periods at low CO concentrations or other situations involving differences in the variables listed), more complex modeling methods are indicated and a simple default method recommended here, which allows of the important effect of activity level and V_E on CO uptake, is to calculate the actual uptake dose of CO with time as %COHb.

Table 63.9 *C · t* product exposure doses for incapacitation and death by CO for different species at rest and during light activity

	Incapacitation		Fatal	
	CO at rest ppm · min	CO light activity ppm · min	CO at rest ppm · min	CO light activity ppm · min
Human 70 kg	80,000–100,000	30,000–35,000	~110,000–240,000	~60,000–190,000
Baboon ~20 kg		34,000		
Macaque 3–4 kg	38,000–40,000	27,000		
Rat ~ 300 g	30,000–40,000	22,000–36,000	162,000	

Calculation of %COHb Using the Liner Uptake Stewart Model the Exponential Coburn Forster Kane Model

For short exposures at high concentrations when the blood concentration is well below saturation level, an approximate prediction of COHb concentration can be made assuming a linear relationship. Such an equation is derived from experimental human exposures by Stewart et al [69].

$$\%\mathrm{COHb} = \left(3.317 \times 10^{-5}\right)(\mathrm{ppm\,CO})^{1.036}(\mathrm{V_E})(t) \quad (63.16)$$

where
ppm CO = CO concentration (ppm)
V_E = Volume of air breathed per minute (L/min)
t = Exposure time (min)

Thus, for the examples shown in Fig. 63.12, which were calculated using the Coburn-Forster-Kane (CFK) equation [34], a concentration of 50 %COHb is predicted following a 1-h exposure to 2200 ppm CO, while the Stewart equation predicts 49 %COHb. However, for a 4-h exposure the CFK equation predicts 50 % COHb from 840 ppm, while the Stewart equation would predict 50 %COHb from 550 ppm over 4 h, or a concentration of 72 %COHb from 840 ppm.

Justification of the linear uptake relationship under high concentration/short exposure duration circumstances is illustrated by a series of primate exposures carried out over a 1000 to 8000 ppm concentration range. These experiments were performed using an active behavioral model [62], with the endpoint being loss of consciousness, which occurred at approximately 34 % COHb. The results are illustrated in Fig. 63.14 which shows time to incapacitation for different inhaled CO concentrations. At each concentration the inhaled dose (Ct product) required to produce incapacitation in ppm CO · min is constant as predicted by the linear uptake model of Haber's rule.

Accurate predictions of CO uptake can be made for a range of situations by using the CFK equation, provided that a number of variables are taken into account. For a particular individual the most important variable is V_E, which varies considerably depending on the level of activity of the subject. Figures for this variable and others can be obtained from standard reference data [77]. Figure 63.20, generated from these data, shows the calculated time to incapacitation (loss of consciousness) for a 70 kg human exposed to different CO concentrations at three levels of activity. The figure shows that the degree of activity can have a major effect on time to incapacitation. It must also be remembered that V_E

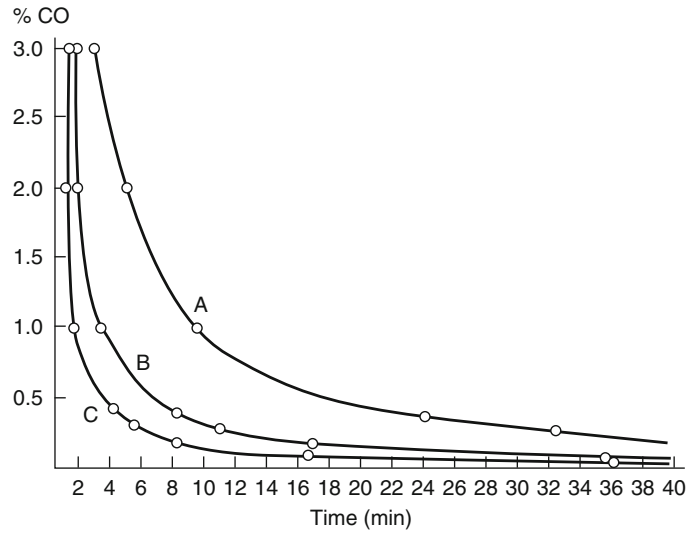

Fig. 63.20 Time to incapacitation by carbon monoxide for a 70 kg human at different levels of activity. *Curve A*—40 % carboxyhemoglobin V_E 8.5 L/min at rest sitting; *Curve B*—30 % carboxyhemoglobin V_E 25 L/min, light work (e.g., walking 6.4 km/h); *Curve C*—20 % carboxyhemoglobin V_E 50 L/min, heavy work (e.g., slow running 8.5 km/h, or for walking 5.6 km/h up a 17 % gradient)

per kilogram of body weight is greater for small subjects, which means that children will take up CO much more rapidly than adults and succumb much earlier, while uptake in small laboratory animals is even more rapid. An assumption made in these calculations is that the level of activity and hence the V_E remain constant during the exposure. In practice there is a tendency for the level of activity and ventilation to vary during the course of an exposure. During the early stages building occupants may be at rest or sleeping with a low V_E. Once alerted by the fire their V_E is likely to increase due to emotional concerns and increased physical activity such as walking to escape. Ventilation may then begin to decrease slightly as the point of incapacitation is approached. It is considered that with a model for predicting time to incapacitation (unconsciousness), errors due to reduced ventilation will be minor, since the primate experiments demonstrate that there is little change in V_E until the point of incapacitation. Once the subject becomes unconscious, the V_E and hence the rate of CO uptake will be considerably reduced, particularly if the subject was previously engaged in heavy work. It is, therefore, possible that for calculating time to death allowance could be made for a low V_E (~6 L/min) once incapacitation has occurred. Not making this allowance does err slightly on the side of safety.

Table 63.10 shows physical work rate, oxygen consumption and minute ventilation (V_E) for average adult humans engaged in different activities [67]. Different data would be needed for children or adults with bodyweights significantly different from 70 kg V_E depends primarily on the body size of the subject and the level of physical activity. Data can be obtained from physiology reference sources and Table 63.10. V_E also depends upon the concentration of inhaled CO_2. This effect is negligible at ambient CO_2 concentrations but is an important factor in fires, where the concentration can be as high as 10 % CO_2.

The rate of CO uptake increases approximately in proportion as V_E increases, however there is an upper limit for the rate of diffusion of CO from the air into the blood in the lungs, which is

Table 63.10 Work rate, oxygen consumption and minute ventilation for different activities (for ~70 kg Bodyweight)

Activity	Speed km/h	Work kcal/min	Work Watts	V_{O2} L/min STPD[a]	V_E l/m ATPS[b]

[b]ATPS = Ambient temperature and pressure saturated

represented as DL_{CO} expressed in mL/min/unit partial pressure of inhaled CO. This effect is not considered by the Stewart equation but is taken into account in the CFK equation. This means that at very high V_E levels the Stewart equation may somewhat overestimate the rate of CO uptake. Figure 63.21 compares the predictions of the Stewart and CFK equations in young adult males (70 kg bodyweight) for CO uptake expressed as %COHb calculated for CO exposure concentrations of 1000 and 4000 ppm at different V_E levels representing sedentary, light activity and fast walking. The Stewart predictions are linear, as are the CFK predictions for the first 20 min or so, but after this time the CFK predictions become more curved as %COHb begins to approach, equilibrium concentrations. For 1000 ppm CO the rates of uptake are similar for both calculation methods up to around 25 %COHb, but the CFK values then start to deviate from the linear Stewart model as the blood concentration tends to equilibrate, especially at the higher V_E level. For 4000 ppm CO, a concentration more typical of a serious exposure during a fire, the rates of uptake are very similar and almost linear for all three V_E levels up to around 30–40 %COHb at which dose loss of consciousness is predicted. For these calculations a variable expression for DL_{CO} was used :

$$DL_{CO} = (16.147 \times \ln(V_E)) - 16.05 \quad (63.17)$$

Where

DL_{CO} = CO mL/min/mmHg CO partial pressure at STPD

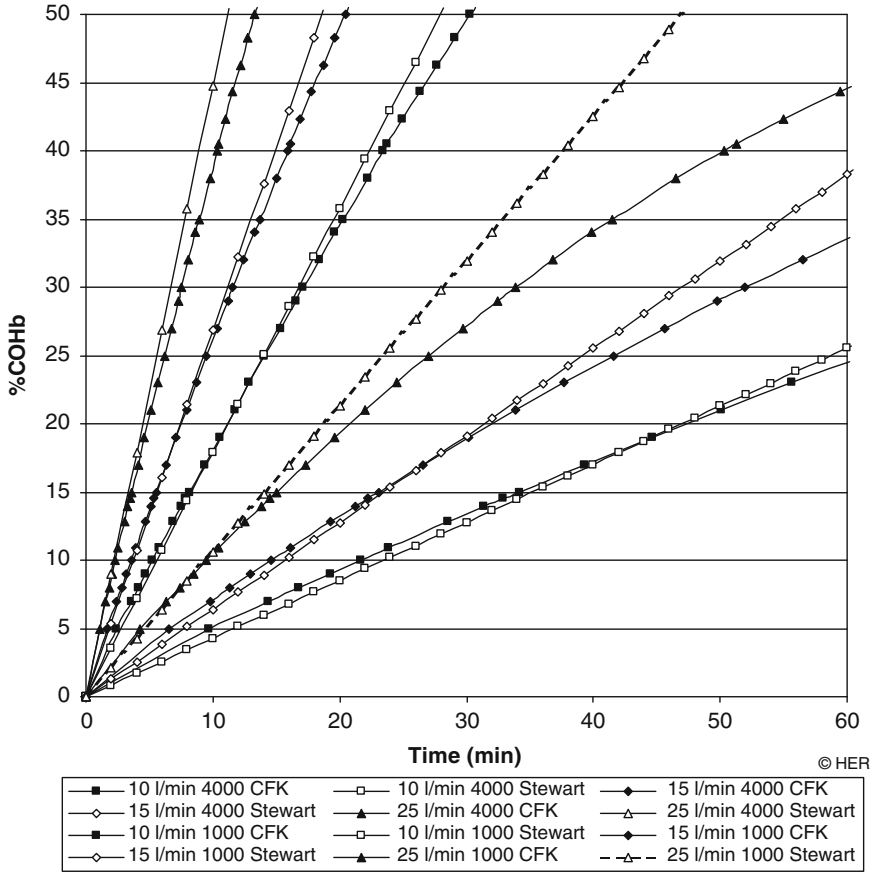

Fig. 63.21 Comparison of calculated CO uptake as % COHb using the Stewart and CFK equations for a 70 kg man (Blood volume 5621 mL, Hb 15.94 g/100 mL, DL_{CO} varies as Equation 63.17 at V_E 10, 15 and 25 L/min, CO 1000 and 4000 ppm)

These deviations illustrate that the rate of CO uptake is not a simple function of V_E. This limitation on the extent of increase in rate of CO uptake with increasing V_E has been allowed for to some extent with the V_{CO2} function, which is intended to be used as multiplier for the rate of CO uptake during exposure to combined CO and CO_2 mixtures in fire, allowing for the increase in V_E caused by the CO_2. As described in the section on CO_2, Equation 63.35 is used instead of Equation 63.33 to allow for these inefficiencies in uptake with increasing V_E.

The Stewart [69] and CFK [34] equations enable reasonably good predictions of time to incapacitation or death for short (less than 1 h) or long (greater than 1 h) exposures, respectively, to constant concentrations of CO in air. In fires, however, victims are exposed to concentrations of CO that change during the course of the fire. For smoldering fires the CO concentration may grow slowly and remain fairly constant over long periods, but for early flaming fires and many fully developed fires where the victim is in a remote location, the CO concentration may increase rapidly over a short period of time as in Fig. 63.22. It is, therefore, necessary to be able to apply the uptake models to situations where the CO concentration is not constant. For most situations, fluctuations in CO concentration do not present a problem since incapacitation depends on the total dose of CO inhaled, in the form of COHb, and is not affected by the immediate CO concentration. The COHb concentration is thus dependent on the average CO concentration over the period of exposure, and significant errors will not occur even if the CO concentration falls somewhat at certain stages of the exposure. Errors in predicting the COHb concentration are possible if the CO concentration drops dramatically toward the end of an exposure, or if it decreases moderately during a prolonged exposure of several hours duration, when COHb concentrations can approach equilibrium with the inhaled CO concentration. In this case a fall in CO may result in a decrease in COHb concentration. The basic rule to apply is that fluctuations are unlikely to cause the COHb concentration to deviate from that predicted by assuming the constant average concentration throughout, providing the CO concentration is on a rising trend, is stable, or is well above the equilibrium concentration with the blood COHb.

Ct Product and Fractional Incapacitating Dose

Although the average CO concentration during a fire exposure can be used to predict COHb

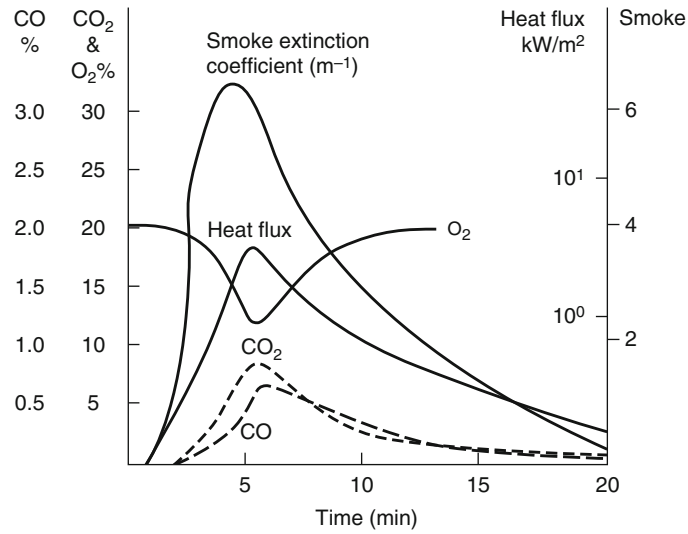

Fig. 63.22 Smoke, heat, and gases during single armchair room burn. Armchair is polystyrene with polyurethane cushions and covers. Room is 39 m^3 with open doorway. Gases measured in doorway at 2.1 m height [52]

concentration and time to incapacitation, another useful concept for predicting incapacitation or death is the relationship with concentration-time (Ct) product, which is a representation of CO "dose." In changing fire conditions the Ct product may be obtained by integrating the CO concentration/time curve. The dose inhaled may then be related to the dose required to cause incapacitation, and the fraction of an incapacitating dose at any time, t, may be calculated, incapacitation occurring when the fractional dose reaches 1.0. Since the Ct "dose" actually represents the COHb concentration, the fractional dose would be better represented by the ratio of the COHb concentration at time, t, with the COHb concentration known to cause incapacitation or death, rather than by simple Ct product ratios. The Stewart equation [69] can be rewritten in the form of COHb ratios, requiring only a knowledge of the CO concentration and the exposure time, as follows:

$$F_{I_{CO}} = 3.317 \times 10^{-5}[\mathrm{CO}]^{1.036}(V)(t)/D \quad (63.18)$$

where

[CO] = Carbon monoxide concentration (ppm v/v 20 °C)

V = Volume of air breathed each minute (L)

t = Exposure time (minutes)

D = Exposure dose (percent COHb) for incapacitation

The following values may be taken for V and D. Other data for V may be taken from Table 63.10.

Activity level of subject	V_E(L/min)	D (percent COHb)
Resting or sleeping	8.5	40
Light work—walking to escape	25	30
Heavy work—slow running, walking up stairs	5	20

The suggested default case for escaping occupants would be that of light work.

This concept of Ct product fractional dose is also useful for predicting incapacitation and death from other fire products and combinations of products, as will be discussed later in this chapter.

CO Washout After Fires

For subjects rescued alive from a fire breathing air or oxygen the CO is gradually excreted via the lungs and the %COHb decreases according to a washout curve. A simple washout model is given by:

$$\%COHb_t = \%COHb_0 e^{-kt} \quad (63.19)$$

Where:

$\%COHb_t$ = %COHb after t minutes

$\%COHb_0$ = %COHb at start time

k = half life constant depending upon treatment and body size

The value of k depends upon the treatment (air, normobaric oxygen or hyperbaric oxygen) and the body size. Although the rate of excretion should be similar for adults, it is much more rapid in small children. The model can be applied to individuals by using a factor related to the ratio of basal metabolic rates in subjects with different body sizes, obtained from published data. The predictions for children from the model have been validated against half-life data obtained from incidents involving children. For different body sizes and treatments k was therefore estimated in terms of the ratio of basal metabolic rates (Table 63.11).

Hydrogen Cyanide

Hydrogen cyanide (HCN) has been measured in the blood of both fatal [78] and nonfatal [79] fire

Table 63.11 Values of half-life constant (k) for different treatments and body sizes

Body size and air mixture inhaled	k	Resting metabolic rate kcal/h/kg
70 kg adult on air	0.0026	1.12
70 kg adult on normobaric oxygen	0.0115	1.12
70 kg adult on 3 bar oxygen	0.0301	1.12
28 kg child	0.0167	1.63
14 kg child	0.0219	2.1

This and other CO washout modeling methods are described in Purser [67]

victims. However, in the Strathclyde fire fatality study high concentrations of hydrogen cyanide in the blood of victims were usually associated with lethal levels of carboxyhemoglobin, so that the role of hydrogen cyanide as a cause of incapacitation was difficult to determine [78]. It is also difficult to relate blood cyanide levels from samples collected after a fire to likely HCN exposure, since the dynamics of HCN uptake and removal from the blood are poorly understood [67, 80–82].

Although the ultimate effects of HCN exposure (consisting of unconsciousness with cerebral depression) are similar to those produced by CO, the pattern of toxicity during the early stages is very different. Whereas the onset of CO intoxication is slow and insidious, HCN intoxication tends to be rapid and dramatic. The physiological signs of incapacitation produced in monkeys by an atmosphere containing HCN are shown in Fig. 63.23 [80] As with CO the immediate effects were relatively minor, consisting of a slightly raised ventilation, but at some time during a 30-min exposure period there was a marked increase in respiration (hyperventilation), the RMV increasing up to four times. Within 1–5 min of the start of this episode of hyperventilation the animals lost consciousness. This was accompanied by EEG signs of severe cerebral depression; loss of muscle tone; and marked

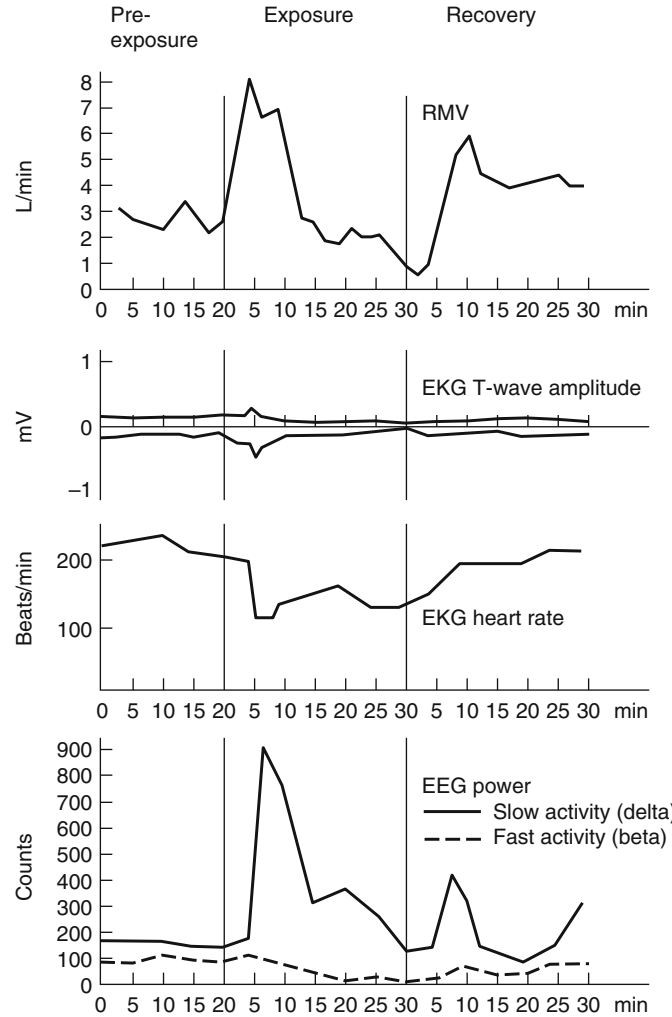

Fig. 63.23 Physiological effects of an atmosphere of HCN gas (147 ppm) on monkeys [80]

effects upon the heart and circulation, including a significant decrease in heart rate, arrhythmias, and changes in the EKG waveform indicative of cardiac hypoxia. This hyperventilatory episode was caused by the stimulatory effects of cyanide on respiration. Since the cyanide was taken in via inhalation, a positive feedback situation resulted, and inhaled cyanide caused hyperventilation that increased the rate of HCN uptake and in turn provided a stronger hyperventilatory stimulus. Once the animals became unconscious the hyperventilation subsided and they went into a slow decline for the remainder of the exposure. This led eventually to a cessation of breathing in some cases, which would have proved fatal if exposure had not been terminated. It was therefore possible for an animal to survive a continuous HCN exposure for some time after the point of incapacitation. Once exposure was terminated the recovery was rapid and almost complete within 5–10 min.

The pattern of incapacitation for HCN is somewhat different from that produced by CO in that the effects occur more rapidly, as unlike CO, HCN is not held almost exclusively in the blood but is carried rapidly to the brain [83]. Although the accumulation of a dose is one factor, the most important determinant of incapacitation with HCN appears to be the rate of uptake, which in turn depends on the HCN concentration in the smoke and the subjects' respiration. Thus in the animal experiments [37, 80], it was found that at HCN concentrations below approximately 80 ppm the effects were minor over periods of up to 1 h, with mild background hyperventilation. At concentrations above 80 ppm up to approximately 180 ppm, an episode of hyperventilation with subsequent unconsciousness occurred at some time during a 30-min period; there was a loose linear relationship between HCN concentration and time to incapacitation. Above 180 ppm the hyperventilatory episode began immediately with unconsciousness occurring within a few minutes.

The exact reason is not known but one factor appears to be related to the relationship between the rate of uptake of HCN and the dynamics of its distribution between different body fluid compartments. This results in a spike in systemic plasma cyanide resulting from the hyperventilatory episode. This may deliver a pulse of cyanide to the heart and brain resulting in collapse before the cyanide fully perfuses other body organs and tissues so that the concentration evens out throughout the body. Another likely contributory cause of loss of consciousness during the hyperventilatory episode is a transient hypocapnia (lower then normal level of carbon dioxide in the blood) and respiratory alkalosis. During this episode ventilation increases by approximately a factor of three, which will result in a temporary respiratory alkalosis with a reduction in blood P_{CO2}. The pH change results in a left shift in the oxygen dissociation curve and the P_{CO2} reduction in a reduced cerebral blood flow, effects known to result in syncope (loss of consciousness) in humans [84]. The effect is likely to be enhanced by the direct effects of cyanide on heart rate and cardiac output, as well as direct effects on cerebral metabolism. The combined result is the reported transient loss of consciousness. The loss of consciousness then results in a decrease in respiration and circulation, enabling P_{CO2} and pH to recover towards normal levels, while the direct effect of cyanide on metabolism results in a metabolic acidosis and increased cerebral blood flow. This may be the reason that animals are seen to make some recovery during this stage of an exposure, followed by a slow decline until exposure is terminated.

Data on human exposures to HCN are limited but Kimmerle [65] does quote some approximate data showing a similar effect in humans, with incapacitation occurring after 20–30 min at 100 ppm HCN and after 2 min at 200 ppm, death occurring rapidly at concentrations exceeding approximately 300 ppm (Table 63.12).

Other data suggest that human victims might be able to survive higher concentrations of HCN for shorter periods. McNamara [87] suggests 539 ppm as the 10-min LC_{50} for humans, and there is a report of a survival from an accidental exposure to 444 ppm [85]. An experimental human exposure to 530 ppm HCN was survived without immediate symptoms for 1.5 min, although a dog exposed at the same time suffered

Table 63.12 Incapacitation by inhaled hydrogen cyanide

HCN (ppm)	Species and effects	Author
100	Loss of consciousness after 23–30 min in primates and humans	Purser [80], Kimmerle [65]
200	Loss of consciousness after approximately 2 min	Purser80, Kimmerle [65]
300+	Death occurs "rapidly"	Kimmerle [65]
444	A man survived an accidental exposure	Bonsall [85]
530	A man, Barcroft, survived a 1.5 min exposure—his dog exposed at the same time died	Barcroft [86]
539	Suggested 10-min LC_{50} in humans	McNamara [87]
1000	One breath may cause loss of consciousness	Purser

respiratory arrest [73]. Dogs are known to be particularly susceptible to cyanide poisoning [87], but it does seem likely that, to some extent, with HCN (as with CO) body size influences time to incapacitation, and that a human would be able to tolerate exposure to a given concentration longer than a cynomolgus monkey. With HCN and CO, physical activity would be likely to cause more rapid uptake in adults, and uptake would be more rapid in children because of their smaller body size. The primate data, therefore, seem to provide a reasonable model for humans, possibly erring slightly on the side of safety.

The differences between CO and HCN in terms of the relationship between inhaled concentration and time to incapacitation are illustrated in Fig. 63.14. Whereas CO gives a smooth curve with incapacitation occurring at a constant *Ct* product of approximately 27,000 ppm · min for all CO concentrations, the almost linear portion of the HCN curve results in a *Ct* product of approximately 2000 ppm · min at 100 ppm HCN and 400 ppm · min at 200 ppm, with very rapid incapacitation at higher HCN concentrations. This deviation from Haber's rule (which predicts a constant *Ct* product) was recognized by Haber himself in 1924, when he stated that the *Ct* product for HCN depended on the exposure concentration [32]. The effect is to render concentrations in the range greater than 150 ppm more toxic than would be predicted from the effects of longer exposures to lower concentrations.

A Model for the Prediction of Time to Incapacitation by HCN in Fires

From these results it is possible to predict that HCN concentrations below a threshold concentration of approximately 80 ppm will have only minor effects over periods of up to 1 h.

From 80 to 180 ppm the time to incapacitation (unconsciousness) t_{ICN} will be between 2 and 30 min. For concentrations above approximately 180 ppm incapacitation will occur very rapidly (within 2 min). In order to derive an expression for calculating time to incapacitation as a function of inhaled HCN concentration a trend line has been fitted to the entire data set for the primate experiments. This includes data for exposures to HCN gas in air, HCN generated from thermal decomposition of polyacrylonitrile, HCN from thermal decomposition of rigid and flexible polyurethane foams, all in resting primates. These data are plotted in Fig. 63.24. The results are very similar for the pure HCN gas exposures and those to the decomposition product atmospheres for which HCN gas was the dominant toxicant although small amounts of other nitriles were also present and some CO from the polyurethane foams. Also shown in Fig. 63.24 are data for time to incapacitation in resting and exercising rats. Times to incapacitation in the resting rats for a given HCN concentration are somewhat longer than in the primates, but those for exercising rats are somewhat shorter, as would be predicted from the increased respiration and hence rate of HCN uptake, and higher metabolic demand, in the exercising animals.

In order to derive an expression for time to incapacitation for humans, it is considered that the monkey data provide the most useful model. Because the monkeys were much smaller animals than humans (approximately 4 kg versus

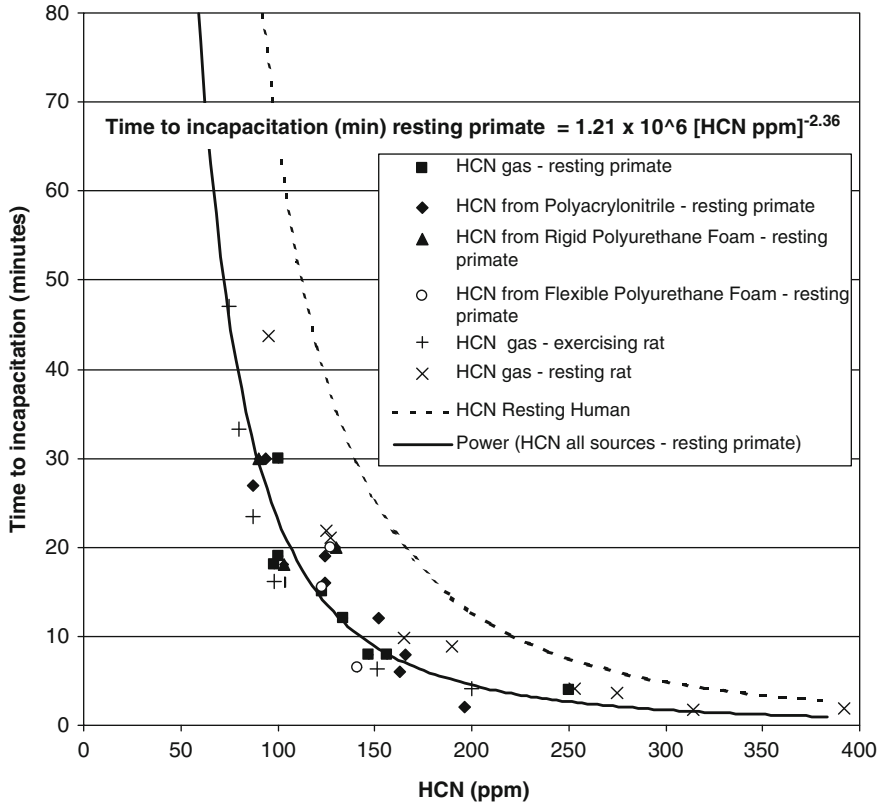

Fig. 63.24 Measured times to incapacitation as a function of HCN concentration in macaque monkeys, resting and exercising rats, and predicted for humans

70 kg for humans) at a given level of physical activity and respiration it is to predicted that the rate of uptake and therefore time to incapacitation would be somewhat shorter than for an adult human. Comparing the resting metabolic rates for monkeys and humans as a function of body size, it is estimated that the time required for a human to inhale the same dose as a monkey would be increased by approximately a factor of 2.83, although for a human infant the relationship would be approximately the same as for the monkey.

In practice, it is considered that time to incapacitation in the average adult human engaged in light physical activity (such walking to escape from a fire), would be similar to that in a resting monkey. On this basis it is proposed that for estimation of time to incapacitation for escaping humans for design purposes, the primate trend line expression should be used directly as follows:

$$t_{ICN} = \frac{1.2 \times 10^6}{[CN]^{2.36}} \tag{63.20}$$

Where:
t_{ICN} = time to incapacitation (minutes)
[CN] = Inhaled HCN concentration (ppm)

This exponential expression gives a reasonably good fit with the data (regression coefficient 0.84).

A more general expression for humans engaged in different levels of physical activity would take into account of the 2.83 metabolism factor and the level of respiration is:

$$t_{ICNg} = \frac{2.43 \times 10^7}{[CN]^{2.36} \times V_E} \tag{63.21}$$

Where:
t_{ICNg} = time to incapacitation (minutes)
[CN] = Inhaled HCN concentration (ppm)
V_E = respiratory ventilation (L/min)
2.43×10^7 is the trend line constant $1.21 \times 10^6 \times 2.83$ (ratio of basal metabolic rate kJ/h/kg bodyweight between monkey and human) $\times$ 7.1 L/min resting human V_E

This expression for humans is consistent with the limited human data available.

HCN could be particularly dangerous in fires due to its rapid "knockdown" effect, and low HCN levels in the 100–200 ppm range could cause fire victims to lose consciousness rapidly and, consequently, to die later as a result of accumulation of CO or some other factor. A small change in HCN concentration could also cause a large decrease in time to incapacitation; for example, doubling the concentration from 100 to 200 ppm could bring the incapacitation time down from approximately 22 min to approximately 4 min [65, 80].

Although this relationship should enable reasonable predictions to be made of time to unconsciousness for subjects exposed continuously to HCN, especially over the critical range between 80 ppm (below which incapacitation is unlikely over periods of up to 1 h) and 180 ppm (above which incapacitation will be rapid), real fires will involve exposures to changing concentrations. One method of predicting time to incapacitation or death would be to take the average concentration over the period of exposure. Although approximate times to incapacitation can be estimated with this method it is prone to error because of the departure from Haber's rule. In practice, since short exposures to high concentrations are more likely to cause incapacitation than longer exposures to lower concentrations, averaging the concentration tends to give longer estimates of time to incapacitation than would be expected. This method also does not include the concept of fractional dose. A better model would include some degree of weighting to allow for the enhanced effect of high concentration exposure and also enable incapacitation to be estimated in terms of *Ct* product fractional dose.

A method for estimating fractional dose to incapacitation has been developed for the rat by Hartzell et al. [39] based on this concept. In that model the *Ct* product over short periods of time is expressed as a fraction of the *Ct* product required to cause incapacitation or death at that concentration. The fractions for each short time interval are summed until the fraction reaches unity, which indicates incapacitation [39]. This approach should enable reasonable predictions of time and dose to incapacitation and death to be made, provided that the HCN concentration is stable or increasing (Hartzell et al. have found a good correspondence between calculated predictions and experimental data in rats). This approach can be used to derive a fractional dose model for humans based on the time to incapacitation equation (Equation 63.22), derived from primate and human data. The default expression recommended for fire engineering design applications uses the expression for resting primates as a predictor of active adult humans.

Dose to incapacitation = (ppm HCN)$(t_{I_{CN}})$

Therefore, for a short exposure time, t, to a given HCN concentration

$$F_{I_{CN}} = \frac{(\text{ppm HCN})(\text{t})}{(\text{ppm HCN})(t_{I_{CN}})} \tag{63.22}$$

where $F_{I_{CN}}$ is the fraction of an incapacitating dose.

Taking $t = 1$ min, this simplifies to

$$F_{I_{CN}} = \frac{1}{t_{I_{CN}}} \tag{63.23}$$

which is given by:

$$\text{Default case}: F_{ICN} = \frac{[CN]^{2.36}}{1.2 \times 10^6} t \tag{63.24}$$

$$\text{General case}: F_{ICNg} = \frac{[CN]^{2.36} \times V_E}{2.43 \times 10^7} \text{t} \tag{63.25}$$

If the fractional doses per minute, $F_{I_{CN}}$ or $F_{I_{CNg}}$ are summed throughout the exposure, the dose and time to incapacitation can be predicted.

Example A subject is exposed to 90 ppm HCN for 15 min, then to 180 ppm HCN for 3 min. Using the default case expression:

HCN concentration (ppm)	F_{ICN} for 1 min		
90	0.034	$0.034 \times 15 =$	0.51
180	0.175	$0.175 \times 3 =$	0.525
		F_{ICN} after 17 min	0.86
		F_{ICN} after 18 min	1.035

Incapacitation is therefore predicted between 17 and 18 min

[CN] represents the concentration of cyanide (ppm). If necessary this can be corrected for the presence of other nitriles besides HCN and for the protective effect on cyanide poisoning of NO and NO_2. [CN] can then be calculated as

$$[CN] = [HCN] + [\text{Total organic nitriles}] - [NO + NO_2] \quad (63.26)$$

For more detailed predictions of time to incapacitation in adult humans for application to evacuation models or incident investigations Equation 63.25 may be used with appropriate values for V_E depending on the activity level of the subject

Cyanide in Blood

The importance of HCN as a cause of incapacitation and death in fires can be underestimated due to poor understanding of the dynamics of cyanide uptake, dispersal and metabolism in the body, and the inadequate database of blood cyanide measurements from both injured and dead fire victims. Carboxyhemoglobin is the only blood toxin routinely measured in fire victims, and when blood cyanide is measured (usually postmortem), the sample and measurements are often taken a day or more after exposure.

Evidence from the primate experiments reported above, and from further experiments where measurements were made of arterial blood cyanide during and after exposure [81], shows that when HCN is inhaled for short periods at air concentrations above approximately 150–200 ppm, loss of consciousness results from a transient high plasma cyanide concentration. HCN uptake rate is then greatly reduced when the subject loses consciousness (or dies) and the cyanide in the plasma disperses throughout the body fluids, leaving a low immediate post-exposure plasma concentration. Also, cyanide decomposes rapidly in cadavers [88], by approximately 50 % in 1–2 days, and may subsequently decrease further or even increase slightly in stored blood. For these reasons, blood cyanide concentrations measured in fire victims are often relatively low, but when blood samples are obtained immediately after exposure [89], higher, toxicologically significant or life-threatening levels are detected. It is suggested that, in freshly obtained whole blood samples, levels of 2.0–2.5 μg CN/mL should be considered capable of causing incapacitation and 3.0 μg CN/mL should be considered lethal, whereas for samples not taken and analyzed immediately after exposure, these concentrations/effect ranges should be at least halved, depending on the time of storage.

From the perspective of establishing the extent of exposure to HCN at the fire scene and the likely contribution of HCN exposure to incapacitation and death during an incident it is necessary to establish the relationship between blood cyanide and tissue cyanide measurements made from samples taken at autopsy and the likely blood cyanide concentrations at the time of exposure. Unlike the relationship between postmortem blood carboxyhemoglobin concentration and carbon monoxide exposure at a fire scene, which can be assessed quantitatively (as described in a previous section), interpretation of blood cyanide data is much more challenging. A particular set of issues relates to changes in cyanide levels in cadavers and in stored blood samples. These have been measured and reviewed in some detail by McAllister et al [82]. Essentially the main issues with respect to interpretation of blood cyanide data are as follows:

- There is low a natural background concentration of cyanide in blood, which is slightly elevated in smokers and following ingestion

of certain foodstuffs (non-smokers 0.075 μg/mL, smokers 0.184 μg/mL) [78].

- As described in the previous section, short exposure to high cyanide concentrations can cause incapacitation at a fire scene within a few minutes in association with transient high blood cyanide concentrations, which can then decrease to much lower levels once incapacitation has occurred, so that blood concentrations at a fire scene at the time of death may be considerably lower than during the critical exposure period when incapacitation occurred.
- Cyanide is unstable in the blood of cadavers and there can be a considerable decrease between death at a fire scene and the time when a blood sample is taken at autopsy. Curry [90] found in a case of death by inhalation of cyanide vapor, that the blood level taken at the moment of death was 3.5 μg/mL while samples taken at autopsy the next day were 1.0 μg/mL (femoral) and 0.5 μg/mL (carotid), a decrease of approximately 79 %. Ballantyne et al. [91] took samples at intervals from 15 rabbits killed by intravenous. KCN (8 mg CN^-/kg bodyweight) stored at a temperature of 10–15 °C. The blood concentrations decreased from 5.41 μg/mL immediately after death, by 30 % after 1 day and 62 % after 3 days, and then to near zero after 14 days.
- Another problem is that cyanide levels continue to decrease in blood stored after removal. Ballantyne [92] studied the effect of storage under three conditions (room temperature 20 °C), refrigerated (4 °C) and frozen (−22 °C). The results were that at room temperature and 4 °C there were considerable decreases of blood level, which fluctuated with time. After 3 months at 4 °C there was an approximate 20 % decrease in concentration.
- Change in cyanide concentration in frozen blood samples: In the above study, small changes occurred in blood samples following freezing and re-thawing. Frozen samples containing significant cyanide concentrations were generally the same after 3 months as when they were first taken. The exception was the control blood, which showed a small increase of approximately 0.1 μg/mL within a few days of freezing, the levels then remaining constant for the remainder of the 3 months. Although this was a small increase it represented a large percentage change in the control value of 0.03 μg/mL. The increase is considered to be due to re-conversion of small amounts of thiocyanate to cyanide. This effect is considered likely to be significant only when examining low concentrations of cyanide such as is found in the blood of smokers, but minor in the context of blood cyanide concentrations relevant to cyanide poisoning during fires.
- In some situations large increases in blood cyanide have been found to occur in stored blood samples. Although not fully understood, this phenomenon is considered to be due to contamination of samples by cyanogenic bacteria. However in several large studies of post-mortem blood samples taken from fire victims [61, 64, 81] such increases have not been reported.

Table 63.13 summarizes reports and opinion on blood cyanide concentrations associated with signs of different severity, although these should be taken as only a very approximate guide for the reasons stated.

Hypoxia

Apart from the tissue hypoxia caused by CO and HCN, hypoxia in fires can also be caused by exposure to low oxygen concentrations. To some extent, a lowered oxygen concentration in the inspired air or a lowered oxygen concentration in the lungs (during exercise for example) is a normal physiological occurrence, and there are compensatory mechanisms that tend to maximize the supply of oxygen to the brain. When a subject is placed in a hypoxic situation, there is a reflex increase in cerebral blood flow and also, up to a point, the unloading of oxygen from the blood is more efficient at lower arterial and venous blood oxygen concentrations [38]. These factors

Table 63.13 Blood cyanide concentrations and signs

Blood cyanide (μg/mL)	Signs
0.2–0.5	No signs (Hall [93])
0.5–1.0	Flushing, tachycardia (Hall)
1.0–2.5	Intoxicated, narcotized (Hall)
1.0–2.0	Lowest level suggested as compatible with death from acute cyanide poisoning (Ballantyne and Marrs [94])
1.7	Human fatality (Ballantyne and Marrs)
2.0	Concentration immediately after death in rabbits (Ballantyne) [83]
2.15	Rapid loss of consciousness in dogs (Ballantyne and Marrs)
2.4	Human fatality (Ballantyne and Marrs)
2.5	Rapid loss of consciousness in primates (Purser et al. [80])
2.5–3.0	Coma (Hall)
3.4	Rapid loss of consciousness in primates (Purser et al.)
3.5	Human case at death −0.75 μg/ul at autopsy next day (Curry [90])
3.6	Rapid death in dogs (Ballantyne and Marrs)
5.0	Human fatality (Ballantyne and Marrs)
In summary:	
~2.0–2.5	Concentration in fresh post-mortem blood consistent with incapacitation due to HCN
~3.0	Concentration in fresh post-mortem blood consistent with death due to HCN
~1.0–1.25	Concentration consistent with incapacitation due to HCN in post-mortem blood not taken and analyzed immediately after exposure
~1.5	Concentration consistent with death due to HCN in post-mortem blood not taken and analyzed immediately after exposure

compensate to a large degree for any decrease in the oxygen concentration of the inspired air. When cynomolgus monkeys were exposed to atmospheres containing 15 % oxygen, no deleterious effects occurred beyond a slight increase in heart rate [37].

However, a time is reached where these compensatory mechanisms fail; a 10 % oxygen atmosphere produced a marked cerebral depression in monkeys [37]. In humans hypoxia due to lack of oxygen (hypoxic hypoxia) has been studied extensively, particularly hypoxia that occurs at high altitudes [38]. As in monkeys there is little effect down to 15 % O_2, beyond a slightly reduced exercise tolerance, but at approximately 10 % O_2 effects suddenly become severe (consisting of lethargy and impaired consciousness), and similar effects have been reported in human volunteers breathing 12 % oxygen for periods of 15 min or more [38, 95]. It is possible, however, to identify a number of degrees of physiological and behavioral decrement, and for low-oxygen hypoxia certain signs can be related to particular exposure concentrations. From experiments in humans the effects have been classified into four phases as follows [26, 38, 54, 65] (Table 63.14), the appropriate altitude ranges and equivalent sea-level oxygen concentrations being given for each phase.

If a subject is suddenly placed into a low-oxygen environment, a finite time elapses before the blood gas concentration equilibrates with the new conditions, and a certain degree of physiological effect then occurs, depending on the equilibrium blood concentration attained. The time-to-effect functions described in the next section have been based on the concept of a certain "dose" of hypoxia being taken up over a period of time to reach equilibrium at the chosen endpoint of severe incapacitation (the catastrophe point). The concept of the catastrophe point relates to observations, mainly during exposures of primates to the asphyxiant gases CO, HCN, and low-oxygen hypoxia [37, 62], that due to physiological compensatory mechanisms there is very little decrement in physiological status or behavioral task performance as the severity of an exposure increases, until a certain point is reached when tissue hypoxia becomes critical and deterioration becomes very marked and very rapid, usually leading to unconsciousness. This endpoint, therefore, marks the sudden change in a potential fire victim from a condition of near normality to a condition in which escape would not be possible.

A Model for the Prediction of Time to Incapacitation by Hypoxia in Fires

Incapacitation due to oxygen lack, consisting of loss of consciousness, occurs when the oxygen

Table 63.14 Effects of low oxygen hypoxia at altitude and equivalent sea level reductions in percent oxygen

Sea level-3000 m equivalent to 20.95–14.4 % O_2 at sea level	**Indifferent phase**
	Minor effects on visual dark adaptation and beginnings of effects on exercise tolerance towards 15 % O_2
3000–4500 m equivalent to 11.8–14.4 % O_2 at sea level:	**Compensated phase**
	Relatively mild effects, Slightly increased ventilation and hear rate, slight loss of efficiency in performance of complex tasks and short-term memory, some effects on judgment. Maximal exercise work capacity reduced
4500–6000 m equivalent to 9.6–11.8 % O_2 at sea level:	**Manifest hypoxia**
	Degradation of higher mental processes and neuromuscular control, loss of critical judgment and volition, with dulling of the senses and a marked increase in cardiovascular and respiratory activity. Emotional behavior may vary from lethargy and indifference to excitation with euphoria and hallucinations. Particularly dangerous during fire exposures, representing the catastrophe point as a victim passes form this stage into the fourth stage at approximately 10 % O_2 (or COHb or blood cyanide concentrations producing an equivalent degree of brain hypoxia)
6000–7600 m equivalent to <7.8–9.6 % O_2 at sea level:	**Critical hypoxia**
	Rapid deterioration in judgment and comprehension leading to unconsciousness followed by cessation of respiration and finally of circulation at death.

supply to cerebral tissue falls below a certain critical value, which in turn occurs when the partial pressure of oxygen in the cerebral venous blood falls below 20 mmHg [38]. Due to the effects of the compensatory mechanisms, to residual oxygen in the lungs, and to oxygen stores available from the blood, a certain period of time elapses before the oxygen tension of venous blood declines to this critical level when a subject is suddenly faced with a reduced oxygen atmosphere after breathing normal air [26]. The time taken for this depletion depends on the level to which the oxygen concentration falls, but also on the activity of the subject (which affects oxygen demand) and the RMV. It is, therefore, possible to plot time to loss of consciousness against oxygen concentration. Studies of this kind have been performed on human subjects, principally for hypoxia caused by exposure to reduced atmospheric pressures simulating the effects of high altitudes, which has similar effects to those of exposure to reduced oxygen concentrations at sea level. Figure 63.25 shows such a plot of time of useful consciousness for humans at rest following sudden decompression (less than 1 s transition time) to a range of simulated altitudes. The data are adapted from Luft [38] and are expressed in terms of altitude. The equivalent sea-level oxygen concentrations have been added to the figure and also the percentage oxygen vitiation (i.e., the equivalent decrease in percentage oxygen concentration at sea level below the normal concentration of 20.9 % oxygen).

From this curve it is possible to derive an equation that should give a reasonable prediction of time to loss of consciousness $\left(t_{I_o}\right)$ for a victim exposed to a hypoxic fire environment, as follows

$$\left(t_{I_o}\right)\text{min} = \exp[8.13 - 0.54(20.9 - \%\text{O}_2)] \tag{63.27}$$

where (20.9—%O_2) is %O_2Vit (percent oxygen vitiation).

As with exposure to HCN, time to incapacitation for exposure to low-oxygen concentrations does not follow Haber's rule, since short exposures to severe hypoxia cause incapacitation very rapidly, and long exposures to modest hypoxia have little effect (e.g., at 17 % O_2Vit, $Ct = 17 \times 0.33 = 5.61$ % · min, while at 11.3 % O_2Vit, $Ct = 11.3 \times 7.73$

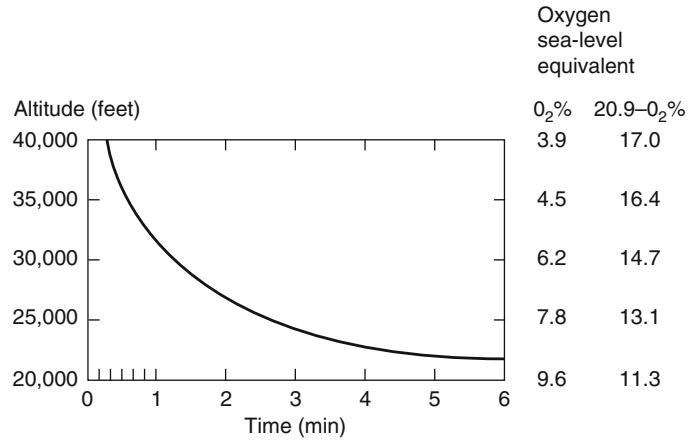

Fig. 63.25 Time of useful consciousness on sudden exposure to high altitudes (less than 1-s transition time). Scales also show equivalent sea-level percent oxygen concentration and percent oxygen vitiation (decrease below 20.9 % O_2) [38]

$= 87.3\ \% \cdot \text{min}$). In attempting to predict time or dose to incapacitation or death for a subject exposed to changing oxygen concentrations, it is therefore necessary to apply a weighting factor to allow for these deviations from ideal behavior. As with HCN this may be achieved by using the fractional effective dose concept as follows:

For a constant level of hypoxia, the time to incapacitation due to oxygen depletion is given by

$$t_{I_o} = \exp[8.13 - 0.54(20.9 - \%O_2)] \quad (63.28)$$

Dose to incapacitation $= (20.9\text{—}\%\ O_2)\ (t_{I_o})$

Therefore, for a short exposure time, t, to a given level of oxygen vitiation

$$F_{I_o} = \frac{(20.9 - \%O_2)(t)}{(20.9 - \%O_2)(t_{I_o})} \quad (63.29)$$

where F_{I_o} = fraction of an incapacitating dose of hypoxia, and where $t = 1$ min. This equation simplifies to

$$F'_{I_o} = 1/t_{I_o} \quad (63.30)$$

If the fractional doses per each minute are summed throughout the exposure, the dose and time to incapacitation can be predicted.

Example A subject is exposed to a concentration of 10 % oxygen for 5 min followed by 7.8 % oxygen for 1.5 min. For 10 % O_2 (10.9 % O_2Vit)

$$t_{I_o} = \exp[8.13 - 0.54(20.9 - 10)]$$
$$1/t_{I_o} = 0.106$$

For 7.8 % O_2 (13.1 % O_2Vit)

$$t_{I_o} = 2.8748$$
$$1/t_{I_o} = 0.3478$$
$$F_{I_o} = 0.106 \times 5 + 0.3478 \times 1.5$$
$$= 0.105$$

Therefore, loss of consciousness is predicted at 6.5 min.

A Model for the Prediction of Hyperventilation and Time to Incapacitation by Carbon Dioxide

Carbon dioxide (CO_2), like carbon monoxide, is universally present in fires. Although carbon dioxide is not toxic at concentrations of up to 5 %, it stimulates breathing, so that at 3 % the RMV is approximately doubled and at 5 % tripled [25]. This hyperventilation, apart from being stressful, can increase the rate at which other toxic fire products (such as CO) are taken up.

For asphyxiant gases such as CO or HCN it is likely that the increased uptake resulting from carbon dioxide induced hyperventilation will significantly reduce time to incapacitation and death. The ventilatory response to carbon dioxide varies among individuals and reported data also

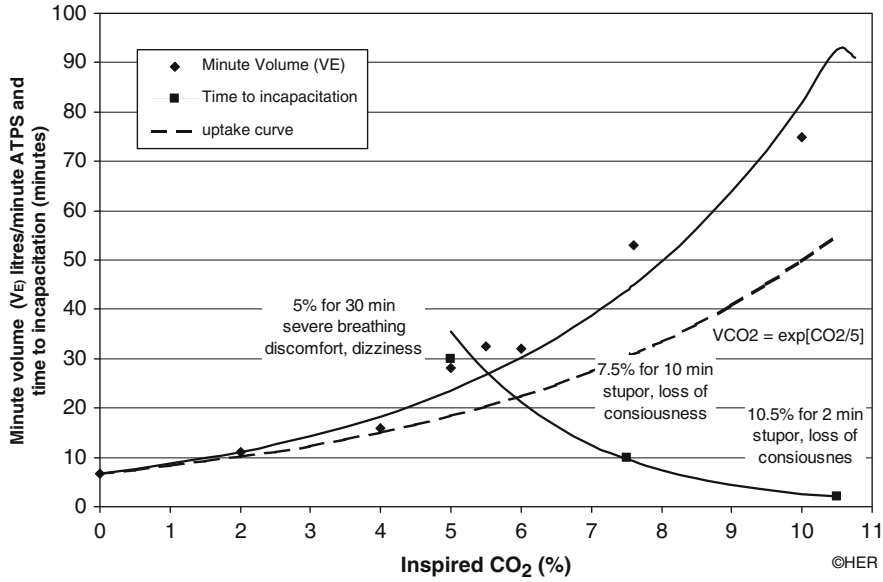

Fig. 63.26 Ventilatory response to carbon dioxide, proposed curve for calculating effects on rate of uptake of CO, HCN and irritants, and incapacitating effects of inhaling 5–10 $\%CO_2$ [96–99]

vary. An average curve has been constructed from data given in three sources [96–98] and is presented in Fig. 63.26, giving the following regression equation

$$\mathrm{RMV(L/min)} = \exp(0.2496 \times \%\mathrm{CO_2} + 1.9086) \tag{63.31}$$

From this expression a multiplication factor ($V\mathrm{CO_2}$) can be calculated for the enhanced uptake of other asphyxiant gases as follows

$$V\mathrm{CO_2} = \frac{\exp(0.2496 \times \%\mathrm{CO_2} + 1.9086)}{6.8} \tag{63.32}$$

where 6.8 L/min is a suggested figure for the resting RMV at the background CO_2 concentration. This equation has been simplified to

$$V\mathrm{CO_2} = \exp\left(\frac{[\mathrm{CO_2}]}{4}\right) \tag{63.33}$$

On further examination of this relationship it is considered that, although it provides a reasonable estimate of the change in $V\mathrm{CO_2}$, it gives an exaggerated value for the increase in uptake rate for other gases, primarily because the efficiency of uptake decreases as ventilation increases. This is particularly the case for CO uptake for which $\mathrm{DL_{CO}}$, the maximum rate of diffusion into the blood and erythrocytes, becomes a limiting factor at high levels of respiratory ventilation. A modified expression has, therefore, been derived based on that used in the CFK equation [34], which gives a somewhat lower prediction for the increase in uptake rate of other gases. A slightly higher figure has also been used for the resting V_E. The modified equation is as follows:

$$V\mathrm{CO_2} = \frac{\exp(0.1903 \times \%\mathrm{CO_2} + 2.0004)}{7.1} \tag{63.34}$$

which has been simplified to

$$V\mathrm{CO_2} = \exp\left(\frac{[\mathrm{CO_2}]}{5}\right) \tag{63.35}$$

At concentrations of approximately 5 % and above carbon dioxide is itself an asphyxiant, but for elevated CO_2 concentrations (hypercapnia) the change in degree of incapacitation with exposure concentration is more gradual than

with hypoxia. From approximately 3 % up to 6 % there is a gradually increasing degree of respiratory distress. This becomes severe at approximately 5–6 %, with clinical comments from subjects such as "breathing fails to satisfy intense longing for air" or "much discomfort, severe symptoms impending," with headache and vomiting also occurring [99]. Although due to the gradual equilibration process these signs tend to worsen during exposure, it seems unlikely that they would proceed as far as loss of consciousness over the course of a 30- or even a 60-min exposure period. However, once the concentration of carbon dioxide is in the 7–10 % plus range, a new set of signs consisting of dizziness, drowsiness, and unconsciousness is superimposed on the severe respiratory effects. A time factor does enter here due to gradual uptake, with loss of consciousness being more certain, and occurring earlier (over a period of a few minutes) as the exposure concentration approaches and exceeds 10 % [65, 66, 99, 100]. Approximate tolerance times for the distressing effects on breathing and the onset of asphyxia for humans are shown in Fig. 63.26. The effects are perceptible to subjects from 3 % as increasingly rapid breathing and at approximately 6 % become intolerable within 20 min. Symptoms of dizziness, headache, and fatigue start to occur at concentrations above 7 %, with danger of unconsciousness occurring within a few minutes increasing from 7 % to 10 %. Loss of consciousness is likely within 2 min at 10 % CO_2 in humans [99].

As with HCN and low-oxygen hypoxia, intoxication by carbon dioxide does not follow Haber's rule (Ct for 10 % CO_2 = 20 % · min, Ct for 5 % CO_2 = 175 % · min). From the approximate data in Fig. 63.26 an expression predicting approximate time to incapacitation $t_{I_{CO_2}}$ has been derived as follows:

$$t_{I_{CO_2}} = \exp(6.1623 - 0.5189 \times \%CO_2) \tag{63.36}$$

Using the fractional-dose concept previously described for HCN and hypoxia, it is possible to predict approximate dose to incapacitation, provided that the CO_2 concentration is stable or increasing, as follows:

For a constant CO_2 concentration

$$t_{I_{CO_2}} = \exp(6.1623 - 0.5189 \times \%CO_2)$$

$$\text{Dose to incapacitation} = (\%CO_2)\left(t_{I_{CO_2}}\right)$$

Therefore, for a short exposure time, t, to a given CO_2 concentration

$$F_{I_{CO_2}} = \frac{(\%CO_2)(t)}{(\%CO_2)\left(t_{I_{CO_2}}\right)}$$

where $F_{I_{CO_2}}$ = fraction of an incapacitating dose, and where t = 1 min. This equation simplifies to

$$F_{I_{CO_2}} = \frac{1}{t_{I_{CO_2}}} \tag{63.37}$$

If the fractional doses per minute are summed throughout the exposure, the dose and time to incapacitation can be predicted.

Example A subject is exposed to a concentration of 5 % CO_2 for 20 min, followed by 9 % CO_2 for 2 min.

$$\text{For } 5\%\,CO_2,\ t_{I_{CO_2}} = 35.44;\ 1/t_{I_{CO_2}} = 0.0282$$
$$\text{For } 9\%\,CO_2,\ t_{I_{CO_2}} = 4.45;\ 1/t_{I_{CO_2}} = 0.2247$$
$$Ft_{I_{CO_2}} = 0.0282 \times 20 + 0.2247 \times 2 = 1.01$$

Severe incapacitation with probable loss of consciousness is, therefore, predicted at approximately 22 min.

Interactions Between Toxic Fire Gases

Although data on the concentration/time/dose relationships of the dangerous and lethal asphyxiant effects in humans of individual fire gases and interactions between them are necessarily limited, they are adequate for the construction of a usable incapacitation model. Estimates of likely degrees of interaction are based on physiological data from individual gases and on such experimental data for gas combinations as do exist.

Effect of Carbon Dioxide on Effects of CO, HCN, and Low-Oxygen Hypoxia

The interaction likely to be most important is that hyperventilation due to carbon dioxide exposure increases the rate of uptake of other toxic gases and thus decrease the time to incapacitation (or the time taken to inhale a lethal dose), in proportion to the increase in ventilation. This interaction is likely to be most important with respect to CO and HCN intoxication. An expression for calculating the increase in V_E resulting from exposure to different carbon dioxide concentrations is given in the section on CO_2, but as an approximation it should be assumed that there would be little effect below 3 % CO_2, while at 3 % CO_2, V_E is doubled, so time to incapacitation by CO and HCN should be halved. At 5 % CO_2, V_E would be approximately tripled and time to incapacitation would be approximately one-third of that in the absence of carbon dioxide. There is a possibility that the effects on time to incapacitation would not be so dramatic, since there is evidence that the presence of carbon dioxide may counteract the leftward shift in the oxygen dissociation curve caused by carbon monoxide, somewhat counteracting its deleterious effects [101]. However, in the absence of experimental data on combination exposures it is best to ignore this possible beneficial effect, since the effect on uptake rate is likely to be dominant. A similar effect on uptake may also occur with HCN. With regard to low oxygen, carbon dioxide has been shown to have a marked beneficial effect on resistance to incapacitation. This result is partly due to the hyperventilatory effect that increases the rate of oxygen uptake and partly due to the rightward shift in the oxygen dissociation curve caused by carbon dioxide. This effect improves the delivery of oxygen to the tissues, counteracting the respiratory alkalosis that otherwise occurs [67, 102, 103]. There is evidence from experiments on the effects of combinations of asphyxiant gases with CO_2 in rodents that, with severe exposures, postexposure lethality is increased by the presence of CO_2. When animals are severely affected and suffering from a hypoxia-induced metabolic acidosis, this appears to be enhanced by the further acidotic effect of CO_2 inhalation, and the animals then fail to recover after exposure under conditions when they would otherwise be expected to do so. The hyperventilation induced by CO_2 will also increase the uptake of substances that irritate the lung, which affects gas exchange in the lung during exposure and also tend to cause toxic effects some time after exposure. Experiments in rodents provide evidence that this is so, with increased deaths possibly caused by postexposure acidosis and increased lung damage. Exercise also causes a CO_2-driven hyperventilation, and there is evidence that this may also cause deaths when rodents are exposed to irritants at normally sublethal concentrations [104].

Interactions Between CO and HCN

Some studies have been made of interactions between CO and HCN with varying results [105]. On theoretical grounds little interaction is to be expected, since CO diminishes the carriage of oxygen in the blood and its delivery to the tissues, while HCN diminishes the ability to use oxygen once delivered to the tissues. It is, therefore, to be expected that either one or the other gas would constitute the rate-limiting step in oxygen supply and utilization. However, the consensus view is that there is at least some additive effect between these two gases. Experiments in primates have shown that time to incapacitation by HCN is slightly reduced by the presence of near-toxic concentrations of CO [86, 105], and the rate of uptake of CO may be increased by the hyperventilatory effect of HCN.

There are several reasons why CO and HCN toxicities may be additive. One reason is the hyperventilation resulting from HCN exposure, which further increases the rate of uptake of cyanide and of any CO present. Another possibility may relate to competition for sites on cytochrome a3 between oxygen and cyanide. Since CO exposure reduces oxygen delivery and arterial $P_{O2,}$ this may alter the balance in favor of cyanide binding to the a3 sites at the mitochondrial level. Certainly

it was found that administration of oxygen was beneficial to cyanide intoxicated primates, improving their clinical condition, and the beneficial effects of oxygen have been reported in a number of other studies. Since oxygen is known to be present in excess during cyanide intoxication, it is difficult to understand why administration of further oxygen would be beneficial, unless it improved the competitive balance with cyanide at the active sites.

Another possible reason derives from a proposed mechanism of CO toxicity. CO has been found to exert a direct effect on tissue toxicity at the mitochondrial level in addition to its effects on the blood [106]. Particularly when the uptake of CO is rapid, it has been suggested that sufficient dissolved CO may reach the tissues to exert direct toxic effects. In vitro, CO has been shown to exert an inhibitory effect on oxygen metabolism. Although the affinity of cytochrome oxidase for CO is considerably less than that of cyanide, it is possible that some degree of additive inhibition of oxygen metabolism may occur at the tissue level. Piantatosi et al. [106] studied cytochrome oxidation-reduction responses to CO and HCN in the intact brains of fluorocarbon-circulated rats (i.e., with all hemoglobin removed) and found that CO and HCN caused inhibition at two different sites in the electron transport chain, whereby b-type cytochromes were sensitive to CO but not cyanide, while cytochrome aa_3 and $c + c_1$ were sensitive to cyanide but not CO. Although the effects of such interaction in intact animals are not fully resolved, it raises the possibility of some form or additive interaction between CO and HCN at the mitochondrial level.

In these circumstances it is probably safest to assume that these gases are additive in terms of time to incapacitation and dose to death and that incapacitation or death will occur when the fraction of the toxic dose of each one adds up to unity.

Interactions Between CO and Low-Oxygen Hypoxia

The most likely interaction between CO and low-oxygen hypoxia would be some degree of addition, since both reduce the percentage oxygen saturation of arterial blood, and CO also impairs the delivery of oxygen to the tissue by causing a leftward shift of the oxygen dissociation curve [101]. It is possible that during the early stages of CO exposure in hypoxic subjects the CO occupies the upper, oxygen-free part of the oxygen dissociation curve, and therefore has little effect. Von Leggenhager [62, 74] reports that subjects at rest at altitude remain symptom free at low levels of CO saturation. However, it is likely that the effect of more severe exposure to CO in a hypoxic subject would be additive to some extent, as reported by Heim [107] and McFarland et al [108].

Interactions Between Irritant Smoke Products and Asphyxiant Gases

An important point is the possible interaction between irritant smoke products and asphyxiant gases. This effect is particularly strong when rats and mice are exposed to smoke, since the rodent response to irritation of the upper respiratory tract is a marked decrease in respiratory rate and V_E. Thus if CO is present in the smoke, the rate of uptake will be considerably reduced if the smoke is irritant. This sometimes leads to misleading results in combustion product toxicity tests, where a material producing irritant smoke will have an apparently low LC_{50}, although high CO concentrations are present in the atmosphere.

This marked, prolonged decrease in respiratory rate does not occur in humans or nonhuman primates; indeed, in primate smoke experiments, irritant products tend to increase rather than decrease ventilation (although not sufficiently to increase CO toxicity) [37, 61].

NO and NO_2 (designated as NO_x in mixtures) also act as asphyxiants, reducing oxygen carriage in the blood due to the conversion of hemoglobin to methemoglobin. To this extent their asphyxiant effects can be considered additive with those of HCN and CO. However, methemoglobin combines with HCN in the blood, thereby reducing its asphyxiant effect. NO_2 is also a potent lung irritant.

Summary of Overall Interactions

In summary, data on interactions between the asphyxiant gases CO, HCN, low oxygen, and CO_2 are limited, but where deleterious interactions are known it would be prudent to include them in the incapacitation model, if only to err on the side of safety. For this reason it is proposed that the interactions should be quantified in the incapacitation model as follows:

1. Assume that CO and HCN are directly additive (1:1) on a fractional dose basis (the evidence suggests that they are additive but that the additive interaction may actually be less than unity).
2. NO and NO_2 (designated as NOx in mixtures) also act as asphyxiants, reducing oxygen carriage in the blood due to the conversion of hemoglobin to methemoglobin. To this extent their asphyxiant effects can be considered additive with those of HCN and CO. However, methemoglobin combines with HCN in the blood, thereby reducing the cyanide asphyxiant effect. NO_2 is also a potent lung irritant
3. The effects of irritants on lung function also cause some hypoxia and so an additive term is included consisting of the FLDirr
4. The rate of uptake of all these asphyxiant gases (CO, HCN, NOx and irritants) depends on the respiratory ventilation (V_E) of the subject in relation to body size, which in turn depends upon their level of physical activity For design purposes it is assumed that the subject is an adult engaged in light work such as walking along an escape route.
5. The main effect of carbon dioxide is to increase the breathing rate and thus the rate of uptake of asphyxiant gases (CO, HCN, NOx and irritants). A multiplicatory term VCO_2 is used to calculate this effect.
6. Low oxygen hypoxia will be additive with the overall hypoxic effects of CO and HCN, but is not increased by VCO_2 (in fact it is improved).
7. The beneficial effects of increased CO_2 on the hypoxic effects of CO and low oxygen hypoxia resulting from right shifting of the oxyhaemoglobin dissociation curve are ignored
8. The direct intoxicating effects of CO_2 are considered unlikely to occur before other effects so are normally ignored but exposure to 7 % CO_2 or higher itself causes incapacitation within a few minutes.

Taking into account these interactions it is possible to derive a general expression for calculating uptake, fractional effective doses and time to incapacitation from asphyxia as described in the next section.

Implications of Interactions for Predicting Time to Incapacitation in Smoke Atmospheres and Derivation of an Overall FED Expression for Asphyxia

In general, although there is evidence for interactions between toxic fire gases, whether these are likely to be important in practice depends on the composition of actual fire atmospheres, which is discussed in a later section of this chapter. For most practical situations, it is considered that HCN is unlikely to be the main driver of time to incapacitation providing the nitrogen content of the burning fuel does not exceed 1 % by mass. The composition of fire atmospheres will then be such that for asphyxiant effects, CO will be the most important toxic product, and the most important interaction will be an increased rate of CO uptake due to hyperventilation caused by CO_2. The additional effects of HCN aphyxia will contribute to the effects of CO-induced asphyxia, and may significantly reduce time to incapacitation when fuels contain more than 1 % nitrogen and the HCN concentration exceeds approximately 50 ppm. Since NOx concentrations in fires are low, their direct contribution hypoxia and effects on HCN toxicity are likely to be small. Low oxygen hypoxia is likely to be a minor term for situations where subjects are exposed to growing compartment fires, but may constitute a major term if subjects

are suddenly exposed a smoke atmosphere containing less than approximately 12 % oxygen, for example when opening a door on a compartment fire. Similarly, sudden exposure to a CO_2 concentration exceeding 7 % CO_2 could itself result in rapid intoxication and collapse. The rate of uptake or all toxic gases and particulates also depends upon the physical activity level and ventilation of the subject.

On this basis the simplified fractional dose equation for asphyxiation for an adult engaged in light work would be[1]

$$\mathrm{F_{IN}} = \left[\left(\mathrm{F_{I_{CO}}} + \mathrm{F_{I_{CN}}} + F_{I_{NOx}} + FLD_{irr}\right) \times VCO_2 + F_{I_O}\right] or\, \mathrm{F_{I_{CO_2}}} \qquad (63.38)$$

where

F_{IN} = Fraction of an incapacitating dose of all asphyxiant gases

$F_{I_{CO}}$ = Fraction of an incapacitating dose of CO

$F_{I_{CN}}$ = Fraction of an incapacitating dose of HCN

Note: If necessary this can be corrected for the presence of other nitriles besides HCN and for the protective effect on cyanide poisoning of NO and NO_2. [CN] can then be calculated as: $[CN] = [HCN] + [\text{Total organic nitriles}] - 0.67[NO + NO_2]$

$F_{I_{NOx}}$ = Fraction of an incapacitating dose of $NO + NO_2 (= [NOxppm \times tmin]/1500)$

FLD_{irr} = Fraction of an irritant dose contributing to hypoxia (This term represents a correction for the effects of irritants on lung function and is developed in the section "Post-Exposure Lung Inflammation and Survival." This term may be omitted if the effects of asphyxiant gases only are under consideration)

VCO_2 = Multiplication factor for CO_2-induced hyper-ventilation

F_{I_O} = Fraction of an incapacitating dose of low-oxygen hypoxia

$F_{I_{CO_2}}$ = Fraction of an incapacitating dose of CO_2

For a simple analysis, the direct asphyxiant effects of NO_x those of NO_x on HCN asphyxia the fraction of an incapacitating dose of CO_2 may be ignored without significant error.

A more general form of the equation incorporating V_E as a user-defined variable is:

$$F_{IN} = \left(F_{ICOg} + F_{ICNg} + F_{INOxg} + FLD_{irrg}\right) \times V_E \times V_{CO2} + F_{I_O} \qquad (63.39)$$

Activity level of subject	V_E (L/min)
Resting or sleeping	8.5
Light work—walking to escape	25
Heavy work—slow running, walking up stairs	50

Both the total volume of air breathed each minute and the efficiency of uptake have upper limits so that a limiting value for $V_E \times V_{CO2}$ of 70 L/min is recommended.

Each individual term in the FED equation is itself the result of the following equations, which give the FED for incapacitation for each gas and the multiplication factor for CO_2, where t is the exposure time at a particular concentration in minutes. The FED acquired over each period of time during the fire are summed until the total FED_{IN} reaches unity, at which point incapacitation (loss of consciousness) is predicted. In order to allow for differences in sensitivity and to protect susceptible human subpopulations a factor of $\times$ 0.3 FED should allow for safe escape of nearly all individuals. For especially vulnerable groups a factor of $\times$ 0.1 FED may be considered. Death is predicted at approximately two to three times the incapacitating dose.

For a 1-min exposure to each gas at a concentration C

$$F_{I_{CO}} = 3.317 \times 10^{-5}[\mathrm{CO}]^{1.036}(V)(t)/D \qquad (63.18)$$

where

[1] The effect of CO_2-induced hyperventilation will be to increase the rate of uptake of inhaled gases as a function of the increase in ventilation. Another approach to the quantification of this effect would be to multiply the concentration of each gas by VCO_2 in the FED expression for that gas rather than in Equation 63.38. This would produce a similar result to Equation 63.38, except for the effect of HCN inhalation, for which a greater value of $F_{I_{CN}}$ corrected for VCO_2 would result. This would represent a more conservative approach, but overall it is considered that this might overemphasize the toxic effects of HCN.

[CO] = Carbon monoxide concentration (ppm v/v 20 °C)
V_E = Volume of air breathed per minute (liters/min)
t = Exposure time in minutes
D = Exposure dose (percent COHb) for incapacitation

For the default case the value of V is 25 L/min and the value of D is 30 %COHb.

For the general case (F_{ICOg}) the V_E term is removed from Equation 63.18.

The default form of the fractional incapacitating dose for HCN (F_{ICN}) is as follows:

$$F_{ICN} = \frac{[CN]^{2.36}}{1.2 \times 10^6} t \tag{63.24}$$

where
CN = HCN concentration (ppm v/v at 20 °C)
t = Exposure time in minutes

For the general case application in Equation 63.39 the term F_{ICNg} is given by:

$$F_{ICNg} = \frac{[CN]^{2.36}}{2.43 \times 10^7} t$$

which is Equation 63.25 with the VE term removed). If necessary this can be corrected for the presence of other nitriles besides HCN and for the protective effect on cyanide poisoning of NO and NO_2. CN can then be calculated as $[CN] = [HCN] + [\text{Total organic nitriles}]\text{-}0.67[NO + NO_2]$

$$VCO_2 = \exp\left(\frac{[CO_2]}{5}\right) \tag{63.35}$$

$$FLD_{irr} = FLD_{HCl} + FLD_{HBr} + FLD_{HF} + FLD_{SO_2} + FLD_{NO_2} + FLD_{CH_2CHO} + FLD_{HCHO} + \Sigma FLD_x \tag{63.15}$$

where ΣFLD_x = FLDs for any other irritants present.

For the general case application in Equation 63.39 the term FLD_{irrg} is given by

$$FLDirrg = FLD/25$$

For the general case application in Equation 63.39 the term N_{INOxg} is given by

$$F_{INOxg} = F_{Inox}/25$$

For the direct effects of low oxygen hypoxia and incapacitation from inhaled carbon dioxide the general case expressions are the same as those for the default case:

$$F_{Io} = \frac{1}{\exp[8.13 - 0.54(20.9 - \%O_2)]} \tag{63.40}$$

$$F_{I_{CO_2}} = \frac{1}{\exp(6.1623 - 0.5189 \times \%CO_2)} \tag{63.41}$$

Figure 63.27 shows an expanded detail of asphyxiant gas profiles during the first 10 min of the single armchair room burn that is presented in more detail in Fig. 63.22. The histograms show the average concentrations of each gas at minute intervals during the first 6 min of the fire, the figures for which are given in Table 63.15. The HCN concentration was not measured in this fire, but it is likely to have been present as a major toxic product. Possible HCN concentrations have, therefore, been suggested for inclusion in the model and are shown in a histogram.

Applying the expressions for the fractional incapacitating dose of each gas to the data in Table 63.15, the total fractional dose of all asphyxiant gases for each minute during the fire (F_{IN}) has been calculated according to Equation 63.21 and summed for each successive minute during the fire, as shown in Table 63.16. Incapacitation (loss of consciousness) is predicted at 5 min when the fractional incapacitating dose exceeds unity ($F_{IN} = 1.2$).

The Exposure of Fire Victims to Heat

There are three basic ways in which exposure of fire victims to heat may lead to incapacitation and death: by (1) heat stroke, (2) body surface burns, and (3) respiratory tract burns.

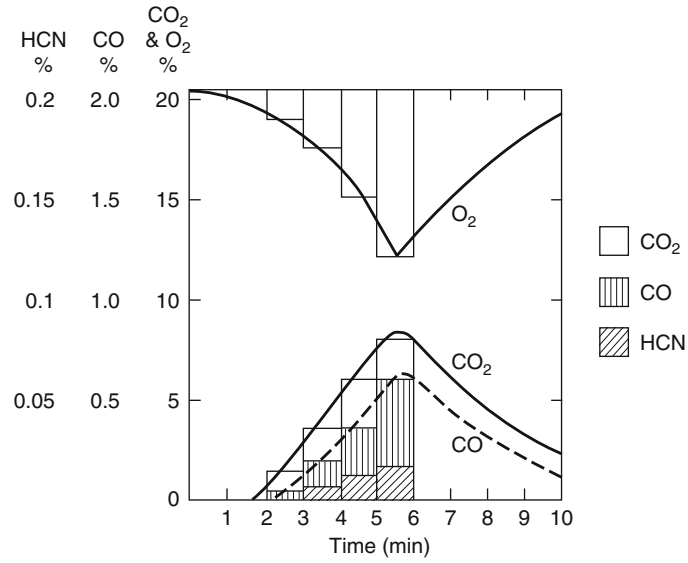

Fig. 63.27 Expanded detail from Fig. 63.22—average concentrations of asphyxiant gases each minute (histograms) from gas profiles (curves) measured during the first 10 min of a single armchair (polystyrene with polyurethane cushions and covers) room burn [52] Since HCN was not measured but was likely to have been present as an important toxic product, possible concentrations have been suggested for inclusion in the model

Table 63.15 Average concentrations of asphyxiant gases each minute during the first 6 min of the single armchair room burn shown in Fig. 63.27

Time (min)	1	2	3	4	5	6
CO ppm	0	0	500	2000	3500	6000
HCN ppm	0	0	0	75	125	174
CO_2%	0	0	1.5	3.5	6	8
O_2%	20.9	20.9	19	17.5	15	12

Table 63.16 Fractions of an incapacitating dose of asphyxiant gases calculated from the data in Table 63.15 According to Equation 63.38 for 1-min intervals during the single armchair room burn Shown in Fig. 63.27 (contributions from NOx and FLD are ignored for simplicity)

Time (min)	1	2	3	4	5
F_{lco}'	0	0	0.017	0.074	0.130
$+F_{lcn}'$	0	0	0.000	0.022	0.074
$\times VCO_2$	0	0	1.442	2.376	4.434
$=$	0	0	0.025	0.228	0.905
$+F_{lo}$	0	0	0.001	0.002	0.007
$=$ Total	0	0	0.026	0.230	0.912
Running total (F_{IN})	0	0	0.026	0.256	1.168
or:					
F_{lco_2}	0	0	0.005	0.013	0.047
Running total (F_{IN})	0	0	0.005	0.018	0.065

$F_{IN} = 1.2$ at 5 min due to the combined effects of CO, HCN, and low-oxygen hypoxia, the uptake of which was increased by CO_2, and incapacitation is predicted at between 4 and 5 min. Although carbon dioxide was present at concentrations sufficient to have caused significant hyperventilation, the fractional incapacitating dose for asphyxiation by carbon dioxide was only 0.065 at 5 min, and this is, therefore, unlikely to have had any effect

Heat Stroke (Hyperthermia)

If a subject is exposed to a hot environment, especially if the humidity is high and the subject is active, there is a danger of incapacitation and death due to hyperthermia. The time to effect and the type of hyperthermia depend principally on the heat flux to which the subject is exposed and are greatly affected by factors such as the amount and type of clothing and degree of work performed. A detailed analysis of the parameters that determine heat transfer to subjects over a range of environmental conditions and levels of activity, and the protective effects of different types of clothing, is given by Berenson and Robertson [109], and Simms and Hinkley [110].

Simple hyperthermia involves prolonged exposure (approximately 15 min or more) to heated environments at ambient temperatures too low to cause burns. Under such conditions, where the air temperature is less than approximately 120 °C for dry air or 80 °C for saturated air, the main effect is a gradual increase in the body core temperature [111]. Increases above the normal core temperature of 37 °C up to

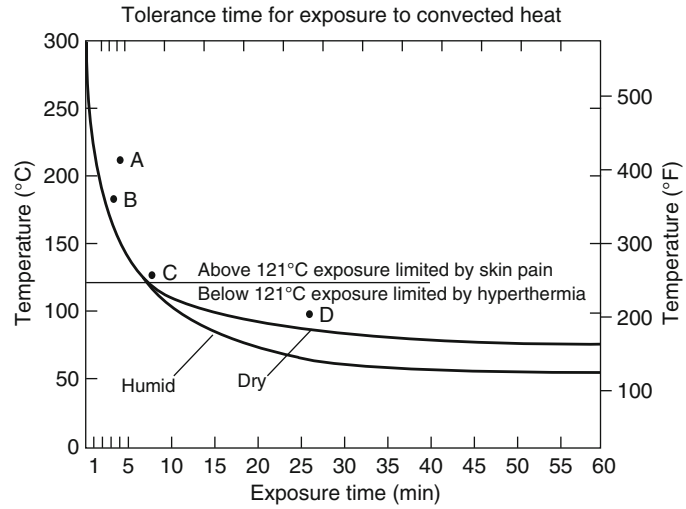

Fig. 63.28 Thermal tolerance for humans at rest, naked skin exposed, with low air movement (less than 30 m/min) (Adapted from Blockley [111]. See text and Table 63.17 for discussion of data points A to D) [110, 113, 114]

Table 63.17 Reported tolerance times for exposures to hot air

Temperature (°C)		Time (min)		Reference	Letter in Fig. 63.28
Dry air					
	110	25		Simms and Hinkley [110]	D
	180	3		Simms and Hinkley [110]	B
	205	4	Bare headed, protected	Veghte [113]	A
	126	7		Elneil [114]	C
Humid air	32 at 100 % RH	32	Men working	Leithead and Lind [115, 116]	

approximately 39 °C are within the physiological range and can occur at normal ambient temperatures during hard exercise, but once 40 °C is reached consciousness becomes blurred and the subject becomes seriously ill. Further increase causes irreversible damage, with temperatures above 42.5 °C being fatal unless treated within minutes [109, 112]. The time taken to reach such a state depends on a number of variables including those mentioned. Figure 63.28, adapted from Blockley [111], shows approximate tolerance times for unclothed subjects at rest, under conditions of low air movement (30 m/min). At temperatures below 120 °C tolerance is limited by hyperthermia, whereas above this temperature pain followed by burns become important. The data points A to D (for clothed subjects) were taken from various authors and are added for comparison. At temperatures below 120 °C evaporative cooling from sweat is important, so that humidity has a considerable influence on tolerance time. Clothing, therefore, offers some immediate protection at temperatures above 120 °C but at lower temperatures may reduce tolerance time by impeding heat loss due to evaporative cooling. Details of the data points and authorship are given in Table 63.17.

Experiments conducted with pigs by Moritz et al. [117] confirm the basic signs of hyperthermia, with death occurring principally due to circulatory collapse associated with severe cardiac irregularities (ventricular tachycardia).

A second situation described by Moritz et al. [117] involves exposure to high temperatures for short periods (less than 15 min), and here hyperthermia is accompanied by cutaneous burns (in pigs at temperatures above 120 °C). When deaths occurred soon after exposure to severe heat (within 30 min)

the cause was considered to be due not to burns but to a rise in blood temperature. In this situation the exposure duration was insufficient to raise the body core temperature greatly, but if the temperature of the blood in the heart reached 42.5 °C, the animal died within a few minutes from circulatory collapse.

It therefore seems that a victim exposed for more than a few minutes to high temperatures and heat fluxes (exceeding 120 °C) in a fire is likely to suffer burns and die either during or immediately after exposure, due principally to hyperthermia. Victims surviving the hyperthermia phase may die later due to burns of the upper respiratory tract, particularly the larynx, or due to the secondary effects of skin burns. A victim or fire fighter exposed to temperatures unlikely to cause burns (less than 120 °C) may also suffer heat stroke after a prolonged exposure (exceeding 15 min), especially if the humidity is high and the person is working hard.

Skin Burns

According to Buettner [118], pain from the application of heat to the skin occurs when the skin temperature at a depth of 0.1 mm reaches 44.8 °C, which agrees with the finding of Lawrence and Bull [119] that discomfort was experienced when the interface between a hot handle and the skin of the hand reached 43 °C. The sensation of pain is followed soon afterward by burns, causing incapacitation, severe injury, or death depending on their severity. The time from the application of heat to the sensation of pain, and from pain to the occurrence of burns of various degrees of severity, depends on the temperature, or more properly, the heat flux to which the skin is exposed. The effects of heating the skin are essentially the same whether the heat is supplied by conduction from a hot body, convection from air contact, or by direct radiation [118, 120]. Curves for the relationship between time and effect have been published for conducted heat from a "hot handle" [120, 121] and radiant heat. The relationship between time and effect is exponential (Fig. 63.29). Thus, for conduction from heated metal at 60 °C, pain occurs after 1 s and a burn after 10 s, while at 80 °C pain occurs at 100 ms and a burn after 1 s contact.

Pain, therefore, occurs when the difference between the rate of supply of heat to the skin surface exceeds the rate at which heat is conducted away by an amount sufficient to raise the skin temperature to 44.8 °C. The thermal inertia of human skin is similar to that of water [118] or wood [120] with a value of $k\rho c$ for the surface (depth 0.1 mm) of 1.05 W/mK. For the skin surface the rate of heat removal is not considered to be affected by blood supply [118] except for the fingertips, where blood flow may

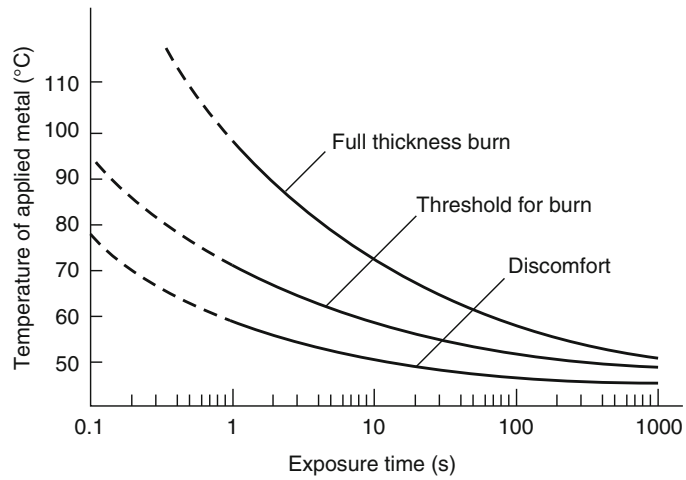

Fig. 63.29 The relation between time and the temperature of metal to cause thermal injury to skin (values below 1 s are extrapolated) [120]

be sufficient to remove a significant amount of heat [118]. However, blood supply may have some effect on the occurrence of burns, especially to the deeper layers of the skin [120]. Obviously, rates of heating and the occurrence of pain and burns are greatly affected by the extent and type of clothing [110, 117, 123, 124], but only effects on naked skin are considered here. The temperature increase of the skin for the situation in which constant radiant heat is absorbed by the upper surface of the skin, or heat from a hot air current is applied to the skin, may be calculated as follows [118]:

$$T - T_0 = \frac{2Q\sqrt{t}}{\sqrt{\pi k\rho c}} \qquad (63.42)$$

where

T = Final temperature of skin at 0.1 mm depth
T_0 = Starting temperature of skin at 0.1 mm depth
Q = Heat supply (W/m^2)
$k\rho c$ = 1.05 W/mk
t = Time (s)

Conducted Heat The effect of conducted heat is related to the temperature of the hot object and its thermal inertia, depending on the interface temperature between the object and the body tissue at the skin surface [120, 124], as illustrated by the examples in Table 63.18.

A skin temperature of 43 °C causes pain and some cellular damage, whereas a temperature of 60 °C coagulates tissue protein. A brass block heated to 60 °C will produce a partial thickness skin burn within 10 s, pain within 1 s and a full thickness burn after approximately 100 s [120]. The time/temperature relationships for these effects of conducted heat are shown in Fig. 63.29.

Table 63.18 Theoretical contact temperatures between skin at 35 °C and a selection of hot bodies at 100 °C [124]

Material of hot body	Contact temperature (°C)
Mild steel	98
Glass	82
Wood	65
Cork	46

Convected Heat For a victim attempting to escape from a fire, the most important sources of heat exposure are radiation from hot areas and convection from hot gases. Pain and the likelihood of skin burns occur at air temperatures above approximately 120 °C. The rate of heat transfer from hot air to the skin depends on the rate of ventilation, humidity, and the protective value of clothing as well as air temperature. The effects of these parameters are described by Berenson and Robertson [109], and Simms and Hinkley [110]. However, for unprotected areas such as the head, data on naked skin are relevant, and the data shown in Fig. 63.28 for temperatures above 120 °C provide limits for tolerance to the painful effects of contact with hot air.

Apart from the problem of hyperthermia, dry air has been tolerated by humans as shown in Table 63.17 Moritz et al. [117] state that dry air at 300 °C injured unprotected skin within 30 s in pigs and dogs. Pigs also suffered burns at 150 °C after 100 s and after 400 s at 100 °C. However, it was considered that humans would be more resistant to burns, especially at temperatures below 120 °C, due to the protective effect of sweating. Air with a high level of humidity not only reduces or prevents heat loss through sweat, but also delivers more heat to the skin. Thus, Moritz et al. [116] found that steam at 100 °C destroyed the epidermis of dogs within a few seconds.

Figure 63.28 shows curves for tolerance time of convected heat for both dry and humid air. A search for the original data used to produce these curves has not been successful, but on careful consideration it seems likely that the humid curve must represent air that was humid (perhaps saturated) at *room* temperature, which was then heated subsequently and was, therefore, nowhere near saturated with water vapor at higher temperatures. This must be the case because the capacity of air for water vapor increases dramatically at temperatures above 60 °C, so that the amount of deliverable latent heat also increases. In practice, 60 °C has been found to be the highest temperature at which 100 % water-vapor saturated air can be breathed. Since all

fires produce a considerable amount of water from combustion, it is possible that the presence of water vapor may be an important neglected hazard in some fires. As an approximate guide, the volume concentration of water vapor derived from fuel combustion in fire effluent is similar to the CO_2 concentration, which can be up to around 10 %. This amount is less than the concentration in saturated air at the breathable limiting temperature of 60 °C (which is 20 % H_2O). For this reason it is considered that the water vapor content of normal fire effluent is not likely to present a serious hazard. However, a serious hazard can occur if water is applied to a large fire but fails to extinguish it.

Radiant Heat For radiant heat, clothing also greatly influences tolerance times, but again, data on naked skin are relevant to exposure of unprotected areas such as the head. Figure 63.30 [109], shows the relationship between time to skin pain and radiant heat flux. Data points A to E, taken from a number of authors (detailed in Table 63.19) have been added for comparison. Points B through E agree with the curve presented by Berenson, but data from one source (Perkins et al.) [122] (points labeled A) deviate somewhat from the rest. From Perkins's data (which were produced by experiments where thermal injury was caused by exposing subjects to radiant heat from a searchlight), the heat fluxes for erythema (reddening of the skin said to coincide with pain [120]) appear rather higher than the heat flux limits for pain supplied by the other authors. This is possibly due to differences in the wavelength and, thus, degree of penetration of the radiation [118]. The searchlight data do, however, show the relationship between time to erythema, time to partial skin burn, and time to full-thickness skin burn. The shape of the radiant heat tolerance curve suggests a fairly obvious tolerance limit for exposure to radiant heat of 0.25 W/cm^2 (2.5 kW/m^2), which is that suggested by Babrauskas [52].

Behavioral and Incapacitating Effects of Skin Pain and Burns Experiments on the effects of radiant heat exposure on behavior of humans have been performed during the development of an "active denial system (ADS)" [121]. This system is designed to incapacitate exposed subjects by inducing skin pain by exposure by heat radiation at a frequency of 95 GHz. This frequency is selected to pass through clothing and heat the

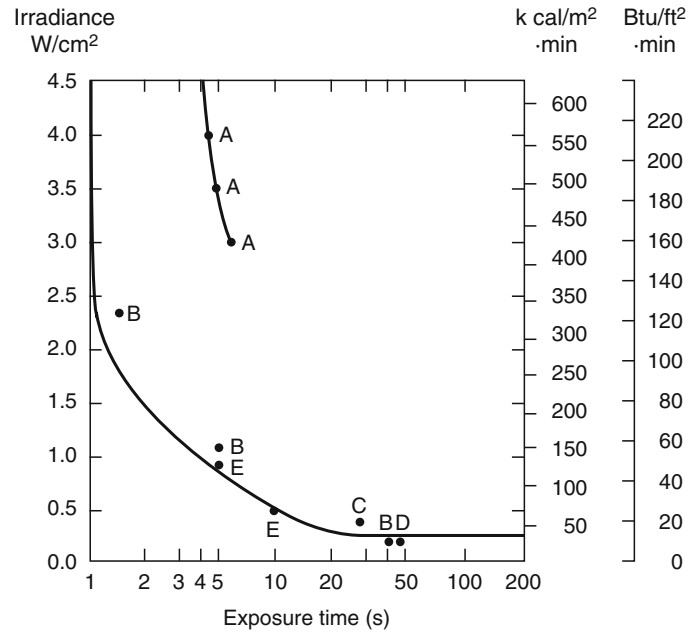

Fig. 63.30 Time to severe skin pain from radiant heat [109]. See text and Table 63.19 for discussion of data points A to E [110, 113, 122, 125, 126]

skin at depth of 0.4 mm without further penetration. The ADS "repellent" effects occur when the skin at this depth is heated just above 43–44 °C, while first degree burns occurred at around 51 °C and second-degree burns at around 58 °C. Exposed subjects reported sensation of intense pain, which they were highly motivated to avoid. One subject stated that it was not so much that he decided to escape from exposure but more that his body took over and forced him to move. This gives some indication of the effects of pain from skin heating in fire victims. In situations where a subject can move away from the heat source they are likely to do so. Where escape involves moving towards or into the heat source, such as entering hot smoke, or under a heat source, such as crossing a room under a hot upper layer, then it is likely that they will be unable or extremely unwilling to do expose themselves for more than a second or so once the heat flux exceeds the pain threshold.

Consequences of Body Surface Burns Apart from the immediate pain caused by exposure to heat and by skin burns, as well as the accompanying psychological shock and fear, incapacitation may result from body surface burns during or after a fire due to physiological shock. In this situation loss of body fluids into the burn results in circulatory failure and a fall in blood pressure, which may lead to collapse and even loss of consciousness [64, 117]. The immediate effect of burns and the later chances of recovery depend on a number of factors such as the site and extent of the burn, the depth of the burn, the age of the victim, and the treatment received [120]. Although victims may continue to function for some time with severe burns, and survivals have occurred with up to 80 % body surface area burns [120], in general, if 35 % or more of the body surface area is burned the chances of survival are low. Young adults generally have the best chance of survival, with a 50 % chance of surviving a 50 % body surface area burn, whereas children and old people are the most vulnerable, with a 50 % chance of surviving a 20 % body surface area burn in the elderly (Fig. 63.31) [64, 120]. The depth of burn is classified on a scale of six degrees. First-, second-, and third-degree burns involve damage to the skin from which it can recover, while fourth-degree burns require skin grafts. Fifth- and sixth-

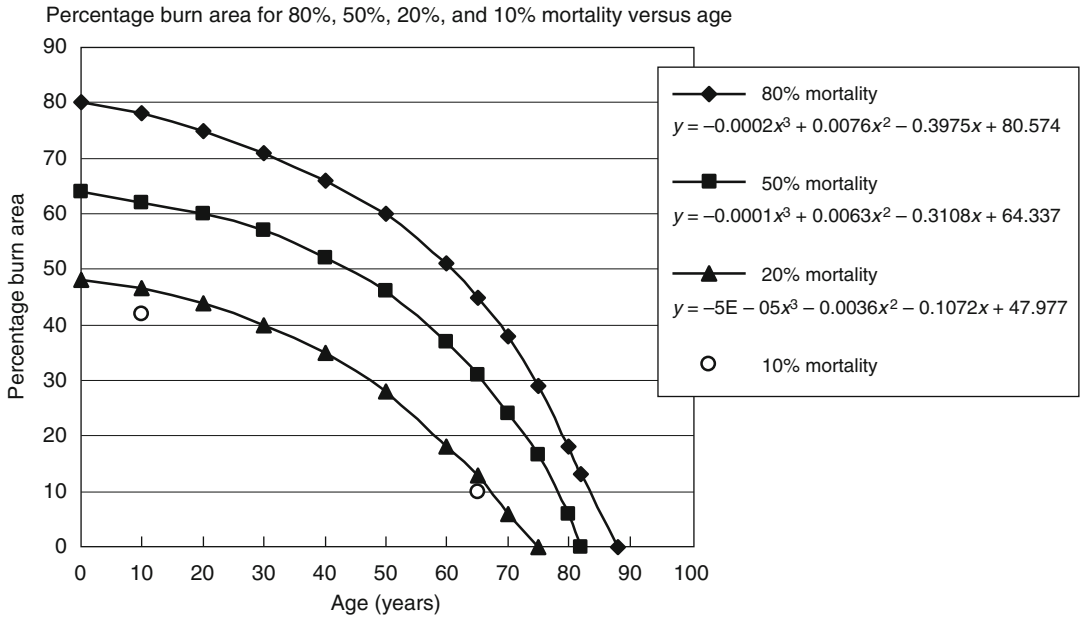

Fig. 63.31 Relationship between burn area, age, and mortality [120]. Equations show polynomial fits to curves

degree burns involve destruction of muscle and/or bones, respectively [64]. Another scheme classifies burns as partial-thickness skin burns, which will heal, or full-thickness burns, which require grafts [120].

If the victim survives the initial period of shock, death may occur over a period of up to a few weeks due to secondary effects on the brain, heart, lungs, liver, and kidneys [64]. The most common secondary effect and cause of death involves the lungs [64, 123, 127, 128], consisting of pulmonary edema resulting from effects on the circulatory system secondary to shock and metabolic acidosis. Postexposure treatment to replace body fluids and control acidosis are important in improving the prognosis for survival. If the victim survives the respiratory distress resulting from edema during the first week after exposure, pneumonia may then develop as a further, possibly fatal, complication [64, 129–131].

This fatal damage to the lungs may occur following body surface burns when there has been no inhalation of heat or toxic gases. In many fire victims, however, damage to the respiratory tract and lungs results from a combination of all three causes [64, 129–131].

Thermal Damage to the Respiratory Tract

Thermal (as opposed to chemical) burns to the respiratory tract never occur in the absence of burns to the skin of the face [131, 132]. Heat damage to the respiratory tract is even more dependent on the humidity of inhaled hot gases than are skin burns. As a result of the low thermal capacity of dry air and the large surface area of the airways, which are lined with a wet surface and good blood supply, thermal burns are not induced by dry air below the top of the trachea. However, steam at around 100 °C is capable of causing severe burns to the entire respiratory tract down to the deep lung, due to its higher thermal capacity and the latent heat released during condensation. These effects of inhaled hot gases are demonstrated by the work of Moritz et al. [117] in which anesthetized dogs and pigs breathed hot air, flame from a burner, or steam, supplied through a cannula to the larynx. Dry air at 350 °C and flame from a blast burner at 500 °C caused damage to the larynx and trachea but had no effect on the lung, whereas steam at 100 °C caused burns at all levels. In these experiments

the most important site of damage was the larynx, and death resulted from obstructive edema of the laryngopharynx within a few hours of exposure. This work was taken further by Zikria [131] using steam burns in dogs, induced by a 15-s application of steam at 100 °C via an endotracheal tube. The animals survived the initial effects and a number of phases of reaction were observed. The first phase consisted of necrosis and edema in the tracheobronchial airway and early lung parenchymal edema within 1 h. This result was followed by increasing parenchymal edema, sloughing of the mucosa, and collapse of lung segments. The next phase after 24 h consisted of bronchopneumonia behind respiratory tract obstructions.

All these effects occur in fire victims, but it is difficult to separate the effects of thermal inhalation burns from edema and inflammation due to burns caused by irritant chemical smoke products, or edema secondary to body surface burns, all of which may be involved [64, 129–131]. Thus, fire victims with facial burns subjected to endoscopy have been found to have burns well into the respiratory tract [132]. If these lesions are caused by heat, it would imply that fire atmospheres resemble steam rather than dry air in terms of their thermal capacity. However, it is possible that such lesions are caused by chemical smoke irritants, which have been shown to produce fatal pulmonary edema and inflammation in the absence of heat [60]. Unfortunately, data on the thermal capacity and latent heat of actual fire atmospheres are not readily available, although it may be possible to calculate probable values from knowledge of fire atmosphere temperature and composition.

The situation is, therefore, complicated but from a fire engineering standpoint a number of basic points may be useful.

1. Thermal burns to the respiratory tract will not occur unless the air temperature and/or humidity are sufficient to cause facial skin burns.
2. Dry air at around 300 °C may cause burns at the larynx after a few minutes. This may result in life-threatening obstructive edema of the larynx within an hour if not treated, although damage to the deeper structures of the lung is unlikely. It is possible that such laryngeal burns may occur at lower temperatures down to approximately 120 °C depending on the duration of exposure, and breathing dry air at these temperatures would be painful. Laryngeal burns followed by obstructive edema are common findings in fire victims and are important causes of incapacitation and death during and immediately after fires [64, 129–131].
3. Humid air, steam, or smoke with a high thermal capacity or latent heat (due to vapor content or suspended liquid or solid particles) may be dangerous at temperatures of around 100 °C causing burns throughout the respiratory tract. It may be possible to predict the likely effects of hot-smoke atmospheres if thermal capacity or latent heat were measured.
4. In practice, fire victims may be affected by the inhalation of chemically irritant smoke, by hot humid gases, and by the secondary effects on the lung of body surface burns, all of which may combine to cause fatal respiratory tract lesions during the hours, days, or weeks following the fire exposure. However, these effects are probably less likely to be fatal during exposure to the fire atmosphere over periods of less than 30 min.
5. Heat flux and temperature tenability limits designed to protect victims from incapacitation by skin burns should be adequate to protect them from burns to the respiratory tract.

Model of the Prediction of Time to Incapacitation by Exposure to Heat in Fires

There are three basic ways in which exposure to heat may lead to incapacitation: through heat stroke (hyperthermia), skin pain and burns, or respiratory tract burns. Thermal burns to the respiratory tract from air containing less than 10 % by volume water vapor do not occur in

the absence of burns to facial skin. Therefore, tenability limits with regard to skin pain and burns are normally lower than for thermal burns to the respiratory tract. Thermal burns to the respiratory tract may occur on inhalation or air above only 60 °C when saturated with water vapor, as may occur when water is used for fire extinguishment.

The tenability limit for exposure of skin to radiant heat is approximately 2.5 kW/m^2, below which exposure can be tolerated for at least several minutes. Radiant heat at this level and above causes skin pain followed by burns within a few seconds, but lower fluxes can be tolerated for more than 5 min. For situations where occupants are required to pass under a hot smoke layer in order to escape, this radiant flux corresponds approximately to a hot layer temperature of 200 °C. Above this threshold, time (minutes) to different endpoints for effects of exposure to radiant heat $t_{I\text{rad}}$, at a given radiant flux of qkW/m^2, is given by Equation 63.41 [133, 134].

$$t_{Irad} = \frac{r}{q^{1.33}} \tag{63.43}$$

where r is the radiant heat exposure dose [(kW · m^{-2})$^{4/3}$·min] required for any given endpoint:

Radiant heat endpoint for exposed skin	r (kW · m^{-2})$^{4/3}$ min
Severe skin pain	1.33–1.67
Second-degree burns	4.0–12.2
Third degree (full-thickness) burns	16.7

The threshold for pain occurs at an r value between approximately 1.33 and 1.67 (kW · m^{-2})$^{4/3}$ min. Second-degree burns occur at 4.0–12.2 (kW · m^{-2})$^{4/3}$·min and third-degree (full-thickness) burns at approximately 16.7 (kW · m^{-2})$^{4/3}$·min. The wide range given for second-degree burns reflects the effects of blistering. If the heating rate is low enough for blisters to form, this presents some degree of protection so that a higher-exposure dose is required. It is proposed that a figure of 1.33 (kW · m^{-2})$^{4/3}$min is used to represent a tolerance threshold and 10 (kW · m^{-2})$^{4/3}$min a threshold for incapacitation and serious injury. For infrared radiation it is also proposed that 10 (kW · m^{-2})$^{4/3}$min represents a fatal level for a vulnerable population (over 65 years of age) or a 1 % fatality level for the average population, whereas 16.7 (kW · m^{-2})$^{4/3}$min represents a 50 % probability lethal level for the average population. Radiant heat tends to be directional in fires, so that the main problem tends to be local heating of particular areas of skin. The air temperature and, hence, that of the air breathed and that in contact with other parts of the body may be relatively low, even when the radiant flux is high. For this reason the main hazard is pain and burns to the skin, rather than hyperthermia. Skin temperature depends on the relationship between the rate of heat supply to the skin surface and the removal of heat from inner layers by the blood. There is, therefore, a threshold radiant flux below which significant heating of the skin is prevented, but above which rapid heating of the skin occurs.

For exposures of up to 2 h to convected heat from air containing less than 10 % by volume of water vapor, the time (minutes) to incapacitation $t_{I\text{conv}}$ at a temperature T (°C) is calculated from Equation 63.44, which is derived from Fig. 63.28.

$$t_{I\text{conv}} = 5 \times 10^7 T^{-3.4} \tag{63.44}$$

This expression tends to follow the worst-case (100 % humidity) line. It also deviates somewhat from Blockley's curve at the high and low ends. It is, therefore, a somewhat nonconservative expression for exposure to higher temperatures and somewhat overconservative at the low-temperature end. The following expressions have been developed for the midhumidity case, giving a better fit to the empirical data.

Tolerance time t_{tol} (minutes) under midhumidity conditions is then given by

$$t_{\text{tol}} = 2 \times 10^{31} \times T^{-16.963} + 4 \times 10^8 \times T^{-3.7561} \tag{63.45}$$

where T is the ambient temperature (°C). This expression is considered suitable for calculating tolerance time as a possible tenability limit for design purposes. For other applications, such as

probabilistic risk assessments or forensic investigations other endpoints may be required. These may include those when serious injury from severe hyperthermia or second-degree burns (considered to represent a point of incapacitation for the average occupant) or the time to a potentially lethal heat exposure (involving prolonged hyperthermia and/or third-degree burns) may occur.

Based on the hyperthermia data and the relationship between heat doses causing pain and those causing serious injury or causing fatal third-degree burns, similar expressions have been derived for predicting time to serious injury and death.

Time (minutes) to serious injury or severe incapacitation

$$t_{\text{injury}} = 5 \times 10^{22} \times T^{-11.783} + 3 \times 10^{7} \times T^{-2.9636} \quad (63.46)$$

Time (minutes) to fatal exposure conditions with extensive third-degree burns is then given by

$$t_{\text{fatal}} = 2 \times 10^{18} \times T^{-9.0403} + 10^{8} \times T^{-3.10898} \quad (63.47)$$

These expressions are related to exposure to heated air with less than 10 % water content by volume.

As with toxic gases, the body of a fire victim may be regarded as acquiring a "dose" of heat over a period of time during exposure, with short exposure to a high radiant flux or temperature being more incapacitating than a longer exposure to a lower temperature or flux. The same fractional incapacitating dose model as with the toxic gases may be applied and, providing that the temperature in the fire is stable or increasing, the fractional dose of heat acquired during exposure can be calculated by summing the radiant and convected fractions using Equation 63.46

$$\text{FED} = \int_{t_1}^{t_2} \left(\frac{1}{t_{I\text{rad}}} + \frac{1}{t_{I\text{conv}}} \right) \Delta t \quad (63.48)$$

Note: $t_{I\text{rad}}$ will tend to zero as q tends to <2.5 kW/m^2.

Table 63.20 Limiting conditions for tenability caused by heat [18]

Mode of heat transfer	Intensity	Tolerance time
Radiation	<2.5 kW · m^{-2}	>5 min
	2.5 kW · m^{-2}	30 s
	10 kW · m^{-2}	4 s
Convection	<60 °C 100 % saturated	>30 min
	100 °C <10 % H_2O[a]	12 min
	120 °C <10 % H_2O	7 min
	140 °C <10 % H_2O	4 min
	160 °C <10 % H_2O	2 min
	180 °C <10 % H_2O	1 min

[a] v/v

Thermal tolerance data for unprotected skin of humans suggest a limit of about 120 °C for convected heat, above which considerable pain is quickly incurred along with the production of burns within a few minutes. Depending on the length of exposure, convective heat below this temperature may still result in incapacitation due to hyperthermia. Examples of tolerance times to different radiant fluxes and air temperatures are shown in Table 63.20. Conducted heat is physiologically important only when skin is in contact with hot surfaces, such as door handles. A 1-s contact with metal at 60 °C can cause burns.

The radiant component from immersion in hot air is negligible, but in situations in which subjects are immersed in hot smoke, there will be a significant radiant component from hot smoke particles in addition to convective heat transfer from contact with hot gases. One way to estimate the effect of such an exposure is to calculate the FED from the radiant heat flux ($1/t_{I\text{rad}}$) and sum it with the FED from the convected component ($1/t_{I\text{conv}}$) as in Equation 63.48. Another method is to calculate the total heat flux from the radiant and convected components of the smoke. On this basis it is proposed that the total incident flux to the skin of a person immersed in hot smoke is given by

$$q = \varepsilon\sigma\left(T_i^4 - T_m^4\right) + h_c(T_i - T_m)/1000 \quad (63.49)$$

where

q = Heat flux (kW/m^2)
T_i = Heat source temperature (°K)
T_m = Material surface temperature (°K)
ε = Emissivity (0.05 for a gas to 1 for a black body, perhaps 0.5 for smoke)
σ = Stefan Bolzmann constant (5.67×10^{-8} Wm^{-2} K^{-4})
h_c = Convective heat transfer factor. For air this depends on the flow rate past the object. It will be approximately 5–8 for slow-moving air.

The first term in the equation represents the radiant component of heat flux and the second term represents the convected component of heat flux. Using this equation it is, therefore, possible to calculate total heat flux from the ambient surroundings at body height. The radiant component is relatively small at low temperatures and is negligible for hot air due to its low emissivity. However, for smoke the emissivity is likely to be much higher (around 0.5) so that at higher temperatures both components should be considered in order to calculate the total heat flux to the skin. In addition to the heat flux from the fire effluent enveloping a subject additional heat radiation is likely from hot upper layers and/or directly from the fire. If the subject is in air (with a low emissivity), below a hot smoke layer, the only significant radiative heat flux sources are likely to be the upper layer, the fire, or hot surfaces.

Time to the different heat effect endpoints for total heat fluxes in excess of 2.5 kW/m^2 is then given by Equation 63.49 using the appropriate exposure dose endpoints as the numerator:

1.33 (kW · m^{-2})$^{4/3}$ min (tolerance limit/pain/first-degree burns)
10 (kW · m^{-2})$^{4/3}$ min (severe incapacitation and second-degree burns)
16.7 (kW · m^{-2})$^{4/3}$ min (fatal exposure with third-degree burns)

For all the expressions in this section estimation of the time to effect is based on measured effects on exposed skin of subjects for given exposures to hot air or different levels of incident radiant heat flux. An alternative approach would be to calculate heat transfer into a subject and the temperature of the skin at different depths with time. The BURNSIM model has been developed using this method for radiant heat [135].

Example of a Calculation of Time to Incapacitation for Physical Fire Parameters and Irritancy

In a previous section the single armchair room burn shown in Fig. 63.22 was used to illustrate how the model for prediction of asphyxiation could be applied to a practical fire scenario. To complete the incapacitation model it is necessary to include calculations for the effects of physical parameters (heat, smoke optical density) and mass loss concentration as an indication of irritancy. The curves for radiant heat, air temperature, smoke extinction coefficient, and mass loss during the first 10 min of the armchair burn are shown in Fig. 63.32.

Of the physical factors likely to affect a victim during the fire exposure, the majority are basically concentration or intensity related rather than dose related, and for these factors tenability limits have been set (radiant heat, smoke optical density, and sensory irritancy). The other two factors, convected heat and lung irritancy, are primarily dose related, but lung irritant effects are likely to be relatively minor until after exposure, which leaves the fractional incapacitating dose of convected heat to be calculated. The average temperatures per minute during the first minutes of the fire are shown as histograms in Fig. 63.32 with Table 63.21 showing the fractional incapacitating dose calculation.

Convected Heat The effects of exposure to convected heat increase dramatically in this type of fire as shown in Fig. 63.32. Incapacitation, mainly due to skin pain and burns, is predicted sometime during the fourth minute, when the air temperature is 220 °C. The situation then rapidly worsens, and it would seem likely that severe and probably fatal burns or fatal hyperthermia would be sustained by any victim remaining in the fire during the fifth minute. Even if the victims were protected to some extent

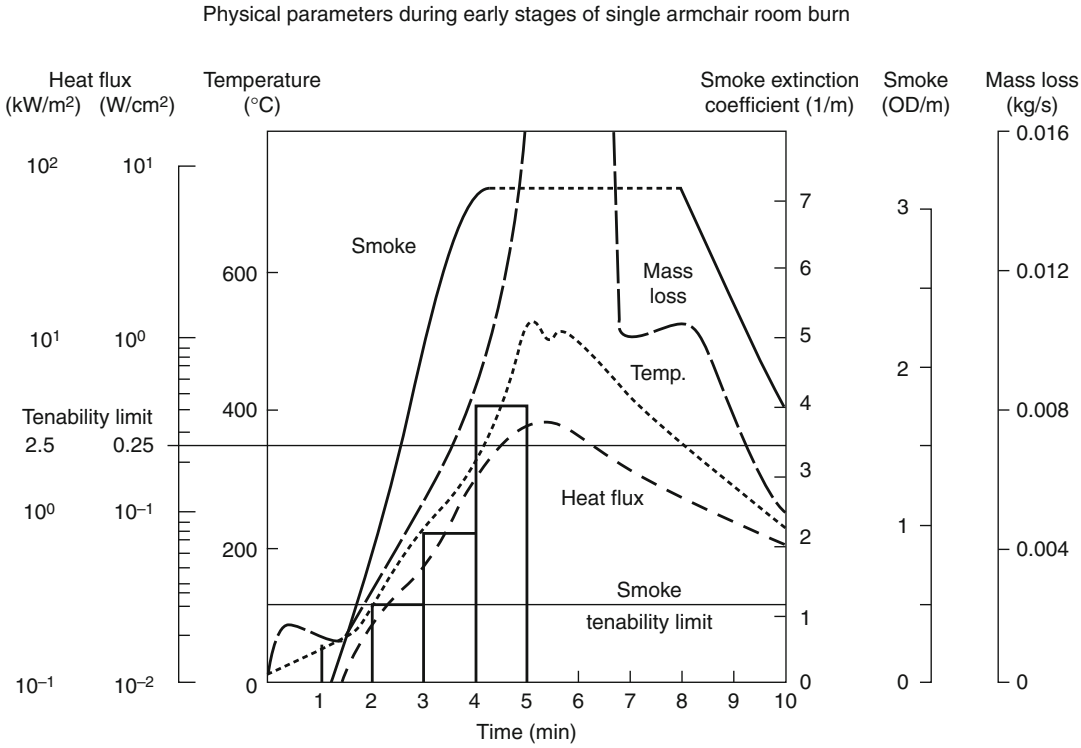

Fig. 63.32 Profiles for heat (radiant flux and temperature), smoke, and mass loss rate during the first 10 min of a single armchair (polystyrene, with polyurethane cushions and covers) room burn [52]. (Expanded detail from Fig. 63.22) Histogram shows average temperature each minute during the first 5 min

Table 63.21 Calculation of fractional incapacitating accumulation of convected heat for the single armchair room burn data shown in Fig. 63.32 (Calculated According to Equation 63.44)

Time (min)	1	2	3	4	5	6
Average temp. (°C)	20	65	125	220	405	405
F_{lh}	0	0.02	0.19	1.57	15.55	15.55
Cumulative F_{lh}			0.21	1.78	17.33	32.88

Incapacitation occurs when $F_{lh} = 1$, and is, therefore, predicted during the fourth minute of exposure

by clothing, they would sustain burns to the face and probably fatal burns to the larynx. The occurrence of lung burns would depend on the thermal capacity (principally the latent heat) of the smoke.

Radiant Heat From Fig. 63.32, it would seem that the effects of radiant heat would be relatively minor in this fire compared to the effects of convected heat. The radiant heat peaks at just above 3 kW/m^2 during the sixth minute and, therefore, just exceeds the tenability limit. Nevertheless, the radiation alone would probably be sufficient to cause some burns and seriously inhibit escape during the sixth minute, and there would almost certainly be some degree of additive effect with convected heat.

Smoke From the point of view of its obscurational effects, incapacitation by smoke is concentration related rather than dose related. For this series of chair burns, Babrauskas sets a tenability limit of extinction coefficient 1.2/m (OD/m 0.52) [52]. This would give approximately 2 m visibility, which should be adequate for escaping from a room and could be used as a tenability limit for input into the model. Incapacitation due to visual obscuration would occur at the end of the second minute. The smoke curve is rising very steeply at this point, with an OD/m of 1 at the beginning of the third

minute. Escape would, therefore, become extremely difficult and certainly slow during the third minute, unless the victim was familiar with the surroundings and able to find the exit in the dark.

Irritancy As stated in the section "Irritant Fire Products" in this chapter there are two factors to consider: the immediate incapacitation due to the painful effects of sensory irritation of the eyes and respiratory tract, adding to the obscurational effects of smoke and disrupting escape behavior, and the later inflammatory effects on the lung that may cause death after exposure.

The first consideration is whether the victim would be able to escape from the fire. In this context, sensory irritation is the most important. This is concentration related, so to predict the irritancy of the smoke, it is necessary to know the RD_{50} concentration of the atmosphere produced by the materials involved under the particular decomposition conditions existing in the fire. Most importantly, it is necessary to know the concentration/time profile of the fire products in terms of mass loss per liter of air (NAC mass loss). Although the mass loss curve for the armchair is shown in Fig. 63.32, there are no data on the volume of air into which this mass was dispersed during the fire; so for the purposes of this example it will be necessary to make an estimate of possible mass loss concentration. Also, since the RD_{50} of the polyurethane and polystyrene components of the chair under flaming conditions are unknown, it will be necessary to use estimated values.

In the discussion of irritancy, a general tenability limit for severe sensory irritation was set at a concentration of 1 mg/L NAC mass loss, and an incapacitating dose for serious postexposure lung inflammation was set at 10 mg/L NAC mass loss for 30 min (a Ct product of 300 mg · min/L). From the general conditions, the smoke curve, and the CO concentration curve, it is estimated that the tenability limit for sensory irritancy would be exceeded during the third minute, greatly adding to the deleterious effects of smoke on vision and escape behavior.

With regard to lung irritation, it is estimated that the average mass loss concentration over the first 5 min of the fire would be approximately 10 mg/L. If so, this would represent a fractional incapacitating dose of 50 mg · min/L, which would probably be insufficient to cause significant lung damage after exposure, compared to the more serious effects of heat exposure. However, if the average mass loss concentration over the first 5 min should reach 60 mg/L, serious effects on the lung would likely occur after and probably during exposure.

Interactions In terms of physiological effects, it is likely that there would be some degree of interaction between asphyxia and several of these physical factors, but it is likely that most would be relatively minor during the fire, except for some possible enhancement of pulmonary irritation due to the hyperventilatory effect of CO_2 during the fourth to sixth minutes of the fire. A reasonable model can be used in which asphyxia, sensory irritancy, and the effects of heat and visual obscuration can be treated separately. Interactions may be more important at the behavioral level. The interaction between sensory irritation and visual obscuration has been mentioned and there is some experimental evidence for such an interaction in humans [50]. After exposure, as mentioned in the section "The Exposure of Fire Victims to Heat," the effects of skin burns, respiratory tract burns, and chemical irritation (and even possibly CO asphyxia) all combine to increase the probability of fatal pulmonary edema and inflammation.

Summary From the analyses performed, the effects on a victim exposed to the conditions in the armchair room burn (see Fig. 63.22) are predicted as follows:

1. Toward the end of the second minute and beginning of the third minute, the smoke optical density and mass loss/liter would sufficiently exceed the tenability limits for visual obscuration and sensory irritancy to severely inhibit escape from the room.
2. During the fourth minute, the average temperature was 220 °C and sufficient heat would be accumulated in the skin surface to cause skin burns resulting in incapacitation.

3. During the fifth minute, a victim is likely to lose consciousness due to the combined effects of the accumulated doses of asphyxiant gases.
4. It is predicted that a victim escaping or rescued after the fourth minute would suffer severe postexposure effects due to skin burns, plus pulmonary edema and inflammation that might well be fatal (due to the combined effects of inhaled hot gases, chemical irritants, and the pulmonary secondary effects of skin burns). After the sixth minute, it is likely that a rescued victim would die at some time between a few minutes and 1 h due to the effects of asphyxia and circulatory shock.

It is unlikely that an otherwise healthy adult would be able to escape from such a fire if he or she remained longer than 3 min after ignition. However, 3 min is a long time in which to leave a room, so that providing the victim is awake and aware of the fire, is not otherwise incapacitated, and does not stay after 2 min in an attempt to fight the fire or rescue belongings, it is likely that he or she would be able to escape without serious injury. In the next section, data on real fire victims are examined in an attempt to relate fire conditions to actual injury and death statistics.

A full worked example of the application of these methods to an FED analysis for smoke, toxic hazards and heat, with accompanying Figures and Table is presented in this chapter in the section "Worked Example of a Simplified Life Threat Analysis".

Worked Example of a Simplified Life Threat Hazard Analysis

In the previous sections, the various elements of a physiological FED model for predicting time to incapacitation of occupants during full-scale fires have been developed. The following section consists of a worked example including tenability calculations for all toxic and physical hazards: time-to-escape efficiency impairment from the effects of optical obscuration by smoke, time-to-escape efficiency impairment from sensory irritation, time to incapacitation by asphyxiant gases, time to incapacitation due to skin pain and burns from radiant and convected heat, and time to inhale a lethal exposure dose of lung irritants. The worked example is for data from the single armchair open room burn involving a rapidly growing fire in an armchair constructed from polystyrene with polyurethane covers and cushions. The fire conditions are illustrated in Fig. 63.22. Figure 63.27 shows expanded details of the asphyxiant gases with the concentrations averaged during each minute. Figure 63.32 shows details of the profiles for radiant heat flux, temperature, smoke concentrations and mass loss rate.

Table 63.22 shows the input data and calculation results for the life threat hazard analysis calculation using the methods described. The results of the analysis are presented in Fig. 63.33. This figure shows plots of the FED for smoke, FIC for sensory irritation, and FED values for each hazard parameter as they increase with time. The endpoints of escape impairment or loss of tolerability (for smoke obscuration and irritants) and incapacitation (for heat and asphyxiant gases) are reached when the line for each parameter crosses 1. Higher FECs and FEDs indicate more severe effects. For irritancy, incapacitation is predicted at FEC_{irr} values of approximately 5–10 and for asphyxiation death is predicted at FED_{in} values of approximately 2–3.

The analysis is designed to predict the severity of each hazard and the time during the fire at which it becomes significant. The toxic gas concentrations, smoke optical density, temperature, and radiant heat flux have been averaged over each of the first 6 min of a theoretical furniture fire but are generally similar to conditions obtained in the smoke layer at head height in some experiments performed in ISO room tests. The analysis shows that the smoke obscuration is the first hazard confronting a room occupant. The level of obscuration exceeds the tenability limit for irritant smoke in a small enclosure after the second minute, with an FEC of 1. The second hazard to confront the occupant

The endpoint, escape impairment (for smoke obscuration and irritancy), or incapacitation (for heat and asphyxiant gases) is reached when the FIC or FED value reaches 1

Limiting values are in bold. Lethal values are approximately two to three times incapacitating levels for dose-related parameters, and incapacitation five to ten times the FIC

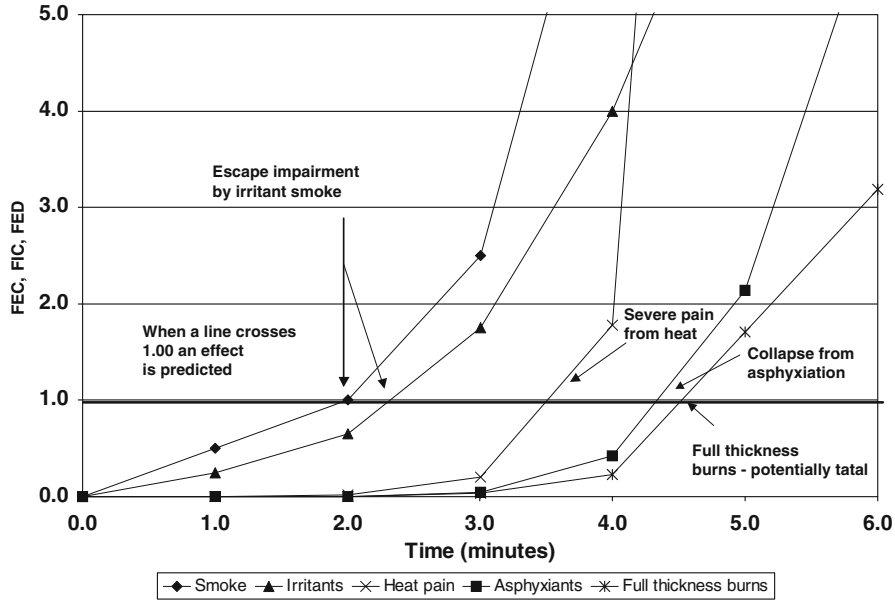

Fig. 63.33 Plots of FED analysis calculated in Table 63.22 (Copyright HER)

is irritancy. This becomes significant during the third minute, exceeding an FIC of 1 at 3 min. The tenability limit designed to protect vulnerable individuals (FIC 0.3) is exceeded approximately 1 min earlier. It is therefore predicted that after the second minute the level of obscuration and the irritancy of the smoke would be sufficient to impair and possibly prevent escape from the room due to difficulty in seeing and increasing pain in the eyes and respiratory tract. The effects of radiant and convected heat then become significant, crossing the tenability limit during the fourth minute and reaching an FED_{heat} value of 1.70, so that it is predicted that a room occupant would suffer severe skin pain and burns due to the effects of convected heat. Extensive, potentially fatal, full-thickness burns are predicted during the fifth minute.

During the fifth minute the radiant flux reaches the tenability limit of 2.5 kW/m^2, so that skin pain would be predicted within seconds due to radiation alone, were it not that the temperature has already exceeded the limiting exposure dose. Also during the fifth minute the FED_{IN} reaches 2.14, predicting that anyone breathing the smoke would lose consciousness due to asphyxia and might die after 6 min. The level for exposure to asphyxiants considered to provide protection for vulnerable sub-populations (FED_{IN} of 0.1) is crossed at approximately 3.5 min, and that to allow for more normal sensitivity variations (FED_{IN} 0f 0.3) a few seconds later, and only half a minute before the FED_{IN} reaches 1. The exposure dose of irritants is very small during the first 6 min of the fire, so that there should be little danger of postexposure lung damage. An important point about all these parameters is that the FIC and FED curves are rising very steeply after the tenability threshold (FIC or FED of 1) is crossed. This means that even if the true exposure concentrations or exposure doses required to cause incapacitation were higher than the tenability limits chosen there would be little effect on predicted time to incapacitation.

The overall prediction is that for this fire, escape would become difficult during the third minute and incapacitation could occur due to the effects of irritant smoke. A person remaining in the room after this time would suffer severe pain and burns after 4 min, which would probably be lethal a minute or so later. The would lose consciousness during the fifth minute. In this analysis it is assumed that the head of a room occupant

would be in the smoke at all times. In practice, if the room doorway was open, the hot, effluent-rich layer would descend from the ceiling to a level probably between 1 and 1.2 m above the floor as the chair reached its peak burning rate. A more sophisticated analysis could allow for the possibility that a room occupant might be at, or move to, a lower level in the room. If the height of the smoke layer with time is measured, then it is possible to allow for this factor in the calculation.

Chemical Composition and Toxicity of Combustion Product Atmospheres

In the preceding sections, the effects of individual asphyxiant gases and irritant chemical products known to occur in fires have been described together with their interactions. As described in the next section on "Fire Scenarios and Victim Incapacitation", the range of toxic substances and their relative concentrations vary considerably in the fire effluent mixtures produced by different fuels under different combustion conditions. An important aspect of combustion toxicity studies has been to examine the chemical composition and toxic effects of such effluent mixtures to determine the range of toxic effects and the extent to which they can be understood in terms of the small number of major substances described.

The effects of decomposition conditions on chemical product formation in different types and stages of fires, and the resultant toxicity, have been shown in a series of experiments involving exposures of primates to combustion products [61]. In these experiments, a number of materials were decomposed under a range of temperatures and oxygen supplies designed to simulate some of the conditions described previously. In one series of experiments, a study was made of the effects of temperature on the pyrolysis of three materials—polyacrylonitrile, flexible polyurethane foam, and wood. These were decomposed at 300, 600, and 900 °C to cover as far as possible the full temperature range known to occur in fires, simulating conditions where oxygen supply might be limited. Another set of experiments was then carried out on a further range of polymers to examine the effects of nonflaming and flaming oxidative decomposition on toxicity over midrange temperatures (440–700 °C). These conditions were chosen to embrace the conditions known to give the greatest complexity of products, particularly with polymers that are known to be sensitive to oxidation in product formation. In this series the test materials were rigid polyurethane foam, polypropylene, polystyrene, and nylon. In all cases, the sublethal toxic effects of exposure were evaluated using primates.

With the series of pyrolysis experiments, it was found that up to midrange temperatures, a rich product mix occurred, whereas at 900 °C clear atmospheres containing high yields of simple, low molecular weight products occurred. Thus for wood, which contains oxygen in its structure, the principal products at lower temperatures were oxidized organics, which caused upper respiratory tract and lung irritancy. There was a relatively low CO yield with wood, causing signs of asphyxia at sufficiently high wood nominal atmosphere concentrations. Polyacrylonitrile produced relatively low yields of HCN and other nitriles, causing signs of cyanide intoxication [16]. With the flexible polyurethane foam, the lower-temperature atmospheres consisted principally of a dense yellow isocyanate smoke, which was a powerful lung irritant capable of causing severe pulmonary inflammation after exposure [60, 61, 136, 137]. Low yields of CO and HCN resulted with this foam.

At 900 °C the isocyanate smoke from flexible polyurethane foam was destroyed, giving a clear atmosphere consisting mainly of HCN and CO, the main signs being of cyanide poisoning. Polyacrylonitrile also produced high yields of HCN, causing cyanide intoxication, and wood produced clear atmospheres consisting principally of CO.

An example of the effects of oxidation on product formation and toxicity is given by the effects of polypropylene decomposition products. Under pyrolytic conditions, polypropylene decomposed to give a nontoxic

atmosphere consisting of hydrocarbon fragments (see Chap. 62, Table 62.10). Under nonflaming oxidative conditions, some of these fragments were oxidized to form a highly irritant atmosphere that caused upper respiratory tract and lung irritation during exposure and severe pulmonary inflammation after exposure [60, 61]. There were also minor signs of CO-induced asphyxia. Under flaming conditions the pyrolysis and oxidation products were partially destroyed, with the most important products being carbon monoxide, carbon dioxide, water, and some irritants. The principal toxic effect of this atmosphere was CO intoxication with some signs of irritancy. With flaming atmospheres, however, the nature and degree of toxicity depend on the efficiency of combustion. By varying the decomposition conditions it is possible to substantially alter the toxicity.

From the animal exposures to these thermal decomposition and combustion product atmospheres, the major findings were that despite the great complexity in chemical composition of the test atmospheres, the basic toxic effects were relatively simple. For each individual atmosphere, the toxicity was always dominated either by an asphyxiant gas (CO or HCN) or by irritants. The toxicity of each atmosphere was, therefore, basically that of the major component that was present at its most toxic concentration. For asphyxia, the effects of individual atmospheres were virtually identical to those of either CO or HCN as individual gases at the same concentrations as they were present in the smoke atmosphere.

The presence of low concentrations of hydrocarbons (which are potentially asphyxiant at high concentrations) and of CO_2 in the 1000–7000 ppm range did not contribute to the asphyxia. The effects of irritant products on respiratory patterns for primates did not affect the pattern of CO or HCN asphyxia. There may have been a marginal additive effect of CO on HCN toxicity, but in these cases the pattern of asphyxia and times to incapacitation were very similar to those produced by equivalent HCN/air mixtures. Irritant effects did, of course, occur in these exposures in conjunction with asphyxia, but there was no interaction between them, in that irritancy did not affect the progress of asphyxia, and asphyxiant gases did not affect the response to irritants.

As a result of this work, and other studies described in Chap. 62 it can be stated with some confidence that the asphyxiant effects of fire atmospheres should be predictable on the basis of the common asphyxiant gases CO, HCN, low O_2, and CO_2, with a contribution from irritants, and that the models derived from the work on individual gases should be valid. It is also possible with current knowledge to predict approximately the potential of a fire atmosphere to cause sensory irritation or lung inflammation from a chemical analysis of the product composition.

Fire Scenarios and Victim Incapacitation

From the point of view of both product composition and toxic hazard, it is possible to distinguish four basic types of fire (see Table 63.3).

1. Non-flaming thermal decomposition and smoldering fires hazardous mainly to victims the room of origin of the fire
2. Early flaming fires hazardous mainly to victims in the room of origin
3. Small oxygen-vitiated fires in poorly ventilated enclosures (pre-flashover underventilated fires) hazardous to victims both in the room of origin or a remote location
4. Fully developed or postflashover fires hazardous to victims remote from the fire

In the United Kingdom, 80 % of fire deaths and injuries occur in domestic dwellings. In just over half of these cases the casualties occur in the compartment or origin of the fire. This class of fire is responsible for the highest incidence of deaths (60 %) and a high incidence of injuries (39 %). These fires occur mostly in living rooms or bedrooms and in upholstery or bedding [7]. In these cases, fire is often confined to the material first ignited. The toxic hazard in such fires depends on whether there is a long period of smoldering or a rapidly growing flaming fire.

As described, injuries and deaths occurring in the room of origin usually involved burns and toxic smoke, while most casualties in enclosures beyond the fire enclosure are from smoke and toxic gases.

Smoldering Fires

The work of Woolley and his colleagues at the U.K. Fire Research Station [63] showed that at midrange temperatures (400–700 °C) such as those found in smoldering fires or in the vicinity but beyond the flame zone of early flaming fires, materials are decomposed into pyrolysis products and oxidation fragments containing a mixture of asphyxiant and irritant gases and particulates. Under these conditions, the highest yields of a variety of potentially toxic products are formed (see Table 63.3 and Chap. 62, Table 62.10), many of which are irritant [61, 63] and since incomplete oxidation is favored, CO yields are high with CO_2:CO ratios approaching unity. CO is therefore likely to be an important toxic component. The formation of high yields of HCN is, however, not normally favored [61]. For many materials the product mix remains fairly constant over this temperature range, although the yields may increase somewhat with temperature.

Although toxic products are formed under these conditions, the rate of evolution is slow, smoke is seldom dense, and room temperatures are relatively low. A potential victim, therefore, has ample time to escape if alerted sufficiently early but may be overcome by fumes after a long period of time if unaware of the danger, particularly if asleep. The main danger here is almost certainly asphyxia by CO, with possibly a small contribution from low oxygen if the victim is in a room with a poor air supply [61, 138–141]. It is not possible from fire statistics to determine how often this type of fire occurs, since in many cases smoldering fires become flaming fires before they are detected. However, it is likely that fires estimated to have burned for 30 min or more before discovery have involved long-term smoldering, and it may be relevant that for victims in the 19–49 age group, deaths are 20 times more likely in this situation than for fires discovered within 5 min of ignition, which are often rapidly growing flaming fires [7].

The ability of smoldering fires to build up concentrations of CO capable of causing incapacitation and death in potential victims has been shown in large-scale fire tests [142]. A good example of such a situation is presented by a FED analyses of a series of tests carried out at NIST [143, 144], where two armchair types made from a standard and a fire-retarded polyurethane foam with cotton covers (combustible mass 5.7 kg) were burned in a simulated small apartment (volume 101 m^3) consisting of a burn room (11.8 m^3), connected via a corridor 12 m long to a target room (volume 12.08 m^3) (Tables 63.23 and 63.24). The armchairs were tested by flaming ignition of the seat back and also by smoldering caused by one or two cigarettes placed in the seat angle for approximately 1 h, followed either by spontaneous flaming or ignition from a flaming source. Under smoldering conditions, approximately 1 kg of foam was decomposed in just over 1 h. The smoke layer had reached the floor after 1 h, but there was a concentration gradient for smoke and toxic gases between the burn room and the target room. The major asphyxiant gas present was CO, which gradually increased in concentration in the burn room from 180 ppm during the first 13 min to 1000 ppm between 67 and 75 min. This was sufficient to have caused incapacitation (i.e., loss of consciousness) in just over 1 h in the burn room but probably not in the target room where the concentration was lower. When flaming ignition occurred, the armchair burned very rapidly and produced high concentrations of asphyxiant gases that would have been almost immediately fatal in the burn room. Within the target room an occupant would have become unconscious within less than 1 min and received a fatal dose within 2 min. The smoke in the system was also very irritant, and it is likely that anyone spending more than 1 h in the burn room would have suffered serious and possibly fatal lung damage, even if that person had been rescued. This example illustrates the dangers of

Note: By 71 min the mass loss exposure dose of irritants was approximately 300 g · m^3 · min, which may cause some lung damage

smoldering conditions, which can continue for several hours and spread lethal products throughout a building, creating danger for the sleeping, trapped, or otherwise incapacitated occupant. Since such fires often change to flaming before they are discovered, it is difficult to know the true incidence of incapacitation and death occurring during the nonflaming phase of fires. For this example, both the standard and fire-retarded (FR) chairs would have caused incapacitation after 1 h in the burn room, but due to its higher yield of CO and irritants, the FR chair would also cause incapacitation in the target room soon after, and death in the burn room after 1.5 h of smoldering. The standard foam death at both locations would occur within 1 min of the spontaneous transition to flaming after 75 min. These dangers can be overcome by the provision of

detection and warnings, but the silting of detectors can be important for effective operation.

Flaming Fires

For flaming fires where the victim is in the room of origin, the hazard relates to the early stages of fire growth. Such fires often grow quickly, but even the most rapidly growing flaming fires take approximately 3 min to reach levels of heat and gases hazardous to life [52], unless exposed subjects are intimate with the fire. As Fig. 63.22 shows, the hazard in this situation relates to a number of factors, all of which may reach life-threatening levels simultaneously as the fire reaches the rapid phase of exponential growth. In the high temperature, well-oxygenated flames of early flaming fires, much of the thermal decomposition products are consumed to form simple, comparatively innocuous products such as CO_2 and water, the CO_2 to CO volume ratios being high initially even up to the 500–1000 range and then decreasing to the region of 50–100 as the oxygen concentration decreases toward 15 %. Since CO is only approximately 10–50 times as toxic as CO_2, it is conceivable that in this type of fire CO_2 could present more of a toxic hazard than CO. However, as the CO_2 concentration in the fire compartment approaches 5 % and the O_2 concentration decreases toward 15 %, the combustion becomes less efficient and the CO_2 to CO ratios decrease to the region of 50–100, CO becoming a more important toxic factor.

With such flaming fires, the yields of irritant, oxidized fragments and of CO are generally lower than under nonflaming conditions, but the yields and relative rates of production of CO_2, CO, and irritant smoke depend on the rate and efficiency of combustion. As Fig. 63.22 and Table 63.3 show, the atmospheres obtained in a rapidly growing fire can develop asphyxiant concentrations of CO_2 (greater than 5 %), CO (greater than 1000 ppm), and low oxygen (less than 15 % O_2), as well as some dense irritant smoke from products escaping the flame zone. During the early, fuel-controlled, stages of compartment fires both the rates of fire growth and yields of products depend on the physical and chemical properties of the fuel. Initially the toxic hazards are low, because the mass loss rate of the fuel is low, and for most common non-flame retarded natural and synthetic polymers, the yields of toxic products and smoke are low. Also, any products formed are carried into the upper layer under the ceiling and above heat height for the occupants. If the fuels are flame-retarded then the combustion efficiency is reduced, so that higher yields of toxic products are formed, but the rate of initial fire growth, and therefore the rate of upper layer filling and descent, tends to be slower, allowing more time for escape before exposure.

As the fire grows the fuel mass loss rate increases. If fire is in the open, or in a large, high, well-ventilated enclosure such as an atrium, then combustion remains efficient for non-flame retarded fuels and a large, fuel-controlled fire results. If the fire occurs in a single-storey enclosure with a relatively low ceiling, then as the fire grows the upper layer fills down, so that the flames enter the somewhat oxygen-depleted upper layer. The fuel-air equivalence ratio increases and the combustion efficiency decreases so that high yields of smoke and toxic substances are produced by all fuels (as measured in compartment fire and bench-scale experiments involving a wide range of fuels) [138, 145, 146]. This stage therefore represents a transition to pre-flashover ventilation-controlled combustion conditions. This stage is much more hazardous to occupants both within and beyond the fire enclosure because the fire is larger, so that the mass loss rate is greater than during the early, well-ventilated, stage, the yields of toxic species are much greater and the upper layer descends below head height so that room occupants are likely to be exposed. The effects of combustion conditions on toxic product yields is reviewed in Purser et al [140, 141].

Under vitiated flaming combustion conditions and the severe conditions found in high-temperature postflashover fires [16, 138, 140, 141, 147] (upper-layer temperature exceeding

800 °C) where oxygen concentrations are low, there is a major change in decomposition in that the main pyrolysis products break down into low molecular weight fragments and can contain high concentrations of asphyxiant substances such as CO and HCN, with low CO_2 to CO ratios (see Table 63.3).

Conditions in the enclosure of fire origin become fatal to exposed victims from the effects of heat and toxic products before the onset of flashover. For victims beyond the enclosure of origin the toxic effluents from ventilation-controlled pre- and post-flashover fires can spread throughout buildings producing lethal conditions beyond the enclosure of origin. As effluents spread within buildings the temperature decreases as they mix with air beyond the enclosure of origin and as heat is lost to the structure. Toxic effluents are also subject to dilution, but no depletion due to losses for CO and HCN. For smoke particulates and acid gases, some losses to the walls can occur over period of 10s of minutes under static conditions, but are generally minor in fresh effluent plumes from large fires as they flow through buildings.

Victims in the enclosure of origin are therefore likely to be confronted simultaneously by high temperatures and heat radiation, smoke, and high concentrations of CO, HCN, irritants and CO_2 accompanied by low O_2, any one of which could incapacitate and prevent escape. Victims in remote locations are likely to be overcome by toxic smoke rather than by heat.

The inability of victims to escape from such fires seems to depend on a number of factors. Casualties include a higher proportion of young children and the elderly than does the general population. (In 1978, fatalities in bedding fires for those over 65 were seven times those expected from the distribution in the 1978 population [7, 64].) People who are incapacitated by a previous period of smoldering or by some other infirmity (such as a physical disability or alcohol or drug intoxication) are obviously more at risk [64]). However, there seem to be two other factors of importance: (1) the behavior of the victim and (2) the exponential rate of fire development.

In many cases, the victim has a short period in which to carry out the correct actions enabling escape, after which he or she is rapidly trapped. Some victims may be asleep during this critical escape "window," but there are also reports of situations where the victim was aware of the fire from time of ignition but remained in an attempt to extinguish the fire or for some other reason failed to leave before the phase of very rapid fire growth when heat and asphyxiant gases rapidly reach life-threatening levels as combustion becomes inefficient. Another, perhaps surprising, finding is that victims often appear to be unaware of the fire and are discovered in a burned-out chair or bed where they have remained. The insidious nature of CO intoxication has been described; it also seems that irritant smoke products often fail to wake sleeping victims, although a sudden noise such as of breaking glass may do so. It may seem odd that acrid fumes may fail to alert sleeping victims, but a possible explanation may lie in the adaptation to sensory irritation during continuous exposure reported for the experiments with CS gas [36]. In smoldering fires, the concentration buildup of irritants is slow, allowing time for adaptation to occur. There may be no subsequent response to a high concentration that, if presented suddenly (as, for example, with smelling salts), would rouse the subject. Other victims appear to have roused themselves at some stage of the fire but have been overcome, again probably by CO or HCN, before they are able to escape and are found behind a door. There are also cases reported by survivors where a victim has attempted to extinguish a rapidly growing flaming fire but failed to leave in time and is discovered near the fire having been overcome by fumes [139]. Unfortunately, reports of such effects on victims are largely anecdotal, and systematic studies of fire victim experience are few. The apparent anomaly of why so many casualties occur in the room of fire origin when theoretically there should be time to escape would seem to be a particular area that needs further investigation. The following pilot study has, therefore, been made of this problem.

Pilot Study of Room-of-Origin Deaths

As stated, the results of large-scale fire tests suggest that even in a worst-case situation there should be a period of at least 3 min before conditions in a rapidly growing flaming fire become untenable, and in many cases fire growth will take considerably longer. From a knowledge of the toxicity of fire products, it would, therefore, seem that a normal, healthy, waking individual should be able to escape from such situations without much difficulty, while a sleeping or otherwise incapacitated victim may be overcome by a smoldering or slowly growing fire, as well as by a rapidly growing fire. To test this hypothesis, an examination was made of the 1981 U.K. statistics, specifically for textile fires in dwellings for casualties in the 19–49 year age group, a group most likely to be active and able-bodied. The data are summarized in Table 63.25 for fires estimated to have been discovered within 5 min of ignition (most likely to have been rapidly growing flaming fires) and for fires where the time to discovery is estimated to have been 30 min or more (most likely to have involved a period of prolonged smoldering before severe flaming).

The data show that there were 23,082 fires in the first category, but only four fatalities, while for the second category there were fewer fires (5870) but 20 fatalities, a ratio per fire of 1:20. Obviously, a number of interpretations could be put on these data, but it does seem that people in this active age group are often able to escape from rapidly growing fires in domestic-sized compartments. Fatalities are much more likely in fires that have undergone a period of prolonged smoldering, when victims may have been overcome by prolonged, low-level exposure to asphyxiant fumes. If this is the case, perhaps there should be more concern about the ability of materials to continue smoldering, with toxic gas buildup over a long period of time then often followed by transition to flaming, at least in the context of this class of fire.

Table 63.25 Fatal casualties in room of fire origin (textile fires in dwellings for 1981 [7], age group 19–49 years)

Time to discovery (min)	Number of fires	Number of fatalities
<5	23,082	4
>30	5870	20
		Ratio 1:20

Small Restricted-Ventilation Fires in Closed Compartments

Closed-room fires are hazardous situations, wherein a smoldering, or especially a flaming, fire quickly uses up the available oxygen, and as the oxygen concentration falls after a minute or so of burning the combustion becomes inefficient, producing a dense smoke rich in carbon monoxide and other toxic products. These, together with the lowered oxygen concentration in a room, can produce a rapidly lethal atmosphere. An example is a fire case involving an adult and a 4-year-old child. Both were in a small bedroom for a short time during which the adult went to sleep and the child is thought to have ignited a small piece of foam using a cigarette lighter. The fire was discovered after a few minutes, when the door was opened by a family member, who extinguished the very small fire with a bucket of water. Both the adult and child were dead, with blood carboxyhemoglobin concentrations of about half a lethal level. Based on the dimensions of the room, it is calculated that the decomposition of approximately 0.5 kg of material would be sufficient to lower the oxygen concentration to 10 % and give carbon monoxide concentrations of approximately 1 % or more, which together with other toxic products would cause incapacitation and death within a few minutes. With such small fires it would seem that early detection and warning, coupled with materials giving a slow fire growth, would greatly increase the probability of escape and survival.

During the period when most occupants are at risk, the majority of fires in small, enclosed, buildings (such as houses, flats, hotels, boarding houses, cellular offices, and small shops) are likely to be restricted ventilation (vitiated) pre-flashover fires. However, if external

windows or doors are open or (as often happens) are opened at a later stage of the event, then flashover may occur. The characteristics of restricted ventilation fires are that there are three main regions at which combustion reactions occur. One is at the interface between the solid (or liquid) fuel and the base of the flame, where fuel materials are decomposed and partially oxidized by heat to form the gaseous fuel for the fire. The second is in the lower part of the flame zone, where air and fuel gases combine to produce heat and primary products. The third is in the vitiated hot zone in the upper part of the flame and beyond where hot, partially combusted fuel gases react in a restricted oxygen atmosphere to produce high yields of irritant and asphyxiant smoke products. These conditions occur when the upper layer has filled down to a low level above the fire in the fire enclosure and where partially combusted fire effluent may be recycled into the fire from outside the fire enclosure. Such fires are usually relatively small, often being limited to the item first ignited, sometimes involving some decomposition (nonflaming or vitiated flaming) of combustible materials at high levels in the room (such as paint, coving, or objects placed on cupboards or the upper levels of bookcases or racks).

The main hazards from such fires during the critical stages are likely to be from irritant smoke and asphyxiant gases. Inefficient combustion leads to high yields of these toxic smoke products. Apart from the immediate vicinity of the fire, the temperatures in the fire enclosure and beyond are not particularly high, so that heat is usually not the primary hazard.

These descriptions of fire scenarios illustrate that fire hazards, particularly the toxic hazards, vary considerably depending on the combustion conditions. In buildings, the majority of fires hazardous to occupants are likely to involve vitiated flaming combustion conditions to some extent, either pre- or postflashover depending on the scenario. This is likely to be especially true of fires in domestic dwellings, which account for the vast majority of injuries and deaths. Most fire deaths in the United Kingdom (61 % in 1992) [7] result from small fires when the victim is in the room of fire origin. In order to study the development of hazardous conditions in typical domestic fires and to develop a series of realistic design fires for smaller enclosures with restricted ventilation, a series of 23 fires were been carried out at the Fire Research Station over a number of years. These fires were carried out in three experimental rigs (Fig. 63.34), consisting of a room–corridor rig, a room–corridor–room rig, and a typical domestic two-story house. The first rig simulates conditions for a fire in a small enclosure connected via a corridor to a source of ventilation, such as an open door or window, or a much large interior space. The second rig simulates conditions in a small single-story apartment, whereas the third simulates conditions for house fires. For all these experiments the fire was in one room and the developing fire conditions were measured in the fire room and other locations throughout the experimental rigs. The majority of fires involved single items of upholstered furniture (armchairs).

In order to give an example of the developing conditions in a typical fire in a domestic house and the likely hazards faced by occupants, one of these experiments is described. This experiment involved a common situation in which a fire was started in the seat of an armchair. The armchair was typical of modern furniture, upholstered with combustion modified foam and fire retardant back coated acrylic covers. A flaming ignition source was used, consisting of a No. 7 wood crib, which is approximately equivalent to two-three sheets of newspaper. The armchair was placed in the downstairs lounge with the door to the hallway open. Upstairs, the front bedroom door was open and the back bedroom door shut. The kitchen and bathroom doors were also shut. Figures 63.35 and 63.36 show the developing conditions in the lounge and bedroom, with estimates of the developing hazards faced by occupants of the lounge and open bedroom. For each of Figs. 63.35 and 63.36 the upper graphs show the gas and smoke concentrations, whereas the lower graphs show the hazard development at head height for a standing occupant. The hazard development is expressed in terms of the FEC (smoke), FIC

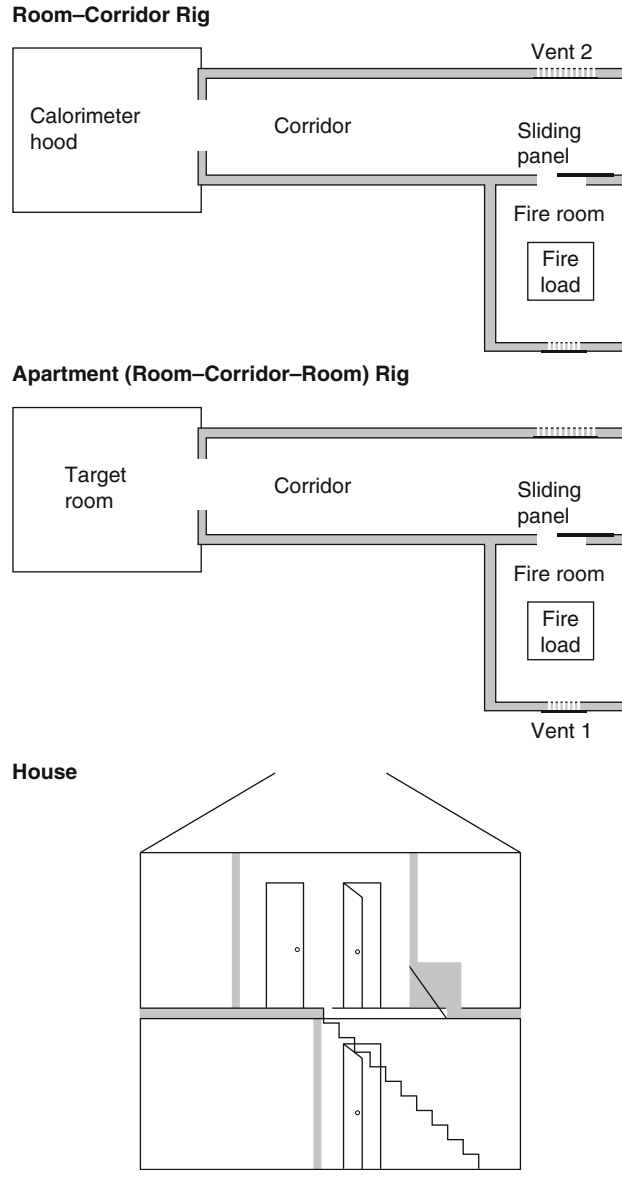

Fig. 63.34 Full-scale fire test rigs [138]

(fractional irritant concentration), or FED (fractional effective dose) for each hazard parameter. This means that for each parameter a tenability limit is reached when the line crosses 1 on the *y*-axis. The graphs for the fire gases show that in the lounge the fire grows slowly at first producing some smoke but then grows more rapidly after about 4 min. From about 5 min the oxygen concentration in the fire room starts to decrease so that at around 9 min the fire self-extinguishes. The peak temperature at the ceiling in the hottest region above the fire was 350 °C. The peak carbon monoxide concentration was 1.1 % and the peak hydrogen cyanide concentration was 1100 ppm. The ionization smoke detector in the lounge was triggered at 0.5 min and the optical detector at 1.5 min. The first hazard confronting an occupant of the lounge would be smoke, and from the smoke analysis it is considered that the smoke would be irritant. The line for irritant smoke crosses the tenability limit at around 1.5 min in the lounge. From this point, a room

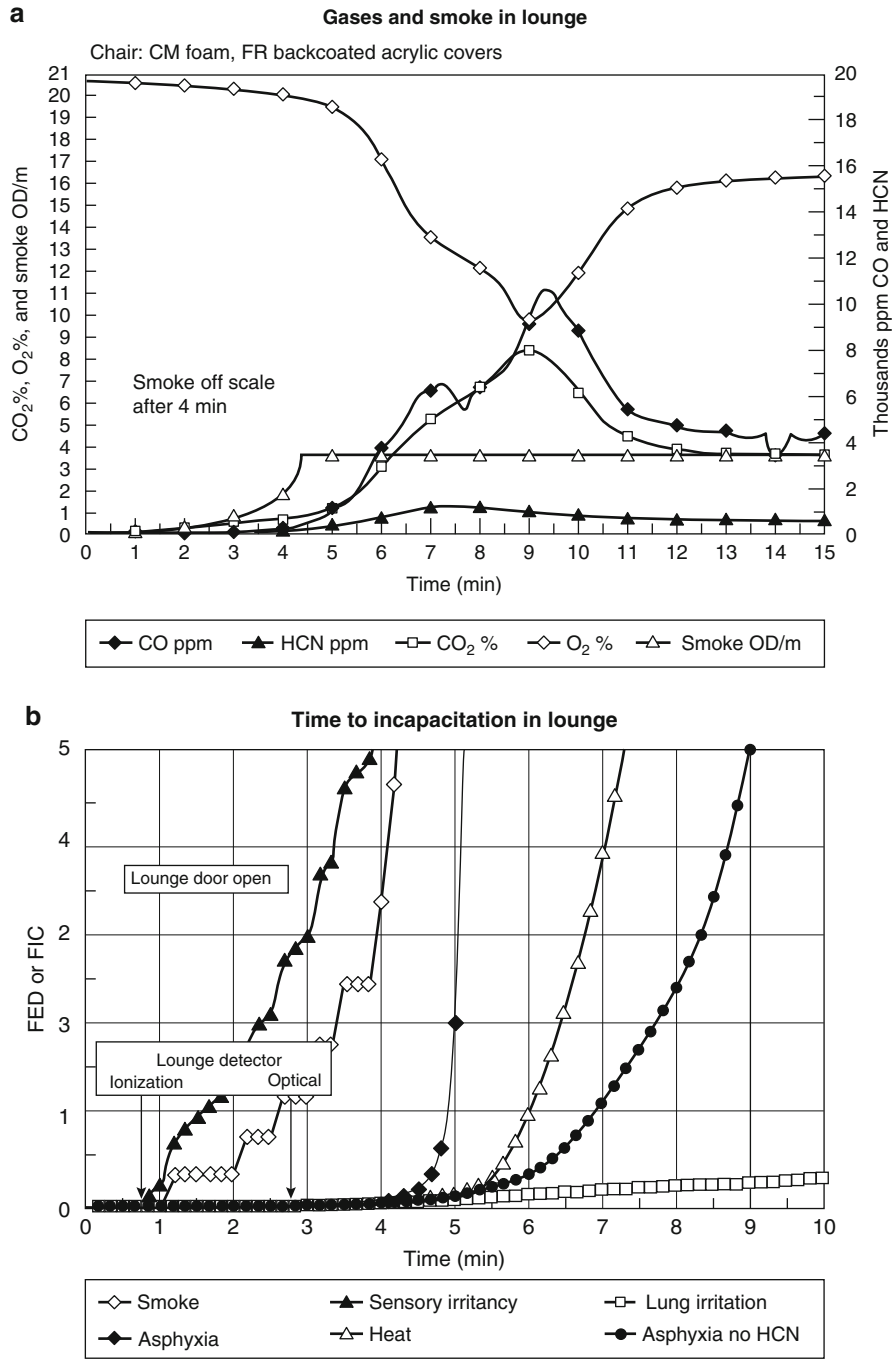

Fig. 63.35 Gases, smoke, and hazard analysis in lounge for armchair fire in house [18]

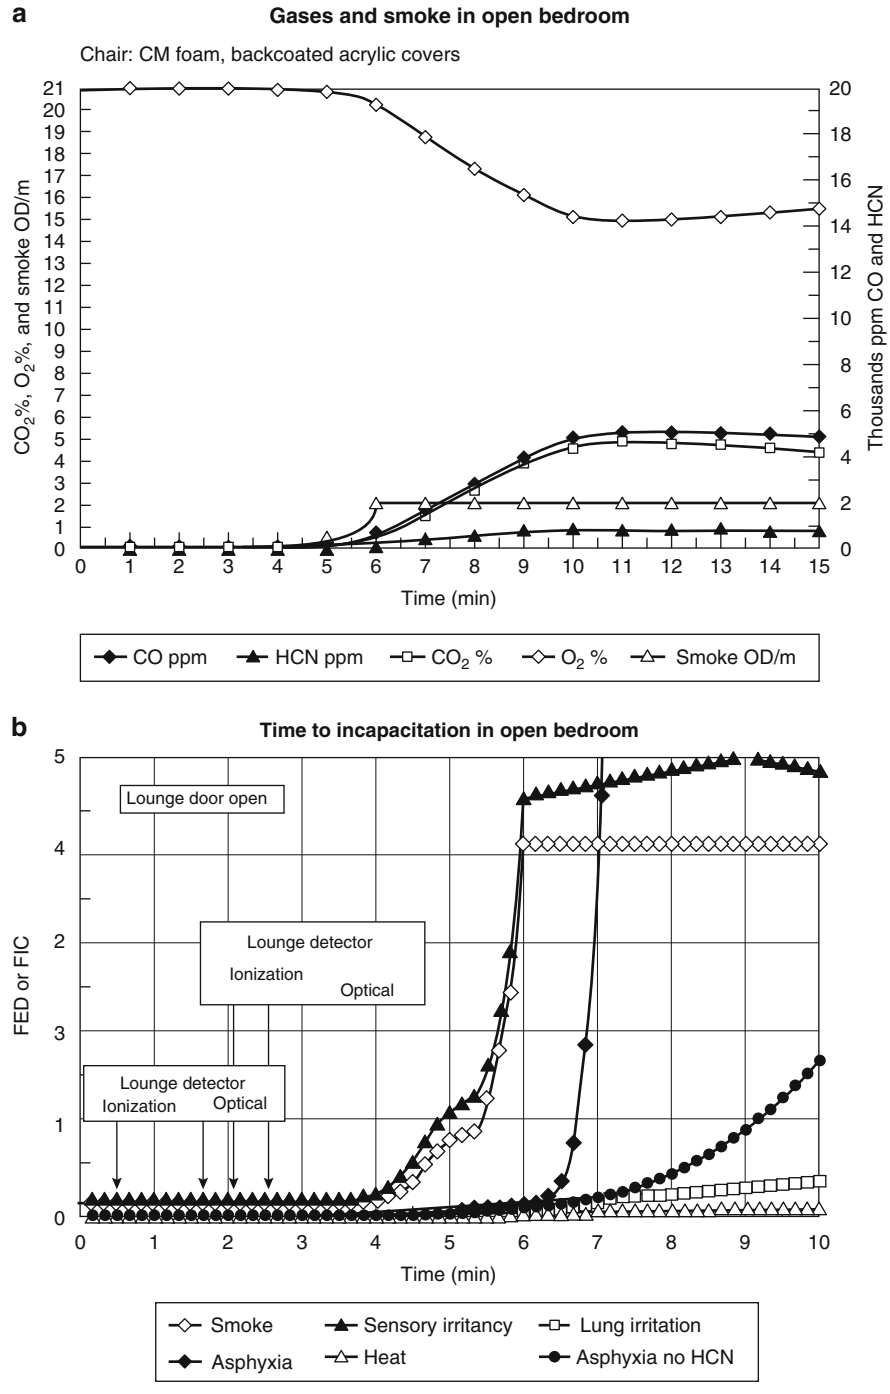

Fig. 63.36 Gases, heat, and hazard analysis in open bedroom for armchair fire in house [18]

occupant would experience difficulties in seeing, due to painful eye irritation and the presence of smoke, and breathing difficulties. It is likely that these effects would hamper, but probably not prevent, room occupants from finding their way out of the room to the front door. One minute later, the purely visual obscuration effects of the smoke (i.e., assuming the smoke was nonirritant) reach the tenability limit of 2 m visibility. If occupants were still in the room at 5 min, it is predicted that they would collapse unconscious due to the effects of asphyxiant gases. This collapse is largely due to the presence of hydrogen cyanide. If there was no cyanide present, it is predicted that collapse would not occur for a further 2 min (at 7 min). At 8 min it is predicted that an occupant would be overcome by heat, suffering burns to unprotected skin.

Figure 63.36 shows the conditions in the open upstairs bedroom. The smoke and gases start to increase significantly from around 4 min, but there was sufficient smoke on the upstairs landing to trigger the ionization smoke detector at around 2 min and the optical detector at around 2.5 min. The gas and smoke concentrations increase more gradually than in the lounge, since they are well mixed by the time they reach the bedroom. From around 11 min the smoke and gas concentrations are similar throughout the house. The temperature in the bedroom peaked at around 60 °C after 9 min. The hazard analysis shows that irritant smoke is predicted to be a problem from around 4.5 min. After this time bedroom occupants might experience some difficulties in finding their way out of the room and down the stairs. They would also have to decide whether it would be better to close the bedroom door and stay in the room until the fire brigade arrived or to attempt to escape via the door or window. Analysis of the conditions in the closed bedroom showed protection for some 20 min or so if the door was closed throughout. If open bedroom occupants were still in the room after approximately 5.5 min, it is predicted that they would collapse unconscious from the effects of asphyxiant gases. As with the lounge, this is predominantly due to the effects of hydrogen cyanide, conditions remaining tenable for around 9.5 min if this gas is absent. The temperature in the bedroom is insufficient to cause incapacitation.

This example shows how typical flaming furniture fires are likely to develop and threaten the occupants of a domestic house. The main hazards, in order, are first irritant smoke and second asphyxiant gases, particularly hydrogen cyanide and carbon monoxide. The fires are often small, being limited to the item first ignited, and self-extinguish when the oxygen concentration decreases. In practice, many domestic fires begin by a variable period of nonflaming/smoldering before flaming ignition occurs. This may last for several hours. Depending on the nature of the smoldering materials, a hazard may develop, primarily from carbon monoxide. The house fills with a slowly thickening and irritant smoke, which may trigger detectors before the situation becomes dangerous. Another possibility is that the fire will grow rapidly, possibly to flashover. This is particularly likely if external doors or windows are open (or if windows break and fall out). Such large fires commonly develop when occupants are roused during the early stages and open external doors or windows during the fire to affect escape or rescue. The conditions rapidly become fatal, due to the large amounts of heat and toxic smoke produced, and there is often considerable damage resulting from fire spread throughout the building. All data from the 23 fire tests have been placed on a CD-ROM database. Further details of the fire loads and results of tests are given in Purser et al [148]. Table 63.26 shows examples of four fires in terms of times to alarm and different tenability limits.

Figures 63.37 and 63.38 illustrate the times between ignition, detection, and the various tenability criteria in the lounge and bedroom for these and other fires [138, 148].

For all fires except Experiment CDT 16, the fire room door was open to the remainder of the apartment or house. Figure 63.37 shows similar results in the apartment rig to those in the two-story house for the same type of chair (Experiments CDT 11, 21, and 23), but when fire-retarded covers were used, the tenability

times for asphyxia are increased by approximately 1.5 min (Experiments CDT 17 and 18). The importance of HCN as a primary cause of incapacitation in these fires is shown by comparing the asphyxia with HCN bar with asphyxia without HCN bar. If no HCN were present, the time to asphyxia is increased by up to 2.5 min. For flaming fires in the fire room, ionization detectors triggered 1–2 min earlier than optical detectors, although optical detectors would be expected to trigger earlier if the fires had been initiated by a nonflaming source. Times in Fig. 63.37 are for optical detectors on the upstairs landing ceiling. For this location there was only a small difference between ionization and optical triggering times as shown in Fig. 63.37. Figure 63.38 shows the situation in the open upstairs bedroom. In this situation the results are similar to those from the fire room, in that times to loss of tenability from asphyxia are several minutes longer for the chairs with fire-retarded covers.

Hazardous situations in fires develop as a result of a complex interaction between the building, the burning contents, and the occupants. When evaluating materials, it is important to consider not just the toxic potency of the combustion products but also the overall fire risk and burning behavior of the item. Although some modern materials and flame-retardant systems may present possible toxic potency and environmental problems, they give rise to considerable overall benefits if they reduce the number of fires occurring. It is also obvious that slow fire development, buying time for occupants to escape, is beneficial, particularly when linked with efficient detection and warning systems. It is likely that a combination of these factors has led to recent reductions in fire deaths

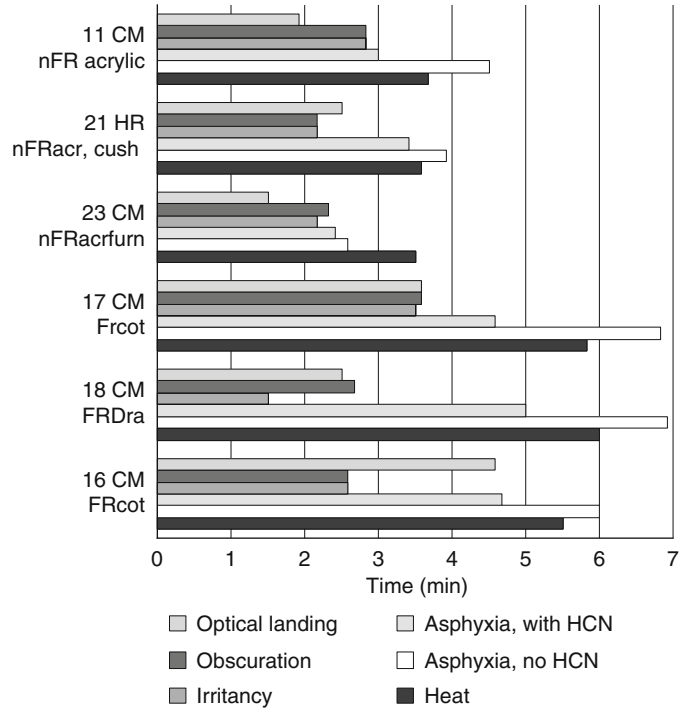

Fig. 63.37 Time to detection and effect for armchair fire in the lounge (fire room). Key: 11 CM nFR acrylic (armchair, non-fire-retarded acrylic covers, combustion modified foam—apartment rig), 21 h nFRacr, cush (nonFR acrylic covers, combustion modified foam, foam scatter cushions—house), 23 CM nFRacrfurn (nonFR acrylic covers, combustion modified foam, fully furnished room—house), 17 CM FRcot (FR back-coated cotton covers, combustion modified foam—house), 18 CM FRDra (FR back-coated acrylic covers, combustion modified foam—house), 16 CM FRcot (same as for 17, but fire room door closed)

compared with the early 1980s. Although the majority of fires and toxic effluent derive mainly from building contents rather than the structure, it is evident that the building and its systems are very important factors in the development of the fire and its hazards. In the domestic context, the type, maintenance, and placement of smoke alarm systems are likely to be important in the provision of early warnings to occupants. The simple expedient of closing doors and windows on unoccupied rooms is also likely to considerably reduce fire hazards while providing a tenable escape route. The use of sprinklers and smoke venting systems are other important strategies, particularly in nondomestic buildings.

These restricted-ventilation fires in enclosed compartments (compartments varying in size from a single closed room to the entire internal volume of an enclosed apartment or store unit) tend to remain relatively small as long as the boundaries remain enclosed (no open doors or windows), with the fire itself generally restricted to a small area of a room. However, as described in the examples presented, the vitiated fire effluent, which contains high concentrations of toxic products, rapidly contaminates all contiguous open areas remote from the source with a lethal atmosphere, resulting in many casualties occurring in remote locations. An even greater degree of contamination occurs when there is more ventilation so that fires can become fully developed.

Fully Developed Fires

The third scenario involves large, fully developed fires where casualties occur remote from the source of the fire. This type of fire has progressed beyond the stage of local growth and has spread from the material first ignited to others. The fire may still be largely confined to the compartment or area of origin, but large amounts of toxic smoke are formed, which spread throughout buildings, giving rise to lethal atmospheres remote from the actual fire, and often penetrating beyond compartment boundaries. Apart from being a common occurrence in domestic dwellings, such situations often occur in public buildings where there may be major loss of life in a single incident. Materials in such fires are subjected to substantial external heat flux and in some cases to oxygen deficient environments. Under the severe conditions found in such high-temperature, post-flashover fires with low oxygen concentrations, the basic pyrolysis products break down into low molecular weight fragments and can contain high concentrations of asphyxiant substances such as CO and HCN, with CO_2 to CO ratios of less than 10 [63].

Under such conditions, a building can fill rapidly with a lethal smoke capable of causing incapacitation and death within minutes. Fires where the victim is remote from the compartment of origin are responsible for the highest incidence of nonfatal casualties (48 %) and a large proportion of deaths (37 %) in the United Kingdom [7]. Many such fires are likely to be non-flashover fires, but a proportion involve fires progressing to flashover. The victim is still five times more likely to be killed by smoke than by burns and is often unaware of the fire during the crucial early phase, so that the gases may not penetrate to the victim until the fire has reached its rapid growth phase and the victim is already trapped. The major causes of incapacitation and death in this type of fire are almost certainly asphyxiant gases, particularly CO and HCN, which can build rapidly to high concentrations (although the role of irritants in causing incapacitation and impeding escape attempts may be crucial to victim survival).

An example of such a fire is provided by some studies of the effects of the penetration of a large external fuel fire into the cabin of an airplane, as happened in the Manchester Airtours fire [149]. Table 63.27 shows the results obtained inside the cabin of a Boeing 707 containing a few rows of seats opposite an open doorway, outside which was 50 gal of burning aviation fuel [143, 150]. The rapid involvement of the cabin contents gave rise to a dense smoke containing large amounts of carbon monoxide and hydrogen cyanide at a measurement point halfway down the fuselage. Incapacitation is predicted just after 2 min followed rapidly by

Table 63.27 Average concentrations of toxic and physical hazards and fractional incapacitating doses over 30-s periods during aircraft cabin fire

Time to tenability limit for radiant heat: 2 min 45 s
Effects of irritants
Over period between 1 and 4 min: average respirable particulates 6.7 mg/L
Average total particulates 11.6 mg/L
Average HCl concentration 1027 ppm
Average HBr concentration 1228 ppm
It is considered that the oily, be highly irritant and extremely painful to eyes and breathing, causing incapacitation and impairing escape attempts. It is considered likely that these irritants reached high concentrations (approaching 1000 ppm total acid gases) early in the fire at approximately 1–1.5 min, from which time escape capability would be significantly impaired. It is likely that sufficient irritants would be inhaled up to 4 min to cause life-threatening postexposure lung damage

death, mainly from the effects of hydrogen cyanide (high concentrations of which were found in the blood of the Manchester victims). For this experiment there were two large vents, the doorway next to the external fuel fire near the rear of the cabin and a door at the front of the cabin. This flow-through ventilation coupled with the small cross-section area of the fuselage resulted in rapid fire growth once the seats were ignited.

Although in many large fires the original fuel and the major source of heat and toxic products may be the contents, a significant contribution may be made by construction products. Of great importance in some cases are surface coverings or components with a large surface area, such as doors or partitions. Surface coverings may contribute to flashover spread (as in the Dublin Stardust disco fire and the Station Nightclub fire) and may release a bolus of toxic products very quickly, which may have a serious incapacitating effect on victims. An example would be vinyl wall coverings or the vinyl laminates used in aircraft cabins. PVC releases all its hydrogen chloride at a low temperature (approximately

250–300 °C), so that, as a fire develops and the hot layer reaches this temperature, HCl may be suddenly released. In another aircraft fire test conducted by the FAA, high concentrations of HCl and HF occurred in the cabin atmosphere before other gases reached toxic levels [147]. Another problem with surface materials treated with halogenated flame-retardants is that if the fire reaches a sufficient size to cause the retardants to off-gas, the remaining fuel residue is may no longer be protected an so become vulnerable to a sudden flashover.

In general, although in some cases fire and heat may eventually kill victims, this is usually preceded by dense, highly toxic smoke that can spread rapidly throughout a space or a building, which is usually responsible for the initial incapacitation of occupants, as well as being the cause of many deaths.

A common feature in many major fire disasters is a failure in early detection and effective warnings. In many cases the fire was detected at an early stage, and some attempts were made to deal with the fire, but often there was a failure to instruct people to leave while the fire was small and a failure to realize that a small fire grows with exponential speed into a life-threatening one. For example, in Summerland [151] the initial fire was considered non-threatening, and occupants were encouraged to remain seated rather than to leave. At the Manchester Woolworth's fire [152] people continued to eat in the restaurant area while the fire was growing on the other side of the sales floor. At the Bradford stadium fire people watched the early fire development at the end of the stand and did not begin to move until a late stage. At the Dupont Plaza hotel, the fire began in an unoccupied furniture storage area but was discovered and fought at an early stage; however, mass evacuation of the hotel did not occur until after the fire went to flashover and started to spread. At the Beverly Hills Supper Club fire [151], 20 min elapsed between discovery and evacuation instructions. At a number of major incidents in transport situations (road and rail tunnels or stations) the fires were discovered at an early stage, but considerable times elapsed as information passed up management chains before evacuation warnings and other emergency actions were taken. Examples include the Kings Cross fire subway station fire [151] in which the escalator fire was burning for some time before attempts were made to close the station, the Daegu subway train fire, the Mont Blanc road tunnel fire and the Dusseldof airport fire [24, 153]. At the Dublin Stardust disco, the fire grew unnoticed behind a partition. It could be said that when people are able to perceive a fire as a possible threat to their life, it may already be too late to escape. In the majority of these cases, evacuation occurred at a late stage and there were failures in the provision of accurate, authoritative, and informative evacuation instructions.

General Comment

The severe asphyxiant incapacitation and subsequent death of many fire victims are almost certainly due to the common asphyxiant gases. However, the effect of irritants in impeding escape is an important consideration, and it is not obvious from asphyxiant gas profiles why so many fatalities occur in the room of fire origin. Useful information may be obtainable from survivors who have experienced exposure to dense, irritant smokes and from case studies of room of origin fires.

Possible Routes to Mitigation of Toxic Hazard

For smoldering fires it would be advantageous if materials were designed to self-extinguish, and if the formation of products other than CO during decomposition (such as oxidized hydrocarbon fragments or CO_2) could be encouraged. Early audible warning by smoke alarms may be particularly advantageous, as sound often appears to alert victims where the presence of irritant smoke or heat fails.

For early flaming fires where the victim is in the room of origin, any measure that limits the rate of growth once ignition has occurred will give a victim more time to extinguish a small fire or escape from a growing one.

For fully developed fires where the victim is remote from the point of origin, the most important mitigating factors are early warning and containment of the fire and gases within the original fire compartment.

The development of hazardous situations in a fire involves a whole range of factors, including fire development from ignition to the post-flashover spread of fire and smoke, toxicity, and the interaction of the fire with the structure and with passive and active fire protection, as well as escape-related factors, including detection, warnings, the provision of escape routes, wayfinding, physiological and behavioral impairment, and escape movements or rescue. In designing a system to be safe in fire, all these factors should be considered, and the ultimate evaluation of safety depends on whether it is possible to ensure, by performing a life threat hazard and risk assessment, that the occupants can reasonably be expected to have escaped before they are exposed to levels of heat and smoke that may endanger health and threaten life.

The Use of Fractional Effective Dose Methodology in Fire Investigation

The (FED) methods described for calculating exposure doses and times to incapacitation and death from fire data have proved to be a useful tool for investigating fire incidents in which occupants have been injured or died. It has been applied usefully to investigations of several major incidents including the Dupont Plaza fire, the Mont Blanc Tunnel fire [24] and the Rosepark Care home fire [25]. Where data have been obtained on the fire conditions (time-concentration curves for toxic products and heat in these fires), either from full-scale fire reconstruction experiments of from fire modeling computations, it is possible to calculate the predicted effects on occupants and their timing. Beyond this, when forensic data are available from the victims (primarily blood carboxyhemoglobin and cyanide concentrations, extent of smoke deposition in the lungs and extent of burns), it has been possible to use FED calculations to partially validate the fire test or fire modeling calculations.

A difficulty with incident re-creation tests and fire models is that, due to the variability of fires, it can be difficult to establish exactly how close results are to the conditions in the actual incident. From the time-concentration curves of CO in a fire, it is possible to calculate the uptake by exposed subjects and hence the %COHb in the blood at the time of death or rescue (if these times are known). For subjects dying in the fire, the calculated %COHb level can be compared directly with the actual levels measured at post-mortem. For fire survivors, if the post-fire treatment (in terms of air exposure or oxygen therapy) is known and the time at which a blood sample was taken in hospital is known, then it is possible to back-calculate from the CO wash-out curve to find the %COHb at the time of rescue, which can be compared with the forward-calculated value. If there is reasonably good agreement between the forward and back-calculated values, then this provides a good indication that the combustion conditions and history of the test or modeled fire were close to those occurring during the actual incident. The same considerations apply to the blood cyanide concentrations, burns and smoke deposition. In practice, the FED and forensic approaches tend to be complementary with the fire testing and modeling approaches, in that while some uncertainties often apply to both methods, when used together the level of confidence in the findings can be considerably enhanced.

One example of the use of these methods was for the Mont Blanc Tunnel fire inquiry [24]. During this fire, it was possible to establish the time at which some vehicle occupants had stopped in the tunnel, had attempted to walk back towards the French portal and the locations at which they had collapsed and died. From CFD modeling calculations of the vehicle fire, smoke data recorded in the tunnel and FED modeling, it was possible to calculate how long occupants would have been able to walk along the tunnel, how fast they would move in the smoke and when (and especially at what location) they would have been overcome by heat and toxic gases. The results of these calculations showed a good agreement between the actual time and location of collapse and the times and locations

of collapse calculated according to the CFD and FED modeling. The CFD and FED modeling was therefore validated, and the combined approach provided a good understanding of the conditions during the fire and effects on the tunnel occupants.

Another example was application to the Rosepark Nursing Home fire [25, 27]. In this incident a brief intense fire involving mixed fuels and some exploding aerosol cans occurred at night in a cupboard opening onto a corridor. Ten elderly sleeping occupants of open rooms off this corridor died at the scene, while two who had their room doors closed were rescued after approximately an hour, but were overcome by toxic smoke exposure and subsequently died in hospital. During the fire, a fire door between the main fire corridor and the next compartment was blown open by the pressure pulses as the aerosols exploded so that a considerable quantity of smoke passed through, resulting in five occupants of open or partly open rooms off this corridor being overcome so that two died after rescue. A full-scale reconstruction of the affected part of this building and the fire incident was carried out by BRE on behalf of the Scottish Office and the Procurator Fiscal. FED calculations were applied to the fire test data to calculate timing and effects on the occupants, assuming the conditions in the reconstruction were similar to those during the actual incident. Forensic data, principally the %COHb concentrations and extent of burns in the decedents and those rescued from the fire were also examined. Figure 63.39 shows the time-concentration curves of toxic gases and heat in the fire corridor. Figure 63.40 shows the FED hazard analysis for a standing corridor occupant.

The FED calculations show dense smoke from 4 min after ignition, with collapse from the effects of asphyxiant gases predicted after 5.5 min due mainly to the effects of HCN and CO, with a lethal (50 %COHb) level of CO predicted by 6.5 min. Severe pain from convected heat exposure is predicted after 6 min in the corridor. The smoke and toxic gas conditions at bed height in the open rooms were similar to those in the corridor, but temperatures at bed height were much lower. It was therefore predicted that all open room occupants would

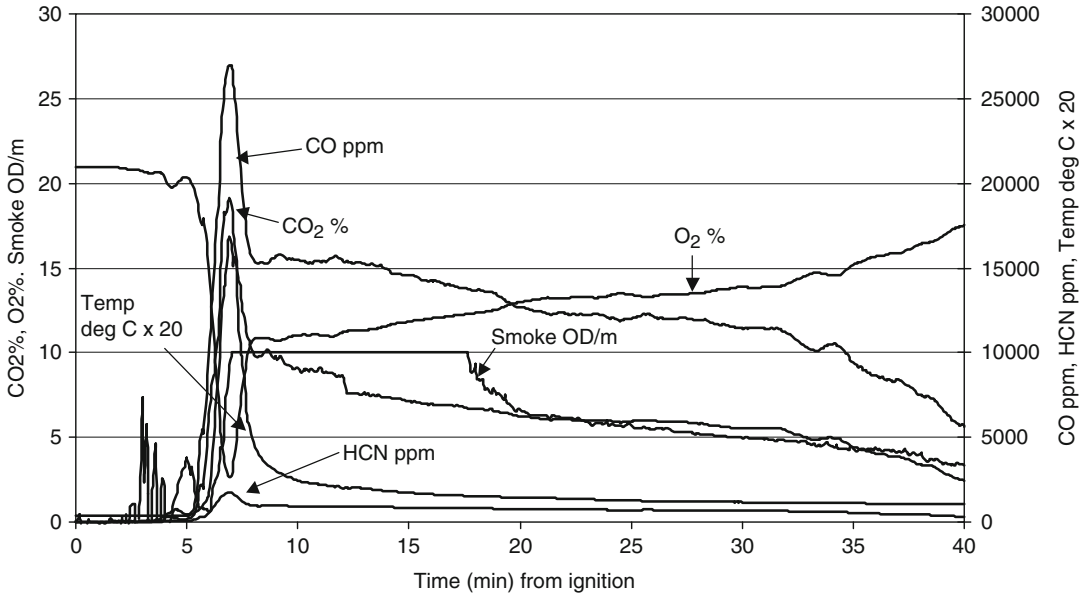

Fig. 63.39 Smoke, toxic gases and temperature profile in the fire corridor during the BRE full-scale recreation of the Rosepark nursing home fire. Conditions in the open bedrooms off this corridor were similar except that temperature at bed height was considerably lower

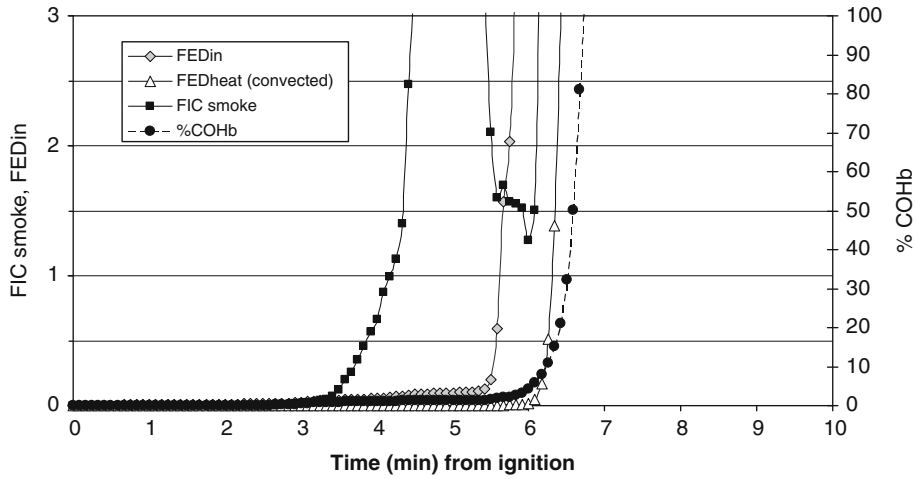

Fig. 63.40 Fractional effective dose hazard analysis for the corridor fire profile shown in Fig. 63.39

have been overcome and died within a few minutes due to the effects of asphyxiant gases, with lethal %COHb blood levels but no burns, and this was the finding from the forensic data, with all room occupants dead at the fire scene when the fire service entered the area. These findings and the pattern of fire damage were supportive that the reconstructed fire conditions were similar to those in the incident, but since the exact times of death for the room occupants were unknown, these findings could not fully validate the fire conditions. Figure 63.41 shows the conditions in one of the closed rooms off the fire corridor from which the uptake of CO (% COHb) could be calculated for the room occupant. The time of rescue for this occupant is known as well as her subsequent treatment and the %COHb concentration in her blood measured soon after her arrival at hospital. Figure 63.42 shows the FED analysis in terms of the forward-calculated %COHb from the fire data and the back-calculated %COHb from the actual blood data.

As the figures shows there are some uncertainties in these calculations. The forward calculated CO uptake depends on the bedroom CO concentration curve, but also on the activity level hence V_E of the subject. From the reported activities of this subject, her average V_E is estimated at between 6 and 8 L/min. Also, although the exact time she arrived at the hospital and the fact that she received oxygen by face-mask after rescue are known, the exact time at which her blood sample was taken was not recorded, so three estimates were made based upon the emergency room records. Despite these uncertainties, there is a good agreement between the range of forward and back-calculated values, which therefore validates the test fire conditions in terms of CO concentrations against those in the actual incident. For the occupants of rooms off the corridor beyond the fire door, a similar set of calculations showed consistently higher actual % COHb blood levels in the rescued occupants than the forward calculated values, from which it was concluded that the penetration of smoke through the fire door (and other leakage paths) in the actual incident was somewhat greater than that in the reconstruction test.

Appendix 1: Summary of Toxicity and Heat Hazard Assessment Model Calculation Equations

The main expressions for applications to the fire safety engineering design calculations are presented in this section. Wider applications and more detailed discussions of the physiology

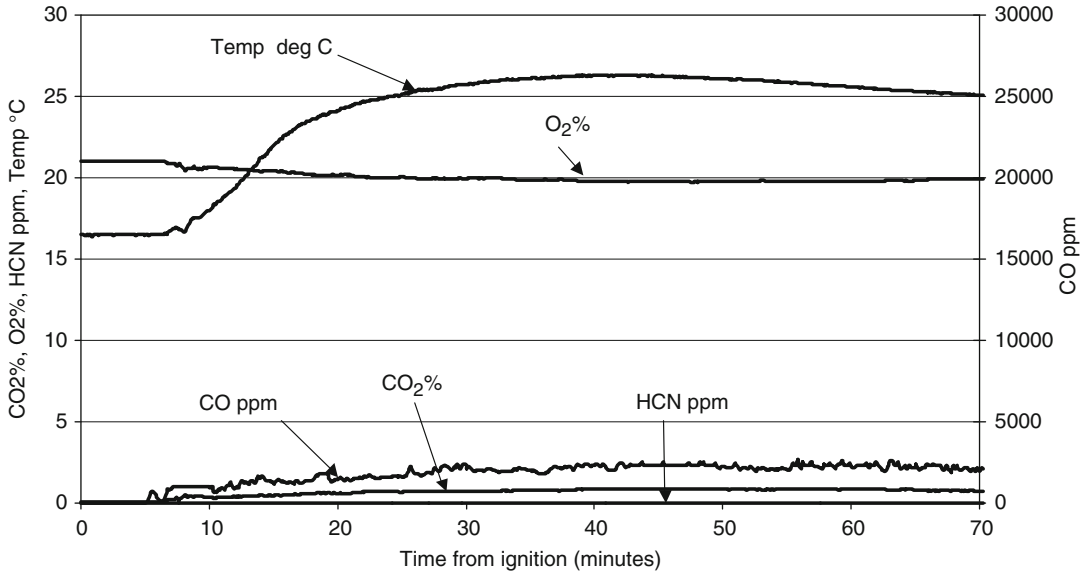

Fig. 63.41 Smoke, toxic gases and temperature profile for a closed room off the fire corridor during the BRE full-scale recreation of the Rosepark nursing home fire

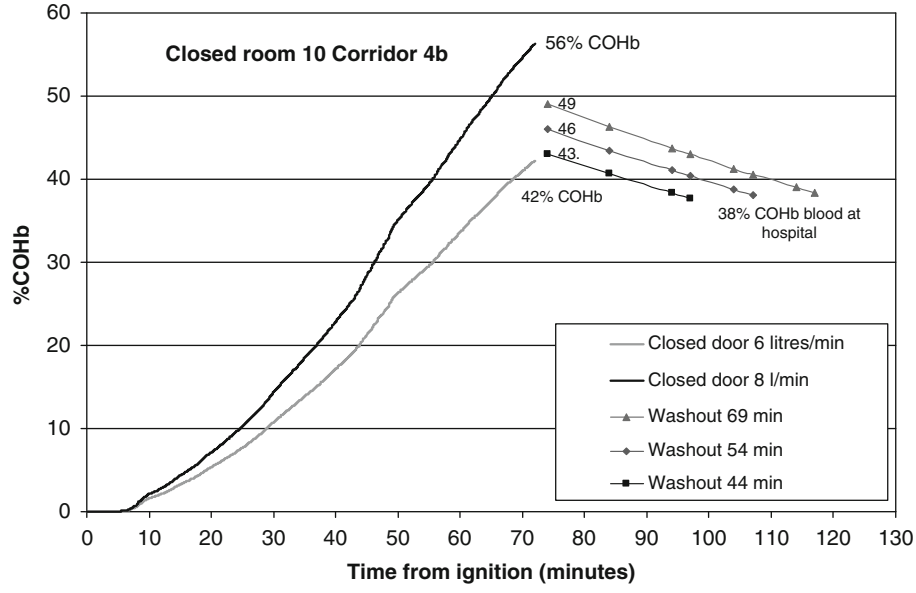

Fig. 63.42 Forward calculated %COHb level for the occupant of closed room 10 from the CO and CO_2 gas profiles in Fig. 63.41, assuming sleeping and standing V_E values of 6 and 8 L/min compared with %COHb levels back-calculated to the time of rescue after 72 minutes when oxygen was started, using three estimates of the time when the blood sample was taken after arrival at hospital

and derivation of the expressions have been presented in the relevant main sections of the chapter.

Effects of Fire Effluent and Heat

Estimates of potential hazards to enclosure occupants in terms of fire effluent or heat can be made by consideration of the following two sets of information:

1. The time-concentration (or time-intensity) profiles for the major toxic products, optically dense smoke and heat in the fire at the breathing zone of the occupants, which in turn depend on
   (a) The fire growth curve in terms of the mass loss rate of the fuel (kg/s) and the volume into which it is dispersed (kg/m^3) with time
   (b) The yields of toxic products, smoke, and heat in the fire (e.g., kg CO per kg of material burned)

   Guidance on calculation methods for these terms is given in other chapters in this handbook. Some information is provided in this chapter and Chap. 62 on toxic product yields under a range of fire conditions and also in Chap. 16 [19] and Chap. 36, [20]. A guide to the general characteristics of fires is shown in Table 63.3 and examples of fire profiles in Figs. 63.8 and 63.22.
2. The concentration/time/toxicity relationships of these products, in terms of the toxic or physiological potency of the heat and effluent (the exposure concentration, kg/m^3), or exposure dose (kg · m^{-3} · min or ppm · min) required to cause toxic effects (and the equivalent effects of heat and smoke obscuration). This term includes consideration of the following three aspects:
   (a) Exposure concentrations or doses likely to impair or reduce the efficiency of egress due to behavioral and/or physiological effects
   (b) Exposure concentrations or doses likely to produce incapacitation or prevent egress due to behavioral and/or physiological effects
   (c) Lethal exposure concentrations or doses

   Guidance on calculation methods for items (a) and (b) are presented in this section, whereas lethality is considered in the main chapter.

The fire profile should be characterized in terms of the following range of parameters, measured over successive short periods (<1 min) at the breathing zone of a potential victim:

1. Mass loss of material decomposed divided by the volume of air into which the material is dispersed in (mass loss concentration)
2. Carbon monoxide concentration
3. Hydrogen cyanide concentration (if materials containing >1 % by mass nitrogen are present)
4. Carbon dioxide concentration
5. Oxygen concentration
6. Incident radiant heat flux to subject
7. Air temperature
8. Smoke optical density (and particulate concentration)
9. Irritant acid gas concentrations (HF, HCl, HBr, SO_2, NO and NO_x)

   Note: If the total content of halogens in the fuel is less than approximately 5 % of the burning fuel mass, the total sulfur content less than 2 %, and the nitrogen content less than 5 %, the contribution to irritancy from acid gases can be considered minor as a first approximation.
10. Concentrations of organic irritant species (especially acrolein, formaldehyde, and crotonaldehyde)

    Note: In practice the relevant yield data for the key irritant organic species are seldom available, and not all the important species have been identified. In general it can be assumed that all smoke from compartment fires involving mixed fuel will contain concentrations of irritant organic species in

proportion to the smoke optical density. Overall irritancy can then be expressed in terms of smoke optical density (or particulate concentration) plus the contribution from irritant acid gases if present in significant concentrations (see 9 above).

These data may be obtained from large-scale fire tests or calculated using fire dynamics models with appropriate data on toxic product yields under a variety of fire conditions: specifically, smoldering/nonflaming, early (well-ventilated) flaming, developed small vitiated (underventilated) flaming, and fully developed/postflashover underventilated fires.

The hazard assessment is based on a "step-through" approach whereby the extent of the hazard is calculated for each successive minute (or other appropriate time interval) during the fire until the point is reached where different hazard endpoints are predicted. The behavioral and physiological effects of exposure to toxic smoke and heat in fires combine to cause varying effects on escape capability, which can lead to physical incapacitation and permanent injury or death.

For a basic fire engineering design there are two main considerations:

- The time at which the concentration of smoke reaches a level such that safe escape is compromised due to
  (a) Behavioral and physiological effects of exposure to heat and toxic smoke on escape behavior and ability
  (b) In the absence of direct exposure, behavioral effects caused by seeing fire effluents on escape behavior

  The effects of exposure to smoke result from impaired vision due to the optical opacity of smoke and from the painful effects of irritant smoke products on the eyes and respiratory tract. Occupant movement speed and wayfinding ability is impaired. Behavioral effects of seeing or being immersed in smoke result in a proportion of occupants being unwilling to approach smoke or heat-logged areas or escape routes.
- The time at which the exposure dose of asphyxiant toxic gases or heat reaches a level at which occupants are likely to become incapacitated, such that they cannot save themselves and are likely to die within a minute or so unless rescued.

In a regulatory or design evaluation context, it is possible to consider several different approaches:

1. *Simple criteria for tenability based on zero exposure*. Where a design fire calculation is based on a descending upper layer of hot smoke filling an enclosure or escape route, engineering tenability criteria are often based on a minimum clear layer height of 2.5 m above the floor and a maximum upper-layer temperature of 200 °C. Occupants are considered to be willing and able to escape in clear air under such a layer and the downward heat radiation is considered tolerable.
2. *Tenability criteria accepting some degree of smoke exposure in relation to willingness to enter or ability to move through smoke*. In situations where smoke is mixed down to near floor level, some building occupants might move through dense smoke in some situations, but in other situations people might be unwilling to enter smoke logged escape routes, turn back, or be unable to find an exit. Where heat is not an issue, the immediate effects of smoke depend on the visibility distance and the sensory irritancy of the smoke if people are exposed directly. For such situations it is necessary to set tenability criteria for design purposes, depending on the level of adverse effects on occupants considered acceptable or unacceptable.

In a number of studies of fires in buildings, a proportion of people (approximately 30 %) were found to turn back rather than continue through smoke-logged areas (see main section on effects of smoke in this chapter and Chap. 58). The average density at which people turned back was at a "visibility" distance of 3 m. This represents an optical density ($OD \cdot m^{-1}$) of 0.33, (extinction coefficient 0.76) with women more likely to turn back than men. A difficulty with this kind of statistic is that, in many fires in buildings, there is a choice between passing

through smoke to an exit or turning back to take refuge in a place of relative safety such as a closed room. In some situations, people have moved through very dense smoke when the fire was behind them, whereas in other cases people have failed to move at all.

Behavior might also depend on whether layering permits occupants to crouch down to levels where the smoke density is lower and whether low-level lighting is used to improve visibility. Based on considerations such as these in relation to parameters such as the size and complexity of the building, it is possible to set design limits for optical density of smoke (see Table 63.5).

As an approximate guide, it might be assumed that occupants will not use an escape route if the visibility in that route is less than 3 m (OD/m = 0.33, extinction coefficient 0.76). However, if they enter an escape route contaminated to this optical density and become exposed to the smoke, then their ability to progress depends on both the optical density and the irritancy of the smoke. Based on the finding that people move as if in darkness at a visibility of 5 m in irritant smoke and that smoke from most fires contains a variety of irritant chemical species, the following generic design tenability limits are proposed on the basis that concentrations exceeding these levels could impair or even prevent occupants' safe escape (for situations where the concentrations of acid gases are considered unlikely to be significant due to the fuel composition):

Small or domestic enclosures: visibility 5 m

$$(\text{OD/m} = 0.2 \text{ or } \alpha_k\ 0.5)$$

Large enclosures: visibility 10 m

$$(\text{OD/m} = 0.08 \text{ or } \alpha_k\ 0.18)$$

where OD/m is $\log_{10}(I_o/I)$, the logarithm of the ratio of the intensities of light transmitted over a path length of 1 m from a light source to a receiver in the absence and presence of smoke, respectively. The light extinction coefficient α_k is $\ln(I_o/I)$.

For situations where smoke is expressed in terms of particulate mass concentration, these equate to approximately 0.7 and 0.3 g particulates/m^3, respectively (where particulates g/m^3 ~ 0.356 × OD/m).

Where concentrations of acid gases are likely to be a significant factor, then the tenability limit for irritant smoke should be calculated according to Equation 63.11.

These effects of smoke on behavior and suggested design limit criteria are summarized in Table 63.5.

Another advantage of using these smoke concentration limits as tenability criteria is that the concentrations of asphyxiant gases present are most unlikely to exceed levels capable of causing incapacitation (loss of consciousness) in exposed occupants within 30–60 min.

These proposed design criteria are intended to represent a low probability that occupants will feel trapped and fail to escape. For a probabilistic design, incident investigation, or evacuation simulation, it may be of interest to estimate the number of individual occupants likely to remain in place. This approach considers the subsequent tenability as the fire develops, and also provides an estimate of the number of occupants likely to attempt to move through smoke, the effects of smoke on their wayfinding ability and walking speed, and their subsequent tenability. At any time during an escape simulation, the key parameters are the smoke density at head height for each occupant (who may be waking erect or stooping) as they move through the escape route and the tenability conditions in terms of toxic gases and heat exposure. For occupants walking through smoke, walking speeds show some variability between individuals, but the average speed has been shown to be approximately proportional to the smoke density down to a minimum of around 0.3 m/s for people walking in darkness. For able-bodied occupants walking through typically irritant fire smoke, a suggested expression for average unrestricted walking speed (Wsmoke [m/s]) as a function of extinction coefficient α_k is

$$\text{Wsmoke}(\text{m/s}) = -0.1364 \times \text{Ln}\,\alpha_k + 0.6423 \quad (63.10)$$

Where Wsmoke = walking speed in moderately irritant smoke

For a population of able-bodied occupants a standard deviation is 0.157 is suggested (see Fig. 63.16 in the main section on smoke).

3. *Tenability criteria accepting some degree of smoke exposure in relation to calculated time of incapacitation*. Although the foregoing smoke density limits may be used as design limits, they do not represent conditions under which escape is necessarily prevented, and do not allow for occupants remaining in place. A design calculation should therefore also evaluate predicted time to incapacitation due to the effects of heat or toxic gases. It might also be important to know the time between the visibility criteria being exceeded and that when incapacitation is predicted, especially for probabilistic design. The methods presented are designed to predict time to incapacitation (loss of consciousness) for an average person, after which a factor should be applied to allow for more susceptible members of the occupant population.

Time to loss of tenability due to smoke, irritants, asphyxiant gases, and heat in fires is calculated using fractional effective dose (FED) methodology as described in the following sections.

For the effects of the density or average irritancy of fire smoke on escape capability, the tenability limits already described are recommended, so that at any time during a fire:

$$\text{FEC}_{\text{smoke}} = (\text{OD/m})/0.2 \text{ for small enclosures or } (\text{OD/m})/0.08 \text{ for large enclosures} \quad (63.9)$$

This equation allows for the predicted irritancy of the smoke from fires involving mixed building contents.

Sensory Irritancy

Where significant concentrations of irritant acid gases are likely to be present the overall irritant concentration (FIC_{irr}) is given by Equation 63.11, on the basis of the assumption that all irritants capable of damaging lung tissue are additive in their effects,

$$\text{FIC} = \text{FIC}_{\text{HCl}} + \text{FIC}_{\text{HBr}} + \text{FIC}_{\text{HF}} + \text{FIC}_{\text{SO}_2} + \text{FIC}_{\text{NO}_2} + \text{FIC}_{\text{CH}_2\text{CHO}} + \text{FIC}_{\text{HCHO}} + \sum \text{FIC}_x \quad (63.11)$$

where $\sum \text{FIC}_x$ = FICs for any other irritants present. Each term in Equation 63.11 consists of a fraction for which the numerator is the concentration of the specific gas present at a particular time during the fire divided by the concentration of that gas predicted to cause a specified endpoint (either escape impairment or incapacitation). The proposed denominator values for each gas are given in Table 63.6 (SFPE escape impairment or SFPE incapacitation recommended)

It is predicted that each gas at the concentration in Table 63.6 is likely to be sufficiently irritating to affect escape efficiency in the majority of subjects and may cause incapacitation in susceptible individuals. A factor of 0.3 FEC for escape impairment should allow for safe escape of nearly all exposed individuals. As with the outcome for smoke, the sensory effects of irritants have been found to occur immediately on exposure at concentrations causing significant impairment [154, 155].

Lethal Effects of Inhaled Irritants

In addition to the immediate concentration-related painful effects on the eyes and respiratory tract, as occupants inhale irritant smoke an increasing dose of irritant gases and particulates is delivered into the deep lung. During exposure this is considered to impair respiratory efficiency (for example as a result of bronchoconstriction), thereby contribution somewhat to the overall asphyxiant effects of inhaled toxic gases. The inhaled irritants also cause inflammation and edema in the deep lung if a sufficient dose is inhaled. This requires a period of several hours

to develop, and can result in severe and sometimes fatal respiratory impairment over a period of approximately 2–36 h after rescue, especially in elderly or otherwise health-impaired subjects. Since lung irritation has relatively little effect on escape capability, it can be omitted from an escape calculation. For design considerations relating to occupant survival and health effects or for incident investigations, however, lung irritation can be an important consideration.

Equation 63.15 is a proposed expression for the accumulating fraction of a lethal exposure dose of lung irritants (FLD_{irr}). The fraction of a lethal dose (FLD) for each irritant is calculated as the *ct* product exposure dose during a period in the fire (e.g., in ppm · min) expressed as a fraction of the lethal exposure dose. The lethal effects of the different irritants are assumed to be additive on the same basis as the irritant effects, so that the total FLD_{irr} for each time period is given by Equation 63.15:

$$FLD_{irr} = FLD_{HCl} + FLD_{HBr} + FLD_{HF} + FLD_{SO_2} + FLD_{NO_2} + FLD_{CH_2CHO} + FLD_{HCHO} + \Sigma FLD_x \quad (63.15)$$

where ΣFLD_x = all the FLDs for any other irritants present.

The FLD_{irr} for short periods of time during the fire are summed until the FLD_{irr} reaches unity, when it is predicted that a lethal dose has been inhaled. The lethal exposure doses for each irritant gas used for the denominators of each term in Equation 63.15 are shown in Table 63.6.

Tenability Limits and Hazard Calculations for Asphyxiant Gases

The main cause of incapacitation and death during and immediately after fires is exposure to asphyxiant gases. Incapacitation results from loss of consciousness due to the combined effects of carbon monoxide, hydrogen cyanide, and carbon dioxide, with some additional effects from low-oxygen hypoxia and inhaled irritants. Loss of consciousness prevents escape and further uptake of asphyxiants while comatose is likely to result in death within a further minute or so. The most useful tenability endpoint to work to is, therefore, considered to be loss of consciousness ($FED_{IN} = 1$), with design limits set to prevent an occurrence. Since individual susceptibility varies in the population, this prediction represents the median of the distribution of exposure doses resulting in collapse. Approximately 11.3 % of the population is considered likely to be susceptible below an FED of 0.3 (see ISO 13571 [21]). For design purposes it will be necessary for the designer or regulatory authority to select an FED level suitable to protect vulnerable subpopulations in the chosen application (e.g., 0.3 or some other value depending on the application). The effects of combinations of asphyxiant gases causing incapacitation in fires are considered to be approximately additive, but the following interactions need to be considered:

- The FEDs for CO and HCN are considered directly additive as has been demonstrated experimentally.
- The effects of irritants on lung function also cause some hypoxia and so an additive term is included consisting of the FLD_{irr} .
- The main effect of carbon dioxide is to increase the breathing rate and, thus, the rate of uptake of CO and HCN. A multiplicatory term, VCO_2, is used to calculate this effect.
- Low-oxygen hypoxia will be additive with the overall effects but is not increased by VCO_2 (in fact oxygen uptake is improved).
- The direct intoxicating effects of CO_2 are considered unlikely to occur before other effects and so are normally ignored.
- The overall rate of uptake of asphyxiant gases depends upon the volume of air breathed each minute (V_E), in relation to body size, which in turn depends mainly upon the level of physical activity. For design purposes, it is assumed that the subject is an adult engaged in light work such as walking along an escape route.

On this basis a simplified version of the overall FED equation (Equation 63.38) for asphyxiants is as follows. (A more comprehensive version is presented in the main section on asphyxiant gases.)

$$\mathrm{F_{IN}} = \left(\left(\mathrm{F_{I_{CO}}} + \mathrm{F_{I_{CN}}} + F_{I_{NOx}} + FLD_{irr}\right) \times VCO_2 + F_{I_O}\right) or\ \mathrm{F_{I_{CO_2}}} \quad (63.38)$$

where

F_{IN} = Fractional effective dose for incapacitation (loss of consciousness) due to asphyxiants

$F_{I_{CO}}$ = Fractional effective dose for incapacitation by CO

$F_{I_{CN}}$ = Fractional effective dose for incapacitation by HCN

$\mathrm{FLD_{irr}}$ = Fractional lethal dose for irritants

Note: Where significant concentrations of acid gases are present this term is calculated according to Equation 63.15. Otherwise it may be expressed in terms of smoke optical density as $\mathrm{OD/m} \times \mathrm{t(min)}/90$.

VCO_2 = Multiplicatory effect of inhaled CO_2

F_{I_O} = Fractional effective dose for incapacitation by low-oxygen hypoxia

$\mathrm{F_{I_{CO_2}}}$ = Fraction of an incapacitating dose of CO_2 (but can be ignored without significant error for most cases)

A more general form of the simplified equation incorporating V_E as a user-defined variable is:

$$F_{IN} = \left(F_{ICOg} + F_{ICNg} + FLD_{irrg}\right) \times V_E \times V_{CO2} + FED_{IO} \quad (63.39)$$

Activity level of subject	V_E (L/min)
Resting or sleeping	8.5
Light work—walking to escape	25
Heavy work—slow running, walking up stairs	50

Both the total volume of air breathed each minute and the efficiency of uptake have upper limits so that a limiting value for V_E x V_{CO2} of 70 L/min is recommended.

For each of these gases it is necessary to obtain an expression for the fraction of a dose required to cause incapacitation. The derivation of these expressions is detailed in the section "Asphyxiation by Fire Gases and Prediction of Time to Incapacitation" in this chapter. Basically, the exposure dose acquired over any period of time during a fire is expressed as a fraction of the dose required to cause incapacitation for each asphyxiant component. These are then summed and corrected for VCO_2 and V_E to provide an overall F_{IN} for each time period.

The expressions used to calculate the FEDs for each individual component are as follows:

For the effects of CO the FED is expressed in terms of percent COHb. This is representative of the dose of CO actually inhaled and presents a more accurate estimate of the CO dose than the Ct product dose of 35,000 ppm · min, which does not allow for physiological variables affecting uptake. The denominator is the percent COHb predicted to cause loss of consciousness in an active (escaping) person, which is 30 %COHb (or 40 %COHb for a resting person). The numerator is the Stewart Equation [69], by which the percent COHb in the subject is calculated from the inhaled CO concentration in the fire, the exposure time, and the volume of air breathed each minute:

$$F_{I_{CO}} = 3.317 \times 10^{-5}[\mathrm{CO}]^{1.036}(V)(t)/D \quad (63.18)$$

where

[CO] = Carbon monoxide concentration (ppm v/v 20 °C)

V_E = Volume of air breathed per minute (liters/min)

t = Exposure time in minutes

D = Exposure dose (percent COHb) for incapacitation

For the default case the value of V is 25 L/min and the value of D is 30 %COHb.

For the general case ($\mathrm{F_{ICOg}}$) the V_E term is removed from Equation 63.18.

Note 1 This expression (the Stewart equation) was obtained from young adult male human volunteers. It is suitable for adults in situations where the CO concentration is high in relation to the blood COHb concentration (as for most flaming fires and short exposure durations). Where long exposures may lead to near equilibrium conditions, the Coburn-Forster-Kane [34] (CFK) equation should be used (see Appendix 2) since significant deviations from the Stewart

equation may then occur. The Stewart equation somewhat underestimates uptake rates for children. Where more precise CO uptake calculations are required, differences in body size (including children) can be accommodated using the CFK equation. For a basic design, use of the Stewart equation is recommended. Differences in body size and other susceptibilities can be considered as allowed for in the overall safety margin chosen to accommodate more susceptible subpopulations (e.g., an FED of 0.3 or other endpoint).

Note 2 As an alternative to using this expression (the Stewart equation) the FED_{Ico} may be expressed as a CO exposure dose ratio. This method is used for ISO 13571 [21] For this method the FED_{Ico} is expressed as CO ppm × t/35,000. This is approximately equivalent to a "light work" case for a subject breathing approximately 20 L air per minute.

For the effects of hydrogen cyanide and low-oxygen hypoxia, the expressions are more complex because the denominators are not constants. Exponential expressions have been developed to fit the time to incapacitation versus exposure concentration curve from experimental exposures in nonhuman primates (HCN) and humans (hypoxia). The default form of the fractional incapacitating dose for HCN (F_{ICN}) is as follows:

$$F_{ICN} = \frac{[CN]^{2.36}}{1.2 \times 10^6} t \qquad (63.24)$$

where
CN = HCN concentration (ppm v/v at 20 °C)
t = Exposure time in minutes

For the general case application in Equation 63.39 the term F_{ICNg} is given by:

$$F_{ICNg} = \frac{[CN]^{2.36}}{2.43 \times 10^7} t$$

which is Equation 63.25 without the VE term. For the general case application in Equation 63.9 the term FLD_{irrg} is given by

$$FLDirrg = FLD/25$$

The expression for low oxygen hypoxia is

$$F_{I_O} = t/\exp[8.13 - 0.54(20.9 - [\%O_2])] \qquad (63.50)$$

where
$[\%O_2]$ = Oxygen concentration (% v/v at 20 °C)
t = Exposure time (minutes)
I = Exposure dose for incapacitation

Similarly, a curve has been fitted to the effect of CO_2 on ventilation (breathing volume per minute) based on human experimental data.

Ventilatory stimulation by CO_2:

$$VCO_2 = \exp([CO_2]/5) \qquad (63.35)$$

where $[CO_2]$ is the carbon dioxide concentration (% v/v at 20 °C).

FEDs are calculated for successive short periods during the fire and then integrated with time in order to calculate the time when incapacitation is predicted (FED = 1).

Since occupants must at least walk in order to escape from a fire, the default case suggested is that for light work. However, this could be varied according to the case. For example, a sleeping person escaping from a basement might start by being at rest, but then awaken, walk to a stair (light work), and then climb the stairs (heavy work).

Note: Due to the rapid (t^2) rate of increase of asphyxiant gas concentrations in most flaming fires, variations in individual susceptibility and uncertainties in prediction of incapacitating doses tend to have relatively minor effects on predicted times to incapacitation.

Tenability and Hazard Calculations for Development of Pain, Incapacitation, Injury, and Death from Exposure to Heat and Burns

There are three basic mechanisms by which heat exposure may lead to incapacitation and death in fires:

1. Heat stroke (hyperthermia)
2. Skin pain followed by body surface burns
3. Respiratory tract burns

The effects of heat are described in detail in the section "The Exposure of Fire Victims to Heat" in this chapter. Hyperthermia involves prolonged exposure (approximately 15 min or more) to heated environments at ambient temperatures too low to cause burns. Under such conditions, where the air temperature is less than approximately 121 °C for dry air or 80 °C for saturated air, the main effect is a gradual increase in body core temperature [111]. Hyperthermia leads to confusion and collapse. Exposure to air temperatures above approximately 121 °C (or to radiant heat fluxes above 2.5 kW/m^2) leads to pain to exposed skin followed by body surface burns and hyperthermia if exposure is prolonged. Respiratory tract burns can also occur if exposure to heated air is sufficient to cause facial burns.

For a basic engineering design it is proposed that a tenability endpoint for exposure to heat should be taken as the limits of heat tolerance due either to the onset of hyperthermia or to severe pain to exposed areas of skin (such as the head and hands). It is proposed that under such conditions exposed building occupants may be unable to escape (if affected by hyperthermia) or unwilling to move through painfully hot environments.

Note: It is known that in some fires people have moved through (and escaped from) scenarios under conditions hot enough to cause severe burns. It is suggested that severe incapacitation is likely to occur under conditions that may cause second-degree burns. It is suggested that death is likely to occur under conditions that may cause third-degree burns. For situations where endpoints such as these are of interest, see the section "The Exposure of Fire Victims to Heat" in this chapter.

There are also three basic heat exposure scenarios for building occupants during a fire:

1. Exposure to convected heat in a hot air environment
2. Exposure to radiant heat direct from a fire or from a hot upper smoke layer
3. Exposure of a subject immersed in hot smoke—subjected to both radiant heat from hot smoke particles and convected heat from contact with hot gases in the hot smoke environment

Experimental human exposure data are available for the first two cases, from which time-tolerance curves have been obtained for exposure to convected or radiant heat. For direct exposure to radiant heat (e.g., from a fire or heater), empirical relationships between exposure time and effect have been measured by a number of authors. For these experiments heat radiation is expressed in terms of received heat flux (kW/m^2). The relationship between heat flux and time to pain is presented in this section, whereas a detailed treatment of time and exposure dose of radiant heat for pain, second and third-degree burns is presented in the section "Radiant Heat" of this chapter and in Hockey and Rew [133]. Survivability issues are also discussed.

The tenability limit for exposure of skin to radiant heat is approximately 2.5 kW/m^2, below which exposure can be tolerated for at least several minutes. Radiant heat at this level and above causes skin pain followed by burns within a few seconds, but lower fluxes can be tolerated for more than 5 min. For situations where occupants are required to pass under a hot smoke layer in order to escape, this radiant flux corresponds approximately to a hot smoke layer temperature of 200 °C. Above this threshold, time (minutes) to incapacitation due to radiant heat $t_{I\mathrm{rad}}$ at a radiant flux of q (kW/m^2) is given by Equation 63.43.

$$t_{I\mathrm{rad}} = \frac{1.33}{q^{1.33}} \tag{63.43}$$

where

$t_{I\mathrm{rad}}$ = Time to endpoint (pain in this case) (minutes)

q = Heat flux (kW/m^2)

Calculating Effects of Exposure to Convected Heat Only

Some experimental data are available for exposure of unclothed or lightly clothed subjects to hot air environments in terms of tolerance time to pain or hyperthermia. The Blockley [111] curve shown in Figure 63.28 is for dry air and humid air (saturated at normal room temperature), which is then heated. This is very different from the effects of air saturated with water at higher

temperatures. Water is a serious potential problem in fires due to its high latent heat. If fire effluent contains water at above 100 °C (i.e., steam), it releases considerable heat if it comes in contact with the skin or is inhaled. Although the hazards of contact with steam are well known, it may be less obvious that air saturated with water vapor at lower temperatures can be dangerous. The highest temperature at which saturated air can be breathed for more than a few minutes is 60 °C. As an approximate guide, the volume concentration of water vapor in fire effluent is similar to the CO_2 concentration, which might reach as much as 10 % and is less than the concentration in saturated air at the breathable limiting temperature of 60 °C. For this reason it is considered that the fuel-derived water vapor content of normal fire effluent is not likely to present a serious hazard except where steam may be generated by the application of water for fire suppression.

An expression has been derived for exposures of up to 2 h to convected heat from air containing less than 10 % by volume of water vapor. The following expression has been developed for the midhumidity case from Blockley [111] and other data. Tolerance time t_{tol} (minutes) is then given by

$$t_{tol} = 2 \times 10^{31} \times T^{16.963} + 4 \times 10^{8} \times T^{3.7561} \quad (63.45)$$

where T is room temperature (°C).

Another expression presented in the section "The Exposure of Fire Victims to Heat" (Equation 63.44) tends to follow the worst-case (100 % humidity) line. It also does not fit the empirical data as well, deviating somewhat from Blockley's curve at the high and low ends. It is, therefore, a somewhat non-conservative expression for exposure to higher temperatures and somewhat over-conservative at the low temperature end.

As with toxic gases, the body of a fire victim may be regarded as acquiring a "dose" of heat over a period of time during exposure, with short exposure to a high radiant flux or temperature being more incapacitating than a longer exposure to a lower temperature or flux. The same fractional incapacitating dose model as with the toxic gases may be applied and, providing that the temperature in the fire is stable or increasing, the fractional dose of heat acquired during exposure can be calculated.

For Equations 63.43 and 63.45, the fractional effective dose of heat received each minute is given by the reciprocal of the expression.

For situations when a subject is exposed to both radiant heat (e.g., from a heated upper layer) and convected heat from exposure to heated air, the overall heat dose received may be estimated by summing the radiant and convected fractions using Equation 63.48:

$$\mathrm{FED} = \int_{t_1}^{t_2} \left(\frac{1}{t_{I\mathrm{rad}}} + \frac{1}{t_{I\mathrm{conv}}} \right) \Delta t \quad (63.48)$$

The doses acquired in each unit of time are then integrated. The tenability limit is predicted when the FED for heat = 1.

An alternative method for estimating tolerance time for exposure to combinations of radiant and convected heat, especially for the case of a subject immersed in hot smoke, is presented in the section "Model of the Prediction of Time to Incapacitation by Exposure to Heat in Fires" in this chapter. Consideration is also given to the estimation of time to second-degree burns (representing incapacitation) and third-degree burns (representing a potentially lethal exposure).

A worked example of a simplified life threat hazard analysis is presented in Table 63.22.

Appendix 2: Coburn-Forster-Kane Equation for the Uptake of Carbon Monoxide in Man

The Coburn-Forster-Kane (CFK) equation [34] provides an accurate method for predicting the blood carboxyhemoglobin concentration in humans (or various animal species) resulting from exposure to a given concentration of carbon monoxide. The theoretical predictions of the equation have been validated for humans by experimental human exposures to carbon monoxide [35, 75]. The strength of the equation is that it is based on numerical values for all the main constants and variables that determine the uptake of CO into the

blood; it is, therefore, not based on a simple empirical fit to observed uptake data in individuals, as are other CO uptake equations [31, 39]. The result is a powerful equation that can be used to predict CO uptake over wide ranges of concentrations and time scales and can accommodate variables such as the degree of activity of the subject, body size (for men, women, or children), blood volume, hemoglobin concentration, and lung function status, all of which can affect CO uptake and, therefore, time to incapacitation or death for a given subject, as well as CO washout after exposure when breathing air or oxygen. The equation should be equally applicable to animals, providing of course that data for the various constants and variables are available. The disadvantage of the CFK equation is its complexity. In particular, several of the variables need to be calculated from other equations, which in turn contain variables that must be calculated from further equations. The data in the text and figures in this chapter are all based on CO uptake for a 70-kg human, either at rest (RMV approximately 8.5 L/min, engaged in light work [e.g., walking 6.4 km/h—RMV approximately 25 L/min]) or engaged in heavy work (e.g., slow running 8.5 km/h or walking 5.6 km/h up a 17 % gradient—RMV (i.e., V_E) approximately 50 L/min) [77]. In this Appendix, data for necessary constants and equations for the derivation of all variables, with their sources, have been provided to enable uptake calculations to be made for any particular situation.

The basic Coburn Forster Kane equation is a differential equation developed initially to calculate %COHb in blood for endogenous production of CO using all the major physiological parameters [34]. The equation is written as follows:

$$\frac{d(HBCO)_t}{dt} = \frac{V_{CO}}{V_B} - \frac{1}{V_B\left(\frac{1}{DLco} + \frac{(PB - P_{H_2O})}{V_A}\right)}\left(\frac{(HbCO)_t \overline{P}c_{O2}}{(HBO_2M} - P_{Ico}\right) \tag{63.51}$$

Peterson and Stewart [35, 156] used the model to calculate CO uptake and %COHb for male students exposed to different inhaled CO concentrations and found a good agreement. They used the following integrated form of the equation, which has been used to calculate the CFK uptake curves presented in this chapter:

$$\frac{A[HbCO]_t - BVco - P_{Ico}}{A[HbCO]_0 - BVco - P_{Ico}} = \exp(-tA/VbB) \tag{63.52}$$

All volumes are STPD (standard temperature and pressure, dry i.e., 1 atm and 0 °C) and the various terms in the two forms of the equation are as follows:

$$A = \overline{P}c_{O_2}/M[HbO_2] \tag{63.53}$$

$$B = 1/DLco + P_L/V_A \tag{63.54}$$

M = ratio of the affinity of blood for CO to that for O_2 (the Haldane constant) = 218

$[HbO_2]$ = mL of O_2 per mL blood. This depends on the extent of saturation, but at 100 % saturation I gram of Hb will hold 1.38 mL of oxygen (or CO) (at STPD).

$$[HbO_2]_{\max} = 1.38[Hb]/100 \tag{63.55}$$

[Hb] = Hb concentration (g/100 mL whole blood). Normal ranges are: Adult males 13.5–18.0, Adult females 11.5–16.4

$[HbCO]_t$ = mL of CO per mL of blood at time t

$[HbCO]_0$ = mL of CO per mL of blood at the beginning of the exposure, taken as 0.8 % COHb = 0.00176 mL CO/mL blood for non-smokers

$\overline{P}c_{O_2}$ = average partial pressure of oxygen in lung capillaries, mmHg

Vco = rate if endogenous CO production mL/min, set at 0.007 mL/min

$DLco$ = diffusivity of the lung for CO, mL/min/mmHg
P_L = barometric pressure minus vapor pressure of water at body temperature (760–47 = 713 mmHg)
Vb = blood volume, mL, 74 mL/kg bodyweight (approximately 5500 mL for a 70 kg human) (or 66.8?)
P_{Ico} = partial pressure of CO in the inhaled air, mmHg
V_A = alveolar ventilation rate, mL/min
t = exposure duration (minutes)
$e = 2.7182$

Expressions for different input terms required are as follows:

$$A_r(m^2) = 11.7(cm^2/g)W(g)^{0.667} \quad (63.56)$$

Where:
A_r = Body surface area (m^2)
W = Bodyweight in grams or kilograms as indicated

$$DLco(ml/\text{min}/mmHg) = \left(\frac{1}{\left(-0.0287\left(\frac{150}{W(kg)}\right)^{0.667}\right) + \frac{0.1188}{A_r(m^2)}}\right) \text{ [Ref. 161]} \quad (63.57)$$

Alternatively Bernard and Duiker [158] treated DL_{co} as a variable related to oxygen consumption (up to 4 L O_2/min)

$$DLco = 35{Vo_2}^{0.33}(ml/\text{min}/mmHg) \quad (63.58)$$

$$Vo_2 = 0.001V_E(ml/\text{min})/22.274 - 0.0309(L/\text{min}STPD) \text{ [Ref. 77]} \quad (63.59)$$

$$V_A = 0.933V_E(ml/\text{min}) - 132f(m/\text{min}) \text{ [Ref. 35]} \quad (63.60)$$

$$f = \exp(0.0165V_E(ml/\text{min}) + 2.3293 \text{ [Ref. 35]} \quad (63.61)$$

where
Vo_2 = rate of oxygen consumption (L/min STPD)
V_E = respiratory minute volume (mL/minSTPD)
f = respiratory frequency (breaths/min)

Alternatively:

$$V_A = V_E(mL/\text{min}) - (W(kg)/V_T)V_D(mL/\text{min}STPD) \quad (63.62)$$

$$V_D = 2.24W(kg)(mLSTPD) \quad (63.63)$$

$$V_T = 7.4W(kg)(mLSTPD) \quad (63.64)$$

where:
V_D = anatomical dead space (mL STDP)
V_T = respiratory tidal volume (mL STDP)

Appendix 3: Tenability Limits

Asphyxiants Concentrations at which there would be danger of incapacitation (loss of consciousness) and death after approximately 5 and 30 min exposure in a person engaged in light activity are shown in Table 63.28.

Irritants The initial painful effects of irritants (sensory irritation) are mainly on the eyes and upper respiratory tract. These effects do not worsen with prolonged exposure and may even lessen. The toxic effects on the lungs increase with prolonged exposure, are often most serious some hours after exposure, and may cause death.

For sensory irritation two levels are presented: level a represents unpleasant and quite severely disturbing eye and upper respiratory tract irritation; level b represents severe eye and upper respiratory tract irritation with severe pain, blepharospasm, copious lacrimation, and mucus secretion accompanied by chest pain. For deaths, the levels represent concentrations at which there

Table 63.28 Tenability limits for incapacitation or death from exposures to common asphyxiant products of combustion

	5 min		30 min	
	Incapacitation	Death	Incapacitation	Death
CO	6000–8000 ppm	12,000–16,000 ppm	1400–1700 ppm	2500–4000 ppm [65, 105]
HCN	150–200 ppm	250–400 ppm	90–120 ppm	170–230 ppm [65, 80]
Low O_2	10–13 %	<5 %	<12 %	6–7 % [33, 37, 65]
CO_2	7–8 %	>10 %	6–7 %	>9 % [33, 37, 65]

Table 63.29 Tenability limits for sensory irritation or death from irritant substances

	Sensory irritation		Death (minutes)		
	a	b	5	10	30
Acrolein (ppm)	1–5 [33, 159]	5–95 [159, 160]	500–1000 [160]	150–690 [39, 160]	50–135 [39, 160]
HCI (ppm)	75–300 [33]	300–11,000 [159, 161]	12,000–16,000 [159, 161]	10,000 [160]	2000–4000 [33]

is danger of death occurring during or immediately after exposure.

In general, smokes are irritating when they contain oxidized organic products [16]. The most irritating of these substances known to occur commonly in smokes from a number of different materials is acrolein. Another well-known irritant is the acid gas hydrogen chloride, which is evolved during the thermal decomposition of polyvinyl chloride (PVC). Data on these two products are presented in Table 63.29 as examples of irritant effects.

David A. Purser has a Ph.D. in neurophysiology and a diploma in toxicology from the Royal College of Pathologists. As former director of combustion toxicology research at Huntingdon Research Centre, England, and subsequently as associate director of the Fire Safety Engineering Centre in the Fire and Risk Sciences Division at BRE Ltd., Watford, England, he has worked on fire chemistry, combustion toxicology, fire assessment, fire incident investigation, building code development and human behavior in fires for over 35 years. Since retiring from BRE in 2006, he continues with consultancy and academic work, as adjunct faculty at the University of Maryland (until 2014) and visiting professor at the Universities of Greenwich and Central Lancashire UK. He was a member of the Scientific Advisory Committee of the US National Association of State Fire Marshals

(until 2014). He chaired the British Standards Committee on fire hazards until 2011 and serves as an expert on the International Organization for Standardization (ISO) fire hazard and fire safety engineering subcommittees and working groups.

Jamie L. McAllister has a Ph.D. in Toxicology from the University of Maryland, School of Medicine in Baltimore. Her doctoral studies focused on the exposure of fire victims to carbon monoxide and hydrogen cyanide and the development of a physiological-based hydrogen cyanide uptake model. Dr. McAllister is also a licensed Professional Engineer and holds a Bachelor and Master of Science in Fire Protection Engineering from the University of Maryland, College Park. Dr. McAllister currently serves as the Leader of the Fire & Facilities Safety Group at the National Institute of Standards and Technology in Gaithersburg, MD.

Engineering Data

64

S.M.V. Gwynne and K.E. Boyce

Introduction

This chapter is an updated version of the previous chapter "Evacuation Timing" that appeared in the fourth edition of the *SFPE Handbook*. This new version of the chapter represents a significant change to previous versions, moving from a narrative description of important case studies that include data to a tabular representation of a broader range of data-sets. It is hoped that this approach provides a useful reference resource for readers [1, 2].

Evacuation and human behavior in fires is an important consideration in any fire safety engineering design. Research in this area essentially started in the mid-1950s with the work of John Bryan [3] and was continued over the proceeding decades by numerous researchers from within fire safety and those in adjacent areas of research [4]. A renewal of enthusiasm in this work was observed with the arrival of many new researchers into the field in the 1990s and the advent and adoption of performance-based fire safety design (see Chap. 57). The improved understanding that this work generated, and the subsequent modeling capabilities that it both suggested and facilitated, forms the basis of a key element of the fire safety equation; i.e. comparing the time for a population to reach safety with the time for the conditions to become untenable, typically adopted as part of performance-based design (see Chap. 57). This work is enabled and driven by the availability of detailed, comprehensive and appropriate data to support the development of theories and engineering practice alike. This chapter represents an attempt to help the reader locate and select data for use in this work.

It is generally (although not universally) acknowledged that "hard" fire science alone cannot solve the fire problem; knowledge of human behavior is also essential [5]. The vagaries of human performance cannot be eliminated from the design process. There is a degree of skepticism in the field of fire safety engineering as to whether human behavior in fire can be understood and then represented credibly in egress analysis [6]. However, the expansion of this section of the handbook and the increasing reference to human response in regulatory documentation and guides [7, 8] is nothing if not evidence of the broad recognition that, although difficult, it is a 'necessary evil'. This chapter provides a summary of some of the key data (predominantly produced after 1985) that might support those in the fields of fire safety and fire engineering who are attempting to understand and represent human behavior in fire. This chapter should provide a useful introduction to this data and point to key reference sources for the practitioner to employ in their work.

Work on understanding evacuation and human behavior in fire, developing tools to assess it and then producing designs that account

S.M.V. Gwynne (✉) • K.E. Boyce

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_64, © Society of Fire Protection Engineers 2016

for it, is multi-disciplinary in nature and requires expert input from a variety of sources. This input may take the form of ideas, models, theories and data. The variety of this input produces new ideas in the field, disparate opinions and expertise. It also introduces many inconsistencies in the terminology and techniques employed, the assumptions made and the overall objectives. These inconsistencies may influence model development, configuration, application and then the interpretation of the results produced by the model.

It should also be noted at the outset that human behavior in fire is still a relatively immature area of analysis. This is true of our understanding of basic phenomena (see Chap. 58), but particularly true of the numerical data-sets available to describe egress performance. These data originate from different sources, are provided in different formats, are based on different assumptions and described in different ways [9]. This chapter attempts to take these differences into account allowing the reader to select between the data available in as informed a manner as possible.

Given the variety of data sources available and the data formats employed, only a summary of each selected data set is provided in this chapter, providing insight into the data available and aiding the data selection process. As such this chapter provides a resource to inform the reader's selection of data, but it is essential that he/she should further investigate the data from the original source as part of the selection process. The limitations of the data available are acknowledged and therefore the informed selection between these often partial and incomplete data-sets becomes all the more important.

Using this Chapter

This chapter is intended to aid the representation of egress performance within engineering models (see Chaps. 59 and 60). There is an enormous variety in the methods adopted and the assumptions made in these models—and therefore in the data used by them. The model may be embedded within regulatory codes (i.e. the behavioral assumptions made in order to develop the regulatory rules), it may be an empirical model (where the data forms the very basis of the model), an engineering model (where data is used to derive relationships that then represent some aspects of the response), or a simulation model (where data allows the more complex computer-based tools to be configured, calibrated and validated, see Chaps. 59 and 60). This variety is reflected in the impact that the selection of different data-sets will have on the results produced by these models.

This chapter will support the use of these models by presenting data that could be used in the quantification of egress performance as part of regulatory assessment (the primary function), and presenting data that enables the examination of design variants, developing procedures, or further research. The chapter is intended to provide an overview of this data. It will provide, in most cases, a *tabular* summary of a range of data-sets available for the basic behavioral elements required to assess egress performance. These elements, derived from the basic engineering timeline which is typically used to describe expected performance phases [10], will be briefly discussed. The data-sets will be presented in the same format within each of the core behavioral elements identified, thus simplifying comparison between them. These behavioral elements have been deliberately selected as those that are fundamental to the most basic egress analysis (see Chaps. 59 and 60). It is hoped that this approach will allow the reader to compare the appropriateness of the data-sets shown and then follow up on the details of the data-sets once an initial selection has been made. The tables will provide information sufficient for the reader to identify whether the data set is representative of the scenario that they wish to represent. However, it is essential that the reader accesses the original source of the data set (also provided in the table) for further information to enable them to utilize it with confidence. It is acknowledged that this chapter presently excludes some data that might be of value; specifically, data regarding the decision-making process during the evacuation is not included. Although this data is critical,

it is not widely employed within the modeling or the performance based design process (irrespective of how much the authors would like it to be). Given space constraints, this is left to be addressed elsewhere (see Chap. 58).

This chapter is not intended to provide definitive guidance on which of the data-sets should be used in particular scenarios of interest. This decision should be taken through examining this chapter in conjunction with several of the other chapters in this handbook. It would currently be impractical to provide definitive data-sets for the myriad scenarios that may be examined and the many engineering models that might be employed [11, 12]. This chapter is, therefore, intended to provide the reader with sufficient information to identify data-sets of interest and then explore them further; i.e., provide an initial reference for the fire safety engineer to focus their search and guidance to aid in this search. In addition, there are a number of online resources that the reader may consult to find contemporary reviews of the data available [13–16]. Even here, the reader is advised to seek out the original source material to ensure suitability.

The data-sets might be used in a number of ways including:

- Configuring hydraulic calculations for use e.g. augmenting the guidance provided in Chap. 59.
- Developing hydraulic calculations independently from Chap. 59.
- Configuring egress tools for use (see Chaps. 59 and 60). For instance, providing model parameter values to be used in representing a particular scenario (see Chap. 57).
- Developing egress tools (see Chaps. 59 and 60).
- Examining the assumptions of the work of others (see Chap. 57).
- Performing expert analysis i.e. helping to support a particular expert opinion regarding evacuee performance.

The approach outlined has been adopted to ensure that it benefits a range of potential readers, although primarily focused at the fire safety engineer. It is expected that engineers, designers, those assessing designs (e.g. Authorities Having Jurisdiction (AHJ)), model developers and researchers may find value in the data-sets provided. These users will have different requirements of the data-sets presented and needs that might only be completely satisfied through a full and lengthy description of each data-set.

Using the Data Provided

The data described in this chapter should not be employed without an understanding of the subject matter involved; i.e. human behavior in fire. The data-sets provided in this chapter are intended to be used in conjunction with the methods and data provided in a number of the companion chapters in this handbook. It is therefore highly recommended that the reader examines all of the chapters in this section prior to selecting any of the data-sets for further use. This should then at least provide a basic understanding of the key factors and behavioral elements to be taken into consideration during the selection process. When taken as a whole, this set of chapters should provide the reader with sufficient information to understand expected human response, quantify this response, represent this response as part of engineering analysis (within a design scenario) and then interpret and present the results in an informed manner. A schematic of the assumed relationship between the subject areas covered in these chapters is presented in Fig. 64.1, although it is recognized that the exact relationship between these chapters will be somewhat dependent upon the nature of the application.

As noted above, the user will typically require a basic understanding of the subject matter involved. The currently available theories which explain human response in fire are provided in Chap. 58. This chapter should form the basis of any analysis as it describes the subject matter involved and enables the reader to develop a qualitative understanding of the evacuation process with the evacuee as the focus

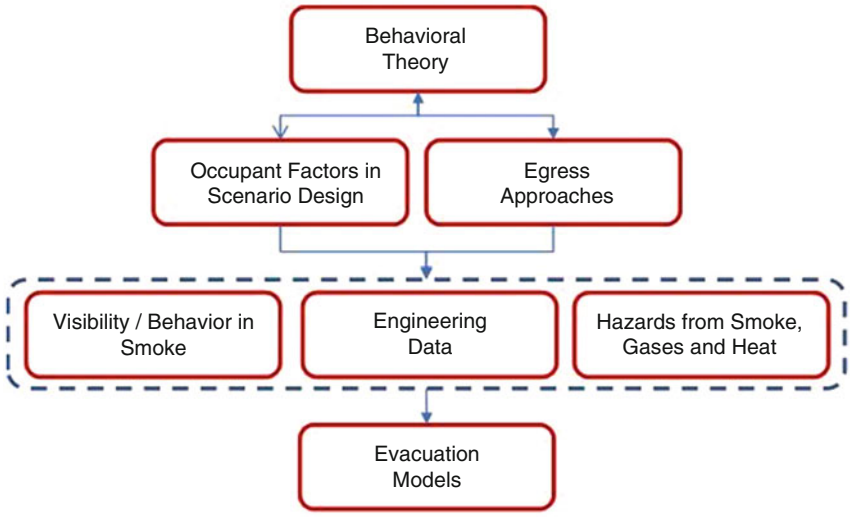

Fig. 64.1 Relationship between subject areas in this section

before attempting to quantify performance. The nature of the engineering design process and the emergency procedures that might appear within that process are described in Chaps. 56 and 57. These chapters formulate the way in which the behavioral theories might be applied; i.e. what aspects of the underlying subject matter should be represented and what impact might they have in a real-world environment. Chapters 61 and 63 provide data to quantify this design process; they provide a numerical underpinning to the qualitative and scenario-based descriptions outlined earlier. These chapters are vital in translating the real-world elements into the simulated environment. Finally, Chaps. 59 and 60 describes the models that might be applied to utilize this data in order to assess performance within the simulated environment.

Quantifying Egress

This section discusses the key factors that influence the quantification of egress. In section "Subject Matter: Human Behavior in Fire", the primary subject matter of egress analysis, i.e. human behavior in fire, is briefly discussed. An understanding of the subject matter directly influences how the models are constructed, the data that is deemed to be required and then use of the data within the quantification process.

Section "Engineering Timeline" describes the engineering timeline. This is important as it defines, at a high-level, the core components that need to be represented during the engineering analysis and therefore that need to be supported by data. As has been noted, in reality, individuals operate at a more refined level and in a more complex manner. It is the discrepancy between the individual and engineering levels that often leads to misinterpretation of the data available. It is anticipated that the following sections will help the reader address some of the issues highlighted.

Subject Matter: Human Behavior in Fire

In contrast to the panic model previously assumed, the response of an individual during an incident can be better characterized as involving a decision-making *process* [17, 18]. This process is influenced by internal and external elements that can interact and change as the incident progresses. If this response is oversimplified or ignored, then the engineer may neglect key elements that they need to represent using the data available. It is therefore important

to understand the key subject matter elements that may be represented or ignored in specific data-sets in order to assess their appropriateness for the application in question. These elements include:

- The procedures in place within the structure as dictated by the resident organization,
- The environmental conditions to which the individual is exposed at any point in time,
- The actions of those around the individual given the relationships that exist between them,
- The physical, cognitive, sensory and experimential attributes of the individual,
- The information available and the sub-set of this information that is noted by the individual (given their current alertness, attention levels and actions),
- The individual's perception of this information, their ability to understand it and to assess the situation and the threat posed to them or significant others,
- The individual's role and position within the current group/organizational/social structure, and the associated norms and responsibilities with this role,
- The viable options available to the individual in any situation,
- The individual's ability to assess and select a response option, given the temporal, physical and social constraints present, and
- The ability of the individual to enact this option [19].

The decision making process is a highly coupled, iterative process where each of the elements are often interchanged and modified in real-time, depending on the scenario faced. Understanding this process and the factors that influence response is critical for model development and model application; i.e. critical to the engineering process in general [20, 21]. Although this process is complex, it is comprehensible and is in contrast to both the panic model (where an almost complete absence of process is assumed) and stimulus-response approach (where the process is reduced to individual responses initiated only by external triggers).

The decision making process is then an important influence upon performance and therefore upon the data that might be collected. Any data collected or used will need to account for the key elements of this process (see Chap. 58). However, these elements may be combined, simplified or deliberately omitted in the data representation (along with other limitations with our understanding of the subject matter). It is therefore important that the manipulation of these elements in the original data analysis needs to be clearly understood and justified this can only be achieved through an understanding of the decision-making process itself.

This description of the decision-making process is very much from the individual's perspective. The combined actions and interactions of individuals produce emergent conditions by which a design might then be judged during an engineering analysis (see section "Engineering Timeline" discussing the engineering timeline). Within the engineering analysis, these emergent conditions may be predicted by the model employed or imposed by the user [22]. The data will need to reflect some aspect of the engineering timeline (see Fig. 64.2). In reality the partitions present in the timeline may not be sufficient to reflect the complexity and variety of the individual decision-making processes or the associated data. It is therefore important for the engineer to understand the compromises being made by selecting certain data-sets.

The individual decision-making process is described in more detail in Chap. 58. This process can also be accounted for within the scenario design; i.e., the outcome of the decision-making process can be reflected in the scenarios to which the egress models are employed. This is described in Chap. 57. In addition, the manner in which the decision-making process and associated behavioral actions are represented within the egress models applied is described in Chaps. 59 and 60. As is apparent, the assumption that the individual goes through a decision-making process during an evacuation is fundamental to many of the chapters in this section. In this chapter, the decision-making process

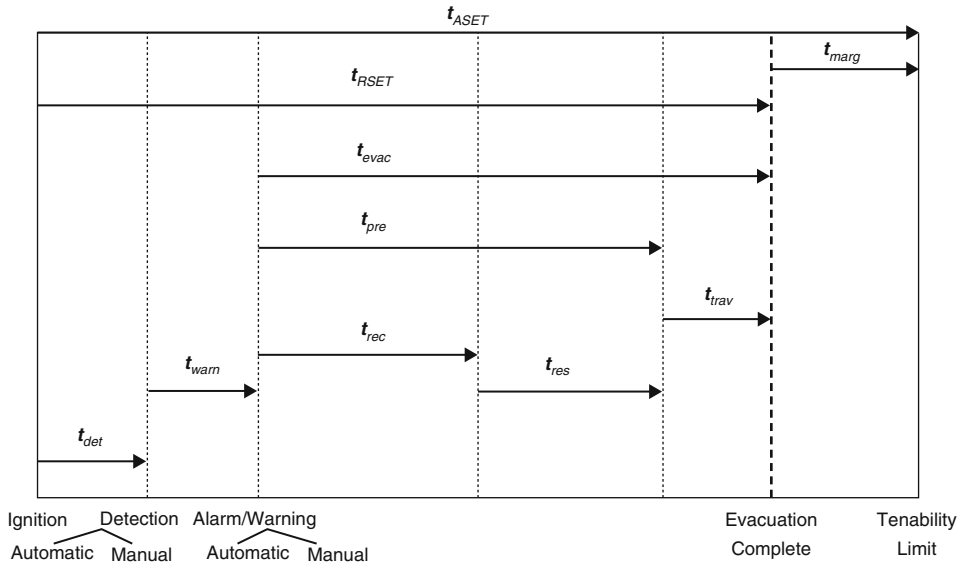

Fig. 64.2 Engineering timeline

influences the categorization of the data-sets and the manner in which the data is presented.

Engineering Timeline

Typically, engineering and computational models are employed to establish an engineering timeline, or some aspect of it. This timeline represents the total evacuation process, which is broken down into several distinct components. This timeline typically operates at the level of the population, rather than the individual and is therefore a simplification of numerous individual actions and responses that take place, the complexity of which has been alluded to above and in Chap. 58. The components within the timeline are therefore aggregates of lower level performance, based on technical or human resources. Different versions of this timeline are available in numerous regulatory and guidance documents [7, 22, 23]. A version of this timeline is shown in Fig. 64.2. This timeline also represents subject areas discussed in other chapters in this Handbook.

The engineering timeline shown in Fig. 64.2 includes the following components:

- *Detection time* (t_{det})—The interval between fire ignition and the first detection of the fire by a device or an individual.
- ***Warning time*** (t_{warn})—The interval between detection of the fire and the time at which an alarm signal is activated or notification of occupants takes place.
- ***Pre-evacuation time*** (t_{pre})—The interval between the time at which a general alarm signal or warning is given and the time at which the first deliberate evacuation movement is made. This consists of two components: recognition time and response time.
- *Recognition time* (t_{rec})—The interval between the time at which the alarm signal is perceived and the time at which the occupant interprets this signal as indicating a fire/emergency event. This time includes investigation and milling, for example, to determine the situation.
- *Response time* (t_{res})—The interval between recognition time and the time at which the first move is made to evacuate the building. This time includes activities such as fire-fighting, warning others, gathering family members and pets, dressing, retrieving

personal belongings, calling the fire department, and so on.

- ***Travel time*** (t_{trav})—The time needed, once movement toward an exit has begun, for all occupants to reach a place of safety.
- *Evacuation time* (t_{evac})—The time from the alarm signal to the time at which the occupants reach a place of safety. This is the sum of the pre-evacuation time (t_{pre}) and the travel time (t_{trav}).
- *Required Safe Escape Time* (t_{RSET})—The calculated time necessary between ignition of a fire and the time at which all occupants can reach an area of safety. This is the sum of the detection time (t_{det}), the warning time (t_{warn}) and the evacuation time (t_{evac}). This is equivalent to the escape time (t_{esc}).
- *Available Safe Egress Time* (t_{ASET})—The calculated time available between ignition of a fire and the time at which tenability criteria are exceeded in the means of egress. t_{ASET} should be longer than t_{RSET} by an acceptable margin of safety.

The terms highlighted in bold are the focus of this chapter. It should be noted that the terms used to describe t_{RSET} can vary. The term Required Safe Escape Time [7] is adopted here, but *Required Safe Egress Time* [23] is also often used. The exact terminology employed to describe the other components also differs based on its origin and intended use. This has been described in detail by Gwynne [9], where a range of different terms is explored. A summary of the various terms employed for two of the key behavioral components, t_{pre} and t_{trav} are provided in Table 64.1.

The engineering timeline extends from the time of ignition to when untenable conditions are reached. The time of ignition is the starting point of the fire event. Following ignition, a time should be calculated for detection to take place. Detection could take anywhere from a few seconds to a few hours depending on the type of fire and the detection devices in place. Detection could be accomplished by staff/occupants who discover the fire or perceive cues of the incident (e.g., smell of smoke) or through the activation of a detection system.

Table 64.1 Range of terminology used to describe behavioral components

Timeline behavioral component	Terminology employed	
t_{pre}	Pre-response time	PIA (perception, interpretation, action) time
	Response time	Time to initial move
	Pre-evacuation time	Pre-egress activity time
	Pre-movement time	Time to start evacuation
	Pre-travel activity time	Pre-evacuation activity time
	Delay time	Time to start
	Start-up time	Dawdle time
t_{trav}	Movement time	Arrival time
	Event time	Clearance time
	Evacuation movement time	Evacuation time
	Travel time	Trans-movement decisions
	Egress time	Time

An elapsed time might need to be calculated between detection and alarm activation. In some cases, these two events are almost simultaneous; for instance, smoke detectors are often linked to a general alarm which issues an immediate warning signal. There could, however, be a delay between detection and alarm, for example, if occupants discover a fire and have to manually activate the fire alarm signal at a pull-station, or where a procedure is in place that requires confirmation of the incident by a member of staff and staff communication to allow the public alarm to be provided [11, 12].

The first two components of the RSET calculation i.e., t_{det} and $t_{warn,}$ can be formed from a combination of technological and/or human resources and the balance of these resources will depend on the scenario and on the procedural measures in place to respond to it. Where automatic detection and alarm is employed, typically, t_{det} and t_{warn} will be determined with reference to manufacturer's guidance on sensor response and often do not take staff activities into account. However, this is not always the

case and in some instances human resources play a more prominent role and therefore need to be accounted for within the engineering timeline.

The selection of the procedural resources employed to detect and alert will be influenced by a number of factors; e.g., the cost, the infrastructure, the nature of the occupancy and the expected incident scenarios. However, it is certainly possible that staff (or other occupants) will be involved in the detection of the original incident and the raising of the alarm and it is important to recognize that this involvement might delay the point at which the pre-evacuation phase begins for the general population; i.e., there is a potential delay as staff interpret the cues available to them and then respond.

Any delay in detection and warning (also previously referred to as Pre-Warning time [11, 12, 24, 25] may be procedural and/or cognitive (i.e. part of the formal procedure) and/or dependent on the decision-making activities of the staff in question. The need for and extent of human involvement in issuing a warning can vary depending on the emergency response procedures of the affected building and the detection and warning systems used.

Typically, the delay in detection and warning is either not accounted for in engineering analysis or is based on the time for the technical system in place to detect the incident, rather than the staff response to it. Just as with the pre-evacuation time for an evacuee, these times i.e. t_{det} and t_{warn} can amount to a significant time period depending on the nature of the event, the technological and human resources available, the nature of the space, the staff involved, the staff hierarchy present and the procedures in place.

There are often legitimate reasons as to why staff involvement prior to the raising of the alarm is deemed necessary in some buildings, especially major public venues: (a) an evacuation can lead to significant disruption to the normal operation of the building; (b) starting an evacuation automatically regardless of the circumstance is not only commercially costly, but also unacceptable to the public, and may prejudice later evacuee interpretation of emergency alarms; (c) evacuation is not without risk and can produce additional (and more significant) hazards than the original incident; (d) the evacuation may need to be carefully managed, requiring staff to be briefed and in position before commencement or (e) depending upon the circumstances a full scale evacuation of a building may not be the most appropriate course of action. Many of these potential procedural influences can be recognized during the design phase and, as such, the engineer may be able to factor these into the design process through the use of an extended warning/delay time.

Often, detection and notification systems have 'failsafe' measures to ensure that once an incident has been detected it is not entirely ignored. For instance, should a detection signal not be acknowledged or acted upon within a certain period of time e.g., 2 min then a general alarm will automatically be signalled. If enabled, these may provide an upper limit as to the warning time in such a procedure. However, where this measure is deliberately overridden, disabled or absent, then the warning delay may not be limited or predicted by the 'failsafe' setting associated with the system. Again, the potential for this may be acknowledged within the design process, albeit that it is difficult to quantify.

The engineer might therefore choose to include a detection and warning delay component to account for the staff decision-making and response activities, especially if they form part of the formal procedure and can therefore be expected to take place. In effect, the warning period could be better represented by including an estimate of the accumulation of individual staff decision-making processes and subsequent activities that go to delay the provision of the warning.

When a cue, a warning by a notification system or an individual has been perceived, then the population has the opportunity to commence evacuation. However, typically there is a delay between initial awareness of the incident and purposive movement towards safety, the pre-evacuation time (t_{pre}) which is due to the population's interpretation of the information available and/or actions that they might need to perform prior to evacuating. Purser (and others)

identified that pre-evacuation time comprises of two subcomponents; i.e. recognition and response [26]. In the recognition phase, the occupant will perceive information such as the fire alarm signal, the sight of smoke, or warning by others. Interpretation of this information may take some time. As information on the unfolding event is perceived, the occupant will start responding by taking different actions such as investigating the situation, attempting to fight the fire, calling for help, and gathering belongings and family members i.e. actions that do not necessary move them closer to a place of safety. Eventually the decision to evacuate the building, to search for a refuge or to protect-in-place will be taken, which will complete the pre-evacuation phase (assuming that the entire population decides to eventually evacuate). In this chapter, the data is typically presented in terms of the overall pre-evacuation time. Where the data is broken down to a lower level (e.g. recognition and response), this is also noted.

The travel time only starts when the occupant has initiated movement towards a place of safety, whatever that might be. In this context, travel relates to the movement performed as part of the evacuation process. It is acknowledged that an individual may also move during the pre-evacuation phase, but it is assumed here that this is addressed in the pre-evacuation delay experienced. In its most basic form, travel time should be calculated from the traversal time to move along the specified egress route and the flow time through various elements of the egress system (as discussed in Chap. 60). In reality, an evacuee may engage in numerous activities during this phase that are not directly involved in moving towards a place of safety (see Chap. 58). However, these are not typically (or explicitly) represented in an egress analysis, except where they involve an evacuee responding to the evacuation movement of others; e.g. being delaying in congestion.

All the times previously discussed together comprise The Required Safe Escape Time (t_{RSET}) is calculated from the time of ignition until the last occupant to evacuate has reached a location of safety. This time should be less than the time for untenable conditions to occur in the egress path (t_{ASET}). The time between the population reaching safety and the conditions becoming untenable should be sufficient to provide an acceptable margin of safety (t_{marg} in Fig. 64.2). The t_{RSET} value can therefore be formulated as follows

$$t_{RSET} = t_{det} + t_{warn} + t_{pre} + t_{trav}$$

Depending on the scenario, each of the t_{RSET} phases can have a significant impact on the time for the target population to reach safety. Although there is some general (primarily qualitative) discussion of the detection time, t_{det} and the warning time t_{warn} in section "Detection and Warning Phases: Human Aspect", of this chapter, the focus here is on the primary behavioral components: t_{pre} and t_{trav}. The data-sets described will relate specifically to the quantitative assessment of these components and the factors that might contribute to this assessment.

In section "Model Approaches and Data Requirements", the approaches adopted within egress models are discussed, specifically relating to the requirements that these approaches place on the data available.

Model Approaches and Data Requirements

Establishing the time for a population to reach safety is relatively complex, and it is considerably more difficult than estimating movement time alone (see Chap. 58 and previous section). The various attempts at representing this process as part of egress analysis are described in Chaps. 59 and 60.

There are a range of different models that are used to explicitly or implicitly establish egress performance; i.e. models that produce a *quantitative* assessment or assume a performance level. These models require a range of data either in their development or their application in support of the behavioral model in situ [22]. The various types of models employ different techniques, cover different areas of the evacuation process

and operate at different levels of sophistication and refinement. As a consequence, models require data in different formats and to address different subject matter. Models can be broadly categorized into six different types, each with their own data needs:

1. Prescriptive Codes: Pre-defined rules based on experience (i.e., expertise and lessons learned from real incidents), that are then codified into a guidance/regulatory framework. Data are used to support the development of these rules, which form an implicit behavioral model. This data is not used to subsequently apply the model (as might the case in other types of models) but rather to support the development of the rules.
2. Full-scale evacuation demonstration: The use of a representative population and scenario (s), e.g. the evacuation of an actual office block to gain insight into performance of a structure under specific conditions. Data may be used to help inform expectations regarding performance and then organize the management and data-collection activities. In this context, the mock evacuation is taken as an indication of how the population may perform during an actual incident; i.e., is a model of reality.
3. Theoretical Model/Expert analysis: Data-sets are used to develop a theory describing some performance component. A set of theories are then employed as part of expert analysis/engineering judgment to assess some issue. This assessment may well use further data to support the analysis and make it more specific. This process is highly dependent on the availability and use of data from the development of the theories to their application.
4. Engineering calculation at the level of the *Structure*, based on empirical correlation/analysis: Empirical data relating to an entire structure are analyzed to produce high-level functions to predict performance assuming similarities (i.e., at the structural level). Data-sets are used directly in the production of the model and in the application to examine the performance of other similar structures. Data-sets may also be used in verification and validation of the model developed.
5. Engineering calculation at the level of the *Component* (Hydraulic models): Data-sets are collected from the evacuation of structures and then analyzed to produce low-level component-based functions to predict performance at the component level (e.g., doorway, corridor, stair, etc.). These are then chained together to represent the egress performance along paths out of the structure based on the flow, speed and density relationships assumed and the structural and occupancy assumptions made. Data-sets are then used directly in the production of the model and in the application. Data-sets may also be used in verification and validation of the model developed.
6. Computational Egress models: These tools include the coding of the previous three bullets. These provide different levels of sophistication and have different data requirements depending on the nature of the model itself. These may require data both to develop and configure the models for use. Data-sets may also be used in verification and validation of the model developed.

Egress models will employ different methods to produce a performance assessment [22]. Each model type also represents the key components (e.g., the structure, the population, behavior, procedural activities, environmental conditions, etc.) in some form using different techniques and to a different degree of refinement (see Chap. 60). More refined models represent individual agents and their movement within a detailed representation of the structural space; i.e. where the internal structure, obstacles, etc., are represented. In this space, the simulated agents may be subject to environment, behavioral and procedural influences present, i.e. they attempt to represent some of the influences and processes described previously in a simplified manner. Conversely, other models employ a less refined representation with the population flowing between more crudely defined architectural spaces. Other models fall somewhere in

between these two extremes [22, 27]. The variety of this representation (and therefore the relationship with the data available) is further complicated through the approach employed to represent evacuee behavior, i.e. whether it focuses on movement alone, has a behavioral model, or somewhere in between (see also Chaps. 59 and 60). *In addition to each model needing data in their development*, *each has their own data needs in their application*; *however*, *they will all need data in order to be applied at all*.

Depending on the sophistication of the model, they could be employed in a number of different application modes, each of which places a different onus on the user and on the data required. For instance, the level of configuration required of the user will be dependent on the sophistication of the model, the predictive capabilities of the model and the application. This will influence the scope and detail required of the data-sets sought out. This is described in more detail in Chap. 60.

Human Behavior Data

The evolution of the field has led to an incomplete, disorganized and disparate understanding of the subject of human behavior in fire. This has been due in part to the diverse background of those contributing to the field (e.g., engineers, social scientists, field researchers and model developers) and the changing opinions in the field as to what constitutes necessary information.

Human behavior in fire is not adequately supported by the data available [9] and this should be understood before interrogating the data-sets presented. This suggests that there may well not be an ideal data 'fit' for the scenario at hand, i.e. compromises are often required. The data-sets that are available are therefore often not sufficient, i.e. not sufficiently comprehensive or detailed for the range of intended applications. This limitation should influence model development, selection and application. This constraint underlies the selection of the approach adopted during this chapter which is to provide a synopsis of a wide variety of data-sets rather than a detailed narrative of a limited number of seminal research or well publicized incidents.

Given the increased use of these egress calculation techniques (through greater adoption of performance based design to accommodate innovation, ethical issues, financial issues), it is essential that the underlying methods employed are appropriate to their respective, often wide ranging applications. These methods require the provision of accessible, detailed and unambiguous data in order for them to be appropriately configured and validated. Empirical data-sets addressing human performance are difficult to locate, not sufficiently detailed, dispersed, and are often employed without sufficient understanding of the context in which they were collected. The application of this data could be improved with better knowledge of:

- The conditions of the event from which the data originated,
- The methods used before and after the event to collect and analyze the data, and
- A detailed representation of the data itself.

Without this context data can be misunderstood and misapplied. The intention here is to provide sufficient information for the user to identify the underlying conditions influencing the data and/or identify where omissions exist regarding our understanding of these conditions. The importance of context is discussed in the following sections.

Data Collection: Context

Data can be obtained using a variety of research methods and data collection techniques. It is important to understand how the data was obtained, since the choice of research method and data collection techniques can influence the validity (internal and external) and reliability of the results. Validity refers to the correctness of the study findings; in other words, the extent to which it measures what it is supposed to measure. Internal validity is the extent to which cause and effect relationships can be accurately identified within the study, whereas external

validity refers to whether the findings of the study are generalizable to a real-life setting. It is often useful to consider the external validity of the research relative to the objective of the study. For example, if a study aims to determine the effectiveness of a particular type of alarm system on pre-evacuation time, then the external validity of an announced evacuation would be lower than that of an unannounced evacuation since it is expected that in the latter case participants' behavior would be more similar to a real emergency than in the former. This may influence the value which is placed on the data that is subsequently produced. Reliability, on the other hand, refers to the repeatability of a study; i.e. whether the study is properly documented such that the conditions can in fact be characterized and described in detail and that the data collection techniques used are sufficiently precise. Although not explicitly considered here in relation to the data sets presented, the validity of any data-set should be established by the reader when examining the appropriateness of the data-sets for use. It is therefore important when considering any data set to determine how representative, detailed, comprehensive, consistent and robust the data is and whether it is appropriate for this data to be used in the application at hand.

Broadly speaking, research methods can be categorized as follows [9].

- Experimental trials:
  - Hypothetical scenarios (e.g. response to video playback, simulated environment, tabletop exercises, large-scale pre-planned field exercises, etc.). Typically, those taking part are aware that they involved in the event given the artificial nature of the surroundings and the obvious preparations required to organize and conduct the scenario. For instance, getting participants to control an avatar within a simulated environment, or asking commanders to respond to simulated feedback within a command room.
  - Controlled experiments (e.g. laboratory trials). Again, typically participants would be aware of the nature of the trials being conducted. These might focus on, for example, a particular act (time to ascend stairs, open a door), a particular influence of a factor on performance (the impact of smoke on decision-making, etc.), or behavior in a specific situation (e.g. being alone, in a group, etc.), The user of data produced by small-scale component tests should be aware of the primary performance factor being examined and how this might be integrated into the analysis being performed. This will allow them to establish the credibility of the claims made—especially regarding other secondary or peripheral factors derived from the data-set.
  - Field investigations (drills, etc.). These may be announced or unannounced. Depending on the nature of the experiment, the population involved may have some forewarning of the event, may not be exposed to deteriorating environmental conditions, and/or may become aware that the event is not real. All of these may influence the external validity of the results produced.
- Case Studies / Formal incident investigations. These are performed in order to understand the events during an actual incident and what factors contributed to it [9]. Such investigations tend to focus on establishing the chain of events and factors that contributed to the outcome, rather than producing quantitative estimates of times or capabilities relative to the time line. The user should therefore be cautious if presented with such from this type of study.

It should be noted that not all of these research methods are represented in the various tables that present the data-sets examined here. However, this does not preclude the reader from encountering them in data-sets not presented here or in the presentation of future data-sets.

In reality, the individual is part of a temporal-spatial environment formed within the structure in which the incident has occurred, the history of the structure's use, and the procedural framework associated with the incident—the physical, historical and procedural environment [22].

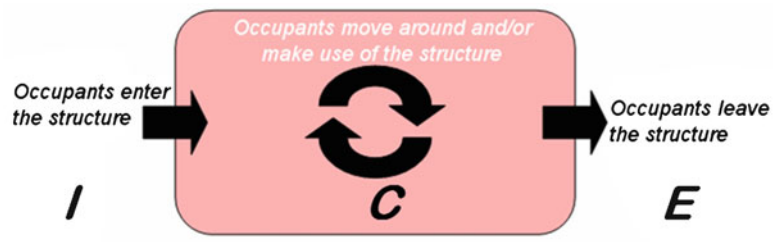

Fig. 64.3 ICE—the three phases of people movement [27]

This is briefly described below in order to further elaborate on the importance of *context* when understanding the data available, its limitations, its applicability to the target scenario and then how it might eventually be employed.

A building can be seen as a people movement system that operates in three phases: ingress (people enter the building), circulation (people use the building) and egress (people leave the building). Therefore, for the building to function people have to arrive and enter the building; during its use, people circulate around the building and, eventually, people leave the building (see Fig. 64.3). Data may relate to any of these phases—it may have been collected when people entered, used or left a building under different situations. This is not reflected in the engineering timeline which (deliberately) partitions the events into distinct separate sections. This is obviously a simplification. In this chapter the description of the data-sets makes reference to these phases where appropriate and where known.

The acronym ICE (ingress, circulation and egress) is used to describe the system of people movement [27–29]. The phases shown in Fig. 64.3 are highly coupled—they co-exist and interact; for instance, people may enter a building while others use and leave the building. Furthermore, the way that a building is entered may influence the way that it is left, which is important during any egress analysis. These phases may also occur at any point during the engineering timeline, or vice versa. This has implications for the understanding and use of movement data; i.e., the phase of movement during which a data-set was produced may not necessarily be the same phase to which it is required to be applied. For instance, escalator data is typically collected during circulation movement, but might conceivably be applied in future analyses where escalators are employed as a component used in an emergency. This does not necessarily preclude its use or prevent there being a significant overlap between the underlying conditions and the expected behavior; however, it is important for the data user to be aware of this in order for them to use the data in an informed manner.

In this chapter data-sets representing general circulation, emergency egress and non-emergency egress are presented. In the description of each data-set, the nature of the event being represented is made clear using abbreviated terms (real incident [I], circulation movement [C], an announced evacuation drill [AE], an unannounced evacuation drill [UE] or an experimental trial [ET]), reflecting the variety of emergency/non-emergency circulation and egress being represented.

Data Collection: Techniques

Data collection techniques are the "measuring instruments" of the research study; i.e., these can be employed during the data collection activities of the various research methods highlighted previously. These instruments can be used individually, but often studies combine them to improve the quality of the research. Triangulation of data using different instruments can be used to corroborate findings and lead to improved validity and reliability of results i.e. data. Data collection techniques commonly used in human behavior in fire research can be broadly categorized as surveys (including interviews and questionnaires), observations, reviews and simulations.

- Surveys—getting information from a sample. Data collected through questionnaires or interviews designed to determine the characteristics, actions, opinions etc., of a particular sample. The user should be aware of the nature of the survey (e.g., whether it was open or closed), the content (e.g., what was actually being asked), the mode (telephone, online, face-face), the sampling approach adopted, and the size and nature of the sample obtained
- Observations—getting information on the sample. Movement/actions are directly observed in some form, without necessarily relying on the verbal communication with those involved. The technique employed to collect the data will influence the format in which the data is collected, the focus of data collection resources, the nature of the data collected, whether the data relates to a time, a space, a person, a condition, etc., and the overall precision and accuracy of the data. There are a number of methods available to collect data:
  - Stationary video camera—providing a fixed stream of information for a particular location/situation, using existing CCTV/security cameras or specially located cameras. This data source has the potential to record behavior in both emergency and non-emergency situations; therefore the user of the data should be aware that there may be discrepancies between the scenario recorded and the scenario of interest,
  - Roving video camera—allows for capturing of progressive conditions experienced by selected individuals or groups,
  - Still photograph—allows a snapshot of a situation to be established at a point(s) in time,
  - Human observer—allows individuals to make manual numerical and/or descriptive observations,
  - Human participant—first person accounts of researcher participation in a situation (either contrived or accidental).
  - Electronic Sensor/Automated Measurement/RFID technology—devices deliberately inserted (often requiring the participants to carry a device) into a location to monitor movement/behavior.
  - Scanner—non-visual methods (e.g. laser techniques) to establish the movement of populations. Often this does not involve identifying those involved.
- Simulated data—generating information on the sample. The use of computational tools to explore egress performance under conditions that could not be explored directly, such as catastrophic fire conditions. The strength of this type of data is highly dependent upon the nature and sophistication of the model used. It may be one of the few options available to investigate performance under extreme conditions; however, the limitations of the model, the process and the data produced should be clearly understood. Simulated or compiled data (e.g. engineering curves) are often confused with direct observations and so great care should be used to identify the source appropriately.

Although not based on new data, the review of existing material/secondary resources such as academic literature, journalistic sources, anecdotal evidence, and material from adjacent fields of research [20, 30–32] i.e. compiling information on/from previous samples, can also provide additional evidence. The value of the source will be dependent on the appropriateness and credibility of the secondary source given the intended application. The ability to assess this appropriateness will largely be influenced by the background information provided by the original authors.

Third-party data users need to be aware of the data collection methods employed to better assess the underlying research, the validity and reliability of the data, and hence the suitability of this data for their needs.

Data Collection: Process

Data does not exist independently of the collection process, i.e. data are not collected in a vacuum. The data collection process requires

decisions to be made at a number of stages, and these directly influence the scope and refinement of the data, and the applicability of this data. Hence, it is important to understand the process by which data are produced in order to apply it appropriately and responsibly.

Initially, a decision has to be made by someone to acquire or seek out data—an omission or weakness in the data available has to be noted and a need established. The data acquisition process is therefore selective. The data collection methods selected may be based on their appropriateness, but also based on less rational reasons, e.g., available expertise, cost, convenience and these choices directly influence the credibility and applicability of the data.

Once the research is conducted, the data are extracted and analyzed and then the data and the derived understanding are described and presented, i.e., the data is distilled into a representative state from a raw form and summarized along with the background information that is available (according to the information collected) and deemed worthy of inclusion by the researchers. When researchers produce a document and present the data, they decide what is relevant and specifically what is relevant to the project at hand. This means that sometimes insufficient information is presented on the data collection methods, context or the results to enable selection to be made in an informed manner by third parties.

The data-sets are then shared with an audience of interested third parties (in academic journals, conferences or readers of this handbook). Having had access to the data, these third parties (engineers, modelers, other researchers) attempt to understand the data according to the presented format and the associated background information and, on this basis, the data are then applied. However, it is important to note that not only is data acquisition selective, but data use is also selective and not necessarily based on the appropriateness of the data itself, i.e. third party users of data may not necessarily source or utilize the most appropriate data for their application, but instead make judgments based on those sources with which they are most familiar or to which they have ready access. This choice is compounded and made difficult by the limited background information associated with the data and the data being provided in a summarized form. In such circumstances the likelihood of data being inappropriately employed for a particular application is increased.

There are a number of opportunities within this process for the data to be misrepresented, misunderstood and misapplied. In most instances, only a sub-set of the data collected is shared, i.e., it is shared in a reduced/distilled format rather than in a complete format. Potentially, and more importantly, in the vast majority of cases only a limited amount of information is provided on the background conditions evident during the original event, i.e., the scenario that produced the data. The reduced data-set and limited context then requires a greater degree of interpretation by the third party. This increases the potential for the underlying causal factors being misunderstood, the results being misinterpreted, and the data-set being inappropriately applied. Although it may be impossible for the third party viewer to understand the content of the information omitted, it may be possible for them to ascertain the type of information omitted and then draw their own conclusions—determining whether or not this omission is critical.

When viewing past data collection, it is important to understand the assumptions made by the data collectors. The collector's 'theoretical' assumptions would have influenced the methods employed, the data collection techniques used and the data actually collected. The format adopted in this chapter represents an attempt to intervene in this process by providing the reader with sufficient background information for them to establish the appropriateness of a data-set (and the data included and excluded), and also to encourage data users to become aware of the importance of understanding the context in which any data set was developed whenever data-sets are to be employed in the future.

Data Selection and Representation

The intention is that the data-sets described in the following sections are presented in sufficient detail such that they might reasonably be employed as part of the engineering process where deemed applicable. Where there is sufficient data to support it, a table is produced. Where there is insufficient data, the data-sets are described in the text, with a detailed description of each data-set provided.

The following paragraphs describe the sources of the data and the structure of the data presentation. *An attempt has been made to ensure consistency between the table designs and content to allow comparison and to improve accessibility*.

Sources of Data

Data has been sought from those sources typically considered as credible outlets within the field. These outlets include:

- Journal publications: Journal of Fire Protection Engineering, Fire Safety Journal, Fire Technology, Fire and Materials, Safety Science, International Journal of Performance-Based Fire Codes, Journal of Applied Fire Sciences, Building and Environment, Journal of Transportation Engineering Transportation Research Record, Physica A, and
- Conference proceedings: International Association Fire Safety Science (IAFSS), Interflam, Pedestrian and Evacuation Dynamics (PED), Human Behavior in Fire, Asia-Oceania Association for Fire and Technology, Mobility and Transport for Elderly and Disabled People.

In addition to these publications, other reports were included, where deemed appropriate; for instance, reports of National Bureau of Standards (NBS), National Institute of Science and Technology (NIST), National Fire Protection Association (NFPA), National Research Council Canada (NRCC), Fire Protection Research Foundation (FPRF), Lund Department of Fire Safety Engineering, Building Research Establishment (BRE, UK), VTT (Finland), Fire Research Institute of Japan.. Occasionally, PhD dissertations which are readily accessible (on-line) are also included, although these were identified and used on a more selective basis.

These sources were identified according to the following criteria:

- Publically available—so that the sources can be followed up by interested readers,
- Written in English (or where translations were available on request)—so that the resources can be understood by those reading this handbook,
- Published after 1985—so that the data sources are fairly contemporary. Note that the authors have taken a decision, in a very select number of cases, to include data pre-1985. The decision to include this data was on the basis that the data represented seminal work with respect to that behavioral component, a data set which is commonly used and cited, or where no other more contemporary data was identified.

For each of the core behavioral components, a table is presented which provides not just the data but background information that allows the reader to understand the context in which the data was collected, the scenarios associated with the data-sets and the data collection methods employed. Thus, the user is armed with information which will facilitate an assessment of the potential validity, utility and applicability of the data and enable an informed selection of the data which is most appropriate to his/her application.

Currently, there is some debate regarding the applicability of egress-related data collected during the 1950s–1970s. This includes the work of Pauls [33], Fruin [34], amongst others. In many instances, this data still forms the basis for much of the current egress analysis (using engineering calculations and/or egress models). A number of these authors have requested that their work not

be included in current handbook chapters as this may be seen as suggesting that the data should still be used in engineering calculations. This data is therefore not presented in detail here. However, if the reader is interested in this data, detailed reference to it can be found elsewhere [33–35].

Structure of Data Presentation

The data-sets are presented according to each of the key behavioral components that comprise the engineering timeline described previously, i.e., detection and warning phases, pre-evacuation phase and travel phase:

- Detection and Warning Phase: This focuses on the delays in the time for the alarm to be raised in the absence (or override) of automatic detection and alarm system; i.e., when detection and general alarm is reliant on the actions of staff only that can lead to significant delays between detection and notification.
- Pre-Evacuation Phase: This focuses on the pre-evacuation times of occupants who are awake in a range of buildings including Transport, Assembly, Health Care, Educational, Industrial, Mercantile, Residential, and Business premises. It also presents data on important components of pre-evacuation time for those who are asleep (i.e., the time to awaken and the probability of awakening), as well as considering the influence of impairment on time to prepare to evacuate which can be considered another component of pre-evacuation time in some circumstances. The data in this section is therefore sub-divided into the following three categories:
  - Pre-Evacuation—Awake
  - Pre-Evacuation—Asleep,
  - Pre-Evacuation—Impaired
- Travel Phase: This focuses on data related to the movement characteristics (i.e. speed and flow of people). These are provided for each of the most common escape route components namely, horizontal, stairs, exits and escalators. Unimpeded movement speeds of the elderly and others with mobility impairments on the horizontal, ramps and stairs are also presented as is data on both upright and crawling speeds in smoke. The data in this section is therefore sub-divided into the following six categories:
  - Horizontal Movement (flow/speed/unassisted/assisted impaired),
  - Stair Movement (flow/speed/impaired/elderly),
  - Exit (flow/traversal speeds),
  - Escalators (flow, speed),
  - Ramps (for unassisted/assisted mobility impaired)
  - Situational Vulnerabilities (Smoke-upright, Smoke-crawling)

Data-sets are presented for each of the behavioral elements above in tabular form. A simple representation of the engineering timeline is provided at the beginning of each behavioral element to signify the phases to which it relates (see Table 64.2).

The tables are presented in as standardized a format as possible—certainly within each of the components presented. The tabular format includes a description of the background conditions under which the data was collected, when and how the data was collected and the key results derived. Other information important to the understanding and interpretation of the key

Table 64.2 Phase from the engineering timeline within which the behavioral components fall

t_{det}	t_{warn}	t_{pre}	t_{trav}	t_{det}	t_{warn}	t_{pre}	t_{trav}	t_{det}	t_{warn}	t_{pre}	t_{trav}
Detection and Warning Phases				Pre-Evacuation Phase				Travel Phase			

results are also presented. This then places the data in context, allowing the reader to better discriminate between the data-sets and select between them. The importance of many of the attributes of the data collection process and event scenario is apparent—primarily as they apply directly to the selection and application of the data. For instance, the building in which the original data collection took place may be a key criterion in the reader's selection process. Similarly, the nature of the population and the procedure employed. However, the reader should also be cognizant of the nature of the original incident (i.e. the source of the material) and the manner in which the data were collected. Although, this may only be considered an indirect impact on the relevance of the data it directly affects the external validity of the data collected and the format/content of this data. Understandably, some of the behavioral components have different attributes—given the nature of the component being represented and the detail in which the data-sets are presented. However, in all instances, the following attributes are described (although not necessarily in exactly the same format depending on the different data represented)

- Source (original reference)
- Observational Conditions represented by:
  - L: Location: the country or city in which the event took place (if known)
  - N: Nature—this can relate to the component being examined in the event (real incident [I], circulation movement [C], an announced evacuation drill [AE], an unannounced evacuation drill [UE] or an experimental trial [ET]) and Location (if known)
  - SC: Spatial Configuration
  - P: Participants or Sample (with A: Age, G: Gender and I: Impairment)
  - E: Environmental conditions are presented where the information is available; otherwise, the 'E:' is removed for brevity
  - V: Variable—specifically, the variable (s) that influence the data collected (i.e., the independent variables)
- Sample/Data Collection Considerations/ Method—data collection techniques are identified as being an [I]nterview, [S]urvey, [V]ideo, [E]xisting or [O]bserver based.
- Results—unless otherwise stated, these are presented in the following format: **average** [**standard deviation**, **minimum—maximum**] and are aligned with the most influential factors presented in the other columns where appropriate. Omissions are denoted with a hyphen (-).
- Additional Information

In order to reduce the space taken up by these tables, several abbreviations are used to ensure that the maximum amount of information is provided. These are outlined next to each of the tables where they are used in order to improve the reading of the data presented along with a description of additional factors described in each type of table (e.g., configuration, performance attributes, etc.). Additionally, in many of the cases, background information is absent, due to limitations in the original description of the data collection process or the event scenario. Where information is missing in the original source material this absence is noted (typically through the presence of a dash '–').

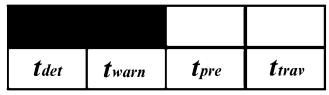
Many of the reference sources provide multiple data-sets that reflect often subtly different conditions. In order to distinguish clearly between these data sets an 'Observational Conditions' column in each table provides background information on the data and, in particular, the Variable (V) entry records factors that distinguish the data sets presented. These conditions are wide ranging and may represent: differences in the samples used (e.g. different age groups, abilities), independent variables that the researchers set out to investigate (e.g. type of alarm), the nature of the event (e.g. announced/ unannounced evacuation), or spatial configuration of the experimental set up (e.g. up/down direction on stairs/escalator). In each case the variables are noted and abbreviations (derived from those outlined earlier in this section) given. These abbreviations are then used elsewhere in the respective tables to distinguish the values of each variable and to clearly identify (in the results column) which results relate to which combination of variables.

Data-Sets

The data-sets are presented in the following sections. These cover three phases of the engineering timeline: *Detection and Warning*, *Pre-Evacuation* and *Travel*.

In each section, an overview is provided regarding the structure of the associated tables, along with a brief discussion of previous attempts to compile equivalent types of data together, where appropriate. These brief discussions are only intended to indicate that previous reviews exist and indicate the format that some of these reviews have taken. It should not be assumed that these reviews are preferred over the many others that may have been performed.

Detection and Warning Phases: Human Aspect



As noted previously, in an engineering design, both human and/or technological resources may be employed to detect an incident and raise the general alarm to initiate the evacuation procedure; i.e., any delay in detection and warning (also previously referred to as Pre-Warning time [11, 12, 24, 25], may be procedural and/or cognitive. Where automatic detection and alarm is employed, typically, t_{det} and t_{warn} will be determined with reference to manufacturer's guidance on sensor response and often do not (and may not need to) take staff activities into account.

However, it is certainly possible that staff (or other occupants) will be involved in the detection of the original incident and the raising of the alarm and it is therefore important to recognize that this involvement might delay the point at which the pre-evacuation phase begins for the general population.

The human element in establishing warning times therefore arises in any situation in which the behavior of an individual intervenes between the detection of a fire and the raising of the general alarm [11, 12, 24, 25]. The need to determine the times required for persons aware of the incident to initiate warnings to affected occupants is recognized in fire safety engineering standards [11, 12, 24, 25]. However, limited guidance is available on the behavioral parameters involved, how the evacuee behavior should be managed and how they can be quantified in a design context.

In reality, the delays associated with these activities may be difficult for the engineer to estimate precisely. However, the engineers may choose to either insert estimates based from previous incidents to provide some representation of this phenomena where deemed relevant or compile an estimate based on expected procedural activities (discussed in detail elsewhere [11, 12, 24, 25]. Examples of such delays from real incidents (both fire and non-fire emergencies) are shown in Table 64.3.

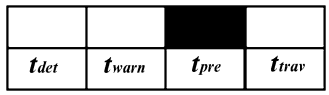
Staff decision-making may occur in a number of situations, e.g., in discovering a fire, interpreting cues first hand (and recognizing them as indicating a real incident), or being notified of an incident (i.e., via the notification system at the fire panel, by other members of staff, by members of the occupant population,

Table 64.3 Estimated staff-related delays from historical incidents [22, 24, 25]

Fire incident	Delay period (minutes)	Number of fatalities
King Cross Subway station	<15	31
Dusseldorf Airport	<27	16
Dupont Plaza Hotel	10	97
Chesterfield Littlewoods Department store	0.5–1	2
Nagasaki Store Fire	6	15
Tokyo security staff training	3.9	–
Ulster Department Stores	0.5–1.0	–

etc.). In these instances, staff members will need to perceive, interpret, determine and then perform the action—in much the same way as other occupants, all of which takes time. Although staff may be better trained and have more experience (both of which will influence the extent of any delay), they would still have to go through this process, delaying their response and, in turn, the response of the general population of the building. The understanding and representation of this component is still relatively immature and, as such, there are relatively few data-sets available to support the representation of this phenomenon within the engineering process.

Pre-evacuation Phase



The time that occupants take to initiate their evacuation movement can be difficult to estimate. In the past, this delay was often not included in an engineering analysis at all [36]. Although, this certainly made the calculation easier (i.e. fewer components needed to be assessed), it also potentially underestimated the expected evacuation times in many of the scenarios examined.

In the calculation of an expected total time to evacuate a building, it is now common practice for engineers to include some time to account for a delay to the start of evacuation, the t_{pre}. This may be achieved simplistically, by segregating the pre-evacuation phase from the travel phase, or in a more coupled manner where the nature of the pre-evacuation phase can influence the development of the travel phase. The tables in the following sections should help an engineer identify such pre-evacuation times.

There have been a number of previous efforts to explore the pre-evacuation phase and produce a collection of the data-sets available. Key advances in compiling pre-evacuation data-sets were made by Fahy and Proulx [37], who collected together a range of data-sets while presenting contextual information to aid the reader's assessment (see Table 64.4).

Other pre-evacuation data (referred to as pre-movement) has been compiled by Shi et al. in a similar format, although in this case data was categorized primarily according to the occupancy type [38]. Bruck and colleagues [39–41], Purser and Bensilum [10] and Proulx and McQueen [42] also provide detailed summaries of their own research regarding pre-evacuation responses. Gwynne also examined a range of pre-evacuation data-sets in order to identify how vulnerabilities in the population might be addressed using notification systems and to identify where gaps might exist in our understanding [43, 44].

Peacock et al. performed a detailed analysis of egress trials conducted by NIST [45, 46]. Although, this focused upon stair travel, a number of pre-evacuation data-sets, based on data collected from buildings ranging from 6 to 31 floors in height, were also summarized. These evacuations produced average pre-evacuation times of between 89 and 224 s [45, 46].

Other pre-evacuation times are presented by the type of occupancy involved in the original event and are described in Tables 64.5, 64.6, 64.7, 64.8, 64.9, 64.10, 64.11, and 64.12. In these tables, pre-evacuation times for business, residential, mercantile, industrial, educational, health care, assembly and transport occupancies are provided. Broadly speaking, the same information is provided throughout Tables 64.5, 64.6, 64.7, 64.8, 64.9, 64.10, 64.11, and 64.12: Source Observational Conditions (Location (country where known), Nature, Spatial Configuration, Participants, Environment and Variables), Procedure (Strategy, Staff, Technology), Sample (Collection method and Size), Results (Mean, Standard Deviation, Range in Seconds). Information is only included in the tables if it appeared in the original source or if can readily be derived. If the information is derived by the authors, this is noted in the table. The Additional Information column is used to provide the reader with more

detail on other data or analysis provided in the original source.

In this examination, pre-evacuation time data have been collected in several ways, primarily from evacuation exercises and experimental/laboratory trials. This data, at least in part, reflects the decision-making process of those involved. Therefore, the credibility (or at least the applicability) of the data collected is dependent upon the information available to the target population during the event since that impacts the external validity of the research. Of critical importance here is whether the participants were aware that it was a drill/experiment rather than a real incident. Prior knowledge may well have influenced the nature of their response, the participants' ability to prepare for their response and the time they took to respond. It should be noted that in a real incident, the information available to those involved would differ significantly according to the cues available to them and differs from a situation where people definitively know that the incident is not real. *A positive understanding of the negative* (*unambiguous warning of the drill before it commences*), *is not equivalent to the negative understanding of the positive* (*evacuee assessment of a smoke cue that may or may not indicate a threat to the individual*).

It is important to note that the different data-sets represent markedly different pre-evacuation time distributions. A number of characteristics that could have impacted on the pre-evacuation time have been identified and discussed previously [7, 36]. It is presently understood that the pre-evacuation time will vary according to situational, structural, procedural, organizational, behavioral and environmental factors present. Kuligowski provides a detailed description of the factors that influence the pre-evacuation phase [20], some of which are also discussed in Chap. 58 of this handbook. A brief overview of the factors derived from the most recent work on human behavior is presented below.

It should be noted that not all of the factors discussed in the following paragraphs are represented in the data-sets described, often because this information was not available in the original source. It may not therefore be feasible for engineers to account for these factors within the data selected. However, even if it is not possible or feasible for the engineer to account for these factors, it is still important for them to be aware of their impact during an actual incident. *Where the factors can be identified within the data-sets*, *it is noted in the description below*.

Building type, *layout and complexity*. The building type and layout provides the spatial environment within which the event occurs. It may determine the nature of the occupants, the resources employed, the hazards present, and the social/organizational hierarchy present and may influence the types of actions that might be expected within a particular space. As such, it is a primary influence upon the scenario produced in physical, sociological and psychological terms. The way each floor and the whole building are organized has an impact on the familiarity and use of the space by an occupant both before and during an incident; e.g. through visual access to routes and exit points. Occupants are more likely to spend time obtaining information or devising a plan of action in a complex building or in a building where wayfinding is difficult. The way the building is designed may or may not also provide occupants with visual access to the behavior of others, to the original incident or to procedural attempts at notifying them as the target population. *If available*, *the building type and the population are described in the Observational Conditions column* (*under Spatial Configuration and Participants*). *The data-sets are also categorized according to the type of occupancy within which the event occurred. This factor was selected as it is likely to be the first factor that the engineer encounters and is likely to form the base assessment of the scenario represented. Where available*, *the number of floors involved in the structure is also given.*

Procedure—Notification System—the technology employed as part of the procedure to inform the target population that an incident

has occurred. This may include a range of different technologies, each of which carries different types of information, suggests different degrees of urgency and which have different degrees of comprehension and intelligibility. This would typically need to be represented as part of the engineering design process. *If available, the technological resources that are part of the emergency procedure are described in the Procedure column* (*under Technology*). *Typically these are systems that alert that something has happened using sirens*, *bells*, *horns* [*AL*]; *using a T-3 fire alarm system* [*T3*]; *provide information beyond simply an alert using a live voice notification* [*LV*], *a pre-recorded voice notification* [*PV*], *or a voice notification where the nature of the voice was unclear* [*-V*]).

Procedure—Human Resources—Staff form a key component within the procedural response. It is widely recognized that the presence of well-trained, engaged, authoritative and informed staff presents the most effective means to initiate occupant response [28, 63, 82, 83]. *If available the human resources that are part of the emergency procedure are described in the Procedure column* (*see* section "Pre-evacuation Phase") *under Staff. It should be noted that only those staff for whom specific mention of their particular role was made in the original source are included.*

Alertness and limitation. Occupants may have situational or innate characteristics that reduce their alertness. Occupants may be asleep, intoxicated, or impaired all of which might reduce the information available to them. *The impact of alertness is addressed in* section "Pre-evacuation Phase: Asleep" (i.e. *that people may be sleeping when cues are provided*) *while the impact of impairment is addressed in* section "Pre-evacuation Phase: Impaired".

Focus—Commitment and background noise. In situations where occupants focus their attention on a particular point, e.g., at a cinema, attention may be diverted from critical environmental and procedural cues. Similarly, in environments where aural or visual background noise is present, the cues available to the population may be confounded and confused, delaying their response. Occupants may also be committed to their actions, potentially having committed resources to the performance of this action, making them reluctant to interrupt it on the basis of ambiguous cues. *The impact of commitment is not addressed* per se *in* Tables 64.5, 64.6, 64.7, 64.8, 64.9, 64.10, 64.11, and 64.12, *although the building type may give some indication of the range of activities undertaken by the samples involved. The presence of background noise is noted where known in* section "Pre-evacuation Phase: Asleep" *in relation to the response of sleeping persons.*

Training—Training is a characteristic of the organizational structure within a building, since training should be specifically tailored to each building evacuation procedure present. That is not to say that the populations do not bring more general experience to an incident; however, this is more difficult to predict and quantify within the engineering process. The likelihood and nature of occupant training will depend on the occupancy type; for instance, in public buildings, occupants are unlikely to be trained for that specific building, whereas some form of training is likely to be the norm for office spaces (although the sophistication of this training may vary significantly).

False alarms. The number of false alarms in a building is an important determinant of the efficiency of this system to warn occupants. If the number of false alarms is high, the pre-evacuation time will likely be extended since occupants are unlikely to look for information and will be less receptive to other cues.

Familiarity. Occupants who are familiar with a building, who have participated in evacuation drills, and who are aware of the evacuation procedure are more likely to start evacuation rapidly. What is not well understood is the point at which the performance of drills and training exercises starts to make the occupant

population skeptical of the information being provided.

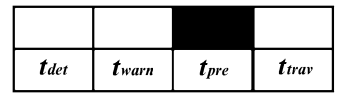
Social Affiliation. The nature of the relationship between the occupant and the surrounding population will influence the manner in which information is perceived and the actions subsequently performed. It will influence the responsibility felt by an occupant for those around them, information exchange, perceived risk and the preparatory actions that might be performed before movement to safety is initiated. *Social affiliation is not presented in the tables*; *however*, *the building type and sample description may give some indication of the types of relationships present among the sample*.

Event Conditions and Proximity to Event. The nature and severity of the incident will influence the type of cues provided to the population. Their proximity to the incident will influence access to these cues, the degree of ambiguity and the perceived sense of risk derived from the cues received.

Surrounding Population and their Actions. The population can be a source of information, with their actions indicating their interpretation of the incident and the options available. However, research has also suggested [84] delayed responses in the presence of others, given their identity and actions. These influences have been referred to as informational and normative social influence [85]. They may also limit viable responses, should routes become overloaded or congestion develops, discouraging the use of certain routes.

The core data-sets relating to the pre-evacuation phase are presented in Tables 64.5, 64.6, 64.7, 64.8, 64.9, 64.10, 64.11, and 64.12. These relate to a range of occupancies and scenarios—cutting across the various factors highlighted above. Further data-sets, exploring the status of the population (i.e. whether they are asleep) and the impairments present in the population (e.g. whether additional preparatory actions are required by the occupants before they initiate egress movement) are presented in more detail in sections "Pre-evacuation Phase: Asleep" and "Pre-evacuation Phase: Impaired" below.

Pre-evacuation Phase: Asleep



As discussed, an extended pre-evacuation time is often the most significant component of the evacuation process. As shown in Table 64.4, these values can range from seconds to hours. Indeed, it is possible that when occupants are asleep the pre-evacuation times could be especially prolonged. Comprehensive reviews of the research literature on arousal from sleep have previously been conducted by Bruck and colleagues [39, 86, 87]. As noted by Bruck [39] this literature falls into two categories: the first comprises investigations into the characteristics of sleep and in particular the arousal thresholds of persons related to the various stages of sleep across the night to different sound stimuli; the second comprises of more focused investigations by those interested in the response of individuals in fire situations who have investigated the likelihood of wakening to a range of specific fire cues, including smoke detector alarms. Since the context of this chapter is in relation to human behavior data for use in fire safety design, the focus here is on the latter. The main findings are summarized in Table 64.13. Table 64.13 includes the summaries already presented in previous literature reviews [39, 86], but has also been updated to include studies conducted post 2005.

Table 64.13 presents the results of a series of experimental trials [ET] conducted in controlled environments (in household, laboratory or hospital settings). Table 64.13 contains information on the Source of the data, the Observational Conditions under which the study was conducted (Location (country in which conducted), Nature of the study (since these were all experimental trials [ET], this section provides details of the experimental set up including the nature of the alarm presentation, stage of sleep, and the

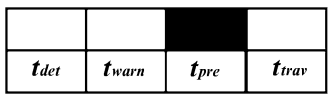
measure used to determine awakening), Spatial Configuration (own, home, laboratory), Variables, the Experimental Sample (Nature and Size), the Signal Employed (Type, Frequency and Intensity), Results (Mean Auditory Threshold, percentage of Awakening and Time to Awaken as appropriate). The Additional Information column provides other information that may have influenced the outcome [39] regarding the study, e.g., the presence or absence of background noise (if known) and whether subjects were primed to expect a signal or were naïve in this respect.

The main method adopted in the included studies is that of a *constant stimulus* being presented to the participants. In this case, the frequency of responses is simply measured within the sample to determine the percentage of participants that awoke and the time it took them to awaken. Another common method which is used to determine, not just the response to a particular signal of certain frequency/volume but the waking thresholds (or AAT—Auditory Arousal Thresholds) for the participants, is the *method of limits* [39]. In this approach, a tone of a standard frequency is presented to a sleeping person at a specific intensity and the intensity increased (usually in five dBA intervals) if there is no response within a certain time period. A response or "no response" to each presentation enables the auditory arousal threshold (AAT) for the person to be obtained. This results in a mean AAT rather than a percentage awakening output (since all eventually awake).

Table 64.13 only provides a summary of some of the most significant data in this area. For a more in-depth treatment of this complex subject area the reader is directed to the comprehensive reviews of Bruck and colleagues [39, 86, 87].

Pre-evacuation Phase: Impaired



Research has shown that during the pre-evacuation phase, building occupants spend time in various activities prior to evacuation. In public spaces, these activities commonly include gathering belongings, turning off computers, packing belongings away, etc. In some evacuation scenarios, particularly in dwellings or other occupancies with sleeping accommodation, these 'preparation activities' may also include turning on bedside lights and getting dressed. This 'preparation time' can be considered a sub-component of the 'pre-evacuation' time and it is recognized that this time could be considerably longer for some individuals, e.g., people with disabilities.

Two studies have directly compared the 'preparation time' for disabled and able-bodied persons. An early study by Pearson and Joost [103] was designed specifically to determine the preparation times of subjects exposed to a simulated fire emergency in a residential setting. The first study involved 18 healthy able-bodied male undergraduate students, 11 blind persons (4 female and 7 male aged from 21 to 58) and 9 male wheelchair users. The second study involved 20 healthy young adults (3 male and 17 female aged from 30 to 48), 20 elderly persons in good health (4 male and 16 female aged 59–79) and 20 elderly with arthritic impairments (3 male and 17 female aged 55–80). Each subject was required to complete a range of scenarios that involved the completion of various activities such as searching for a personal item, donning clothes, retrieving personal effects, and activating lights. Pearson and Joost's [103] study concluded that the mean time for blind subjects to complete these activities was 2.47 times greater than that of young, able-bodied subjects and the mean time for wheelchair users was 2.36 times greater than that of able-bodied subjects.

A later study by Shields et al. [104] also compared the time to prepare to evacuate as part of three evacuation studies of hotel accommodation involving mixed ability populations, including four wheelchair users. Two of these studies were designed to simulate day-time evacuation of hotel accommodation in which participants were initially located in a chair or in their wheelchair and were asked to retrieve a personal item from a drawer before leaving the

room. In the third study, designed to simulate a night-time scenario, participants were initially lying on the bed, and were required to turn on a bedside light, get into their wheelchair (if applicable) and retrieve a personal belonging from a drawer before leaving the room. The results from the Shields' studies suggest that wheelchair users took 1.6 and 1.9 times longer than able-bodied persons to perform the tasks which comprised the day time scenario and 2.4 times longer than able-bodied to perform the tasks which comprised the night time scenario.

These findings are interesting and suggest that, in situations where those with impairments are present, the expected pre-evacuation times might then be increased given the potential difficulties in responding and the need for preparation. However, it is important to note that in both studies the samples were small and the range and severity of disability rather limited. Therefore they should be treated as indicative only and used with care. For a more detailed understanding of the factors described and the base values collected in each case, the reader is referred to the original source material.

Travel Phase

Egress models (engineering or computational) require a number of basic quantitative and qualitative information in order to configure the initial scenario to be examined, i.e. to reflect the core behavioral elements of the engineering timeline. As mentioned these include the pre-evacuation time (addressed in previous sections), quantitative travel elements (travel speed, flow conditions/constraints and their relationship to population density) and qualitative elements (route availability and choice). This section focuses upon the quantitative travel elements only—Chaps. 57 and 58 should be referred to for the more qualitative factors mentioned.

In an engineering context, crowd movement is quantitatively specified using three key characteristics. These are density, speed, and flow. These underpin the engineering hydraulic model presented in Chap. 59 and are also employed or generated in computational egress models. Within the hydraulic model, relationships are assumed between density and speed, and density and flow that then directly influence the results produced. As such, data is often collected relating the three measures in this manner. It is debatable as to the exact causal relationship between flow/speed and density, with density being both an emergent property of crowd movement and a constraining factor. However, in this instance, the relationship is retained given the format and content of the data-sets provided.

Population density is generally expressed as the number of persons in a unit area of measured space, e.g. 2.0 persons/m^2. Alternatively, this factor can be represented by (i) using the inverse of density, that is, the area per person or pedestrian module (occupancy levels), e.g. 0.5 m^2 (5.4 ft^2) per person, (ii) the distance maintained between occupants, in terms of headway or proximity, or (iii) the perpendicular projected area occupied by the population over a unit area (e.g., m^2/m^2) [105, 106]. Given that the density (persons/unit area) is still most commonly used, it will be adopted here and a more comprehensive discussion of this issue is left for future editions of this chapter. It is acknowledged that there are limitations with all of these methods of representation, including the population density. These limitations include the averaging of the densities over a large area, the inclusion of persons within the variable that are not directly influencing movement, and the variety of body sizes not represented within the analysis [105].

Speed is the distance covered by a moving person in a unit of time, e.g. 1.0 m/s (3.3 ft/s). The term "flow" is often used in a casual, non-technical way when the general term "movement" is implied, or when speed is actually being specified. However, flow is specifically the number of people that pass some reference point in a unit of time, e.g. 2.0 persons/s. Flow can be presented in relation to the unit width, in which case it is termed the specific flow and it is presented in units of persons/unit width/time period or it can be presented across a component of a particular width where it is presented in units

of persons/time period. In the tables which follow the specific flow is typically employed; however, it will be made clear for each of the data-sets where other formats are employed.

Assuming no other constraint is present, people can move at their desired speed (given their innate capabilities) if there is sufficient space available for them to move freely, i.e. if the surrounding population does not constrain their movement. The desired speed may change with motivation, which can be influenced by time constraints, social considerations and perceived risk, amongst other things, e.g., the nature of the scenario. However, as the space available reduces, so the ability of the individual to maintain their desired speed, and act on their intentions, is reduced. There is a relationship between the ability to maintain a speed and the local population density.

Relationships between speed and density for specific terrains are provided in Chap. 59. These are based on the work of Nelson and Maclennan [107], who derived these relationships from the work of Fruin [34], Pauls [33], and Predtechenskii and Milinskii [106] *inter alios*. The relationships derived by Nelson and Maclennan [107] represent engineering approximations of several diverse data-sets. As such, these relationships should not be seen as empirical data but as engineering representations.

Another example of this engineering representation is shown in Fig. 64.4. This is derived by Pretorius [108] from the work of Nelson and Maclennan [107] and Kholshevnikov et al. [109]. Kholshevnikov et al. [109] highlighted the different influences that population density might have upon the physical and psychological factors influencing individual movement. Pretorius transposed this onto the assumed relationship between speed and flow produced by Nelson and Maclennan [107] and presented in the SFPE handbook. Pretorius achieved this by using slightly different body sizes (derived from Still [110]) and assuming an engineering rather than empirical approach.

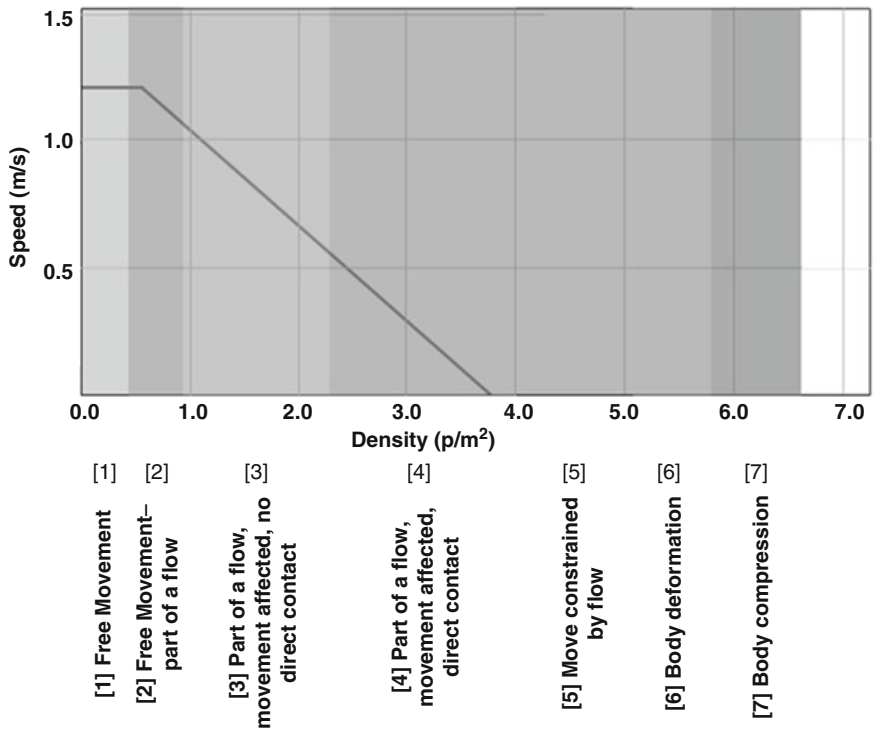


Fig. 64.4 Derived relationship between speed and density [108]

The relationship between flow and density is more complex, given the number of variables involved, i.e., that flow is dependent on the speed of movement and the number of people moving. This relationship tends to be a higher order function than that between speed and density.

The relationship between speed, flow and density becomes more complex as the degrees of freedom in movement increases—the relationship is different on the horizontal from that on the vertical, where movement is more three dimensional in nature. Indeed, some have questioned the direct relationship between speed/flow and population density on stairs, given the impact of the stair configuration upon gait and forward movement [105]. Notwithstanding, the direct relationship is implicitly assumed in much of the data presented, and the nature of this relationship is not investigated here.

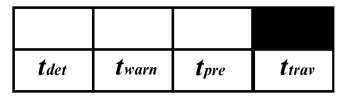
A number of reviews of movement data already exist in the literature; they either combine disparate data-sets from a variety of different researchers, or summarize the work of a suite of data collection exercises performed by the same researcher(s). In the following sections, some of these reviews are presented as examples of data-sets collected for a particular behavioral or movement element. However, a number of broader reviews exist that relate to more than one element. These include reviews by Predtechenskii and Milinskii [106], Smith [111], Tubbs and Meacham [112], Thompson [113], Fahy and Proulx [37], Graat et al. [114], Lord et al. [115], Daamen [116], Teknomo [117], Helbing [118], Fruin [34], and Pauls [33]. Many of these broader reviews have been conducted as part of research dissertations and so fall outside of the relatively narrow scope of this chapter.

It is important for the user to understand the nature of the relationship between these variables before applying any of the data presented in this chapter. Some of the models (engineering or egress) assume this relationship [27]. Others can adopt different relationships depending on the data provided to them or the rules embedded, with the relationship occasionally predicted and generated rather than imposed. Either way, it is important for the reader to understand that this relationship is often assumed without due reference to the implications of this assumption.

When employing these quantitative data-sets, a number of qualitative engineering decisions will need to be made. These relate to the use of the space (width) available, the routes available and the routes used, amongst many others. The selection and credible combination of these qualitative decisions are discussed in detail in Chap. 57. The routes available during an incident will be influenced by the environmental conditions present (discussed in Chaps. 61 and 63). The choice and use of the available routes will be influenced by a number of population characteristics (discussed in Chap. 58) and procedural measures (discussed in Chaps. 56 and 58). Guidance should therefore be sought from these other chapters in order to frame the use of the quantitative data-sets presented below.

In the following sections the movement on the horizontal (see section "Travel Phase: Horizontal Movement"), on stairs (see section "Travel Phase: Stair Movement (Up and Down)"), through exits (see section "Travel Phase: Exits and Narrowings"), on escalators (see section "Travel Phase: Escalators (Up and Down)"), in smoke (see sections "Vulnerabilities: Situational: Movement in Smoke" and "Vulnerabilities: Innate: Impaired Movement") and movement involving those with impairment (see section "Vulnerabilities: Innate: Impaired Movement") is discussed. Where there is other important review material or material that does not meet the selection criteria highlighted in section "Sources of Data" then this is briefly discussed as are the table formats employed.

Travel Phase: Horizontal Movement



A number of previous reviews have been conducted exploring the relationship between density and speed [37, 38, 109, 113, 116, 119–122]. Irrespective of the material covered, an array of different approaches (i.e. numerical, graphical, descriptive, tabular, etc.), have been adopted to

summarize the data and equations have been derived [9]. The approach adopted by a particular reviewer is likely to have been influenced by their theoretical understanding of the factors involved, the purpose of the summary, e.g. intended application area, and the material included in the review itself. Several examples of the different approaches adopted are presented below. The reader is encouraged to examine some of the reviewed material and analysis available from the original source, as a great deal of it falls outside of the remit of this chapter.

Kholshevnikov et al. presented their own work and that of a number of other Russian/Soviet researchers performed over a period of approximately 30 years [109]. This data was gathered in a number of different building types, population types and in a range of environmental conditions. Of particular note in this work is the extreme population densities included in the reviewed material (see Fig. 64.5).

Brocklehurst [120] and Daamen [116] both reviewed a range of material relating to the speeds produced during general circulation activities but presented the material in different ways. Brocklehurst [120] examined the work of Hankin and Wright, Peschel, Henderson, Helbing, Fruin, Older, Polus, Still and presented the average speeds produced given the background factors present during the original events. These factors included the nature of the event, the location, densities, gender/age of the population and the speeds produced. Daamen [116] produced a graphical representation of the data of Fruin, Weidmann, Virkler, Older, Sarkar, and Tanariboon, a functional representation of speed and flow (including the data of O'Flaherty, Lam, Navin, Pauls, Pushkarev in addition to those represented graphically) and mean speed

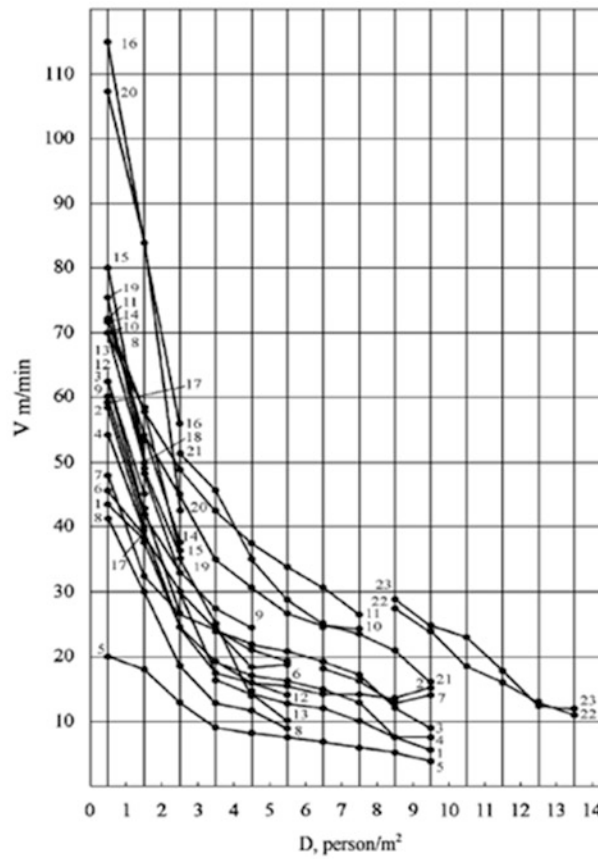


Fig. 64.5 Speed—density relationship for horizontal movement presented by Kholshevnikov et al. [109] (Reproduced from original)

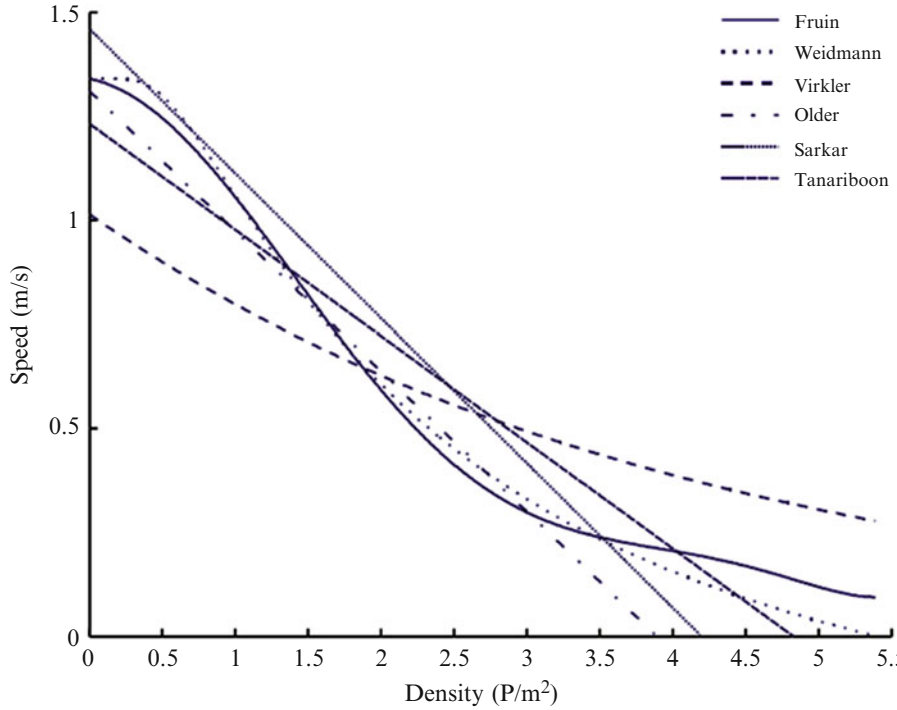

Fig. 64.6 Speed—density relationships summarized by Daamen [116] (Reproduced from the original)

estimates (from data of Daly, Fruin, Hankin and Wright, Henderson, Hoel, Knoflacher, Koushki, Lam, Morrall, Navin, O'Flaherty, Older, Pauls, Roddin, Sarkar, Sleight, Tanariboon, Tregenza, Virkler, and Young). It should be noted that both Brocklehurst [120] and Daamen [116] presented significant reviews of data within their doctoral theses; dissertations such as these are useful sources of data, given the space available for a more detailed review and description of the material available (see Fig. 64.6).

Al-Gadhi [119] also examined a number of pedestrian sources (as well as many collected himself from situations such as the Hajj) that included unidirectional and bidirectional movement, whilst Schadschneider et al. [122] examined several different sources that might be used to support an understanding of evacuation dynamics to facilitate numerical and computational model development. This included a variety of different sources (in terms of the scenario, the geographical origin and the age of the data), including the work of Weidman, Predtechinskii and Milinskii, Older and Helbing [122].

Thompson [113], in his seminal thesis outlining his model development, presented a broad review of core data in order to develop an understanding of the data required to develop a computational egress model and indeed went on to collect his own data in order to develop his model. Thompson [113] summarizes, in some detail, the work of a number of key researchers including Fruin, Predtechenskii and Milinskii, Hankin and Wright, Pauls, Weston and Marshall, Peschl, Ando et al., and Polus, Schofer and Ushpiz.

Finally, in the same vein as the work conducted by Fahy and Proulx [37], Shi et al. [38] attempted to collect together a small number of data-sets in order to develop a database; although in this instance it was conducted to support the development of evacuation modeling tools. Shi et al. [38] produced a table where the data was categorized according to several factors deemed to influence the results produced (see Table 64.14); i.e. free movement or

Table 64.14 Summary of walking speeds produced by Shi et al. [38] (Reproduced from original)

Influencing factors		Speed (m/s)	Range (m/s)	References
Walking type	Free move		1.2–1.8	[120, 219]
	Exit move		0.8–1.5	
Walking conditions for corridors, doorway on ship	Low	1.4		[24, 219]
	Optimum	0.70		
	Moderate	0.39		
	Crush	0.10		
Place type	Public place		0.51–1.27	[56, 220]
	High-rise apartment	1.05	0.57–1.20	
	apartment	0.95	0.56–1.12	
Occupant type[a]	Children	1.08		[131]
	Female elderly	1.04		
	Male elderly	1.05		
	Elderly	1.04		
	Female adult	1.24		
	Male adult	1.30		
	Adult	1.27		

exit movement, density levels (low, optimum, moderate, crush), location type and occupant type. Other comparable reviews have also been conducted [114, 117, 118, 124–126].

Data appears (both within fire engineering and from adjacent areas of analysis) in a number of formats and representing an array of different scenarios. This data broadly reflects the difference performance capabilities of pedestrians under different physical and social conditions.

An examination of the review material available was conducted and the data simplified and compiled into a single figure (see Fig. 64.7). Given the lack of contextual information, the different criteria used to include representative data-points and the different results formats used, this figure should, at very best, be seen as only indicative. However, it is does crudely demonstrate that much of the data collected (and the relationships produced) focus on a relatively narrow band of population densities; i.e. between 0 and 6 persons/m^2. Furthermore, the range of speeds produced within this envelope of densities appears to narrow as the density increases—from a relatively wide range of speeds between 0 and 2 persons/m^2 that narrow beyond 4 persons/m^2. This claim is supported by the work presented by Kholshevnikov [67, 109].

A summary of a range of data relating to travel speeds achievable during horizontal movement are presented in Table 64.15, while the subsequent flow rates produced are described in Table 64.16. It should be noted that there is some overlap between the data described above and the data-sets that appear in Tables 64.15 and 64.16. In Table 64.15, the following information is provided: Source, Observational Conditions (Location, Nature, Spatial Configuration, Participants, Environment, Variable), Sample (Collection method and Size), Results (Density, Speed, Relationship between Speed and Density), and Additional Information. In Table 64.16, the following information is provided: Source, Observational Conditions (Location, Nature, Spatial Configuration, Participants, Environment, Variable), Sample (Collection method and Size), Results (Density, Specific Flow, Relationship between Flow and Density), and Additional Information. In both cases, this information is only provided if it appears in the original source or if can readily be derived. In a limited number of cases, the values provided in the tables, although not given explicitly in the original source, have been derived from other information provided in the original source; e.g., a calculation of a mean

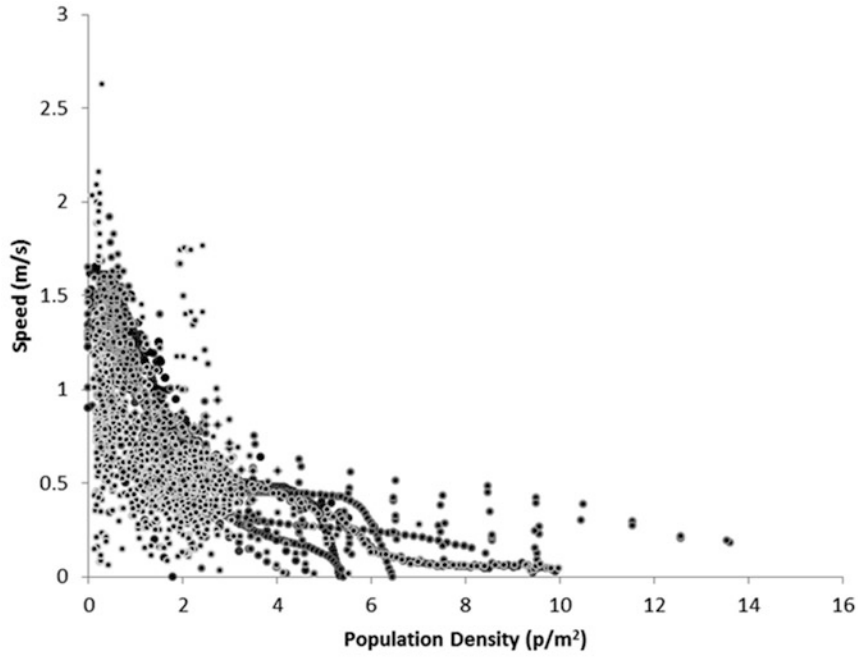

Fig. 64.7 Simplistic compilation of reviewed data on horizontal movement speed derived from the work of Hankin, Helbing, Oeding, Daamen (Weidmann, Virkler, Tanariboon, Sarkar, Polus, Lam), Predtechiniski and Milinskii, K+V, VTT, Weston and Marshall, Navin, V+S, Mori, Averill, Ando, Hoskins, Duives [13–15]

from the source data. If a value has been derived in this way, then that is noted in the table beside that value.

Travel Phase: Stair Movement (Up and Down)

t_{det}	t_{warn}	t_{pre}	t_{trav}

In tall structures, especially those where elevators have not been approved for use in fire emergencies, stair movement may form a considerable part of the overall t_{RSET} calculation. Even in lower rise buildings, stair movement may still be a pivotal, especially for those with difficulties traversing stairs. Indeed, stair movement has determined the outcome of a number of serious incidents [8, 20, 37, 145]—with both the attainable speed, the impact of congestion, fatigue/rest effects, and the direction of required movement all influencing the nature of the outcome.

Movement on stairs presents a different challenge than horizontal movement given the extra degree of freedom available in the movement, the constraints imposed by the stair design and the additional effort required to traverse the stair component. In addition, the relationship between density and speed/flow may be more complex during vertical movement than it is on flat surfaces. For instance, the size and configuration of the treads may have a confounding influence upon this relationship. This issue has recently been examined by Hoskins [105].

Over the last few decades, a number of researchers have examined pedestrian and evacuee performance on stairs. Some [11, 12, 37, 105, 109, 114, 115] have addressed the quantitative aspects of stair movement e.g. speeds and flow rates, while others [33, 146, 147] have focused on the more qualitative aspects of stair movement, e.g. spacing, passing, merging behavior, counter-flow, lane formation, group behavior, gait, falls, handrail use.

Given the importance of stair movement, there are a number of significant reviews available regarding stair data. Some of these, such as

the work of Hoskins [105], have attempted to derive representative functions to describe the relationship between density and speed on stairs, and have provided a detailed review of a range of other speed/flow conditions produced and the maximum densities measured by researchers such as Pauls, Khisty, Kagawa, Proulx, Shields, Kratchman, Hostikka, Peacock, Fruin, Daly, Tanaboriboon, Lee, Ye, Galea, Averill, Melinek, Predtechinskii, Templer, Smith, Frantzich, Boyce, Wright, and Fujiyama [105]. It should be noted that Hoskins [105] then goes on to produce a different formulation to generate stair speeds from that typically employed relating stair flow/movement to the physical conditions present.

Shi et al. [38] also examined stair movement data and categorized it according to dimensions, incline and configuration of the stair. Peacock et al. [45] summarized their own studies involving the evacuation of a series of structures involving stair movement, placed the evacuations in a historical context (see Fig. 64.8) and then compared the speed/density relationships with the SFPE curve derived by Nelson and Maclennan (see Fig. 64.9).

Kholshevnikov et al. [73] presented a summary of movement data relating stair descent speeds to population density within multi-purpose, sports buildings, universities, schools, street areas and experimental rigs in the Soviet Union/Russia over a 30 year period. The results are shown in Fig. 64.10. Once again, the elevated population densities present in the Russian studies, relative to the other studies presented above (e.g. those of Peacock et al. [45]) should be noted. Other reviews include those produced by Fahy and Proulx [37] (that categorize performance according to building type and presence of high densities), Graat et al. [114] (where the speeds are categorized according to direction of movement and location type), and Lord et al. [115] (where speeds are categorized according to direction, demographics, and likelihood).

A compilation of a range of data relating to travel speeds during movement on stairs is presented in Table 64.17, while the subsequent flow rates produced are presented in Table 64.18. In Table 64.17, the following information is provided: Source (Author and Year),

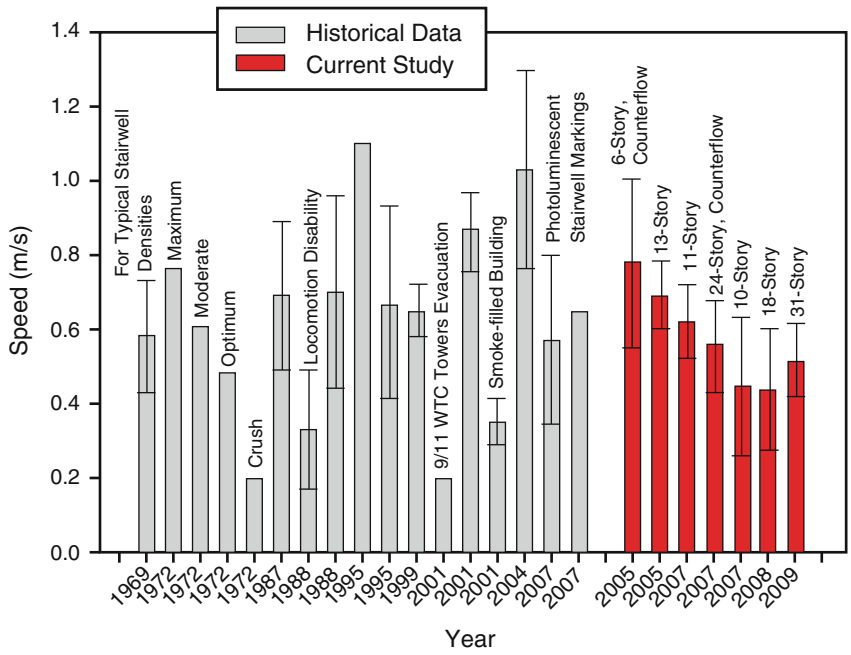

Fig. 64.8 Historical comparison of stair speeds produced by Peacock et al. (Reproduced from original [45])

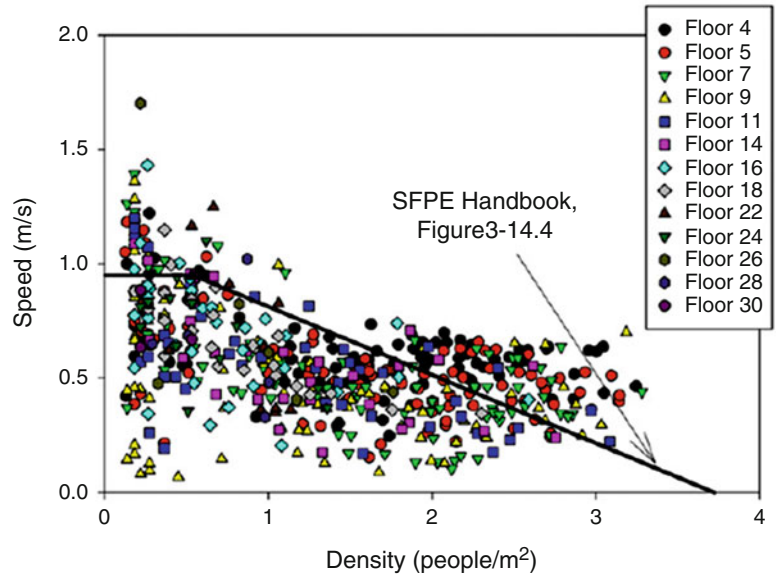

Fig. 64.9 Comparison of speed-density relationships—Peacock et al. and SFPE produced by Peacock et al. (Reproduced from original [45])

Table 64.17 (continued)

Source	Observational conditions (L: location, N: nature, SC: spatial configuration, P: participants, E: environment, V: variable)	Configuration: Direction (up/down)	Configuration: Slope	Configuration: Distance (m/steps/storeys)	Sample: Collection method	Sample: Size	Results: Density: Mean/range of means (persons/m^2 unless otherwise specified)	Results: Incline Speed: Mean/range of means (m/s) ± standard deviation	Results: Relationship speed and density	Additional information
Ono et al. [128]	L: São Paolo, Brazil	Down	–	3 storeys	Video	906 (am)	–	0.11–2.07	–	Drill procedure involved classes being led out in single file with a leader. Paper gives evacuation times each drill, frequency distribution speeds for all drills, breakdown of mean speeds and confidence intervals by age and drill and max and min speed by age. Noted that changing densities and contraflows
	N: [AE]– three trials conducted in each of 2 time periods (morning and afternoon)					706 (pm)				
	SC: school									
	P: aged 5-17; data relates to age range 6-14.									
	V: movement rate of young adults across different times									
Kadokura et al. [148]	L: Japan, 2007–11		30.6°	25 storey	Video and 22 observers whose arrival was an indicator of travel speeds	E1: 116	–	E1–3: 0.62* ± 0.15 (speed of observers across all phases)	–	Paper gives graphical representation of speed of observers on each floor
	N: [-E] (phased evacuation strategy) E1: floor 4–6, phase 1 E2: floor 7–12 + Floor 21–25, phase 2) E3: floor 13–20, phase 3)					E2: 304		E2: 0.74 ± 0.12 (speed of observers phase 2, F 7–12)		*Average speed 0.9 m/s when measured individually
	SC: 25 storey office building					E3: 443				
	P: 5516 (2088 participants)									
	V: movement rate given procedure employed (E1–3)									

Kholshhevnikov et al. [67]	L: Moscow, Russia	CD1: down	–	–	Video	S1: 152*	<1	[0.34–1.16][a]	Paper derives relationships between speed and density for each age group	[a]Dependent on age grouping
	N: ET					S2: 249*	1–2	[0.33–0.97][a]		Paper gives breakdown of walking speeds by density for different age groups as well as standard deviations, confidence intervals
	SC: 8 kindergartens					S3: 240*	2–3	[0.34–0.88][a]		
						S4: 133*	3–4	[0.33–0.78][a]		
	P: [S1–12— children mixed gender and age (<3–7 years)]					S5: 42*	4–5	[0.32–0.72][a]		
						S6: 4*	5–6	0.68 (aged 5–7)		
	V: movement given direction (CD1–2) and age of participants—S1–12)	CD2: up	–	–	Video	S7: 172*	<1	[0.34–1.32][a]		
						S8: 202*	1–2	[0.34–1.07][a]		
						S9: 227*	2–3	[0.33–0.89][a]		
						S10: 108*	3–4	[0.34–0.76][a]		
						S11: 24*	4–5	[0.45–0.67][a]		
						S12: 3*	5–6	0.40 (aged 4–5)		
						*Determined from information given in tables				
Hoskins [105]	L: USA	Down	CS1–2: 32.5° (2 of)	24 storeys	Video	258/364 evacuees per stair	1.67 ± 0.55	0.72 ± 0.25	$s = \frac{1}{1.93 + 0.51D}$ (from slowest occupant category)	It should be noted that some of the data quoted here overlaps with the data described by Peacock et al. [45]
	N: [AE]		CS3–4: 32.5° (2 of)	10 storeys		436/371	1.83 ± 0.63	0.59 ± 0.23	$s = \frac{1}{0.30 + 0.35D}$ (upper bound)	
	SC:11 stair configurations, in office buildings		CS5–8: 38.2° (4 of)	62 storeys		113/156/121/217	1.01 ± 0.48	0.61 ± 0.12	$s = \frac{1}{0.93 + 1.67D}$ (lower bound)	
	P: mixed age and gender		CS9: 36.9° (1 of)	18 storeys		312	1.89 ± 0.69	0.48 ± 0.20		
	V: movement rate given component slope (CS1–11)		CS10–11: 33.1°(2 of)			684/519	1.72 ± 0.61	0.44 ± 0.15		
						0.28–3.51 (range of observed densities across all)		[0.07–2.02] (range observed speeds across all)
