Fibrous Nature and Porosity of Material Fibrous or porous materials allow greater access of air than otherwise (solid wood is not subject to spontaneous ignition at normal ambient temperatures, but woodchips and sawdust certainly are!). The concept that packing such porous materials by compression will increase the CAT by oxygen exclusion is badly flawed. This procedure increases the density (thus *lowering* the CAT) and has virtually no effect on the availability of oxygen. During the preflame development, the oxygen requirement is very low; by the time overt flame is observed, there are usually broad channels of destroyed material (chimneys) that will allow ready access.

Pure cotton in a test oven with a nitrogen atmosphere has been shown to undergo spontaneous ignition but with a longer induction period than in the presence of air [47]. This could be due to adsorbed oxygen on the cellulose fibers or due to exothermic decomposition of the cellulose in the absence of air [48].

Otherwise "harmless" materials (i.e., liquids with very high flashpoints) can undergo spontaneous ignition at temperatures more than a hundred degrees below either their flashpoints or their so-called autoignition temperatures. The familiar drying oils (flashpoints around 230 °C) spread on cotton afford such an example, igniting sometimes at room temperature under the appropriate conditions. In bulk such oils pose little threat of fire causation.

Similarly, hydraulic fluids, specifically designed for nonflammability and with extremely high flashpoints, can undergo spontaneous ignition if allowed to leak onto thermal lagging, such as mineral wool, fiberglass, and so forth, which are characterized by having particularly high surface areas. Practical cases of this and experimental tests have been reported by Britton [49], with particular reference to ethylene oxide fires. More recently a modeling project has been carried out [50, 51] based on adaptation of the Semenov theory of ignition to a porous solid that was wetted with combustible liquid.

Temperature of Stacking The factor of temperature of stacking is simple—the hotter the worse! The main question is, How hot? The CST (critical stacking temperature) is only weakly dependent on the ambient temperature at low ambient temperatures, but it is sensitive to the size of the hot body. This situation arises with freshly manufactured products such as foodstuffs (milk powder, flour, instant noodles, fried batter, etc.), synthetic materials such as chipboard, cotton bales straight from the ginning process, bagasse straight from the sugar mill, fresh laundry (usually in commercial quantities), and so on.

To evaluate the CST requires full testing to obtain the parameters for the material (such as E, Q, κ, etc.) and then application of one of the methods in the literature for its calculation. Thomas [40] has given a method for hot spots of material, and Gray and Scott [52] have given a generalization of this, removing the approximation to the Arrhenius function made by Thomas. A simpler method of calculation of the CST has been given by Gray and Wake [53]. It uses a spatially averaged temperature in the Arrhenius function and then obtains exact results for this simplified problem.

Length of Time Undisturbed Material that has been in place for longer than usual is reason to suspect spontaneous ignition as a fire cause. Many industrial procedures involve the temporary storage of materials that are *normally* above their CAT but that are not left undisturbed for a period longer than or equal to their TTI. Thus under normal circumstances fire does not occur even though the TTI is regularly exceeded. If processes are slowed down for some reason, or storage is prolonged due to vacation, fire can occur even though no other parameters have been changed.

The Aftermath

There are very often very characteristic signs of spontaneous ignition even after it has been the cause of a very large fire. Internal charring and ash is very characteristic in cellulose materials. Combustion starts in the well-insulated internal areas of the body, and warm or hot combustion products rise by convection through the path of least resistance (which is not always vertically upward), forming a "chimney" of discolored and partially combusted material. Because large bodies of material are rarely uniform in density or porosity, there can be more than one chimney formed and this is the norm. The occurrence of multiple chimneys and consequent discovery of more than one heavily charred or ashed area inside the body have led to erroneous charges of arson on the basis of the myth that more than one fire seat means the fire was deliberately lit. When a chimney reaches the edge of the body, smoke first becomes visible, then ingress of air causes flame. The latter may engulf more flammable materials in the building, and the whole structure can be destroyed while the spontaneously combusting material may well be chugging away slowly throughout most of its volume. This can even be the case after the fire has been extinguished. The result is then plenty of evidence as to the cause and origin of the fire. The author has measured temperatures as high as 200 °C in buried, spontaneously ignited material more than 2 weeks after the extinction of the fire!

The internal burning of large piles or stacks of material can cause mechanical instability, and often the body collapses inward in the later stages of ignition. This inward collapse can cause some confusion in excavations, which should always be carried out if spontaneous ignition is suspected along with photographic and thermocouple temperature probe records at all stages.

It should be emphasized that the occurrence of significant amounts of unconsumed, spontaneously ignitable material does not mean that spontaneous ignition was not the cause of the fire. Frequently, oily rags are recovered almost intact from the bottom of waste bins that have been the seat of very large fires. The lower rags tend to be protected from incineration by a layer of char and also by lack of oxygen in the lower reaches of the bin.

Case Histories and Examples

Cottonseed Meal: Living Dangerously

A transit warehouse temporarily storing cottonseed meal to a depth of about 3 m burned down and was completely destroyed. The length and breadth of the building were much larger than the depth of the meal, so the relevant physical dimension (for substitution into the formula for $\delta_{critical}$) was 3 m. Spontaneous ignition was suspected because of the known presence of unsaturated fatty acids prone to this. Standard CAT tests for small laboratory samples were carried out, and the extrapolation to life size was expected to be reasonably accurate because only small amounts of water were present and wet reaction was not suspected.

The body of meal in the warehouse turned out to be supercritical for the average ambient temperature in the area. The unusual factor in this particular case was the fact that the meal had been left undisturbed for much longer than usual due to a transport strike. It remained in place for longer than the TTI, although under normal circumstances it would have been moved on to customers well before significant self-heating could take place.

In this case an enlightened management installed underfloor ducting to produce a high-pressure air blast capable of rearranging the meal substantially from time to time. A similar solution has long been practiced for coal stockpiles, although in that case the disturbance is usually caused by a front-end loader.

Flaming Instant Noodles

Some years ago an instant noodle factory burned down soon after new management had taken over. New management was not satisfied with the throughput of the production line and wanted higher productivity. The latter was dependent on the speed of a single conveyer belt that conveyed the raw noodles through a hot oil bath, then under a number of powerful fans to remove excess oil and cool the cooked noodles for packing and palleting. Increasing the speed of the conveyer certainly increased the throughput in proportion, but the smaller length of time the noodles spent in the hot oil resulted in incomplete cooking. Thus the oil-bath temperature was increased substantially to compensate for this and again produce fully cooked noodles. However, the faster moving belt was now conveying cooked noodles to the packing area in a shorter time than before, *and* they were also coming out of the fryer hotter than before. The result was that they were packed and palleted at a significantly higher temperature than under previous management.

Although the scientific and technological literature contained no reference to spontaneous ignition of noodles, their porous and oily nature indicated a possibility that this could occur. This was confirmed by laboratory tests obtaining the CAT for a particular size noodle block. On this basis a full series of tests was carried out, and the parameters for the noodles obtained from the Frank-Kamenetskii plot in the usual way. With these parameters available, it was possible to calculate the CST for a pallet full of noodle packages as these were shrink-wrapped onto the pallets and completely encased in plastic, that is, the whole pallet full of noodles was in fact the body in question. The calculated CSTs (for a range of feasible ambient temperatures) turned out all to lie above the temperatures reached with the old process parameters but well below the temperatures reached with the new high-productivity parameters. The "bean counters" managed to achieve a productivity of zero until the factory was rebuilt.

Bagasse Storage: Some Complex Chemistry

The sugar industry in Australia wished to use bagasse containing the usual 50 % moisture as a biomass for cogeneration of electricity as large excess tonnages are produced biannually. Removal of moisture increases the calorific (and hence monetary) value of the material as a fuel, provided it can be removed at no energy

cost. At the same time it has been known for some time that large piles of bagasse are prone to spontaneous ignition and self-heating with consequent loss of value and also considerable pollution from the combustion products. An obviously desirable aim would be to create piles of bagasse that are not large enough to be supercritical but nevertheless large enough to self-heat significantly and hence drive off some of the moisture at no cost. Thus one would turn a dangerous energy release into a benefit. Clearly the balance would have to be just right. Consequently, a major research project was undertaken, both experimental and theoretical.

Application of the standard laboratory test methods to bagasse [54] results in a prediction of critical radius for a pile at ambient temperature 30 °C, which is an order of magnitude greater than the observed value. This is now known to be due to the fact that laboratory test CATs are above 100 °C and simply drive off the moisture before the self-heating can get under way. The extrapolated results are therefore only good predictors for dry piles of material. In practice the water content of bagasse is close to 50 % on a dry-weight basis, and this has recently been shown to be instrumental in partaking in a heat-producing reaction in addition to the one predominating in the dry material at higher temperatures [20, 21]. This wet reaction has been characterized in isothermal calorimetric measurements over the temperature range 30–90 °C, and in this range the high-activation-energy dry reaction is almost completely shut down by the negative exponential in the Arrhenius function.

The wet reaction does not follow an Arrhenius temperature dependence at all, rather having a maximum rate at about 55–60 °C. It also has a sharp, almost discontinuous dependence on water concentration, cutting out completely below 20 % moisture. These characteristics are probably responsible for its occurrence being mistaken for microbiological activity. Inclusion of such complex chemistry in a generalization of the Frank-Kamenetskii theory for distributed temperatures, as well as the evaporation, condensation, and diffusive movement of water vapor through the pile, results in probably the most complex modeling yet of ignition phenomena.

Nevertheless, this model describes quantitatively the behavior of real bagasse piles and answers the questions that led to its creation, that is, How does one choose a pile size in order to maximize the water removal without losing the pile to spontaneous ignition? The modeling is described in a number of publications (e.g., Gray et al. [12]) and shows that present-day computing power coupled with appropriate knowledge of physical parameters enables quantitative or at worst semiquantitative modeling of spontaneous ignition situations with input of realistic chemistry and transport processes. Such developments have also taken place in the modeling of realistic chemistry in gas-phase ignition of hydrocarbons and related organic materials.

It seems that we are not far from a situation where the simplified theories that have been useful tools for so long (with their empirical corrections) will be superseded by more detailed calculation of the required properties such as CATs and CSTs. Nevertheless, the simplified theories will never lose their pedagogical value and will remain a firm conceptual foundation for more sophisticated models.

Milk Powder: A Numerical Example

This example is due to Beever [55]. In a milk-drying plant, air entering the spray dryer was heated to 200 °C, and it was thought that surfaces in the region of the inlet would also reach this temperature. Any collection of powder on hot surfaces could cause spontaneous ignition, which would not only spoil the product but also act as a source of ignition for a dust explosion. These have occurred in milk-drying plants with devastating consequences. Farther down the dryer, where there was deemed to be a greater likelihood of powder accumulation, surface temperatures of 80 °C occurred. Three laboratory basket sizes were tested with half side-lengths of 0.025, 0.0375, and 0.050 m. The CATs of these were 171 °C, 156 °C, and 141.5 °C, respectively.

For a cube we can substitute the value 2.52 for δ_{critical} in Equation 20.20:

$$\ln\left[\frac{\delta_{\text{critical}} T_{a,\text{critical}}^2}{r^2}\right] = 41.85 - \frac{9497}{T_{a,\text{critical}}}$$

We can make r the argument of this equation and then substitute for $T_{a,\text{critical}}$ as required. If we require the critical temperature for a layer of material, we would use the value for δ_{critical} appropriate to an infinite slab, that is, 0.88. For such a flat layer with ambient temperature on each side of 200 °C, a critical thickness of 0.017 m is obtained. For the cooler regions of the dryer at 80 °C, a critical thickness of 0.4 m is obtained. It was decided that these critical thicknesses were sufficiently realistic to require regular cleaning inside the dryer to remove buildup. This problem is actually more complicated than indicated here because the critical parameters are rather sensitive to moisture content, the critical thickness increasing significantly with moisture content, which can be up to 4 % [56].

Technical and Legal Matters

SADT

Many definitions, particularly those published by the United Nations (UN), the International Maritime Organisation (IMO), and the U.S. Department of Transportation (DOT), are incorporated *in toto* in various regulations and statutes, thus attaining a rigorous legal standing. As a result, they assume a status that scientifically they do not deserve by virtue of being wrong, ambiguous, confusing, or all three and more.

The centerpiece of such consideration is the *self-accelerating decomposition temperature*, or SADT. *Some* of the definitions of SADT (there could be more) are presented here. The UN's *Manual of Tests and Criteria* [35], in its section "Recommendations on the Transport of Dangerous Goods," contains at least four definitions. Some are inconsistent with each other and some are actually defined so as to be *up to 5 °C above the critical ambient temperature*. The materials could therefore blow up well below the SADT!

Definition 1. Test Method H1—U.S. SADT Test

The SADT is defined as the lowest oven temperature at which the sample temperature exceeds the oven temperature by 6 °C or more.

The test is run for 7 days, the time origin being when the sample temperature is 2 °C below the oven temperature, assuming the body is at room temperature when inserted. The occurrence of three completely arbitrary numbers (7 days, 2 °C, and 6 °C) should arouse suspicion in even the most scientifically illiterate person that this SADT definition cannot be a fundamental property of the body tested. Detailed considerations using fundamental thermal ignition theory show that the SADT definition does not indicate that the test body will not blow up below the SADT. Some materials could do so, and similarly some may not do so when placed in an ambient temperature above the SADT.

On the other hand the *critical ambient temperature* (CAT) defined and discussed in this article is a rigorous dividing value between ignition and subcritical self-heating. Why any version of the SADT would have found its way into the scientific fringe literature of regulation and litigation is rather incomprehensible, but things get worse when we consider the UN tests H2 (adiabatic storage test) and H3 (isothermal storage test). We will not go into the experimental details of these tests but go straight to the definitions of SADT arising out of them. Both tests make use of a diagram (plotted from the test results) that is in fact identical to Fig. 20.1. This diagram is given as Figure 28.4.2.2 and again as Figure 28.4.3.2 in the *Manual of Tests and Criteria*. Both of these diagrams show and explicitly refer to the *critical ambient temperature* but unbelievably go on to define the SADT as follows.

Definition 2. Test Methods H2 and H3—The Adiabatic Storage Test and Isothermal Storage Test, Respectively

The SADT is the CAT rounded up to the next higher multiple of 5 °C.

It follows from this that

Every material can blow up below its SADT as defined by UN tests H2 and H3.

The U.S. Department of Transportation uses SADT values *measured by any of these tests* to

impose requirements for temperature-controlled transportation (CFR 49). Clearly it does not err on the side of safety.

ASTM E698-01

ASTM E698-01 is entitled *Standard Test Method for Arrhenius Constants for Thermally Unstable Materials,* and the abstract states [57]:

> The kinetics of exothermic reactions are important in assessing the potential of materials and systems for thermal explosion. This method provides a means for determining Arrhenius activation energies and pre-exponential factors using differential thermal methods.

A paper has recently been published [58] that throws very considerable doubt on the activation energies obtained by this method notwithstanding the caveats in the standard itself. Calcium hypochlorite can be used to illustrate a difficulty arising from the lack of sensitivity of typical differential scanning calorimetry (DSC) results when two reactions are involved and they have widely differing kinetic parameters. The Kissinger plot gives a good straight line but in fact the presence of a low activation energy, low-temperature reaction is not detected. The exotherm obtained relates to the high-temperature, high activation energy reaction, albeit somewhat inaccurately. In the large-scale practical situation the low-temperature reaction is in fact the cause of thermal ignition, and the conclusions drawn from DSC results are dangerously in error.

Modeling experiments in which either reaction is left out show that the *low-temperature reaction* does not show an exotherm until a temperature about 200 °C above the position of the exotherm for the *high-temperature reaction* under the conditions of DSC tests.

The practically dangerous low-temperature reaction does not produce heat at a sufficiently high rate to be detected in a typical DSC until very high temperatures. Before such high temperatures can be reached during a temperature ramp, the material is consumed by the high-temperature reaction, and the low-temperature reaction is missed completely.

Such errors in activation energies are disastrous in the prediction of critical ambient temperatures because these are extremely sensitive to the activation energy. Generally speaking, the very factors that endow a substance with the propensity to ignite spontaneously also tend to increase the "correction factor" for the standard method of data extraction from DSC results. These are well known to be low thermal conductivity, low activation energy, large heat of reaction, and high pre-exponential factor. The fact that necessary corrections to classical DSC results are directly proportional to the Frank-Kamenetskii parameter very clearly illustrates this problem for the use of DSC in estimating self-ignition propensities in self-heating materials.

Nomenclature

C_v	Heat capacity at constant volume per unit mass (J/K·mol)
c	Concentration (mol/m^3)
c_f	Feed concentration in CSTR (mol/m^3)
CAT	Critical ambient temperature (K)
CST	Critical stacking temperature (K)
E	Activation energy (J/mol)
F	Feed rate in CSTR (m^3/s)
$f(c)$	Chemical reaction rate (mol/m^3·s)
Q	Heat of reaction (J/mol)
R	Universal gas constant (J/mol·K)
r	Characteristic radius
S	Surface area (m^2)
T	Temperature (K)
T_a	Ambient temperature (K)
$T_{a,\text{critical}}$	Critical ambient temperature (CAT) (K)
T_f	Feed temperature in CSTR (K)
TTI	Time to ignition (s)
u	Dimensionless temperature (RT/E)
u_a	Dimensionless ambient temperature
V	Volume of self-heating body (m^3)
ν	Dimensionless concentration (c/c_0)
δ	Frank-Kamenetskii parameter
θ	Frank-Kamenetskii dimensionless temperature
ρ	Bulk density (mol/m^3)
κ	Thermal conductivity (W/m·K)
χ	Heat-transfer coefficient (W/m^2·K)
ε	Inverse dimensionless heat of reaction

τ	Dimensionless time
l	Dimensionless heat transfer coefficient
Bi	Biot number ($\chi r/\kappa$)
$\partial()/\partial n$	Differential coefficient in a direction normal to the boundary of the body

Brian Gray has published extensively on spontaneous combustion and ignition of gases and solids, gas ignition, flame propagation, and related topics for many years. He now runs a combustion consulting company in Sydney, Australia, and was professor of chemistry at Macquarie University, Sydney, from 1976 to 1998.

Flaming Ignition of Solid Fuels

21

José Torero

Introduction

This chapter will describe how heating of a solid fuel leads to flaming ignition. The discussion will be centred on flaming ignition of solid fuels but will not address smouldering or spontaneous ignition since these subjects will be covered in Chaps. 19 and 20 respectively. Thus, the presence of a source of heat decoupled from the solid and fuel gasification will be assumed throughout the chapter.

The main focus of this chapter is to assist the reader in understanding the phenomena, assumptions and simplifications embedded in different models and tests that attempt to predict ignition phenomena or to extract the parameters controlling it. The methodology to be followed goes from the general to the specific. Therefore, the problem will be initially formulated in as general a manner as possible. A series of common simplifications will then be made leading to reduced formulations. These simplifications are introduced for many reasons that include:

- Simplifications where the nature of the material studied allows the exclusion of some specific phenomena
- Simplifications where some processes disappear due to the characteristics of the test used to assess the material
- Simplifications where the required precision does not warrant the inclusion of higher levels of complexity
- etc.

To highlight the impact of simplifications, whenever possible, a comparison between the comprehensive description and the reduced formulation will be made to allow the reader to assess potential errors. As this chapter progresses the resulting formulations become simpler and of greater practical use, nevertheless the impact of the assumptions strengthens increasing the potential for error or misuse of the information. The chapter closes with a presentation of the simplest methodologies that correspond to classic treatments and are mainly associated to standard tests.

Most of the existing data on ignition is intimately related to the methodology used to extract it. Therefore, it is always conditioned by the nature of the test procedures, the hardware used and by the data analysis method. Given that the objective of this chapter is to provide a phenomenological description of flaming ignition of solid fuels emphasis will be given to the different processes and not to reviewing available data. Throughout this chapter the reader will be directed to other chapters and references where data will be presented in the context of the testing protocols used to obtain it. As an example, some of the most comprehensive compilations of ignition data can be found in Chap. 36, in textbooks such as Ref. [1] or professional guidelines [2].

The Process of Ignition

When a solid material, initially at ambient temperature, is subject to an external source of energy the temperature of the exposed surface starts to increase. This moment will be defined as the onset of the ignition process, $t = 0$. A series of physical and chemical phenomena are initiated as the energy reaches the surface of the material. This chapter will attempt to describe these phenomena.

Without loss of generality and for simplicity, the ignition process will be described in a one-dimensional frame of reference with a single coordinate, x. Only one surface of the material will be heated and the origin of the coordinate system, $x = 0$, will be placed at the exposed surface of the material. This frame of reference will move with a velocity V_R as the fuel consumes and the surface regresses. For some materials regression rates are very small and can be neglected, but this will not be assumed at this stage. A schematic of a generic solid material undergoing heating is presented in Fig. 21.1. Figure 21.1 also shows all the different variables that evolve through the heating process. These variables will be described in detail later.

For simplicity, all processes involved will be divided in two groups, those associated with the solid phase and those with the gas phase. The solid phase treatment will lead to a description of the production of gas phase fuel ($\dot{m}''_P$) and the gas phase analysis will focus on how the ensemble of gaseous fuel and oxidizer lead to a flame. The solid phase will be treated first (section "The Solid Phase"), then the boundary conditions between both phases will be established, to finalize with a description of what happens in the gas phase (section "The Gas Phase").

The Solid Phase

The temperature of the solid, initially at ambient (T_o), increases as the heat reaches the surface of the material. Highest temperatures will be

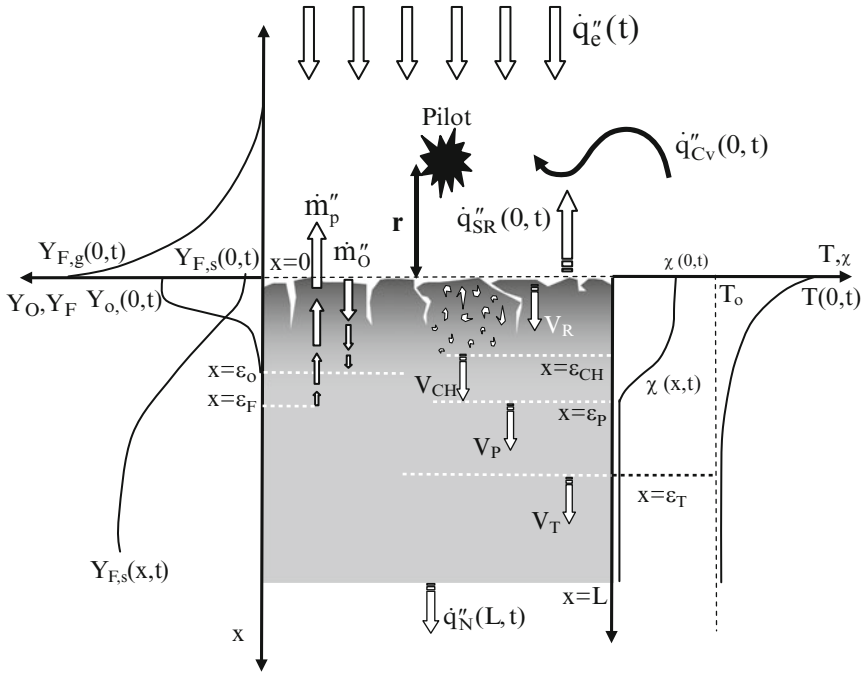

Fig. 21.1 Schematic of the different processes occurring as a material undergoes degradation prior to ignition induced by an external source of heat

achieved close to the surface, but energy transfer in-depth will result in an increase in temperature of a significant part of the solid. Therefore, the temperature will vary in-depth and in time, thus temperature needs to be represented as a function of both variables, T(x,t). Figure 21.1 shows a generic representation of the temperature distribution at a particular instant in time, t. The evolution of the temperature is defined by an energy balance in control volumes between both surfaces of the solid (x = 0 and x = L). The surfaces will define the heat transfer in/out of the solid fuel or mathematically, the boundary conditions. It is important to note, that if other dimensions were to be considered, similar boundary conditions will have to be established at each surface of the material.

Pyrolysis Process

The process by which the solid transforms into gas phase fuel is called pyrolysis and generally implies the breakdown of the molecules into different, most of the time smaller, molecules. This is an important difference between solid and liquid gasification. In the case of liquids a change of phase is not necessarily accompanied by a chemical change (see Chap. 18 for details on ignition of liquids). Pyrolysis tends to be an endothermic process generally controlled by many chemical reactions (some time hundreds) which are a strong function of the temperature. Most pyrolysis reaction rates tend to be described by Arrhenius type functions of the temperature

$$\dot{\omega} = A Y_O{}^m Y_S{}^n e^{-E/RT} \qquad (21.1)$$

But could also be described by other simple expressions like polynomials such as

$$\dot{\omega} = C Y_O{}^m Y_S{}^n (T/T_o)^b \qquad (21.2)$$

The reaction rate is generally defined in units of inverse seconds $(\dot{\omega}[1/s])$ and only when multiplied by the fuel density gives a gasification rate per unit volume ($\dot{\omega}'''$, kg/s.m^3). The constant "A" is also given in inverse seconds (1/s) and generally named the pre-exponential constant. In the case of a polynomial description, "A" will be replaced by another constant that is here defined as "C." These constants are a characteristic of each specific chemical reaction. "E" is the activation energy whose magnitude is also specific to each reaction and "R" has the value of 8.314×10^{-3} kJ mol^{-1} K^{-1}.

The process of pyrolysis can be extremely complex and depending on the fuel and heating characteristics can follow distinctively different paths. These paths can be a compendium of numerous reactions that could be sequential or compete against each other. Furthermore, the chemical pathways followed can be strongly influenced by the presence of oxygen as indicated in Equations 21.1 and 21.2. In both equations Y_O and Y_S are intended to be generic representations of oxygen and solid fuel mass fractions participating in the solid degradation and "m" and "n" are constants.

It is important to note that while degradation of some fuels will show dependency on the oxygen concentration many others will not [3, 4]. In those cases "m" is assumed to be zero.

The chemical pathways leading to the pyrolysis of most solid fuels of interest in fire are fundamentally incomplete as much as the constants associated to the equations that will serve to quantify the rate of each reaction step. Many studies have evaluated reduced chemical mechanisms for the pyrolysis of different solids [5–7] but there is still great uncertainty on the chemical pathways, the number of steps required and the constants associated to them [8, 9]. Figure 21.2 shows an example of chemical kinetic compiled obtained for PMMA by using an expression similar to Equation 21.1.

Thermo-Gravimetric Analysis (TGA) has been used in the past to establish reduced chemical reaction mechanisms as well as the associated constants. The principles behind TGA studies and some applications to materials relevant to fire are presented in Chap. 7. As an example, a reduced kinetic mechanism for polyurethane (PU) can be found in Ref. [6]. The authors propose a four step mechanism of the form:

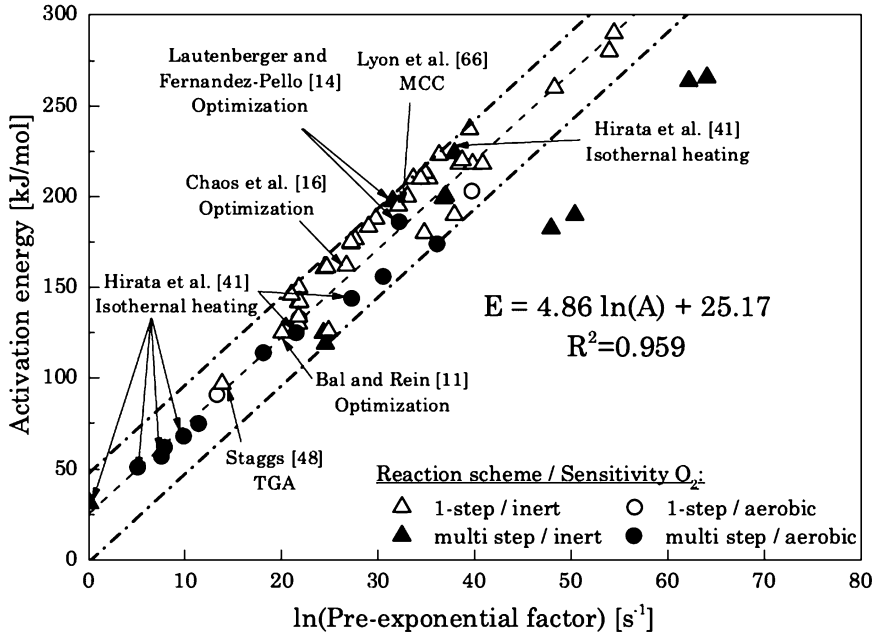

Fig. 21.2 Kinetic parameters of the pyrolysis decomposition of PMMA as reported in the literature [8]

$$
\begin{aligned}
&\text{Step i} = 1 \quad \text{PU} \rightarrow \nu_{\beta,\,p}\ \beta\text{-PU} + \nu_{g,\,p}\ \text{Gas}\\
&\text{Step i} = 2 \quad \beta\text{-PU} \rightarrow \nu_{c,\,p\beta}\ \text{Char} + \nu_{g,\,p\beta}\ \text{Gas}\\
&\text{Step i} = 3 \quad \begin{cases} \text{PU} + \nu_{O2,o}\ O_2 \rightarrow \nu_{c,o}\ \text{Char} + \nu_{g,o}\ \text{Gas} \\ \beta\text{-PU} + \nu_{O2,o}\ O_2 \rightarrow \nu_{c,o}\ \text{Char} + \nu_{g,o}\ \text{Gas} \end{cases}\\
&\text{Step i} = 4 \quad \text{Char} + \nu_{O2,c}\ O_2 \rightarrow \nu_{r,c}\ \text{Residue} + \nu_{g,c}\ \text{Gas}
\end{aligned}
$$

where the reaction rate for each step $(\dot{\omega})$ is presented by an expression of the form of Equation 21.1. The first two steps encompass purely thermal degradation, while the last two steps include oxidation. Two intermediate products are formed from the initial degradation of the polyurethane, β-PU and Char. While the terms Gas and Residue represent the gaseous and solid products of the degradation. It is important to note that there are sequential and competing reactions; while steps 1 and 2 are sequential, step 3 competes with both previous steps. The authors use independent TGA data [10] to obtain all 12 constants thus establishing a complete model for the degradation of polyurethane.

Figure 21.3 shows two curves extracted from Ref. [6] where the model is compared to experimental data for inert and air atmospheres. The figures show the sample mass loss rate as a function of time. The effect of oxygen and the impact of the heating rate are evident from the data. The results show very good agreement with the four step model for all conditions studied.

Despite the generalized use of TGA data, there is increasing recognition that pyrolysis reaction pathways are sensitive to the heating rate. The basic nature of TGA studies requires heating rates of the order of 1–20 °C/min which is generally an order of magnitude slower that heating rates typical of fires. Recent studies have

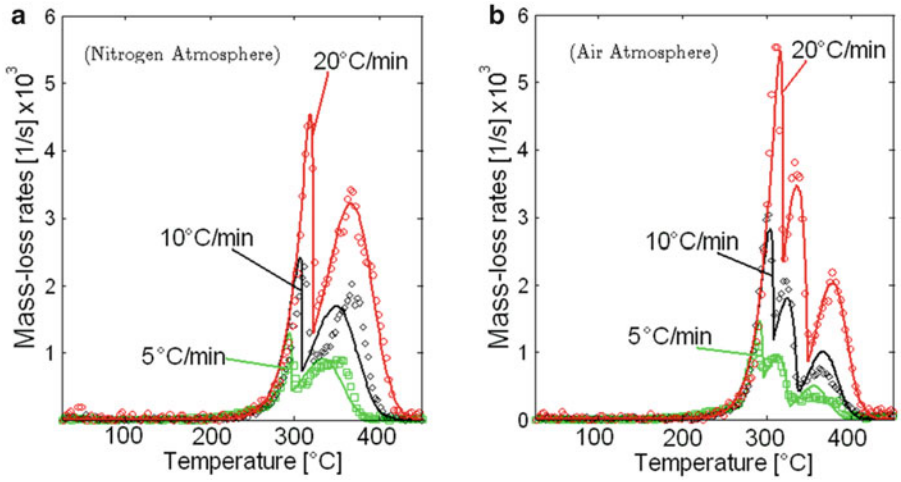

Fig. 21.3 TGA data for polyurethane extracted from reference [10] (*symbols*) superposed to the reduced kinetic model from reference [7] (*lines*) for inert atmosphere (**a**) and air (**b**)

established methodologies that use standard test methods and advanced optimization techniques to establish reduced reaction schemes and their associated constants [7, 11–14]. Although, these procedures allow exposing the materials to heating rates typical of fires and obtaining comprehensive sets of constants they have only been applied to a reduced number of materials. Currently, these methodologies remain fundamentally research tools.

It is important to note that the qualitative and quantitative agreement described in the above example is not usual for materials commonly present in fire and the problem of establishing the chemistry of pyrolysis is far from being solved. Therefore, when studying flaming ignition of solids it is common to make strong simplifications to handle chemical degradation as the solid fuel is heated. Such simplifications will be made later and their impact will be assessed.

The Production of Gaseous Fuel

Before flaming ignition can occur, fuel in the gas phase needs to be produced. Solid materials that are not susceptible to spontaneous ignition will show very little evidence of chemical reactions at ambient temperatures, thus can be deemed as inert. The reaction rates associated to pyrolysis can be considered negligible and therefore the material will not follow any transformation. As the temperature increases the reaction rates increase and the solid fuel starts changing. Given the temperature distribution within the material, the rates of decomposition are a function of "x," with larger production of pyrolyzates close to the surface and lower production in-depth.

Local production of fuel is not the only important variable. The gas phase fuel produced might be the result of a combination of pyrolysis and oxidation reactions, thus its composition might include large quantities of fully oxidized compounds such as carbon dioxide (CO_2), partially oxidized gases such as carbon monoxide (CO) and other molecules that can have all levels of partial oxidation. Therefore, together with the reaction rates, the mass fraction of inert gases needs to be subtracted leaving the remaining reactive gases. As an example, Kashiwagi and Nambu [15] studied the degradation products of cellulosic paper showing that there is a significant presence of inert gases like water vapour, fully oxidized gases like CO_2, partially oxidized products like CO and fuel like CH_4 and H_2.

There is very little data available on the degradation products of most materials relevant to fire, therefore, the mass fraction of flammable gases present in the local products of degradation will be described here by means of a single variable, $Y_{F,s}(x,t)$, which represents a global contribution of all compounds that can be further

oxidized. Figure 21.1 represents $Y_{F,s}(x,t)$ as an increasing function with a minimum at the surface ($Y_{F,s}(0,t)$). This is based on the assumption that where there is a higher presence of oxygen there is higher levels of oxidation.

Oxygen can migrate inside a fuel resulting also in an in-depth distribution ($Y_O(x,t)$) that reaches ambient values at the surface ($Y_O(0,t)$). In-depth oxygen and fuel diffusion is controlled by the structure of the solid. Some materials are highly permeable and allow unrestricted transport of species in and out of the solid. For other materials oxidation will occur only very close to the surface and could be potentially neglected. The permeability of the fuel can be a function of many variables including the degradation and consumption of the material and has deserved very little attention in the fire literature. In the absence of a well defined permeability function, here, a simple variable associated to the fuel permeability ($\chi(x,t)$) will be introduced and assumed to describe in a generic manner the fraction of the fuel produced that can flow through the solid material. It has to be noted that $\chi(x,t)$ is not strictly a permeability function (as per Darcy's law) but a combination of permeability, porosity and any fractures within the material.

Oxygen and fuel concentrations will be controlled by the local permeability and by production/consumption rates, thus indirectly by the temperature distribution ($T(x,t)$). This makes necessary to treat them independently, therefore two independent variables emerge, $\varepsilon_F(t)$ and $\varepsilon_O(t)$. The former represent the region where fuel is being produced while the latter represents the region where oxygen is present in relevant quantities.

If all the reactions occurring can be represented in an Arrhenius form (Equation 21.1) then the local mass production ($\dot{m}'''_P(x,t)$) can be the summarized into a function of the form:

$$\dot{m}'''_P(x,t) = Y_{F,s}(x,t)\sum_{i=1}^{i=N}\left[A_i Y_O^{m_i}(x,t) Y_S^{n_i}(x,t) e^{-E_{i_i}/RT(x,t)}\right] \tag{21.3}$$

where the summation is not truly a sum of all the different "N" reaction steps but just some global combination of them that includes sequential and competitive reactions.

To obtain the total fuel production at the surface per unit area ($\dot{m}''_P(0,t)$) it is necessary to integrate Equation 21.3 across the entire depth including the permeability function described above. It is important to note that fuel produced in-depth does not have to come out, and in many cases pressure increases within the fuel structure can be observed. The effects of permeability and pressure are combined in a complex manner to define the flow within the porous medium. This remains an unresolved problem, thus the use of a simple variable such as $\chi(x,t)$ is justified. Integrating Equation 21.3 we obtain the following expression

$$\dot{m}''_P(0,t) = \int_0^L \chi(x,t)\left(Y_{F,s}(x,t)\sum_{i=1}^{i=N}\left[A_i Y_O^{m_i}(x,t) Y_S^{n_i}(x,t) e^{-E_{i_i}/RT(x,t)}\right]\right)dx$$

Assuming that any production of fuel is negligible for $x > \varepsilon_F$ then the boundaries of integration can be changed to

$$\dot{m}''_P(0,t) = \int_0^{\varepsilon_F} \chi(x,t)\left(Y_{F,s}(x,t)\sum_{i=1}^{i=N}\left[A_i Y_O^{m_i}(x,t) Y_S^{n_i}(x,t) e^{-E_{i_i}/RT(x,t)}\right]\right)dx \tag{21.4}$$

Where the chemical reactions are left in a generic form while recognizing that, due to the absence of oxygen, the reactions occurring between $\varepsilon_O < x < \varepsilon_F$ might differ significantly from those occurring between $0 < x < \varepsilon_F$.

To summarize, the production of fuel is controlled by the following variables:

Temperature	$T(x,t)$
Local fuel concentration	$Y_S(x,t)$
Local oxygen concentration	$Y_O(x,t)$
Residual fuel fraction	$Y_{F,s}(x,t)$
Permeability function	$\chi(x,t)$
Oxygen penetration depth	$\varepsilon_O(t)$
Reactive depth	$\varepsilon_F(t)$
Kinetic constants	A_i, m_i, n_i, E_i

Charring

For the purpose of ignition of a solid fuel the process of charring has an impact on both heat and mass transport therefore needs to be briefly addressed. A general summary of the chemical processes leading to charring can be obtained in Chap. 7, and more details form Cullis and Hirschler [16] for polymers and in the case of wood from Drysdale [17], thus will not be described here. Instead an attempt will be made to explain the role of charring in ignition.

For charring materials pyrolysis leads to the production of gaseous fuel (pyrolyzate) and a residual solid phase char. The char is mainly a carbonaceous solid that could be further decomposed. The secondary decomposition could be complete, leading to an inert ash or to a secondary char that can be further decomposed in a single or multiple steps. Non-charring materials decompose leaving no residue behind.

From the perspective of ignition, the exposed surface represents the boundary between the gas and the solid. This boundary moves as the material is completely removed. The rate at which the surface moves is the regression rate (V_R). For charring and non-charring materials, this will be the boundary where complete consumption of the fuel is achieved. Although, regression rates can be very different between charring and non-charring materials, at the surface, the main difference between the two material types is the temperatures that can be achieved. Carbonaceous chars can reach much higher temperatures, leading in many cases to vigorous oxidation (surface glowing) that can be the catalyser for gas phase ignition. This will be part of the gas phase discussion. In what concerns the production of fuel, the differences appear mostly in-depth where temperature is controlled by heat transfer through the char and fuel production is affected by an overall permeability function. The effects of permeability were described above and temperature effects on fuel production will be discussed in the context of the calculation of the temperature distributions.

The Thermal Depth (ε_T)

When a heat flux is applied to one of the solid surfaces, the heat travels across the solid fuel. Initially only a very small area is affected, but as the thermal wave travels through material a larger and larger fraction of the solid is heated. The velocity of the thermal wave is represented in Fig. 21.1 by $V_T(t)$. $V_T(t)$ is a function of time because it will decrease as the thermal wave moves away from the heating source and towards the cold back surface. The region that has been heated is quantified by the characteristic length $\varepsilon_T(t)$. It is important to note that, given that temperature is a continuous function, $\varepsilon_T(t)$ has to be arbitrarily defined simply as the end of the heated region. There is no exact mathematical definition for this length but physically it means that the temperature is approaching ambient temperature ($T \approx T_0$) or the gradient of the temperature is approaching zero ($dT/dx \approx 0$). The proximity that temperature or the gradient have to achieve when approaching these targets is only a matter of what precision is required by those making the analysis.

The length scale $\varepsilon_T(t)$ is extremely important because it characterizes solids into different groups. This breakdown enables the simplification of the energy equation and the generation of simple analytical expressions for the temperature distribution. For the purpose of ignition, solid fuels are classified in:

Semi-infinite Solid ($L > \varepsilon_T$) If the thermal wave is far from the end of the sample, the heat coming from the exposed surface has still not migrated to the back end. The temperature at the back end is ambient (T_0) and there are no heat losses through this surface. The thickness of the sample is no longer a relevant quantity and therefore the fuel can be treated as a semi-infinite solid ($L \rightarrow \infty$). Materials do not show semi-infinite solid behaviour forever, as time progresses the thermal wave will eventually reach the end of the sample. In many cases materials will behave as semi-infinite solids for the period of interest, in which case the assumption of $L \rightarrow \infty$ is valid. The boundary condition for the energy equation becomes:

$$x = L \rightarrow \infty \tag{21.5}$$

$$\dot{q}''_N(\infty, t) = 0$$
$$T = T_0$$

Thermally-Thick and Thermally-Thin Solid ($\varepsilon_T \geq L$) The thermal wave has reached the end of the sample and therefore heat losses at the back end need to be quantified. The thickness of the sample, L, becomes a relevant dimension of the problem and a boundary condition for $x = L$ needs to be defined. This group can be sub-divided into two different cases, thermally thick and thermally thin. A solid can be defined as thermally thick if a significant thermal gradient exists within the solid through the period of ignition. In contrast, in a thermally thin solid the gradient is negligible for most of the time before ignition. A simple criterion based on the Biot number (Bi) is generally used for the purpose of establishing if a material is thermally thin or thick. The Biot number is defined as $Bi = hL/k$, where "h" is a global heat transfer coefficient (W/m^2K) and "k" is the thermal conductivity (W/mK). If $Bi << 1$ then temperature gradients inside the solid are negligible, while if the Biot number is not much smaller than unity then temperature gradients need to be considered. While this is an important distinction for the energy equation, it does not have an effect on the boundary condition at $x = L$, so if $\varepsilon_T \geq L$ then the boundary condition is defined as:

$$x = L \tag{21.6}$$

$$-k\left.\frac{dT}{dx}\right|_{x=L} = \dot{q}''_N(L, t)$$

where $\dot{q}''_N(L, t)$ will be left as a generic heat loss term at the back end of the solid fuel.

The Pyrolysis (ε_P) and Charring Depths (ε_{CH})

Within the region where the temperature has increased above ambient significant chemical activity can occur. The chemical activity leads to the production of fuel at a rate specified by equations of the type of (21.1) or (21.2). The depth at which the chemistry can be assumed to be significant is commonly defined as a pyrolysis depth (ε_P) which propagates at a velocity V_P. As with the thermal depth, there is no mathematical function that describes the location of the pyrolysis front, $x = \varepsilon_P$ because the reaction equations are also continuous functions. Nevertheless, if the assumption is made that pyrolysis reactions have high activation energy then the transition between the zones of significant and negligible reactivity can be considered as being abrupt [18]. This permits the definition of critical parameters that can be considered to define the onset of pyrolysis. The most common parameter is a pyrolysis temperature, T_P, below which the solid fuel can be considered inert. It is important to note that the pyrolysis temperature is not a true physical parameter but a simple way to track the onset of high activation chemical reactions.

As described above, for $x > \varepsilon_P$ the solid can be considered inert, thus thermal properties can be defined as those of the original solid fuel. The thermal properties relevant to ignition are

Density	$\rho(x,t)$	Kg/m^3
Thermal conductivity	$k(x,t)$	W/m.K
Specific heat	$C(x,t)$	J/kg.K

which are all functions of temperature. Since the temperature varies in-depth they are also functions of "x." The evolution of these properties with temperature for common materials can be found in most heat transfer book [19], nevertheless, for materials typically present in fires (wood, complex plastics, composites, etc.) these properties are in many cases unknown [20, 21].

For $x > \varepsilon_P$ the chemical reactions have initiated the decomposition of the material. The relevant properties remain the same, nevertheless pyrolysis introduces further changes to the properties. The gasification of the fuel and its transport towards the surface will strongly affect the density, while any potential voids will force to redefine thermal conductivity and specific heat to account for the existence of at least two phases.

The process of pyrolysis can lead directly to gasification with no residue (non-charring) or to a carbonaceous residue (charring). Figure 21.1 shows the case of a charring material where a second front for charring ($x = \varepsilon_{CH}$) is formed behind the pyrolysis front. The charring front will propagate at a velocity V_{CH} and will leave behind a residue that will have a new set of properties that are potentially very different to those of the fuel. The properties are still the permeability, the density, thermal conductivity and specific heat but precise values are mostly unknown for most chars issued of materials relevant to fires.

It is common to see in the char region large voids and cracks that compromise the one-dimensional treatment provided here. These have been considered when addressing materials such as wood but will not be described here.

Melting and the Evaporation of Water

Melting or water evaporation have not been considered in the description of the ignition until this point. These two processes are endothermic phase changes that can have a significant effect on the temperature distribution in the solid. Numerous models have been built in the past to describe the heat sinks associated to melting and several studies have attempted to quantify the impact of melting on practical situations such as dripping.

Phase changes are generally incorporated to the energy equation as heat sinks where some rate function is created to describe the conversion from one phase to the other. The simplest procedure is to assign a critical temperature to the phase change (i.e. 100 °C for water) and a heat of melting or evaporation (ΔH_M). Once the fuel or water reaches this temperature it is converted to the high temperature phase. The phase change process is assumed to be infinitely fast and therefore the rate is defined by the available energy reaching the location where the phase change is occurring. All the energy is then used for the phase change and the thermal wave can only proceed once the transition has been completed. This approach is inappropriate if the available energy is very low, in this case thermodynamic equilibrium equations will define the rate of vaporization or melting. Other more complex models that include processes such as re-condensation can be found in the literature but will not be discussed here.

The consequences of melting or water evaporation are various. Phase changes can affect the thermal properties of the fuel significantly and can result in motion of the molten fuel or water vapour. This leads to convective flow of energy or mass transfer.

Understanding the physical processes behind phase change does not represent a great challenge. Furthermore, the potential impact of phase change on ignition is clear. Thus it is evident that any predictive tool for ignition should attempt to quantify the impact of phase change on ignition. Nevertheless, the formulation of a model that can describe these processes in a comprehensive manner is extremely complex and the measurements that could serve for its validation are mostly non-existent.

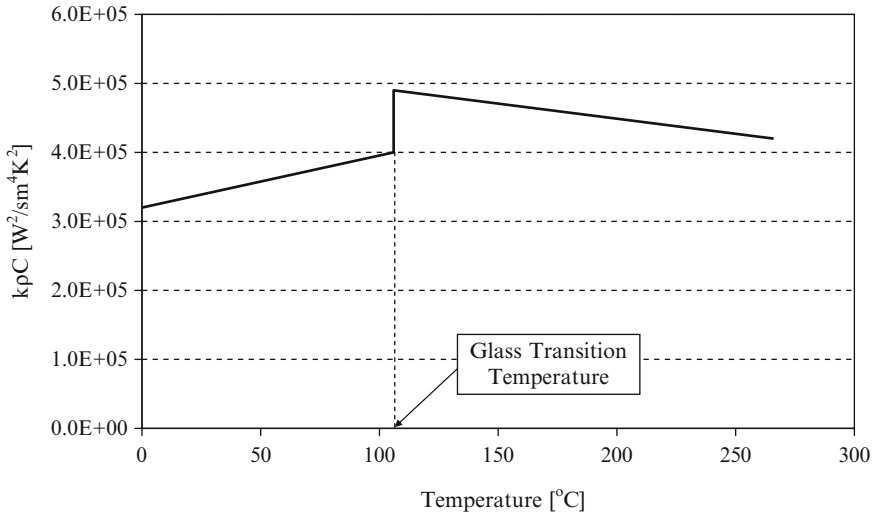

Fig. 21.4 Evolution of the product of the thermal conductivity, density and specific heat (kρC) for PMMA as a function of temperature

Given that, phase change is fundamentally an additional heat sink that will have to be incorporated to the energy equation in an arbitrary manner, it is justifiable to exclude the treatment of this subject from the present analysis. Nevertheless, this is done with the clear warning that its exclusion will have a significant impact on any quantitative assessment of the ignition process.

Other processes that deserve to be addressed are softening or glass transition. Many materials such as thermoplastics will undergo gradual or drastic property changes with temperature. These property changes are not endothermic but will affect the progression of heat through the sample and could lead to dripping. Softening or glass transition will be directly incorporated in the analysis through the variable properties described in section "The Pyrolysis (ε_P) and Charring Depths (ε_{CH})". An example of how these properties change with temperature is shown in Fig. 21.4. Figure 21.4 presents the evolution of the product of all three thermal properties (kρC) for PMMA as a function of temperature, indicating the abrupt change occurring at the glass transition temperature.

The Temperature Distribution

As explained in section "The Production of Gaseous Fuel", to determine the fuel production it is necessary to define the evolution of the temperature inside the solid fuel. This can be achieved by defining a comprehensive energy equation. Figure 21.4 represents a typical control volume for $x < \varepsilon_P$ where all the main heat transfer mechanisms are incorporated.

For the purposes of this description the coordinate system will be anchored to the regressing surface, thus "x" will move with a velocity V_R. A mass flow of fuel will therefore cross the control volume presented in Fig. 21.5 carrying energy in and out ($\dot{q}''_S$). The gaseous products of pyrolysis and oxygen diffusion will also carry energy in and out of the control volume ($\dot{q}''_P$, $\dot{q}''_O$ respectively) and the generic expression for the mass flow of these gases ($\dot{m}''_P$, $\dot{m}''_O$) incorporates the regression rate. Heat is conducted in and out of the control volume ($\dot{q}''_{CND}$) and for generality in-depth radiative absorption is allowed ($\dot{q}'''_{RAD}$). Since for $x < \varepsilon_P$ the temperature is sufficiently high to allow for chemical reactions all heat

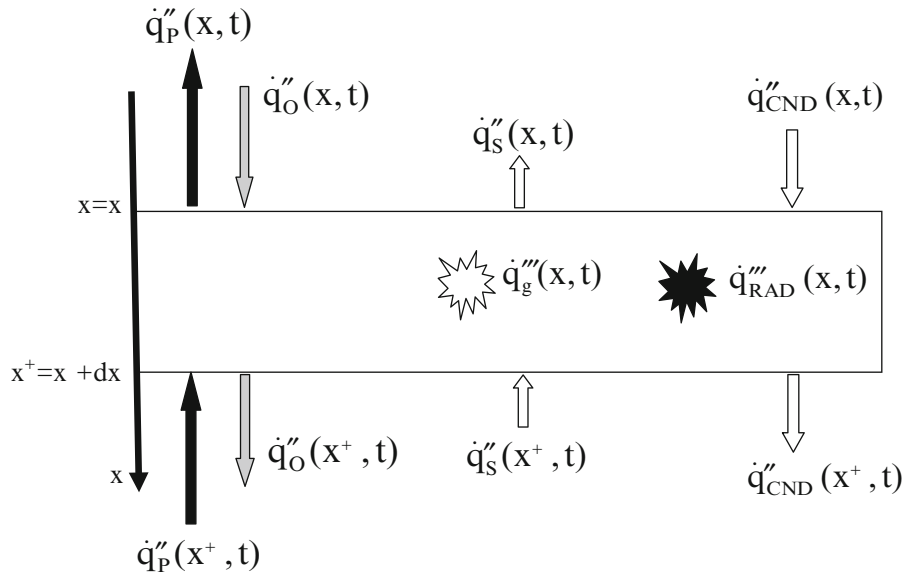

Fig. 21.5 Typical control volume for $x < \varepsilon_P$ showing the main heat transfer mechanisms

Table 21.1 Summary of all energy transport within a generic control volume for $x < \varepsilon_P$. $\Delta H_{P,i}$ is the net heat resulting from each individual chemical reaction. The net heat will be endothermic for most pyrolysis processes and exothermic for oxidative reactions. The summation is not truly a summation, but as explained earlier, is the overall set of chemical reactions where some could be sequential and others competing

Description	In	Out	Formulation
Energy transported by gaseous fuel traversing the control volume	$\dot{q}''_P(x^+,t)$		$\dot{m}''_p(x^+,t)C_{P,P}(x^+,t)T_P(x^+,t)$
		$\dot{q}''_P(x,t)$	$\dot{m}''_p(x,t)C_{P,P}(x,t)T_P(x,t)$
Energy transported by oxygen traversing the control volume		$\dot{q}''_O(x^+,t)$	$\dot{m}''_O(x^+,t)C_{P,O}(x^+,t)T_O(x^+,t)$
	$\dot{q}''_O(x,t)$		$\dot{m}''_O(x,t)C_{P,O}(x,t)T_O(x,t)$
Energy transported by solid fuel traversing the control volume	$\dot{q}''_S(x^+,t)$		$\rho_S(x^+,t)V_R(t)C_S(x^+,t)T(x^+,t)$
		$\dot{q}''_S(x,t)$	$\rho_S(x,t)V_R(t)C_S(x,t)T(x,t)$
Heat conduction	$\dot{q}''_{CND}(x,t)$		$-k_S\frac{dT}{dx}\Big\|_{x=x}$
		$\dot{q}''_{CND}(x^+,t)$	$-k_S\frac{dT}{dx}\Big\|_{x=x^+}$
Radiative absorption	$\dot{q}'''_{RAD}(x,t).dx$		$\dot{q}'''_{RAD}(x,t).dx$
Chemical energy (generation/sink)	$\dot{q}'''_g(x,t).dx$		$\sum_{i=1}^{i=N}\Delta H_{P,i}\rho_S(x,t)\left[A_i Y_O^{m_i}(x,t)Y_F^{n_i}(x,t)e^{-E_i/RT(x,t)}\right]$

sources and sinks associated to all chemistry need to be included. Table 21.1 summarizes all terms incorporated in Fig. 21.5.

Estimation of the net heat transfer will lead to a change in the energy accumulated within the control volume. The following expression summarizes the energy balance:

$$\frac{\partial E_{CV}}{\partial t} = \left[\dot{q}''_S(x^+,t)+\dot{q}''_P(x^+,t)+\dot{q}''_0(x,t)+\dot{q}''_{CND}(x,t)\right] - \left[\dot{q}''_O(x+,t)+\dot{q}''_{CND}(x+,t)+\dot{q}''_S(x,t)+\dot{q}''_P(x,t)\right] + \dot{q}'''_{RAD}(x,t)\,dx + \dot{q}'''_g(x,t)\,dx$$

where $E_{CV} = \rho_S(x,t)C_S(x,t)T(x,t)\ dx$, which after appropriate substitutions results in the general energy equation for the control volume.

$$\frac{\partial[\rho_S C_S T]}{\partial t} = \frac{\partial}{\partial x}\left[k_S \frac{\partial T}{\partial x}\right] + \frac{\partial\left[\dot{m}''_P C_{P,P} T_P\right]}{\partial x} - \frac{\partial\left[\dot{m}''_O C_{P,O} T_O\right]}{\partial x} + \frac{\partial[\rho_S V_R C_S T]}{\partial x} + \dot{q}'''_{RAD} + \sum_{i=1}^{i=N} \Delta H_{P,i} \rho_S \left[A_i Y_O^{m_i} Y_S^{n_i} e^{-E_i/RT}\right] \quad (21.7)$$

Given the differential nature of the equation all variables are assumed to be functions of "x" and "t" so these dependencies are no longer indicated. Many of the terms are left in a generic form and not quantified. Their quantification is complex, thus a more detailed discussion will be provided later in those cases where it is necessary.

The solution to Equation 21.5 will provide the evolution of the temperature distribution along the sample and as a function of time (T(x,t)). This solution can then be incorporated in Equation 21.4 to establish the fuel production rate. It is important to note that thermal equilibrium between phases has not been assumed, thus there are three different temperatures in Equation 21.5, T, T_P and T_O. Expressions similar to Equation 21.5 can be defined for each phase and will have to be solved in a simultaneous manner. The boundary condition will be the exchange of heat between phases, this is generally done using empirical correlations for heat transfer in porous media [22]. The alternative approach is to demonstrate thermal equilibrium between the phases (heat transfer is much faster than mass transfer within the pores), in which case all temperatures will be the same and only Equation 21.5 will have to be solved.

To summarize, and in addition to the variables established in sections "The Production of Gaseous Fuel" and "The Pyrolysis (ε_P) and Charring Depths (ε_{CH})", the temperature distribution is controlled by the following variables:

Thermal conductivity	$k_S(x,t)$
Specific heat	$C_S(x,t)$ $C_{P,P}(x,t)$ $C_{P,O}(x,t)$
Density of the solid	$\rho(x,t)$
Regression rate	$V_R(t)$
Mass flow	$\dot{m}''_P$ $\dot{m}''_O$
Temperature of the gas phase	T_P T_O
Radiative properties of the solid (absorptivity, $\alpha_S(x,t)$)	$\alpha_S(x,t)$
Heat of reaction	$\Delta H_{P,i}$

The Surface Boundary Conditions (x = 0 and x = L)

Figure 21.1 shows all the different modes of heat transfer through the surface control volumes. In theory, control volumes at $x = 0$ and $x = L$ could be represented in a generic manner that makes them identical. In practise this is generally not the case because materials tend to have an exposed face and one that is in contact with some backing. The backing will define a conductive boundary condition while the open face a convective/radiative one. For illustration purposes, this distinction will be made here and the exposed face will be defined as an open boundary, thus $\dot{q}''_N(0,t)$ will include convection and radiation, while the back-face, $\dot{q}''_N(L,t)$, will be attached to a substrate, thus will be defined as an impermeable conductive boundary condition. It needs to be emphasized that this is an arbitrary simplification that is only done to illustrate two different types of boundary conditions because they are mutually exclusive. In many cases a material might be sandwiched between two solids or exposed at both ends. The appropriate choice of boundary conditions needs to be made

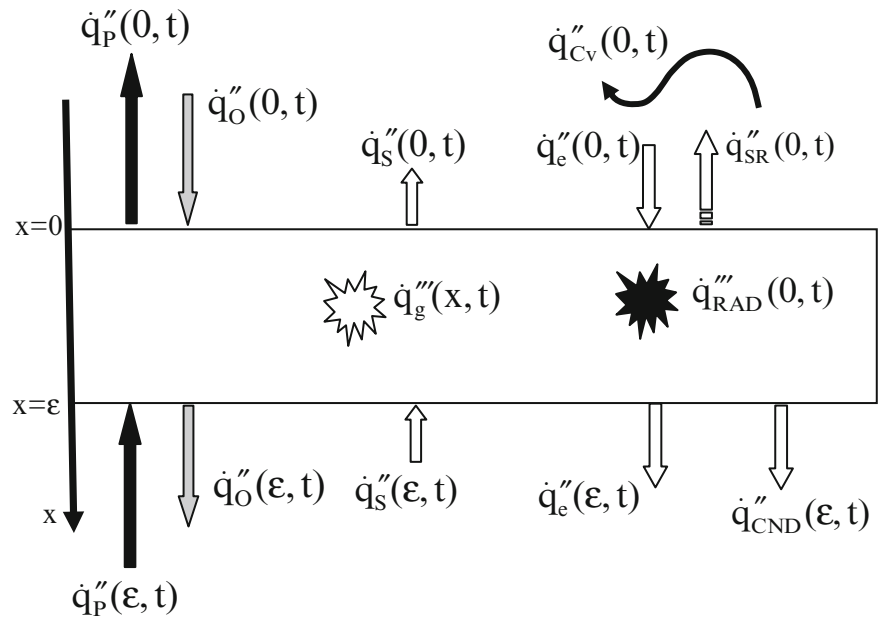

Fig. 21.6 Boundary control volume for x = 0 showing the main heat transfer mechanisms

but the processes to be described will not be different.

Figure 21.6 shows the open boundary condition (x = 0) at a specific point in time. The different components are mainly those described in Table 21.1 leading to a very similar expression for the energy balance as that presented in section "The Temperature Distribution". So at the x = 0 surface

$$\frac{\partial E_{CV}(0,t)}{\partial t} = \left[\dot{q}''_S(\varepsilon,t) + \dot{q}''_P(\varepsilon,t) + \dot{q}''_0(0,t)\right] - \left[\dot{q}''_O(\varepsilon,t) + \dot{q}''_{CND}(\varepsilon,t) + \dot{q}''_S(0,t) + \dot{q}''_P(0,t) + \dot{q}''_{SR}(0,t) + \dot{q}''_{Cv}(0,t)\right] + \dot{q}'''_{RAD}(x,t)\varepsilon + \dot{q}'''_g(x,t)\varepsilon$$

where the terms that remain undefined are described in Table 21.2. Radiation absorption within the surface control volume is represented as $\dot{q}''_{RAD}(0,t)\varepsilon = \dot{q}''_e(0,t) - \dot{q}''_e(\varepsilon,t)$ to remain consistent with the notation of the previous section.

For the boundary control volume the characteristic thickness $\varepsilon \to 0$, which eliminates all energy transported by mass flow, radiation absorption and energy generation. The final expression for the exposed boundary condition is then:

$$0 = k_S \left.\frac{\partial T}{\partial x}\right|_{x=0^+} - \varepsilon_S(0,t)\sigma\left(T^4(0,t) - T_0^4\right) - h_{Cv}(t)\left(T(0,t) - T_0\right) \tag{21.8}$$

Table 21.2 Summary of all energy transport within the surface control volume. Only terms not presented in Table 21.1 are described here. The Stefan-Boltzmann Constant is: $\sigma = 5.670 \times 10^{-8}$ W/m^{2}K^4, $\varepsilon_S(0,t)$ is the surface emissivity and h_{Cv} is the convective heat transfer coefficient. Only for illustration purposes two different approaches are used to describe radiation, absorption is allowed to happen in-depth while emission is treated as a surface process. The spectral emissivity and absorptivity of the material will define the most appropriate treatment for each specific case

Description	In	Out	Formulation
Radiation from the exposed surface to the environment		$\dot{q}''_{SR}(0,t)$	$\varepsilon_S(0,t)\sigma\left(T^4(0,t)\text{-}T_0^4\right)$
Convective losses from the surface		$\dot{q}''_{Cv}(0,t)$	$h_{Cv}(T(0,t)\text{-}T_0)$
External radiative heat-flux	$\dot{q}''_e(0,t)$		$\dot{q}''_e(0,t)$

A similar treatment can be followed with the back end boundary condition (x = L). In this case the back surface is assumed to be in direct contact with another solid. Mass transfer, convection and radiative losses to the environment are therefore precluded. The boundary condition will only include conductive terms and can be described as:

$$0 = -k_S \left.\frac{\partial T}{\partial x}\right|_{x=L^-} + k_B \left.\frac{\partial T_B}{\partial x}\right|_{x=L^+} \tag{21.9}$$

where k_B is a global thermal conductivity of the backing material that could include the thermal resistance between the two solids. In most cases the contact between both solids is not perfect, leaving air gaps or requiring adhesives, in these cases it is important to define the thermal conductivity in a manner that includes the contact resistance. The variable T_B is the temperature of the backing solid, these temperature will come out of a solution to an additional energy balance of the form of Equation 21.5. Note that if k_B is very small the backing can be assumed as an insulator and the boundary condition can be summarized to no losses at the back. This eliminates the need to solve a second energy equation for T_B.

To summarize, and in addition to the variables established in sections "The Production of Gaseous Fuel", "The Pyrolysis (ε_P) and Charring Depths (ε_{CH})" and "The Temperature Distribution", the temperature distribution is controlled by the following variables:

Global thermal conductivity of the backing material	$k_B(x,t)$
Temperature of the backing material	$T_B(x,t)$
Emissivity of the solid	$\varepsilon_S(x,t)$
Convective heat transfer coefficient	$h_{Cv}(t)$
Ambient temperature	T_0

The Gas Phase

The sequence of events leading to the ignition of a gas phase flame will be described in this section. It will be assumed that gaseous fuel emerges from the solid following the description provided in section "The Solid Phase".

After the onset of pyrolysis gas begins to emerge from the fuel surface, initially in very small quantities, but as ε_F and T(x,t) increase Equation 21.4 shows that the fuel mass flux will increase. The emerging fuel will encounter the ambient oxidizer and eventually produce a flammable mixture. Given that fuel is migrating into the oxidizer flow, the definition of a flammable mixture is not a simple one. In standard test methods the ambient flow is well defined, mixed convection generated by a horizontal heated surface and the extraction system in the cone calorimeter [23], natural convection resulting from a vertical heated surface in the LIFT apparatus [24] and forced convection over the fuel surface (horizontal or vertical) in the FM Global Fire Propagation Apparatus [25]. In real fires, flow fields are defined by the flames

themselves and by the geometry of the environment (obstacles, fuel geometry, etc.) with the possibility of complex flow patterns. The only mechanisms to establish the fuel distribution within the gas phase are detailed measurements or modelling [26–28]. Nevertheless, from a phenomenological perspective, to achieve ignition, what is required is to achieve a flammable condition in at least one location in the gas phase.

The definition of a flammable mixture is for the fuel concentration to be found between the Lower or Lean Flammability Limit (LFL) and the Upper or Rich Flammability Limit (UFL). Although the LFL and UFL are apparatus dependent measurements, it is clear that the precision required for flaming ignition of solids does not require a more universal description of flammability. For a more detailed discussion on flammability limits and their limitations the reader is referred to Chap. 12.

Auto-ignition

Once a flammable mixture has been attained, this mixture needs to increase in temperature until a combustion reaction can occur. This process is described in great detail by Torero [29] and by Fernandez-Pello [30, 31], who cites a series of experiments by Niioka [32] where ignition is studied using a stagnation point flow over a solid fuel surface. In these experiments the heat to initiate the combustion reaction is provided by a hot flow impinging on a fuel surface that acts as a heat sink. Niioka [32] identifies an induction time and a pyrolysis time. The pyrolysis time corresponds to the time required to attain a flammable mixture while the induction time is the time for the mixture to reach a temperature at which ignition can occur. Given the specific configuration, the pyrolysis time decreases with the flow velocity (enhanced heat transfer to the fuel surface) while the induction time increases (reduced residence time in the gas phase). Although these observations are not universally applicable, they serve to illustrate the process of auto-ignition. Fernandez-Pello [30, 31] describes Niioka's conclusions graphically by means of the schematic, this schematic is simplified and presented in Fig. 21.7. Figure 21.7 shows how the summation of the pyrolysis and induction times leads to an ignition time.

In auto-ignition there is no hot spot that will serve as an initiation point for the reaction, thus the mixture has to absorb enough energy to reach ignition. The exact amount of energy required for ignition can be associated to a Damköhler number [18]. The Damköhler number corresponds to the ratio between a local residence and chemical time. The chemical time represents the necessary

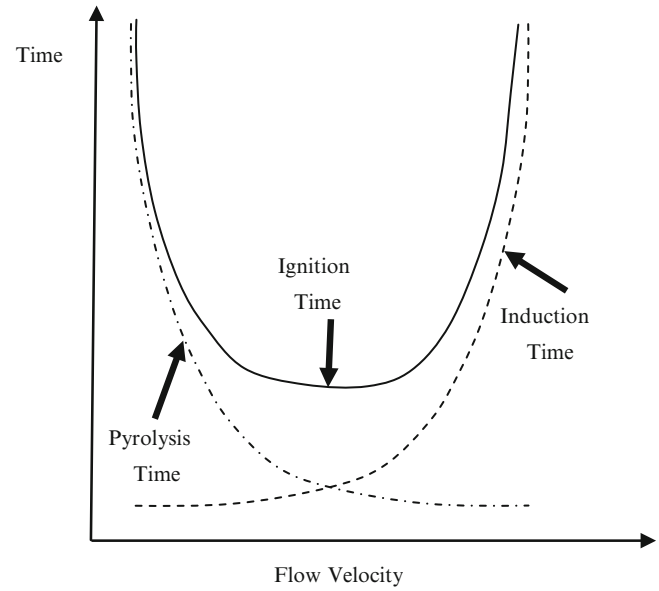

Fig. 21.7 Schematic of the characteristic times involved in the ignition of a flat plate subject to a hot stagnation point flow. This schematic is based on the work by Niioka [32] and adapted from Fernandez-Pello [30, 31]

time for the reaction chemistry to occur and is expressed as the inverse of the reaction rate. Combustion reactions can be described by expressions like that presented in Equation 21.1 thus the chemical time is directly affected by the temperature of the reactants. The higher the temperature, the greater the reaction rates and the shorter the chemical time. The residence time is a measure of the strain (or dissipation rates) or the time the reactants remain together at a specific location thus it is directly related to the velocity field. The faster the flow or the velocity gradients, the shorter the residence time. If the chemical times are shorter than the residence times the reaction has enough time to proceed and a flame can exist. A critical Damköhler number for ignition can then be established, above which a combustion reaction can proceed [18]. In the schematic presented in Fig. 21.7, critical Damköhler numbers will be attained at both sides of the ignition curve preventing ignition. This is probably the most precise way to describe ignition but it requires the full resolution of the flow and temperature fields as well as comprehensive knowledge of the kinetic constants associated to the combustion reaction. While the flow field can be resolved by means of Computational Fluid Dynamics (CFD) the chemistry of most fire related fuels still remains uncertain. Qualitative assessment of the Damköhler number for ignition has only been achieved for a few very well defined experimental conditions such as stagnation flows [6, 32, 33] or boundary layers [34]. Other alternative representations of the ignition conditions that rest on the same fundamental approach have been discussed by Quintiere [35] and by Gray and Lee [36].

An important aspect of the ignition process that remains to some extent unresolved is the origin of the heat that is necessary for the gaseous fuel to reach the critical Damköhler number. If the air flow is hot, like in Niioka's experiments [32], then the energy will come from the oxidizer and the problem is immensely simplified. If the oxidizer is cold and there is an external radiative heat source, then solid and gas will heat at different rates. The solid will absorb heat and its surface temperature will change following Equation 21.5 while the gas will absorb heat based on its absorptivity and dissipate it in a manner governed by the flow field. The absorptivity of the gas is a strong function of the fuel type and concentration, thus also requires detailed knowledge of the flow field. The two possible outcomes are that the gas phase heats faster than the solid phase or the opposite. In the former case ignition will occur away from the fuel surface, since the fuel will act as a heat sink for the gas. In the latter case, ignition will occur closer to the fuel surface since the fuel acts as a heat source. This latter scenario is common with charring materials where oxidation of the char contributes to increase the surface temperature [37].

It is clear that auto-ignition is a complex process that fully involves interactions of the solid and gas phases. Therefore, to characterize auto-ignition of solid fuels it is necessary to established well defined experimental conditions and simplifications to the analysis. Data obtained from different experimental conditions and with a specific analysis will generally not be compatible with other data that was obtained from a different experiment or deduced by means of an alternative analysis. Thus, scatter in the reported data is common for auto ignition.

Data on auto-ignition is generally reported as Auto-Ignition Temperatures (AIT) which corresponds to a recorded temperature at the moment where ignition of a flame is first observed. A summary of much of the data available is presented in Chap. 14 of Ref. [1] together with a series of references to relevant papers and textbooks [38, 39]. Given the complexity of the processes leading to auto-ignition, these values can only be taken as reference values that are a direct function of the specific test conditions. Generally, significant discrepancy is found in the literature where reported Auto-Ignition Temperatures can vary in more than 150 °C for the same material. The greatest discrepancies tend to be found when the orientation of the solid fuel is varied and the fluid mechanics and heat transfer are significantly altered [1]. Auto-Ignition Temperatures are most consistent for

gaseous mixtures (Chap. 12) and liquid fuels (Chap. 18) where tests are conducted in enclosed vessels where the fuel has been fully evaporated.

Piloted Ignition

As discussed in the previous section, the process of auto-ignition is extremely difficult to describe in a quantitative manner, even under simple experimental configurations. Therefore, as an example, it is not practical to rely on auto-ignition to describe the susceptibility of solid materials to ignite. A mechanism to simplify the process is to include a pilot flame or a hot spot. This is a practical experimental simplification that has a basis on reality, since in most ignition scenarios there will be a region of high temperature. The presence of a pilot strongly simplifies the gas phase processes and reduces the influence of environmental variables. While characterization of the flow field is still required to establish the presence of a flammable mixture, it is no longer necessary to resolve heat transfer between phases or to define the absorption of energy by the gas. In the presence of a pilot, ignition can be assumed at the moment where a flammable mixture (LFL) is attained at the location of the pilot.

Currently, all standard test methods that attempt the description of the ignitability of solids use some form of a pilot. In some cases, the pilot is a large flame [24] while in others is either a small pilot flame [25] or a high energy spark [23]. Both methods have their advantages and disadvantages, sparks produce only local heating thus have a weaker tendency to influence the solid phase by acting as a heat source. - Nevertheless, given their small volume, ignition is strongly influenced by the spark location. The flow field has to establish a flammable mixture at exactly the location of the pilot. In contrast, large pilot flames have a tendency to supply heat to the fuel surface, but cover a large volume, therefore are less sensitive to the flow field. Because of its practical relevance, all subsequent discussion will concern piloted ignition.

To attain the LFL at the pilot location it is necessary to resolve the momentum and mass transport equations simultaneously with the surface boundary conditions explained above. Figure 21.1 shows an arbitrary distribution of the fuel concentration external to the sample, $Y_{F,g}$. A similar representation could be made for the oxygen concentration ($Y_{O,g}$). The characteristic equation that describes the flow field is as follows:

$$\rho_0 \frac{D\vec{u}}{Dt} = -\nabla P + \rho_0 \vec{g} + \mu_0 \nabla^2 \vec{u} \qquad (21.10)$$

Where $\vec{u}$ is the velocity field, ρ_0 the density of the air, P the pressure field, $\vec{g}$ the gravity vector and μ_0 the viscosity of the air. Temperature dependencies of the properties have been omitted for simplification assuming that air is the main constituent and it will remain close to ambient temperature. Conservation of fuel and oxygen concentrations can then be defined by:

$$\rho_0 \frac{DY_{F,g}}{Dt} = \rho_0 D_{F,O} \nabla^2 Y_{F,g} \qquad (21.11)$$

$$\rho_0 \frac{DY_{O,g}}{Dt} = \rho_0 D_{F,O} \nabla^2 Y_{O,g} \qquad (21.12)$$

where species transport is assumed to be non-reactive, thus the source/sink has been omitted. This is an adequate assumption for pure mixing. To obtain the solution of Equations 21.8, 21.9 and 21.10 it is necessary to add the following variables to those established in sections "The Production of Gaseous Fuel", "The Pyrolysis (ε_P) and Charring Depths (ε_{CH})", "The Temperature Distribution" and "The Surface Boundary Conditions (x=0 and x=L)":

Density of air	ρ_0
Velocity field	$\vec{u}$
Pressure field	P
Viscosity of air	μ_0
Diffusivity of fuel in air	$D_{F,0}$
Pilot location	$\vec{r}$

At this point, there is no need to specify a critical Damköhler number for ignition because

of the presence of the pilot, although in absolute rigour, this assumes that the flow conditions are such that blow-off of the flame kernel does not occur, thus the pilot will allow the establishment of a flame across the flammable mixture.

"Flash Point" and "Fire Point"

Once ignition has been achieved a flame can propagate through the regions where a flammable mixture is present consuming the reactants. Independent of the flow field, it is most likely that a flammable mixture will be established close to the solid fuel surface. The pyrolysis rates at the moment when the flame is established will determine if a flame can continue to exist or if the combustion reaction will cease after the gas phase mixture is consumed. The feedback from the flame will enhance pyrolysis, but usually, the relatively large thermal inertia of the solid will result in a slow response, therefore it will be necessary for pyrolysis rates to be sufficient even in the absence of the flame heat feedback. If pyrolysis rates are not sufficient, the flame will extinguish and continuous pyrolysis will lead once again to the formation of a flammable mixture and subsequent ignition. This manifests itself as a sequence of flashes that precede the establishment of a flame over the combustible solid. This process is identical to the "flash point" generally associated to liquid fuels (Chap. 18) and for solid fuels has been described in detail by Atreya [37].

The transition between the "flash point" ignition and the established flame, which could also be named the "fire point" in an analogy with liquid fuels, deserves especial attention. The characteristics of the diffusion flame established on a solid fuel surface are defined by the flow field and the supply of fuel. The rate at which both reactants reach the flame zone defines the flame temperature and thus the characteristic chemical time. If the amount of fuel reaching the flame is small, then the flame temperature will be low and the chemical time will be long. As described above, the flow field defines the residence time. A second critical Damköhler number appears, but this time is one of extinction. This concept has been described many times explicitly in the combustion literature [18] but only implicitly in the fire literature. There are only few studies where a critical extinction Damköhler number has been presented to describe the "fire point" but in all cases they concern idealized flow fields that allow establishing a direct correlation between fuel production and flame temperature [33, 34]. In most discussions simplifications have been assumed leading to simpler parameters that can serve as surrogates for the Damköhler number. Williams [40] discusses a critical gas phase temperature below which extinction will occur. If the residence time remains unchanged, then extinction is only associated to the chemical time, thus can be directly linked to a critical gas phase temperature. It can be further argued that extinction is much more sensitive to temperature than to flow, thus only radical changes in the residence time need to be addressed making this criterion a robust one. A more practical surrogate to the Damköhler number is a critical fuel mass flux criterion. Under specific testing conditions the flow field will remain invariable. In this case the attainment of a critical mass flux of fuel will be the single parameter defining the flame temperature and thus the Damköhler number [41, 42]. Furthermore, under more restrictive conditions the critical mass flux can be associated to a critical solid phase temperature [43]. Drysdale [17] and Beyler [44] provide a detail description of the classic approaches to this subject while Quintiere and Rangwala address some of the more current studies [45].

The sequence of events relating "flash" and "fire" points is not trivial because they represent distinctively different processes. For piloted ignition, the "flash point" only requires a flammable mixture while for the "fire point" the rate of fuel supply has to be enough to achieve a chemical time shorter than the residence time. Thus a number of different scenarios can be observed that in many cases can affect the consistency of different ignition studies. A simple example will be used to illustrate this. For example; if the pilot is very close to the fuel surface then a flammable

mixture will be achieved at the pilot location soon after the onset of pyrolysis. In this case fuel supply will be far from that required to sustain a flame. A significant delay will exist between flash and fire points where several flashes will be observed. If the pilot is distanced from the fuel surface it will take longer to attain a flammable mixture and therefore at the moment of the first flash the fuel supply would have increased and a smaller number of flashes will be observed before the flame is fully established. Greater separation of the pilot from the fuel surface might result in the flammable mixture being attained at the pilot location at the same time as the fuel supply is sufficient to sustain a flame. In this case the fire point will correspond with the first flash. A further increase in the distance between pilot and fuel will not change the physical manifestation but will continue to delay ignition. In this case ignition will occur when a flammable mixture is attained at the pilot but will not be related to the flash or fire points. This example has been presented to illustrate the sensitivity of ignition studies to different variables and the importance of detailed observations to the validity of conclusions and comparisons. In this case pilot location was used as the example, but a similar analysis could be made with the heat flux, the oxygen concentration, the flow field [31, 46] or the ambient pressure [47].

The only added variable required to model the "fire point" will be the critical Damköhler number for extinction ($Da_{e,cr}$) or any equivalent way to represent the extinction condition. As mentioned above, other criteria can be used to establish the extinction condition and that are partially equivalent to the critical Damköhler number. Such criteria are a critical mass transfer numbers (B_{cr}) [34, 48], critical mass fluxes [11, 28, 30, 42] or critical temperatures (T_{cr}) [17, 35, 40, 43, 45].

Simplifications and Standardization

To predict flaming ignition of a solid fuel is necessary to solve Equations 21.1, 21.2, 21.3, 21.4, 21.5, 21.6, 21.7, 21.8, 21.9, and 21.10. A number of authors have attempted the solution to these equations for a number of materials. Furthermore, they have in some cases added further complexity by including phenomena such as intumescent behaviour [49] or bubbling [50]. Extensive reviews of these modelling efforts can be found in Refs. [4, 51–54] and some of the more recent modelling exercises have achieved significant success [55–59]. In most cases some simplifications have been necessary and in general the critical limitation of these models is associated to the inadequate definition of many of the relevant variables and parameters listed in the previous sections. As mentioned before, the current trend is to optimise parameters by fitting complex models to specific experimental results by means of sophisticated optimization techniques. The optimization process results in ranges of possible values for all parameters stipulated. The results have then been extrapolated to other experimental conditions. While success has been reported [6, 7], these optimization processes are only as good as the models whose parameters they optimize. It is therefore important to note that even in the most complex models some simplifying assumptions have been made. Currently, the use of such models remains a research subject with increasing applicability to the modelling of flaming ignition of solid fuels.

This section will take the equations presented in previous sections and suggest simplifications that will lead to models commonly used in the analysis of standard test methods evaluating the flaming ignition of solid fuels.

The Inert Solid Assumption

The assumption that the solid remain inert until ignition is probably the most far reaching of all proposed simplifications. As a result of this assumption the energy equation is dramatically simplified. Despite the far reaching implications of assuming that the solid remains inert until ignition there is very limited work that assesses the validity of this assumption.

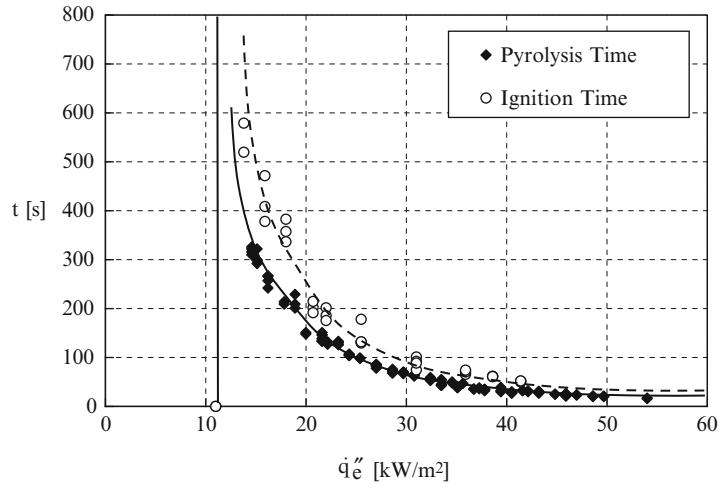

Fig. 21.8 Characteristic ignition delay times (t_{ig}) and times to the onset of pyrolysis (t_P) for PMMA and a wide range of external heat fluxes extracted from Ref. [60]. Onset of pyrolysis or ignition did not occur below 11 kW/m^2

To the knowledge of the author, the only explicit studies that discuss the importance of assuming that the material is inert are those by Fereres et al. [42], Dakka et al. [60] and Beaulieu and Dembsey [61]. In the first two studies transparent Poly(methyl methacrylate) (PMMA) was used while on the latter work the detailed analysis is done with black PMMA but a number of other materials serve to confirm the conclusions. Despite the bias towards PMMA, the discussion is appropriate here to illustrate the potential errors associated to this simplification.

Figure 21.8 presents characteristic ignition delay times (t_{ig}) and pyrolysis delay times (t_P) for PMMA. The ignition delay time was recorded as the first flash while the pyrolysis delay time as the moment when the fuel initiates its endothermic degradation. The onset of pyrolysis was characterized by means of mass loss measurements, flow visualization and IR-Thermography. These results show that for these particular experiments there is a significant difference between the "flash point" and the onset of pyrolysis (could be up to 100 %) therefore the assumption that the fuel remains inert until ignition might not be justified.

The breakdown of the inert solid heating assumption is further discussed by Beaulieu and Dembsey [61] who show that an analysis following this approximation will lead to shorter ignition delay times for realistic heat fluxes. The biggest errors were observed at the higher heat fluxes. Their tests were done for a comprehensive array of materials and with heat fluxes up to 200 kW/m^2.

Despite these experimental results, this assumption still remains the backbone of all standard test method analyses for ignition [23–25]. If this approach is followed and the regression rate is assumed to be negligible, $V_R \approx 0$, Equation 21.5 is reduced to

$$\frac{\partial[\rho_S C_S T]}{\partial t} = -\frac{\partial}{\partial x}\left[-k_S \frac{\partial T}{\partial x}\right] + \dot{q}'''_{RAD} \quad (21.13)$$

And the boundary conditions to

$$x = 0 \quad 0 = k_S \left.\frac{\partial T}{\partial x}\right|_{x=0^+} - \varepsilon_S(0,t)\sigma\left(T^4(0,t) - T_0^4\right) - h_{Cv}(t)(T(0,t) - T_0) \quad (21.14)$$

$$x = L \quad 0 = -k_S \left.\frac{\partial T}{\partial x}\right|_{x=L^-} + k_B \left.\frac{\partial T_B}{\partial x}\right|_{x=L^+} \tag{21.15}$$

Absorption of Radiation and Global Properties

The next major simplifications that are commonly accepted are to assume that most of the incident heat flux is absorbed at the surface ($\alpha(t) \approx 1$) and that the thermal properties of the solid can be considered invariant ($\rho_S(x,t) \approx \overline{\rho}_S$, $C_S(x,t) \approx \overline{C}_S$, and $k_S(x,t) \approx \overline{k}_S$). These assumptions further simplify Equation 21.11 because it allows neglecting in-depth radiative absorption. The thermal properties can then be extracted from the differential terms and external radiation now appears in the exposed boundary condition:

$$\overline{\rho}_S \overline{C}_S \frac{\partial [T]}{\partial t} = \overline{k}_S \left[\frac{\partial^2 T}{\partial x^2}\right] \tag{21.16}$$

$$x = 0 \quad 0 = \overline{k}_S \left.\frac{\partial T}{\partial x}\right|_{x=0^+} + \dot{q}''_e - \sigma\left(T^4(0,t) - T_0^4\right) - h_{Cv}(t)\left(T(0,t) - T_0\right) \tag{21.17}$$

$$x = L \quad 0 = -\overline{k}_S \left.\frac{\partial T}{\partial x}\right|_{x=L^-} + \overline{k}_B \left.\frac{\partial T_B}{\partial x}\right|_{x=L^+} \tag{21.18}$$

There is little true justification in the literature to support these assumptions, nevertheless they are of practical use since for many fire related materials the absorptivity (or emissivity) will approach unity [62], or in the case of testing the material surface can be treated with a coating that has these properties [25].

A series of recent studies have explored the absorptivity [63] of PMMA and the interaction between the heat source and PMMA [64, 65]. Figure 21.9 shows that when using an electrical resistance (cone heater [23]) the transmissivity of PMMA can be neglected and the absorption can be assumed to occur at the surface. Instead, when using tungsten lamps (from the Fire Propagation Apparatus [25]) in-depth absorption cannot be neglected. This information allowed explaining significant differences in the piloted ignition delay times obtained with both tests but mostly emphasize the potential importance of assuming an absorptivity of unity.

Furthermore, thermal properties vary with temperature, but a global set of properties can be established to provide a good fit to ignition data. An example of a comprehensive assessment of the impact of variable thermal properties is provided by Steinhaus [66].

The Boundary Conditions

To standardize the ignition process it is important to provide a controlled environment, so that test results can be consistent between laboratories and different users of the standard. Therefore, standard test methods provide clear definition of the environmental conditions, thermal characteristics of the backing material and pilot location [23–25]. Equations 21.8, 21.9 and 21.10 do not have to be solved to obtain the fuel concentration at the pilot location. Instead the impact of the gas phase on the results is ignored. This is done on the basis that flow conditions are the same between tests thus their impact on the transport of fuel and oxidizer to the pilot is the same.

Standardization of the flow conditions has a deep effect on the meaning of the results. The thermal properties associated to the analysis are no longer true thermal properties of the material but global properties that are a combination of the solid and the standardized gas phase

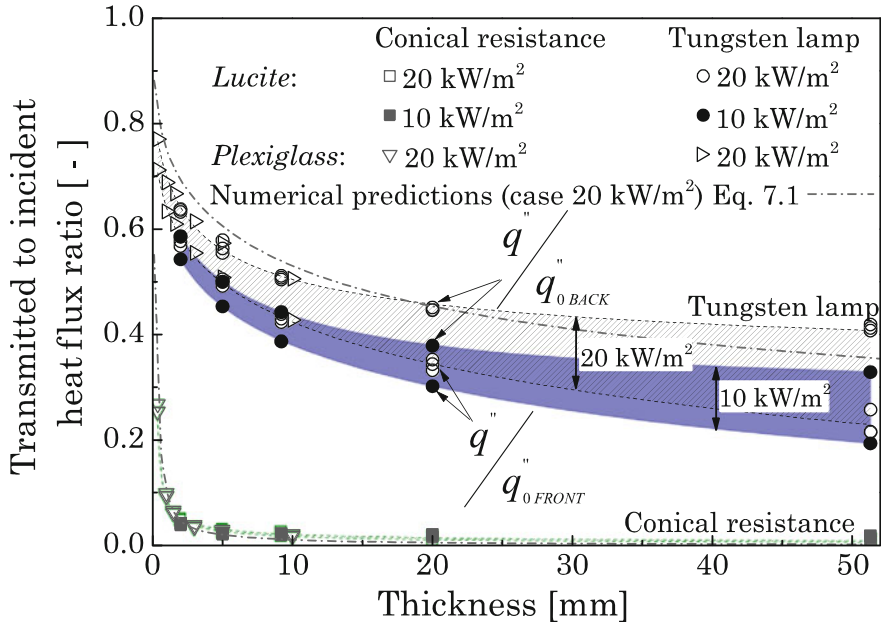

Fig. 21.9 Transmitted to incident heat flux ratio for clear PMMA samples (*Lucite* and *Plexiglass*) exposed to a radiative source (conical resistance and tungsten lamp) providing 10 and 20 kW/m^2 for thicknesses ranging between 0.375 and 51 mm [65]

conditions. This is of critical importance, because, as a product of standardization, test results can be compared among themselves (if the same method is used), nevertheless can not be extrapolated to conditions different to those of the test. This applies to other standard tests or to real fire conditions. Cordova et al. [46] provides a graphical assessment of the effect of varying the flow conditions on the resulting thermal properties showing that small variations in the flow field can result in drastic variations of the resultant thermal properties.

It is common to apply ignition data from standard tests to fire models and is only recently that CFD models such as the Fire Dynamics Simulator (Version 5 and above) allow realistic representations of the solid phase that include true thermal properties [67]. It is important to note that extrapolation is not necessarily incorrect. Nevertheless, it has to be done with great care to guarantee that the effect of the environment on the thermal properties can either be neglected or an appropriate correction is provided.

Different test methods will use different flow fields therefore values for the convective heat transfer coefficient vary with the authors. A commonly cited value is 15 W/m^{2}K. Furthermore, it is common to linearize surface radiation to define a single total heat transfer coefficient ($h_T \approx 45$ W/m^{2}K). More precise values and models are present in the literature [26–28, 31] but they correspond to very specific scenarios and therefore are hard to generalize.

Most test methods define the backing material as a good insulator ($\overline{k}_B \rightarrow 0$) neglecting heat losses through the back end of the sample. Finally, characteristic ignition delay times can be considered much shorter than the time required for the thermal wave to travel through the sample therefore $L > \varepsilon_T$ and the solid is generally assumed as semi-infinite.

These last set of simplifications are truly not necessary because a simple numerical solution can be obtained without linearizing surface radiation or assuming a semi-infinite solid. Many studies have attempted to establish the impact of these simplifications by means of numerical

solutions that relax these assumptions, the most recent of these papers is by Mowrer [68]. If surface radiation is described by means of constant heat transfer coefficient, then a correction is necessary to account for the growth of this coefficient as the surface temperature increases. Mowrer [68] showed that a correction to the global thermal properties could be made to account for this effect. The back end boundary condition is a more difficult problem. For low heat fluxes the thermal wave reaches the end of the sample, $L < \varepsilon_T$, before ignition occurs and heat is exchanged between the sample and the insulating material. Quantification of this heat exchange can be done numerically, as indicated in section "The Surface Boundary Conditions (x=0 and x=L)", but this is not a simple process because it needs to properly describe the different components associated to the way the sample is arranged during tests. The alternative solution of providing a well defined insulating boundary and neglecting back end losses has been preferred and detailed analyses have been conducted to characterize the physical arrangements of sample and insulating material. Among the most comprehensive of these studies is presented in Ref. [69].

If all these assumptions are made, Equations 21.12, 21.17, and 21.18 can be reduced to:

$$\overline{\rho}_S \overline{C}_S \frac{\partial T}{\partial t} = \overline{k}_S \left[\frac{\partial^2 T}{\partial x^2}\right] \tag{21.19}$$

$$x = 0 \quad 0 = \overline{k}_S \left.\frac{\partial T}{\partial x}\right|_{x=0^+} + \dot{q}''_e - h_T(T(0,t) - T_0) \tag{21.20}$$

$$x \to \infty \quad 0 = -\overline{k}_S \left.\frac{\partial T}{\partial x}\right|_{x=L^-} \tag{21.21}$$

The Ignition Condition

If the solid is assumed to be inert until ignition and the gas phase can be summarized into a single total heat transfer coefficient (h_T) this amounts to the assumption that ignition will occur at the onset of pyrolysis and that these process can be simply characterized by the attainment of a characteristic surface temperature that is commonly labelled the ignition temperature, T_{ig}. If the sample is suddenly exposed to an external heat flux, then the time delay between exposure and ignition is named the ignition delay time, t_{ig}. These two parameters represent then the entire process of ignition.

A final link can be made to establish a critical ignition condition. If the ignition delay time is infinitely long, then there will be no gradients of temperature within the solid and surface heat losses will be equivalent to the heat input. This represents the minimum heat flux required to achieve T_{ig}, and thus flaming ignition of the solid fuel. This heat flux is named the minimum heat flux for ignition, $\dot{q}''_{0,ig}$. Since surface temperatures are more difficult to measure than heat fluxes, the minimum heat flux for ignition can be used to establish the ignition temperature. Equation 21.18 can then be re-written to

$$T_{ig} = T_0 + \frac{\dot{q}''_{0,ig}}{h_T} \tag{21.22}$$

Equation 21.14 is an idealized expression that assumes that no temperature gradients exist in the solid, this can lead to errors in the calculation of T_{ig}. To establish a relationship between external heat fluxes and surface temperature that includes in-depth heat transfer a sample can be allowed to reach thermal equilibrium and the surface temperature recorded. The obtained relationship represents a more accurate representation of Equation 21.14 and can be used to extract ignition temperatures from measured heat fluxes. A graphic representation of this relationship can be found in Ref. [34].

Again, both minimum heat flux for ignition and ignition temperature are not material properties but a combination of the material and the specific environmental conditions associated to the test [46]. Extrapolation to realistic scenarios and fire models has to be done with significant care.

The Solution

Imposing a constant external heat flux ($\dot{q}''_e$ = constant) and using all the above assumptions allows for an analytical solution to Equation 21.13. This solution establishes the evolution of the solid temperature as a function of time. This solution can be found in any heat transfer book [19] but was first postulated for the flaming ignition of a solid fuel by Quintiere [70] and incorporated in ASTM E-1321 [24]. Alternate solutions have been postulated for other test methods and will be briefly discussed in Chaps. 28 and 36. More detailed discussion of methodologies and nomenclature can be found in the description of the standard tests [23, 25].

The solution for T(x,t) is given by

$$T(x,t) - T_0 = \frac{\dot{q}''_e}{(h_T)}\left[\operatorname{erfc}\left(\frac{x}{\sqrt{4\overline{\alpha}_D t}}\right) - e^{\frac{(h_T)}{\sqrt{\alpha_D}\sqrt{\overline{k}_S\overline{\rho}_S\overline{C}_S}}x + \frac{(h_T)^2}{\overline{k}_S\overline{\rho}_S\overline{C}_S}t}\operatorname{erfc}\left(\frac{(h_T)}{\sqrt{\overline{k}_S\overline{\rho}_S\overline{C}_S}}t^{\frac{1}{2}} + \frac{x}{\sqrt{4\overline{\alpha}_D t}}\right)\right] \tag{21.23}$$

Where $\overline{\alpha}_D = k_S/\rho_S C_S$ is the global thermal diffusivity and "erfc" is the complement to the error function. To obtain the surface temperature (T_s), x is set equal to 0 and $T = T(0,t) = T_s$. Therefore Equation 21.21 simplifies to:

$$T_s = T_0 + \frac{\dot{q}''_e}{(h_T)}\left[1 - e^{\left(\frac{(h_T)^2}{\overline{k}_S\overline{\rho}_S\overline{C}_S}\right)t}\operatorname{erfc}\left(\frac{(h_T)}{\sqrt{\overline{k}_S\overline{\rho}_S\overline{C}_S}}t^{\frac{1}{2}}\right)\right] \tag{21.24}$$

from Equation 21.15,

$$\overline{T} = \frac{\dot{q}''_e}{(h_T)} \tag{21.25}$$

can be defined as a characteristic temperature and,

$$t_c = \frac{\overline{k}_S\overline{\rho}_S\overline{C}_S}{(h_T)^2} \tag{21.26}$$

is defined as a characteristic time. Equation 21.15 is the general solution to the surface temperature at all levels of incident heat flux. To obtain the ignition delay time (t_{ig}) the surface temperature (T_s) is substituted by T_{ig} and Equation 21.15 can be rewritten as:

$$T_{ig} = T_0 + \overline{T}\left[1 - e^{\frac{t_{ig}}{t_c}}\operatorname{erfc}\left(\left(\frac{t_{ig}}{t_c}\right)^{\frac{1}{2}}\right)\right] \tag{21.27}$$

To avoid the complex form of the error function simplified solutions have been proposed in the literature [70, 71]. In order to solve for the ignition delay time (t_{ig}) a first order Taylor series expansion of Equation 21.18 is conducted. The range of validity of this expansion is limited, thus cannot be used over a large range of incident heat fluxes. Thus, the domain has to be divided at least in two.

The first domain corresponds to high incident heat fluxes where the ignition temperature (T_{ig}) is attained very fast, thus $t_{ig} << t_c$. Application of the first order Taylor Series Expansion to Equation 21.18 around $t_{ig}/t_c \to 0$ yields the following formulation for the ignition delay time (t_{ig}):

$$\frac{1}{\sqrt{t_{ig}}} = \frac{2}{\sqrt{\pi}\sqrt{\overline{k}_S\overline{\rho}_S\overline{C}_S}}\frac{\dot{q}''_e}{(T_{ig} - T_0)} \tag{21.28}$$

As can be seen from Equation 21.19, the short time solution for the ignition delay time (t_{ig}) is independent of the total heat transfer coefficient term (h_T). Thus the ignition delay time (t_{ig}) is

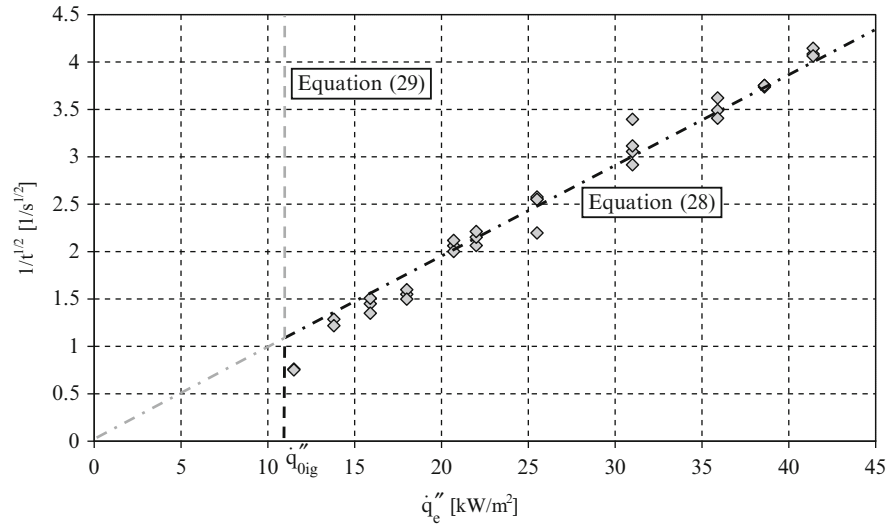

Fig. 21.10 Ignition delay time ($1/t_{ig}^{-0.5}$) for different external heat fluxes using PMMA as a solid fuel (Data extracted from Ref. [60])

only a function of the external heat flux ($\dot{q}''_e$) and the global properties ($\overline{k}_S$, $\overline{\rho}_S$, $\overline{C}_S$) of the solid fuel and the ignition temperature (T_{ig}).

For low incident heat fluxes $t_{ig} \geq t_c$, the Taylor series expansion is made around $t_{ig}/t_c \rightarrow \infty$, where the first order approximation yields:

$$\frac{1}{\sqrt{t_{ig}}} = \frac{\sqrt{\pi} h_T}{\sqrt{\overline{k}_S \overline{\rho}_S \overline{C}_S}} \left[1 - \frac{h_T \left(T_{ig} - T_\infty \right)}{\dot{q}''_e} \right] \quad (21.29)$$

Equations 21.19 and 21.20 establish the relationship between ignition delay time and external heat flux. It is convenient to express the ignition delay time data presented in Fig. 21.7 as $1/\sqrt{t_{ig}}$ where T_{ig} is obtained from the experimental minimum heat flux for ignition and Equation 21.14. Such a plot is presented in Fig. 21.8. Substituting T_{ig} in Equation 21.19 allows extracting the product of the three thermal properties ($\overline{k_S \rho_S C_S}$) as a single experimental parameter representing the global material properties controlling flaming ignition of solid fuels that can be considered semi-infinite. Quintiere terms this product the thermal inertia [70] (Fig. 21.10).

When describing ignition propensity of solid fuels is customary to summarize the description of the materials on the basis of only two parameters, the ignition temperature, T_{ig}, and the thermal inertia, $\overline{k_S \rho_S C_S}$. Several tables have been produced in the past with comprehensive lists of materials typical of fires. As an example, Table 21.3 presents the data as compiled by Quintiere [70]. A comprehensive list is not presented here because a comprehensive compilation of data is provided in Appendix 3 or in Refs. [1] and [2].

Thermally Thin Materials

A very similar analysis can be conducted for thermally thin materials where in the absence of thermal gradients and after all relevant simplifications Equations 21.13, 21.20, and 21.21 can be combined into a single energy equation and a boundary condition

$$\overline{\rho}_S \overline{C}_S L \frac{\partial T}{\partial t} = \dot{q}''_e - h_T (T(t) - T_0) \quad (21.30)$$

Table 21.3 Ignition data from ASTM E-1321 per Quintiere [72]

Material	T_{ig} [°C]	$\overline{k_S \rho_S C_S}$ [(kW/m^{2}K)^2.s]
Wood fiber board	355	0.46
Wood hardboard	365	0.88
Plywood	390	0.54
PMMA	380	1.00
Flexible foam plastic	390	0.32
Rigid foam plastic	435	0.03
Acrylic carpet	300	0.42
Wallpaper on plasterboard	412	0.57
Asphalt shingle	378	0.70
Glass reinforced plastic	390	0.32

$$x = L \quad \dot{q}''_N(L,t) = 0 \tag{21.31}$$

when the external heat flux is much larger than the losses this equation can be integrated to deliver Equation 21.22 [73].

$$t_{ig} = \frac{\overline{\rho}_S \overline{C}_S L\left(T_{ig} - T_0\right)}{\dot{q}''_e} \tag{21.32}$$

This is once again not a necessary assumption but has the practical advantage of leaving the product $\overline{\rho_S C_S}$ as a single experimental parameter that can be extracted from the slope of a simple plot presenting $1/t_{ig}$ vs $\dot{q}''_e$. $\overline{\rho_S C_S}$ represents then the global material properties controlling flaming ignition of thermally thin solid fuels. A comprehensive data review of this product is provided in Refs. [1] and [2].

Summary

A review of flaming ignition of solid fuels has been presented. Emphasis has been given to a comprehensive description of all processes involved. Some minor simplifications have been made to the original formulation leading to approximately 30 variables and parameters controlling flaming ignition of a solid fuel.

A section follows where the common simplifications associated to the methodologies of interpretation of standard test methods are applied. Analytical solutions are obtained showing that the description of the ignition process can be summarized to two material related parameters and two specified environmental conditions (T_0, $\dot{q}''_e$). The material related parameters are as follows:

Thermally thin materials	T_{ig}	$\overline{\rho_S C_S}$
Thermally thick materials	T_{ig}	$\overline{k_S \rho_S C_S}$

It is important to insist that these parameters are a function of the material and the environmental conditions at which they were obtained. They can be directly applied for comparison between materials (flammability assessment) but extrapolation to conditions beyond the tests where they were obtained is not always possible and if performed, has to be done with great care.

Electrical Fires

22

Vytenis Babrauskas

Introduction

An electrical fire is generally understood to be a fire that is caused by the flow of an electric current or by a discharge of static electricity. It is not defined as a fire involving an electrical device or appliance. For example, a fire on an electric range that occurs due to overheating and ignition of the oil in a deep-fry pan is not classed as an electrical fire, even though it involves an electrical appliance. Conversely, an electrical device or appliance is not always needed for an electrical fire to occur. Lightning-caused fires are a form of electrical fires and these can ignite, for example, a dry bush, which is not an electrical device.

As with other categories of fires, there are three main aspects of electrical fires to be considered: ignition, combustion behavior, and suppression. This chapter deals mostly with the ignition aspects. Combustion behavior of electrically initiated fires is normally dominated by the fuel characteristics of the primary combustibles that are involved. These will most commonly be cellulosic or plastic fuels, although with some sustained electrical faults combustion of aluminum (e.g., busbars) can play a significant role. Copper and steel generally do not burn even in worst-case electrical fires. Sustained burning of aluminum generally does not take place except in installations of at least 480 V and of high current capacity. The traditional segregation of electrical fires as Class C fires has been based primarily on concerns of potential shock hazard to fire-fighting personnel. But research studies [1, 2], show that this would be a realistic concern only for high-voltage installations. Even for these, the hazard is minimal. For example, the most recent study on this topic [3] showed that a fire fighter would have to be holding a straight-stream nozzle 1.0 m from a 45 kV power line for a shock hazard, defined as 10 mA passing through the body, to be created. For a fog nozzle, no hazard could be produced at a 2.0 m distance even with a 200 kV line (smaller distances were not measured) and current with the 200 kV line was only 0.35 mA.

This chapter discusses the differences between electric current and static electricity, outlines the various forms of heating that can take place due to electrical activity, and discusses how ignition of various substances may take place due to electrical activity. The electrical characteristics of lightning are also discussed, since this is a form of electrical discharge. Several reviews of electrical fires have been published by Babrauskas [4–6]; these provide additional details on the status of research and practical applications.

Static Electricity and Electric Current

In the simplest terms, electricity is a form of energy associated with the movement of

V. Babrauskas (✉)

DOI 10.1007/978-1-4939-2565-0_22, © Society of Fire Protection Engineers 2016

electrons. The movement can be sustained (i.e., electric current) or not. Sustained movement requires a conductive path to be established, but the limited movement of electrons possible in insulators can allow charge separation to occur. Once this happens and a certain amount of charge is accumulated, a discharge may be possible and this whole process is known as static electricity. Static electricity, however, does not mean an absence of electric current, since current (flow of electrons) occurs both in charging and in discharging. Instead, static electricity is a somewhat imprecise concept implying that the primary flow of electrons is either in insulators or in conductors that are not connected into the form of a closed circuit.

Electrical Discharges

Breakdown Phenomena

Electrical *breakdown* means that a substance that is normally an insulator suddenly (and possibly just temporarily) breaks down, and becomes a conductor. The process is somewhat different in gases, liquids, and solids. In a gas, the medium is *self-healing*—if the driving force is removed, the medium restores itself essentially to its original condition, although a slight chemical change may occur (e.g., some ozone can be created by an electrical discharge in air). Liquids are also largely self-healing, but the chemical changes entailed may have some long-term implications. The best example of this is oil-filled transformers that can withstand a certain amount of discharges if these are not too energetic. But each discharge causes degradation of the liquid and eventually the transformer may suffer a catastrophic failure due to this degradation. Discharges in solids, on the other hand, are usually highly destructive. With most solid materials, an electrical discharge creates a path that is permanently damaged or destroyed. The majority of insulating solids are organic substances and a discharge through an organic solid has the effect of carbonizing the material, but a portion of the material may also be ablated.

A more detailed explanation [7] of the breakdown process is as follows. Due to cosmic radiation and other factors, a small number of free electrons are always present in air. If an electric field is applied, the electrons move in the direction opposite to the electric field (i.e., to the positive electrode). If the electric field is sufficient, an electron can travel only a short distance before it collides inelastically with an atom/molecule and ionizes it, now leaving two free electrons. Both of these electrons now continue to travel and each one will again collide, and create a new pair of electrons (original electron, plus electron removed from an atom) at this collision. It can be seen that this process leads to exponential growth and one electron, starting at the cathode, will result in n electrons reaching the anode, where $n = e^{\alpha d}$, with d = gap distance and α = Townsend's first ionization coefficient, with has the units of 1/distance. The value $1/\alpha$ then represents the distance between successive ionizing collisions. The generation of electrons is further augmented by the positive ions which are created in the process and which move, much more slowly, towards the cathode. When a positive ion collides with the cathode, it then liberates γ electrons, with γ being known as Townsend's second ionization coefficient. If only electrons that naturally get liberated from the cathode enter into this process, augmented by electrons liberated due to collisions with neutral species along the path, then the discharge (a discharge is the flow of a detectable amount of current) is called a *Townsend discharge*, named after J. S. Townsend, an early researcher of gas discharges. A Townsend discharge is nonluminous and the current flow is small. If the process increases so that a sizable current starts to flow, term *breakdown* is applied, and the two main types of breakdown modes are: electric arc (if sustained) and electric spark (if not). An electric arc requires that a sufficiently high current (more than approximately 0.1 A) be available.

As soon as a conducting path gets established across the gap, the delivery of energy into the arc channel rapidly increases, but the rate of current growth is largely determined by the external circuit parameters. The actual arc channel starts out

small, then grows rapidly in *diameter*. This radial growth is so fast that it is modeled as a shock wave propagation [8]. The shock front, however, does not correspond identically with the channel boundary. The channel expands in two stages. Initially it expands by means of the expanding shock wave until the shock wave detaches from the luminous core. After that point it detaches more slowly until an ultimate value is reached. During the initial expansion phase, the channel conductivity [9] is 1.5×10^4 S m^{-1} and the channel radius r (mm) increases [10] according to:

$$r = 294 \frac{I^{1/3} t^{1/2}}{\rho_o^{1/6}}$$

where I = current (A), t = time (s), and ρ_o = ambient density of air (kg m^{-3}).

Paschen's Law

The kinetic energy W gained by an electron when accelerated by an electric field E over a distance L is:

$$W = EeL$$

where e is the charge of the electron (1.6022×10^{-19} C). The simplest estimate of breakdown would be that a self-sustained avalanche is created when W attains a sufficient value so that a traveling electron can knock off an outer-shell electron from molecules of the gas through which it is traveling. The distance L is the mean free path (average distance between two collisions) for an electron in ambient air, which is experimentally found to be about 0.4 μm. This value is not to be confused with the mean free path of the molecules of air, which is around 0.068 μm, a smaller distance to the fact that air molecules are much larger than electrons. The energy required to ionize an oxygen molecule is 13.5 eV, while for nitrogen it is somewhat higher at 15.8 eV. An electron volt (eV) is a unit of energy equal to 1.6022×10^{-19} J. Thus, the simple estimate would be that breakdown would occur when

$$E = \frac{W}{eL} = \frac{13.5 \times 1.6022 \times 10^{19}}{1.6022 \times 10^{19}\left(0.4 \times 10^{-6}\right)}$$
$$= 34 \times 10^6 \mathrm{Vm}^{-1} = 34 \mathrm{MVm}^{-1}$$

This estimate is about a factor of 10 too high, and this is because this simplest effort at estimating ignored the electron avalanche effect. In actual fact, breakdown in air at 1 atm requires a field of roughly 3 MV m^{-1}, and Paschen's paper of 1889 [11] is credited with defining a relation between breakdown voltage, spacing of electrodes, and gas pressure, which has become known as Paschen's Law. According to Paschen's Law, the pressure × gap distance product is the controlling variable and the breakdown voltage V is given by:

$$V = \frac{c_1 pd}{c_2 + \ln(pd)}$$

where p = pressure, d = gap distance, and c_1 and c_2 are constants. Thus, when the electric field exceeds about 3 MV m^{-1}, breakdown is estimated to occur. Modern measurements [12] of Paschen's Law curves for air and for nitrogen are shown in Fig. 22.1. For gaps greater than about 0.1 mm, it can be seen that the curve is essentially a straight line. For smaller gaps, however, the breakdown voltage does not go to zero and, instead, a minimum breakdown voltage is found. This minimum of the Paschen curve is approximately 340 V, and it occurs at a Pd product of 0.007 atm-mm. In other words, in ambient air, the minimum breakdown voltage occurs for a gap of 0.007 mm (7 μm). This is an exceedingly small distance, and two conductors this far apart would appear to be touching to the naked eye.

For practical applications, it can be more convenient to present results in the form of the *dielectric strength* (MV m^{-1}), which is the breakdown voltage divided by the distance between the electrodes. This is shown in Fig. 22.2 and indicates that for larger distances, the dielectric strength of air is approximately 3.0 MV m^{-1}; the value for nitrogen is quite similar.

Paschen's Law is not absolute but rather depends on experimental conditions. These

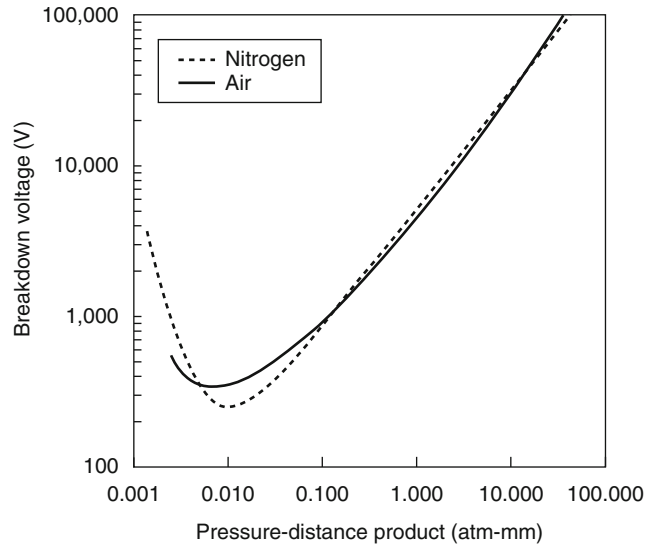

Fig. 22.1 The breakdown voltage (Paschen's Law) between spherical electrodes in air and nitrogen. The voltage refers either to DC voltage or to the peak value, for AC voltage (From Ignition Handbook [7], used by permission)

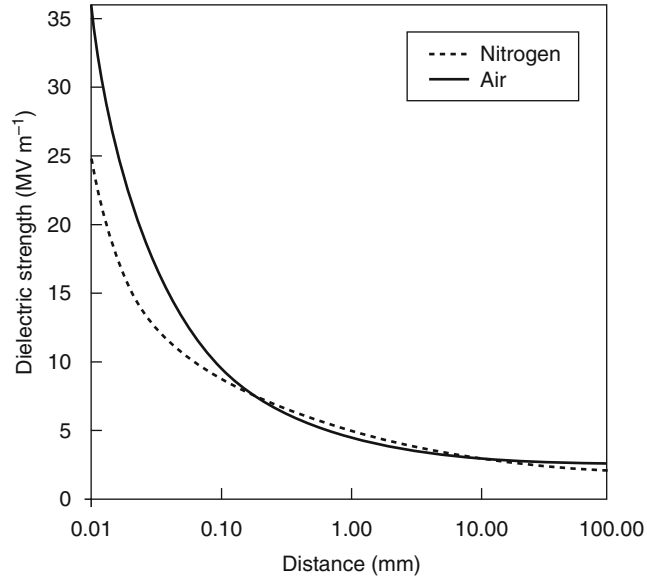

Fig. 22.2 The dielectric strength at 1 atm, as a function of distance (From Ignition Handbook [7], used by permission)

include electrode shape, the material of the electrodes, electrode surface contamination, humidity, and the polarity (if electrodes are not identical). The law also assumes that the impressed electric field is uniform and deviations occur if the field has nonuniformities.

Paschen's Law curves are identical for both AC and DC voltages. But since AC voltages are normally described by their root-mean-square (rms) values and not the peak values, if results are to be applied to AC voltages, then the values indicated in Fig. 22.1 need to be divided by $\sqrt{2}$. Thus, on an rms basis, the minimum AC breakdown voltage is $340/1.414 = 240$ V(rms). It must be emphasized that Paschen's Law is not used in the design of low-voltage equipment. There are many standards worldwide that govern gap sizes (clearances) required for low- or medium-

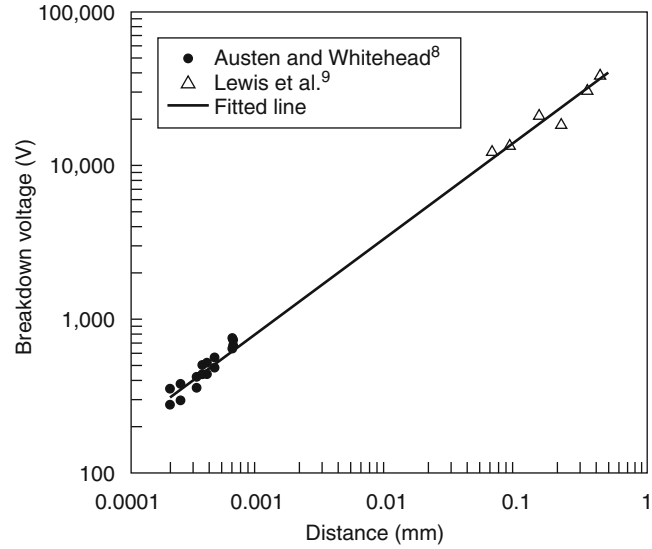

Fig. 22.3 Breakdown voltage for mica as a function of gap distance

voltage equipment, but they all mandate values much larger than the minimum that would suffice to prevent breakdown. This is for serviceability reasons and also takes into account surges.

Dielectric Strength of Solid or Liquid Insulators

The dielectric strength of solids and liquids can also be characterized by similar graphs, but only limited specialized references exist [13]. Most of this literature covers solely the HV regime, and data for voltages below 1 kV are extremely scarce. Mica is one of the rare insulators for which low-voltage data are available, with the results of Austen and Whitehead [14] and Lewis et al. [15] being shown in Fig. 22.3. For polymers, some data obtained by Abed [16] on polystyrene, PVC, and PTFE are shown in Fig. 22.4. Also shown are data on polyethylene obtained by Mason [17] and a single data point given by Austen [18]. The latter indicates that breakdown occurs at 150 V when the insulation thickness is reduced to 0.003 mm. The most common insulator for low-voltage[1] wiring is poly(vinyl chloride), PVC. A more recent review paper [19], however, indicated that no breakdown data for PVC are available below 0.07 mm, at which thickness the breakdown voltage is still in the kV range (approximately 7 kV).

The available data suggest that plastics most likely show a relationship where the breakdown voltage approaches zero as the electrode spacing becomes infinitesimal. But the available data are too few to establish this quantitatively.

Arcs

Definitions of *Arc* and *Spark* Both an electric arc and an electric spark fall under the general definition of a continuous, luminous discharge of electric current crossing a gap or an insulating surface between two conductors [7]. They are distinguished in that an arc is a sustained event while a spark is transient. Matters are clouded by the fact that some researchers refer to a "spark phase" of an arc, but this type of definition is not widely held and is not used in fire safety engineering. *Spark,* however, also has another very different definition: a small incandescent particle. For clarity, the latter can be referred to as a *mechanical spark*.

[1] *Low voltage* is defined by various institutions as being lower than 600, 660, or 1,000 V.

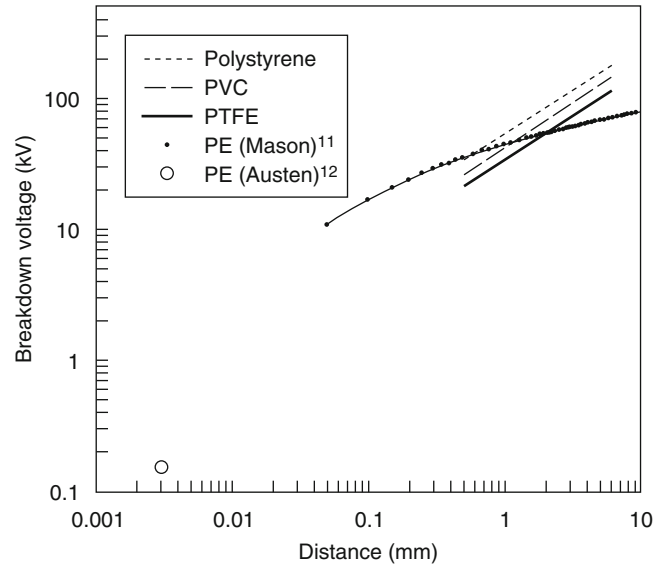

Fig. 22.4 Breakdown voltage for several polymers as a function of gap distance

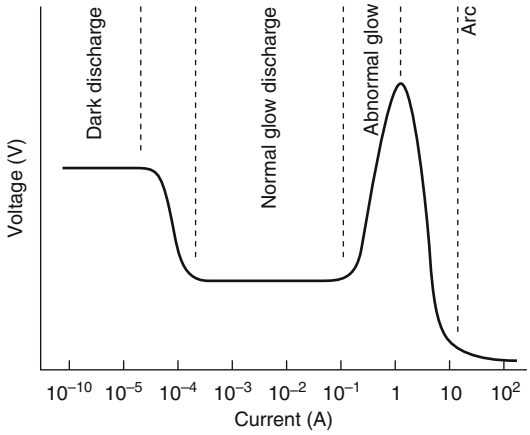

Fig. 22.5 Schematic representation of steady-state voltage and current for several discharge types (From Ignition Handbook, used by permission)

Characteristics of an Arc An arc is actually only one of several types of steady electrical discharges that are possible, as shown in Fig. 22.5. But, of these, only the arc is important from a safety viewpoint, and it corresponds to discharges of the highest current and the lowest voltage.

The temperature of an arc can vary widely. Under ambient pressure conditions, it is commonly 6,500–12,000 K but can reach 50,000 K. The primary factor governing arc temperature is the arc current. Experimental data, along with some theoretical predictions, are shown in Fig. 22.6. Also shown is the following empirical data fit:

$$T = 6,500 I_a \leq 4.5\,\text{A}$$

$$T = 4,010 + 1,658 \ln I_a I_a > 4.5\,\text{A}$$

The theoretical predictions are only loosely obeyed, so the empirical data fit should be sufficient for calculation purposes.

Means of Creating Arcs An arc can be created by a variety of means, primarily the following:

- Raising the voltage across a fixed pair of electrodes until breakdown occurs
- Opening or closing the contacts in a current-carrying circuit
- Transitioning from arcing across a carbonized path (arc tracking)
- Glow-to-arc transition
- Introducing ionized gases in between two electrodes (e.g., from a flame)

Creating an arc by raising the voltage across a fixed pair of electrodes is very common for testing purposes. It also occurs in some accidental circumstances, as discussed below.

Contact arcs regularly occur in electric switches, relays, and similar devices. They also occur inadvertently, when, for example, two bare

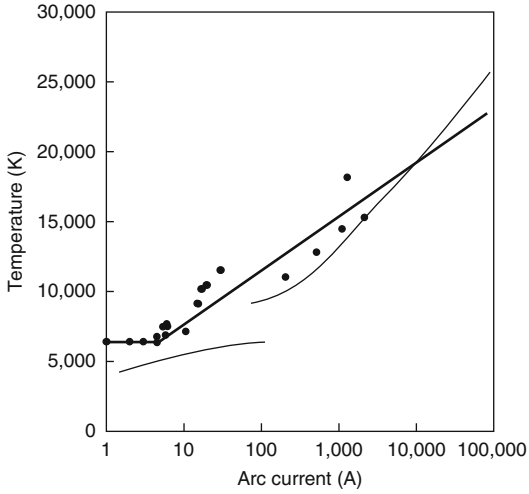

Fig. 22.6 Temperature of arcs in ambient-pressure air, along with predictions from theory (*light lines*) and an experimental data fit (*bold line*) (From Ignition Handbook, used by permission)

current-carrying conductors are accidentally shorted. When considering electric switch contacts, the arc caused by closing the switch is called a make-arc (or closing arc), whereas the arc caused in opening the switch is a break-arc (or opening arc, or parting arc). The process of creating an arc (at voltages that may be much less than Paschen's Law minimum of 340 V) is quite similar for both types of contact arcs. In the case of a break-arc the steps involved are the following:

1. The electrodes that were originally touching at numerous spots start to touch at only a few very small spots.
2. A high current density passes through the small metal diameter of contact area that is available.
3. The metal bridge joining the two contacts starts to melt.
4. The bridge elongates and rises in temperature.
5. The bridge reaches the metal's boiling point, becomes unstable, and ruptures.
6. Voltage rises rapidly across the gap, thermionic emission from the hot cathode starts, and eventually the gap becomes ionized and an arc forms.
7. The diameter of the arc expands from that of the bridge to its eventual free-burning diameter.

The voltage across the gap at the moment of rupture is only approximately 1 V. The reason Paschen's Law does not apply is that it describes the characteristics of room-temperature, nonionized gases, and the space between the contacts is ionized and at high temperature. Even though 10–15 V is needed for the steady-state operation of an arc, the arc is able to initiate with only a 1 V drop due to inductive effects of the wiring.

In closing switch contacts (a make-arc), the sequence of events is very similar. Contact is initially made at only a few high spots. These have limited current-carrying capacity and proceed to melt and rupture, at which point an arc develops. That arc is normally extinguished by heat losses when the contacts close together more tightly.

Arcing across a carbonized path (arc tracking) is arcing that is supported by a carbonized path on a solid, as discussed below, and this is a low-current process. If this process continues and accelerates, one possible outcome is a normal, high-current arc across air. The conditions leading to this have not been explored in detail, however. Glow-to-arc transition is a rare phenomenon not normally encountered in fires [20].

The dielectric strength of a hot, ionized gas is tiny compared to that of normal ambient air. Thus, when the distance between two conductors is such that there would be no possibility of breakdown in normal air, introducing ionized gases in between two electrodes (e.g., from a flame) can lead to arcing. This is why, in many fires, a large number of artifacts are found suggesting that an arc occurred there. It is not because several different places arced simultaneously and each erupted into fire [21]. Instead, a single fire introduced flames into various locales where conductor-to-conductor spacing was such that arcing could not be supported in ambient air but could be supported in an ionized, hot medium.

Arc Flash The thermal radiation from an arc is referred to as *arc flash* and a sustained, high-current arc can lead to severe injury or death of an individual so exposed. IEEE Std 1584 [22] provides a

calculational method for estimating arc flash radiation, whereas ASTM F 1506 [23] and ASTM F 1959 [24] provide procedures for assessing the actual effectiveness of protective clothing.

Arc Extinguishment A DC arc will extinguish only if the power supply is removed or if enough material erodes to make the gap too large. In an AC circuit, an arc will self-extinguish 2 × 60 times (2 × 50 times with 50 Hz power) per second, each time the current goes to zero. But it may reignite thereafter if conditions are right. Whether or not the arc reignites afterwards depends on whether the arc channel can recover so that it will not break down again with the new imposed voltage. Arcs in circuits of less than 150 V tend to extinguish and not reignite when the waveform goes through the zero crossing. Arcs in circuits of over 600 VAC tend to draw very high currents and, consequently, may be relatively safer since a circuit protection device is likely to open. Voltages between 150 and 600 V are considered the most hazardous in regard to fires being ignited from arcing [25]. This is because the arcs tend to not be extinguished, yet the current flows are small enough that circuit protection devices operate slowly. Typical waveforms [26] for arcing in 120 VAC circuits are shown in Fig. 22.7. Note the intermittent nature of the arc as it extinguishes and reignites.

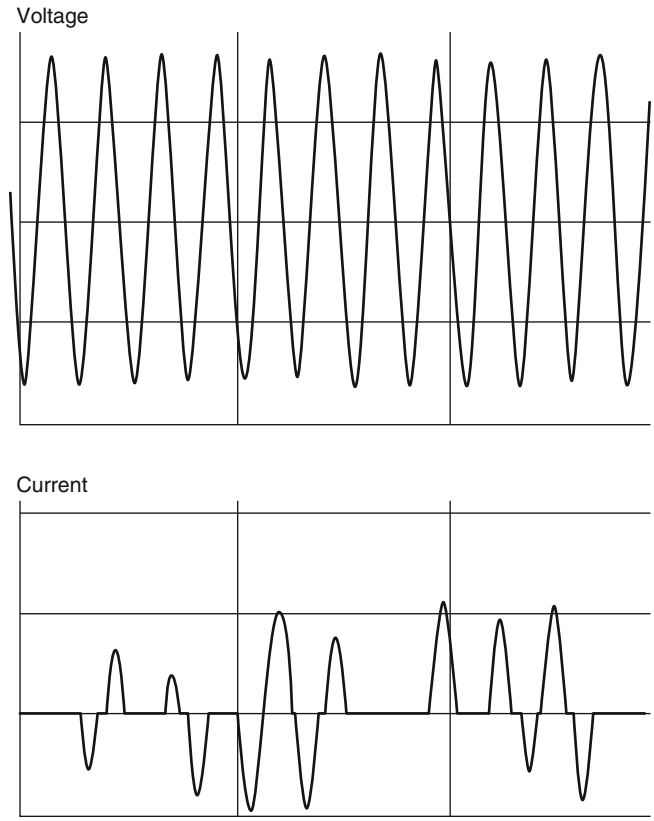

Fig. 22.7 Typical waveforms during a branch-circuit arcing event

Ignition Modes Involving Electric Current

Sparking or Arcing

Electric sparking or arcing can ignite materials in all phases: gases, liquids, solids, liquid aerosols, and dust clouds. Ignition in gaseous and dust cloud media has been studied extensively. Ignition in bulk liquids is rare, apart from oil-filled transformers and other HV devices. Ignition of liquid sprays, fogs, or aerosols is problematic in some industries, however. Ignition of solids from arcing or sparking is common but has not been researched to any satisfactory degree.

Gases If an atmosphere exists where a flammable gas has been dispersed into an oxidant gas (commonly air) and the mixture is within its flammable limits, spark ignition is generally very easy. Arc ignition has normally not been studied. Since a very low-energy transient energy discharge ignites such mixtures, a sustained energy discharge will be much more capable of ignition. For this reason, the phenomenon is referred to as spark ignition rather than arc ignition. Flammability limits for a number of gases are given in Chap. 17. A larger collection of data is provided in the *Ignition Handbook* [7]. Some values for minimum ignition energy (MIE) are given in Table 22.1; more extensive tables are available in the *Ignition Handbook* [7]. It should be observed that these energies are exceedingly small and are tabulated in millijoules. To appreciate the magnitude, one can consider the fact that if a coffee mug is raised by 0.3 m, its potential energy is increased by roughly 1.0 J.

Table 22.1 Minimum ignition energy (MIE) of some common gases and vapors

Substance	Energy (mJ)
Acetone	2.15
Acetylene	0.03
Ammonia	680
Benzene	0.91

Dust Clouds Dust clouds are significantly more difficult to ignite than gases, but explosions due to this cause remain an important concern in manufacturing, mining, and agricultural industries. The lower flammability limit of dust clouds has generally been erroneously reported in most data compilations because apparatuses used to measure the lower flammability limit (LFL) of dust clouds have had gross, systematic errors, leading to reported values for many substances being much lower than their true value [7]. But, as a very rough rule, dust clouds will not reach their LFL unless visibility is down to zero in that location. The upper flammability limit (UFL) for dust clouds is rarely measured, simply because it is generally very difficult to generate a dust cloud that exceeds the UFL.

Minimum ignition energies have been tabulated and it is believed that those are more reliable. Some typical values are shown in Table 22.2. Unlike gases, where MIE values are typically below 1 mJ, MIE values for dust clouds are typically some two orders of magnitude higher. Nonetheless, these are all still low, even though they are higher than for gases.

Solids Ignition of solids from electric sparks or arcs is unfortunately common. The cause can be

either static electricity or circuits carrying an electric current. Some of the mechanisms have been studied, and these are discussed later. However, the problem of understanding the response of solid materials to a spark or arc ignition source has been neglected. Apart from metals and some other rare substances, there are no combustible solids with an ignition temperature over 1,000 °C. Figure 22.6 shows that the temperature of an electric arc is at least 6,500 K and may be much higher. Yet, an electric arc impinging onto a combustible solid is not necessarily assured of igniting it. There are two primary factors operating in such cases: (1) The arc impingement may be very brief, many combustible materials can resist enormous heat fluxes if these are sustained only briefly. (2) The material may ablate too rapidly to allow ignition. These mechanisms, however, are understood only qualitatively—there have not been research studies to successfully quantify them.

Arcing Across a Carbonized Path

Many electrical fires are due to arcing across a carbonized path. If a carbonized path is created where current may potentially flow, arcing may then occur along this path, possibly leading to ignition either of the combustible insulator itself, or some other nearby fuel. A carbonized path can be created in at least three ways [27], such as the following:

1. Arc tracking
2. Overheating (by electrical overcurrent, external radiant heating, etc.)
3. Impingement of fire on solid electrical insulation material

Arc Tracking Of these three possibilities, substantive research has been done only on arc tracking. Arc tracking is a progressive creation by electrical means of a carbonized path along the surface of an insulator that separates two current-carrying conductors. Arc tracking is subdivided into two types: dry tracking and wet tracking. Dry tracking can be induced by causing an electric arc to impinge onto the surface of an organic material. Wet tracking can occur if a film of water covers the surface of the insulator and spans between two conductors.

The electric conductivity of pure water is very low, but when ionic contaminants are dissolved in water, its conductivity increases and it becomes possible to create a current flow if the layer of moisture has access to conductors from both sides of the line. The flow of current then has a drying effect on the moisture layer. The drying is nonuniform, and eventually dry patches

start to be formed along the current path. With buildup of carbonization along the path, small electrical discharges, called scintillations, can then occur. Since part of the current flow is through an electrolyte of significant resistance, these scintillations represent a very small current flow and would not trip any overcurrent-protection devices. The ultimate event, if it occurs, is the actual flaming ignition of the material over which tracking is occurring.

If the tracking is dry, the processes that occur along the surface are similar. Although an overcurrent-protection device cannot be expected to protect against arcing across a carbonized path (unless this escalates to a high-current fault), arc fault circuit interruption (AFCI) devices, which have been developed in recent years [28], are intended to respond to this condition; because they are relatively new, however, field-performance data do not yet exist, although it is known that some models of first-generation devices have not been highly successful [29].

Surprisingly, temperatures up to 1,000 °C can be generated by such surface leakage discharges. These elevated temperatures then continue the process of polymer carbonization. Thus, in the tracking process, a carbon track is laid down along the surface, and that track has a low enough resistivity that current can subsequently start to flow along the carbonized track, which, in turn, causes more carbonization and more heating. A runaway situation can then develop. Scintillations can vary widely in their discharge energy, with the low end of the scale being mild events that would not be expected to damage metals (although they might ignite some potential targets). Nakamura et al. [30] measured scintillations on PVC and reported values that ranged from 100 to 3,000 J. But, they did not endeavor to set up their experiments to elicit the lowest possible discharge energy.

To create arc tracking, a vastly lower voltage can suffice than for breakdown in air between two electrodes. For example, with many plastics, Yoshimura et al. [31] found that 600 VAC was sufficient to cause an arc discharge across a 4 mm gap. By contrast, breakdown across a 4 mm gap in air requires about 10,000 VAC. On cables, wet tracking will normally not be initiated unless a conductive moisture film exists that has electrical contact to two conductors that have a voltage difference between them. This may happen if a cable is mechanically damaged so that two current-carrying conductors are exposed. Moisture then collects on the damaged area, and pollutants are present that ionize the layer. But on some materials, arc tracking does not require a direct contact between an electrode and the surface of the insulator; tracking over phenolic and melamine surfaces can be initiated even when the electrodes are separated by gaps of about 0.25 mm from the insulator surface. In general, in low-voltage circuits, a carbonized path is probably most commonly created by a poor connection or other source of locally elevated temperatures, but moisture or pollutants can also be of significant importance.

Oba [32] conducted experiments where he damaged the insulation on Japanese PVC-insulated power cable to expose the conductors and then sprayed electrolyte onto the area to initiate arc tracking. By varying the AC voltage supplied to the cord, he obtained a char length relation as a function of voltage (Fig. 22.8). Below 50 V, progress of charring

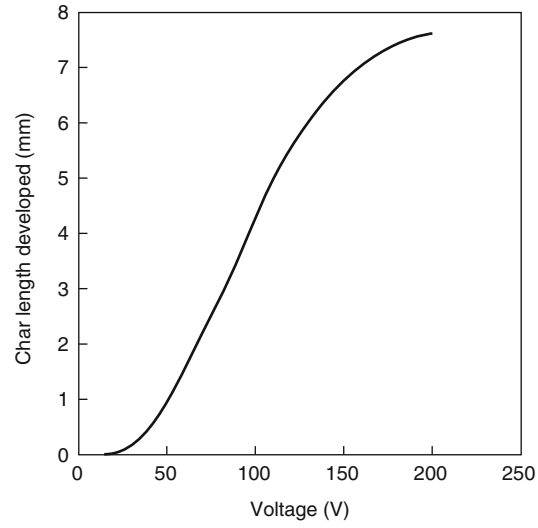

Fig. 22.8 Char length developed after 70 h in the wet arc-tracking experiments of Oba (From Ignition Handbook, used by permission)

was very limited. He repeated the experiments by depositing powdered carbon onto the damaged area and found, in that case, for arc tracking to occur, the applied voltage had to exceed 24 V. Below 50 V, small incandescent spots could be produced but not flaming ignition. Flaming ignition was readily possible for voltages of 100–150 V. Above 200 V, flaming ignition readily occurred, but increased char lengths were not obtained since the events were explosively forceful and blew off the carbonized material and the melted conductor portions. Under other conditions, much less than 24 V is sufficient to cause arc tracking. Bernstein [33] reports that arc tracking can occur in 6 V battery circuits, provided the battery has sufficient current capacity to sustain the arc. Arc-tracking problems have been troublesome in a variety of models and types of motor vehicles in circuits operating at around 14 VDC (nominal 12 V) [7].

For polymers, the molecular structure is the main determinant of arc-tracking propensity [34]. Aliphatic polymers (e.g., polyethylene, PTFE) tend not to undergo arc tracking, whereas aromatic ones or ones containing alternating double bonds (e.g., phenolic, polyethylene terephthalate, polystyrene) do because the latter, when pyrolyzed, leave residues that are electrically conductive or semiconductive. Also tending to exhibit arc tracking are polymers that, although lacking aromatic rings or double bonds originally, form rings or double bonds during thermal degradation; PVC and polyacrylonitrile are examples.

It was also found that oxygen is not a requisite for the formation of arc tracks and that materials can be made to arc-track in a nitrogen atmosphere. Generally, arc tracking can only happen if a polymer can char, since a conductive track can only be established in char. Practical difficulties arise in evaluating this because charring is not an absolute property of polymers but, rather, depends on environmental details. It has also been found [35] that arc tracking is promoted by the presence of halogen atoms in the polymer. Conversely, alumina trihydrate ($Al_2O_3 \cdot 3H_2O$), a common filler for many polymers, is highly effective in reducing the arc-tracking propensity in certain polymers [36, 37].

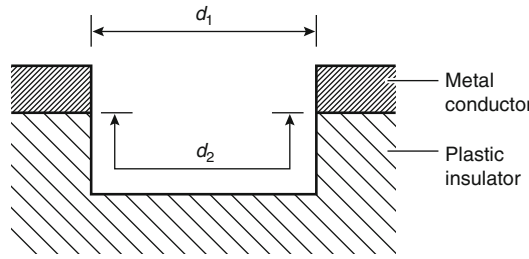

Fig. 22.9 Simplified view illustrating clearance and creepage distances (From Ignition Handbook, used by permission)

Most research studies have not focused on the time element and none have done so in a systematic way. The minimum current needed, however, has been studied. Wilkins and Billings [38] obtained the following minimum values: PVC 0.15–0.20 mA, PVA 0.3 mA, Ebonite (butadiene/methylstyrene rubber) 1.1 mA, phenolic/paper 1.15 mA, polycarbonate 1.2 mA, and PTFE 2.3 mA.

Creepage In design, the resistance to arc tracking is controlled by two means: (1) selection of well-performing insulation materials, and (2) observing adequate creepage distances. The latter concept is illustrated in Fig. 22.9. For arcing in air from metal to metal, the governing distance is called the clearance distance, d_1. But since arc tracking proceeds only along solid surfaces, the distance across which arc tracking must travel, if failure is to occur, is called the creepage distance, d_2. Creepage distances are set down in numerous military and industrial specifications, but the rationale is usually empirical and not much scientific research is available on the topic.

Surface Flashover

Fire protection engineers need to be aware that the term *flashover* is used in a very different way in electrical engineering, where it means "a discharge which occurs over the surface of a solid dielectric in a gaseous or liquid medium." [39]

The dielectric strength of air is lower than that of any commonly used electrical insulators, so if the path through air and the path through a solid insulator are of similar length and breakdown occurs, it will go through air, not through the solid insulator. The surface of an insulator may become polluted so that its breakdown strength becomes low; this problem is common in locales exposed to salty air near the sea. The material with the lowest breakdown strength may be this pollutant film and, if breakdown occurs along this film, it is referred to as "surface flashover." This reaction does not constitute arcing across a carbonized path, since the path, although of low breakdown strength, is not carbonized. The problem is relevant only to high-voltage (HV) circuits and would be a source of ignition only in the vicinity of HV installations.

Overloads and Related Phenomena

Gross Overloads Excessive overload can lead to fires, but this condition is much rarer than is an arcing fault. It can arise if either a circuit breaker is faulty or a cable is used that is of much smaller gauge than is the rating of the circuit breaker. Both of these situations are relatively uncommon. Ampacity ratings of wires and cables are conservative enough that an overload of roughly 2× is not expected to create any significant problems, at least in the short term (long-term thermal degradation of insulation material is a separate issue).

If a sufficiently overloaded condition persists, then cables may be able not just to ignite but also to create a propagating, self-sustained fire. Experimental studies [7] indicate that, for this event to occur, the current carried must be 300–700 % of the rated current (ampacity). However, all existing tests have been short-term. Even a current at 200 % of rated ampacity, if sustained for a protracted period of time, may deteriorate the insulation enough so that carbonization can begin. Eventually, failure may not be the melting and shorting commonly involved in ignitions from short-term overloads but, rather, some form of tracking damage.

Ignition in the excessive-overload mode is unlikely to occur if the cable is in a circuit that is protected by a circuit breaker/fuse correctly matched to the rating of the cable, since tripping would occur rapidly under 3× and greater overloads. But ignitions can readily occur if a much smaller gauge cable is used than corresponds to the rating of the circuit breaker. An overload may not directly ignite an insulated wire but may significantly raise the temperature of both the wire and the insulator. Old-style rubber-insulated wires used to be prone to a sleeving effect, whereby insulation closest to the wire is thermally degraded and shrinks back from the conductor.

For wires insulated with thermoplastic insulation (including the majority of today's common cable types), a somewhat different effect is found. Elevated temperatures cause copper to elongate but the insulation to shrink. As a result, copper wires readily "pop out" of the softened insulation. A direct metallic contact can then occur, with this short circuit being a localized place of ignition [7]. By contrast, if a PVC-insulated cable is externally heated (by fire or otherwise), it usually chars rather than melts. But melting, rather than charring, may occur if the external heating is with a very low heat flux [40], below about 15 kW m^{-2}. Bubbling of thermoplastic insulation has been experimentally found only to occur from overcurrent and not due to external heating [40].

Excessive Thermal Insulation Ampacity ratings for cables are based on a certain amount of convective cooling being available, which can be defeated by thermal insulation. Thus, even if the current passed through a cable is within its rating, embedding it in thermal insulation can cause the temperature to rise to values that are no longer reasonable for the particular class of insulation used. If, in addition, an overload condition is created, the heating can be greatly exacerbated. Bunching of cables together can also lead to overheating, since ampacity ratings envision only a limited aggregation of adjacent conductors. Goodson et al. [41] observed a house

during construction where charring damage was already found on bunched NM cables. Thus, they ran wall-cavity tests using bunched, 90 °C-rated NM cables and obtained charring when the stud cavity was insulated with polyurethane foam insulation.

Prior to World War II, knob-and-tube wiring was common in the United States. This form of wiring uses two separate conductors that are not grouped into a cable but are individually strung on widely spaced porcelain knobs. The current-carrying capacity of this form of wiring is dependent on there being unobstructed air cooling of the wires. Fires have occurred when the wires were buried in thermal insulation. A similar problem can be encountered when extension cords, which are rated for exposed-air use, are buried under thermally insulating objects or else are coiled in multiple layers on a cord reel while carrying a high current but one still within the nominal rating.

Stray Currents and Ground Faults Stray currents occur when circumstances cause current to flow through paths not intended to carry current. Ground faults are a well-known example [42]. They can occur if a conductor is abraded or damaged and contacts metal siding, roofing, and so on. Kinoshita et al. [43] documented that a current of only 5 A was required for ignition when a three-conductor, PVC-insulated cable contacted a galvanized iron roof. The Consumer Product Safety Commission (CPSC) has hypothesized that the Beverly Hills Supper Club fire, one of the deadliest U.S. fires of the twentieth century, was made possible by improper wiring of the neutral conductors and triggered by a ground fault that occurred [44].

If a building has conductive components throughout it, such as metal lath, aluminum siding, an electric fault can result in an electrified house, leading to multiple ignitions [7]. The fault is commonly contact with HV wiring.

An unusual mode of ignition from a ground fault is where current flows through a gas line. The current can cause overheating of the metal and lead to a rupture of the pipe [45].

In recent years, a related problem has been fires or explosions in houses due to use of CSST (lightweight corrugated stainless steel tubing) gas piping instead of black iron [46]. These products proved to be particularly susceptible to puncturing by lightning strikes, which do not need to be direct enough to cause other damage. Gas escapes from the small holes created and a gas explosion or a house fire ensues. In cold climates, it is not rare for individuals to thaw a frozen water pipe by attaching a welding transformer and passing current through it. Fires have resulted due the very large currents that are involved [47].

Overvoltage, Floating Neutrals, and Surges Ignitions from an overvoltage is relatively rare, as concerns branch-circuit wiring. The materials used for wires and wiring devices are well able to withstand the normal surges that are a regular event in a power distribution system. To experience ignitions, one of the following events is generally needed:

1. Lightning strike
2. Accidental delivery of high voltage into low-voltage wiring
3. A floating neutral
4. A large voltage spike (surge)

Lightning strikes can result in massive ignitions, not just of wiring but also of all sorts of combustibles.

Occasional fire reports are encountered in which, due to some malfunction in the power distribution network, high voltage got applied to wiring intended to carry only 120/240 V. A case is documented [48] in which a utility transformer fault caused all the ground-fault circuit interrupter devices in a house to fail, along with igniting a fire due to an explosion of a TV set. In another case, a faulty transformer caused the service entrance wires to ignite and burn inside a house. A systematic study of such fires does not exist, but ignition should be considered very likely any time that such a failure occurs.

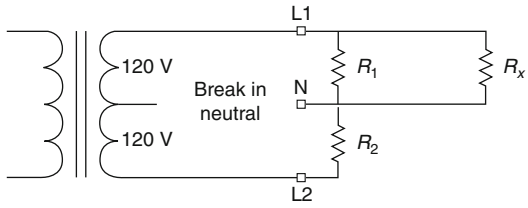

Fig. 22.10 Floating neutral (From Ignition Handbook, used by permission)

A floating neutral (sometimes called *open neutral*) can lead to ignition in 120/240 V wiring circuits due to a special nature of that circuit topology.[2] In a single-phase service entrance, there are three current-carrying wires: two hot wires and one neutral. Figure 22.10 illustrates the normal feed from an outdoor transformer to a building. Inside the building, the system becomes effectively a four-wire system, since a safety grounding wire is also run that is connected to the neutral and terminates at a ground rod.[3]

All 240 V loads are directly connected across L1 and L2 and do not depend on the presence of the neutral. But 120 V loads are connected across N and either L1 or L2. If a neutral is in place, the loads will receive the intended 120 V voltage. However, if a break occurs in the neutral, the voltage delivered to 120 V loads can swing widely, in principle from barely above 0 to almost 240 V, although in practice the range is not quite as large. Figure 22.10 shows the circuit arrangement. The voltage present across a particular load R_x will be determined by the voltage divider action of other loads in the system, designated as R_1 and R_2. The voltage across R_x will be

$$V_x = \frac{240}{1 + \frac{R_2}{R_1} + \frac{R_2}{R_x}}$$

Most electrical or electronic equipment can ignite if a voltage much in excess of the intended one is fed to it. Conversely, most devices will not ignite if the voltage delivered to them is too low. Electric motors, however, are an exception, and flaming fires can result from certain motors running at a sufficiently undervoltage condition.

An ignition due to undervoltage can also occur if one hot leg of a 240 V circuit is disconnected. If the circuit has any 240 V appliances and these are energized, then they can transfer power from the live leg to the disconnected leg. But the delivery will be through a sizeable resistance and much less than 120 V will be delivered.

The preceding discussion ignored the presence of the ground wire. According to The *National Electrical Code* [49], a grounding electrode must be connected from the neutral to an earth ground at the service entrance. But, provided that the neutral is functioning properly, this ground wire serves no observable function. Consequently, there may be little to prevent its deterioration or abuse over the years. If a break in the neutral then occurs, a sizable current can flow through the ground wire. If the ground wire passes near or through combustibles, and an excess current ends up flowing through it, then an ignition might occur at that place. Fires have also been reported [50] in installations using armored cable when a floating neutral occurred and current that would normally flow through the neutral instead flowed through the armor.

Surprisingly large voltage spikes can be found on 120/240 V systems. Without any overt fault conditions, simply the operation of a motor controller can create a 2,000–3,000 V spike [51]. The majority of voltage surges, however, are due to external—not in-premises—factors. The primary causes are lightning, electrical utility switching transients, and failures of components in the high-voltage electrical transmission system [19].

To evaluate the role of voltage surges, it is essential to recognize that there is a fundamental dividing-line voltage. Surges above approximately 6,000 V(peak) lead to a "sparkover of clearances" widely throughout the house. In other words, the householder will typically find the majority of outlets and other electrical devices have suffered calamitous damage, and

[2] The discussion here is based on electrical practice in North America.

[3] Mobile homes normally have a four-wire service from pole to building.

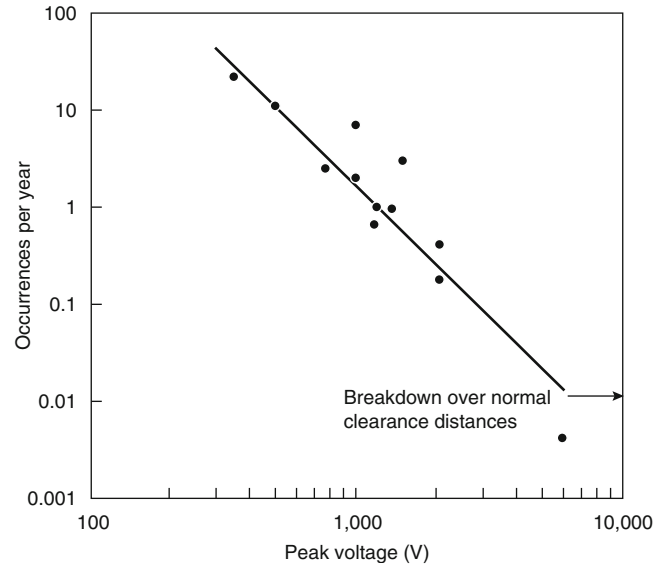

Fig. 22.11 Surge voltages experienced in branch-circuit wiring

possibly multiple fires were ignited. Conversely, surges below about 6,000 V(peak) will generally appear benign. But appearances may be deceiving in the case of surges that are in the kilovolt range but below 6,000 V. The 6,000 V value corresponds to the level at which wiring devices[4] that are properly designed, installed, and operated will typically suffer a breakdown. But devices that have a manufacturing or installation defect may break down at less than 6,000 V. The hazard comes about if that breakdown is not visually obvious (e.g., concealed inside a wall or within plastic).

A breakdown of plastic insulation will lead to the formation of a carbonized path along which the discharge occurred. As explained earlier, once a carbonized path is formed that extends electrode to electrode, arc tracking can start. The process is slow, although an exact time frame has not been established. In one documented case, electrical fires due to this cause occurred after a modest lightning strike struck a house that did not initially lead to fire or widespread visible electrical damage. The fires erupted about 4 months after the lightning strike [19]. In the case of breakdown of insulation due to below-6,000 V surges or spikes, a delayed fire can occur in the following two ways:

1. The initial fault clears itself and the circuit breaker is not tripped (or fuse not blown).
2. The circuit breaker trips, but the householder resets it, and operation seems "normal."

In either case, after a certain period in which arc tracking progresses unnoticed, fire breaks out.

It should be noted that applying Paschen's Law to clearances typically specified by electrical standards, it would be expected that widespread sparkover of clearances would require about 6,500 V(rms) or 9,200 V(peak). The empirical observation that 6,000 V(peak) is typically sufficient evidently reflects the fact that devices in the field do not quite behave as ideally as their laboratory testing would suggest.

The 6,000 V(peak) value is vastly greater than the operating voltage of $120\sqrt{2} = 170$ V(peak). But such peak voltages are not rare, as indicated by several field studies. Figure 22.11 indicates that an individual house would expect to suffer such a surge roughly once every 100 years [19]. Thus, the risk for an individual house is

[4] This refers to outlets, plugs, and similar devices. Electric and electronic appliances are often designed to much less stringent standards and may fail or start burning at significantly smaller surge levels.

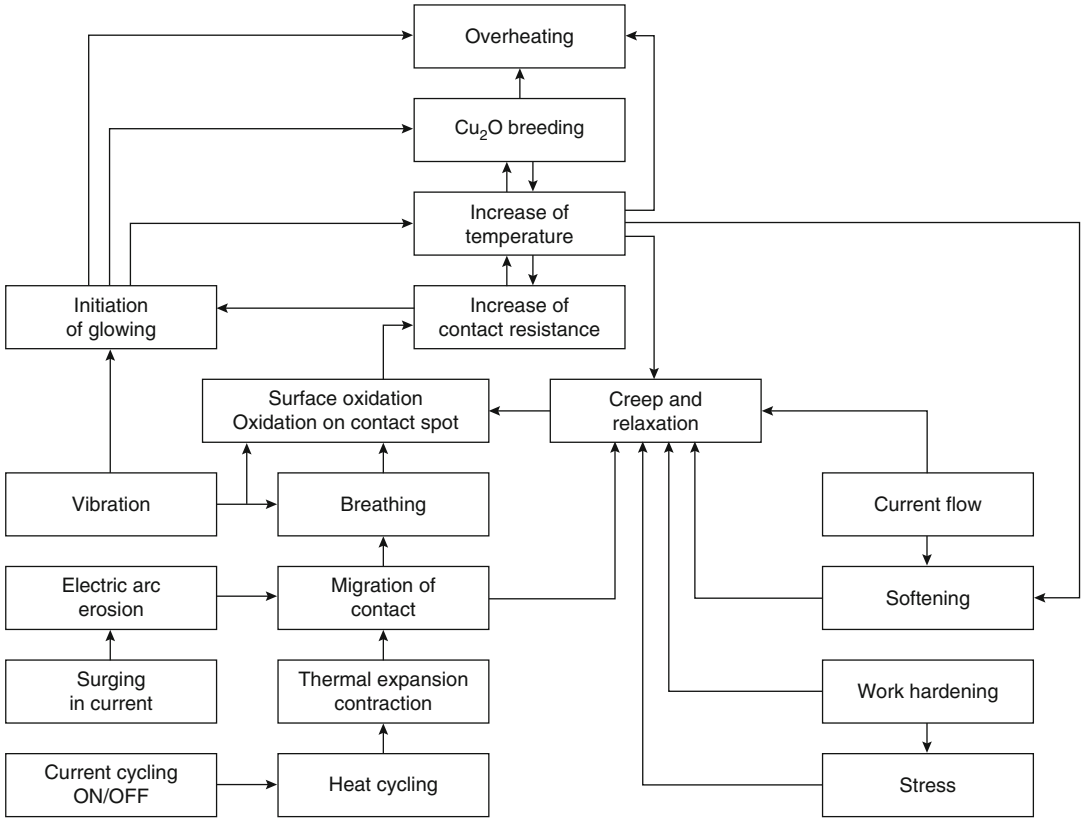

Fig. 22.12 Mechanisms for overheating at electrical connections, as outlined by Kuroyanagi et al [52] (From Ignition Handbook, used by permission)

low, but within a given community there can be a number of such events every year. It must be noted that the field studies were all completed before the current era of widespread use of surge suppressors. Thus, houses where a sizable number of surge-suppression devices are used can be expected to be at lower risk than these statistics indicate.

Overheating Connections

Failures of electrical connections are generally due to manufacturing defects, installation defects, design defects, abuse, damage, or environmental effects. In addition, it can be expected that much like any other mechanical device, an electrical connection will have a finite lifetime, but—apart from the aluminum-wiring problem discussed later—there currently exist no useful studies on this point.[5]

The physics and chemistry of electrical connections are very complex, as illustrated by the phenomenological flowchart put forth by Kuroyanagi and coworkers [52]. From Fig. 22.12 it can be seen that numerous phenomena are involved, but not all have been studied systematically and in detail. In the simplest terms, failure can be understood to involve the following factors:

- Localized heating takes place, due to smaller effective area available for current flow compared to a bulk, undamaged conductor.

[5] The NFPA Research Foundation is currently conducting a study on aging electrical wiring and there may be conclusions obtained from it concerning the potential lifetime of electrical connections.

- Heating accelerates oxidation and promotes creep.
- Creep causes relaxation of the mechanical forces restraining the connection, leading to fewer micro-areas through which effective current flow can take place.
- This relaxation further raises the temperature, which further accelerates oxidation.
- Oxidation diminishes the area through which current can readily flow.
- Expansion and contraction from thermal cycling may cause further loosening. This may cause certain areas of micro-contact to make and break, while a more severe effect entails irrecoverable plastic deformations. Thermal cycling may be due to ambient temperature fluctuations, or due to fluctuations in current, leading to changes in I^2R heating.
- The presence of moisture or corrosive gases in the environment can accelerate failure due to additional chemical degradation. In the case of PVC insulation, once sufficient overheating takes place, HCl gas will get liberated from the plastic, and this is highly corrosive.
- The presence of vibrations also serves to make and break micro-contact areas, resulting in worsening of the connection.

The simplest theoretical model of an overheating connection is obtained by assuming that heat is produced at a constant rate in an infinitesimally thin plane section across the wire. The wire is represented as a cylinder without any change of geometry at the point of connection [53]. The solution for the temperature of that cross section is

$$\Delta T(t) = q'' \sqrt{\frac{r}{2\pi\lambda h}\gamma\left(\frac{1}{2}, t/\tau\right)}$$

where

q'' = Power density at the plane section (W m^{-2})
r = Radius of the wire (m)
λ = Thermal conductivity of the wire (W m^{-1} K^{-1})
h = Effective heat transfer coefficient from the surface of the wire (W m^{-2} K^{-1})
γ = Incomplete gamma function [54]

and the time constant τ (s) is given by

$$\tau = \frac{r}{2}\frac{\rho C}{h}$$

where ρ = density (kg m^{-3}) and C = heat capacity of copper (J kg^{-1} K^{-1}). The equilibrium value of the temperature rise is

$$\lim_{t\to\infty} \Delta T(t) = q'' \sqrt{\frac{r}{2\lambda h}}$$

As an example, for a copper wire of 14 AWG, $r = 1.63/2 = 0.815$ mm, $\rho = 8{,}890$ kg m^{-3}, $C = 385$ J kg^{-1} K^{-1}, and $\lambda = 400$ W m^{-1} K^{-1}. Assuming that $h = 50$ W m^{-2} K^{-1}, and that 10 W is dissipated in the connection, giving $q'' = 10/\text{p}r^2 = 4.8 \times 10^6$ W m^{-2}. Then

$$\Delta T(\infty) = 4.8 \times 10^6 \sqrt{\frac{0.815 \times 10^{-3}}{2 \times 400 \times 50}} = 685$$

If the ambient temperature = 20 °C, then the temperature at the overheating connection will be 20 + 685 = 705 °C, which is much higher than the ignition temperature of most combustibles. This theoretical treatment is highly simplified; nonetheless, it indicates that very high temperatures can be anticipated.

In the early stages of failure, bad connections give little external evidence of their deteriorating condition. It is sometimes considered the infrared (IR) thermal imaging can be used as a preventive maintenance operation, since the technique can graphically show hot spots. However, research studies have shown that this is not possible until very late in the process [55]. In the earlier stages, the cool metalwork surrounding the overheated spot essentially preclude finding and identifying the spot.

Evidence of overheating is clear when mechanical connections between two current-carrying conductors start to show glowing. Normally, good electric connections should not be subject to a temperature rise much in excess of that for the conductors themselves. This depends on the connection having a very low resistance. Most metals that are used for carrying electrical current are subject to oxidation when exposed to

atmosphere. The metal oxide film formed on the surface has a very high resistivity. Thus, a connection where the mating parts are oxidized will be a high resistance connection and will overheat if significant current is passed through it. Temperatures of a glowing connection vary widely, but peak values at the hottest point have been measured from 1,100 °C [56] to 1,500 °C [57, 58], for copper connections. Temperatures up to approximately 300 °C have been measured on metal parts some distance away from the hot point [54]. Even though copper melts at 1,083 °C, much higher temperatures can be found, since the hottest portion is on the metal oxide which is being formed and not on the metallic copper.

One of the earliest studies on glowing connections was published [59] in 1961 (Fig. 22.13) and it was found that the connection acts as a nonlinear circuit element. For currents over 10 A, drops of around 2 V were found. But for small currents, voltage drops in the tens of volts can be found. At a maximum current of 20 A, 50 W is dissipated in a copper/brass connection and around 35 W for copper/iron. The study also noted that the power dissipation depends only on the materials involved and not on the nominal size of the contacts.

The Cu_2O breeding process at a glowing connection has been studied by several Japanese research groups [60, 61], that provided numerous details of this complex process [7]. One of the things learned was that the process is primarily confined to solid conductors; significant currents are hard to sustain at a glowing connection of a stranded wire—the wire tended to break at the point of heating.

Overheating can occur in electrical connections of all types, but historically the most notorious case was that of *aluminum wiring* during the early 1970s. In the late 1960s some U.S. house builders introduced a cost-cutting measure whereby aluminum was substituted for copper conductors in house-wiring branch circuits. This substitution was done without adequate research or field-testing and the outcome was a rash of house fires. The Consumer Products Safety Commission and the National Institute of Standards and Technology (NIST) conducted extensive studies on the phenomenon and found that the problem occurs due to a combination of metallurgical factors including creep, hardness,

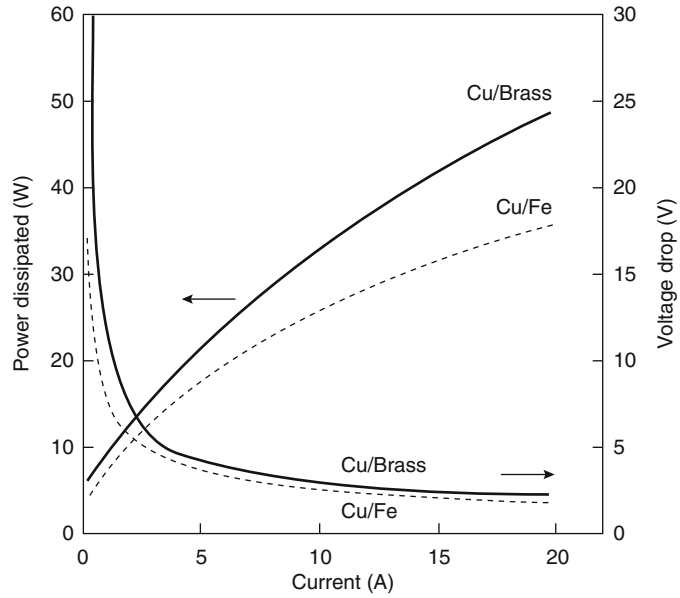

Fig. 22.13 Power dissipation and voltage drop across glowing connections of two types (From Ignition Handbook, used by permission)

and oxide characteristics [7]. The outcome is that small-diameter aluminum wires[6] cannot be reliably terminated by a screw connection and show rapid deterioration and failure. Details concerning the failures of various specific types of electrical connections can be found in the *Ignition Handbook* [7].

Ejection of Hot Particles

Electrical short circuits and arcs sometimes eject incandescent metal particles (i.e., mechanical sparks, sometimes called 'ejecta'). These particles can then ignite nearby combustible materials, especially if the material is low density or smolder-prone. The particles can be propelled a modest distance in a residential wiring situation; for instance, in one study [62] particles were found up to 1.5 m away. It has also been documented [7] that ignition-causing particles can be ejected from openings in a receptacle (which can superficially appear to be undamaged) and from within a metal box with a metal cover (since small holes are invariably contained).

Miscellaneous Phenomena

Some additional phenomena have been documented but are rare. These include harmonic distortion-caused overload, eddy currents, and dendrites [7]. Slightly less rare is the formation of adventitious batteries, which involves a potential difference created by electrochemical action when an electrolyte is present in conjunction with two dissimilar metals. This process sometimes leads to a hydrogen explosion, since the electrolysis process separates water into hydrogen and oxygen [7]. Numerous studies have been published examining the possibility of very strong radio-frequency fields causing sparks and ignition of flammable atmospheres, but it does not appear that any actual incidents have been reported [7].

Time for Fire to Initiate from an Electrical Cause

One area in which research is seriously lacking is for the time frame associated with electrical fires. In some cases, such as a major lightning strike or a high-current arcing fault in a 480 VAC busbar, the ignition may be essentially immediate. But in the case of the most common faults—a bad connection or arcing across a carbonized path—overt ignition usually takes a long time after the initial conditions were established for the fault. These processes are qualitatively known to be of long term, but means for quantification do not currently exist.

Static Electricity

General Principles

Static electricity represents electric charges that are notionally static; that is, they are collected on a surface and are not continuously flowing in an electrical current. The steps involved in a static electricity discharge are schematically illustrated in Fig. 22.14. For significant charge separation (sometimes loosely called *charge generation*) to

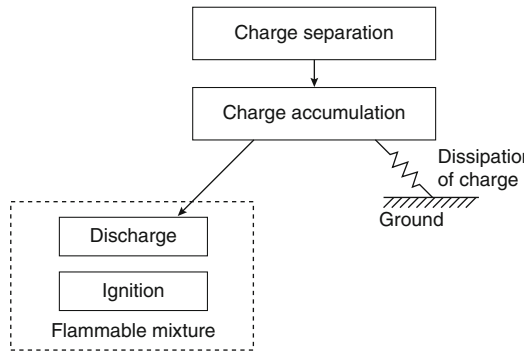

Fig. 22.14 Static electricity fundamentals (From Ignition Handbook, used by permission)

[6] The problem is only pertinent to small-diameter, 10 AWG (2.588 mm) or smaller, conductors; service-entrance cables and other large-diameter aluminum conductors can generally be reliably terminated.

occur, at least one material must be involved that is an electrical insulator. An electrical insulator is considered to be a substance that has a resistivity above about 10^8 Ω-m, which includes most organic substances.

Means by Which Charge Separation Occurs

Electric charge may be separated by the following means [7]:

1. Contact and separation or friction between solids
2. Relative motion at a phase interface (liquid–solid, liquid–gas, or between two liquid phases)
3. Induction (whereby charge is moved due to the presence of an electric field), also sometimes termed *polarization*
4. Ion collection from a discharge process (e.g., from corona discharge)
5. Double-layer charging
6. Fragmentation of solids having nonuniform surface charge densities
7. Mechanical fracture (electron emission due to strained or ruptured bonds within solids), also termed *piezoelectrification*
8. Thermal cycling (e.g., charging by freezing), also sometimes termed *pyroelectrification*

Contact or friction between two dissimilar substances can produce a charge separation if either of the two substances is an insulator. The contact may be solid-solid, solid–liquid, or liquid-liquid. The most common modes pertinent to fire ignitions are the following:

1. Contact and separation between dissimilar solids
2. Flowing powders
3. Flowing liquids

A mild amount of charging can be created simply when two surfaces come into firm contact and are then separated. Friction merely enhances the charging by increasing the effective area of contact. Traditional wisdom is that not only must the materials be dissimilar, but that sizable charging will take place only if they are far apart on the *triboelectric series*, which is a rank-order listing of materials according to how much of a negative or positive charge they tend to collect [63]. The triboelectric series is determined by the material's dielectric constant [64], however, current understanding is that electrification is not precluded in contact between objects made of the same material. Thus, plastic chips falling down a chute made of the same plastic are known to be able to undergo electrostatic charging [65]. It is believed that this may involve both physical factors (e.g., stresses at the surface) and chemical factors (contamination).

Electrification due to ionized gases flowing past surfaces can arise, but if the gas is at normal temperatures (i.e., not a hot plasma) and is not contaminated with solid or liquid particles, then the charging that can be achieved is trivial, amounting to less than a volt [66]. Gases that contain solid–liquid aerosols or gas streams that generate liquid or solid particulates (e.g., the discharge of a CO_2 extinguisher, the rapid evaporation of liquid propane) can pick up a sizable charge, however.

For certain materials, moisture in the air promotes the dissipation of charge since it decreases the electrical resistivity of some materials; it never affects the separation of charge. For many other materials, however, the resistivity is not lowered due to atmospheric moisture. Adding vapor-phase moisture does not actually change the electrical conductivity of the air; adding a mist or spray, however, raises the conductivity [67].

Discharge Types

Discharges of static electricity can involve the following geometries:

- Discharge between two conductive electrodes
- Discharge involving one conductive electrode and a diffuse insulating medium
- Discharge from one mist or cloud to another

Apart from events taking place solely in the atmosphere (which are considered later in the section called "Lightning"), discharges involved in accidental ignitions are classified as the following:

1. Spark
2. Corona discharge
3. Brush discharge
4. Powder heap discharge
5. Propagating brush discharge (Lichtenberg discharge)
6. Lightning-like discharge

Additional details on discharges are given in the *Ignition Handbook* [7] and by Britton [68].

Spark

A normal electric spark discharge occurs through the air separating two electrodes when the electric field reaches a value of approximately 3 MV m^{-1}. Thus, for a gap distance d, the voltage V required is $3d$, where V is in megavolts and d is in meters. For a spark to be incendive, the gap distance normally must be equal to or greater than the quenching distance. Considering 2 mm as a typical quenching distance, the voltage required is on the order of 6 kV. Up to about 1,000 mJ can be delivered in a static-discharge spark. This is a sizeable amount of energy, well beyond the minimum ignition energy (MIE) of most substances. Spark discharges are distinguished from other electrostatic discharges in that breakdown occurs across the *whole* gap separating two electrodes.

Corona Discharge

A corona discharge (sometimes called *point discharge*) is a slow, diffuse discharge that originates at a metallic electrode and branches out in a diffuse manner into space or towards poorly conducting surfaces. A corona discharge requires an electrode that has a needle-like point, typically less than 5 mm diameter. Charging such an electrode results in an electric field which is distorted, being generally low, but much greater near the point. When the electric field exceeds the local dielectric strength, breakdown occurs. Corona discharge has the lowest energy of the electrostatic discharge types. It is visible as a violet glow in a darkened room. A corona discharge can also occur in the presence of second electrode, but is still considered a 'one-electrode' discharge since the discharge does actually reach the second electrode. A minimum voltage of about 2–6 kV is necessary for a corona discharge to occur, with smaller potentials needed for finer-pointed needles. The maximum energy normally realizable from a corona discharge—not much over 0.01 mJ—would even theoretically suffice to ignite only the most ignitable of gases, such as CS_2 or H_2. However, actual ignition requires that the energy be delivered into a small kernel, and the diffuse nature of a corona discharge precludes that. Corona discharges are often used in processes and machinery as a safety measure for lowering charge accumulation.

Brush Discharge

When a grounded conductor is brought into an electric field that is near its dielectric breakdown strength, a gas discharge can occur in the form of a brush discharge. The discharge is able to occur because of electric field distortion introduced by the electrode, which locally raises the field above its breakdown value. The name comes from the brush-like shape of the discharge. It differs from a corona discharge, in that the latter is visually observed to be diffuse. A brush discharge is similar to corona discharge in being a low-energy, one-electrode discharge, but whereas a corona discharge requires a needlelike electrode, a brush discharge occurs when electrodes have a radius of 5–50 mm.

The incendivity of brush discharges is proportional to the radius—larger-radius conductors are more likely to lead to ignition than ones of smaller radius. Commonly, the high electric field will occur due to the presence of a charged insulator. It is estimated that the energy from a brush discharge will not exceed about 4 mJ. In addition, most of the energy released during a brush discharge does not contribute to incendivity, since the energy is not just localized at the place where a flame kernel is formed. The high electric fields necessary for a brush discharge are readily found in many powder operations, in mists, and also with movement of plastic films.

Circumstances leading to a brush discharge can include:

- approaching a highly-charged insulator such as plastic films or plastic pipes with a finger or a metal tool;

- discharging of solids from plastic bags in the vicinity of metal parts;
- filling a tank at a high velocity with an insulating liquid, with the charged liquid surface approaching an internal fitting that can act as an electrode;
- lowering a conductive cup, etc., into a highly charged liquid;
- projection of metal parts into a cloud of highly charged dust or aerosol;
- pouring of insulating powders into silos when the fill surface approaches a conductive fitting;
- projection of ships' masts, flagpoles, or antennas into a powerful atmospheric electric field—this is known as St. Elmo's fire.

Even though about 3.6 mJ can be delivered in a brush discharge [69] and there are dust clouds that have an MIE $\approx$ 1 mJ, most studies have concluded that brush discharges will not ignite dust clouds [70], provided that the cloud is not a hybrid dust/gas mixture.

Powder Heap Discharge

In some cases, when rapidly filling large containers such as silos or flexible intermediate bulk containers (FIBC) with powders, a much higher charge can build up in the settled powder than was present in the air through which the material moved and a discharge can then take place. This occurs because a growing volume of powder is aggregated, plus when the powder is compacted, its charge likewise gets compacted if the powder is insulating and charge cannot get dissipated. The powder heap discharge is also called a *cone discharge* or a *bulking discharge*. It occurs along the exposed surface of the powder. A minimum particle size [71] of ca. 0.1 mm is needed for powder heap discharge to occur, but the majority of the actual incidents have involved polymeric resin particles in the 1–10 mm range.

Early recommendations used to state that up to 10 mJ can be delivered in a single discharge step. Some indirect evidence suggests that discharges as large as 1,000 mJ may be anticipated for large particles flowing into a large silo. A minimum product feed rate is needed for a powder heap discharge to occur. This has been estimated at 3,000–5,000 kg h^{-1} for 3 mm particles, rising to 25,000–30,000 kg h^{-1} for 0.8 mm particles [81]. Powders having a resistivity of less than 10^{10} Ω-m are conservatively judged to not be susceptible to explosions from powder heap discharges [72]; powders which have caused explosions have had resistivities $> 10^{12}$ Ω-m.

Propagating Brush Discharge

A very vigorous discharge can occur when certain conditions are met for the charging of a surface. There is a limit to the amount of surface charging that can be sustained on a surface without discharging by ionizing the air (2.65×10^{-5} C m^{-2}). This limit can be increased if a double layer of charges of opposite polarity is accumulated.

A way for this to occur is when an insulating layer is directly on top of a grounded metallic layer. This allows opposite polarity charges to build on the second side of the insulating layer (Fig. 22.15). Under those conditions, the maximum surface charge is governed by the breakdown strength of the insulator, which may be on the order of 20–40 MV m^{-1}, instead of the 3 MV m^{-1} for air.

In addition, the dielectric constant of many common insulators is 2–4 times that of air. These two factors combine to give maximum surface charges of around 5×10^{-4} C m^{-2}, and

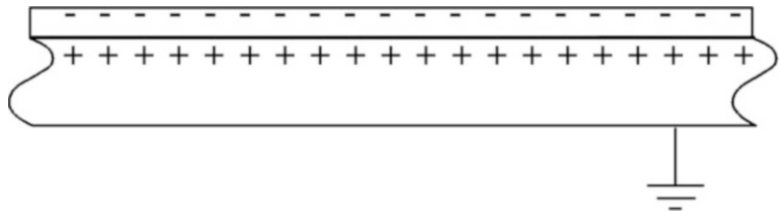

Fig. 22.15 Double-layer charging (charge pairing) occurring when a charged insulator is adjacent to a grounded conductor

it is considered that 2.5×10^{-4} C m^{-2} is the minimum surface charge needed for a propagating brush discharge. With very thin films of certain plastics, surface charge densities up to 8×10^{-3} C m^{-2} have been measured [73].

A propagating brush discharge can ignite most flammable mixtures, including dust clouds. A discharge occurs in one of two ways: (1) a grounded electrode is brought near the charged insulator surface; or n a dielectric breakdown of the insulating layer, resulting in a local puncture. A minimum voltage of ca. 4 kV is needed for a propagating brush discharge to occur with very thin films (10–20 μm) rising to 8 kV for 0.2 mm thick ones. Up to ca. 1,000 mJ can be delivered in a propagating brush discharge.

Circumstances leading to a propagating brush discharge can include:

- conveying an insulating powder at high velocity through plastic pipes or bins that are grounded on their exterior;
- conveying an insulating liquid at high velocity through plastic pipes that are grounded on the outside, or metallic pipes that have an insulating interior coating;
- loading of insulating powders into large, non-conductive silos;
- high velocity operation of conveyor belts that have metallized outer surfaces and an insulating core;
- repeated collisions of dust particles on an insulating surface atop a grounded layer.
- In some cases, a propagating brush discharge can occur without an overt grounded layer, for instance when rain is falling on a plastic pipe conveying an insulating powder [74].

Lightning-Like Discharge

Lightning in the atmosphere can occur when water droplets and ice particles are charged to very high potentials. Since particles in dust clouds will also pick up an electric charge, lightning-like discharges have been observed to occur in the dust clouds formed during volcanic eruptions. What is unanswered is whether such discharges can occur on a smaller scale, to wit, in connection with storage silos. A number of accidents have been blamed on such discharges, but the details of the circumstances have never been clear. Lightning-like discharges would presumably be able to ignite almost any combustible matter, so the conditions—if any—that might lead to such lightning would be important to quantify.

Electrostatic Charging and Discharging of Solids

For simple geometries, the amount of charge that an isolated solid can accumulate and the voltage to which it can be charged can be computed [7]. The maximum charge density, σ_{max} (C m^{-2}), that can be built up on the isolated object is given by:

$$\sigma_{max} = \varepsilon \varepsilon_o E_{max}$$

where ε = dielectric constant (–), ε_o = permittivity of vacuum (8.854×10^{-12} S s m^{-1}), and the abbreviation C denotes coulombs, whereas S denotes Siemens. Since the dielectric constant for air = 1.0 and E_{max}, the breakdown strength of air, is approximately 3 MV m^{-1}, then σ_{max}, the maximum charge density possible for an isolated object in air = 26.5 μC m^{-2}. If the object is spherical, then its area = $4\pi r^2$, where r = radius (m), and the maximum charge that can accumulate on it is

$$Q_{max} = 4\pi r^2 \times 26.5 = 333\, r^2 \mu C$$

Now, since voltage V is, by definition, equal to the field strength E times distance,

$$V = E_{max} r = 3.0 \times 10^6 r$$

which gives the maximum voltage to which the spherical object can be charged in air. But capacitance C is defined as = Q/V,

$$V = \frac{Q}{C} = \frac{Q}{4\pi\varepsilon\varepsilon_o r} = E_{max} r = 3.0 \times 10^6 r$$

Then the capacitance with respect to ground of an isolated sphere can evaluated as

$$C = 4\pi\varepsilon\varepsilon_o r$$

where C = capacitance (farads; F), and the symbol C here must not be confused with the unit C denoting coulombs. Assuming that no losses occur, the energy W (joules) that can be delivered from a spark discharge is

$$W = \frac{1}{2}CV^2$$

Substituting the above gives

$$W = 501r^3$$

For many hydrocarbon vapors, a value of MIE ≈ 0.25 mJ is applicable. Then, to cause an incendive discharge from a charged, isolated body, its radius must be at least

$$r = \left(\frac{0.25 \times 10^{-3}}{501}\right)^{1/3} = 0.008\,\text{m}$$

Since this limit is only 8 mm, it would be very difficult to develop a safety measure on limiting the physical size of bodies that pick up a charge. In practice, somewhat higher minimum sizes will pertain, since ideally efficient conditions will not be present for discharge. For a propane-air mixture (MIE = 0.26 mJ), a minimum radius of 12 mm was found necessary in order to have an incendive discharge [75]. Capacitance values for some common objects are given in Table 22.3.

Electrostatic Charging and Discharging of Persons

A mild shock due to electrostatic discharge is common for human beings. Such discharges can also be incendive. Shoes charge the wearer because each time the foot is raised, the capacitance to ground is decreased and charge accumulates on the person. Charging readily occurs when apparel is worn that is highly insulating and the apparel contacts and separates from external objects. The charge picked up on the apparel then induces a similar charge in the body. Although standard values are sometimes proposed for the capacitance of a human being, the actual capacitance [76] varies with the thickness of the footwear, as shown in Fig. 22.16.

The resistance of the human body [77], measured to a fingertip, is about 1,300–2,000 Ω, but if the person undergoes a discharge via a grasped metallic object, the body's effective resistance may be only 360–700 Ω.

Table 22.3 The estimated capacitance of some objects

Object	Capacitance (pF)
Buckets, small drums	5
55-gal drum	100
Automobile	500
Tank truck	1,000
Large tractor-trailer	3,000

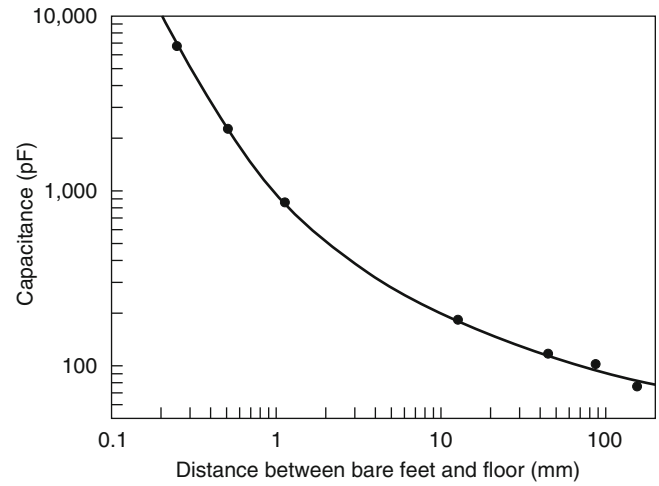

Fig. 22.16 Effect of footwear thickness on the capacitance of a person (assumed standing on a floor of moderate conductivity) (From Ignition Handbook, used by permission)

In dry air, the body can charge up to 5–25 kV, although voltages toward the high end of this range are uncommon and are limited by corona discharge. Thus, under the worst circumstances, the energy that is stored and is available for release in a spark is

$$W = \frac{1}{2}CV^2 = \frac{1}{2} \cdot 300 \times 10^{-12} \cdot \left(25 \times 10^3\right)^2 = 94 \text{ mJ}$$

If this much energy could be effectively applied, it would be enough to ignite all common ignitable vapors and also many dusts. However, more typical values of stored energy due to friction of apparel are 5–20 mJ. A value of 25 mJ has been adopted by a British standard [78] as the maximum practical value needing to be considered. At an RH of 50 %, a person walking on a carpet will generate no more than about 3 kV, and for RH greater than or equal to 60 % it is impossible to create a significant voltage [79]. Thus, the problem is limited to dry atmospheric conditions.

Guidelines are also available (Table 22.4) which relate the energy discharge from a person to the sensation [68, 80]. A perceptible sensation corresponds requires that the person be charged to about 2 kV [64]. In view of the above results, discharges that are perceptible but not severe are likely to lead to ignition if the person is in a space containing a gas in its flammable range. However, since people do not generally walk around in flammable atmospheres, it is found that electrostatic discharge from humans is actually a rare cause of unwanted ignition of gases [81].

Table 22.4 Human responses corresponding to various levels of discharge energy

Energy	Response
1 mJ	Perceptible
10 mJ	Prick
30 mJ	Sharp prick
100 mJ	Slight jerk
250 mJ	Severe shock
> 1 J	Possible unconsciousness
> 10 J	Possible cardiac arrest

Electrostatic Charging and Discharging of Granular Materials

When granular materials—powders, dusts, grains, and so on—are in motion, they can pick up a charge. Insulating powders—those with a resistivity greater than about 10^{12} Ω-m—do not easily dissipate a surface charge they may acquire and, thus, can be prone to spark discharges. This is especially a problem if they are conveyed or stored in insulating pipes or silos. The tendency for powders to pick up a charge is roughly proportional to their surface/mass ratio (or inversely proportional to particle diameter). The resistivity of powders changes drastically with moisture. At conditions of RH greater than 60–65 %, any charge formed is rapidly leaked away and hazardous conditions would not be expected [82].

Discharging of dry chemical (sodium bicarbonate or ammonium phosphate/ammonium sulfate) fire extinguishers can cause static electricity buildup. It was found experimentally that this can result in charging voltages that would correspond to discharge energies of up to 54 mJ [83]. Energies of this magnitude may ignite many dusts, not just gases.

Pneumatic transport systems cause a buildup of charge largely due to bends in the pipeline, but within a few meters of travel distance a steady-state value of charge is reached [84]. For a given air velocity, increasing the product mass flow rate decreases the charging tendency. Charging tendency is also reduced by reducing air velocity and by increasing particle size of the granular material.

Electrostatic discharges commonly occur whenever granular materials are pneumatically conveyed. These are typically nonincendive corona discharges. It is the possibility of spark discharges or other more energetic forms that forms the crux of the fire safety problem in these applications. Silos can build up very high potentials when granular materials are conveyed into them; in one study [84], up to 150 kV was measured.

During loading or conveying of powders, local non-incendive discharges (corona and possibly brush discharges) may occur which are helpful, rather, than deleterious, since they serve to reduce the charge buildup. Based on this observation, to reduce the incendivity of bulking discharges, it is commonly recommended that a grounded wire be strung through the center of a container receiving insulating powders. This causes small corona-like discharges to occur to the grounding wire, instead of large sparks to the container itself. A ground wire is equally effective if the container is insulating, instead of conductive [85]. The ground wire must be thin (around 1 mm) in order to ensure a corona-like discharge.

Electrostatic Charging and Discharging of Liquids

Many liquids are prone to undergo charge separation when they move past either a solid surface or the interface with another liquid. If a sufficiently high charge is accumulated, an electric discharge may occur. This discharge may cause an ignition under appropriate fuel-air ratio conditions. Charge relaxation readily occurs if the liquid has a high electric conductivity and for such liquids a high charge does not build up. Unfortunately, many organic liquids (i.e., aliphatic, aromatic, and cyclic hydrocarbons; ethers; some silicones) are good insulators (Table 22.5). Liquids with conductivities less than 5×10^{-11} S m^{-1} are considered to be of low enough conductivity that electrostatic hazards must be carefully guarded against. However, if the conductivity is extremely low, then ionized species that could cause charge buildup are also largely absent. Liquids with a conductivity of less than 10^{-13} S m^{-1} are considered to be in the latter category. Thus, the peak hazard involves liquids with conductivities from 10^{-13} to 5×10^{-11} S m^{-1}. Pure hydrocarbons do not exhibit electrostatic charging; however, even impurities at the 0.001 ppm level change this

Table 22.5 Electrical conductivity of common liquids [7]

Hazard	Example substances	Typical electrical conductivity (S m^{-1})
	Hexane	10^{-17}
Low:	Carbon disulfide	8×10^{-16}
Conductivity less than 10^{-13}	Benzene	5×10^{-15}
	Heptane	3×10^{-14}
	Xylene	10^{-13}
	Dioxane	10^{-13}
	Toluene	10^{-12}
High:	Cyclohexane	2×10^{-12}
Conductivity of 10^{-13}–5×10^{-11}	Styrene	10^{-11}
	Kerosene	1.5×10^{-11}
	Hexamethyldisilazane	2.9×10^{-11}
	Jet-A fuel	$2–3 \times 10^{-11}$
	Gasoline	10^{-10}
	Turpentine	4×10^{-10}
	Crude oils	10^{-9} to 10^{-7}
	Halogenated hydrocarbons	10^{-8}
Low:	Methyl alcohol	10^{-7}
Conductivity greater than 5×10^{-11}	Ethyl alcohol	1.4×10^{-7}
	Cetones	10^{-5}
	Water: deionized	10^{-5}
	Iso-propanol	10^{-4}
	Water: acid rain	10^{-2}

situation [86]. The presence of a small amount of water in the product can increase the electrostatic charging effect up to 50-fold.

For insulating liquids flowing in conducting pipes, the charge density (C m^{-3}) picked up is linearly proportional to the liquid's flow velocity, and the charge density reaches a steady-state value after a certain distance down the pipe, with the charging voltage being roughly proportional to the flow velocity. However, when liquids flow in insulating pipes, little streaming current occurs because the charge induced in the pipe walls does not get dissipated to ground. Flows that consist of two-phase liquids, liquids with suspended solids, or mixtures of immiscible liquids tend to build up higher charges than single-phase liquids. Charge buildup can especially increase if the liquid flows through a fine-pore filter.

When a low-conductivity liquid is in motion in a conducting pipe, not just separation but also an actual flow of charge occurs. This flow is called a streaming current and it arises because ions in the liquid tend to move with the flow, while the opposite charge on the wall dissipates to earth. For it to occur, the liquid must have a conductivity in the range of about 10^{-13}–10^{-7} S m^{-1}. Experimental studies [87] indicate that, for these liquids, the streaming current I (amperes) can be estimated as

$$I = 9.42 \times 10^{-6}(uD)^2$$

where u = velocity (m s^{-1}) and D = diameter (m). An empirical expression [88] for the charge density is

$$Q''' = 5 \times 10^{-7}\, u/D$$

Moisture and impurities can greatly increase the charge density, but experiments have to be set up carefully to illustrate this. The effect is not found unless the liquid is pumped through filters [89]; charge generation associated with tank-loading in the absence of filtering does not show deleterious effects of impurities. Metallic trash in tanks can act as 'charge collectors' and greatly reduce the charge density necessary to cause an electrostatic discharge [89]. The effect takes place since small metallic objects can be buoyed up by turbulence or by foaming of the product. The combination of filtering and splash loading was found to be highly conducive to discharges; removing either of the two factors greatly diminished the potential for a discharge. In low-viscosity liquids, splash loading by itself produces a charged foam in the tank which can lead to discharges even when the inflowing liquid has little charge on it.

Liquid sprays can cause intense static electrification; this was first observed near waterfalls in the nineteenth century and is called spray electrification [90]. The process occurs due to the presence of a double layer of charge at the liquid surface. Small pieces of material in the form of droplets removed from the surface can then possess an unbalanced charge. By this process, a water stream may ignite a flammable atmosphere, and this concern arises in operations, for example, where a water spray is used to clean equipment that was used to store flammable liquids.

Lightning

Electrical Characteristics

Lightning becomes possible because electric charge can become separated and accumulated in clouds. Clouds are highly complex entities and, even today, the physicochemical environment of clouds is by no means comprehensively understood. One theory by Ermakov and Stozhkov [91] is illustrated in Fig. 22.17.

Thundercloud formation begins when a cold air mass meets a warm one. Ionized, warm, moist air rises but is then progressively cooled at higher elevations and condensation of water vapor on nucleation centers begins. In the initial phase, condensation proceeds faster on negatively charged nuclei than on positive ones, and the upward air flux produces large-scale separation of charge and a resultant electric field. The latent heat released in condensation assists the buoyancy of the upward air current. Cosmic rays produce ionized showers of particles.

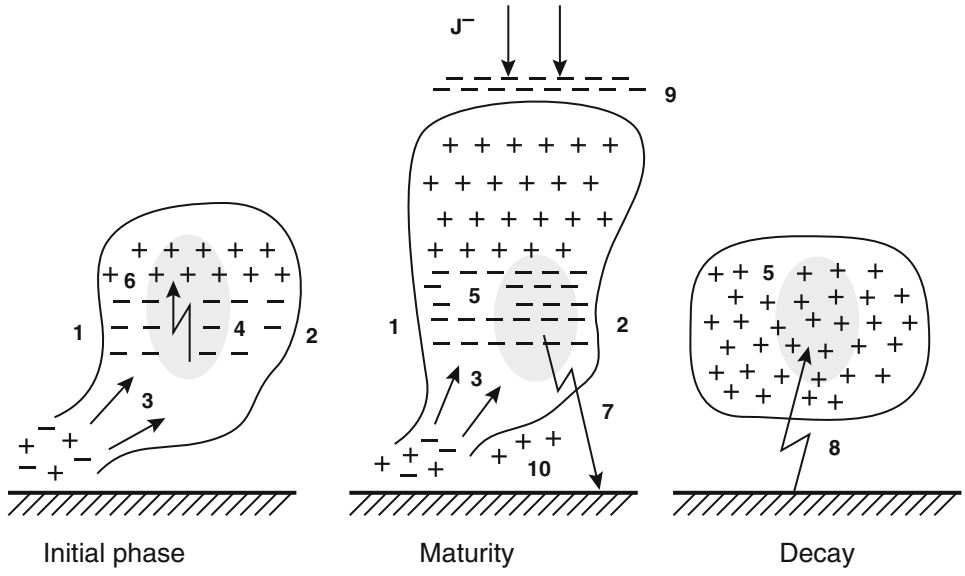

Fig. 22.17 Formation of thunderclouds as described by Ermakov and Stozhkov [91]. 1, warm air front; 2, cold air front; 3, ascending flux of wet ionized air; 4 and 5, extensive air showers produced by primaries with energies over 10^{14} eV or 10^{15} eV, respectively; 6, cloud-to-cloud lightning; 7, cloud-to-ground lightning; 8, ground-to-cloud lightning; 9, negative screen layer; 10, positive charge at cloud base; J^- current of negative ions from the ionosphere to the top of the cloud

When the electric field exceeds 0.2–0.3 MV m^{-1}, electron avalanches occur; ionized tracks link with each other and form a conducting tree structure, which allows cloud-to-cloud discharges to occur. In the mature phase, droplets grow and coagulate. There are ascending and descending airflows and the cloud becomes asymmetric with an excess of negative charge at its base. The electric field between the cloud and earth's surface increases, leading to cloud-to-ground discharges. *Thunder* is an acoustic shock wave that originates in the gas breakdown region and then propagates out through the air.

The origins of a lightning strike are due to a separation of charges in clouds. Lightning becomes possible when a potential of 10–100 MV with respect to the ground has been reached. A lightning flash is composed of several events. The actual discharge begins with the formation of the first stepped leader, which is a localized gas breakdown of about 50 m length. The process continues in a stair-step fashion until a leader gets to within about 50 m of the ground (or an object on the ground). The negative charge of the stepped leader induces a positive charge in the earth below. Protruding grounded objects start to conduct heavier point-discharge currents.

A streamer then arises from one of these objects or from the earth itself, connects to the leader, and starts a return stroke. The return stroke is the brightly visible lightning stroke. After the first return stroke, a dart leader may descend directly to the ground without stair-stepping. This dart leader is ball shaped. It will be followed by a second return stroke. There may be three or four, but occasionally many more, strokes per the total event, comprising the lightning flash. The total lightning flash may last from 0.01 to 2 s, with 0.2 to 0.4 s being typical, but each individual stroke only lasts about 30 μs. The interval between strokes may be around 40 ms.

The current carried by the stepped leader is small, only on the order of 100 A. But each return stroke will typically carry 10–20 kA of current, and peak currents in excess of 100 kA are occasionally recorded. A cloud-to-ground stroke may discharge about 25 C per stroke. The average length of a stroke is 3 km, and the average energy

released is 10^5 J m^{-1}, making an average energy release of 3×10^8 J per stroke [92].

In electrical circuit terms, a lightning stroke can be considered a constant-current source. Therefore, the energy dissipated in the object along its path is

$$\int I^2 R dt$$

where I = current (A), R = resistance (Ω), and t = time (s). This accounts for the much greater damage found for objects of poor conductivity than for metals. Design values for the current of 100–200 kA are commonly used [93] since only about 1 % of lightning strokes give currents in excess of 200 kA [92].

The current from a second or subsequent stroke is typically less than half that of the first one. When a lightning strike occurs, nearby metallic objects can have a current induced in them, including not only electrical wiring but also other metallic objects such as building beams. The electric field induced by a lightning strike of a known current value can be estimated [94] according to:

$$E = 33\frac{I}{r}$$

where E = electric field (V m^{-1}), I = current (kA), and r = distance from strike (km). Thus, for example, a strike with a current of 100 kA is expect to induce a field of 1,100 V m^{-1} at a distance of 3 km.

A *direct strike* to a building or structure is one where the ground-side termination of the lightning bolt attaches to any part of the building. A *side flash* is a strike where the lightning bolt terminates on a nearby object, but a secondary flash occurs from that locale to the building. A side flash is considered to also be a type of direct strike. An *indirect strike* is one where the main bolt terminates elsewhere, but some energy from the bolt is delivered to the building by means of power lines, metallic underground pipes, or other conductive paths.

Ignitions from Lightning

The primary damages [95] to residences from lightning are the following:

- Brick, concrete, and other solid surfaces moved or cracked
- Plumbing pipe punctures
- Holes burned or punctures in roofs
- Arc damage to metal structures such as window frames
- Arcs across wiring

The last three of these, of course, may also be accompanied by ignition of combustible materials. Because the temperature rise in an object is proportional to its resistance, a metallic object (e.g., a lightning rod) may sustain limited temperature rise, whereas a poor conductor such as wood may become ignited.

Multiple ignitions from a single strike are not rare. Whether combustibles will be ignited from a lightning flash or not depends critically on whether there is a flow of continuing current in the channel after the stroke. About 25–50 % of lightning strikes exhibit this characteristic—these are sometimes called hot bolts. Lightning strikes that are positive (i.e., the cloud being positive with respect to the ground) are much rarer than the converse, but these are precisely the ones that are most likely to cause ignitions, since their peak currents and total charge transfer are much larger. Positive flashes do not have the stepped-leader characteristic of the common, negative strikes, and consist of a single stroke, followed by a period of continuing current flow.

The probability [96] of igniting a house fire from a lightning strike is much higher if the house has plastic plumbing pipes as opposed to metallic ones. This is because the lightning current may flow to ground through a metallic pipe network, but if electric wiring is the only substantive metallic path, the current is likely to go through electric wiring, where heating will be much greater due to the smaller area of the conductors.

Safety Measures Against Lightning

The lightning rod was invented by Benjamin Franklin in 1752. This is a metallic rod which is grounded at one end and raised in the air at the other. When the initial streamers from the cloud start to form, there is not a highly specific place along the ground level where the initial return stroke is preferentially located. By providing a ground-potential conductor in the air, a preference is established, and the lightning current flows down the rod (which must be of adequate dimension in order not to overheat).

Franklin recommended that the tip of the rod (*air terminal*, in the jargon of the lightning protection industry) be pointed, because this leads to a point discharge. In earlier times, this point discharge (corona discharge) was considered necessary to 'attract' the lightning stroke. More recently, experiments showed that a smoothly rounded tip is more successful in attracting lightning to itself and avoid strikes to nearby objects [97]. The first comprehensive engineering guide to proper installation of lightning protection systems was published by Anderson [98] in 1879 and, perhaps surprisingly, few of his recommendations have been overturned by more modern research. Müller-Hillebrand [99] reviewed some of the early concepts of lightning protection.

A lightning protection system basically comprises three main components:

- air terminals
- downconductors
- ground terminals.

Franklin recommended that each air terminal provides a downward 'cone of protection,' with the cone's angle from vertical being 58°. The origin of this recommendation is unclear and it was evidently not evolved from experiments. Subsequent experience suggested that this angle is much too large, and during the nineteenth century the recommendations slowly went downward to about 30°. However, even using a 30° angle of protection, failures were documented [100]. In more recent times, Lee [100] synthesized a design method for protecting buildings, evolved from advanced calculations used by electric utilities for protection of power lines. The method is applicable only to structures of 45 m height or less and is described in the following way: Imagine a rolling sphere of 45 m radius (Fig. 22.18). The sphere starts rolling along the ground from a distance far away from the structure in question, then roll up to and over the structure and its protective air terminal(s). If the sphere only ends up touching the air terminal(s) and the ground and cannot come into contact with the structure to be protected, then air terminals of sufficient height and quantity have been erected, otherwise additional protection is needed. This more realistic protection concept is more liberal than the 30° fixed-angle scheme for low structures and more conservative for high structures. The 45 m dimension is used because it corresponds to the typical length of the stepped leader, which is about 50 m.

In view of the enormous currents of around 20,000 A that are involved in a lightning strike, it is perhaps surprising that gigantic-size

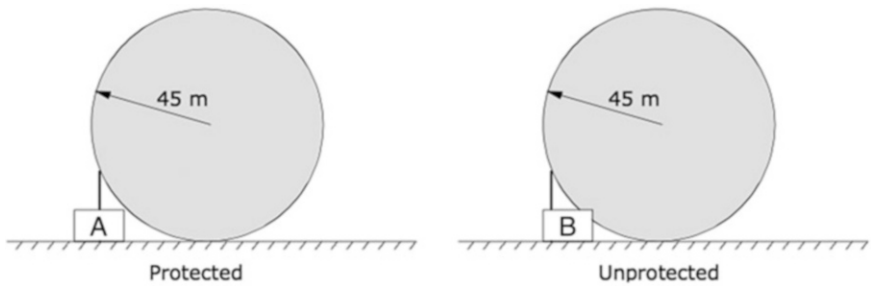

Fig. 22.18 Sphere of protection from an air terminal: structure A is protected, structure B is not

downconductors are not required to safely conduct the electricity. The minimum size of conductor does not need to be huge since the flow of current is so brief—much less than 1 s—and heating is proportional to the time of current flow. The simplest model that can predict this is the adiabatic lumped-capacitance model:

$$W = I^2Rt = \rho C_p V\left(T_f - T_o\right)$$

where W = energy (J) flowing into a piece of metal, I = current (A), R = resistance (Ω), t = time (s), ρ = density (kg m^{-3}), C_p = heat capacity (J kg^{-1} K^{-1}), V = volume (m^3), T_f = final temperature (°C), and T_o = initial temperature (°C). This assumes that the current flow is constant over the time t; if the current flow is varying, then the expression becomes:

$$W = R\int I^2 dt = \rho C_p V\left(T_f - T_o\right)$$

where R is assumed to be time-invariant and has been taken outside the integral. Applying the above relation to copper wire, ρ = 8,890 kg m^{-3}, C_p = 385 J kg^{-1} K^{-1}, $V = A \cdot L$, where A = cross-sectional area (mm) and L = length (m). The resistance of a copper wire can be expressed as:

$$R = \rho_e \frac{L}{A}$$

where ρ_e = electrical resistivity of copper = $1.7241 \times 10^{-8}\ \Omega \cdot \mathrm{m}$. The initial temperature T_o can be taken as 20 °C, while the final (allowable) temperature T_f must be set to some reasonable value below the melting point. Since the downconductor may come into contact with combustibles such as dry leaves, it seems appropriate to limit T_f to 200 °C. Based on studies of lightning discharges, $\int I^2 dt = 5 \times 10^6\ \mathrm{A}^2 \cdot \mathrm{s}$ is commonly used. The equation can then be evaluated as:

$$1.7241 \times 10^{-8}\left(\frac{L}{A}\right) \cdot 5 \times 10^6 = 8890 \times 385\,(A \cdot L)180$$

and it can be noted that the actual length of the wire sensibly cancels out of the equation. This gives $A^2 = 1.4 \times 10^{-10}\,\mathrm{m}^4$, or $A = 1.18 \times 10^{-5}\,\mathrm{m}^2 = 11.8\ \mathrm{mm}^2$. If the temperature criterion were the melting point of copper (1,083 °C), then A = 4.9 mm^2, using the same 'action integral' of $5 \times 10^6\ \mathrm{A}^2 \cdot \mathrm{s}$.

In US practice, however, a more conservative approach is taken, with conductor areas being greater than 11.8 mm^2, in order to allow for mechanical damage, some unusually potent lightning strikes, etc. The most commonly followed guidance is that published by NFPA [101]. NFPA 780 divides structures into two Classes, Class I being those up to 75 ft (22.9 m), with Class II being those higher. For Class I structures, the required downconductor area is 29 mm^2 for copper and 50 mm^2 for aluminum. The cross-sectional area required for copper conductors in Class II service is 2× that for Class I. Generally, stranded or braided conductors are used, to minimize loss of current-carrying capacity due to skin effect (this electromagnetic effect pertains to transient current flows and leads to current flowing disproportionately near the surface). A lead coating is often used to minimize loss of metal due to corrosion from flue gases. Properly-installed and maintained lightning protection systems are highly effective, with one report [102] quoting old US studies giving 99.3 % and 99.9 % effectiveness values.

For configuration of the air terminal, modern studies by Moore et al. [103] concluded that the optimum tip-height to tip-radius ratio is about 680. Thus, a rod erected at 10 m height ought to have a tip of 14.7 mm radius.

Ignition and Values of Voltage, Current, or Power

Are there minimum values of voltage, current, or power that must be exceeded for ignition to be possible? Sometimes the stance is taken that, under certain circumstances, an energized electrical device cannot be the source of a fire.

This stance is usually couched in terms of power but has also been couched in terms of current or voltage. For example, some authors [104] claim that ignition is not possible for devices that cannot consume more than 20 W. Certain UL standards [105] consider the limit to be 15 W. A more conservative view [106] is "several watts." Such a limit would be attractive in that it can simplify such standards, but there does not exist a research basis that would support these notions.

Instead, research findings indicate that minuscule values may suffice, ones that are so low as to not form a useful criterion. For example, some flammable gas mixtures can be ignited by arcing from a resistive circuit having only 4–5 V, whereas in inductive circuits, a 0.5 V power supply may suffice [7]. In terms of power, it has been documented that breaking an 0.95 W incandescent lamp can suffice to cause an explosion of a methane/air mixture, whereas a broken 3 W lamp can cause an explosion of coal dust in air [107].

Although solids are generally harder to ignite than gases or dust clouds, very limited testing indicates that exceedingly low values can also suffice for solids. For example, a Dacron comforter was ignited from a 6 W night-light lamp, bamboo decorations from a 25 W lamp, and cellulose attic insulation from a 50 W lamp [7]. Notebook paper was ignited [7] from a resistor rated at 1/8 W that was dissipating 1.25 W at the time. Power values associated with arc-tracking ignitions have rarely been explored, but in one study it was found that 4.8 W sufficed to ignite PBT plastic [108]. This should be interpreted in the context that PBT is one of the more arc-tracking resistant plastics and plastics more prone to arc-tracking (such as PVC) would presumably require less.

Finally, it must be noted that the values cited above are values that sufficed to cause an ignition or explosion during limited testing. These values are not intended to imply lower-value limits. Ignitions, in fact, may occur under conditions or regimes not encompassed in the research that has been published to date.

Electrical Explosions

Most explosions in which electricity plays a role can be grouped into three categories:

1. Pure arc explosions
2. Pure fuel explosions
3. Mixed mode explosions.

In a pure electrical arc explosion, the main source of explosion energy is the arc itself. Combustion, i.e., oxidation, plays only a modest role, if any. In the case of copper or steel conductors, oxidation is generally negligible, while in the case of aluminum conductors some of the exothermicity comes from oxidation of the aluminum.

For such explosions to be damaging, significant arc power is normally required. Thus pure arc explosions are mostly of interest in high voltage transmission and distribution equipment, in industrial facilities, or in commercial installations where significant short-circuit currents are available.

Pure fuel explosions are ones where the only role of electricity is to provide a spark or a low-energy arc, with the explosion energy corresponding to burning of fuel. The most common example is spark from an electrical switch causing an explosion in a house which filled with natural gas. This category also includes electrically initiated explosions of solid or liquid explosives, for example, by use of an exploding bridgewire. Pure fuel explosions are treated in depth in the *Ignition Handbook* [7] but are outside the scope of this Chapter. In addition, there are numerous monographs which discuss the physical, chemical, or civil engineering aspects of explosions of all types [109–113].

Mixed mode explosions are explosions which are initiated by an electric spark, arc, or hot surface, and where the fuel was delivered due to an electrical fault. The best known mixed mode explosions are explosions of oil-filled transformers and explosions of underground electric distribution cables, including manhole explosions. In these explosions, an electrical fault gasifies the dielectric liquid or solid,

which is then ignited by a localized source of energy. Mixed mode explosions are also experienced when lead-acid batteries explode and in other cases of adventitious generation of hydrogen. In recent years, explosions of residential dishwashers have been identified as an additional example of mixed mode explosions. (Explosions in a purposive hydrogen-production facility initiated by an electric spark are categorized as pure fuel explosions, since an electric fault does not play a role in generating the fuel.)

Basic Phenomena

Electric arc explosions involve complicated phenomena, and none of the standard monographs on explosions cover this specialized topic. The only review of the topic has been by Babrauskas [114], and here some of the main findings will be summarized.

Electric arcing in circuits with sizable maximum short-circuit current capacity can be a highly energetic effect. In fact, buildings have collapsed due to arc pressure, since in an enclosed space some surprisingly large pressures can be built up. For instance, in one test explosion overpressures of 83 atm were obtained. The magnitude of this can best be appreciated by considering that a fuel-air deflagration will typically attain only around 7–8 atm, barring pressure-piling effects or other turbulence enhancements. During normal operation of a circuit breaker, arc pressures of roughly 3 atm magnitude can be expected [115], but these devices are designed to sustain the pressures generated by the normal arcing associated with circuit opening.

Arc explosions are not rare in industry, and in other situations where 480 V, or higher, voltages are utilized, but published case histories are scarce. Neither of the two large electrical accident compilations [116, 117] mentions the subject. Lee [118] published four brief case histories, Crawford et al. [119] documented seven case histories of arc explosions inside motor terminal boxes, including one fatality, while Heberlein et al. [120] described two non-fatal explosions inside motor control centers. The best-known incident was in an Atlanta high-rise building that took place on 30 June 1989. The fumbling of an electrician replacing a fuse caused a 480 VAC bus duct explosion [121] and the explosion and subsequent fire led to five fatalities.

Lightning strikes can lead to arc explosions in any type of premises. In 1773, Lind demonstrated that if a conductor from a lightning arrester is run down through a house, but with a small gap in this conductor, this can form a spark gap and a strike to the arrester can result in an arc explosion capable of destroying the house [122]. Individuals have been bodily knocked over when in proximity both to electrical fault arcs and lightning strikes, although interestingly often there have been negligible injuries to the individual knocked over [123]. But in cases where roofs collapse, the outcome may be traumatic if persons are present underneath.

Eardrum rupture can be expected at explosion overpressures of 19 kPa (10 % probability) or 45 kPa (50 % probability), while death due to lung damage is 120 kPa (10 % probability) or 141 kPa (50 % probability). The above values come from an extensive statistical study by Eisenberg et al. [124]; older data are somewhat different, but not greatly. In any case, they indicate that it does not take large overpressures for injury or death to result from explosion pressures.

An arc explosion arises due a very rapid heating of air or other medium. In the process, electrical energy is converted into other forms of energy: dissociation, ionization, and heating of the gas, including its compression; thermal radiation; and conduction losses into adjacent solids such as electrodes.

In addition, some electrode metal is vaporized and this contributes to the total volume which is being explosively heated, yet, the role of chemical reactions has only recently been explored. When an arc breakdown is initiated, energy gets deposited into the arc channel at a rate much greater than can be removed from the area by the shock wave that is created. This causes a rapid pressure rise and, if the arc energy is sufficiently high, this will be perceived as an explosion.

For a low-energy arc, the perceived sound may simple be a 'snap,' 'crackle,' or 'pop.' But within the scientific community there is not an agreed-upon, quantitative definition of the term 'explosion,' nor are there studies to quantify the fraction of the arc energy that gets delivered as sound energy, i.e., vibrations in the 20–20 kHz range.

In an open environment, arc pressures will rarely be highly destructive. Theoretical modeling suggests that very high pressures may be created, but experimental studies do not bear this out, which only show overpressures below about 10 kPa. However, if arc explosions occur within enclosures which are sealed, or nearly so, then, as mentioned above, huge overpressures may be found.

Electric arc explosions are not combustion phenomena—they are predominantly physical explosions, due to very rapid conversion of electrical energy into heat. Chemical reactions play a role, but only a supporting role, in such explosions. Recent studies suggest that chemical reactions are mainly ones which convert air to species such as O_3 and NO_x. While these may comprise oxidation, they are very different from a fuel-air explosion of a normal sort. Some of the electrode metal is also vaporized in an arc explosion, and arc temperatures are high enough so that presumably much of this metal vapor may get oxidized. However, the electrode oxidation effect is quantitatively only a small part of the heat balance in an arc explosion. Thus, first-order estimates of arc explosions treat the process solely as converting electrical energy to heat and ignore chemical reaction contributions.

Shock Waves from Electric Arcs

If in a gaseous medium there is an abrupt change in pressure, temperature, or volume created at some location, a wave will be generated which will propagate through the medium. The wave can be a sound wave, a shock wave, or both, depending on the characteristics of the source. In the case of an electric arc, while a shock wave will be generated and it is audibly perceived as an explosion (unless of very small scale), the shock wave does not constitute a detonation, which would require that the shock wave be supported by an exothermic reaction occurring behind the shock front. For subsonic sound waves in air, the decay in pressure with distance from the source goes as $1/\sqrt{r}$ for the infinite-cylinder geometry and $1/r$ for the sphere. But for shock waves, these simple wave-equation relationships are not applicable.

A reasonably short arc will be represented by a short cylinder, but this is not a geometry that lends itself to simple theoretical solutions. Baker presented calculated data on a point sources [125], along with experimental data on bursting explosions of short cylindrical vessels and spherical vessels. His results showed that, unless only examined over small intervals, the actual relationship is not even of a power-law type.

In an electric arc, when breakdown is initiated, a narrow conducting filament first bridges the gap, and then grows rapidly in diameter until it reaches an ultimate value and the 'arc channel' is fully established. In the course of this, there are two disturbances that a propagated: a sound wave propagating at the speed of sound and a shock wave propagating at two or three times that.

Flowers [126] made detailed measurements and found velocities of 1,000–2,000 m s^{-1} for the radial expansion of the arc channel; these are well above the 340 m s^{-1} of sound speed, indicating that shock waves are being generated in all cases. The arc channel eventually reaches a steady-state diameter and no longer expands, and Flowers found that a time of 3–35 μs was required for the final diameter to be attained in his experiments, but the actual value is dependent on external circuit parameters which limit the current growth rate.

When the final diameter is achieved, Flowers found that the arc channel cross-sectional area is linearly proportional to the current, with the proportionality being 11 A mm^{-2}. Later Vanyukov et al. showed that the expanding shock front and the channel are initially of the same diameter, but subsequently the channel typically approaches a maximum diameter, while the shock front continues expanding outwards

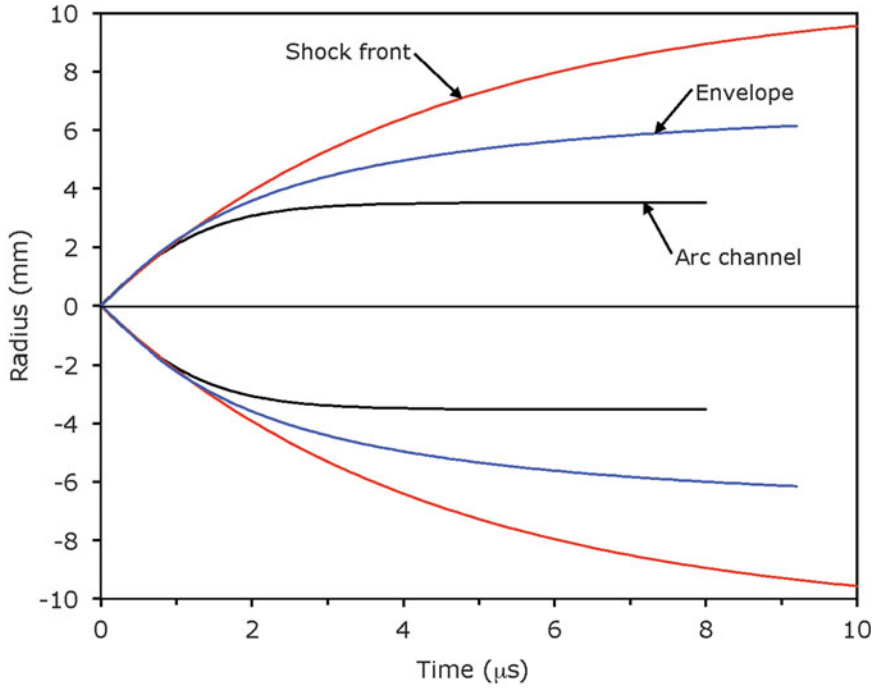

Fig. 22.19 Results of Vanyukov et al. on the expansion of the arc channel and growth of the shock wave

[127] (Fig. 22.19). Intermediate between these is the 'envelope,' which is the boundary between compressed gas (outside the boundary) and rarefied gas (inside). In some cases, however, arc channel diameter growth continues for a protracted period, especially at higher current values [128].

Pressures from Arcs in the Open

Baker [125] treated arc explosions in the open using results from acoustical theory. The pressure rise $\Delta p = (p_1 - p_o)$ is assumed to be due to the arc effectively generating a certain volume V of air at the ambient density ρ_o. Then from acoustical theory, the pressure rise at any particular distance r (m) from the arc is:

$$\Delta p = \frac{\gamma - 1}{\gamma} \frac{\dot{P}}{4\pi r p_o}$$

where $\dot{P}$ = first derivative of electrical power developed in the arc (W s^{-1}), and γ is defined as: $\gamma = c_p/c_v$. Air can assumed to be an ideal diatomic gas, giving $\gamma = 7/5 = 1.4$. This equation predicts that the pressure rise will vary linearly with $\dot{P}$ and decrease with distance proportionally to $1/r$.

The only extensive series of experiments available to examine the relationship between $\dot{P}$ and the pressure rise has been that of Drouet and Nadeau [129]. Unfortunately Fig. 22.20 suggests that there was a systematic error in the measurements. The slightly different than expected slope for long arcs could well be due to a limitation of theory, but the short-arc results are most likely erroneous, not only because they have a dissimilar slope, but mainly because they imply that in excess of 100 % of the power of the arc is realized as compression of air.

Pressures from Arcs in an Enclosure

If an arc discharge occurs within an enclosure which is of modest size, then the whole enclosure will get measurably pressurized. In addition, of course, there will be local shock wave propagation,

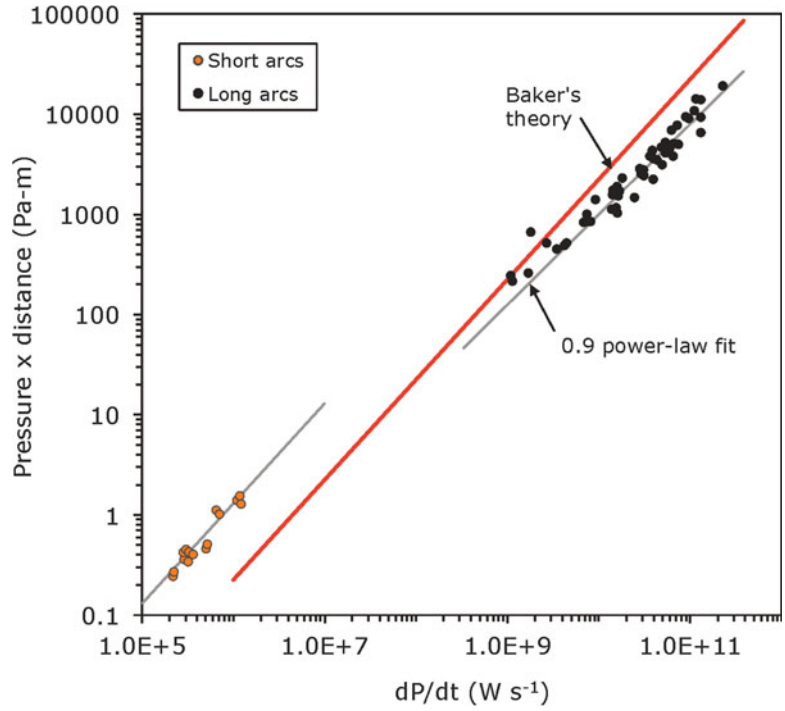

Fig. 22.20 The results of Drouet and Nadeau compared to Baker's theory

and also reflections of shock waves from compartment walls. Modeling such details in the system would require numerical calculations. But, for many practical purposes, what is of most interest is the peak, quasi-steady overpressure that is achieved, and this can be approximated in a simple way. Neglecting all transient and hydrodynamic effects, the discharge of an arc in a single, closed compartment can be treated as an ideal gas within a isolated, isochoric (constant volume) system. If an amount of heat or energy ΔW is injected into the volume, the change in pressure Δp is [130]:

$$\Delta p = \frac{R}{Mc_v}\frac{\Delta W}{V}$$

where M = molar mass, R = universal gas constant = 8.314 J mol^{-1} K^{-1}, and c_v constant-volume heat capacity (J kg^{-1} K^{-1}). Using the relations between c_v, c_p, and γ, the relation is more usefully written as:

$$\Delta p = (\gamma - 1)\frac{\Delta W}{V}$$

This shows that, all else being equal, the overpressure is inversely proportional to the volume. Consistent with the theoretical prediction, when using very small enclosures and large arc currents, some exceedingly large pressures can be obtained. Graneau [122] conducted experiments in a tiny cubical cavity, 12.7 mm on a side (2×10^{-6} m^3), with the electrode gap also being 12.7 mm. For a spark discharge of 40 kV and a peak current of 38 kA, he measured an average pressure of 409 atm in the cavity, with even higher pressures during the peak of the discharge. Baldrey and Hudson [131] conducted tests within a small pressure vessel and got an overpressure of 83 atm in the worst case. Numerous other studies have also been published [114].

The analysis is complicated since not all of the electrical energy delivered actually goes into heating the gas. Conversely, in the case of aluminum electrodes, an additional energy term comes from the combustion of the aluminum. Thus, because of differing experimental conditions, published results tend to lack generality. An additional complication is that many studies were done not on fully sealed enclosures, but on ones with certain small openings. This makes the results highly dependent on the specifics of the geometry.

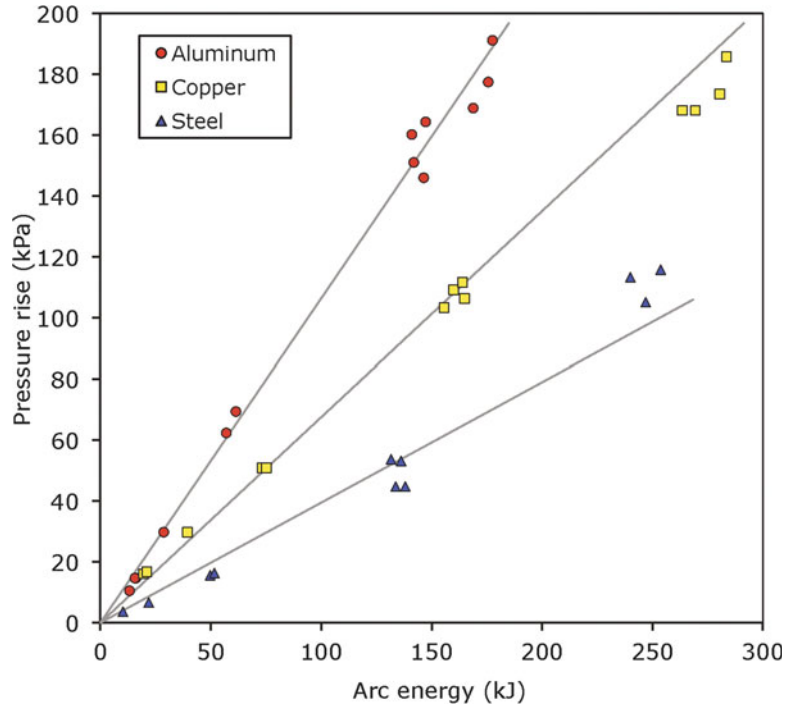

Fig. 22.21 Arc pressure rise, as function of electrode material, measured by Tanaka et al. in an 0.32 m^3 enclosure for 0.1 s duration AC arcs

In addition, many studies were at very low overpressures. Such results are more readily amenable to analysis, but do not necessarily reflect on more damaging explosion incidents. An example of results where at least moderately high overpressures were achieved is the study of Tanaka et al [132]. Figure 22.21 shows their results obtained for AC arcs of fixed 0.1 s duration. The higher values obtained for aluminum electrodes reflect the contribution of the combustion of electrode metal.

Efforts have been made to use commercial CFD codes for computing pressure rises in enclosures, but the validity of such efforts has been problematic. Capelli-Schellpfeffer et al. published two CFD modeling studies intended to simulate an experimental arc fault in 480 VAC switchgear in which an arc energy of 20 kJ was delivered and a peak overpressure of 2.6 atm was measured [133]. In the first study [133], a peak of 0.2 atm was computed, while in the second [134] a peak of 16,000 atm was predicted. Interestingly, the same 20 kJ value of arc energy was used by Caillard et al. [135] but in a capacitive discharge circuit and they predicted a peak overpressure of 1,700 atm while measuring a peak of 0.26 atm. Other researchers [136] obtained reasonable agreement, but only by using a custom-designed CFD code.

Summary

Fires arising due to static electricity or electric current can be difficult to understand for the nonspecialist because, apart from fire science, the separate discipline of electrical science is invoked. Partly because of this discipline-straddling nature of the phenomenon, research has not been as vigorously pursued as in some other aspects of fire science. But at the present time, the fundamentals have been well enough established that general guidance can be given. The ways by which the "heat" leg of the fire triangle is produced in electrical fires has been outlined in this chapter. The most highly specialized of these mechanisms is the electrical arc, and its characteristics have been reviewed in this chapter. Electric arc explosions are a highly specialized phenomenon and are primarily physical explosion, rather than chemical, although some chemical reactions may occur.

Nomenclature

A	Area (m^2)
C	Capacitance (F)
C_p	Heat capacity, constant-pressure ($J\ kg^{-1}\ K^{-1}$)
C_v	Heat capacity, constant-volume ($J\ kg^{-1}\ K^{-1}$)
c_1	Constant (-)
c_2	Constant (-)
D	Diameter (m)
d	Distance (m)
d_1	Clearance distance (m)
d_2	Creepage distance (m)
e	Charge of the electron (C)
E	Electric field ($V\ m^{-1}$)
h	Heat transfer coefficient ($W\ m^{-2}\ K^{-1}$)
I	Current (A)
L	Distance (m)
M	Molar mass (kg/mol)
p	Pressure (Pa)
P	Power (W)
$\dot{P}$	First derivative of electrical power ($W\ s^{-1}$)
q''	Power density ($W\ m^{-2}$)
Q	Charge (C)
Q'''	Charge density ($C\ m^{-3}$)
r	Radius (m)
R	Resistance (W)
R	Universal gas constant (8.314 $J\ mol^{-1}\ K^{-1}$)
t	Time (s)
T	Temperature (K)
u	Velocity ($m\ s^{-1}$)
V	Potential difference ("voltage"; V)
V	Volume (m^3)
W	Energy (J)
α	Townsend's first ionization coefficient, (m^{-1})
ε	Dielectric constant (–)
ε_o	Permittivity of vacuum ($S\ s\ m^{-1}$)
γ	Ratio C_p/C_v (—)
γ	Incomplete gamma function (–)
γ	Townsend's second ionization coefficient (-)
λ	Thermal conductivity ($W\ m^{-1}\ K^{-1}$)
ρ	Density ($kg\ m^{-3}$)
ρ_e	Electrical resistivity of copper ($\Omega \cdot m$)
σ	Charge density ($C\ m^{-2}$)
τ	Time constant (s)

Surface Flame Spread

23

Yuji Hasemi

Introduction

Surface flame spread is a process of a moving flame in the vicinity of a pyrolyzing region on the surface of a solid or liquid that acts as a fuel source. It is distinct from flame propagation in a premixed fuel and oxygen system in that the surface spread of flame occurs as a result of the heating of the surface due to the direct or remote heating by the flame generated from the burning surface. The surface flame spread is very often critical to the destiny of fires in natural and built environments. This spread applies whether the fire is an urban conflagration or is the first growth after ignition of a room's draperies. This chapter provides fire safety engineers with an overview of surface flame spread during the growth of a fire and the modeling of different modes of flame spread to improve understanding of their effects on the outcomes of fires.

Surface Flame Spread Basics

Flame Spread Process

The surface flame spread is caused as a result of the cycle of the following processes:

1. Vaporization of solid or liquid due to the heating from flame over the fuel's surface
2. Mixing of the pyrolized gas and oxygen in the vicinity of the fuel surface
3. Combustion of the pyrolized gas and formation of the diffusion flame
4. Heating of the unburnt fuel surface to ignition temperature from the diffusion flame

The oxygen and fuel concentrations together with the heat transfer between the flame and the solid phase strongly affect the process. Taking the surface flame spread as a successive ignition front over a combustible object, the speed of spread and its sustainability are controlled by the balance of the flame heating and the rise of surface temperature (see Chap. 21). If the flame ignites the virgin surface of the area larger than that of the burning surface before local extinction, the spread will accelerate. From this point of view, relative configuration of the flame to the surface is critical for the dynamics and the hazard of surface flame spread.

Flame spread in the direction of the mean flow due to wind or buoyancy is called wind-aided or concurrent spread, and, on the contrary, flame spread occurring in a direction opposite to that is called opposed-flow spread.

Difference of the significance of the mode of flame spread for fire safety can be illustrated through the typical process of fire growth in a room with highly combustible lining ignited on the floor, as shown in Fig. 23.1. The spread of fire over the floor is a typical opposed-flow spread because the flame induces unheated air along the

This chapter is based in part on material by Professor J. Quintiere appearing in previous editions of this handbook.

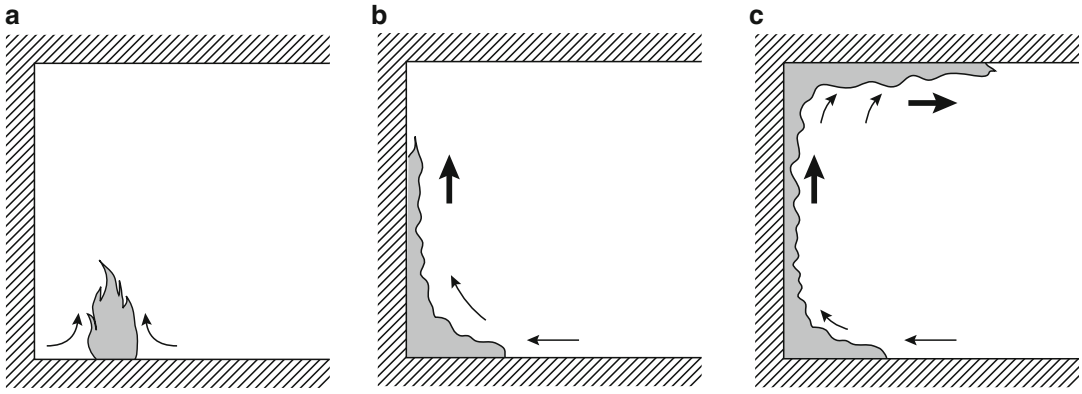

Fig. 23.1 Orientation of combustible surface and the modes of flame spread over (**a**) floor, (**b**) wall, and (**c**) ceiling

carpet surface in the direction against the spread of the flame (Fig. 23.1a). The surface flame spread at the initial stage of a room fire is generally slow and can even be unstable; but once the wall lining is ignited, the buoyancy makes the flame develop along its surface and exposes the lining surface above the burning region to the flame (Fig. 23.1b). This condition generally makes the flame spread much faster than on the floor, even if the floor and the wall are lined with identical material.

If not extinguished at this stage, fire may finally reach and ignite the ceiling. The buoyancy makes the flame spread laterally beneath the ceiling toward the opening, exposing the overall surface of the ceiling to the flame heating (Fig. 23.1c). As widely recognized, flame spread beneath the ceiling is generally fast and could cause flashover by igniting remaining furniture and wall surface far from the ignition source within the room. The Bradford Stadium fire disaster in the United Kingdom (1985) is one of the most significant examples of lateral flame spread beneath a combustible roof or ceiling. During lateral flame spread beneath the ceiling, downward flame spread over the wall lining is often observed within the smoke layer. It is an opposed-flow spread, yet its spread velocity is generally fast due to the additional heating from the smoke layer.

As seen in the growth of room fire, the wind-aided flame spread presents a number of key processes escalating the hazard of building and mass fires. In mass fires such as urban conflagrations and forest fires, fire brands have an additional but sometimes essential role in enhancing fire spread in the wind direction. The importance of opposed-flow flame spread can become significant when the temperature of the fire environment has been raised enough to preheat the wide range of surfaces of combustibles. Although the two modes of flame spread are apparently distinct from each other, there is notable ambiguity in fires on an inclined combustible surface. On an upward inclined surface, the angle between the flame flow and the surface is reduced with an increase of the angle of inclination, and finally the flame begins to crawl over the surface [1] (Fig. 23.2). This change occurs generally at 15–30°, depending on the width, side confinements, and other conditions; inclination of roofs, escalators, and slopes for wheelchairs are generally within the range where wind-aided flame spread is anticipated. The escalator fire at the Kings Cross Subway Station Fire Disaster (1987) is a significant example of wind-aided flame spread along an inclined configuration under the enhancement of buoyancy due to the confinement of air supply by the side walls [2].

Research Background

Large numbers of experiments on and models of surface flame spread with diverse levels of theoretical sophistication and practical relevance

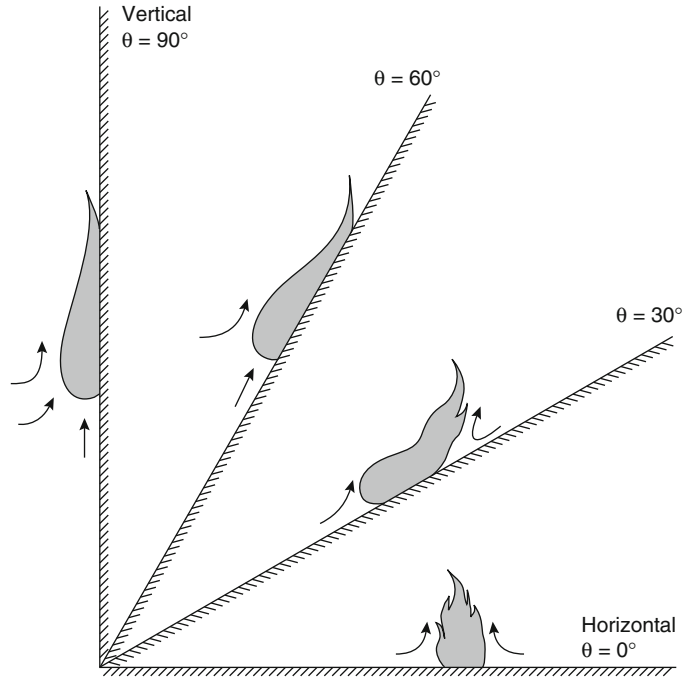

Fig. 23.2 Change of the mode of surface flame spread according to the slope angle

have been conducted, and it is impossible to make a precise review of all the important research on this subject. It is recommended to seek comprehensive reviews such as Drysdale [3], Quintiere [4], Fernandez-Pello and Hirano [5], Hirano [6], and Williams [7]. However, as long as surface flame spread is discussed for the assessment of fire safety of natural or artificial composites, the phenomena are generally modeled as a thermal process causing the successive piloted ignition on the surface due to the heating from the burning of the material itself under the gravity and the atmospheric conditions of the earth.

Active research on thermal modeling of surface flame spread has occurred since the late 1960s, and significant progress was made in the basic understanding of flame spread through theoretical sophistication and laboratory experiments throughout the 1970s. Later, during the 1980s, the approach was extended to turbulent flames for the application to the fire hazard assessment of lining materials. In the 1990s, further studies were conducted to analyze and assess the general behavior of room fires through input from and validation against large-scale tests with around one-story-high wall specimens or with standard and larger-scale room tests. These studies have revealed the importance of the surface configurations on the general behavior of flame spread; examples of acceleration of flame spread on grooved combustible surfaces, in corner walls, and in a vertical, inclined, or downward channel lined with combustible material show the significance of the configuration effect. Together with the substantial progress in the measurement technology of the combustibility of materials through the 1980s and the 1990s, these studies have made it possible to predict surface flame spread in a room to some extent using material properties obtained from bench-scale tests.

Wind-Aided Flame Spread

The wind-aided flame spread is the most important mode of surface flame spread for fire hazard assessment. In this section, modeling and assessment are introduced regarding the two most significant examples of wind-aided flame spread in building fires: upward wall flame spread and

flame spread beneath the ceiling. Upward wall flame spread along a wall has drawn the particular interest of fire safety engineers for its primary importance in the determination of the destiny of a room fire and for the rich variety of configurations of wall surfaces that may influence the general behavior of flame spread. In this section, theories of wind-aided flame spread developed essentially for wall fires are applied to provide technical insight in the assessment of room fires or the combustibility of lining materials in general.

Upward Turbulent Wall Flame Spread

Figure 23.3 is a schematic of upward flame spread typical of wind-aided flame spread. The flame spread is thus perceived in two different manners: first by the advancement of flame front and second by the advancement of the ignition front of the solid surface. The rate of movement of the ignition front is normally defined as the flame spread velocity for modeling purpose. The location of the ignition front of a burning surface, $x_p(t)$, is identified as the location where surface temperature has reached the ignition temperature, T_{ig}.

Flame Heat Transfer For Fig. 23.3, one-dimensional thermal conduction in the direction normal to the wall surface can be reasonably assumed and evolution of the surface temperature at x above the fire origin at time t, $T(x,t)$, is formulated as

$$T(x,t) - T_o = \int_0^t \dot{q}''_f(x,\tau)\phi(t-\tau)d\tau \qquad (23.1)$$

where

T_0 = Initial surface temperature

$\dot{q}''_f$ = Flame heat flux

$\phi(t-\tau)$ = Impulse response of the surface temperature at timet t to the surface heat flux at τ

$\phi(t-\tau) = [\pi k\rho c(t-\tau)]^{-1/2}$ and $\phi(t-\tau) = [\rho c\delta(t-\tau)]^{-1}$ apply for a thermally thick wall and for a thin wall with thickness of δ respectively with k, ρ, and c thermal conductivity, density, and specific heat of the solid. Equation 23.1 can be solved for flame spread velocity, $V_p = dx_p/dt$, for simple conditions by further introducing engineering relations on the flame heat flux, $\dot{q}''_f = F(x,\tau)$.

Flame heat flux is normally represented as relative location to the flame length, x_f; that is, $\dot{q}''_f = F(x/x_f)$, Applying the Froude modeling for the flame height (see Chap. 21) to a line fire along a wall, x_f is generally expressed as function of heat release rate per unit width as

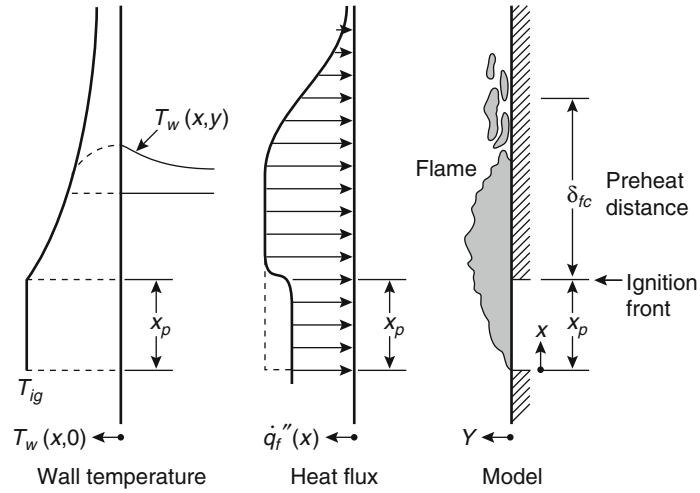

Fig. 23.3 Upward wall flame spread [9]

$$x_f/D = k\dot{Q}_\ell^{*n} \tag{23.2}$$

Where

D = Characteristic lengthof the burning area (normally height or depth), $\dot{Q}_\ell^* = \dot{Q}_\ell/cT_0\rho_\infty g^{1/2}D^{2/3}$.

k = Empirical coefficient

$\dot{Q}_\ell$ = Heat release rate per unit width of fire source

Figure 23.4 illustrates a relation between heat release rate per unit width and flame length for line burners against a constant temperature inert wall. It shows that $k = 6.0$ for intermittent flame and $n \sim 2/3$ for $\dot{Q}_\ell \geq 1.0$, as anticipated for an ideal line source by dimensional analysis [8]. The value of k depends on the definition and measurement of flame length, and experimental k values range from 4.65 to 7.0 [8–11]. Newman and Wieczorek reviewed reported values for k and n [12]. With $n = 2/3$ in Equation 23.2, flame length is found to be independent of the dimension of the burning region and is represented as

$$x_f = \left(k^{3/2}/c_pT_o\rho_\infty g^{1/2}\right)^{2/3}\dot{Q}_\ell^{2/3} = k'\dot{Q}_\ell^{2/3} \tag{23.3}$$

The k' value is roughly 0.01 k; for Fig. 23.3, k' value is found to be $k' = 0.057$ m$^{1/3}$ kW$^{-2/3}$, whereas k' values in literature range from 0.043 m$^{1/3}$ kW$^{-2/3}$ to 0.067 m$^{1/3}$ kW$^{-2/3}$ [8, 9, 12, 13]. For a limited range of $\dot{Q}_\ell$, flame length can be linearized against heat release rate or the characteristic length of burning region for engineering purposes as

$$x_f \approx k_f\dot{Q}_\ell = k_f\dot{Q}_\ell''D = aD \tag{23.4}$$

where $\dot{Q}_\ell''$ is the characteristic heat release rate per unit width, k_f, and $a \equiv k_f\dot{Q}_\ell''$ depends on heat release rate, but $k_f \sim 0.006$–0.01 m^2/kW is suitable for lining materials in practice [14–16].

Figure 23.5 is a general relation between the total incident heat flux from wall flame to wall surface and the distance from the lower edge of the burning surface normalized by x_f. It is a summary of experiments on wall flames

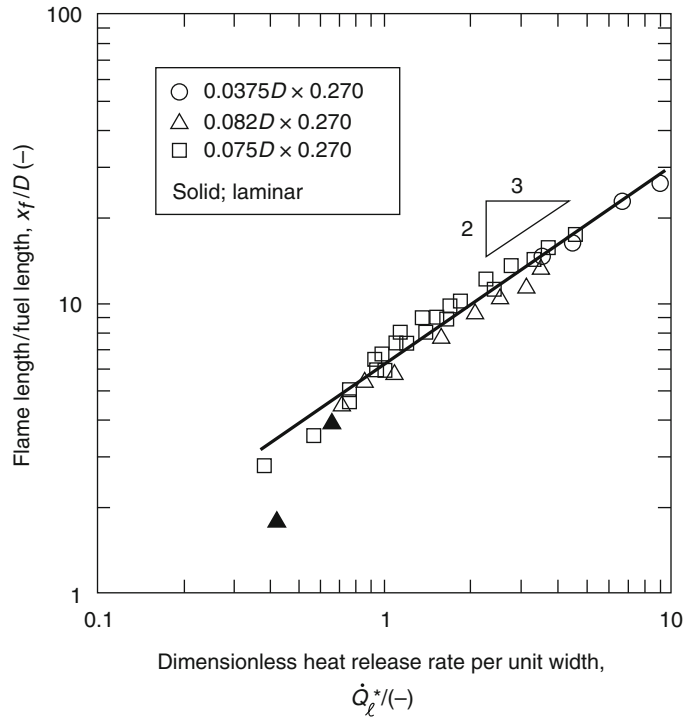

Fig. 23.4 Relation between the length of intermittent wall flame and dimensionless heat release rate per unit width [9]

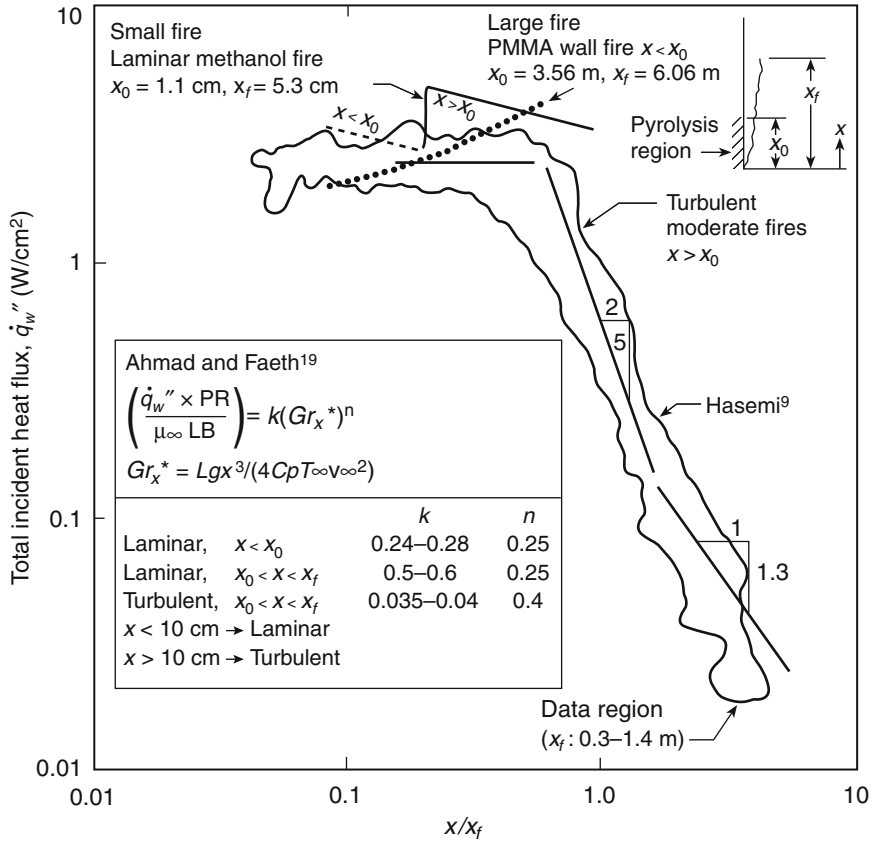

Fig. 23.5 Wall flame incident heat flux for materials [17], for laminar flames [19], and for a large PMMA wall fire [18]

from steady porous burners, vertical wicks, and burning of specimens of finite-surface area of materials in practice [9, 17–19]. For more detailed flame heat flux data and correlations on different configurations, see Chap. 25.

As thermal conduction theories suggest, response of surface temperature to heat input depends significantly on the thickness of the solid; modeling of surface flame spread requires different approaches for thermally thick solid and thin materials. Except for items such as paper, garments, or draperies in a room, in practice most solids should behave as thermally thick under flame spread conditions. Engineering treatment of surface flame spread might appear to regard solids thicker than 1 mm as thermally thick. Up to a thickness of 1–2 cm, flame spread could depend on thickness and on the substrate material adjacent to the solid. Based on these factors, it is apparent that the thermally thick case is more significant.

With the unique dependence of flame heat flux on dimensionless height, x/x_f, Equation 23.1 can be solved to provide a characteristic steady flame spread velocity $V_p = x_p/t$ for a thermally thick solid as

$$V_p = \left[\int_0^\infty \dot{q}_f''(\xi + x_p)/\sqrt{\xi d\xi}\right]^2 / \pi k\rho c\left(T_{ig} - T_o\right)^2 \tag{23.5}$$

The numerator has the dimension of $(\mathrm{kW/m^2})^2$ m, and Equation 23.5 can be represented more simply as $\dot{q}_{fc}'' 2\delta_{fc}$ with characteristic flame heat flux, $\dot{q}_{fc}''$, and characteristic

preheat distance, δ_{fc}. Equation 23.5 is thus expressed as

$$V_p = 4\dot{q}_{fc}^{''2}\delta_{fc} \Big/ \pi k\rho c\left(T_{ig} - T_o\right)^2 = \left(x_{fc} - x_p\right) \Big/ t_{ig}^* \tag{23.6}$$

where

$$x_{fc} = x_p + \delta_{fc}$$
$$t_{ig}^* \equiv \pi k\rho c\left(T_{ig} - T_o\right)^2 / 4\dot{q}_{fc}^{''2}$$

Equation 23.6 is essentially in the same form with the flame spread velocity obtained for flame heat flux decaying exponentially with distance from the ignition front [20]. The preheat distance, δ_{fc}, is essentially the distance between the flame front and the ignition front.

Controlling Parameters of Upward Wall Flame Spread In Equation 23.6, it is important that the characteristic preheat distance, δ_{fc}, is essentially controlled only by the heat release rate in a one-dimensional flame configuration, and $k\rho c(T_{ig} - T_0)^2$ is the central part of material property to control ignitability.

Another important parameter that may control the general behavior of flame spread is the local burnout. Consider local burnout occurring at t_b after the local ignition (Fig. 23.6), $D = V_p t_b$. If the local burnout time is short compared to the characteristic time to ignition, it will become difficult to sustain successive thermal ignition on the surface. Taking the linearized flame length approximation (Equation 23.4), we introduce the following dimensionless flame spread acceleration factor: [14]

$$b = (a - 1) - t_{ig}{}^*/t_b \tag{23.7}$$

where $(a - 1)$ represents the significance of flame heating, and if $t_{ig}{}^*/t_b$ is large, it will become difficult for successive ignition to sustain. Obviously, $b = 0$ stands for Equation 23.6 and is the condition for the achievement of steady-state spread. The sign of b dictates the general behavior of wind-aided flame spread: $b > 0$ will lead to the acceleration of spread, whereas $b < 0$ will result in the deceleration of spread and finally autonomous extinction. There is more sophisticated discussion on the general behavior of wind-aided flame spread [15, 16, 21–24], which may still await future validation. But every kind of thermal model and analysis based on the linearized flame length approximation (Equation 23.4) finally eventuates the recognition of b as the central parameter for the assessment of hazard of flame spread.

Figure 23.7 is a summary of the correlation between the time to flashover in ISO 9705 room-corner tests with combustible linings and b [14]. The elements of b, namely a, $t_{ig}{}^*$, and t_b, are all material properties that can be quantified with bench-scale tests such as the cone calorimeter. Although there is still some discussion on what external heat flux level should be chosen for the quantification, use of 30–50 kW/m^2 external radiant flux seems to lead to reasonable explanation of the growth of room fire from Equation 23.7. For a charring material, heat release rate generally decays with time after the sharp peak just after the ignition and can be more suitably represented by an exponential function of time, namely $\dot{Q}^{''}(t) = \dot{Q}^{''}_{\max}\exp(-t/t_c)$. Analysis of the results of room-corner tests and the cone calorimeter on wood-based materials suggests use of $k_f\dot{Q}_{\max}$ and t_c for a and t_b respectively leads to a result consistent with Fig. 23.7 [15, 22] for such materials.

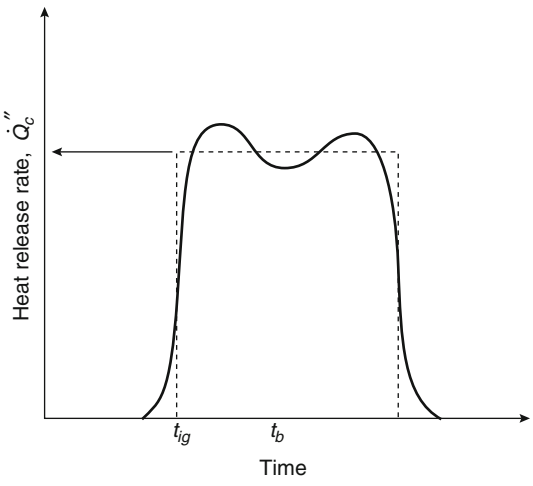

Fig. 23.6 Time history of heat release rate from fixed area burning surface

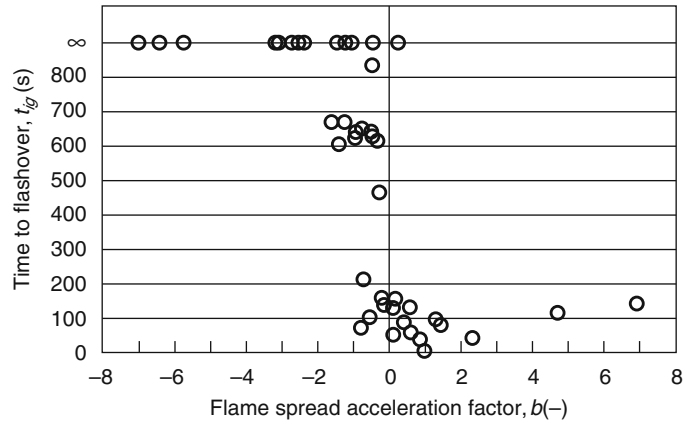

Fig. 23.7 Time to flashover in the ISO 9705 room-corner test versus the flame spread acceleration factor [14]

Equation 23.7 is simple but provides useful insights in the overall understanding of wind-aided flame spread. It is especially noteworthy that material properties are not the single factor to quantify this equation. Time to ignition and time to burnout are dependent on the ambient temperature and external heating; and a, essentially the flame-length to pyrolysis-length ratio, can be augmented not only by external heating through enhancement of vaporization but also by increase of pyrolizing surface area due to any finishing treatment such as roughness and grooves. Existence of the source of external heating has thus two implications for the acceleration of flame spread: first through the increase of the temperature of the unburnt surface and second through the promotion of vaporization of fuel due to additional heating of the burning surface [25]. Grooves or trench-like configurations of the burning surface can reduce air entrainment to the vaporizing region and extend the flame length. Configuration effect is as important as material properties in the fire safety assessment of any assembly with a combustible surface.

Flame spread can be significantly enhanced in parallel wall configuration, where the flame on either wall stimulates pyrolysis and preheating of the other surface and generates mutual acceleration of flame spread. If the wall distance is small compared to the wall width, the air supply to the burning surface will be restricted and further prolong the flame length. Even though parallel-wall configuration is not common in building design, commodities or cargoes piled in warehouses or in mass merchandise outlets often make "valleys with combustible cliffs," which can be considered as parallel walls from the flame spread point of view. A number of fire tests of cargoes and commodities in typical warehouse configuration demonstrate significant acceleration of fire growth in such a configuration [24, 26]. A cavity within a wall or a roof sandwiched by combustible surfaces is another significant example capable of showing the parallel-wall effect. Surface flame spread can be further enhanced in a vertical or inclined cavity by the stack effect due to general temperature rise within the cavity. The fast fire spread throughout whole high-rise building at the Beijing Television Cultural Center fire (2009) is partly attributed to these configuration effects. The vertical long cavity lined with polymer insulation within the facades on both sides of the building should have helped acceleration of fire spread once the fire penetrated into the cavity.

Also, in a corner of walls, flame is generally prolonged due to the restriction of entrainment and the mutual radiation between the walls, which can result in faster flame spread. There are experiments and measurements of upward turbulent flame spread on nearly full-scale specimens of various materials in practice [11, 18, 26–29]. These reports would provide valuable information necessary for consideration in running large-scale flame spread tests with materials in practice.

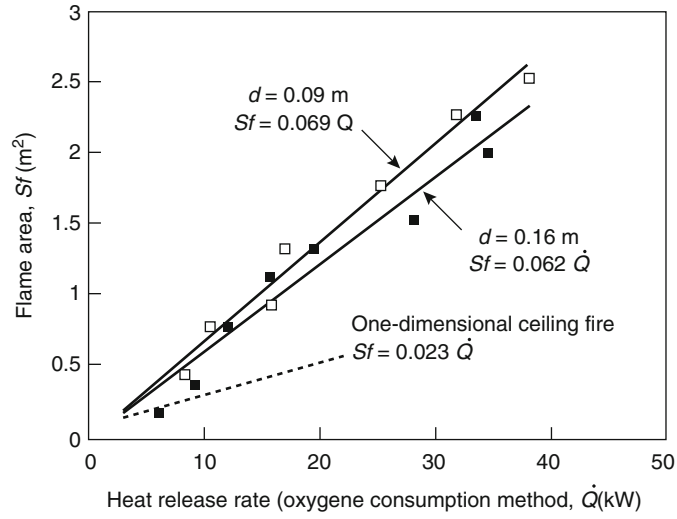

Fig. 23.8 Area covered by ceiling flame versus effective heat release rate [30, 31]

Surface Flame Spread Beneath Ceiling

Although fewer studies have been conducted on the ceiling fires, the mechanism of the surface spread is essentially similar to the upward wall spread. Flame spreading beyond the pyrolysis front is the dominant force for the successive ignition of unburnt ceiling surface. According to the measurements of flame size and flame heat flux for one-dimensional ceiling flames in a corridor-like configuration and for circular ceiling flames from downward porous propane sources [30] (Fig. 23.8), the area covered by a visible ceiling flame is nearly proportional to the heat release rate, and the heat release rate per unit flame area is significantly larger for one-dimensional flames than for circular flames. This situation indicates uniform entrainment of air beneath a ceiling flame, but the rate of entrainment could depend on the configuration. Flame length is thus proportional to heat release rate per unit width in corridor configuration, $x_f = 0.0122\ \dot{Q}_{le}$ with $\dot{Q}_{le}$ as the effective heat release rate per unit width (kW/m) for corridor ceiling configuration [31] and proportional to the half power of heat release rate beneath an unconfined ceiling.

As shown in Chap. 25, total heat flux from the ceiling flame to the ceiling surface can be represented as a unique function of distance from the windward edge of the burning surface divided by the flame length. From these facts, the engineering framework for the assessment of surface flame spread on a wall applies suitably for the flame spread beneath a combustible ceiling, whereas such physical constants as a should be different from the wall fire configuration.

Under an unconfined ceiling, heat flux within the solid ceiling flame is decreased weakly with distance within the range of 20–30 kW/m^2, and is generally weaker than in upward wall flames of similar heat output, because of the buoyancy reducing the thickness of ceiling flame.

Ambient thermal conditions and surface configurations of the ceiling could also affect the general behavior of flame spread beneath the ceiling. One of the important issues to be considered in the understanding and fire hazard assessment of flame spread beneath the ceiling in a room is the effect of preheating due to ceiling jet and smoke layer, which normally come in contact with the ceiling earlier than flame in a likely fire growth scenario in a room. Corridor ceiling flame spread tests lined with medium-density fiberboard (MDF) with uniform external radiation to the ceiling surface demonstrate significant sensitivity of the ultimate burn length to pilot flame length ratio, x_{poff}/x_{po}, to the ceiling

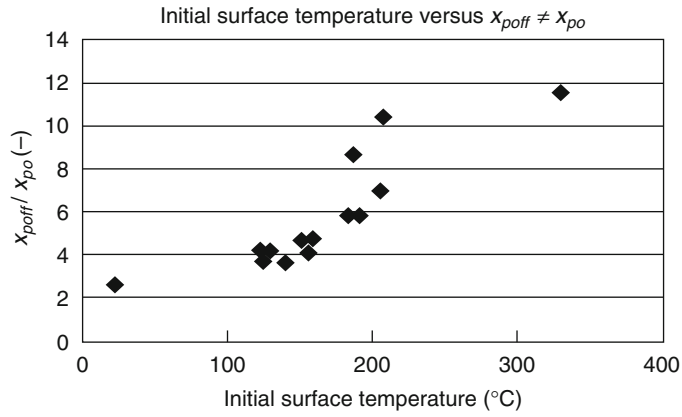

Fig. 23.9 Relation between the surface temperature due to external heating at piloted ignition to ceiling and the ultimate burnt length to pilot flame length ratio for MDF [31]

surface temperature just prior to the ignition by pilot flame, T_o (Fig. 23.9) [31]. T_o was controlled by the upward radiant panel. In the tests resulting in $x_{poff}/x_{po} > 10$, almost the whole ceiling surface was finally pyrolyzed and flame spread itself was strongly accelerated. Flame spread was less sensitive to heat flux within the range of 0–10 kW/m^2. The remarkably fast flame spread beneath a nearly unconfined roof/ceiling observed at the event of the Bradford Stadium fire disaster (1985) is attributed partly to the use of roof material of low ignition temperature. Increase of the effective combustible surface area due to beams, decorations, and so forth can also increase *a* value and accelerate flame spread. Stenstad and Karlsson have demonstrated a significant example of such effect by a large-scale experiment [32].

Opposed-Flow Flame Spread

Mechanism of Opposed-Flow Flame Spread

In the opposed-flow spread, the front of the pyrolyzing region moves in the opposite direction of the flame flow. As seen in Fig. 23.10, the unburnt surface beyond the pyrolysis front is heated by remote flame; the flame spread velocity is less dependent on flame length or heat release rate, and the distance that the flame heating covers should be quite limited. For this reason, in the modeling of opposed-flow flame spread, spread velocity is normally assumed as steady state. Consider that the pyrolysis front traverses Δ within the time interval τ on a combustible solid of the thickness δ small enough to ensure practically uniform temperature across the thickness with no heat loss from the back surface. The flame spread velocity can be given by $V_p = \Delta/\tau$, and the energy conservation for the control volume Δ distance from the pyrolysis front can be described as

$$\rho c \delta V_p \left(T_{ig} - T_o\right) = \dot{q}'' \Delta \tag{23.8}$$

The net flame heat flux due to the gas-phase conduction can be given by

$$\dot{q}'' \approx k_g \left(T_f - T_r\right)/\Delta \tag{23.9}$$

where k_g, T_f, and T_r are gas-phase conductivity, flame temperature, and reference temperature for the control volume. T_r can be correlated with either T_{ig} or T_o. From these equations, the flame spread velocity can be represented as a function of thermal properties and the configuration condition as

$$V_p = k_g \left(T_f - T_r\right)/\rho c \delta \left(T_{ig} - T_s\right) \tag{23.10}$$

The flame temperature, T_f, should ideally be taken as that due to adiabatic stoichiometric combustion but, in general, could be thought of as less due to heat losses and chemical kinetic effects. Under these ideal theoretical considerations, it can be shown that

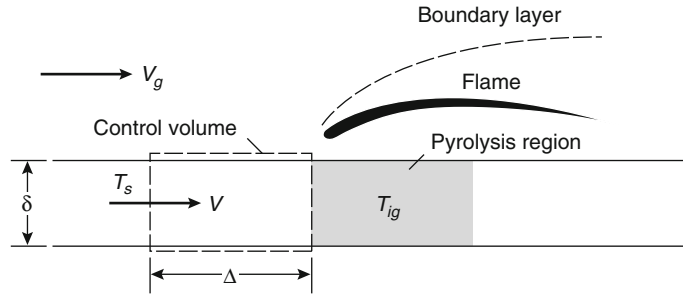

Fig. 23.10 Energy conservation in opposed-flow spread

$$T_f - T_{ig} = \frac{\left(T_\infty - T_{ig}\right) + \left(Y_{ox,\infty}/rc_g\right)\left(\Delta H - L\right)}{1 - Y_{ox,\infty}/r} \tag{23.11}$$

where ΔH and L are heat of combustion and heat of gasification of the solid fuel, respectively. T_∞ and $Y_{\mathrm{ox},\infty}$ are gas-phase ambient temperature and oxygen concentration, respectively, and r and c_g are stoichiometric mass ratio of oxygen to fuel and specific heat of the gas phase, respectively. Because $\Delta H/L$ and $Y_{\mathrm{ox},\infty}/r$ are large, and heat of combustion per unit mass of consumed oxygen, ΔH_{ox}, is nearly constant for most of combustible solids in practice (13 kJ/g), the flame temperature can be approximated as

$$T_f - T_{ig} \approx Y_{ox,\infty}\Delta H_{ox}/c_g \tag{23.12}$$

and we realize that the flame temperature is primarily sensitive to only the ambient oxygen concentration. This suggests that flame spread over a ceiling would be reduced in a room as the oxygen within the smoke layer near it is reduced.

For a thermally thin solid, δ can be taken as constant. Combining Equations 23.8 and 23.9, flame spread velocity is given as

$$V_p = \Delta/\tau = k_g\left(T_f - T_o\right)/\rho c\delta\left(T_{ig} - T_r\right) \tag{23.13}$$

For a thermally thick solid, δ should represent the depth of thermal penetration, which depends on time; that is, from the heat conduction equation for a semi-infinite thick slab as $\delta = \sqrt{k\tau/\rho c}$. Substituting this into Equation 23.8, we have

$$V_p = \dot{q}''^2\Delta/k\rho c\left(T_{ig} - T_o\right)^2 \tag{23.14}$$

In Equations 23.13 and 23.14, the flame spread velocity is apparently independent of the opposed-flow velocity, V_g. However, the independence is only the case as long as chemical effects are unimportant. Chemical kinetic effects become important when the time for chemical reactions to be completed in the flame, t_{chem}, becomes long compared to the fluid flow transit time through the flame, t_{flow} . If the flow is too fast, chemical reaction will be incomplete. Because the flow transit time is proportional to V_g-1 and mixing should be enhanced by the decrease of V_g, the flow transit time to chemical reaction time ratio, normally referred to as the Damköhler number, Da, can be represented as

$$Da = t_{\mathrm{flow}}/t_{\mathrm{chem}} \propto 1/V_g^2 \tag{23.15}$$

The flame spread velocity is reduced with an increase of Da. Taking the flame spread velocity given by Equation 23.10 as $V_{p,\mathrm{ideal}}$, the actual flame spread velocity to $V_{p,\mathrm{ideal}}$ ratio can be illustrated qualitatively as shown in Fig. 23.11.

However, for a thermally thick solid, the relation between flame spread velocity and opposed-flow velocity is more complicated. Figure 23.12 is a significant such example showing either increase or decrease of V with V_g depending on the ambient oxygen concentration [33]. This illustration suggests the dependence of $V_{p,\mathrm{ideal}}$ on V_g in the flame spread over a

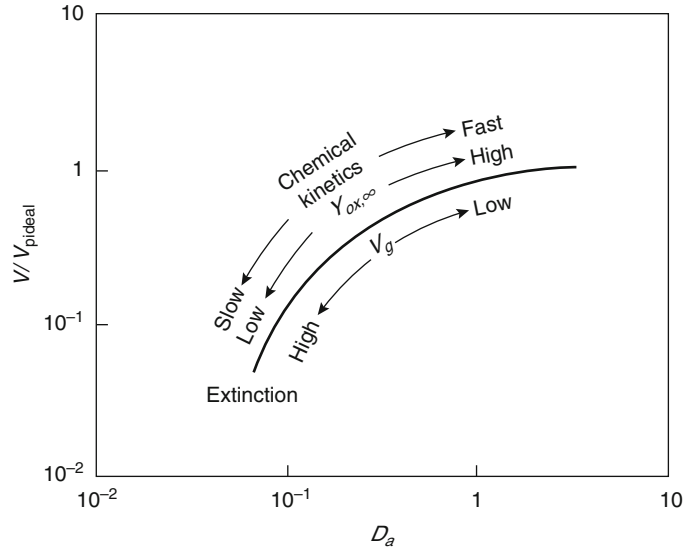

Fig. 23.11 Qualitative dependence of opposed-flow flame spread with Damköhler number, Da

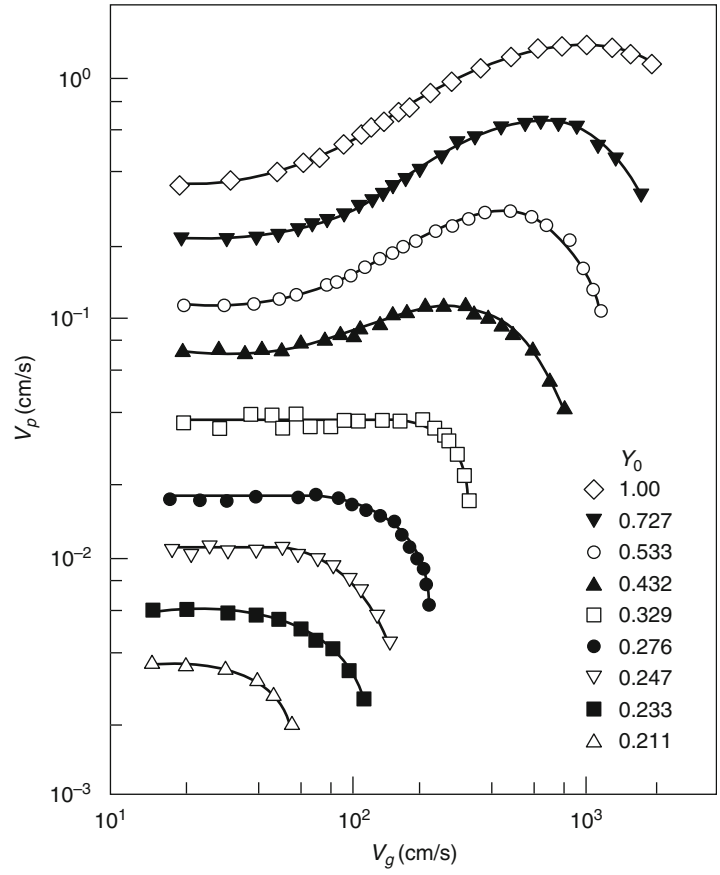

Fig. 23.12 Effect of opposed-flow velocity and oxygen concentration of flame spread speed for thick PMMA (Taken from Fernandez-Pello et al.) [33]

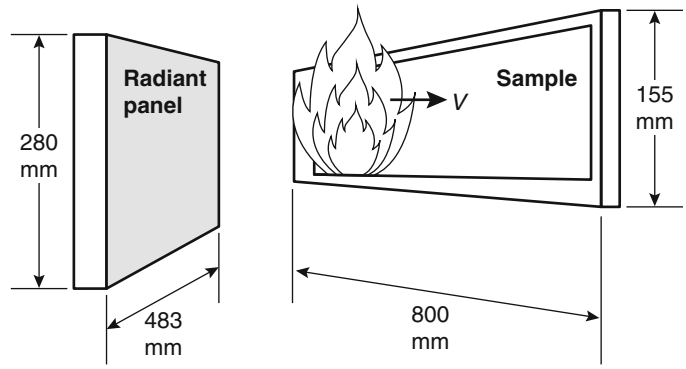

Fig. 23.13 Outline of the heating and flame spread in the LIFT apparatus

thermally thin solid. Attributing this effect to the dependence of the preheat distance, which is the length of the control volume shown in Fig. 23.10, and assuming the balance of gas-phase heat conduction with convection due to the opposed flow has the velocity of V_g, $\rho_g c_g V_g \partial T/\partial x \approx k_g \partial^2 T/\partial x^2$, then the following estimate can be derived:

$$\Delta \approx k_g/\rho_g c_g V_g \tag{23.16}$$

By substituting Equations 23.9 and 23.16, Equation 23.14 yields the expression first derived by de Ris: [34]

$$V_p \approx V_g\left(k_g\rho_g c_g\right)\left(T_f - T_r\right)^2/k\rho c\left(T_{ig} - T_o\right)^2 \tag{23.17}$$

Modeling of Opposed-Flow Flame Spread

Significant progress has been made on the understanding and modeling of opposed-flow flame spread, but most of the research has concentrated on poly(methyl methacrylate) (PMMA) and other rather ideal materials from the viewpoint of combustion and pyrolysis modeling. Few models have been attempted on the opposed-flow turbulent flame spread over charring materials and composites in practice. Because it is the numerator of Equation 23.17 that is hard to quantify for materials in practice, Equation 23.17 can be rewritten as

$$V_p \approx \Phi/k\rho c\left(T_{ig} - T_o\right)^2 \tag{23.18}$$

with Φ, a parameter depending on V_g and $Y_{ox,\infty}$ that could be quantified with a bench-scale test for practical materials. Quintiere and Harkleroad [14] examined this approach using the lateral ignition and flame spread test (LIFT) apparatus (Fig. 23.13) and have quantified the effective opposed-flow flame spread properties as summarized in Table 23.1. See Chap. 21 for more detail on the ignitability parameters. Equation 23.18 also suggests the importance of the ignitability parameter, $k\rho c(T_{ig}–T_o)^2$ for the fire hazard assessment of any material. Existence of a source of external heating, such as exposure to smoke layer, flame sheet spreading beneath the ceiling, and the like, may have a significant influence on the spread velocity.

Mass Fires

Urban fires, wildland fires, and forest fires are serious fire disasters in various districts. The conflagrations at the Great Hanshin earthquake (1995) revealed significant risk of earthquake urban fires in Japan and other districts featuring urban areas densely inhabited with buildings with relatively weak fire protection. Land development of wildland near urban districts in North America and Australia has caused a risk of occurrence of urban–wildland interface fire disasters. Albini reviewed research resources for forest and wildland fires [35]. Recent investigation

witnesses the increase of the frequency and the hazard of forest fires in polar Russia, Alaska, and Canada since about the 1990s [36].

Flame spread in a forest or in an urban district depends on radiant heat transfer, convective heating, and leeward spread of fire brands due to wind or the slope of the terrain. Figure 23.14 is a summary of the fire spread velocity for urban and wildland fires superimposed on the correlation between fire spread velocity and wind velocity summarized on Japanese urban fires from the 1910s to the 1950s [37, 38]. The significant fire spread velocity recorded in past urban and wildland fires, from the order of 100 m/h to 10 km/h,

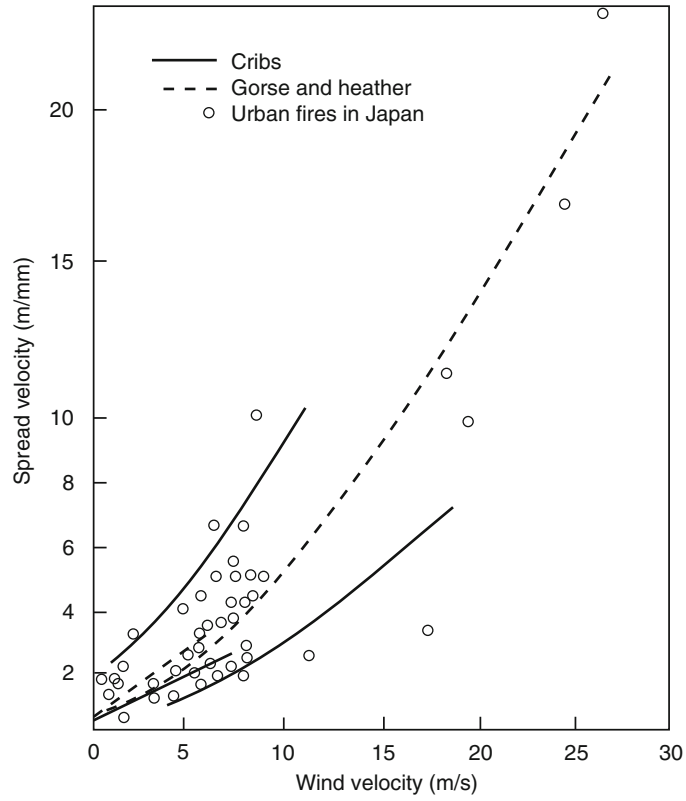

Fig. 23.14 Comparison of rates of fire spread for urban and wildland fires as a function of wind speed (From Kawagoe [38] and Thomas [37])

cannot be explained by convective or radiant heating and suggests the importance of the role of fire brands in the wind-aided spread of mass fires.

In urban fires, collapse of wooden buildings due to fire is the typical and most significant source of fire brands. In wildland and forest fires, the porous bush along the terrain is involved, and dried bush, fallen bark and pine needles, and so forth can be typical sources of fire brands. Even though weight per area of bush, bark, and dried leaves is small and their flaming might not last so long, they are quick to ignite by fire brand due to the large surface area to weight ratio of these materials. In that sense, fire brands should have primary importance in the growth of forest fires. However, in more severe fires, the crowns of the trees may also be involved.

Flame Spread Over Liquids

Flame spread over a horizontal pool of liquid fuels is essentially opposed flow, but its spreading velocity is very often significantly larger than estimated from the thermal theory [39]. The difference is attributed to the convective flow within the liquid moving concurrently with the flame. The convection is due to the surface tension, which is reduced with increase of temperature and pulls the flame toward the unburnt surface of the liquid. This is illustrated in Fig. 23.15 for a thin liquid layer, δ. Under steady conditions, the viscous forces on the control volume are balanced by the surface tension forces. Thus, the shear stress, τ, at the bottom surface equals the surface tension gradient ($d\sigma/dx$) along the free surface:

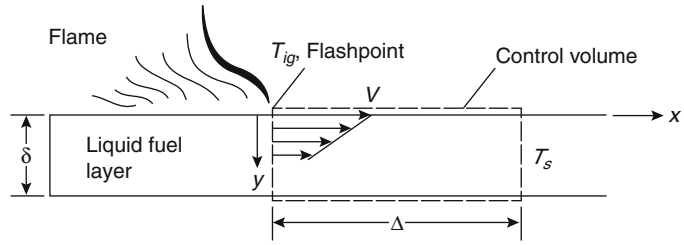

Fig. 23.15 Enhanced flame spread speed in liquids due to surface-tension induced flow

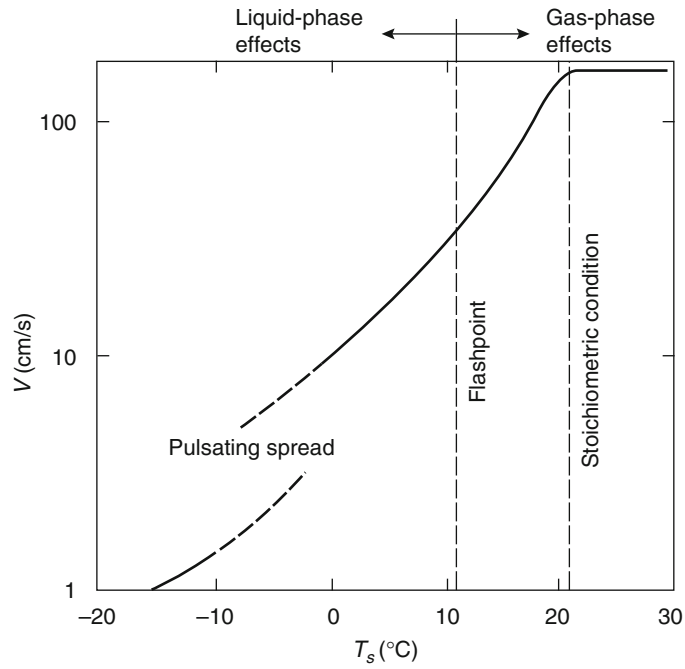

Fig. 23.16 Relationship between the liquid temperature and the rate of plane flame spread of methanol, based on Akita [40]

$$\tau = d\sigma/dx = (d\sigma/dT)(\partial T/\partial x) \qquad (23.19)$$

For a thin liquid layer, the surface tension effect results in nearly a Couette flow (constant shear) over the layer thickness, δ. Hence, it can be approximated that

$$\tau = (\mu \partial u/\partial y)_{y=0} \approx \mu V/\delta \qquad (23.20)$$

where μ is the liquid viscosity. By further approximating the surface tension gradient as a difference over length Δ, the flame speed can be estimated as

$$V = \frac{\left[\sigma(T_s) - \sigma\left(T_{ig}\right)\right]\delta}{\mu\Delta} \qquad (23.21)$$

provided $\sigma(T)$, the surface tension, is known as a function of temperature for the liquid, and Δ can be estimated for the conditions of speed. Also, δ, as in the thermally thick case for solids, is only the physical liquid depth for pools less than about 1 mm and, therefore, must be reinterpreted for pools of larger depth. For example, one might estimate δ as $\sqrt{(\mu/\rho)(\Delta/V)}$ for the deep-pool case.

Typical flame spread characteristics over a liquid fuel are sketched in Fig. 23.16 for liquid methanol from the data of Akita [40]. Below the flashpoint, $T_s < T_{i\ g} \sim 11$ °C, the spread is governed by transport phenomena within the liquid fuel. For initial liquid bulk temperatures above the flashpoint, a flammable mixture

always exists everywhere above the surface so that propagation is governed by gas-phase effects. Above a liquid temperature, which corresponds to stoichiometric conditions above the surface, the flame speed remains constant and usually above the normal premixed laminar flame speed. A study by Ito and Kashiwagi [41] used holographic interferometry to examine the liquid phase for subflashpoint liquid bulk temperatures. They examined the pulsating region depicted in Fig. 23.16, and the adjacent uniform region of spread just below the flame; both appear to contribute to flame spread rate in the uniform region.

Summary

This chapter has provided the practicing engineer with some insight into the nature of fire spread over materials. In general, surface flame spread depends on the heat transfer processes at the flame front. These transport processes depend not only on the fuel but also on the fuel's configuration and orientation and on ambient environmental conditions. Thus, estimates of flame spread require complex analysis and specific material data. The current state of knowledge does provide limited formulas and material data to make some estimates. In this chapter, the full scope of flame spread phenomena has not been addressed. For example, flame spread in mines, ducts, and buildings presents an entirely new and complex array of conditions. Thus, flame spread on materials must be evaluated in the context of their use, and appropriate data must be made available for proper assessments of materials.

Nomenclature

a	$k_f \dot{Q}''_\ell$
b	flame spread acceleration factor $(= (a - 1) - t_{ig}^*/t_b)$
c	specific heat of solid
c_g	specific heat of gas
c_p	specific heat of air
δ	fuel thickness
δ_{fc}	characteristic preheat distance
D	characteristic length of the burning area (height, etc.)
Da	Damköhler number
Δ	distance from the pyrolysis front
ΔH	heat of combustion
ΔH_{ox}	$\Delta H/r$
g	gravitational acceleration
k	$x_f/\dot{Q}_\ell^{*n}$
k'	constant $\left(k^{3/2}/c_p T_o g^{1/2}\right)^{2/3} \dot{Q}_\ell^{2/3}$
k	$x_f/\dot{Q}_\ell$
k_g	gas thermal conductivity
L	heat of gasification
μ	viscosity
q''	heat flux due to gas-phase conduction
q_f''	flame heat flux
q_{fc}''	characteristic flame heat flux
$\dot{Q}_\ell$	heat release rate per unit width
$\dot{Q}_\ell$	dimensionless heat release rate per unit width
$\dot{Q}_{\ell e}^*$	effective heat release rate per unit width
r	stoichiometric mass ratio oxygen/fuel
ρ	density
ϕ	impulse response function
Φ	opposed-flow preheat factor (numerator in n)
σ	surface tension
t	time
t_b	time to local burnout
t_c	characteristic decay time of pyrolysis
t_{ig}^*	characteristic time to ignition
τ	time
T_f	flame temperature
T_{ig}	ignition temperature
T_o	initial surface temperature
T_r	reference temperature
T_s	surface temperature
T_∞	ambient temperature
V_g	gas velocity
V_p	flame spread velocity
x_f	flame length
x_p	pyrolysis front length
x_{po}	pilot flame length
x_{poff}	maximum pyrolysis front length
$Y_{ox,\infty}$	mass fraction of oxygen
x, y	coordinates

Superscripts

$\cdot$	per unit time
$'$	per unit length
$''$	per unit area

Smoke Characterization and Damage Potentials

24

Jeffrey S. Newman, Geary G. Yee, and Paul Su

Introduction

Smoke is a mixture of (1) particulates consisting of soot, semi-volatile organic compounds (SVOC), and solid inorganic compounds; and (2) non-particulates consisting of very volatile organic compounds, volatile organic compounds, and liquid and gaseous inorganic compounds. Soot creates bridging between electrical conductors and conveys corrosive products, resulting in damage to electronics and electrical circuits through leakage current and corrosion, while SVOC and non-particulates stain and impart malodor to surfaces. Soot is also a very effective adsorbent and transport mechanism for SVOC, non-particulates and inorganic compounds.

The smoke problem (exclusive of toxicity or escape potential considerations) is ultimately characterized by the quantification of damage due to the deposition of combustion products onto building surfaces and contents (e.g., equipment, furnishings, and commodities). It is instructive to categorize the assessment of smoke damage potentials into two regimes: "far-field" at some distance away from the fire/smoke source and "near-field" close to the source, where it is likely to have simultaneous heat damage (and water damage such as in the case of fire sprinkler protection). In general, fire damage in the "near-field" is dominated by heat/water damage with smoke of a much lesser impact, while smoke can often be the governing damage mechanism in the "far-field" and, due to extent of travel and area coverage, of far greater impact.

Figure 24.1 illustrates, for example, the various components that are necessary to evaluate smoke damage potentials, especially in the "far-field". As shown in the figure, the impact of the smoke deposition profile resulting from smoke release, typically from a fire event, is quantified by the comparison of a defined damage function with its associated damage threshold. As will be subsequently discussed, the damage function can represent a variety of types of smoke damage including leakage current, corrosion and stain/odor. The deposition profile is assessed through the coupling of smoke generation, the characterization of pertinent smoke properties and the transport of smoke resulting in time and spatially resolved concentration profiles. Detection and active response both affect and are affected by these concentration profiles. Knowledge of the smoke deposition velocity is also an important component for the quantification of the resulting smoke deposition profile.

For reference, the solid gray-shaded blocks shown in Fig. 24.1 will be covered in detail in this Chapter while the three unshaded blocks labeled Concentration Profile, Transport and Generation are place holders that are outside of this Chapter's scope. In should be noted that

Generation refers to heat and gas species' production and is a function of the prescribed fire scenario with the content of Chap. 36 of this Handbook providing useful specific smoke and heat generation properties for a variety of materials. Transport and Concentration Profile data can be obtained from any number of physical correlations [1] or computer models [2, 3] coupled with the prescribed Generation information. Finally, Detection/Response is shown in light gray as it is covered only as an overview of important considerations as relating to the smoke Deposition Profile with details on detection given in Chap. 40 of this Handbook.

Deposition Profile

Deposition Velocity

The process by which smoke can deposit on various surfaces is often complex and can result from either a single dominant physical mechanism or a combination of mechanisms including particle inertia, sedimentation or gravitational settling, Brownian diffusion, thermophoresis or thermodiffusion, and electrostatic precipitation [4]. For electrically neutral aerosols, the governing mode of smoke deposition is primarily dependent on whether the transport flow is laminar or turbulent and the particle size.

The flow regime for smoke particle motion can be characterized by the magnitude of the particle Reynolds number, i.e.,

$$\mathrm{Re}_p = \frac{\rho_g d_p V}{\eta} \tag{24.1}$$

where ρ_g is the gas density, d_p the particle diameter, V the particle velocity and η is the gas viscosity.

Laminar Flow ($\mathrm{Re}_p < 1$)

1. For smoke particles >1 μm in diameter, the deposition is primarily due to gravitational settling. Stokes's Law applies to particle motion when inertial forces are negligible compared with viscous forces, and gives the particle terminal settling velocity, V_{TS} as

$$V_{TS} = \frac{\rho_p d_p^2 g}{18\eta} \tag{24.2}$$

where g is gravitational acceleration.

2. For smoke particles <1 μm in diameter, both Brownian diffusion as well as gravitational settling are important deposition mechanisms. An important assumption in Equation 24.2 is that the relative velocity of the gas at the surface of the particle is zero, which is not met for particle sizes that approach the mean free path of the gas. The particles move faster than predicted by Stokes's law and a slip correction factor, C_c, is needed [5]:

$$C_c = 1 + \frac{2.52\Lambda}{d_p} \tag{24.3}$$

where Λ is mean free path, which is 0.066 μm for air at 1 atm and 20 °C. The slip correction factor is a multiplicative factor applied to the right-hand side of Equation 24.2, increasing the terminal settling velocity.

Turbulent Flow ($Re_p > 1$)

1. For smoke particles >1 μm in diameter, the deposition begins to be influenced by both particle inertia as well as viscous effects, which was first shown by Friedlander and Johnstone in 1957 [6]. Inertial deposition occurs when a particle near a wall (surface) in the turbulent region is given sufficient lateral velocity toward the wall to be transported through the laminar layer and deposit on the wall (surface). The particle settling velocity transitions from a d_p^2 dependence in the Stokes regime to a $d_p^{1/2}$ dependence in the Newton drag regime. This transition can be accounted for by the introduction of a drag coefficient, C_D, in the calculation of settling velocity, i.e.,

$$V_{TS} = \left[\frac{4\rho_p d_p g}{3C_D\rho_g}\right]^{1/2} \tag{24.4}$$

Figure 24.2, for example, illustrates the functional relationship between C_D and Re_p for spherical particles. Numerous correlations have been developed to describe the drag coefficient and Reynolds number functional relationship. A particularly useful formulation covers the transition region ($1 < Re_p < 1000$) [4]:

$$C_D = \frac{24}{Re_p}\left(1 + 0.15Re_p^{0.687}\right) \tag{24.5}$$

2. For smoke particles <1 μm in diameter, Brownian diffusion becomes important. The

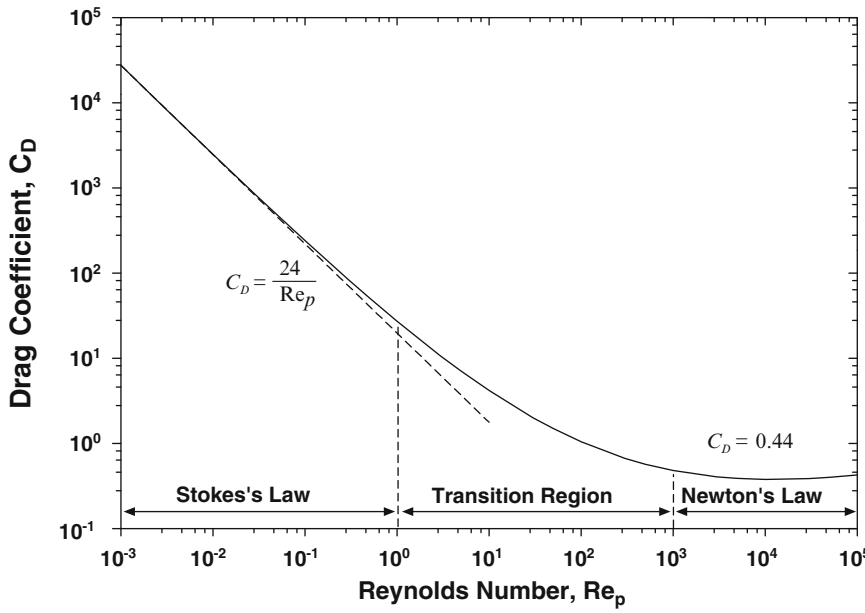

Fig. 24.2 Drag coefficient versus particle Reynolds number

diffusion coefficient of an aerosol/smoke particle can be expressed in terms of particle properties by the Stokes-Einstein derivation [7]. In this derivation, the diffusion force on the particles, which causes the particles' net motion along the concentration gradient, is equated to the force exerted by the gas resisting the particles' motion, i.e.,

$$D = \frac{k_B T C_c}{3\pi\eta d_p} \tag{24.6}$$

where D is the particles' diffusion coefficient, k_B Boltzmann's constant and T is the absolute temperature.

Thermophoresis can be important where large temperature gradients exist, e.g., from a smoke hot layer to a cold surface such as a wall or ceiling in an enclosure. Thermophoresis is the aerosol particle movement that results from the force exerted by a temperature gradient in a gas, resulting in a flow in the direction of decreasing temperature. This would be the dominant mechanism for very small particles <0.1 μm, even at small gradients of 1 °C/cm [4].

In addition, another phenomenon can occur at relatively high smoke concentrations. Cloud settling or mass subsidence occurs when the smoke concentration is sufficient to cause the entire cloud to move as an entity at a velocity significantly greater than the individual particle settling velocity [8]. (An aerosol or smoke cloud is defined as a region of high smoke concentration having a definite boundary in a much larger region of smoke-free air.) The difference in density causes the bulk motion of the smoke particles.

Table 24.1 gives illustrative examples of experimentally measured smoke deposition velocities for "far-field" conditions, i.e., locations away from the combustion/smoke source, where the primary observed deposition mechanism was characterized as gravitational settling [9]. As indicated in the table, the deposition velocities are on the order of 10^{-4} m/s and are quite similar in two different scale enclosures (1 m^3 smoke box and a 1200 m^3 enclosure). For "near-field" conditions, e.g., on the ceiling above a fire or for direct flame impact on an adjacent wall, the primary deposition mechanism is generally accepted as thermophoretic, with the deposition velocity dominated by the local temperature gradient. Thus, the thermophoretic smoke deposition velocity [10–12] is given by:

Table 24.1 Smoke deposition velocities [9]

	Deposition velocity (10^{-4} m/s)	
Material	1.0 m^3 smoke box	1200 m^3 enclosure
Nylon	2.5	–
Polycarbonate	1.9	–
Polyethylene	–	1.2
Polymethylmethacrylate	2.1	1.9
Polypropylene	–	1.3
Polyvinylchloride	1.4	–
Polystyrene	6.9	7.3

$$V_{TH} = \frac{K_{TH}\eta}{\rho_g T}\left(\frac{dT}{dx}\right) \tag{24.7}$$

where the gas properties are evaluated at the film temperature, i.e., the average between the wall and gas temperature at the location of interest. dT/dx is the gas phase temperature gradient at the surface. K_{TH} is the thermophoretic velocity coefficient which approaches a constant value of 0.55 as the Knudsen Number, given by the ratio of the molecular mean free path length Λ to the smoke particle diameter d_p, becomes large (>10) [11]. Examples of the characterization and quantification of fire-induced thermophoretic deposition are given in Refs. [13–16].

Detection Overview

While the detailed design of smoke detection systems is given elsewhere in this Handbook (Chap. 40), it is instructive to present here a brief overview of detection criteria as well as the potential need for specific smoke characteristics. Fire detection is achieved by using various types of detectors: (1) heat detectors (e.g., fixed-temperature, rate-of-rise sensors); (2) chemical compound – smoke detectors (e.g., ionization, photoelectric sensors and gas detectors such as CO or CO_2 sensors);

(3) flame detectors (e.g., ultraviolet and/or infrared sensors), etc. For effective detection of a fire, the most important parameter to evaluate is the total time associated with:

1. the occurrence of a specified hazard to people, buildings and contents created by the fire, t_H;
2. the transit time of the fire product(s) to the detector location, t_t;
3. the fire growth time to reach a detectable level of fire product(s) at the detector location, t_f;
4. the detector response time once t_f has occurred, t_D; and
5. the "effective" response time once the fire has been detected, t_E. The relationship between these times can be expressed as [17, 18]:

$$t_r = t_H - \left(t_t + t_f + t_D + t_E\right) \tag{24.8}$$

where t_r = residual time, which must be greater than or equal to zero. As an example, t_H depends on the defined hazard, which is a function of material properties and configuration and, for the smoke problem, would be the time to reach a specified damage threshold as outlined in Fig. 24.1. Similarly, t_f is identified with the generation step in the figure and t_t with the transport step.

In general, the response of a smoke (or gas species) detector can be treated as a first-order system coupled with a time lag, i.e.,

$$\frac{dC_s}{dt} = \frac{1}{\tau}[C_o(t - t_l) - C_s(t)] \tag{24.9}$$

where C_s is the instantaneous smoke concentration as measured by the detector at time t; C_o, identified with the concentration profile step in Fig. 24.1, is the "true" of reference concentration (outside the detector) at time $t - t_l$; τ is the detector time constant; and t_l is the lag time. Two apparent detector characteristics, τ and t_l, can be noted in Equation 24.9. τ can be thought of as the time constant for the specific sensor used in the detector, while t_l is associated with a delay in smoke (or a specific gas species) transport to the sensor such as through filters, sampling lines, etc. Equation 24.9 can be used to assess the detection time associated with the detection/response step in Fig. 24.1.

Smoke Characterization

The characterization of smoke requires increasingly more specific information concerning instantaneous smoke properties, particularly when assessing fire environments in enclosures. These properties include volume fraction, mass concentration, generation efficiency, particle size and yield. Smoke characteristics and yields of chemical compounds can change dramatically with a change in ventilation conditions, such as in an enclosure environment where the supply of air may be restricted. Quantifying changes in smoke properties have been shown to be useful in addressing the impact of ventilation on fire chemistry, which in turn relates to the smoke damage potential of a given fire scenario.

Optical techniques to characterize smoke are especially attractive since they provide continuous measurements without disturbing the environment. When a monochromatic beam of light passes through smoke, the fraction of light transmitted can be expressed as

$$\frac{I}{I_o} = \exp(-OD_\lambda l) \tag{24.10}$$

where I is the transmitted intensity; I_o is the initial intensity; OD_λ is the optical density (also referred to as the turbidity or extinction coefficient) of the smoke (m^{-1}); and l is the optical path length (m). The optical density is an intricate function of the smoke particle diameter, the smoke size distribution, the incident light wavelength and the complex refractive index of the smoke. It has previously been shown that the smoke volume fraction (i.e., the ratio of the smoke particle volume to the total gas volume) for a variety of materials can be related to the optical density through the following expression [19]:

$$f_v = \frac{OD_\lambda \lambda}{c} \tag{24.11}$$

where λ is the incident wavelength; and c is defined as an average coefficient of smoke extinction. For over-ventilated conditions, the

smoke mass concentration, C_s (kg/m^3) can be related to the smoke volume fraction through the smoke particle density, i.e.,

$$C_s = \rho_s f_v = \frac{\rho_s OD_\lambda \lambda}{c} \tag{24.12}$$

Reported values [19–23] for ρ_s typically range from 800 to 1800 kg/m^3, with 1100 to 1500 kg/m^3 common values. This perceived discrepancy in density is primarily related to the measurement technique, although combustion conditions and the specific material smoke source can influence the "apparent" density. For example, a value of 1100 kg/m^3 has been shown to be the resulting "apparent" density for a wide range of materials during over-ventilated flaming combustion and is recommended when optical methods are used to assess the relationship represented by Equation 24.12 with a value for c of 7.0 [19]. This value for the density has also been shown to derive consistent smoke yields for various materials. However, it is more important to maintain the ratio of ρ_s to c as a constant than to use a specific value for the smoke particle density. Thus, if value of 8.0 is used for c, a value of 1300 kg/m^3 should be used for the corresponding density. It should be noted that the ratio of $c/\rho_s\lambda$ is equivalent to the often referenced mass specific extinction coefficient, which has been extensively tabulated and generally shown to be relatively independent of fuel type [24–27].

Smoke Particle Size

Smoke particle sizes are typically characterized by specifying some representative particle diameter with a corresponding size distribution. Particle size characteristics are often represented by a log-normal particle size distribution function. For this type of distribution, the log of the particle diameter follows a Gaussian distribution. Therefore, the geometric mean diameter, d_g, is given by:

$$\ln d_g = \frac{\sum n_i \ln d_i}{N} \tag{24.13}$$

where n_i is the number of particles with diameter d_i and N is the total number of particles. The geometric standard deviation, σ_g, is given by:

$$\ln \sigma_g = \left[\frac{\sum n_i \left(\ln d_i - \ln d_g\right)^2}{N-1}\right]^{1/2} \tag{24.14}$$

The geometric standard deviation is dimensionless with a value equal to or greater than 1.0. One geometric standard deviation represents the range of particle sizes from (d_g/σ_g) to $(d_g \times \sigma_g)$. A variety of representative diameters can be used based on particle volume or mass. (For example, Refs. [15] and [30] tabulate the geometric particle diameters and distributions for a number of materials under both flaming combustion and pyrolysis.) A particularly useful particle representation uses the concept of an aerodynamic equivalent diameter (d_a), which is the diameter of a unit-density sphere having the same gravitational-settling velocity as the measured particle. The aerodynamic equivalent diameter takes into account the shape, roughness, and aerodynamic drag of the particle [4]. For example, Stokes's law, given in Equation 24.2, rewritten in terms of d_a and a standard particle density, ρ_0 (1000 kg/m^3) gives the following for the terminal settling velocity, V_{TS} in air:

$$V_{TS} = \frac{\rho_0 {d_a}^2 g}{18\eta} \tag{24.15}$$

Table 24.2 presents the aerodynamic equivalent mass mean diameter, d_{ag} for smoke generated from flaming plastic fires in various scale enclosures [9] and ducts/low velocity wind tunnels [28, 29]. The width of the distribution, σ_g is also given for reference. References [15] offers a detailed summary review of aerodynamic diameters from a number of additional materials including gases and liquids under various other configuration and combustion conditions.

Table 24.2 Aerodynamic mass mean diameter of smoke from flaming plastics[a]

Material	d_{ag}, μm	σ_g	Environment

Damage Functions

Leakage Current

Leakage current between two conducting elements occurs as a result of circuit bridging due to the presence of a conducting medium between the elements, such as water, conductive ions, soot, or dust. The increase of leakage current on electronic circuit boards can change overall circuit characteristics, e.g., degrade and/or damage circuit properties. This principle has been used to design a leakage current target for the measurement of smoke corrosivity [31–33]. The target, as shown in Fig. 24.3, has a comb-like pattern made of thin strips of copper with 40 insulating spaces between them. The dimensions of the target are shown in the figure. Specifically, for example, with respect to the manufacture of semiconductors, leakage current is uncontrolled ("parasitic") current flowing across region(s) of semiconductor structure/device in which no current should be flowing. Leakage is one of the main factors limiting increased computer processor performance. The presence of ionic compounds and soot in smoke deposited on the surface of a semiconductor is expected to damage the processor's functionality through an increase in leakage current.

An example of leakage current (LC) data for polycarbonate smoke deposition versus relative humidity (RH) is shown in Fig. 24.4 [34]. Values of measured LC somewhat surprisingly remain nearly constant at $1.8 \pm 0.3 \times 10^{-4}$ A over the range of relative humidity from 30 % to 90 %. For reference, measured LC data for targets without exposure are also plotted in the figure, and as expected are much smaller than for targets exposed to polycarbonate smoke. For example, at 90 % RH, the LC of an unexposed target at 1.1×10^{-6} A is much smaller than the LC of 1.8×10^{-4} A for a target exposed to the polycarbonate smoke. This indicates that the effect of soot bridging is the major contributor to the increase of LC for targets exposed to polycarbonate smoke and the contribution due to increase of RH is relatively minor. Reference [34] also gives similar data for nylon and polyvinylchloride. Figure 24.5 presents normalized smoke leakage currents for nylon, polycarbonate and polyvinylchloride. The data in the figure were normalized by dividing the leakage current results as illustrated in Fig. 24.4 by the average smoke deposition (g/m^2) which occurred over the duration of the LC target exposure. As indicated in Fig. 24.5, the average normalized LC ranges from $7.2 \pm 0.5 \times 10^{-5}$ A-m^2/g for nylon to $6.1 \pm 0.9 \times 10^{-4}$ A-m^2/g for polycarbonate. Relative humidity appears to have a limited effect, with a trend to slightly lower normalized LC above 60 % RH. Table 24.3 summaries the average results for the three materials studied.

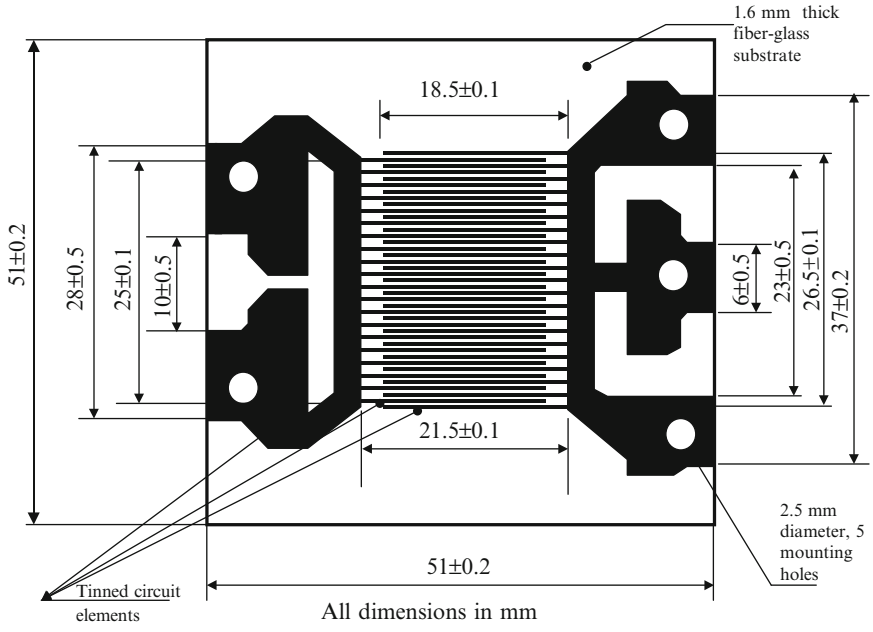

Fig. 24.3 Sketch of leakage current target (Taken from Ref. [32])

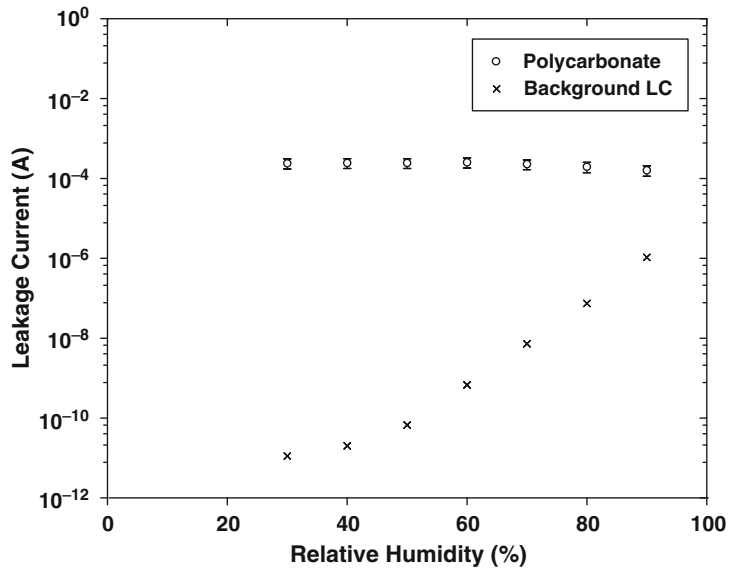

Fig. 24.4 Leakage current versus RH for LC targets exposed to polycarbonate smoke

Corrosion

Corrosion involves the reaction between a metal or alloy and its environment. It is an irreversible interfacial reaction, which causes the gradual deterioration of metal surface by moisture and corrosive chemicals. In aqueous or humid environments, corrosion is an electrochemical reaction in nature; it involves electron (e^-) transfer between anodic and cathodic

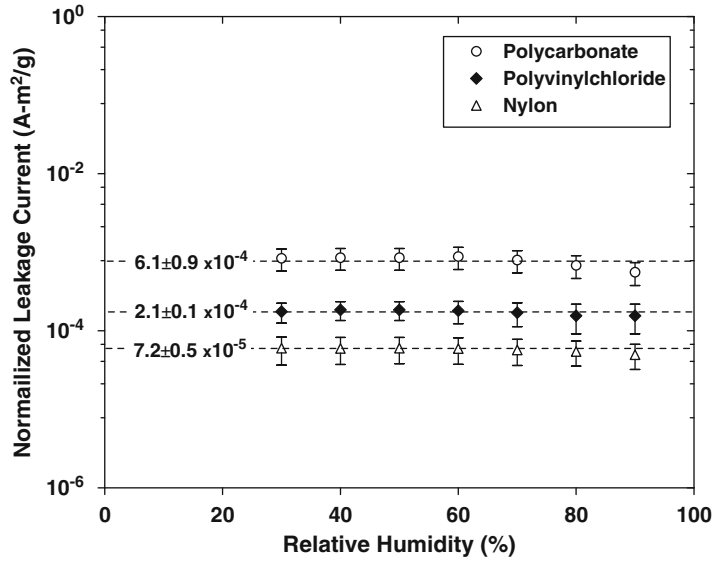

Fig. 24.5 Normalized leakage current versus relative humidity

Table 24.3 Leakage currents [34]

Material	Average leakage current (10^{-5} A)	Average smoke deposition (g/m^2)	Average normalized LC (10^{-4} A-m^2/g)
Nylon	18 ± 3	0.30 ± 0.11	6.1 ± 0.9
Polycarbonate	9.6 ± 0.5	0.45 ± 0.02	2.1 ± 0.1
Polyvinylchloride	0.94 ± 0.07	0.13 ± 0.02	0.72 ± 0.05

reaction sites. For corroding metals, the anodic reaction is the oxidation of a metal to its ionic state:

Anodic reaction:	$M \Rightarrow M^{n+} + ne^-$	[1]
Specific examples of anodic reactions:	$Cu \Rightarrow Cu^{2+} + 2e^-$	[2]
	$Al \Rightarrow Al^{3+} + 3e^-$	[3]
	$Sn \Rightarrow Sn^{2+} + 2e^-$	[4]

The cathodic reaction is a reduction process. For metallic corrosion, cathodic reactions like Reactions [5–7] are frequently encountered. In acid solutions, hydrogen evolution and oxygen reduction reactions (Reactions [5] and [6]) are the main cathodic reactions. In neutral or basic solutions, oxygen reduction reaction (Reaction [7]) is the primary cathodic reaction.

Cathodic reactions:		
Hydrogen evolution	$2H^+ + 2e^- \Rightarrow H_{2(g)}$	[5]
Oxygen reduction (acid solutions)	$O_2 + 4H^+ + 4e^- \Rightarrow 2\,H_2O$	[6]
Oxygen reduction (neutral or basic solutions)	$O_2 + 2H_2O + 4e^- \Rightarrow 4OH^-$	[7]

In general, corrosion caused by smoke is due to the presence of inorganic anions in smoke such as chloride (Cl^-), bromide (Br^-), and fluoride (F^-) plus moisture in the environment. In fires, corrosive combustion products such as HCl, HBr and HF are emitted along with the other combustion products, which are present as gases, liquids and solids. The corrosive combustion products are generally emitted as gases and liquids with inorganic anions in the structure. The non-corrosive combustion gases and liquids are emitted as inorganic and organic compounds and water, whereas solids are emitted as soot and inorganic metals and dust. The solid combustion products are broadly defined as particulates and the gaseous and liquid combustion products are broadly defined as non-particulates. The mixture of particulates and non-particulates that include products with inorganic atoms is defined as smoke. The main hazards regarding the exposure

Table 24.4 Failure mechanisms and causes for electrical/mechanical equipment damage

Failure mechanism	Failure cause
Corrosion	Metal contacts, cause open circuits
Shorts	Circuit bridging between contacts, cause leakage of current and shorts
Contact resistance	Coating of electrical contacts
Binding	Mechanical equipment (timers, hard disk drives, etc., impeded)

of electrical/mechanical equipment to smoke is the damage due to circuit bridging, corrosion, and binding, defined as smoke corrosivity. Circuit bridging occurs in reducing surface insulation and increasing leakage current for digital safety systems, multiplexers and functional circuit boards. In contrast, corrosion damage by acids and anions from smoke can be observed either short term or long after the fire. Smoke contamination also leads to other types of electrochemical corrosion degradation of circuit boards, such as dendrite metal migration between conduction lines, localized corrosion of uncoated metal wires and contacting areas, etc. Failure mechanisms and causes for electrical/mechanical equipment as a result of exposure to smoke are listed in Table 24.4 [35, 36].

The linear polarization resistance (LPR) and electrical resistance techniques based on electrochemistry can be used to evaluate smoke-induced corrosion on metals. The LPR technique enables the corrosion rate of metals in solution to be measured as in milli-inch per year (mpy). For example, the smoke and acid gases produced during material combustion can be captured and passed through a water-based solution. The corrosivity (or corrosion rate) of the solution can then be measured by the LPR technique. Table 24.5 shows LPR data for nylon, polycarbonate and polyvinylchloride from Ref. [34]. The normalized corrosion rate is defined as corrosion rate normalized with the amount of soot deposited on filters prior to acid gas collection in a water-based solution. Solutions from the polyvinylchloride tests demonstrated the highest corrosion rates among these three materials

Table 24.5 Smoke corrosion rates of copper [34]

Material	Corrosion rate (mpy)	Average smoke deposition on filters (10^{-5} g/m^2)	Average normalized corrosion rate (10^5 mpy-m^2/g)
Nylon	0.78 ± 0.17	0.38 ± 0.13	2.40 ± 1.50
Polycarbonate	0.03 ± 0.02	1.24 ± 0.43	0.03 ± 0.03
Polyvinylchloride	13.31 ± 4.3	2.19 ± 0.95	6.25 ± 0.76

averaging 13.31 mpy, while solutions from the polycarbonate tests demonstrated the lowest corrosion rates averaging 0.03 mpy. Similarly, solutions of polyvinylchloride tests demonstrated the highest normalized corrosion rates among these three materials tested averaging 6.25×10^5 mpy-m^2/g; solutions of polycarbonate tests exhibited the lowest normalized rates averaging 0.03×10^5 mpy-m^2/g.

Smoke Stain

In the characterization of staining of a surface from smoke deposition, it is useful to understand the mechanism by which the surface can undergo a discernable change in appearance. When light strikes an opaque object, as shown in Fig. 24.6, the total amount of reflected light is characterized as two distinctly different light reflections from the surface: specular reflection and diffuse reflection. Specular reflection is light that is directed at an angle opposite to the incident light and is perceived by the observer to be glare caused by the shininess or glossiness of the sample. To see the apparent color of the sample, observers must move their eyes away from the glare (specular) and concentrate on examining the diffuse (scattered) reflectance from the sample. Any changes in this diffuse reflectance due to deposition of smoke would be an indication of staining, i.e., potential smoke damage. Brightness is defined as the diffuse reflectivity of an opaque surface to light in the blue portion of the spectrum. Brightness is typically measured at an effective wavelength of 457 nm. Light of this wavelength appears blue to the human eye. In the appearance of paper, for example, brightness is an especially important property not only

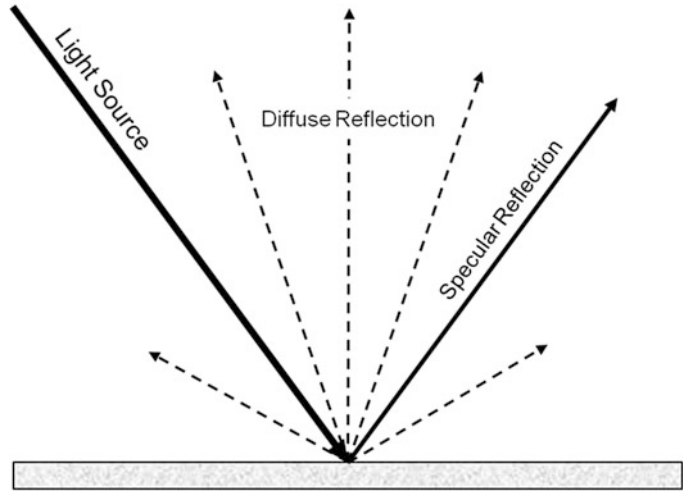

Fig. 24.6 Reflectance of light

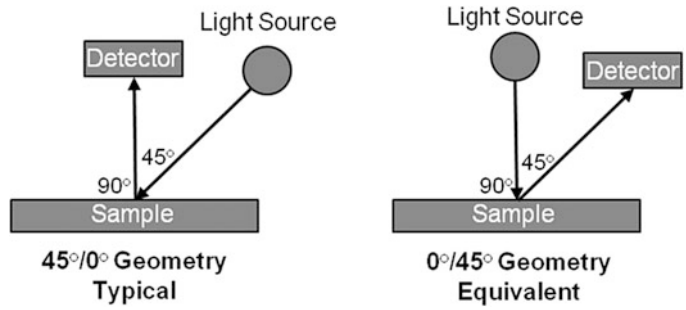

Fig. 24.7 Measurement of brightness

because of its aesthetic value, but also because of its effect on legibility and contrast between print and paper. Brightness should not be confused with "whiteness". The degree of whiteness of a paper conveys information on its color neutrality. It should be noted that the measurement of brightness is also an important tool in the characterization of the appearance of textiles, especially in the effectiveness of detergent cleaning agents.

A widely accepted method of brightness measurement, designated "Brightness 457", is described by TAPPI (Technical Association of the Paper Industry) Standard T 452 [37]. The method evaluates brightness at an effective wavelength of 457 nm and is illustrated by Fig. 24.7. Brightness 457 measures brightness with directional light incident at 45° with respect to the normal to the sample as shown by the illustration on the left in the figure. The detector is mounted on the normal and receives light reflected along the normal-conditions sometimes expressed by the shorthand notation (45° illumination, 0° observation). An equivalent geometry is shown on the right in the figure, where illumination is provided on the normal and the detector is located on the incident at 45° and can be described as (0° illumination, 45° observation). While the difference in optical geometry between the two configurations leads to equivalent brightness readings, the 0°/45° geometry in general provides a somewhat better measurement for surfaces that may be coated non-uniformly.

Figure 24.8 plots data from Ref. [38] for the characterization of smoke deposition from the combustion of polystyrene, polymethylmethacrylate and paper (i.e., liner board used in the manufacture of corrugated boxes) onto 47 mm dia filter targets. In the figure, the brightness change is plotted as a percent difference

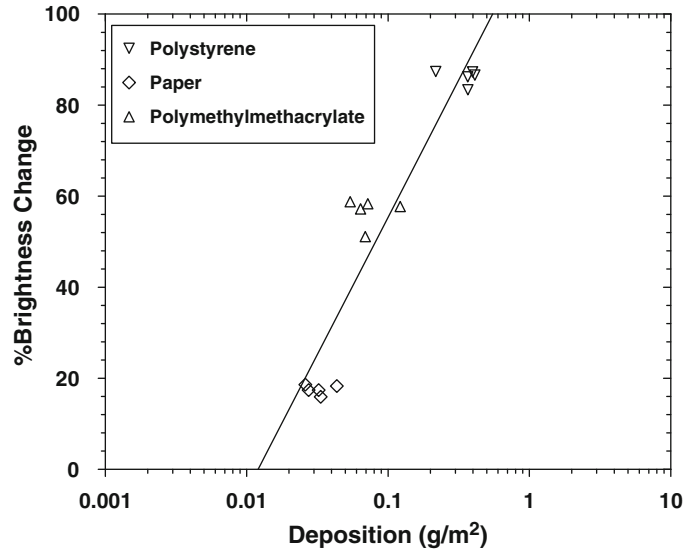

Fig. 24.8 Change in brightness versus deposition

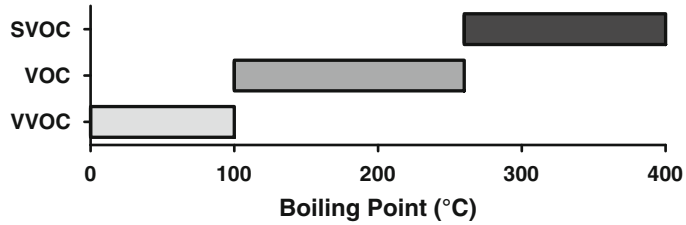

Fig. 24.9 Classification of volatile organic compounds by boiling point

from an uncontaminated reference of the filter substrate (polytetrafluoroethylene) versus smoke deposition for each of the tested materials. The black line through the data in the figure is given by

$$\%\,Brightness\ Change = 116 + 26.2 \times \ln Deposition \tag{24.16}$$

where *Deposition* has units of g/m^2. See Ref. [38] for additional experimental details including a calibration of the brightness measurement technique with carbon black.

Smoke Odor

While the particulate portion of smoke deposition consisting of solid soot particles, semi-volatile organic compounds (SVOC) and solid inorganic compounds is responsible for stain damage, the non-particulates in deposited smoke are the likely source for any potential odor damage. Smoke deposited from fires is highly porous [20] and can contain substantial quantities of adsorbed organic compounds [39, 40]. These non-particulates typically consist of volatile (VOC) and very volatile (VVOC) organic compounds that have boiling points between 0 °C and about 260 °C. Figure 24.9 illustrates the approximate boiling point ranges for each of the three classes of volatile organic compounds. Potential odors derived from smoke deposited after a fire can result from either dislodged smoke particles containing odor causing VOCs and VVOCs or direct desorption of organics from surfaces contaminated by smoke. The quantification of odor is highly complex and can require the quantification of five basic properties: (1) intensity, (2) degree of offensiveness, (3) character, (4) frequency and (5) duration.

Table 24.6 Total adsorbed volatiles onto deposited smoke [38]

Material	Volatile mass fraction (g volatiles/g deposited smoke)
Paper	0.31 ± 0.08
Polystyrene	0.35 ± 0.06
Polymethylmethacrylate	0.11 ± 0.02

The combination of these properties characterizes the perception of odor and ultimately any potential damage or risk contributed by smoke particles [41].

It can be useful to take a global approach to quantify odor from smoke due to the complexity of characterizing the perception of odor. For example, all volatile and semi-volatile organic compounds (VOCs and SVOCs) can be treated as potential odorants and consolidated into a single value associated with the deposition of smoke from the combustion of a given material. A useful technique [38] is to pass a known volume of smoke through quartz filter targets. Any deposited smoke is then analyzed by standard Thermal Desorption-Gas Chromatography-Mass Spectroscopy (TD-GC-MS) methods to assess the quantity and character of any adsorbed volatiles. Table 24.6 summarizes the total measured volatiles using this methodology normalized by the total mass of deposited smoke for paper, polystyrene and polymethylmethacrylate for data presented in Ref. [38].

While little is known about the quantitative adsorption of organics onto smoke particulates, the adsorption capacity of activated carbon has been widely investigated and has been shown to be very close to smoke particulates as well as characterized with similar adsorption mechanisms. [42] Therefore, the following analysis and discussion is directed toward activated carbon as a viable surrogate for the understanding of adsorption of organics onto smoke particulates.

The adsorption process of volatile organics onto activated carbon can be evaluated by assuming that a dynamic equilibrium, as proposed by Langmuir [43], exists between adsorbed gaseous molecules and the free gaseous molecules:

$$A_g + S \overset{adsorption\rightarrow}{\leftarrow desorption} AS \tag{24.17a}$$

where A is a gas molecule and S is a smoke particulate adsorption site. At equilibrium, the overall rate constant K is given by:

$$K = \frac{k_{ad}}{k_d} = \frac{[AS]}{[A_g][S]} \tag{24.17b}$$

where k_{ad} is the adsorption rate constant, k_d is the desorption rate constant and the bracketed quantities are the molecular concentrations. Using benzene as a representative VOC present in typical smoke from polymeric materials, the relative adsorption and desorption rate processes can be assessed. Figure 24.10, for example, plots the *ln* of the rate constant versus the inverse of the absolute temperature (1/K) [44]. As shown in the figure, the desorption rate of benzene gas molecules has a much stronger dependency on temperature than the adsorption rate. For example, desorption rates reduce by a factor of about 100 for a 100 °C drop in temperature, while adsorption rates reduce by less than a factor of 10 for the same temperature drop. The divergence in adsorption/desorption rates is illustrated further in Fig. 24.11, where the *ln* of equilibrium constant is plotted versus 1/K. Therefore, devolatilization rates of organics from deposited smoke particulates are expected to be low at normal ambient temperatures.

Figure 24.12 gives the adsorption capacity of benzene onto activated carbon versus the concentration of benzene relative to the saturation concentration. As shown in the figure, the adsorption capacity reaches a plateau for a mass fraction of about 0.38 (g of benzene adsorbed per g of activated carbon). This is similar to the mass fractions of VOCs found to be adsorbed on smoke deposited from paper and polystyrene, 0.31 and 0.35, respectively. This would suggest that the deposited smoke from these two materials is nearly saturated with volatile organic compounds. An explanation for lower mass

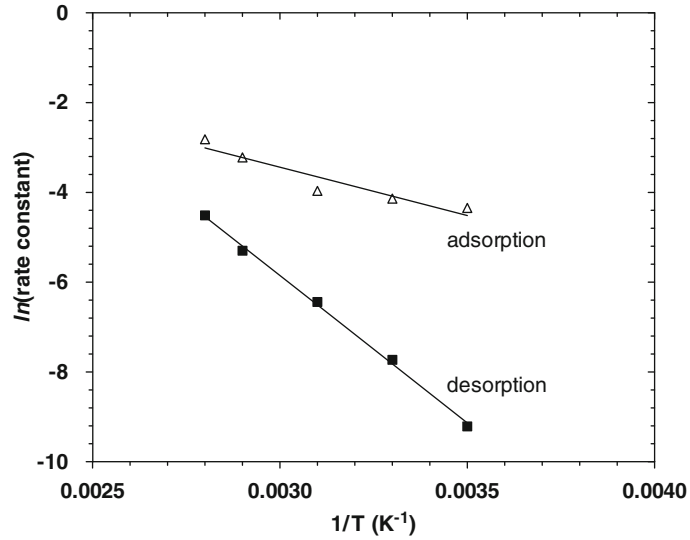

Fig. 24.10 Adsorption-desorption rate constants for benzene onto activated carbon

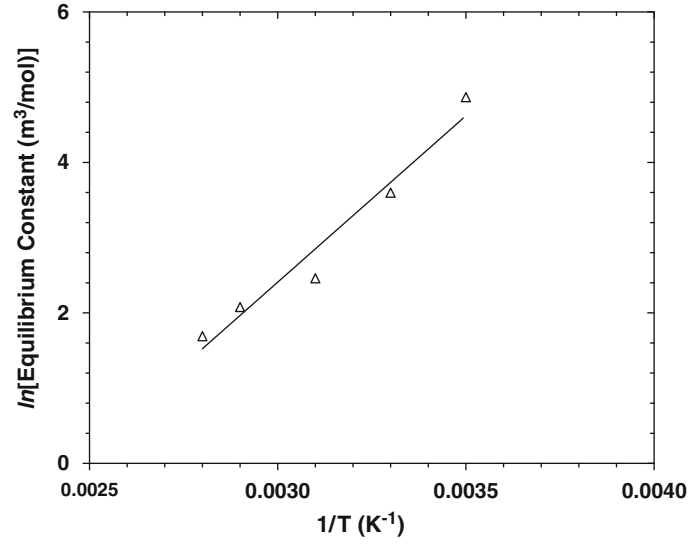

Fig. 24.11 Equilibrium constants for benzene onto activated carbon

fraction of 0.11 found for polymethylmethacrylate may reside in the somewhat unique combustion mechanism for polymethylmethacrylate, which initially decomposes into a monomer leading to the production of small highly combustible molecules [45]. This process could likely result in the production of fewer intermediate stable VOC products. Finally, for comparison purposes, Table 24.7 gives activated carbon adsorption capacities for two other common VOCs found in deposited smoke – acetone and toluene [46]. Similar capacities as previously discussed for benzene are noted and appear to be independent of the moisture condition of the activated carbon.

Damage Thresholds

The specification of damage thresholds can be rather arbitrary depending on the type of anticipated damage. For example, leakage

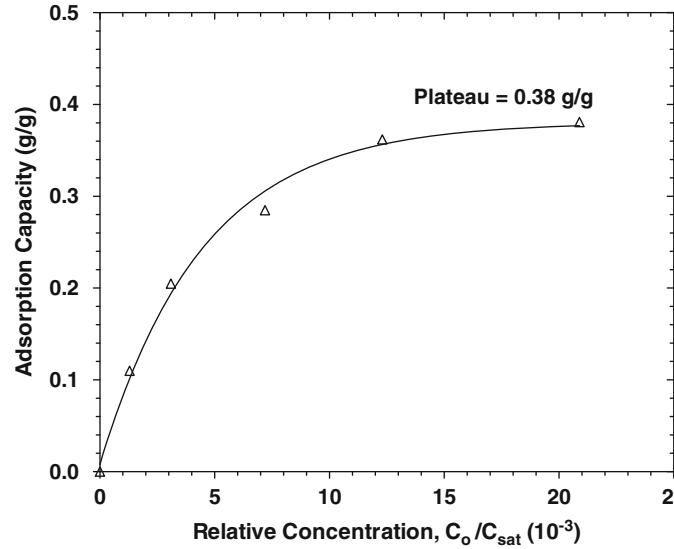

Fig. 24.12 Adsorption capacity of benzene onto activated carbon

Table 24.7 Activated carbon adsorption capacities [46]

	Activated carbon	
VOC	State	Adsorption capacity (g/g)
Acetone	Dry	0.33
	Wet	0.34
Toluene	Dry	0.41
	Wet	0.41

Table 24.8 Leakage current classifications

Leakage current (A)	Class
$LC < 10^{-8}$	Very low
$10^{-6} > LC > 10^{-8}$	Low
$LC > 10^{-6}$	High

current damage thresholds, while defined broadly, are relatively well-specified. Conversely, stain and odor thresholds are primarily driven by perception. Suggested specific thresholds are covered in the following discussion for leakage current and stain. A methodology for setting of odor thresholds is also proposed.

The classification or ranking of leakage current (LC) has been proposed in an ASTM draft, as shown in Table 24.8 [47]. Leakage currents less than 10^{-8} A are classified as very low, currents between 10^{-8} and 10^{-6} A are classified as low, while currents greater than 10^{-6} A are classified as high. This classification system can be used as one of the criteria for evaluating smoke damage of electrical circuits by measuring the value of LC for targets exposed to different materials as given previously in Table 24.3. The specific application would be used to denote the target LC levels, with smoke exposure to highly sensitive electronic components most likely in the very low range (e.g., semiconductor fabrication facilities and data centers) and machine components in the low range (e.g., machine shops and printing facilities).

As noted above, stain and odor damage thresholds are driven by human sensory perception unlike damage thresholds for leakage current. The field of psychophysics [48], for example, attempts to quantitatively study perception through the functional relationships between the physical properties of stimuli and the psychological responses to them. In particular, one important quantifier is the "Difference Threshold" (or "Just Noticeable Difference" often abbreviated as JND). The JND is the minimum amount by which stimulus intensity must be changed in order to produce a noticeable variation in sensory experience. Weber's Law

Table 24.9 Weber fractions for various stimuli

Stimuli	Weber fraction
Brightness	0.079
Loudness	0.048
Finger span	0.022
Heaviness	0.020
Line length	0.029
Taste	0.083
Electric shock	0.013
Odor	0.25

[48] (also known as the Weber–Fechner law) states that the JND depends on a percentage of change in a stimulus rather than on a fixed amount of change:

$$k_W = \Delta S/S \tag{24.18}$$

where ΔS represents the difference threshold (JND), S represents the initial stimulus intensity and k_W signifies that the proportion on the right side of the equation remains constant despite variations in the S term. k_W is typically referred to as the Weber fraction and is given in Table 24.9 for sensory perception response to a number of different stimuli [49, 50].

The Weber fractions for brightness and odor, i.e., 0.079 and 0.25, respectively, are of particular interest for assessing smoke damage thresholds for stain and odor. Applying a brightness threshold of 0.079 [corresponding to a % *Brightness Change* of 7.9 % in Equation 24.16] to the smoke deposition data in Fig. 24.8, results in a smoke damage threshold of ~0.015 g/m^2 for smoke stain.

Odor thresholds for smoke damage are somewhat more difficult to assess than those for stain. A useful approach is first to establish a reasonable odor baseline without smoke deposition for the target surface. If, for example, the target surface is a typical packaging material, then the inherent concentration of volatile organic compounds (VOCs) of the packaging would be relevant. For instance, odor in recycled packaging papers has been related to several VOCs such as phenols and aldehydes [51]. The typical average concentration is about 100 ppm (or 1.0×10^{-4} g VOC per g paper). Similar or higher VOC concentrations have been found for other types of papers and plastic packaging materials [52–54]. The food and pharmaceutical industries are particularly concerned with odor and/or taste transfer from VOCs contained in product packaging. For example, the sources of VOCs in paper packaging can be from the original paper manufacturing process, including the paper itself, inks, binders, adhesives and coatings. Recycled paper, especially from newspaper, can have VOC contents of up to 4000 ppm (or 4.0×10^{-3} g VOC per g paper) [55].

As a further illustration, the baseline odor threshold for a typical paper boxed commodity stored in a warehouse can be determined by a combination of three factors: (1) the packaging VOC content, (2) the paper density (often referred to as basis weight or grammage in g/m^2) and (3) the odor difference threshold or Weber fraction (i.e., 0.25). Typical paper densities for liner board used to construct the paper box range from a low of 125 g/m^2 to a high of over 440 g/m^2. Using 100 ppm as a typical average VOC content with a paper density of, for instance, 200 g/m^2, the baseline volatile organic content of the target paper surface can be estimated as:

$$\left[\frac{100\,x\,10^{-6}\,g\,VOC}{g\,paper}\right] \times \left[\frac{200\,g\,paper}{m^2\,paper}\right] = \left[\frac{0.020\,g\,VOC}{m^2\,paper}\right]$$

The odor threshold corresponding to the JND would be 25 % higher or 0.025 g VOC/m^2.

Example Application to Semiconductor Fabrication Facilities

Semiconductor fabrication facilities are high-value properties that contain very expensive process equipment and related support equipment. During semiconductor fabrication, process liquid heating and other electrical sources present potential ignition hazards. Note that semiconductor fabrication cleanrooms are always provided

with sprinkler protection, and the likely fire scenario involves combustible plastics resulting in complete equipment loss due to heat damage in the vicinity of the fire origin, and partial or complete loss at some distance from the fire origin due to smoke damage. The majority of smoke damage is due to surface contamination, leading to leakage current and long-term corrosion on electronic products and equipment. As previously described, this type of damage can be linked to smoke deposition by the use of damage functions. Therefore, the estimation of smoke damage in semiconductor cleanrooms requires a methodology that connects the fire source and the damage function, and allows for mapping the damage area for a given facility size.

Damage Estimation Model

The general model for estimating smoke damage is described in detail in Ref. [56], and includes the definition of the fire source based on experiments, simulation of smoke transport and deposition using numerical models, and calculation of smoke damage based on measurements. When fire scenarios involve fire growth and sprinkler suppression, current theories and models can not predict either the burning rate or the smoke generation rate and the fire source needs to be defined based on experimental data. Figure 24.13 illustrates the procedures and data sources for this general model. It should be noted that an important assumption and limitation of the transport model is that CO_2 is an adequate surrogate for smoke, with smoke particles transporting as the gas phase. This assumption may not hold for larger smoke particles.

Fire Scenario and Results

The selected fire scenario [56] uses a numerical simulation following the geometry of a typical bay-and-chase cleanroom configuration. Figure 24.14 shows a cleanroom module used in the numerical simulation. This module stands for a section of four pairs of clean bays in the middle of the left half of the cleanroom. The clean bays with wet bench and etch tools (two right bays) were duplicated to create a four-bay long module. The simulated fire source consists of a growing polycarbonate fire within a cleanroom stocker which peaks at a heat release rate of about 300 kW. (Stockers are self-contained units used for the storage of in-process and finished semiconductor wafers, which are commonly stored in plastic boxes in open shelves within the stocker.) Figure 24.15 plots the maximum expected smoke deposition versus radial distance from the stocker fire. The damage functions for polycarbonate (i.e., leakage current from Table 24.3 and corrosion from Table 24.5) can be used to convert the smoke deposition values in the figure into the corresponding expected leakage currents and corrosion rates. These results are given in Fig. 24.16. Finally, applying the proposed leakage current damage thresholds as given in Table 24.8, yields expected smoke damage potentials as illustrated in Fig. 24.17.

Nomenclature

c	Average coefficient of smoke extinction
C_c	Slip correction factor
C_o	Reference concentration
C_s	Smoke mass concentration
d_a	Aerodynamic equivalent mass diameter
d_{ag}	Aerodynamic equivalent geometric mean mass diameter
d_g	Geometric mean diameter
d_p	Particle diameter
D	Diffusion coefficient
f_v	Smoke volume fraction
g	Gravitational acceleration
η	Gas viscosity
I	Transmitted light intensity
I_o	Initial light intensity
k_{ad}	Adsorption rate constant
k_B	Boltzmann's constant
k_d	Desorption rate constant
k_W	Weber fraction
K	Overall rate constant
K_{TH}	Thermophoretic velocity coefficient
l	Pathlength
LC	Leakage current
λ	Wavelength of light
Λ	Mean free path
n_i	Number of particles with diameter d_i
N	Total number of particles
ρ_g	Gas density
ρ_o	Standard particle density
ρ_s	Smoke particle density
σ_g	Geometric standard deviation
Re_p	Particle Reynolds number
OD_λ	Optical density at wavelength λ
S	Stimulus
ΔS	Change in stimulus
t	Time
τ	Time constant
T	Temperature
V	Particle velocity
V_{TH}	Thermophoretic deposition velocity
V_{TS}	Terminal settling velocity

Jeffrey S. Newman, retired, was an assistant vice president and principal engineer for FM Global. He specialized in characterization of fire environments including modeling, flammability of materials, smoke damage, full-scale fire testing, and smoke and fire detection.

Dr. Geary G. Yee is a physical chemist and senior research specialist for FM Global. He has specialized in polymer pyrolysis, microbial corrosion, small lab-scale fire testing, smoke characterization, and material failure analysis.

Dr. Paul Su is a senior research specialist and technical team leader for FM Global. He has specialized in materials and corrosion research including corrosion testing and control, failure analysis, smoke corrosivity, nanomaterials research, and chemical product development.

Heat Transfer from Fires to Surfaces 25

Brian Y. Lattimer

Introduction

The heat transfer from fires to adjacent surfaces is an important consideration in many fire analyses. Some example applications that may require knowledge of the heat transfer from a flame include heating and failure of structural beams, heat transfer through walls and ceilings, and the ignition and flame spread along combustible surfaces.

Flames transfer heat to adjacent surfaces primarily through convection and radiation. Techniques for efficiently modeling the heat transfer from flames are still being developed; however, experimental data and empirical correlations have been generated to predict flame heat transfer for a number of common geometries. This chapter will focus on the data and empirical correlations that have been developed.

Empirical correlations for predicting heat transfer from flames are typically simple to use; however, their use is usually limited to a particular type of fire or the geometry of the surface being heated. The types of fires considered in this chapter include

- Exposure area fires (burning objects)
- Wall and ceiling fires
- Window flames

Exposure area fires are burning objects located adjacent to or near the surface being heated. Wall and ceiling fires are those fires produced by a burning wall or ceiling. Window flames are flames extending outside of a compartment containing a fire.

The heat transfer from fires has been characterized for a range of different surface geometries. The geometries included in this chapter are

- Flat vertical wall
- Flat unconfined and confined ceilings
- Parallel flat vertical walls
- Corner walls at 90°
- Corner walls at 90° with a ceiling
- Horizontal I-beams beneath a ceiling

The majority of the data presented in this chapter is from water-cooled heat flux gauge measurements. Using these data, correlations were developed from tests where important parameters were varied (i.e., heat release rate, fire base dimension, etc.). The range of the data and the correlating parameters need to be taken into consideration before applying the correlations. For example, the heat flux along the length of the flame has historically been correlated with flame length measured in that particular study. Measured flame lengths can vary depending on the measurement technique, definition, and surrounding geometry. For the studies considered in this chapter, the data were nondimensionalized with either the average (50 % intermittent) flame length or the flame tip length. Therefore, heat flux correlations should be applied using either the flame length correlation developed in the study or one that has been demonstrated to predict the flame length in that study.

Heat Transfer Boundary Condition

The heat flux boundary condition for a material surface exposed to a fire includes the exposure heat flux from the fire and the reradiation losses from the surface. The exposure heat flux from the fire is composed of a radiative heat flux plus a convective heat flux. The heat flux boundary condition for a fire heating an adjacent surface is

$$-k\frac{dT}{dx} = q_s'' = \varepsilon_s q_{\text{rad}}'' + h\left(T_f - T_s\right) - \varepsilon_s \sigma T_s^4 \tag{25.1}$$

assuming negligible heating from the surroun ding environment.

Heat Flux Gauges

The radiation and convective heat flux terms in Equation 25.1 are difficult to accurately calculate due to the dependence of these terms on geometry and fire properties. As a result, water-cooled total heat flux gauges are commonly used to measure the maximum total exposure heat flux (or cold surface heat flux) from fires in different configurations. The maximum total exposure heat flux measured using the gauge can be used to quantify the heat flux into the material surface.

The total heat flux onto a water-cooled heat flux gauge is described by the following equation:

$$q_{hfg}'' = \varepsilon_{hfg} q_{\text{rad}}'' + h\left(T_f - T_{hfg}\right) - \varepsilon_{hfg}\sigma T_{hfg}^4. \tag{25.2}$$

These gauges are cooled so that their surface temperatures remain near ambient (20–80 °C), and they are coated with a high emissivity paint $(\varepsilon \sim 0.95)$ to maximize the absorbed radiation. Cooling the gauge surface maximizes the convective heat transfer and minimizes the radiative losses; thus, the cooled heat flux gauges measure the maximum total exposure heat flux.

The heat flux measured using the gauge can be used to determine the heat flux to an adjacent surface being heated by a fire. By solving for the radiation from the fire in Equation 25.2, the equation for the boundary condition in Equation 25.1 becomes

$$q_s'' = \frac{\varepsilon_s}{\varepsilon_{hfg}}\left[q_{hfg}'' - h\left(T_f - T_{hfg}\right) + \varepsilon_{hfg}\sigma T_{hfg}^4\right] + h\left(T_f - T_s\right) - \varepsilon_s \sigma T_s^4 \tag{25.3}$$

Assuming the heat transfer coefficient at the heat flux gauge is the same as the heat transfer coefficient at the material surface, Equation 25.3 can be reorganized resulting in

$$q_s'' = \frac{\varepsilon_s}{\varepsilon_{hfg}} q_{hfg}'' + \left(1 - \frac{\varepsilon_s}{\varepsilon_{hfg}}\right) hT_f - h\left(T_s - \frac{\varepsilon_s}{\varepsilon_{hfg}} T_{hfg}\right) - \varepsilon_s \sigma\left(T_s^4 - T_{hfg}^4\right) \tag{25.4}$$

As a result, the need to determine the radiation heat flux from the fire has been removed. However, this expression still requires the gas temperature near the surface to be measured, T_f, and the emissivity of the adjacent surface, ε_s, to be known in order to calculate the net heat flux into the surface. Assuming the emissivity of the adjacent surface is equal to the heat flux gauge emissivity $\left(\varepsilon_s = \varepsilon_{hfg}\right)$, Equation 25.4 reduces to the following:

$$q_s'' = q_{hfg}'' - h\left(T_s - T_{hfg}\right) - \varepsilon_{hfg}\sigma\left(T_s^4 - T_{hfg}^4\right) \tag{25.5}$$

Through Equation 25.5, the net heat flux into an adjacent surface can be determined using the heat flux from a water-cooled gauge, gauge temperature, gauge emissivity, and heat transfer coefficient. The gauge temperature and emissivity are typically known; therefore, the only unknown is the convective heat transfer coefficient.

An estimate of the local heat transfer coefficient, h, is needed to calculate the heat flux into the material. The heat transfer coefficient is dependent on the local velocity, gas temperature, and geometry. For natural convection on

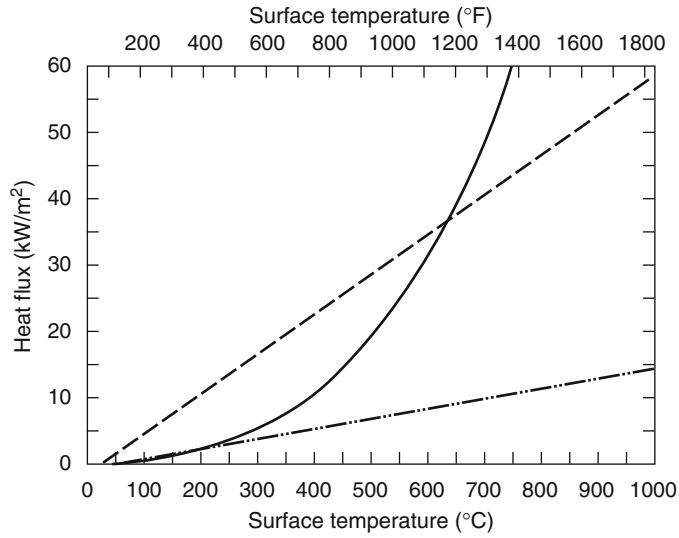

Fig. 25.1 Magnitude of the radiative and convective terms in Equation 25.5: radiation (—); convection with h = 0.015 kW/(m^2-K) (– · · –); and convection with h = 0.050 kW/(m^2-K) (– – –)

horizontal and vertical surfaces, the heat transfer coefficient varies from approximately 0.010 to 0.020 kW/m^2-K. These coefficients apply to fires flowing against walls or along ceilings. Higher heat transfer coefficients are expected in areas where fires impinge on surfaces. Based on data from Kokkala [1, 2] and You and Faeth [3, 4], the local convective heat transfer coefficient where a diffusion flame impinges on a ceiling is on the order of 0.050 kW/(m^2-K).

Figure 25.1 contains a plot of the radiative and convective heat flux terms in Equation 25.5 that are subtracted from the measured heat flux. The convective term is plotted using convective heat transfer coefficients of 0.015 kW/m^2-K and 0.050 kW/m^2-K. The radiative term is larger than the convective term at temperatures higher than 300 °C with a heat transfer coefficient of 0.015 kW/m^2-K and at temperatures greater than 600 °C with a heat transfer coefficient of 0.050 kW/m^2-K. Based on results in this plot, a non-conservative boundary condition will result if the heat transfer coefficient is over estimated.

The following examples are provided to illustrate how the heat flux into the material varies as the material surface temperature increases and how different assumptions (i.e., surface emissivity, heat transfer coefficient) affect the heat flux into the material surface.

Example 1 A water-cooled heat flux-gauge is used to measure the total incident heat flux from a fire against a wall painted black. The measured heat flux is 30 kW/m^2 and the water cooling the gauge is measured to be 350 K. Both the wall emissivity and the heat flux gauge have a surface emissivity of 0.95, and the heat transfer coefficient is 0.01 kW/m^2-K. Determine the net heat flux into the wall when the wall surface temperature is 600 K, 700 K, and 800 K.

Solution Equation 25.5 can be used to determine the heat flux into the wall when the wall is at different temperatures.

$$q_s'' = q_{hfg}'' - h\left(T_s - T_{hfg}\right) - \varepsilon_{hfg}\sigma\left(T_s^4 - T_{hfg}^4\right)$$

$$q_s'' = 30 - 0.01(T_s - 350) - (0.95)\left(5.67 \times 10^{-11}\right) \times \left(T_s^4 - 350^4\right)$$

- Wall surface temperature of 600 K

$$q_s'' = 30 - 0.01(600 - 350) - (0.95)\left(5.67 \times 10^{-11}\right) \times \left(600^4 - 350^4\right)$$

$$q_s'' = 21.3 \text{ kW/m}^2$$

- Wall surface temperature of 700 K

$$q_s'' = 30 - 0.01(700 - 350) - (0.95)\left(5.67 \times 10^{-11}\right) \times \left(600^4 - 350^4\right)$$

$$q_s'' = 14.4 \text{ kW/m}^2$$

- Wall surface temperature of 800 K

$$q_s'' = 30 - 0.01(800 - 350) - (0.95)\left(5.67 \times 10^{-11}\right) \times \left(800^4 - 350^4\right)$$
$$q_s'' = 4.2 \text{ kW/m}^2$$

Example 2 A water-cooled heat flux gauge is used to measure the total incident heat flux from a fire against a wall. The heat flux gauge measured a heat flux of 30 kW/m^2 while the gas temperature was measured to be 1173 K. The water cooling the gauge was measured to be 350 K. The heat flux gauge has a surface emissivity of 0.95, and the heat transfer coefficient is 0.01 kW/m^2-K. With a wall surface temperature of 700 K, determine the net heat flux into the wall if the surface emissivity is 0.94, 0.90, 0.70, and 0.50. In each case, what is the percent error associated with assuming the wall surface emissivity is equal to the heat flux gauge surface emissivity?

Solution Due to the surface emissivity of the wall being different from that of the heat flux gauge, the heat flux into the wall is determined using Equation 25.4:

$$q_s'' = \frac{\varepsilon_s}{\varepsilon_{hfg}} q_{hfg}'' + \left(1 + \frac{\varepsilon_s}{\varepsilon_{hfg}}\right) hT_f - h\left(T_s - \frac{\varepsilon_s}{\varepsilon_{hfg}} T_{hfg}\right) - \varepsilon_s \sigma \left(T_s^4 - T_{hfg}^4\right)$$
$$q_s'' = \frac{\varepsilon_s}{0.95} 30 + \left(1 - \frac{\varepsilon_s}{0.95}\right) 0.01(1173) - 0.01\left(700 - \frac{\varepsilon_s}{0.95} 350\right) - \varepsilon_s 567 \times 10^{-11}\left(700^4 - 350^4\right)$$

The heat flux into the surface where the wall and the gauge have the same emissivity is taken from Example 1b and is $q_s'' = 14.4$ kW/m^2.

- Surface emissivity of 0.94

$$q_s'' = 14.2 \text{ kW/m}^2$$

The assumption of equal surface emissivity results in a heat flux 0.7 % higher.

- Surface emissivity of 0.90

$$q_s'' = 13.9 \text{ kW/m}^2$$

The assumption of equal surface emissivity results in a heat flux 3.8 % higher.

- Surface emissivity of 0.70

$$q_s'' = 11.8 \text{ kW/m}^2$$

The assumption of equal surface emissivity results in a heat flux 17.7 % higher.

- Surface emissivity of 0.50

$$q_s'' = 9.8 \text{ kW/m}^2$$

The assumption of equal surface emissivity results in a heat flux 31.8 % higher.

Example 3 A water-cooled heat flux gauge is used to measure the total incident heat flux from a fire against a wall painted black. The measured heat flux is 30 kW/m^2 and the water cooling the gauge is measured to be 350 K. Both the wall emissivity and the heat flux gauge have a surface emissivity of 0.95. With a wall surface temperature of 700 K, determine the net heat flux into the wall with heat transfer coefficients of 0.01 kW/m^2-K, 0.015 kW/m^2-K, and 0.02 kW/m^2-K.

Solution Equation 25.5 can be used to determine the heat flux into the wall when the wall is at different temperatures.

$$q_s'' = q_{hfg}'' - h\left(T_s - T_{hfg}\right) - \varepsilon_{hfg} \sigma \left(T_s^4 - T_{hfg}^4\right)$$
$$q_s'' = 30 - h(700 - 350) - (0.95)\left(5.67 \times 10^{-11}\right)\left(700^4 - 350^4\right)$$

- Heat transfer coefficient of 0.01 kW/m-K

$$q_s'' = 14.4 \text{ kW/m}^2$$

- Heat transfer coefficient of 0.015 kW/m-K

$$q_s'' = 12.6 \text{ kW/m}^2$$

- Heat transfer coefficient of 0.02 kW/m-K

$$q_s'' = 10.9 \text{ kW/m}^2$$

Adiabatic Surface Temperature

The adiabatic surface temperature has been proposed as a means for quantifying the thermal boundary condition in fire environments [5–8]. The adiabatic surface temperature is the surface temperature that would exist if the surface were perfectly insulated. From Equation 25.1, the adiabatic flame temperature is defined as

$$0 = \varepsilon_s q_{rad}'' + h\left(T_f - T_{ast}\right) - \varepsilon_s \sigma T_{ast}^4 \quad (25.6)$$

Combining with Equation 25.1, a relationship between the heat flux at the surface and the adiabatic surface temperature is

$$q_s'' = \varepsilon_s \sigma \left(T_{ast}^4 - T_s^4\right) + h\left(T_{ast} - T_s\right) \quad (25.7)$$

The expression provides a relationship between the adiabatic surface temperature and the heat flux to the surface. Equation 25.7 has a form similar to Equation 25.1 when the radiation term, q_{rad}'', is taken as the radiation from a blackbody source, σT_{rad}^4. Based on this, adiabatic surface temperature can be thought of as an effective gas temperature that embodies the radiation and convection gas temperatures. The adiabatic surface temperature can then be used as the boundary surface temperature for calculating the thermal response of materials exposed to fire conditions, knowing the heat transfer coefficient and surface emissivity. The adiabatic surface temperature has been successfully used as an effective gas temperature to quantify the thermal boundary condition for thermo-structural analysis [6, 8]. Analysis has not been reported on whether the boundary condition using the adiabatic surface temperature provides the same results as using cold surface heat flux measurement, q_{hfg}'', and Equation 25.5.

Plate thermometers have been used to measure the adiabatic surface temperature in furnace environments [5–8]. Due to the time constant of the devices [5–8], the adiabatic surface temperature measurement provided by plate thermometers need to be carefully considered in applications where the fire environment is transient.

Objects Immersed in Flames

Some of the highest heat fluxes measured from diffusion flames have been measured in tests with objects immersed in large, open hydrocarbon pool fires. In these tests, small and large objects (relative to the fire size) were placed within the pool fires. These tests were performed to evaluate the heat transfer from fires to large objects such as fuel tanks, weapons, and nuclear containers.

The maximum heat fluxes measured in these tests are summarized in Tables 25.1 and 25.2. From data in these tables [9–19], the size of the object relative to the pool fire has a significant impact on the incident heat flux to the object.

Table 25.1 Heat fluxes to objects immersed in large pool fires [9–19]

Test	Pool size	Fuel	Peak heat flux (kW/m^2)
AEA Winfrith [9]	0.5 × 9.45 m	Kerosene	150
US DOT [9]	Not listed	Kerosene	138
USCG [9]	Not listed	Kerosene	110–142
US DOT [9]	Not listed	Kerosene	136–159
Sandia [9]	Not listed	Kerosene	113–150
HSE Buxton [9]	Not listed	Kerosene	130
Shell Research [9]	4.0 × 7.0 m	Kerosene	94–112
Large cylinder [10]	9.1 × 18.3 m	JP-4	100–150
Small cylinder [10]	9.1 × 18.3 m	JP-4	150–200
Russell and Canfield [10]	2.4 × 4.8 m	JP-5	175

Large calorimeters were measured to be exposed to heat fluxes of 100–150 kW/m^2. McLain [17] and Taylor et al. [18] measured slightly lower heat fluxes (75–85 kW/m^2) in their tests with large items that were similar in size to the pool fire. In studies with small calorimeters, peak heat fluxes were measured to range from 150 to 200 kW/m^2. The difference in the heat fluxes measured for small and large items immersed in pool fires has been attributed to the difference in the convective heat transfer coefficient, the flame thickness, and the impact of the object on the flame temperature. Small-scale calorimeter data provide a bound for heat fluxes to an item immersed in a pool fire. Based on the available data, a bounding heat flux of 175 to 200 kW/m^2 is possible.

Table 25.2 Heat fluxes to different size objects immersed in fires [10–19]

Object	Peak heat flux (kW/m^2)
Large calorimeter [10]	100–150

[a]Object size comparable to pool fire size

Exposure Fires

Fires Adjacent to Flat Walls

Heat fluxes from exposure fires adjacent to flat walls have been experimentally studied using propane sand burners and characterized for various burning objects. The experimental study provides a systematic approach of calculating heat fluxes for this geometry.

An extensive experimental study was performed by Back et al. [20] to characterize the heat transfer from a fire to a directly adjacent wall. In this study, fires were generated using square propane sand burners with edge lengths of 0.28, 0.37, 0.48, 0.57, and 0.70 m. Heat flux fields were measured for fires ranging from 50 to 520 kW.

A plot of the peak heat fluxes measured for each type of fire evaluated is shown in Fig. 25.2. Peak heat fluxes for the different fires evaluated were determined to be a function of fire heat release rate. This dependence was attributed to the larger size fires resulting in thicker boundary layers, which is related to the radiation pathlength. Based on gray-gas radiation theory, the authors found the following relation adequately represented the data:

$$q''_{cl} = q''_{\text{peak}} \quad z/L_f \leq 0.4 \tag{25.8}$$

These peak heat fluxes were measured in the lower part of the fire ($z/L_f \leq 0.4$) along the

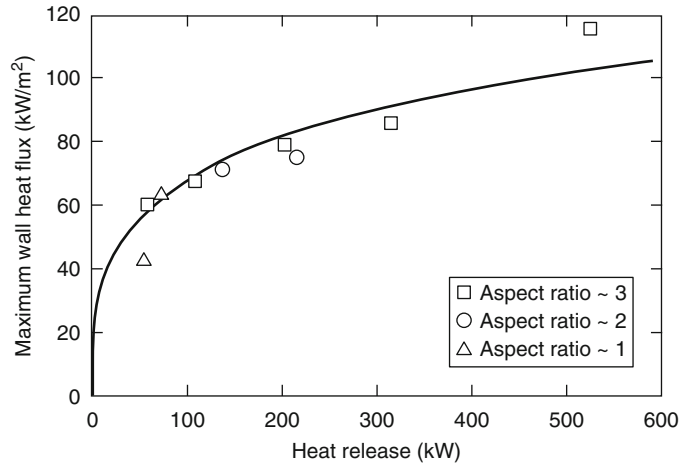

Fig. 25.2 Peak heat release rates measured in square propane burner fires against a flat wall [20]

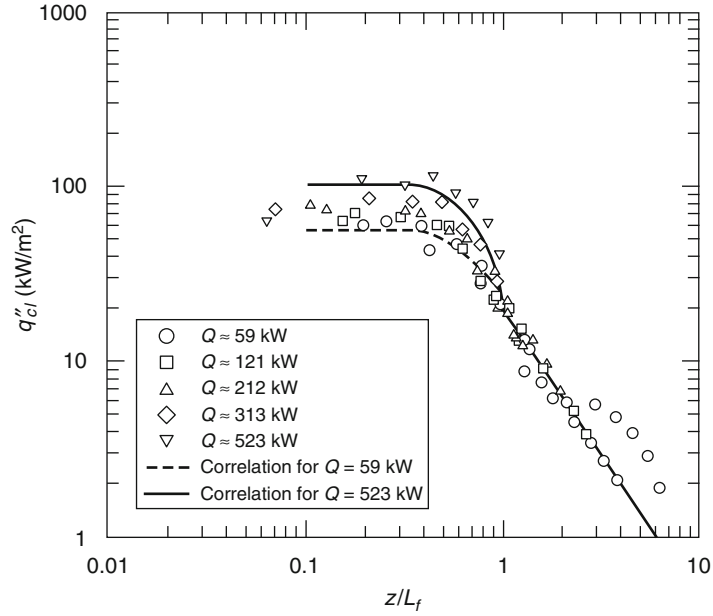

Fig. 25.3 Vertical heat flux distribution along the centerline of a square propane burner fire adjacent to a flat wall [20]

centerline, with the flame length taken from Heskestad [21]:

$$L_f = 0.23Q^{2/5} - 1.02D \tag{25.9}$$

Above this region, the heat fluxes were measured to decrease with distance above the fire. The heat flux data measured along the centerline is shown in Fig. 25.3. Lines in this plot are a general correlation of the centerline data:

$$q''_{cl} = q''_{\text{peak}} \quad z/L_f \le 0.4 \tag{25.10a}$$

$$q''_{cl} = q''_{\text{peak}} - \frac{5}{3}(z/L_f - 2/5)\left(q''_{\text{peak}} - 20\right) \quad 0.4 < z/L_f \le 1.0 \tag{25.10b}$$

$$q''_{cl} = 20\left(z/L_f\right)^{-5/3} \quad z/L_f > 1.0 \tag{25.10c}$$

Heat fluxes were measured to decrease with horizontal distance from the centerline, as shown in Fig. 25.4. The normalized lateral heat flux distribution data shown in Fig. 25.4 was found to be half-Gaussian in shape over the half width of the burner. The line in the plots is a fit to the data in Fig. 25.4a:

$$q'' = q''_{cl}\exp\left[-\left(\frac{x}{0.5D}\right)^2\right] \quad \frac{x}{0.5D} \le 1.0 \tag{25.11a}$$

$$q'' = 0.38q''_{cl}\left(\frac{x}{0.5D}\right)^{-1/7} \quad \frac{x}{0.5D} > 1.0 \tag{25.11b}$$

Heat fluxes from burning objects to an adjacent wall have been measured for a variety of items; however, limited data have been published on this work [22, 23]. Heat fluxes at the rim of wastebasket fires were reported by Gross and Fang [22]. At the rim, heat fluxes as high as 50 kW/m^2 were measured; however, the authors noted that peak heat fluxes for these fires occurred approximately 0.22 m above the rim.

Mizuno and Kawagoe [23] performed experiments with upholstered chair fires against a flat wall. In these tests, Mizuno and Kawagoe measured heat fluxes to the wall of 40–100 kW/m^2 over the continuous flaming region (~$z/L_f < 0.4$). All of these tests were performed using foam-padded chairs.

Fires in a Corner

Fires in a corner of a room lined with a combustible material have been shown to cause more

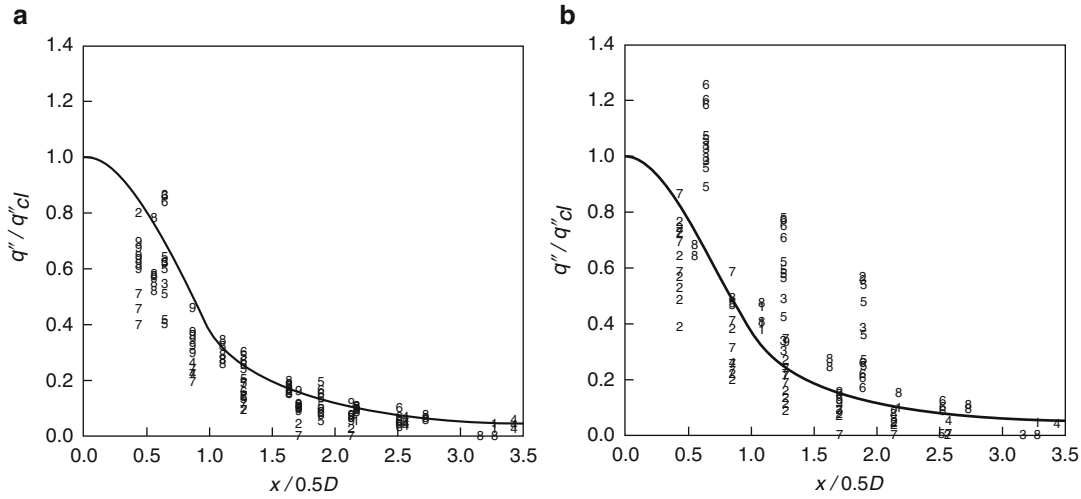

Fig. 25.4 Lateral heat flux distribution with distance from the centerline of square propane burner fires against a flat wall [20] (**a**) in the flaming region and (**b**) in the plume

rapid flame spread and growth to flashover compared to cases with fires in other locations within the room. For these reasons, a significant amount of work has been performed to characterize the heat fluxes produced by corner fires. Heat flux measurements have been performed both in an open environment to quantify the heat flux due to the exposure fire alone and within rooms to measure the heat flux due to the exposure fire and the room environment.

The heat flux from the exposure fire has been quantified in several studies performed in an open laboratory environment [24–29]. All the studies were performed in a noncombustible corner with a ceiling except the study of Kokkala [26], which was performed in a noncombustible corner without a ceiling. A comparison of the heat flux fields measured in the study with a ceiling [29] and the study without a ceiling [26] is shown in Fig. 25.5. Note that the contour plot of Lattimer and Sorathia is relative to the floor, while the plot of Kokkala is relative to the top of the burner. Lattimer et al. used a burner 0.15 m high.

Up to approximately 1.8 m above the floor, the heat flux distributions are similar. In the case with the ceiling, the ceiling jet and the radiation from the fire flowing along the ceiling were heating the top part of the wall. This resulted in higher heat fluxes farther out from the corner along the top part of the wall.

A series of fire tests were performed by Lattimer and Sorathia [29] to develop empirical correlations to estimate heat fluxes from an exposure fire to the walls and ceiling of a corner. Tests were performed using 0.17-, 0.30-, and 0.50-m square propane burners placed directly against the corner. Heat flux fields were measured for fires ranging from 25 to 300 kW.

Correlations were developed for three regions in the corner: along the height of the walls in the corner, along the top of the walls near the ceiling, and along the ceiling. The region containing the walls in the corner extended from the top of the fire to approximately 1.8 m above the floor, which is approximately the ceiling height minus twice the ceiling jet thickness ($\delta = 0.1H$). Correlations for the top part of the walls, which are heated by the ceiling jet, were developed using data at locations greater than 1.8 m above the floor.

Along the height of the walls in the corner, the peak heat fluxes were typically measured near the base of the fire. The peak heat fluxes along the height of the walls in the corner were measured to be a function of the fire diameter, as shown in Fig. 25.6. The curve in Fig. 25.6 is a

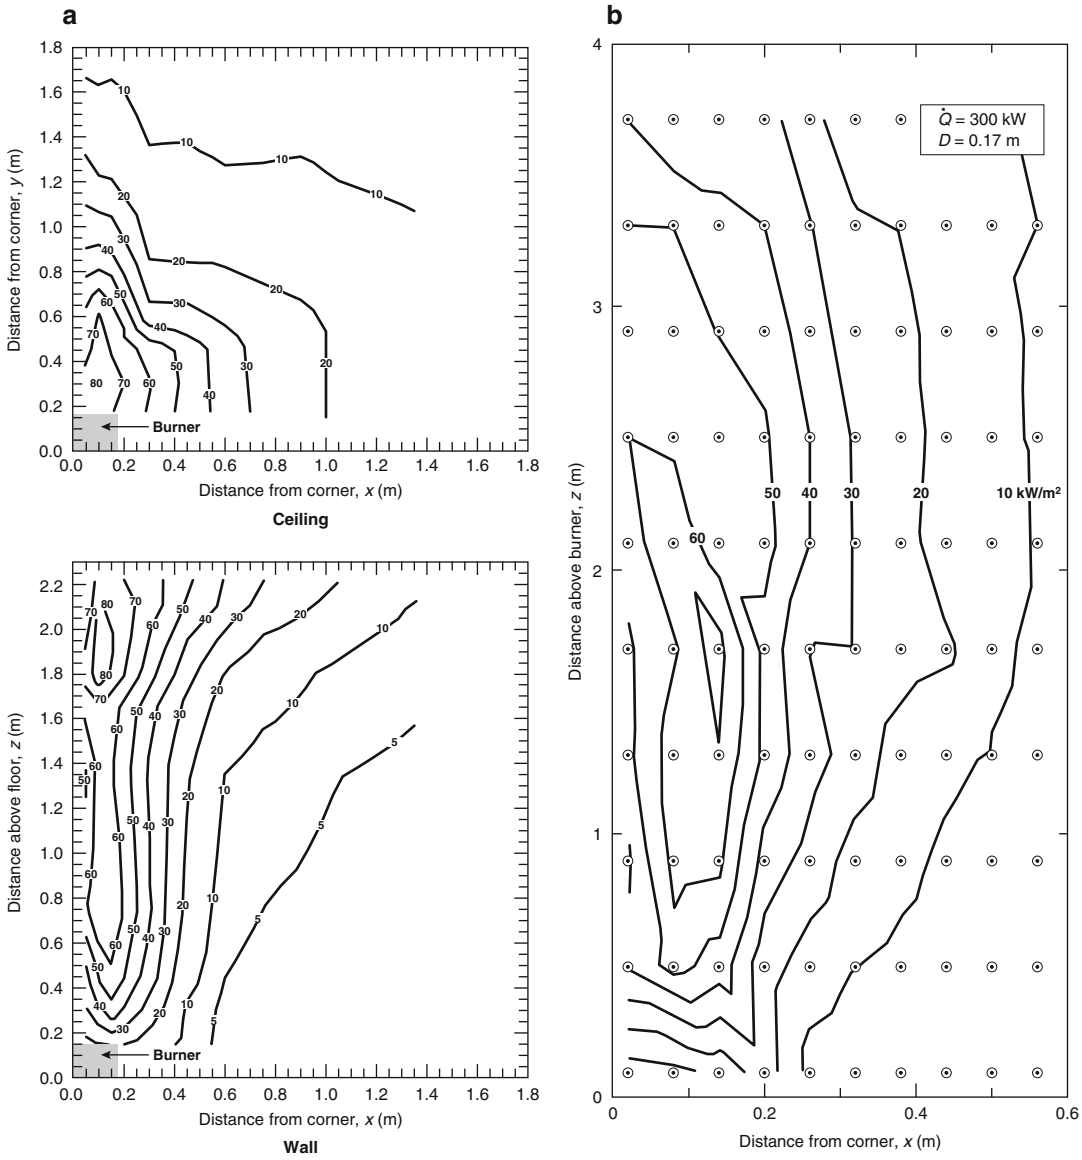

Fig. 25.5 A comparison of the heat flux fields produced in a corner (**a**) with a ceiling [29] and (**b**) without a ceiling [26]. The fire was produced by a 0.17-m-square propane burner with a heat release rate of 300 kW. Note data of Lattimer and Sorathia [29] are plotted relative to the floor, and the data of Kokkala [26] are plotted relative to the top of the burner

correlation to the data and is expressed using the following relation:

$$q''_{\text{peak}} = 120[1 - \exp(-4.0D)] \qquad (25.12)$$

The vertical distribution in the maximum heat flux along the walls near the corner is shown in Fig. 25.7 plotted with the vertical distance normalized with respect to the flame tip,

$$L_{f,\text{tip}}/D = 5.9Q_D^{*1/2} \qquad (25.13)$$

where

$$Q_D^* = \frac{Q}{\rho_\infty C_p T_\infty \sqrt{g} D^{5/2}} \qquad (25.14)$$

Peak heat flux levels were measured in the lower part of the flame ($z/L_{f,\text{tip}} \leq 0.4$) and decreased

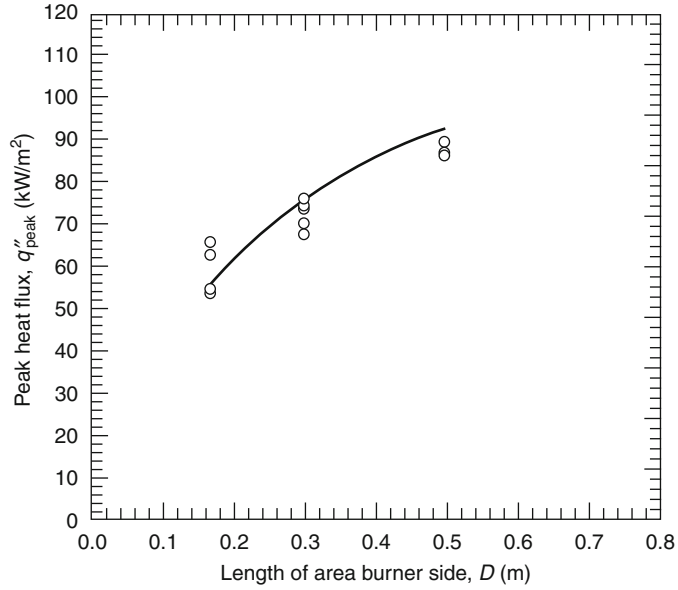

Fig. 25.6 Peak heat flux along the height of the walls in the corner [29]

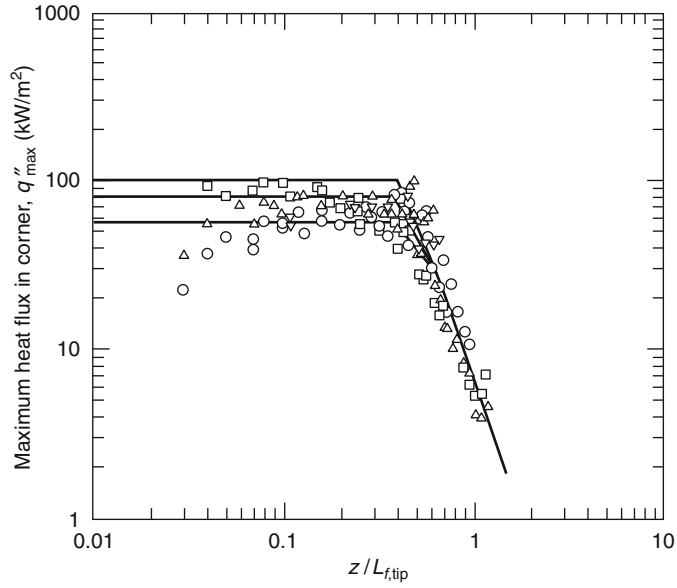

Fig. 25.7 Maximum heat fluxes to the walls near the corner with square burner sides of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□), and fire sizes ranging from 50 to 300 kW [29]

with distance above $z/L_{f,\text{tip}} = 0.4$. A general correlation to represent this behavior is

$$q''_{\max} = q''_{\text{peak}} \quad z/L_{f,\text{tip}} \le 0.4 \tag{25.15a}$$

$$q''_{\max} = q''_{\text{peak}} - 4\left(\frac{z}{L_{f,\text{tip}}} - \frac{2}{5}\right)\left(q''_{\text{peak}} - 30\right) \quad 0.4 < z/L_{f,\text{tip}} \le 0.65 \tag{25.15b}$$

$$q''_{\max} = 7.2\left(\frac{z}{L_{f,\text{tip}}}\right)^{-10/3} \quad z/L_{f,\text{tip}} \ge 0.65 \tag{25.15c}$$

This is similar to the form used by Back et al. [20] to correlate heat fluxes from an exposure fire to a wall (see Equations 25.10a, 25.10b, and 25.10c), except the constants are different.

The horizontal distribution in the heat flux along the wall is shown in Fig. 25.8 to best

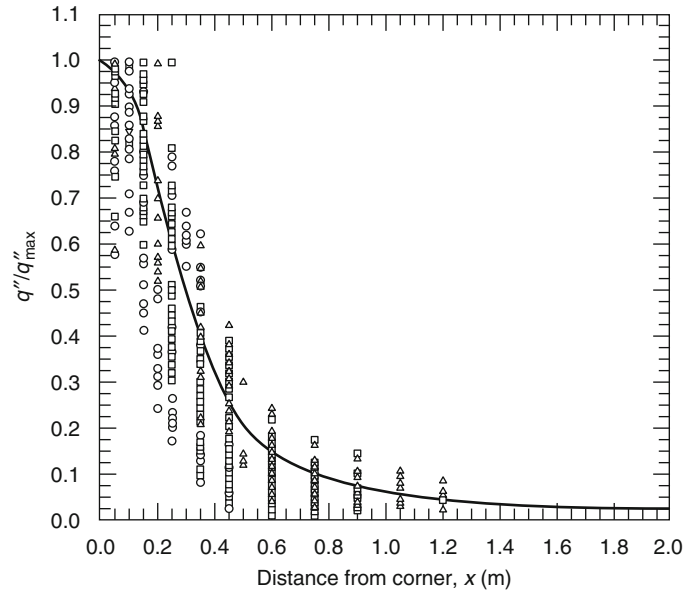

Fig. 25.8 Lateral distribution in the heat flux along the walls with distance from the corner with square burner sides of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□), and fire sizes ranging from 50 to 300 kW [29]

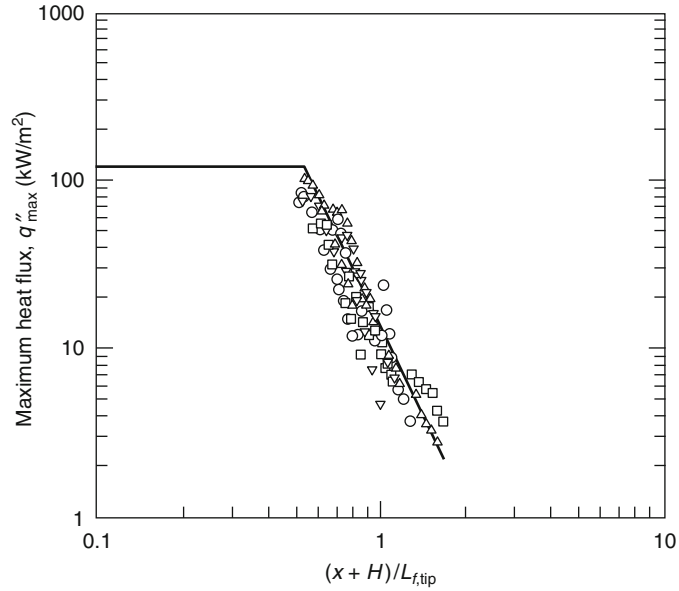

Fig. 25.9 Maximum heat flux along the top of the walls during a corner fire test with square burner sides of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□), and fire sizes ranging from 50 to 300 kW [29]

correlate with actual distance from the corner [29]. This was attributed air being entrained in the corner, pushing the fire into the corner. Near the corner the shape is half-Gaussian; however, heat fluxes outside of this decrease slower. The trend in the data, which is shown as the line in Fig. 25.8, can be represented using the following relations:

$$q'' = q''_{max}\exp[-7.5x^2] \quad x \leq 0.4 \text{ m} \quad (25.16a)$$

$$q'' = 0.058q''_{max}x^{-1.8} \quad x > 0.4 \text{ m} \quad (25.16b)$$

It has not been established whether this correlation holds for fire sources larger than 0.50 m in length on a single side.

Along the top part of the wall the maximum heat fluxes were measured at locations less than 0.15 m below the ceiling. The maximum heat fluxes are shown in Fig. 25.9 plotted against the

normalized distance along the flame $(x + H)/L_{f,\text{tip}}$, where x is the distance from the corner. These heat fluxes can be estimated using the following relations:

$$q''_{\max} = 120 \quad \left(\frac{x+H}{L_{f,\text{tip}}}\right) \leq 0.52 \qquad (25.17a)$$

$$q''_{max} = 13.0\left(\frac{x+H}{L_{f,\text{tip}}}\right)^{-3.5}\left(\frac{x+H}{L_{f,\text{tip}}}\right) > 0.52 \qquad (25.17b)$$

The assumed plateau in the correlation was based on the maximum heat flux expected from a flame, according to Equation 25.12.

The heat fluxes to the ceiling were determined to be a function of normalized distance along the flame length, $(r + H)/L_{f,\text{tip}}$. All of the ceiling heat flux data taken in the study with a square burner in the corner are shown in Fig. 25.10. Heat fluxes along the ceiling due to the exposure fire were similar to those measured along the top of the wall. This resulted in similar correlations to estimate the heat flux to the ceiling:

$$q'' = 120 \quad \left(\frac{r+H}{L_{f,\text{tip}}}\right) \leq 0.52 \qquad (25.18a)$$

$$q'' = 13.0\left(\frac{x+H}{L_{f,\text{tip}}}\right)^{-3.5}\left(\frac{r+H}{L_{f,\text{tip}}}\right) > 0.52 \qquad (25.18b)$$

Again, the assumed plateau in the correlation was based on the maximum heat flux expected from a flame, according to Equation 25.12.

Similar levels were measured by Hasemi et al. [25] with an exposure fire in the corner, simulated burning corner walls, and an exposure fire and simulated burning corner walls in the corner.

Room Environment Effects Corner fires are currently used to evaluate fire growth potential of a combustible lining material. As such, several studies have been conducted to characterize the heat flux from an exposure fire inside a room [30–33]. In these cases, the heat flux to the surface will be due to both the exposure fire and the room environment.

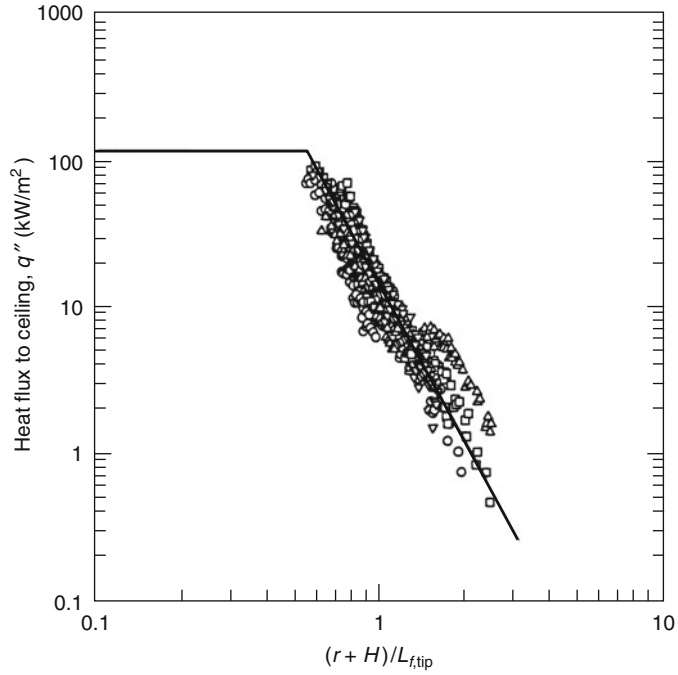

Fig. 25.10 The heat flux along the ceiling above a fire located in a corner for tests with square burner sides of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□), and fire sizes ranging from 50 to 300 kW [29]

The effect of the room environment on the heat fluxes was clearly demonstrated through the work performed by Dillon [33] in an ISO 9705 room [34]. The incident heat fluxes from the fire were determined by measuring the temperature rise at several locations on an insulated steel plate. Heat fluxes were calculated using a two-dimensional heat balance on the plate. Heat fluxes included contributions from both the exposure fire and the room environment. Using the surface temperature measurements and initial heat flux measurements after the burner was ignited, the heat fluxes to the hot steel plate were corrected for both reradiation from surfaces in the room and heating by the hot gas layer.

The effects of the room environment on the heat fluxes to the corner boundaries is discussed here for the case with a 300 kW fire in the corner, produced using a 0.17-m square burner. The heat fluxes shown in Fig. 25.11a represent the heat flux from the fire only, as measured using a heat flux gauge (i.e., cold surface). Note that the top of the burner is 30 cm above the floor. In general, the heat fluxes in Fig. 25.11a compare well with the total heat flux data shown in Fig. 25.5a.

Heat fluxes shown in Fig. 25.11b correspond to heat fluxes due to the fire and the room environment (i.e., hot gas layer and reradiation from walls), as measured using a heat flux gauge. For this room environment, the heat fluxes including the room environment were higher than the heat fluxes from the exposure fire to a cold wall. The magnitude of the increase depends on the elevation inside the room. Measurements in the lower part of the room showed less of an increase compared with those near the ceiling. Heat fluxes in the upper part of the room increased by as much as 20 kW/m^2, an increase largely attributed to the hot gas layer that forms inside the room during the fire. For the 300-kW fire inside the ISO 9705 compartment, average gas temperatures in the upper part of the room were measured to be approximately 680 K. Note that the heat flux due to the room environment is dependent on the gas layer temperature, which is dependent on the fire size, room geometry, ventilation, and thermal properties of the boundaries. A room or fire different from that used to produce the data in Fig. 25.11b may result in a different gas layer temperature, which will result in a different heat flux contribution due to the room environment.

Heat fluxes due to the hot layer environment inside a room were measured by Tanaka et al. [35]. In tests conducted in a 3.3-m-wide, 3.3-m-deep, 2.35-m-high room with the propane fire in the center of the room, heat fluxes were measured at different locations on one of the side walls. The average heat flux measured in the upper layer formed inside of the room is shown in Fig. 25.12 versus the layer temperature for different compartment door widths. The line in the plot represents the blackbody heat flux using the layer gas temperature, $q'' = \sigma T_g^4$. As seen in the Fig. 25.12, the blackbody heat flux using the layer gas temperature provides a reasonable estimate of the incident heat flux to the walls inside a compartment; however, the measured heat fluxes are generally higher than the blackbody heat flux. A more detailed investigation of the heat flux to compartment fire surfaces was performed by Toflio et al. [36] Through this study, it was determined that the higher heat flux was attributed to convection between the hot gas layer and the wall. In addition, as fires became large in size, radiation exchange between the fire and the walls could also increase the heat flux to wall surfaces.

Effects of Fire Standoff Distance Several researchers have investigated the effects of moving the exposure fire away from the corner (i.e., standoff distance) [24, 30, 37]. As one might expect, moving the fire away from the corner decreases the heat fluxes to the room boundaries. Tests were performed by Williamson et al. [30] in a full-scale ISO 9705 room using a 0.30-m-diameter burner. Heat fluxes to the wall were strongly dependent on whether the flame was attached to the corner walls or burned freely near the wall. At a heat release rate of 40 kW, with the burner against the corner walls, the flame was attached to the walls and heat fluxes were measured to be as high as 50 kW/m^2. When

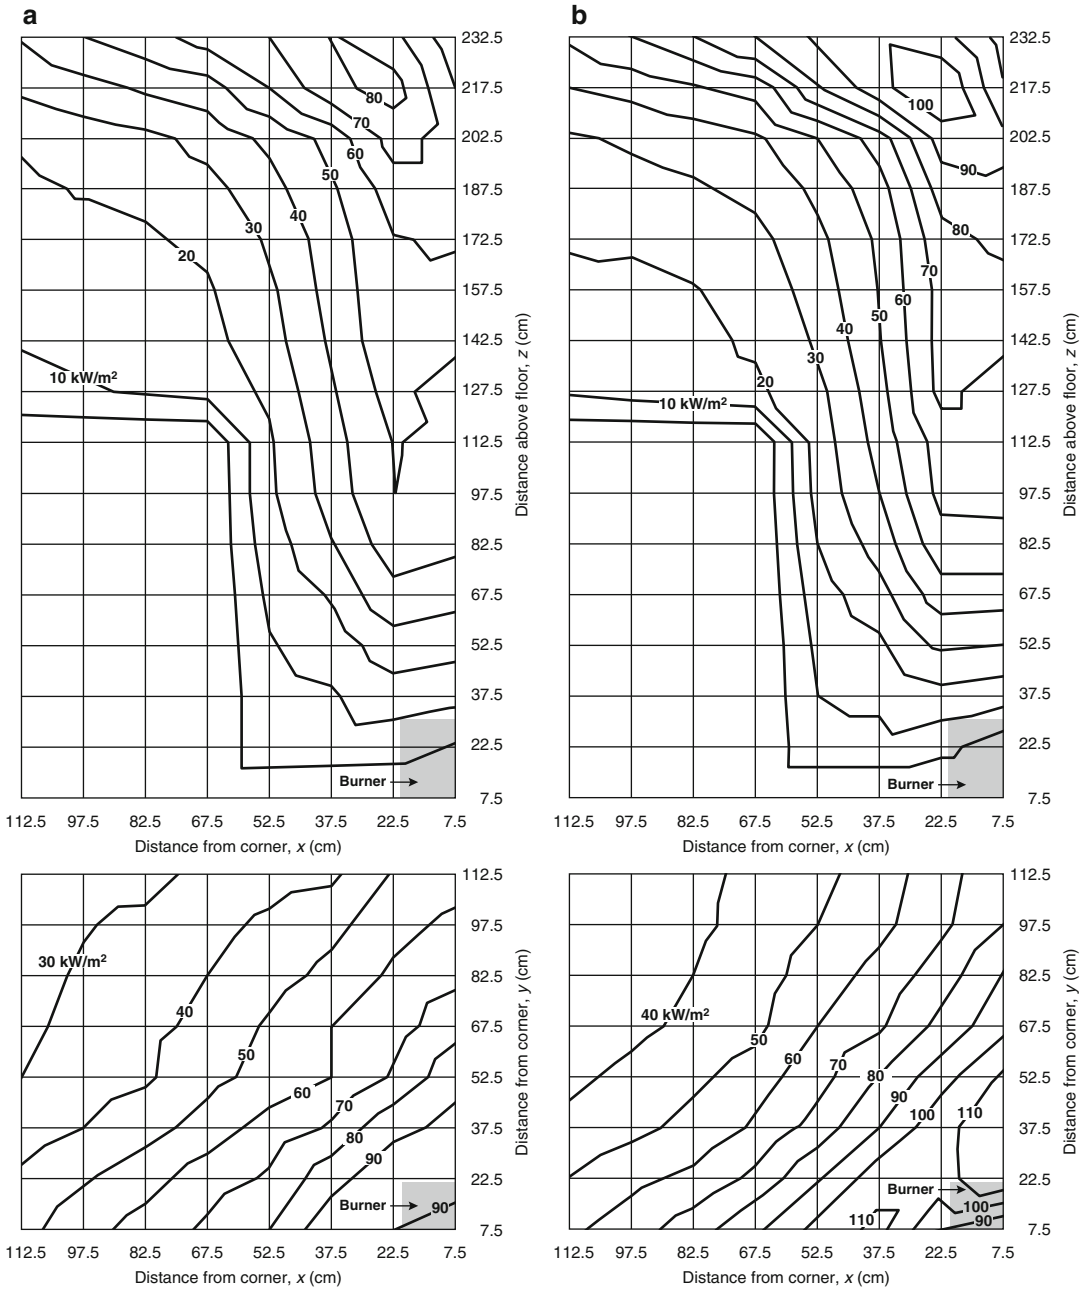

Fig. 25.11 Heat fluxes to corner boundaries from (**a**) 300-kW, 0.17-m square propane sand burner exposure fire alone to a "cold" surface and from (**b**) the 300-kW exposure fire and the room environment [33]

the fire was moved 50 mm from the walls, the flames were observed to be detached from the walls with the highest heat fluxes measured to be approximately 25 kW/m^2. In tests with a heat release rate of 150 kW, the fire was observed to be attached to the walls and heat fluxes of 40–60 kW/m^2 were measured at the walls. Additional work needs to be performed to investigate distances at which fires attach to nearby surfaces, such as a flat wall or walls in a corner.

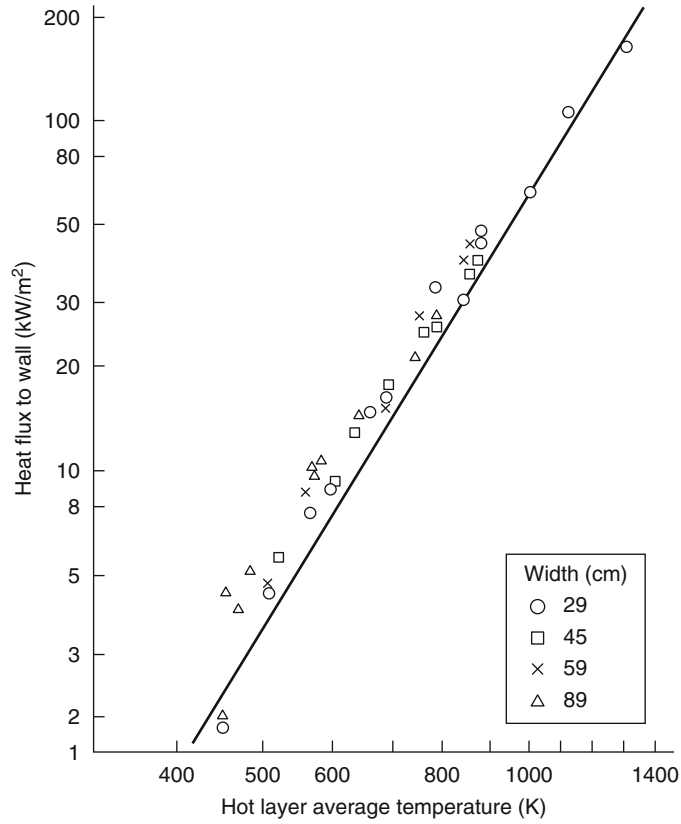

Fig. 25.12 Heat flux to the walls inside a compartment containing a hot gas layer [35]

Fires Beneath Unconfined Ceilings

There have been several experimental and theoretical studies performed on fires impinging on an unbounded ceiling [1–4, 38–41]. Total heat fluxes from fires and fire plumes impinging on the ceiling were measured by Hasemi et al. [38], You and Faeth [3, 4], and Kokkala [1, 2].

Hasemi et al. [38] conducted a series of fire tests using propane gas burners located at different distances beneath a noncombustible ceiling. Fires as large as 400 kW (approximated) were considered in the study. Heat flux gauges were used to measure the incident heat flux along the ceiling at different distances away from the fire centerline, or stagnation point. The measured heat flux at the stagnation point is shown in Fig. 25.13 to plateau at approximately 90 kW/m^2. In order to collapse the data, the flame tip length was normalized with respect to the distance between the ceiling and fire, H, plus the virtual source location, z'. The virtual source location for this geometry was determined using the following relations:

$$z' = 2.4D\left(Q_D^{*2/5} - Q_D^{*2/3}\right) \quad Q^* < 1.0 \tag{25.19a}$$

$$z' = 2.4D\left(1 - Q_D^{*2/5}\right) \quad Q^* \geq 1.0 \tag{25.19b}$$

where Q_D* is defined as in Equation 25.14 with D being the diameter of the exposure fire. The length of the flame, $L_{f,\text{tip}}$, in this geometry is defined as the distance between the fire and the ceiling, H, plus the radial extension of the flame out from the center of the fire, L_H. The location of the flame tip in this geometry was found to correlate with Q_H*, which is defined the same as in Equation 25.14 except D is replaced by H. The flame tip correlation was determined to be

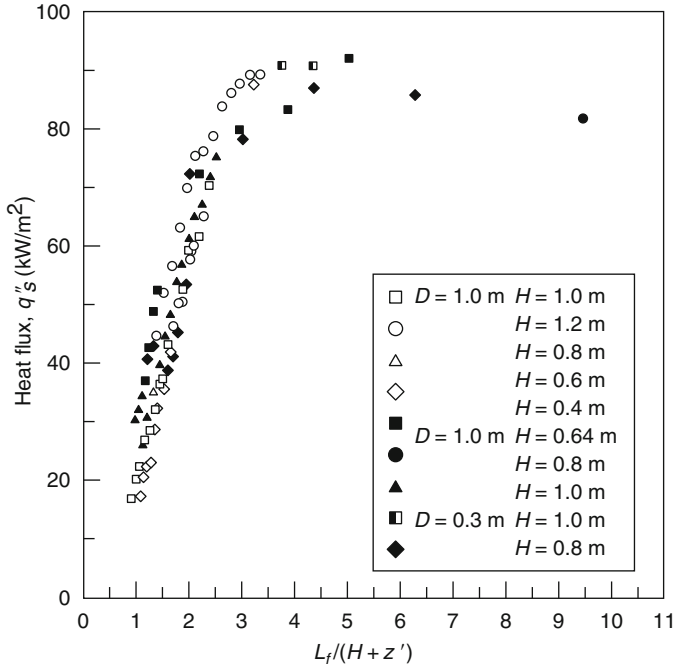

Fig. 25.13 Stagnation point heat fluxes on an unbounded ceiling with a fire impinging on it [38]

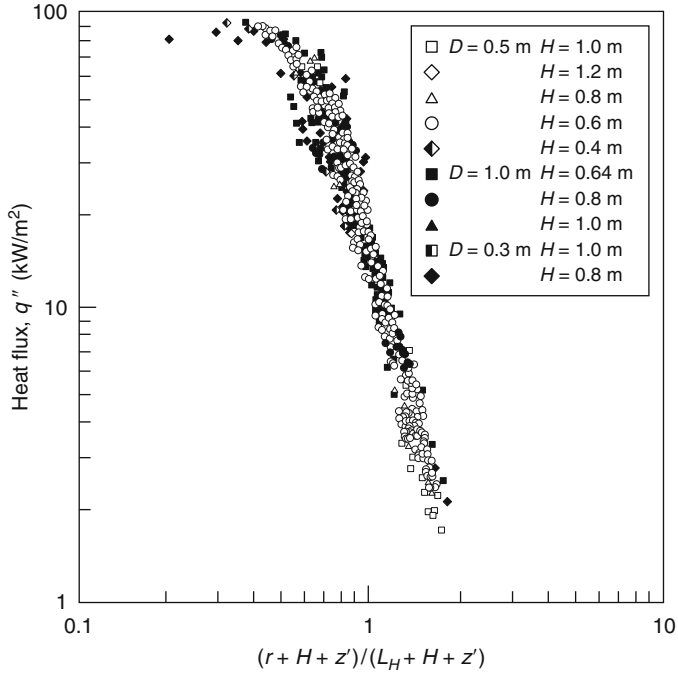

Fig. 25.14 Heat fluxes to a ceiling due to a propane fire impinging on the surface [38]

$$\frac{(L_H + H)}{H} = L_{f,\text{tip}}/H = 2.89 Q_H^{*1/3} \qquad (25.20)$$

The heat flux was measured to decrease with distance from the fire stagnation point. Figure 25.14 contains a plot of the heat flux to the ceiling as a function of location within the flame. The correlation recommended by Wakamatsu [42] can be used to predict the heat fluxes:

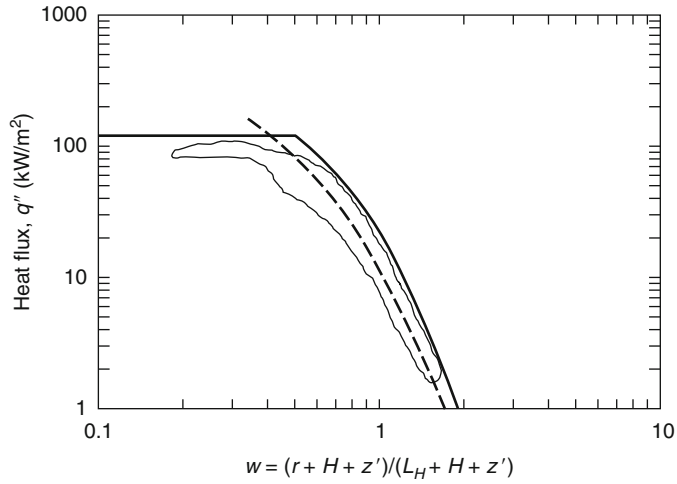

Fig. 25.15 A comparison of the best fit curve proposed by Wakamatsu [42] (– –) and a bounding fit to the data (—). The unbounded ceiling data of Hasemi et al. [38] is represented as the outlined area

$$q'' = 518.8e^{-3.7w} \tag{25.21a}$$

where

$$w = \left(r + H + z'\right)/\left(L_H + H + z'\right) \tag{25.21b}$$

Figure 25.15 contains a plot of Equation 25.21a (dashed line) along with a representation of the data of Hasemi et al. [38] for a flat unbounded ceiling. Equation 25.21a adequately estimates the data when w is greater than 0.45 but significantly overestimates heat flux levels for smaller values of w. Based on the data from Hasemi et al. [38] and other data from fires impinging on I-beams mounted to a ceiling [43], a correlation was developed to predict the bounding heat flux levels to an unconfined ceiling:

$$q'' = 120 \quad w \leq 0.5 \tag{25.22a}$$

$$q'' = 682\exp(-3.4w) \quad w > 0.5 \tag{25.22b}$$

where w is defined in Equation 25.21b. This correlation is shown in Fig. 25.15 as the solid line. The peak heat flux of 120 kW/m^2 at w less than or equal to 0.5 bounds nearly all of the heat flux measurements made in this range for the studies of Hasemi et al. [38] and Myllymaki and Kokkala [43].

Heat flux measurements with smaller fires (<11 kW) beneath a ceiling were made by Kokkala [1, 2] and You and Faeth [4]. Kokkala used natural gas as a fuel and measured heat fluxes to plateau at 60 kW/m^2 at the stagnation point (Fig. 25.16). Due to the small burners used in this study ($D = 0.064$ m), Kokkala's data collapsed without applying a virtual source origin correction. Heat fluxes measured in the natural gas fire tests were lower than those measured by Hasemi et al. [38], an effect that can partly be attributed to the higher radiation levels from the propane flames. The heat fluxes measured by Kokkala [1] at different locations from the stagnation point are plotted in Fig. 25.17. The distribution in the heat flux along the ceiling radially out from the stagnation point was measured to be similar to that measured by Hasemi et al. [38] with larger propane gas fires.

Fires in Corridors

There are few reported studies that have measured heat fluxes to the ceiling or walls of a corridor. Hinkley et al. [44–46] performed experiments with a town gas burner located at the end of a hallway. Tests with a noncombustible ceiling were performed in a 1.2-m-wide hallway using a range of heat release rates (170–600 kW) with the burner at various distances (0.37–1.20 m) below the ceiling. Heat fluxes were determined through temperature

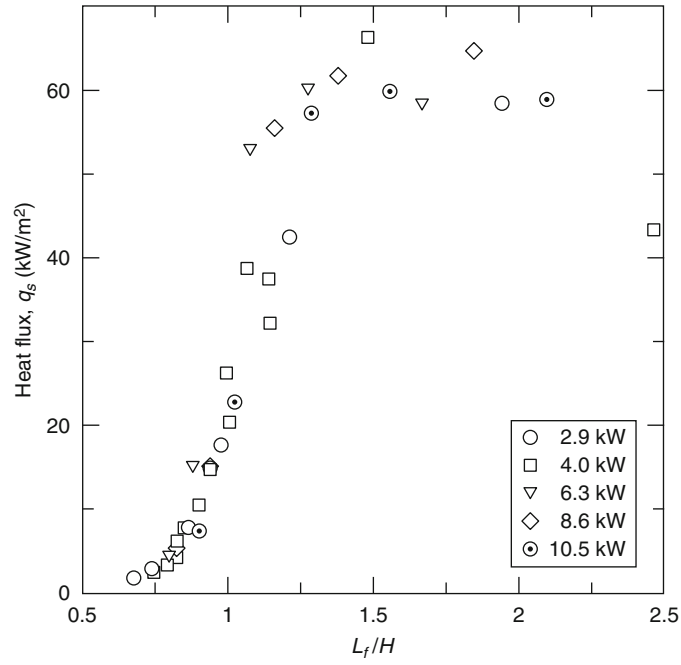

Fig. 25.16 Heat fluxes at the stagnation point on a ceiling for tests with natural gas fires impinging on the ceiling [1]

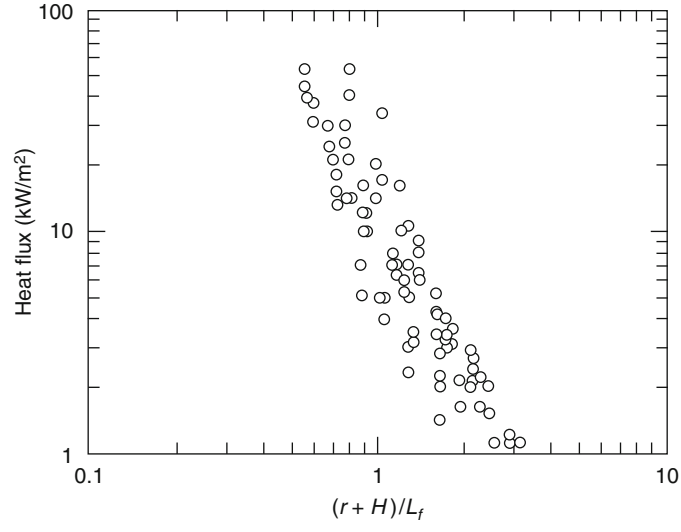

Fig. 25.17 Heat fluxes to a ceiling due to a natural gas fire impinging on the surface [1]

measurements on exposed and unexposed sides of the ceiling material.

The heat fluxes determined in these experiments are provided in Fig. 25.18, plotted as a function of $(x + x')/L$, where x' is the virtual source and L is the flame length from the virtual source. This plot indicates that heat fluxes as high as 160 kW/m^2 can exist in these types of scenarios. The increase in the heat flux over the unconfined ceiling data of Hasemi et al. [38], with peak heat fluxes of approximately 90 kW/m^2, may be due in part to the thicker layer of flames formed in the corridor. However, due to the method used to develop the heat fluxes, the accuracy of the heat flux data reported by Hinkley et al. is uncertain [44, 45].

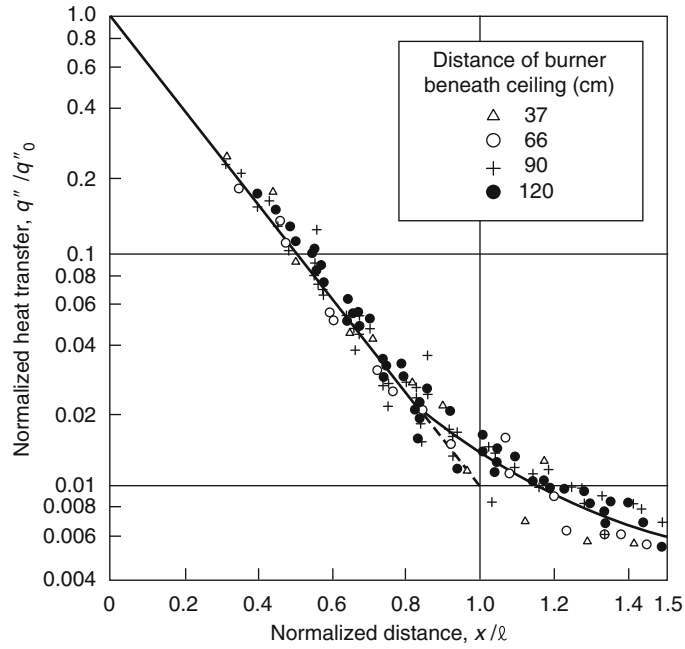

Fig. 25.18 Heat fluxes to the ceiling in a corridor with an exposure fire at the closed end [44]

Lattimer et al. [47] conducted a separate study to measure and correlate heat fluxes from a fire at the closed end of a corridor. The apparatus and burner were similar to that used by Hinkley et al. [45] The corridor was 2.44 m (8 ft) long, 1.22 m (4 ft) wide, and 2.1 m (6.8 ft) high, with one end of the corridor blocked. The bottom portion of the corridor was open to allow air to flow freely into the corridor along its length. Tests were conducted with the interior surface of the corridor apparatus lined with a 25-mm (1.0 in.) thick, 96 kg/m^3 (6 lb/ft^3) Unifrax Durablanket noncombustible ceramic blanket.

A rectangular propane gas sand burner was located at the blocked end of the corridor. The burner had dimensions of 1.15 m (3.8 ft) wide and 0.46 m (1.5 ft) deep. Tests were conducted with the burner located 0.60 m (2.0 ft) and 1.1 m (3.6 ft) below the ceiling and using heat release rates ranging from 100 to 400 kW.

Thermal characterization included the measurement of flame lengths, total heat flux to the ceiling, and gas temperatures just below the ceiling. Total heat flux was measured using water-cooled Schmidt-Boelter-type heat flux gauges. Flame lengths were visually determined during the tests and were reported as total flame lengths, which include the part of the height of the flame below the ceiling and the flame extension along the ceiling.

Figure 25.19 contains a plot of the flame length data from this study along with data from Hinkley et al. [45] in a similar corridor apparatus. The flame length data from these tests agree well with flame lengths reported by Hinkley et al. [45] The correlation in the plot is described using the following relation:

$$L_{f,\text{tip}} = 0.075 Q'^{2/3} \tag{25.23}$$

where $L_{f,\text{tip}}$ is the total flame length determined by adding flame height below a ceiling with flame extension along a ceiling (m) and Q' is the heat release rate of the fire per unit width of a hallway (kW/m). The correlation represents a best fit to the corridor data as well as larger-scale test data from fires in tunnels [48], which is a similar geometry. The correlation with the corridor and tunnel flame length data is shown in Fig. 25.20. The data are a reasonable fit for all the data but do underpredict the higher heat release rate data by Hinkley et al. [45]

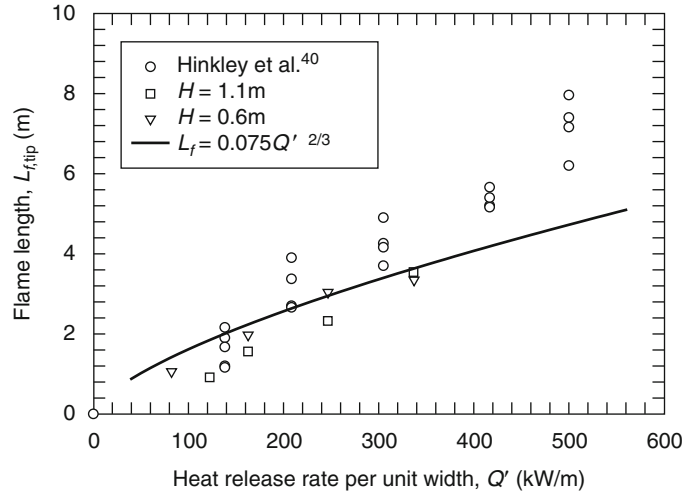

Fig. 25.19 Flame length data from tests in corridor tests by Lattimer et al. [47] and Hinkley et al. [45]

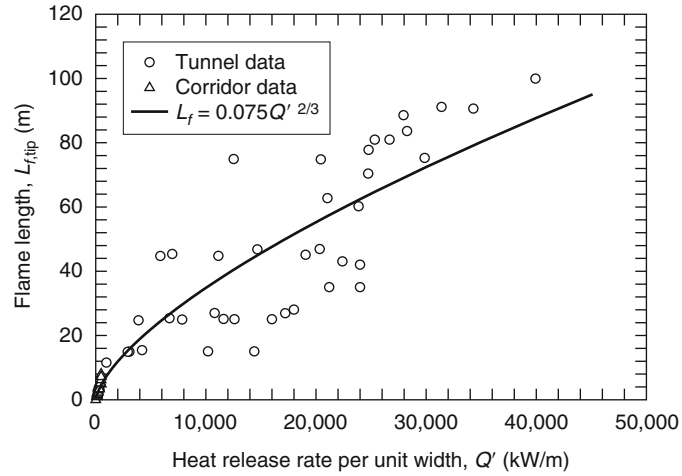

Fig. 25.20 Flame length correlation compared with corridor and tunnel data [48]

A plot of the average heat fluxes to the corridor ceiling is provided in Fig. 25.21 as a function of dimensionless distance along the flame length. Also shown in the plot are some of the data from Hinkley et al. [45] The data from these tests match well with data from the tests by Hinkley et al. [45] A correlation for the heat flux along the ceiling is also shown in the figure and can be predicted through these equations:

$$q'' = 160 \quad \left[(x+H)/L_{f,\text{tip}}\right] < 0.25 \tag{25.24}$$

$$q'' = 26.39\left[(x+h)\right]/L_{f,\text{tip}}\Big]^{-1/3} \quad \left[(x+H)/L_{f,\text{tip}}\right] \geq 0.25 \tag{25.25}$$

where H is the distance between the fire and the corridor ceiling (m), x is the distance along the corridor (m), and $L_{f,\text{tip}}$ is the flame tip length (m). Close to the impingement point of the fire, the heat fluxes were measured to reach 160 kW/m^2. This is 70 kW/m^2 higher than similar fires in an unconfined ceiling geometry.

All of these tests are with the gas burner width being the same as the corridor width. As the width of the fire is decreased relative to the corridor width, heat fluxes are expected to provide results closer to the unconfined ceiling data. Heat release rate and fire location below the ceiling will also affect heat fluxes to the ceiling in these situations.

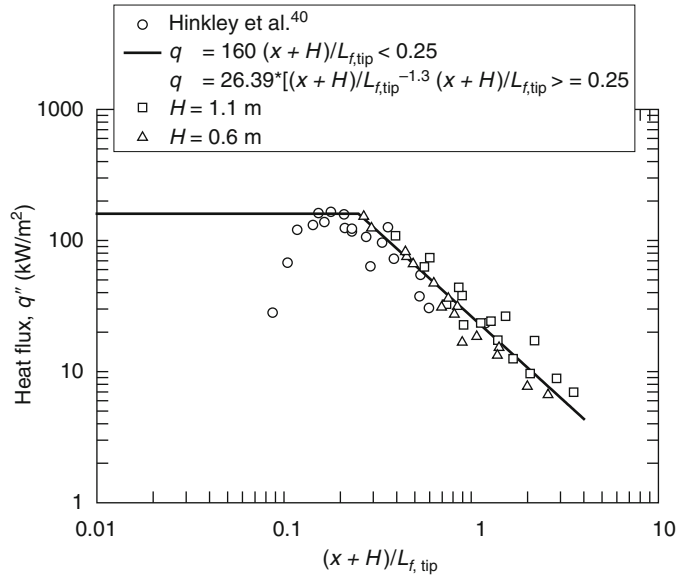

Fig. 25.21 Heat fluxes to a corridor ceiling with dimensionless distance along the flame length

Fires Beneath I-Beams

Three studies have evaluated the heat flux incident onto an I-beam mounted to a ceiling with an exposure fire impinging on the beam [38, 43, 49]. These studies all measured the heat flux to the four surfaces shown in Fig. 25.22 on the I-beam: downward face of the lower flange, upward face of the lower flange, the web, and downward face of the upper flange. For each of these surfaces, heat fluxes were measured from the stagnation point of the fire (centerline of the fire) past the location of the flame tip.

The study by Wakamatsu et al. [49] provides a framework for determining heat fluxes to different parts of the I-beam. The I-beam evaluated in the study was 3.6 m long, a web 150 mm high and 5 mm thick, and flanges 75 mm wide and 6 mm thick. Tests were performed using fires from 0.5- or 1.0-m propane burners with heat release rates ranging from 100 to 900 kW. The distance between the fire source and I-beam was also varied.

When the fire impinges on the I-beam, the flame length is different on the lower flange compared to the flame length on the upper flange (Fig. 25.23). Flame lengths along the lower flange, L_B, were shorter than those observed

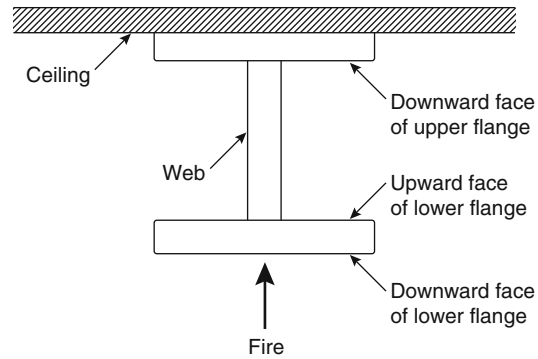

Fig. 25.22 Location of heat flux measurements on I-beams

near the upper flange, L_C. Heat fluxes along the lower flange were taken to be a function L_B while heat fluxes to other surfaces were related to L_C. Flame lengths were related to the dimensionless Q^*, as defined in Equation 25.14, with D being replaced by the appropriate distance between the fire and the flange,

$$Q^*_{H_B} = \frac{Q}{\rho_\infty C_p T_\infty \sqrt{g} H_B^{5/2}} \tag{25.26}$$

$$Q^*_{H_C} = \frac{Q}{\rho_\infty C_p T_\infty \sqrt{g} H_C^{5/2}} \tag{25.27}$$

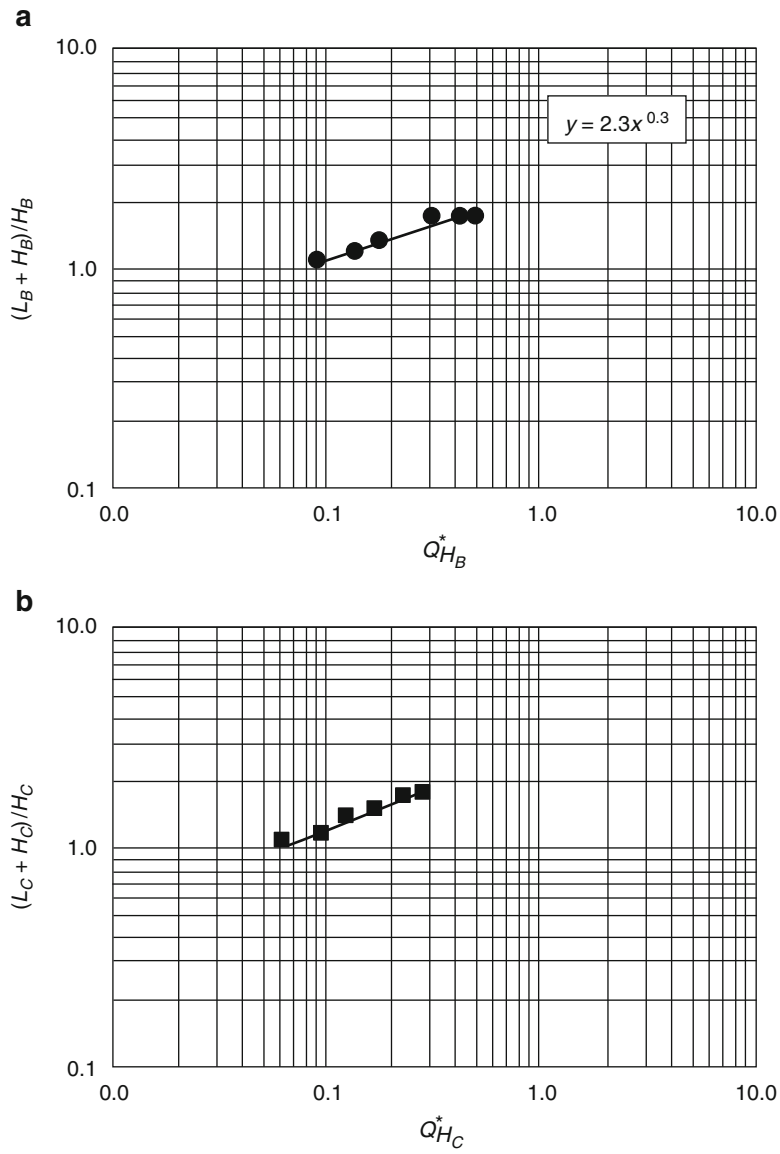

Fig. 25.23 Flame lengths (**a**) along the lower flange (Equation 25.28a) and (**b**) along the upper flange in I-beam tests performed by Wakamatsu et al. [49]

Correlations were developed to predict the flame tip length along the lower and upper flanges:

$$(L_B + H_B)/H_B = 2.3Q^{*0.3}_{H_B} \qquad (25.28a)$$

$$(L_C + H_C)/H_C = 2.9Q^{*0.4}_{H_C} \qquad (25.28b)$$

The heat flux measured at the stagnation point on the downward face of the lower flange was found to be the same as that measured for a fire beneath a ceiling (Fig. 25.24). The location of the virtual origin, z', was determined using Equation 25.19. The variation in the heat flux along the downward face of the lower flange with horizontal distance, r, from the stagnation point is shown in Fig. 25.25. The data appear to fall between the range of the data measured in the unconfined ceiling tests, which are represented by the dashed and solid lines. These heat fluxes were the highest measured on the I-beam assembly and can be estimated using the following correlation:

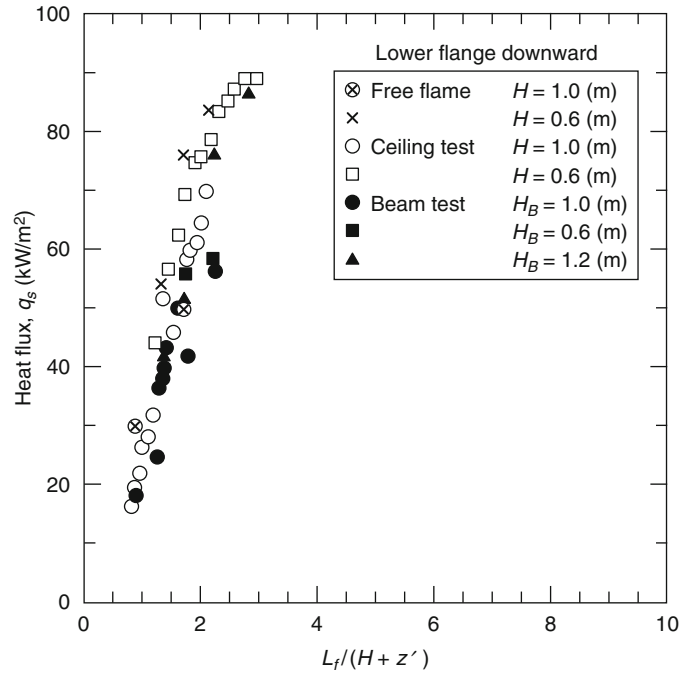

Fig. 25.24 Heat flux at the stagnation point on the downward face of the lower flange [49]

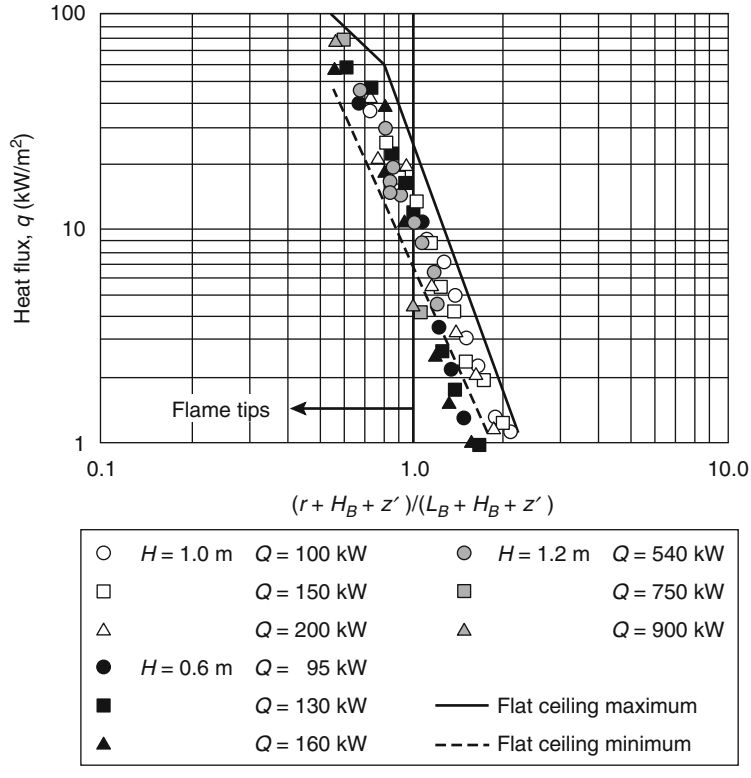

Fig. 25.25 Heat flux along the downward face of the lower flange [49]

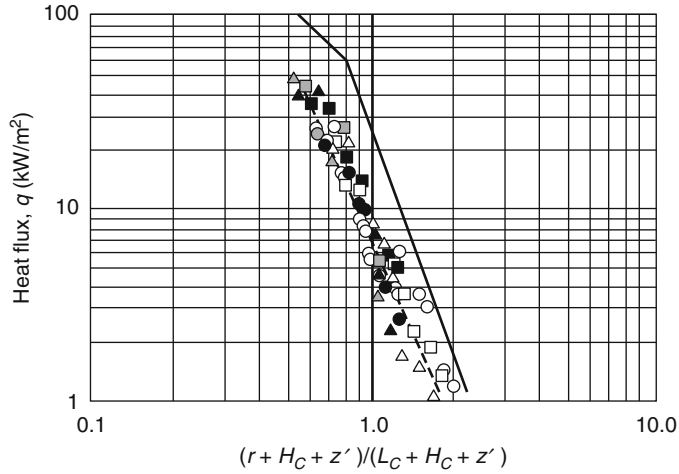

Fig. 25.26 Heat flux along the upward face of the lower flange (key same as in Fig. 25.25) [49]

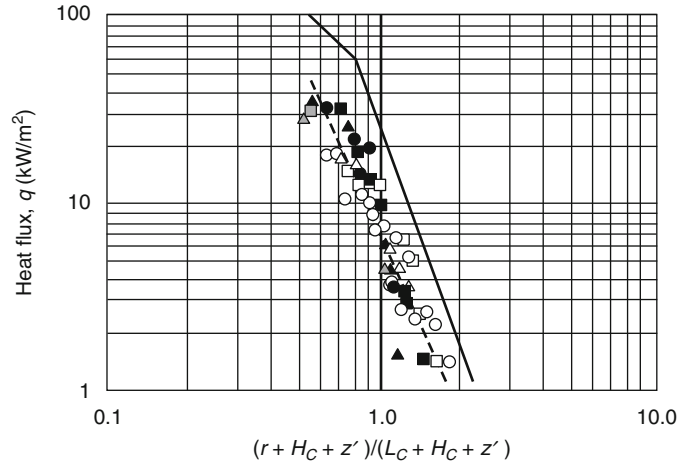

Fig. 25.27 Heat flux along web (key same as in Fig. 25.25) [49]

$$q'' = 518.8e^{-3.7w} \quad (25.29a)$$

where

$$w = \left(r + H_B + z'\right)/\left(L_B + H_B + z'\right) \quad (25.29b)$$

The heat fluxes to the upward face of the lower flange and the web are shown in Figs. 25.26 and 25.27 to be lower than those on the downward face of the lower flange. This was attributed to the lower flange shielding these parts of the I-beam from radiative and convective heat transfer. These data can be represented by the following expression:

$$q'' = 148.1e^{-2.75w} \quad (25.30a)$$

where

$$w = \left(r + H_C + z'\right)/\left(L_C + H_C + z'\right) \quad (25.30b)$$

The lowest heat fluxes on the I-beam were measured on the downward facing part of the upper flange. As seen in Fig. 25.28, heat fluxes to this part of the I-beam are slightly less than those measured on an unconfined ceiling. Heat fluxes to the downward face of the upper flange can be estimated using the following fit to the data:

$$q'' = 100.5e^{-2.85w} \quad (25.31a)$$

where

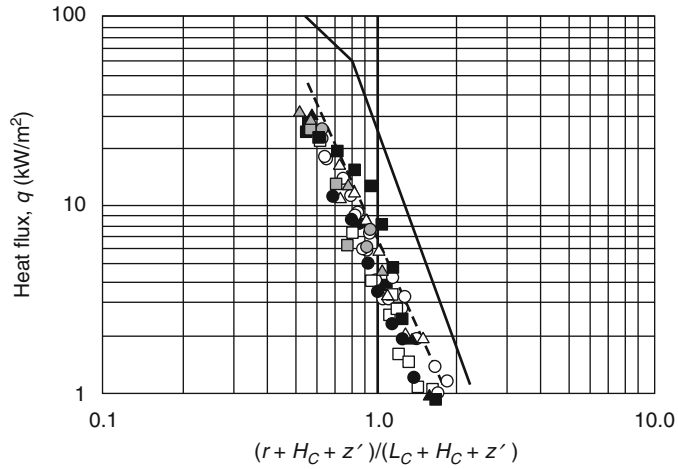

Fig. 25.28 Heat flux along the downward face of the upper flange (key same as in Fig. 25.25) [49]

$$w = \left(r + H_C + z^{'}\right) / \left(L_C + H_C + z^{'}\right) \quad (25.31b)$$

Myllymaki and Kokkala [43] evaluated the use of the approach and data of Wakamatsu et al. [49] to estimate heat fluxes onto I-beams exposed to fires as large as 3.9 MW. They found that for fires over 2.0 MW, the correlations suggested for the upward face of the lower flange, web, and downward face of the upper flange underestimate the heat flux to these areas on the I-beam. For these large fires, the I-beam becomes completely engulfed in fire. As a result, heat fluxes on all parts of the I-beam follow the correlation suggested for the downward face of the lower flange provided in Equation 25.29. Heat fluxes to the downward face of the lower flange, the upper flange, and the web are shown in Fig. 25.29, along with the correlations recommended by Wakamatsu [42]. The highest heat fluxes measured in the tests performed by Myllymaki and Kokkala [43] were approximately 130 kW/m^2 and were along the downward face of the upper flange.

Data from these studies demonstrate that the heat flux to the I-beam can be conservatively estimated using the bounding heat flux correlation in Equation 25.32:

$$q^{''} = 120 \quad w \leq 0.5 \quad (25.32a)$$

$$q^{''} = 682\exp(-3.4w) \quad w > 0.5 \quad (25.32b)$$

using the appropriate expression for w provided in Equations 25.29b, 25.30b, and 25.31b. Figure 25.30 provides a plot of this correlation along with the I-beam data [43].

Burning Walls and Ceilings

Fires from burning boundaries typically produce thinner flames than those generated by exposure fires. As a result, heat fluxes from burning boundary flames are typically lower than those measured for exposure fires in a similar geometry. As was the case with heat fluxes from exposure fires, heat fluxes from burning boundaries are dependent on the geometry of the burning surfaces.

Wall Fires

Heat fluxes from a burning wall flame back to the surface have been studied fairly extensively. Most of the work in this area has been performed with smaller fires. Though the data indicate that these heat fluxes are dependent on both fire size and smoke production, no reported study has fully characterized this behavior.

Much of the detailed heat flux measurements for fires produced by burning flat surfaces have been done with smaller-scale fires (<100 kW). Through this work, the heat fluxes from flames

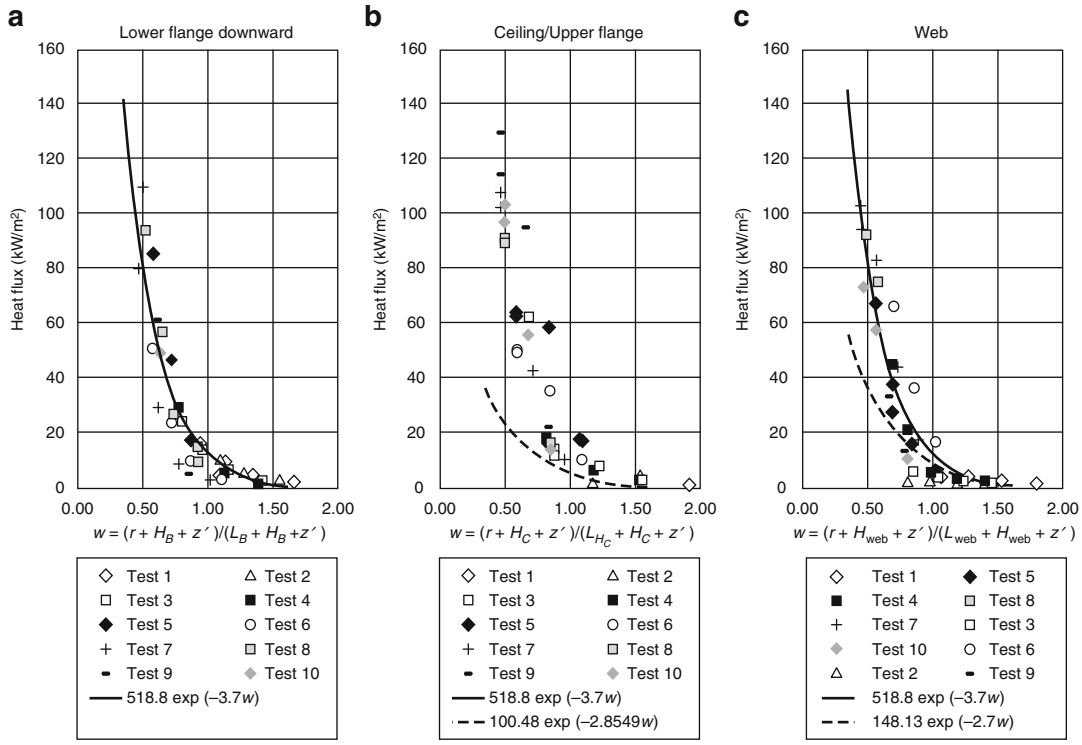

Fig. 25.29 Heat fluxes measured at the (**a**) downward face of the lower flange, (**b**) upper flange, and (**c**) the web on an I-beam in the study by Myllymaki and Kokkala [43], with fires as large as 3.9 MW

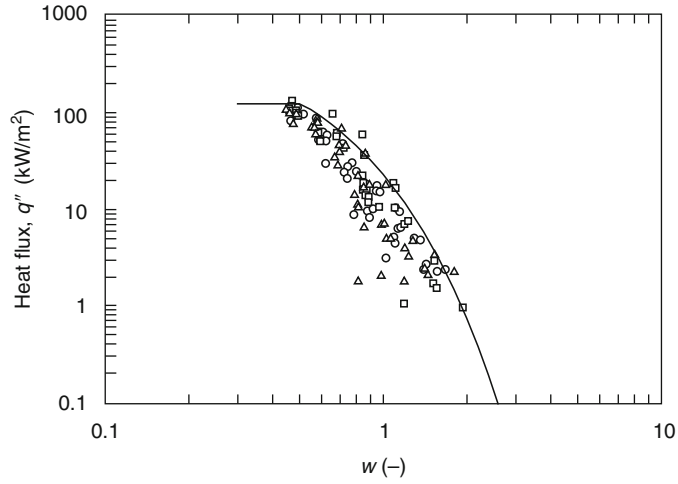

Fig. 25.30 Heat flux measured on the bottom flange (○), web (□), upper flange (Δ) of an I-beam mounted below an unbounded ceiling for fires 565–3870 kW [43]. The line in the plot is the curve given in Equation 25.32

produced by a variety of different burning materials have been characterized [50–53]. All of these studies were conducted with fires over flat, solid surfaces except the study of Ahmad and Faeth [50, 51], which was performed using wicks soaked in different alcohols. Ahmad and Faeth performed flat wall fire experiments using a 0.66-m-wide, 0.81-m-high flat wall test apparatus, with the lower part of the wall being an alcohol-soaked wick. Different wick heights

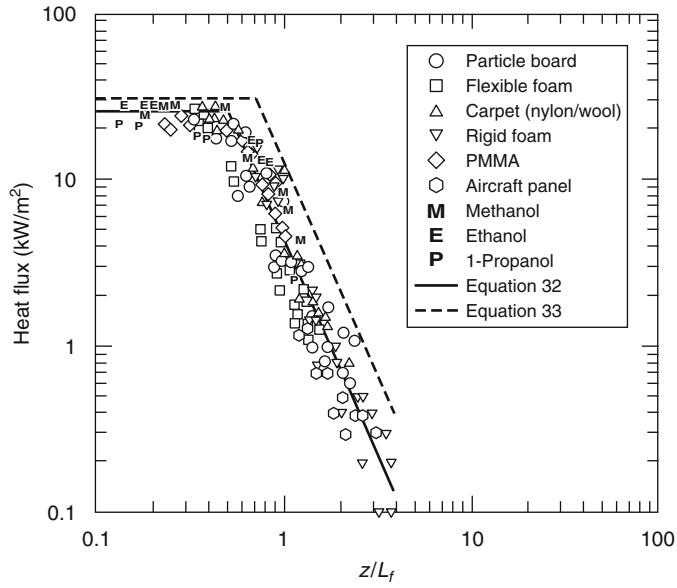

Fig. 25.31 The heat fluxes from burning flat surfaces for fires less than 100 kW [50–52]

and different types of alcohol were included in the study. Data from Quintiere et al. [52] were attained using samples 0.28 m by 0.28 m exposed to different external heat fluxes to generate different heat release rate fires from the same sample. Experiments performed by Orloff et al. [53] were conducted using a 0.41-m-wide, 1.57-m-high sample of PMMA.

Data from the studies of Ahmad and Faeth [50, 51] and Quintiere et al. [52] are shown in Fig. 25.31. Heat fluxes are approximately 20–30 kW/m^2 in the lower part of the flame ($z = 0.5L_f$) for a wide range of fuels. Peak heat fluxes measured by Orloff et al. [53] (22 kW/m^2) were also in this 20–30 kW/m^2 range. The value of L_f can be determined by using a flame height correlation for a line fire, such as that proposed by Delichatsios: [54]

$$L_f = 0.052Q'^{2/3} \tag{25.33}$$

where Q' is the heat release rate per unit length of burning wall.

Several empirical correlations have been proposed in the literature [55–58] to predict heat fluxes to walls. All correlations assume a constant heat flux in the lower part of the fire and a power law decay above this. The difference in these correlations is the peak heat flux over the bottom part of the fire and the empirical constants that govern the decay. Similar to that proposed by Hasemi [55], the line in the plot is an average fit to the data:

$$q'' = 25 \quad (z/L_f) \le 0.5 \tag{25.34a}$$

$$q'' = 4.4(z/L_f)^{-2.5} \quad (z/L_f) > 0.5 \tag{25.34b}$$

A more conservative fit that bounds this data set was developed:

$$q'' = 30 \quad (z/L_f) \le 0.7 \tag{25.35a}$$

$$q'' = 12.3(z/L_f)^{-2.5} \quad (z/L_f) > 0.7 \tag{25.35b}$$

Line burners have been used by some researchers to simulate a fire produced by a burning surface such as a wall. Hasemi [55, 59, 60] measured the heat flux from a methane line burner fire to an incombustible wall. In this study, the fire heat release rate per unit length of burner (0.30 m) was varied from 16.7 to 218.2 kW/m and two different liner burner widths (0.037 m and 0.082 m). For the test conditions considered, the heat fluxes along the flame are seen in Fig. 25.31 to be similar for each test condition. In addition, heat fluxes measured in this study are shown in Fig. 25.32 to be similar

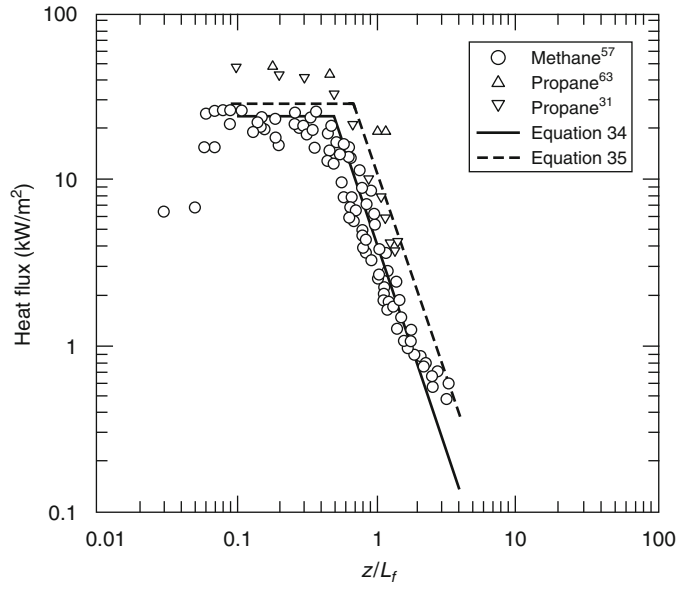

Fig. 25.32 The heat fluxes from methane line burners against a flat wall [29, 55, 61]

to those shown in Fig. 25.31. The correlations presented in Equations 25.34 and 25.35 adequately bound the data. Line burner experiments using propane as fuel have resulted in higher heat fluxes than those measured with methane as the fuel. In tests using propane with $Q' = 83 - 167$ kW/m, Kokkala et al. [61] and Lattimer [29] both measured heat fluxes of approximately 45 kW/m^2 in the lower half of the flame ($z = 0.5\ L_f$). Though not shown on the plot, Foley and Drysdale [62] measured 40–50 kW/m^2 from propane line burners with $Q' = 11.6$ and 20.9 kW/m. These data indicate that the radiation from the fire to the surface is dependent on fuel smoke production.

Slightly larger-scale fire tests were performed by Kulkarni et al. [63, 64] In this study, heat flux measurements were made along the length of different 0.3-m-wide, 1.2-m-high samples of solid combustibles. Fires were initiated using a line burner at the bottom of the sample, and heat fluxes were continuously measured during the test. Heat fluxes and flame lengths were continuously monitored as the fire spread along the combustible material. These transient heat flux and flame length measurements were averaged over particular time periods and plotted to determine the heat flux at different locations along the flame length.

Figure 25.33 provides the heat flux data for the different materials included in the study. Peak heat fluxes measured for the different materials were measured to range from 25 to 60 kW/m^2. Heat fluxes from burning masonite board, cardboard, and white pine board were in the 20 to 30-kW/m^2 range, similar to that measured in experiments by Ahmad and Faeth [50, 51] and Quintiere et al. [52]. However, fires involving PMMA, polyurethane foam, and velour fabric were all measured to produce heat fluxes greater than 30 kW/m^2. The PMMA and polyurethane foam had the highest flame lengths of all the materials (~1.75 m), which is comparable to the flame lengths reported by Quintiere et al. [52] for similar materials (PMMA and flexible foam). This indicates that the heat release rates for the PMMA and polyurethane foam are comparable in the two studies. The reason for the differences in the peak heat fluxes (e.g., 30–60 kW/m^2 in tests by Kulkarni et al. [63, 64] with PMMA, while 20–26 kW/m^2 in tests by Quintiere et al. [52]) is not known.

Less detailed heat flux measurements have been reported in the literature for larger fires. Orloff et al. [65] and Delichatsios [54] reported data on heat fluxes from flames produced by a 3.6-m-high burning PMMA wall. Total heat fluxes incident on the PMMA were calculated

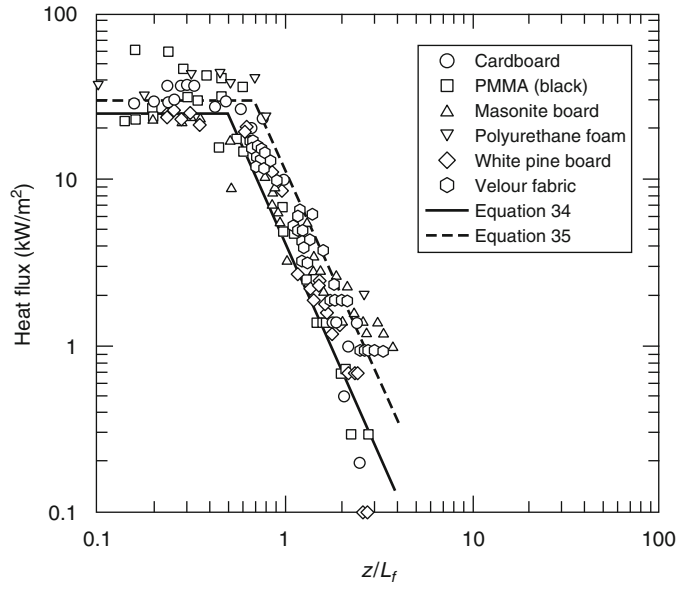

Fig. 25.33 Heat fluxes for different materials [64, 64]

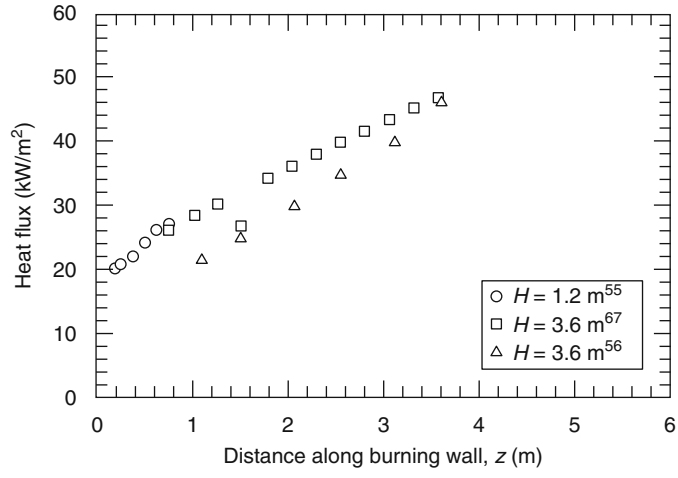

Fig. 25.34 Heat flux from a PMMA wall flame back to the fuel surface [53, 54, 65]

using theory and mass loss rate data. Heat fluxes are shown in Fig. 25.34 to increase with height. All the data in this plot were at positions where z/L_f is less than 0.5. This behavior is different than that observed with smaller fires, where heat flux is relatively constant over this region.

Markstein and de Ris [66] also explored the effects of larger fire size and soot production on the heat flux incident on the burning surface. The apparatus used in the study was 0.38 m wide and 1.98 m high, with the bottom 0.79 m of the wall being a sintered metal gas burner. Heat flux data for methane, ethane, ethylene, and propylene fires were reported. The impact of fire size on the heat flux distribution along the height of the panel is shown in Fig. 25.35. Similar to the PMMA results, the heat fluxes were measured to increase with height in the test with the higher heat release rate (816 kW/m).

The heat flux from the flame is shown in Fig. 25.36 to also be a function of fuel smoke production rate. Methane and ethane have low smoke yields (less than 0.013 g/g) [67] and are measured to produce heat fluxes as high as

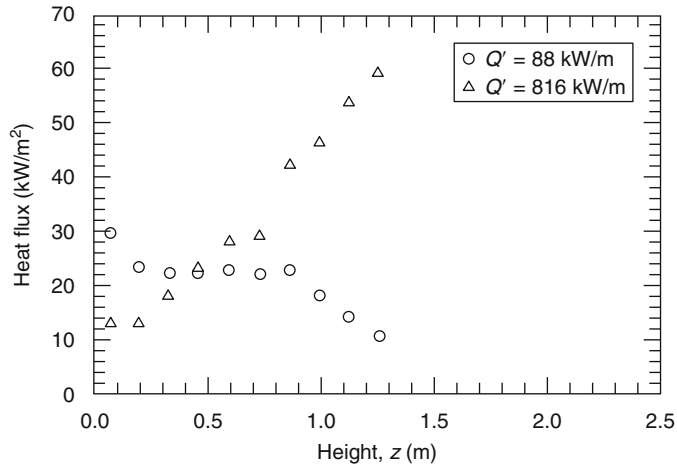

Fig. 25.35 Heat fluxes along a propylene gas wall fire at different heat release rates per unit width [66]. Burning wall height was 0.79 m

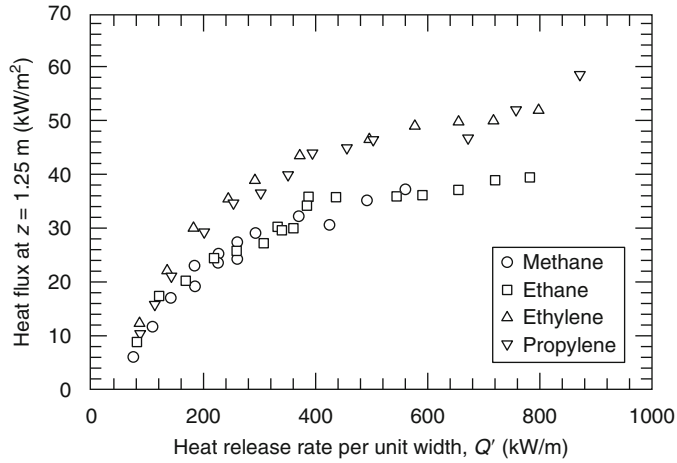

Fig. 25.36 Heat flux at a height of z = 1.25 m for different size fires and different fuels [66]. Burning wall height was 0.79 m

35–38 kW/m^2. The smoke yield of ethylene (0.043) [67] is less than that of propylene (0.095), but similar heat fluxes were measured with height along the apparatus. Peak heat fluxes of 59 kW/m^2 were measured for the largest propylene fire considered in the study.

Heat fluxes were measured in tests on large (2.4-m-high, 0.60-m-wide) plywood walls [68]. The peak heat fluxes measured in these tests are provided in Table 25.3 for various preheat levels. As the heat release rate per unit width increases, the heat flux from the fire to the wall increases. Though heat fluxes are not as high as those measured for a burning PMMA wall, the heat flux is 8–20 kW/m^2 higher than the 30-kW/m^2 peak level measured in the smaller-scale tests.

Table 25.3 Peak heat flux from flames measured in 2.4-m-high, 0.60-m-wide plywood wall experiments [68] (measurements up to 1.8 m above floor)

Fuel	Radiant exposure (kW/m^2)	Heat release rate per unit width Q′ (kW/m)	Peak heat flux (kW/m^2)
Plywood	4.8	175	38
(Finished side exposed)	5.2	197	40
	7	292	45
Plywood	7.5	217	45
(Unfinished side exposed)	11	417	50

Similar experiments were performed by Ohlemiller and Cleary [69] on composite panels. The peak heat fluxes measured in this study are provided in Table 25.4. Similar to

the results of Delichatsios et al. [68], heat fluxes were measured to increase with an increase in heat release rate (i.e., increase in external heat flux).

Data presented in this section demonstrate that both heat release rate and smoke production rate of the fuel can influence the heat flux levels produced by wall flames back onto the burning surface. Larger fires with high smoke production rates can result in heat fluxes to the walls of approximately 60 kW/m^2. Additional research needs to be performed to better quantify the transition between the smaller-fire experiments and the large-fire results.

Table 25.4 Heat fluxes from 1.2-m-High, 0.3-m-wide Composite panel fires [69]

Fuel	Radiant exposure (kW/m^2)	Heat release rate per unit width Q' (kW/m)	Peak heat flux (kW/m^2)
Fire-retarded vinyl ester	2.5	—	35
	7.5	—	48
	11	—	52
Polyester	0	—	35

Corner Wall Fires

Limited work has been performed to quantify the heat fluxes from burning boundaries in a corner. In general, the heat fluxes produced by burning corner walls are higher than those produced by a wall flame.

Qian et al. [70, 71] measured heat fluxes produced in a corner of burning PMMA walls beneath an incombustible ceiling. In these experiments, a 1.6-m-high corner was lined with 12.7-mm-thick PMMA 0.20 m in width. During the tests, the walls were ignited using a torch at the bottom of the corner and were allowed to burn until flames had spread to the top of the walls. The peak heat release rate of the fire was estimated to be 80 kW. The heat fluxes measured during the growing fire are shown in Fig. 25.37. In the lower half of the flame, heat fluxes were measured to be, on average, 33 kW/m^2. Above this, the heat fluxes were measured to decay similarly to heat fluxes measured for wall fires (see Equations 25.35 and 25.36).

A series of experiments were conducted by Hasemi et al. [25] using L-shaped sintered

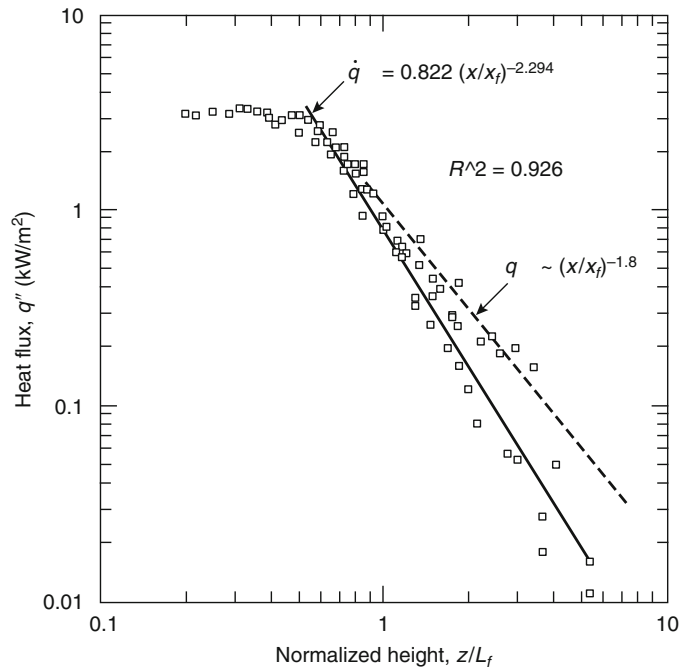

Fig. 25.37 Heat flux from burning PMMA corner walls (1.6 m high and 0.20 m wide) [71]

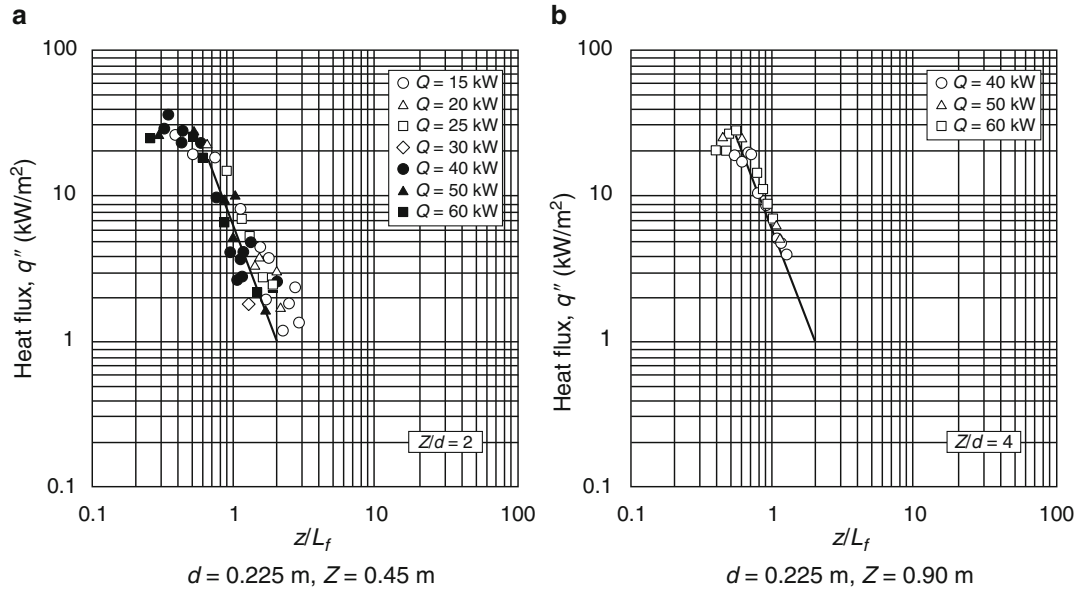

Fig. 25.38 Heat fluxes to a corner from a simulated burning corner fire using propane as fuel [25]

metal burners mounted to the walls of the corner to simulate burning corner walls. Using propane gas as fuel, experiments were conducted using two different burner sizes (0.23 m wide and 0.45 m high, 0.23 m wide and 0.90 m high) mounted to an open corner of walls with no ceiling. The heat fluxes above the burners in these fires are provided in Fig. 25.38 for fire heat release rates of 15–60 kW. The line on the plots represents the decay in the heat flux of a wall fire. Peak heat fluxes in the lower part of the flame were measured to range from 28 to 38 kW/m^2 and were constant up to approximately half the flame length. Above this, heat fluxes were measured to decay in a manner similar to that determined for burning walls.

Hasemi et al. [72] also performed tests in a 1.8-m-high corner with a ceiling. Tests were performed with the top 1.35 m of the corner lined with 0.23-m-wide sintered metal burners and with the top 0.45 m of the corner lined with sintered metal burners. Heat fluxes to the ceiling were measured to be as high as 40 kW/m^2, while heat fluxes as high as 60 kW/m^2 were measured along the top of the walls near the ceiling.

Lattimer et al. [29] performed a detailed study using L-shaped propane line burners in the corner. Burners were placed in a 2.4-m-high corner with a ceiling, with all surfaces constructed of noncombustible materials. In this study, heat fluxes were measured for different size burners (single side length of 0.17 m, 0.30 m, and 0.50 m) and various heat release rates (50–300 kW).

Similar to the approach used to develop the heat flux correlations for area burners, burning boundary correlations were developed for three regions in the corner: along the height of the walls in the corner, along the top of the walls near the ceiling, and along the ceiling. The region containing the walls in the corner extended from the top of the fire to approximately 1.8 m above the fire, which is approximately the ceiling height minus twice the ceiling jet thickness ($\delta = 0.1H$). Above 1.8 m was considered to be the region along the top of the wall, or the wall-ceiling interface region.

Heat flux data for these fires were normalized with respect to the flame tip location. The flame tip was the farthest distance at which flaming was visually observed. In cases where the fire impinged and flowed along the ceiling, the flame tip length was taken to be the corner height plus the flame extension along the ceiling. Lattimer et al. [29] developed the following

correlation to predict the flame tip of a burning boundary fire:

$$L_{f,\text{tip}}/d = 5.9Q_d^{*1/2} \tag{25.36}$$

where dimensionless Q_d* is

$$Q_d^* = \frac{Q}{\rho_\infty C_p T_\infty \sqrt{g} d^{5/2}} \tag{25.37}$$

Equations 25.35b and 25.36 are similar to those used in predicting flame heights from area burners in a corner except the length scale is *d,* which is the width of the burning area on the wall or the side of a single L-shaped burner. In the L-shaped line burner tests, d is the length of a single side; however, in a burning corner d was found to be the average width of the burning on the walls. For fires in a 2.4-m-high corner, the width of the burning 0.90 m above the floor was found to adequately represent the average burning width [29].

The vertical distribution in the maximum heat flux along the walls near the corner is shown in Fig. 25.39 plotted with the vertical distance normalized with respect to the flame tip. Peak heat fluxes were measured over the initial half of the flame length. Above this, heat fluxes decayed in a fashion similar to that observed for wall fires. The line in the plot represents a fit to the data, which can be described by the following expressions:

$$q''_{\max} = 70 \quad (z/L_f) < 0.5 \tag{25.38a}$$

$$q''_{\max} = 10(z/L_f)^{-2.8} \quad (z/L_f) > 0.5 \tag{25.38b}$$

Heat fluxes in the decay region $(z/L_f) > 0.5$ decrease with dimensionless height raised to the -2.8 power, which is a slightly lower power than the decay for wall fires (-2.5).

Peak heat fluxes in the corner are shown in Fig. 25.40 to have some dependence on the heat release rate of the fire. The increase in the peak heat flux with increase in fire size was attributed to an increase in radiative pathlength. Assuming the gases to be gray, the following curve fit was developed:

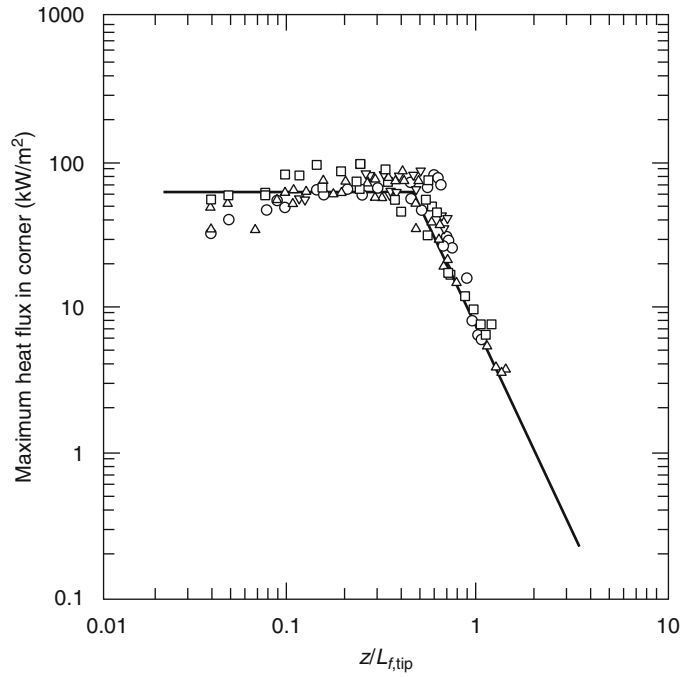

Fig. 25.39 Heat flux from simulated corner wall fires back to the corner walls at a height less than 1.8 m above the floor. L-shaped line burner with single side lengths of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□) and fire sizes ranging from 50 to 300 kW [29]

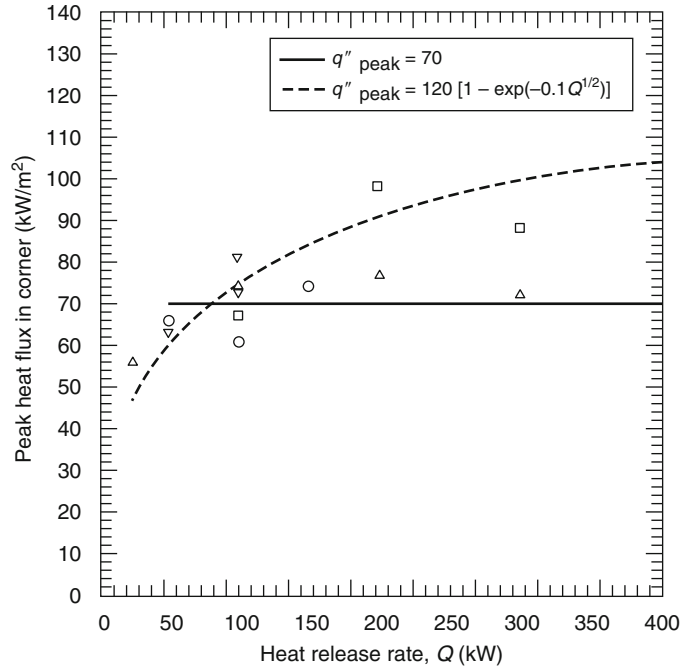

Fig. 25.40 Peak heat flux to the walls in the corner as a function of wall heat release rate less than 1.8 m above the floor. L-shaped line burner with single side lengths of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□) and fire sizes ranging from 50 to 300 kW [29]

$$q''_{\text{peak}} = 120\left[1 - \exp\left(-0.1Q^{1/2}\right)\right] \quad (25.39)$$

Based on Equation 25.38b, a more conservative fit to the data in Fig. 25.39 was developed:

$$q''_{\max} = q''_{\text{peak}} \quad (z/L_f) \le 0.5 \quad (25.40a)$$

$$q''_{\max} = q''_{\text{peak}} - 5(z/L_f - 0.5) \quad \left(q''_{\text{peak}} - 27\right) \quad 0.5 < (z/L_f) \le 0.7 \quad (25.40b)$$

$$q''_{\max} = 10.0(z/L_f)^{-2/8}(z/L_f) > 0.7 \quad (25.40c)$$

The maximum heat fluxes along the height of the corner shown in Figs. 25.39 and 25.40 were measured approximately 0.05–0.10 m outside of the corner. Heat fluxes decrease with horizontal distance from the corner. The horizontal heat flux distributions at heights less than 1.8 m above the floor are shown in Fig. 25.41 to be half-Gaussian in shape over the flame, but decays slower than predicted by a half-Gaussian curve outside of the flaming region. The line in this plot is a fit to the data, which can be represented by the following expressions:

$$\frac{q''}{q''_{\max}} = \exp\left[-1.0(x/d)^2\right] \quad \frac{x}{d} < 1.3 \quad (25.41a)$$

$$\frac{q''}{q''_{\max}} = 0.30\left(\frac{x}{d}\right)^{-1.8} \quad \frac{x}{d} \ge 1.3 \quad (25.41b)$$

Burning boundary beneath a ceiling will form a ceiling jet that will heat the top part of the walls and the ceiling. The maximum heat flux along the top part of the walls is shown in Fig. 25.42. The line in the plot represents a fit to the data, which can be represented by the following expressions:

$$q''_{\max} = 120 \quad \left(\frac{x+H}{L_{f,\text{tip}}}\right) \le 0.52 \quad (25.42a)$$

$$q''_{\max} = 13.0\left(\frac{x+H}{L_{f,\text{tip}}}\right)^{-3.5}\left(\frac{x+H}{L_{f,\text{tip}}}\right) > 0.52 \quad (25.42b)$$

The assumed plateau in the correlation is based on the maximum heat flux expected from a flame in this configuration. This correlation is the same as that determined for area fires in a corner.

The heat flux to the ceiling was correlated to the dimensionless distance away from the burner,

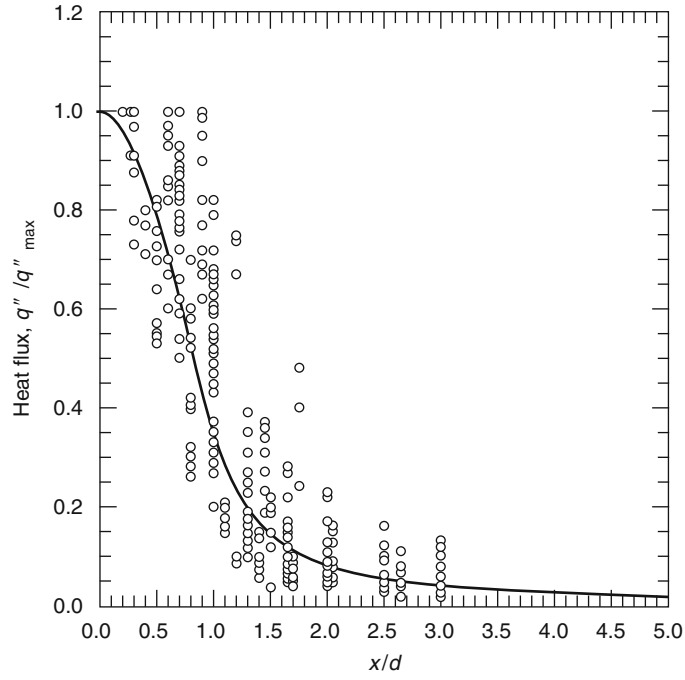

Fig. 25.41 Horizontal heat flux distribution on the walls out from the corner at a height less than 1.8 m above the floor [29]

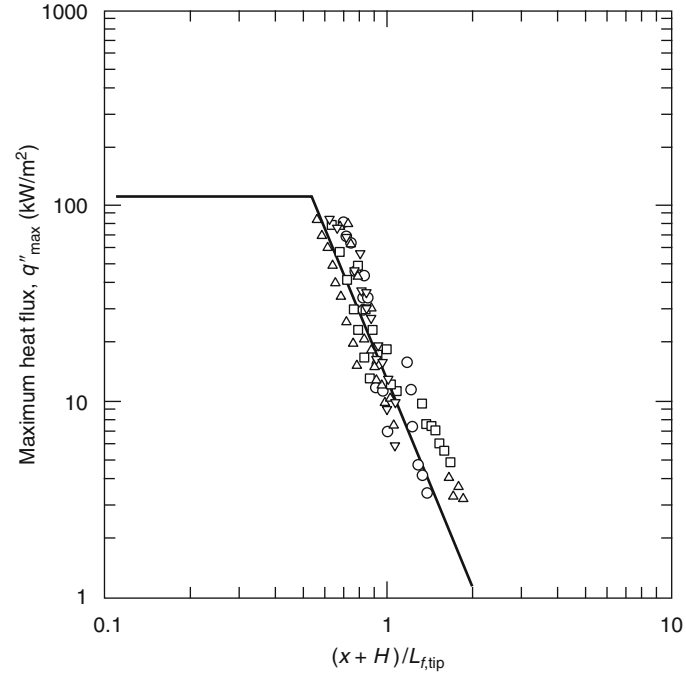

Fig. 25.42 Maximum heat flux along the top of the walls with a simulated burning boundary fire in the corner. L-shaped line burner with single side lengths of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□) and fire sizes ranging from 50 to 300 kW [29]

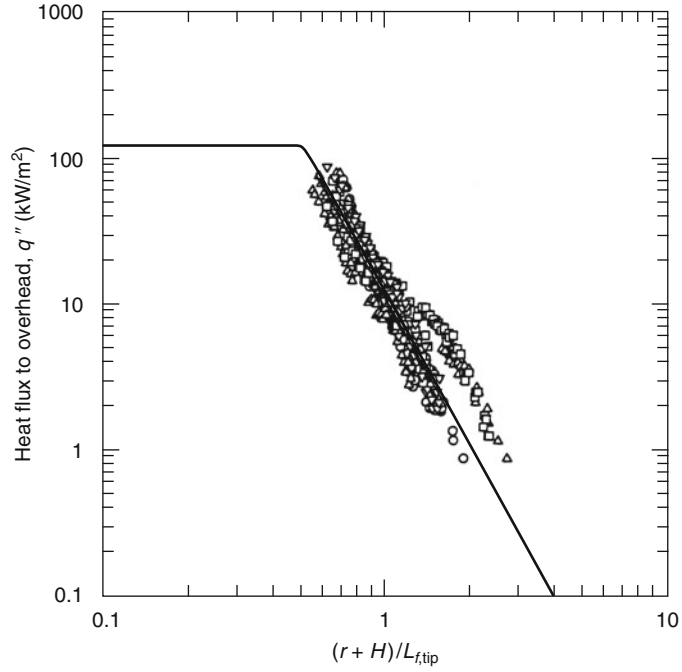

Fig. 25.43 Heat flux along the ceiling with a simulated burning boundary fire in the corner. L-shaped line burner with single side lengths of 0.17 m (○), 0.30 m (Δ), 0.30 m (elevated) (▽), and 0.50 m (□) and fire sizes ranging from 50 to 300 kW [29]

$(r + H)/L_{f,\text{tip}}$. A plot of the heat flux versus this dimensionless parameter is shown in Fig. 25.43. The line in this plot is a fit to the data, which are represented through the following relations:

$$q'' = 120 \quad \left(\frac{r+H}{L_{f,\text{tip}}}\right) \leq 0.52 \qquad (25.43a)$$

$$q'' = 13.0\left(\frac{r+H}{L_{f,\text{tip}}}\right)^{-3.5}\left(\frac{r+H}{L_{f,\text{tip}}}\right) > 0.52 \qquad (25.43b)$$

This is the same relation used for the top of the corner walls, except the length scale in the overhead data is r. In addition, this is the same relation determined using the ceiling heat flux data from tests with an area burner.

Ceiling Fires

Heat fluxes from burning ceilings have been evaluated for both unconfined ceilings and ceilings in a corridor. Due to buoyancy effects, flames from burning ceilings tend to be relatively thin. As a result, peak heat fluxes from burning ceilings range from 20 to 30 kW/m^2, which is similar to those measured for small wall fires.

Unconfined Ceiling Fires Heat fluxes from unconfined ceiling fires were measured by Hasemi et al. [73] using different sizes of sintered metal propane gas burners mounted into a 1.8-m-square incombustible ceiling. Using two different circular burner sizes ($D = 0.09$ and 0.16 m), heat flux to the ceiling was measured for fire heat release rates of 2.5–38 kW.

The radius of the flame (intermittent) measured using the two burners is shown in Fig. 25.44 to be slightly dependent on burner size, with the larger burner having a lower radius. However, as the fires become larger, the dependence on burner diameter becomes small. Flame lengths are proportional to the heat release rate raised to the one-half power.

Hasemi et al. [73] also measured the heat fluxes as a function of distance from the center of the burner. The measured heat fluxes are shown in Fig. 25.45 to be at peak levels in the first $0.4L_f$ and then decay with distance from the burner. Peak heat fluxes were measured to range from

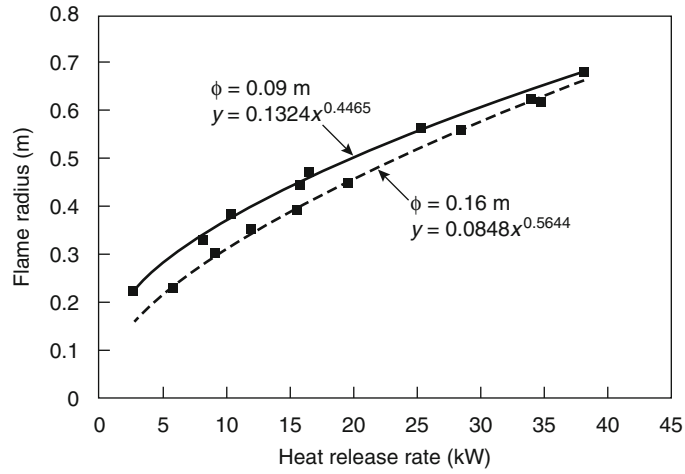

Fig. 25.44 Flame radius produced by a simulated burning ceiling in an unconfined area [73]

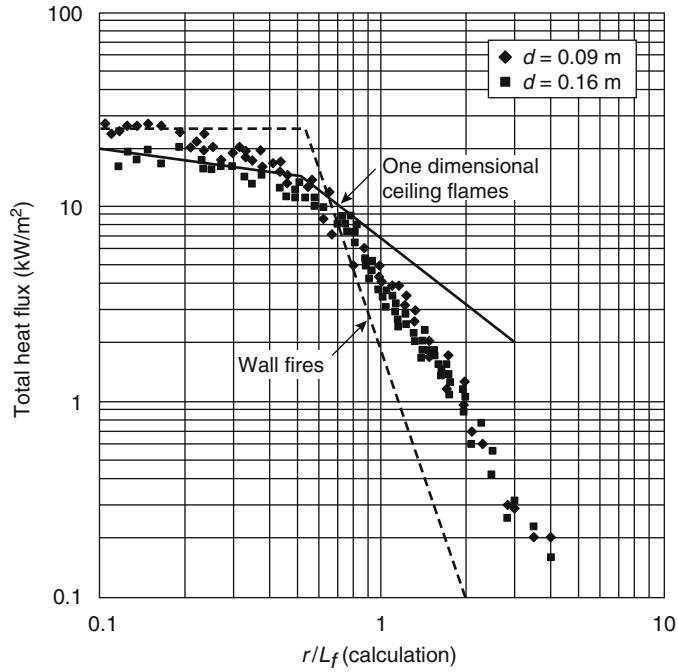

Fig. 25.45 Heat flux from fires beneath an unconfined ceiling [73]

16 to 27 kW/m^2, with the smaller burner producing higher heat fluxes. These peak heat fluxes were similar to those measured for burning ceilings in a corridor (i.e., one-dimensional ceiling flames) and for small wall fires. Heat fluxes from the unconfined ceiling fires were measured to decay at a rate between that measured for wall fires and that observed for a burning ceiling in a corridor.

Ceiling Fires in a Corridor Heat fluxes from flames produced by burning ceilings in a corridor were investigated by Hasemi et al. [72]. Tests were performed beneath a 2.73-m-long ceiling with two 0.10-m-high soffits mounted along the length of the ceiling to form a 0.30-m-wide channel. At the closed end of the channel, a 0.30-m-wide, 0.04-m-long porous propane burner was mounted in the ceiling. Heat flux distributions along the

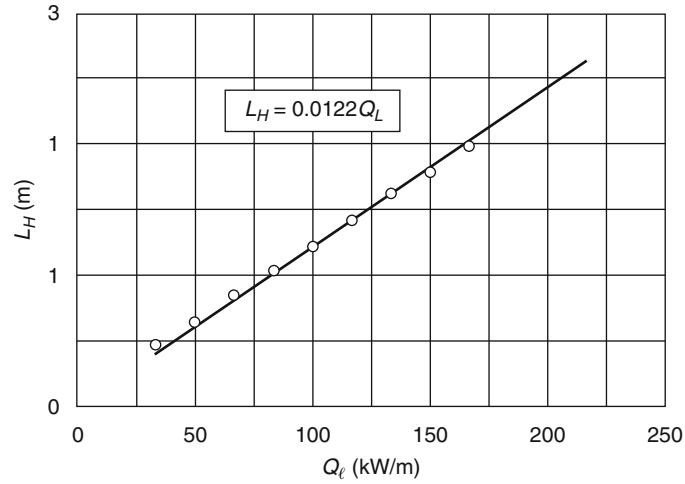

Fig. 25.46 Flame length produced by a burning ceiling in a corridor [72]

corridor were measured for fire heat release rates ranging from 10 to 50 kW (33–166 kW per meter of corridor width).

The intermittent flame lengths from these fires are seen in Fig. 25.46 to increase linearly with heat release rate per unit hallway width. A fit to these data produced the following relation to predict flame length due to a burning ceiling in a corridor:

$$L_f = 0.0122Q^{'} \qquad (25.44)$$

The heat flux distributions along the center of the corridor are shown in Fig. 25.47 for the different fires considered in the study. The line in the plot represents a best fit to the methane line burner data of Hasemi [55]. Heat fluxes were measured to be constant at approximately 20 kW/m^2 up to 0.4 L_f. Above this, heat fluxes were measured to decay at a slower rate than that previously measured for wall fires. Heat fluxes along a flame from a burning ceiling in a corridor (not shown in the figure) can be determined using the following expressions:

$$q^{''} = 20 \quad (x/L_f) \leq 0.4 \qquad (25.45a)$$

$$q^{''} = 6.36(x/L_f)^{-5/4} \quad (x/L_f) > 0.4 \qquad (25.45b)$$

Burning Parallel Vertical Surfaces

A common configuration encountered when commodities are being stored in rooms or warehouses is parallel vertical surfaces. As a result, several studies have focused on both experimentally and analytically characterizing this configuration [62, 74, 75]. Ingason and de Ris [76] also performed experiments in a rack storage configuration with a fire between four equally spaced storage towers.

Part of the work by Tamanini [74, 75] investigated the effects of wall spacing on the fuel mass loss rate of combustible parallel vertical walls. Walls were 0.94 m high and 0.460 m wide with the spacing varied from 0.470 to 0.025 m and no floor at the base of the walls. The average fuel mass loss rate was measured to increase (i.e., the average heat flux to the wall increased) with an increase in spacing until the spacing was less than 0.076 m. At a spacing of 0.038 m or less, the average mass loss rate was less than that measured with no parallel wall. At a spacing of 0.038 m (or wall height divided by spacing of 25 with a fire size of approximately 180 kW), the flames from the two burning surfaces were observed to merge together approximately two-thirds the distance up the walls.

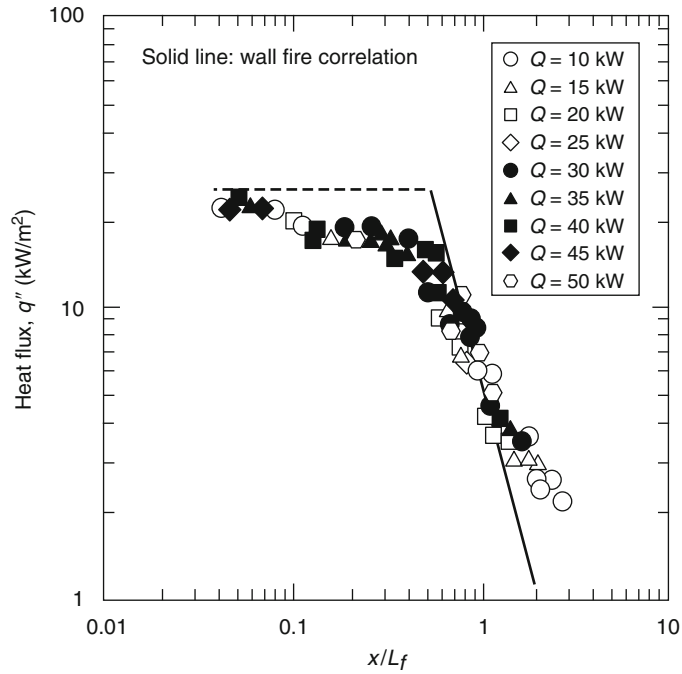

Fig. 25.47 Heat fluxes to the ceiling of a corridor [72]

Though not evaluated in this study, the presence of a floor may cause the flames to merge together at larger spacings.

Heat fluxes due to a fire between two parallel vertical surfaces were measured by Foley and Drysdale [62]. The study was performed using two 0.61-m-wide, 0.81-m-high walls separated by a gap of 0.06, 0.10, or 0.14 m. The fire was a 0.60-m-long propane line burner that had either a 11.6-kW/m or a 20.9-kW/m heat release rate per unit length. One of the walls was instrumented with four heat flux gauges that could be moved to measure the heat flux distribution on the walls. Heat fluxes were measured as far as 0.150 m from the centerline of the wall. For the different gap and heat release rate fires, heat fluxes were measured with the burner against the instrumented wall and with the fire in the center of the gap between the two walls. The effect of air entrainment flow path was also evaluated by performing tests with and without a floor between the panels. Results were correlated using a/d where the spacing between the walls, a, is divided by the burner length, d, and the dimensionless quantity Q_d^*, as defined in Equation 25.14, with d being the burner length.

The heat flux distributions measured with the fire against the instrumented wall are shown in Fig. 25.48. As seen in Fig. 25.48a, heat fluxes reached as high as 80 kW/m^2 with an open base (no floor between the walls). Heat fluxes on the panel can be estimated using the following expression:

$$q'' = 67.38\left\{z(a/d)^{0.36}/\left[Q_d^{*2/3}d\left(y'/d\right)^{0.38}\right]\right\}^{-1.47} \tag{25.46}$$

where $y' = 0.5d - y$ with y being the horizontal distance from the burner centerline.

With the base of the walls closed (a floor between the walls) and the fire against the instrumented wall, the heat flux data in Fig. 25.48b were seen to be as high as 70 kW/m^2. Heat fluxes for this case are slightly lower than the open-base case. A similar expression to that in Equation 25.45b was developed by Foley and Drysdale [62] to predict heat fluxes with the base of the walls closed:

$$q'' = 23.31\left\{z(a/d)^{0.905}/\left[Q_d^{*2/3}d\left(y'/d\right)^{2/3}\right]\right\}^{-1.2} \tag{25.47}$$

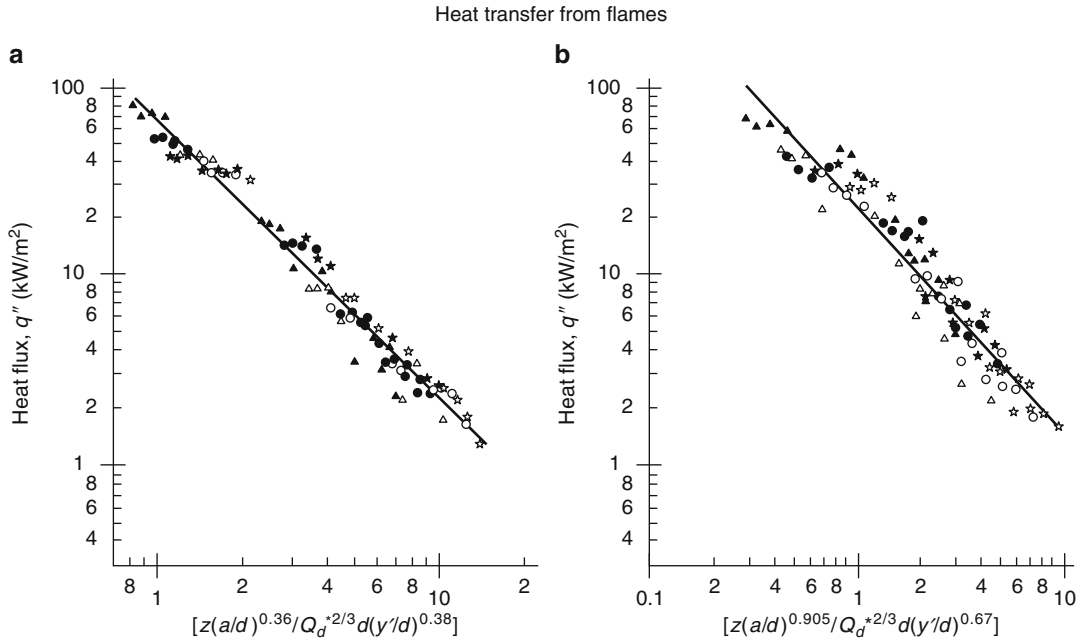

Fig. 25.48 Heat fluxes measured with the fire against the instrumented wall with (**a**) an open base (no floor in the gap) and (**b**) a closed base (a floor in the gap): 0.140-m spacing (⋆), 0.10-m spacing (○), 0.060-m spacing (Δ); open symbols, $Q' = 11.6$ kW/m; closed symbols, $Q' = 20.9$ kW/m [62]

Heat fluxes were also measured with the fire in the center of the gap between the two walls. In the case with an open base (no floor), the heat fluxes were measured to be 50 % lower than those measured with the fire against the instrumented wall. As seen in Fig. 25.49a, the peak heat flux was measured to be approximately 30 kW/m^2. This decrease was attributed to the air being drawn up at the base of the walls, preventing the fire from attaching to the instrumented wall. The line in the figure is the best fit to the data, which are given by the following expression:

$$q'' = 22.71\left\{z(a/d)^{1.04}/\left[Q_d^* d\left(y'/d\right)^{0.806}\right]\right\}^{-0.797} \quad (25.48)$$

The case with the base closed and the fire in the center of the gap resulted in the highest heat fluxes measured in the study. As seen in Fig. 25.49b, heat fluxes greater than 100 kW/m^2 were measured in this case. In the tests with the high heat fluxes, the flames were observed to occupy the width of the gap. This behavior was attributed to only allowing air to be entrained into the fire through the sides of the gap. The following expression can be used to estimate the heat flux to the walls for this case:

$$q'' = 23.94\left\{z(a/d)^{1.7}/\left[Q_D^* d\left(y'/d\right)^{1.34}\right]\right\}^{-1.04} \quad (25.49)$$

Additional research needs to be performed with this configuration to further validate the results. Larger-scale tests need to be conducted to verify the results of Foley and Drysdale [62]. In addition, the transition from wall fire heat fluxes to gap fire heat fluxes needs to be identified. Heat fluxes produced by area fires between parallel walls also need to be quantified.

Exposure Fires and Burning Walls and Ceilings

A series of tests were performed by Lattimer et al. [77] to investigate the use of steady-state heat flux correlations, developed using burners

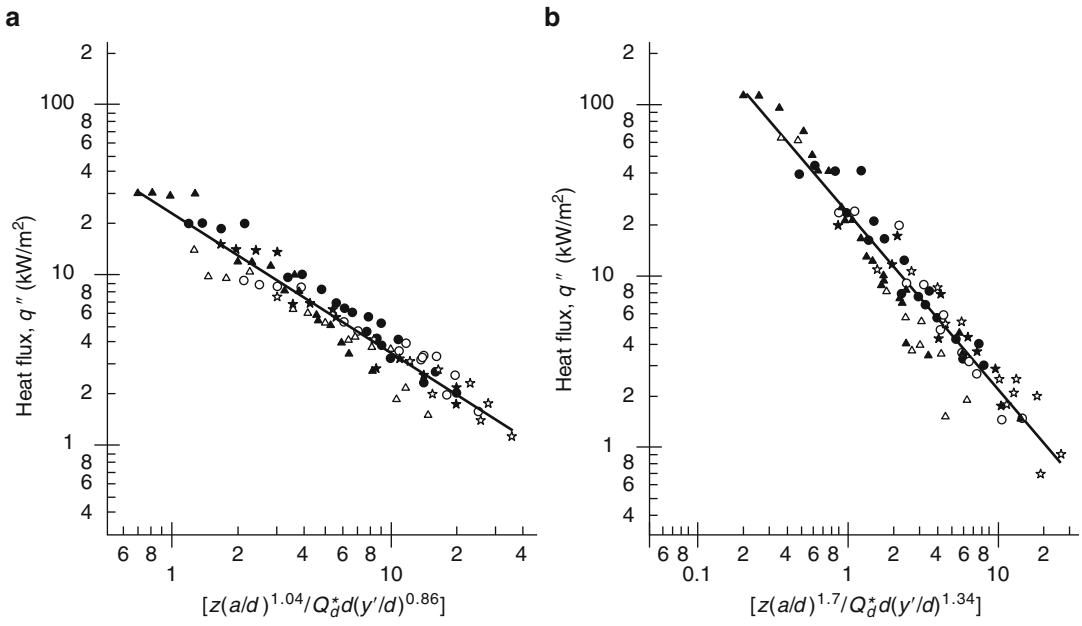

Fig. 25.49 Heat fluxes measured with the fire in the center of the gap with (**a**) an open base (no floor in the gap) and (**b**) a closed base (a floor in the gap): 0.140-m spacing (⋆), 0.10-m spacing (○), 0.060-m spacing (Δ); open symbols, $Q' = 11.6$ kW/m; closed symbols, $Q' = 20.9$ kW/m [62]

and noncombustible boundaries, for estimating the heat fluxes in growing fires. Three tests were performed in an 2.4-m-high, 2.0-m-wide open corner lined with a combustible material. A single test was performed on three different lining materials: 12-mm-thick Douglas fir plywood, 12-mm-thick E-glass fire-retarded vinyl ester, and 88-mm-thick sandwich composite (76-mm-thick balsa wood with 6-mm-thick E-glass fire-retarded vinyl ester facings). The initiating fire in the test was a square propane sand burner with a 0.17 m side length and a heat release rate of 100 kW for 10 min followed by 300 kW for 10 min, total test time of 20 min. Total heat release during the test was measured by performing oxygen calorimetry on the gases collected in an exhaust hood, and flame lengths were measured through visual observation. Heat fluxes were measured 0.075 m from the corner along at eight different elevations, 0.15 m below the ceiling along the top of the wall, and along the ceiling on a 45° diagonal out from the corner. Due to mounting the heat flux gauges along the top of the wall too far below the ceiling, no comparison between predicted and measured heat fluxes was done for the region along the top of the wall.

Transient data were averaged every 30 s to create a reasonable amount of data to compare to the developed correlations. A comparison of the flame length predicted using Equations 25.13 and 25.36 and the measured flame length is shown in Fig. 25.50. The dimensionless length used in this calculation was the width of the burner, D, while the burning had spread laterally less than the width of the burner. When the average lateral flame spread 0.90 m above the floor exceeded the burner width, the dimensionless length was taken to be the horizontal flame front location 0.9 m above the floor. The flame front at 0.9 m above the floor was approximately the average flame front on the wall.

Heat fluxes to the walls near the corner are provided in Fig. 25.51. Measured heat fluxes were slightly higher than values predicted by both the initiating fire correlation and the burning boundary correlation (assuming the heat flux is

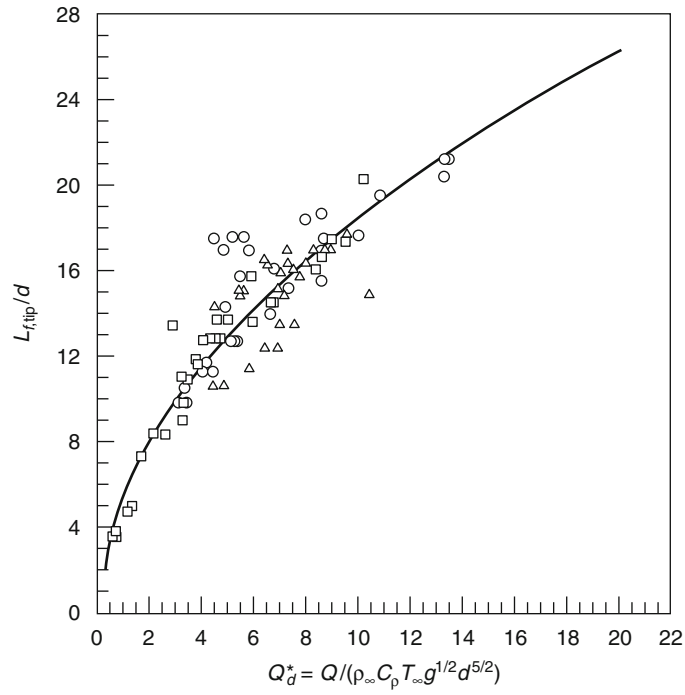

Fig. 25.50 Flame lengths measured in combustible corner fire tests compared with the flame length correlations developed for initiating and burning boundary fires in Equations 25.13 and 25.36: plywood (□), E-glass FR vinyl ester (○), sandwich composite (Δ) [77]

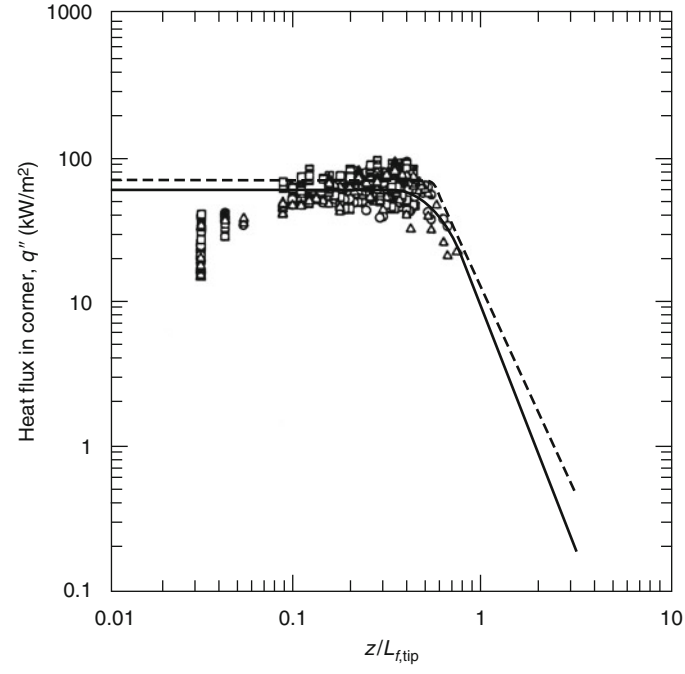

Fig. 25.51 Heat fluxes along the height of the corner in tests with different combustible boundaries compared with the heat flux predicted using Equation 25.38 (—) and Equation 25.15 (– – –): plywood (□), E-glass FR vinyl ester (○), sandwich composite (Δ) [77]

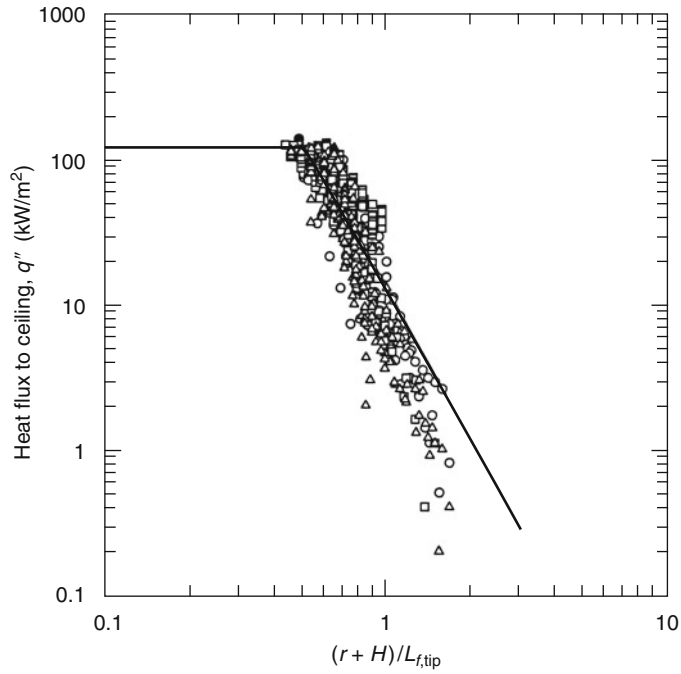

Fig. 25.52 Heat fluxes to the ceiling during open corner tests with the corner lined with a combustible material compared with the heat flux predicted using Equation 25.43: plywood (□), E-glass FR vinyl ester (○), sandwich composite (Δ) [77]

independent of the wall heat release rate). Inspection of the data indicates better agreement between the data and the correlations can be achieved using the initiating fire correlation up to when ignition occurs in the corner. After this, the corner wall heat flux correlations in Equations 25.38b and 25.40 can be used to estimate heat fluxes in the corner.

A comparison of the heat fluxes along the ceiling and the heat fluxes predicted using Equation 25.43 is shown in Fig. 25.52. In general, heat fluxes are adequately predicted by the correlation, with heat fluxes as high as 130 kW/m^2 measured during a test. This indicates that Equation 25.43 can be used to estimate heat fluxes to the ceiling near the corner containing the fire.

Fires from Windows

Fires that have reached flashover conditions typically result in burning outside of the actual burn room. Flames from postflashover fires extending out of a building through a window will buoyantly rise along the exterior of the building. Experiments characterizing the heat fluxes to the wall above the window of a postflashover compartment fire have been performed by Oleszkiewicz [78, 79], Thomas and Bullen [80], and Beitel and Evans [81]. In these studies, heat fluxes as high as 200 kW/m^2 have been measured.

Experiments performed by Oleszkiewicz [78, 79] were conducted using two differently sized full-scale rooms with a wall above the window that extended as much as two stories above the burn room (Fig. 25.53). The effects of window size, window aspect ratio, and fire size inside the compartment were evaluated in the study. Heat fluxes from the flames extending outside the burn room for different door sizes and different fires sizes are shown in Figs. 25.54 and 25.55 for propane gas fires. Note that the heat release rate of the fires stated in Figs. 25.54 and 25.55 is the ideal heat release rate of the compartment fire, which was determined from the gas flow rate and the heat of combustion for propane. Data in Fig. 25.54 show the effect of fire heat release rate and window size on the heat flux 0.5 m above the window. The distribution in the heat flux along the height exterior wall is shown in Fig. 25.55 for the case with a window 2.6 m wide and 1.37 m high.

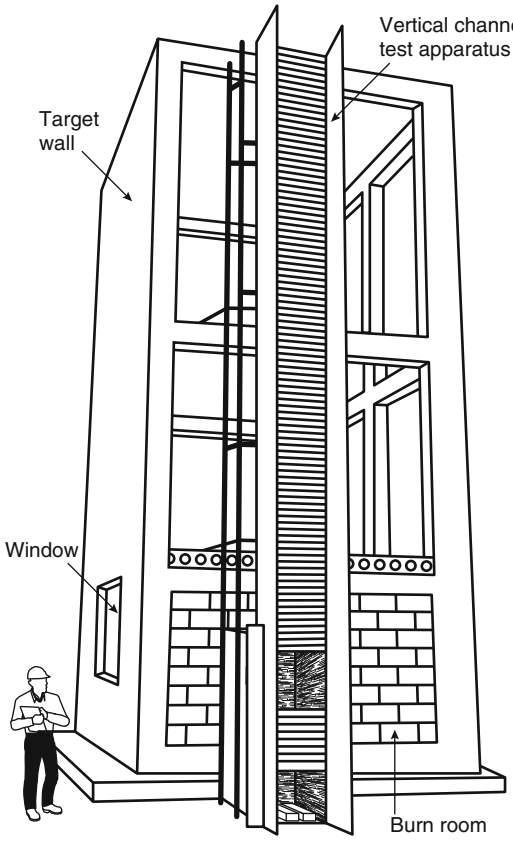

Fig. 25.53 Exterior wall fire test facility used by Oleszkiewicz [79]

Quintiere and Cleary [32] found that flame lengths for this situation can be estimated using the relation developed by Yokoi [82]. With L_f being the distance from the bottom of the opening to the average flame height, the heat release rate outside of the compartment, Q, and the effective diameter of the window, D, can be used to predict the flame length above the window with the following expression:

$$L_f = 0.0321\left(\frac{Q}{D}\right)^{2/3} \tag{25.50a}$$

where

$$D = 2\sqrt{\frac{H_o W_o}{2\pi}} \tag{25.50b}$$

Heat Fluxes in Standard Tests

Heat fluxes in some standard tests are provided in this section to compare with heat fluxes measured in realistic geometries presented in this chapter. Heat fluxes in room-corner tests such as ISO 9705 and NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room*

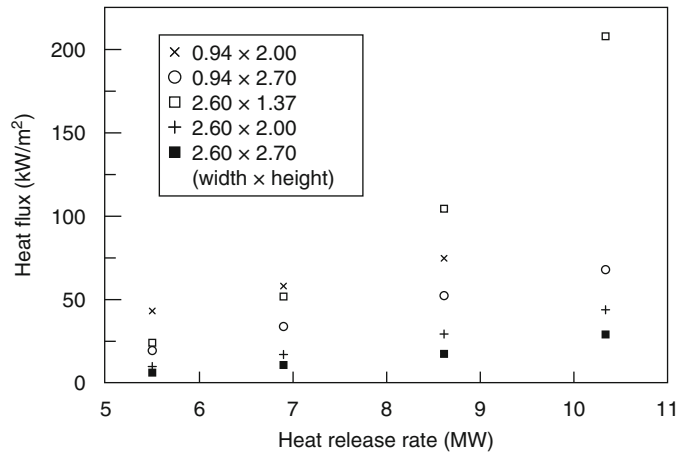

Fig. 25.54 Heat fluxes from a window flame 0.5 m above the top of the window for different size propane fires inside the compartment [79]

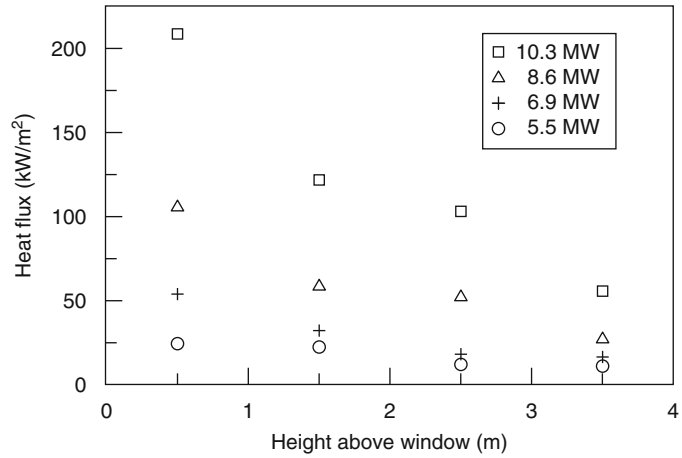

Fig. 25.55 Heat fluxes from window flames along the exterior wall above a 2.6-m-wide, 1.37-m-high window [79]

Fire Growth, can be determined using heat flux data previously presented in the section on heat fluxes from exposure fires in a corner. This section will focus on heat fluxes produced in other tests including fire resistance test furnaces and the ASTM E84 flame spread test. Note that these heat fluxes, along with most data previously presented for room-corner tests, were typically measured with a noncombustible, insulating surface mounted to the test apparatus. The heat flux to actual test specimens could be different depending on specimen thermal properties, the occurrence of sample ignition and burning, as well as other factors.

Fire Resistance Tests

Several furnace fire exposures are used throughout the world to evaluate the fire resistance of products. These fire exposures have peak temperatures ranging from 1050 °C to 1350 °C after a 3-h exposure (Fig. 25.56). The type of exposure used depends on the end-use application of the product. Tunnel and offshore oil rig applications have the highest temperature, most severe fire exposures, whereas less severe exposures are used for different building applications.

The ASTM E119 [83] and ISO 834 [84] time-temperature curves are perhaps the most common furnace exposures used in fire resistance testing. These furnace exposures are utilized to evaluate the fire resistance of structural elements on buildings, on ships, and in some transportation applications (e.g., railcars). ASTM E119 is primarily used in North America whereas ISO 834 is used more internationally (e.g., Europe and Australia). As seen in Fig. 25.56, the two time-temperature curves are similar, with the ISO 834 temperatures being slightly higher at times greater than 1 h. The ASTM E119 furnace exposure is measured using shielded thermocouples, whereas the ISO 834 furnace exposure is measured using sheathed thermocouples.

Though the time-temperature curves in these tests are similar, the actual heat flux exposure early in the ASTM E119 fire exposure is more severe due to the type of thermocouples used to control the furnace [85, 86]. The European standard EN1363-1 [87] uses the ISO 834 time-temperature curve, but the furnace is controlled using plate thermometers, which provide a more severe exposure compared with ISO 834 thermocouples for the test duration [88, 89]. Compared with ASTM E119 shielded thermocouples, Sultan [90] measured that plate thermometers resulted in a slightly less severe exposure during the first 10 min of the test, but thereafter the thermal exposures were the same.

The total heat flux measured in an ASTM E119 furnace test is provided in Fig. 25.57 for a wall and floor furnace. Total heat fluxes were measured using a water-cooled Gardon gauge.

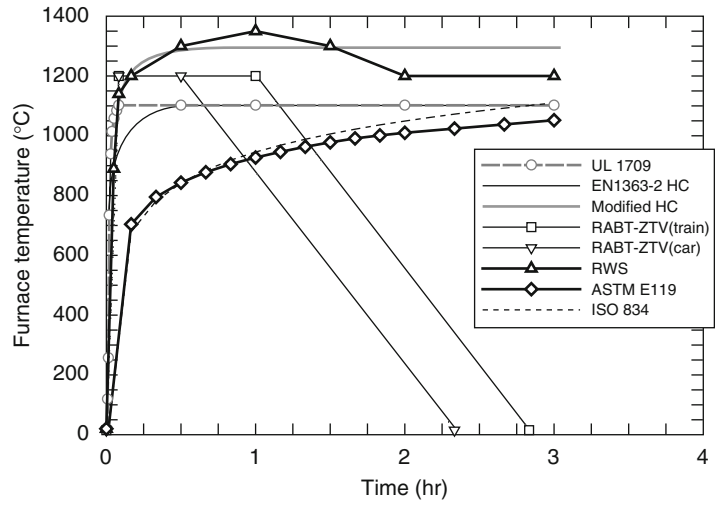

Fig. 25.56 Furnace time-temperature exposure curves

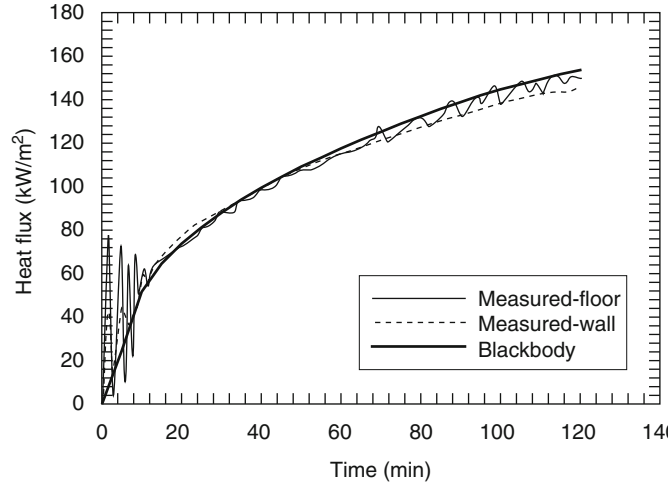

Fig. 25.57 Heat flux measured during ASTM E119 furnace exposure in floor and wall furnaces. Blackbody heat flux was calculated from the ASTM E119 furnace temperature curve

In this test, gaseous fuel was used and the temperature was controlled with ASTM E119 shielded thermocouples [91]. The wall furnace was lined with ceramic fiber while the floor furnace was lined with brick. The same furnace controlled with a plate thermometer provided similar heat flux levels at times after 10 min. Also provided in the plot is the blackbody heat flux based on the furnace temperatures specified in ASTM E119. As seen in the figure, the blackbody heat flux is similar to heat fluxes measured in the furnace except during the initial 10 min.

The higher temperature fire exposure curves in Fig. 25.56 are used to evaluate products used in petrochemical, offshore oil platform, and some tunnel applications. The UL 1709 [92] hydrocarbon pool fire exposure and the EN1363-2 [93] hydrocarbon curve (HC) are typically used for offshore oil platform applications, whereas the other higher-temperature curves are used to represent a large hydrocarbon fire inside a tunnel.

The UL 1709 and EN1363-2 [93] both have a maximum gas temperature of 1100 °C; however, the UL 1709 exposure reaches 1100 °C faster than does the EN1363-2 exposure (in 5 min versus after 25 min, respectively). Unique to this fire exposure curve, the UL 1709 fire exposure also has a heat flux requirement. During a calibration test with a UL 1709 exposure, the heat flux as measured from a water-cooled heat flux gauge mounted to a calibration specimen must be

204 ± 16 kW/m^2 while the furnace temperature is 1093 ± 111 °C. This heat flux is approximately equal to the blackbody heat flux at the furnace temperature (i.e., 1093 °C results in a blackbody flux of 197 kW/m^2).

The curves for tunnel applications have peak temperatures that range from 1200 to 1350 °C. The RABT-ZTV curves were developed in Germany to represent different vehicle fires in tunnels. These curves reach a peak temperature of 1200 °C in 5 min and remain at that temperature for 30–60 min. Thereafter, the temperatures decrease linearly with time to ambient conditions after 2.5–3.0 h. Estimated peak heat fluxes, as the blackbody flux using the peak furnace temperature, in these tests are 267 kW/m^2. A modified version of the EN1363-2 HC curve has been used in France to represent fires in tunnels. The Modified HC curve peaks at 1300 °C instead of 1100 °C. Estimated peak heat flux in this test, based on the blackbody flux using the peak furnace temperature, is 347 kW/m^2. The RWS fire curve was developed by the Rijkswaterstaat, Ministry of Transport, in the Netherlands based on results from testing conducted by TNO in the Netherlands. The RWS curve peaks at a temperature of 1350 °C, which is the highest of all time-temperature curves. Estimated peak heat flux in this test, based on the blackbody flux using the peak furnace temperature, is 393 kW/m^2. The potential for these temperatures in tunnel fires was validated through vehicle testing in the Runehamar test series, where temperatures ranging from 1280 °C to 1365 °C were measured [48].

ASTM E84 Tunnel Test

The ASTM E84 test is a "tunnel" test that provides flame spread and smoke production data from wall and ceiling lining materials. The test chamber is approximately 18 in. (0.46 m) wide, 12 in. (0.30 m) high, and 25 ft (7.63 m) long, with a gas burner located at one end and exhaust ducting located at the other. The test material is oriented on the "ceiling" of the tunnel by attaching a 24-ft (7.32-m) long sample of the test material to the underside of the removable lid of the test chamber. A flow of 240 ft/min (1.22 m/s) is established through the test chamber. The initiating fire is an 88 kW gas burner located at one end of the sample. The flames from the two burner pipes impinge on the sample at two off-center locations, producing a flame that flows 1.2 m down the sample.

Parker [94] measured heat fluxes from the initiating fire with a noncombustible ceiling in the tunnel. The highest heat fluxes were measured where the burner flames impinge on the ceiling. A plot of heat flux, measured using a water-cooled heat flux gauge, at this location is shown in Fig. 25.58. The heat flux during the initial 2 min of the test was 20–30 kW/m^2. By 4 min, the heat flux increased to 50–60 kW/m^2 where it

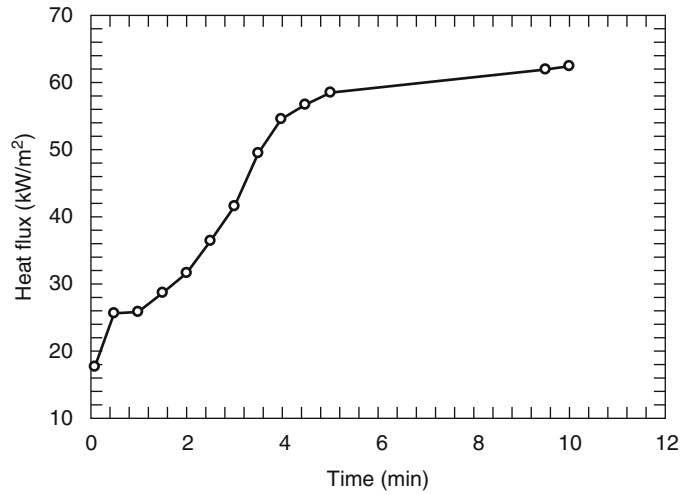

Fig. 25.58 Heat flux at the ASTM E84 burner impingement point

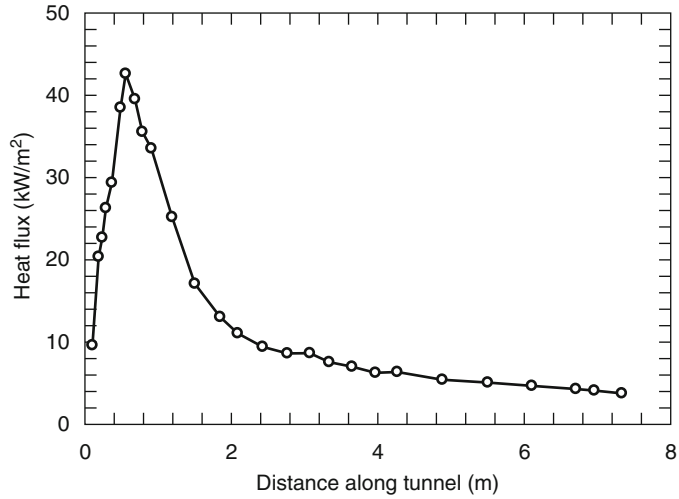

Fig. 25.59 Calculated incident heat flux along the length of the ASTM E84 tunnel

remained for the duration of the test (10 min). The increase in heat flux with time was attributed to reradation from the tunnel surfaces.

Incident heat fluxes along the center of the tunnel length were calculated using surface temperature measurements. Figure 25.59 provides the heat fluxes after a 20-min exposure, which is 10 min longer than the actual test. Heat fluxes near the burner are approximately 40 kW/m^2 and then decrease rapidly with distance along the tunnel. In a test with flames along the entire length of the tunnel, heat fluxes were calculated to be 70 kW/m^2 at 2.0 m from the burner and 30 kW/m^2 at the end of the tunnel 7.3 m from the burner.

Cable Tests

Gandhi et al. [95] measured heat fluxes due to the exposure fire in three different standard cable tests : UL 910, UL 1666, and UL 1685. Heat fluxes were measured using water-cooled Gardon gauges.

The UL 910 test is conducted in the ASTM E84 tunnel apparatus to evaluate low power cables without conduit in air handling spaces. The sample is in a horizontal orientation for this test with the flame impinging on the underside of the cables. Average heat flux measurements along the length of the ASTM E84 tunnel where the cable would be located over the test period are shown in Fig. 25.60. The peak heat flux was measured to be 49 kW/m^2 approximately 1.0 m down the tunnel. The heat fluxes are similar to those determined by Parker [94], except the Gandhi et al. [95] measured the peak heat flux location 0.5 m further down the tunnel. Gandhi et al. [95] stated that this difference may be due to using actual heat flux gauges instead of using an inverse method as well as the sample location differences. Transient heat fluxes measured by Gandhi et al. [95] determined that the heat fluxes increase during the test by approximately 10 kW/m^2 at locations 0.13–1.65 m along the tunnel.

A UL 1666 test is used to evaluate cables used in high rise buildings installed in riser shafts or floor-to-floor installations. The sample is in a vertical orientation in this test adjacent to a diffusion burner. The exposure fire in this test produces a peak heat flux of 43 kW/m^2 0.30 above the burner and decays to 6 kW/m^2 by 1.5 m above the burner.

A UL 1685 test is performed to evaluate cables used in applications other than air handling or floor-to-floor. The sample is located in a vertical orientation during the test with a propane gas-air premix burner impinging on the bottom of the cables. The exposure fire produced peak heat fluxes of 46 kW/m^2 at the burner elevation and decayed to 2 kW/m^2 by 1.5 m above the burner.

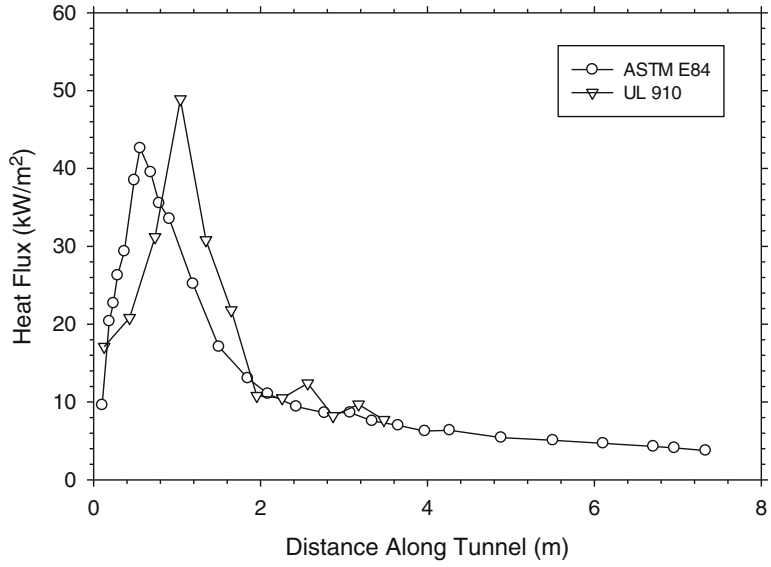

Fig. 25.60 Test average heat fluxes measured in the UL 910 experiment by Gandhi et al. [95] compared with the ASTM E84 measurements made by Parker [94]

Effects of Other Variables

The environment in which a fire is burning can affect the heat flux levels incident on the surface. Studies have been conducted by Atreya and Mekki [96], Santo and Tamanini [97], Mekki et al. [98], and Chao and Fernandez-Pello to evaluate the impact of oxygen concentration on the heat fluxes transferred by flames to surfaces. In tests with methane fires, Atreya and Mekki [96] found that flame radiation (and the total heat flux to the surface) was increased by increasing the oxygen concentration.

More important for most problems in fire is the effect of decreasing the oxygen concentration on heat fluxes from the flame. Santo and Tamanini [97] found that decreasing the surrounding oxygen concentration from 20.9 % to 18.0 % the radiative flux to an external target was decreased to an external target by 40 %. This decrease was attributed to a decrease in lower soot concentrations in flames in lower oxygen environments. Chao and Fernandez-Pello [99] found that this reduction in heat transfer to the surface reduces the flame spread rate along combustible panels.

Nomenclature

a	spacing between parallel walls (m)
C_p	specific heat capacity of air at 300 K (0.998 kJ/[kg-K])
d	length of single side on L-shape burner, length of line burner, width of burning area on corner wall (m)
D	length of single side of square burner, diameter (m)
g	acceleration of gravity (9.81 m/s^2)
H	distance between fire and ceiling (m)
H_B	distance between fire and lower flange of I-beam (m)
H_C	distance between fire and upper flange of I-beam (m)
H_o	height of room window (m)
h	convective heat transfer coefficient (kW/[m^2 -K])
k	thermal conductivity (kW/m-K)
L_B	flame tip length along lower flange of I-beam (m)
L_C	flame tip length along upper flange of I-beam (m)
L_{web}	flame tip length along center of web on I-beam (m)

L_f average flame length (m)
$L_{f,\text{tip}}$ flame tip length (m)
L_H flame extension along ceiling away from stagnation point (m)
Q fire heat release rate (kW)
Q' fire heat release rate per unit width (kW/m)
Q^* dimensionless parameter, $Q_D^* = \frac{Q}{\rho_\infty C_p T_\infty \sqrt{g} D^{5/2}}$, with D being length scale
r distance from corner or stagnation point to measurement location (m)
q'' heat flux (kW/m^2)
T_f local gas temperature (K)
T_g room gas temperature (K)
T_s material surface temperature (K)
T_∞ ambient temperature (300 K)
W_o width of room window (m)
w dimensionless distance along ceiling or I-beam, $w = \left(r + H_B + z^{'}\right)/\left(L_{HB} + H_B + z^{'}\right)$
x horizontal coordinate (m)
y horizontal coordinate (m)
y' distance from center of line burner, $y^{'} = 0.5d - y \ \ (m)$
Z burner height (m)
z vertical coordinate (m)
z' virtual source location (m)

Greek Letters

ε material surface emissivity (−)
ρ_∞ ambient density of air (1.2 kg/m^3)
π constant (3.14159)
σ Stefan-Boltzman constant $\left(5.67 \times 10^{-11} kW/\left[m^2 - K^4\right]\right)$

Heat Release Rates

26

Vytenis Babrauskas

Introduction

Calculations of fire behavior in buildings are not possible unless the heat release rate of the fire is known. This chapter on heat release rates provides both theoretical and empirical information. The chapter is organized so that theory and basic effects are considered first, then a compendium of product data is provided, which is arranged in alphabetic order.

Definitions

The essential characteristic that describes quantitatively *How big is the fire?* is the heat release rate. This is so important that it has been described as the single most important variable in fire hazard [1]. The heat release rate (HRR) of a burning item is measured in kilowatts (kW). It is the rate at which the combustion reactions produce heat. The term "burning rate" is also often found. This is a less specific term, and it may either denote the HRR or the mass loss rate. The latter is measured in units of kg s^{-1}. It is best to reserve 'burning rate' for non-quantitative fire descriptions and to use either HRR or mass loss rate, as appropriate. The relationship of these two quantities can be expressed as:

$$HRR = \Delta h_c \times MLR \qquad (26.1)$$

where h_c is the effective heat of combustion (kJ kg^{-1}) and MLR is the mass loss rate (kg s^{-1}). Such an equation implies that HRR and MLR are simply related by a constant. This is not in general true. Figure 26.1 shows the results obtained from a test on a 17 mm sample of Western red cedar. It is clear that the effective heat of combustion is not a constant; it is roughly 12 MJ kg^{-1} for the first part of the test, but increases to around 30 MJ kg^{-1} during the charring period at the end of the test.

In principle, the effective heat of combustion can be determined by theory or by testing. In practice, if the effective heat of combustion is not a constant, then experimental techniques normally involve directly measuring the HRR, rather than using Equation 26.1.

Measuring the HRR, Full-Scale

The simplest case is when full-scale HRR can be directly measured. This can be grouped into two types of techniques:

- Open-burning HRR calorimeters
- Room fire tests.

Open-burning HRR calorimeters were developed in the early 1980s at NIST by Babrauskas and colleagues [2] and at FMRC by Heskestad [3]. The operating principles of these calorimeters are described in Chap. 27. Based on this work, a large number of different test

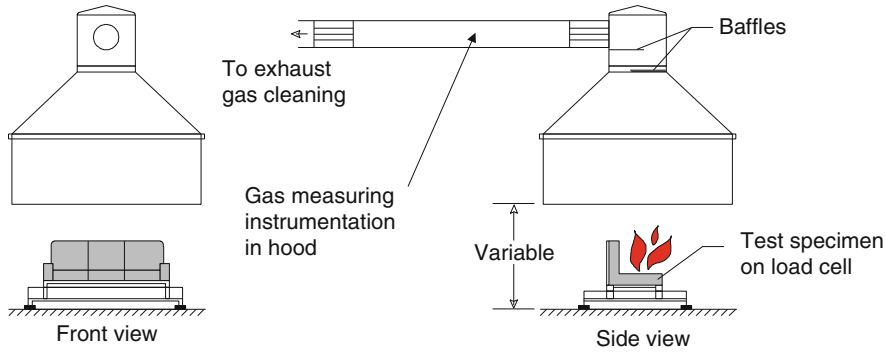

Fig. 26.2 NORDTEST NT FIRE 032 calorimeter

standards have been issued, for example [4–8]. A discussion of a number of other standards can be found [9].

The NORDTEST furniture calorimeter [7] is shown in Fig. 26.2. Open-burning HRR measurements are simpler to make since a test room does not need to be constructed. The HRR within a room and under open conditions are, clearly, identical at very low HRR. What happens at higher values of HRR depends on the situation at hand. If the fire is so large that room flashover can be reached (about 1.5–1.75 MW if ventilation is through a single normal-sized door opening) then actual room HRR values post-flashover can be drastically different from their open-burning rates. This is due primarily to additional radiant heat flux contribution from the hot gas layer and the hot room surfaces, although ventilation effects can also play a role.

For upholstered chairs, extensive studies have shown that room effects are only at the 20 % level up to a 1 MW fire [10]. The same study, however, showed that for mattresses, a room presence effect shows up at much lower HRR values. For liquid pools, the HRR is strongly

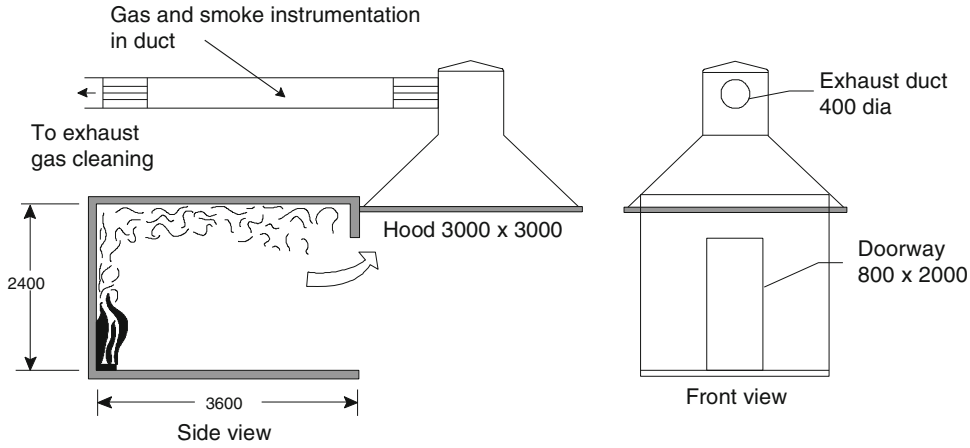

Fig. 26.3 ISO 9705 room HRR test

affected by the surrounding room [11]. For most other commodities, this issue has not been studied.

The degree by which the room affects the HRR is largely determined by how 'open' the fuel package itself is. A liquid pool on the floor has a view factor of 0 to itself and 1.0 to the room. By contrast, the reason that chairs tend to be little-affected by the room is that the chair 'sees' its own surfaces to a significant extent, rather than being fully-exposed to the room. Some useful error analyses of large open calorimeter measurements have been reported [12]; a theoretical discussion of the 'ideal' large scale calorimeter has also been presented [13].

Room fire tests should be commissioned when room effects are anticipated to be strong, or when a more precise estimate is needed. Apart from cost, there is a drawback to room fire testing. This is because the

HRR measured in a room fire cannot be extrapolated to any rooms with larger ventilations. Open-burning HRR data could, by contrast, be applicable to such well-ventilated rooms.

The development of the modern room HRR test took place at several institutions, including Fisher and Williamson at the University of California [14], Lee at NIST [15], and Sundström at the Swedish National Testing and Research Institute [16]. Room test standards include [17, 18] and also [4, 5]. A typical standard room fire test, ISO 9705 is shown in Fig. 26.3; a similar room fire test is ASTM E 2257 [19]. This test equipment is available for commercial testing in North America, Europe, Asia, and other places.

Measuring the HRR, Bench-Scale

To measure the HRR in a bench-scale test is nowadays an easy task. Most commonly, the Cone Calorimeter [20] developed at NIST by Babrauskas will be used (Fig. 26.4). These instruments are available at commercial and research laboratories worldwide. The procedures for conducting Cone Calorimeter tests are described in ASTM E 1354 [21] and ISO 5660 [22]. Other HRR calorimeters, such as the Ohio State University apparatus or the Factory Mutual Research Corp. Flammability Apparatus are also in use at some laboratories. A textbook is available which discusses many of the details of HRR measuring technology [23]. Thus, the modeler can assume that if at least enough material is available to run several small samples (100 mm × 100 mm, in the case of the Cone calorimeter), an empirical HRR curve can be obtained by running bench-scale tests.

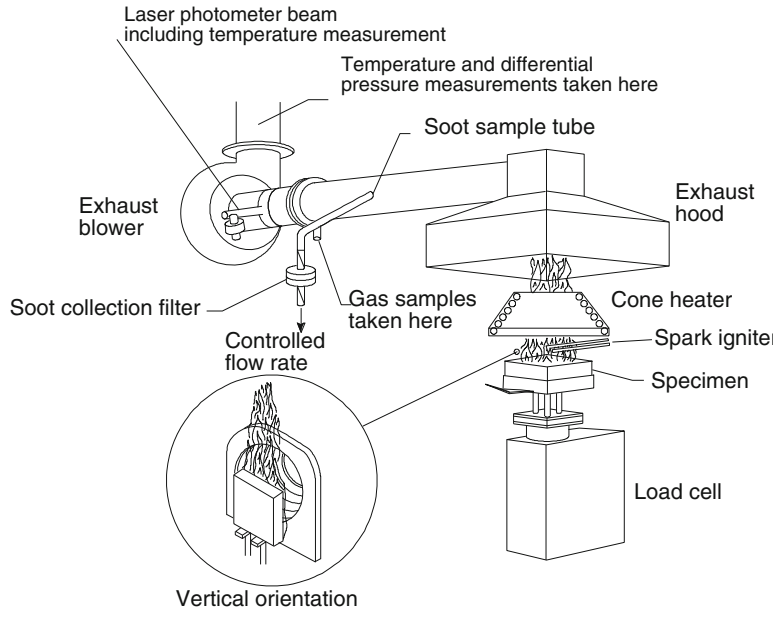

Fig. 26.4 The cone calorimeter

Measuring the HRR, Intermediate-Scale

The newest experimental technology for determining the HRR is intermediate-scale calorimetry. Various earlier efforts have been made, but the first instrument to receive standards support is the ICAL, developed at Weyerhaeuser [24] (Fig. 26.5). It has been standardized as ASTM E 1623 [25]. This test method accommodates 1.0 m by 1.0 m specimens, which allows for complex or highly non-homogenous constructions to be tested. However, since the data are still not of full scale, some additional analysis is needed to be able to utilize the test data in fire modeling.

Modeling Implications for Using Full-Scale HRR Data

If access is available to full-scale HRR data, then the task of defining the fire is on a solid basis. Even here, however, there are a number of problems and caveats. Apart from the obvious issue that the available full-scale data must be known to describe the specific fuel source in question (and not some possibly very differently performing 'similar' item), there are some additional concerns. Supposing one finds full-scale test results on one's exact commodity, can the data simply be used unquestioningly? The answer, of course, is not. There are two main issues:

- The available data may be open-burning calorimetry data. One must then determine if there is an enclosure effect to be accounted.
- The available data may be room fire data, but the test enclosure may not correspond to the room for which modeling is to be done.

The first of these issues was briefly touched on above already. The availability of quantitative guidance is lacking. For upholstered chair fires in a room of about the size of the ISO 9705 room, one can estimate a 20 % augmentation over the open-burn rates when considering fires in the 100–1000 kW range. For mattresses, the effect is large and without adequate guidance. For liquid pools, a pool sub-model must be specifically present in the fire model used, since no simple approximation is adequate. For wood cribs, there are formulas for guidance [26], although of course wood cribs are hardly a feature of most real fires. For other combustibles, neither data nor guidance is available.

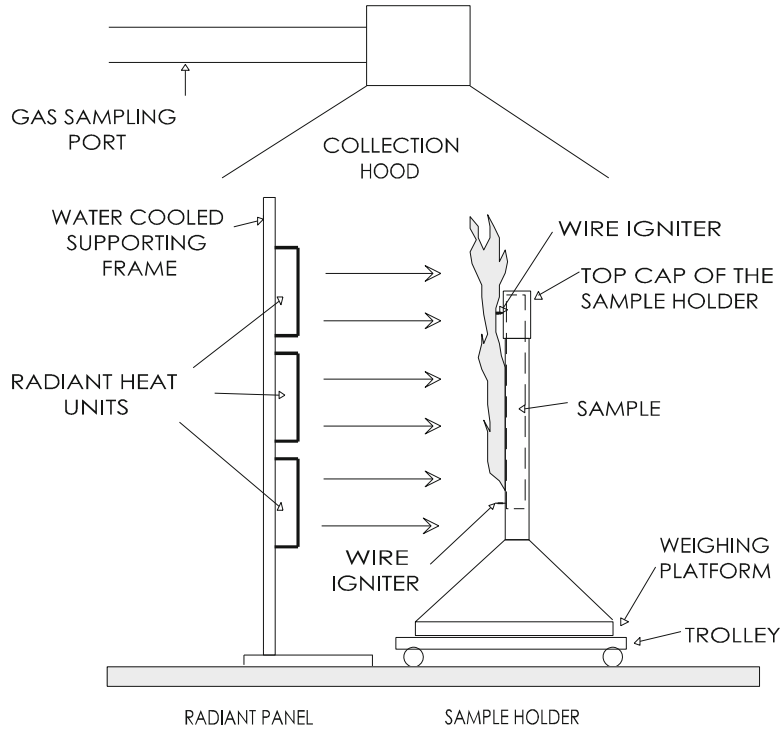

Fig. 26.5 Intermediate scale (ICAL) calorimeter

A very similar problem is faced when the modeler has available full-scale HRR data, but the test was run in a room of rather different size or ventilation conditions than is the intended application. Only two studies on this topic have been published in the literature. Kokkala and colleagues compared [27] some room wall/ceiling linings in a large room to the values obtained in the ISO 9705 room. Also, during the CBUF project some furniture fires were done in rooms of two scales [10]. Neither of these studies looked at this issue comprehensively enough to yield numerical guidance.

Some European designers have proposed that 250 or 500 kW m^{-2} of floor area is an appropriate peak value of HRR according to which to design buildings of almost any kind [28]. It is not clear how these values were obtained, but one must consider whether they are conservative. Figure 26.48 gives HRR data for one pallet and half a pallet loads of some elastomer pellets. While these are 'industrial' materials, nonetheless substances of similar heat of combustion and state of aggregation can readily be found in shops, storage rooms, and various other places in diverse building types. The test data showed that the whole-pallet test had to be extinguished at about 4500 kW m^{-2}; the fire was still growing, and its ultimate HRR would have been higher.

Growth curves for the FM data listed in Table 26.8 are not available; nonetheless the peak values of roughly 2,000–20,000 kW m^{-2} are sobering. Goods of this kind cannot occupy anywhere close to 100 % of the floor area, of course, but even assuming coverage at ¼ to ½, the actual HRR values are enormous. Now, there are clearly occupancies where it is impossible to introduce high fuel loads—swimming facilities may be an example. But other facilities, even if designed to be spartan in actual use (e.g., ceremonial lobbies) may sustain large fuel loads during construction, remodeling, expansion, and similar activities.

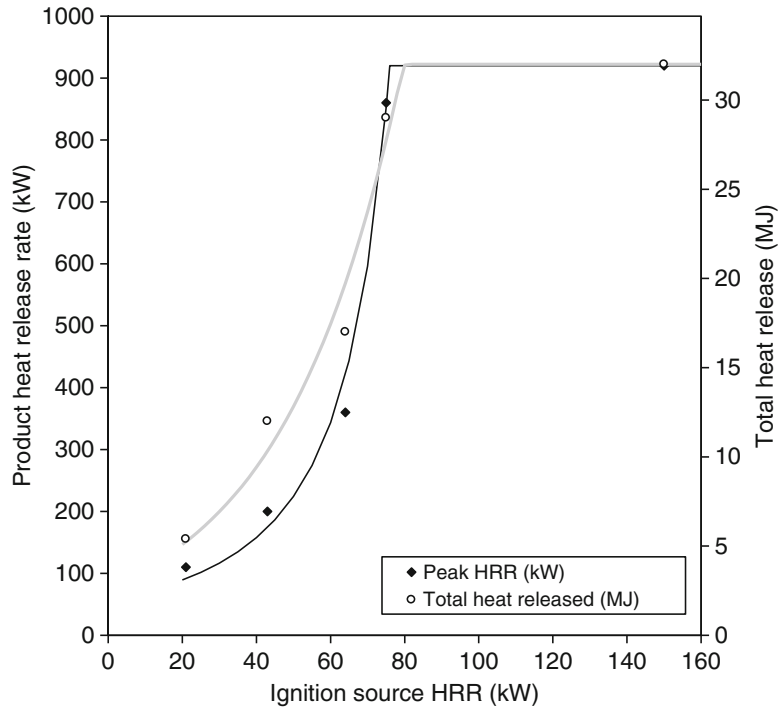

Fig. 26.6 Effect of ignition source on the HRR of PVC foam wall coverings

Effect of Ignition Source on Full-Scale HRR

Full-scale tests for HRR usually do not impose an *overall* radiant heat flux and are ignited with localized flame sources. But locally, the heat fluxes from various ignition sources will differ both in their magnitude and in the size of the area subjected to the heat flux. Most plastic commodities that do not contain fire retardants (and are not made from an intrinsically-FR plastic) can be ignited with very small flame sources, often no bigger than a paper match. FR commodities, however, will resist ignition from small flames, but may be ignited from a large-flame ignition source. Commonly, such products show an all-or-nothing behavior. That is, ignition sources below a certain size will cause essentially no heat release from the test article, while a larger ignition source may cause a large fraction of, if not the total, combustible mass of the article.

For example, it was shown [29] that a television cabinet made from a plastic fire retarded to the extent of obtaining a V-0 classification in the UL 94 [30] test gave no heat release when using a 10 kW burner, but burned well when exposed to a 30 kW burner. Dembsey [31] conducted room tests on rooms partially lined with a PVC-foam wall covering. His results are shown in Fig. 26.6. Note that the curve is very steep and could be represented reasonably by a step-function. Apart from a few examples, this type of data, unfortunately, is very rarely available for practical commodities of engineering interest.

Effects of Other Variables

Some *thermoplastic materials* have a highly pronounced tendency to melt and flow. Consequently, commodities made from these materials, when burning, will often exhibit object burning above the floor and an accompanying pool fire at the floor, formed by the melt material. Sherratt and Drysdale [32] studied the problem in intermediate scale, by burning vertical polypropylene sheets above various floor materials.

Major differences were found both in the peak HRR and in the time-resolved HRR curve, depending on the floor type. The differences were largely attributable to thermal characteristics (thickness, density, thermal conductivity, etc.) of the floor materials. Upholstered furniture using plastic foam padding often burns with a secondary pool fire underneath, however, this behavior occurs only in some cases.

Modeling with Bench-Scale HRR Data

If full-scale data on HRR are available, then these are simply used in the fire model. In many cases, however, such data are not available, often due to cost of testing or unavailability of large size specimens. In such cases, it is desirable to be able to use bench-scale data, denoted as and measured in units of kW m^{-2}. With the bench-scale HRR, there are two main questions: (1) can it be predicted from some more fundamental measurements? and (2) how can the full-scale HRR be predicted from the bench-scale HRR?

Predicting Bench-Scale HRR from Fundamental Considerations

The former question has been of considerable interest to fire researchers, but practical engineering methods are not yet at hand. This task is often described as creating a 'pyrolysis model,' since the degradation of a material when it is exposed to heat is known as pyrolysis. When a material heats up, degrades, ignites, and burns, some very complicated physical and chemical phenomena are taking place. In addition to a change of phase, there is often flow of moisture simultaneously with heat flow.

The material may undergo several different types of phase changes during the decomposition process, each accompanied by changes in density and porosity. Bubbles may be created within the bulk of the material and migrate to the surface. These may be accompanied by molten flow ejection at the surface. Oxygen may or may not directly interact with the surface to create a glowing combustion.

The chemical reactions being undergone are commonly several in number and occurring at different temperature regimes. Finally, the material may undergo large-scale cracking, buckling, or sloughing. Each of these physical phenomena may significantly affect the rate of specimen decomposition. From even this very brief description, it is clear that computing the pyrolysis of a material may be a difficult task. Thus, today for any fire hazard analysis purposes, HRR is invariably measured, rather than being computed from more fundamental theory.

Readers wishing to look more closely at the type of modeling needed to represent the pyrolysis process can refer to the dissertation of Parker [33] as a good example of how charring materials need to be treated. Some half-dozen other dissertations have been written on the same topic. Melting type materials have proven to be even more interesting as a subject of advanced research. Several hundred of papers have been published on various aspects of modeling the pyrolysis behavior of just one common material, poly(methylmethacrylate). References [34–40] can provide an introduction to this research.

Predicting Full-Scale HRR from Bench-Scale Data: Overview

Prediction of full-scale HRR is probably the single most important engineering issue in successful modeling of fires. Schematically, we may write that:

$$\dot{q} = \int \dot{q}'' dA \tag{26.2}$$

This representation does not fully reveal the difficulties involved. More explicitly,

$$\dot{q}(t) = \int \dot{q}''(t, x, y, z) dA(t) \tag{26.3}$$

This makes more clear that the instantaneous per-unit-area HRR is a function of time and also of the location of the burning element. The instantaneous burning area, A(t), is also a function of time. In addition, while we have not written this explicitly, $\dot{q}''(t)$ depends on the heating boundary conditions to the element. This quantity usually identified as the *heat flux* or *irradiance* incident upon the element. The latter term is commonly used since in full-scale fires the heating is dominated by the radiant component.

By examining the nature of dA(t), we can also identify the role of flame spread in characterizing the HRR of full-scale fires. A bench-scale HRR test specimen is usually ignited nearly-instantaneously over its entire surface. Full-scale fire, by contrast, nearly always exhibit finite spread rates. The flame spread velocity in a full-scale fire can be identified with the movement of the boundaries of the flame-covered area dA(t). Flame spread may occur in several directions over walls, ceilings, floors, and over individual surfaces of discrete commodities burning in a space. Consequently, it can be seen that tracking flame spread and dA(t) is a major undertaking. This task, by its nature, is incompatible with zone-type of fire models, since it presumes that a mechanism is in place to track very small surface elements. Such mode line is variable with CFO models [41] the quality of production is dependent on fuel type and the user needs to verify the permanent details.

Our approach will have to be restricted to identifying some of the attempts which have been made to simplify the problem in order to make it tractable for zone modeling. Simplifications are not yet possible for the 'general' case. Instead, we must examine specific combustibles, for which appropriate flame spread representations have been established. This is illustrated in a number of the sections below. Before we do this, however, it is important to examine in more detail some of the variables which influence the HRR.

Predicting Full-Scale HRR from Bench-Scale Data: The Role of Irradiance

Engineering variables such as HRR, ignitability, flame spread, etc. are sometimes viewed as material fire properties. This is a useful view, but it must be kept in mind that such 'properties' are not solely properties defined by the physical/chemical nature of the substance. Instead, they are also determined by the boundary conditions of exposure. The boundary conditions can be divided into two types: (1) intended, and (2) unintended. The intended boundary conditions include irradiance (since the heat fluxes in room fires are dominated by the radiant component, the terms irradiance and imposed heat flux are used interchangeably) and thickness. Unintended boundary conditions, sometimes known as *apparatus-dependencies*, include such factors as edge effects, perturbations due to non-uniform heating, drafts and uncontrolled air velocities, etc. The latter are usually small if a well-designed test apparatus was used for measuring the response of the specimen.

The most significant intended boundary condition is the heat flux imposed on the specimen. This variable is crucial and no reduced-scale HRR results have meaning without knowing the irradiance. A test apparatus can impose a very wide range of specimen irradiances. For example, the Cone Calorimeter is capable of irradiances from zero to 100 kW m^{-2}. For the user of the data, the crucial question becomes what irradiance to select when requesting a test. There are no simple answers to this, but we summarize here the main conclusions of an extensive study [42].

The major consideration in the selection of the test irradiance must come from a knowledge of heat fluxes associated with real fires. In theory, this could range from zero to an upper value which would be $\varepsilon\sigma\left(T_f^4 - T_o^4\right)$, where ε = emissivity (–), σ = Stefan-Boltzmann constant (5.67 10^{-11} kW m^{-2} K^{-4}), T_f = flame temperature (K), and T_o = ambient temperature (K). But the

$\varepsilon \approx 1$ for larger flames, and the ambient temperature contribution is insignificant, since $T_o << T_f$.

The adiabatic flame temperature for most organic fuels [43] is approximately 2300 K. This would give a maximum irradiance limit of some 1500 kW m^{-2}. This limiting value is, of course, nearly 10 times the actual maximum that is found in building fires of normal types. Thus, it is evident that the theoretical bounds to possible heat fluxes do not offer any guidance for testing. Instead, it is necessary to look at experimental data on heat fluxes found in actual building fires. We divide this into several types of building fires to be examined. More detailed data on heat fluxes from various objects and ignition sources is contained in the *Ignition Handbook* [44].

(a) **Heat fluxes in the vicinity of ignition sources**

First, we must be clear by what is meant by 'ignition source.' The innate definition of the term does not have limits—a burning building can be the ignition source to its neighboring building, as can a fire bomb. For discussion here, however, ignition sources can be limited to those that are small with respect to a fully-developed room fire. Since the latter will be in the range of over 1 MW, the range of fires considered to be ignition sources might be taken as $<$ ca. 300 kW.

A NIST study examined various ignition sources, ranging from 5 W to over 300 kW [45]. The sources included both realistic igniting objects (cigarettes, matches, burning paper lunch bags, etc.) and schematic ones (small gas burners and wood cribs). It was found that, as the power output of the ignition source increased, the peak heat flux generally did not increase. Instead, only the area covered by the peak heat flux progressively increased. For flames ranging from a 0.3 kW Bunsen-type burner to a 50 kW wastebasket, the peak fluxes were remarkably constant at 30–40 kW m^{-2}. Thus, for HRR from objects being ignited with a small ignition source, a test irradiance of 35 kW m^{-2} can be selected. There are some unusual sources having a much higher flux, and these are discussed elsewhere [42].

For larger burners, such as used in room fire tests, higher heat fluxes may have to be assumed. For porous square-faced gas burners, the wall heat flux was found to depend on the burner face size [46]. In some cases, fluxes up to 65–80 kW m^{-2} were noted, although for most cases fluxes of 30–50 kW m^{-2} are considered appropriate [47].

At the extreme, ignition can occur due to a high velocity jet, such as from a failure on an oil-drilling rig. There, heat fluxes in the vicinity of 150–300 kW m^{-2} have been observed [48]. Such situations, however, are very specialized. For ignitions from small wood cribs or other solid-fuel ignition sources, it can be estimated that the heat flux to adjacent objects in the same 35 kW m^{-2} range as for small flaming sources. The picture is more complicated, however, for the heat flux from these sources to the object underneath. These heat fluxes may be much higher [42], but they are highly non-uniform and difficult to model.

(b) **Heat fluxes in preflashover room fires**

After ignition, the combustibles in a room can be considered to be exposed to preflashover conditions. Heat fluxes occurring in preflashover room fires will vary widely. Away from the initial source of fire there will be essentially no heating at all. Near a small initial fire source, heat fluxes of the sort described in the preceding section will be seen. With increasing fire spread and involvement, a hot gas layer will build up below the ceiling. The heat fluxes will be significantly hotter within this layer than in lower spaces. Söderbom [49] found values typically $<$ 45 kW m^{-2} at the center of the ceiling during preflashover fires. The value at the floor level is, of course, always $<$ 20 kW m^{-2} prior to flashover, since attaining 20 kW m^{-2} at floor level is one definition of flashover [50]. Since there is surprisingly little general guidance on this point, the user will have to make some assumptions or *ad hoc* calculations.

(c) **Heat fluxes on burning walls**

Heat fluxes from burning items of larger types have, in general, not been studied in enough detail to be systematically known. The notable exception is for upward flame spread on vertical

surfaces. For this configuration, a number of studies have explored the heat fluxes from the flame to the yet-unignited portion of the surface.

Hasemi studied this problem in detail [51] and provided correlations. For his experiments, peak values of ca. 25 kW m^{-2} were seen for the region downstream of the ignited area, but before the tip of the flames; beyond the flame tip, fluxes were no longer constant, but dropped off further downstream. Additional similar data have also been presented in a summary form [52]. Work by Kulkarni and co-workers has enlarged the diversity of material types to have been studied [53]. The value of 25 kW m^{-2} is seen from these more extensive studies to be the lower bound of where data are clustered—most of the data are in the interval from 25 to 45 kW m^{-2}. Thus, a value of 35 kW m^{-2} might better capture the mean behavior.

A 35 kW m^{-2} heat flux, then, can be used to characterize the peak level of heating to a vertical surface element from its own upstream flame, just prior to its ignition. This value will need to be increased if the material is so situated as to be in a hot gas layer that is accumulating in the upper reaches of the room. Apart from the data of Söderbom, discussed above, this additional heating has not been studied in detail.

(d) **Heat fluxes in post-flashover room fires**

The maximum temperatures actually seen in post-flashover room fires are ca. 1100 °C. A perfect black-body radiator at that temperature would produce heat fluxes of approximately 200 kW m^{-2}. Actual heat fluxes measured in post-flashover room fires can come close to this value, but are usually somewhat lower. For instance, examining the extensive room burn data of Fang [54], one finds the following ranges of experimental results shown in Table 26.1.

Table 26.1 Heat fluxes measured in postflashover room fires

	Heat flux (kW m^{-2})		
	Ceiling	Walls	Floor
Maximum	106–176	116–229	119–143
Average	68–147	91–194	–

One might reasonably conclude that a heat flux of ca. 150 kW m^{-2} would be needed to properly represent the environment of the post-flashover room fire. Today's bench-scale HRR apparatuses, however, can only go to about 100 kW m^{-2} or less. Interestingly, the inability to realistically create the heat fluxes of the post-flashover fire has not been seen to be a problem in fire testing. Often, the situation is avoided in its entirety by assuming that the maximum burning rate that will occur within the room is consistent with the available oxygen supply [55]. Nonetheless, if for more detailed fire modeling the HRR of individual items in the post-flashover fire would be required, such high heat flux values would be required.

The Dependence of the HRR on the Heat Flux

In the simplest case, the relationship of the HRR to the irradiance is very simple, as shown in Fig. 26.7. Here, we see that the HRR depends in a linear manner on the irradiance. The curve does not pass through the origin due to the existence of flame flux. The total heat flux seen by the specimen can be viewed as comprised of two components: the external irradiance, and the flux from its own flame. Only if the flame flux were zero would the curve pass through the origin. Otherwise, the x-axis intercept is equal to (minus) the flame flux.

Flame flux is very difficult to measure experimentally, as decomposing materials tend to foul the instrumentation and invalidate the readings. A value of ca. 35 kW m^{-2} has been reported for the flame flux of PMMA burned in the horizontal orientation in the Cone Calorimeter [56]. In another study, estimates of flame flux were made for several plastics burned in a similar manner [57]. These showed 30, 25, and 14 kW m^{-2}, respectively, for nylon, polyethylene, and polypropylene. The furniture research program CBUF [10] determined that the flame fluxes in the Cone Calorimeter associated with fabric/foam composites are in the range 20–25 kW m^{-2}. Finally, some data are

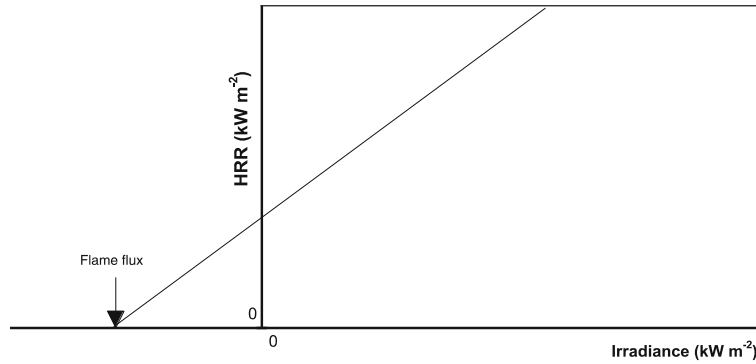

Fig. 26.7 The simplest form of HRR dependence on irradiance

available [58] for liquids in containers of similar size as a Cone Calorimeter specimen holder. Flame fluxes of about 10–15 kW m^{-2} are seen for alcohols and about 15–20 kW m^{-2} for some hydrocarbons (heptane, methylmethacrylate, toluene, styrene).

The value appears to depend only slightly on the chemical nature of the fuel. Gore et al. [58] specifically determined that this value does not increase with increasing fuel sooting tendencies. All of the above data refer specifically to the horizontal specimen orientation. There is very little data for the vertical orientation, although Janssens deduces that for wood products the vertical-orientation flame flux is ca. 10–15 kW m^{-2}, of which only about 1 kW m^{-2} is due to radiation [59].

With regards to linearity, the following very broad generalization can be made: for many products, over a substantial heat flux range, the HRR is linearly proportional to the heat flux. This generalization, however, will be seen to have only limited utility, since it is rarely known *a priori* whether or not it will be obeyed. Furthermore, there is a distinct tendency for most materials and products to deviate from linearity at very high and at very low heat fluxes.

This behavior is best illustrated by an example. Some data obtained by Sorathia and co-workers [60] on advanced composites are shown in Fig. 26.8. It is clear that the results are somewhat linear, but not precisely so. Some old, but still suggestive data were obtained in the 1970s by Parker [61]. His results for a number of fire-retardant grades of polyurethane foam are shown in Fig. 26.9. Of the five formulations shown, three show somewhat linear behavior, whereas two clearly do not. For most categories of specimens, however, substantially linear behavior can be seen.

Predicting Full-Scale HRR from Bench-Scale Data: The Effect of Thickness

The same material may be used in different applications in varying thicknesses. Thickness does affect the HRR response. In general, a thin material will show a spike of HRR, whereas a thick product will commonly (but not always) show some quasi-steady period of burning. This variable has not been extensively explored, and there is not much guidance available. Figure 26.10 shows results from Paul [62] on a thermoplastic, PMMA. This illustrates that near-steady burning behavior can be seen when the thickness approaches ca. 20 mm. Some similar data on polyethylene [63] have been published, but the maximum thickness specimens examined in that study, 10 mm thick, did not reach steady burning.

Data for medium-density wood fiberboard obtained by Tsantaridis [64] are shown in Fig. 26.11. If tested over the standard substrate (lightweight mineral fiber blanket), wood-family materials show a second HRR peak which corresponds to the accelerated burning when the specimen becomes nearly burned through.

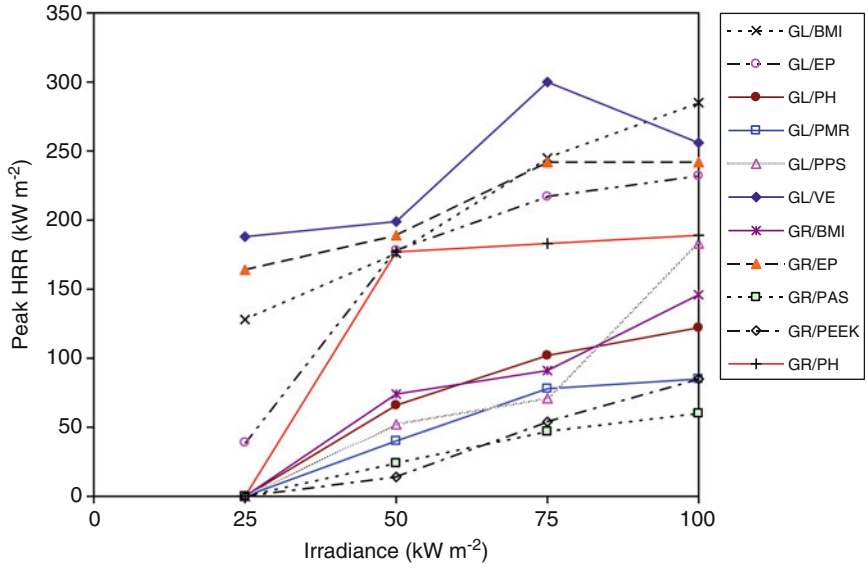

Fig. 26.8 Response to irradiance of some advanced composite materials. Reinforcements: *GL* glass, *GR* graphite. Resins: *BMI* bismaleimide, *EP* epoxy, *PAS* polyaryl sulfone, *PEEK* poly(ether ether ketone), *PH* phenolic, *PMR* monomer-reactant polyimide, *PPS* polyphenylene sulfide, *VE* vinyl ester

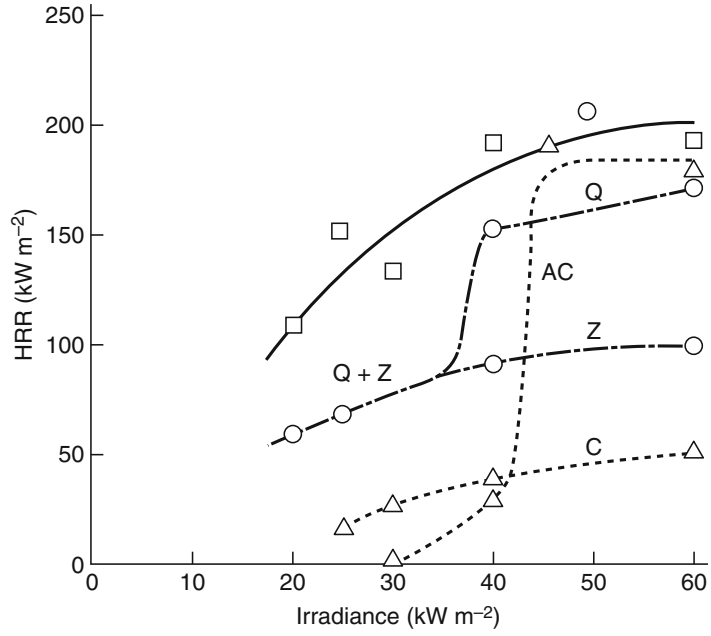

Fig. 26.9 HRR of FR polyurethane foams, as measured in the NBS I calorimeter by Parker

For foams, by contrast, no reasonable amount of thickness will normally show steady-state burning. Of special interest are polystyrene foams. These are normally very low density foams of around 16 kg m^{-3}. When exposed to heat, PS foams tend to collapse their cell structure and become a thin liquid film. This occurs before ignition takes place. Thus, after ignition what is burning is a thin coating on whatever was the substrate. This is the reason why the HRR of PS foams tends to be so apparatus-dependent that it is hard to discern

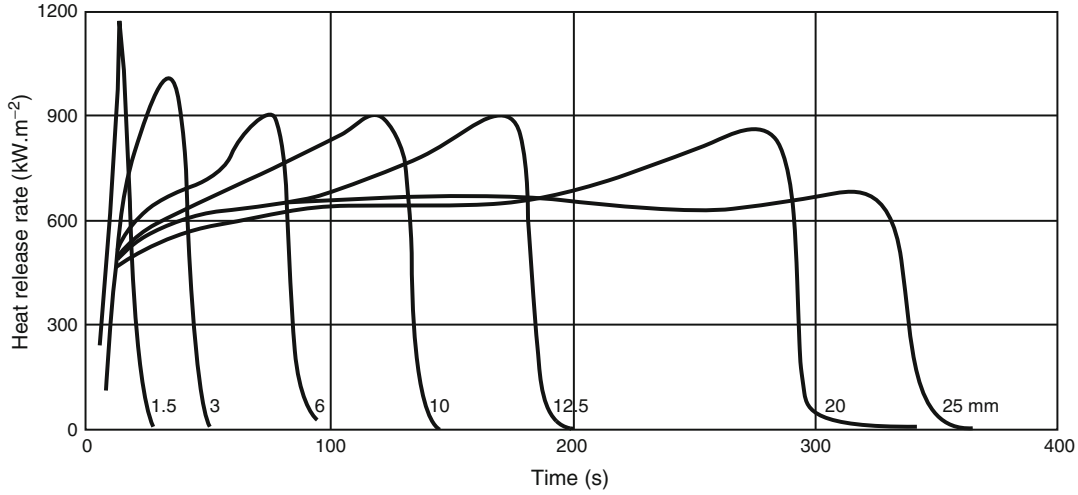

Fig. 26.10 Effect of thickness on the HRR for PMMA (heat flux = 35 kW m^{-2})

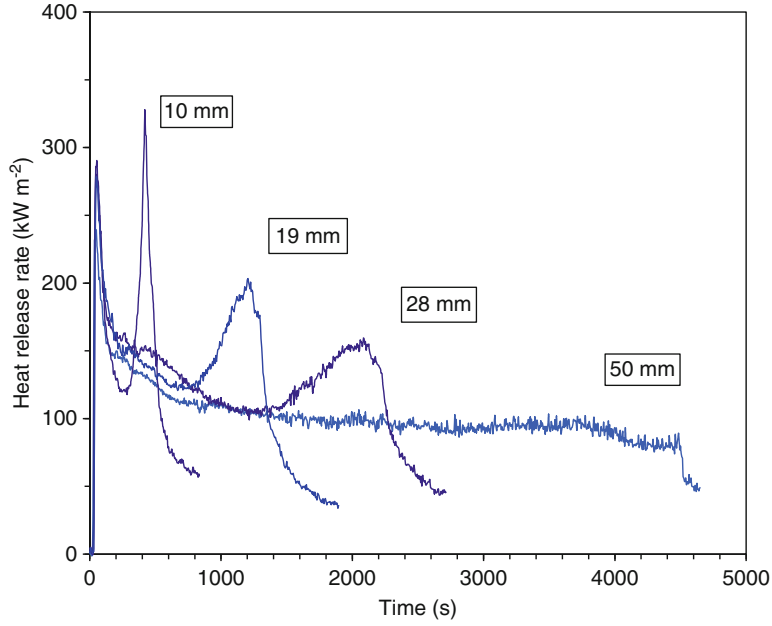
Fig. 26.11 Effect of thickness on the HRR for medium-density fiberboard (heat flux = 50 kW m^{-2})



any 'intrinsic' response of the material at all: its performance is totally dominated by the specimen-holder and edge conditions [65].

Predicting Full-Scale HRR from Bench-Scale Data: The Effect of Orientation

Routine testing in the Cone Calorimeter is specified by the ASTM standard to be done only in the horizontal orientation. This is because (1) many products show serious testing difficulties (e.g., melting) when tested in the vertical orientation. (2) Conversely, the vertical orientation does not provide 'a better simulation' of the burning of vertical objects. This is because there is no direct connection between flame fluxes in a bench-scale test and in a real-scale fire. The actual fluxes occurring in a real-scale fire are determined by many factors, including

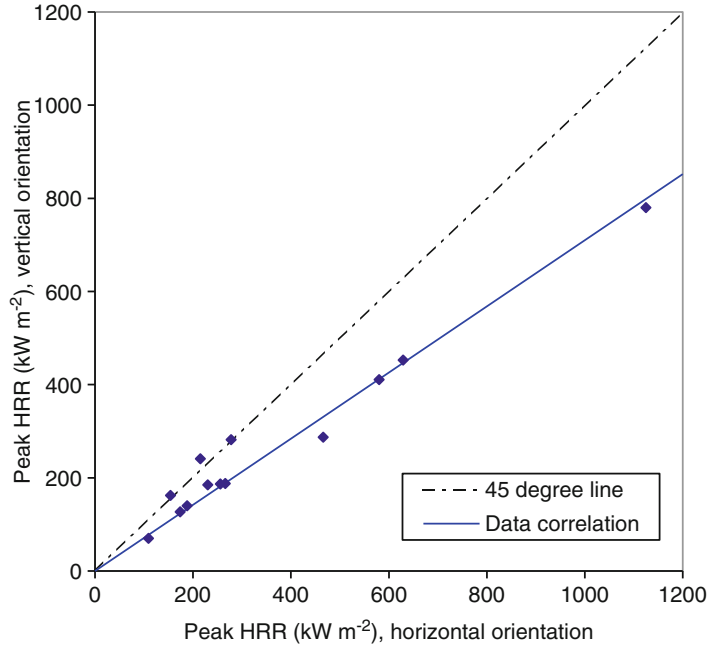


Fig. 26.12 Orientation effect on the peak HRR, as determined from two Cone Calorimeter round robins

size of room, thickness of hot gas layer, flame spread occurring over other surfaces, etc. None of these are subject to the control of the bench-scale apparatus but, rather, must be specifically modeled.

Orientation effects will also make a difference during the bench-scale testing of specimens. Even though routine testing is done only in the horizontal orientation, a small body of work exists where both orientations were explored. This is best illustrated by the results of two round robins which were conducted on the Cone Calorimeter, one under the auspices of ASTM and one under ISO. The data were taken at two irradiances, 25 and 50 kW m^{-2}, and the results are briefly summarized in the Appendix to ASTM E 1354 [20]. Such results are especially valuable since the values tabulated are the 'best estimate' values and are not subject to the specific errors of any one particular laboratory. A comparison for the peak HRR is shown in Fig. 26.12, while the comparison for the 180 s average value of HRR is given in Fig. 26.13. In both cases, the data points plotted represent all of the data analyzed within the two round robins for which horizontal and vertical orientation results were obtained on a product.

For the peak HRR, a least-square regression gives that:

$$\dot{q}''_{pk}\ (V) = 0.71\ \dot{q}''_{pk}\ (H) \qquad (26.4)$$

While for the 180 s average HRR, the corresponding relation is:

$$\dot{q}''_{180}\ (V) = 0.72\ \dot{q}''_{180}\ (H) \qquad (26.5)$$

Both can be adequately approximated by the general relation that:

$$\dot{q}''\ (V) = 0.7\ \dot{q}''\ (H) \qquad (26.6)$$

This clearly verifies that the thin, boundary-layer type flames occurring in the vertical orientation provide a lower heat flux than the pool-like flames in the vertical orientation.

Predicting Full-Scale HRR from Bench-Scale Data: Other Controlling Variables

Numerous other variables can, in principle, affect the HRR of specimens. This can include local velocities, scale and intensity of turbulence, etc. For room fire modeling purposes, such effects

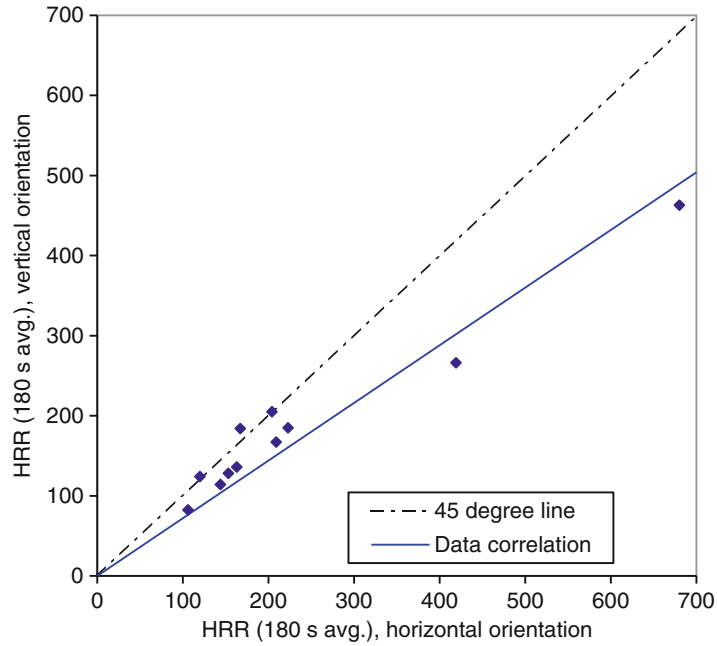

Fig. 26.13 Orientation effect on the 180-s-average HRR, as determined from two Cone Calorimeter round robins

can be assumed to be small. Two effects which are often of specific interest, however, are scale and vitiation effects. Scale effects are, in principle, normalized out when the per-unit area variable is computed. These effects will not be zero, however.

One factor affecting them is the flame flux found in the bench-scale test apparatus. This will have some scale effect. The studies in this area are not extensive. A study using a custom Cone Calorimeter with 200 mm × 200 mm specimen size tested horizontally found only a very small scale effect, when compared to standard Cone data [66]. A comparison between the ICAL and the Cone Calorimeter for a series of wood products showed that systematic differences were surprisingly small, despite the 10× difference in linear dimension of the specimens [67]. Note, however, that in this case the specimens were tested in the vertical orientation. In such orientation, the specimen flames are thin and there is little variations with scale. Of additional guidance is a study by Orloff [68] where a vertical 3.56 m high PMMA slab was burned. The mass loss rate, per unit area was found to be:

$$\dot{m}'' = 5.32 + 3.97x \qquad (26.7)$$

where x is the vertical distance (m). Note that this result implies that there is but little variation for specimens with height < 0.5 m, but significant increases for very large specimens.

In the case of objects burning in the horizontal orientation, large 'pool' flames surmount the specimen. The flux from such flames will vary greatly with scale. Guidance provided for estimating burning rates of pools (addressed later in this chapter) can be directly applied to this case.

HRR for Real Products

For many objects and commodities, published HRR are not available, thus, laboratory tests will have to be run if an answer is needed. For some commodities, however, exemplar data have been published and are available to the public. The tabulated test data can be very useful as generic representatives of items constructed of these materials, and with this general geometry.

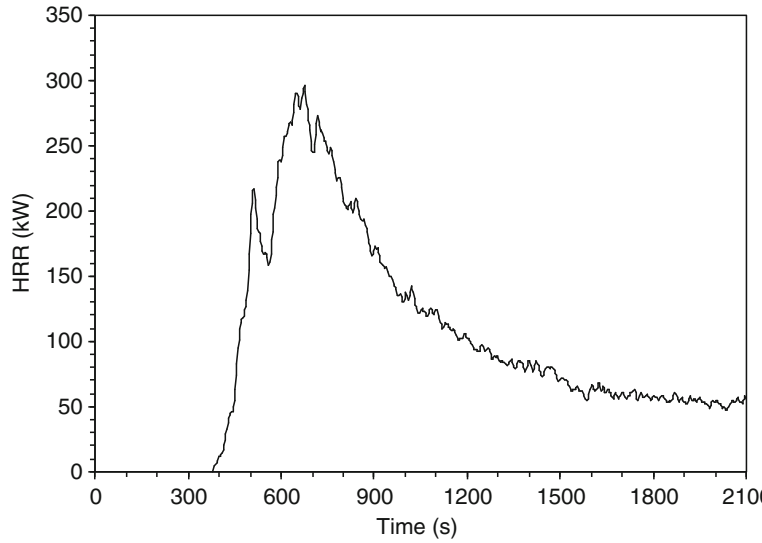

Fig. 26.14 HRR of a small air conditioner with a plastic housing

Where the analysis is intended to evaluate a specific product, that product should be tested in a suitable calorimeter and the data then used in the analysis. It must be strongly emphasized that in no case should generic database information be used when the purpose of the analysis is to seek regulatory approval for a product or to demonstrate the performance of a specific product in a court of law. In all such cases, actual laboratory testing on the item in question must be done.

In the case of a few product categories, methods are available for estimating large-scale HRR on the basis of bench-scale HRR data. The question then becomes: where can bench-scale HRR data be found? For a few product categories, some data are provided in the sections below. For the user interested in a more comprehensive look at bench-scale HRR data, the textbook *Heat Release in Fires* [23] and the Cone Calorimeter Bibliography [69] are good sources. Also, Chap. 36, "Combustion Characteristics of Materials and Generation of Fire Products," provides some data on pure chemicals.

For convenience, the sections below are arranged alphabetically by type of product. However, many of the ideas are an offshoot of pioneering studies on pool fires. Thus, it is recommended that the user first read through the section on "pools" before progressing to other product categories.

Air Conditioners

Beard and Goebeldecker [70] tested a small European in-room air conditioner 466 × 406 × 855 mm high. The unit had an ABS plastic housing, polystyrene foam inside, and a mass of 35 kg, of which 26 kg remained post-test; the total HR was 212 MJ (Fig. 26.14).

Audio Equipment

EFRA [70] tested two bookshelf-size micro-stereo systems, each comprising a receiver and a pair of stereo speakers. The receiver enclosures were made HIPS plastic, but one system had fiberboard speaker cabinets (P), while the other had HIPS cabinets (G). The systems were both very small, with the mass before test being only 4.1 kg (specimen G) and 4.9 kg (specimen P). Figure 26.15 shows the HRR results for the two tests.

Bedding

Ohlemiller et al. [71] tested inert beds (twin-size) with 12 different bedding combinations, with the peak HRR values found ranging from 38 to 200 kW. Detailed HRR curves are shown in Fig. 26.16 for one bedding combination. This

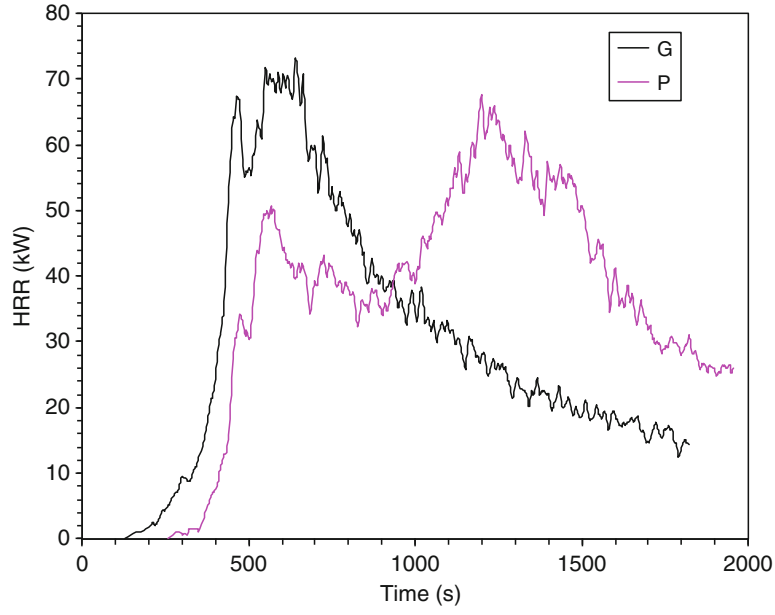

Fig. 26.15 HRR values for two small stereo systems

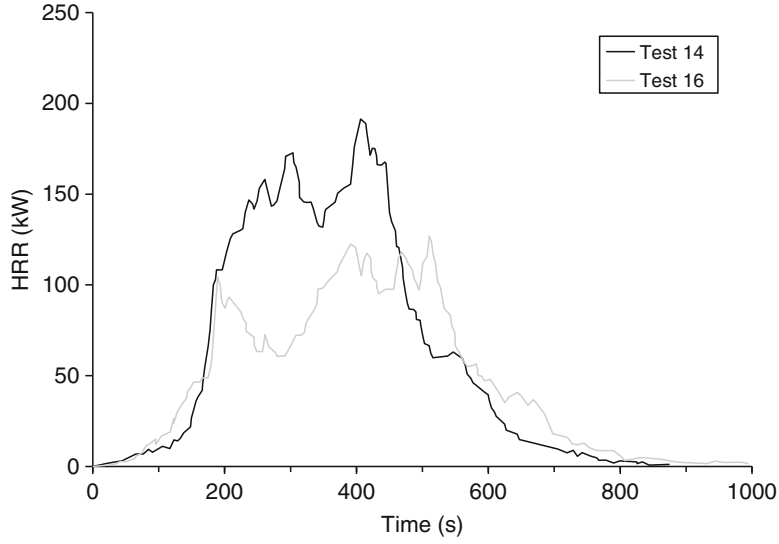

Fig. 26.16 HRR results for two replicate tests for a bedding set on an inert, twin-size bed

combination involved 2 polyester/cotton sheets, a mattress pad, a pillow, an acrylic blanket, and a medium-weight comforter. The HRR (average for the replicates) was exceeded by only one other combination, which gave values about 5–10 kW higher. The latter comprised two polyester/cotton sheets, a mattress pad, a pillow, a polyester blanket and a medium-weight comforter. The pillows were filled with polyester fiber filling in for both combinations and were covered with a polyester/cotton pillow case. Detailed HRR curves were not published for other combinations. The lowest peak HRR values were for a combination with two sheets and a pillow only, which showed 38 and 73 kW for the two replicates.

NRCC [72] conducted four tests on bedding and got peak HRR results up to 388 kW.

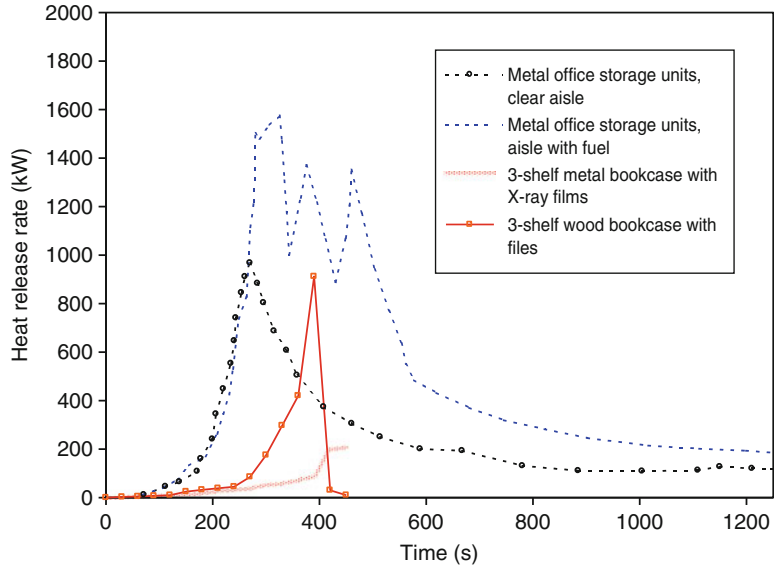

Fig. 26.17 HRR of storage units

Bookcases, Casegoods and Storage Units

In most cases, for storage furniture the fire hazard is created by the contents, not by the furniture item itself. An exception is modular storage units made of thermoplastic materials, which tend to burn very vigorously [73], but quantitative HRR data have not been published. Storage furniture made of wood or wood covered with thin layers of thermosetting plastic tend to resist ignition unless filled with combustible contents. Some data are illustrated in Fig. 26.17. The metal office storage units tests [147] arrangement involved two tiers of shelving with an 0.76 m aisle in between. Each test contained 480 kg of paper fuel load in shelving units totaling 1.67 m^2 of floor area. For the configuration with fuel in the aisle, only 3 kg was placed in the aisle, but this extra fuel provided a major difference in fire severity. The data on X-ray film shelves and wooden bookcase are from Ref. 170. For storage of paper files, it is known that the arrangement is more important than the quantity of fuel. Especially, storing files in cardboard boxes so that they can exfoliate exacerbates burning. Exfoliation occurs when paper folders are placed parallel, rather than perpendicular to the front of the shelf. When fire attacks the front, folders progressively fall out and burn in the aisle. While well-known, this effect has not been documented with HRR testing.

Boxes and Packaging

Full-scale tests were run at Western Fire Center [74] to measure the HRR of fruit/berry baskets (i.e., small plastic containers), packaged in cardboard shipping cartons, and assembled into pallet loads. In each case, no fruit goods were actually included, the boxing material being packaged as would be delivered from the manufacturer. For all tests, only a single pallet was used. Identification of materials is given in Table 26.2, while HRR results are given in Fig. 26.18. Southwest Research Institute [75] tested pallets similar to Sample A, but assembled as a 2 × 2 × 2 array of pallets. This test gave a peak HRR of 8695 kW and the results are shown in Fig. 26.19.

Carpets and Other Floor Coverings

Carpets which are in the room of fire origin are not likely to contribute significantly to fire

Table 26.2 Packaged fruit cartons tested in shipping pallets

Sample	Overall dimensions of pallet load (m)	Mass before test (kg)	Mass after test (kg)	Peak HRR (kW)	Eff. heat of comb. (MJ/kg)
A	0.75 × 1.14 × 1.83	393	307	4923	17.3
B	1.02 × 1.26 × 1.83	308	222	3553	14.0
C	0.99 × 1.19 × 1.87	421	393	3044	12.1
D	1.33 × 0.80 × 1.17	430	344	896	11.9
E	1.18 × 1.07 × 2.29	461	319	3894	11.0
F	1.00 × 1.22 × 2.00	254	192	4280	13.9

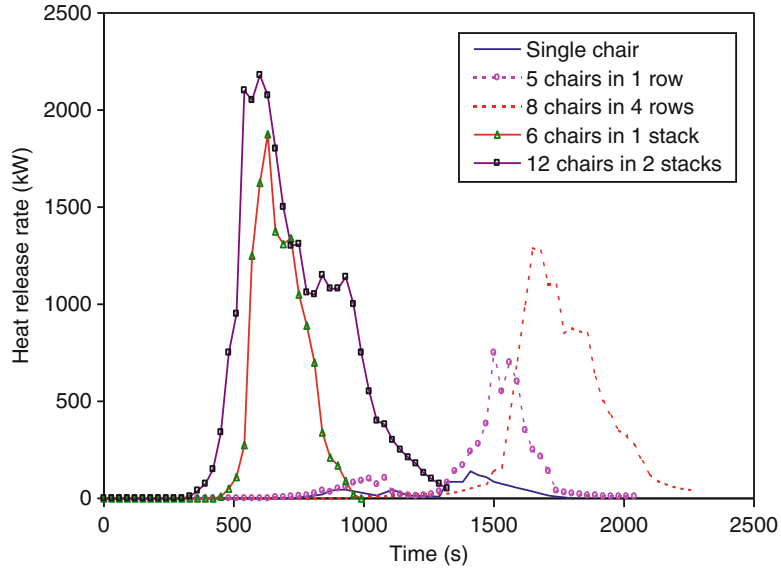

Fig. 26.20 HRR of stackable chairs, polypropylene with steel frame, no padding

growth. This has been demonstrated experimentally [76]. It is also consistent with modeling considerations: the floor area is convectively cooled and has normally the smallest view factor to the hot regions, which tend to be in the upper regions. The same material may be much more hazardous if installed on wall surfaces, although it must be pointed out that commercial textile wall coverings are normally similar, but not identical to carpeting.

The hazard from floor coverings arises when an unsuitable product is used in a corridor, especially if this is an escape path. In such situation, very rapid flame spread and high HRR can result due to the fact that the corridor floor covering becomes involved due to a room fire feeding it. Not only carpeting, but solid materials such as linoleum and wood parquet flooring are also subject to becoming fully involved down the length of a corridor. A recent study has quantified this behavior and has also provided a predictive method [77]. It is shown that floor coverings with a peak HRR of less than 200 kW m^{-2}, measured in the Cone Calorimeter under an irradiance of 25 kW m^{-2} tend not to show accelerating flame spread down a corridor.

Some carpeting materials can present a rapid fire spread hazard when installed on stairs. A residential carpet installed over a stairway has been measured to produce a peak HRR of 3 MW [78]. The test carpet was 80 % acrylic/20 % nylon; no other types of carpeting were explored.

Chairs, Stackable

Stackable chairs are most commonly used in hotels and banqueting facilities. These chairs typically have metal legs and frame and only a small amount of combustible padding or structural material. Thus, a single chair can be expected to represent negligible hazard. However, when not in active use, they are stored in tall piles and many of these piles may be aggregated together. The hazard of even a single pile of modest height can be notable. Figure 26.20 illustrates some typical data on non-upholstered, molded chairs [169]. Figure 26.21 illustrates some data on lightly-upholstered chairs [79]. For the latter, the effect of radiant augmentation from burning in a corner is also illustrated.

Clothing Items

Two men's jackets (anoraks) were tested by SP [10] as potential ignition sources. One was a

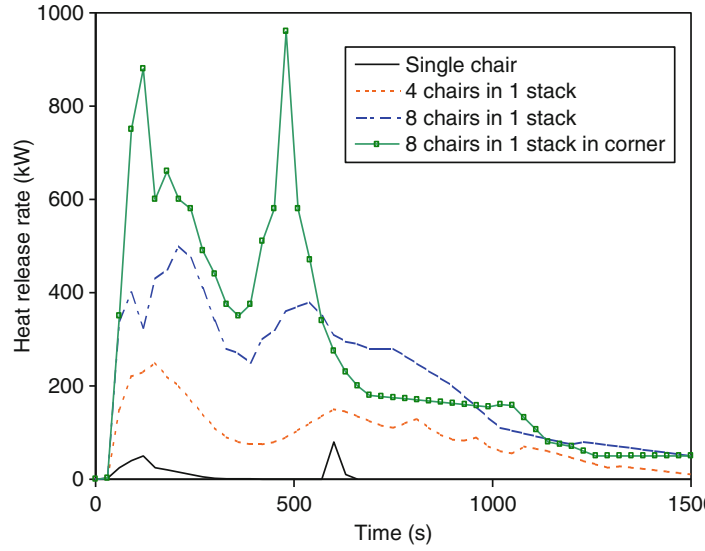

Fig. 26.21 HRR of metal-frame, upholstered stacking chairs

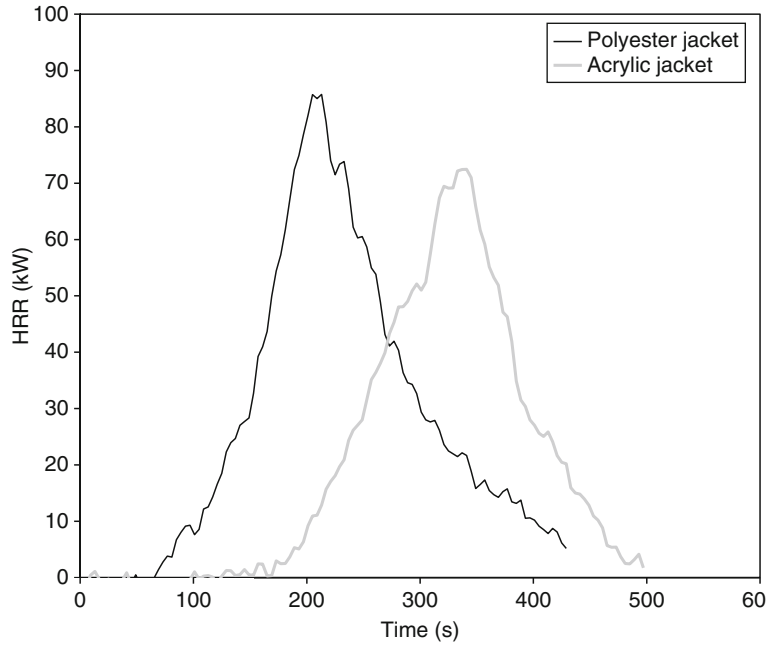

Fig. 26.22 HRR of men's jackets (laid loose)

'polyester' jacket with an outer fabric comprising 65/35 cotton/polyester, an inner fabric of 100 % polyamide, and a filling of 100 % polyester wadding. The total weight was 739 g. The second jacket tested was an 'acrylic' jacket with a fabric of nylon/Taslan and a filling of 100 % acrylic wadding. The total weight was 618 g. The HRR of these jackets are shown in Fig. 26.22. Stroup et al. [80] measured the HRR of racks of men's suits, such as might be found in a retail shop. Each rack held 48 suits, made of polyester and wool and arranged in two rows vertically. The

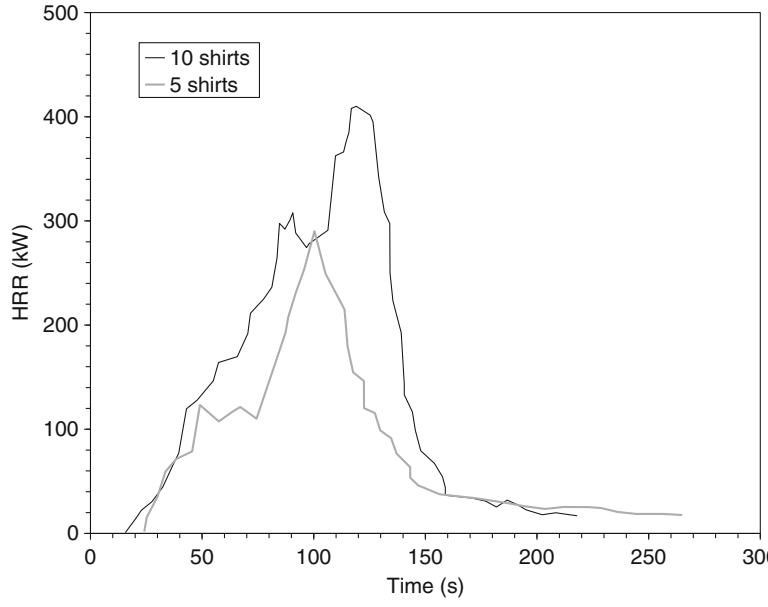

Fig. 26.23 HRR of hanging, cotton shirts

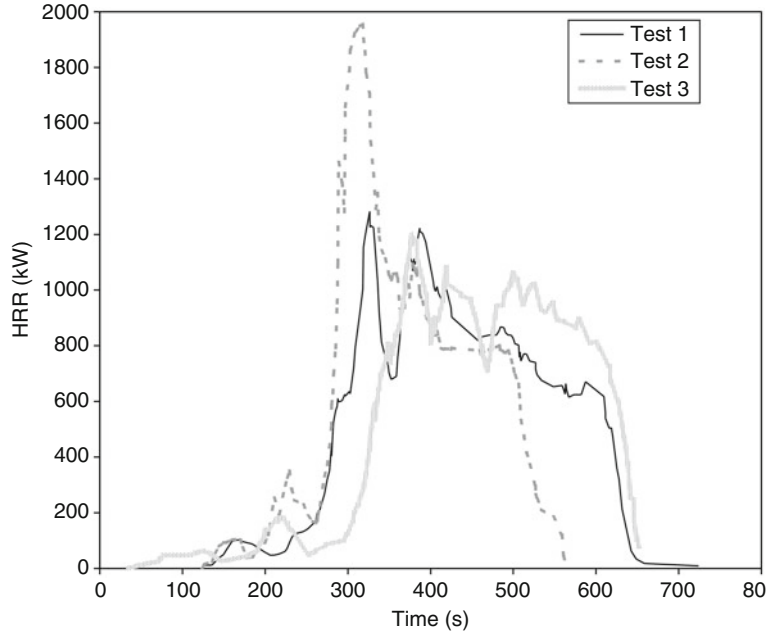

Fig. 26.24 HRR of racks of men's suits; the rack was 1.8 m long (arranged as two rows side-by-side)

results of three replicate tests are shown in Fig. 26.24. There is a lot of scatter, since the suits fall as they are burning. Japanese results [81] were reported for cotton shirts, hanging on a rack. These results are given in Fig. 26.23. The authors also tested a single hanging cotton shirt, which gave a peak HRR of 70 kW, and a pile of 10 folded shirts, which only showed a peak of 35 kW. Additional data are given under "Shop displays" later in this chapter.

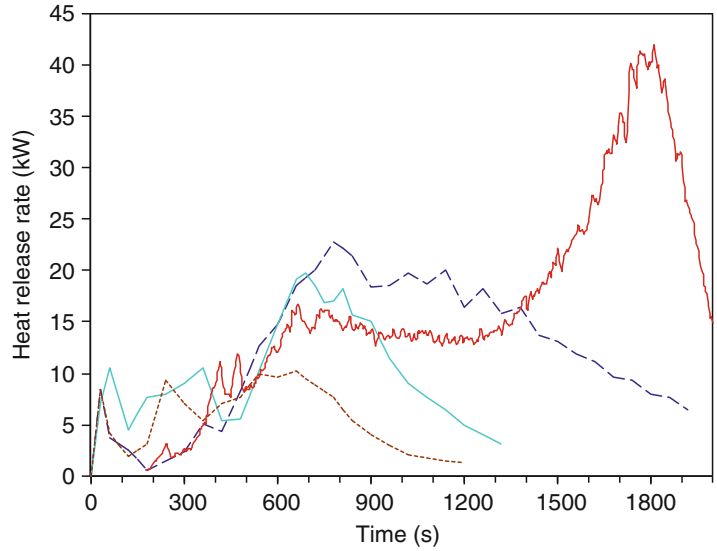

Fig. 26.25 HRR of coffee makers

Coffee Makers

The HRR of several coffee makers weighing 0.8–1.4 kg is shown in Fig. 26.25 [70, 169]. The material for the unit showing the highest HRR was identified as polypropylene [70], the others were not specified.

Computers and Electronic Equipment

Here are given results on HRR testing of computers and electronic equipment, set up as intended to be used. Additional results are given under *Industrial commodities* for packaged goods.

Computer CPUs. Two computer CPUs were tested by SP [82]. One was made by IBM, using a plastic facing rated V0 according to UL 94 [30]. This could not be ignited from a small ignition source. The second unit, of HP manufacture, could be ignited by a small ignition source and its HRR is shown in Fig. 26.26.

Computer keyboards. Bundy and Ohlemiller [83] tested at NIST three polystyrene computer keyboards weighing 580 g. These were ignited with a needle flame and the results are shown in Fig. 26.27.

Computer mice. Edenburn [84] tested two brands of computer mice. Both were ignitable by a needle flame and one brand showed a peak HRR of 3.6 kW and a total heat release of 1.20 MJ. The second brand was tested in the Cone Calorimeter with an applied external heat flux. Using a 25 kW m^{-2} flux, a peak HRR of 5.0 kW was found and a heat release of 1.35 MJ; at a 50 kW m^{-2} heat flux, a peak HRR of 6.1 kW and a heat release of 1.45 MJ were found.

Computer monitors. Bundy and Ohlemiller [83] tested at NIST a series of 480 mm (19 in.) computer monitors of the CRT type. Three ignition sources of progressively greater intensity were used: a needle flame, a burning polystyrene keyboard, and a radiant panel providing a heat flux of 21 kW m^{-2} onto the specimen (Table 26.3). Selected results are shown in Figs. 26.28, 26.29, 26.30, 26.31, and 26.32.

Computer printers. Three computer printers were tested by SP [85]. All were of the personal type, manufactured by Epson, HP, and Lexmark; the results are given in Fig. 26.33. The printers were tested without paper or toner.

Computer tapes. A test was conducted on a set of open steel shelves holding 90 computer

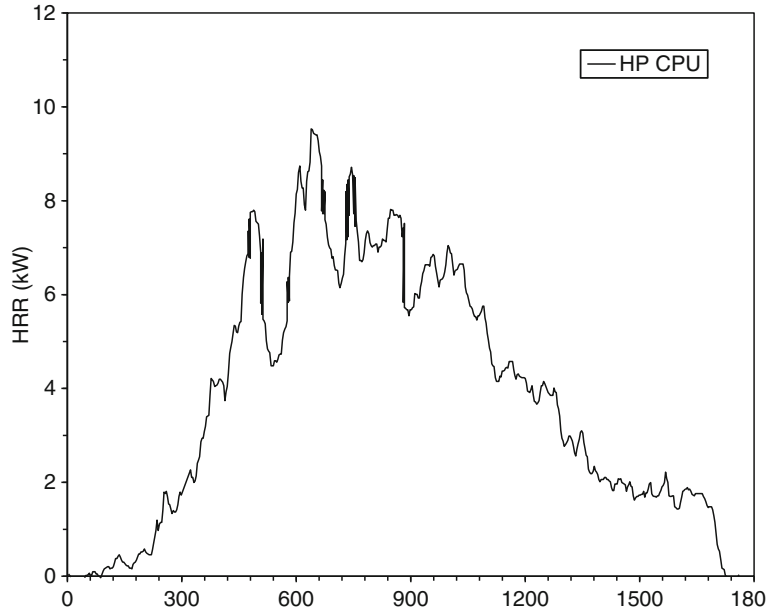

Fig. 26.26 HRR of computer CPU tested by SP

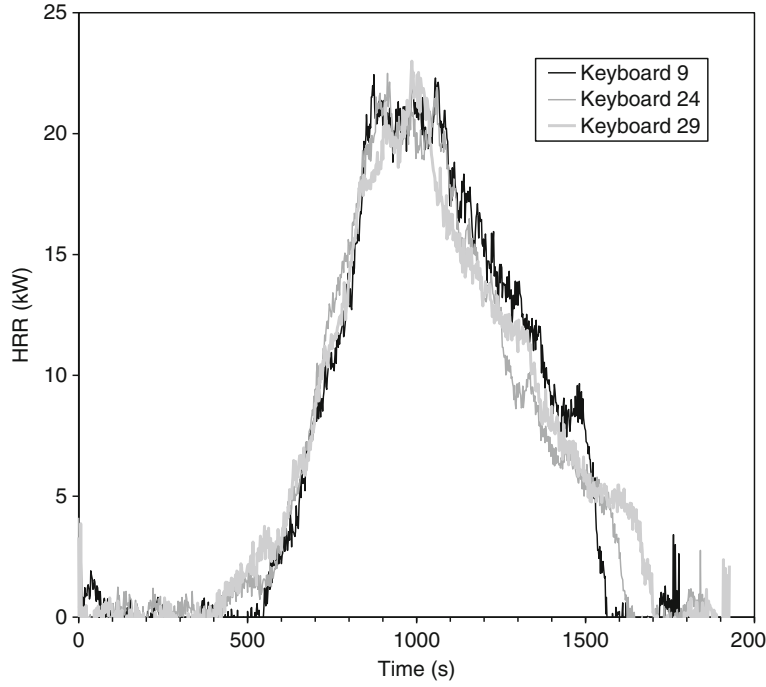

Fig. 26.27 HRR of polystyrene computer keyboards tested at NIST

tapes [86]. The tapes were 300 mm diameter and the total mass of 99 kg was distributed on four shelves, two tiers deep. The results are given in Fig. 26.34.

Racks with computer equipment. Zicherman and Stevanovic [87] tested stainless steel mesh-type racks containing computer and electronic equipment. The rack size was

1.73 m high, 0.92 m wide, and 0.61 m deep, with each rack having six shelves. The top shelf contained a CRT monitor and a personal computer, the next four shelves each contained two small data acquisition units (each fully metal-cased), while the bottom shelf held a dot-matrix printer and a 75 mm high stack of computer paper. A keyboard and a power strip were hung from the top shelf. Three tests were run on replicate units. A barbeque lighter was used to ignite the computer monitor in Test 1, the stack of paper in Test 2, and likewise the paper in Test 3. Test 3 differed from the others in that each of the top five shelves also contained a 0.60 × 0.90 cardboard sheet, which was treated with an antistatic treatment. The sheets were located directly on top of each shelf and underneath the electronic equipment. The HRR results are shown in Fig. 26.35. They have an important

instructive value in demonstrating that minor changes in the fuel loading or fuel arrangement can have drastic influences on the HRR. In this case, introducing the cardboard sheets raised the peak HRR from 155 kW (Test 2) to 528 kW (Test 3). Conversely, changing the ignition location had a major effect on the time of the peak, but essentially no effect on the HRR peak value (146 kW in Test 1, 155 kW in Test 2).

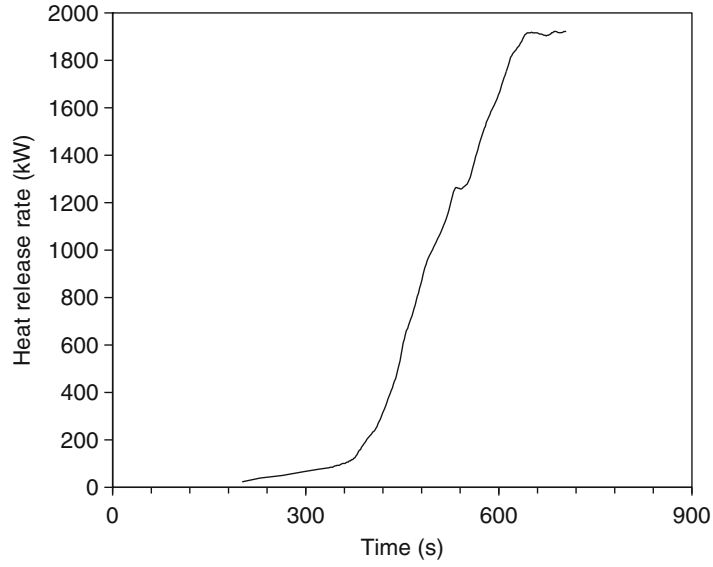

Fig. 26.34 HRR of a rack of computer tapes

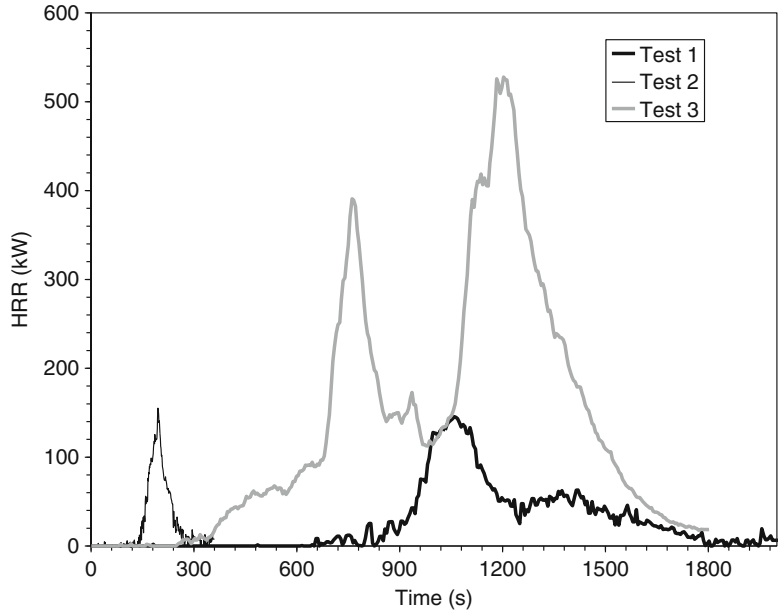

Fig. 26.35 HRR of computer equipment racks

Miscellaneous electronic equipment cabinets. Babrauskas et al. [88] tested two types of plastic business machine cabinets. The cabinets were tested as pairs (two identical units) and ignited with a 50 kW burner. The cabinets had 3 mm wall thickness and each pair of cabinets weighed 3.5 kg. The HRR results are shown in Fig. 26.36.

Two series of tests on steel cabinets used for housing nuclear power-plant control electronics were conducted by VTT [89, 90]. These showed HRR peaks of 100–200 kW. The authors also proposed computation formulas for predicting the HRR level to cause internal cabinet 'flash-over' and for burning to reach a ventilation limit [91]. Such computations are based on the

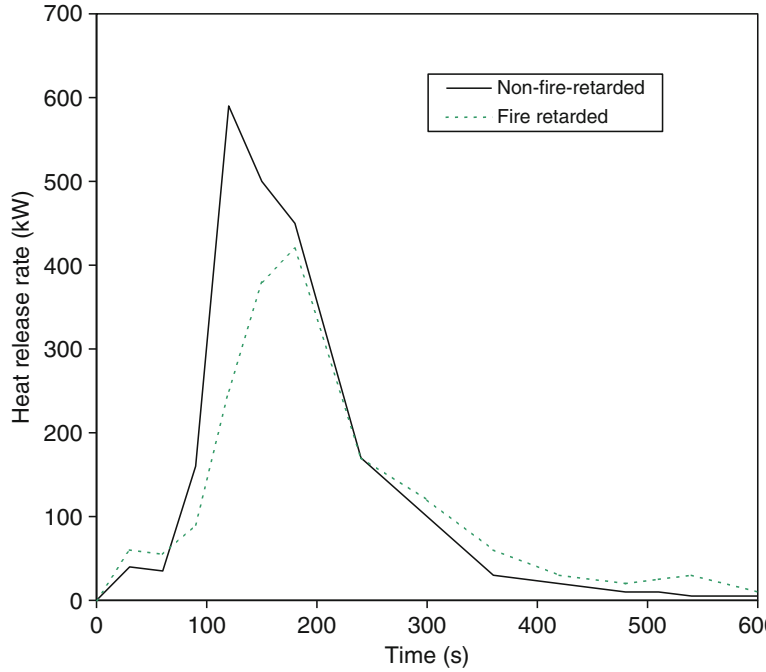

Fig. 26.36 HRR of business-machine cabinets made from polyphenylene oxide

assumption that air flow occurs only through fixed cabinet openings. In such cases, the peak HRR (or, a quasi-steady-state plateau) can be computed and actual testing would not be needed. However, some cabinets may react to fire by effectively increasing their air inflow area, e.g., if doors warp open or fall from the cabinet. Researchers at Institut de Radioprotection et de Sûreté Nucléaire (IRSN) extended the VTT theory and conducted numerous validation experiments [92]. They found that, in most cases, predictions based on ventilation-controlled burning were quite closely borne out by experiments. In a few cases, fires did not develop sufficiently to cause internal flashover, and the theory conservatively over-predicts the HRR for such instances. With an extremely flammable fuel (PMMA), but one which is probably unrealistic for actual industrial electronics cabinets, they did note that actual HRR can exceed the prediction, since some of the pyrolysis gases which lack sufficient oxygen to burn inside the cabinet can leave the cabinet and burn as a fire plume outside. However, since industrial electronics equipment is usually selected with at least some attention being paid to avoidance of excessive flammability behavior, in their tests with actual electronic equipment—as opposed to PMMA—they did not find any instances of such external burning.

Cribs (Regular Arrays of Sticks)

Cribs here are taken to mean regular, three-dimensional arrays of sticks. Each stick is of a square cross-section and of a length much greater than its thickness. The sticks are placed in alternatingly oriented rows, with an air space separating horizontally adjacent sticks. (See Fig. 26.37). Wood crib burning rates have been studied longer than any other product, with early data available from the 1930s [93]. Different analysis formulas have been presented over the years by numerous authors. Here we present a method of analysis [26] based largely on the voluminous experimental data of Nilsson [94] on wood cribs and the functional form suggestions of Yamashika and Kurimoto [95]. The scant available data on plastic cribs are from Harmathy [96] and Quintiere and McCaffrey [97]. The conditions of most interest

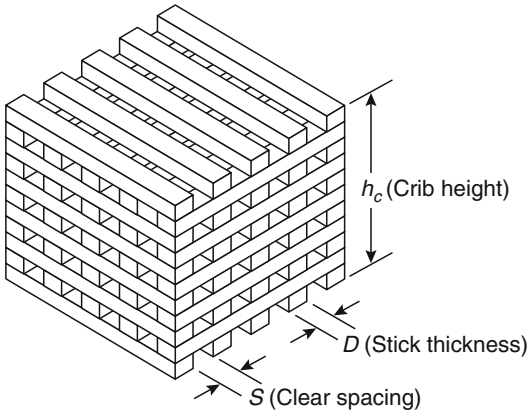

Fig. 26.37 General arrangement of a wood crib

are when cribs are ignited instantaneously, as with the use of a small amount of combustible liquid underneath. The first group of equations below represents this case. There is occasionally an interest in a crib fire where only one end of a crib is ignited, and a slow fire propagation is seen. An analysis for this situation has also been made [98]. A similar analysis is also available for the center-ignited, fire-spreading crib scenario [99].

For cribs ignited uniformly overall, the burning rate can be governed by one of three conditions: (1) the natural limit of stick surfaces burning freely; this limit applies to cribs with wide inter-stick spacings; (2) the maximum flow rate of air and combustion products through the air holes in the crib; this governs for tightly packed cribs; and (3) the maximum oxygen that can be supplied to the room; this effect is discussed separately. The numerical expressions are as follows:

Fuel surface control:

$$\dot{m} = \frac{4}{D} m_o v_p \left(1 - \frac{2 v_p t}{D}\right) \tag{26.8}$$

or

$$\dot{m} = \frac{4}{D} m_o v_p \left(\frac{m}{m_o}\right)^{1/2} \tag{26.8a}$$

with

Table 26.4 Fuel type versus regression velocity v_p for cribs

Material	v_p
Wood	$2.2 \times 10^{-6} D^{-0.6}$
Polymethylmethacrylate	$1.4 \times 10^{-6} D^{-0.6}$
Thermosetting polyester	$3.1 \times 10^{-6} D^{-0.6}$
Rigid polyurethane foam	$3.8 \times 10^{-6} D^{-0.6}$

$$m = m_o - \sum_i^t \dot{m}_i(t_i)\Delta t \tag{26.9}$$

Crib porosity control:

$$\dot{m} = 4.4 \times 10^{-4} \left(\frac{S}{h_c}\right)\left(\frac{m_o}{D}\right) \tag{26.10}$$

Room ventilation control:

$$\dot{m} = 0.12 A_v \sqrt{h_v} \tag{26.11}$$

The *least* of Equations 26.8, 26.10, or 26.11 is to be taken as the governing rate (Equation 26.11 is discussed later in this chapter). Equation 26.8a is necessary instead of the simpler Equation 26.8 when a switch of burning regime occurs during the course of the fire, e.g., the burning changes from porosity control to fuel surface control at some point. This can happen since Equation 26.8 or (26.8a) is a time-dependent expression. Thus, a crib may start burning under porosity or room ventilation-controlled conditions, then later switch to fuel surface control.

In the above equations, D is the stick thickness, m_0 is the crib initial mass, t is the time since ignition, h_c is crib height, S is the clear spacing between sticks, and room ventilation variables are A_v, the ventilation opening area, and h_v, the ventilation opening height. The fuel surface regression velocity, v_p, depends on the stick thickness and on the fuel type, as shown in Table 26.4. The experimental data for the plastic materials are extremely scant, however, so the values should be viewed as indicative rather than quantitative.

For the case of the center-ignited crib, the burning regimes are divided according to whether at a particular time the flame spread has reached the edge of the crib. This time is defined as t_0.

$$t_o = 15.7n \tag{26.12}$$

where n = the number of sticks per row. For time $t < t_o$, the following relation holds [99]:

$$\dot{m} = 0.0254\, m_o \frac{v_p t^2}{n^2 D} \tag{26.13}$$

For $t > t_o$, Equations 26.8 through 26.11 are used. The heat release rate is determined from Equation 26.1. For plastics, the heat of combustion is commonly fairly constant and can be taken from tabulations or from Cone Calorimeter testing. For wood cribs, commonly the heat of combustion is taken to be 12×10^3 kJ kg^{-1}. However, as illustrated in Fig. 26.1, the heat of combustion of wood is a varying function of time. A better procedure would be to either predict the HRR of wood cribs directly, without going through Equation 26.1, or else to be able to have recourse to a realistic value of Δh_c (t). Neither of these possibilities have currently been developed.

Room Fire Effects Experimentally, it has long been observed [94] that, unlike a pool fire, which can burn in a room in a highly fuel-rich manner, a wood crib does not burn more than approximately 30–40 % fuel rich. Conditions more fuel rich than that are not sustained, presumably, because of the highly vitiated air being supplied to the crib under those conditions. The stoichiometric fuel pyrolysis rate can be estimated as [11]

$$\dot{m}_p(st) = \frac{1}{r} \cdot 0.5 A_v \sqrt{h_v} \tag{26.14}$$

where the stoichiometric air/fuel mass ratio, r, for wood can be taken as $r = 5.7$. Comparing, then, the maximum pyrolysis rate given by Equation 26.11 with the stoichiometric rate given by Equation 26.14, it can be seen that a limit of approximately 37 % fuel rich is reached when Equation 26.11 becomes the governing limit to the burning rate. Similar limits may possibly exist for other classes of combustibles, but experimental data are only available for wood cribs.

Curtains

Thermoplastic curtains often do not sustain any appreciable burning when ignited by a flame. Instead, a small piece ignites, but it falls off and the rest of the material still in place does not burn. The dropped-down material will usually continue burning, but its HRR will be trivial. There is no systematic study available that would elucidate under what conditions curtains will burn in place (and release a significant amount of heat), versus burning only to a trivial extent.

Even if curtains ignite and burn in place, the heat content and HRR are generally moderate, but curtains can contribute to the severity of a fire by quickly propagating fire over large surfaces. Moore has done the most extensive study of curtains and draperies [100]. His test specimens were ignited with a match along the bottom. The results are summarized in Table 26.5 and Fig. 26.38. His results show primarily the effect of fabric weight. Lightweight fabrics, of weight around 125 kg m^{-2}, can show heat release rate peaks almost as high as heavy ones (around 300 kg m^{-2}); however, their potential to ignite surrounding objects is much smaller, as demonstrated in Fig. 26.38. These conclusions hold for both thermoplastic and cellulosic materials, but not for constructions using foam backings, for which insufficient data were available. Whether the curtain was in the closed or in the open position seemed to make little difference. The reason for the more severe fire performance of the heavyweight curtains was largely due to their increased burning time, which was typically about twice that for the lightweight curtains. Additional data on the HRR of curtains have been published by VTT [156] and by SP [101].

Yamada et al. [102] conducted full-scale tests on curtains of 0.9–1.2 m width and 2.0 m length. They tried 10, 30 and 50 kW square burners and found that generally at least the 30 kW burner needed to be used if full flame development was to be reached. Polyester curtains, both FR and non-FR, melted and failed to show a sustained

fire, as did FR cotton and FR rayon. Acrylic, modacrylic, non-FR rayon and non-FR cotton showed sustained burning, attaining 100–250 kW peak HRR values when subjected to the 50 kW ignition source.

Decks

The California Office of State Fire Marshal reported some HRR tests [103] done on outdoor decks, comparing wood, wood/plastic composite, and various all-plastic constructions. For samples sized 0.61 × 0.61 m, a redwood deck gave a peak HRR of 12 kW. Wood/plastic composites ranged between 10 and 394 kW, while all-plastic products ranged from 10 to 1055 kW.

Desks

Chow et al. [104] measured the HRR of a small wooden office desk. The desk was 0.6 × 1.2 × 0.8 m high The ignition source

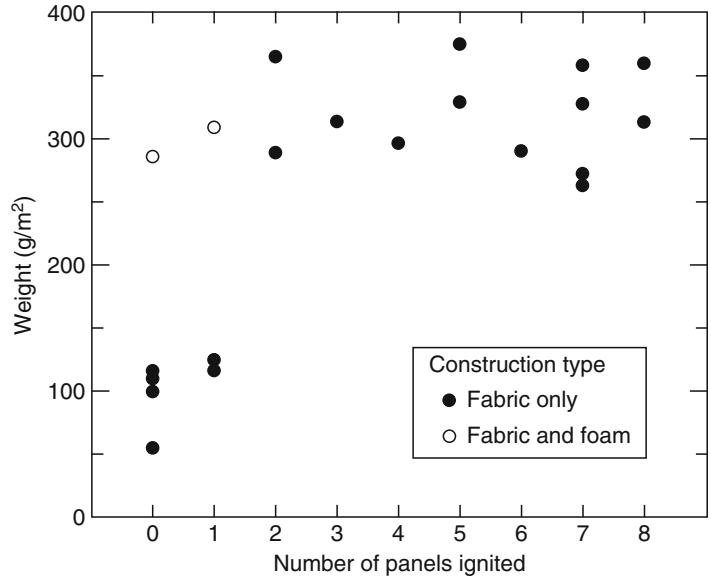

Fig. 26.38 Effect of fabric weight on number of curtain panels ignited

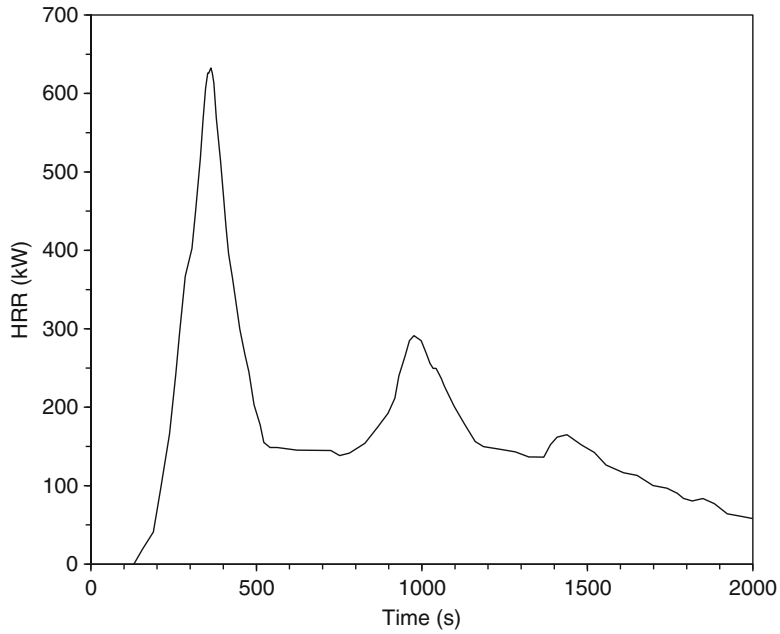

Fig. 26.39 HRR of a wooden desk tested by Chow et al.

was a pool of 0.5 L gasoline which, by itself, produced a peak HRR of 40 kW. These results are shown in Fig. 26.39.

Dishwashers

VTT tested [105] European dishwashers using a propane burner of 1 kW. The specimens are described in Table 26.6, while test results are shown in Fig. 26.40. These results must *not* be applied to appliances used in North America, since European appliance styles are different from North American ones and also because local standards are such as to permit appliances of greater flammability in Europe. HRR data on North American dishwashers are not available.

Dressers

A test of a wooden dresser has been conducted by NIST [106], see Fig. 26.41.

Dryers

Results for a small European clothes dryer (40 kg) have been published [70]. Even though use of plastics in North American clothes dryers has been increasing, nonetheless it would appear that the unit was more typical of the European market than the American one. In the test (Fig. 26.42), 11 kg of mass was lost and 253 MJ of heat was released.

Table 26.6 European dishwashers tested by VTT

Specimen	D1	D2
Initial mass (kg)	35.6	47.5
Mass loss (kg)	6.1	8.4
Peak HRR (kW)	476	347
Total heat (MJ)	165	206

Electric Cable Trays

Cable tray fires present almost an endless plethora of combinations of cable materials, tray construction, stacking, ignition sources, etc. Only a very few of these have been explored. The most systematic studies available are those from Tewarson et al. [107] and Sumitra [108]. A useful engineering analysis of their data has been prepared by Lee [109]. Lee provided a basic correlation of Tewarson's and Sumitra's data (see Fig. 26.43), which shows that the peak full-scale heat release rate $\dot{q}_{fs}$ (kW m^{-2}) can be predicted according to bench-scale heat release rate measurements:

$$\dot{q}_{fs} = 0.45\dot{q}''_{bs} \cdot A$$

where $\dot{q}''_{bs}$ is the peak bench-scale HRR (kW m^{-2}), measured under 60 kW m^{-2} irradiance, and A is the exposed tray area actively pyrolyzing (m^2). The active pyrolysis area, in turn, is estimated from Fig. 26.44, which gives dA/dt as a function of $\dot{q}''_{bs}$. Thus, at any given time, t,

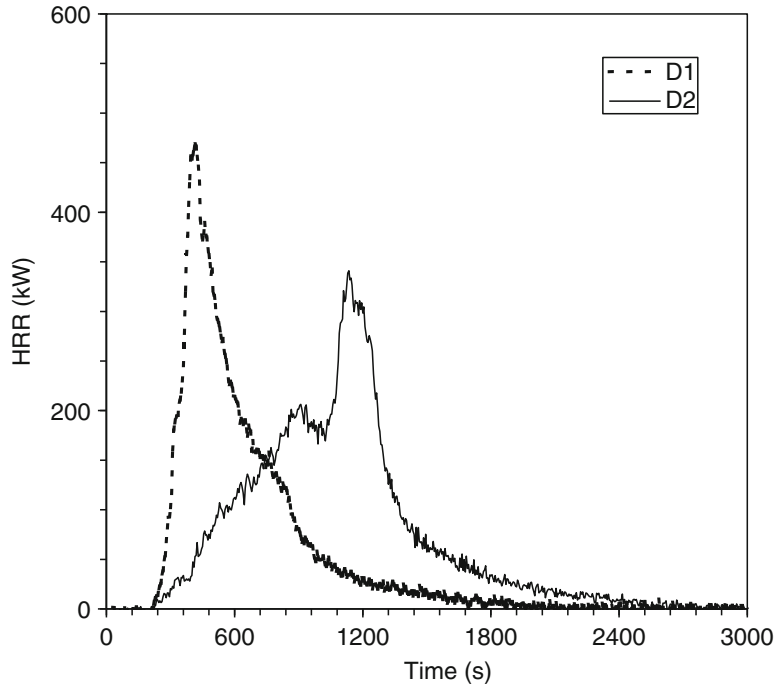

Fig. 26.40 HRR of European dishwashers tested by VTT

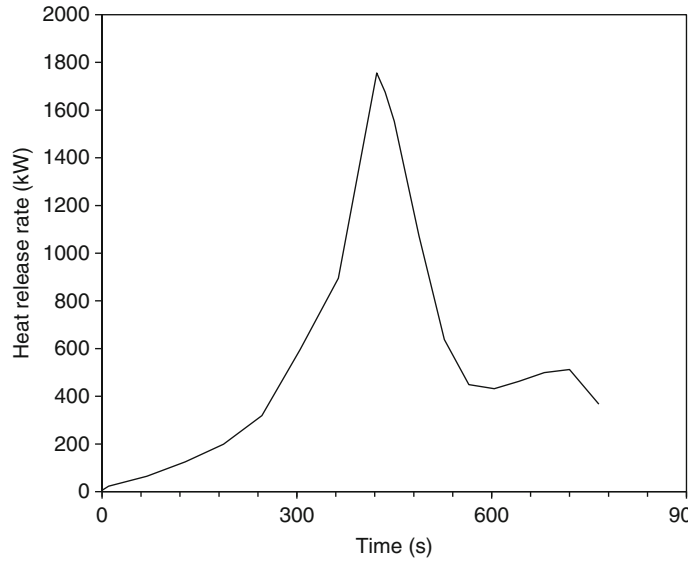

Fig. 26.41 HRR of wooden dresser

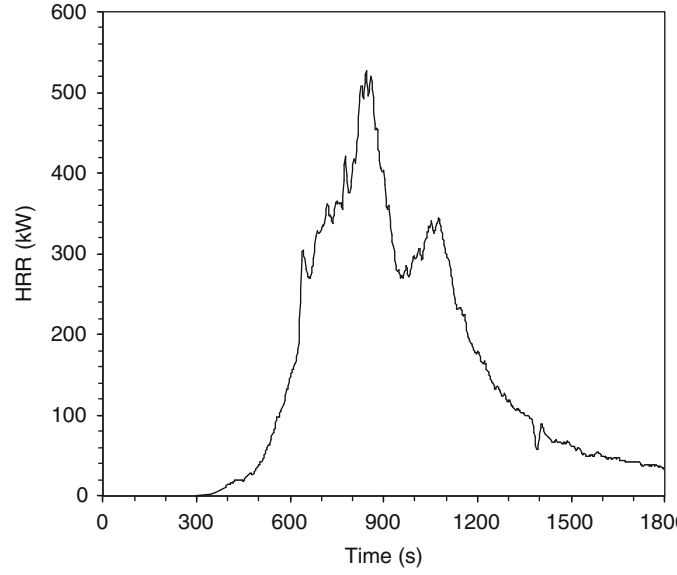

Fig. 26.42 HRR for a small European clothes dryer

$$A(t) = A_o + \frac{dA}{dt} \cdot t$$

Finally, Table 26.7 gives a selection of measured values of $\dot{q}''_{bs}$ for various cable types.

Foodstuffs

SP reported on a test [110] to simulate the burning of snack foods in a shop. Retail bags of two types of snacks were tested in a single test—potato chips and cheese nibbles. A total fuel load of 275 kg was set up in a tightly-packed, three-shelf high shelving unit, 5.4 m long. The HRR results are shown in Fig. 26.45. Visual observations indicated that potato chips burned more vigorously than cheese nibbles.

NIST [111] ran two full-scale tests on bags of potato chips on a rack with open-wire-mesh shelves. Each shelf had 20 bags of potato chips. The bags were arranged five across and four

[a]Test not conducted

deep, with a total fuel load of 27.1 kg. Each bag of chips was approximately 200 mm wide by 100 mm (thick) by 360 mm high. Each bag weighed 33.8 g, of which chips accounted for 32.5 g and the plastic bag for the rest. The potato chip ingredients were listed by the manufacturer as: potatoes, sunflower oil and salt. Two replicate heat release rate experiments were conducted (Fig. 26.46). It is interesting to note that the NIST tests showed the same peak HRR (6 MW) as the SP test, albeit with a much shorter duration time due to the fact that the fuel load was 1/10 of SP amount.

Industrial Stored Commodities

Pallet loads of plastic-based commodities are commonly stored in factories, warehouses, and wholesale establishments. Most tests have involved multiple pallets being tested, and most of these have also involved some manner of water application being done during the test. But there have been a few tests reported where single pallet-loads were tested, without water. SP [112] tested single pallet-loads of four kinds:

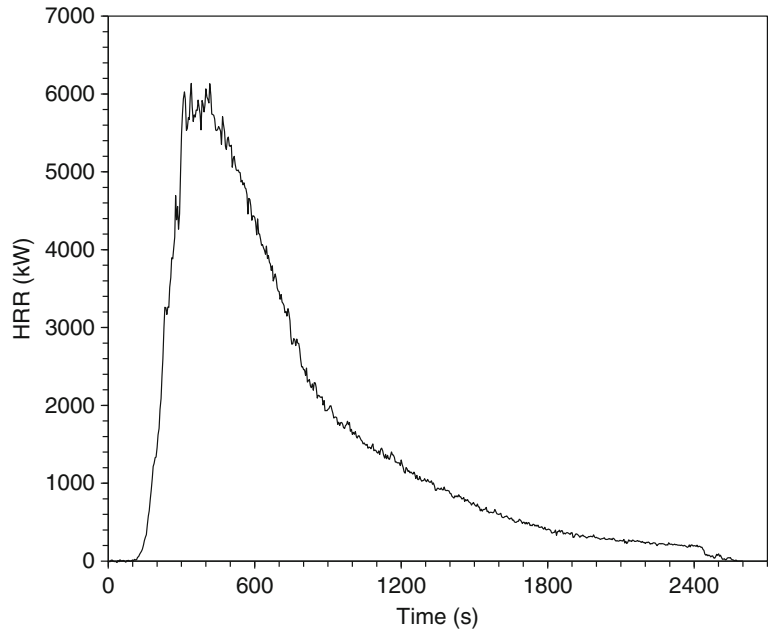

Fig. 26.45 HRR of potato chips and cheese nibbles set up in a shop display unit

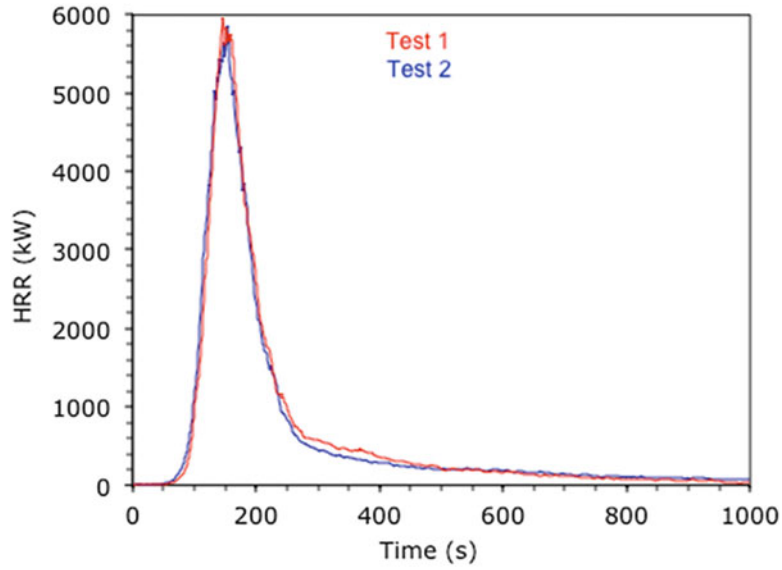

Fig. 26.46 Potato chip bags tested at NIST

- FM Group A plastic standard commodity (see Table 26.10)
- CEA standard commodity. Each corrugated-cardboard box is 450 × 550 × 370 mm and each (wood) pallet holds 12 boxes in a 2 × 2 × 3 array. Each box weighs 805 g and is filled with 340 g of polystyrene chips. The pallet-load is 800 × 1200 mm with a height of 1110 mm, excluding the pallet itself.
- SCEA standard commodity. This is a Swedish version of the CEA, with each box being 380 × 570 × 380 mm. Each box weighs 700 g and holds 420 g of chips. The pallet-load is 800 × 1200 mm with a height of 1140 mm, excluding the pallet itself.
- Large SCEA standard commodity. This is a variant where the box is 800 × 600 × 500 mm. Each box weighs 1470 g and contains 1220 g of chips. Each pallet holds a 1 × 2 × 2 array of boxes.

The HRR results for these tests are shown in Fig. 26.47.

Despite the intention being that Group A plastics represent a severe fire hazard, some plastic commodities produce significantly more HRR. In tests by Babrauskas [113], pellets of SBR (styrene-butadiene rubber) were packed in paper bags and loaded on a wooden pallet, with a total weight of 680 kg of pellets. The pallet was over-wrapped with clear plastic film and spillage did not occur during the test. The full-pallet test was ignited with a propane torch at the bottom. The half-pallet test was ignited with a propane torch at the top. The full-pallet test (Fig. 26.48) showed a HRR of close to 7 MW when conditions required that the commodity be extinguished; peak HRR conditions had not been reached.

Heskestad [114, 115] analyzed a large series of palletized[1] storage tests conducted at FM in 1975 by Dean [116]. These experiments pre-dated the availability of HRR calorimeters, so Heskestad obtained peak HRR values by using mass loss rate data and values of effective heat of combustion. The test arrangement was 2 × 2 × 3 pallets high, with a flue space running in only one direction. Heskestad also analyzed a later series of rack-storage tests by Yu and Kung [117, 118]. The test arrangement was 2 × 2, with heights being two, three, or four pallets, and with flue spaces running in both directions.

[1] 'Palletized' denotes a storage configuration where pallets are stored directly on top of each other, without use of shelving.

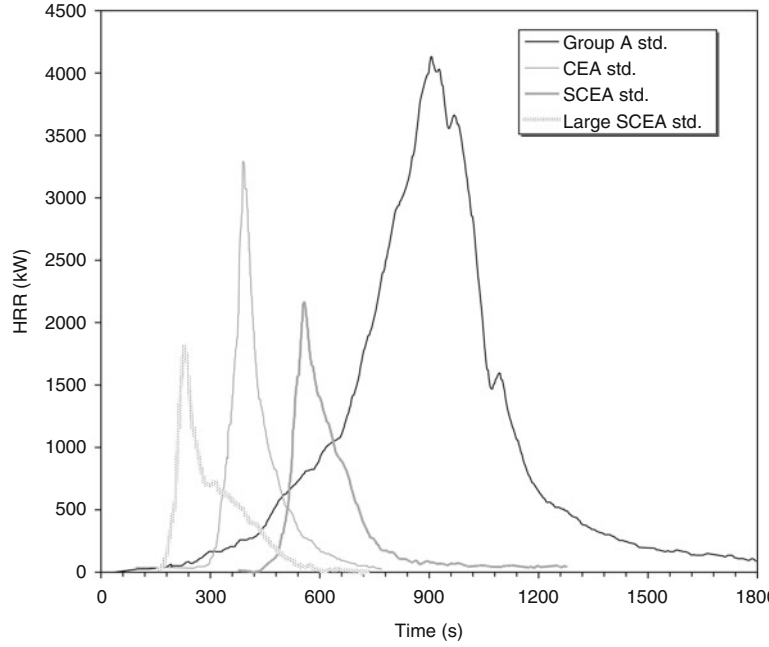

Fig. 26.47 HRR of single pallet-loads of various commodities tested at SP

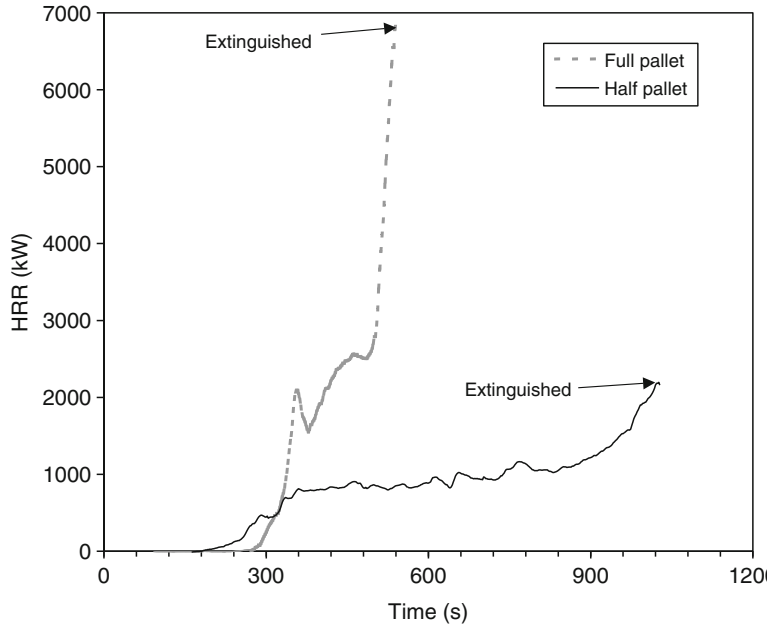

Fig. 26.48 HRR of pallets holding bags of SBR pellets

Heskestad's tabulated peak HRR values are given in Table 26.8. The peak HRR values were obtained by dividing the value in kilowatts by the floor area occupied by the commodity. The palletized test commodities occupied a floor area of 2.44 × 2.59 m, while the rack storage tests were 2.29 × 2.29 m. The cardboard cartons with metal liner are 'FM Standard Class II Commodity' (Table 26.10 [119, 122]) while the PS cups are 'FM Standard Plastic Commodity'

Table 26.9 Miscellaneous stored commodities tested by FM

Commodity	Storage ht. (m)	Peak HRR (kW m^{-2})
Fiberglass (polyester) shower stalls, in cartons	4.6	1,400
Mail bags, filled	1.52	400
PE letter trays, filled, stacked on cart	1.5	8,500
PE and PP film in rolls	4.1	6,200

(Group A Plastic). Note that there does not exist a scaling rule that would enable HRR values to be computed for stack/rack heights other than those tested. Thus, the reported values could conservatively be applied to shorter heights, but cannot be extrapolated to greater heights. Some older data [120] are listed in Table 26.9. These have not been re-analyzed by Heskestad.

The effect of storage height [121] on the HRR growth curve for Class II commodities is shown in Fig. 26.49. An initial period of limited fire growth has been removed from these curves. These results are from FM testing in the 1980s. Also shown is the HRR curve for a $2 \times 2 \times 2$ array tested in 2005. For much of the time, the HRR exceeded the earlier results. This is because FM identified that the standard Class II commodity supplied in 2005 is somewhat different than that supplied earlier [125]. The early fire growth period [122] for Class I, III, and IV commodities is shown in Fig. 26.50. The early fire growth period for the FM Standard Plastic Commodity is shown in Fig. 26.51. These results are based on early FM studies [123, 124] which were

Table 26.10 FM Commodities and standard test commodities

Class	Products	Examples	Test commodity
Class I	Essentially noncombustible; may be in light cardboard cartons and may be on wood pallets	Glass, minerals, metals, ceramics	Single-wall corrugated cardboard carton measuring 21″ (0.533 m) on side, divided into five horizontal layers by corrugated cardboard sheets. Each layer was divided by interlocking cardboard partitions forming a total of 125 compartments. Each compartment occupied by one 16-oz (0.47 l) glass jar, without lid, open side facing down to prevent collection of water. A pallet load consists of one wood pallet and eight of the above-described cartons.
Class II	Class I products with more or heavier packaging and containers	Class I products in multiwall cartons, boxes, or barrels.	Double triwall (approx. 25 mm thick total) corrugated cardboard carton measuring 42" (1.07 m) on a side containing a 24 ga. (0.56 mm) sheet metal liner box measuring 38″ × 38″ × 36″ (1.07 × 1.07 × 1.02 m) high. A pallet load consisted of one wood pallet and one the above described cartons.
Class III	Combustible products in combustible wrapping or containers on wood pallets. May contain a limited amount of plastic.	Products of wood, paper, leather, and some foods	Single-wall corrugated cardboard carton measuring 21″ (0.533 m) on a side, divided into five horizontal layers by corrugated cardboard sheets. Each layer divided by interlocking corrugated cardboard partitions forming a total of 125 compartments. Each compartment occupied by one 16-oz (0.95 l) paper jar (wide mouth container/ cup), without lid, open side facing down to prevent the collection of water. A pallet load consists of one wood pallet and eight of the above described cartons.
Class IV	Class I, II, or III with considerable plastic content in product, packaging or pallets	Typewriters and cameras of metal and plastic parts	Single-wall corrugated cardboard carton measuring 21″ (0.533 m) on a side, divided into five horizontal layers by corrugated cardboard sheets. Each layer divided by interlocking corrugated cardboard partitions forming a total of 125 compartments. Each compartment occupied by forty 16-oz (0.95 l) polystyrene and eighty-five 16-oz (0.95 l) paper jars (wide mouth container/ cup), without lids, open side facing down to prevent the collection of water. A pallet load consists of one wood pallet and eight of the above described cartons.
Standard plastic (Group A Plastic)	Commodities containing a greater amount of plastic than would be permitted in Class IV commodities		Single-wall corrugated cardboard carton measuring 21″ (0.533 m) on a side, divided into five horizontal layers by corrugated cardboard sheets. Each layer divided by interlocking corrugated cardboard partitions forming a total of 125 compartments. Each compartment occupied by one 16-oz (0.95 l) polystyrene jar, without lids, open side facing down to prevent the collection of water. A pallet load consists of one wood pallet and eight of the above described cartons.

conducted in their Norwood MA facility. Also shown are the results obtained in 2005 at their West Gloucester RI facility for the 2 × 2 × 2 configuration [125].

Additional FMRC data for different commodities loaded onto wooden pallets are shown in Fig. 26.52. The egg carton test [126] used foam-polystyrene egg cartons of 12-egg capacity. Polyethylene bags were used to hold 200–216 of these egg cartons, open and nested into each other. Each pallet held about 20.4 kg of egg cartons. Each pallet contained about 22.7 wood, and the load also contained about 0.4 kg polyethylene. In this test, a low density of water extinguishment was applied, but this did not appear to significantly reduce the HRR of the commodity. Only the convective portion of the HRR was measured. Polystyrene shows a very high radiant heat release fraction, thus, to account for the radiant fraction and for the diminution due to water spraying, the total HRR curve shown in Fig. 26.52 was estimated by multiplying the measured convective portion by a factor of 2. The polyurethane foam results [127] are for a three-tier (4.27 m high) stack of foam in cardboard boxes and used a PUR foam of high HRR; other results (not shown) were also obtained by FM for fire-retardant grades. The PET (polyethylene terephthalate) bottles test [128] used 46 bottles of a 2 L size packed into single-wall corrugated cardboard boxes. Each box contained 2.55 kg of plastic and 1.29 kg of cardboard. Total test arrangement comprised eight pallet loads arranged in a 2 × 2 × 2 arrangement. Each pallet contained eight cartons of the size 0.53 × 0.53 × 0.53 m. The

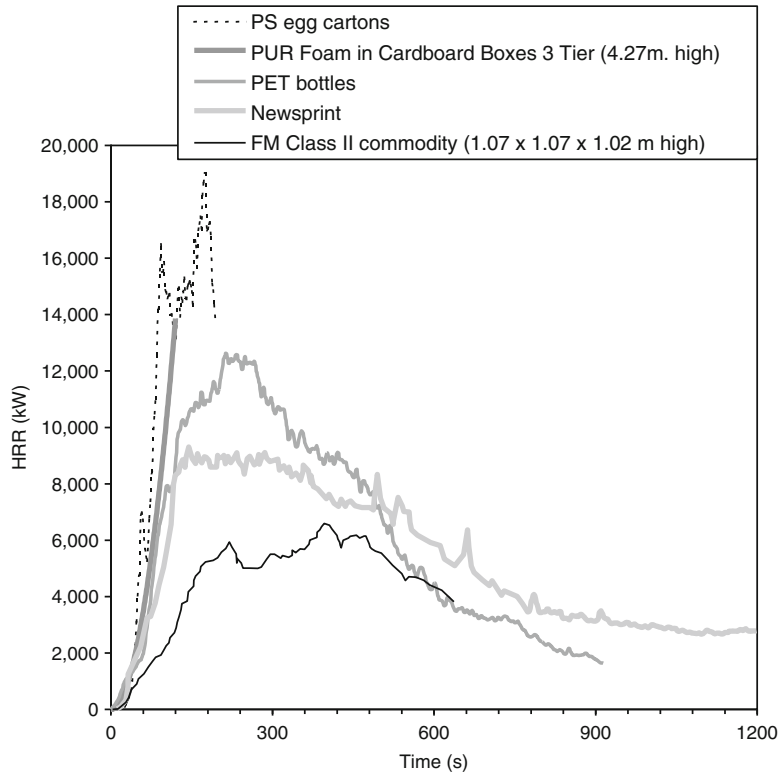

Fig. 26.52 FMRC HRR results for several additional commodities

Table 26.11 Boxed computer items tested by Hasegawa et al.

Code	Items	Peak HRR (kW)
P1	Boxed monitors, one pallet of 12	4700
P8	Boxed monitors, one pallet of 12, point-source ignition	5030
P5	Boxed monitors, one pallet of 12 (stabilized from collapse)	6400
P6	Boxed monitors, two pallets (side-by-side) of 12 each	17,300
P10	Boxed monitors, stack of two pallets high, 10 per pallet	14,100
P3	Boxed desktop computers, one pallet of 16	1400
P7	Boxed desktop computers, pallet of 16 + boxed accessory boxes on top	8190
P9	polystyrene foam in boxes	6730
P11	Monitor boxes, one pallet of 12	4600

newspaper test [129] comprised 8.2 kg of shredded newsprint placed in a $0.53 \times 0.53 \times 0.51$ m single-wall corrugated cardboard box of 2.73 kg. Eight cartons comprised one pallet load. The pallets were arranged in a $2 \times 2 \times 2$ arrangement. The newsprint test [130] used a $2 \times 2 \times 2$ arrangement of pallets, each load being $1.07 \times 1.07 \times 1.02$ m high. The Class II commodity results are from Khan [130].

Packaged computers and computer accessories were tested by Hasegawa et al. [131, 132]. They tested pallet-loads of packaged goods and also individual items, as packaged and boxed in individual cardboard boxes. The items were ignited using a line burner placed near the bottom edge of the package or stack. Ignition sources in the range of 50–200 kW were used. Table 26.11 identifies the specimens tested, while Figs. 26.53 through

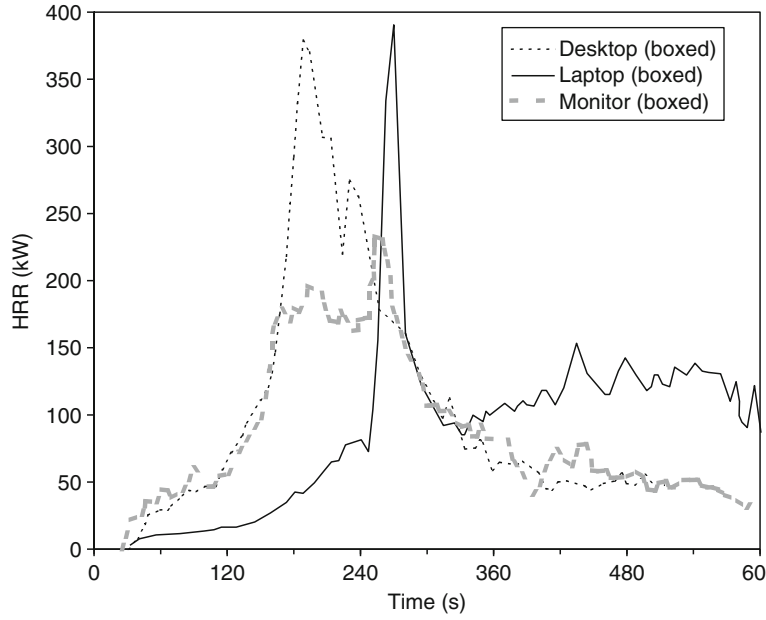

Fig. 26.53 HRR of single, packaged and boxed computers and monitors

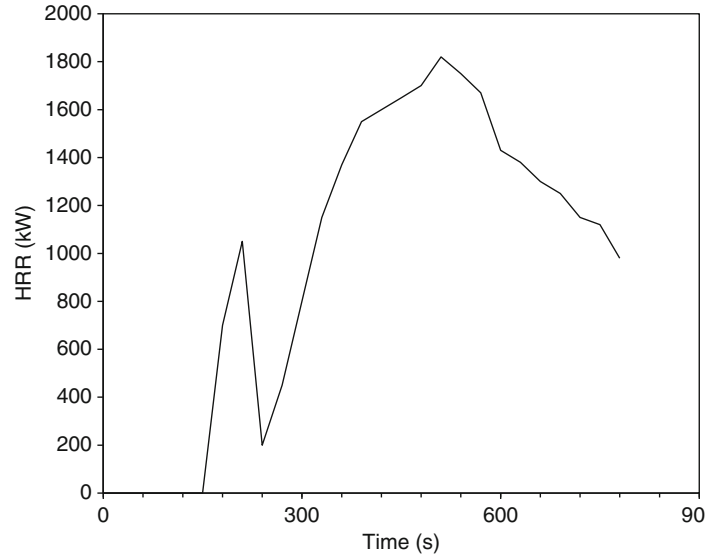

Fig. 26.54 HRR of a stack of polystyrene foam boards

26.57 show the results. The monitors were 16.8 kg each, while the desktop computers were 4.9 kg ea. The pallet load in test P1 collapsed during test and the full HRR was not registered, consequently, it was re-tested with supported sides.

A stack of expanded polystyrene boards was burned by Dahlberg at SP and results are reported by Särdqvist [97]. The total stack size was 1.2 × 1.2 × 1.2 m, with a mass of 1.4 kg. Ignition was with a 1 MW burner at the side of the stack. The HRR curve is shown in Fig. 26.54. Numerous other example data are tabulated by Särdqvist [97].

Dillon et al. [133] tested several commodities in a furniture calorimeter: acrylic yarns in boxes,

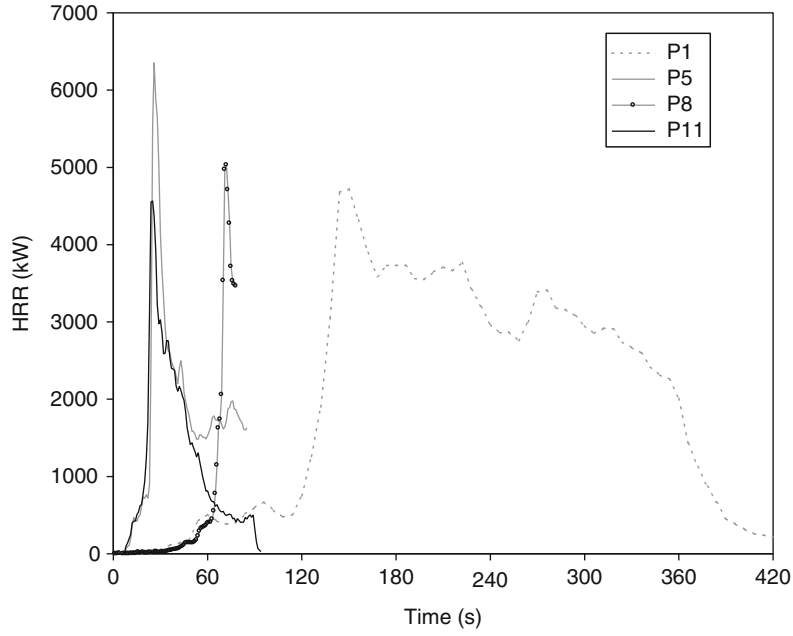

Fig. 26.55 HRR of pallets of packaged, boxed computer monitors

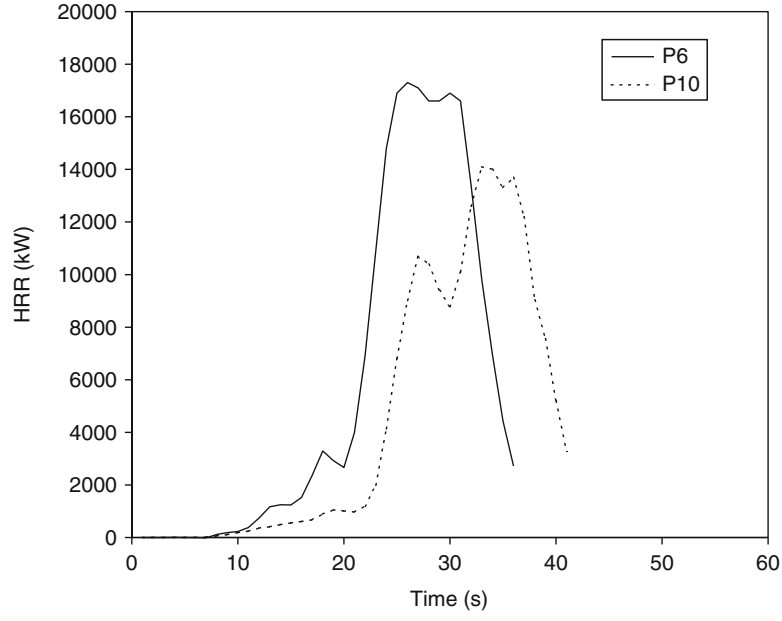

Fig. 26.56 HRR of pallets of packaged, larger arrays of computer monitors

computer monitors (US models, 430 mm [17″] screen) packed in shipping boxes, plastic coolers, and potato chip bags packed in cardboard boxes. The coolers with both insulated with polyurethane foam and had polyethylene outer shells; the #1 sample had a polystyrene liner while the #2 sample had a polypropylene liner. The computer monitors were padded with

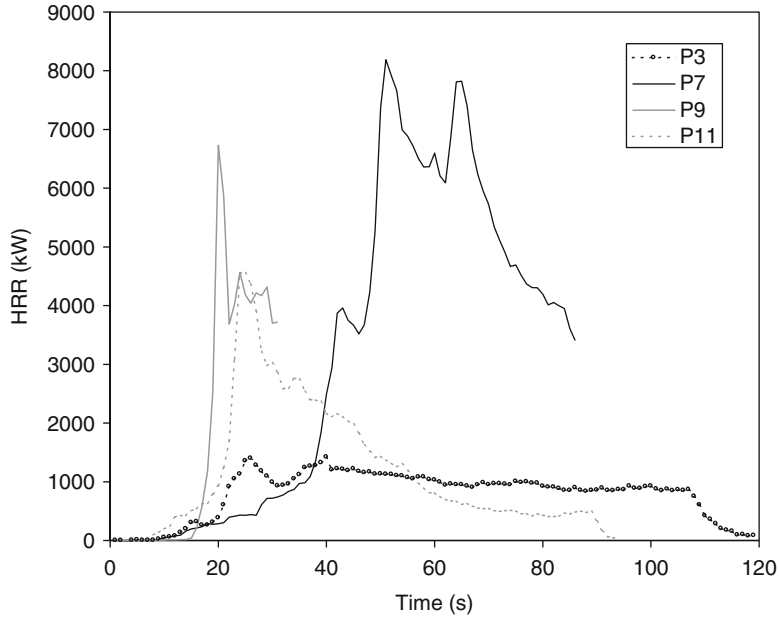

Fig. 26.57 HRR of pallets of miscellaneous computer items

Table 26.12 HRR of packaged household commodities tested by Dillon et al.

Commodity	Mass (kg)	Peak HRR (kW)	Time to peak (s)	Total HR (MJ)
Acrylic yarn skeins	8.7	263	210	127
Computer monitor	24.6	140	398	70
Cooler #1	6.4	400	648	147
Cooler #2	5.2	276	702	128
Potato chips	8.3	322	230	139

expanded polystyrene foam, as is customary for shipping. Their results are summarized in Table 26.12.

A study has been reported on burning pallet loads of organic peroxides [134]. Liquids were packaged in plastic containers within cardboard boxes, while solids were packaged in cardboard drums. The data are given only for a few packaging configurations with sufficient data not being available to generalize HRR predictions to other configurations.

For all rack storage tests, the times are very strongly affected by the ignition source location. Not enough data exist to make general correlations, but Fig. 26.58 illustrates the basic effect. The storeroom test [135] comprised a mocked-up small storeroom in a retail shop, with miscellaneous goods boxed in cardboard boxes, placed on shelving 2.4 m high. A small amount of additional shelving was provided across an aisle 1.4 m wide. The FMRC test involved pallets in a 2 × 2 × 2 arrangement. In the storeroom test, ignition was at the base of the face of the 'main' storage rack. The FMRC test [136] used the standard FMRC procedure whereby an igniter is also placed at the base, but is located internally, at the two-way intersection of flue spaces between piles. The data for the storeroom test are plotted as real time, while the FMRC test data were shifted 470 s to make the steep HRR rise portions coincide. From a comparison of this kind, one can roughly estimate that igniting a rack at the front face causes events to occur 470 s later than would happen if ignition were at the center of the flue spaces.

Kiosks

NIST have reported [137] some HRR results on full-scale tests of kiosks. These are the booths used in shopping malls, exhibitions, and other

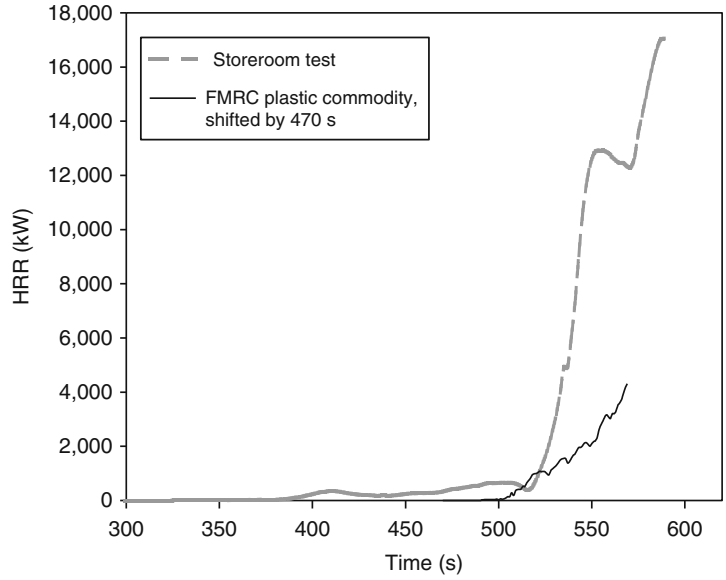

Fig. 26.58 Effect of ignition source location on fire development

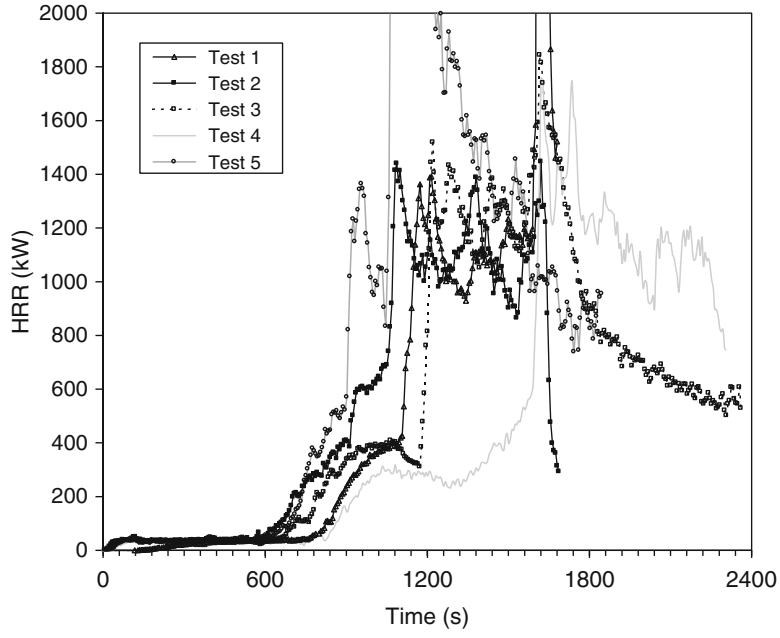

Fig. 26.59 HRR of display kiosks

places wherein a small amount of merchandise display or sales occur. Some HRR curves are illustrated in Fig. 26.59 for a kiosk, built largely of wood, which measured 1.2 m × 1.2 m × 2.1 m high. Tests 2–5 are all of the same sized kiosk, but refer to various configurations of the openable panels. Test 5 appears to have been more severe since all the panels were closed. Test 1 involved the same kiosk placed in a room, rather than in the furniture calorimeter.

Luggage

At the LSF Laboratories, Messa [138] tested the HRR of two suitcases filled with clothes. Ignition was with a square-ring burner applying approximately 5.5 kW. The test articles are described in Table 26.13 and the results are given in Fig. 26.60.

Magazine Racks

Chow et al. [139] conducted full-scale tests on several steel magazine racks, holding magazines, newspapers, and books. Ignition was with a small pool of gasoline. Test details are given in Table 26.14, while HRR results are shown in Fig. 26.61. The larger ignition source used Test 2 led to much greater HRR, despite the fact that the mass of paper goods was smaller than in Test 3. While all tests were conducted in an ISO 9705 room, the large HRR in Test 2 was evidently attributable to room-effect radiant heat flux reinforcement, which was of less significance for the other tests. Thus, for design purposes, only Tests 1 and 3 should be considered, unless the end-use environment is a relatively small room.

Table 26.13 Test description for suitcases tested at LSF

Condition	Soft suitcase	Hard suitcase
Mass empty (kg)	0.98	5.20
Mass filled (kg)	3.06	10.34
Burner HRR (kW)	5.5	5.5
Burner application time (s)	180	240
Total heat released (MJ)	33.4	139.0

Mattresses

Despite the relatively simple shape of mattresses, the prediction of mattress HRR from bench-scale data is difficult. Even the use of full-scale HRR data is problematic, due to a peculiarity of mattress fires. Most other combustibles interact only modestly with their environment, until large HRR values are reached or until room flashover is being approached. Liquid pools on the other hand, as discussed below, interact very strongly with a room, if either the room size or the available ventilation are not very large in comparison to the pool's HRR. The identical phenomenon is

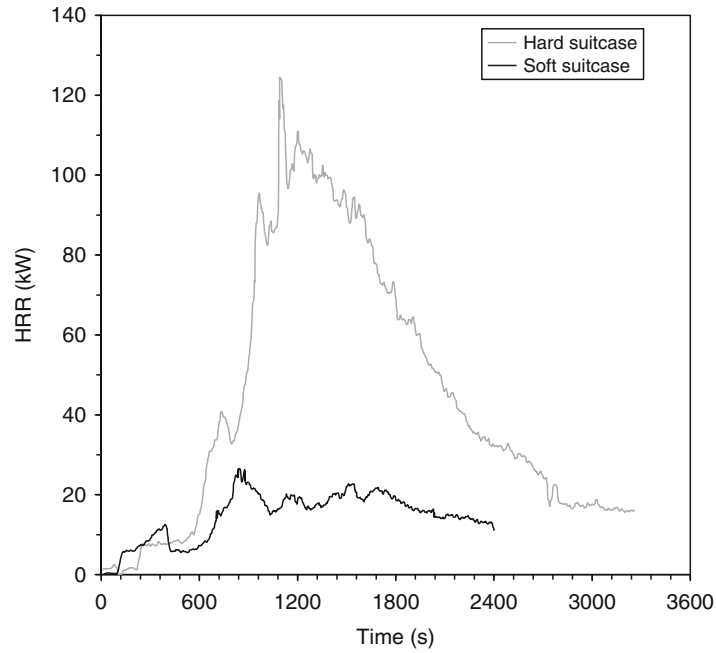

Fig. 26.60 HRR of suitcases

Table 26.14 Details of magazine rack tests

Test no.	Size of each rack (WxH), m	Location of racks in room	Mass of paper goods (kg)	Ignition source, quantity of gasoline (L)
1	1 × 2.2	Left, back	15	2
2	2 × 2.2	Back, right	60	15
3	2 × 2.2	Left, back, right	90[a]	3

Neoprene	FR cotton	18	70	89
Cotton/jute	FR cotton	13	40	43

observed with mattresses. Thus, there may not be a single value of the HRR of a mattress, the HRR having to be considered related to the room itself.

Some example data are compiled in Table 26.15 to illustrate the peak full-scale HRR values that are found for common material combinations [45]. The full-scale test protocol used a complete set of bedding; ignition was achieved with a wastebasket. Figure 26.62 illustrates the relation of bench-scale to full-scale

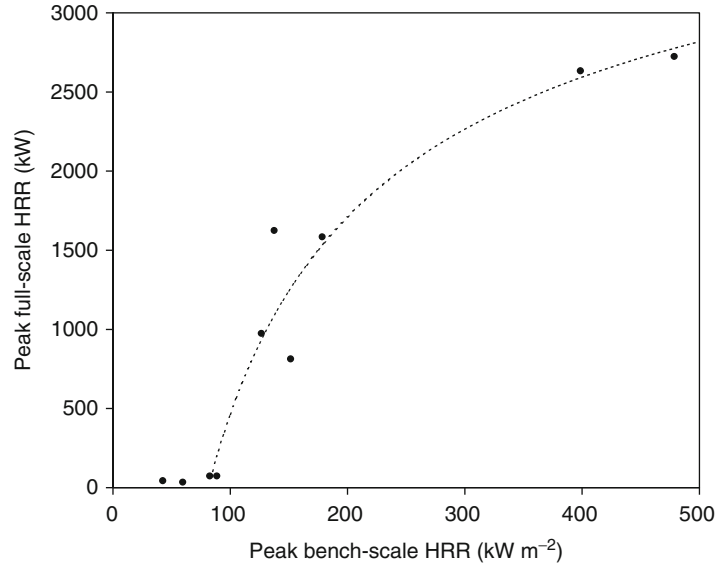

Fig. 26.62 HRR of mattresses predicted from bench-scale results. Full-scale tests under conditions of negligible room effect; bench-scale HRR measured at 25 kW m^{-2} irradiance

Table 26.16 Some mattress HRR data; full-scale data include room effect of small bedroom

FR cotton batting	Polyester	15.7	22	45
Neoprene	PVC	14.9	19	31

data from the same data set, where full-scale testing was done under conditions not leading to significant room fire effect. Not enough specimens were tested to develop a usable correlation, so the results should be taken only as indicative.

King-size mattresses dating from before the Federal HRR regulations can produce very high HRR values, even absent a room effect. NIST [140] tested a king-size bed assembly which contained box springs and an innerspring mattress consisting of polyurethane foam and felted cotton padding. Additional bedding included two pillows, pillowcases, two sheets, and a comforter. Two tests were run in an open calorimeter—in one test, an electric match was used to ignite the bed, while in the other test a newspaper-filled wastebasket was the ignition source. Unlike the typical findings in the case of upholstered furniture, here the ignition source type had a major effect, with the larger ignition source resulting in a peak HRR over 5000 kW, while the smaller only showed about 3500 kW and burner a longer

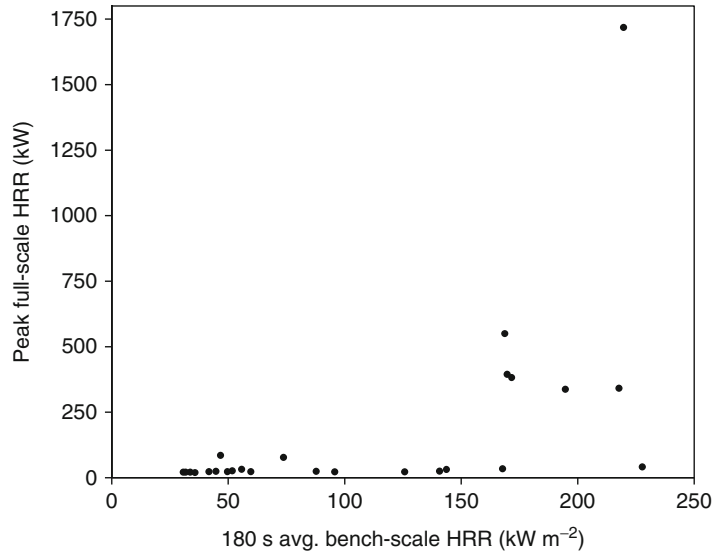

Fig. 26.63 HRR of mattresses predicted from bench-scale results. Full-scale tests under conditions of significant room effect; bench-scale HRR measured at 35 kW m^{-2} irradiance

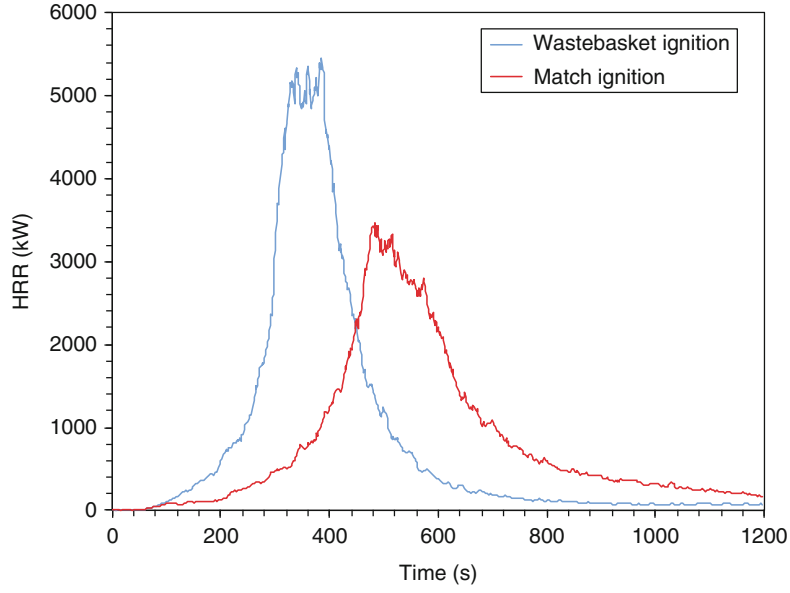

Fig. 26.64 Effect of ignition source on king-size bed assemblies

time at a slower rate (Fig. 26.64). In either case, however, the HRR values would suffice to cause flashover in a bedroom environment, especially in view of the fact that the HRR would be much higher due to room effect augmentation.

Some full-scale data obtained under conditions where a strong room interaction effect was seen are shown in Table 26.16 [141, 142]. The full-scale test setup was different for this data set, in that no bedding was used and ignition was with a burner flame at the edge of the mattress. Thus, some mattresses were able to show essentially zero HRR since bedding was not available to sustain burning, and the ignition source could be 'evaded' by receding specimens. A relation between full-scale and bench-scale

Table 26.17 Results on mattress from the CBUF study

Pk. HRR furn. calor. (kW)	Pk. HRR room (kW)	Springs	Thick. (mm)	Thick. factor	$\dot{q}''_{60}$	$\dot{q}''_{180}$	$\dot{q}''_{180} \times$ th. fac.	q''_{tot}	Prop. fire

275	NA	N	90	1.00	111	118	118	45	Y
348	471	Y	20	0.40	327	159	64	30	Y
313	1700	N	100	1.00	256	191	191	62	Y
917	2550	N	140	1.00	232	198	198	37	Y

results from this study is shown in Fig. 26.63. The behavior in that study was found to be:

- Mattresses with a bench-scale HRR (180 s average value) of < 165 kW m^{-2} led to room fires of less than 100 kW.
- Mattresses with a bench-scale HRR (180 s average value) of > 165 kW m^{-2} generally led to room fires on the order of 1–2 MW.
- The transition between those extremes was very abrupt.

The sharp transition between trivial fires and room flashover conditions can be attributed to the details of the test room, but also to the use of an ignition source which specimens of intermediate characteristics could 'evade.'

Additional data on mattress HRR have been published by SP [143], Lund University [144], and in the CBUF project [10]. The CBUF study included full-scale room fire tests, open-burning furniture calorimeter tests, and Cone Calorimeter tests. The mattress results are given in Table 26.17. In both of the full-scale test environments, no bedding was used, but a square-head burner was applied to the top surface of the specimen, precluding complications from any receding-surface behavior. The bench-scale test data presented were obtained at a 35 kW m^{-2} irradiance. The results indicate that, when tested in the standard ISO 9705 room, a very drastic room effect occurs for open-air HRR values over about 300 kW.

The bench-scale data indicated that when widely varying mattress thicknesses exist, a simple relation of bench-scale to full-scale HRR cannot be sought, even if only predictions of open-burning (furniture calorimeter) results would be desired. As a first cut, it was concluded that mattresses can be grouped into two groups—those leading to propagating fires (the mattress being consumed in flaming combustion during a relatively short time), and those that do not. The former can be considered to be of the highest hazard, while the latter present only trivial hazard. Since, for practical reasons, all mattress composites must be tested in the Cone Calorimeter using a 50 mm thickness, to take into account effects due to thin mattresses, a thickness factor is defined:

$$Th.fac. = \min\left(\frac{thickness, mm}{50},\ 1.0\right)$$

For mattresses where the innersprings are used, the thickness is measured from the top of the mattress down to top of the metal springs; it is not the total thickness. To determine whether the mattress fire will propagate or not, the following rules were developed:

If $\dot{q}''_{180} \cdot (Th.fac.) < 100$ kW m^{-2}
and

$$\dot{q}''_{60} < 250 \text{ kW m}^{-2}$$

then,

$\dot{Q} < 80\ kW$ (non-propagating fire)

else,

$\dot{Q} > 80\ kW$ (propagating fire)

The HRR values over 80 kW in fact are flashover values of up to 2.5 MW, but the scheme does not assign a specific HRR number. Qualitatively, this scheme reflects the type of abrupt behavior change found in earlier studies

(Fig. 26.63), but here some more refined rules were developed that avoid non-predictions which would occur from simple correlation. During the same CBUF project, a more sophisticated mattress fire model has been developed by Baroudi et al.; this model is not easy to use, but details are available [10, 145].

In the US, mattresses made after July 1, 2007 have been required by law to conform to the 16 CFR 1633 standard of the Consumer Product Safety Commission. The latter augments the previous standard (16 CFR 1632) for smoldering by a flaming test procedure. The primary requirement for the new standard is that the peak HRR not exceed 200 kW; in addition the total heat release during the first 10 min of test must not exceed 15 MJ. NRCC [72] tested an example of one such mattress and did confirm a peak HRR < 200 kW. However, a room fire test run with this same model of mattress, an equally-conforming mattress foundation, and a set of bedding produced a peak HRR of 1812 kW. This would likely lead to flashover in a room of the ISO 9705 room size and doorway dimensions. Another test run by NRCC showed an extreme radiant feedback effect, since mattresses not made to the Federal standard typically showed HRR values in excess of 3000 kW even for small mattress sizes, while a bunk bed attained > 6000 kW in the room test.

Mining Equipment

Hansen and Ingason [146] tested two pieces of mining equipment, burning them in an underground mine facility. The first item was a Toro 501 DL diesel-powered wheel loader. The machine weighs 36,000 kg and stands 2.85 m tall. The structure is steel, but it also contains rubber tires, hydraulic oil, diesel fuel, and smaller components, including driver's seat, cables, etc., for an estimated fuel content of 76 GJ, the majority of this being the giant tires. The second item was a Rocket Boomer 322 drilling rig. This item weighs 18,400 kg and stands 2.95 m tall. Its fuel content was estimated at 46 GJ, with the fuel comprising hydraulic oil, hoses, tires, diesel fuel, cables, and

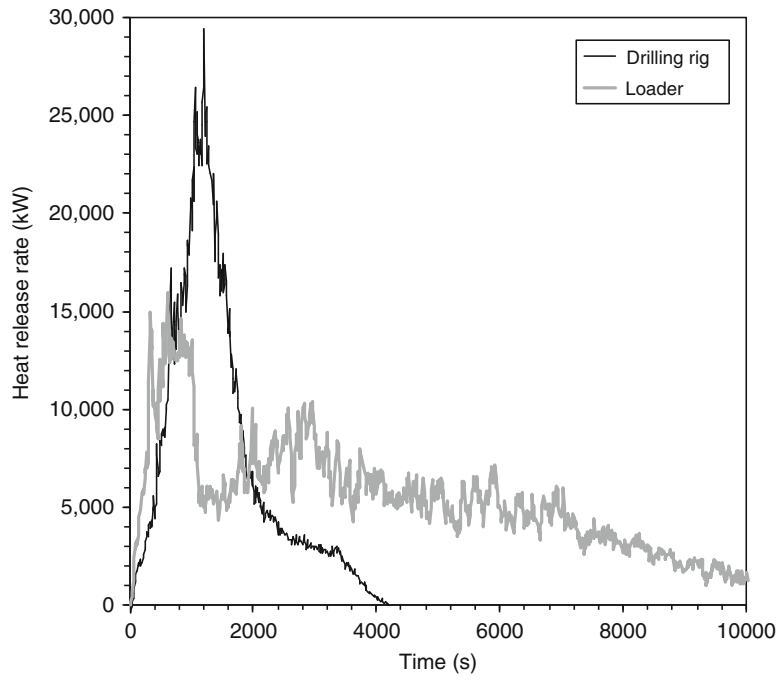

Fig. 26.65 HRR for two types of mining equipment

miscellaneous smaller items. With both items, the fuel tank was partly emptied and poured out to create a pool fire under the specimen, and this pool was ignited to start the fire. Figure 26.65 shows the HRR results, with loader achieving a peak value of 15.9 MW, while the drilling rig showing 29.4 MW.

Office Furniture

Office worker cubicles ('workstations') have been tested in several projects at NIST [147–149]. Figure 26.66 show that severe fire conditions can be generated by these arrangements. In some cases, fires of nearly 7 MW were recorded from the burning of a single person's workstation. The identification of the main conditions in these tests is given in Table 26.18. In one test series [147] replicates were tested in an open furniture calorimeter, then the configuration was tested again in a room test; this is illustrated in Fig. 26.67.

In 2004, NIST [150] reported results of some tests of modern office furniture, i.e., primarily plastics-based. Two full-scale tests were conducted, a single person cubicle, and a four-person cluster of cubicles. The one-person cubicle was tested in an open environment, while the four-person cluster was in a semi-open arrangement: three walls and a ceiling were present, but not the fourth wall. The results (Fig. 26.68) indicate both a radiant augmentation due to the ceiling and an augmentation due to multiple fuel

Table 26.18 Workstations tested by NIST in 1988 and 1992

Code	Combustible mass (kg)	Description	Number of sides w. acoustic panels	Ref.

loads being present in direct proximity. In that same study, NIST also ran open calorimeter tests on two office chairs, a swivel chair and a chair with a fixed metal frame (Fig. 26.69). The gross mass for the chairs were 20.5 kg, and 11.8 kg, respectively, but the mass of the combustible portions was not evaluated, although the major fraction of the total mass was the mass of the steel components. The swivel chair had major components comprising hard-plastic shell material, and the fire involvement of these components was the cause of the second HRR peak.

Additional tests were conducted by Kakegawa et al. [151] at Japan's National Research Institute of Fire and Disaster. Each test was started by a

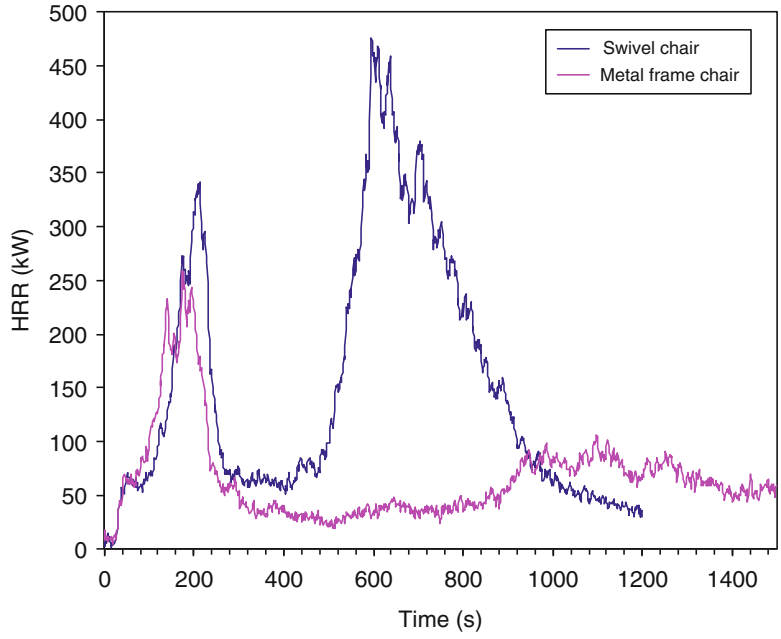

Fig. 26.69 HRR results for the two office chairs tested

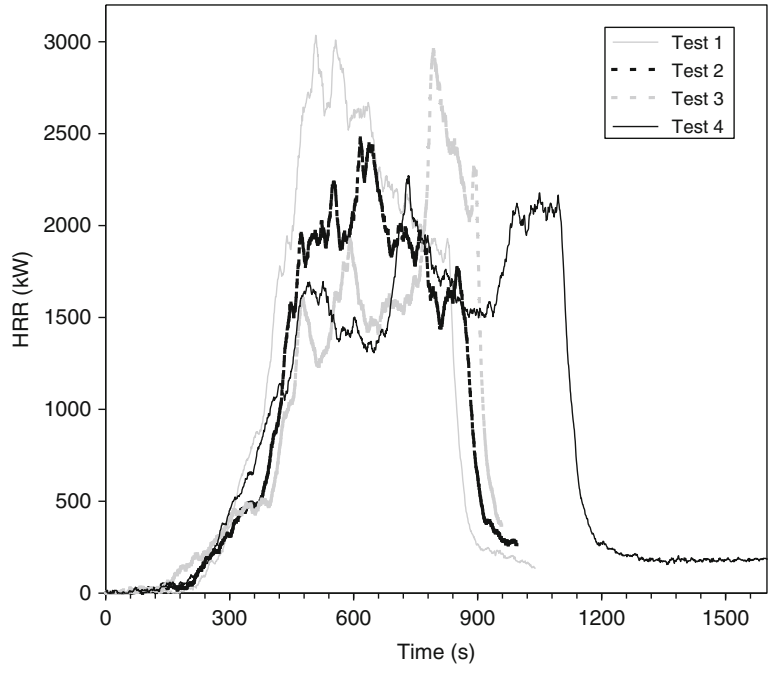

Fig. 26.70 HRR of four-unit workstations tested at NRIFD

polypropylene wastebasket filled with 0.2 kg of paper. The wastebasket, by itself, was found to show a peak HRR of 50–60 kW. The desks were of modern metal-frame construction, with plastic trim parts. In addition, the workstations contained small filing cabinets, telephones, chairs, computers, and a modest amount of office paper. The HRR results for the four-unit

Table 26.19 Workstations tested by NRIFD

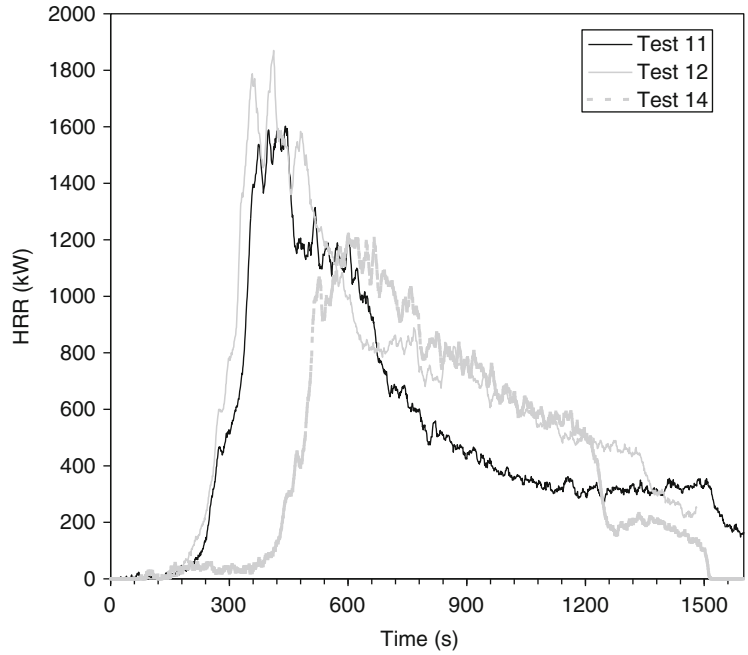

Fig. 26.71 HRR of one-unit workstations tested at NRIFD

workstations are shown in Fig. 26.70, while those for the one-workstation units are shown in Fig. 26.71. Even though the four-unit workstations had a very high fuel load, the HRR values were lower than the American units studied at NIST. This is presumably due to a more protected arrangement of the fuel, plus the fact that only short (0.45 m high) partition panels were used (Table 26.19).

Pallets

Conceptually, a wood pallet is a similar arrangement to a wood crib. The geometry, however, is different. Instead of being composed of identical rows of square-section sticks, pallets are made up of rectangular elements in a traditionally dimensioned configuration as shown in Fig. 26.72. The fire safety concern with pallets arises when they are idle and stacked many units high. Krasner [152] has reported on a number of tests where the burning rate of pallets was measured. A typical experimental heat release rate curve is shown in Fig. 26.73. This curve shows that, much like for a wood crib, a substantially constant plateau burning can be seen if the stack is reasonably high. The results for a standard pallet size of 1.22 × 1.22 m can be given as a general heat release rate expression

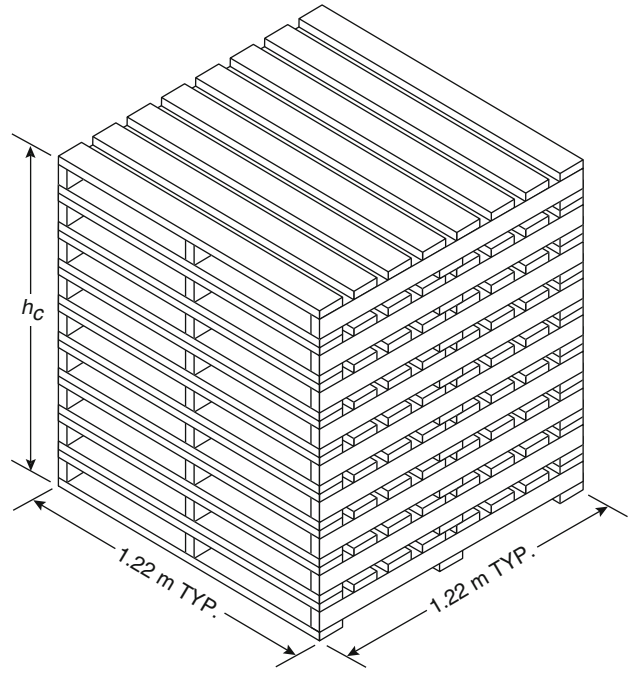

Fig. 26.72 The geometric arrangement of a stack of wood pallets

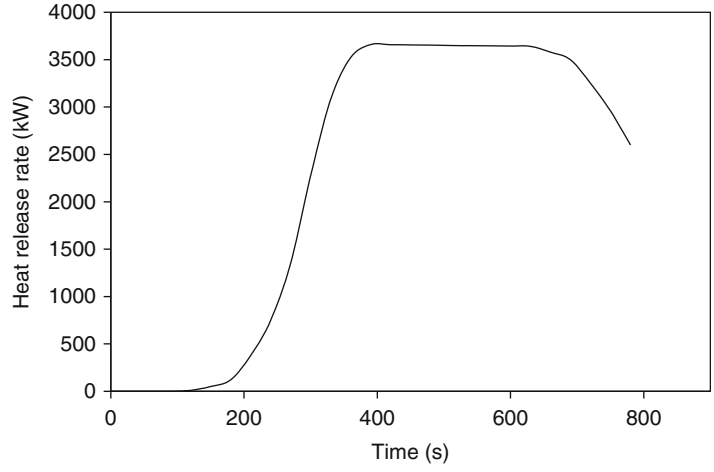

Fig. 26.73 HRR of a typical wood pallet stack (1.22 × 1.22 × 1.22 m high)

$$\dot{q} = 1368\left(1 + 2.14h_p\right)(1 - 0.03M) \qquad \dot{q}'' = 919\left(1 + 2.14h_p\right)(1 - 0.03M)$$

where h_p is stack height (m), M is moisture (%), and a net heat of combustion of 12×10^3 kJ kg^{-1} has been assumed. For convenience in applying to nonstandard pallet sizes, this can be expressed on a per-unit-pallet-floor-area basis as:

The agreement between the above equations and experimental data is seen to be good over a wide range of pallet heights (Fig. 26.74), but the expressions do somewhat overpredict the burning rates if applied to short stacks, with stack height $h_p < 0.5$ m.

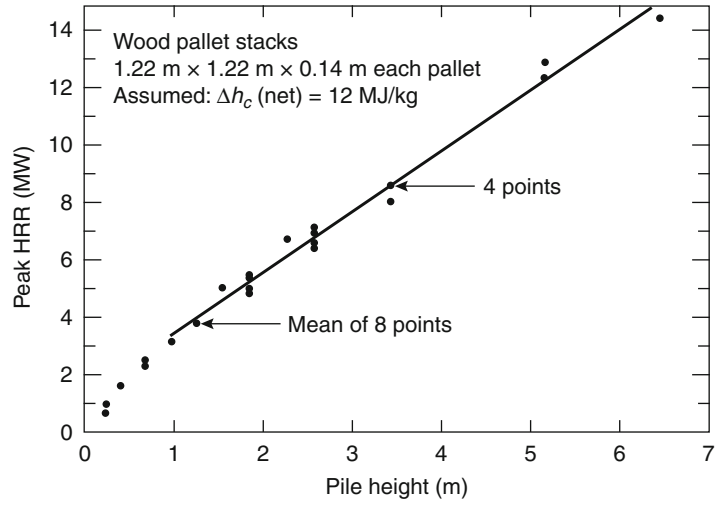

Fig. 26.74 Dependence of pallet HRR on stack height

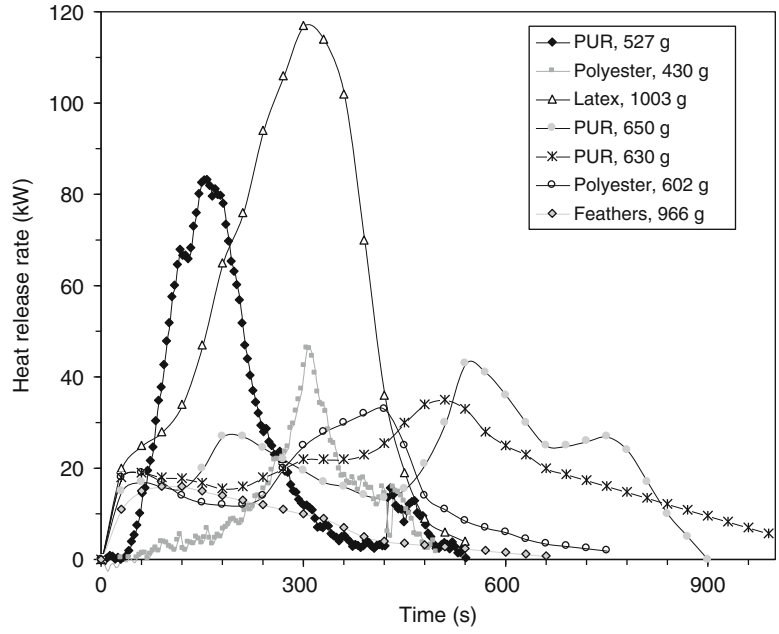

Fig. 26.75 HRR of pillows

Pillows

Pillow tests have been reported by NIST [153] and SP10. The results are given in Fig. 26.75.

Pipe Insulation

The available data are from the configuration where pipe insulation is used to entirely cover the ceiling of a test room. The test method used is a variant of ISO 9705 especially configured for pipe insulation testing [154]. Data on this configuration have been published by Wetterlund and Göransson [155] and by Babrauskas [156].

Plants and Vegetation

Trees, Natural

Some tests on Christmas trees were reported by VTT [157] and by Damant and Nurbakhsh [158].

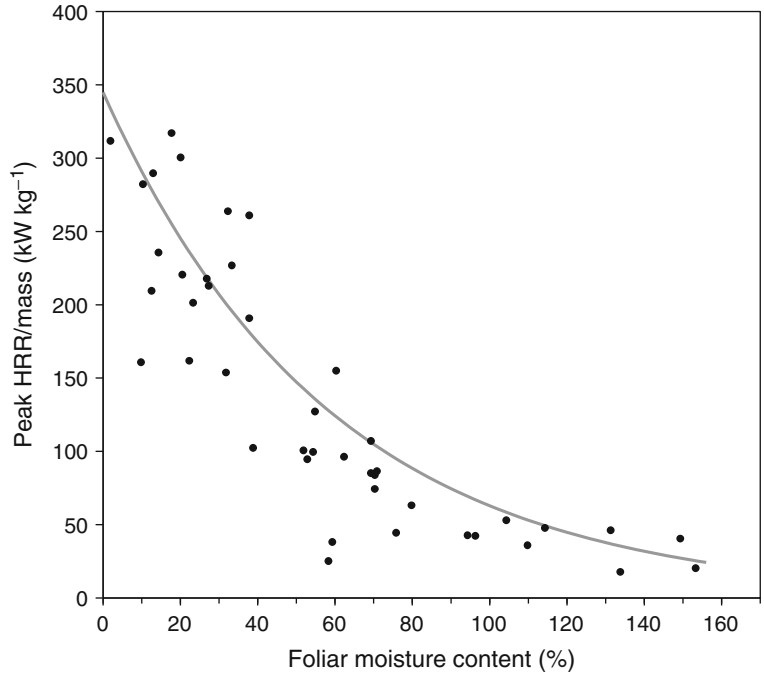

Fig. 26.76 The peak HRR for Douglas-fir Christmas trees, as a function of moisture and mass

Newer studies, however, indicated that these tests, which examined only a few trees, did not capture the full range of HRR values associated with Christmas trees. The main variables that govern the HRR of Christmas trees are the following:

- Moisture content of the needles
- Mass of the tree
- Species
- Ignition source used

Moisture is the dominant variable and this had not been studied previously. The results of an extensive series of fire tests [159] on Douglas-fir (*Pseudotsuga menziesii*) trees are shown in Fig. 26.76, while the HRR of a typical test is illustrated in Fig. 26.77. The trees were about 2.1 m tall, had an average mass of 11 kg. The trees were cut, placed in a watering stand, and watered according to various watering programs. The average tree was kept for 10 days prior to testing. The relation of the curve fit in Fig. 26.76 is:

$$\dot{q}/mass = \frac{400}{1 + 0.0538MC}$$

where MC = foliar moisture (%) and the units of $\dot{q}/mass$ are kW kg^{-1}. Moisture is measured on a dry basis, so values can readily exceed 100 %; also note that it is the needle (foliar) moisture that governs the burning behavior—trunk moisture is not a relevant variable. The mass of the tree used here is the entire mass; Evans et al. [160] suggested that if data are available only for the foliar mass, but not the mass of the entire tree, the approximation be used:

$$mass = 2 \times mass_{foliar}$$

To ignite trees with a small flame requires that the moisture content be below 50–60 %. Otherwise, ignition is still possible if using larger combustible objects. In the work reported, the trees which could not be ignited by a small flame were all ignited by first igniting wrapped gift packages placed under the tree. For design purposes, it should be adequate to assume that the heat release curve is a triangle. This requires knowing only the peak HRR and the total heat released. To estimate the latter, it was found in the tests that the Christmas trees showed an effective heat of combustion of 13.1 MJ kg^{-1}. Thus, from knowing the mass of the tree and the effective heat of combustion, the total heat

release may be estimated. The needle moisture may not be known for design purposes. It is governed both by the watering program and by the innate biology, e.g., the species, of the tree. No model is available at the present time that can predict the moisture. However, the research indicated that Douglas-firs are a notably short-lasting species. The data points shown in Fig. 26.76, with one exception, represent trees that had been on display for less than 16 days; some were watered carefully and regularly, while others were not. Other species of Christmas trees, such as Noble fir or Fraser fir are considered to be longer-lasting, but are less commonly bought.

A smaller test series on Scotch pine trees was tested at NIST by Stroup et al. [161]. They examined trees of 2.3–3.1 m height and mass between 9.5 and 20.0 kg; with one exception, the trees were of mass 12.7 kg or greater. Apart from one tree, which is not considered here since it was not successfully ignited, the trees were left without water for 3 weeks in a room at 50 % RH and 23 °C. Ignition was with an electric match to a lower branch of the tree. The Scotch pines were substantially taller and heavier than the Douglas-firs, so it is not surprising that higher peak HRR values were attained. The peak HRR values ranged from 1620 to 5170 kW. Normalized per mass, the average was 183 kW kg^{-1}, with the range being 103–259 kW kg^{-1}. The moisture of the branches was not recorded, but presumably was <20 % in all cases. Comparing to the above results, Douglas-firs showed about 160–330 kW kg^{-1}. This would suggest that there is a species effect and that Scotch pines show a HRR/mass ratio approximately 0.75 of that found for Douglas-firs. This conclusion is very tentative, however, since the test programs did not use the same test protocol. Part of the difference might also be attributed to a height effect, since this cannot separately be taken into account.

Madrzykowski [162] ran more recent tests at NIST on 2.05–2.54 m tall Fraser fir trees with a moisture content of 6–9 %. The peak HRR values ranged from 3231 to 4344 kW, while the mass of the specimens ranged from 10.97 to 13.81 kg, giving an average peak HRR/mass value of 286 kW kg^{-1}, with a range of 218–348 kW kg^{-1}. The author also ran one interesting test where a tree was burned lying on its side, instead of vertical. This gave a much lower peak HRR value of 1603 kW, indicating a major role of geometry.

Jackman et al. [163] tested Noble fir and Norway spruce specimens. For a relatively dry (26 % MC) Noble fir (16.3 kg, 3.07 m tall) they got a peak HRR of 2880 kW. A similar Norway spruce (20 % MC, 14.9 kg, 3.02 m high) showed only 1590 kW. Because very few tests were run, this should not be taken to indicate an intrinsic species effect.

Bushes, Natural

Stephens et al. [164] tested Tam juniper (*Juniperus savina tamariscifolia*) shrubs of various moisture contents, ignited by a medium gas flame. For MC < 50 %, rapid combustion resulted and samples showed 1800–2100 kW peak HRR. Specimens of 50–80 % MC typically showed 600–800 kW, while specimens of higher MC did not burn significantly. Unfortunately, neither the mass nor the size of the specimens were specified, except that they were denoted as "mature." Shrubs of this species in general reach about 0.45 m height and cover about 1 m of width.

Etlinger [165] conducted more extensive tests on a series of decorative-shrub species: Armstrong juniper (*Juniperus chinensis* 'Armstrongii'), hedge saltbush (*Rhagodia spinescens*), milkflower cotoneaster (*Cotoneaster lacteus*), mountain lilac (*Ceanothus ray* 'Hartman'), oleander (*Nerium oleander*), purple rockrose (*Cistus purpureus*), quail bush (*Atriplex lentiformis*), sageleaf rockrose (*Cistus salvifolius*), Santa Barbaras ceanothus (*Ceanothus impressus* 'Eleanor Taylor'), trailing rosemary (*Rosmarinus officinalis* 'Prostrata'), and vine hill manzanita (*Arctostaphylos densiflora* 'Howard McMinn'). The bushes were typically in the range of 0.5–1.0 m tall and weighed 1–3 kg. He ignited the bushes first with a 40 kW burner, which did not cause the specimens to show a significant HRR output, followed by an exposure to a 150 kW burner. Some typical results upon exposure to a 150 kW burner are shown in Fig. 26.78.

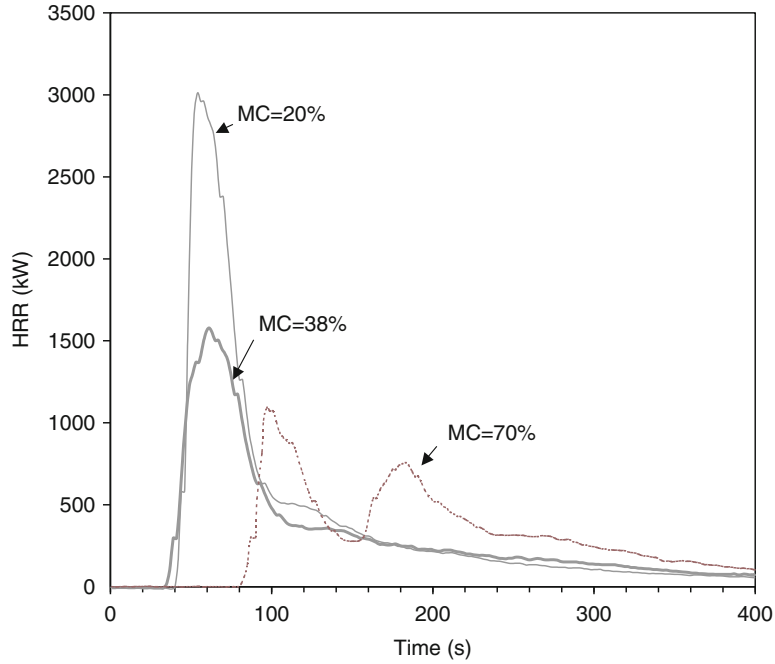

Fig. 26.77 Typical HRR curves of Douglas-fir Christmas trees

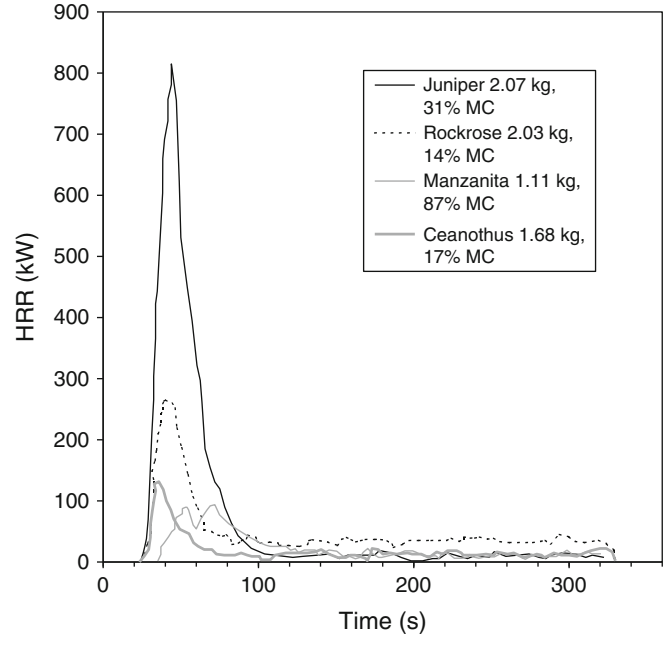

Fig. 26.78 Typical HRR for bushes obtained by Etlinger

A summary of Etlinger's peak HRR values is shown in Fig. 26.79. There is a significant amount of scatter, but the results for the bushes are not systematically different from those for trees, which are also shown on the same plot. Thus, a single expression for the peak HRR can be derived which is suitable for both trees and bushes:

$$\dot{q}/mass = \frac{700}{1 + 0.1295MC}$$

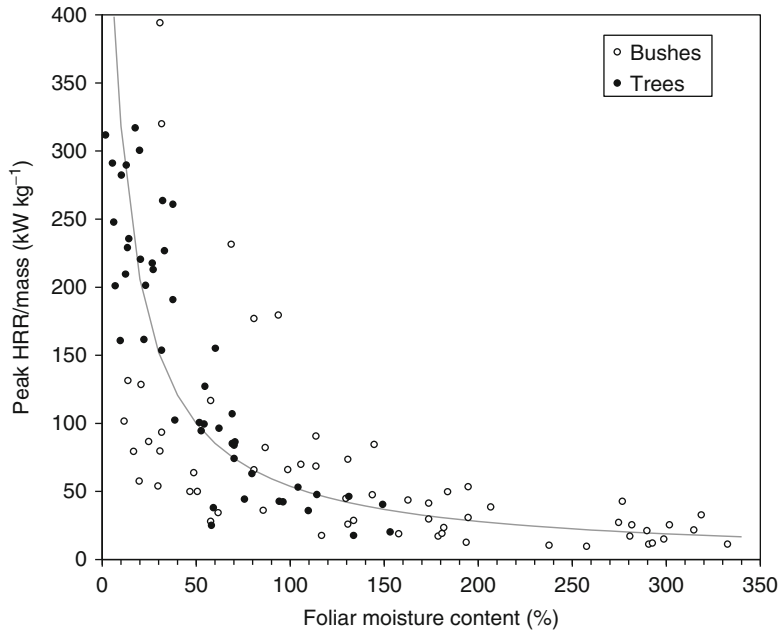

Fig. 26.79 HRR of bushes and trees, plotted on a unified basis

Trees, Plastic

UL had published a procedure for testing artificial Christmas trees. This was identified as Subject 411 [166]. It was eventually withdrawn due to lack of activity in this area, but the basic test procedure is sound. In the UL procedure, the ignition source comprises 454 g of shredded newspaper, conditioned at 35–40 % RH, and dispersed in a 610 mm diameter circle around the base of the tree. The newspaper is ignited at four points around the perimeter of the circle. This ignition source is realistic, since it represents the effect of burning gift packages or decorations at the base of the tree. Babrauskas [167] tested PVC trees of 4.2–4.7 kg mass and 1.96–2.01 m height.

Figure 26.80 shows the results for two replicates using the exact using the UL procedure and a third test where the newspaper was ignited at one point only. The specimens proved impossible to ignite with a small flame, but using the UL procedure they produced rapidly developing fires, with 500 kW being attained 11–20 s after ignition. The peak flame heights of the two specimens ignited in four places was 4.8–5.1 m. Using the Zukoski [168] or McCaffrey [169] flame height/HRR correlations, such flame heights imply peak HRR values of 2800–3100 kW. The values actually measured are systematically low due to two reasons: (1) mixing dilution effects due to use a large, room-sized calorimeter hood; and (2) inability of instrumentation to respond to a fast-growing fire.

Jackman et al. [162] tested three artificial trees (2.0–2.5 m height) and obtained peak HRR values of 100–400 kW. It is not clear whether these low values represent an intrinsically low HRR of these trees (of unspecified plastic) or whether it simply reflects the fact that an ignition source was used which is much less serious than the one in the UL procedure.

Bushes, Plastic

Some HRR data on plastic house plants are shown in Fig. 26.81 [170].

Pools, Liquid or Plastic

Possibly the simplest geometric arrangement of fuel is a liquid (or thermoplastic) pool. Over the last four decades, an enormous number of studies have been conducted where pool burning was

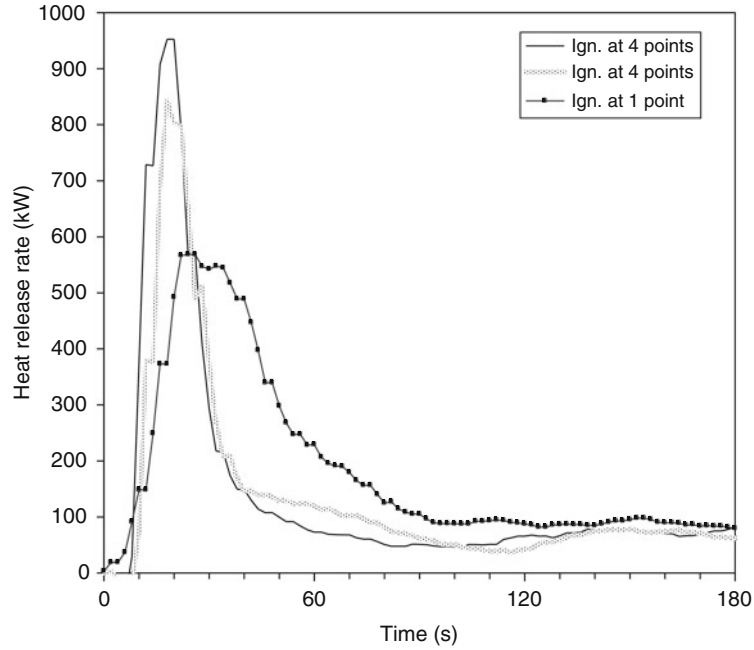

Fig. 26.80 Recorded HRR for PVC Christmas trees (actual HRR was greater, due to very fast rise time)

considered theoretically or measured empirically. The most systematic early study was by two Russian researchers, Blinov and Khudiakov [171]. Their results were analyzed by Hottel [172], who pointed out that conservation of energy can be applied to the pool:

$$\dot{q} = \dot{q}'' \times A = \left(\dot{q}_r'' + \dot{q}_c'' - \dot{q}_{rr}'' - \dot{q}_{loss}''\right) \times \left(\frac{\Delta h_c}{\Delta h_g}\right) \times A$$

where $\dot{q}$ is the heat release rate of the pool; double-prime denotes per unit area; A is the area of the pool (m^2); $\dot{q}_r''$ is the radiant heat flux absorbed by the pool; $\dot{q}_c''$ is the convective heat flux to the pool; $\dot{q}_{rr}''$ is the heat flux re-radiated from the surface of the pool; and into $\dot{q}_{loss}''$ are lumped wall conduction losses and non-steady terms. The heat of gasification is Δh_g (kJ kg^{-1}), while the (lower, or net) heat of combustion is Δh_c. Note that some authors use the symbol L for the heat of gasification. The heat of gasification is defined as the enthalpy required to bring a unit of mass of liquid-phase substance at 25 °C to the gaseous state at the temperature T_b, its boiling point. It should not be confused with the latent heat of evaporation Δh_v, which is the enthalpy required to change a unit mass of liquid to a gas at 25 °C. The relation between these two quantities is:

$$\Delta h_g = \Delta h_v + (T_b - 25) \times C_{pv}$$

where we have taken the simplification that C_{pv}, the heat capacity of the vapor (kJ kg^{-1} K^{-1}) is a constant. An extensive tabulation of these constants is provided by Babrauskas [173].

Table 26.20 The burning regimes for liquid pools

Diameter (m)	Burning mode
< 0.05	Convective, laminar
0.05–0.2	Convective, turbulent
0.2–1.0	Radiative, optically thin
> 1.0	Radiative, optically thick

Hottel's analysis of Blinov and Khudiakov's data showed two basic regimes are possible: radiatively dominated burning for large pool diameters, D, and convectively dominated burning for small D. Furthermore, in the convective regime the flow can be either laminar or turbulent (being always turbulent for radiatively driven pools), while in the radiative regime the flames

can be optically thin or thick. These distinctions can, in the simplest analysis, be made solely on the basis of pool diameter. Such a simple classification is possible if the pool is strictly circular, radiant heating is only from the pool's flames and not augmented by external sources, and there are no interferences to the flow streamlines which could trip the onset of turbulence. In such a simplified case, the regimes can be identified as in Table 26.20.

In the convective limit (small pools), one may make the following approximation:

$$\dot{q} = \dot{q}_c'' \times \left(\frac{\Delta h_c}{\Delta h_g}\right) \times A$$

however, the values of $\dot{q}_c''$ to be taken are not easily determined. Some additional details are given in [174]. For fire hazard analysis purposes, liquid pool fires will rarely be significantly dangerous if they are smaller than about 0.2 m in diameter. Thus, it will often only be necessary to treat pools burning in the radiative regime. In the radiative regime, it is found that data for most organic liquids can be well correlated by:

Table 26.21 Pool burning: thermochemical and empirical constants for a number of common organic fuels

[a]See text

$$\dot{q} = \Delta h_c \dot{m}''_\infty \left(1 - e^{-k\beta D}\right) \times A$$

This requires determining two empirical constants: $\dot{m}''_\infty$ and the term $(k\beta)$; the first of these is the asymptotic mass loss rate per unit area as the pool diameter increases towards infinity; the second is the product of the extinction-absorption coefficient k and the beam-length corrector β. These constants are given in Table 26.21 for a number of common fuels.

The net heat of combustion, Δh_c, is also listed in the table. In principle, a slightly lower value, the *effective heat of combustion*, should be used instead of the net heat of combustion that is determined with oxygen bomb calorimetry. Some bench-scale values of a combustion efficiency factor to convert oxygen bomb values into experimentally-measured values are given in Chap. 36, "Combustion Characteristics of Materials and Generation of Fire Products." For most liquids, however, the bench-scale values are not greatly below unity and realistic large-scale measurements are not available, thus the improvement in accuracy by extrapolating from bench-scale results may be nil.

Alcohol fuels show minimal radiative flux, in comparison to other fuel types. Thus, the best recommendation previously had been to use constant values of $\dot{m}''$, independent of diameter. Based on some newer test results [175], it is clear that a diameter effect does exist, although it cannot be expressed in standard form. Thus, it is recommended that for methanol or ethanol the values be used: $\dot{m}'' = 0.015$ (D < 0.6 m); $\dot{m}'' = 0.022$ $(0.6 < \mathrm{D} < 3.0$ m); and $\dot{m}'' = 0.029$ (D > 3.0 m).

The above discussion implicitly assumed that the pool depth is at least several millimeters. If liquids are spilled on a horizontal surface that has no low spots and no diking, then a liquid layer will form that is less than 1 mm thick. *Thin-layer pools* of this nature (which can occur in arson cases) show a lower HRR than do pools of greater depths. Putorti et al. [176] studied gasoline spills on wood parquet, vinyl floor tiles and carpeting. When a specified volume of liquid is spilled, the problem to be solved can be separated into two components: (1) determining the area of the spill, or, equivalently, the spill thickness; and (2) determining the HRR per unit area.

For wood floors, Putorti found the $A = 1.5\ V$, where $A =$ area (m^2) and $V =$ volume (L). For vinyl tile, a similar relation was also found, but the constant being 1.8. Converted into layer thicknesses, the thickness for wood was 0.67 mm

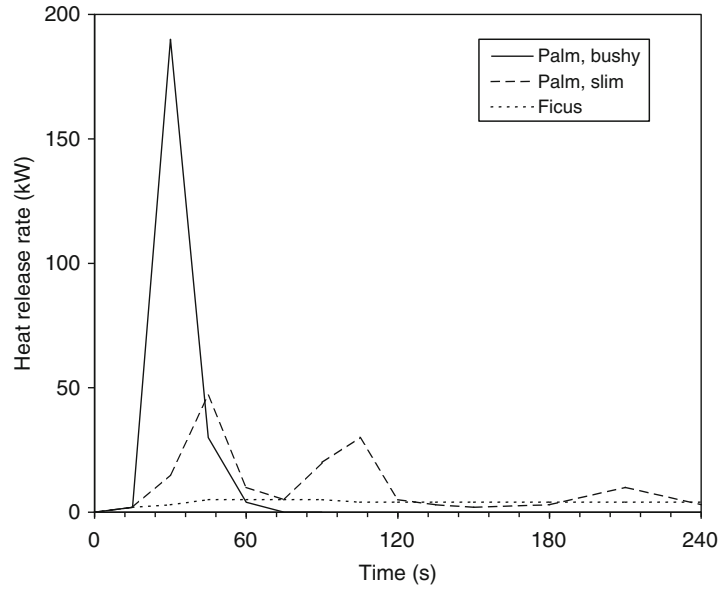

Fig. 26.81 HRR of plastic house plants

and for vinyl tile it was 0.56 mm. Earlier work has indicated that a relation of this kind should only be applied to smooth floor surfaces. For rough, absorptive surfaces a constant thickness is not obtained, and larger spill volumes produce, effectively, greater layer thicknesses [177].

Putorti's study with carpets both indicated large differences between carpet types and also showed that the data could not be represented as a constant layer thickness. The HRR per unit area values are shown in Fig. 26.82. For the solid surface pours, the spill areas were in the range 0.4–1.8 m^2. As presented above, pools of large depths in this size range would show HRR values of 1900–2400 kW m^{-2}. Thus, the carpet-surface values are about 70–80 % of values that would have been computed using the normal pool fire formulas. The smooth-surface values, however, are only about 1/5 of the values that would be found for pools of sizable depths.

A similar study by Gottuk et al. [178] also describes HRR values for spills on hard surfaces that are, very roughly, about 1/5 of those for 'normal' pools. The relationships found by Putorti can only be expected to hold on dead-flat surfaces. If surfaces are crooked, then ponding at low spots will occur and uniform spill depths should never be anticipated.

DeHaan [179] conducted two tests using 1.9 L of Coleman camping fuel. This is a straight-run petroleum distillate containing normal and iso-alkanes ranging from hexane to undecane. When poured on an unpadded carpet, a HRR peak of 1150 was found, with a burning time of roughly 3 min. When poured upon a carpet that had an pad underneath it, a lower HRR peak (890 kW) was found, the peak was slightly delayed (85 s, versus 65 s) and there was a long tail to the HRR curve.

The discussion above pertains only to open-burning fires. Thus, the literature-derived burning rates can be used only in the case of a very large, well-ventilated room (compared to the size of the fire). If calculations show that the 'free-burning' pool would cause a temperature rise of more than, say, 100 °C, then it is clear that radiative feedback will start being important and such an approximation cannot be made. No simple formulas exist for computing the enhanced burning rates when a pool receives significant room radiation. If computations under these conditions are necessary, the theoretical study of Babrauskas and Wickström [11] should be consulted. The computer program COMPF2 [180] can also be used to treat this case.

The problem of pool burning is interesting from a combustion science point of view, and over the years there has been a very large number of studies which attempted to go beyond empirical predictions [181–184]. In addition, work is occurring to provide more detailed experimental measurements for specific fuels [185, 186].

Table 26.22 HRR of European refrigerators

Specimen	R1	R2	R3
Initial mass (kg)	70.0	67.2	43.7
Mass loss (kg)	18.0	14.3	18
Peak HRR (kW)	2125	1816	852
Extinguishment time (s)	925	722	–
Total heat (MJ)	537	404	432

Refrigerators

VTT tested [105] two European refrigerators using a propane burner of 1 kW (designated R1, R2), while EFRA tested a single refrigerator (R3), ignited with a needle-flame burner. The specimens are described in Table 26.22, while test results are shown in Fig. 26.83. The VTT specimens were extinguished before the ultimate peak burning would have occurred, while the EFRA specimen was not. These results must not be applied to appliances used in North America, since European appliance styles are different from North American ones and also because local standards are such as to permit appliances of greater flammability in Europe.

Shop Displays

Chow [187] tested shop displays of three types: clothing display, compact disc (CD) display, and

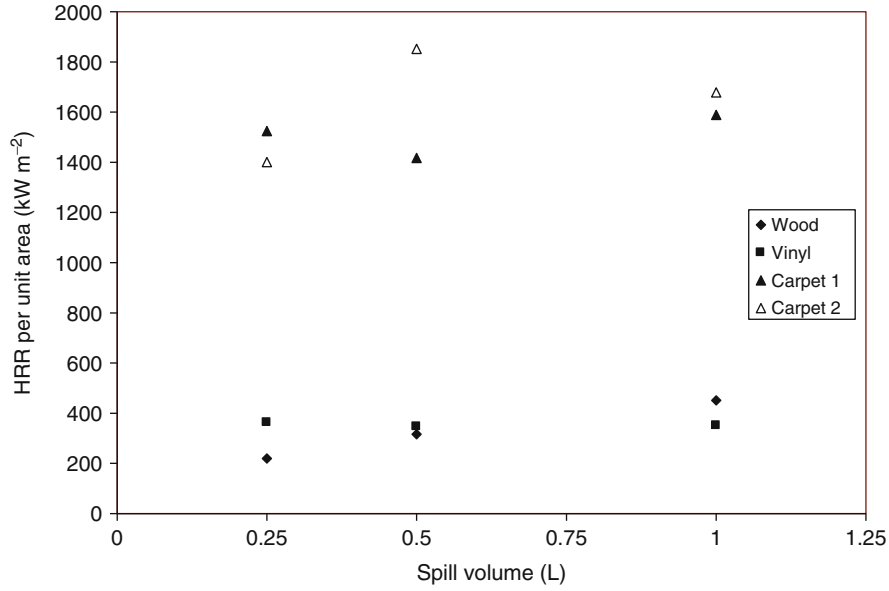

Fig. 26.82 HRR of thin pools of gasoline over various surfaces

Table 26.23 Shop-display commodities tested by Chow

Display type	Combustible mass (kg)	Size (m)	Ignition source (kW)	Peak HRR (kW)
Clothing			470	2400
Compact discs		2 ea, 1.5 m wide × 1.6 m high	1100	
Newsstand	15	2 ea, 1 m wide × 2.2 m high	400	3600

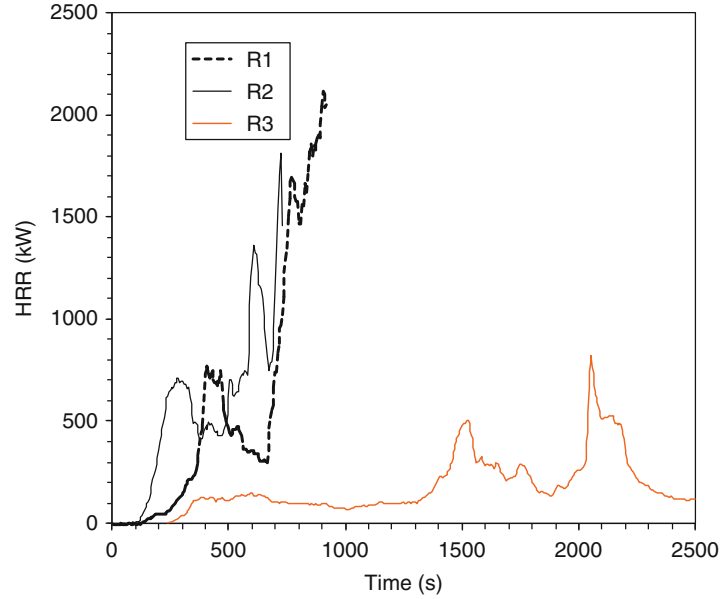

Fig. 26.83 HRR of European refrigerators tested by VTT and EFRA

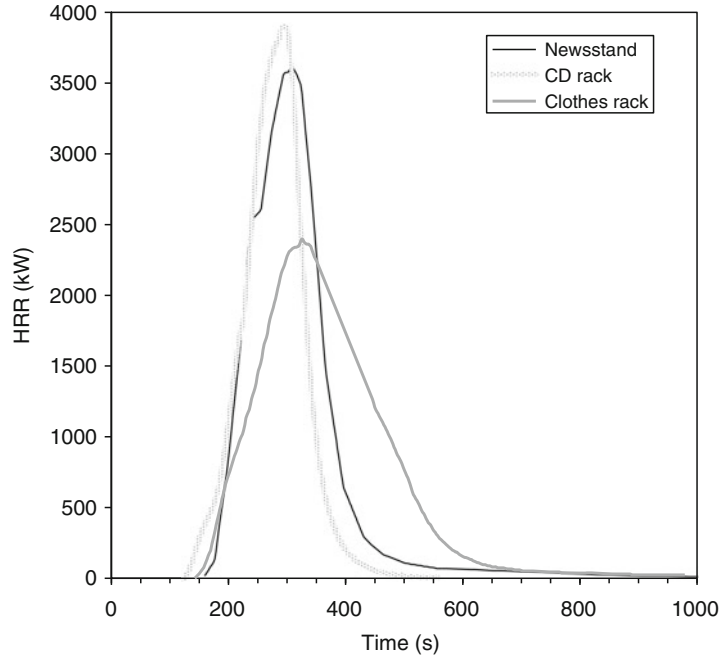

Fig. 26.84 HRR of various shop-display commodities tested by Chow

newsstand. The clothing display comprised all-cotton T-shirts arranged on four small display racks. The CD display contained a total of 240 discs. The ignition source in each case was a small pool of gasoline, to represent an arson fire. The results are shown in Table 26.23 and Fig. 26.84.

Television Sets

The burning characteristics of TV sets depend greatly on whether they have been made for the North American market, following the requirements of UL, or not. In countries where UL standards do not apply, plastic TV cabinets are generally highly flammable, commonly being made of plastics that only have an HB rating according to the UL 94 [30] procedures. These are readily ignitable from small-flame ignition sources and burn vigorously when ignited [44, 188]. By contrast, sets made for the North American market have to obtain a V-0 classification under UL 94 and will resist ignition from small flame sources.

Babrauskas et al. [88] tested at NIST small polystyrene television cabinets of two types, fire-retarded and not. Since the circuit components contribute negligible HRR in comparison to the outer shell, only the cabinets were tested. Two very small ("personal size") units were tested side-by-side in each test. This can represent either two appliances or simply the mass of one larger set.

SP tested two television sets [29], a US-market set with housing having a V-0 rating, and a Swedish set with a housing having an HB rating. The US set was a 690 mm (27 in.) model, while the Swedish one was 710 mm (28 in.). The US set had a total combustible mass of 6.5 kg, with 2.9 kg comprising the enclosure, while the Swedish set had 6.0 and 2.7 kg, respectively. The Swedish set was successfully ignited and burned with a small flame the size of a match flame. The US set resisted ignition from this source and was then subjected to a 10 kW burner. With this challenge, the set burned, but showed little HRR beyond the 10 kW of the source. Finally, the test protocol chosen was a 30 kW burner. The burner HRR was subtracted out from the data shown in Fig. 26.85.

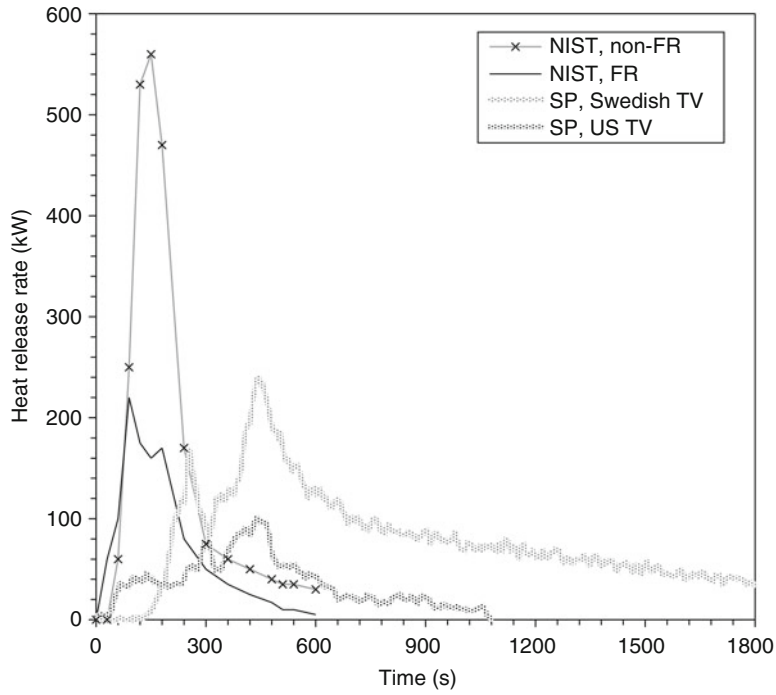

Fig. 26.85 HRR of various television sets tested by NIST and SP

Table 26.24 European televisions tested by VTT

Specimen	TW1	TW3	TP1	TP2	TP3
Type	Wood	Wood	Plastic	Plastic	Plastic
Size (inches)	24	26	28	25	28
Initial mass (kg)	32.7	39.8	31.8	24.4	30.5
Mass loss (kg)	10.2	10.2	5.2	4.6	5.3
Peak HRR (kW)	230	290	274	239	211
Total heat (MJ)	146	150	140	116	137

VTT conducted two projects where TV sets were tested. In the first study [156], they tested two old, 1960s vintage (black-and-white) televisions with large wood cabinets; these were ignited with a small cup of alcohol. In a newer study [105], they tested modern plastic-cabinet televisions using a propane burner of 1 kW. The specimens are described in Table 26.22, while test results are shown in Fig. 26.86. Nam et al. [189] tested a modern TV set (plastic cabinet) together with a wood stand for it. They obtained peak HRR values of 200–300 kW, although the peak took 20–40 min to reach.

The most recent results come from Hoffmann et al. [190] who tested TV sets in a wooden entertainment center. The ignition source was a small amount of alcohol for HB-rated cabinets. For the V-0 rated cabinets, some small consumer goods, HB rated, were first ignited and these were then used to ignite the test TV sets (Tables 26.24 and 26.25). After the initial peak (Fig. 26.87), the burning involved the wood entertainment center, thus the latter portion of these HRR curves is not germane to TV sets per se.

Transport Vehicles and Components

Passenger car HRR was measured at the Fire Research Station [191] and VTT [192]. The FRS laboratory examined a 1982 Austin Maestro and a 1986 Citroën BX, while VTT examined a Ford Taunus, a Datsun 160, and a Datsun 180. The dates of manufacture were only stated as late 1970s. These results are shown in Fig. 26.88. Additional tests were reported by MFPA [193] and SP [194]. MFPA tested a Citroën, a Trabant, and a Renault Espace, while SP tested a Fiat 127 of unspecified vintage. These results are shown in Fig. 26.89. The peak values range

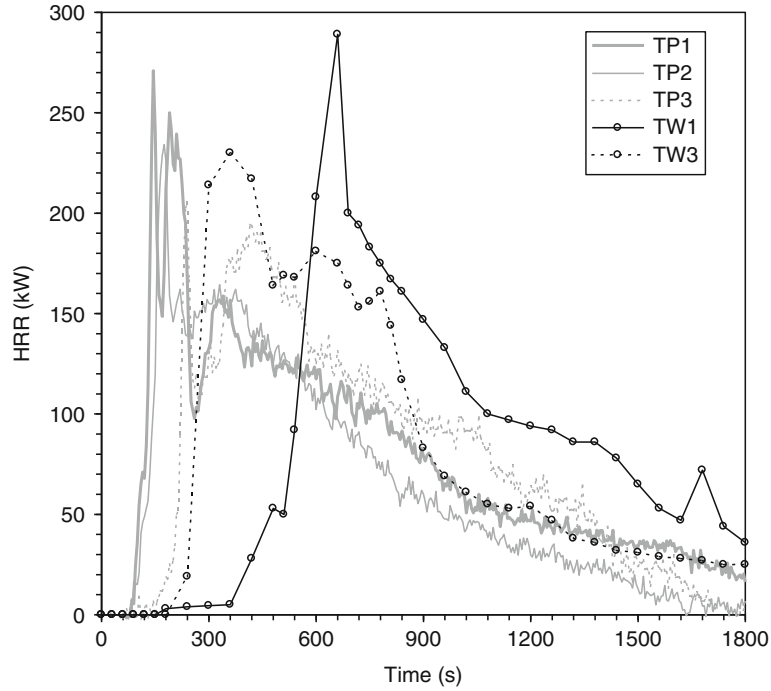

Fig. 26.86 HRR of European television sets tested by VTT

from 1.5 to 8.5 MW. These numbers are rather widely disparate and it is not fully clear why, except that this is not due to the fraction of polymer content onboard.

Some very extensive testing was conducted at CTICM, as shown in Fig. 26.90. Test 2 was a Renault 18 (951 kg), Test 3 a Renault 5 (757 kg), Test 4 another Renault 18 (955 kg), while the specimens for the remaining tests were only identified as a "Large car, 1303 kg" (Test 7), and "Small car, 830 kg" (Test 8). Additional tests were run in a two-car configuration, involving one small car (790 kg) side-by-side to a large car (1306 kg). These results are shown in Fig. 26.91, but test details were not published. The mass loss values are shown in Table 26.26.

Okamoto et al. [195] ran a series of experiments where they tested replicates of the same vehicle (Toyota Cressida, also known as Mark2 GX81) but varied the test conditions (Table 26.27). Figure 26.92 shows the HRR results; spikes judged to be spurious were

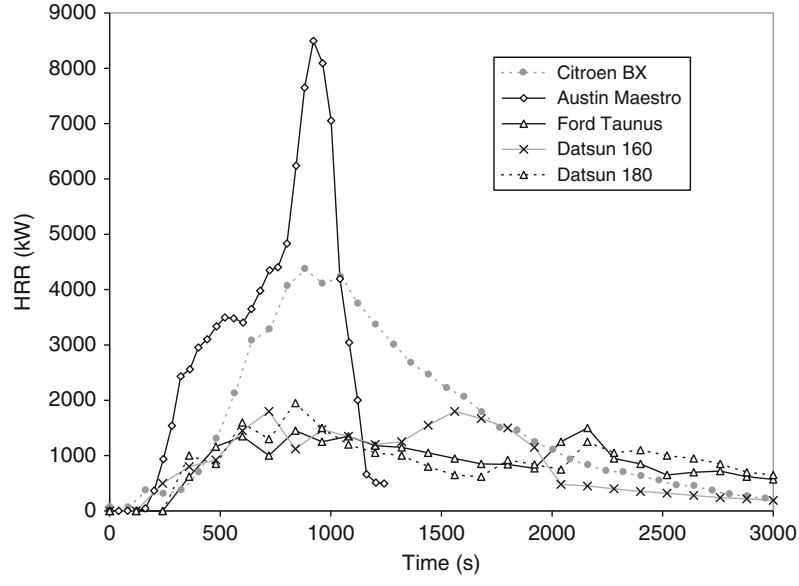

Fig. 26.88 HRR of cars tested at FRS and VTT

removed from these data. In Test B, an explosion occurred at 1517 s, when pyrolysates accumulated in the passenger compartment suddenly ignited. Explosions did not occur with the other tests. The tests are especially valuable since, in their paper, the authors documented many details of fire development in these experiments. The results suggest that small differences in test conditions can affect the time scale of fire development in an automobile quite notably, also that windows should be open if maximum HRR conditions are to be elicited. It

C	Closed	10	Center of the second row seat	–	–
D	Closed, exc. part of left-front window	10	Center of the third row seat	4094	5153

is also noteworthy that the total HR values were nearly identical for all tests.

Okamoto et al. [196] later ran tests on minivan type vehicles, using only one model of vehicle (Nissan Serena), but four different test conditions (Table 26.28). The vehicle weighed 1440 kg and had a 2.0 L gasoline-powered engine. Same as for the sedan vehicles, the HRR development was ragged and not approximately triangular or constant (Fig. 26.93). In Test C, the fire self-extinguished due to dropping oxygen levels since no windows broke.

Ohlemiller and Shields [197] tested a number of individual components from a passenger vehicle (a minivan). The components that has a mass of around 2 kg or less all showed small HRR

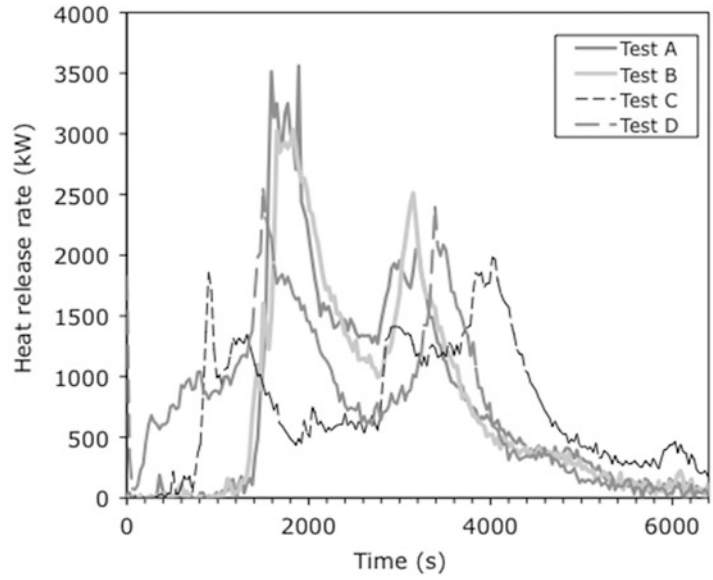

Fig. 26.92 HRR results for automobiles tested by Okamoto et al.

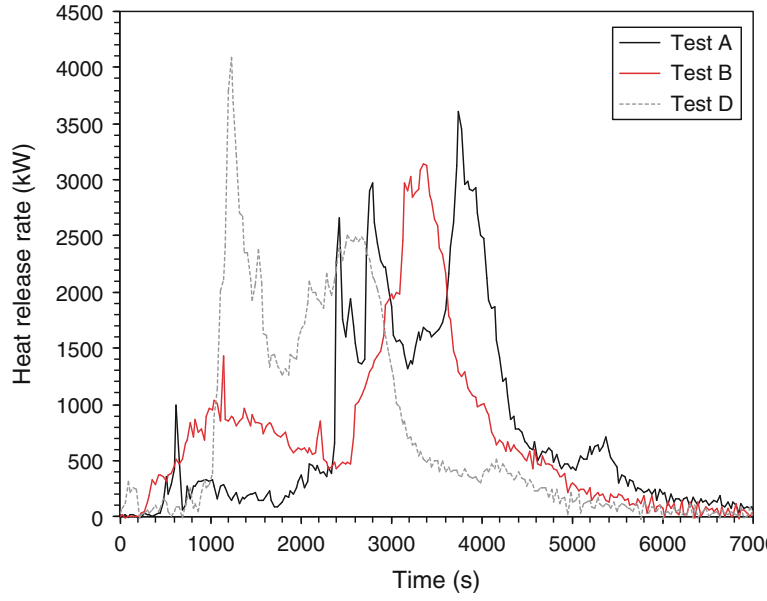

Fig. 26.93 HRR results for minivans tested by Okamoto et al.

values, typically less than 80 kW. Three components, however, showed substantial HRR values—an empty plastic fuel tank (8.5 kg), a passenger seat (8 kg), and an instrument panel (10.6 kg). The HRR curves for these items are shown in Fig. 26.94. In a separate study, Ohlemiller [198] tested one production version of an automotive HVAC unit, along with two experimental versions containing fire-retardant agents. The non-FR version showed HRR in excess of 200 kW, while the FR versions developed only about 5 kW.

Railway car results were reported by SP [197] and by Steinert [198]. Figure 26.95 shows a passenger railway car (European type IC train) reported by SP and an ICE train car by Steinert, who also published the data labeled as "two halves." The latter comprised two half cars, one being aluminum

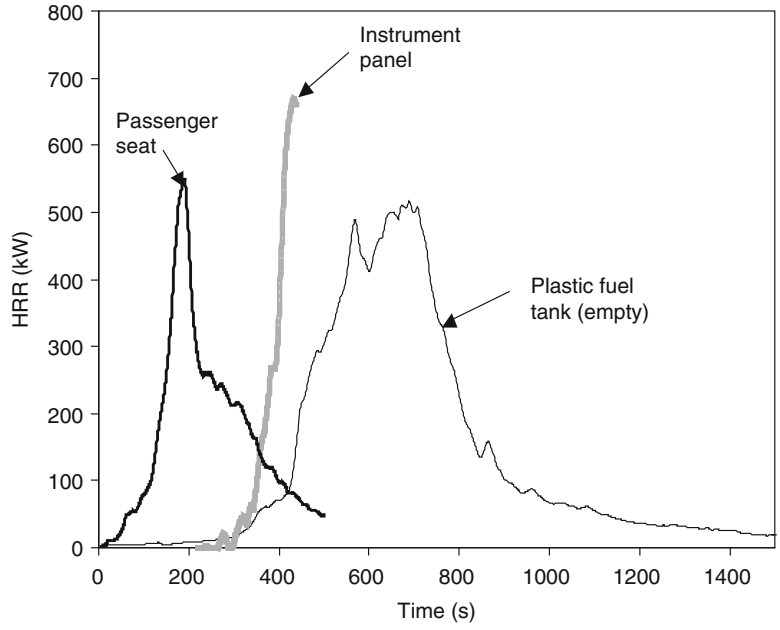

Fig. 26.94 HRR of some larger components from a passenger vehicle

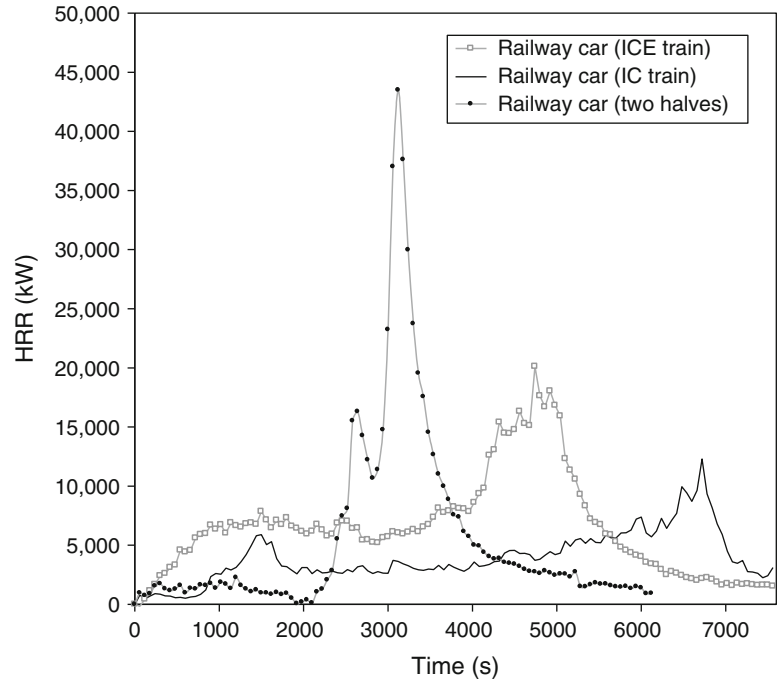

Fig. 26.95 HRR of railway cars

and the other steel. These were abutted to form one test specimen. A fire was ignited in the aluminum car, but did not become rapid until windows failed at around 40 min. SP also reported results on two subway cars [205] and half a tram car [169]; these results are shown in Fig. 26.96. Data on school buses from SP [199] and Steinert [200] are shown in Fig. 26.97.

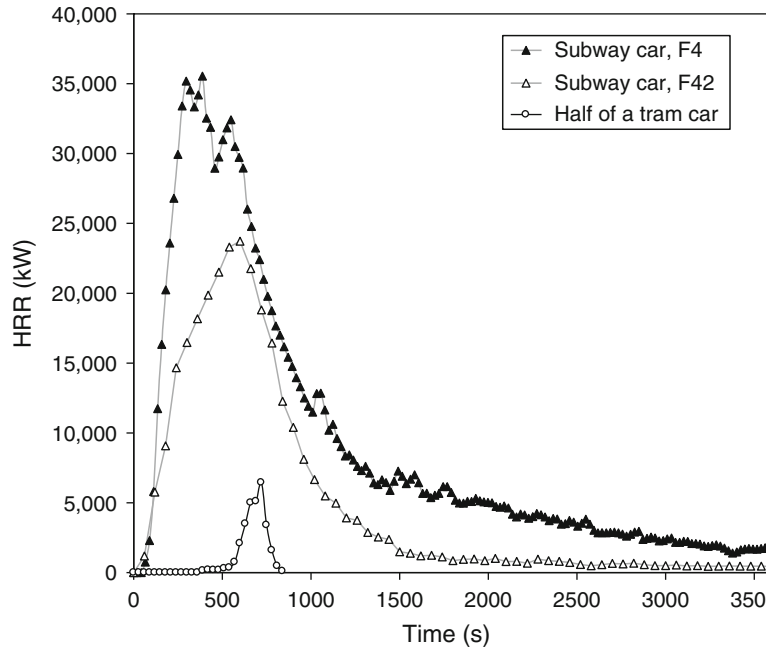

Fig. 26.96 HRR of subway cars and half a tram car

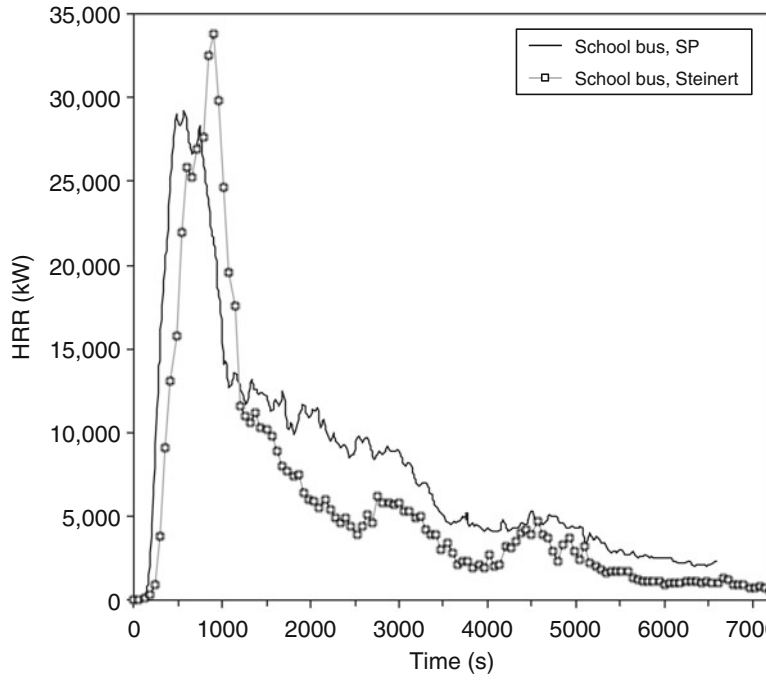

Fig. 26.97 HRR of school buses

A number of researchers have tested portions of various heavy vehicles. Tests on transport seating were done at SP [201]. They measured an array of four double bus seats and a similar arrangement of train seats. The foam was HR polyurethane, while the cover was a viscose/wool/polyester/polyamide blend for the bus seats and 100 % wool fabric for the train seats. These HRR results are shown in Fig. 26.98.

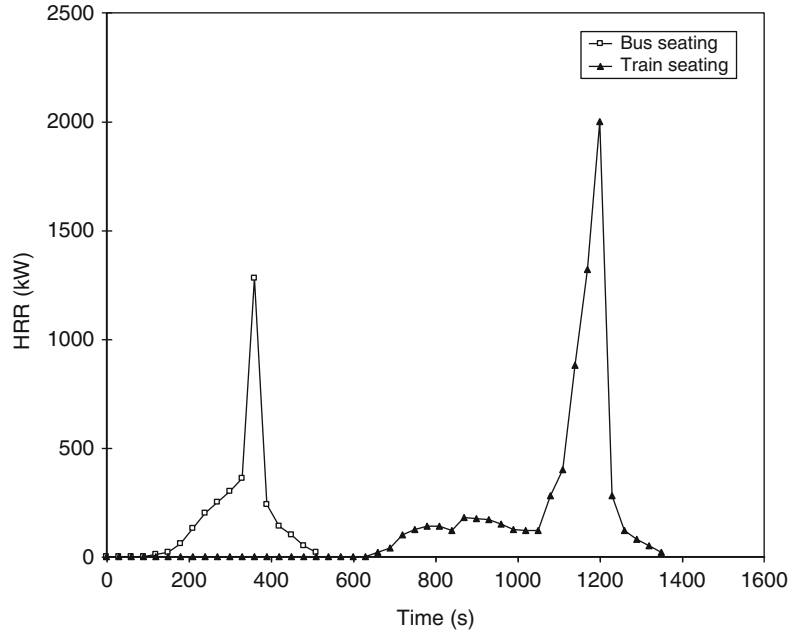

Fig. 26.98 HRR of seating components of heavy vehicles

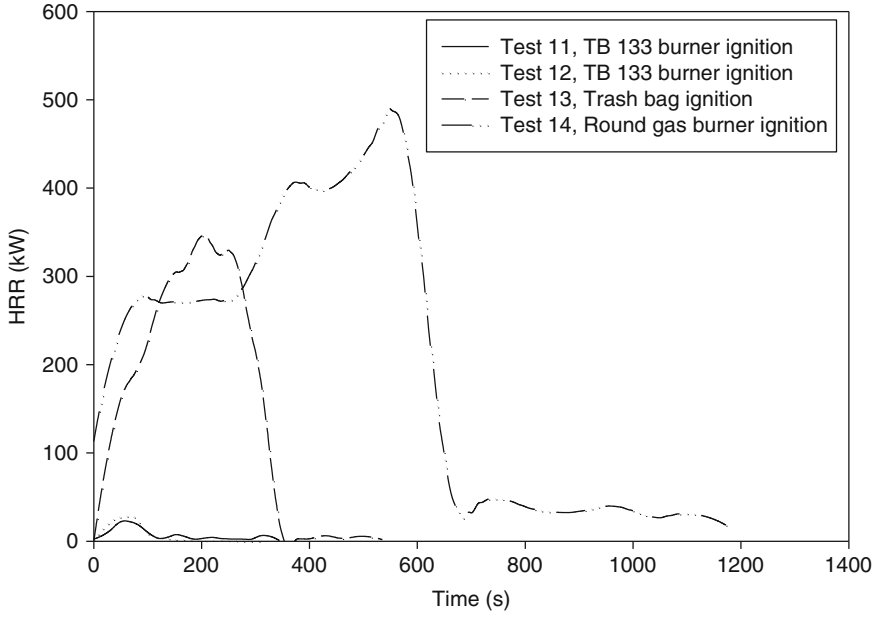

Fig. 26.99 HRR of Amtrak seats (pair), as tested by NIST, exposed to various ignition sources

NIST conducted tests [202] on a pair of Amtrak seats, presented with various ignition sources; these results are shown in Fig. 26.99. In the same research study, NIST also tested sleeping Amtrak berths; these results are shown in Fig. 26.100. Quite high HRR values were seen from Amtrak wall/soffit carpeting tested in the same study (Fig. 26.101). These test specimens were only 1.0 m wide by 1.5 m high for wall carpeting, while the test that also added soffit carpeting had an 0.5 m deep carpeted soffit. Additional test results were obtained for Amtrak

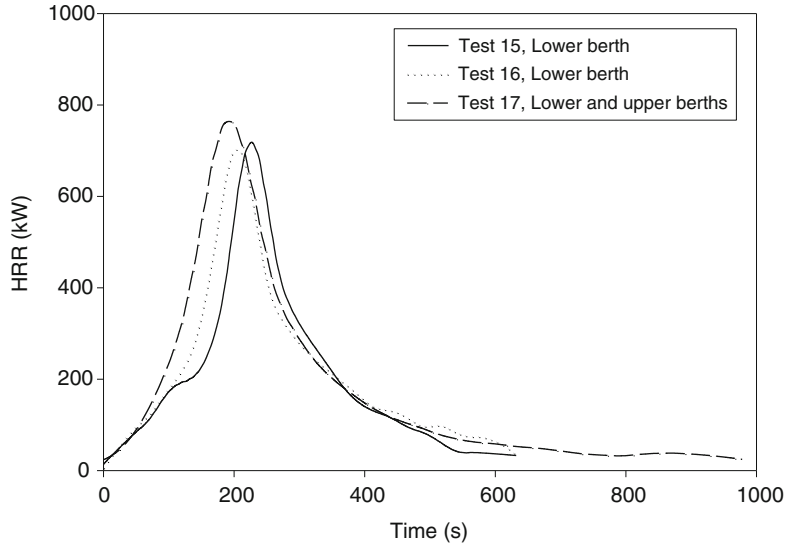

Fig. 26.100 HRR of Amtrak sleeping berths

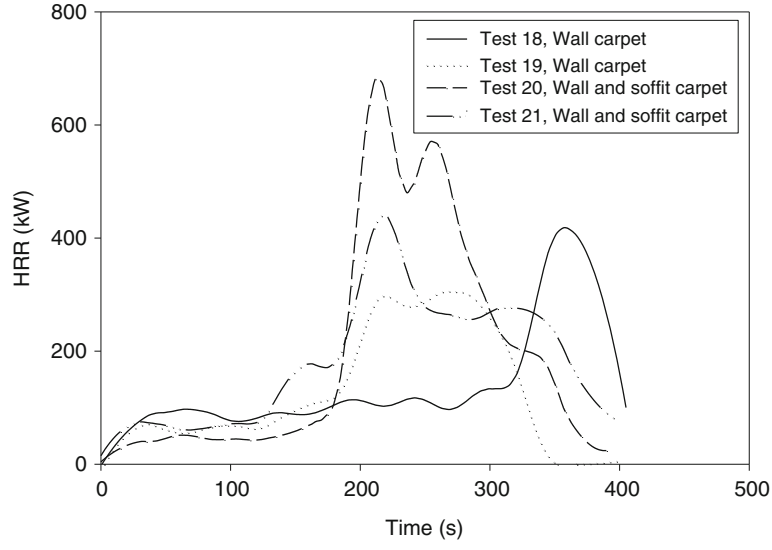

Fig. 26.101 HRR of Amtrak wall carpet and wall/soffit carpet specimens

window drapes (Fig. 26.102) and compartment door privacy curtains (Fig. 26.103). Amtrak window assemblies are made from polycarbonate glazing material and also have polymeric gasketing and trim; these show substantial HRR (Fig. 26.104).

Vehicle tires can ignite from an overheated axle and can release a substantial amount of heat if they burn. There is one study in the literature which documents such a fire. Hansen [203] burned a pair of 285/80 R22.5 truck tires mounted on a tandem wheel arrangement. The HRR curve is given in Fig. 26.105.

Vehicle tires are also prone to be ignited and to burn in tire dumps. The HRR will depend directly on the geometry and on the amount of tires involved. Some quantitative HRR experiments have been reported [204] on experiments done at the Fire Research Station. These experiments were for flaming tires, but most recent tire dump problems have been associated with a smoldering condition and no

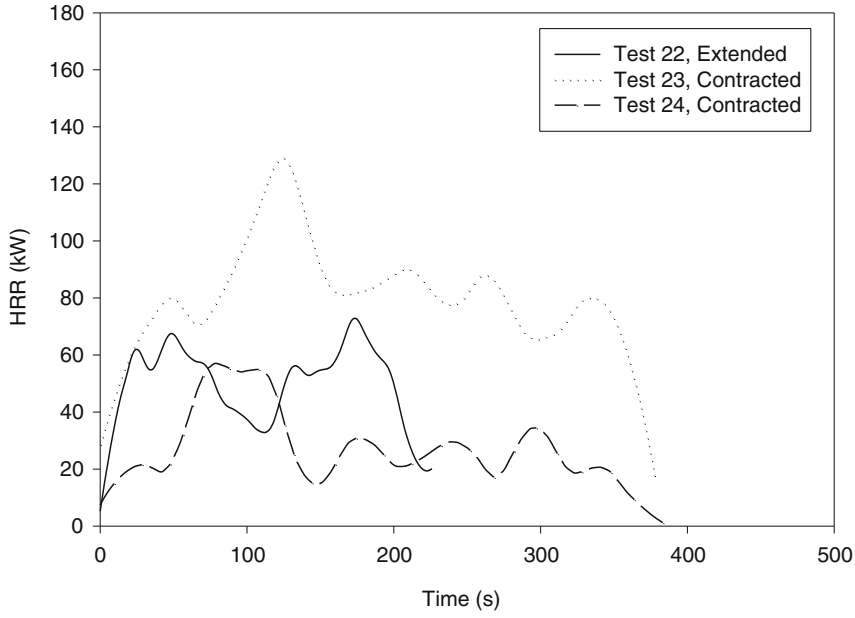

Fig. 26.102 HRR of Amtrak window drapes

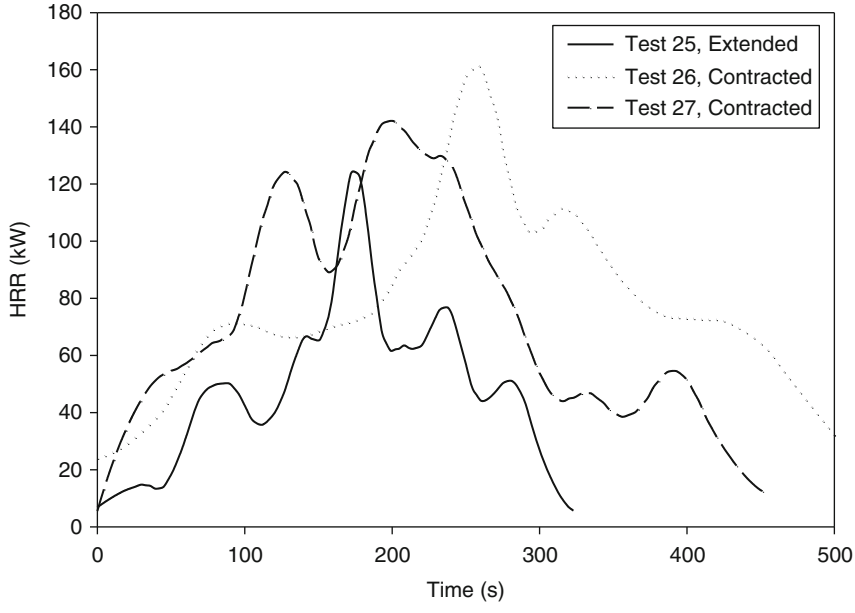

Fig. 26.103 HRR of Amtrak privacy curtains

HRR quantification under these conditions has been reported.

Tests were also reported on two plastic mud guards [205], as used on large tanker trucks. One specimen failed to get ignited from a 100 kW burner, while the HRR for the second specimen is shown in Fig. 26.105. The ignition source was a 100 kW burner, and its HRR has not been subtracted from the results shown.

Table 26.29 Characteristics of the SP Runehamer Tunnel tests

Test	Load	Total mass (kg)	Peak HRR (MW)	Time to peak (s)	Total heat release (MJ)	Fire growth rate during linear-growth period (MW s^{-1})
T1	380 wood pallets, 74 polyethylene pallets	11,010	201.9	1110	242,000	0.335
T2	216 wood pallets, 240 PUR foam mattresses	6,930	156.6	846	141,000	0.438
T3	Mixed goods, comprising plastic and wood furniture, fixtures, and toys; also 10 large tires	8,550	118.6	600	131,000	0.273
T4	600 cardboard cartons with 18,000 polystyrene cups, 40 wood pallets	2,850	66.4	444	57,000	0.282

For heavy-goods vehicles, the heat content of the combustibles being hauled is likely to greatly exceed the heat content of the vehicle itself. Thus, a recent research program at SP conducted by Ingason and Lönnermark [206] ("Runehamer Tunnel tests") characterized the HRR of some typical commodities of this type. Four large-scale tests were conducted (Table 26.29), with the results shown in Fig. 26.106. The commodities were arranged as volume 10.45 m long, 2.9 m wide, and 4.5 m high, but were not enclosed by a trailer body. In many cases, the trailer body is aluminum or tarpaulin, thus nearly-free burning may be expected in such worst-case situations.

For all except T4, the goods themselves were wrapped with polyethylene film. The authors especially noted that the primary period of fire growth in each case, up to ca. 100 MW (66 MW in the case of test T4), was linear and not of a t^2 type. These linear-growth rates are given in Table 26.29. These results are especially noteworthy since they represent the highest HRR fires, of realistic products thus far studied. An earlier European research program [207–209] estimated the HRR of a truck loaded with 2,000 kg of modern upholstered furniture; however, these estimated HRR values, as derived by several investigators, varied widely.

Netted	0.63	Milk cartons	0.41	29	13	3.0
Solid	0.53	Shredded paper	0.20	14	18	7.3
Netted	0.53	Milk cartons	0.41	29	15	5.8

Trash Bags and Containers

Bench-scale measurements of trash are not readily feasible, due to the naturally irregular arrangement of these combustibles. There are full-scale test results available, however, that can suggest appropriate values to be used in different circumstances. A small "bathroom size" (6.6 L) plastic wastebasket stuffed with 12 milk cartons used at NIST as an ignition source in early HRR testing [45] was found to show a HRR of about 50 kW, sustained for about 200 s.

This value evidently represents a worst-case condition, since most researchers have measured significantly lower HRR rates. For example, Mehaffey et al. [210] tested a similar wastebasket filled with mixed paper/plastic fuel load and obtain a HRR curve which can be approximated as being 30 kW for 60 s. NIST [140] tested slightly larger, 8.5 L "office style" round polypropylene wastebaskets, filled with sheets of newspaper, totaling about 300 g of newspaper in a 315 g container. These gave peak HRR values of 28–35 kW and an active burning time of ca. 800 s. Table 26.30 shows some additional data [156], where, over a certain range, increasing packing density is seen to increase the heat release rate. Some typical trash-bag fires are shown in Fig. 26.107 [109].

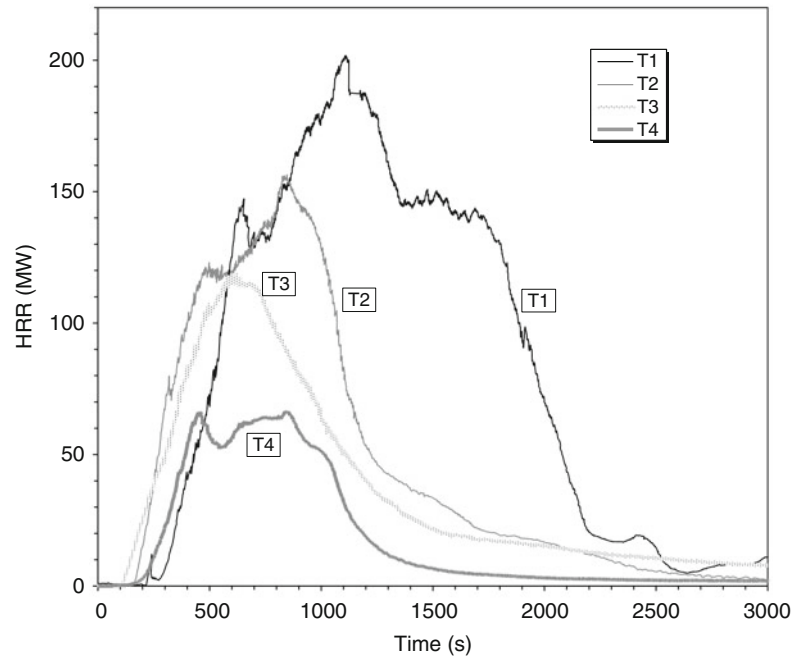

Fig. 26.106 HRR of representative heavy-goods vehicle cargo, as determined in SP's Runehamer Tunnel tests

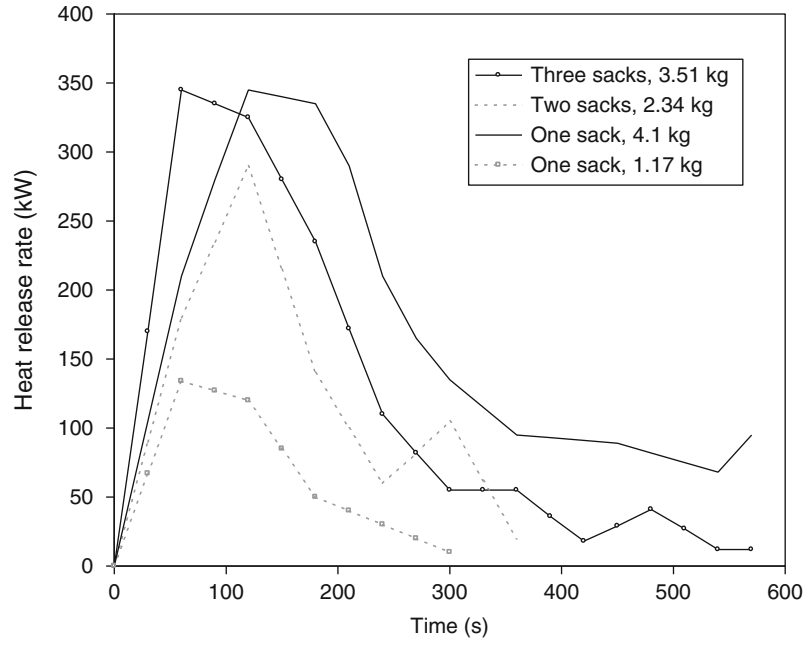

Fig. 26.107 HRR of trash bags

Lee has correlated the peak heat release values according to the effective base diameter and packing density [109]. Figure 26.108 shows that the total burning rate (kW) increases with effective base diameter, but decreases with the tighter packing densities. Figure 26.109, conversely, illustrates that when the results are normalized per unit base area, a downward trend is seen. The correlations according to packing density should only be considered rough observations, and not firm guidelines. For design purposes, the range of 50–300 kW appears to cover the bulk of the expected fires

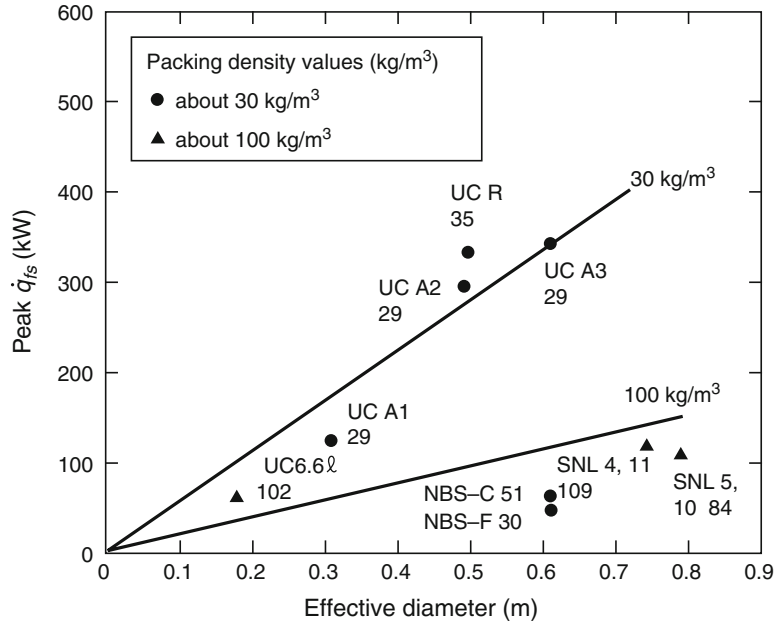

Fig. 26.108 Peak HRR of trash fires

Table 26.31 Peak HRR of small wastebaskets

	Fuel load	
Wastebasket material	PS	paper
Steel	12	8
Polyethylene	50	30
Polypropylene	50	40

from normal residential, office, airplane, or similar occupancy trash bags and trash baskets.

Yamada et al. [102] measured the HRR of 6.5–11.8 L wastebaskets made of steel and plastic and filled with paper and polystyrene foam trash. The peak HRR values found are shown in Table 26.31. The authors concluded that the HRR characteristics could be reasonably well represented by one of two paradigms: (1) 30 kW for 600 s; or (2) 50 kW for 300 s.

NIST conducted tests [200] on trash bags collected from Amtrak overnight trains. The bags were about 450 mm diameter and 800 mm high and were ignited with a 25 kW burner. Test results are shown in Fig. 26.110. Based on these results, NIST researchers endeavored to create a 'standard' trash bag by filling the bag with 110 sheets (2.7 kg) of crumpled newspaper; these results are shown in Fig. 26.111.

NIST also tested [211] 30-gal size (136 L) plastic trash containers made from high-density polyethylene (HDPE) and filled with construction-site debris. The debris included cut pieces of lumber, sawdust, cardboard, paper, cups, food wrappers and pager bags. The containers were 515 mm diameter, 700 mm tall and had a mass of 3.6 kg. The debris totaled 10 kg for each test. Figure 26.112 shows the results for two test replicates.

Tests have been reported on some very large (364 L, 96 gal) polyolefin garbage cans (wheeled, household type) [212]. These were tested empty, and they were ignited with the wood crib specified in UL 1975 [213]. That particular crib weighs 340 g and is ignited with 20 g of excelsior. Three tests were conducted; two gave fairly similar peak HRR values (2383 and 1942 kW), while the third one was much lower at 977 kW (Fig. 26.113). Such variability is typical of polyolefin products, when they are tested in an arrangement where the product can melt and recede from the ignition source.

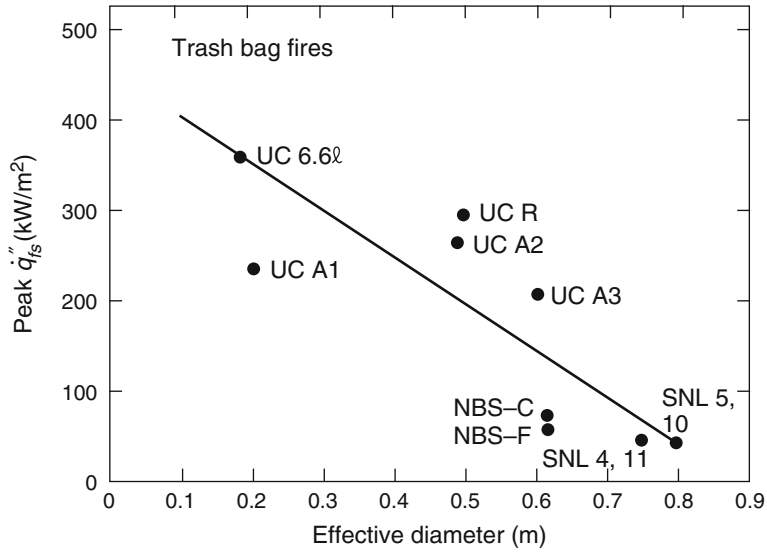

Fig. 26.109 Trash heat release rates, normalized per unit base area

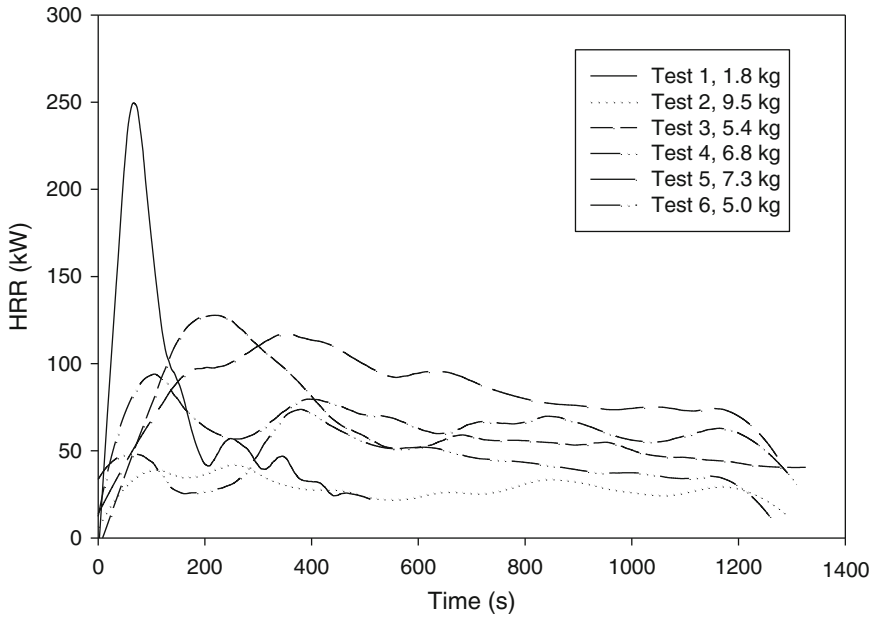

Fig. 26.110 HRR of Amtrak trash bags in NIST tests

Upholstered Furniture

The HRR of upholstered furniture can be determined in three different ways: (1) by room fire testing; (2) by testing in the furniture calorimeter; (3) by conducting bench-scale tests in the Cone Calorimeter and then using a mathematical method to predict the full-scale HRR. Of all the occupant goods that can be found in a normal residence, upholstered furniture normally has the highest HRR, thus knowledge of its performance is essential for many applications.

Until the 1970s, upholstered furniture used to be made from 'traditional' materials. Thus,

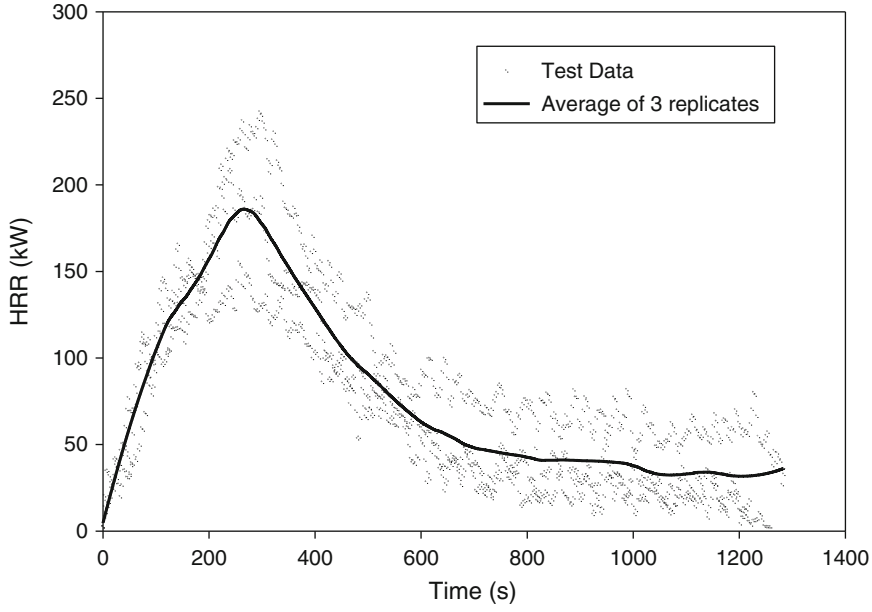

Fig. 26.111 HRR of 'standard' Amtrak trash bag, based on crumpled newspaper

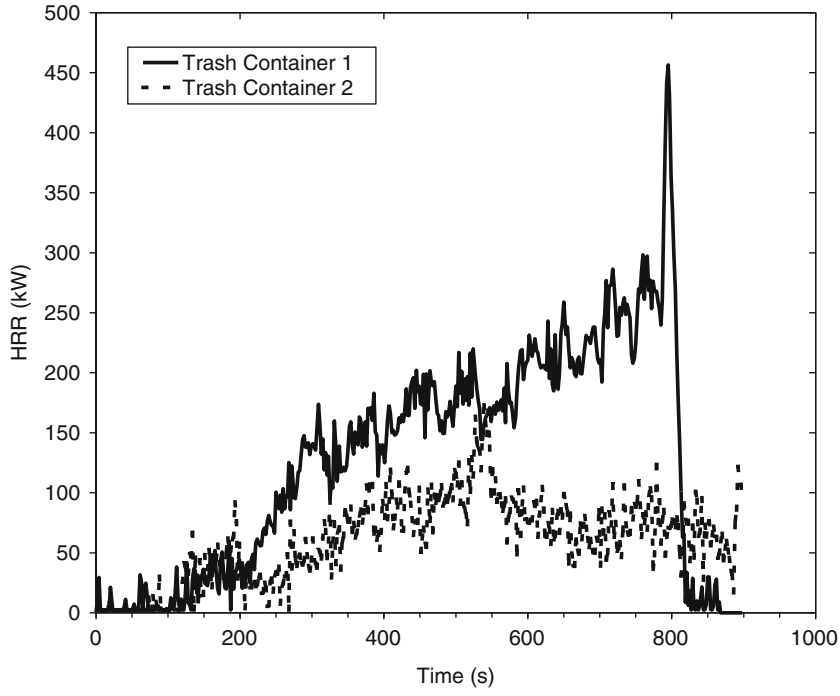

Fig. 26.112 HRR of 136-L HDPE trash containers filled with construction-site debris

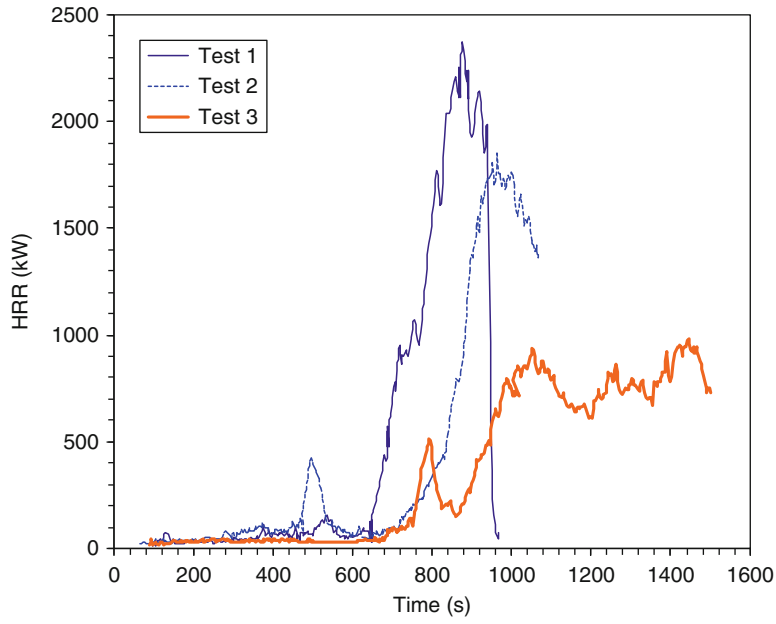

Fig. 26.113 HRR of 364 L (96 gal) PE garbage cans

during the 1950s and 60s, in the US furniture commonly had a wood frame, steel springs, cotton batting padding, and an upholstery fabric which was commonly a natural fiber such as wool, silk, or cotton. A fraction of the furniture used latex foam padding instead of cotton batting. In earlier-yet times, furniture was commonly stuffed with rubberized horse hair. By the 1970s, however, the predominant padding material became polyurethane foam, and fabric selection became very wide, including both thermoplastic synthetics and natural fibers. The HRR of the modern furniture were found to be many times that of traditional types [214], apart from the special case of latex foam. The latter shows HRR values distinctly higher than for polyurethane foam, but the material has a finite life and few specimens would survive to this day.

Figure 26.114 illustrates several furniture items tested at NIST [2]. Chair F21 used polyurethane foam complying with the 1975 California TB 117 standard [215] and polyolefin fabric. A specimen using ordinary polyurethane foam gave essentially identical results. This level of performance represents a very common, but unfortunately worst-performance furniture item widely bought by consumers. Specimen F32 is a sofa made from the same materials. Chair F24 illustrates the large improvement in HRR when cotton fabric is substituted for polyolefin fabric. The peak HRR decreases by about 2/3, from 2 MW to 700 kW. Further improvements, at present, are not readily available on the retail market. Contract furniture can be procured to advanced specifications, however, notably California TB 133 [213]. The latter limits the peak HRR to values less than 80 kW, which will present negligible fire hazard in almost any circumstance.

In the case of the tests discussed above, ignition was from the flame of a 50 kW burner placed at the side of the specimen, representing the burning of a small trash can. Such an ignition source provides the minimum time between ignition and peak HRR. The effect of ignition source on the HRR curve has been found to be almost exclusively that of time shifting—use of smaller flames, non-flaming sources, or placing of ignition sources in less vulnerable locations results in an increase of time to peak HRR (Fig. 26.115), but otherwise does not have a statistically significant effect on the HRR curve [216–218].

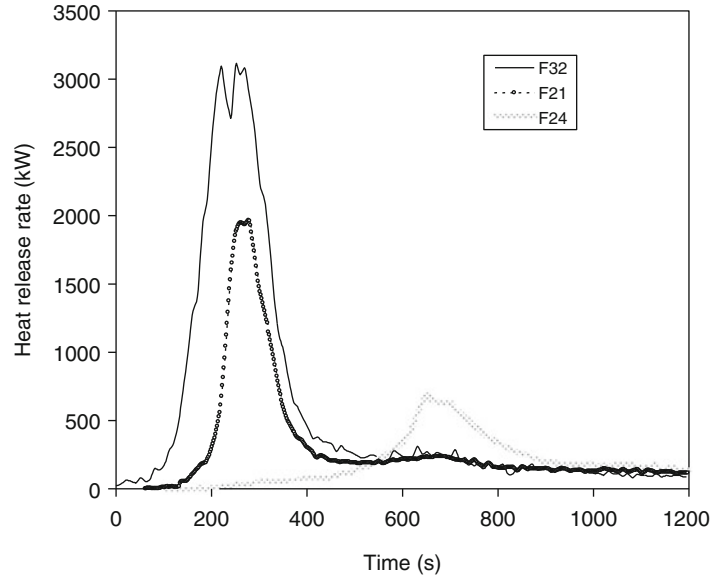

Fig. 26.114 HRR of several upholstered furniture items tested at NIST

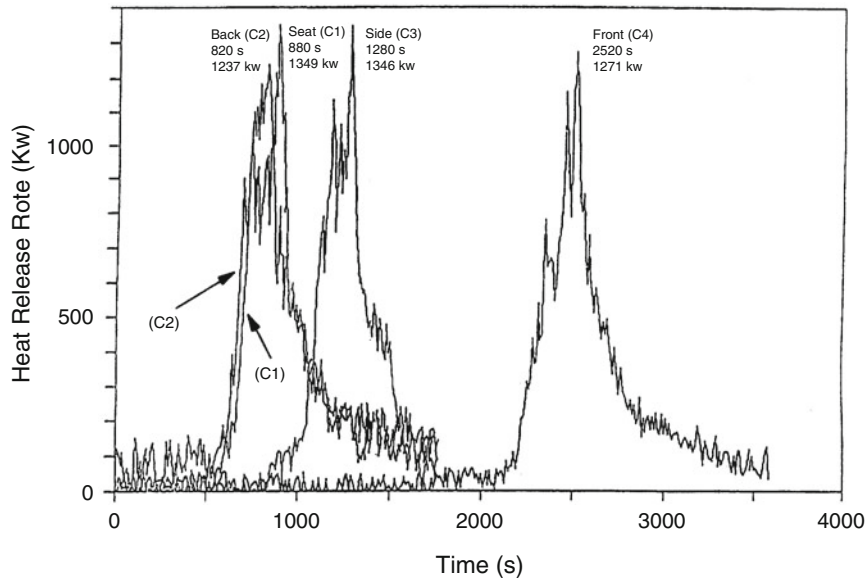

Fig. 26.115 Effect of ignition source location on the HRR curve of upholstered chairs [214]

Foams with fire retardant chemical additives (FR) improve the fire performance only if large loadings are used. Furniture made for the State of California had been required to use FR foams since 1975, but the loading of FR chemicals used was very small (3–5 %). For furniture with a HRR high enough to be a room fire hazard, such minimal FR levels have no effect on HRR [219]. A recent study with a very small ignition source compared the performance of furniture with non-FR foams and with TB117 foams using cotton upholstery [220]. Using specially constructed, non-commercial furniture for testing, no effect was found for three-seater sofas, and an effect was only seen for single-seat chairs. But the latter were of a design where even the

non-FR version showed HRR values so low (approx. 400 kW) as to not comprise a room fire hazard.

Interestingly, the same study reported test results for a large number of commercial chairs and sofas burned for comparison. With few exceptions, the latter showed peak HRR values in the range of 900–2500 kW (Fig. 26.115), indicating that the custom-made furniture was not representative of the retail residential furniture market. Furniture made to the 1975 TB117 standard was actually not intended to have lower HRR values but, rather, to resist small-flame ignitions. However, studies also showed that it was ineffective for that purpose [221]. During recent years, concerns have emerged that the 1975 TB117 standard, while ineffective from a fire safety point of view, resulted in use of noxious chemicals which have been found to have environmental toxicology problems [222]. Consequently, in 2012 the State of California replaced the 1975 TB117 regulation with TB117-2012. The latter is a cigarette-ignition (smolder resistance) test and will not require use of toxic FR chemicals to meet test requirements.

A Cone Calorimeter-based prediction method was proposed by Babrauskas and Walton, based on data obtained in 1982 [223]. This was the earliest effort, and was based on a data set comprising materials primarily from the 1970s. Since that time, the materials in use by the furniture makers changed substantially and, especially, some highly improved materials became available to the contract furniture market. In addition, predictive techniques readily available in the early 1980s were less sophisticated than those developed more recently. Thus, during the course of the European fire research program CBUF, two new predictive models were developed [10, 145]. 'Model I' is a relatively simple model and is described below briefly. A more advanced model was also developed and its details are provided in the above references.

To use the CBUF Model I, Cone Calorimeter data must first be obtained at an irradiance of 35 kW m^{-2}. A well-controlled specimen preparation method is needed, and this is provided in ASTM E 1474 [224]. Then, one determines if the furniture item is likely to sustain a propagating fire, or whether a moderate external flame source will simply result in limited burning and no propagation. This is determined from the 180 s average of Cone Calorimeter HRR results. If $\dot{q}''_{180} < 65$ kW m^{-2}, then no propagation is assumed to occur; otherwise further calculations are made to estimate the peak HRR. The scheme is as follows:

If

$$(x_1 > 115) \; or \; \left(\dot{q}''_{35-tot} > 70 \; and \; x_1 > 40\right) \; or \; (style = \{3,4\} \; \text{and} \; x_1 > 70)$$

then $\dot{q}_{fs} = x_2$

Else,

If $x_1 < 56$

then $\dot{q}_{fs} = 14.4\, x_1$

Else, $\dot{q}_{fs} = 600 + 3.77 x_1$

where $x_1 = (m_{soft})^{1.25}$ (style factor A) $\left(\dot{q}''_{35-pk} + \dot{q}''_{35-300}\right)^{0.7} (15 + t_{ig-35})^{-0.7}$

and the subscript *35* denotes that the Cone Calorimeter HRR tests run at a 35 kW m^{-2} irradiance. The m_{soft} is the mass of the 'soft' = combustible parts of the item (kg); it includes fabric, foam, interliner, dust cover, etc., but does not include the frame nor any rigid support pieces.

And, $x_2 = 880 + 500\left(m_{soft}\right)^{0.7}$(style factor A) $\left(\frac{\Delta h_{c,eff}}{\dot{q}''_{35-tot}}\right)^{1.4}$

Here, $\Delta h_{c,eff}$ is the test-average effective heat of combustion in the Cone Calorimeter (MJ kg^{-1}), and $\dot{q}''_{35-tot}$ is the total heat released

Table 26.32 Style factors used in the CBUF model for predicting upholstered furniture heat release rates

Type of furniture	Style factor A	Style factor B
Armchair, fully upholstered, average amount of padding	1.0	1.0
Sofa, 2-seat	1.0	0.8
Sofa, 3-seat	0.8	0.8
Armchair, fully upholstered, highly padded	0.9	0.9
Armchair, small amount of padding	1.2	0.8
Wingback chair	1.0	2.5
Sofa-bed (convertible)	0.6	0.75
Armchair, fully upholstered, metal frame	1.0	0.8
Armless chair, seat and back cushions only	1.0	0.75
Two-seater, armless, seat and back cushions only	1.0	1.0

at a flux of 35 kW m^{-2}. Another correlation predicts the total heat release:

$$q_{tot} = 0.9\, m_{soft} \times \Delta h_{c,eff} + 2.1\left(m_{comb,\,tot} - m_{soft}\right)^{1.5}$$

where $m_{\mathrm{comb,tot}}$ denotes the total combustible mass of the item (kg), that is, everything except metal parts.

Finally, the time to peak, t_{pk} (s) for the full-scale item is estimated as:

$$t_{pk} = 30 + 4900(\text{style factor B})\left(m_{soft}\right)^{0.3}\left(\dot{q}''_{pk\#2}\right)^{-0.5}\left(\dot{q}''_{trough}\right)^{-0.5}\left(t_{pk\#\,1} + 200\right)^{0.2}$$

where the 'peak' and 'trough' notations refer to the fact that, in the general case, the Cone Calorimeter HRR of furniture composites shows two main peaks and one trough in between them. The style factors are obtained from Table 26.32.

With these values computed, a triangular HRR curve can then be constructed. The peak HRR and the time to peak are given directly, while the base width of the triangle is determined from the calculated total heat release of the furniture item.

Video Games

Edenburn [225] tested the joystick controller from video game console having a plastic enclosure made from ABS (UL 94 V-2 rated). When ignited with a needle flame, the unit showed a peak HRR of 6.7 kW and a total heat release of 2.52 MJ. HRR results for the main portion (console) were not provided.

Wall/Ceiling Lining Materials

Combustible interior finish materials are substantially more difficult to treat than free-standing combustibles. They cannot be measured in a device such as the furniture calorimeter, and require any full-scale study to be a room fire. The materials cover a large area, but the area of active flame involvement is generally not predictable, except after flashover, when in many cases it can be assumed that all surfaces are involved. In the early 1980s, a series of wall materials was studied by Lee at NIST [15] in full-scale room fires, and also in bench-scale, with the Cone Calorimeter. This work comprised the first attempted correlation between bench scale and full scale for wall lining materials. For several materials in the test series, which included both cellulosics and plastics, it was found that, after flashover, the per-unit-area full-scale heat release rates, were approximately

the same as the values obtained from the Cone Calorimeter. Lee's work did not yet lead to a predictive method, since no technique for estimating the flame-covered area, A(t) was found.

At about the same time, Babrauskas found that full-scale fire development on wall/ceiling linings could be approximated [226] by the expression $\dot{q}''_{bs-pk}/t_{ig}$, where the HRR value and the ignition time were obtained from the Cone Calorimeter. The $1/t_{ig}$ factor effectively represented the growth of A(t), but such a scheme was only semi-quantitative.

The first successful quantitative method came with the work of Wickström and Göransson in 1987 [227]. The model was based on the premise that the full-scale scenario involves the combustible materials located on the walls and ceiling of the ISO 9705 room. Note that the same material is expected to be placed on both walls and ceiling. The model uses the principle of area convolution and elaborates on Babrauskas' assumption that $1/t_{ig}$ controls the growth of the burning area. The model was later extended and extensively validated in the European research program EUREFIC, EUropean REaction to FIre Classification [228]. The primary assumptions in the model are:

1. The burning area growth rate and the HRR are decoupled.
2. The burning area growth rate is proportional to the ease of ignition, i.e. the inverse of the time to ignition in small scale.
3. The history of $\dot{q}''$ at each location in the full scale is to be the same as in the Cone Calorimeter test.

The model pays mind to the observation that burning patterns on wall/ceilings can be very different and, especially, that some products stop spreading fire under certain conditions, while others continue. The basic area growth regimes are illustrated in Fig. 26.117, where the regimes are marked in Roman numerals. The fire spread may follow three different routes. At points 'A' and 'B' fire spread may or may not continue, based on whether a calculated fictitious surface temperature is higher than a critical value. The calculation is based on data from the Cone Calorimeter. Within the different flame spread regimes, the burning area growth rate depends on ignitability, i.e. time to ignition in the Cone Calorimeter. Once the flame spread rate

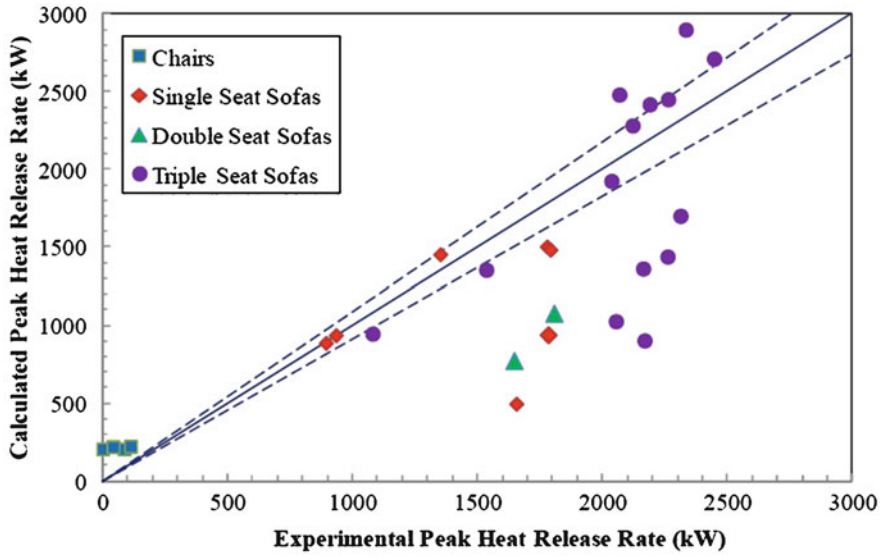

Fig. 26.116 SwRI test results on commercial residential furniture showing that peak HRR values are primarily in the range of 900–2500 kW

is determined, the HRR is calculated assuming that $\dot{q}''$ is the same in small and large scale. This is understood to be a simplification. The HRR depends on the actual heat flux level received by the product as a function of time. Experience showed, however, that the errors average out and can be included in empirical constants. The method is only of moderate difficulty to apply, but the description is somewhat lengthy. Details are available [23]. This reference also contains graphs illustrating the kind of agreement that is obtained between predictions and experiments.

While highly successful for its intended purpose, the EUREFIC model does have notable limitations. It:

- Can only treat the standard ISO 9705 room, with the standard doorway for ventilation
- Only predicts the ISO 9705 100/300 kW burner
- Requires that the material be on both walls and ceiling
- Cannot deal with products that do not ignite in the Cone Calorimeter at a 25 kW m^{-2} irradiance.

It must be remembered that the primary purpose for developing this model was to predict product performance categories to be obtained in the ISO 9705 test, while only using bench-scale Cone Calorimeter data. For its intended purpose, it has been an unquestionable success.

The above limitations indicate that the EUREFIC model, while a major breakthrough, was certainly not the final answer to modeling needs for wall/ceiling products. Two extensions have been proposed to generalize the applicability of this model. Göransson, one of the developers of the EUREFIC model, proposed an extension [229] to encompass a 'huge-scale' room. Such a test room was constructed at VTT. Its dimensions were 6.75 m by 9.0 m, with a ceiling height of 4.9 m. The door opening, 0.8 by 2.0 m high, however, was the same as for the ISO 9705 room. The burner operation was at the 100 kW level for 10 min, then at 300 kW for another 10 min, finally at 900 kW for 10 more minutes. An extended model was created for this situation by introducing a new set of regimes to correspond to the 900 kW burner level. In addition, it was found that the constant had to be modified for the 100 and 300 kW time periods. The agreement between model and prediction was very good, but only five tests were available for validation at the huge scale.

A second extension was developed by Sumathipala and coworkers [230, 231]. This model extends the applicability to the case of the room fire test studied by Lee [15]. The dimensions of that room are almost identical to the ISO room. The differences arise because (a) the two burner regimes are 40 and 160 kW, (b) the burner face size is different, and (c) the product is normally mounted on walls only, rather than walls and ceiling. The authors, however, in their development work, included tests of both rooms in both mounting configurations. The success of these extension confirms that the basic ideas behind the EUREFIC model are sound and can potentially have flexibility. On the other hand, it must be borne in mind that even the extensions are 'hard-wired' configurations and do not yet approach a technique which could be applicable towards user-selected room sizes, burner levels, and product configurations.

Perhaps the most ambitious model so far for wall/ceiling products has been one developed by Karlsson and coworkers [232–234]. Karlsson's model incorporates much more of current concepts of plumes, flame length calculations, ceiling jets, and similar constructs than does the EUREFIC model. The model has the same 'hard-wired' limitations that the EUREFIC model has in terms of ignition sources, product configuration, and room size being fixed. Another wall/ceiling model was developed by Quintiere and Cleary [235–237] and extended by Janssens and coworkers [238].

Wardrobes

Information on the HRR of wardrobes is available from a NIST study [239]. The test wardrobes are illustrated in Fig. 26.118; data

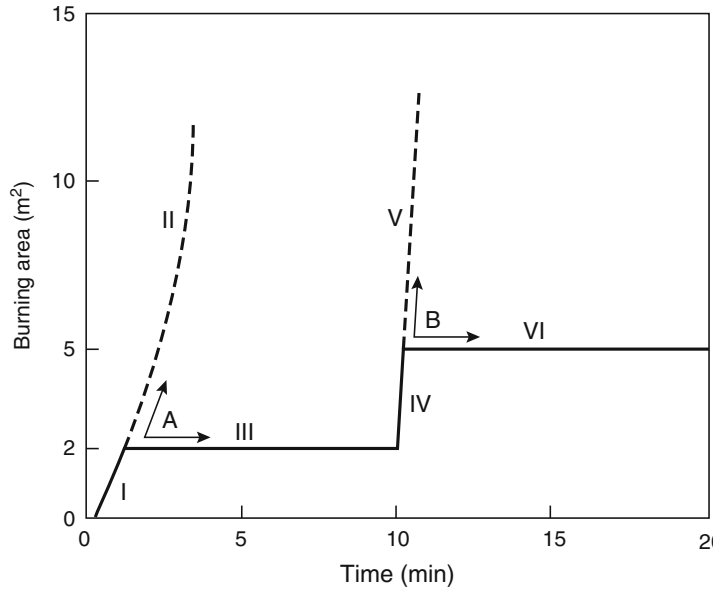

Fig. 26.117 EUREFIC fire spread regimes

Table 26.33 The HRR properties of wardrobes

Test No.	Construction	Wardrobe combustible mass (kg)	Clothing and paper (kg)	Peak HRR (kW)	Total heat released (MJ)	Avg. heat of combustion (MJ kg^{-1})
21	Steel	0	1.93	270	52	18.8
43	Plywood, 12.7 mm thick	68.3	1.93	3100	1068	14.9
41	Plywood, 3.2 mm thick, unpainted	36.0	1.93	6400	590	16.9
42	Plywood, 3.2 mm thick, 1 coat FR paint	37.3	1.93	5300	486	15.9
44	Plywood, 3.2 mm thick, 2 coats FR paint	37.3	1.93	2900	408	14.2
61	Particleboard, 19 mm thick	120.3	0.81	1900	1349	17.5

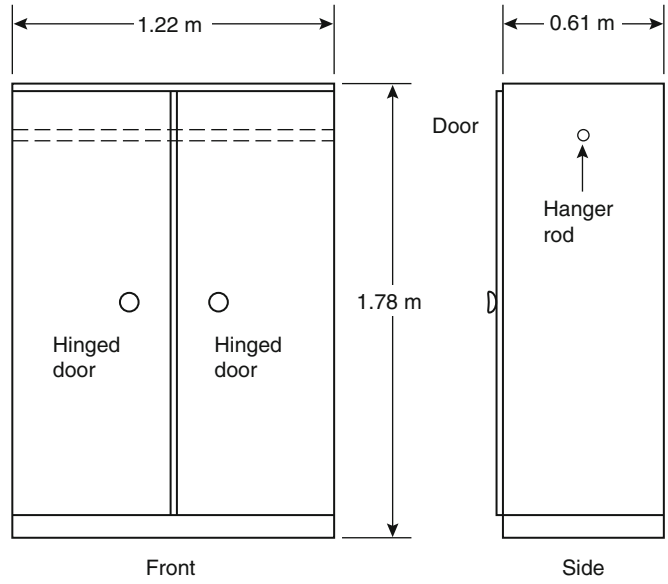

Fig. 26.118 Configuration of the tested wardrobes

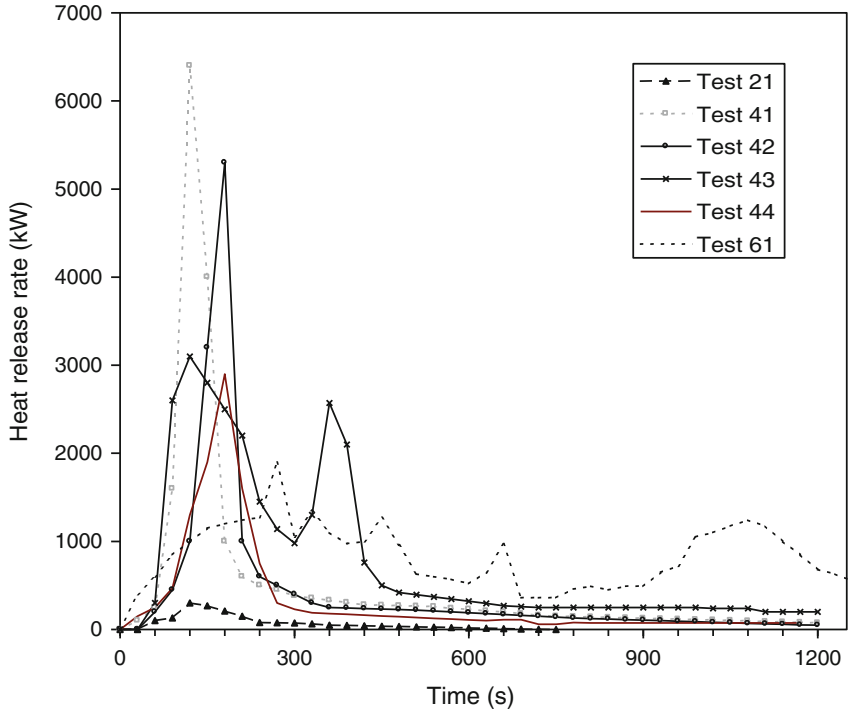

Fig. 26.119 HRR of various wardrobes

Table 26.34 European washing machines tested by VTT

Specimen	W1	W2	W3
Ignition source (kW)	1	1	300–550
Initial mass (kg)	69.3	69.9	63.3
Mass loss (kg)	10.1	10.4	12.3
Peak HRR (kW)	345	431	221
Total heat (MJ)	259	245	383

are given in Table 26.33 and Fig. 26.119. The wardrobes were outfitted with a small amount of clothing, or simulated clothing, and some paper. Tests were not run on the clothes items by themselves. However, since in the case of the steel wardrobe, the only other combustible present was the paint on the metal, it is reasonable to assign a value of about 270 kW peak for the 1.93 kg clothes load. The most important conclusion, however, was that, for combustible constructions, the peak HRR is inversely dependent on wardrobe panel thickness (and, by contrast, no simple connection to combustible specimen mass is seen). Thus, while the total heat content of the 19 mm particleboard specimen is high (see Table 26.33), its peak HRR is quite low, since flame spread and fire involvement proceed more slowly over a thick material (Fig. 26.120).

Washing Machines

VTT tested [105] European washing machines. The specimens are described in Table 26.34, while test results are shown in Fig. 26.120. The specimens were extinguished before the ultimate peak burning would have occurred. These results must not be applied to appliances used in North America, since European appliance styles are different from North American ones and also because local standards are such as to permit appliances of greater flammability in Europe (Fig. 26.120). HRR data on North American washing machines are not available.

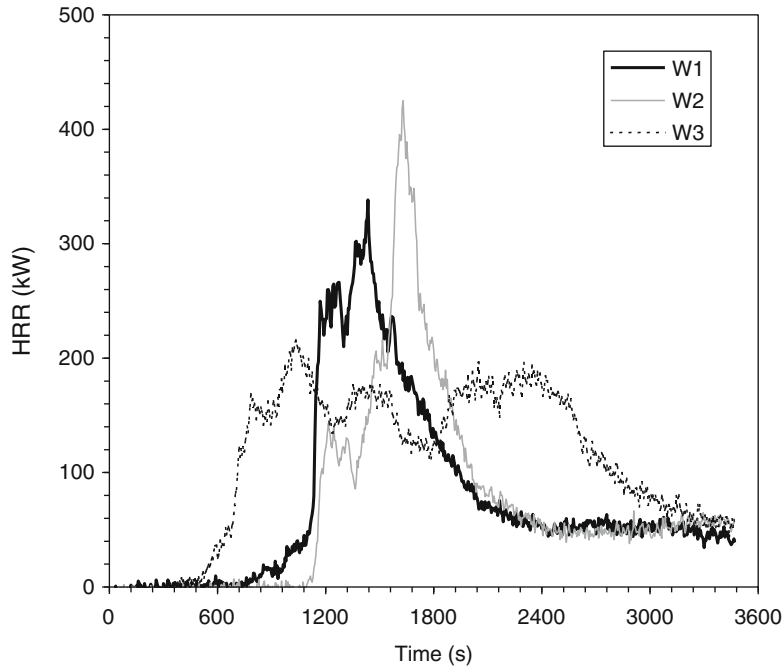

Fig. 26.120 HRR of European washing machines tested by VTT

Windows, Plastic

In applications where vandal resistance is needed, polycarbonate windows are sometimes used. This material is combustible, and limited testing was reported by Peacock et al. [240]. The tests indicated that it is hard to derive an 'innate' HRR value. The windows do not burn unless a sustained flame or heat source is applied. In that case, the HRR of the product increases with increasing severity of the ignition source. For a 50 kW exposure source, a test window showed an additional 50 kW HRR, with a burning time of ca. 80 s. For a 200 kW exposure source, the window peak HRR was about an additional 250 kW, but with a longer duration of about 200 s, at progressively diminishing HRR values.

Estimating the HRR for General Combustibles

The previous edition of the Handbook suggested a hypothetical method for estimating the HRR for general combustibles. This was based on some very simplified assumptions, especially that flame spread could, in the first approximation, be ignored. Further experience gained with additional classes of combustibles, as discussed above, suggests that such a condition will only very rarely hold. Furthermore, the user has no way of knowing when it might hold. Thus, prudent design practice should now demand that first recourse be made to the specific sections above which may address the modeler's needs. If they do not, then testing is indicated. For the modeler wishing to start up a major research activity, the schemata outlined for upholstered furniture, mattresses, and wall/ceiling lining should serve as illustrations of appropriate starting points in theory and practice. It must be pointed out, however, that such research programs have proven to be complex and that quick or inexpensive results cannot be expected.

Uncertainty of HRR Measurements

As in any engineering measurement, uncertainty in HRR measurements can be subdivided into:
1. Bias,

Table 26.35 The 95 % confidence limits for HRR test apparatuses as determined from recent round robins

				Peak HRR		Total HRR	
Apparatus	Year	Labs	Levels	r (%)	R (%)	r (%)	R (%)
Cone calorimeter	2000	4	16	17	23	8	15
ICAL	1999	3	8	56	67	72	118
SBI	1997	16	30	38	54	47	71
Room calorimeter	1994	12	5	65	79	25	41

2. Random error, sometimes termed 'precision uncertainty.'

Bias is properly minimized by use of calibration standards; for HRR testing this often comprises a metered flow of a calibration gas of high purity. Another source of bias that can be minimized, when appropriate, is specific to oxygen-consumption calorimetry bases measurements. For most testing, a standard oxygen consumption constant value of 13.1 MJ per kg of oxygen consumed is used. A small number of substances of fire-safety interest show oxygen consumption constants substantially different from this standard value. If the molecular composition of the substance is known, a correction can always be made to eliminate this source of bias.

Most of the instruments in which the HRR measurements are made have been subjected to round robins ("inter-laboratory trials") to quantify the magnitude of random error that can be expected. Comparative values have been compiled by Janssens [241], as shown in Table 26.35. For a number of them, several round robins have been conducted, thus the data shown are identified by year. SBI denotes the European Single Burning Item test [242], which is a regulatory HRR test for building products that uses two wall panels in a corner configuration, without ceiling. The values tabulated refer to the 95 % confidence intervals; standard deviations can be obtained by dividing the figures shown by 2.8.

Calorimetry

27

Marc Janssens

Introduction

Heat release rate is the single most important variable in fire hazard assessment [1]. Various test methods for measuring the heat release rate of materials and products under different conditions have therefore been developed. This chapter is dedicated to these test methods. An apparatus used for measuring heat release rate is referred to as a *calorimeter* and the measurement of heat release rate is called *calorimetry*.

The importance of heat release rate in fire hazard assessment was first recognized in the early 1970s by Smith at Ohio State University [2]. Smith and coworkers developed one of the first small-scale test methods for measuring the heat release rate of planar products exposed to radiant heat [3]. They also proposed various procedures to assess compartment fire hazard on the basis of the small-scale data. These procedures ranged from simple calculation methods [4] to a relatively complex computer model [5]. This work was initiated at a time when the most accurate measuring techniques for heat release rate were not available and when computer fire modeling was still in its infancy. Moreover, Smith advocated a practical approach based on engineering judgment rather than detailed science. Hence, his test and fire hazard assessment methods were far from perfect and received major criticism [6, 7]. Nevertheless, Smith deserves recognition as one of the pioneers of heat release rate calorimetry.

With compartment fire hazard assessment as the primary application, there is a need for high-quality heat release rate data and, consequently, for devices and methods to measure it accurately. The first of two basic approaches to assess the fire hazard of a material consists of an experimental evaluation in full scale. Typically, this approach requires multiple large-scale fire tests covering all relevant fire scenarios and end-use conditions. The second option is the use of small-scale data, primarily heat release rate, in conjunction with a calculation procedure to estimate full-scale fire performance. The second approach is significantly more versatile, and time- and cost-effective. With the continuous improvement of the predictive capability and accuracy of fire models and calculation methods, the latter has become the preferred approach.

This chapter begins with a brief discussion of the oxygen bomb calorimeter, which is used to measure the maximum amount of heat that can be released from combustion of a material. The oxygen bomb calorimeter has significant limitations. For example, materials and products are not evaluated under realistic fire conditions. Also, the total heat released is measured as opposed to the heat release rate as a function of time, that is, no information is obtained concerning the dynamic behavior of the material.

Various heat release tests have been developed to address these limitations. These test methods all rely on one of four measuring techniques, which are described in detail in the next section. This is followed by a discussion of the effect on the measurements of various small-scale calorimeter features and construction details. In the next section a brief description is provided of commonly used calorimeters ranging in size from small to industrial scale. The chapter concludes with a discussion of the use and application of heat release rate data and a section on uncertainty of heat release rate measurements.

Oxygen Bomb Calorimetry

Oxygen Bomb Calorimeter Test

The maximum amount of heat that can be released during combustion of a material can be determined in an oxygen bomb calorimeter. An oxygen bomb calorimeter consists of a sealed stainless steel container (the "bomb") in which a small quantity of material (approximately 1 g) is combusted at high pressure (30 bar) in pure oxygen (Fig. 27.1). The heat released is measured on the basis of the temperature rise of the surrounding water vessel (adiabatic method) or the heat loss needed to keep the water temperature constant (isoperibol method). Standard procedures for measuring the gross heat of combustion of solid materials are described in ASTM D5865 and ISO 1716.

The building and life safety codes promulgated by the National Fire Protection Association (NFPA) make a distinction between noncombustible and limited combustible materials. Limited combustible materials must have a potential heat of 8.2 MJ/kg or less as determined by NFPA 259, *Standard Test Method for Potential Heat of Building Materials*. According to this method, the potential heat of a material is determined as the difference between the gross heat of combustion of the material measured with an oxygen bomb calorimeter and the gross heat of combustion of its residue after heating in a muffle furnace at 750 °C for 2 h.

Fig. 27.1 Oxygen bomb calorimeter

Gross Versus Net Heat of Combustion

The gross heat of combustion of a solid or liquid fuel is measured in an oxygen bomb calorimeter as described in the previous section. Because the cooling water temperature remains close to ambient during a test, all water vapor generated in the combustion process fully condenses. The measured gross heat of combustion therefore includes the heat released due to condensation

of the water vapor. In practice, combustion products are usually removed from the system at a temperature above the dew point. It is therefore more realistic to quantify the potential heat released in a fire assuming that all water vapor remains in the gaseous state. The corresponding heat released per mass unit of fuel burnt is referred to as the net heat of combustion. It is equal to the gross heat of combustion measured in an oxygen bomb calorimeter minus the heat of vaporization of the water in the products of combustion, which is a function of the moisture and hydrogen content of the fuel:

$$\Delta h_{c,\text{net}} = \Delta h_{c,\text{gross}} - (8.936 Y_H + Y_W)\Delta h_v \tag{27.1}$$

where

$\Delta h_{c,\text{net}}$ = Net heat of combustion (kJ/g)
$\Delta h_{c,\text{gross}}$ = Gross heat of combustion (kJ/g)
Y_H = Mass fraction of hydrogen in the fuel (g/g)
Y_W = Moisture content of the fuel (g/g)
Δh_v = Latent heat of vaporization of water (2.442 kJ/g at 25 °C)

ASTM has developed test standards to determine the moisture content and hydrogen content in a variety of solid fuels, e.g., ASTM D3173 and ASTM D5373, respectively.

The gross heat and net heat of combustion are usually reported at a standard temperature of 25 °C. Gross heat and net heat of combustion values for a wide range of materials can be found in Appendix C, "Fuel Properties and Combustion Data."

Techniques for Measuring Heat Release Rate

The development of the oxygen consumption technique in the late 1970s was a major breakthrough in the accurate measurement of heat release rate in fire tests. Inferior methods had been used prior to that. The most practical of the older methods is still used today for applications that do not require the highest accuracy. The older methods and the oxygen consumption technique (and the related carbon oxide generation technique) are described in this section.

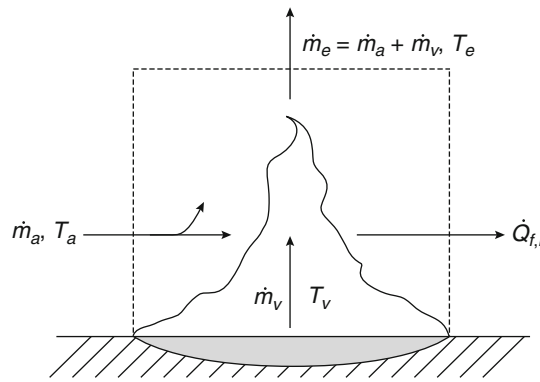

Fig. 27.2 Gas-phase energy balance

Sensible Enthalpy Rise Method

Consider the energy balance of a gas-phase control volume enclosing the flame of a burning specimen (Fig. 27.2). Air enters the control volume at a flow rate $\dot{m}_a$ and temperature T_a. The enthalpy of this air can be written as

$$h_a = h_a^0 + c_p(T_a - T_0) \tag{27.2}$$

where

h_a = Enthalpy of air at temperature T_a(kJ/g)
h_a^0 = Enthalpy of air at reference temperature T_0(kJ/g)
c_p = Average specific heat of air between T_0 and T_a(kJ/g · K)
T_a = Temperature of the air entering the combustion zone(K)
T_0 = Reference temperature (K)

Part of the heat flux that strikes the exposed surface is conducted into the specimen. The resulting heat flow raises the temperature of the solid and decomposes some fraction into combustible fuel vapors. The vapors are generated at a rate $\dot{m}_v$ and enter the control volume at temperature T_v. Assuming that the specific heat of all gases is approximately constant and temperature independent (a reasonable approximation), the enthalpy of the fuel vapors can be written as

$$h_v = h_v^0 + c_p(T_v - T_0) \tag{27.3}$$

where
h_v = Enthalpy of volatiles at temperature T_v (kJ/g)
h_v^0 = Enthalpy of volatiles at reference temperature T_0 (kJ/g)
T_v = Temperature of volatiles entering the combustion zone (K)

The fuel vapors mix with air and are converted in the flame to products of combustion. The total flow rate, $\dot{m}_e$, of combustion products, which includes some excess air, has a temperature T_e and enthalpy given by

$$h_e = h_e^0 + c_p(T_e - T_0) \tag{27.4}$$

where
h_e = Enthalpy of combustion products at temperature T_e (kJ/g)
h_e^0 = Enthalpy of combustion products at reference temperature T_0 (kJ/g)
T_e = Temperature of combustion products leaving the control volume (K)

T_e is higher than the mass-weighted average of T_a and T_v because of the heat released by combustion in the flame, $\dot{Q}$. However, only a fraction of this heat contributes to the temperature rise of the gases. This fraction is referred to as the convective fraction of the heat release rate. The remaining fraction of $\dot{Q}$ is lost and is denoted as $\dot{Q}_{f,1}$. For the most part $\dot{Q}_{f,1}$ is lost in the form of thermal radiation to the walls of the calorimeter (closed configuration) or to the environment (open configuration). A small part of $\dot{Q}_{f,1}$ consists of convective and radiative feedback to the fuel surface. Assuming that gas-phase transients and pressure gradients can be neglected, application of the first law of thermodynamics for the control volume in Fig. 27.2 results in

$$\dot{Q}_{f,1} = \dot{m}_a h_a + \dot{m}_v h_v - \dot{m}_e h_e \tag{27.5}$$

where
$\dot{Q}_{f,1}$ = Convection and radiation heat loss rate from the flame(kW)
$\dot{m}_a$ = Mass flow rate of air entering the combustion zone(g/s)
$\dot{m}_v$ = Generation rate of fuel volatiles(g/s)
$\dot{m}_e$ = Mass flow rate of combustion products leaving the control volume(g/s)

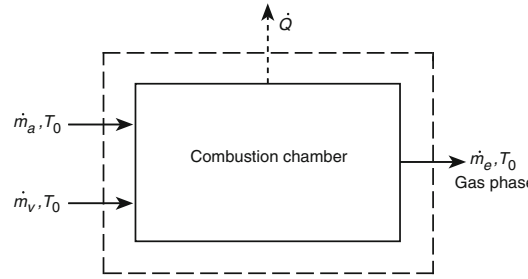

Fig. 27.3 Hypothetical combustion chamber

Suppose now that the same flow rates of air and volatiles, both at temperature T_0, are mixed in a hypothetical combustion chamber. Furthermore, assume the combustion reactions in the chamber are identical to those in the flame in Fig. 27.2, and the products of combustion are cooled down to the reference temperature T_0 without condensing water. This hypothetical situation is shown in Fig. 27.3.

Application of the first law of thermodynamics for the combustion chamber control volume in Fig. 27.3 leads to

$$\dot{Q} = \dot{m}_a h_a^0 + \dot{m}_v h_v^0 - \dot{m}_e h_e^0 \tag{27.6}$$

where $\dot{Q}$ is the total rate of heat released by combustion in the flame (kW).

$\dot{Q}$ is identical in Figs. 27.2 and 27.3 but is distributed in different ways. By expressing the heat released per unit mass of volatiles, an effective heat of combustion can be defined as

$$\dot{m}_v \Delta h_{c,eff} \equiv \dot{Q} \tag{27.7}$$

or per unit exposed area

$$\dot{m}_v'' \Delta h_{c,\mathrm{eff}} \equiv \dot{Q}'' \tag{27.8}$$

where
$\dot{m}_v''$ = Generation rate of fuel volatiles per unit area of fuel surface$(\mathrm{g/m^2 \cdot s})$
$\Delta h_{c,\mathrm{eff}}$ = Effective heat of combustion$(\mathrm{kJ/g})$
$\dot{Q}''$ = Total rate of heat released per unit area of fuel surface$(\mathrm{kW/m^2})$

$\Delta h_{c,\mathrm{eff}}$ is for the combustion reactions as they take place in the calorimeter. $\Delta h_{c,\mathrm{eff}}$ must be

distinguished from the net heat of combustion, $\Delta h_{c,\text{net}}$. The difference between $\Delta h_{c,\text{eff}}$ and $\Delta h_{c,\text{net}}$ is very significant for charring materials such as wood. In an oxygen bomb calorimeter; nearly all the mass of wood is consumed, leaving a small fraction of noncombustible ash (usually less than 1 % by mass). The net heat of combustion, $\Delta h_{c,\text{net}}$, of dry wood is in the range of 16–18 MJ/kg. When exposed under real fire conditions, only 70–80 % of the mass is converted to volatiles that burn almost completely. The heat of combustion of the volatiles, $\Delta h_{c,\text{eff}}$, measured in a small-scale calorimeter is only 12–13 MJ/kg. A solid char residue remains, primarily consisting of carbon, with a net heat of combustion of approximately 30 MJ/kg. In an oxygen bomb calorimeter, most of this char is also burnt, explaining why $\Delta h_{c,\text{net}}$ exceeds $\Delta h_{c,\text{eff}}$ by 25–50 %. Even for materials that do not form a char, $\Delta h_{c,\text{eff}}$ can be significantly lower than $\Delta h_{c,\text{net}}$ if combustion of the volatiles in the small-scale calorimeter is incomplete. In this case, the products of combustion contain measurable amounts of combustible components such as CO, soot, unburnt hydrocarbons, and so forth. The ratio of $\Delta h_{c,\text{eff}}$ to $\Delta h_{c,\text{net}}$ is defined as combustion efficiency, χ. For clean-burning gaseous fuels, such as methane, χ is close to unity. For fuels that produce sooty flames, including gases, χ can be significantly lower. For example, χ for acetylene is approximately 0.75. χ values for a number of gases, liquids, and solids are listed in Chap. 36, "Combustion Characteristics of Materials and Generation of Fire Products."

Substitution of Equations 27.2, 27.3, 27.4, and 27.6 into Equation 27.5 leads to

$$\dot{Q} - \dot{Q}_{f,1} = c_p \dot{m}_e (T_e - T_0) - c_p \dot{m}_a (T_a - T_0) - c_p \dot{m}_v (T_v - T_0) \tag{27.9}$$

The stoichiometric air-to-fuel ratio ranges between 3 and 16 for most fuels. Moreover, small-scale calorimeters are usually operated with excess air. For example, the standard initial flow rate in the cone calorimeter is 30 g/s. Based on the oxygen consumption principle (see below), the stoichiometric flow rate of air for a 10 kW fire (practical upper limit in the cone calorimeter) can be calculated as 10 kW/3 kJ per g of air = 3.3 g/s. Thus, the air supply in the cone calorimeter is at least nine times stoichiometric, or at least $9 \times 3 = 27$ times the generation rate of volatiles. Usually, the ratio is much greater. Hence, $\dot{m}_v$ is negligible compared to $\dot{m}_a$ and Equation 27.9 can be approximated as

$$\dot{Q} - \dot{Q}_{f,1} \approx \dot{m}_a c_p (T_e - T_a) \tag{27.10}$$

This equation is the basis for the sensible enthalpy method. Heat release rate is calculated from the temperature rise $T_e - T_a$ of the gases flowing through a calorimeter. A schematic of a calorimeter based on this principle is shown in Fig. 27.4.

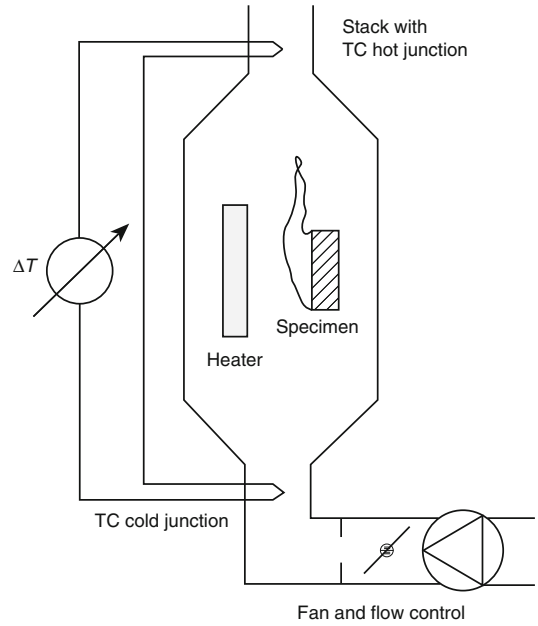

Fig. 27.4 Sensible enthalpy rise calorimeter

There are a few problems with the practical implementation of this technique. The main concern is that only a fraction of the heat released in the flame is used to raise the sensible enthalpy or temperature of the gases. Therefore, it is necessary to recover or measure the loss term $\dot{Q}_{f,1}$. Some calorimeters have water-cooled walls that trap most of the losses. These losses can be estimated by measuring the enthalpy rise of the cooling water. However, due to the additional

hardware and instrumentation, such calorimeters are rather complex and difficult to operate.

A more popular method relies on a gas burner calibration to determine $\dot{Q}_{f,1}$ in the assumption that the losses are fuel independent. Defining the loss fraction, χ_r, by

$$\dot{Q} - \dot{Q}_{f,1} \equiv (1 - \chi_r)\dot{Q} \qquad (27.11)$$

where χ_r is the fraction of total heat release rate lost by radiation.

The symbol χ_r is chosen for this fraction because $\dot{Q}_{f,1}$ consists primarily of radiation. If the calorimeter is operated with a constant airflow rate $\dot{m}_a$, Equation 27.11 can be written as

$$\dot{Q} \approx \frac{\dot{m}_e c_p}{1 - \chi_r}(T_e - T_a) \equiv k(T_e - T_a) \qquad (27.12)$$

where k is the calibration constant (kW/K).

The calibration factor, k, is determined from a gas burner calibration with known $\dot{Q}$. By repeating the calibration over a range of heat release rate levels, k can be determined as a function of $\dot{Q}$ or T_e. If the specimen is enclosed with the heater, Equation 27.12 is still valid, provided a reference temperature T_r is used instead of T_a. The temperature difference $T_r - T_a$ results from the heat transfer between the heater and the airflow through the enclosure. T_r is therefore a function of heater setting, to be determined via calibration.

Ed Smith's rate of heat release test developed at Ohio State University is the most well-known and most widely used calorimeter based on the sensible enthalpy rise method [3]. The test method is described in detail in a separate section.

Substitution Method

For practical reasons, calorimeters based on the sensible enthalpy rise method use a closed configuration. The specimen and heater(s) are located inside a metal box, which may be (partly) insulated. The dynamic response of the enclosure to changes in the thermal environment creates problems in the practical implementation of the sensible enthalpy rise method. After ignition, part of the heat released by a burning specimen is transferred by radiation to the enclosure walls. A fraction of this heat is stored in the walls, causing an increase of their temperature, in turn resulting in an enhanced heat transfer with the air flowing through the box. The result is that, for a material that quickly reaches steady burning conditions, there is a delay for T_e to reach the corresponding steady temperature. A similar phenomenon occurs when the heat release rate from the specimen decreases or after the specimen burns out and the heat release rate goes back to zero. Under unsteady burning conditions, T_e constantly lags behind the temperature corresponding to the instantaneous heat release rate. Several methods have been suggested to mathematically address this problem, but none are completely satisfactory [8–12].

The substitution method was developed to eliminate problems associated with thermal lag. The method requires two runs to determine the heat release rate of a material under a given set of conditions. The first run uses a similar arrangement as shown in Fig. 27.4. The temperature difference $T_e - T_a$ is measured as a function of time. The second run uses the same apparatus, airflow rate, and radiant heat flux. However, the specimen is replaced by a noncombustible dummy specimen and a substitution gas burner. The flow of gas to the burner is controlled in such a way that the temperature difference $T_e - T_a$ closely follows the curve measured during the first run. Figure 27.5 shows a schematic of the substitution run.

Presumably, the dynamics are identical in both runs. Hence, problems with thermal lag have been eliminated, and the heat release rate of the specimen can be determined from the fuel flow rate to the burner in the second run. Unfortunately, implementation of this method is not trivial, because a sophisticated control system is needed for the second run. Moreover, due to the addition of substitution runs, the number of tests required to evaluate a material is doubled.

The substitution method was first implemented at Factory Mutual [13]. The apparatus was designed to measure the heat release

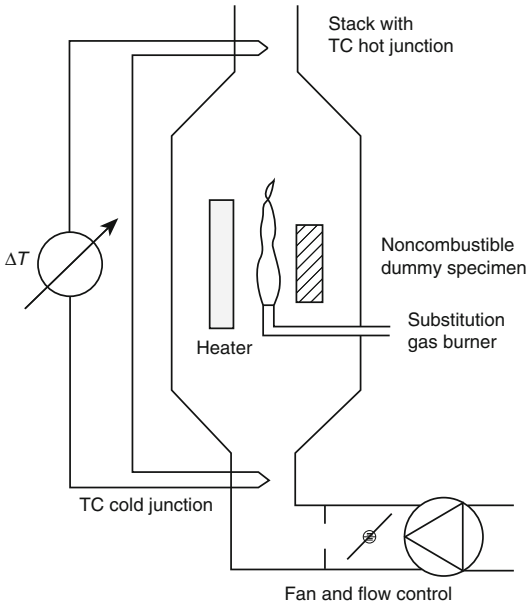

Fig. 27.5 Second run with substitution burner

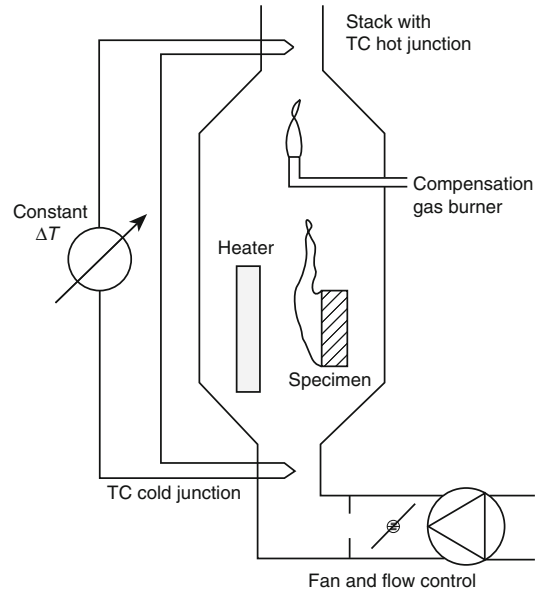

Fig. 27.6 Compensation calorimeter

rate from roof assemblies. A small-scale substitution calorimeter was developed at the Forest Products Laboratory [14].

Compensation Method

A compensation calorimeter is similar to a substitution calorimeter, except that the burner is operated while a specimen is exposed. A schematic is shown in Fig. 27.6. Initially, the burner flow rate is chosen so that the corresponding heat release rate exceeds that of any material to be tested. During a test, the gas flow rate to the burner is controlled so that $T_e - T_a$ remains constant. The heat release rate corresponding to the reduction in flow rate to the burner is equal to the heat release rate from the specimen.

The compensation method also eliminates problems with the dynamic response of the calorimeter enclosure. In theory, a compensation calorimeter is operated at a constant temperature. This would resolve another problem associated with the assumption that $\dot{Q}_{f,1}$ is fuel independent, whereas in reality it is not ($\dot{Q}_{f,1}$ is a strong function of the sootiness of the flame).

In practice, however, the specimen and burner have to be separated to avoid that radiation from the burner flame enhances radiant heat flux to the specimen. Hence, the calorimeter enclosure is not truly isothermal, and the problem remains unresolved. As with substitution calorimeters, the burner flow control system makes compensation calorimeters rather complex and difficult to operate. As a result, they are suitable only for research and not for routine testing.

Compensation calorimeters were developed at the National Bureau of Standards [15, 16] and Stanford Research Institute [17].

Oxygen Consumption Method

In 1917, Thornton showed that for a large number of organic liquids and gases, a nearly constant net amount of heat is released per unit mass of oxygen consumed for complete combustion [18]. Huggett found this also to be true for organic solids and obtained an average value for this constant E of 13.1 MJ/kg of oxygen [19]. This value may be used for practical applications and is accurate with very few exceptions to within ±5 %. Thornton's rule

implies that it is sufficient to measure the oxygen consumed in a combustion system in order to determine the net heat released. This is the basis for the oxygen consumption method for measuring heat release rate in fire tests.

The first application of the oxygen consumption technique in fire research was by Parker on the ASTM E84 tunnel test. [20] During the late 1970s and early 1980s, the oxygen consumption technique was refined at the National Bureau of Standards (NBS, currently the National Institute of Standards and Technology, or NIST). The oxygen consumption method is now recognized as the most accurate and practical technique for measuring heat release rates from experimental fires. It is widely used throughout the world, for both small-scale and large-scale applications.

Thornton's Rule

The exact value of E for a specific fuel is equal to the net heat of combustion of the fuel divided by the mass of oxygen needed for complete combustion of a mass unit of fuel. The mass of oxygen required for complete combustion of a mass unit of fuel can be determined from the stoichiometry of the combustion reactions. Consider, for example, the following equation to describe complete combustion of methane:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \qquad (27.13)$$

This equation indicates that 64 g of oxygen are required for complete combustion of 16.04 g of methane. Hence, the mass of oxygen needed to burn 1 g of methane is $r_0 = 64/16.04 = 3.99$ g O_2/g CH_4. Because the net heat of combustion of methane is 50.04 kJ/g, the net heat released per mass unit of oxygen consumed is equal to $E = \Delta h_{c,\text{net}}/r_0 = 50.04/3.99 = 12.54$ kJ/g O_2.

An extensive list of E values can be found in Chap. 36; in Tables C2–C4 and in the literature [21, 22]. A summary of average values for different categories of fuels and polymers based on the data in Chap. 36 is given in Table 27.1. This table also lists values for the amount of heat released per mass unit of CO_2 and CO generated (E' and E'', respectively). Although there is more variation between different categories, these values are also reasonably constant within a given category of fuels or polymers.

Volatiles or Condensed Phase?

An interesting question is whether the oxygen consumption technique measures heat release rate for the volatiles or the solid fuel. Thermal methods approximately measure heat release rate from the volatiles. However, Huggett's constant of 13.1 kJ/g is based on the average net heat of combustion for a large set of materials. Hence, one would expect that oxygen consumption calorimetry gives the heat released by the fuel in its natural state at ambient temperature, because that is how the fuel is supplied in an oxygen bomb calorimeter.

The question can be examined in more detail for some synthetic polymers by comparing the net heat of combustion of the polymer to that of the corresponding monomer. If one were to burn a monomer in an oxygen consumption calorimeter, the products of complete combustion would be the same as for the corresponding polymer, provided test conditions are identical. Therefore, measured heat release rate would be the same in the two cases. However, the net heat of combustion is higher for the monomer. The difference with the net heat of combustion of the polymer is the net heat released in the polymerization process.

Table 27.2 gives values for the net heat of combustion of nine polymers and their monomers. The former are taken from Huggett; [19] the latter are obtained by adding the heat of polymerization as reported in the literature [23]. Table 27.2 confirms that the oxygen consumption technique measures net heat release rate of a solid fuel. The heat release rate from the volatiles is always higher, but not by as much as indicated in the last column of the table, because only a fraction of polymeric fuels decomposes back into the monomer (see Chap. 7, "Thermal Decomposition of Polymeric Materials").

Table 27.1 E, α, E' and E'' values for different fuel and polymer categories

Implementation of the Oxygen Consumption Method

The basic requirement to use the oxygen consumption technique is that all combustion products are collected and removed through an exhaust duct. At a distance downstream sufficient for adequate mixing, both flow rate and composition of the gases are measured. A schematic of an oxygen consumption calorimeter is shown in Fig. 27.7. It is not necessary to measure the inflow of air, provided the flow rate is

measured in the exhaust duct. Therefore, oxygen consumption calorimeters are typically open, to avoid that part of $\dot{Q}_{f,1}$ that is reflected by the calorimeter walls and reaches the specimen surface. This would result in an uncontrolled radiant heat flux, in addition to that from the heater.

The practical implementation of the oxygen consumption technique is not straightforward. Application of Thornton's rule to the combustion system shown in Fig. 27.8 leads to the following equation for the heat release rate:

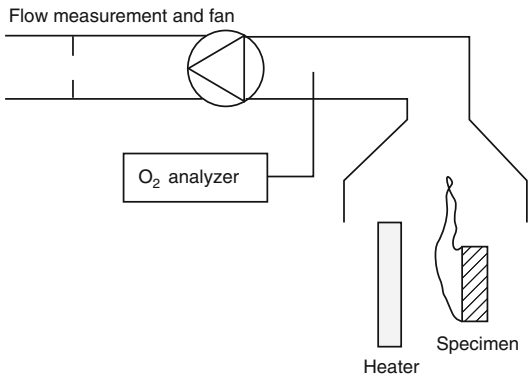

Fig. 27.7 Oxygen consumption calorimeter

$$\dot{Q} = E\left(\dot{m}_a Y^a_{O_2} - \dot{m}_e Y^e_{O_2}\right) \tag{27.14}$$

where

E = Heat release per mass unit of oxygen consumed ($\approx 13.1\text{kJ/g}$)
$Y^a_{O_2}$ = Mass fraction of oxygen in the combustion air(0.232 g/g in dry air)
$Y^e_{O_2}$ = Mass fraction of oxygen in the combustion products(g/g)

There are three problems with the practical implementation of Equation 27.14. First, oxygen analyzers measure the mole (volume) fraction and not the mass fraction of oxygen in a gas sample. Mole fractions can be converted to mass fractions by multiplying the mole fraction with the ratio between the molar mass of oxygen and the molar mass of the gas sample. The latter is usually close to the molar mass of air (≈29 g/mol). Second, water vapor is removed from the sample before it passes through a paramagnetic analyzer, so that the resulting mole fraction is on a dry basis. Third, flow meters measure volumetric rather than mass flow rates. The volumetric flow rate in the exhaust duct, normalized to the same pressure and temperature, is usually slightly different

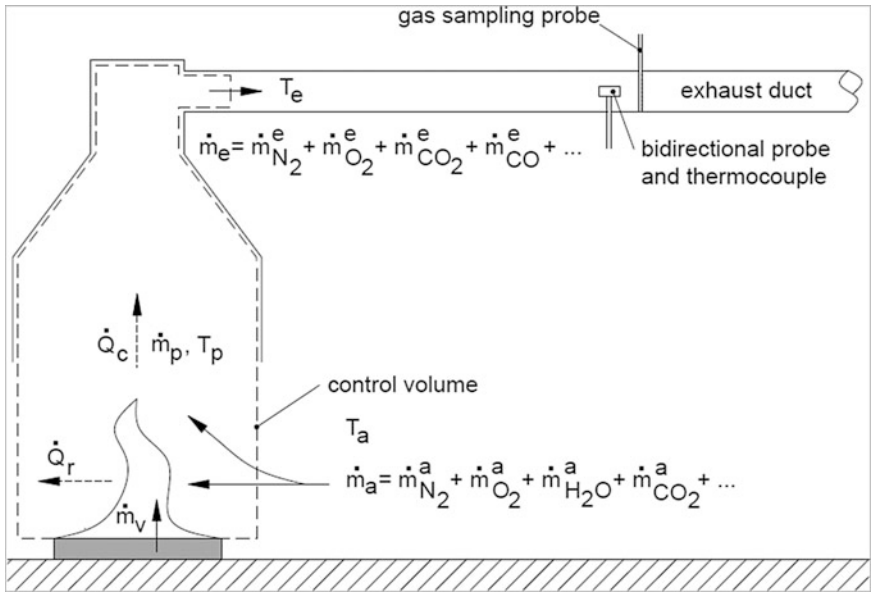

Fig. 27.8 Mass flow rates in oxygen consumption calorimeter

from the inflow rate of air because of expansion due to the combustion reactions.

Parker [24] and Janssens [25] solved these problems and developed equations for calculating rate of heat release by oxygen consumption for various applications. The equations are a function of the extent of the gas analysis. The oxygen concentration must be measured as a minimum. However, the accuracy can be improved by adding instrumentation for measuring the concentration of other gases.

Equations for the two most common configurations of gas analyzers are discussed below. Detailed derivations are not repeated here and can be found in the aforementioned references. Modified equations to address specific circumstances or problems, such as heat release rate measurements during suppression experiments, from fires with significant soot yields, or during experiments conducted in a vitiated (reduced O_2) environment, can also be found in the literature [26–28]. Derivation of detailed equations for carbon oxide calorimetry, a technique that is used extensively by FM Global, can also be found in the literature [29, 30]. Carbon oxide calorimetry is discussed in section "Carbon Oxide Calorimetry".

Only O_2 Measured

In this case all water vapor (by a chiller and moisture sorbent) and CO_2 (by a chemical sorbent) must be removed from the exhaust gas sample stream before O_2 is measured. This leads to the assumption that the sample gas consists of only O_2 and N_2. The resulting equation for calculating heat release rate is

$$\dot{Q} = E\frac{\phi}{1+\phi(\alpha-1)}\dot{m}_e\frac{M_{O_2}}{M_a}\left(1-X^a_{H_2O}-X^a_{CO_2}\right)X^{A^a}_{O_2} \tag{27.15}$$

with

$$\phi = \frac{X^{A^a}_{O_2}+X^{A^e}_{O_2}}{\left(1-X^{A^e}_{O_2}\right)X^{A^a}_{O_2}} \tag{27.16}$$

where

ϕ = Oxygen depletion factor
α = Volumetric expansion factor
$\dot{m}_e$ = Mass flow rate in the exhaust duct of the calorimeter(g/s)
M_{O_2} = Molecular mass of oxygen(28 g/mol)
M_a = Molecular mass of the combustion air(29 g/mol for dry air)
$X^a_{H_2O}$ = Actual mole fraction of water vapor in the combustion air
$X^a_{CO_2}$ = Actual mole fraction of carbon dioxide in the combustion air
$X^{A^a}_{O_2}$ = Measured mole fraction of oxygen in the combustion air
$X^{A^c}_{O_2}$ = Measured mole fraction of oxygen in the exhaust flow

As the composition of the fuel is usually not known, some average value has to be used for α. Complete combustion of carbon in dry air results in $\alpha = 1$. If the fuel is pure hydrogen, α is equal to 1.21. A commonly-used value for α is therefore 1.105. The average value and standard deviation for the fuels in Table 27.1 is 1.093 ± 0.066. $X^a_{H_2O}$ can be calculated from the relative humidity and temperature in the laboratory. Typically it is of the order of 1–2 % in a temperature-controlled laboratory.[1] $X^a_{CO_2}$ in dry air is approximately 390 ppm.[2] Note that the symbols for oxygen mole fraction measured in the combustion air (prior to a test) and the exhaust flow include a superscripted *A*. This is to make a distinction between the actual and measured mole fractions of oxygen, because the latter are for a dry gas sample.

Equation 27.15 is expected to be accurate to within ±10 %, provided combustion is complete; for example, all carbon is converted to CO_2. The error may be larger if CO or soot production is

[1] For example, air at 20 °C, 1013 mbar and a relative humidity of 50 % contains 1.2 % of water vapor by volume.

[2] The concentration of carbon dioxide in the atmosphere is measured at the Mauna Loa Observatory in Hawaii. The average concentration measured in 2010 was 390 ppm. The concentration varies annually by about 3–9 ppm, but the annual average has steadily increased by about 74 ppm since 1958, when the measurements were first recorded.

considerable, or if a significant amount of combustion products consists of species other than CO_2 or H_2O (e.g., HCl). The error is partly due to the uncertainty of E and α. If more exact values are available, accuracy can be improved by using those instead of the generic values of 13.1 kJ/g and 1.105.

O_2, CO_2, and CO Measured

In this case, only water vapor is trapped before the exhaust gas sample reaches the analyzers. CO in many cases is negligible. The rate of heat release in those cases can be calculated from Equation 27.15 with the minor modification that $X^a_{CO_2}$ is not included in the expression inside parentheses. In addition, ϕ is slightly different and follows from

$$\phi = \frac{X^{A^a}_{O_2}\left(1 - X^{A^e}_{CO_2}\right) - X^{A^e}_{O_2}\left(1 - X^{A^a}_{CO_2}\right)}{\left(1 - X^{A^e}_{O_2} - X^{A^e}_{CO_2}\right)X^{A^e}_{O_2}} \tag{27.17}$$

where

$X^{A^a}_{CO_2}$ = Measured mole fraction of carbon dioxide in the combustion air

$X^{A^c}_{CO_2}$ = Measured mole fraction of carbon dioxide in the exhaust flow

Generally, adding CO_2 does not greatly improve the accuracy of measuring heat release rate. However, adding a CO_2 analyzer eliminates the need for an expensive sorbent to scrub CO_2 from the gas sample.

If a significant fraction of carbon in the fuel is converted to CO instead of CO_2, the equations can be corrected to take incomplete combustion into account. Heat release rate is then calculated from

$$\dot{Q} = \left[E\phi - (E_{CO} - E)\frac{1-\phi}{2}\frac{X^{A^e}_{CO}}{X^{A^e}_{O_2}}\right] \frac{\dot{m}_e}{1+\phi(\alpha-1)}\frac{M_{O_2}}{M_a}\left(1 - X^a_{H_2O}\right)X^{A^e}_{O_2} \tag{27.18}$$

with

$$\phi = \frac{X^{A^a}_{O_2}\left(1 - X^{A^e}_{CO_2} - X^{A^e}_{CO}\right) - X^{A^e}_{O_2}\left(1 - X^{A^a}_{CO_2}\right)}{\left(1 - X^{A^e}_{O_2} - X^{A^e}_{CO_2} - X^{A^e}_{CO}\right)X^{A^a}_{O_2}} \tag{27.19}$$

where

E_{CO} = Heat release per mass unit of oxygen consumed for CO(17.6 MJ/g)

$X^{A^c}_{CO}$ = Measured mole fraction of carbon monoxide in the exhaust flow

One might wonder under what conditions the CO correction becomes significant. Figure 27.9 shows the ratio of heat release rate obtained by ignoring CO to the actual heat release rate, as a function of the ratio of measured CO to CO_2 mole fractions in the exhaust flow for methane and for a gaseous fuel of composition $(CH_2O)_n$. According to Roberts, the molecular formula of

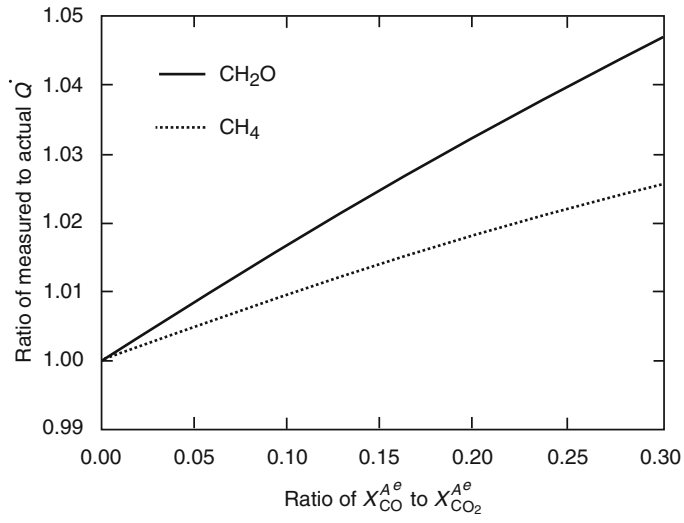

Fig. 27.9 Effect of ignoring CO on $\dot{Q}$ error

the latter represents the thermal degradation products of beech wood [31]. For the CO effect examined here, this fuel represents a "worst case" because it contains enough oxygen for combustion of all hydrogen. Methane gives a practical lower limit for the error, because it is the hydrocarbon with the highest hydrogen-to-carbon ratio.

There is some experimental evidence that the yield of CO in underventilated fires reaches an upper limit approximately equal to 0.2 kg of CO per kg of fuel, when the equivalence ratio exceeds unity [32]. For the fuels considered here, the limit corresponds to a CO/CO_2 mole fraction ratio of 0.27. Figure 27.9 indicates that, even under the worst conditions, the error by ignoring CO generation is less than 5 %.

Carbon Oxide Calorimetry

An alternative method for measuring heat release rate is based on the fact that amount of heat released per mass unit of carbon dioxide and carbon monoxide generated is also relatively constant within a category of fuels or polymers (see Table 27.1). This method is particularly useful for oxidizers [33]. Application to the combustion system shown in Fig. 27.8 leads to the following equation for the heat release rate:

$$\dot{Q} = E'\left(\dot{m}^{e}_{CO_2} - \dot{m}^{a}_{CO_2}\right) + E''\dot{m}^{e}_{CO} = E'\left(\dot{m}_e Y^{e}_{CO_2} - \dot{m}_a Y^{a}_{CO_2}\right) + E''\dot{m}_e Y^{e}_{CO} \tag{27.20}$$

where

E' = Heat released per mass unit of carbon dioxide generated(kJ/g);
E' = Heat released per mass unit of carbon monoxide generated(kJ/g);
$\dot{m}^{e}_{CO_2}$ = Exhaust flow rate of carbon dioxide (g/s);
$\dot{m}^{a}_{CO_2}$ = Inflow rate of carbon dioxide from ambient environment (g/s);
$\dot{m}^{e}_{CO}$ = Exhaust flow rate of carbon monoxide (g/s);
$Y^{e}_{CO_2}$ = Carbon monoxide mass fraction in the exhaust flow(−);
$Y^{a}_{CO_2}$ = Ambient carbon monoxide mass fraction (−); and
Y^{e}_{CO} = Carbon monoxide mass fraction in the exhaust flow(−).

Khan et al. give values for E' and E'' of 13.3 kJ/g ± 11 % and 11.1 kJ/g ± 18 %, respectively (Chap. 36). Practical implementation of Equation 27.20 faces the same challenges as that of Equation 27.14. The following equations can be used to calculate the generation rates of carbon dioxide and carbon monoxide [34]:

$$\dot{m}^{e}_{CO_2} - \dot{m}^{a}_{CO_2} = \frac{X^{A^e}_{CO_2}\left(1 - X^{A^a}_{O_2}\right) - X^{A^a}_{CO_2}\left(1 - X^{A^e}_{O_2} - X^{A^e}_{CO}\right)}{1 - X^{A^e}_{O_2} - X^{A^e}_{CO_2} - X^{A^e}_{CO}} \frac{\dot{m}_e}{1 + \phi(\alpha - 1)} \frac{M_{CO_2}}{M_a}\left(1 - X^{a}_{H_2O}\right) \tag{27.21}$$

with

$$\dot{m}^{e}_{CO} = \frac{X^{A^e}_{CO}\left(1 - X^{A^a}_{O_2} - X^{A^a}_{CO_2}\right)}{1 - X^{A^e}_{O_2} - X^{A^e}_{CO_2} - X^{A^e}_{CO}} \frac{\dot{m}_e}{1 + \phi(\alpha - 1)} \frac{M_{CO}}{M_a}\left(1 - X^{a}_{H_2O}\right) \tag{27.22}$$

Practical Considerations

The equations presented in the previous sections are rather complex and it is very easy to make mistakes. To illustrate the point, Lattimer and Beitel reviewed 17 different standard test methods for measuring heat release rate based on oxygen consumption calorimetry [35]. They found errors in the equations for 12 of the 17 standards. In total, 22 equations were found to be in error. Because it is difficult to avoid

errors in transcribing to a spreadsheet program even with the correct equations, it is essential to do so very carefully and to double-check the results.

Improper setup and maintenance of the gas sampling and analysis system is another common cause for errors. The proper sorbent columns have to be installed depending on the configuration of gas analyzers used. It is necessary to use three columns in series when only oxygen is measured. The first column contains a drying agent. The second column contains a sorbent to scrub the CO_2 from the gas sample. The third column also contains a drying agent and is necessary to remove water vapor that is generated by the CO_2 scrubber. If carbon oxide analyzers are used, a drying column is all that is needed.

Silica gel is a commonly used drying agent in chemistry labs. However, it is not suitable for most oxygen consumption calorimetry applications because of the generation of CO_2 [36]. Drierite® is commonly used instead of silica gel, but some batches seem to have the same problem. Ascarite® is the most commonly used CO_2 scrubbing agent.

Finally, the analyzers are calibrated with certified zero and span gases at the start of each testing day and sometimes more than once a day. It is absolutely essential that flows and pressures during these calibrations are the same as during testing.

Factors Affecting Small-Scale Heat Release Measurements

This section examines the effects of some calorimeter construction details on quality and accuracy of the measurements. The discussion results in some guidelines for building the "ideal" small-scale calorimeter for a specific application.

Open or Closed Configuration

Calorimeters that utilize a measuring technique other than oxygen consumption consist of a closed "box" configuration. Combustion air is supplied to one side of the box, and combustion products are removed from the opposite side. Specimen, heater, and ignition device typically are located inside the box. Advantages of a closed configuration are that airflow rate can be measured at the inlet under clean and soot-free conditions, the combustion air can be heated, and the oxygen concentration in the air can be increased (by adding O_2) or decreased (by adding N_2) from ambient. Disadvantages are thermal lag due to heating or cooling of the enclosure walls and uncontrolled radiation feedback from the enclosure walls to the specimen.

To address the first disadvantage, various numerical procedures have been proposed for correcting the temperature signal measured with calorimeters based on the sensible enthalpy rise method [8–12]. These procedures are based on a mathematical model of the calorimeter consisting of two first-order systems in series. The first system has a rather small time constant (between 8 and 30 s for various calorimeters) and is related to the heat capacity of the gases flowing through the calorimeter. The second system has a large time constant (200–930 s for various calorimeters), which is associated with the heat capacity of the calorimeter walls. The correction procedures adjust the output signal for thermal lag, using discrete forward and inverse Laplace transform techniques.

In spite of the complex calculations, the resulting correction may not always be accurate due to the crude mathematical model for the calorimeter. A more convenient, and perhaps equally accurate, correction method relies on an electronic compensator as described in ASTM E906 and ASTM E1317. The compensator electronically corrects the output signal of the exhaust thermocouples, based on the negative feedback of a wall temperature signal.

The oxygen consumption method also has a time delay, but with properly adjusted sampling flows and oxygen analyzer, this delay consists almost entirely of the transport time for a gas sample from the combustion zone to the analyzer [37]. Because flow rates in the exhaust duct and sampling lines do not change significantly during a test, this delay time is approximately constant.

It can be determined with gas burner calibrations and can be easily addressed by shifting the gas analysis data over the appropriate time interval.

To obtain accurate measurements for thin materials that produce a heat release vs. time curve that has the form of a single sharp peak, it is necessary to make corrections for the response time of the oxygen analyzer [12]. An oxygen analyzer is modeled as a first order system and its time constant is obtained from gas burner step response measurements.

The second disadvantage can be eliminated only by using blackened water-cooled calorimeter walls. If the walls are allowed to heat or cool freely, they emit radiation, which varies with time. Part of this radiation reaches the specimen surface and enhances the radiant heat flux from the heater in an uncontrolled fashion. Obviously, the need for water-cooled walls makes the apparatus much more complex and costly.

Problems with thermal lag and radiation feedback to the specimen can be eliminated by using an open configuration. Solid objects must be water cooled or sufficiently remote from heater and specimen so that they do not interfere with the controlled radiant heat flux to the specimen. A closed configuration can be recommended only for specialized applications, for example, to study the effect of oxygen concentration or temperature of the combustion air on heat release rate and burning behavior.

Type of Heater

Heat release rates must be measured at constant heat flux levels over a range that is relevant for the fire scenario of interest. The heat flux can be provided with a gas burner flame in contact with the specimen or with a radiant panel remote from the specimen.

Incident heat flux from impinging gas burner flames can be adjusted only over a narrow range. To increase the heat flux from a gas burner, either the flame size has to be increased, or a fuel with higher soot yield has to be used. Usually, these parameters can be adjusted only slightly or not at all. It is very difficult to set and maintain a specific heat flux level because a major fraction of the heat transfer is convective. Moreover, the burner gas and combustion products mix with fuel volatiles, which affects burning behavior. In short, impinging flames are not desirable as the external heat source in heat release rate calorimeters.

It is much easier to create constant and uniform exposure conditions if the incident heat flux is primarily radiative. Porous gas panels as well as electrical heating elements are used for this purpose. The radiant heat flux can be adjusted by changing the power of the heater or by changing the distance between heater and specimen. If the second method is used, practical upper and lower limits to the range of radiant heat flux levels can be created. If the heater is too close to the specimen, convective heat transfer becomes significant. Therefore, the upper limit corresponds to the minimum distance that has to be maintained in order to ensure predominantly radiative heat transfer. The lower limit is determined by the uniformity of the incident radiant heat flux, which drops with increasing distance between heater and specimen. The exact limits depend on the geometrical configuration, the power of the heater, and the degree of nonuniformity of the incident heat flux profile that is deemed acceptable.

Another important aspect is the ability of the heater to maintain the radiant heat flux at a constant level during a test. If the heater is operated at a constant power level, incident radiant heat flux changes during testing. At the start of a test, a cold specimen is inserted. The specimen acts as a heat sink, resulting in a decrease of the heater temperature and consequently a decrease of the incident radiant heat flux. After ignition, the heat released by the specimen results in an increase of the heater temperature and incident radiant heat flux.

To maintain incident radiant heat flux during a test, it is therefore necessary to keep the temperature of the heater constant. This is very difficult with a gas panel, but relatively straightforward for electrical heating elements. With the oxygen consumption method, another drawback of using a gas panel is that its products of combustion

result in an oxygen depletion that is usually much larger than the oxygen consumed for combustion of the specimen. Thus, small fluctuations in panel flow can result in significant error of the measured heat release rate. This "baseline" problem can be avoided by using a separate exhaust system for the heater.

It is clear from the preceding discussion that an electrical heater is preferable over a gas panel. Two types of electrical heaters are used: high and low temperature. The former are commonly tungsten filament lamps that operate at temperatures close to 2600 K. According to Wien's displacement law, peak radiant heat flux from such lamps is at a much shorter wavelength than for real fires, with temperatures in the range of 600–1400 K. Piloted ignition studies on plastics and wood have shown that these materials absorb much less radiation in the visible and near-infrared range than at higher wavelengths [38, 39]. On the basis of these findings, it can be concluded that commercially available low-temperature elements are preferable over high-temperature lamps. Such elements typically operate between 800 and 1200 K, a range that is representative of real fire exposure conditions.

Type of Ignition Pilot

Heat release rate tests are usually conducted with an ignition pilot. The use of a pilot reduces the variation in time to sustained flaming between multiple tests conducted under identical test conditions. Because the duration of the preheat period prior to ignition affects burning rate after ignition, use of a pilot also improves repeatability of heat release rate measurements. Furthermore, piloted ignition is used because it is representative of most real fires and conservative in other cases.

The ignition pilot in small-scale fire tests consists of a small gas burner flame, a glowing wire, or an electric spark. An impinging flame should not be used because it locally enhances the incident heat flux to the specimen. Another problem with pilot flames is that they are sometimes extinguished by fire retardants or halogens in the fuel volatiles. A glowing wire is not an efficient method for igniting fuel volatiles, sometimes leading to poor repeatability. An electric spark remains stable when fire retardants or halogens are present. However, it occupies a small volume, so that the positioning of the spark plug is more critical than with other types of ignition pilots.

Specimen Size

The ideal situation would be if small-scale heat release rate data could be used directly to predict burning rate in real-scale fires. Unfortunately, the minimum specimen size that is required to allow for such a straightforward prediction is not practical. As described earlier, the burning rate of a specimen is a direct function of the net heat flux transferred to the fuel. The net flux is equal to the total of external heat flux, flame convection, and flame radiation, minus radiative heat losses from the fuel surface and heat losses (or gains) at the specimen edges.

The Russian work on the effect of diameter on pool fire burning rate by Blinov and Khudiakov gives some insight into this problem. A detailed discussion of this work and its implications is given by Drysdale [40]. If the pool diameter is less than 0.03 m, flame convection is laminar and burning rate increases with decreasing diameter. If the pool diameter exceeds 1 m, flame convection is turbulent and burning rate is independent of diameter. There is a transition region between these two limits, with a minimum burning rate for a pool diameter of approximately 0.1 m. This work indicates that specimen size in a heat release rate calorimeter must be at least 1 m for the results to be independent of scale. This is indeed not feasible in practice. The Russian pool fire data also indicate that heat transfer at the edges becomes excessive at diameters below 0.1 m. Therefore, specimen size in small-scale calorimeters should be at least 0.1 m.

To predict real-scale burning rates, differences in flame heat transfer, and up to a lesser extent heat transfer at the edges, have to

be considered. Östman and Nussbaum reported ignition and heat release data for 13 materials and two specimen sizes [41]. Increase in specimen size from 0.1 m × 0.1 m to 0.2 m × 0.2 m resulted in a slight reduction of piloted ignition time. Average heat release rate over the first minute after ignition on a per-unit-area basis increased by approximately 12 % at exposure levels exceeding 25 kW/m^2. Larger increases were observed at the 25 kW/m^2 exposure level and for peak heat release rate.

Janssens and Urbas presented a comparison of heat release rate data for nine wood products obtained in the cone and an intermediate-scale calorimeter [42]. A 100-fold increase in specimen size resulted in only a 10 % increase of the heat release rate. This modest effect can be explained by the fact that the heat feedback from the flame is relatively insensitive to specimen area for testing in the vertical orientation, in particular for materials, such as wood, that do not produce very luminous flames.

Depending on the specimen size in a small-scale test, there is a limit on the degree of non-uniformity and irregularity of the product being tested, if the test conditions are to be representative of end-use conditions. Therefore, there might be some merit in choosing a specimen size that exceeds the minimum of 0.1 m. However, the main trade-off is that a larger specimen requires a larger and more powerful heater to achieve uniform incident radiant heat flux to the specimen. It should be recognized that, no matter what the specimen size is, there are assemblies and composites for which it is not possible to prepare representative small-scale specimens. Intermediate-scale or full-scale tests are needed to evaluate the fire performance of such assemblies and composites.

Edge Effects

An issue that is closely related to specimen size is that of edge effects. These effects have been studied extensively in the cone calorimeter. ASTM and ISO standards of the cone calorimeter prescribe that, except for calibrations with polymethylmethacrylate (PMMA), the specimen is to be wrapped with aluminum foil on the sides and bottom. The main purpose of the foil is to eliminate mass transfer along all boundaries except the exposed face of the specimen. Furthermore, the ISO standard requires all tests be conducted in the horizontal orientation with the stainless steel retainer frame.

Toal et al. tested several materials with and without foil wrapping, and with and without the retainer frame [43, 44]. They found that the retainer frame reduces peak heat release rate, and lengthens the burning time. This is to be expected because the retainer frame is a relatively large mass of steel that acts as a heat sink, reducing the energy transferred to the specimen.

Urbas and Sand were also concerned with the heat sink effect of the retainer frame [45]. They designed an alternative retainer frame, composed of an insulating collar made of medium-density or high-density refractory material. Their conclusion was that the best edge conditions were obtained using the insulating frame with insulation material that most closely resembles the specimen in thermal properties. Researchers at FM Global proposed a similar approach to address edge effects in a small-scale calorimeter [46].

Babrauskas et al. conducted a very extensive study of the effects of specimen edge conditions on heat release rate [47]. The objective of this study was to further examine the issues raised by Toal et al. and by Urbas and Sand, and to develop definitive recommendations. Specimens of 10 materials were tested in the horizontal orientation at 50 kW/m^2 using three configurations: without retainer frame, with retainer frame, and with an insulated retainer frame akin to that developed by Urbas and Sand [45]. All specimens were wrapped in aluminum foil. The study concluded that the use of an insulated frame gives heat release rate values that are slightly closer to the expected true values. However, the insulated frame makes the test procedure significantly more complicated, so that it is not recommended for routine testing.

If the standard retainer frame is used, Babrauskas et al. recommended that heat release rate data be expressed on the basis of an effective exposure area of 0.0081 m^2. The standard retainer frame reduces the actual exposed area from 0.1 m × 0.1 m to 0.094 m × 0.094 m, or from 0.01 to 0.0088 m^2. The recommendation by Babrauskas et al. [47] to further reduce the exposed area to an effective value of 0.0081 m^2 indicates that the heat sink effect of the retainer frame reduces heat release rate values by approximately 8 %.

Östman and Tsantaridis tested 11 products in the cone calorimeter in the horizontal orientation at 50 kW/m^2, with and without the retainer frame [48]. They also found that the use of the retainer frame results in a reduction of heat release rate greater than what can be explained by the reduction of the exposed area. For the average heat release over the first 3 min following ignition, they found an average reduction of 8 %, identical to Babrauskas et al. [47] However, for maximum heat release rate, they found reductions as high as 25 %.

It can be concluded from these studies that the specimen holder configuration in a small-scale heat release rate test may have a significant effect on the measurements. This effect should be addressed if the test data are used to predict performance in real fires.

Specimen Orientation

Products do not necessarily have to be tested in the same orientation as they are used. For practical reasons, the preferred orientation for small-scale testing is horizontal facing upward. The vertical orientation might be preferable for collecting specialized data for research purposes.

Airflow

Standard rate of heat release test methods are operated under overventilated conditions. Plenty of excess air is supplied, so that the measurements are not affected by lack of oxygen. However, specialized studies have been conducted to evaluate the effect of ventilation and vitiation and to determine the 'Limiting Oxygen Concentration', which is an important parameter in the design of fire protection systems that rely on a reduction of oxygen concentration in the room [49, 50]. Such studies require a closed configuration.

Other Measurements

Heat release rate calorimeters often include additional instrumentation to measure parameters that are important in characterizing the fire performance of materials. Perhaps the most important additional measurement is that of mass loss rate. Most calorimeters can be provided with a load cell to measure specimen mass loss, but this can be very difficult in a closed configuration. Mass loss rate is obtained from numerical differentiation of the mass loss measurements. Smoke meters are added to measure smoke obscuration in the exhaust duct. Both white light and laser light systems are being used. Toxic gas species can be measured in the exhaust duct with additional gas analysis equipment. Such equipment ranges from standard infrared CO and CO_2 analyzers to complex online Fourier transform infrared (FTIR) instrumentation. Whether instrumentation can be added depends mainly on the design and construction details of the calorimeter.

Commonly Used Small-Scale Calorimeters

Ohio State University (OSU) Calorimeter

This apparatus, originally designed by Ed Smith at Ohio State University, is one of the most widely used and best-known small-scale calorimeters [3]. The test method was first published as a proposed ASTM standard in 1980. In 1983, it was adopted as ASTM E906. The standard was recently amended to include two configurations of the test apparatus. Configuration A is that which the Federal Aviation

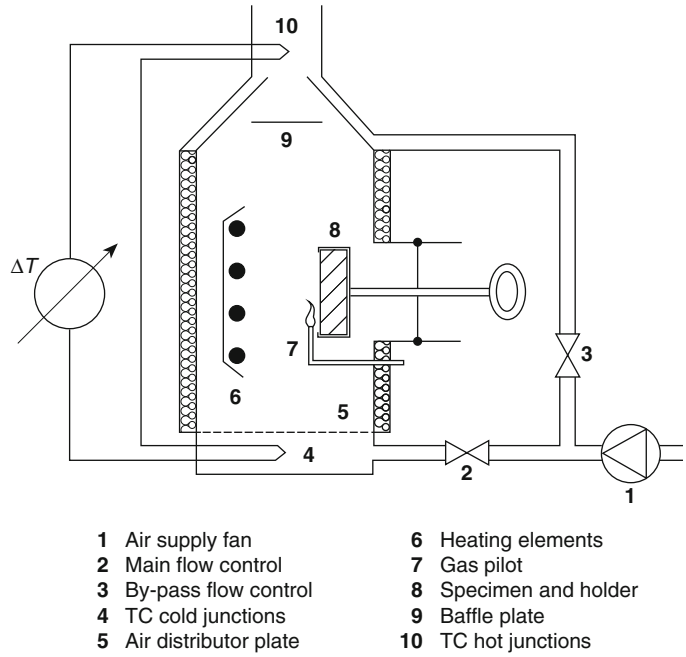

Fig. 27.10 Ohio State University (OSU) calorimeter

Administration (FAA) uses for assessing aircraft cabin materials at a radiant heat flux of 35 kW/m^2. The test procedure in this configuration is also described in the FAA *Aircraft Material Fire Test Handbook* [51]. Configuration B is the original configuration. Both configurations rely on thermopile measurements. Several laboratories have modified the OSU calorimeter to measure heat release rate based on oxygen consumption.

Thermopile Versions

A schematic view of the apparatus is shown in Fig. 27.10. The apparatus consists of an insulated metal box. The conical wall section between the combustion chamber and the stack is hollow. Air flows through this cavity and mixes with the combustion products downstream of the thermocouple hot junctions. However, recovery of the wall heat losses is not fully accomplished. The main features of the OSU apparatus are described below.

Measuring technique. Heat release rate is determined by the sensible enthalpy rise method. The temperatures of inflowing air and outflowing gases are measured with a thermopile of three type K thermocouples. The hot junctions are located symmetrically along a diagonal of the stack cross section, above the baffle plate. The cold junctions are located below the air distributor plate. An electrical compensator is used to correct the temperature signals for thermal lag. The factor k in Equation 27.12 is obtained from line burner calibration runs.

Configuration. Heater and specimen are located inside a box with approximate dimensions of 0.2 m $\times$ 0.41 m $\times$ 0.64 m. The side walls of the box are insulated, and the hollow top wall section is cooled with air.

Heater. The vertical radiant heat source measures approximately 0.3 m $\times$ 0.3 m and consists of four silicon carbide heating elements. A steel masking plate is located in front of the elements to improve uniformity of the incident heat flux distribution over the specimen. The maximum incident heat flux to a vertical specimen is approximately 65 kW/m^2.

Ignition pilot. The optional ignition source is a pilot flame of 2 mL/s methane, premixed with 14 mL/s air. The pilot flame either impinges on

the specimen at the bottom (point ignition), is located in the gas phase at the top of the specimen (pilot ignition), or is not used.

Specimen size and orientation. For testing in the vertical orientation, specimens with an exposed area of 0.15 m × 0.15 m are positioned parallel to the heating elements. Specimens can be tested in the horizontal orientation with the aid of an aluminum reflector foil, which reflects the radiation from the heating elements to the specimen. In this case, the maximum radiant heat flux is reduced to 50 kW/m^2 and the specimen size is 0.11 m × 0.15 m. The use of the reflector plate is awkward and cumbersome, so that testing in the horizontal orientation with the OSU apparatus is not recommended.

Airflow. Total airflow rate is 40 L/s, of which only 10 L/s passes through the combustion chamber and the remaining 30 L/s flows through the upper hollow wall section. Nevertheless, the airflow rate through the combustion chamber contains enough oxygen to feed a 36 kW fire. Because the heat release rate from test specimens rarely exceeds 20 kW, burning conditions in the OSU apparatus are always overventilated. The airflow rates are measured accurately with standard orifices.

Additional measurements. The ASTM E906 standard does not include a mass loss measurement but has a smoke measuring system with a white light source in the stack.

The FAA established a committee in 1978 to examine the factors affecting the ability of aircraft cabin occupants to survive in a postcrash environment. The committee recommended research to evaluate the fire performance of cabin materials and development of a method using radiant heat for testing cabin materials. As a result, the FAA conducted an extensive series of full-scale fire tests and evaluated numerous small-scale tests for their capability to provide results that correlate well with full-scale performance.

The OSU apparatus, standardized as ASTM E906, was found to be the most suitable for material qualification. Improved flammability standards and requirements for airplane cabin interior materials based on ASTM E906 first went into effect in 1986 [52]. The limits for acceptance were based on heat release rate measured at a radiant heat flux level of 35 kW/m^2. Peak heat release rate could not exceed 100 kW/m^2, and average heat release rate over the first 2 min following ignition had to be 50 kW/m^2 or less.

Originally, the test method used by the FAA was identical to ASTM E906. More recently, some significant modifications have been made [11]. The FAA method now uses a thermopile of five thermocouples, a lighter specimen holder, and a modified test procedure to minimize problems associated with thermal lag [52]. The FAA criteria for acceptance were revised in 1990 to 65 kW/m^2 for peak heat release rate during the 5 min test and to 32.5 kW/m^2 for average heat release rate over the first 2 min following ignition [52].

Oxygen Consumption Versions

When oxygen consumption calorimetry became the preferred method for measuring heat release rate, fire research laboratories in the United States, Canada, and Sweden modified their OSU apparatus. These modifications typically consisted of the elimination of the original thermopile, the addition of a gas sampling probe and gas analysis equipment, and some adjustments to the airflow rates [6, 53–55].

The Forest Products Laboratory (FPL) made two additional significant modifications [54]. An auxiliary heat flux meter was added beneath the specimen to monitor incident radiant heat flux during a test. Measurements obtained with this auxiliary meter indicated that the incident radiant heat flux to a burning wood specimen increases significantly during a test. For example, the incident radiant heat flux to a Douglas fir plywood specimen at the end of a 10-min burning period increased by 20 % over the 35 kW/m^2 baseline. This is due to the fact that the heater elements in the OSU calorimeter are supplied with constant power and are not temperature controlled, and

that the calorimeter walls are allowed to heat up (or cool down) during testing.

The fact that exposure conditions in the OSU calorimeter are not constant is a major weakness of the apparatus. It is nearly impossible to remedy this problem. The addition of an auxiliary heat flux meter is highly recommended to record and account for the time-varying exposure conditions.

The second modification at FPL was the addition of a load cell to measure specimen mass loss during a test. This was a rather difficult task due to the geometry of the apparatus and the mechanism for inserting specimens. The FPL load cell design seemed to be satisfactory, demonstrating the feasibility of measuring mass loss in the OSU apparatus.

Cone Calorimeter

The cone calorimeter was developed at the National Bureau of Standards (NBS) by Dr. Vytenis Babrauskas in the early 1980s [37]. It is presently the most commonly used small-scale calorimeter. The apparatus and test procedure are standardized in the United States as ASTM E1354 and NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* and internationally as ISO 5660. Standard cone calorimeter specimens are exposed in an open environment with abundant supply of ambient air for combustion. Some laboratories have used a modified version of the standard apparatus to conduct studies in vitiated or oxygen-enriched atmospheres.

Standard Version

A schematic view of the apparatus is shown in Fig. 27.11. The main features are summarized below.

Measuring technique. Heat release rate is determined by the oxygen consumption method. The gas flow rate in the exhaust duct is calculated from the pressure drop across and temperature at an orifice plate in the duct. A methane burner calibration is performed to determine the orifice constant.

Configuration. Cone heater, spark igniter, specimen holder, and load cell are located beneath the hood. The standard configuration is open, with free access of air to the combustion zone.

Heater. The heater consists of a 5 kW electrical heating element wound inside an insulated stainless steel conical shell. The heater can be oriented horizontally or vertically to perform tests in either orientation. When tests are performed in the horizontal orientation, the specimen is positioned approximately 25 mm below the bottom plate of the cone heater. Flames and products of combustion rise and emerge through a circular opening at the top of the heater. Maximum radiant heat flux to the specimen exceeds 100 kW/m^2.

Ignition pilot. An electric spark is used as the ignition pilot at the top of vertical specimens and over the center of horizontal specimens.

Specimen size and orientation. Specimen size in both orientations is 0.1 m × 0.1 m. The optional retainer frame in the horizontal orientation and the standard specimen holder in the vertical orientation reduce the exposed area to 0.094 m × 0.094 m.

Airflow. Combustion products and dilution air are extracted through the hood and exhaust duct by a high-temperature fan. The initial flow rate can be adjusted between 10 and 32 L/s. Volumetric flow rate remains relatively constant during testing. Some cone calorimeters include additional instrumentation to optionally control and maintain the mass flow rate through the exhaust duct.

Additional measurements. The specimen is mounted on a load cell. Most cone calorimeters include instrumentation for measuring light extinction in the exhaust duct (using a laser light source, described in ASTM E1354 and ISO 5660-2). Instrumentation to measure concentrations of soot, carbon dioxide, carbon monoxide, and other gases is commonly added.

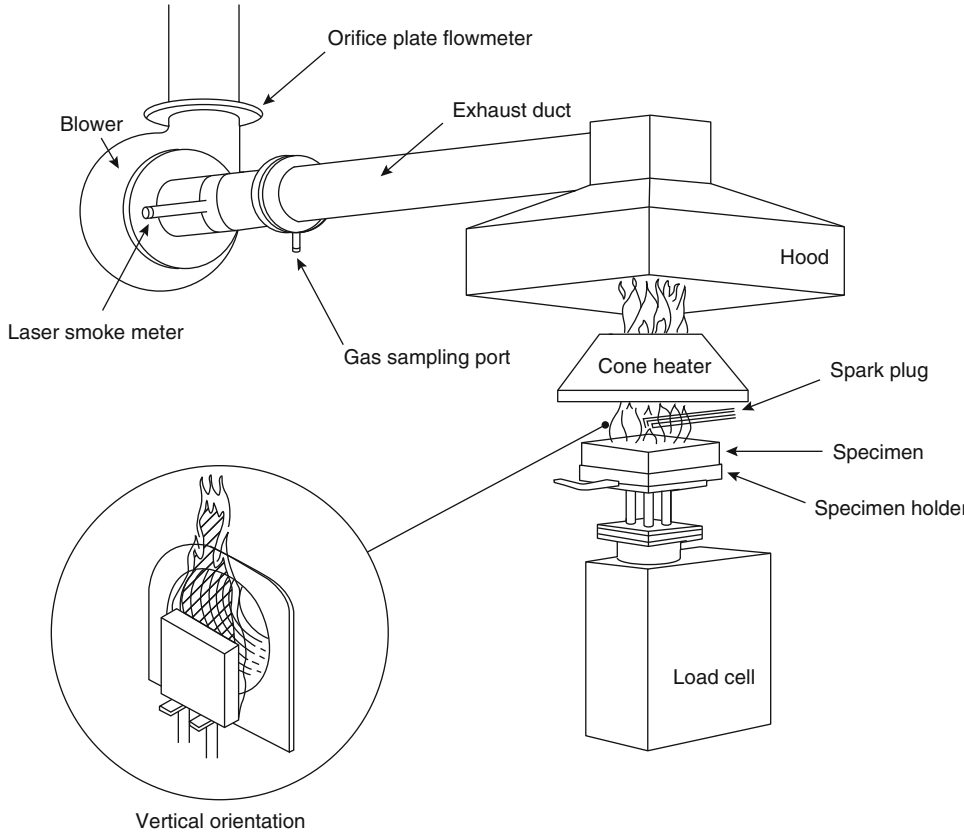

Fig. 27.11 Cone calorimeter

Modified Versions

A number of laboratories have used the cone calorimeter to study the effect of reduced or increased oxygen on the burning behavior of materials [28, 49, 56–59]. An enclosure was built around the heater and load cell and a mixture of nitrogen and oxygen, or air, was supplied to create the desired environment.

Fire Propagation Apparatus

Factory Mutual Research Corporation (FMRC, currently FM Global Research) developed the fire propagation apparatus (originally referred to as the combustibility apparatus) to measure heat release rate and generation rates of smoke and combustion products [60]. A schematic of the apparatus is shown in Fig. 27.12.

Originally, only convective heat release rate was measured on the basis of enthalpy rise of the exhaust gases. Test results reported since the late 1970s also include total heat release rates calculated from oxygen consumption or carbon dioxide generation. Several industrial laboratories in France, Germany, and the United States constructed the apparatus in the 1980s.

Tewarson used the apparatus to determine fire hazard indices [61] and material properties for fire modeling [62]. He also investigated the effect of environmental conditions (such as oxygen concentration in the combustion air) on heat release rate and burning behavior. The results of his extensive research are summarized Chap. 36. The fire propagation apparatus is standardized as ASTM E2058 and has the following main features:

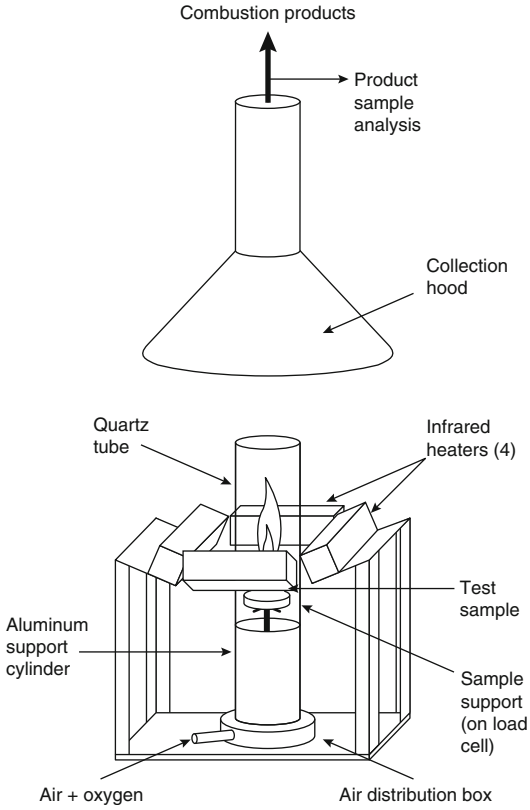

Fig. 27.12 Fire propagation apparatus

Measuring technique: Total heat release rate is determined by the oxygen consumption method. Tewarson also used carbon dioxide generation to calculate heat release rate. However, the amount of energy generated per mass unit of carbon monoxide generated is much more fuel dependent than the amount of energy produced per mass unit of oxygen consumed. Therefore, this technique is not as universally accepted as the oxygen consumption method.

Configuration: Tests are conducted in a semiopen environment. The specimen is located inside a segmented quartz tube, 0.66 m in length and 0.17 m in diameter. A mixture of oxygen and nitrogen is supplied at the bottom of the tube. A stainless steel funnel and vertical exhaust duct are located at some distance above the tube. Dilution air is entrained in the area between the tube and the exhaust system. The total flow of gases through the exhaust duct is determined by measuring pressure drop across a precalibrated orifice. The original apparatus had a vertical exhaust duct. A commercial version with a horizontal duct was recently developed.

Heater: Four heaters, which are located coaxially outside the quartz tube, are used to generate an incident heat flux to the specimen with a maximum of 65 kW/m^2. The electrical heaters operate at high temperatures so that the spectral distribution of the emitted radiation is not representative of that present in most fires. This problem is discussed elsewhere in this chapter.

Ignition pilot: The ignition pilot burner consists of a 6.35-mm stainless steel tube. The burner is supplied with a mixture of 60 % ethylene and 40 % air by volume, at a flow rate to create a stable flame length of 10 mm. The flame is located 10 mm above the horizontal specimen surface or 10 mm from the vertical specimen surface.

Specimen size and orientation: Horizontal specimens measure 0.1 m × 0.1 m or 0.1 m in diameter. ASTM E2058 also describes a procedure for upward flame spread experiments on 0.1 m × 0.3 m vertical planar specimens or 0.8-m-long cable specimens in an environment of 40 % oxygen in nitrogen.

Airflow: Total gas flow rate supplied to the bottom of the quartz tube is 3.3 L/s. Oxygen content of the combustion air can varied between 0 % and 60 %. Oxygen concentrations below ambient are used for simulating ventilation-controlled fires. Oxygen concentrations above ambient are used to increase flame radiation simulating larger fires [63]. Pure nitrogen is used to determine the heat of gasification.

Additional measurements: The apparatus includes instrumentation to measure specimen mass loss, smoke obscuration, and concentrations of O_2, CO_2, and CO in the exhaust flow. An optional hydrocarbon analyzer can be attached as well.

FAA Microscale Combustion Calorimeter

Recently, the U.S. Federal Aviation Administration (FAA) developed the Microscale Combustion Calorimeter (MCC) to assist with the development of fire-resistant polymers for use in commercial passenger aircraft. A schematic of this micro-scale calorimeter is shown in Fig. 27.13.

The apparatus is described in ASTM D7309. A milligram-size specimen is heated at a constant rate between 0.2 and 2 K/s. Decomposition can take place in nitrogen (method A) or in a mixture of nitrogen and oxygen (method B). When method A is used, char-forming specimens do not decompose completely and leave a solid residue. In this case the volatiles are mixed with a metered supply of oxygen in the combustor to obtain the heat release rate of the volatiles. When method B is used, the specimen is completely consumed. The temperature of the combustor is set at approximately 900 °C to completely oxidize all specimen gases. Oxygen consumption calorimetry with E = 13.1 kJ/g is used to measure heat release rate.

The MCC is different from the calorimeters described in the previous three subsections because the primary result is the heat release rate per mass unit of fuel volatiles as a function of time or pyrolysis chamber temperature (as opposed to the heat release rate per unit exposed specimen area as a function of time). The heat release rate per mass unit of fuel volatiles is referred to as the specific heat release rate, $Q(t)$, and is expressed in W/g. A typical result of an MCC test is shown in Fig. 27.14. The following five parameters are calculated when method A is used:

1. The heat release capacity $\eta_c \equiv Q_{max}/\beta$ in J/g·K, where Q_{max} is the maximum value of $Q(t)$ and β is the heating rate in K/s.
2. The heat release temperature T_{max} in K as the pyrolysis chamber temperature at which $Q(t) = Q_{max}$.
3. The specific heat release h_c in J/g as the area under the $Q(t)$ curve.

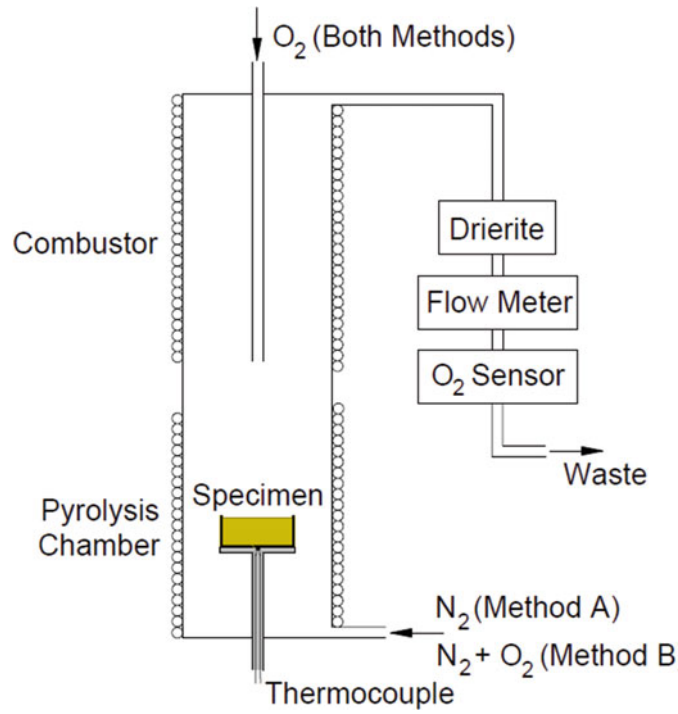

Fig. 27.13 Fire propagation apparatus

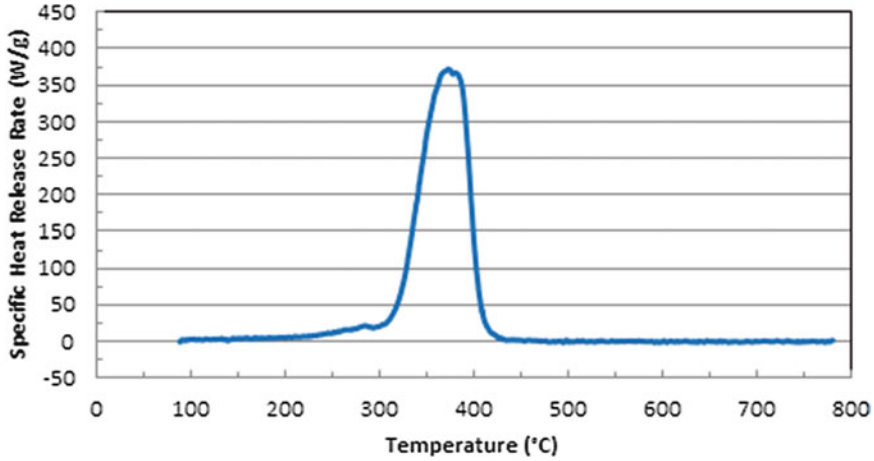

Fig. 27.14 Specific heat release rate versus MCC pyrolysis chamber temperature for PMMA

4. The pyrolysis residue $Y_p \equiv m_p/m_o$ in g/g, where m_p is the residual mass of the specimen at the end of the test.
5. The specific heat of combustion of the specimen gases $h_{c,gas} \equiv h_c/(1-Y_p)$ in J/g.

For method B only three parameters are calculated:

1. The combustion temperature T_{max} in K as the pyrolysis chamber temperature at which the specific heat release rate is a maximum, i.e., $Q(t) = Q^0_{max}$.
2. The combustion residue $Y_c \equiv m_c/m_o$ in g/g, where m_c is the residual mass of the specimen at the end of the test.
3. The net calorific value h_c^0 in J/g as the area under the $Q(t)$ curve.

Comparative Studies Between Different Small-Scale Tests

A number of comparisons are reported in the literature on how results obtained with different calorimeters for the same material compare. Östman et al. reported on a comparison of heat release data for 13 building materials obtained with the modified OSU, the cone calorimeter, and an open calorimeter developed by Sensenig at NBS [64]. Agreement was remarkably good with a correlation coefficient exceeding 90 % for average heat release rate over the first minute following ignition.

Babrauskas compared peak heat release rate from various calorimeters for five aircraft wall paneling materials [65]. He found good agreement between the fire propagation apparatus and the cone calorimeter. However, he also found that the peak heat release rate from the OSU apparatus was approximately 50 % of the peak from the cone calorimeter. Whether thermopile or oxygen consumption were employed seemed to have only a minor effect on the results from the OSU apparatus. Unfortunately, correlation of average heat release rate was not reported, so that a comparison with the work of Östman et al. is not possible.

Tran compared heat release rate curves for Douglas fir plywood from the cone calorimeter, and the OSU apparatus modified for oxygen consumption [54]. First and second peaks agreed well, but the OSU data exceeded the cone calorimeter data by up to 20 % between the peaks. The increased burning rate can be explained by the enhanced radiant heat flux to the specimen due to temperature rise of the calorimeter walls and heater during a test. Tran tested the same material in the OSU apparatus with the vertical specimen holder from the cone calorimeter and found no effect.

Kandola et al. tested several aircraft interior fabrics in the OSU calorimeter according to the

FAA specification and in the cone calorimeter [66]. They found that the specimens ignited much earlier in the OSU apparatus and that the heat release rates were significantly lower in the cone calorimeter. The heat flux in the cone calorimeter had to be increased to 50 kW/m^2 to obtain comparable heat release rates as measured in the OSU calorimeter at 35 kW/m^2.

Two comparative studies were conducted involving electrical cables. Gandhi et al. measured shorter ignition times and lower heat release rates in the fire propagation apparatus than in the cone calorimeter for communication cables [67]. Carman et al. compared oxygen consumption and thermopile measurements for six different types of cables [68]. Good agreement was obtained between the two measurement techniques under flaming conditions.

The thermal combustion properties measured in the MCC are related to flammability characteristics of the material [69–73]. For example, the heat release temperature from method A approximates the surface temperature at ignition. The net calorific value from method B approximates the net heat of combustion measured in an oxygen bomb calorimeter.

Heat release data from small-scale calorimeters are always apparatus dependent. Differences in geometry, test conditions, and mounting methods explain discrepancies between the results from different calorimeters. Apparatus-specific factors must be considered and addressed in a comparison between different calorimeters or when the data are used to predict performance in real fire conditions.

Intermediate- and Large-Scale Calorimeters

This section covers commonly used intermediate- and large-scale calorimeters. Collection and extraction of the products of combustion generated in these calorimeters are usually accomplished in a specific manner. The standard hood and exhaust duct are described before the main features of different intermediate- and large-scale calorimeters are summarized.

Standard Hood and Exhaust Duct

To measure heat release rate in a fire test based on the oxygen consumption technique, it is necessary to collect all combustion products and to measure the oxygen concentration and flow rate of the effluents. A properly designed hood and exhaust duct with the necessary instrumentation are used for this purpose. Various intermediate- and large-scale calorimeters described in subsequent sections use the same standard hood and exhaust duct setup shown in Fig. 27.15.

The square opening of the hood is approximately 2.4 m × 2.4 m and the bottom of the hood is 2.4–3.0 m above the floor of the laboratory. Skirts can be hung down from the hood to minimize spilling. Baffle plates in the plenum or an orifice plate at the entrance of the exhaust duct are used to provide proper mixing of the exhaust gases.

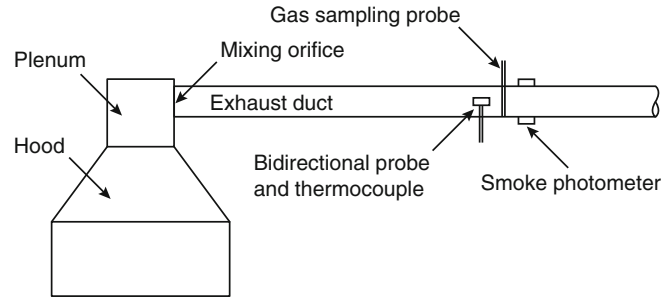

Fig. 27.15 Standard calorimeter hood and exhaust duct

The instrumentation section is located at a distance from the entrance to the exhaust duct of at least 10 times the diameter, that is, 4.0 m for the standard 0.4-m-diameter exhaust duct. The measuring section consists of a combination of a bidirectional probe and thermocouple, a gas sampling probe, and a light extinction measurement system. A straight section of pipe of a length at least six times the diameter is located downstream of the measuring section.

The distance between the base of the fire and the bottom of the hood determines the peak heat release rate that can be measured for a burning object located beneath the hood [74]. On the one hand, the hood has to be sufficiently elevated above the fire to avoid flame impingement. Flame impingement has two undesirable effects. First, flames impinging on a relatively cold surface are quenched, which adversely affects completeness of combustion. Second, radiation from hot metal surface enhances the burning rate of an object located beneath the hood above that of a free burn.

The maximum heat release rate without flame impingement on the standard hood is approximately 1 MW. This is consistent with the fact that the flame height of a 1 MW fire with an effective diameter of 1.5 m is approximately 2.2 m based on Heskestad's flame height correlation (see Chap. 13, "Fire Plumes, Flame Height, and Air Entrainment"):

$$L_f = 0.235\dot{Q}^{2/5} - 1.02D = 0.235(1000)^{2/5} - 1.02(1.5) \approx 2.2\text{m} \quad (27.23)$$

where
L_f = Flame length(m)
$\dot{Q}$ = Heat release rate(kW)
D = Effective diameter of the fire(m)

On the other hand, the hood cannot be located too high above the burning object to avoid spilling. The skirts are helpful in this respect.

An ideal exhaust system extracts combustion products at the same rate as the flow rate in the plume when it enters the hood. This results in the highest and most accurate measurement of oxygen depletion because no additional air above what is entrained in the plume is drawn into the exhaust duct. The plume flow rate at a height of 2.2 m above a fire with an effective diameter of 1.5 m can be estimated from the simple equation developed by Thomas et al. [75] (see Chap. 13):

$$\dot{m}_p = 0.188\frac{\pi}{4}D^2z^{3/2} = 0.188\frac{3.14159}{4}1.5^2 2.2^{3/2} = 1.08\,\text{kg/s} \quad (27.24)$$

where
$\dot{m}_p$ = Plume flow(kg/s)
z = Height above the fire(m)

Assuming a radiative loss fraction of 30 %, which is a typical value for many fuels (see Chap. 36), this corresponds to a volumetric flow rate of 2.8 m^3/s at a temperature of 650 °C. Intermediate- and large-scale calorimeter test standards that specify the hood and exhaust system described in this section typically require an exhaust fan with a capacity of 3.5 m^3/s.

Intermediate-Scale Calorimeter (ICAL)

One of the limitations of the cone calorimeter is that only relatively small samples can be evaluated. As a result, products that have joints or layered materials with a thickness exceeding 50 mm can generally not be tested in the cone calorimeter in a representative manner. For those types of products or assemblies, a larger calorimeter, such as the intermediate-scale calorimeter (ICAL) described in ASTM E1623, is required.

The ICAL apparatus consists of an array of gas heaters, forming a vertical radiant panel with an approximate height and width of 1.33 m and 1.54 m, respectively (Fig. 27.16). The standard test specimen measures 1 m × 1 m and is positioned parallel to the radiant panel. The heat flux to the specimen is preset in the range of 10–60 kW/m^2 by adjusting the distance to the panel. Gas flow to the panel is controlled to

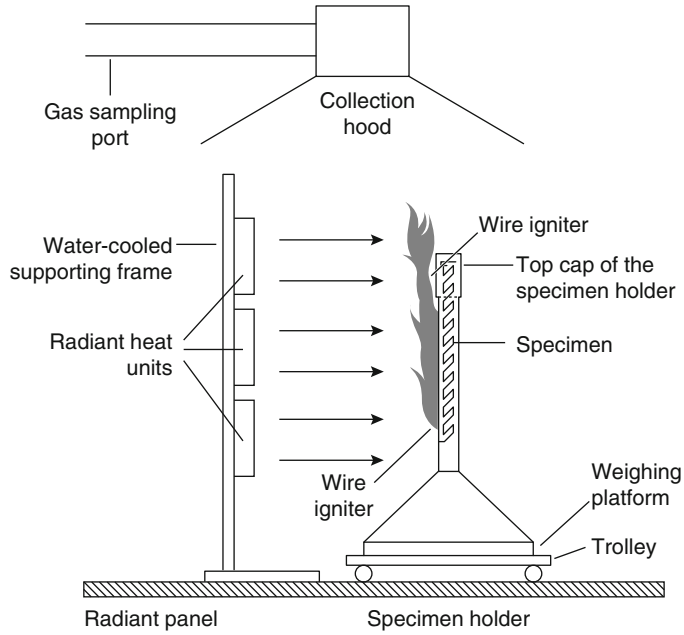

Fig. 27.16 ICAL apparatus

maintain the temperature to the panel and consequently the heat flux to the specimen during a test. The products of pyrolysis from the specimen are ignited with hot wires located close to, but not in contact with, the specimen at its top and bottom. The specimen is placed in a holder that is put on a load cell to measure mass loss during testing.

Panel and specimen are positioned beneath the standard hood described in the previous subsection. Measurements of oxygen concentration, flow rate, and light transmission in the exhaust duct are used to determine the heat release rate and smoke production rate from the specimen as a function of time. Because the combustion products from the radiant panel are also captured in the hood, it is necessary to subtract the corresponding heat release rate or smoke production rate to determine the contribution from the specimen.

Furniture Calorimeter

Often it is very difficult to determine the burning behavior of complex objects on the basis of the fire performance of their individual components. For example, it is very hard to determine the burning behavior of upholstered furniture on the basis of the fire characteristics of the foam, fabric, and framing materials and to account for the geometry and configuration of the furniture and how it is ignited. It is much more practical to measure the heat release rate and related properties for the complete object.

Furniture calorimeters were developed in the 1980s in several laboratories to obtain this kind of data [76, 77]. The first furniture calorimeter test standard was published in 1987 in the Nordic countries as NT Fire 032.

A furniture calorimeter consists of a weighing platform that is located on the floor of the laboratory beneath the standard hood (Fig. 27.17). The object is placed on the platform and ignited with the specified ignition source. The products of combustion are collected in the hood and extracted through the exhaust duct. Measurements of oxygen concentration, flow rate, and light transmission in the exhaust duct are used to determine the heat release rate and smoke production rate from the object as a function of time.

Furniture calorimeter test standards have been developed in ASTM for chairs (ASTM E1537),

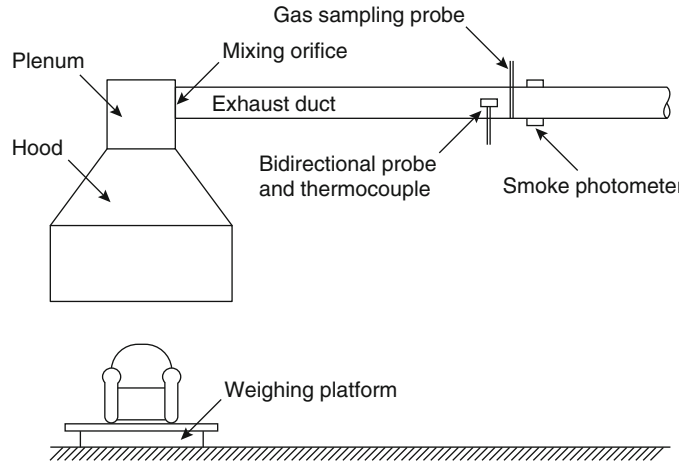

Fig. 27.17 Furniture calorimeter

Table 27.3 Ignition sources specified in fire tests for chairs and mattresses

		Gas burner ignition source			
Test method	Specimen	No.	Type	Heat output	Location of application
ASTM E1537 CAL TB 133	Single chair	1	Square	19 kW for 80 s	Horizontal seating surface
ASTM E1822	Stacked chairs	1	Line	18 kW for 80 s	Bottom chair front edge
ASTM E1590	Mattress (set)	1	Line	18 kW for 180 s	Front bottom edge
CAL TB 603	Mattress (set)	2	Line	19 kW for 70 s	Top surface
16 CFR 1633			Line	10 kW for 50 s	Vertical along side

mattresses (ASTM E1590), and stacked chairs (ASTM E1822). The California Bureau of Home Furnishings and Thermal Insulation (CBHFTI) published California Technical Bulletins (CAL TB) 133 and 603. These documents describe fire test procedures to qualify seating furniture and mattresses, respectively, for use in public occupancies in the state of California. Acceptance is primarily based on a peak heat release rate and 10-min total heat release limits of 80 kW and 25 MJ for chairs (CAL TB 133) and 200 kW and 25 MJ for mattresses (CAL TB 603). The primary difference between the different fire test methods for chairs and mattresses is the ignition source, which has been demonstrated to affect heat release rate [78]. The main features of the gas burner ignition source specified in different methods are given in Table 27.3.

All mattresses sold in the United States must comply with the heat release requirements specified in 16 CFR 1633. The method and requirements are identical to CAL TB 603, except that the 10-min total heat release limit is reduced to 15 MJ. The fire test method for mattresses and mattress/box spring sets described in this document was developed at the National Institute of Standards and Technology (NIST) in a research program sponsored by the Sleep Products Safety Council (SPCS), an affiliate of the International Sleep Product Association (ISPA) [79–81].

The original version of CAL TB 133 specified that the test specimen be located in a corner against the back wall of a 3.7 m × 3.0 m × 2.4 m room with a 1.0 m × 2.1 m open doorway in the front wall. The ignition source consisted of five double sheets of loosely-wadded newspaper inside a chicken wire cage placed on the back of the seat. Acceptance was based primarily on a maximum temperature rise of 111 °C just below the ceiling above the chair. Subsequent NIST research resulted in the development of the

presently used gas burner as an alternative ignition source [82]. The gas burner flame generates an equivalent thermal insult but is much more repeatable and reproducible than the original ignition source.

The NIST research project also resulted in an equivalent heat release rate criterion and demonstrated that the room effects are negligible for heat release rates below 600 kW [83]. Later studies found significant effects at lower heat release rates and proposed a threshold of 460 kW [84]. Because this is still much higher than peak heat release rate limits specified in regulations, all furniture and mattress test standards discussed here permit the use of an open furniture calorimeter configuration as an alternative to the room configuration. In fact, all test standards except 16 CFR 1633 allow two room configurations: the original CAL TB 133 room and a smaller 3.7 m $\times$ 2.4 m $\times$ 2.4 m room commonly used for room/corner testing (see below).

Room/Corner Test

Room/corner tests are by far the most frequently conducted large-scale fire experiments throughout the world. This section provides a historical overview of the development of room/corner test protocols and summarizes the resulting test standards in use today.

Historical Overview

Much of the work toward the development of a standard room/corner test was performed in the United States in the late 1970s and early 1980s. The need for a standard room fire test and some aspects of its design were discussed by Benjamin in 1977 [85]. Subsequent research in North America to arrive at a standard full-scale test was conducted primarily by Fisher and coworkers at the University of California (UCB) [86] and by Lee at the National Bureau of Standards (NBS) [87].

Considerable seminal research was also performed in the Nordic countries. An extensive project to construct a full-scale room calorimeter was conducted in Sweden [88, 89]. No oxygen consumption measurements were made at that time. A heat balance was obtained by comparing the theoretical heat release from combustion of gaseous fuel to the sum of the heat losses. The heat losses consisted of convection through the doorway, conduction through the walls and ceiling, and radiation through the doorway.

Heat convection through the doorway was estimated by measuring gas velocity and temperature at many points in the doorway. Heat conduction through the surrounding surfaces was calculated based on total heat flux, radiation, and surface temperature data. Heat loss by radiation through the door was calculated from radiometer measurements.

Initially, a series of quasi-steady calibration tests were conducted in an inert room. Three different circular propane gas burners were used with diameters of 0.2, 0.3, and 0.4 m, respectively. Heat balance calculations showed reasonable agreement, with convection losses being dominant. In subsequent tests with surface finishes, a heptane pool fire with a heat release rate of approximately 50 kW was used as the ignition source.

Ahonen et al. at the Technical Research Center of Finland (VTT) studied the effects of different gas burner ignition sources on room/corner fire growth [90]. Tests were conducted for each combination of three burner sizes (0.17 m $\times$ 0.17 m, 0.305 m $\times$ 0.305 m, and 0.5 m $\times$ 0.5 m) and three square wave heat release rates (40, 160, and 300 kW). Oxygen consumption calorimetry was used for measuring heat release rate. The burner was placed in a corner in the back of the room. Ceiling and all walls except the front wall were lined with 10-mm-thick particleboard with a density of 720 kg/m^3.

The following six criteria were used to determine the time to flashover:

- Flames emerging through the door (flameover)
- Total heat release rate of 1 MW
- Total heat flux to the floor of 20 kW/m^2
- Specified rate of smoke production
- Temperature of 600 °C at the geometric center of the room
- Total heat flux to the floor of 50 kW/m^2

With the time to flashover defined as the average of the six criteria, the following remarkable results were obtained:

- At the 40 kW level, the medium-sized burner resulted in flashover first, followed by the smaller burner, and then the larger burner.
- At 160 kW, the largest burner resulted in flashover first, quickly followed by the other two configurations.
- At 300 kW, the trend was the same as at 160 kW with an even smaller spread between the three results.

The effect of burner size was most significant at the lowest heat release rate, with the medium-sized burner being the most severe. At higher exposure levels, the size of the burner had no significant effect. Radiative and convective heat transfer from the burner flame were shown to depend on burner size and heat release rate and had a significant effect on the performance of the material tested. On the basis of the results, the medium burner size and heat release rate were recommended.

Room/Corner Test Standards

Several standard room/corner test protocols are now available and are specified in codes and regulations for qualifying interior finishes. For example, U.S. model building codes require that textile wall coverings for use in unsprinklered compartments meet specific performance requirements when tested according to NFPA 265, *Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls*. The principal requirement of these tests is that flashover does not occur. The same codes also require that all other interior wall and ceiling finish materials comply with requirements based on NFPA 286, including a limit on the total smoke released.

The Safety Of Life At Sea (SOLAS) convention, promulgated by the International Maritime Organization (IMO), permits the use of combustible bulkhead and ceiling linings on high-speed craft, provided they meet stringent fire performance requirements based on assessment according to ISO 9705. ASTM E2257 is the American version of ISO 9705.

The test apparatus and instrumentation described in the NFPA and ISO room/corner test standards are very similar (Fig. 27.18). However, some significant differences exist in terms of specimen configuration and ignition source.

The apparatus consists of a room measuring 3.6 m deep by 2.4 m wide by 2.4 m high, with a single ventilation opening (open doorway) measuring approximately 0.8 m wide by 2.0 m high in the front wall. Walls and ceiling are lined for tests according to ISO 9705. For tests according

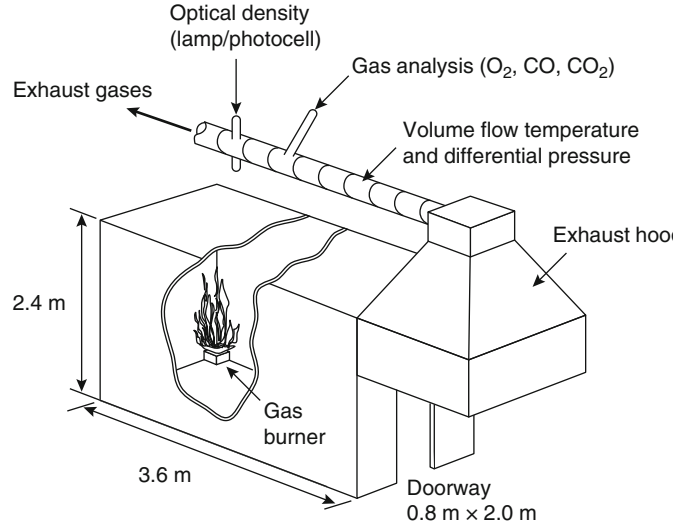

Fig. 27.18 Room/corner test

to the NFPA standards, the interior surfaces of all walls (except the front wall) are covered with the test material. NFPA 286 is also suitable for evaluating ceiling finishes (see below).

The test material is exposed to a propane burner ignition source, located on the floor in one of the rear corners of the room opposite the doorway. The burner is placed directly against (ISO 9705 and NFPA 286) or at a distance of 50 mm from (NFPA 265) the walls. The ISO burner consists of a steel sandbox measuring 0.17 m × 0.17 m × 0.145 m, with the top surface 0.145 m above the floor of the room. Propane is supplied to the burner at a specified rate such that a net heat release rate of 100 kW is achieved for the first 10 min of the test, followed by 300 kW for the remaining 10 min (20-min test duration unless terminated when flashover occurs). The NFPA burner consists of a steel sandbox measuring 0.305 m × 0.305 m × 0.152 m, raised so that the top surface is 0.305 m above the floor of the room. Propane is supplied at a specified rate so that a net heat release rate of 40 kW is achieved for the first 5 min of the test, followed by 150 kW (NFPA 265) or 160 kW (NFPA 286) for the remaining 10 min (15-min test duration unless terminated when flashover occurs). A fundamental difference between NFPA 265 and NFPA 286 is the fact that the flame from the burner alone just touches the ceiling in NFPA 286. This makes it suitable for assessing the fire performance of interior ceiling finish, an application for which NFPA 265 is unsuitable. This effect is partly due to the higher energy release rate of the NFPA 286 burner, but primarily because of the burner being in direct contact with the walls, thereby reducing the area over which the flames can entrain air and increasing the overall flame height.

All combustion products emerging from the room through the open doorway are collected in the standard hood. Instrumentation is provided in the exhaust duct for measuring heat release rate based on the oxygen consumed (ISO and NFPA standards) and smoke production rate (ISO 9705 and NFPA 286 only). The room contains a single heat flux meter located in the center of the floor. The NFPA standards also specify that seven thermocouples be installed in the upper part of the room and doorway to measure the temperature of hot gases that accumulate beneath the ceiling and exit through the doorway. In addition to quantitative heat release and smoke production rate measurements, time to flashover (if it occurs) is one of the main results of a room/corner test. Different criteria are commonly used to define flashover; for example, upper layer temperature of 600 °C, flames emerging through the doorway, heat flux to the floor of 20 kW/m^2, heat release rate of 1 MW, and so forth.

Single Burning Item Test

The European reaction-to-fire classification system for construction products except floor coverings (EN 13501) is based primarily on performance in this test. An SBI test in progress is shown in Fig. 27.19. Two specimens of the material to be tested are positioned in a specimen holder frame at a 90° angle to form an open corner section. Both specimens are 1.5 m high. One specimen is 1 m wide and is referred to as the long wing. The other specimen is 0.5 m wide and is referred to as the short wing. During a test,

Fig. 27.19 SBI test in progress (Photo courtesy SwRI.)

the specimens are exposed for 20 min to the flame of a triangular-shaped diffusion propane gas burner operating at 30 kW. The specimen holder and primary gas burner are mounted on a trolley that can be moved in and out of an enclosure of 3 m ± 0.6 m wide, 3 m ± 0.6 m deep, and 2.4 m ± 0.1 m high. The enclosure walls consist of noncombustible materials (concrete block, calcium silicate board, etc.) and/or gypsum board, and have windows to allow the operator to observe the test. The mean height and maximum heat flux from the 30 kW burner flame are approximately 0.8 m and 35 kW/m^2, respectively [91].

Prior to a test, the specimens are placed in the holder, and the trolley is rolled into the enclosure and positioned under an insulated hood. During a test, the products of combustion are collected in the hood and are extracted through an exhaust duct. Instrumentation is provided in the duct to measure temperature, velocity, gas composition (O_2, CO_2, and CO), and smoke obscuration.

The velocity and gas composition data are used to determine heat release rate on the basis of the oxygen consumption technique. Materials are tested in triplicate. Classification is based primarily on fire growth (FIGRA) and smoke development (SMOGRA) indices that are equal to the peak heat release and smoke production rate, respectively, divided by the time to reach the peak. FIGRA and SMOGRA limits were established based on performance in the ISO 9705 room/corner test as the reference scenario [92].

Industrial-Scale Calorimeters

Industrial-scale calorimeters consist of a larger version of the hood and exhaust duct shown in Fig. 27.15. To handle fires up to 10 MW in size for a short duration, the hood must be at least 6 m × 6 m in size or 6 m in diameter and is typically located 6.5 m or higher above the floor of the laboratory. The fan must be capable of extracting combustion products through a 0.9-m-diameter exhaust duct at a minimum rate of 15 m^3/s. A larger calorimeter and higher fan capacity are needed to handle more severe experimental fires.

Cooper presented useful guidelines to address the special challenges associated with the design of an industrial-scale calorimeter [74]. ASTM E2067 is a standard practice for conducting accurate heat release rate measurements at the multi-megawatt level.

The first industrial-scale calorimeter for fires into the multi-megawatt range was built at Factory Mutual around 1980 [93]. This calorimeter, also referred to as the FM fire products collector, was designed to measure heat and other fire products from test fires up to a size associated with sprinkler activation in commodity warehouse storage and other representative occupancies.

Approximately 10 years later, a similar industrial-size calorimeter for heat release rate measurements up to 10 MW was constructed at the National Testing Laboratory (SP) in Sweden [94]. Since then several other laboratories—such as the National Research Council of Canada, the Fire Research Station in the United Kingdom, the Bureau of Alcohol, Tobacco, Firearms and Explosives (ATF) Fire Research Laboratory, the National Institute of Standards and Technology (NIST), Southwest Research Institute and Underwriters Laboratories in the United States—developed the capability of measuring heat release rate from large fires into the megawatt range.

Use and Application of Heat Release Rate Data

The primary use of heat release rate data is in support of fire hazard assessment of materials and products. Small- and intermediate-scale data can be used in conjunction with mathematical models to predict the performance of materials and products in real fire scenarios. Heat release rates measured in large- and industrial-scale calorimeters can be used directly in support of a fire hazard assessment.

Small-Scale Calorimeter Data

Predictive models that are available for fire hazard assessment on the basis of small- or intermediate-scale heat release rate data vary widely in complexity. The extent of the heat release rate data that are needed varies according to the complexity of the model. Room/corner testing is a widely accepted approach to assess the fire hazard of interior finish materials. The room/corner scenario is used here to illustrate the different types of predictive models and corresponding requirements for input data from small-scale calorimeters.

There are three distinct types of room/corner test models: regression models, analytical models, and physics-based models. Regression models express a relationship between a particular room/corner test performance characteristic, for example, the time to flashover, and small-scale fire test data for the same product. Regression models are based on a statistical analysis of room/corner and small-scale test data for a set of products and can be used as a screening tool. Analytical models predict fire growth but do not simulate the room environment. Physics-based models predict how the room environment varies as a function of time and how flames spread over the walls and ceiling of the compartment. There is a strong interaction between regression and physics-based models because the conditions in the room determine the heat that is transferred back to the wall and ceiling surfaces, which affects the flame spread and the heat release and smoke production rate of burning wall and ceiling sections.

Regression Models

The least sophisticated models are based on regression analyses. The following equation, obtained by Östman et al. based on an analysis of test data for 28 materials in the cone calorimeter and according to ISO 9705, serves as a good example of this type of room/corner test modeling [95].

$$t_{fo} = 0.0716 \frac{t_{ig}^{0.25} \rho^{1.72}}{\left(Q_{300}''\right)^{1.30}} + 57.4 \qquad (27.25)$$

where

t_{f0} = Time to flashover (s)

t_{ig} = Time to ignition in the cone calorimeter at 50 kW/m^2 (s)

ρ = Density of the material (kg/m^3)

Q_{300}'' = Total heat released at 50 kW/m^2 during 300 s following ignition (MJ/m^2)

This equation can be used to predict room/corner test performance on the basis of small-scale data for materials that have not been tested in the room. With this approach the dynamics of the heat release curve are lost entirely. There is no difference in the prediction of full-scale performance for two materials with heat release curves of very different shapes, provided the heat release rate parameter and ignition time used in the correlation are identical. The predictions are valid for one scenario and geometry only. For example, Equation 27.25 cannot be used to predict the time to flashover for the NFPA 265 and NFPA 286 room/corner tests. The main advantage of this approach is that a minimal amount of small-scale testing is needed to obtain the necessary input data.

Analytical Models

The approach outlined in the preceding subsection can be improved by using a heat release curve at a single radiant heat flux level. Thus, the dynamic effects of the room fire on the exposure level are ignored while the dynamics of the heat release curve are largely maintained. The radiant heat flux level is chosen so that it is a representative average (over space and time) for the fire scenario that is being modeled [96]. Representative heat flux levels for the room/corner test scenario range from 25 to 50 kW/m^2.

The single heat release curve is used in combination with a flame spread algorithm to predict heat release rate as a function of time in the room/corner test. The flame spread algorithm can be very simple but needs at least some

ignition data for the material. The burning area expands as time proceeds and new sections of the material are ignited. The heat release rate is calculated at discrete time increments, Δt. The flame spread algorithm calculates the expansion of the burning area at every time step. The heat release rate in the room/corner test at a particular time is then obtained by adding the contributions from all incremental areas to the heat release rate from the ignition burner at that time:

$$\dot{Q}_t(t_N) = \dot{Q}_b(t_N) + \sum_{i=0}^{N} A_i \dot{Q}''(t_N - t_i) \quad (27.26)$$

where

$\dot{Q}_t$ = Total heat release rate in the room/corner test(kW)
t_N = Time after N time increments Δt from the start of the test, equal to$N\Delta t$(s)
$\dot{Q}_b$ = Heat release rate from the ignition burner(kW)
A_i = Incremental area ignited at time t_i(m^2)
$\dot{Q}''$ = Heat release rate measured in the cone calorimeter(kW/m^2)
t_i = Time afteritime increments Δt from the start of the test, equal to $i\Delta t$(s)

This method automatically accounts for burnout. The most widely known room/corner test model of this type was developed by Wickström and Göransson [97].

Physics-Based Models

Direct Use of Heat Release Rate Measurements at Multiple Heat Fluxes

The modeling approach described in the preceding subsection can be refined by using heat release rate curves obtained at multiple heat fluxes. This makes it possible to account for the fact that the incident heat flux to each incremental area varies with time. The problem, however, is that the heat release rate of an incremental area at a particular time cannot be determined from direct interpolation of the heat release rate curves measured in the calorimeter. This is because it takes more time at lower heat fluxes to completely consume the material than at higher heat fluxes. To address this problem, heat release rate has to be expressed as a function of a progress variable that is consistent at different radiant heat flux levels.

Smith and Green conducted experiments in the OSU calorimeter at different heat flux levels and tested the same material at time-varying heat fluxes [98]. They were able to reconstruct the heat release rate curve measured under dynamic exposure conditions from interpolation between the curves obtained at fixed radiant heat fluxes using total heat release as the progress variable. Mitler used total mass loss as the progress variable [99]. Janssens suggested using char depth as a suitable progress variable for wood [100].

The following modification to Equation 27.26 represents an improved room/corner test model that accounts for the effect of incident heat flux on heat release rate. Total heat release rate is used as the progress variable.

$$\dot{Q}_t(t_N) = \dot{Q}_b(t_N) + \sum_{i=0}^{N} A_i \dot{Q}''\left[\dot{q}_{e,i}''(t_N), Q_i''(t_N)\right] \quad (27.27)$$

where

$\dot{q}_{e,i}''$ = Incident heat flux to A_i(kW/m^2)
$\dot{Q}_i''$ = Total heat release from A_i(MJ/m^2)

The model calculates the incident heat flux and keeps track of the total heat release rate for each incremental area. A room/corner test model of this type was developed by Smith et al. at Ohio State University [5].

The primary limitations of using this type of model are that (1) it is based on the assumption that the heat flux from the material's own flame in the small-scale calorimeter is comparable to that in the room/corner test, and (2) Equation 27.27 is assumed to be valid regardless whether the incident heat flux is purely radiative (as in the small-scale calorimeter) or partly convective (as, for example, in areas of the room

where the material is exposed to the flame of the ignition source). These limitations can be addressed, at least in an approximate manner, but not without making the approach much more complex.

Use of Heat Release Properties

A more fundamental approach to account for the effects of time-varying heat fluxes on heat release rate is based on two material properties that can be measured in a small-scale calorimeter. These properties are the effective heat of combustion, $\Delta h_{c,\text{eff}}$, and the heat of gasification, Δh_g. Both properties have the units of kJ/g or MJ/kg.

The effective heat of combustion is the ratio of heat release rate to mass loss rate measured in a small-scale calorimeter.

$$\Delta h_{c,\text{eff}} \equiv \frac{\dot{Q}''}{\dot{m}''} \tag{27.28}$$

where

$\dot{Q}''$ = Heat release rate per unit exposed area(kW/m^2)
$\dot{m}''$ = Mass loss rate per unit exposed area$(\text{g}/\text{m}^2 \cdot \text{s})$

The effective heat of combustion at a particular time t can be calculated by substituting the values for $\dot{Q}''$ and $\dot{m}''$ at that time in Equation 27.28. A curve of $\Delta h_{c,\text{eff}}$ as a function of time can be determined in this manner. Unfortunately, mass loss rate data are often very noisy and the calculated time-varying heat of combustion values may not have any physical meaning. More meaningful values are obtained by calculating an average $\Delta h_{c,\text{eff}}$, over a specified time period by substituting average values of $\dot{Q}''$ and $\dot{m}''$ over that time period in Equation 27.28.

Dillon et al. proposed three methods to calculate the effective heat of combustion [101]. The first value is equal to the ratio of the first peak heat release rate and mass loss rate at the same time. The second value is obtained as the ratio of the average heat release rate over the peak burning period and the mass loss rate over the same period. The peak burning period is defined as the period around the first peak heat release rate during which the heat release rate is at least 80 % of the first peak heat release rate. The third value is equal to the ratio of total heat released and total mass loss over the entire flaming period.

The heat of gasification is defined as the net heat flow into the material required to convert one mass unit of solid material to volatiles. The net heat flux into the material can be obtained from an energy balance at the surface of the specimen. Typically, a sample exposed in a small-scale calorimeter is heated by external heaters and by its own flame. Heat is lost from the surface in the form of radiation. A schematic of the heat balance at the surface of a burning specimen in the cone calorimeter is shown in Fig. 27.20. Hence, Δh_g is defined as

$$\Delta h_g \equiv \frac{\dot{q}''_{\text{net}}}{\dot{m}''} = \frac{\dot{q}''_e + \dot{q}''_f - \dot{q}''_l}{\dot{m}''} \tag{27.29}$$

where

$\dot{q}''_e$ = Heat flux to the specimen surface from external sources(kW/m^2)
$\dot{q}''_f$ = Heat flux to the specimen surface from the flame(kW/m^2)
$\dot{q}''_l$ = Heat losses from the exposed surface (kW/m^2)

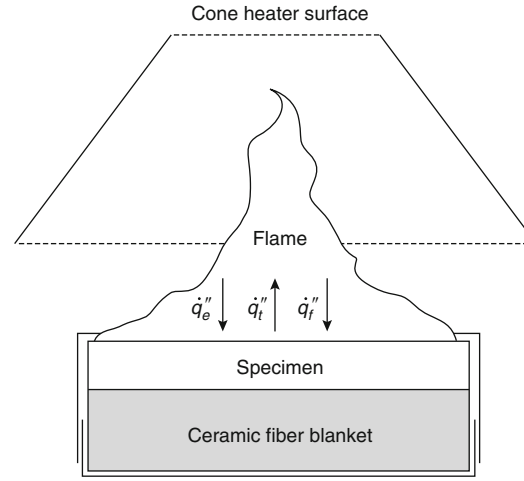

Fig. 27.20 Heat balance at the surface of a burning cone calorimeter specimen

If the flame is approximated as a homogeneous gray gas volume, the heat flux from the flame can be expressed as follows:

$$\dot{q}_f'' = \dot{q}_{f,c}'' + \dot{q}_{f,r}'' = h^*(T_f - T_s) + \sigma \varepsilon_f T_f^4 \tag{27.30}$$

where

$\dot{q}_{f,c}''$ = Convective fraction of the flame flux $(\mathrm{kW/m^2})$
$\dot{q}_{f,r}''$ = Radiative fraction of the flame flux $(\mathrm{kW/m^2})$
h^* = Convection coefficient corrected for blowing $(\mathrm{kW/m^2 \cdot K})$
T_f = Flame temperature (K)
T_s = Surface temperature (K)
σ = Boltzmann constant $(5.67 \cdot 10^{-11} \mathrm{kW/m^2 \cdot K^4})$
ε_f = Emissivity of the flame

The flow of combustible volatiles emerging through the exposed surface of the specimen adversely affects the convective heat transfer between the flame and the surface. This effect is referred to as "blowing." The flame flux in a small-scale calorimeter is primarily convective, in particular in the vertical orientation, and flame absorption of external heater and specimen surface radiation can be neglected.

The heat losses from the surface can be expressed as

$$\dot{q}_l'' = \sigma \varepsilon_s (T_s^4 - T_\infty^4) \tag{27.31}$$

where

ε_s = Surface emissivity of the specimen
T_∞ = Ambient temperature (K)

Some materials exhibit nearly steady mass loss rates when exposed to a fixed radiant heat flux. T_s for these materials reaches a steady value after a short initial transient period and all terms in Equation 27.29 are approximately constant. Δh_g can then be obtained by measuring steady mass loss rates at different radiant heat flux levels and by plotting $\dot{m}''$ as a function of $\dot{q}_e''$. The reciprocal of the slope of a straight line fitted through the data points is equal to Δh_g. The intercept of the line with the abscissa is equal to $\dot{q}_l'' - \dot{q}_f''$. Tewarson et al. [62] and Petrella [102] have used this technique to obtain average Δh_g values for a large number of materials. Tewarson et al. also conducted tests in vitiated O_2-N_2 mixtures and found $\dot{q}_f''$ to decrease linearly with decreasing oxygen concentration. Analysis of these additional experiments made it possible to separate $\dot{q}_f''$ and $\dot{q}_l''$.

Many materials, in particular those that form an insulating char layer as they burn, take a long time to reach steady burning conditions or may never reach steady conditions. Equation 27.29 is still valid for such materials, but the heat and mass fluxes and resulting Δh_g values vary with time. Tewarson and Petrella have used the method described in the preceding paragraph to determine average Δh_g values for nonsteady burning materials using average mass loss rates. They found that average $\dot{m}''$ is still an approximately linear function of $\dot{q}_e''$. However, the average heat of gasification values obtained in this manner may not have any physical meaning. For example, Janssens demonstrated that the values based on average mass loss rates are too high for wood and suggested a method to determine Δh_g as a function of char depth [103].

Dillon et al. proposed six methods to calculate the heat of gasification [101]. The first three values are derived from Equation 27.29 and are equal to the reciprocal of the slope of a linear fit through data points of peak mass loss rate, average mass loss rate over the peak burning period, and average mass loss rate over the entire flaming period respectively plotted as a function of heat flux. The other three values are equal to the appropriate heat of combustion times the reciprocal of the slope of a linear fit through data points of first peak heat release rate, average heat release rate over the peak burning period, and average heat release rate over the entire flaming period respectively plotted as a function of heat flux.

Physically meaningful nonsteady values for Δh_g can be obtained from Equation 27.29, with $\dot{q}_f''$ and $\dot{q}_l''$ calculated from Equations 27.30 and

27.31, respectively. These calculations require values for h^*, ε_f, T_f, ε_s, and T_s. All parameters, except T_s, do not vary greatly during a test and can be estimated relatively easily [104]. T_s, however, may change significantly as a function of time. The surface temperature can be measured, but that presents some major challenges. Janssens obtained T_s as a function of time for wood specimens exposed in the cone calorimeter by solving the equation for heat conduction through the char layer using an integral technique. [100] The resulting values for Δh_g are consistent with a theoretical analysis [105] and calculated Δh_g values based on measured surface temperatures [106]. A drawback of this approach is that thermal properties of the material's char are needed.

The discussion in this subsection is useful in clarifying a common misconception. Often it is believed that materials used in a particular end-use orientation should be tested in that orientation. This is not necessarily correct. Heat release rate is independent of specimen orientation. However, the heat release rate in a calorimeter under otherwise identical conditions is higher in the horizontal than in the vertical orientation. This is because the heat feedback from the flame is much greater in the horizontal orientation. In that orientation, the flame is a relatively large volume of hot gas located above the specimen. The flame is a thin sheet in front of a vertical specimen, leading to a much lower heat feedback. However, neither of these situations is comparable to that in a real fire, where burning areas and flame volumes are much larger and heat flux from the flame is much higher regardless of orientation of the fuel surface.

Hence, the best approach is to interpret small-scale measurements in terms of material properties that are independent of the test apparatus. These material properties can then be used to predict full-scale performance using a method that accounts for the effect of the enhanced heat flux from large flames. The preceding reasoning indicates that small-scale testing in the vertical orientation is preferable, because the heat feedback to the flame is smaller and errors of flame flux estimates are relatively less important. However, for practical reasons, it is often preferable to run small-scale tests in the horizontal orientation to avoid problems with, for example, melting and dripping of the specimen.

The equation to calculate the total heat release rate in a room/corner test based on a model that relies on heat release rate properties has the following form:

$$\dot{Q}_t(t_N) = \dot{Q}_b(t_N) + \sum_{i=0}^{N} A_i \frac{\dot{q}''_{\text{net},i}(t_N)}{\Delta h_g} \Delta h_{c,\text{eff}} \tag{27.32}$$

where $\dot{q}''_{\text{net},i}$ is the net heat flux to A_i (kW/m^2). A room/corner test model of this type was developed by Quintiere [107].

Intermediate-Scale Calorimeter Data

Products that have joints or layered materials with a thickness exceeding 50 mm can generally not be tested in a small-scale calorimeter in a representative manner. The ICAL is suitable to obtain heat release rate data for these products. The ICAL also has some practical advantages over small-scale calorimeters for measuring $\Delta h_{c,\text{eff}}$ and Δh_g [106]. The four approaches discussed in the previous section can be used in support of a hazard assessment of such products based on ICAL data.

Furniture Calorimeter Data

The primary application of furniture calorimetry is to obtain heat release rate data for input into zone models such as CFAST. [108] Furniture calorimeters are designed to obtain data under free burning conditions. However, the heat release rate of a burning object inside a room might be higher due to heat feedback from the hot upper smoke layer and heated walls and ceiling. Although this effect is not very significant during the early stages of a compartment fire, it can become significant as the fire approaches flashover. Zone models are typically

not capable of accounting for this effect, except for some simple geometries for which the effect of external heat flux on burning rate can be calculated.

Industrial-Scale Calorimeter Data

Industrial-scale calorimeters can be used to obtain heat release rate data from large objects in support of the design of passive fire protection of structures. For example, heat release rates from motor vehicles have been measured in several laboratories throughout the world [109–115]. The data obtained in these tests were used to develop guidelines for passive fire protection of structural steel in parking garages.

Industrial-scale calorimeters are also used to determine the hazard classification of commodities. The level of active fire protection required to protect a warehouse is based on the hazard classification of the commodity stored in the warehouse. Standard methods for commodity classification have been developed in the United States and Sweden [116]. For example, FM 3995 describes a protocol to determine the hazard class of plastic pallets and other products. The commodity configuration consists of eight pallet loads of products, each measuring 1.1 m × 1.1 m × 1.1 m. The commodities are placed on a double-row rack segment in a standard 2 × 2 × 2 array with each pallet separated by 150 mm. The commodities are ignited at the bottom in the center of the array. Water is applied to the fire by a special applicator located 200 mm above the top surface of the commodity. The water is applied at the time that a sprinkler system located in a warehouse at 3 m above the commodity would activate. The activation time is calculated based on the convective heat release rate measured during the test and a sprinkler activation program akin to DETACT-QS [117]. Tests are performed at three different water application rates in the range of 0.11–0.39 gpm/ft^2 (4.5–15.9 mm/min) and the commodity is classified based on the heat release rates measured in the tests. The FM Global commodity classification system in ascending order of hazard is as follows:

- Class I: noncombustible products on wood pallets
- Class II: Class I products in slatted wooden crates, solid wooden boxes, multiple thickness corrugated cartons, or equivalent combustible packaging material on wood pallets
- Class III: packaged or unpackaged wood, paper, natural fiber cloth or products therefrom on wood pallets
- Class IV: Class I, II, or III products containing no more than 25 % by volume of expanded plastic or polyurethane or 15 % by weight of unexpanded plastic or polyurethane in ordinary corrugated cartons on wood plastic pallets
- Cartoned Group B unexpanded plastics
- Cartoned Group A expanded or unexpanded plastics
- Idle wood pallets

Uncertainty of Heat Release Rate Measurements

The objective of a measurement is to determine the value of the measurand, that is, the physical quantity that needs to be measured. Every measurement is subject to error, no matter how carefully it is conducted. The true value of a measurand is therefore unknowable because it cannot be measured without error. However, it is possible to estimate, with some confidence, the expected limits of error. This estimate, referred to as the uncertainty of the measurement, provides a quantitative indication of its quality.

The value of the measurand is generally not obtained from a direct measurement but is determined as a function (f) from N input quantities $X_1, X_2, \ldots, X_N$:

$$Y = f(X_1, X_2, \ldots, X_N) \tag{27.33}$$

where

Y = True value of the measurand

f = Functional relationship between measurand and input quantities

X_i = True values of the input quantities ($i = 1 \ldots N$)

The input quantities may be categorized as

- Quantities whose values and uncertainties are directly determined from single or repeated observation
- Quantities whose values and uncertainties are brought into the measurement from external sources such as reference data obtained from handbooks

An estimate of the value of the measurand, y, is obtained from Equation 27.34 using input estimates $x_1, x_2, \ldots, x_N$ for the values of the N input quantities:

$$y = f(x_1, x_2, \ldots, x_N) \tag{27.34}$$

The standard uncertainty of y is obtained by appropriately combining the standard uncertainties of the input estimates $x_1, x_2 \ldots, x_N$. If all input quantities are independent, the combined standard uncertainty of y is given by

$$u_c(y) = \sqrt{\sum_{i=1}^{N} \left[\left. \frac{\partial f}{\partial X_i} \right|_{x_i} \right]^2 u^2(x_i)} \equiv \sqrt{\sum_{i=1}^{N} [c_i u(x_i)]^2} \tag{27.35}$$

where

u = Standard uncertainty
u_c = Combined standard uncertainty
c_i = Sensitivity coefficients

The standard uncertainty of an input estimate x_i is obtained from the distribution of possible values of the input quantity X_i. There are two types of evaluations depending on how the distribution of possible values is obtained:

- A type A evaluation of standard uncertainty of x_i is based on the frequency distribution, which is estimated from a series of n repeated observations $x_{i,k}$ ($k = 1 \ldots n$):

$$u(x_i) \approx \sqrt{s^2(\overline{x}_i)} = \sqrt{\frac{s^2(x_i)}{n}} = \sqrt{\frac{\sum_{k=1}^{n} (x_{i,k} - \overline{x}_i)^2}{n(n-1)}} \tag{27.36}$$

- A type B evaluation of standard uncertainty of x_i is not based on repeated measurements but on an a priori frequency distribution. In this case, the uncertainty is determined from previous measurements, experience or general knowledge, manufacturer specifications, data provided in calibration certificates, uncertainties assigned to reference data taken from handbooks, and so on.

Equation 27.35 is referred to as the law of propagation of uncertainty and is based on a first-order Taylor series approximation of $Y = f(X_1, X_2, \ldots, X_N)$. When the nonlinearity of f is significant, higher-order terms must be included. When the input quantities are correlated, Equation 27.35 must be revised to include the covariance terms. The combined standard uncertainty of y is then calculated from

$$u_c(y) = \sqrt{\sum_{i=1}^{N} [c_i u(x_i)]^2 + 2 \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} c_i c_j u(x_i) u(x_j) r(x_i, x_j)} \tag{27.37}$$

where $r(x_i, x_j)$ is the estimated correlation coefficient between X_i and X_j.

Because the values of the input quantities are not known, the correlation coefficient is estimated on the basis of the measured values of the input quantities. The combined standard uncertainty in Equation 27.37 is usually multiplied by a coverage factor to raise the

confidence level. A multiplier of 2 is often used, which corresponds to a confidence level of approximately 95 %.

Equation 27.37 can be used to calculate the uncertainty of heat release rate measurement based on oxygen consumption calorimetry. For example, Equation 27.15 provides the functional relationship between the measurand (heat release rate) and the input quantities. Assuming the mass flow rate in the exhaust duct is calculated from the differential pressure of and temperature at an orifice plate or bidirectional probe, the output and input quantities are defined as follows:

$$Y \equiv \dot{Q}, \quad X_1 \equiv E, \quad X_2 \equiv X_{O_2}^{A^e}, \quad X_3 \equiv \alpha, \\ X_4 \equiv C, \quad X_5 \equiv \Delta P, \quad X_6 \equiv T_e \tag{27.38}$$

C is the calibration coefficient, which relates the mass flow rate in the exhaust duct to the differential pressure and gas temperature measurements. In a test $\dot{Q}$ is calculated as a function of time based on the input quantities measured at discrete time intervals Δt. The uncertainty of the heat release rate measured at each time interval is estimated from Equation 27.37.

Dahlberg used this approach to determine the uncertainty of heat release rate measured in the industrial-size calorimeter at SP and reported values of ±7 % and ±12 % depending on the use of the CO correction, that is, for Equations 27.18 and 27.15, respectively [118]. Enright and Fleischmann reported an uncertainty of ±5 % for the cone calorimeter [119]. These uncertainties are significantly below the precision obtained from interlaboratory trials involving oxygen consumption calorimeters.

For example, a cone calorimeter round robin resulted in estimates for the peak heat release rate repeatability and reproducibility of 17 % and 23 %, respectively [120]. The discrepancies can be explained by the fact that the uncertainty analyses did not account for dynamic errors and specimen, operator, and heat flux variations. This is consistent with the calculations performed by Janssens, who accounted for the contribution from specimen variations and heat flux measurement errors and obtained an uncertainty of ±11 % for the peak heat release rate of a glass fiber–reinforced plastic measured in the cone calorimeter at a heat flux of 50 kW/m^2 [121].

Summary

Heat release rate is the single most important variable in fire hazard assessment. Various test methods have therefore been developed for measuring heat release rate of materials and products under different conditions. This chapter dealt with calorimeters of various sizes and the use and application of heat release measurements.

The discussion started with a description of the oxygen bomb calorimeter. The most significant limitation of this test is that it does not provide a quantitative measure of heat generation under realistic fire conditions.

The next section described four techniques that have been used to measure heat release rate in fire tests. The sensible enthalpy rise method is the least complicated. The substitution and compensation methods partly address the problem of thermal lag associated with sensible enthalpy rise measurements but require sophisticated control instrumentation. The oxygen consumption method, based on Thornton's rule, was developed in the late 1970s. It is currently the most popular method for measuring heat release rate in fire tests.

The effects of some calorimeter construction details on quality and accuracy of small-scale heat release rate measurements were discussed. Factors examined include configuration (open vs. closed), type of heater, type of ignition pilot, specimen size and orientation, edge effects, and airflow. Four commonly used small-scale calorimeters were briefly described: the Ohio State University calorimeter, the cone calorimeter, the fire propagation apparatus, and the microscale combustion calorimeter. This discussion was followed by a review of studies comparing different small-scale calorimeters.

The chapter continued with a description of the hood and exhaust duct that is specified in many intermediate- and large-scale calorimeter standards. This was followed by a description of

different calorimeters for measuring the heat release rate from chairs, mattresses, and other objects and from wall and ceiling finishes in a corner configuration. Some historical background was provided for the room/corner test. Industrial-scale calorimeters that can be used to measure multimegawatt heat release rates from large objects and commodities were also briefly discussed.

The next section discussed common applications of heat release rate data. Heat release rate data are used primarily in support of fire hazard assessment of materials and products. Small- and intermediate-scale data must be used in conjunction with a mathematical model to predict performance of materials and products in real fire scenarios. General concepts of four types of models were discussed using the room/corner test as an example of a real fire scenario:

- Correlations
- Models based on heat release rate data obtained at a single heat flux
- Models based on heat release rate data obtained at multiple heat fluxes
- Models based on heat release rate properties

Heat release rates measured in large- and industrial-scale calorimeters can be used directly in support of fire hazard assessment. For example, furniture calorimeter measurements can be used to generate heat release rate curves for input in zone models. Industrial-scale calorimeter data can be used to support the design of passive fire protection for structures or to obtain a hazard classification of a commodity.

The chapter concluded with a brief discussion of uncertainty of heat release rate measurements.

His research has focused on computer fire modeling, fire hazard and risk assessment, fire test standards development, and the experimental and theoretical evaluation of material flammability with emphasis on heat release calorimetry.

The Cone Calorimeter

28

Vytenis Babrauskas

Introduction

Chapter 27 describes the history and development of techniques for measuring heat release rate (HRR). This chapter outlines features and details of today's preferred instrument for measuring bench-scale HRR—the cone calorimeter. Other cone calorimeter measuring functions are

1. Effective heat of combustion
2. Mass loss rate
3. Ignitability
4. Smoke and soot
5. Toxic gases

The cone calorimeter is based on the concept of oxygen consumption calorimetry, which is also presented in Chap. 27.

This chapter provides both an introduction to and description of cone calorimeter measurement technology. The cone calorimeter has recently assumed a dominant role in bench-scale fire testing of various products; therefore, an emphasis will be placed on the *why* of various design features. When conducting tests, the cone calorimeter operator needs to consult several other documents. Testing will presumably be in conformance with either ISO 5660 [1] or ASTM E1354 [2]. In addition, the "User's Guide for the Cone Calorimeter" [3] should be consulted. This chapter does not emphasize the operational aspects documented in these references but instead provides the reader with an overall feel for the equipment. Space is not available in this handbook to fully discuss the applications of cone calorimeter data, apart from the review of data given in Chap. 26. Extensive guidance on using cone calorimeter data is given in a textbook on this subject [4]. It also provides example data compilations and information on using cone calorimeter data for predictions of fires.

Summary of Features

A schematic view of the cone calorimeter is shown in Fig. 28.1. Figure 28.2 shows a commercial instrument, and Fig. 28.3 identifies some of the major components. The more salient operational features and limits of the apparatus are

Specimen size	100 × 100 mm, thickness of 6–50 mm
Specimen orientation	Horizontal, face up (standard testing) or vertical (reserved for exploratory studies)
Specimen back-face conditions	Very low loss insulating ceramic fibrous material
Load cell live load capacity	500 g
Load cell tare capacity	3.5 kg
Load cell resolution	0.005 g
Ignition	Electric spark
Heating flux range	0–110 $kW \cdot m^{-2}$
Flux uniformity, horizontal	Typically 2 %
Flux uniformity, vertical	Typically 7 %

(continued)

Sensing principle	Oxygen consumption, only
Maximum instantaneous output	In excess of 20 kW
Normally calibrated range	0–12 kW
Linearity over 0–12 kW range	5 %
Noise intrinsic to oxygen meter	20 ppm O_2
Noise in HRR measurement, over 0–12 kW range	2.5 %
Smoke meter operating range	0–20 m^{-1} (linear)
Smoke meter resolution	0.01 m^{-1}
Soot sampler mass fraction range	0–1 part in 200 (of exhaust gas flow)

Uses of Cone Calorimeter Data

Cone calorimeter data are primarily used for four purposes:

1. comparative evaluation of materials;
2. obtaining of thermophysical constants (fire properties) of materials;
3. as input data to fire models or engineering calculation;
4. for regulatory compliance.

Comparative Evaluation of Materials

Comparative evaluation of materials is the easiest and simplest use of cone calorimeter data. This, in fact, is also where the largest amount of published literature involving cone calorimeter data is found, of which the fire retardants field is a prominent example. There have been hundreds of papers published examining fire retardant formulations with the use of the cone calorimeter. For such studies, modeling or large-scale testing is inappropriate, since the

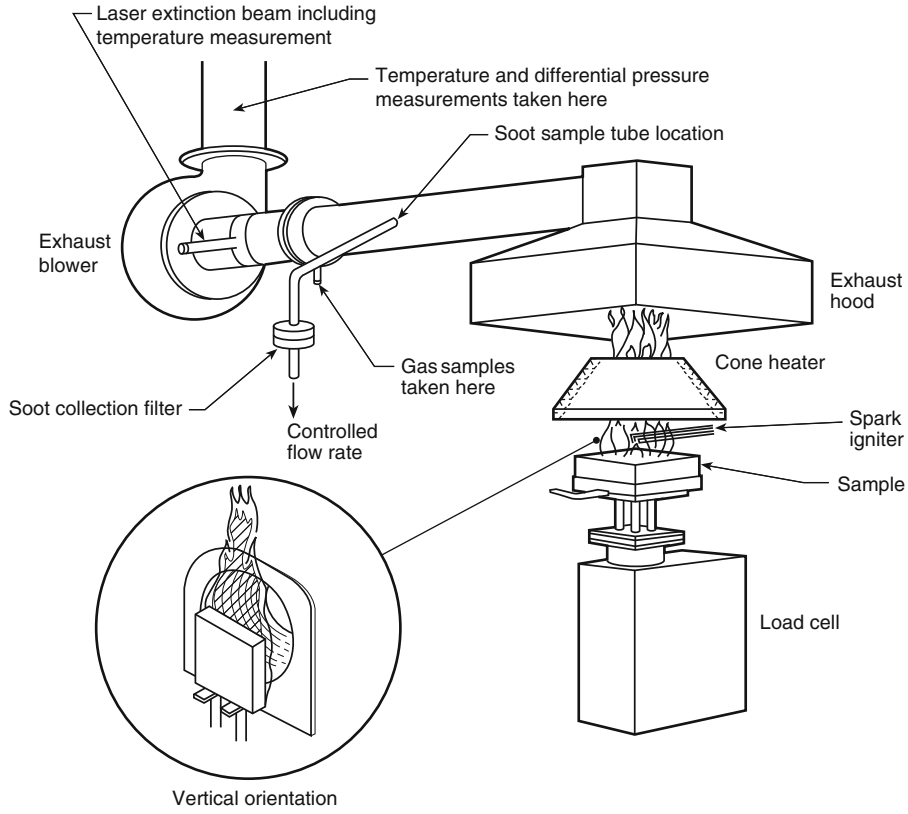

Fig. 28.1 Schematic view of the cone calorimeter

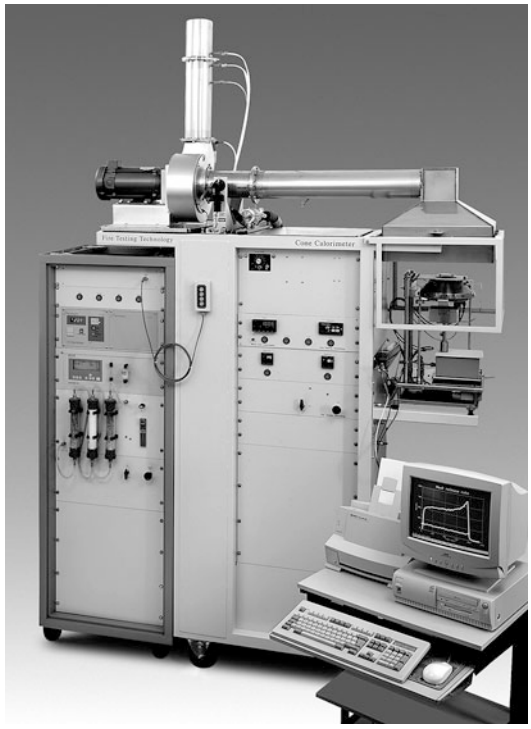

Fig. 28.2 A commercial cone calorimeter (Photo courtesy Fire Testing Technology, Ltd.)

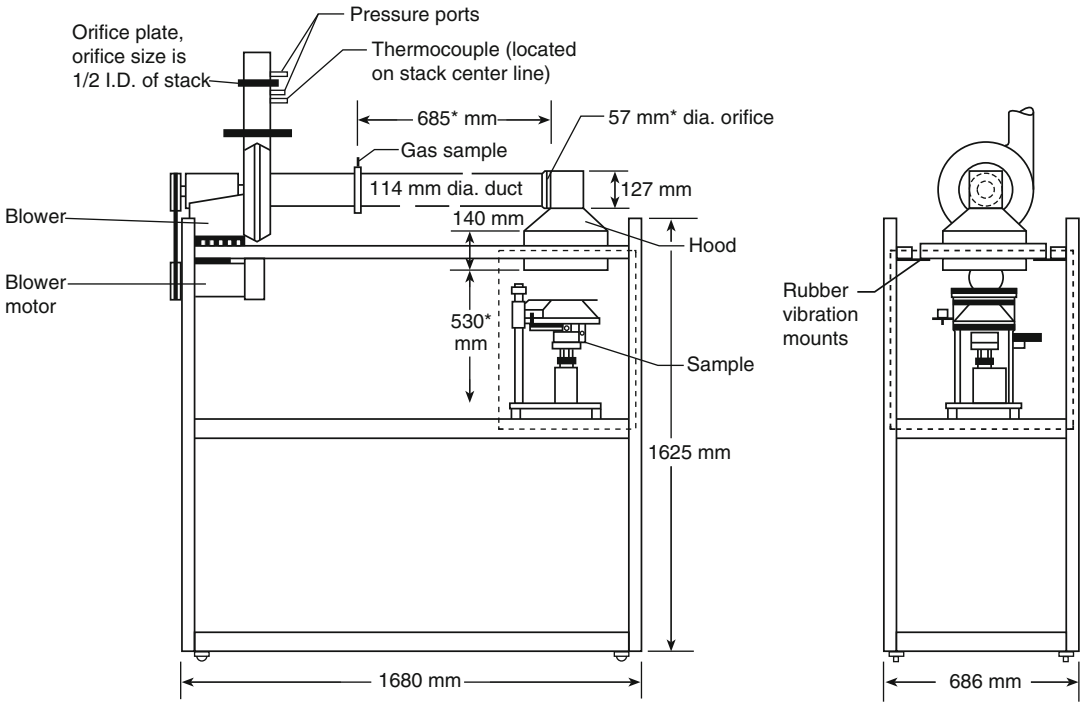
same polymer formulation can be used for a wide array of products. Thus, cone calorimeter data are normally used and a comparative evaluation is made. Most commonly, candidate materials are evaluated simply by comparing their peak HRR values. This approach is not adequate if flame spread in the real-life environment is significant, i.e., if the material is not quickly ignited over its entire face. For taking flame spread into account, albeit in a simplified way, Babrauskas [5] proposed in 1984 that the variable $\dot{q}''/t_{ig}$ be used, which is the ratio of the HRR value to the ignition time. The ignition time was shown to be correlated to flame spread rate, thus, this hazard parameter increases with both increasing HRR and increasing propensity for rapid flame spread. A reasonable semi-quantitative prediction of the time to flashover was possible using this ratio for various wall lining materials. Petrella [6] later proposed a modified rating system where $\dot{q}''/t_{ig}$ is plotted on one axis, while total heat released is plotted on the other. Materials of better performance have both a low $\dot{q}''/t_{ig}$ value and a low total heat release. The most refined scheme



*Indicates a critical dimension

Fig. 28.3 View of major components of the cone calorimeter

which is still simple is the one put forth in 1991 by Cleary and Quintiere [7]. They introduced a parameter b:

$$b = 0.01\dot{q}''_{avg} - 1 - \frac{t_{ig}}{t_b} \qquad (28.1)$$

where $\dot{q}''_{avg}$ = average HRR (kW m^{-2}) at a 50 kW m^{-2} irradiance, t_{ig} = ignition time (s), and t_b = duration of flaming (s). They showed that materials which show $b < -0.4$ have negligible propensity to spread fire, while those with progressively higher values show increased hazard in full-scale applications. The Cleary/Quintiere b is not to be confused with Spalding's B number, sometimes use to characterize hazards of burning liquids.

Obtaining Thermophysical Constants of Materials

The HRR of materials cannot be computed from some ostensibly simple material fire properties, but is rather a complex relationship governed by chemical (reaction kinetics), thermal (heat transfer properties), and mechanical (cracking, delamination, etc.) properties. Thus, in general, it is not possible to deduce some underlying material fire properties from HRR data. However, the situation is more amenable for ignition data, where it is possible to obtain fire properties from cone calorimeter data. This topic is treated at length in the *Ignition Handbook* [8], but here the most useful computation will be identified. For thermally thick materials, Janssens derived the relationship:

$$\dot{q}''_e = \dot{q}''_{cr}\left[1 + 0.73\left(\frac{\lambda\rho C}{h^2_{eff}t_{ig}}\right)^{0.55}\right] \qquad (28.2)$$

According to this, if experimental data are plotted (Fig. 28.4) such that $\dot{q}''_e$ is put on the x-axis and $t_{ig}^{-0.55}$ on the y-axis, then the data will fall in a straight line, with the x-axis intercept being $\dot{q}''_{cr}$. Here $\dot{q}''_e$ = irradiance (kWm^{-2}), $\dot{q}''_{cr}$ = x-axis intercept, t_{ig} = ignition time (s), and $\lambda\rho C$ is the thermal inertia (kJ^2 m^{-4} s^{-1} K^{-2}) of the specimen. From such a plot, the value of thermal inertia can be computed, which is an effective fire property of importance in both ignition and flame spread problems.

Input Data for Fire Models or Calculations

A number of correlational schemes for making engineering calculations on various types of commodities have been developed which are

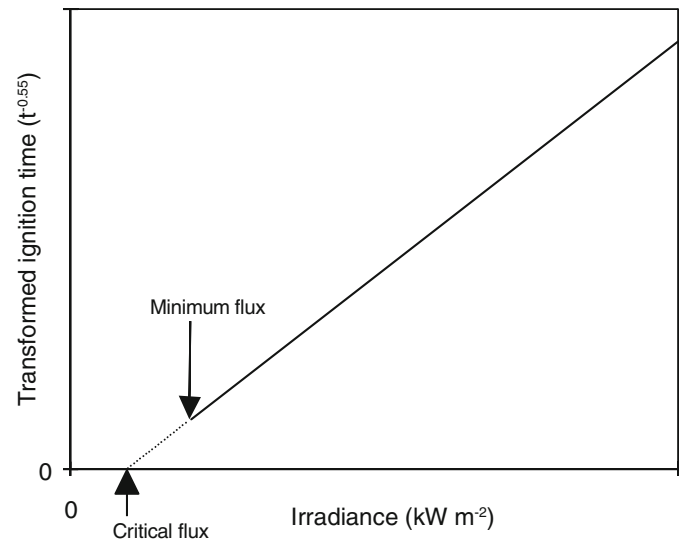


Fig. 28.4 The main variables of the ignitability plot

based on Cone Calorimeter data. These are reviewed in Chap. 26. For more refined models, i.e., zone or CFD models for room fires, the application is more difficult. This is because the HRR is strongly a function of the irradiance. But in most real fires, the irradiance received by any particular locale is a dynamic function of time and is not a constant. Because of this difficulty, it has become more common for modern-day computer codes, e.g., FDS, to adopt a pyrolysis model, rather than using small-scale experimental HRR data as an input. A pyrolysis model effectively is a scheme where the HRR of a small area of material is computed from some sort of input data. But, as discussed above, for realistic materials there generally is no simple series of expression that would be able to predict the HRR, based on the input of a modest collection of constants. Even if the constants can be defined, they must in turn be obtained from experiments, and this is already known to be difficult in the first place. CFD models however may have an option to input small-scale HRR data; typically in that case the HRR at a fixed irradiance is used. Capote et al. [9] illustrated such an approach in modeling train fires with FDS. Aksit et al. [10] described use of cone calorimeter input data for modeling cable tray fires with SOFIE, while Andersson [11] described a more general effort with SOFIE. Tsai et al. [12] described a proprietary CFD model using cone calorimeter data; the model was used solely for calculating ignition behavior of materials.

For zone fire models, the most successful example has been the BRANZfire model of Wade [13–15]. Lattimer et al. [16] described a module for CFAST based on cone calorimeter input data. Janssens and Dillon [17] described a simple room fire model based on cone calorimeter data. Cone calorimeter data have also been used in an application simpler than room fires, the prediction of upward flame spread on vertical panels [18–23].

For some models, it is necessary to know the total heat flux incident on the specimen, not just the external heat flux; the total heat flux is comprised of the external heat flux, plus the flame flux. Hostikka and Axelsson [24] showed an interesting example of CFD modeling by predicting the flame flux in the cone calorimeter.

Regulatory Compliance

The New Zealand building code specifies use of the ISO version of the cone calorimeter standard, ISO 5660 [1], for external wall cladding products. The Building Code of Australia uses cone calorimeter testing to assess fire retardant treated wood for use in bushfire-prone areas. The building code of Japan uses cone calorimeter testing extensively, as a primary measure of the fire performance of surface lining materials [25]. In their application, tests are run at 50 kW m^{-2} irradiance for a duration of 5, 10, or 20 min, depending on the classification sought. In each case, a peak HRR value below 200 kW m^{-2} must be found, with the total heat release being less than 8 MJ m^{-2}, with the latter being a particularly onerous requirement. Taiwan has also adopted similar provisions. IMO, the International Maritime Organization, which provides the regulations for constructing of sea-going vessels, uses cone calorimeter testing for acceptance of "fire restricting material" for high-speed craft in the case of furniture and related materials.

Operating Principle

It is emphasized at this point that the cone calorimeter has been designed to use *only* oxygen consumption calorimetry as its measurement principle [26]. Other calorimeters that on occasion use oxygen consumption principles, for example, the Factory Mutual Research Corporation (FMRC) flammability apparatus (Chap. 27), sometimes incorporate a sensible enthalpy flow measurement technique to arrive at the *convective component* of the heat release rate. In the design of the cone calorimeter, such an approach was deemed to be misleading. The implicit assumption behind this type of measurement is that the fraction of the total heat release being

manifest as the sensible flow enthalpy is a property of the material being tested. Such is not, in fact, the case. The convective fraction is dependent on details of the apparatus design and also on the scale of the specimen [27].

Where high-quality results are required, such as in the cone calorimeter, current-day practice demands that a paramagnetic oxygen analyzer be used. The various manufacturers use measuring schemes that differ in detail, but all rely on the same paramagnetic principle whereby the sensing element is sensitive to the partial pressure of oxygen in the cell. The most significant interferents to this detection principle are NO and NO_2, both of which show a strong paramagnetic response, but not as strong as that of oxygen. Interferents are never a problem in fire testing, however, since O_2 levels measured are 10–21%, whereas concentrations of NO_x are rarely above 100 ppm.

Unlike in applications where oxygen levels are monitored as simply one of many indications of fire hazard, in HRR work it is essential that the instrumentation be designed for the highest possible resolution. Thus, both the ASTM and ISO standards specify that the short-term noise + drift of the oxygen analyzer must be less than or equal to 50 ppm O_2. The best-grade commercial instruments are able to meet a 20 ppm O_2 limit. In addition, the standards provide a significant amount of detail on the layout of the gas sampling system, including desiccation, mass flow control, and bypass flows. All of these aspects have to be in conformance with the specifications for good repeatability and reproducibility performance (see Fig. 28.3) to be achieved.

Because the detection principle responds to oxygen partial pressure, there needs to be a compensation for changes in atmospheric pressure, either with a mechanical back-pressure regulator or by measuring the pressure and correcting electrically. Without compensation, there can be significant error in the calculated heat release rate. Carbon dioxide, the other major component expected to be in the oxygen analyzer, causes less than 0.3 % error in the oxy-gen reading. Extensive practice advice on selecting, setting up, and calibrating oxygen analysis systems is given in Twilley and Babrauskas [3] and in Babrauskas and Grayson [4].

The Radiant Heater

After establishing the operating principle, the next most important feature is the type of heater. In general, such a heater should be able to achieve adequately high irradiances, have a relatively small convective heating component, present a highly uniform irradiance over the entire exposed face of the specimen, and be designed so as not to change its irradiance when the main voltage varies, when heater element aging occurs, or when the apparatus retains some residual heat from the exposure given to a prior specimen.

Range of Heat Fluxes Needed for Testing A room fire burning near its maximum rate can show gas temperatures over 1000 °C, producing corresponding irradiances to walls and contents of 150 $kW \cdot m^{-2}$. Testing under such extreme conditions may not be required; nonetheless, if postflashover fires are to be simulated, irradiances of over 75 $kW \cdot m^{-2}$ should be available, and preferably closer to 100 $kW \cdot m^{-2}$. A significant convective component would negate the purpose of having a radiant ignition test. Rather low convective fluxes can be achieved for specimens oriented horizontally, face up, and with the prevailing airflow being upwards. For vertical specimens, orientation is considered, and it becomes evident that a boundary layer will normally be expected to develop that will add some convective component. The convective boundary layer component is not uniform over the height of a specimen; thus it is seen that better uniformity can also be expected under conditions where the convective component is minimized.

Choice of Heater Type In a real fire, the ignition source is, in most cases, in the vicinity of a combustible. The radiation spectrum depends on the size of the fire. A very small fire can show a substantial fraction of its radiation at

wavelengths characteristic of H_2O, CO_2, and other combustion products [28]. For larger fires—certainly for room fires reaching a hazardous condition—the radiation from the soot tends to dominate. The result is an approximation to a graybody radiation [29]. For such a graybody radiation the temperature is typically in the vicinity of 1000 °C [30]. Experimentally, heater choices for test apparatuses have included gas-fired panels, electric resistance heaters, flames, and high-temperature lamps. Electrical heaters tend to have a near-graybody characteristic and, assuming a dull or oxidized surface condition, a high emissivity. Gas-fired panels derive a substantial portion of their radiation from the ceramic face; thus, while there are discrete molecular wavelength peaks, overall the radiation shows a graybody continuum, typically in the range of 700–1000 °C [31]. High-temperature lamps, which have been used by several investigators [28, 32], typically have radiating temperatures of 2200–3000 °C. The spectral distribution of such a source—further limited by a translucent enclosure—is much different from one operating at 1000 °C. Whether this change in spectral characteristics is important depends on the surface of the material to be ignited. For a material with a radiant absorbance independent of wavelength, this source variation would not matter. Hallman, however, has reported data for a large number of plastics and shows that although there are some specimens with negligible wavelength dependence to their absorbance, the majority shows strong variations [28]. Hallman also measured ignition times of plastics with both a flame source and high-temperature lamps. The effect on ignition times ranges from negligible to more than an order of magnitude, depending on the specimen. For a general-purpose test, flames would probably be the least desirable source of heating. For a bench-scale test, flame size has to be kept small. This means that such flames are optically thin, their emissivity is low, and higher heat fluxes cannot be achieved unless a strong convective component is added.

Design Details Once an electrical radiant heater had been decided upon, design details were also influenced by work at NIST with earlier types of calorimeters. One of the primary requirements of the heater is that it not change the irradiance impressed on the specimen when the specimen ignites. This undesired event is, of course, exactly what happens with several of the older types of calorimeters. The specimen's flames directly heat nearby ironwork, which, in turn, radiates to the specimen. The heater, which had been viewing a cold specimen prior to ignition, also starts to view a hot flame afterwards. The result is that its efficiency increases drastically, giving a rise to its radiating temperature. Based on these observations, guidelines were formulated so that the specimen must, as much as possible, view only

1. A temperature-controlled heater
2. A water-cooled plate
3. The open-air, ambient-temperature environment

Reliance on item 2 increased costs significantly; thus, it was more desirable to use only items 1 and 3. Prior to the development of the cone calorimeter, fire test apparatuses typically controlled the power (or fuel rate) into the heater, but did not maintain it at a fixed temperature.

The Conical Shape The cone calorimeter derives its name from the conical shape of the heater (Fig. 28.5). The decision had been made to use an electric resistance heater, running at a realistic maximum temperature of about 950 °C, but its material and shape still had to be determined. Based on poor experiences with exposed-wire resistance heaters and with silicon carbide rod–type heaters, the tube heater was chosen. The tube heater consists of a resistive wire element inside a protective tube, swaged over a packing of inorganic insulation. The tube is made of Incoloy™ and can be bent to a desired shape.

To determine the best shape, the conical heater used in the ISO 5657 ignitability apparatus [33] was examined. This seemed to be a promising shape. The proper shape had to have a hole in the middle, since otherwise a hot spot would occur at the sample center, where the radiation view factor is the highest. The same

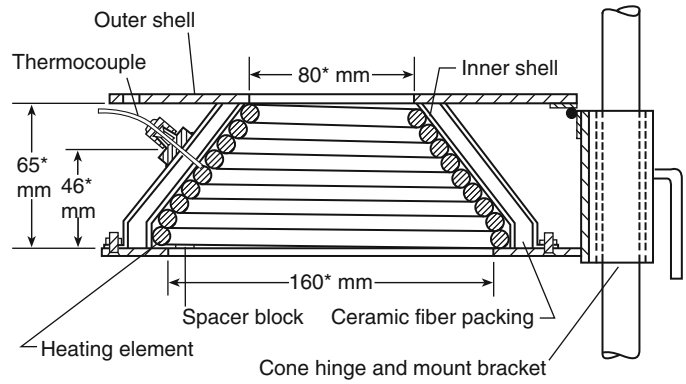

Fig. 28.5 Cross-sectional view through the cone heater

heater had to serve in both horizontal and vertical orientations. In the horizontal orientation, it was essential that all the products of combustion flow out the hole in the middle, and not "splash" on the heater coil itself, nor escape from the underside. The original ISO 5657 design proved to be unsuitable in the former respect. It also had problems with durability and assembly. Thus a totally new design was created, which, however, looked superficially similar to the ISO 5657 cone. With the actual cone calorimeter design, the flames from the specimen do not splash on the heater coil. Instead, a sheath of cold air is pulled up, surrounding the flame plume. Thus, there is not a concern that any surface reactions occur on the heater coil.

The space between the inner and outer cones is packed with refractory fiber. This arrangement helps keep the outside of the unit cool and also helps bring the heater up to operating temperature rapidly.

Emissivity of the Heater The emissivity was characterized by Janssens [34]. The heater coil, once installed and operated a few times, becomes essentially radiatively black. The emissivity itself cannot be directly measured; however, it is possible to compute an approximate view factor, F, for the cone heater. The possibility of measurements is based on a simultaneous determination of the heater surface temperature and the heat flux falling on the heat flux meter, with the meter held in place at the same location where a specimen is situated. Over the range of fluxes of 10–90 kW $\cdot$ m^{-2}, Janssens determined the $\varepsilon \times F$ product to be 0.73, with F being computed as 0.78. Then, solving for ε gives $\varepsilon = 0.91$. Since the temperatures of the heater closely resemble those in room fires, and the emissivity approaches 1.0, this means that the spectral distribution is likely to be very close to that expected from room fires (neglecting the molecular radiation contribution from CO_2 and H_2O). It is important that the heater element be kept in good repair, in order that expected uniformity be achieved. Aging may cause the coil windings to separate and sag. If this occurs, poorer uniformity has been shown to occur [35].

Convective Fraction of the Heating Flux During the development of the cone calorimeter at NIST, a study was conducted to determine the fraction of the heating flux accounted for by the convective contribution [36]. When measured with respect to a water-cooled heat flux meter, the results showed that, in the horizontal specimen orientation, the convective contribution was immeasurably small. In the vertical orientation, the fraction was typically 8–12 %. Janssens later remeasured the vertical configuration [34] using a more accurately calibrated heat flux meter and found that, even for the vertical orientation, the convective transfer is immeasurably small. Thus, it can be stated that the objective of having a test method where the heating is primarily radiant was successfully

met. For modeling of test results, however, one may be more interested in the possibility of convective heat transfer to a specimen that is heated, or even burning, not to a calibration meter constrained by its water-cooling jacket at near-room temperature. Janssens also made some determinations of such actual specimen heating. The direction of the heat transfer was such as to represent a heat loss from the specimen in all cases. A single convective heat transfer coefficient could not be derived, however, since the value was dependent on the irradiance level from the heater. Janssens's results could be represented by:

Irradiance from heater ($kW \cdot m^{-2}$)	Convective heat transfer coefficient h_c ($W \cdot m^{-2} \cdot K^{-1}$)
20	9.0
40	18.0
60	27.0

For practical work, Janssens recommended that an average value of $h_c = 13.5\ W \cdot m^{-2} \cdot K^{-1}$ should be appropriate for work over the common irradiance range of 20–40 $kW \cdot m^{-2}$. The actual details of this small amount of convective heat transfer are pertinent only to certain specialized studies. For most work, it is entirely adequate to assume that the specimen heating is entirely radiative.

Uniformity of the Heating Flux The uniformity of the heating flux over the face of the specimen in the cone calorimeter has been described [36]. Over the range of irradiances from 25 to 100 $kW \cdot m^{-2}$, the ratio of the flux at the specimen center to average flux varied only from 1.00 to 1.06. The peak deviations from average were typically 2 % in the horizontal orientation and 7 % in the vertical. Deviations are higher in the vertical orientation, since the effect of convective fluxes, due to the boundary layer flow, is more pronounced there. Additional measurements have been made in the specimen-depth plane. Control of the surface of the specimen was a special concern to the designers of the ISO apparatus, where a special compressive loading mechanism is provided that attempts to relevel the exposed surface, in case the specimen recedes due to melting. In the cone calorimeter, measurements have been made in the horizontal orientation using a small, 6-mm-diameter Gardon-type heat flux gauge. A flux mapping was obtained starting at the initial surface, and progressing down to the maximum depth of a specimen, which is 50 mm. A normal aluminum foil rectangular specimen wrap was used for these tests, but without any specimen. The results show that, at heating fluxes of both 25 and 50 $kW \cdot m^{-2}$, the deviations over the entire specimen depth are less than 10 %, and can, therefore, be neglected (Fig. 28.6). At the lower depths, reflection from the aluminum foil probably assists in maintaining this uniformity.

Orientation of the Heater and Specimen The normal orientation of the specimen should be

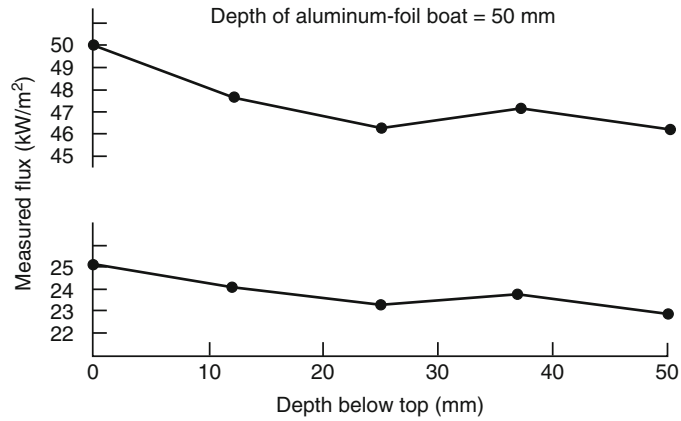

Fig. 28.6 Measured flux at various positions below the top surface of a specimen

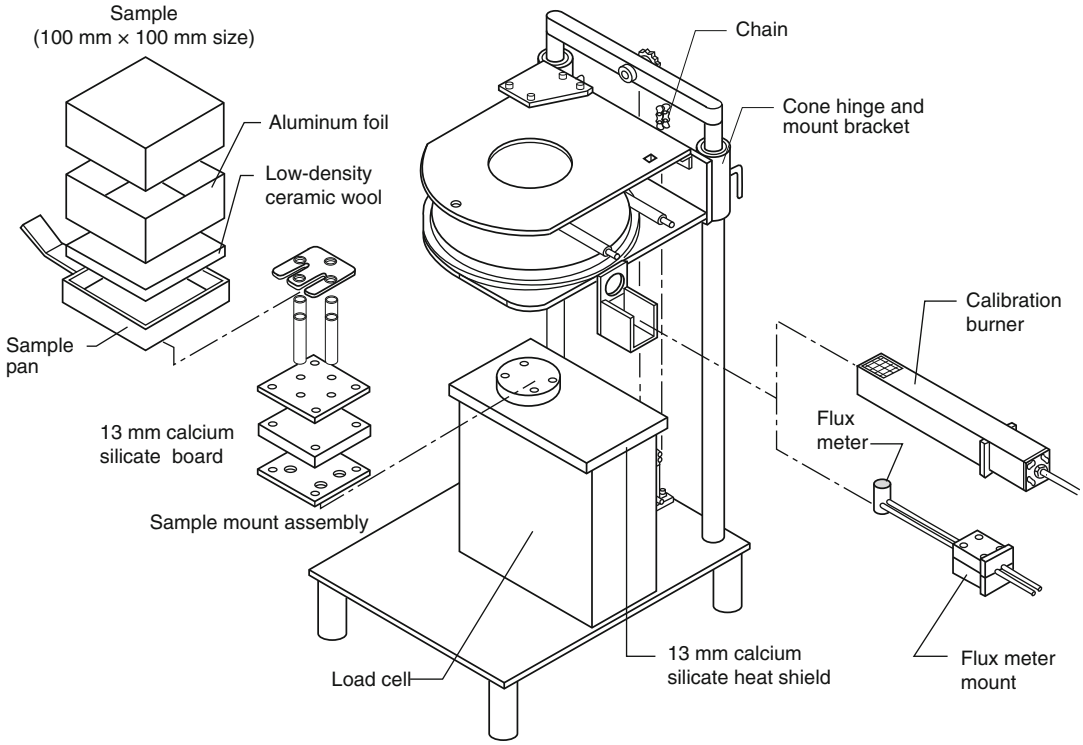

Fig. 28.7 Heater in the horizontal (standard) orientation

horizontal, face up, with the heater being parallel, face down. This allows thermoplastics, liquids, and other melting or dripping samples to be successfully tested. Because it was considered desirable to allow testing in a vertical orientation for certain application exploratory studies, provision was made to swing the heater 90° into a vertical orientation. Vertical orientation testing may be preferable when probing the flame regions or measuring specimen surface temperatures is desired. Figures 28.7 and 28.8 show the comparative horizontal and vertical heater orientations, respectively. It is especially emphasized that no standard testing should be specified for the vertical orientation, *even for products that are normally used in a vertical orientation*. The ASTM standard [2] was amended in 1992 to clarify that the vertical orientation is only for special research studies and not for product testing.

The Shutter

The original NIST design for the Cone Calorimeter did not include a shutter. The operator would just quickly drop the specimen holder on top of the mount plate at the top of the load cell. This was satisfactory for most building products and plastics. However, in 1993 researchers at SP (Technical Research Institute of Sweden) found that there were some reproducibility issues when testing upholstered furniture specimens that ignited very quickly. Thus, they designed a shutter (originally described as "heat shield" and later as "radiation shield") to be interposed between the heater and the specimen surface; this was originally described in a 1996 SP report [37]. The use of a shutter makes it possible to (a) get the load cell to equilibrate before commencing exposure, and (b) provide an nearly step-function initiation of radiant heat flux to the specimen.

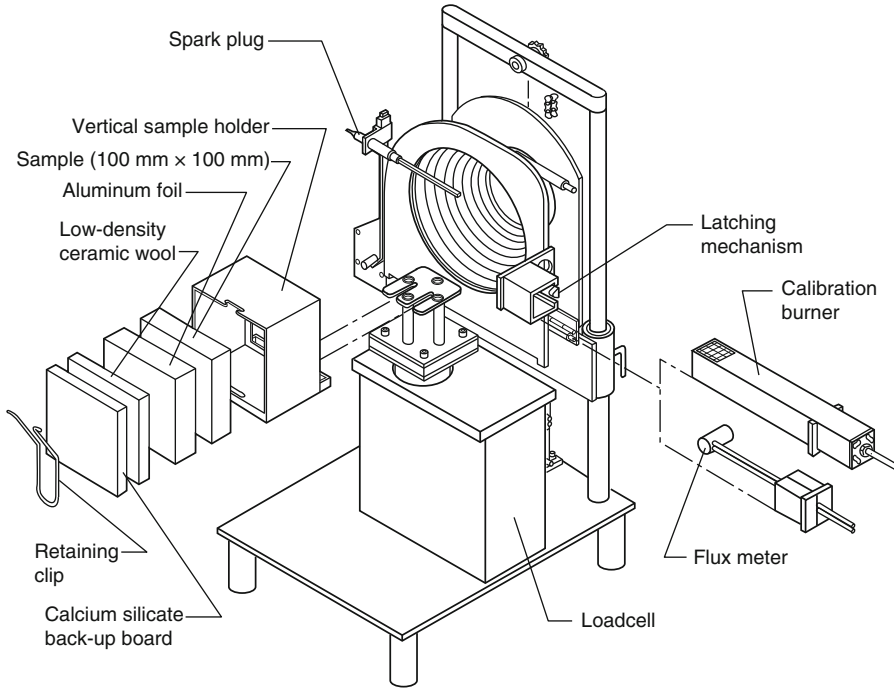

Fig. 28.8 Heater in the vertical orientation

However, with the use of a shutter there is potentially a different type of error that is introduced. A shutter will reflect some heat back to the heater, and will also rise in temperature and reradiate heat flux to the heater. Both of these would cause the heater's temperature to rise. The solution adopted by ASTM [2] and ISO [1] standards was that the shutter should be in place for no longer than 10 s prior to start of test, and that it be either water-cooled with a black coating, or else not water-cooled, but with made of ceramic material or made of reflective metal. The reflective metal option is the least satisfactory, because, while radiation towards the specimen gets eliminated by reflection, the reflection towards the heater does cause its temperature to rise. Thus, the best accuracy is attained with a minimal duration of the shutter's closure. This change was made in the 1997 edition of ASTM E 1354 and in the second edition (2002) of ISO 5660-1.

Airflow

The feasible airflow rate through the system is bound by certain limits. It must not be so fast that ignition results are improperly affected. It must also not be so slow that products of combustion spill out of the hood. If this were a closed system, one would also be concerned about airflow being so slow that the air/fuel ratio drops into the fuel-rich regime. The standard cone calorimeter, however, has been designed for ambient air testing, and this consideration does not apply.

Systematic guidance in this area was not available. However, as an example of the effect of airflow, measurements were made at NIST using the OSU apparatus. Specimens of black polymethyl methacrylate (PMMA) were exposed in the horizontal orientation to a heating flux of 35 kW · m^{-2}. With an airflow rate of 12 L·s^{-1} through the combustion chamber, the ignition time was 209 s. When the airflow rate was doubled to 24 L·s^{-1}, the specimen ignition time increased to 403 s. By contrast, Table 28.1 shows comparative results with the cone calorimeter; it can be seen a flow rate of 24 L·s^{-1} was found to be satisfactory. That flow rate was also about a factor of 2 greater than the minimum at which no spill out of the hood occurs.

The exhaust system uses a high-temperature cast-iron blower to exhaust the gases and an

Table 28.1 Effect of exhaust hood airflow on ignition times in the cone calorimeter[a]

Material	Thickness (mm)	Orientation	Fan setting	Ignition time[b] (s)
PMMA	13	Horizontal	No fan	71
PMMA	13	Horizontal	24 $L \cdot s^{-1}$	76
PMMA	13	Horizontal	41 $L \cdot s^{-1}$	67
PMMA	13	Vertical	No fan	86
PMMA	13	Vertical	24 $L \cdot s^{-1}$	84
PMMA	13	Vertical	41 $L \cdot s^{-1}$	77
Redwood	13	Horizontal	No fan	23
Redwood	13	Horizontal	24 $L \cdot s^{-1}$	24
Redwood	13	Horizontal	41 $L \cdot s^{-1}$	31
Redwood	13	Vertical	No fan	22
Redwood	13	Vertical	24 $L \cdot s^{-1}$	27
Redwood	13	Vertical	41 $L \cdot s^{-1}$	29

[a]At an irradiance of 35 $kW \cdot m^{-2}$

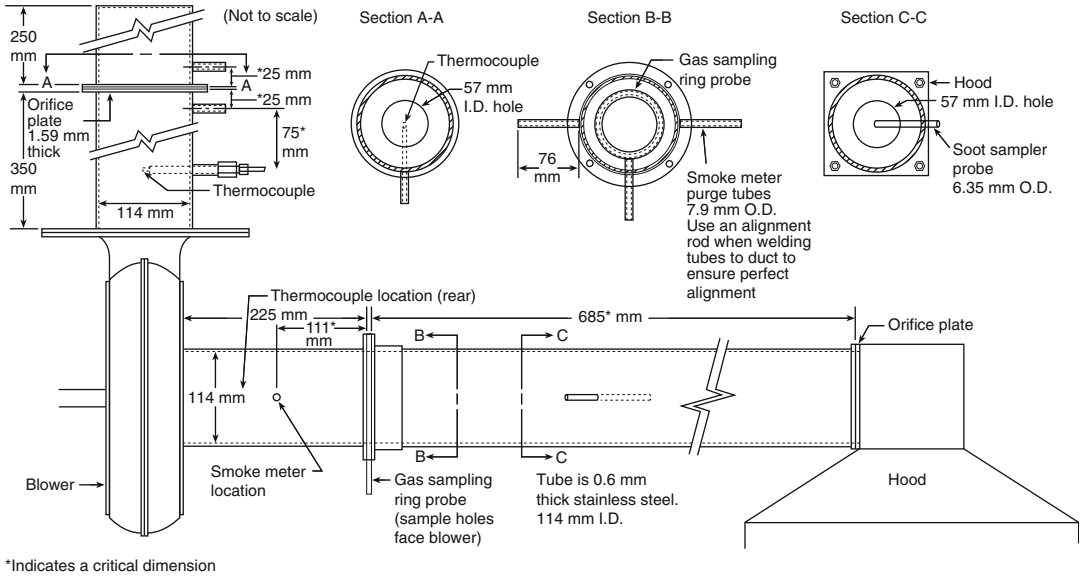

Fig. 28.9 Exhaust duct

orifice plate flowmeter (Fig. 28.9). The orifice plate flowmeter is instrumented with a differential pressure transducer and a thermocouple. For specialized studies, where the entire combustion system is glass enclosed [38], it is possible to go to flow rates below 12 $L \cdot s^{-1}$. With such enclosed systems, accurate measurements can be made down to about 9 $L \cdot s^{-1}$ using the standard orifice plate. For lower flow rates, down to about 5 $L \cdot s^{-1}$, the standard orifice plate is replaced by one with a smaller opening.

Means of Ignition

In some cases no external ignition source is desired, and specimen testing is to be done solely on the basis of autoignition. In most cases, however, an external ignition source is desirable. This ignition source should, in general, not impose any additional localized heating flux on the specimen. Apparatus designs have been developed, with impinging pilots that can, in some cases, produce such high localized

heat fluxes as to burn a hole through the specimen at the point of impingement, yet not ignite it outside of that region [39]. Applications for such devices tend to be specialized, since the general objective of radiant ignition testing is to produce data that can be analyzed in the context of an assumed one-dimensional heat flow. A design using an impinging pilot has an additional difficulty. Since most of the specimen face is not yet heated to the ignition temperature when ignition first begins in the vicinity of the pilot, no unique ignition time can be determined. Instead, there is a significant time spread between when ignition first occurs at the initial location, to when the final portions of the face have been ignited.

The ignitor should reliably ignite a combustible gas mixture in its vicinity. Thus, the location of the ignitor must be chosen so that it is near the place where maximum evolution of pyrolysate gases is expected. Some materials are highly fire-retardant treated, and, when heated, emit vapors that tend to extinguish a pilot flame. The ignitor has to be designed so as not to be extinguished by fire-retardant compounds coming from the specimen, nor by airflows within the test apparatus.

The ISO 5657 apparatus was designed with a "dipping" gas pilot, which is periodically thrust for a short while down close to the specimen face, then retracted. This solution, however, introduces an uncertainty into ignition times and provides further complexity. A gas pilot, based on experience, also requires oxygen premix to achieve a flame that is both small and resistant to blowout [40]. With products high in fire retardant, even such precautions are not likely to lead to a reliable pilot; thus, for instance, the ISO 5657 apparatus uses a second pilot to reignite the main pilot. Pilot stability also tends to be crucially dependent on the physical condition of the pilot tube tip, and significant maintenance can be necessary. Finally, if used in a heat release apparatus, a gas pilot can add noise to the baseline of the heat release measurement. Experimental efforts at the National Bureau of Standards (NBS) had success using the NBS-II calorimeter, a more tractable alternative (i.e., electric spark ignition). This spark plug arrangement for ignition was successful, and so a similar electric pilot was designed for the cone calorimeter. The location of the ignitor should be at the place where the lower flammable limit is expected to first be reached when the specimen begins its pyrolysis. It should, however, not be so close to the specimen surface that minor swelling of the specimen would interfere with the ignition function. In the cone calorimeter, the ignitor locations were chosen so that, when testing in the horizontal orientation, the spark plug gap is located 13 mm above the *center* of the specimen; in the vertical orientation, the spark plug gap is located at the specimen plane and 5 mm above the *top* of the specimen holder.

The actual spark plug arrangement is shown in Fig. 28.10. The spark plug is provided by a special-purpose 10-kV ignition transformer. The spark plug is moved in and out by remote control, operated by an air motor that rotates the shaft on which the spark plug rests. A reversible lock bar is used to adjust the spark-plug-to-heater distance when changing from the horizontal to the vertical orientation (the spark gap is 13 mm away from the heater baseplate in the horizontal orientation, but 25 mm away in the vertical).

Specimen Area and Thickness

Both specimen area and thickness may be expected to have some effect on the ignitability and the heat release rate. The main practical size and thickness limitations come from the fact that the specimens to be tested should exhibit primarily one-dimensional heat transfer. Thus, the configuration should be such that excessive edge effects are not seen. If the specimen thickness is such that it is thermally thick (the heat wave penetration depth being less than the physical depth), then further increases in thickness are not expected to change ignitability results. For thinner specimens, however, there can be expected to be a thickness effect, and the backing or substrate material's thermophysical properties can be of importance.

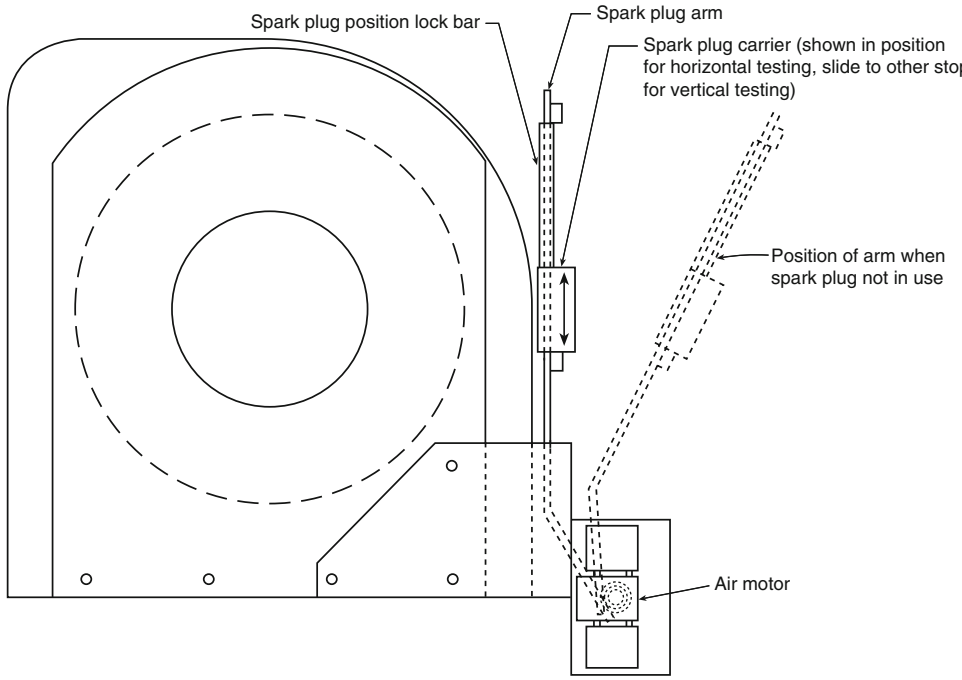

Fig. 28.10 Spark plug, carrier, and air motor

Specimen Area Janssens [34] studied in some detail the general problem of area effect on ignition. The effect is seen to be smaller when irradiances are high rather than low. The exact magnitude of the effect is also dependent on the specimen's thermophysical properties. For specimens of area 0.01 m^2 or larger, however, his results show an increase in ignition time of only about 10 % over what would be seen with a specimen of infinite area. Later, Nussbaum and Östman [41] studied specimens in an experimental apparatus somewhat similar to the cone calorimeter, but accommodating 200 × 200 mm specimens. Their comparison of the ignition times of these larger specimens against the standard 100 × 100 mm ones shows that quadrupling the specimen area decreases the ignition time by about 20 %.

For heat release rate, the specimen size affects the measurement, since flame volume is larger over larger specimens; consequently the flame radiation tends to approach a value of higher emissivity. Nussbaum and Östman also examined heat release rates from larger specimens; the differences were generally of the same order of magnitude as the repeatability of the results. Babrauskas, in commenting on these data [42], discussed tests on larger size, horizontal PMMA samples, where each doubling of the specimen's area increased the heat release rate, per unit area, by about 10 %. The more general treatment of the horizontal specimen, of course, is as a liquid pool. Chapter 26 gives details on the size effect for burning pools. It can be seen that the diameter has to be greater than about 1 m before the specimen area effect becomes negligible.

The effect of specimen size for vertical samples was examined at Factory Mutual Research Corporation (FMRC) in a series of experiments on PMMA walls [43, 44]. The FMRC studies showed little size effect for specimen heights up to 200 mm; beyond 200 mm there was approximately a linear dependence of $\dot{q}''$ on the height. This was true up to the maximum height tested, that is, 3.56 m. Unlike horizontal pools, the rate of heat release was not leveling off at even these sizes, and estimates suggested that the specimen size would have to be increased by

another order of magnitude before a leveling off would be seen.

The conclusion from the above studies was that 100 × 100 mm was a suitable size for bench-scale testing, but that the bench-scale $\dot{q}''$ rates will always be somewhat lower than for full-scale fires.

Specimen Thickness The cone calorimeter is intended for testing actual commercial products. Thus the specimen thickness should be, as much as possible, the thickness of the finished product. There are limitations at both ends of the scale, however. The instrument is restricted to testing specimens not thicker than 50 mm. For products that in their finished state are greater than 50 mm thick, it can readily be seen that, for almost any realizable combination of thermophysical properties and incident radiant fluxes, a 50 mm specimen is thermally thick, and increasing thickness would not change the ignition times [45, 46]. By making calculations for various densities and heat fluxes, it was found that for particleboard the minimum thickness required to ensure that the specimen is thermally thick can be represented by

$$\ell = 0.6\,\frac{\rho}{\dot{q}''} \tag{28.3}$$

where

$$\ell = \text{Thickness}\,(\text{mm})$$
$$\rho = \text{Density}\,(\text{kg}\cdot\text{m}^3)$$
$$\dot{q}'' = \text{Heat flux}\,(\text{kW}\cdot\text{m}^2)$$

This is probably a reasonable rule of thumb for other materials as well. The proportionality of the required thickness to $\rho/\dot{q}''$ is derived from classical heat conduction theory by equating the time for the front surface to reach ignition temperature to the time the rear surface's temperature begins to rise, assuming that the thermal conductivity is proportional to the density. Numerical calculations were necessary to determine a suitable constant because of the impact of front surface heat losses.

For materials that are not thermally thick at the time of ignition, the nature of the backing material or substrate can influence the measured value of the ignition time. In the cone calorimeter, the substrate is a blanket of refractory ceramic fiber material, having a nominal density of 65 $\text{k}\cdot\text{gm}^{-3}$. In use, the material assumes a more compacted density of roughly 100 $\text{kg}\cdot\text{m}^{-3}$. Whenever possible, materials whose thicknesses are less than the minimum suggested in the above formula should be mounted on that substrate material over which they will actually be used. As a practical guide for testing unknown commercial samples, it is desirable to specify that any specimens less than 6 mm thick should always be considered as needing to be tested over their in-use substrate.

Fabrics are a special case. Thin fabrics are sometimes used for constructing air-supported structures; these should be tested with an air space in back, simulating the usage conditions. A special holder has been constructed that allows the fabrics to be pulled taut and held above a dead-air space (Fig. 28.11).

Sample Testing Specifications

Specimen Orientation and Specimen Holders

The specimen holders in Figs. 28.12 and 28.13 show the two specimen holders, respectively. With proper precautions, the horizontal orientation can be used for testing liquids and melting materials, whereas the vertical orientation's small melt trough can only catch a very small amount of molten material. Also, some specimens, when tested in the vertical orientation, show a tendency to lose physical strength and fall out of the holder, which does not happen in the horizontal orientation.

In the vertical orientation, there are several layers of rigid millboard behind the blanket, sufficient in thickness to fill out the depth of the specimen holder. The specimen is wrapped in a single sheet of aluminum foil, covering the sides and bottom. The aluminum foil serves to limit the flow of molten material and prevent it from seeping into the refractory blanket.

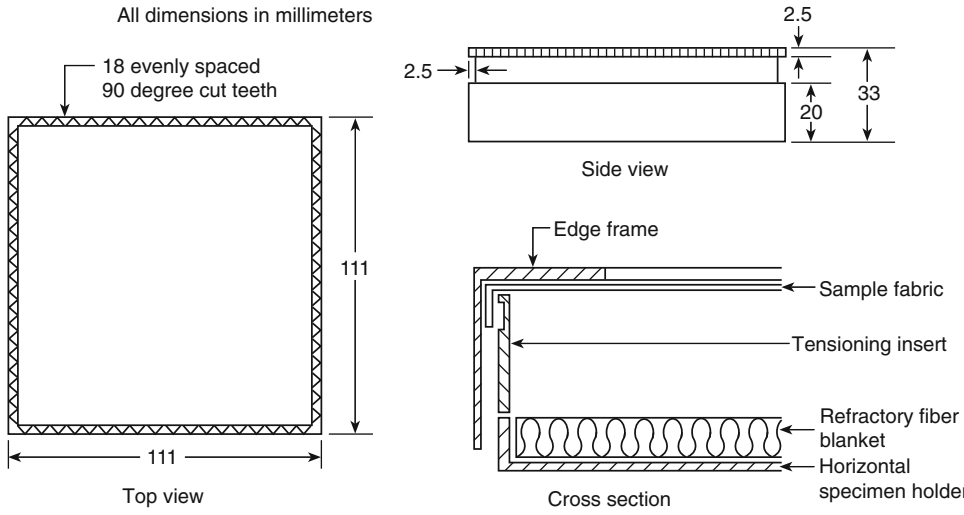

Fig. 28.11 Special holder for testing fabrics and similar thin materials

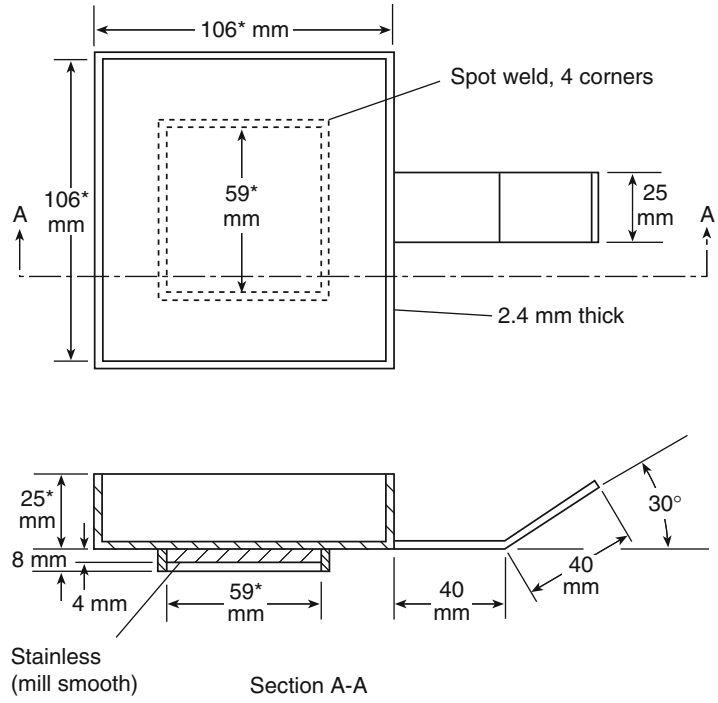

Fig. 28.12 Horizontal orientation specimen holder

Load Cell

Many ancillary measurements made in the cone calorimeter (such as yields of various gas species) require the use of a load cell. Transducers had been tried in various earlier apparatuses, but most suffered because they were not designed for purely single-axis linear motion. That is, if the weight of the specimen was not well balanced, or differential heating stresses occurred, it was

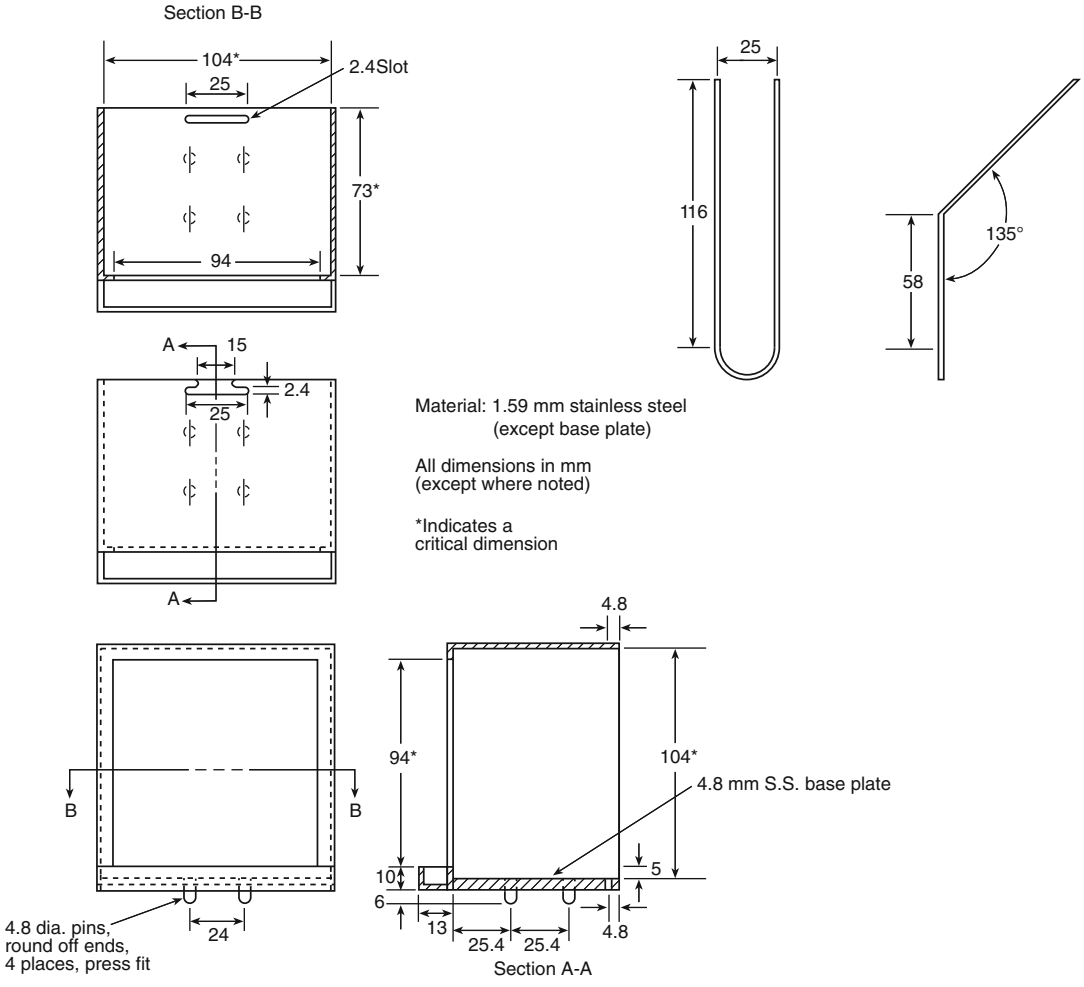

Fig. 28.13 Vertical orientation specimen holder

likely that a mechanical moment (or *torque*) would be applied to the device, with the transducer then being prone to jamming. For the cone calorimeter, a commercial-design load cell was found that permits only up-and-down axial motion while being insensitive to torques or forces from other directions.

The load cell has to accommodate two differently oriented specimen holders and may need to hold additional fixtures. All of these can have substantial—and different—weights, yet must allow accurate mass determination for low-density specimens. The solution adopted was a weighing system that has a large (3.5 kg) mechanical tare adjustment range, along with a sensitive weighing range (500 g). A resolution of 0.005 g is readily achievable.

Figures 28.7 and 28.8 show, respectively, how the horizontal and vertical orientation specimen holders are accommodated on the load cell. The horizontal holder has a square recess on the bottom and simply is placed straight down. The vertical holder is more conveniently inserted directly toward the heater, correctly locating the specimen by four mounting pins on the bottom. In both cases there is a positive specimen location, and the operator does not have to be concerned with how far to insert the holder.

Edge Conditions

Edge Effects In an apparatus such as the cone calorimeter, it is desired that the small-scale test specimen would behave, as much as is possible, like a correspondingly sized element of the full-scale object. If one is dealing with relatively large, flat, full-scale objects, then heat and mass transfer will occur only in the direction perpendicular to the exposed face. There will be no heat or mass flow along either of the face directions. The guidance to be derived from this conceptual model in designing the bench-scale test environment is clear: there should be a minimum of heat or mass transfer at the specimen edges. The aluminum foil used to wrap the specimen usually serves to minimize any mass transfer that may occur. The heat transfer situation, however, is more complicated.

In the vertical specimen orientation, the specimen has to be restrained against falling out; therefore, the vertical specimen holder incorporates a small lip extending 3 mm along the edges. In the horizontal orientation, no special measures need to be taken against falling out. Thus, for many specimens it is satisfactory to simply cover the edges and bottom with aluminum foil, leaving the top exposed in its entirety.

Some categories, however, present special problems—specimens that either have a propensity to ignite first along the outside edge or that, when ignited, burn disproportionately vigorously near the edges. Such behavior is often found with wood specimens and with certain composites. This problem is alleviated by using a stainless steel edge frame for the horizontal orientation, which like the vertical holder provides a 3 mm lip around the edge of the specimen face (Fig. 28.14).

Specimens showing unrepresentative edge burning can be viewed as having a spurious heat gain along the edges when compared against a hypothetical ideal situation of exactly zero heat loss or gain at the edges. When an edge frame is applied, the opposite situation can tend to result, that is, an observed net heat loss from the specimen [47]. The ideal situation of a specimen prevented from showing unrepresentative increased edge burning but equally not sustaining any losses to an edge frame may be difficult to approach in practice. This is still a topic of active study at several institutions.

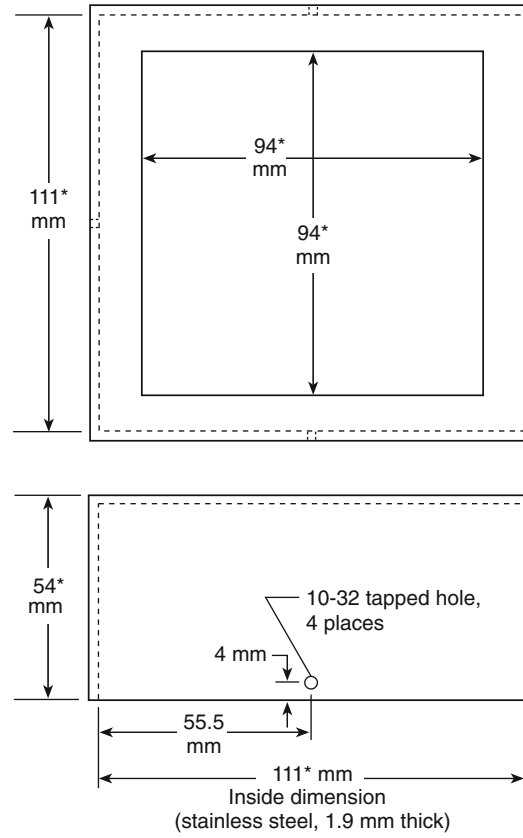

Fig. 28.14 Edge frame for the horizontal specimen holder

In some cases, an edge frame is needed for thermostructural reasons. Some specimens, especially certain composites, can show pronounced edge warping and curling when subjected to heat. The burning of such a specimen would be highly nonuniform if its edges were not held down with an edge frame. In many cases, an edge frame is all that is required. In some cases, however, additional measures such as a wire grid (see below) are required.

Intumescing Samples Intumescence is a common difficulty with fire test specimens, either before ignition or during the burning. The simplest solution used in the cone calorimeter,

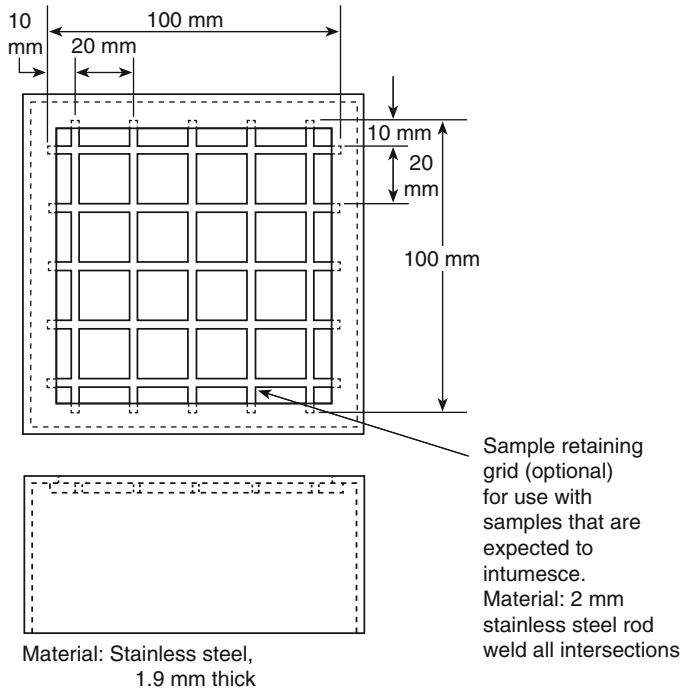

Fig. 28.15 Wire grid

sufficient in many, but not all, cases, is a wire grid placed on top of the specimen. Figure 28.15 shows a medium-weight grid. To minimize effects on measurements, the grid weight should be the smallest possible consistent with providing adequate mechanical restraint to the tested specimen. Effects on measurements will be negligible if the average grid mass is less than 0.6 $kg \cdot m^{-2}$ of specimen face area. This mass corresponds to quite a thin, small grid and will practically be usable only in occasional cases. Additional guidance is given in the NBS "User's Guide for the Cone Calorimeter" [3], but testing laboratories will, on occasion, be required to devise their own special schemes for mounting and restraint.

Smoke Measurement

One of the most essential ancillary measurements performed with the cone calorimeter is smoke obscuration. Widespread dissatisfaction with older, closed-box types of smoke tests [48, 49] caused by the large number of both practical and theoretical difficulties were successfully resolved by developing a flow-through smoke measuring system, using a helium-neon laser as the light source and a sophisticated quasi-dual-beam measuring arrangement. Figure 28.16 shows the overall arrangement of the laser photometer. It is mounted on the exhaust duct at the location shown in Fig. 28.9. A thermocouple is also mounted nearby, since the calculations require a determination of the actual volume flow rate in the duct at the photometer location. The user should consult Geake [49] for details explaining the operation of the laser photometer. Briefly, the light from the laser goes, via two beam splitters, into two detectors. The light reaching the compensation detector is not attenuated by smoke; its signal serves as the reference to cancel out fluctuations in laser output power. The main beam detector measures a signal that is attenuated by the smoke. The optical path is purged by a minute flow of room air through a purge system. The flow is maintained by the pressure differential in the exhaust duct.

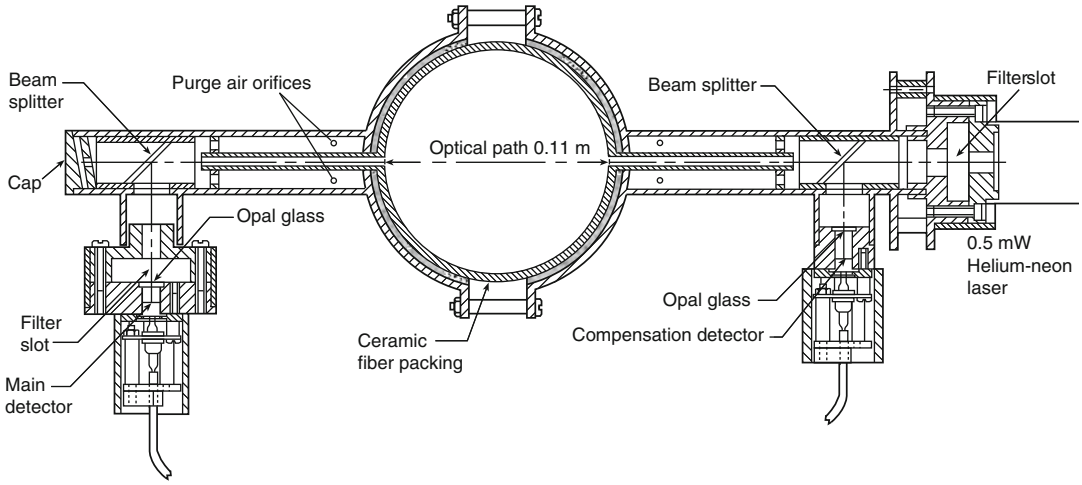

Fig. 28.16 Laser photometer

For certain research purposes, it is advantageous, in addition to obtaining optical smoke obscuration measurement, also to record the gravimetric soot yield by measuring grams of soot evolved per gram of specimen burned. A soot mass sampler is connected to the port indicated in section C-C of Fig. 28.9, and a known mass fraction of the exhaust duct flow is passed through a measuring filter and is weighed before and after the test.

Calibration Equipment

Two basic calibrations are needed: (1) the calibration of the temperature controller for the conical heater and (2) the actual heat release rate calibration. The temperature controller is calibrated using a Schmidt-Boelter-type heat flux meter equipped with a locating collar and inserted in place of the specimen, with its face where the specimen face would be located. No specimen holder is used for this operation. Figures 28.7 and 28.8 show the insertion of the heat flux meter.

The heat release rate is calibrated with a calibration burner inserted into the same bracket used for the heat flux meter (Fig. 28.17). The calibration burner, however, instead of being inserted facing the heater, is inserted so that the discharge opening faces upward. Calibration is accomplished by controlling the flow of high-purity methane going to the burner and comparing it to a known value and using the net heat of combustion for pure CH_4 as 50 MJ · kg^{-1}.

The laser photometer is calibrated by neutral-density glass filters. These are inserted into a filter slot in front of the main beam detector. An auxiliary filter slot is provided in front of the laser. This serves to check the correct balancing of the dual-beam system's common mode rejection ratio.

The NBS "User's Guide to the Cone Calorimeter" [3] details how calibrations are performed.

Miscellaneous Details

Ring Sampler

The combustion products flowing through the exhaust system can be heavily laden in soot, which would cause rapid clogging of the oxygen measurement system if precautions were not taken. The most important precaution is the specially designed ring sampler (Fig. 28.18), which is installed in the exhaust duct with the intake holes facing away from the direction of airflow. A number of small holes are used so as to provide a certain degree of smoothing with respect to duct flow turbulence.

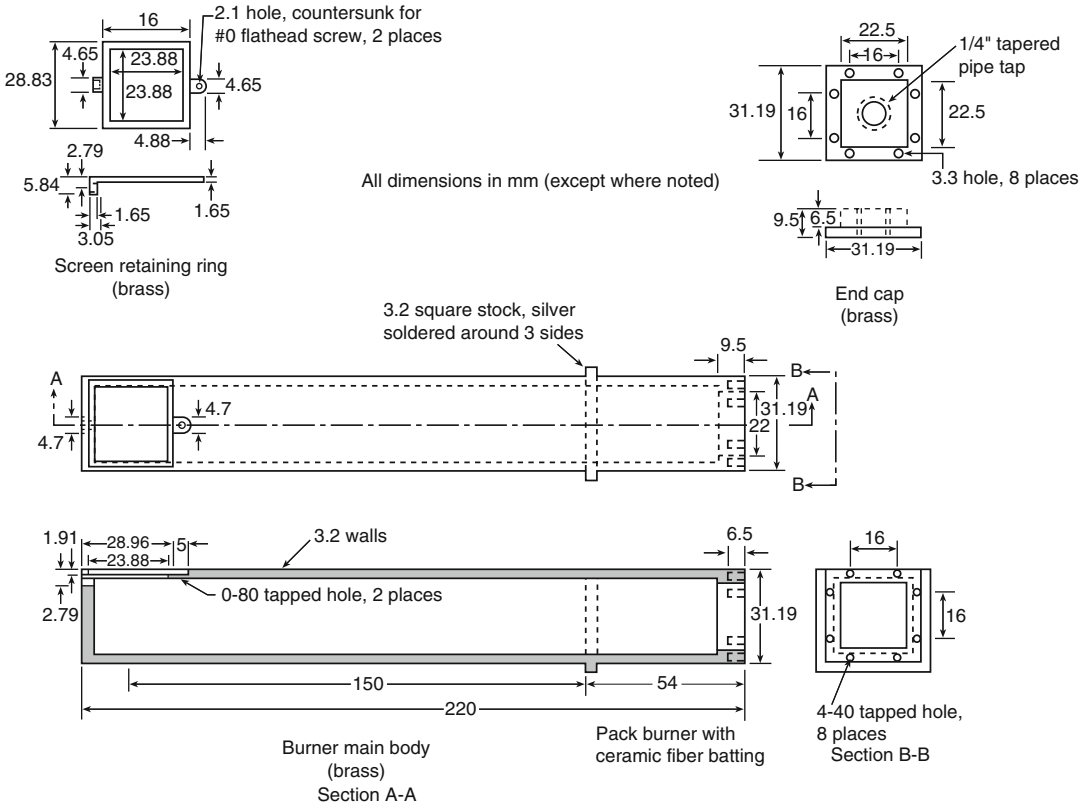

Fig. 28.17 Calibration burner

Additional Gas Analyzers

Many users of cone calorimeters provide not just an oxygen analyzer but also additional gas analyzers to help determine combustion chemistry and toxicity. CO and CO_2 analyzers are simply fitted into the same sampling line serving the oxygen analyzer. Other analyzers, for example, H_2O, HCI, and total unburned hydrocarbons, require a completely separate, heated sampling line system. Such a system also needs to have a heated soot filter at the front.

Special Issues with Product Testing

The cone calorimeter has been used for studying a very wide range of products and materials. In this section, some items of interest are considered where special care needs to be exerted in configuring the samples or in testing.

Liquids

The HRR of liquids is generally not the quantity of interest to regulators and other individuals charged with enforcing fire safety provisions for liquids. In addition, there is no easy way to scale from bench-scale results to large-scale applications. However, some research studies on liquids using the cone calorimeter have been reported. In such studies, use of a circular dish is generally more convenient than using a square specimen. For example, Hayakawa et al. [50] used a 113 mm diameter dish, while Iwata et al. [51] used a 90 mm dish. Liu et al. [52] conducted a study of liquids in the cone calorimeter, accompanied by water mist extinguishment. A number of other studies [53–57] have been reported.

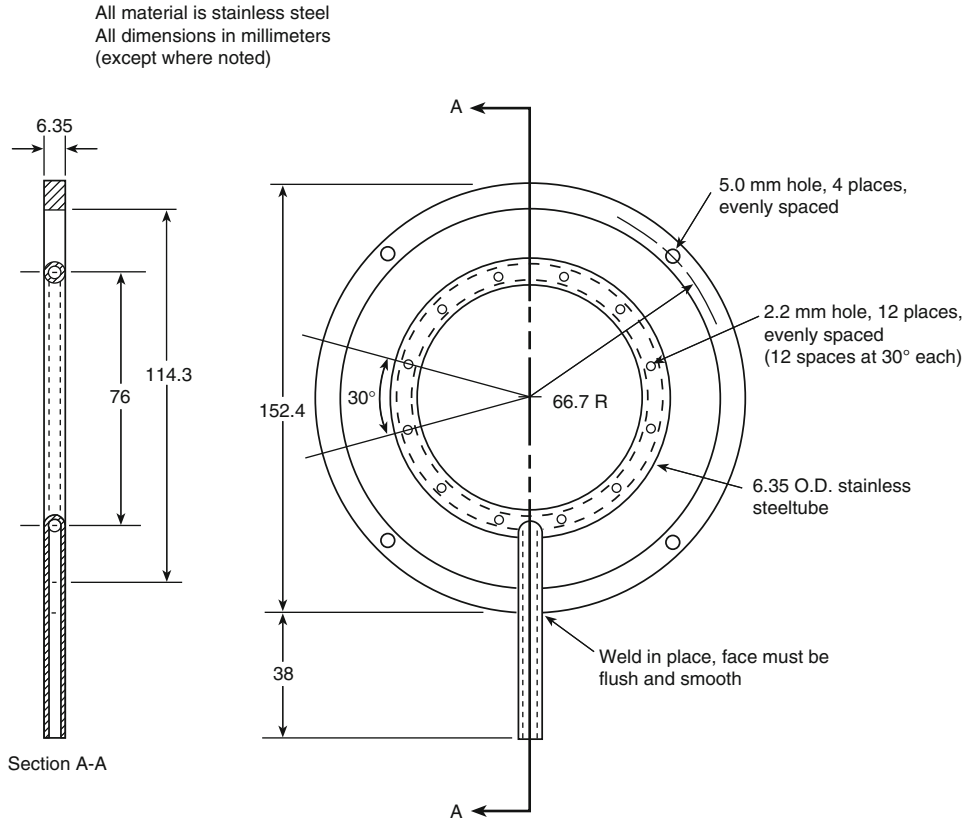

Fig. 28.18 Ring sampler

Electrical Cables

In testing electric cables, pyrolysis gases have a pronounced tendency to flow along the length of the cable interior and burn only at the edges rather than uniformly over the surface. For such specimens, it has often been found useful to coat the cable ends with a sodium silicate cement, such as Insa-Lute Adhesive Cement Paste No. 1, produced by the Sauereisen Cements Co. When the ends are sealed in such a manner, a knife puncture must be made in the face of each piece of cable to avoid pressure buildup and rupture.

Even though electrical cables are circular rather than flat, it has been found that they can be successfully tested in the cone calorimeter. Normally, 100 mm long cable sections are cut and placed side by side, filling up the specimen holder. For this to be practical, the diameter should not be excessive, say less than 15 mm or so.

ASTM has issued a standard [58] on the testing of electrical cables with the cone calorimeter. In the ASTM standard, the cables may either be cut into sections, or else the insulation material alone is to be tested as a flat plaque. The latter will generally not be practical, since cable manufacturers do not produce the plastic in this form. The ASTM standard also permits the ends to be sealed, or unsealed, when actual cable sections are tested.

Grayson et al. [59] documented the results of the FIPEC research program, where electrical cable testing and modeling was done using a wide array of techniques. A very extensive cone calorimeter testing effort is described in this connection. The FIPEC researchers concluded that the best results are obtained when the ends are sealed, except for very small cables

(<4 mm dia.). The sealing did not affect the magnitude of the results, but did improve the repeatability. They also conducted plaque tests on some individual materials.

Intumescing Materials

Intumescing materials can present special problems for testing. Most substances do not intumesce significantly during testing. The exceptions are, of course, intumescent coatings, but also some grades of PVC show a strong tendency to intumesce, as do some a few other materials. The first problem encountered is if the specimen rises sufficiently to contact the spark plug and cause a short. More extreme intumescing can actually result in contacting the heater coil, although this has rarely been seen. Apart from problems with the spark plug (which can be avoided by improvising another ignition arrangement), there is the issue of flux non-uniformity—as the specimen surface rises, it encounters a locale with higher radiant flux.

The original solution for intumescing materials, incorporated into the ASTM [2] and ISO [1] standards, has been to provide a wire retaining grid, which is placed on top of the specimen and held down the edge frame. This generally sufficiently reduces the intumescence to eliminate technical problems. However, this has caused concern for some manufacturers, who considered that their product may not able to achieve the optimal performance that it might in its end-use application, where a thicker layer of intumesced material would be developed.

A procedure was suggested [60] whereby the specimen surface is placed at 60 mm below the base of the heater, instead of 25 mm, in order to allow ample height for expansion. This however also has drawbacks. The heat flux uniformity at such a spacing becomes poor across the face of the specimen. In addition, if a tall hemispherical or elongated configuration is allowed to arise, there is very limited heat flux incident upon the sloped sides of such a specimen.

Low HRR Materials and Noncombustibility

Many building codes, including all in North America, have long taken the stance that materials are to be divided into two kinds: combustible and noncombustible. This kind of categorical yes/no distinction basically reflects the fire knowledge of the nineteenth century, and not the twenty-first, where fire safety engineering is acknowledged to be a profession capable of quantitative assessment of hazards. While codes have numerous and complex provisions on this subject, the most important application, by far, is in regards to materials that are used as either structural members or as lining materials, e.g., wall or ceiling linings. Babrauskas and Janssens recently examined this question in detail [61]. It was concluded that the concept of noncombustibility has no reasonable relationship to life safety, as pertains to sub-surface construction materials, that is, everything except the surface materials. The HRR of surface materials, on the other, is crucial to life safety. But noncombustibility is not useful metric for hazard. It was recommended that a solution which is consistent with fire safety engineering concepts and is presented in a practical way is the Cleary/Quintiere calculation of the '*b*' parameter, in Equation 28.1. A comparison to large-scale room fire test results showed a very good ability of this parameter to distinguish materials which led to hazardous fire conditions, versus ones which did not.

In addition, low HRR materials may show up in the form of composites, where the top layer is highly resistant to burning, while the layer (s) underneath are less so. Such constructions present issues which are discussed in the next section.

Composites

The cone calorimeter is inherently designed to be able to test composite products, provided the layers are can adequately be represented by an

assembly no more than 50 mm deep. In practice, this allows for a reasonable representation of products which are even much thicker, provided that there are not additional layers which are both deep and producing a high HRR. In some cases, however, special precautions need to be taken.

For example, upholstered furniture composites cannot be tested in a representative manner unless the outer layers are constrained to stay in place, instead of crumpling due to exposure to heat. In view of this need, a special test method, ASTM E 1474 [62], was developed for preparing and testing such composites.

Some high-pressure laminates explosively delaminate when subjected to heating. These can only be tested if the use of the wire grid and edge frame eliminates this problem, which it normally does. Another special category of products are ones where the surface layer has a low HRR, while layers underneath show a much higher HRR. If tested simply as a cut specimen, the edges are likely to get involved early, and this may produce unrepresentative burning. The problem was studied by Canadian researchers [63, 64] who developed a special holder which protects the edges of such specimens. The latter was incorporated into the Canadian CAN/ULC S135 standard [65].

Measurements Taken with the Cone Calorimeter

The relevant ISO [1] or ASTM [2] standards mandate certain minimum variables to be recorded. In practice, it is normally desired to make the data from the test be as complete as possible. Cone calorimeter data are normally handled as data tables and files standardized according to the Fire Data Management System (FDMS) prescription [66]. A complete set of data from the cone calorimeter are illustrated there. Here the more important of these are given, somewhat augmenting the ISO and ASTM set. Note that most items must be reported for each test run, and a complete test consists of three runs.

Identification	Various data items must be included here
Preparation	Any nonstandard specimen preparation details must be reported
Test number	Serial number of test; also information on testing laboratory, operator, and so forth
Irradiance	The heating flux set for the test ($kW \cdot m^{-2}$)
Exhaust flow rate	Recorded for completeness, usually the standard value of 24 $L \cdot s^{-1}$
Orientation	Horizontal or vertical
Spark ignition	Yes or no
Edge frame	Yes or no
Wire grid	Yes or no
Area of specimen	(m^2), since may be nonstandard in special cases
Specimen initial mass	(g)
Specimen final mass	(g)
Time to ignition	According to the ISO and ASTM standards, "sustained flaming" (s)
Time to flameout	(s)
Peak $\dot{q}''$	($kW \cdot m^{-2}$)
Peak $\dot{m}''$	($g \cdot s^{-1} \cdot m^{-2}$)
Total q''	($MJ \cdot m^{-2}$)
O_2 consumption	($kJ \cdot kg^{-1}$); this is set to a specific constant value if known, otherwise to 13,100
Effective heat of combustion	($MJ \cdot kg^{-1}$), reported for period of entire test run
Specific extinction rate	($m^2 \cdot kg^{-1}$), reported for period of entire test run
Average mass loss rate	Computed over period starting when 10 % of the ultimate specimen mass loss rate has occurred and ending at the time when 90 % of the ultimate specimen mass loss has occurred ($g \cdot s^{-1} \cdot m^{-2}$)
Average $\dot{q}''$ (60 s)	Computed for the first 60 s after ignition ($kW \cdot m^{-2}$)
Average $\dot{q}''$ (180 s)	Computed for the first 180 s after ignition ($kW \cdot m^{-2}$)
Average $\dot{q}''$ (300 s)	Computed for the first 300 s after ignition ($kW \cdot m^{-2}$)

Note in the above 60, 180, and 300 s averages that, if the test is ended before having burned, say, 300 s, a proper average can still be correctly computed (i.e., at the end of the averaging period a number of zeroes are used for data points past

the end of the test). Since users are often confused by this point, it must be emphasized: it is not sensible to report an "average heat-release rate" without specifying the time interval. The reason has to do with the question of determining the end of the test. The ISO and ASTM standards specify that the end of the test is considered to be

1. After all flaming and other signs of combustion cease
2. While there may still be vestigial combustion evidence, but the mass loss rate has become very small (less than 150 $g \cdot m^{-2}$ being lost during any 1 min)
3. 60 min have elapsed

These rules are needed for establishing some uniformity among testing laboratories. They do not, however, mean that it is technically sound to compare the average of one material that may have burned for 10 min with another that may have burned for 5 min. It is technically sound, however, to compare their burning over the first one, three, and so forth, minutes of test.

Further information on the form, units, and usage of fire properties measured in the cone calorimeter can be found in Babrauskas [67]; specific information on the smoke and soot properties measured in the cone calorimeter is given in Babrauskas and Mulholland [48].

Repeatability and Reproducibility

The repeatability, r, and reproducibility, R, of the cone calorimeter were studied in two sets of interlaboratory trials, one sponsored by ISO and one by ASTM. According to the ISO instructions [68], the definitions of repeatability and reproducibility were taken as

$$r = 2.8\sigma_r$$
$$R = 2.8\sigma_R$$

where σ_r is the repeatability standard deviation, σ_R is the reproducibility standard deviation, and the 2.8 factor comes from specifying the probability level of 95 %.

From the results of the interlaboratory trials, values for r and R were calculated for six variables. These variables, chosen as being representative for the test results, were t_{ign}, $\dot{q}''_{max}$, $\dot{q}''_{180}$, q_{tot}'', $\Delta h_{c,eff}$, and σ_f. A linear regression model was used to describe r and R as functions of the mean overall replicates and overall laboratories for each of the six variables. The regression equations given below also indicate the range of mean values over which the fit was obtained.

The results for time to sustained flaming, t_{ign}, in the range of 5–150 s were

$$r = 4.1 + 0.125 t_{ign}$$
$$R = 7.4 + 0.220 t_{ign}$$

The results for peak heat release rate, $\dot{q}''_{max}$, in the range of 70–1120 $kW \cdot m^{-2}$ were

$$r = 13.3 + 0.131 \dot{q}''_{max}$$
$$R = 60.4 + 0.141 \dot{q}''_{max}$$

The results for 180 s average heat release rate, $\dot{q}''_{180}$, in the range of 70–870 $kW \cdot m^{-2}$ were

$$r = 23.3 + 0.037 \dot{q}''_{180}$$
$$R = 25.5 + 0.151 \dot{q}''_{180}$$

The results for total heat released, $\dot{q}''_{tot}$, in the range of 5–720 $MJ \cdot m^{-2}$ were

$$r = 7.4 + 0.068 q''_{tot}$$
$$R = 11.8 + 0.088 q''_{tot}$$

The results for effective heat of combustion, $\Delta h_{c,eff}$, in the range of 7–40 $kJ \cdot g^{-1}$ were

$$r = 1.23 + 0.050 \Delta h_{c,eff}$$
$$R = 2.42 + 0.055 \Delta h_{c,eff}$$

The results for average specific extinction area, σ_f, in the range of 30–2200 $m^2 \cdot kg^{-1}$ were

$$r = 59 + 0.076 \sigma_f$$
$$R = 63 + 0.215 \sigma_f$$

A comparison of the cone calorimeter repeatability and reproducibility to the values obtained for the ISO 5657 radiant ignition test showed the cone calorimeter results to be about a factor of 2 better.

Fig. 28.19 The NIST controlled-atmosphere cone calorimeter

Special Cone Calorimeters

The standard cone calorimeter has been designed to use room air for combustion. All standard testing is done under such conditions. For special combustion studies, however, it can be of interest to explore the burning of materials at oxygen levels other than 21 %. Such a unit, constructed at NIST, is described in Babrauskas et al. [38]. This controlled-atmosphere unit has already been used for studies of the burning of materials in air supplies with less than 21 % oxygen, with N_2 or CO_2 being mixed into the air stream (Fig. 28.19). It has also been used for pyrolysis studies under pure nitrogen flow conditions. In principle, it could also be used for studies of enriched-oxygen atmospheres; however, the necessary safety procedures for handling high-concentration oxygen streams are required. A unit for handling O_2 mixtures greater than 21 % has been constructed for NASA, but data are not yet available from it. A controlled-atmosphere unit is also appropriate for use when airflow rates of less than 12 $L \cdot s^{-1}$ are required.

All of the present cone calorimeter designs, both standard and otherwise, have been designed for use only under ambient pressures. There is interest at this time from at least one research group to design and construct a unit for aerospace studies that would function under nonambient pressures.

Nomenclature

$\boldsymbol{b}$	Parameter
$\boldsymbol{F}$	View factor (-)
$\boldsymbol{h_c}$	Convective heat transfer coefficient ($W \cdot m^{-2} \cdot K^{-1}$)
ℓ	Thickness (mm)
$\dot{m}''$	Mass loss rate ($g \cdot s^{-1} \cdot m^{-2}$)
$\dot{q}$	Total energy released per unit area ($MJ \cdot m^{-2}$)
$\boldsymbol{q''}$	Total energy released per unit area ($MJ\ m^{-2}$)
$\dot{q}''$	Heat flux ($kW \cdot m^{-2}$)
$\dot{q}''_{180}$	180 s average heat release rate ($kW \cdot m^{-2}$)
$\dot{q}''_{avg}$	Average heat release rate ($kW\ m^{-2}$)
$\dot{q}''$	Irradiance ($kW\ m^{-2}$)
$\dot{q}''_{\max}$	Maximum heat release rate ($kW\ m^{-2}$)
$\dot{q}''_{\text{tot}}$	Total heat released ($MJ \cdot m^{-2}$)

$\dot{q}''_{cr}$	Critical heat flux (kW m^{-2})
r	Repeatability (units dependent on quantity investigated)
R	Reproducibility (units dependent on quantity investigated)
t_b	Duration of flaming (s)
t_{ig}	Ignition time (s)
$\Delta h_{c,eff}$	Effective heat of combustion (MJ · kg^{-1})
ε	Emissivity (-)
$\lambda \rho C$	Thermal inertia (kJ^2 m^{-4} s^{-1} K^{-2})
ρ	Density (kg·m^{-3})
σ_r	Repeatability standard deviation (units dependent on quantity investigated)
σ_R	Reproducibility standard deviation (units dependent on quantity investigated)
σ_f	Average specific extinction area (m^2 · kg^{-1})

Compartment Fire Modeling

29

James G. Quintiere and Colleen A. Wade

Introduction

An approach for predicting various aspects of fire phenomena in compartments has been called *zone* modeling. Based on a conceptual representation for the compartment fire process, it is an approximation to reality. Any radical departure by the fire system from the basic concept of the zone model can seriously affect the accuracy and validity of the approach. The zone model represents the system simply as two distinct compartment gas zones: an upper volume and a lower volume resulting from thermal stratification due to buoyancy. Conservation equations are applied to each zone and serve to embrace the various transport and combustion processes that apply. The fire is represented as a source of energy and mass manifested as a plume, which acts as a pump for the mass from the lower zone to the upper zone through a process called *entrainment*.

The zone modeling approach emerged in the mid-1970s when the effort to study the developing fire in a compartment intensified. Careful measurements and observations revealed characteristics of the compartment fire system. The upper and lower layers (zones) were deemed relatively uniform in temperature and composition. Distinct phenomena were discerned that could be studied in isolation, enabling better predictions of their roles in the compartment fire system.

Fowkes [1], in his work with Emmons on the Home Fire Project, was the first to publish a basis for the zone model approach in his description of the "Bedroom Fire" series conducted at Factory Mutual Research Corporation (FMRC). Almost simultaneously, computer models based on the zone model approach were produced by Quintiere [2], Pape and Waterman [3], and Mitler [4] working with Emmons. Since then the development of such computer models has been prolific, extending early efforts on single rooms to computer codes that can address a number of interconnected rooms, using a number of new fire phenomena and computer features. These advances in fire science, together with computer development, have given the engineer convenient tools for investigating the fire hazard in buildings. A notable illustration of such a tool is the Hazard I software developed by the National Institute of Standards and Technology (NIST) [5], only one of numerous current computer codes and software packages based on the zone model approach. In 1992, Friedman [6] cited 21 zone models in use around the world. In 2003, Olenik and Carpenter [7] revisited the survey and summarised the available computer models and their general capabilities. For a discussion of specific zone computer fire models, see Chap. 31.

DOI 10.1007/978-1-4939-2565-0_29, © Society of Fire Protection Engineers 2016

This chapter outlines the basic conservation equations for the gas zones and describes the various transport and combustion processes that make up the system, referred to as the submodels of the system. As such, they can contribute subroutines to computer codes, which implement the mathematical solution. Discussion of submodels will be limited, but the reader will be referred to appropriate references. In most cases, other chapters of *The SFPE Handbook of Fire Protection Engineering* will be cited. No discussion of a computer code or its numerical solution algorithm will be addressed, since these are issues more of style and mathematics. The presentation will elucidate the mathematical basis of the zone model, its assumptions, its features, and its scope of application. Each user of this approach must sufficiently understand its basis to assess its accuracy and validity. When used correctly, zone models predict the average macroscopic features of compartment fires. There are many examples of comparisons to data that illustrate their level of accuracy, and these will not be repeated here. The user must be skilled in assessing the quality of the data and submodels that directly influence the variables of the problem of interest. It is hoped that the discussion that follows will make the user more knowledgeable or sensitive in making these quality assessments.

Conservation Equations

The building block of the zone model is the conservation equations for the upper and lower gas zones. These equations are developed either (1) by using fundamental equations of energy, mass, and momentum transport in control volume form as applied to the zones, or (2) by using differential equations that represent the conservation laws and integrating them over the zones. However, the momentum equation will not be explicitly applied, since information needed to compute velocities and pressures is based on assumptions and specific applications of momentum principles at vent boundaries of the compartment. An extensive review of control volume equations for mass, species, and energy conservation in a combustion system has been presented by Quintiere [8] and serves as a reference for the equations that follow.

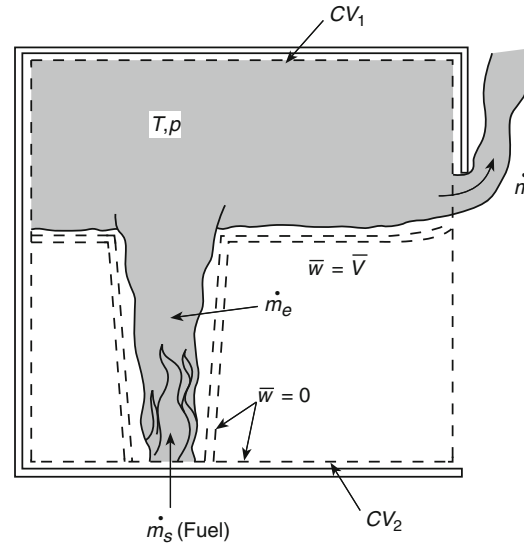

Fig. 29.1 Control volumes selected in zone modeling

Figure 29.1 illustrates a typical zone model for a compartment fire process. It shows a fire plume and a door vent. The hot combustion gases that collect in the upper space of the room and spill out of the vent constitute the upper-layer zone. A control volume, CV_1, is defined to enclose the gas in this upper layer and the fire plume. The lower interface of the upper layer moves with the control volume such that no mass is transferred across this thermally stratified region. The velocity of the control volume along this interface, $\overline{w}$, is equal to the fluid velocity, $\overline{v}$. The temperature of the upper layer is greater than that in the lower layer (zone) which includes all the remaining gas in the room, and is delineated by a second control volume, CV_2. It has been assumed in zone modeling that the volume of the fire plume is small relative to the gas layer or zone volumes, and therefore its effect has been ignored. In general, multiple fire plumes can occur at any height in the room, and multiple vents or mass transport can take place between the zones (CV_1 and CV_2) and the surroundings. In each case mass transport must be appropriately

described in terms of the system variables; however, this may not always be easy or known. The properties of the upper and lower zones are assumed to be spatially uniform, but can vary with time. Thus, temperature, T, and species mass concentration, Y_i, are properties associated with ideal upper and lower homogeneous gas layers. Other assumptions in the application of the conservation laws to the zones are listed below:

1. The gas is treated as an ideal gas with a constant molecular weight and constant specific heats: c_p and c_v.
2. Exchange of mass at free boundaries is due to pressure differences or shear mixing effects. Generally these are caused by natural or forced convection, or by entrainment processes.
3. Combustion is treated as a source of mass and energy. No mechanism from first principles is included to resolve the extent of the combustion zone.
4. The plume instantly arrives at the ceiling. No attempt is made to account for the time required to transport mass vertically or horizontally in the compartment. Hence, transport times are not explicitly accounted for in zone modeling.
5. The mass or heat capacity of room contents is ignored compared to the enclosure wall, ceiling, and floor elements; that is, heat is considered lost to the structure, but not to the contents. Where room contents shield boundary structural surfaces, some compensations can occur in the analysis, but for cluttered rooms this assumption may be poor.
6. The horizontal cross section of the enclosure is a constant area, A. In most cases of zone modeling, rectilinear compartments have been considered. However, this is not a necessary assumption, and enclosures in which A varies with height can easily be handled.
7. The pressure in the enclosure is considered uniform in the energy equation, but hydrostatic variations account for pressure differences at free boundaries of the enclosure; that is, $p \gg \rho gH$. In general, the enclosure pressure, p, is much greater than the variations due to hydrostatics. For example, for $p = 1$ atm $= 14.7$ psi $= 10^2$ kPa (kN/m^2) $= 10^5$ Pa, the hydrostatic variation for a height, $H = 1$ m, gives a pressure difference of $\rho gH = 1.2$ kg/m^3 $\times$ 9.8 m/s^2 $\times$ 1 m $= 10$ kg/m·s^2 $= 10$ Pa (N/m^2).
8. Mass flow into the fire plume is due to turbulent entrainment. Entrainment is the process by which the surrounding gas flows into the fire plume as a result of buoyancy. Empirically, the inflow velocity linearly depends on the vertical velocity in the plume.
9. Fluid frictional effects at solid boundaries are ignored in the current models.

Conservation of Mass

The conservation of mass for a control volume states that the rate of change of mass in the volume plus the sum of the net mass flow rates out for J flow streams is zero

$$A\frac{d}{dt}(\rho z_l) + \sum_{\substack{j=1 \\ (\text{netout})}}^{J} \dot{m}_j = 0 \qquad (29.1)$$

where

ρ = Density of the gas in the control volume (or zone)

z_l = Height of the zone

For the illustration in Fig. 29.1, applying Equation 29.1 to the upper layer (CV_1) would give

$$\sum_{j=1}^{3} \dot{m}_j = \dot{m} - \dot{m}_e - \dot{m}_s \qquad (29.2)$$

where

$\dot{m}$ = Mass flow rate out of the door

$\dot{m}_e$ = Mass rate of entrainment into the fire plume

$\dot{m}_s$ = Mass rate of gaseous fuel supplied

Mass flows at the boundaries can occur due to many phenomena. Therefore, the user or designer of a zone model must include the appropriate mass flow phenomena. For example, in addition to the mass rates in Equation 29.2, mass flows can occur due to forced convection from wind or ventilation effects, from shear entrainment as flows affect layer interfaces, or from cold plumes that could plunge through hot layers.

Conservation of Species

The mass concentration of species i is given by Y_i. By using Equation 29.1 and applying the conservation of mass for species i to a control volume, it follows that

$$\rho z_l A \frac{dY_i}{dt} + \sum_{j=1}^{J} \dot{m}_j \left(Y_{ij} - Y_i\right) = \dot{\omega}_i \qquad (29.3)$$

Where

Y_{ij} = Mass concentration of species i leaving the control volume through the j flow stream

$\dot{\omega}_i$ = Mass concentration rate of species due to combustion

The production term, $\dot{\omega}_i$, in principle, can be described through a knowledge of the chemical equation of the reaction or its particular stoichiometry. Thus, stoichiometric coefficients can be used to represent the production of species and the consumption of oxygen in terms of the mass rate of fuel *reacted*. Stoichiometry is not easily determined, and the fuel gases as they emerge from the pyrolysis of solids can take many chemical forms that differ from the solid fuel's original molecular composition. A partial way to overcome these complications has been to represent the mass production of species for fire in terms of the rate of mass *loss* for the pyrolyzing fuel. Hence, one must be careful to distinguish between the mass of fuel lost and that reacted, and to relate available species yield data to the particular fire conditions of the application. Yield is defined as the mass ratio of species to fuel lost. The yields or production rates may change with fire conditions, and therefore, in general, will not be consistent with data from small-scale tests. For example, the production rate of CO changes markedly with air-to-fuel ratio.

Conservation of Energy

The conservation of energy for the control volume is applied along with Equation 29.1 and the equation of state, $p = \rho RT$, to give

$$\rho c_p z_l A \frac{dT}{dt} - z_l A \frac{dp}{dt} + c_p \sum_{j=1}^{J} \dot{m}_j \left(T_j - T\right) = \dot{\omega}_F \Delta H - \dot{Q}_{\text{net loss}} \qquad (29.4)$$

where

T = Temperature of the gases within the control volume

T_j = Temperature of the gases in the j flow stream crossing the control volume boundary

$\dot{Q}_{\text{net loss}}$ = Net rate of heat transfer lost at the boundary

ΔH = Heat of combustion (taken as a positive quantity)

$\dot{\omega}_F$ = Rate at which the fuel supplied is *reacted*

Usually in zone models it is assumed that all of the fuel supplied can react, provided there is sufficient oxygen available. One assumption on the sufficiency of oxygen is to consider that all the fuel supplied is reacted as long as the oxygen concentration in that control volume is greater or equal to zero, that is,

$$\dot{\omega}_F = \dot{m}_s \quad \text{if} \quad Y_o \geq 0 \qquad (29.5)$$

Thereafter, an excess rate of fuel can exist that can be transported into adjoining zones or control volumes where a decision must be made about whether it can continue to react. At this condition, all of the net oxygen supplied to the control volume is reacted, so that, as long as $Y_o = 0$

$$\dot{\omega}_F = r \times (\text{net mass rate of oxygen supplied}) \qquad (29.6)$$

where r is the stoichiometric fuel-to-oxygen mass ratio. This condition when $Y_o = 0$ in compartment fires is termed the ventilation-limited condition. At this moment, significant changes take place in the nature of the chemical reaction. Notably, incomplete combustion is more likely, and for hydrocarbon fuels this leads to a significant increase in the yield of carbon monoxide and soot. Thus, care must be used in interpreting the results of zone models once ventilation-limited conditions arise, particularly with respect

to the prediction of species concentrations and the extent of burning. Material data used for well-ventilated conditions will no longer apply.

A flame extinction condition can be defined by a flammability line that is based on a critical flame temperature below which extinction occurs and no energy is contributed to the system [9]. Based upon a extinction flame temperature of 1300°C, and incorporating Equations 29.5 and 29.6, the criteria for energy release (or burning rate) is expressed as:

$$\dot{\omega}_F = \begin{cases} \dot{m}_s & ; Y_o > 0 \text{ and } T_f > 1300°\text{C} \\ r\ \dot{m}_o Y_o & ; Y_o = 0 \text{ and } T_f > 1300°\text{C} \\ 0 & ; \quad T_f \leq 1300°\text{C} \end{cases} \tag{29.7}$$

The first term on the left side of Equation 29.4 arises due to the change of internal energy within the control volume. If the temperature is not changing rapidly with time, this term can be small and its elimination gives rise to a quasi-steady approximation for growing fires that allows a more simple analysis. The second term arises from the rate of work done by pressure as the gas layer expands or contracts due to the motion of the thermal stratification interface. Having been rearranged, this term now is expressed as rate of pressure, p, increase for the compartment and is essentially caused by net heat or mass additions to the compartment gases. Except for the rapid accumulation of mass or energy, for compartments with small openings to the surroundings this pressure rise is small, and the pressure nominally remains at nearly the ambient pressure. For example, an addition of 100 kW to a 40 m^3 gas volume in a room with a 0.1 m^2 vent area gives rise to roughly an increase of 10 Pa in less than 10^{-2} s over normal ambient pressure of 10^5 Pa [8]. Any increase in pressure within the compartment could give rise to a flow of mass through a vent, and this term in Equation 29.4 may be associated with a *volumetric expansion* effect. Conversely, a reduction in energy release rate will cause the pressure to drop relative to the ambient. This phenomenon, when cycling between heating and cooling, explains the *breathing effect* for fires in closed buildings.

The third term of Equation 29.4 accounts for the enthalpy flow rates and only applies to j flow streams that enter the control volume, since $T_j = T$ for all flow streams leaving, as long as the uniform temperature assumption still applies.

Summary

The zone model for the compartment fire system consists of two zones: the upper and lower gas layers. The solution process for the layer properties can be visualized by considering the conservation Equations 29.1, 29.3, and 29.4 applied to each zone. The species equation can yield the Y_i for each layer. The mass and energy equations comprise four equations (two for each layer) that permit the determination of the two layer temperatures, one layer height (since the height of the other layer is directly found by difference from the total height of the compartment), and the compartment pressure (which is assumed uniform by Equation 29.4). The densities are found from the ideal gas equation of state in which ρT is approximately a constant. To complete this solution process, each source or transport term in the equations must be given in terms of the above layer properties, or auxiliary relationships must be included for each new variable introduced. The source terms are associated with the $\dot{\omega}_i$ terms, and the transport terms include the j mass flow rates and the boundary heat transfer rates. The extent to which source and transport relationships are included reflects the sophistication and scope of the zone model. Some source and transport terms are essential to a basic zone model, others can be specified as approximations to reality, and others can be ignored when physically irrelevant. These source and transport relationships can comprise subroutines of a zone model computer code. The nature of these submodels is discussed below.

Source Term Submodels

The principal source term for the zone model is the rate of fuel supplied. In an experimental fire this can be known if the fire source is simulated by a gas burner. At the other extreme, the mass of fuel supply can result from a fire spreading over an array of different solid fuels. In general,

$$\dot{m}_s = f(\text{fuel properties, heat transfer}) \quad (29.8)$$

in which the heat transfer to the fuel results from the flame configuration and the heated compartment. The fuel properties are still not completely defined or conventionally accepted for fire applications, since no general theory exists for pyrolysis, and theories of flame spread and ignition are couched in terms of effective fire properties, which are modeling parameters. Nevertheless, data exist for fuel fire properties and can enable approximate models for $\dot{m}_s$ of reasonable accuracy. For example, Tewarson describes how the mass supply and energy release can be determined from fuel properties and tabulates properties for a number of solid fuels (Chap. 36). For realistic items under well-ventilated conditions, Babrauskas has compiled results that could serve as initial estimates for $\dot{m}_s$ in compartment fires (Chap. 26). In under-ventilated compartment fires particularly during the fully developed stage, a more complete submodel should address the fuel response to the thermal feedback from the smoke and compartment walls, and the vitiated oxygen effect on the flame heat flux. The mass of fuel supply (the fuel mass loss rate) can be given as [10],

$$\dot{m}_s = \dot{m}''_s A_{F,b} \frac{Y_{o,l}}{Y_o} + \frac{\dot{q}_{\text{external}}}{L} \quad (29.9)$$

where $\dot{m}''_s$ is the free burning rate per unit area, $A_{F,b}$ is the fuel burning area, $Y_{o,l}$ is the local mass fraction of oxygen feeding the flame, Y_o is the mass fraction of oxygen (ambient), L is the fuel heat of gasification and $\dot{q}_{\text{external}}$ is the total external heat flux feedback from the smoke and the compartment surfaces. The first term on the right hand side of Equation 29.9 represents the vitiated oxygen effect on the flame heat flux while the second term is responsible for the thermal feedback from the smoke and compartment surfaces.

The rate of energy release, $\dot{\omega}_F \Delta H$, required by Equation 29.4 has already been discussed through Equations 29.5, 29.6, and 29.7. The point should be made that the heat of combustion, ΔH, employed must be with respect to the mass of fuel gases pyrolyzed, given by such data as Tewarson's, and is not the theoretical oxygen bomb value for the solid fuel (Chap. 36). Due to incomplete combustion, ΔH will be less than the theoretical value, in general.

The production of species can be described in terms of species yield, γ_i, such that

$$\dot{\omega}_i = \gamma_i \dot{m}_s \quad (29.10)$$

For well-ventilated fires, γ_i may be reasonably constant for a given fuel, as tabulated by Khan et al. (see Chap. 36). In general, it can vary with time and can significantly vary as ventilation-limited conditions are approached and achieved. For example, Tewarson shows that γ_i for CO can vary with equivalence ratio, Φ, where

$$\Phi = \frac{\text{Mass of fuel available}/\text{Mass of oxygen available}}{r} \quad (29.11)$$

where r is the stoichiometric value for complete combustion. Zukoski et al. [11] have shown how this relationship may be applied to compartment fires. The equivalence ratio, Φ, may be computed in a zone (or upper layer) where combustion has occurred by computing the mass concentrations of the "available" fuel and oxygen in the zone. This is done by Equation 29.3 in which $\dot{\omega}_i$ is set equal to zero for both the fuel and oxygen, since this yields the available Y_F and Y_o values, not their actual concentrations in the layer following combustion. The generality of considering $\gamma_i = \gamma_i(\Phi)$ for zone models is still under study, and its use must be considered as exploratory. Nevertheless, it currently offers the only practical approach for estimating species, such as CO, under ventilation-limited conditions in compartment fires.

Mass and Heat Transport Submodels

Entrainment

An essential feature of a zone model is the mass rate of entrainment, $\dot{m}_e$, relationship for the fire plume. This relationship allows the principal mechanism for flow between the lower and upper stratified gas layers. Considerable work has been performed to develop entrainment relationships for pool fires or axisymmetric gas burner fires. Unfortunately both the ideal theoretical plume models and correlations based on data vary widely, and no consensus exists among zone models in practice for the optimum pool fire entrainment model. Rockett [12] illustrates the variations in results he found using different fire entrainment models in the Harvard/NIST Mark VI compartment fire zone model. He found that the layer height, entrainment rate, and layer gas temperature varied by roughly a factor of two among the various models. More useful data rather than ideal mathematical models are clearly needed to resolve this issue of accuracy for a simple pool fire. Yet even a perfect entrainment relationship for an axisymmetric pool fire would not necessarily be perfect in a zone model, because a plume in a compartment can be subject to nonsymmetric airflows that can bend the plume and thus affect its entrainment rate. These wind effects can increase the entrainment rate by as much as two or three times [13], however it is also reported that even small ambient disturbances could provide 20–50 % increases in the measured plume mass flows compared to the 'still' conditions in a laboratory [14].

Rockett [12] has shown that the effect of the entrainment model is crucial to predictions for the developing fire. This research suggests that the entrainment model must be representative of the actual object burning and its location within the enclosure. However while correlations have been developed for axisymmetric plumes and for plumes contacting a wall or corner, no entrainment models exist for an item of furniture; this illustrates a need for further research in this area. Yet this does not mean that the zone model has a fatal flaw; it simply means more systematic data are necessary to expand the versatility of the zone model and its accuracy. Moreover, if a zone model with its selected entrainment relationship tracks well with data from an experimental fire scenario, it can be assumed accurate for simulating the process and can be used with some assurance for that scenario. A catalogue of empirical entrainment relationships for various object fires developed from specialized entrainment apparatus would help resolve the entrainment issue. This apparatus could be developed from the large calorimeter intended to measure energy release rate in which the fire plume is collected in a hood-duct system and the total flow rate is recorded. The reader is referred to Chap. 13 for a more detailed discussion of plume entrainment.

Vent Flows Through Openings in Vertical Partitions

Classic models of fire in a room or building represent the structure with an opening, such as a door or window, to the ambient surroundings. Fire-induced flows through such openings have been well studied, and a widely accepted model exists to compute these flows based on the temperature distribution of the gases on either side of the opening. The theoretical basis of the computation is orifice flow utilizing Bernoulli's equation along a streamline, as illustrated in Fig. 29.2. The velocity at station two is given by

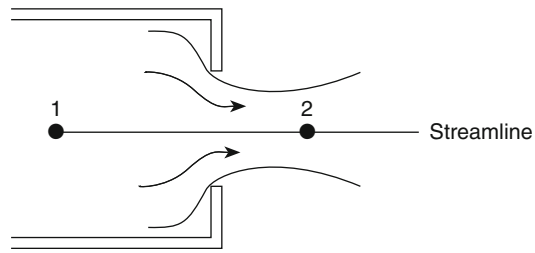

Fig. 29.2 Orifice flow

$$v_2 = \sqrt{\frac{2(p_1 - p_2)}{\rho_1}}. \tag{29.12}$$

where v_1 is assumed to be zero. The mass flow rate is computed by integration over the flow area, A, adjusted by a flow coefficient, C:

$$\dot{m} = C\int \rho_1 v_2 dA \tag{29.13}$$

Emmons suggests that a value of 0.68 for C has an accuracy of ±10 %, except at very low flow rates at the beginning of a fire (see Chap. 15). In general, C will depend on the Reynolds number. Figure 29.3 depicts examples of typical vent flows through an opening in a vertical partition. In both cases Equations 29.12 and 29.13 apply, but the pressure distribution must be described appropriately. For example, in the pure natural convection case shown in Fig. 29.3a, the pressure is determined by the static pressure with respect to the floor pressure, $p(0)$. Actually it is the floor pressure that applies in Equation 29.4 and in the perfect gas equation of state.

The assumption is that the flow velocities are small compared to the vent flow velocities, justifying the static pressure computation. Thus, the vertical pressure distribution on either side of the opening is computed as

$$p(z) = p(0) - \int_0^z \rho g\, dz \tag{29.14}$$

McCaffrey and Rockett [15] illustrate the accuracy of the hydrostatic assumption in Fig. 29.4. The sign of the pressure difference across the opening determines the flow direction. Emmons presents the general equations that enable this computation to be included in a zone model (see Chap. 15). It is by far the most accurate of the submodels, providing the basis for linking rooms together in a zone model, which allows smoke and fire growth computations for a large building.

The flow through an opening in a horizontal partition can be compared to that for the vertical partition, provided the pressure difference is large enough. If there is only a single vent from the fire compartment through a horizontal partition, such as a ceiling, the flow must be oscillatory or bidirectional. The latter case implies a zero pressure difference, with gravity solely determining the flow. A theory for this case has been developed by Epstein [16] and has been implemented by Cooper [17]. For orifice-like vents with zero pressure difference, the volumetric exchange flow rate, V, given by Epstein [16], is approximately

$$\dot{V} = 0.055\left[D^5 g(\rho_1 - \rho_2)\left(\frac{\rho_1 + \rho_2}{2}\right)\right]^{1/2} \tag{29.15}$$

where D is the diameter of the vent and ρ_1 and ρ_2 are the corresponding fluid densities on either side of the vent. For vents of significant depth, L, the coefficient in Equation 29.15 depends on L/D.

Convective Heat Transfer to Surfaces

The $\dot{Q}_{\text{net loss}}$ term in Equation 29.4 is composed of the convective and radiative heat loss to the

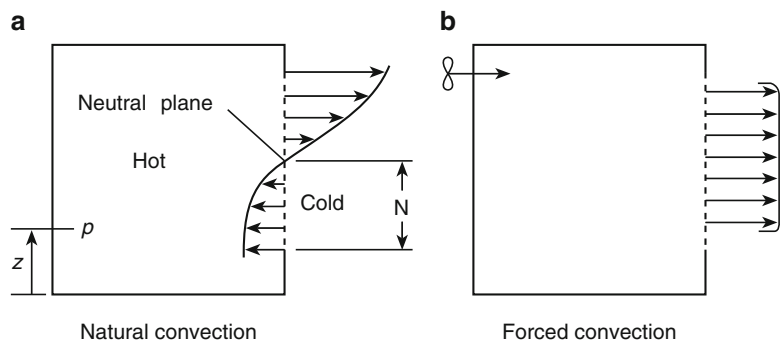

Fig. 29.3 Typical vent flows

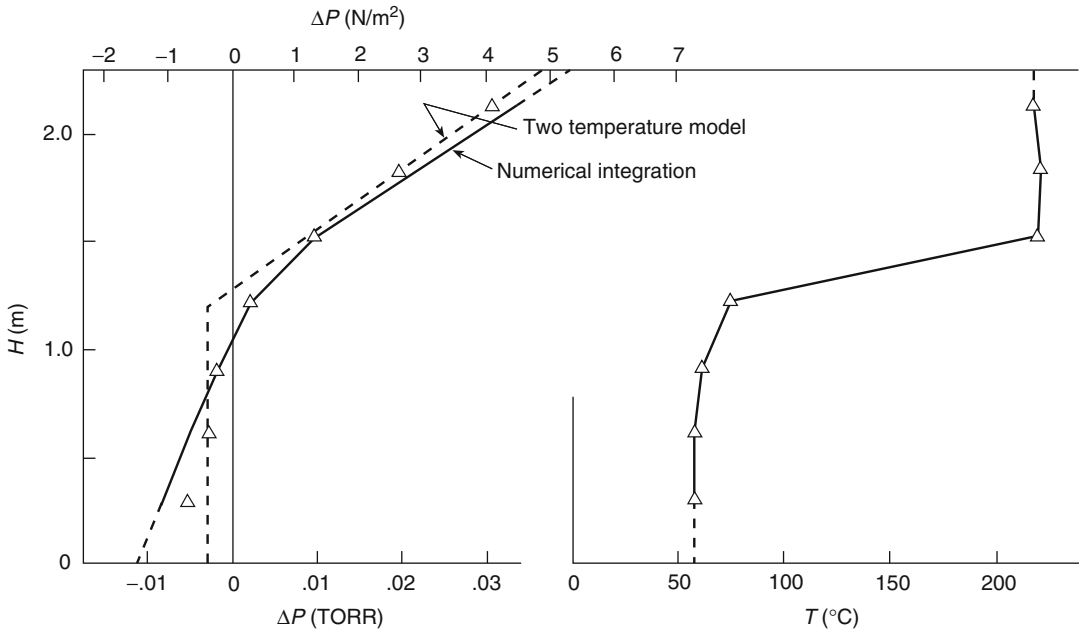

Fig. 29.4 Vertical pressure difference across a room vertical partition compared to a computation based on room fire temperature distribution and a two-temperature zone model approximation using the hydrostatic pressure assumption [15]

boundary surfaces of the layer control volumes. This involves both heat transfer from the gas layers at their bulk temperatures and the heat transfer from the flame. Consistent treatment of the flame and layer gas heat transfer must be carried out for the zone model. If the flame becomes large and fills the upper layer, one cannot count the flame and gas heat transfer without being redundant.

Convective heat transfer to a ceiling by a fire plume has been widely studied at modest scales, such that flame radiation may have been insignificant. Alpert [18] specifically examined only convective heating in contrast to studies by You and Faeth [19] and Kokkala [20] who included flame effects.

In general, convective effects will vary along the ceiling, walls, and floor, and depend on the nature and position of the fire. In some cases an *adiabatic wall temperature* has been appropriately introduced since the driving force for convective heat transfer locally is not the bulk gas layer temperature but rather the local boundary layer temperature, which is not explicitly computed. Convective heat transfer data for the walls and floor of a fire compartment or for rooms beyond the fire compartment have not been developed. Hence, most zone models use estimates from natural convection correlations.

Radiative Heat Transfer

The theory of radiative heat transfer is adequate to develop the needed components for the zone model. However, the theory is not sufficiently developed to predict flame radiation from first principles without very sophisticated modeling of the soot and temperature distributions. Hence, flame radiation is relegated to empirical practices. Radiation from a smoke layer is easier to deal with within the context of a uniform property gas layer for the zone model. One difficulty still is the availability of property data to determine the contribution of smoke particulates to the layer radiation properties. The discussion presented by Tien et al. can be used to begin a development of the radiative equations needed

by the zone model (see Chap. 4). Also, the presentation by Beyler gives empirical approaches to dealing with flame radiation (see Chap. 66). The paper by Forney [21] lays out the theory and equations describing radiation exchange between the gas layers and boundary surfaces.

Conduction Heat Transfer

The radiative and convective heat transfer from the gas must be balanced by conduction heat transfer through the boundary surfaces. This balancing requires a numerical solution to a partial differential equation in conjunction with the ordinary differential equations in time describing the conservation of energy and mass for the gas layers. Usually zone models have considered only one-dimensional conduction, which should be adequate for most applications. Most multiple-compartment models do not consider communication by conduction into the next compartment, treating the structural elements as thermally thick instead. In principle, there is no difficulty with developing an accurate algorithm for conduction through the boundary elements for any conditions. For more information, the reader is referred to the discussion by Rockett and Milke (see Chap. 2).

Mixing Between the Layers

The primary exchange of fluid between the lower and upper gas layers is due to the buoyant effect of the fire plume. Secondary but significant mixing processes can occur due to the other effects. These are shown in Fig. 29.5 and include three phenomena:

1. Exchange due to a cold flow injected into the hot layer
2. Exchange due to shear mixing associated with vent flows
3. Exchange due to wall flows

Phenomenon 1 is the inverse of the hot fire plume penetrating the upper layer. In both cases the fluid at the edge of the plume may not be buoyant enough to penetrate the respective layer. A comparable situation is a cold forced jet introduced vertically into the lower layer. Depending on the relative temperatures, it may not escape the lower layer and, therefore, may not penetrate into the upper layer. These are issues that can be resolved to some extent by research available in the literature on buoyant plumes and jets.

Phenomenon 2 requires the near vent mixing behavior to be characterized. Data suggest that the flow rate of the mixed stream can be significant relative to the vent flow rate, especially for small vents [22]. A correlation for the mixing

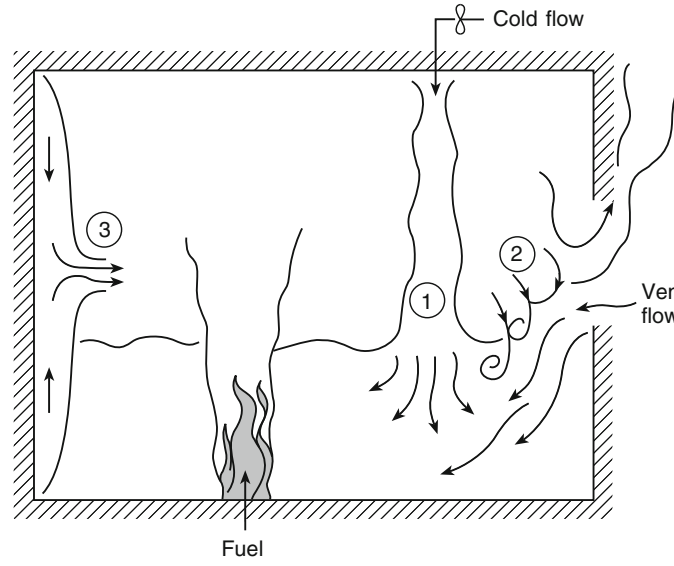

Fig. 29.5 Secondary flows—mixing phenomena. *1*. A cold plume descending from the upper layer into the lower layer. *2*. Shear mixing of an entering vent flow stream. *3*. Wall flows due to local buoyancy effects

rate has been developed from saltwater simulation experiments [23] based on the less than ideal assumption that the cold incoming flow through the opening would behave like a point source buoyant plume. More recently a mixing model has been proposed by Utiskul [24] where the incoming cold air behaves like a jet entering the doorway with a characteristic velocity and diffusing downward because of buoyancy. While the cold air descends, the surrounding hot gas is entrained with a velocity that is proportional to the incoming flow characteristic velocity. An equation for the ratio of mass entrained to the total incoming mass flow was given and single-vent compartment fire experiments were conducted to establish the correlation for the mixing at the quasi-steady state. The correlation exhibited a linear relationship up to an apparent asymptote for the mixing ratio of about 1.3.

Phenomenon 3 has been discussed by Jaluria [25]. He presents relationships that allow the estimation of the rate of transfer of cold fluid adjacent to the wall in the hot upper gas layer into the cold lower gas layer or vice versa.

All of these flows tend to blur the sharp distinction between the upper and lower gas layers, reducing their degree of stratification. Obviously, if sufficient mixing occurs, the layer may appear to become well-mixed or destratified. Destratification should occur naturally in the context of the zone model, and one should not have to switch to a well-mixed compartment model under these conditions.

Relationships for all of these secondary flows have not been developed with confidence nor with full acceptance. However they are important for improving the accuracy of a zone fire model, and additional research is still needed to further establish their validity.

Forced Flow Effects

The effect of forced airflow on fire conditions and smoke spread due to mechanical or natural wind forces has always been an issue in large building fires. Wind effects and the resultant pressure distribution around a tall building have become standard data elements for structural design but have not been utilized for fire safety design. The movement of smoke through a building due to the mechanical ventilation system has been simulated by network models that treat the compartment volume as uniform in properties, including the pressure losses due to vents and duct friction. A two layer zone model has not been linked to the mechanical ventilation system in a building. To create a link, one must include the full-pressure-flow characteristics of fans in both directions to allow for the possibility of the backflow of smoke against the direction of airflow in the ducts. An attempt at this linkage has been presented by Klote and Cooper [26], who hypothesize a fan characteristic relationship. Ultimately an experimental study will be needed to lay a foundation for this analysis.

Fire Growth Rate

In most all zone models, the fire source is considered an input quantity, based on some experimental or empirical data. This limits the simulation capability of a zone model, since fire growth and spread are not modeled. Also the effects of compartment feedback due to thermal and vitiation (oxygen depletion) effects are not taken into account. The versatility and utility of a zone model can only be improved by developing techniques for accommodating realistic fire growth characteristics for building contents and architectural elements. This process will also have an impact on the use and development of flammability tests for hazard analysis and product acceptability.

Embedded Submodels

The detailed physics that one can include in a zone model are only limited by current research and imagination. The zone model can be versatile in accommodating new phenomena, even if they appear inconsistent with the uniform property

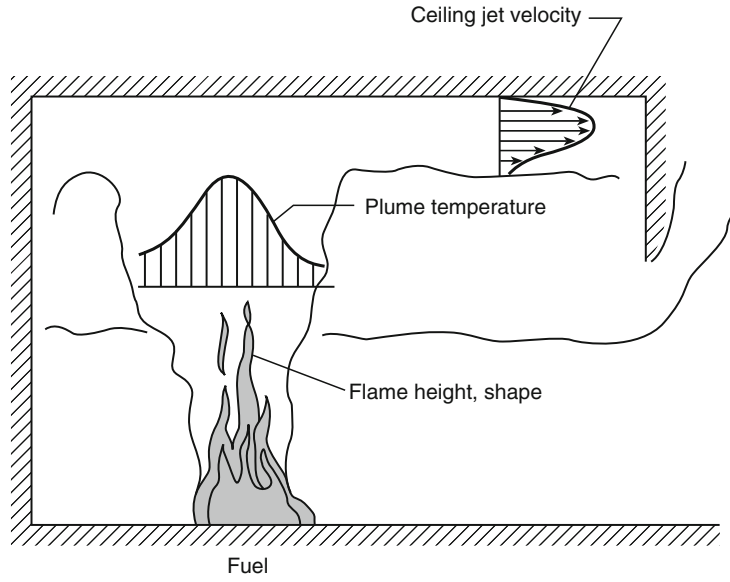

Fig. 29.6 Examples of embedded phenomena

layer assumption. By analogy to the relationship between inviscid flow and boundary layer flow in the analysis of aerodynamic bodies, the layer properties can be regarded as a first-order approximation for higher order analysis. Flame and boundary layer phenomena within the compartment can be computed by regarding the layer properties as infinite reservoirs. These phenomena can be computed after the primary layer properties are computed. Examples of embedded phenomena are shown in Fig. 29.6. Although the combustion region is assumed to be of negligible volume in the zone model formulation, the flame height can be computed along with the velocity and temperature distributions in an axisymmetric fire plume [27]. Other potential embedded phenomena are (1) the ceiling jet, (2) the computation of temperature distributions over the ceiling, (3) the deposition of soot and other products of combustion on surfaces, (4) the heating and degradation of structural elements, (5) balcony spill plumes, (6) flame spread and fire growth for surface linings, and (7) the response of detectors and/or sprinklers.

Unresolved Phenomena

Some significant phenomena are not addressed by the zone modeling approach for fire, such as vent flames, transient flow in corridors, shaft flows (see Fig. 29.7). These phenomena require more research and new strategies to enable them to be included into a zone model. Vent flames are significant for fire growth into the next compartment and usually follow flashover. Information about their rate of heat transfer and extent needs to be computed. Transient corridor flows are important in the analysis of smoke transport through long corridors. The current zone model methodology yields an instantaneous layer that would descend, but the actual process produces a transient ceiling jet. Flows in vertical shafts involve the interaction of plumes with walls, pressure-driven effects, and turbulent mixing.

Selected Reading and Comments

Zone models provide the integrating framework for the phenomena of fire and its fire protection engineering components. Many zone models have been constructed for fire predictions in compartments. They involve the basic conservation equations, submodels describing the particular phenomena included, and the mathematical algorithms for solutions. Some have developed user-friendly interfaces. Most provide documentation on the model and its use. The interested

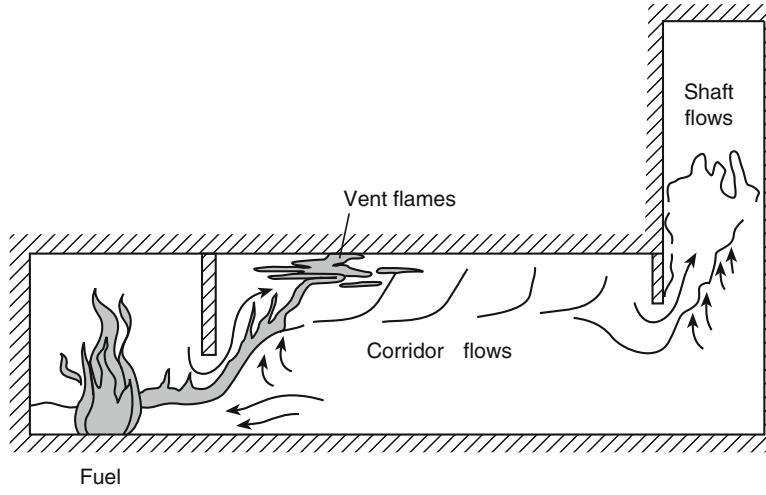

Fig. 29.7 Examples of significant phenomena absent from zone models

reader is referred to some published models for more detailed information [28–31]. Many zone-based computer models exist, similar both in substance and the ability to analyze fire effects in buildings. They can stimulate needed research. However, more effort appears to have gone into the computer code developments rather than the experimental research needed for improvement in the model.

Nomenclature

A	area compartment floor
C	flow coefficient
c_p	specific heat at constant pressure
c_v	specific heat at constant volume
g	acceleration due to gravity
H	compartment height
J	number of flow streams in control volume
m	mass
p	pressure
Q	heat transfer
r	stoichiometric fuel-to-oxygen mass ratio
R	ideal gas constant
t	time
T	temperature
v	fluid velocity
V	volume
w	control volume velocity
Y	mass fraction
z_l	height of control volume or zone
ΔH	heat of combustion
γ_i	yield of species i
ρ	density
Φ	equivalence ratio
$\dot{\omega}_F$	consumption rate of fuel
$\dot{\omega}_i$	production rate of species

Subscripts

e	entrained
f	flame
F	fuel
i	species
j	flow stream
o	oxygen
s	supplied

Superscripts

$(\dot{})$	per unit time

Estimating Temperatures in Compartment Fires

30

William D. Walton, Philip H. Thomas, and Yoshifumi Ohmiya

Introduction

The ability to predict temperatures developed in compartment fires is of great significance to the fire protection professional for protection of human life and property. There are many uses for a knowledge of compartment fire temperatures, including the prediction of (1) the onset of hazardous conditions, (2) property and structural damage, (3) changes in burning rate, pyrolysis rate and heat (energy) release rate, (4) ignition of objects,(5) the onset of flashover and so on.

The fundamental principles underlying compartment fires are presented in Chap. 29. This chapter gives a number of simplified solution techniques.

Fire Stages

In this chapter, compartment fires are defined as fires in enclosed spaces, which are commonly thought of as rooms in buildings, but may include other spaces such as those found in transportation vehicles such as ships, planes, trains, and the like.

Compartment fires are often discussed in terms of growth stages [1]. Figure 30.1 shows an idealized variation of temperature with time along with the growth stages. Fire safety design in terms of evacuation and fire resistance was examined by taking into account fire stage. The stage of ignition and growth are very significant to estimate the time for fire detectors and suppression systems to activate. The stage of fully-developed fire is important for the fire resistance of building loadbearing elements and separating elements.

1. Ignition
2. Growth
3. Flashover
4. Fully-developed fire
5. Decay

Although many fires will not follow this idealization, it provides a useful framework for the discussion of compartment fires. All fires include an ignition stage but, beyond that, may fail to grow, or they may be affected by manual or automatic suppression activities before going through all of the stages listed above.

Growth Stage Definitions

Ignition Stage The period during which the fire begins in a compartment.

Growth Stage Following ignition, the fire initially grows primarily as a function of the fuel itself, with little or no influence from the compartment. The fire can be described in terms of its rate of energy and combustion product generation. A discussion of energy

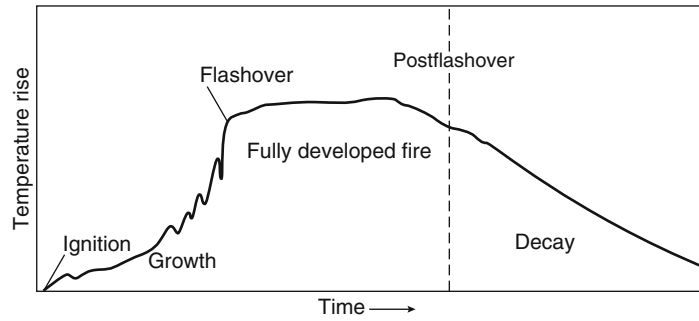

Fig. 30.1 General description of room fire in absence of fire control

generation or burning rate can be found in Chap. 26. If sufficient fuel and oxygen are available, the fire will continue to grow, causing the temperature in the compartment to rise. Fires with sufficient oxygen for combustion are said to be fuel controlled or well-ventilated.

Flashover Flashover is generally defined as the transition from a growing fire to a fully developed fire in which all combustible items in the compartment are involved in fire. During this transition there are rapid changes in the compartment environment. Flashover is not a precise term, and several variations in definition can be found in the literature. However the onset of flashover should be estimated for considering fire safety. Most have criteria based on the temperature at which the radiation from the hot gases in the compartment will ignite all of the combustible contents. Gas temperatures of 300–650 °C have been associated with the onset of flashover, although temperatures of 500–600 °C are more widely used [2]. The ignition of unburnt fuel in the hot fire gases, the appearance of flames from openings in a compartment, or the ignition of all of the combustible contents may actually be different phenomena all related to flashover.

Fully Developed Fire During this stage, the heat release rate of the fire is the greatest. The fire behavior in this stage is influenced by conditions of enclosure such as the size and construction materials, size and form of openings, type amount and distribution of fuel in the enclosure. Frequently during this stage more fuel is pyrolized than can be burned with the oxygen available in the compartment. In this case, the fire is said to be ventilation controlled. If there are openings in the compartment, the unburned fuel will leave the compartment in the gas flow and may burn outside of the compartment. It will cause fire spread to upper floors and neighboring buildings. During the fully developed stage, the environment within the compartment has a significant effect on the pyrolysis rate of the burning objects.

Decay Stage Decay occurs as the fuel becomes consumed, and the heat release rate and temperature within a compartment decline. The fire may change from ventilation to fuel controlled during this period.

Compartment Fire Phenomena

Compartment Fire Model

In order to calculate or predict the temperatures and other properties generated in a compartment fire, a description or model of the fire phenomena must be created. This model will be described in terms of physical equations that can be solved to predict the temperature in the compartment. Such a model is, therefore, an idealization of the compartment fire phenomena. Consider a fire that starts at some point below the ceiling. It releases energy and products of combustion at a rate that may change with time. The hot products of combustion form a plume that, due to buoyancy, rises toward the ceiling above heat source. As the

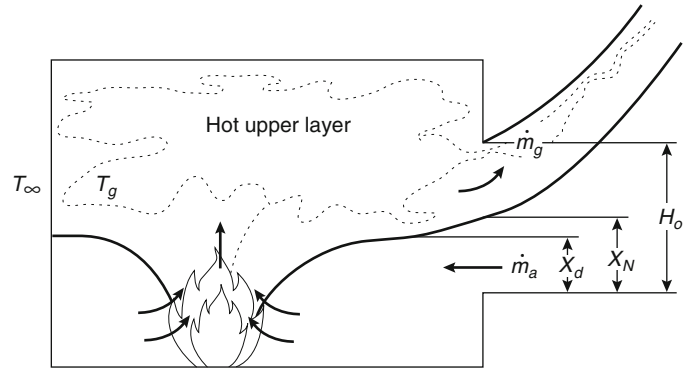

Fig. 30.2 Two-layer model with no exchange between layers except the plume

plume rises, it draws in cool air from within the compartment, decreasing the plume's temperature and increasing its volume flow rate. When the plume reaches the ceiling, it spreads out under ceiling. When the extension of hot current under ceiling reaches the walls, the flow turns downward and forms a hot gas layer that descends with time as the plume's gases continue to flow into it. There is a relatively sharp interface between the hot upper layer and the air in the lower part of the compartment. The only assumed interchange between the air in the lower part of the room and the hot upper layer comprised of products of combustion is through the plume. As the hot layer descends and reaches openings in the compartment walls (e.g., doors and windows), hot gas will flow out the openings and outside air will flow into the openings. This description of compartment fire phenomena is referred to as a two-layer or zone model. The basic compartment fire phenomena are shown schematically in Fig. 30.2.

The two-layer concept assumes that the compositions of the layers are uniform, that is, that the temperature and other properties are the same throughout each layer. Although the temperature of the lower layer will rise during the course of the fire, the temperature of the upper layer will remain greater and is the most important factor in compartment fires. The assumptions may be less valid for very large spaces or for long, narrow spaces such as corridors and shafts. To describe the vertical distribution, multi-layer models were being developed [3].

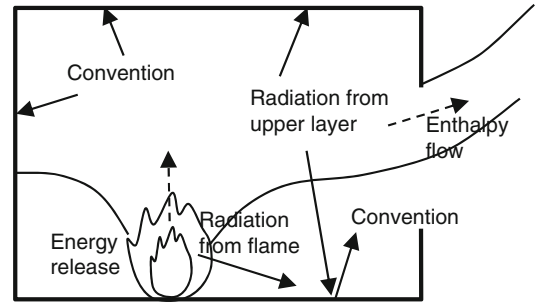

Fig. 30.3 Energy balance of compartment fire during Two-layer condition

Calculation of Compartment Fire Temperatures

The basic principle used to calculate the temperature in a compartment fire is the conservation of energy. In order to estimate the temperature in enclosure, energy balance can be assumed as shown in Fig. 30.3.

As applied to the hot upper layer, the conservation of energy can be simply stated as follows: the energy added to the hot upper layer by the fire equals the energy lost from the hot layer plus the time rate of change of energy within the hot upper layer. From the time rate of change of energy within the hot layer, the temperature of the layer can be computed. Conservation of energy can also be applied to the lower layer. Since the volume of the upper layer changes with time, and mass flows in and out of the upper layer, conservation of mass must be used along with the conservation of energy. Because the

energy generated by the fire and the temperatures in the compartment vary as a function of time, the application of conservation of energy will result in a series of differential equations. For the purposes of examining the components of the conservation of energy, the steady-state expressions for the conservation of energy in the hot upper layer will be used.

The transport of energy in a compartment fire is a very complex process. In order to formulate expressions for the conservation of energy in a practical way, a number of assumptions must be made. It is possible to formulate the equations in a number of ways, based on the level of detail desired. The expressions and assumptions used in this chapter are based on those commonly found in the fire research literature and represent a somewhat simplified description of the phenomena. Additional details may be found in the references cited.

The steady-state conservation of energy for the hot upper gas layer in a compartment can be simply stated as follows: the energy generated by the fire and added to the hot layer equals the energy lost from the hot layer through radiation and convection plus the energy convected out of the compartment openings.

Energy Generated by the Fire

The energy generated by the fire is the primary influence on the temperature in a compartment fire, and much research has been conducted in predicting the energy release rate of many fuels under a variety of conditions. This discussion will focus on flaming combustion, as it is most important in generating a significant temperature rise in a compartment. A discussion of non-flaming combustion is found in Chap. 19. As a fuel is heated it releases pyrolysis products. The amount of pyrolysis products depends on fuel properties, incident heat flux to surface of fuel, oxygen mass fraction in the enclosure and so on. The fortmula to estimate the mass burning rate of the fuel can be given as follows,

$$\dot{m}_f = qA/L \tag{30.1}$$

where

$\dot{m}_f$ = Mass burning rate of the fuel (kg/s)
q = Heat flux to the fuel surface(kW/m^2)
A = Suraface area of the fuel(m^2)
L = Heat of gasification (kJ/kg)

At initial stage in compartment fire, the heat flux to surface of the fuel is due to the flame generated above the fuel. In case that compartment fire reached flashover, it is due to the gas around fuel. If there are oxygen in the enclosure, pyrolysis products react with oxygen, generating heat and producing flames. The rate of energy release is equal to the mass loss rate of the fuel times the heat of combustion of the fuel:

$$\dot{Q} = \dot{m}_f \Delta h_c \tag{30.2}$$

where

$\dot{Q}$ = Energy release rate of the fire (kW)
$\dot{m}_f$ = Mass burning rate of the fuel (kg/s)
Δh_c = Effective heat of combustion of the fuel (kJ/kg)

The effective heat of combustion is the heat of combustion expected in a fire where incomplete combustion takes place. This amount is less than the theoretical heat of combustion as measured in the oxygen bomb calorimeter [4].

The effective heat of combustion is often described as a fraction of the theoretical heat of combustion. The effect of fluctuations is largely neglected.

In fuel-controlled fires, there is sufficient air to react with all the fuel within the compartment. In ventilation-controlled fires, there is insufficient air within the compartment, and some of the pyrolysis products will leave the compartment, possibly to react outside the compartment. For calculating the temperatures produced in compartment fires, the primary interest is the energy released within the compartment.

The pyrolysis rate of the fuel depends on the fuel type, its geometry, and the fire-induced environment. The energy generated in the compartment by the burning pyrolysis products then depends on the conditions (temperature, oxygen concentration, etc.) within the compartment. The processes involved are complex, and some are

not well understood, but for two fire types some simplifying assumptions can lead to useful methods for approximating the energy released by the fire.

Fuel-controlled fires are defined as those in which the pyrolysis rate and the energy release rate are affected only by the burning of the fuel itself and not by the room environment, analogous to a fire burning outdoors on a calm day. Babrauskas has provided data on free-burning fires in Chap. 26. This data is most useful for estimating burning rates of primarily horizontal fuels in preflashover fires, where the primary heating of the fuel is from the flames of the burning item itself. Vertical fuels, such as wall linings and fuels located in the upper hot gas layer, will likely be influenced by the preflashover room environment.

Ventilation-controlled fires are defined as those in which the energy release rate in the room is limited by the amount of available oxygen. The mass flow rate of air or oxygen into the room through a door or window can be calculated from the expressions described below and in Chap. 23. For most fuels [5], the heat released per mass of air consumed is a constant approximately equal to 3000 KJ/kg. Therefore, the rate of energy release of the fire can be approximated from the air inflow rate.

The amount of energy released by the fire that enters the hot upper layer is a function of the fire, layer conditions, and geometry. For most fires, approximately 35 % of the energy released by the fire leaves the fire plume as radiation [6]. (A discussion of flame radiation can be found in Chap. 23.) In a compartment fire, a fraction of the radiated energy reaches the upper layer. The majority of the remaining energy released by the fire is convected into the upper layer by the plume. As the plume rises, it entrains air from the lower layer, thus reducing its temperature and increasing the mass flow rate. For a first approximation, it can be assumed that all of the energy generated by the fire is transported to the upper layer. For a complete discussion of fire plumes see Chap. 13.

Conservation of Mass

The mass flow into the compartment and the flow out are related by

$$\dot{m}_g = \dot{m}_a + \dot{m}_f \tag{30.3}$$

where $\dot{m}_f$ is the mass burning rate of the fuel (kg/s).

The mass flow rate of hot gas out of a window or door is given by Rockett as [7]:

$$\dot{m}_g = \frac{2}{3} C_d W_o \rho_\infty \left[2g \frac{T_\infty}{T_g} \left(1 - \frac{T_\infty}{T_g} \right) \right]^{1/2} (H_o - X_N)^{3/2} \tag{30.4}$$

where

$\dot{m}_g$ = Mass flow rate of hot gas out an opening (kg/s)
C_d = Orifice constriction coefficient (typically ≈ 0.7)
W_o = Width of opening (m)
H_o = Height of opening (m)
ρ_∞ = Ambient air density (kg/m^3)
g = Acceleration due to gravity, 9.8 m/s^2
X_N = Height of neutral plane (m)
T_g = Temperature of the hot upper gas layer (K)
T_∞ = Ambient temperature (K)

The mass flow rate of air into a door or window is given by

$$\dot{m}_g = \frac{2}{3} C_d W_o \rho_\infty \left[2g \left(1 - \frac{T_\infty}{T_g} \right) \right]^{1/2} (X_N - X_d)^{1/2} \times (X_N + X_d/2) \tag{30.5}$$

where

X_d = Height of the interface (m).

The expressions for mass flow in and mass flow out cannot be solved directly for T_g since the height to the neutral plane and interface are unknown. The complete solution of these equations requires expressions for plume entrainment and additional energy equations and is normally carried out only in computer fire models. If the mass burning rate of the fuel is small compared with the mass flow rate of air into the compartment, the mass flow out of the opening may be approximated as equal to the mass inflow

rate. Flows out of vents in the ceiling are discussed in Chap. 66.

For preflashover fires in compartments with typical doors or windows, the neutral plane and interface can be approximated at the midlevel of the opening. This approximation can only be made after the initial smoke filling of the compartment is complete, and flow in and out of the opening is established.

For fires nearing flashover and postflashover fires, the interface between the upper and lower layers is located near the floor, and the flow reaches a maximum for a given upper gas temperature. Rockett [7] has shown the temperature dependence on the flow becomes small above 150 °C and the flow into the compartment can be approximated as a constant multiplied by $A_o\sqrt{H_o}$.

Rockett calculated values for this constant of 0.40–0.61 kg/s · $m^{5/2}$, depending on the discharge coefficient of the opening. Thomas and Heselden estimate the value of this constant at 0.5 kg/s · $m^{5/2}$, which is the value most commonly found in the literature [8]. The resulting approximation is then

$$\dot{m}_a = 0.5A_o\sqrt{H_o} \tag{30.6}$$

where

A_o = Area of opening (m^2)

H_o = Height of opening (m)

The term $A_o\sqrt{H_o}$ is commonly known as the ventilation factor. The first use of this type of opening flow analysis for evaluating postflashover fire test data is attributed to Kawagoe [9]. From early work analyzing such data, the empirical observation was made that wood fires in rooms with small windows appeared to burn at an approximate stoichiometric rate. Although flames emerging from the windows implied that some fuel was burning outside, calculations often suggested that enough air was entering the fire for stoichiometric burning. Empirical observations on wood fires [9] led to

$$\dot{m}_f = 0.09A_o\sqrt{H_o} \tag{30.7}$$

There is now a body of data [10] that modifies this simple proportionality between $\dot{m}_f$ and $A_o\sqrt{H_o}$.

The Conseil International du Bâtiment (CIB) experiments upon which Law [11] has based her method shows a dependence on A_T. It seems possible that the wide use of Equation 30.7 is a result of a concentration of experimental fires in rooms of a limited range of

$$\frac{A_T}{A_o\sqrt{H_o}}$$

where

A_T = Total area of the compartment enclosing surfaces (m^2)

Traditionally, energy balances were often stated in terms of the energy produced by the burning fuel and, thereby, led to an effective heat of combustion of the fuel. However, this practice in principle leads to the same result—the energy produced is related to the air flow for ventilation-controlled fires. Kawagoe [9] and Magnusson and Thelandersson [12] used 10.75 MJ/kg for the effective heat of combustion of wood in the flaming phase for fully developed compartment fires. With 16.4 MJ/kg for the heat of combustion of wood volatiles, this setup corresponds to a combustion efficiency of 10.75/16.4, which is virtually identical to the 0.65 used in several computer models.

By far most data are based on experiments in which the fuel was cellulosic, and much of the experimental data are based on wood in the form of cribs. For the post-flashover burning of a different fuel with a different chemistry, the burning rate expressions may still be used, as long as the fuel is a hydrocarbon producing approximately 3000 kJ for each kg of air consumed in the combustion process. Because different fuels react differently to the thermal environment and will pyrolyze at different rates according to the energy requirements to produce volatiles, one can only estimate temperatures by evaluating the differences or obtain maximum temperatures by using stoichiometry. Fuels more volatile than wood will probably produce lower temperatures inside a compartment, even if the excess fuel produces a greater hazard outside the compartment. The assumptions that the energy is related to the air flow and that the fuel is in stoichiometric proportion will give an upper estimate of

temperatures for ventilation-controlled fires. Since Equation 30.7 is close to stoichiometric, it could, coupled with the effective heat of combustion of wood, give results close to an upper temperature limit for other fuels.

Conservation of Energy

The heat generated by burning materials within a compartment is absorbed by the enclosing surfaces of the compartment and any other structural surfaces, by the surfaces of the fuel, and by the incoming air and any excess fuel. Heat is lost to the exterior in the flames and hot gases that exit from the openings in the compartment enclosing surfaces and by radiation through the openings. Table 30.1 gives an example of an experimental heat balance measured in a small compartment, for which unglazed windows provided ventilation from the start of the fire.

Table 30.1 illustrates the significant amount of heat loss in the effluent gases and shows that, with decreasing window area, a larger proportion of the heat released will be absorbed by the enclosing surfaces. The total heat released, assuming a complete burnout, is directly proportional to the amount of the fire load, but the rate of heat release may also be controlled by the ventilation. In this example, with the lower fire load, both window areas give sufficient ventilation for the fuel to burn at its maximum (free-burning) rate but, with the doubled fire load, the burning rate is not doubled, because the window area restricts the ventilation rate.

Methods for Predicting Preflashover Compartment Fire Temperatures

The solution of a relatively complete set of equations for the conservation of energy requires the solution of a large number of equations that vary with time. Although individual energy transport equations may be solved, in general there is not an explicit solution for a set of these equations. As a result, one of two approaches can be taken. The first is an approximate solution accomplished by hand using a limiting set of assumptions. The second is a more complete solution utilizing a computer program. In either case, a number of methods have been developed. The methods presented are those with the widest apparent acceptance in the fire protection community, each with different assumptions and limitations that should be understood before employing the method. The methods presented in this chapter predict average temperatures and are not applicable to cases where prediction of local temperatures are desired. For example, these methods should not be used to predict detector or sprinkler actuation or the temperatures of materials as a result of direct flame impingement.

Method of McCaffrey, Quintiere, and Harkleroad

McCaffrey, Quintiere, and Harkleroad have used a simple conservation of energy expression and a correlation with data to develop an

Table 30.1 Heat balance measured in experimental fires in a compartment of 29 m^2 floor area with a fire load of wood cribs

			Heat loss from hot gases (%)			
Fire load (kg)	Window area (m^2)	Heat release (kcal/s)	Effluent gas	Structural surfaces	Feedback to fuel	Window radiation
877	11.2	1900	65	15	11	9
	5.6	1900	52	26	11	11
1744	11.2	3200	61	15	11	13
	5.6	2300	53	26	12	9
	2.6	1600	47	30	16	7

approximation of the upper layer temperature in a compartment [13]. Applying the conservation of energy to the upper layer yields

$$\dot{Q} = \dot{m}_g c_p \left(T_g - T_\infty\right) + q_{\text{loss}} \tag{30.8}$$

where
$\dot{Q}$ = Energy (heat) release rate of the fire (kW)
$\dot{m}_g$ = Gas flow rate out the opening (kg/s)
c_p = Specific heat of gas (kJ/kg · K)
T_g = Temperature of the upper gas layer (K)
T_∞ = Ambient temperature (K)
q_{loss} = Net radiative and convective heat transfer from the upper gas layer (kW)

The left-hand side of Equation 30.8 is the energy generated by the fire. On the right-hand side, the first term is the heat transported from the upper layer in the gas flow out an opening. The second term is the net rate of radiative and convective heat transfer from the upper layer, which is approximately equal to rate of heat conduction into the compartment surfaces. The rate of heat transfer to the surfaces is approximated by

$$q_{\text{loss}} = h_k A_T \left(T_g - T_\infty\right) \tag{30.9}$$

where
h_k = Effective heat transfer coefficient (kW/m^{2}K)
A_T = Total area of the compartment enclosing surfaces (m^2)

Substituting Equation 30.9 into Equation 30.8 yields the non-dimensional temperature rise in terms of two dimensionless groups:

$$\frac{\Delta T_g}{T_\infty} = \frac{\dot{Q}/\left(c_p T_\infty \dot{m}_g\right)}{1 + h_k A_T/\left(c_p \dot{m}_g\right)} \tag{30.10}$$

where ΔT_g is the upper gas temperature rise above ambient $(T_g - T_\infty)$(K).

The mass flow rate of hot gas out of a window or door can be rewritten from Equation 30.4:

$$\dot{m}_g = \frac{2}{3} C_d W_o H_o^{3/2} \rho_\infty \left[2g \frac{T_\infty}{T_g}\left(1 - \frac{T_\infty}{T_g}\right)\right]^{1/2} \times \left(1 - \frac{X_N}{H_o}\right)^{3/2} \tag{30.11}$$

where
C_d = Orifice constriction coefficient
W_o = Width of opening (m)
H_o = Height of opening (m)
ρ_∞ = Ambient air density (kg/m^3)
g = Acceleration due to gravity, 9.8 m/s^2
X_N = Height of neutral plane (m)

Since X_N primarily depends on T_g, $\dot{Q}$, and geometric factors (H_o and W_o), $\dot{m}_g$ may be replaced by $\sqrt{g\rho_\infty} A_o \sqrt{H_o}$ in the two dimensionless variables in Equation 30.11, without any loss in generality. The effects of T_g and $\dot{Q}$ are incorporated into the correlation via other terms. Based on an analysis of test data, Equation 30.10 was written as a power-law relationship:

$$\Delta T_g = 480 \left(\frac{\dot{Q}}{\sqrt{g} c_p \rho_\infty T_\infty A_o \sqrt{H_o}}\right)^{2/3} \times \left(\frac{h_k A_T}{\sqrt{g} c_p \rho_\infty A_o \sqrt{H_o}}\right)^{-1/3} \tag{30.12}$$

where
A_o = Area of opening (m^2)
H_o = Height of opening (m)

The numbers 480, 2/3, and −1/3 were determined by correlating the expression with the data from over 100 experimental fires. These data included both steady-state and transient fires in cellulosic and synthetic polymeric materials and gaseous hydrocarbon fuels. Compartment height ranged from 0.3 to 2.7 m and floor areas from 0.14 to 12.0 m^2. The compartments contained a variety of window and door sizes. The term raised to the 2/3 power in Equation 30.12 represents the ratio of the energy released to the energy convected, and the term raised to the −1/3 power represents the energy lost divided by the energy convected.

Substituting the values for ambient conditions of
g = 9.8 m/s^2
c_p = 1.05 kJ/kg · K
ρ_∞ = 1.2 kg/m^3
T_∞ = 295 K
into Equation 30.12 yields [14, 15]

$$\Delta T_g = 6.85\left(\frac{\dot{Q}^2}{A_o\sqrt{H_o}h_k A_T}\right)^{1/3} \qquad (30.13)$$

The heat transfer coefficient can be determined using a steady-state approximation when the time of exposure, t, is greater than the thermal penetration time, t_p, by

$$h_k = k/\delta \quad \text{for} \quad t > t_p \qquad (30.14)$$

The thermal penetration time is defined as

$$t_p = \left(\frac{\rho c}{k}\right)\left(\frac{\delta}{2}\right)^2 \qquad (30.15)$$

where

ρ = Density of the compartment surface (kg/m^3)
c = Specific heat of the compartment surface material (kJ/kg·K)
k = Thermal conductivity of compartment surface (kW/m · K)
δ = Thickness of compartment surface (m)
t = Exposure time (s)
t_p = Thermal penetration time (s)

When the time of exposure is less than the penetration time, an approximation based on conduction in a semi-infinite solid is

$$h_k = \left(\frac{k\rho c}{t}\right)^{1/2} \text{ for } \quad t \le t_p \qquad (30.16)$$

If there are several wall and/or ceiling materials in the compartment, an area-weighted average for h_k should be used.

The limitations as stated by McCaffrey et al. on the use of this method for estimating temperatures are as follows:

1. The correlation holds for compartment upper-layer gas temperatures up to approximately 600 °C.
2. It applies to steady-state as well as time-dependent fires, provided the primary transient response is the wall conduction phenomenon.
3. It is not applicable to rapidly developing fires in large enclosures in which significant fire growth has occurred before the combustion products have exited the compartment.
4. The energy release rate of the fire must be determined from data or other correlations.
5. The characteristic fire growth time and thermal penetration time of the room-lining materials must be determined in order to evaluate the effective heat transfer coefficient.
6. The correlation is based on data from a limited number of experiments and does not contain extensive data on ventilation-controlled fires nor data on combustible walls or ceilings. Most of the fuel in the test fires was near the center of the room.

Example of McCaffrey et al. Method Calculate the upper-layer temperature of a room 3 × 3 m in floor area and 2.4 m high with a door opening 1.8 m high and 0.6 m wide. The fire source is a steady 750 kW fire. The wall-lining material is 0.016 m (5/8 in.) gypsum plaster on metal lath. Perform the calculation at times of 10, 60, and 600 s after ignition. Using Equation 30.12,

$$\Delta T_g = 480\left(\frac{\dot{Q}}{\sqrt{g}c_p\rho_\infty T_\infty A_o\sqrt{H_o}}\right)^{2/3} \times \left(\frac{h_k A_T}{\sqrt{g}c_p\rho_\infty A_o\sqrt{H_o}}\right)^{-1/3}$$

where

$c_p = 1$ kJ/kg·K
$T_\infty = 27$ °C (300 K)
$\rho_\infty = 1.18$ kg/m^3
$A_o = 1.8$ m · 0.6 m = 1.08 m^2
$g = 9.8$ m/s^2
$H_o = 1.8$ m
$\dot{Q} = 750$ kW

$$\begin{aligned} A_T &= A_{walls} + A_{floor} + A_{ceiling} - A_{openings} \\ &= 4 \times (3 \times 2.4) + (3 \times 3) + (3 \times 3) - 1.08 \\ &= 28.8\,m^2 + 9m^2 + 9m^2 - 1.08m^2 \\ &= 45.72m^2 \end{aligned}$$

The wall heat loss coefficient, h_k, is a function of time.

(a) Calculate the thermal penetration time, t_p.

$$t_p = \left(\frac{\rho c}{k}\right)\left(\frac{\delta}{2}\right)^2$$

where
ρ = Wall material density (1440 kg/m^3)
$k = 0.48 \times 10^{-3}$ kW/m·K
$c = 0.84$ kJ/kg·K
$\delta = 0.016$ m
$t_p = 161.3$ s

(b) Calculate h_k at 10, 60, and 600 s.
For $t<t_p$ (10, 60 s),

$$h_k = \left(\frac{k\rho c}{t}\right)^{1/2} \quad k\rho c = 0.581$$

1. At $t = 10$ s,

$$h_k = \left(\frac{0.581}{60}\right)^{1/2} = 0.24 \text{ kW/m}^2\text{·K}$$

2. At $t = 60$ s,

$$h_k = \left(\frac{0.581}{60}\right)^{1/2} = 0.098 \text{ kW/m}^2\text{·K}$$

3. For $t > t_p$ (600 s) at $t = 600$ s,

$$h_k = \frac{k}{\delta} = \frac{0.48 \times 10^{-3}}{0.016} = 0.03 \text{ kW/m}^2\text{·K}$$

(c) Calculate the compartment temperature at the three times using Equation 30.12.
1. At $t = 10$ s,

$$\Delta T_g = 480\left[\frac{750}{(\sqrt{9.8})\,(1)\,(1.18)\,(300)\,(1.08)\,(\sqrt{1.8})}\right]^{2/3} \cdot \left[\frac{(0.24)\;(45.72)}{(\sqrt{9.8})\;(1)\;(1.18)\;(1.08)\;(\sqrt{1.8})}\right]^{-1/3}$$
$$= 480(0.47)^{2/3}(2.05)^{-1/3}$$
$$= 227 \text{ K}$$

2. At $t = 60$ s,

$$\Delta T_g = 480(0.47)^{2/3}(0.837)^{-1/3} = 307 \text{ K}$$

3. At $t = 600$ s,

$$\Delta T_g = 480(0.47)^{2/3}(0.26)^{-1/3} = 453 \text{ K}$$

Method of Foote, Pagni, and Alvares

The Foote, Pagni, and Alvares method follows the basic correlations of McCaffrey, Quintiere, and Harkleroad and adds data for forced-ventilation fires. Using Equation 30.10 and not introducing an expression for doorway flow results in the expression [16]

$$\frac{\Delta T_g}{T_\infty} = 0.63\left(\frac{\dot{Q}}{\dot{m}_g c_p T_\infty}\right)^{0.72}\left(\frac{h_k A_T}{\dot{m}_g c_p}\right)^{-0.36} \tag{30.17}$$

where
ΔT_g = Upper gas temperature rise above ambient (K)
T_∞ = Ambient air temperature (K)
$\dot{Q}$ = Energy (heat) release rate of the fire (kW)
$\dot{m}_g$ = Compartment mass ventilation rate (kg/s)
c_p = Specific heat of gas (kJ/kg·K)
h_k = Effective heat transfer coefficient (kW/m^{2}K)
A_T = Total area of the compartment-enclosing surfaces (m^2)

The coefficient and exponents are based on data from well-ventilated tests in a compartment with a 6 × 4 m floor area and a height of 4.5 m with ventilation rates of 110–325 g/s. The compartment exhaust was through a 0.65 × 0.65 m duct located 3.6 m above the floor. Four air inlet openings were 0.5 × 0.12 m high, with centerlines 0.1 m above the floor. A methane gas burner fire in the center of the floor with heat release rates of 150–490 kW resulted in upper gas temperatures of approximately 100–300 °C.

Foote et al. have shown that the correlation for forced-ventilation fires agrees well with the data presented by McCaffrey et al. for free ventilation fires with

$$\dot{m} \approx 0.1\left(\rho_\infty \sqrt{g} A_o \sqrt{H_o}\right)$$

Example of Foote et al. Method Estimate the temperature in a 5 × 5 m floor area and 4-m-high compartment having 0.025-m (1-in.) thick concrete walls. The forced-ventilation rate is

2.4 m^3/s of air (5000 cfm). Perform the calculation for $t > t_p$. The fire size is given as 1000 kW; ambient air conditions at 300 K. Using Equation 30.17,

$$\frac{\Delta T_g}{T_\infty} = 0.63\left(\frac{\dot{Q}}{\dot{m}_g c_p T_\infty}\right)^{0.72}\left(\frac{h_k A_T}{\dot{m}_g c_p}\right)^{-0.36}$$

where

$\dot{Q} = 1000$ kW
$T_\infty = 300$ K
$c_p = 1.0$ kJ/kg·K
$A_T = 4 \times (5 \times 4) + 2\,(5 \times 5) = 105$ m^2
$\dot{m}_g = (2.4\ m^3/s)\ (1.18\ kg/m^3) = 2.8$ kg/s

Calculate h_k for $t > t_p$. For 0.025-m-thick concrete,

$\delta = 0.025$ m
$\rho = 2000$ kg/m^3
$k = 1.4 \times 10^{-3}$ kW/m·K
$c_p = 0.88$ kJ/kg·K

$$t_p = \left(\frac{\rho c}{k}\right)\left(\frac{\delta}{2}\right)^2 = \left[\frac{(2,000)\cdot(0.88)}{1.4\times 10^{-3}}\right]\left(\frac{0.025}{2}\right)^2 = 196\text{s} \quad \text{for} \quad t > t_p$$

$$h_k = \frac{k}{\delta} = \frac{1.4\times 10^{-3}}{0.025} = 0.056\ \text{kW}/m^2\cdot\text{K}$$

$$\frac{\Delta T_g}{T_\infty} = (0.63)\left[\frac{1,000}{(2.8)\,(1)\,(300)}\right]^{0.72} \times \left[\frac{(0.056)\,(105)}{(2.8)\,(1)}\right]^{-0.36}$$

$$\Delta T_g = (0.14)\,(T_\infty) = 164\ \text{K}$$
$$T_g = 164 + 300\ \text{K} = 464\ \text{K}$$

Method of Beyler and Deal

Beyler and Deal compared a number of methods for naturally ventilated compartments to test data and recommend the method of McCaffrey, Quintiere, and Harkleroad for naturally ventilated compartments. Beyler offers an improved correlation for compartments where the forced-ventilation flow rate is known [17, 18]. This method begins by applying the conservation of energy in the upper layer of a compartment. Combining Equations 30.8 and 30.9 yields

$$\dot{Q} = \dot{m}_g c_p\left(T_g - T_\infty\right) + h_k A_T\left(T_g - T_\infty\right) \tag{30.18}$$

where:

$\dot{Q}$ = Energy (heat) release rate of the fire (kW)
$\dot{m}_g$ = Gas flow rate out the opening (kg/s)
c_p = Specific heat of gas (kJ/kg·K)
T_g = Temperature of the upper gas layer (K)
T_∞ = Ambient temperature (K)
h_k = Effective heat transfer coefficient (kW/m^2K)
A_T = Total area of the compartment enclosing surfaces (m^2)

Rearranging Equation 30.18 yields

$$\Delta T_g = \frac{\dot{Q}}{\dot{m}_g c_p + h_k A_T} \tag{30.19a}$$

or

$$\frac{\Delta T_g \dot{m}_g c_p}{\dot{Q}} = \frac{1}{1 + (h_k A_T)/\dot{m}_g c_p} \tag{30.19b}$$

where $\Delta T_g = T_g - T_\infty$.

A nondimensional temperature rise is defined as

$$\Delta T^* \equiv \frac{\Delta T_g \dot{m}_g c_p}{\dot{Q}} \tag{30.20}$$

and the ratio of the bounding surface loss to the ventilation losses is defined as

$$Y^* \equiv 1 + \frac{h_k A_T}{\dot{m}_g c_p} \tag{30.21}$$

By plotting ΔT^* as a function of ΔY^* for data with experiments with known ventilation rates Beyler and Deal developed a correlation for the effective heat transfer coefficient of

$$h_k = 0.4\max\left(\sqrt{\frac{k\rho c}{t}}, \frac{k}{\delta}\right) \tag{30.22}$$

where
k = Thermal conductivity of the compartment surface (kW/m·K)
ρ = Density of the compartment surface (kg/m^3)
c = Specific heat of the compartment surface material (kJ/kg·K)
δ = Thickness of the compartment surface (m)
t = Exposure time (s)

The expression switches from transient to steady state at a thermal penetration time of $t_p = (\rho c/k)\delta^2$ rather than $t_p = (\rho c/k)(\delta/2)^2$ used by McCaffrey et al. and Foote et al. For the data set Beyler and Deal evaluated, the standard error for their method was 29 K as compared to 51 K for the method of Foote et al., even though the equation uses only one fitting constant.

Beyler and Deal demonstrated that this method works for ventilation to the lower part of the compartment (with or without a plenum) as well as for ventilation to the upper part of the compartment. The Beyler and Deal method was based on data up to 2000 s into fire tests. At longer times, the heat loss model breaks down.

Example of Beyler and Deal Method Estimate the temperature in a 5 × 5 m floor area and 4-m-high compartment with 0.025-m (1-in.) thick concrete walls. The forced-ventilation rate is 2.4 m^3/s of air (5000 cfm). Perform the calculation for $t > t_p$. The fire size is given as 1000 kW; ambient air conditions at 300 K. Using Equation 30.19a,

$$T_g - T_\infty = \frac{\dot{Q}}{\dot{m}_g c_p + h_k A_T}$$

where
$\dot{Q} = 1000$ kW
$\dot{m}_g = (2.4\ \text{m}^3/\text{s})\ (1.18\ \text{kg/m}^3) = 2.8$ kg/s
$c_p = 1.0$ kJ/kg·K
$T_\infty = 300$ K
$A_T = 4(5 \times 4) + 2(5 \times 5) = 105$ m^2

(a) Calculate h_k for $t > t_p$. For 0.25-m-thick concrete,

$\delta = 0.25$ m
$\rho = 2000$ kg/m^3
$k = 1.4 \times 10^{-3}$ kW/m·K
$c = 0.88$ kJ/kg·K

$$h_k = 0.4\left(\frac{k}{\delta}\right) = 0.4\left(\frac{1.4 \times 10^{-3}}{0.25}\right)$$
$$= 0.0224\ \text{kW/m}^2 \cdot \text{K}$$

(b) Calculate the compartment temperature using Equation 30.19a.

$$T_g - 300 = \frac{1000}{(2.8)\,(1.0) + (0.224)\,(105)}$$
$$T_g = 494\ \text{K}$$

Method of Peatross and Beyler

The correlations used in the McCaffrey, Quintiere, and Harkleroad method and the Beyler and Deal method are based on the assumption of normal insulating wall materials. For highly conductive walls such as steel, Peatross and Beyler suggest the use of an alternative heat transfer coefficient [19]. Using a lumped mass analysis for heat transfer through the wall that is appropriate for a highly conductive wall yields

$$m_w'' c \frac{dT_w}{dt} = h_g\left(T_g - T_w\right) - h_\infty T_w \tag{30.23}$$

where
m_w'' = Mass per unit area of the wall (kg/m^2)
c = Specific heat of the wall (kJ/kg·K)
T_w = Wall temperature (K)
t = Time (s)
h_g = Heat transfer coefficient on the hot side of the wall (kW/m^{2}K)
T_g = Upper layer temperature (K)
H_∞ = Heat transfer coefficient on the ambient side of the wall (kW/m^{2}K)

Solving for the wall temperature with the initial condition of the wall at ambient temperature yields

$$T_w = \frac{h_g T_g}{h_g + h_\infty}\left[1 - \exp\left(-\frac{h_g + h_\infty}{m_w'' c} t\right)\right] \tag{30.24}$$

The heat transfer through the wall, $\dot{q}''$, may be expressed in terms of the heat transfer to the hot side of the wall or in terms of an overall effective heat transfer coefficient, h_k.

$$\dot{q}'' = h_g(T_g - T_w) = h_k(T_g - T_\infty) \quad (30.25)$$

Solving for h_k yields

$$h_k = h_g - \frac{h_g^2}{h_g + h_\infty}\left[1 - \exp\left(-\frac{h_g + h_\infty}{\rho\delta c}t\right)\right] \quad (30.26)$$

where
ρ = Density of the wall material (kg/m^3)
δ = Thickness of the wall (m)
h_k = Overall effective heat transfer coefficient W/m^2·K

From the above equations it can be seen that

$$h_k = \frac{h_g h_\infty}{h_g + h_\infty} \quad \text{at} \quad t = \infty$$

$$h_k = h_g \quad \text{at} \quad t = 0$$

From a number of experiments, Peatross and Beyler found the heat transfer coefficients of 30 W/m^2·K for h_g and 20 W/m^2·K for h_∞. Substituting these values yields

$$h_k = 30 - 18\left[1 - \exp\left(-\frac{50}{\rho\delta c}t\right)\right] \quad (30.27)$$

The h_k calculated with this method can be used directly in the Beyler and Deal method. It must be multiplied by 2.5 for use in the McCaffrey, Quintiere, and Harkleroad method to account for the 0.4 fitting constant in the h_k in the Beyler and Deal method.

Example of Peatross and Beyler Method for Forced Ventilation Estimate the temperature in a 5 × 5 m floor area and 4-m-high compartment having 0.00635-m (0.25-in.) thick, 0.5 % carbon steel walls. The forced-ventilation rate is 2.4 m^3/s of air (5000 cfm). Perform the calculation for t = 200 s. The fire size is given as 1000 kW; ambient air conditions at 300 K. Using Equation 30.19a,

$$T_g - T_\infty = \frac{\dot{Q}}{\dot{m}_g c_p + h_k A_T}$$

where
$\dot{Q}$ = 1000 kW
$\dot{m}_g$ = (2.4 m^3/s) (1.18 kg/m^3) = 2.8 kg/s
c_p = 1.0 kJ/kg·K
T_∞ = 300 K
A_T = 4(5 × 4) + 2(5 × 5) = 130 m^2

(a) Using Equation 30.27, calculate h_k for t = 200 s. For 0.25-m-thick, 0.5 % carbon steel,
δ = 0.00635 m
ρ = 7833 kg/m^3
c = 0.465 kJ/kg·K

$$h_k = 30 - 18\left[1 - \exp\left(-\frac{50}{\rho\delta c}t\right)\right]$$
$$= 30 - 18\left\{1 - \exp\left[-\frac{50}{(7833)(0.00635)(0.465)}200\right]\right\}$$
$$= 23.7 \ \text{W/m}^2 \cdot \text{K}$$

(b) Calculate the compartment temperature using Equation 30.19a.

$$T_g - 300 = \frac{1,000}{(2.8)(1.0) + (0.0237)(130)}$$
$$T_g = 470 \ \text{K}$$

Method of Beyler

For compartments with no ventilation the quasi-steady approximation used in many of the methods is not appropriate since the conditions in the compartment will not reach steady state.

Beyler applied a nonsteady energy balance to the closed compartment expressed by the differential equation [17]

$$mc_p \frac{dT}{dt} = \dot{Q} - h_k A_T \Delta T_g \tag{30.28}$$

where

$\dot{Q}$ = Energy (heat) release rate of the fire (kW)
m = Mass of the gas in the compartment (kg)
c_p = Specific heat of gas (kJ/kg·K)
$\Delta T_g = T_g - T_\infty$
T_g = Temperature of the upper gas layer (K)
T_∞ = Ambient temperature (K)
h_k = Effective heat transfer coefficient (kW/m^{2}K)
A_T = Total area of the compartment enclosing surfaces (m^2)
ρ = Density of the compartment surface (kg/m^3)
δ = Thickness of the compartment surface (m)
t = Exposure time (s)

In this case a "closed" compartment has sufficient leaks to prevent pressure buildup, but the leakage is ignored. The mass of the fuel is ignored, and the initial temperature is assumed to be ambient temperature. For constant heat release rate, the solution to Equation 30.28 is

$$\Delta T_g = \frac{2K_2}{K_1^2}\left(K_1\sqrt{t} - 1 + e^{-K_1\sqrt{t}}\right) \tag{30.29}$$

where

$$K_1 = \frac{2(0.4\sqrt{k\rho c})A_T}{mc_p} \tag{30.30}$$

$$K_2 = \frac{\dot{Q}}{mc_p} \tag{30.31}$$

where

k = Thermal conductivity of the compartment surface (kW/m·K)
c = Specific heat of the compartment surface material (kJ/kg·K)

which include the fitting coefficient. Beyler used data with a maximum temperature rise of 150 °C to develop this correlation.

Example of Beyler Method Estimate the temperature in a 5 × 5 m floor area and 4-m-high "closed" compartment having 0.025-m (1-in.) thick concrete walls. Perform the calculation for t = 120 s. The fire size is given as 100 kW; ambient air conditions at 300 K. Using Equation 30.29,

$$\Delta T_g = \frac{2K_2}{K_1^2}\left(K_1\sqrt{t} - 1 + e^{-K_1\sqrt{t}}\right)$$

where

T_∞ = 300 K
t = 120 s

(a) Calculate K_1 using Equation 30.30.

$$K_1 = \frac{2(0.4\sqrt{k\rho c})A_T}{mc_p} = \frac{2\left(0.4\sqrt{(1.4\times10^{-3})(2{,}000)(0.88)}\right)(130)}{(118)(1.0)} = 1.3834$$

where

$m = (100\ \text{m}^3)(1.18\ \text{kg/m}^3) = 118$ kg
c_p = 1.0 kJ/kg·K
ρ = 2000 kg/m^3
$k = 1.4 \times 10^{-3}$ kW/m·K
c = 0.88 kJ/kg·K
A_T = 130 m^2

(b) Calculate K_2 using Equation 30.31.

$$K_2 = \frac{\dot{Q}}{mc_p} = \frac{100}{(118)(1.0)} = 0.84746$$

where

$m = (100\ \text{m}^3)(1.18\ \text{kg/m}^3) = 118$ kg
c_p = 1.0 kJ/kg·K

(c) Calculate the compartment temperature using Equation 30.29.

$$T_g - 300 = \frac{(2)(0.84746)}{(1.3834)^2}\left((1.3834)\sqrt{120} - 1 + e^{-(1.3834)\sqrt{120}}\right)$$

$$T_g = 312.5\ \text{K}$$

Methods for Predicting Postflashover Compartment Fire Temperatures

Method of Babrauskas

The following method is based on the work of Babrauskas [20, 21]. The upper gas temperature, T_g, is expressed according to a series of factors, each one accounting for a different physical phenomenon:

$$T_g = T_\infty + (T^* - T_\infty) \cdot \theta_1 \cdot \theta_2 \cdot \theta_3 \cdot \theta_4 \cdot \theta_5 \tag{30.32}$$

where T^* is an empirical constant = 1725 K, and the factors θ are in Equations 30.38, 30.43, 30.45, 30.46, 30.48 and 30.49.

Burning Rate Stoichiometry, θ_1 The dimensionless stoichiometric coefficient ϕ is defined as

$$\phi = \frac{\dot{m}_f}{\dot{m}_{f,st}} \tag{30.33}$$

where $\dot{m}$ is the fuel mass pyrolysis rate (kg/s), and $\dot{m}_{f,st}$ is the stoichiometric mass burning rate (i.e., no excess fuel and no excess oxygen).

$$\dot{m}_{f,st} = \frac{0.5 A_o \sqrt{H_o}}{r} \tag{30.34}$$

where the ratio r is such that 1 kg fuel + r kg air → (1 + r) kg products. The value of r is readily computable for fuels containing carbon, hydrogen, and/or oxygen from the chemical formula of the fuel, taking the products to be CO_2, H_2O, and N_2.

$$C_x H_y O_z + wO_2 + w\left(\frac{79}{21}\right)N_2 \rightarrow xCO_2 + \frac{y}{2}H_2O + w\left(\frac{79}{21}\right)N_2 \tag{30.35}$$

where

$$w = \frac{2x + 2y/2 - z}{2} \tag{30.36}$$

and

$$r = \frac{[w + w(3.76)]28.97}{12.01x + 1.00y + 16.00z} \tag{30.37}$$

At stoichiometry ϕ = 1, and it is greater than 1 for fuel-rich burning and less than 1 for fuel-lean conditions.

The effect of ϕ on gas temperatures was evaluated by numerical computations using the COMPF2 computer program [22]. The efficiency factor, θ_1, accounts for deviation from stoichiometry and is shown in Fig. 30.4. It is seen that the fuel-lean and the fuel-rich regimes exhibit a very different dependence. For the fuel-lean regime, the results can be approximated by

$$\theta_1 = 1.0 + 0.51 \ln \phi \quad \text{for} \quad \phi < 1 \tag{30.38}$$

Similarly, in the fuel-rich regime a suitable approximation is

$$\theta_1 = 1.0 - 0.05(\ln \phi)^{5/3} \quad \text{for} \quad \phi > 1 \tag{30.39}$$

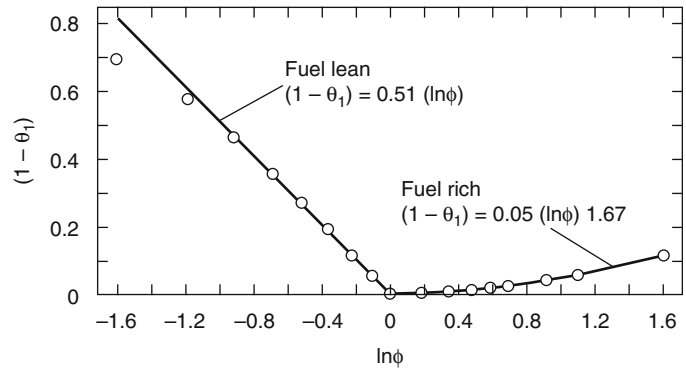

Fig. 30.4 Effect of equivalence ratio

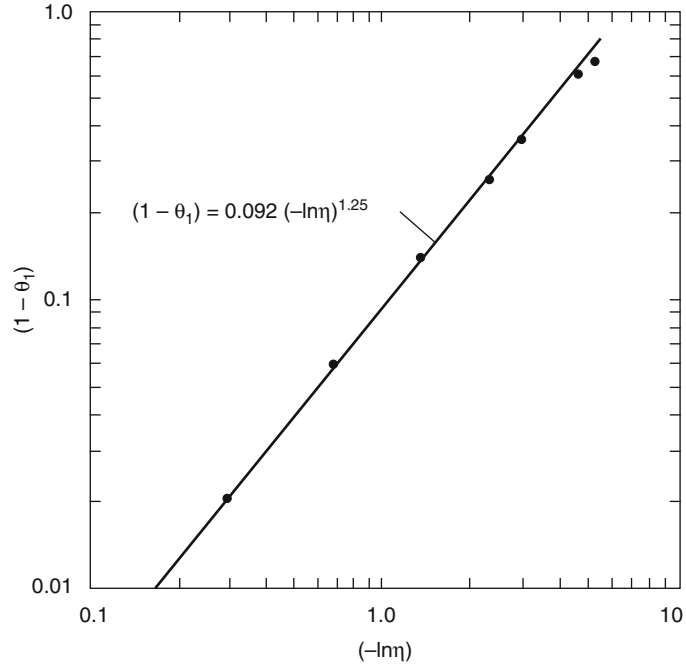

Fig. 30.5 Effect of pool diameter

If heat release rate, $\dot{Q}$, rather than mass loss rate, $\dot{m}$, is used, then

$$\phi = \frac{\dot{Q}}{\dot{Q}_{\text{stoich}}} \tag{30.40}$$

And since the stoichiometric heat release rate is

$$\dot{Q} = 1,500 A_o \sqrt{H_o} \tag{30.41}$$

then

$$\phi = \frac{\dot{Q}}{1,500 A_o \sqrt{H_o}} \tag{30.42}$$

The value of $\dot{Q}$ can be determined from Chap. 26.

A separate procedure is necessary for pool fires, due to the strong radiative coupling. Here

$$\theta_1 = 1.0 - 0.092(-\ln \eta)^{1.25} \tag{30.43}$$

where

$$\eta = \left(\frac{A_o \sqrt{H_o}}{A_f}\right) \frac{0.5 \Delta h_p}{r\sigma\left(T_g^4 - T_b^4\right)} \tag{30.44}$$

where

Δh_p = Heat of vaporization of liquid (kJ/kg)

A_f = Pool area (m^2)

σ = Stefan-Boltzmann constant (5.67×10^{-11} $kW/m^2 \cdot K^4$)

T_b = Liquid boiling point temperature (K)

This expression unfortunately requires an estimate for T_g to be made, so for the pool fire case, a certain amount of iteration is necessary. The relationship above is plotted in Fig. 30.5.

Wall Steady-State Losses, θ_2 The next efficiency factor, θ_2, accounts for variable groups of importance involving the wall surface (which is defined to include the ceiling) properties: area $A_T(m^2)$, thickness L (m), density ρ (kg/m^3), thermal conductivity k (kW/m·K), and heat capacity c_p(kJ/kg·K). This factor is given as

$$\theta_2 = 1.0 - 0.94 \exp\left[-54\left(\frac{A_o \sqrt{H_o}}{A_T}\right)^{2/3}\left(\frac{L}{k}\right)^{1/3}\right] \tag{30.45}$$

and is shown in Fig. 30.6.

Wall Transient Losses, θ_3 For the transient case, Equation 30.45 predicts the asymptotic temperature value. An additional time-dependent factor, however, is needed (Fig. 30.7).

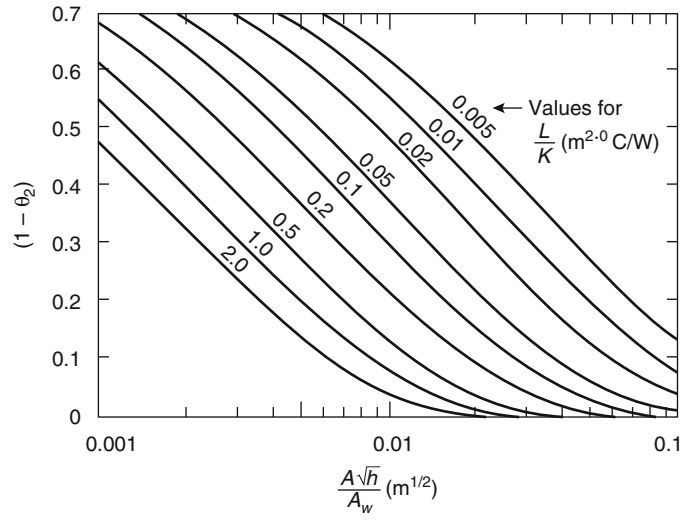

Fig. 30.6 Effect of wall steady-state losses

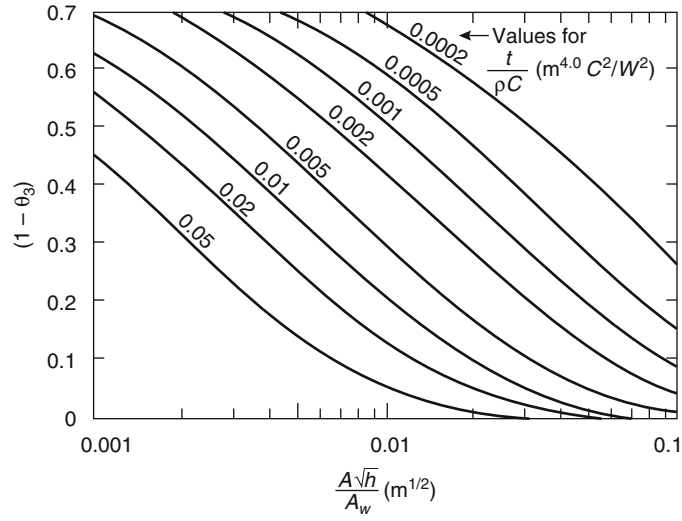

Fig. 30.7 Effect of wall transient losses

$$\theta_3 = 1.0 - 0.92 \exp\left[-150\left(\frac{A_o\sqrt{H_o}}{A_T}\right)^{0.6}\left(\frac{t}{\kappa\rho c}\right)^{0.4}\right] \tag{30.46}$$

where

κ = Thermal conductivity of wall (W/m·K)

c = Specific heat of wall (J/kg·K)

If only steady-state temperatures need to be evaluated, then $\theta_3 = 1.0$.

Wall effects for t just slightly greater than zero are not well modeled with the above relationships for $\theta_2 \cdot \theta_3$; however, this condition is not a serious limitation, since the method is only designed for postflashover fires.

For transient fires, the possibility of two separate effects must be considered. First, the wall loss effect, represented by Equation 30.46, in all fires exhibits a nonsteady character. Second, the fuel release rate may not be constant. Since in the calculational procedure the previous results are not stored, it is appropriate to restrict consideration to fires where $\dot{m}_f$ does not change drastically over the time scale established by θ_3. This "natural" time scale can be determined as the

time when the response has risen to 63 % of its ultimate value, that is, at $\theta_3 = 0.63$, and is

$$t = 2.92 \times 10^{-6}(\kappa\rho c)\left(\frac{A_T}{A_o\sqrt{H_o}}\right)^{1.5} \quad (30.47)$$

Opening Height Effect, θ_4 The normalization of burning rate and wall loss quantities with the ventilation factor $A_o\sqrt{H_o}$ does not completely determine the total heat balance. An opening of a given $A_o\sqrt{H_o}$ can be tall and narrow or short and squat. For the shorter opening, the area will have to be larger. Radiation losses are proportional to the opening area and will, therefore, be higher for the shorter opening. By slight simplification, a representation for θ_4 can be made as

$$\theta_4 = 1.0 - 0.205H_o^{-0.3} \quad (30.48)$$

as shown in Fig. 30.8.

Combustion Efficiency, θ_5 The fire compartment is viewed as a well, but not perfectly, stirred reactor. Thus a certain "unmixedness" is present. A maximum combustion efficiency, b_p, can be used to characterize this state. Since the model assumes infinitely fast kinetics, any limitations can also be included here. Data have not been available to characterize b_p in real fires, but agreement with measured fires can generally be obtained with b_p values in the range 0.5–0.9. The effect of b_p variation can be described by

$$\theta_5 = 1.0 + 0.5 \ln b_p \quad (30.49)$$

as shown in Fig. 30.9.

Method of Law

The area of structural surface to which heat is lost is expressed by $(A_T - A_o)$. For a given fire load, compartments with different values of A_T, A_o, and height H_o will have a different heat balance, and thus the temperatures in the compartments will differ. This is illustrated in Fig. 30.10, which shows how temperature varies with

$$\Omega = \frac{(A_T - A_o)}{A_o\sqrt{H_o}}$$

For low values of Ω (i.e., high ventilation), the rate of heat release is at a maximum, but the heat loss from the window is also large and the resultant temperature is low. For high values of Ω (i.e., low-ventilation areas), there is little heat loss to the outside, but the rate of heat release is also small and the resultant temperature is, again, low.

The curve in Fig. 30.11 has been derived from many experimental fires conducted internationally by CIB [10]. For design purposes, Law has defined it as follows:

$$T_{g(max)} = 6,000\frac{(1 - e^{-0.1\Omega})}{\sqrt{\Omega}} \quad (^\circ C) \quad (30.50)$$

where

$$\Omega = \frac{(A_T - A_o)}{A_o\sqrt{H_o}}$$

and

A_T = Total area of the compartment enclosing surfaces (m^2)
A_o = Area of opening (m^2)
H_o = Height of opening (m)

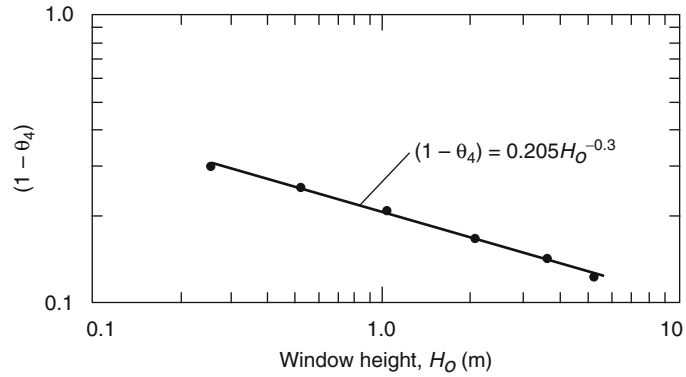

Fig. 30.8 Effect of window height

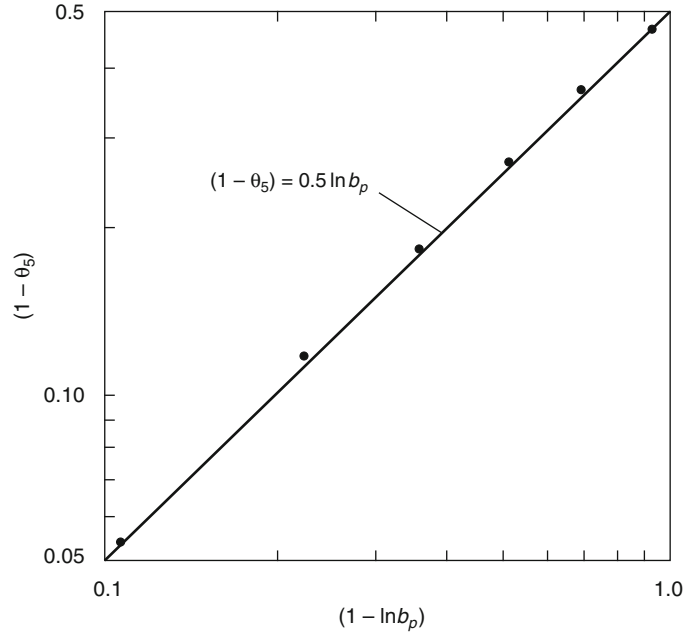

Fig. 30.9 Effect of b_p, the maximum combustion efficiency

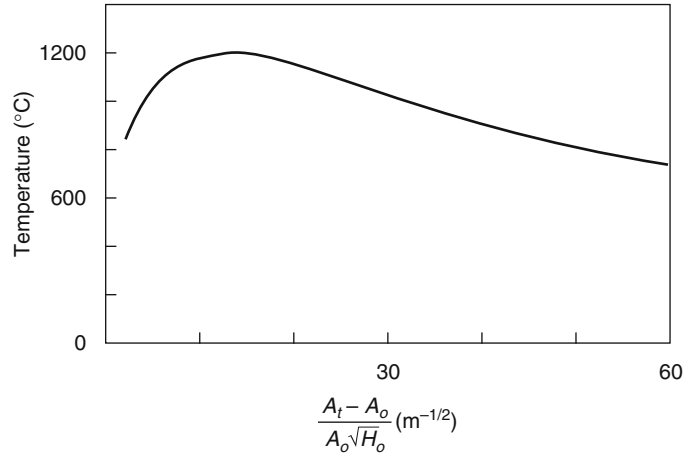

Fig. 30.10 Average temperature during fully developed period measured in experimental fires in compartments

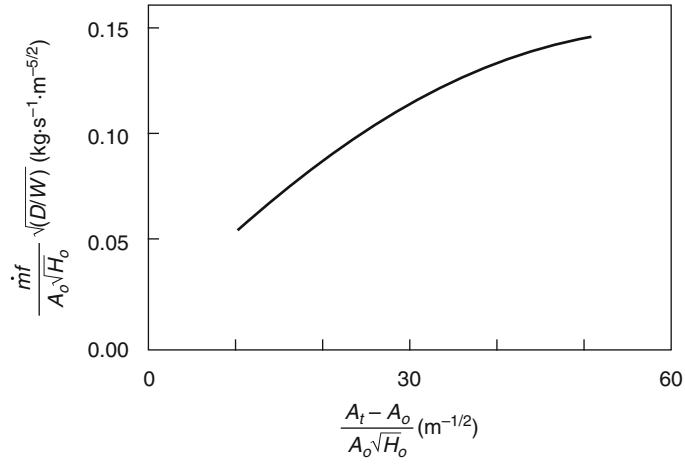

Fig. 30.11 Variation of a rate of burning during fully developed period measured in experimental fires in compartments

This equation represents an upper limit of fire temperature rise for a given Ω. However, if the fire load is low, this value may not be obtained. The importance of the effect of fire load also depends on A_o and A_T, and can be expressed as

$$T_g = T_{g(max)}\left(1 - e^{-0.05\Psi}\right) \ (^\circ C) \qquad (30.51)$$

where

T_g = Average temperature in the compartment (°C)

where

$$\Psi = \frac{L}{[A_o(A_T - A_o)]^{0.5}}$$

where L is the fire load (wood) in kg.

The effect of the fire on the structure depends not only on the value of T_g but also on the duration of heating. The effective fire duration, τ, in seconds, is given by

$$\tau = \frac{L}{\dot{m}_f} \qquad (30.52)$$

where $\dot{m}_f$ is the rate of burning measured in kg/s.

Equation 30.7 implies that the smaller the value of $A_o\sqrt{H_o}$ the lower the rate of burning and the longer the duration. Assuming a complete burnout, therefore, the effect on the structure tends to be more severe for large values of Ω given for small $A_o\sqrt{H_o}$.

For design purposes the following equation has been developed to express the correlation of experimental results [11]:

$$\dot{m}_f = 0.18A_o\sqrt{H_o(W/D)}\left(1 - e^{-0.036\Omega}\right) \quad \xi < 60 \qquad (30.53)$$

where

W = Compartment width (m)

D = Compartment depth (m)

$$\xi = \frac{\dot{m}_f}{A_o\sqrt{H_o}}\left(\frac{D}{W}\right)^{1/2}$$

Equation 30.53 is shown in Fig. 30.11 over the range where the data lie. Both equations are for ventilation-controlled fires. When there is ample ventilation, so that the fuel is free burning, the value of $\dot{m}_f$ depends on L and the type of fuel. For example, domestic furniture has a free-burning fire duration of about 20 min, giving $\tau = 1200$ s and $\dot{m}_f = L/1200$.

The temperatures discussed above are averages measured during the fully developed period of the fire. It is assumed that all fires are ventilation controlled, with the simple relationship for rate of burning given by Equation 30.53, which is near stoichiometric burning, and it is assumed that combustion of 1 kg of wood releases 18.8 MJ in total.

Method of Delichatsios et al.

Delichatsios' proposed a method assuming that [23];

1. determination of uniform maximum gas temperature in the compartment for adiabatic conditions
2. determination of an average heat flux to the compartment boundary during the development of the fire
3. a transient thermal model for the response of the compartment boundary to account for heat losses to the boundary of the compartment.

First, gas temperature in the compartment is defined from the following equation at quasi-steady conditions:

$$\dot{Q}_c = \dot{m}_g c_p\left(T_g^* - T_\infty\right) + \sigma A_o\left(T_g^{*4} - T_\infty^4\right) \qquad (30.54)$$

where

$\dot{Q}_c$ = Heat release rate inside the compartment (kW)

$\dot{m}_g$ = Flow rate of gases out of the compartment (kg/s)

T_g^* = Adiabatic temperature leaving through the opening (K)

T_∞ = Ambient temperature (K)

A_o = Area of the opening (m^2)

Assuming ventilation controlled fire, the heat release rate inside the enclosure can be calculated using following equation.

$$\dot{Q}_c = 1,500A_o\sqrt{H_o} \qquad (30.55)$$

The mass flow rate of hot gas out of the opening can be given by the equation below.

$$\dot{m}_g = 0.5 A_o \sqrt{H_o} \tag{30.56}$$

where

H_o = Height of opening (m)

Substituting Equations 30.55 and 30.56 into Equation 30.54, the following energy balance equation is obtained for the case of ventilation controlled fires.

$$1,500 A_o \sqrt{H_o} = \left(0.5 A_o \sqrt{H_o}\right) C_p \left(T_g^* - T_\infty\right) + \sigma A_o \left(T_g^{*4} - T_\infty^4\right) \tag{30.57}$$

Equation 30.57 can be solved by using simple numerical inversion to obtain the adiabatic temperature. As for Equation 30.57, the adiabatic temperature depends only on $A_o\sqrt{H_o}$.

From the dimensional analysis,

$$\frac{T_g - T_\infty}{T_g^* - T_\infty} = function\left(\frac{\sqrt{t}}{\sqrt{(k\rho c)_w}}\ \frac{\dot{Q}_c}{A_T\left(T_g^* - T_\infty\right)}\right). \tag{30.58}$$

where

A_T = Total area of the compartment enclosing surfaces (m^2)

Compared to the experimental data, the model for gas temperature in the enclosure is proposed below for the growing period of fire before burnout occurs,

$$\frac{T_g - T_\infty}{T_g^* - T_\infty} = 0.5\left(\frac{\sqrt{t}}{\sqrt{(k\rho c)_w}}\ \frac{\dot{Q}_c}{A_T\left(T_g^* - T_\infty\right)}\right)^{1/2} \tag{30.59}$$

Swedish Method

The Swedish method, developed by Magnusson and Thelandersson [12], is based on the conventional mass and energy balance equations. The fire itself is not modeled; heat release rate curves are provided as input and, in all instances, the energy release must be less than stoichiometric. The method does not take into account that the actual mass loss rate may be greater than stoichiometric, with the excess fuel burning outside the compartment. A computer program, SFIRE (versions 1 through 3), is available to perform this method. The results from the computer program have been compared with a large number of full-scale fire experiments, both in the fuel- and ventilation-controlled regimes, with good agreement between theory and experiment. It should be added, however, that most of the experiments involved wood crib fires, which inherently burn slower and produce less excess fuel load than furnishings and other combustibles found in practical fire loads. In the Swedish method, the fire load is expressed in relation to A_T as $\dot{Q} = 18.8\ L/A_T\ \mathrm{MJ/m^2}$.

The design curves approved by the Swedish authorities were computed on the basis of systemized ventilation-controlled heat-release curves taken from Magnusson and Thelandersson [12]. Figure 30.12 shows some typical curves. The curves are calculated for wall, floor, and ceiling materials with "normal" thermal properties from an energy balance which assumes a uniform temperature in the compartment.

Japanese Method

The McCaffery's method (Equation 30.12) was originally derived for fuel-controlled fires [24]. However, the formula was extended to calculate the temperature of ventilation controlled fires as well [25]. The fire temperature in the compartment and fire duration are calculated by

$$T_f = 1,280\left(\frac{Q}{\sqrt{A_T\sqrt{k\rho c}}\sqrt{A_o\sqrt{H_o}}}\right)^{2/3} t^{1/6} + T_\infty \tag{30.60}$$

where

$$t_D = \frac{1}{60}\frac{F_L A_r}{Q} \tag{30.61}$$

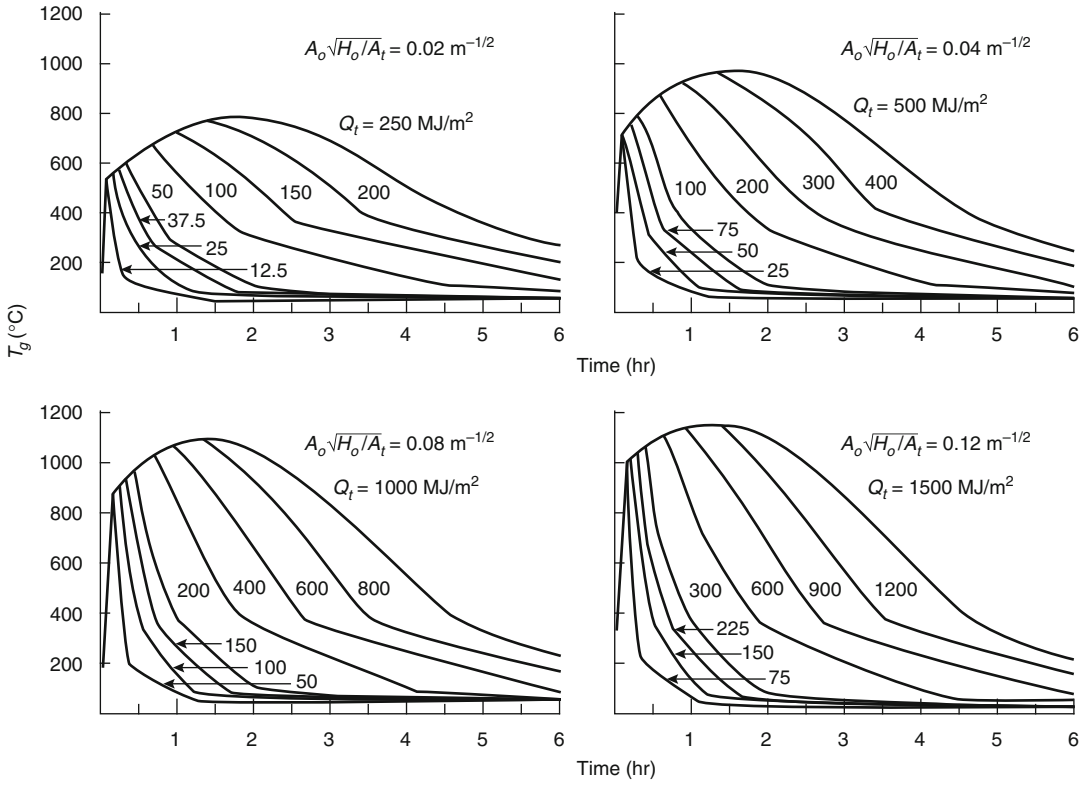

Fig. 30.12 Examples of gas temperature-time curves of postflashover compartment fires for different values of the fire load density $\dot{Q}_t$ MJ per unit of total internal surface area, A_t, and the opening factor $A_o\sqrt{H_o/A_t}$. Fire compartment, type A—from authorized Swedish standard specifications [12]

Q = Heat release rate by combustion (MW)
A_T = Internal surface area of compartment enclosure (m^2)
$\sqrt{k\rho c}$ = Thermal inertia of compartment enclosure (kW·s$^{1/2}$/m^2·K)
A_o = Area of window opening (m^2)
H_o = Height of window opening (m)
T_∞ = Initial and ambient temperatures (°C)
F_L = Fire load density (MJ/m^2)
A_r = Floor area of the room (m^2)
t_D = Fire duration (min.)

The heat release rate is calculated by the burning type index (fraction of ventilation factor to surface area of fuel),

$$\chi = \frac{A_o\sqrt{H_o}}{A_{fuel}}. \tag{30.62}$$

The fuel surface area was assumed to follow the following formula [26].

$$A_{fuel} = 0.26F_L^{1/3}A_{room} \tag{30.63}$$

Using burning type index, the heat release rate is calculated by

$$Q = A_{fuel} \times \begin{cases} 1.6\chi & (\chi \le 0.081) \\ 0.13 & (0.081 < \chi \le 0.1) \\ 2.5\chi\exp(-11\chi) + 0.048 & (0.1 < \chi) \end{cases} \tag{30.64}$$

Example of Japanese Method Calculate the maximum temperature of a room; 3 m width × 3 m in floor depth × 2.4 m high with a door opening installed at 1.8 m high × 0.6 m wide. The internal surface area is 31.32 m^2. The fire load density is 720 MJ/m^2.

The compartment enclosure is made of concrete with $\sqrt{k\rho c} = 1.75$ kW $s^{1/2}/m^2K$. Perform calculation until burnout.

The fuel surface area and ventilation factors are

$$A_{fuel} = 0.26\, F_L^{1/3} A_{room} = 0.26 \times 720^{1/3} \times (3 \times 3) = 21.0\ \text{m}^2$$

$$A_o\sqrt{H_o} = 0.6 \times 1.8 \times \sqrt{1.8} = 1.45\ \text{m}^{5/2}$$

The burning type index is

$$\chi = \frac{A_o\sqrt{H_o}}{A_{fuel}} = \frac{1.45}{21.0} = 0.069$$

As $\chi < 0.081$, fire is ventilation-controlled. The heat release rate and fire duration are

$$Q = A_{fuel} \times 1.6\chi = 21.0 \times 1.6 \times 0.069 = 2.32\text{MW}$$

$$t_D = \frac{1}{60}\frac{F_L A_r}{Q} = \frac{1}{60}\frac{720 \times 3 \times 3}{2.32} = 46.6\ \text{min.}$$

Combining the results, the fire temperature in the compartment can be calculated by the following equation as shown in Fig. 30.13.

$$T_f = 1,280\left(\frac{Q}{\sqrt{A_T\sqrt{k\rho c}}\sqrt{A_o\sqrt{H_o}}}\right)^{2/3} t^{1/6} + T_0$$

$$= 1,280\left(\frac{2.32}{\sqrt{31.32 \times 1.75}\sqrt{1.45}}\right)^{2/3} t^{1/6} + 20$$

$$= 522t^{1/6} + 20$$

For example, the fire temperature at fire duration is

$$T_f = 522 \times 46.6^{1/6} + 20 = 1,009°\text{C}$$

Predicting Flashover

One use of predicted compartment fire temperatures is estimating the likelihood of flashover. The methods used are similar to those used in the prediction of temperature. In one case, that of McCaffrey et al., the method is simply an extension of the temperature calculation.

Method of Babrauskas

Babrauskas uses the energy balance for the upper layer given in Equation 30.8, where the gas flow rate out of the opening is approximated by [27]

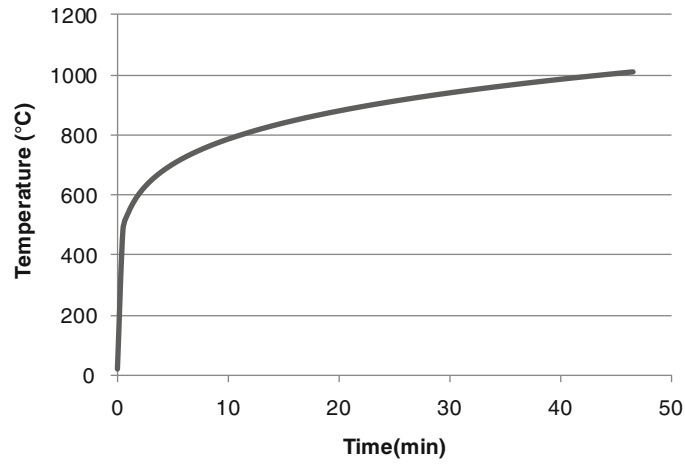

Fig. 30.13 Example of temperature-time curve calculated by Japanese method

$$\dot{m}_g \approx 0.5 A_o \sqrt{H_o} \tag{30.65}$$

The primary energy loss is assumed to be radiation to 40 % of the wall area, which is at approximately ambient temperature:

$$q_{\text{loss}} = \varepsilon\sigma\left(T_g^4 - T_\infty^4\right)(0.40 A_T) \tag{30.66}$$

where
ε = Emissivity of the hot gas
σ = Stefan-Boltzmann constant 5.67×10^{11} kW/m^2·K^4

Combining Equations 30.8, 30.65 and 30.66, using a gas temperature for flashover of 873 K, a specific heat of air of 1.0 kJ/kg·K, an emissivity of 0.5, and assuming the correlation between compartment wall and opening area of

$$\frac{A_T}{A_o\sqrt{H_o}} \approx 50$$

yields a minimum $\dot{Q}$ required for flashover,

$$\dot{Q} = 600 A_o \sqrt{H_o} \tag{30.67}$$

The airflow into the compartment has been approximated as

$$0.5 A_o \sqrt{H_o}$$

The maximum amount of fuel that can be burned completely with this air is known as the stoichiometric amount. For most fuels, the heat released per mass of air consumed is a constant approximately equal to 3000 kJ/kg. Therefore, the stoichiometric heat release rate can be $\dot{Q}_{\text{stoich}}$ calculated:

$$\begin{aligned}\dot{Q}_{\text{stoich}} &= 3{,}000\ \dot{m}_g = 3{,}000\left(0.5 A_o \sqrt{H_o}\right) \\ &= 1{,}500 A_o \sqrt{H_o}\end{aligned} \tag{30.68}$$

From this derivation, it is shown that the minimum $\dot{Q}$ required for flashover equals $0.4\ \dot{Q}_{\text{stoich}}$. Comparing these results with fire tests, Babrauskas found that the data fall within a range of $\dot{Q} = 0.3\ \dot{Q}_{\text{stoich}}$ to $\dot{Q} = 0.7\ \dot{Q}_{\text{stoich}}$. A best fit of the data suggests

$$\dot{Q} = 0.5\ \dot{Q}_{\text{stoich}}$$

which, substituting into Equation 30.68 yields

$$\dot{Q} = 750 A_o \sqrt{H_o} \tag{30.69}$$

The 33 test fires used had energy release rates from 11 to 3840 kW, with fuels primarily of wood and polyurethane. Ventilation factors $A_o\sqrt{H_o}$ ranged from 0.03 to 7.51 m$^{5/2}$, and surface area to ventilation factor ratios

$$\frac{A_T}{A_o\sqrt{H_o}}$$

ranged from 9 to 65 m$^{-1/2}$.

Example of Babrauskas's Method Calculate the heat release rate necessary to cause flashover, using the method of Babrauskas. Assume the same room as in the McCaffrey et al. method example for predicting compartment fire temperatures. From Equation 30.69

$$\dot{Q} = 750 A_o \sqrt{H_o}$$

where
$A_o = 1.08$ m^2
$H_o = 1.8$ m
$\dot{Q} = (750)(1.08)(1.8)^{1/2} = 1087$ kW

Method of McCaffrey, Quintiere, and Harkleroad

The method of McCaffrey, Quintiere, and Harkleroad for predicting compartment fire temperatures may be extended to predict the energy release rate of the fire required to result in flashover in the compartment.

Equation 30.12 can be rewritten as

$$\dot{Q} = \left[\sqrt{g} c_p \rho_\infty T_\infty^2 \left(\frac{\Delta T_g}{480}\right)^3\right]^{1/2} \left(h_k A_T A_o \sqrt{H_o}\right) \tag{30.70}$$

Selecting an upper gas temperature of 522 °C and ambient temperature of 295 K or $\Delta T_g =$ 500 °C for flashover, and substituting values for the gravitational constant ($g = 9.8$ m/s^2), the

specific heat of air ($c_p = 1.0$ kJ/kg·K), and the density of air ($\rho_\infty = 1.18$ kg/m^3), and rounding 607.8–610 yields

$$\dot{Q} = 610\left(h_k A_T A_o \sqrt{H_o}\right)^{1/2} \tag{30.71}$$

where

h_k = Effective heat transfer coefficient (kW/m^{2}K)
A_T = Total area of the compartment surfaces (m^2)
A_o = Area of opening (m^2)
H_o = Height of opening (m)

Using Equation 30.13 yields a slightly different value, 623.6 rounded to 620, of the leading coefficient because of the difference in the value used for the specific heat of air:

$$\dot{Q} = 620\left(h_k A_T A_o \sqrt{H_o}\right)^{1/2} \tag{30.72}$$

The use of either 610 or 620 is acceptable within the accuracy of the expression.

Example of McCaffrey et al.'s Method Estimate the energy release rate required for flashover of a compartment. Assume the same room as in the McCaffrey et al. method example for predicting compartment fire temperatures. Assuming $\Delta T_g = 500$ °C as a condition for flashover, and air properties at 295 K, use Equation 30.71 and assume the compartment has heated for a period of time that exceeds the thermal penetration time.

$$\dot{Q} = 610\left(h_k A_T A_o \sqrt{H_o}\right)^{1/2}$$

where

$$h_k = \frac{k}{\delta} = \frac{0.48 \times 10^{-3}}{0.016} = 0.03 \text{ kW/m}^2\text{K}$$

$A_T = 45.72$ m^2
$A_o = 1.08$ m^2
$H_o = 1.8$ m

Therefore,

$$\dot{Q} = 610\left[(0.03)(45.72)(1.08)\left(\sqrt{1.8}\right)\right]^{1/2} = 860 \text{ kW}$$

Method of Thomas

Thomas uses the energy balance for the upper layer shown in Equation 30.8, where the gas flow rate out of the opening is approximated by [2]

$$\dot{m}_g \approx 0.5 A_o \sqrt{H_o} \tag{30.73}$$

Thomas develops an expression for $\dot{q}_{\text{loss}}$ which assumes the area for the source of radiation for roughly cubical compartments is $A_T/6$:

$$\dot{q}_{\text{loss}} \approx h_c\left(T_g - T_w\right)\frac{A_T}{2} + \varepsilon\sigma\left(2T_g^4 - T_{\text{floor}}^4\right)\frac{A_T}{6} \tag{30.74}$$

where

A_T = Total area of the compartment-enclosing surfaces (m^2)
h_c = Convective heat transfer coefficient (kW/m^2·K)
T_w = Temperature of the upper walls (K)
T_{floor} = Temperature of the floor (K)

From experimental data, Thomas developed an average for $\dot{q}_{\text{loss}}$ of 7.8 A_T. Using an upper layer temperature of 577 °C or a ΔT_g of 600 °C for flashover criterion and $c_p = 1.26$ kJ/kg·K yields an expression for the minimum rate of energy release for flashover:

$$\dot{Q} = 7.8 A_T + 378 A_o \sqrt{H_o} \tag{30.75}$$

Comparison of Methods for Predicting Flashover

Babrauskas has compared the effect of room wall area on the energy release required for flashover, using the above methods [28]. The results of his comparisons, along with some experimental data for rooms with gypsum board walls, are shown in Fig. 30.14. The graph shows the energy required for flashover as a function of compartment wall area, both normalized by the ventilation factor $A_o\sqrt{H_o}$. The method of Babrauskas used in this graph is based on Equation 30.32 with $T_\infty = 25$ °C and $T_g = 600$ °C. Babrauskas observes that over the range of compartment sizes of most

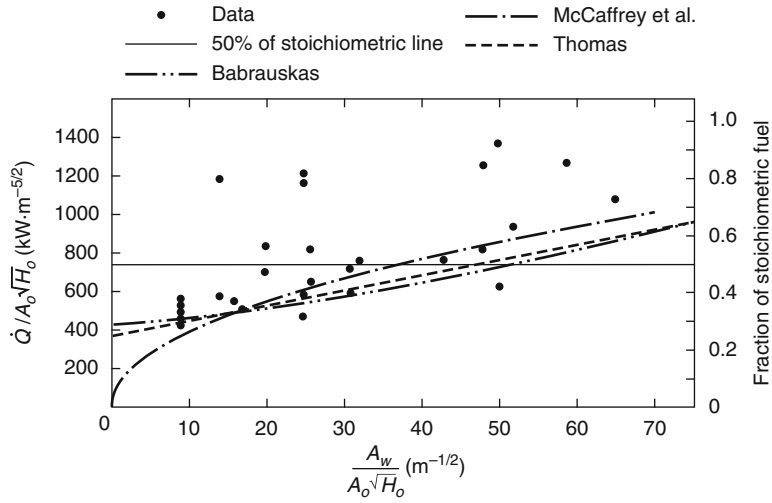

Fig. 30.14 The effect of room wall area (gypsum walls) on the heat required for flashover

interest, all of the methods produce similar results. The method of McCaffrey et al. diverts from the others for small room sizes. Babrauskas notes that all of the methods are a conservative representation of the data.

Nomenclature

$A_{ceiling}$	area of compartment ceiling (m^2)
A_f	pool fire area (m^2)
$A_{\mathbf{floor}}$	area of compartment floor (m^2)
$A_{\mathbf{o}}$	area of openings (m^2)
A_T	total area of the compartment enclosing surfaces (m^2)
$A_{\mathbf{walls}}$	area of compartment walls (m^2)
b_p	maximum combustion efficiency
c	specific heat of the wall (kJ/kg·K)
C_d	orifice constriction coefficient
c_p	specific heat of gas (kJ/kg·K)
D	compartment depth (m)
g	acceleration due to gravity, 9.8 m/s^2
h_c	convective heat transfer coefficient
Δh_c	effective heat of combustion of the fuel (kJ/kg)
h_g	heat transfer coefficient on the hot side of the wall (kW/m^{2}K)
h_k	effective heat transfer coefficient (kW/m^{2}K)
h_∞	heat transfer coefficient on the ambient side of the wall (kW/m^{2}K)
H_o	height of opening (m)
k	thermal conductivity of the wall (kW/m·K)
L	fire load, wood (kg)
m	mass of the gas in the compartment (kg/s)
$\dot{m}_a$	mass flow rate of air into an opening (kg/s)
$\dot{m}_g$	gas flow rate out the opening (kg/s)
$\dot{m}_f$	mass burning rate of fuel (kg/s)
$\dot{m}_{f,st}$	stoichiometric mass burning rate of fuel (kg/s)
$\dot{m}''_w$	mass per unit area of the wall (kg/m^2)
$\dot{q}_{\mathbf{loss}}$	net radiative and convective heat transfer from the upper gas layer (kW)
$\dot{Q}$	energy (heat) release rate of the fire (kW)
$\dot{Q}_{\mathbf{stoich}}$	stoichiometric heat release rate (kW)
t	time (s)
t_p	thermal penetration time (s)
T_b	liquid boiling point (K)
$T_{\mathbf{floor}}$	temperature of the floor (K)
T_g	temperature of the upper gas layer (K)
T_p	thermal penetration time (s)
T_w	wall temperature (K)
T_∞	ambient temperature (K)
W	compartment width (m)
W_o	width of opening (m)
X_d	height of the interface (m)
X_N	height of neutral plane (m)

Greek Letters

δ	thickness of the wall (m)
ε	emissivity of the hot gas
ρ	density of the wall (kg/m^3)
ρ_∞	ambient air density (kg/m^3)
σ	Stefan-Boltzmann constant, 5.67×10^{-11} kW/m^2·K^4

Subscripts

a	air
b	boiling
d	thermal discontinuity
f	fuel
g	gas
N	neutral plane
o	opening
stoich	stoichiometric
T	total
w	wall
∞	ambient

Superscripts

.	per unit time (s^{-1})
$''$	per unit area (m^{-1})

Zone Computer Fire Models for Enclosures

31

William D. Walton, Douglas J. Carpenter, and Christopher B. Wood

Introduction

Understanding the behavior of fire in compartments is of interest to the fire protection engineer for both fire safety design and postfire reconstruction. Such understanding may be obtained by examining experimental fires (full or reduced scale) or by *fire models* using mathematical techniques to represent the processes encountered in compartment fires by interrelated expressions based on physics and chemistry. The two major classes of fire models for analyzing enclosure fire development are stochastic and deterministic.

Stochastic or *probabilistic fire models* generally treat fire growth as a series of sequential events or states. Mathematical rules are established to govern the transition from one event to another (e.g., from ignition to established burning). Probabilities are assigned to each transfer point based on analysis of relevant experimental data, historical fire incident data, and computer model results. *Deterministic fire models* represent the processes encountered in fire by interrelated mathematical expressions based on physics and chemistry. These models may also be referred to as *room* or *compartment fire* models or *mathematical fire* models. Ideally, deterministic models represent the ultimate capability: the evaluation of discrete changes in any physical parameter in terms of the effect on fire hazard. The emphasis in this chapter is on deterministic fire models and, more specifically, zone fire models for enclosures.

Although manual or "hand calculation" methods provide reasonable estimates of specific fire effects (e.g., prediction of time to flashover), they are not well suited for comprehensive analyses involving the time-dependent and highly-coupled interactions of multiple physical and chemical processes present in growing compartment fires. With the advent of the personal computer in the 1980s came the development of computer fire models with increasing complexity. *Computer fire models* perform large numbers of tedious and lengthy calculations (in a fraction of the time required by "hand calculations") and can provide analytical solutions to problems that are impractical to solve manually or for which no simple closed form analytical solution exists. As early as 1985, it had become widely accepted that the future of fire engineering would include various levels of modeling aided by the modern computer [1]. Today, computer models are used in many areas of fire protection engineering, including suppression system design, smoke control system design, and egress analysis that all provide an engineering approximation of the time-varying conditions associated with fires.

The state of the art in computer fire modeling is evolving for two reasons: increases in fundamental knowledge or understanding of the processes and

increases in computer processing speeds. Increased understanding of the processes involved in fire growth improves the technical basis for the models. The capabilities, documentation, and support for a given model can change dramatically over a short period of time. In addition, computer technology itself (both hardware and software) is advancing rapidly. In the past, a large mainframe computer was required to use most available computer fire models. Today, most computer fire models can be run on personal computers. Despite the increased awareness and practical application of fire modeling, current computer-based models are not substantially different from their predecessors; they are just more complex and possess greater capabilities. This chapter will provide a description of the characteristics of zone models, an overview of selected models, and a discussion of the selection, validation, and application of such models.

Zone Models

The most common type of physically based fire model is the *zone* or *control volume* model, which solves the conservation equations (i.e., conservation of mass and energy) for discrete and relatively large control volumes. Although many zone models use two control volumes corresponding to an upper (hot) layer and lower (cool) layer, other zone models may have different approaches for specific problems such as a single control volume for postflashover modeling. A complete discussion of the fundamental principles behind the zone fire model formulation can be found in Chap. 29.

The beginnings of preflashover zone fire modeling can be traced to the mid-1970s with the publication of a description of the fundamental equations by Quintiere [2]. Based on these equations, the first zone fire model published was RFIRES by Pape, Waterman, and Eichler [3], followed shortly by the Harvard model by Emmons and Mitler [4, 5]. Following the publication of these two models, a number of zone fire models for mainframe computers were introduced. In 1985 ASET-B, the first zone model written specifically for the newly available IBM-compatible personal computer, was introduced by Walton [6]. Since that time additional models have been introduced, and most of the models written for mainframe computers have been converted for use on personal computers.

Zone models allow for relatively inexpensive parametric studies by providing results very quickly on modern computers. This capability allows for the combination of engineering judgment and deterministic modeling to isolate particular scenarios of interest when more in-depth field modeling is required to answer the ultimate questions posed for the modeling activity. This section discusses more specific characteristics of zone models that may assist the modeler in making an appropriate model selection.

The dominant characteristic of a zone fire model is the division of the compartment(s) or room(s) into a hot, upper layer and a cooler, lower layer (Fig. 1). The model calculations

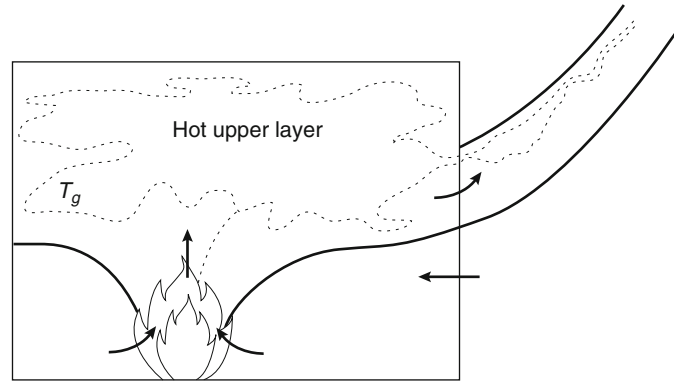

Fig. 1 Two-layer model with no exchange between layers except the plume

provide estimates of key conditions for each of the layers as a function of time. Zone modeling has proved to be a practical method for providing estimates of fire effects in enclosures.

The fundamentals of zone modeling require that a space, room, or compartment be broken up into various zones or control volumes to account for mass and energy driven by the fire. In addition to the room or compartment of origin, some models provide multiroom capability. In these cases, in addition to accounting for control volumes in the room of origin for heat and mass transfer as affected by the fire plume, a multiroom model also accounts for flows out of vents from one room into another or to the "atmosphere." In the room being exposed to fire conditions, where the mass and energy now flow from the compartment of fire origin, the vent plume adds mass and energy to a new control volume in this compartment being exposed.

Heat transfer within zone models focuses on buoyancy-driven flows. In most cases, this flow calculation is implicit as the hot gases produced by the fire are assumed to be instantaneously transported from the fire to the upper layer. Intrinsically, this implies that transport time details are lost in zone models. Some models also calculate the convective heat transfer from the hot layer to the surrounding compartment boundaries whereas others treat this as a lumped-mass loss coefficient, demonstrating how treatment of heat loss from the hot gases may be handled through multiple approaches.

Vent flow handling in zone models often only supports vents that carry horizontal flow and thus do not model holes in floors and ceilings. This restriction does not usually cause difficulty for many commonly occurring fire scenarios. Very early models often did not support vent flows at all. Vents were implicitly handled in the lower layer mathematically so that no pressure buildup occurred within the modeled space, which would have violated a variety of the basic assumptions. These early models were generally only applicable during the early phases of a fire or other limited situations. In addition to natural vents, some models support simulated heating, venting, and air conditioning (HVAC) duct work, in some cases supporting actual interconnections between rooms while in others only approximating overall supply and extraction without specifying interchange between rooms.

Some models attempt to overcome zonal limitations with specialized submodels in addition to the zonal approach. One example is the implementation of detection activation algorithms and the tracking of detection devices, such as fusible links, to predict activation. Other submodels include the switching of the employed governing equations based on the burning regime, such as fuel versus ventilation limited. This is an example of a conversion from a two-zone to a single-zone approach.

Some models add a variety of combustion and fire-related submodels. Pyrolysis and combustion products may be tracked in addition to oxygen to determine whether combustion can occur given the compartment conditions. If combustion is not possible due to lack of oxygen, for example, then these combustion products may ignite if they retain sufficient heat and progress to another compartment where the requisite oxygen is available. Similarly, models sometimes calculate radiative and convective heat transfer along with ignition temperatures of specific objects to predict involvement of additional fuel packages.

Overview of Selected Models

Although the state of the art in understanding fire processes has not yet developed the *ultimate* model, a number of available computer models provide reasonable estimates of selected fire effects. The reader is referred to Friedman [7] and Olenick and Carpenter [8] for a summary of available computer fire models and their general capabilities. The following brief summaries will focus on a representative selection of zone models rather than providing an exhaustive review of the changing state of the art in available computer models.

ASET

ASET (Available Safe Egress Time) is a program for calculating the temperature and position of the hot smoke layer in a single room with closed doors and windows [6]. ASET can be used to determine the time to the onset of hazardous conditions for both people and property. The required program inputs are the heat loss fractions, the height of the fuel above the floor, criteria for hazard and detection, the room ceiling height, the room floor area, a heat release rate, and a species generation rate of the fire (optional). The program outputs are the temperature, thickness, and (optional) species concentration of the hot smoke layer as a function of time and the time to hazard and detection. ASET, written in FORTRAN by Cooper and Stroup [9], can examine multiple cases in a single run. ASET-B is a compact version of ASET written by Walton [6] that was designed to run on personal computers. Species concentrations and time to hazard and detection calculated by ASET are not calculated in the compact ASET-B version.

COMPBRN III

COMPBRN III is primarily used in conjunction with probabilistic analysis for the assessment of risk in the nuclear power industry. The model is based on the assumption of a relatively small fire in a large space, or a fire involving large fuel loads during the early preflashover fire growth period. The model's strengths are (1) emphasis on the thermal response of elements within the enclosure to a fire within the enclosure, and (2) model simplicity. The temperature profile within each element is computed, and an element is considered ignited or damaged when its surface temperature exceeds the user-specified ignition or damage temperature. The model outputs include the total heat release rate of the fire, the temperature and depth of the hot gas layer, the mass burning rate for individual fuel elements, the surface temperatures, and the heat flux at user-specified locations. COMPBRN III was written by Ho et al. [10]

COMPF2

COMPF2 is a computer program for calculating the characteristics of a postflashover fire in a single building compartment, based on fire-induced ventilation through a single door or window. It is intended both for performing design calculations and for the analysis of experimental burn data. Wood, thermoplastics, and liquid fuels can be evaluated. A comprehensive output format is provided that gives gas temperatures, heat-flow terms, and flow variables. The documentation includes input instructions, sample problems, and a listing of the program. The program was written in FORTRAN by Babrauskas [11].

CONTAM

CONTAM is a multizone (nodal) indoor air quality and ventilation analysis computer program designed to predict: (1) airflows in building systems driven by mechanical means, wind pressures acting on the exterior of the building, and buoyancy effects induced by the indoor and outdoor air temperature difference; (2) the dispersal of airborne contaminants transported by airflows; and (3) the exposure of occupants to airborne contaminants. Unlike other fire models, zones in CONTAM are typically building areas connected by airflow paths. CONTAM was developed principally to predict nonfire related conditions within a building and does not have a fire routine; however, the user may specify the temperature in a zone. CONTAM can be useful for evaluating smoke management methods including compartmentation, dilution, pressurization, airflow, and buoyancy. CONTAM consists of two components, a graphical user interface (GUI) and a simulation engine. Once a building representation is developed with the GUI, it is passed to the simulation engine to calculate zone pressures, airflow rates, and contaminant concentrations. The interface also provides a means to graphically review results. CONTAM was written in C by Walton and Dols [12].

CSTBZ1

CSTBZ1 is a computer program for postflashover fires, based on similar basic assumptions as those of COMPF2. The equations of mass and energy conservation are written without neglecting the fuel source term, and several vertical openings in a room can be considered. The equation of heat diffusion into the walls is solved either by a classical explicit finite difference method, or by a new modal approach that offers the capability of storing in a file a few numbers characterizing a given wall, leading to a rapid calculation of the superficial wall temperatures. A sophisticated numerical algorithm was used to solve the equations through uncoupling. The program was written by Curtat and Bodart [13].

CFAST

CFAST (Consolidated model of Fire growth And Smoke Transport) is an upgrade of the FAST program [14] and incorporates numerical solution techniques originally implemented in the CCFM program [15]. CFAST is a multiroom model that predicts conditions within a structure resulting from a user-specified fire. CFAST Version 6 can accommodate up to 30 compartments with multiple openings between compartments and to the outside. The required program inputs are the geometry data describing the compartments and connections; the thermophysical properties of the ceiling, walls, and floors; the fire as a rate of mass loss; and the generation rates of the products of combustion. The program's outputs are temperature, thickness, and species concentrations in the hot, upper layer and the cooler, lower layer in each compartment. Also given are the surface temperatures and heat transfer and mass flow rates. CFAST also includes very limited mechanical ventilation capabilities, a ceiling jet algorithm, capability of multiple fires, heat transfer to targets, detection and suppression systems, and a flame spread model. The CFAST model was developed and is maintained by NIST [16, 17].

BRANZFIRE

BRANZFIRE is a two-zone fire model for predicting the fire environment in an enclosure resulting from a room-corner fire involving walls and ceilings. The zone fire model uses conservation equations based on those found in CFAST. BRANZFIRE predicts ignition, flame spread, and the resultant heat released by the wall and ceiling lining material subjected to a burner fire. The model considers upward flame spread on the walls and beneath the ceiling, lateral flame spread on the walls, and downward flame spread from the ceiling jet. Wall and ceiling flame spread properties are computed from cone calorimeter data. Program outputs include layer height, species concentrations, gas temperatures, visibility, wall temperatures, and heat release rate. BRANZFIRE was written in Visual Basic by Wade [18–20].

JET

JET is a two-zone single compartment model where the compartment is enclosed by a combination of draft curtains and walls. The ceiling may contain fusible links and vents where the vents operate in response to the fusing of the links. The ceiling vents remove hot, upper-layer gas from the compartment. The fire is characterized by a time-dependent heat release rate, a time-dependent radiative fraction, and either a constant or variable fire diameter, which is determined using a heat release rate per unit area for the burning material. Inputs also include the thermal properties of the ceiling. Program outputs include the ceiling jet temperature and velocity, link temperature, and activation times. JET was written in FORTRAN by Davis [21].

FIRST

FIRST is the direct descendant of the Harvard V5 program developed by Emmons and Mitler [4]. The program predicts the development of a fire

and the resulting conditions within a room given a user-specified fire or user-specified ignition. It predicts the heating and possible ignition of up to three targets. The required program inputs are the geometrical data describing the rooms and openings and the thermophysical properties of the ceiling, walls, burning fuel, and targets. The generation rate of soot must be specified, and the generation rates of other species may be specified. The fire may be entered either as a mass loss rate or in terms of fundamental properties of the fuel. Among the program outputs are temperature, thickness, and species concentrations in the hot, upper layer and the cooler, lower layer in each compartment. Also given are surface temperatures and heat transfer and mass flow rates. The FIRST program was written in FORTRAN by Mitler and Rockett [22].

FIRE SIMULATOR

FPETOOL is the descendant of the FIREFORM program [23]. It contains a computerized selection of relatively simple engineering equations and models useful in estimating the potential fire hazard in buildings. The calculations in FPETOOL are based on established engineering relationships. The FPETOOL package addresses problems related to fire development in buildings and the resulting conditions and response of fire protection systems. The subjects covered include smoke filling in a room, sprinkler/detector activation, smoke flow through (small) openings, temperatures and pressures developed by fires, flashover and fire severity predictions, fire propagation (in special cases), and simple egress estimation. The largest element in FPETOOL is a zone fire model called FIRE SIMULATOR. FIRE SIMULATOR is designed to estimate conditions in both pre- and postflashover enclosure fires. The inputs include the geometry and material of the enclosure, a description of the initiating fire, and the parameters for sprinklers and detectors being tracked. The outputs include the temperature and volume of the hot smoke layer; the flow of smoke from openings; the response of heat-actuated detection devices, sprinklers, and smoke detectors; oxygen, carbon monoxide, and carbon dioxide concentrations in the smoke; and the effects of available oxygen on combustion. FPETOOL was written in BASIC by Nelson [24].

FSSIM

FSSIM [25] is a single-zone model originally designed for fire hazard analysis of ships. It includes most of the features of the popular two-zone models but within a single zone fire environment description. It includes HVAC system model components, stack effect, prediction of compartment temperatures, and smoke and gas concentrations, as well as compartment to compartment fire spread, detection, and suppression. It has been applied to ships and buildings with several thousand compartments. Calculations are slower than CONTAM but still much faster than two-zone models and CFD models.

LAVENT

LAVENT (Link-Actuated VENT) is a two-zone model developed to simulate the environment and the response of sprinkler elements in compartment fires with draft curtains and fusible-link actuated ceiling vents. The zone model used to calculate the heating of the fusible links includes the effects of the ceiling jet and the upper layer of hot gases beneath the ceiling. The required program inputs are the geometrical data describing the compartment, the thermophysical properties of the ceiling, fire elevation, the time-dependent heat release rate of the fire, the fire diameter or the heat release rate per unit area of the fire, the ceiling vent area, the fusible-link response time index (RTI) and activation temperature, the fusible-link positions along the ceiling, the link assignment to each vent, and the ambient temperature. A maximum of five ceiling vents and 10 fusible links are permitted in the compartment. The program outputs are the temperature

and height of the hot layer, the temperature of each link, the ceiling jet temperature and velocity at each link, the radial temperature distribution along the interior surface of the ceiling, the activation tie of each link, and the area opened. LAVENT was written in FORTRAN by Cooper [26].

MAGIC

MAGIC is a two-zone fire model for simulations that predict the fire environment as a function of time resulting from a fire in single- or multicompartment geometries, based on a combination of macroscopic conservation equation and empirical correlations for specific phenomena [27]. The required program inputs include the compartment geometry; natural and mechanical ventilation; parameters describing the fire characteristics such as location, fuel type, footprint area, and stochiometric fuel-oxygen ratio; thermophysical properties and location; and any inputs for sprinklers or detectors. The extensive program outputs are customized by the user, but typically include environmental conditions, heat transfer–related outputs, oxygen effects, and flow velocities [28]. MAGIC is being extended to include nonrectangular rooms, convex and sloping ceilings, rooms cluttered with objects, spread of fire through ventilation ducts, and extinction. Although the program can be used for general fire modeling, it was originally intended for nuclear power plant applications. The program is developed and maintained by Electricité de France (EdF).

WPI/FIRE

WPI/FIRE is a direct descendant of the Harvard V [4] and FIRST [22] programs. It includes all of the features of the Harvard program version 5.3 and many of the features of the FIRST program. WPI/FIRE also includes the following additional features: improved input routine, momentum-driven flows through ceiling vents, two different ceiling jet models for use in detector activation, forced ventilation for ceiling and floor vents, and an interface to a finite difference computer model for the calculation of boundary surface isotherms and hot spots. The WPI/FIRE program was written in FORTRAN by Satterfield and Barnett [29], and additions to the program continue to be developed by graduate students at the Center for Fire Safety Studies, Worcester Polytechnic Institute.

BRI2

BRI2 is a two-layer, multi-compartment model to predict smoke spread through large buildings. In addition to conventional zone equations, it includes radiative and convective heat transfer between layers and wall enclosures and species yield prediction using equivalence ratio. For practical purposes, users can input the time-based events such as smoke vent activation, door opening by evacuees etc. The BRI2 program was written in FORTRAN by Tanaka et al. [30].

Selection, Validation, and Application of Zone Models

Selection

The appropriate selection of a zone fire model for a particular application requires significant attention since no existing zone fire model is best for all applications. Although most zone fire models are based on the same fundamental principles, available models can vary significantly in features and capabilities. Appropriate selection of a zone fire model requires sufficient understanding of the assumptions and limitations for any particular model. Frequently, experienced users will employ more than one model to evaluate a particular situation. If several models provide similar results this can increase (although not generally guaranteed) confidence in the results. A significant issue in selecting a zone fire model is model validation, a process by which to assess the predictive capabilities and accuracy of a fire model.

The predictive capability of any model depends on the underlying scientific knowledge and understanding of the phenomenon being modeled and the translation of that knowledge and understanding into a mathematical model. This knowledge may be based upon well-established fire science, secure empirical correlations, or, if these are not available, then the best engineering judgment that can be made [1]. Due to its complexity, there remain substantial voids and shortcomings in the scientific understanding of combustion and fire and associated processes. Obviously, the current level of knowledge supports the development of mathematical models with sufficient predictive capabilities. It is not necessary to understand a phenomenon in every respect in a pure scientific context to exploit the current level of understanding for design and practice purposes. In fact, zone fire models take advantage of "imperfect" knowledge and simplifying assumptions to yield practical and useful results.

Despite imperfect knowledge and simplifying assumptions, properly applied zone models have been shown to be a source of good engineering approximations of fire development within enclosures. Thus, comparison of zone fire modeling results with experimental data is valuable for determining the applicability of a model to a particular situation in the model selection process. As with any fire model, published comparisons of zone fire model results with experimental data are somewhat limited when compared to the range of possible applications.

Validation

With respect to the validation of fire models, ASTM 1355, "Standard Guide for Evaluating the Predictive Capability of Deterministic Fire Models," [31] sets forth a methodology for analyzing a computer fire model, examining two broad conceptual categories. The first category relates to the foundation of the model—its theoretical basis, mathematical equations, and numerical methods. The second category relates to sensitivity, comparison between data and predictions, and actual calculations performed by users. This analysis is ideally performed by the model developer but is sometimes undertaken by other individuals or organizations, such as the Society of Fire Protection Engineers analysis of the thermal detector actuation model DETACT [32]. A critical use of the methodology in ASTM 1355 is to identify sensitive variables associated with the model and to consider those sensitive variables that may have a significant effect in a fire safety design application. They therefore allow an analyst to consider the commensurate uncertainty in the predicted values relating to the input uncertainty and further allow designers to determine safety factors on a more considered basis.

Application

Zone models have enjoyed wide application and general acceptance due to their relatively simplified approach to the modeling problem. Zone fire models have been used or commissioned by engineers and architects, building officials, the fire service, fire investigators, building and fire code developers, materials and systems manufacturers, fire researchers, and educators. Application and use of zone fire modeling include performance-based fire safety design, postfire reconstruction, and fire risk assessment.

With respect to performance-based fire safety design, some fire protection engineers have been able to develop alternative equivalent approaches to meeting the prescriptive requirements of codes through the use of zone fire models. Other applications have utilized zone fire models in fire hazard analyses to develop engineered fire mitigation strategies for unique situations in which a prescriptive approach would not have met specific fire loss criteria. The problem of postfire reconstruction lends itself readily to the use of fire models. Several fire reconstruction case studies of fire incidents using computer models have been published [33–36].

Although zone models have experienced the lion's share of practical applications, the use of

more complex computer fire models has and will continue to increase. This evolution will not render zone models obsolete in everyday practice due to their significant advantages in solving a subset of engineering problems.

In 2011, the Society of Fire Protection Engineers published its engineering guide titled "Guidelines for Substantiating a Fire Model for a Given Application" [37]. Similar to the SFPE's guide on performance-based design, the document recommends a workflow for the modeler. This workflow is captured in a flowchart shown in the document's introduction. As is true with the scientific method, generally, the first step is to define the problem. This is, in fact, a critical step to successful computer fire modeling.

In the absence of a well-defined problem and the applicable parameters that apply to that problem, the next step of selecting a candidate model is unlikely to be properly performed. Running the wrong model may leave the modeler to inaccurate, unreliable, or inapplicable results. However, one of the benefits of using zone models on modern computers is to generally be able to run multiple models in a very short period of time. This can also be done to get preliminary results to better develop the parameters and boundary conditions for use in a fire model requiring much greater time to run, such as a field or CFD model.

The guide goes further to discuss uncertainty and user effects related to model results. Some key studies are discussed as representative of the type of analysis to be considered by the modeler during the work. Some of this work comes out of verification and validation performed by modelers as well as independent studies considering model accuracy. Beyond the specific studies cited, the guide provides recommendations for addressing the uncertainty and user effects. For example, sensitivity and bounding analyses, among others, are methods for examining user effects and their impact on a particular analysis.

Finally, the Guide suggests documenting the findings from this work for use by reviewers, AHJs, and future users of the model results. It addresses the specific concepts of problem definition, candidate model evaluation, verification and validation of the key physics, and evaluating user effects and uncertainties. Good documentation of the modeler's activities in this regard and using the Guide's framework, while helping future reviewers for users of the work, will also benefit the modeler in providing completeness and thoroughness of the model activities.

Modeling Fires Using Computational Fluid Dynamics (CFD)

32

Kevin McGrattan and Stewart Miles

Introduction

It was in the early 1920s that Lewis Richardson first demonstrated the feasibility of solving, using numerical methods, the governing equations of fluid flow [1] for the purpose of weather prediction. It was not for another 50 years that what is now known as computational fluid dynamics (CFD) emerged as a general analysis tool for the full breadth of fluid flow problems including those associated with fire.

In contrast to zone models, the techniques of CFD evolved outside the fire community and were subsequently imported into it. The same basic CFD technology is being developed, applied, verified, and validated for a wide range of applications. Problems and successes demonstrated elsewhere can often be exploited in the fire context, although there are many issues that are unique to fire that can only be the responsibility of the fire community. The same tools that are used to study, for example, heat transfer in an internal combustion engine can also be used to evaluate indoor air movement, early detection of smoke, and the dispersion of combustion products within the atmospheric boundary layer.

CFD provides the potential to study these complicated problems that are only partially amenable to reduced-scale physical modeling because of the large number of non-dimensional groups that need to be preserved to simulate full-scale behavior. Furthermore, CFD has emerged as an important tool because the assumptions employed in zone models limit their range of application to relatively simple fire scenarios that can be described in terms of a small number of idealized components (e.g., unperturbed fire plume, unconfined ceiling jet, uniform hot gas layer).

The starting point for CFD models is the set of partial differential equations that assert conservation of mass, momentum, and energy within the fire and throughout the space surrounding it. These equations are solved numerically to yield time-varying predictions of temperature, gas velocity, gas species concentrations, and so forth, on a three dimensional mesh of control volumes that spans the geometry being modeled. Unlike two zone models, CFD models enforce the conservation laws in each of the thousands or millions of relatively small control volumes. However, the exact solution of the governing equations, resolving fully the length and time scales that occur in the turbulent flows associated with fire, is still beyond the capabilities of even the largest computers currently available. To capture the details of the chemical processes of a fire would require spatial resolution of less than 1 millimeter. As a consequence, it is necessary to modify the governing equations to model the

DOI 10.1007/978-1-4939-2565-0_32, © Society of Fire Protection Engineers 2016

unresolvable turbulence. Two main approaches are currently employed in CFD simulations of fire: large eddy simulation (LES) and Reynolds-averaged Navier-Stokes (RANS) equations, which are described later in this chapter.

In addition to the uncertainties associated with the modeling of turbulent flow, others are introduced by the description of combustion chemistry; radiation; and mass, momentum, and heat transfer at solid boundaries. Further complexity is introduced in the numerical solution of the equation set in which the choice of numerical schemes and the resolution of the numerical mesh strongly influences the quality of the CFD solution. An appreciation of all these issues is important in the successful exploitation of CFD to solve fire problems. It should be recognized that this topic is rapidly evolving and that this chapter can only represent a "snapshot" in time. Whereas a thousand mesh points constituted a detailed CFD solution in the early 1980s, simulations using millions of mesh points are now routine. This number can be expected to increase further, especially as parallel processing becomes more widespread. However, although the modeling of smoke transport may be considered reasonably mature, there remains considerable research and development still to be done with some of the more complex issues related to the underlying combustion and fire science (e.g., flame spread, oxygen vitiation, soot formation, and water suppression). Here the challenges remain considerable and will not be satisfactorily solved for some time yet.

This chapter does not provide a comprehensive description of CFD. There are already numerous introductory textbooks on the subject [2, 3, 4, 5, 6]. Depending on the background of the author(s), these books tend to emphasize techniques developed for particular fields of science and engineering, such as aerospace, meteorology, or combustion. Discussion of issues related to the modeling of fire can be found in review articles by Cox [7, 8] and Novozhilov [9]. Finally, a comprehensive description of the specific algorithms used by a particular CFD model can only be found within the manuals that accompany the software. A recent review by Olenick and Carpenter [10] lists about a dozen CFD models developed specifically for fire. Some of these models were developed for specific fire scenarios or phenomena. Others were developed to handle a variety of fire scenarios, including JASMINE from the Fire Research Station (UK), the Fire Dynamics Simulator (FDS) from NIST (US) and VTT (Finland), SMARTFIRE from the University of Greenwich (UK), and SOFIE, the product of a European consortium. A more recent development is the FireFOAM model from FM Global, which is based on the open source CFD code OpenFOAM. There are also general-purpose CFD models that have been used for fire simulations. These computer programs contain tens to hundreds of thousands of lines of instructions, along with manuals that contain hundreds of pages of documentation of the development, algorithms, and validation of the models.

This chapter provides an introduction to the theory and practice of computational fluid dynamics as applied to the study of fire. Although the mathematical framework for the subject is more than 100 years old, it is only in the past 20 years that computers have become fast enough to make the models practical.

Governing Equations

This section presents the conservation equations of mass, momentum, and energy that constitute the core of any CFD model. The derivation of these equations can be found in any textbook on the subject and will not be included here. Instead, a discussion of the various techniques used to make these equations tractable for numerical solution will follow. The most important of these is the turbulence model, a subject of considerable study and debate.

Conservation Equations

The conservation equations for mass, momentum, and energy for a mixture of gases are briefly

described here. A particularly useful reference for a more detailed description of the equations, the notation used, and the various approximations employed is Anderson et al. [2].

Conservation of Mass

The conservation equation for mass is

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{u} = 0 \tag{32.1}$$

This equation is nothing more than a statement that mass is neither created nor destroyed. In words, the change in the density, ρ, at a given point in the flow field is equal to the net mass flux, $\rho\mathbf{u}$, across the boundary of a small control volume surrounding the point. For fire simulations, it is usually necessary to account explicitly for various individual gaseous species, for example, fuel and oxygen. Thus, the mass conservation equation is often written as a set of transport equations for the mass fractions of the individual gaseous species, Y_α:

$$\frac{\partial (\rho Y_\alpha)}{\partial t} + \nabla \cdot (\rho Y_\alpha \mathbf{u}) = \nabla \cdot (\rho D_\alpha \nabla Y_\alpha) + \dot{m}'''_\alpha \tag{32.2}$$

When all of the species equations are added together, the mass diffusion and production terms on the right-hand side sum to zero, leaving the original mass conservation equation.

Conservation of Momentum

The conservation equation for momentum is

$$\frac{\partial (\rho \mathbf{u})}{\partial t} + \nabla \cdot (\rho \mathbf{u}\mathbf{u}) = -\nabla p + \mathbf{f} + \nabla \cdot \tau \tag{32.3}$$

The momentum equation is written in compact notation here to emphasize that it is essentially Newton's Second Law of Motion, or simply Force = Mass × Acceleration. The forces that drive the fluid consist of the pressure gradient, ∇p, friction (in the form of the viscous stress tensor, τ), and external force terms, $\mathbf{f}$, such as buoyancy. A complete expansion of the various terms can be found in the appendix.

Conservation of Energy

The conservation equation for energy is

$$\frac{\partial (\rho h)}{\partial t} = \nabla \cdot (\rho h \mathbf{u}) = \frac{Dp}{Dt} + \dot{q}''' - \nabla \cdot \mathbf{q} + \varepsilon \tag{32.4}$$

As in the mass conservation equation, the sensible enthalpy, h, at a given point changes according to the net energy flux across the boundary of a small control volume surrounding the point. Now, however, there are additional source terms on the right-hand side of the equation related to the pressure, combustion heat release rate, radiation and conduction, and kinetic energy dissipation, respectively. For fire applications, the contributions from the pressure term and the dissipation term are negligible, except in situations where the compartment of interest is sealed and the pressure rises substantially.

Equations 32.1 through 32.4 constitute a set of partial differential equations for the density (or component mass fractions), velocity, pressure, and sensible enthalpy of the fluid. The momentum equation is actually three equations for the three components of velocity: u, v, and w making five equations for six unknowns. To close the system, an *equation of state* is needed to relate the pressure, p, and sensible enthalpy, h. The latter is a function of the specific heat and temperature of the fluid:

$$h = \int_{T_0}^{T} c_p \, dT \tag{32.5}$$

For most fire applications, it is sufficient to assume a *perfect gas*:

$$p = \frac{\rho \Re T}{\overline{W}}; \quad \overline{W} = \frac{1}{\sum (Y_\alpha / W_\alpha)} \tag{32.6}$$

where $\Re$ is the universal gas constant and $\overline{W}$ is the average molecular weight of the gas mixture.

Additional Assumptions

The foregoing equations form the basis for a wide variety of engineering applications but not

without the further application of simplifying assumptions unique to each field. The only assumptions made thus far are that the fluid is a perfect gas and that the viscous stress is linearly dependent on the strain. A further approximation can be made here, exploiting the fact that fire-driven flows are substantially slower than the speed of sound. By assuming that the pressure is constant (or at most a time-varying average) in the equation of state and the energy equation, the number of unknowns is reduced from six to five, as temperature can now be found from the density. More importantly, there is no longer a need to account for pressure fluctuations that propagate at the speed of sound, a fact that makes the numerical solution of the equations more tractable because the time step size is limited only by the flow speed, not the sound speed [11].

In the sections to follow, additional assumptions will be imposed on the governing equations to apply them to fire and other low-speed thermal processes. Most important is the treatment of the diffusive and source terms that distinguishes one type of CFD model from another.

Turbulence Modeling

The governing conservation equations describe the transport of mass, momentum, and energy via convection and diffusion (material diffusivity, viscosity, thermal conductivity). In large-scale fire applications, convection is the primary mode of transport of heat and combustion products, but the diffusive processes play a significant role in the flames and in boundary layers near solid surfaces. Capturing the large-scale convective transport and the small-scale diffusive processes in the same simulation requires too much computation, even for current-generation computers. Consequently, most practical fire simulations employ models to describe subgrid-scale, or "unresolvable," phenomena. The most important of these are the turbulence models.

The most popular numerical techniques for approximating the governing equations are roughly categorized according to their spatial and temporal fidelity: direct numerical simulation (DNS), Reynolds-averaged Navier-Stokes (RANS), and large eddy simulation (LES). DNS is really nothing more than a direct numerical solution of the governing equations. RANS and LES employ models of the unresolved subgrid dissipative processes. RANS averages over relatively large spatial and temporal scales than those that are characteristic of the given numerical grid or the fundamental frequency of the fire, whereas LES attempts to compute as much of the "resolvable" length and time scales (i.e., the "large eddies") as possible.

Direct Numerical Simulation (DNS)

Direct numerical simulation (DNS) means that the governing equations are solved numerically with no modifications to the form presented above, which implies that all of the relevant temporal and spatial scales are resolved directly without invoking any models to represent the diffusive terms, like the viscosity, thermal conductivity, and material diffusivity. Because this technique demands very fine spatial and temporal resolution (less than 1 mm and 1 ms, respectively), it is limited to small laminar flames and sometimes small turbulent jets. DNS is still not practical for large-scale fire simulations, and nothing more is included in this chapter on the subject.

Reynolds-Averaged Navier-Stokes (RANS)

The approach to modeling turbulence in many commercial and fire-specific CFD models is to solve a statistically time-averaged form of the conservation equations, often referred to as the Reynolds-averaged Navier-Stokes (RANS)[1]

[1] A density-weighted variant of Reynolds averaging (Favre averaging) is often necessary for the treatment of regions where density fluctuations have a significant effect. This variant is not usually necessary for smoke movement studies but can be important close to the fire source. This treatment is not presented here but can be found in, for example, Cox [7].

equations after Osborne Reynolds who introduced the idea over a century ago. The starting point in Reynolds averaging is to decompose the velocity components, enthalpy, and species mass fractions, into a time-averaged component (denoted by an overbar) and a fluctuating component (denoted by a prime):

$$\phi(\mathbf{x},t) = \bar{\phi}(\mathbf{x},t) + \phi'(\mathbf{x},t) \tag{32.7}$$

Notice that for transient flows the time-averaged component is still a function of time, representing the evolution of the mean flow field. In typical fire simulations, the time scale associated with the time-averaged component is on the order of several seconds, whereas that of the fluctuating component is on the order of milliseconds. Substituting the decomposed primitive variables into the conservation equations (Eqs. 32.1, 32.3, and 32.4) and then applying the same time-averaging process to the entire system of equations yields a set of equations that is similar in form to the original equations, with the mass conservation equation remaining unchanged:

$$\frac{\partial(\rho\bar{\mathbf{u}})}{\partial t} + \nabla\cdot(\rho\bar{\mathbf{u}}\bar{\mathbf{u}}) = -\nabla p + \mathbf{f} + \nabla\cdot\bar{\tau} - \nabla\cdot\rho\overline{\mathbf{u}'\mathbf{u}'} \tag{32.8}$$

$$\frac{\partial(\rho\bar{h})}{\partial t} + \nabla\cdot(\rho\bar{h}\bar{\mathbf{u}}) = \frac{Dp}{Dt} + \dot{q}''' - \nabla\cdot\bar{\mathbf{q}} + \bar{\varepsilon} - \nabla\cdot\rho\overline{\mathbf{u}'h'} \tag{32.9}$$

Notice that the Reynolds-averaging process has introduced additional terms on the right-hand sides of the equations and increased the number of unknowns. Thus, the system of equations is no longer closed (i.e., there are more unknowns than equations). The additional terms are referred to as the Reynolds stresses and the turbulent scalar flux, respectively. The scalar, h, is the sensible enthalpy, and similar equations can be derived for the other scalars (e.g., gas species mass fractions). Note that the pressure and density in the preceding equations refer to their time-averaged components.

The majority of commercial and fire-specific CFD models that employ the RANS approach use an eddy viscosity turbulence model to close the set of equations. The basic idea is that the unresolved, turbulent fluctuations can be modeled with diffusive terms that effectively represent the dissipation of turbulent energy:

$$-\rho\overline{u_i'u_j'} = \mu_t\left(\frac{\partial\bar{u}_i}{\partial x_j} + \frac{\partial\bar{u}_j}{\partial x_i}\right) - \frac{2}{3}\delta_{ij}\rho k$$
$$\delta_{ij} = \begin{cases} 1 \text{ if } i = j \\ 0 \text{ if i} \neq \text{j} \end{cases} \tag{32.10}$$

$$-\rho\overline{u_j'h'} = \lambda_t\frac{\partial\bar{h}}{\partial x_j} \tag{32.11}$$

Here μ_t is the turbulent (eddy) viscosity, k the turbulent kinetic energy, and λ_t the turbulent diffusivity, which is related to the eddy viscosity by the expression

$$\lambda_t = \frac{\mu_t}{\sigma_t} \tag{32.12}$$

where σ_t is known as the turbulent Prandtl or Schmidt number, depending on whether the scalar quantity is an energy or species variable. It is usually assigned a constant value depending on the scalar variable in question.

For fire simulations, a two-equation eddy viscosity model is commonly used. This model, in effect, allows the turbulence to be characterized by a velocity and a length scale that varies at each grid cell in the computational domain. The two equation model that is employed in the majority of RANS applications in fire engineering is the k-ε model. Here two additional transport equations are solved; one for the turbulent kinetic energy, k, and one for its rate of dissipation, ε. These quantities form the turbulent viscosity in Eq. 32.10:

$$\mu_t = \rho C_\mu\frac{k^2}{\varepsilon} \tag{32.13}$$

The factor C_μ is an empirical constant. Details of these equations are provided in CFD textbooks. Note that a modification of the basic k-ε model is often made in fire applications, in which buoyancy source terms for the k and ε equations are added. These terms ensure that the effects of

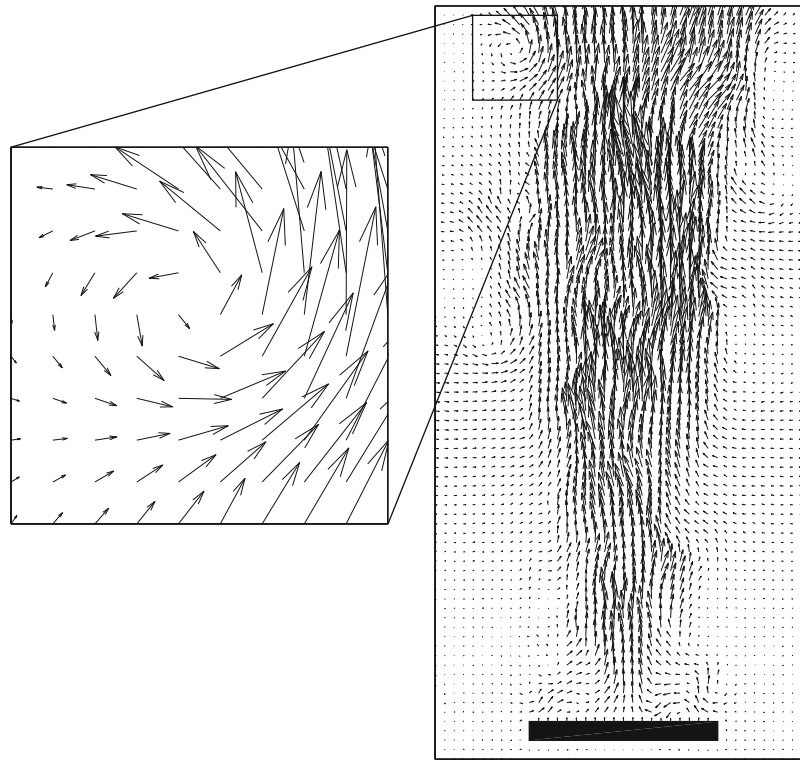

Fig. 32.1 What is meant by "resolvable." At *right* is an instantaneous map of the flow vectors for an LES simulation of a helium plume. the *inset* shows the smallest "eddy" that can be supported by the numerical grid, the spacing of which is indicated by the distance between the *arrows*

stable stratification in hot gas layers and the destabilizing thermal gradients in rising plumes are adequately described. Details are discussed by Cox [8].

The k-ε model has been used successfully for many engineering applications. Its limitation in treating, for example, swirling flows, flow separation, and so on is due partly to the inherent assumption that the modeled turbulence is isotropic, that is, that the unresolved flow field has no cohesive structure. There are a number of variants of the k-ε model, available in commercial CFD models, that claim to provide improved results for some flows (e.g., the RNG k-ε model [12] and the k-ω model [13]). Research into nonlinear eddy viscosity turbulence models that attempt to incorporate directional effects is being undertaken within the CFD community but, as far as the authors are aware, have not been applied to fire problems. Another approach, applied mainly outside of fire, is to solve individual differential equations for Reynolds stresses and turbulent scalar fluxes that appear in Eqs. 32.8 and 32.9. However, the standard k-ε model remains the most commonly used RANS technique in fire applications.

Large Eddy Simulation (LES)

The derivation of LES models is very similar to that of the RANS models, albeit with subtle differences in the interpretation of the decomposition of the primitive variables. RANS emphasizes temporal averaging, whereas LES emphasizes spatial averaging, or *filtering*. Regardless, the mechanics of the derivation are essentially the same, and the simplest of the LES models makes the same "eddy viscosity" argument in replacing the unresolved convection terms with diffusion terms. The key difference between the techniques lies in the magnitude of the diffusive coefficient, the "eddy" viscosity. With LES, one attempts to resolve the flow field as faithfully as possible on a given numerical grid. In other words, flow structures, like swirling

eddies, can span just a few grid cells (Fig. 32.1). To achieve this result, the eddy viscosity must be small enough to avoid smoothing out these small, but resolvable, eddies, but large enough to ensure numerical stability and account for the dissipation of energy at sub-grid scales.

To better understand the eddy viscosity model, the original Navier-Stokes equations are examined. An evolution equation for the kinetic energy of the gas is formed by taking the dot product of the momentum from Eq. 32.3 and the velocity vector **u**:

$$\rho \frac{D\mathbf{u}}{Dt} \cdot \mathbf{u} \equiv \rho \frac{D(|\mathbf{u}|^2/2)}{Dt} = \cdots - \epsilon \qquad (32.14)$$

A term emerges on the right-hand side known as the dissipation rate (see appendix for details):

$$\epsilon \equiv \tau \cdot \nabla \mathbf{u} = \mu \left[2 \left(\frac{\partial u}{\partial x} \right)^2 + \cdots \right] \qquad (32.15)$$

which appears as a source term in the energy conservation equation 32.4:

$$\frac{D}{Dt}(\rho h) = \cdots + \epsilon \qquad (32.16)$$

Extra terms have been hidden to make the point more clearly, and no approximations have been introduced thus far to the Navier-Stokes equations. This exercise merely explains in mathematical terms how the kinetic energy of the flow is converted into thermal energy by the action of the viscosity, μ. In the early 1960s, a meteorologist named Smagorinsky [14] suggested, based mainly on dimensional arguments, that the effect of the viscosity could modeled by a "turbulent" viscosity coefficient:

$$\mu_t = \rho (C_s \Delta)^2 \left[2 \left(\frac{\delta \bar{u}}{\delta x} \right)^2 + \cdots \right]^{\frac{1}{2}} \qquad (32.17)$$

where C_s is an empirical constant, Δ is a filter length comparable to the size of a grid cell, and the expression in brackets has the same functional form as the kinetic energy dissipation rate. The notation $\delta\bar{u}/\delta x$ emphasizes that the turbulent viscosity is calculated from finite difference approximations of the gradients of the computed velocity components. The other diffusive parameters, the thermal conductivity and material diffusivity, are related to the eddy viscosity through the expressions

$$k_t = \frac{\mu_t c_p}{\mathrm{Pr}_t}; \quad D_t = \frac{\mu_t}{\rho \, \mathrm{Sc}_t} \qquad (32.18)$$

The "turbulent" Prandtl and Schmidt numbers are assumed to be constant and of order unity. The appeal of LES is that no additional equations need be solved, as in the RANS k-ε model, and that the dynamics of the fire are captured in the simulation, rendering a more realistic-looking flow field than the time-averaged RANS model. The drawback of LES is that it demands that the model user pay close attention to the choice of numerical grid because the accuracy of the technique can be degraded significantly if there are not enough grid cells to describe the flow field adequately. Various perspectives on LES in general can be found in Pope [15].

Other Approaches

Detached eddy simulation (DES), formulated originally by Spalart et al. [16], combines the RANS and LES approaches discussed above. At solid boundaries and locations where the turbulent length scale is less than the mesh dimension the RANS treatment for turbulence is employed. At other locations, where the mesh is suitably resolved, LES modeling is employed. This approach has the potential benefit of reducing the overall mesh requirement to achieve a given level of turbulent flow resolution. The mesh generation process, however, tends to be more challenging.

A fundamentally different approach to CFD is provided by the so-called Lattice-Boltzmann method (LBM). Instead of the Navier-Stokes equations, the discrete Boltzmann equation is solved in which the fluid is treated as a set of particles rather than as a continuum. These particles are tracked numerically through a

discrete lattice mesh that encompasses the domain of interest, and are allowed to collide with each other and the bounding surfaces. While LBM models offer some advantages over traditional CFD, in particular in respect to complex geometries and parallel computing, the authors are not aware of the application of the Lattice-Boltzmann method to fire problems, and it is not discussed any further.

Source Terms and Boundary Conditions

The governing conservation equations discussed previously do not pertain only to fire scenarios. What constitutes a "fire model" are the conservation equations plus a set of boundary conditions and source terms describing mass, momentum, and energy exchange between hot gases and compartment walls, the reaction of fuel and oxygen, the redistribution of energy by thermal radiation, the spray of water from a sprinkler, the activation of a smoke detector, and dozens of other phenomena that occur in a burning building. Describing these phenomena mathematically is what modeling is all about. In the sections to follow are brief discussions of the boundary conditions and source terms found in the governing equations.

Combustion

The reaction of fuel and oxygen and the associated entrainment of air into the fire plume is the driving source term in the model. The simplest approach to modeling combustion is to ignore the chemistry and assume that the heat is released within a prescribed volume. This may suffice for some applications (e.g., smoke movement associated with a well-ventilated fire), provided a reasonable volume is selected for the release of heat. However, for fire scenarios where the combustion region cannot be predefined or the chemistry becomes important, a combustion model should be employed. The calculation of chemical species is required, for example, where oxygen availability is an important factor or where the composition of the gas mixture is required for the radiation model.

Most engineering models assume that the combustion process can be represented as a single, one-step reaction between fuel and oxygen forming a mixture of products including the major species CO_2 and H_2O and minor species like soot and CO:

$$\mathrm{F} + s\,\mathrm{O_2} \rightarrow \mathrm{P} \tag{32.19}$$

This model is appropriate provided that the detailed kinetics are not important and that the product yields are known from experiment. If the prediction of minor product species such as CO is required, then the assumption of fast, single-step chemistry is no longer valid and a more sophisticated approach is required. An example of such an approach is given at the end of this section.

The most widely used combustion models for fire applications are the Eddy Break-Up (EBU) model of Spalding [17], and the closely related Eddy Dissipation Concept (EDC) devised by Magnussen and Hjertager [18]. The models assume that the consumption of fuel, $\dot{m}_f'''$, is controlled by the rate of molecular mixing of reactants, which in turn is proportional to the rate of dissipation of turbulent eddies:

$$\dot{m}_f''' = -\frac{C\,\rho}{\tau_{\mathrm{mix}}}\min\left\{Y_f, \frac{Y_{\mathrm{O_2}}}{s}\right\} \tag{32.20}$$

C is a dimensionless empirical constant and $\tau_{mix} \approx k/\epsilon$ is the mixing time. RANS and LES models treat the turbulent kinetic energy, k, and the dissipation rate, ε, differently, but the basic idea is the same in both types of models. The heat release rate is obtained by multiplying the fuel mass consumption rate by an effective heat of combustion. Equation 32.20 may be augmented by an additional term involving the products of combustion and also by an Arrhenius expression to limit the rate of reaction in cold mixtures. The EBU and EDC models have the merit of simplicity while permitting heat to be released over a distributed volume determined by the enclosure

geometry and availability of air. Furthermore, the phenomenon of flame lengthening as a consequence of ventilation control is incorporated by this modeling approach. It has been applied with reasonable success by Miles et al. [19] and Holen et al. [20] as it has been in other areas of combustion engineering.

The hazard posed by high temperatures and the loss of visibility due to fire may be compounded by exposure to toxic gases such as carbon monoxide or hydrogen cyanide. Although advanced combustion models may include the capability to predict some of these toxic gas species, it is generally necessary in fire engineering to prescribe the species yields. In other words, the production rate of smoke and other combustion products is usually specified by the user based on experimental measurements. Predicting, rather than specifying, the generation of species such as CO, HCN, and soot requires finite rate chemistry to be included in the combustion model. An approach that has been exploited in a number of fire studies is to assume that the flame is a statistical ensemble of thin laminar flamelets that incorporates detailed chemistry from either experimental measurements or detailed kinetic calculations. Details of this approach may be found in Peters [21] and in the references of Cox [8] and Novozhilov [9]. Magnussen and Hjertager [18] extended the eddy breakup model to include soot formation and oxidation, using the mechanisms suggested by Tesner et al. [22]. This involved the solution of two further transport equations. Soot modeling is, however, difficult and not generally included within current CFD fire computations and remains a topic for research.

Radiation Heat Transfer

The governing conservation equations of mass, momentum, and energy describe the convection and diffusion of hot gases from a fire. However, the redistribution of energy via thermal radiation is very important and needs to be included in the energy transport equation 32.4. What makes radiation heat transfer particularly difficult from a numerical point of view is that radiant energy is propagated at the speed of light, as opposed to the speed of the gas flow or the speed of sound. Numerical flow solvers typically advance the solution of the governing equations using time steps that are constrained either by the flow speed (low Mach number LES) or time steps that are consistent with large-scale changes in the environment (RANS). In either case, the speed of light is essentially infinite; thus, radiant energy is assumed to redistribute itself instantaneously. The simplest model of radiation transport assumes that the gases are non-scattering (the gases only absorb or emit thermal radiation) and gray (the radiation has no spectral dependence). Under these assumptions, the governing equation can be written as

$$\mathbf{s} \cdot \nabla I(\mathbf{x}, \mathbf{s}) = \kappa(\mathbf{x}) \left[I_b(\mathbf{x}) - I(\mathbf{x}, \mathbf{s}) \right] \qquad (32.21)$$

Here, I is the *radiant intensity*, a function of both position, $\mathbf{x}$, and direction, $\mathbf{s}$. The gray-gas assumption neglects the fact that I is also a function of the wavelength, as are the absorption coefficient, κ, and the source term, I_b. To account for wavelength dependence, Eq. 32.21 must be solved over discrete "bands" of the electromagnetic spectrum [23]. However, in fires, soot is the principal emitter and absorber of thermal radiation. Because its radiation spectrum is continuous, it is often assumed that there is no spectral dependence; that is, the participating medium is gray.

Even in its simplest form, the radiation transport equation poses two challenges to the modeler: (1) the prescription of the spatially dependent absorption coefficient, $\kappa(\mathbf{x})$; and (2) the numerical solution. As for the latter, a number of methods have emerged that involve discretizing the equation into a finite number of solid angles and sweeping over the numerical grid until the radiant energy is redistributed. The process is often done gradually over several time steps of the flow solver, depending on the level of temporal fidelity desired. Usually, equivalent or greater temporal resolution is demanded by the flow solver, easing the computational burden of the radiation solver [24].

The prescription of the absorption coefficient, $\kappa(\mathbf{x})$, is challenging because it combines the contributions of soot and gaseous exhaust products. Soot is the main emitter and absorber in practical fire scenarios; thus, any model for must account for it. This requirement has caused difficulties over the years because contributions from the combustion community often emphasize the spectrally dependent properties of CO_2 and H_2O rather than the spectrally independent properties of soot. The dominance of soot in the radiation calculation simplifies the prescription of κ, but at the same time it demands a better description of soot growth and oxidation than the current practical fire models are able to provide.

Regardless of the choice of absorption coefficient and numerical method, the solution of the radiation transport equation is added to the overall solution via a source term in the energy equation 32.4:

$$-\nabla \cdot \mathbf{q}_r(\mathbf{x}) = \kappa(\mathbf{x})\,[U(\mathbf{x}) - 4\pi I_b(\mathbf{x})];$$
$$U(\mathbf{x}) = \int_{4\pi} I(\mathbf{x}, \mathbf{s})\, d\Omega \tag{32.22}$$

The integrated intensity, U, multiplied by κ represents the rate of energy absorbed per unit volume, whereas $4\pi\ \kappa\ I_b$ is the rate of energy emitted per unit volume. The source term is usually assumed to be a blackbody radiator: $I_b = \sigma\ T^4/\pi$. Within the fire itself, the emission term dominates, and there is a net loss of energy from the region, whereas within the relatively cool, smoke-laden upper layer, there is a net gain of energy due to absorption. Because of the uncertainty in the near flame temperature and soot concentration, it is still common practice to prescribe, rather than predict directly via the source term, the fraction of energy lost from the fire via thermal radiation. Typically, 30–40 % is chosen, depending on the fuel type and fire size.

Mass Exchange at Boundaries

Rarely are fire simulations performed for compartments that are completely sealed off from the outside. In most cases, air and smoke pass through open doors or windows, fans blow and extract gases, and items burn and introduce fuel gases into the space. For the modeler, all these phenomena are known as boundary conditions that supplement the governing equations.

Free (or open) boundaries are located where the modeled domain interfaces with the external world beyond. Generally the pressure is specified, typically to a reference or ambient value, and the velocity derivatives normal to the boundary are set to zero. Furthermore, where outflow occurs the normal derivatives of the scalar fields will be set to zero, and where inflow occurs their ambient (atmospheric) values will be assumed. To achieve realistic predictions of air entrainment and smoke exhaust, it may be necessary to locate these boundaries well away from the compartment of fire origin.

Mass inlet boundaries are located where a prescribed source of air enters the computational domain. One example is at mechanical ventilation supplies. Other examples include external wind boundaries and the fuel bed itself if pyrolysis is included in the model in DiBlasi [25]. As for free boundaries where inflow occurs, it is critical that appropriate values are assigned to the sensible enthalpy (temperature) and other scalar fields.

Momentum Exchange at Boundaries

Where the fluid comes into contact with solid objects (compartment walls, for example) boundary conditions are required for the momentum equations and, where appropriate, for the solved turbulence variables. For most applications the no-slip velocity condition is assumed at solid surfaces (i.e., zero flow directly adjacent to the surface). However, the proper specification of boundary conditions is complicated by the fact that the inner region of the turbulent boundary layer adjacent to a solid surface has very sharp velocity gradients. A large number of grid points are required to resolve this region, making the simulation computationally expensive and

impractical for realistic compartments. An alternative, widely used approach to resolving the boundary layer is to use a so-called *wall function* [26], which assumes that the tangential velocity is a logarithmic function of the normal distance from the surface. An empirical relationship relates the wall shear-stress to the resolved variables at the first grid point, and appropriate source terms can be derived for each solved equation. Details are provided in standard textbooks [13].

Care is required in using the wall-function approach to ensure that the first grid point is positioned such that the empirical relationships are valid. Guidance should be taken from the model developer or the model documentation on the appropriate numerical grid to employ at surfaces. Commercial CFD models may offer advanced wall treatments that adapt automatically depending on the grid point and the flow regime, and these should generally be employed if available.

Energy Exchange at Boundaries

Conventional CFD models devote considerable attention to the velocity boundary conditions, but for fire, the energy exchange at solid surfaces is paramount, especially when the surfaces are burning. In fact, pyrolysis modeling is a subject unto itself and is touched on only briefly here. Suffice it to say that almost any treatment of a solid object can be incorporated in a CFD fire model because of the fairly loose coupling that exists between the gas and solid phases.

Hot gases lose heat to the structure at a rate determined by both the thermal properties of the bounding solids and the evolution of conditions within the gas phase. Early in the fire, the walls are nearly at ambient temperature and the rate of heat transfer will, all other things being equal, be at its greatest. Later, as the walls and other surfaces heat up, the rate of heat transfer decreases. In some situations it may be appropriate to treat the solid surfaces as adiabatic (i.e., no heat transfer). However, care must be taken when adopting this approach as heat loss to the surfaces is likely to be an important mechanism. For example, in large compartments or tunnels this heat loss may account for most of the heat losses from the fire, and ignoring it will generate erroneous predictions.

Where there is heat transfer, it is necessary to provide boundary conditions for the enthalpy and radiation equations, which in turn requires the temperature of the solid surface (T_w) be defined at each location adjoining the CFD grid. The surface temperature, together with its emissivity, establishes the radiative heat transfer rate for the radiation transfer equation. For the enthalpy equation the source term is the rate of convective heat transfer ($\dot{q}''_c$) to the surface from the adjoining grid point

$$\dot{q}''_c = h_c \left(T_w - T_g\right) \tag{32.23}$$

where T_g is the gas temperature at the nearest grid point and h_c is the convective heat transfer coefficient. This coefficient can be defined as a constant as in a zone model or, alternatively, a more realistic approach is to compute the coefficient as a function of the local flow regime making use of an empirical wall function akin to that done for the momentum equations and turbulence model.

The definition of the surface temperature is trivial in the case of isothermal boundaries where the surface is maintained at a fixed temperature. In general, however, the conduction of heat into the walls needs to be modeled. If it is assumed that conduction occurs only in the normal direction, then it may be treated by solving a one-dimensional heat conduction equation at each location on the surface adjoining the gas phase grid. The net conduction heat flux into the solid is given by the sum of the net radiation and convection fluxes at the surface.

A more sophisticated solution may be provided by coupling the CFD model with a separate solid phase calculation of the thermal conduction within the solid structure(s). This calculation could take the form of a fully coupled gas and solid-phase model, or a coupling of boundary conditions between a CFD model and a separate solid-phase model. In general, the

required information to be passed from the solid-phase model to the CFD model is the surface temperature and pyrolysis rate and, in the other direction, the convective and radiative heat fluxes.

Open Boundary Conditions

The results of a CFD fire analysis can be sensitive to the location of the "free" (ambient or open air) boundaries at the edge of the computational domain. These should be located at a sufficient distance from the fire source and regions of interest so that they do not incorrectly influence the solution. The setting of ambient values in relation to other boundary conditions may require special attention (e.g., it can dictate whether smoke can be expected to vent naturally in an air-conditioned atrium). Heat losses to solid boundaries can also have a significant influence on smoke movement, particularly where the smoke has cooled down and the amount of heat transferred to walls and ceilings can determine the degree of buoyancy and stratification of the smoke gases.

Visibility

Fire protection applications often require an estimate of visibility, the distance through smoke that a person is expected to be able to see, say, an exit sign. Visibility distance may be derived from a CFD solution using the predicted concentration of soot particulates. The correspondence between smoke concentration and visibility is based on the work of Jin [27] and Mullholland [28] and is commonly implemented into CFD models using the following (or similar) expression for visibility distance:

$$S = \frac{K_1}{K_2 m_s} \tag{32.24}$$

Here K_1 is a constant usually set to 3 for reflecting signs and 8 for illuminated ones, K_2 is the specific extinction coefficient (often taken as 7.6 m^2/g for flaming combustion), and m_s is the mass concentration of soot particles in units of g/m^3. The fire model predicts this latter quantity. Visibility distance calculated in this way at a CFD grid cell represents the visibility corresponding to a homogenous smoke layer and assumes the smoke density at the cell applies everywhere in the domain. Using the CFD solution data, it is possible to perform a more realistic "line of sight" calculation using the computed data at each grid cell along this line [29].

Sprinklers and Fire Suppression

It is fairly straight forward to include a sprinkler activation algorithm within a CFD fire model, based on the RTI (Response Time Index) concept of Heskestad and Bill [30]. This algorithm requires the gas temperature and velocity in the vicinity of the device. Following sprinkler activation, the water spray interaction with the hot gases can be modeled in a variety of ways. It is most often done using a Lagrangian particle tracking sub-model, in which statistically representative water particles are tracked numerically through the gas phase. The impact on the fire gases from the transfer of mass, momentum and heat associated with the trajectories and evaporation of the water particles is included as source terms in the underlying fluid dynamics equations. A good summary of this approach is given by Makhviladze et al. [31]. Water suppression and extinguishment, however, are far more difficult to model, and these phenomena are not generally a practical option for most fire engineering applications.

Fire-Structure Interface

While the modeling of the transport of smoke and heat within the gas phase remains the primary role of a CFD fire model in the majority of fire engineering applications, there are others where the coupling with the compartment boundaries and supporting structures is the main focus. For example, the absorption and

transmission of heat through elements of glazing, possibly to predict the likelihood of failure or to calculate the irradiance where people may be escaping on the unexposed side, might be required. Another example would be to investigate the response of concrete linings to fully developed fire conditions, for example in a road tunnel.

The area where the coupling of CFD and structural response has been considered in most detail is arguably in relation to the fire protection of supporting steel structures. By conducting CFD calculations of reasonably worst case fire scenarios, the thermal conditions to which the steel elements would be exposed can be applied as a boundary condition to the solid phase model describing the transfer of heat and mechanical forces within the structure. In the simplest approach, the analysis would ascertain whether the temperature of the steel elements reaches a critical level beyond which the structure might become unstable or even collapse. The methodology adopted to transfer the information, i.e. surface temperature and convective and radiative thermal fluxes, between the CFD and structural model is non-trivial, and is an area of on-going research, see for example [32].

Numerical Solution

The equations described in the previous sections are all written in continuous form; that is, they are exact representations of the governing conservation laws. Unfortunately, they have no closed form solution except in very limited cases. Therefore, numerical techniques are required to obtain approximate solutions. Even on the fastest computers available, these techniques can be costly in terms of the time consumed by the computer's central processing unit (CPU) and the size of the computer's random-access memory (RAM). Calculation times can range from several hours to several weeks. Memory requirements can range from hundreds of megabytes to tens of gigabytes. In the end, the calculations will produce an enormous amount of data, the processing of which would be impossible if not for graphical tools that have been developed specifically to visualize the computed results in various ways.

Finite Difference Approximation

A commonly used technique for solving the governing conservation equations is known as finite-differencing. The three-dimensional volume of interest, say a room in a building, is subdivided with a mesh made up of many small grid cells, with each cell containing an average value of each flow variable. In general, more grid cells produce a more accurate approximation of the true solution but at increasing computational cost. The simplest meshes consist of cells that are box-shaped with the dimensions of the boxes either fixed or varying. Such a mesh is described as rectilinear. Meshes that conform to the boundaries of complicated objects are known as body-fitted. Fire models that are intended for building applications most often use rectilinear meshes, whereas special applications, like furnaces and combustors, often employ body-fitted coordinate systems.

As an example of how finite-differencing works, consider the discretization of the mass conservation Eq. 32.1 on a three-dimensional rectilinear mesh. The cells are typically indexed by the integers i, j, and k. Each flow variable is represented as an average over the cell volume, $\delta x \ \delta y \ \delta z$, and over the time step, δt. At the start of the simulation, all the flow variables in each grid cell are assigned an initial value, and as the simulation progresses in time, these values are updated at each discrete time step. A common discretization technique is to define scalar quantities at the center of each cell and vector components at their respective cell faces. For example, ρ^n_{ijk} represents the average density in the cell with indices $i\ j\ k$ at the nth time step, whereas u^n_{ijk} and $u^n_{i-1,jk}$ represent the averages of the velocity component u over the faces of the cell that point in the positive and negative directions of x in the standard Cartesian coordinate system. A simple way to advance the density of each cell in time is to write the mass

conservation equation in an approximate form as follows:

$$\rho_{ijk}^{n+1} = \rho_{ijk}^{n} - \delta t\left(\frac{\rho_{i+\frac{1}{2},jk}^{n} u_{ijk}^{n} - \rho_{i-\frac{1}{2},jk}^{n} u_{i-1,jk}^{n}}{\delta x} + \frac{\rho_{i,j+\frac{1}{2},k}^{n} v_{ijk}^{n} - \rho_{i,j-\frac{1}{2},k}^{n} v_{i,j-1,k}^{n}}{\delta y} + \frac{\rho_{ij,k+\frac{1}{2}}^{n} w_{ijk}^{n} - \rho_{ij,k-\frac{1}{2}}^{n} w_{ij,k-1}^{n}}{\delta z}\right) \tag{32.25}$$

Notice that even the simplest of the conservation equations approximated with the simplest of differencing schemes on the simplest of meshes is still fairly difficult to express in a succinct way. In fact, to save space, the density at the respective cell faces, computed as an average of its values in the adjoining cells, is denoted by the $\pm\frac{1}{2}$ in the appropriate subscript. The momentum and energy conservation equations are far more complicated than this one, even though the basic ideas are the same. It is easy to understand why CFD software consists of tens of thousands of lines of computer instructions and that calculations can take hours to weeks to complete, depending on the number of grid cells in the mesh and the complexity of the differencing scheme.

CFD models employ various types of differencing schemes, meshes, physical and numerical assumptions, and so on. No two models are exactly alike, but many have common traits. An informal classification system has evolved within the community of developers to distinguish one model from another. For example, the simple scheme for updating the previous density would be described as a three-dimensional, explicit, conservative, staggered finite-difference scheme that is first order accurate in time and second order accurate in space. Consider each descriptor in turn:

Explicit Versus Implicit Schemes

To say that a numerical scheme is explicit means that the flow variables may be advanced in time based solely on their values at the current time step. In Eq. 32.25, notice that all the values of the density and the velocity components on the right-hand side are taken at the nth time step; thus, advancing the solution in time is merely a matter of computing these terms. An implicit scheme uses values of the flow variables at both the current and next time steps, meaning that there is no direct way of updating the values. Rather, a linear system of equations must be solved. Although they require more computational effort per time step, implicit schemes typically are more numerically stable and permit larger time steps than explicit schemes. In fact, the most commonly used numerical scheme in commercial CFD packages is known as SIMPLE (Semi-Implicit Method for Pressure-Linked Equations). Details may be found in Patankar [4].

Conservative Versus Nonconservative Schemes

A numerical scheme that is described as conservative has the following property: If the right-hand side of Eq. 32.25 were summed over all grid cells, the intermediate mass fluxes would cancel exactly, leaving only the mass fluxes at the boundary of the computational domain. This is the discrete analogue of the Divergence Theorem:

$$\int_V \nabla \cdot \rho \mathbf{u}\, dV = \oint_{\partial V} \rho \mathbf{u} \cdot d\mathbf{S} \tag{32.26}$$

This very desirable property in a numerical scheme ensures that mass is globally conserved, regardless of inaccuracies related to the grid cell size, differencing scheme, or other local effects.

Staggered Versus Co-located Variables

Assigning various flow variables to different locations within the grid cell is a strategy adopted by the developer based on the particular application of the model and the convenience of prescribing boundary conditions, obstructions, and other special features. Suffice it to say that the strategy adopted in Eq. 32.25 is not unique. Other techniques are discussed in Anderson et al. [2] and Ferziger and Peric [3].

Order of Accuracy of the Scheme

A common misconception about numerical schemes is that those with a high order of

accuracy are better than those of lower order. A finite difference is an approximation of a partial derivative, and the order of accuracy relates the degree of approximation. For example, the scheme described in Eq. 32.25 is first order accurate in time because the time derivative of the density at the nth time step is approximated as

$$\frac{\partial \rho}{\partial t} = \frac{\rho^{n+1} - \rho^n}{\delta t} + \mathcal{O}(\delta t) \tag{32.27}$$

The symbol $\mathcal{O}(\delta t)$ represents the *discretization error*—neglected terms from the Taylor series expansion of the density that are proportional to the first and higher powers of the time step size. Another way of characterizing this approximation is to say that it has a forward bias in time. The spatial derivatives in Eq. 32.25 are known as central differences, having neither a forward nor backward bias in the respective coordinate directions. Such differences that incorporate values from the nearest adjacent grid cells are typically second order accurate. Higher-order accuracy requires information beyond nearest neighbors, adding to the cost of computing the finite differences. The potential increases in accuracy are often offset by the decrease in computational efficiency and ease of implementation. A popular trade-off is to use more grid cells with a second-order accurate scheme rather than less grid cells with a higher-order scheme.

Spatial Dimension of the Scheme

There are some fire scenarios where it may not be necessary to solve the fully three-dimensional form of the governing equations. Sometimes, flows through ducts or tunnels can be approximated in two spatial dimensions. Also, where there is a symmetry in the fire scenario (e.g., a simple compartment with a fire in the middle of the room), the computational effort can be reduced by a factor of two by modeling one-half of the geometry. The plane of symmetry is then defined as a symmetry boundary condition at the corresponding edge of the modeled domain. Tunnels are another application in which a vertical symmetry plane is often used, running along the length of the tunnel. Care is required in using symmetry boundaries to ensure that the imposed condition of symmetry is physically realistic. For example, in an LES calculation, it is generally undesirable to use a symmetry boundary because the methodology does not assume the fire to be symmetric (in a time-averaged sense).

Finite Volume Method

A popular alternative to finite-differencing employed in both commercial and fire-specific CFD models is the finite volume method. This method has some of the characteristics of the finite element method employed in structural and solid-phase thermal analysis programs and can be employed with either structured or unstructured meshes. Rather than working with the conservation equations in their differential form, as in Eqs. 32.1–32.4, the finite volume method takes as its starting point the equations in their integral form. For example, integrating equation 32.2 over a control volume V and applying the Divergence Theorem (Eq. 32.26) yields an integral form of the equation:

$$\begin{aligned} &\frac{\partial}{\partial t}\int_V \rho Y_\alpha \, dV + \oint_{\partial V} \mathbf{n}\cdot(\rho Y_\alpha \mathbf{u})\, d\mathbf{S} \\ &= \oint_{\partial V} \mathbf{n}\cdot(D_\alpha \nabla Y_\alpha)\, d\mathbf{S} + \int_V \dot{m}'''_\alpha \, dV \end{aligned} \tag{32.28}$$

The solution domain is subdivided into a finite number of control volumes (cells) in much the same way as in the finite difference method described previously. The crux of the finite volume method is in determining the surface and volume integrals in Eq. 32.28, which in turn requires that the surface values of the solved variables be expressed in terms of the neighboring control volume (node) values, using an appropriate interpolation scheme. A system of algebraic equations is developed as in the finite difference method, the solution of which provides the mean value of the solved variable at each control volume (generally assigned to the

node points). Although the finite volume method was originally employed with structured grids, the trend with modern commercial models has been toward unstructured grids consisting of hexahedral or tetrahedral elements.

The finite volume method is intrinsically conservative (provided the surface fluxes are defined appropriately). It may be explicit or implicit and the mesh may be staggered or co-located. Depending on the numerical approximation of the integrals, the solution may be formally any order of accuracy. For the diffusion terms, a second order (central difference) approach is generally adopted. For the convection terms, matters are more complicated, and the use of central differencing can produce erroneous results in convection-dominated flows when a RANS turbulence formulation is used. First order, or "up-wind," schemes remove the instabilities caused by central differencing, but they can be inaccurate if the grid is not sufficiently fine. A common approach has been to use the so-called "hybrid" scheme [33] in calculating the surface fluxes, which produces stable solutions that are generally more accurate than those provided by a pure first order, upwind approach but not formally as accurate as a second order approach.

Alternative Solution Methods

The finite element method (FEM) is well established for solving the partial differential equations of structural mechanics and solid phase heat transfer, and shares some of the underlying mathematics associated with finite difference and finite volume methods. An unstructured numerical mesh, often composed of tetrahedra, is employed, which makes the method particularly suited to complex geometries. While the finite element method has been applied to fluid flows, its application in the fire field has to date been limited. Other numerical methods that have been employed by the CFD community include spectral methods and boundary elements.

Computer Hardware and Software

CFD solvers are written in a variety of computer languages, most notably Fortran or C. They will run, or execute, on any computer for which a compiler is available to translate the source code into the native machine language. Usually, CFD models consist of three basic parts: an interface that allows the user to input parameters, the flow solver, and a graphical program to display results. It is not unusual for the user interface, flow solver, and graphics utility to be three separate computer programs, sometimes written in different languages, and sometimes run on different computers. For example, the flow solver itself can be run on a remote machine because it does not require any interaction with the user. While a calculation runs somewhere else, the user is free to set up new calculations or process results from a previous one. What were once referred to as "supercomputers" are now simply clusters of conventional computers that are dedicated to running CFD calculations, either serially or in parallel.

The input interface can be a graphical user interface (GUI), a simple text editor, or some combination of the two. Some of the more complex interfaces allow for input data to come from other sources, like a computer-aided design (CAD) program. This is an increasingly important consideration in CFD, as the most time-consuming part of a simulation (for the user, not the computer) is the description of the geometry. It is now possible to simulate the flow of fire-driven gases through entire buildings, but without some automated method of input, the setup process can be tedious.

CFD is becoming more and more routine as computers get cheaper and faster. In addition to the availability of doubly fast CPUs every 18 months, an emerging trend in the industry is to use more than one CPU (and the associated memory) for a single simulation. The technique, known as parallel processing, has been made possible by the development of software that allows data to be transferred rapidly between two or more computers that are working on the

same calculation. The most popular data-passing protocol is message passing interface (MPI). To the CFD developer, MPI is nothing more than a set of "call" statements that can be written into the source code, instructing computer A to send a packet of numbers to computer B and vice versa. The formats of the call statements have been standardized by a committee of interested industry experts, and several very good, and free, implementations of MPI have been released into the public domain. Although writing and running a good, efficient parallel CFD model is still a daunting task, parallel processing does not significantly increase the cost of hardware or software. It is possible to exploit the computers that a company already owns to run CFD models in parallel.

Visualization

As computers get faster and calculations get bigger, there is a tremendous need to render the output of the simulations in some useful form. Certainly, time histories of individual quantities at discrete locations can be saved and readily plotted, much like thermocouple data from a real experiment. But this only tells part of the story. To better understand the flow dynamics, it is necessary to render pictures or animations of the entire computational domain, either in the form of contour plots, flow vectors, streamlines, or tracer particles. This type of output is invaluable to the numerical analyst but still only partially satisfying to the lay person. Perhaps spurred on by the current generation of computer-animated films, some want to see the results of the simulations rendered in a lifelike way, considerably different than conventional CFD output.

This trend to realism is more than superficial. In both design and forensic applications, the realistic rendering of smoke is very valuable, but it requires graphical techniques that stretch the limits of even the best video cards available. Visibility is a key consideration in the design of any large structure, especially given the current trend of open architecture. Unlike temperature or species concentration, visibility is not defined at a point but rather integrated over a path connecting the virtual occupant and the virtual exit sign. The CFD model can produce a spatially and temporally varying smoke density field, but it is difficult or impossible to integrate a priori the density over every possible path between the sign and the moving occupant. Fortunately, graphical techniques are now available that can process the smoke density data and produce at any given time and any given place in any given direction a realistic view through the smoke, allowing the viewer to assess whether or not the sign (or whatever is of interest) would be visible in the event of a real fire.

Verification and Validation

The use of fire models currently extends beyond the fire research laboratories and into the engineering, fire service, and legal communities. Sufficient evaluation of the models is necessary to ensure that users can judge the adequacy of its technical basis, appropriateness of its use, and confidence level of its predictions. The model evaluation process consists of two main components: verification and validation [34]. Verification is a process to check the correctness of the solution of the governing equations. Verification does not imply that the governing equations are appropriate, only that the equations are being solved correctly. Validation is a process to determine the appropriateness of the governing equations as a mathematical model of the physical phenomena of interest. Typically, validation involves comparing model results with experimental measurement. Differences that cannot be attributed to uncertainty in the experimental measurements are attributed to the assumptions and simplifications of the physical model.

It is commonly assumed by model users, particularly those who have purchased expensive CFD software, that verification and validation is the responsibility of the model developers. Certainly, CFD developers do a considerable amount of this type of work, in particular verification, but it is impossible to ensure that the model is

"validated" for every conceivable application. Indeed, the very point of numerical modeling is to predict the outcome of fire scenarios that have not, or cannot be, replicated in a controlled laboratory environment. Thus, the burden of verification and validation must be shared by the model developer and user. The benefit to the user is twofold: first, it confirms that the user can use the software properly, at least for the given application; and second, it assures the user that the model can address the given fire scenario, even providing the user with some estimate of its accuracy.

Verification

The most important task for a CFD modeler is to perform a *grid resolution study* for the particular application at hand. The accuracy of a CFD calculation is dependent on the resolution of the underlying numerical grid. As discussed in Sect. 32, the order of accuracy of a numerical algorithm indicates the rate at which the solution of the discretized governing equations converges towards the solution of the exact equations. For example, if the scheme is second-order accurate in space and time, the error due to the finite difference/volume approximation will decrease by a factor of 4 if the grid cell and time step decrease by a factor of 2. Demonstrating this for a particular application of the model is known as a grid resolution study. Selection of an appropriate grid size should be based on whether or not a particular level of accuracy is achieved for a particular grid cell size.

In addition to a grid resolution study, there are a variety of other tests that a model user should perform to ensure that the model is solving the governing equations correctly, and that the model user is running the model properly. What tests to perform depends on the application. For example, if the application involves a pressure rise in a relatively tight compartment, simple tests should be performed to ensure that the pressure increase obeys the basic laws of thermodynamics. If water droplets are involved, simple tests should be performed to ensure that mass and energy conservation laws are properly applied in the model.

Validation

The typical way to validate a CFD fire model is to compare its results to experimental measurements. This involves two important tasks: (1) selecting appropriate experiments and (2) quantifying the accuracy of the model's prediction of the outcome of these experiments. The following two sections address these two tasks.

Applicability of Validation Experiments

How can one determine if a particular application of the model has been validated? For example, suppose the problem at hand is a fire in a warehouse with a 10 m ceiling, sprinklers, roof vents, and HVAC system. There is probably no experimental data set that is exactly like it, and it would be too expensive to conduct new experiments. How does one determine if any validation work is appropriate for this scenario? The approach taken in a fire model validation study conducted by the US Nuclear Regulatory Commission (NRC) and the Electrical Power Research Institute (EPRI) was to characterize the experiments used in the study in terms of a handful of commonly used non-dimensional quantities from the fire literature [35]. This essentially defines the "parameter space" for which the model was validated. The model users are warned that the models should only be applied within this parameter space. This prevents the tendency by users to simply declare that the model has been validated and can be used for any application. The non-dimensionalized parameters used in the NRC/EPRI study are:

1. *Fire Froude Number,* $\dot{Q}^*$: A convenient way to express the heat release rate of the fire relative to its base area is by way of the non-dimensionalized quantity:

$$\dot{Q}^* = \frac{\dot{Q}}{\rho_\infty c_p T_\infty \sqrt{gD}\, D^2} \tag{32.29}$$

where $\dot{Q}$ is the peak heat release rate of the fire and D is the equivalent diameter of the base of the fire. The Fire Froude Number is a useful quantity for plume correlations and flame height estimates. A large value ($\dot{Q}^* \gg 1$) describes a fire for which the energy output is relatively large compared to its physical diameter, like an oil well blowout fire. A low value ($\dot{Q}^* \ll 1$) describes a fire for which the energy output is relatively small compared to its diameter, like a brush fire.

2. *Flame Height Relative to Ceiling Height, L_f/H*: This ratio is a convenient way to express the physical size of the fire relative to the size of the room. A value greater than one indicates that there is flame impingement on the ceiling, an important consideration when evaluating devices such as sprinklers and smoke detectors. The Flame Height, L_f, is the height of the visible flame, based on Heskestad's correlation [36]:

$$L_f = D\left(3.7\,(\dot{Q}^*)^{2/5} - 1.02\right) \tag{32.30}$$

3. *Global Equivalence Ratio, ϕ*: A convenient way to determine whether a compartment fire is limited by fuel or oxygen is to estimate the ratio of the fuel supply rate, $\dot{m}_f$, to the oxygen supply rate, $\dot{m}_{O_2}$, divided by the stoichiometric ratio, r:

$$\phi = \frac{\dot{m}_f/\dot{m}_{O_2}}{r} = \frac{\dot{Q}}{\Delta h_{O_2}\,\dot{m}_{O_2}} \quad ;$$
$$\dot{m}_{O_2} = \begin{cases} \frac{1}{2}0.23\,A_0\sqrt{H_0} & \text{Natural} \\ 0.23\,\rho\,\dot{V} & \text{Mechanical} \end{cases} \tag{32.31}$$

Here, Δh is the heat of combustion, $\dot{Q} = \dot{m}_f\,\Delta h$ is the peak heat release rate of the fire, $\Delta h_{O_2} = r\,\Delta h$ is the heat of combustion per unit mass oxygen consumed, A_0 is the area of the compartment opening, H_0 is the height of the opening, ρ is the density of air, and $\dot{V}$ is the volume flow of air into the compartment due to a ventilation system. The factor 0.23 is the mass fraction of oxygen in air. If $\phi < 1$, the compartment is considered "well-ventilated" and if $\phi > 1$, the compartment is considered "under-ventilated." In general, under-ventilated fire scenarios are more challenging for the models because the combustion physics are more complicated.

4. *Relative Distance Along the Ceiling, r_{cj}/H*: This ratio indicates the distance from the fire plume of a sprinkler, smoke detector, etc., relative to the compartment height, H. The maximum ceiling jet temperature, important in determining device activation, has been shown to be a function of this ratio.
5. *Relative Distance from the Fire, r_{rad}/D*: This ratio indicates whether a "target" is near or far from the fire. In general, it is more challenging to predict the radiative heat flux to objects near the fire.
6. *Room Length and Width Relative to the Ceiling Height, L/H and W/H*: These ratios are useful mainly when assessing an empirical or zone model because most of the correlations used by these models are limited in terms of compartment aspect ratio. For CFD, extreme values of these ratios might indicate unusual fire behavior.
7. *Ceiling Height Relative to the Fire Diameter, H/D^**: This ratio is a non-dimensional measure of the height of the fire plume. D^* is a length scale that incorporates the heat release rate of the fire:

$$D^* = \left(\frac{\dot{Q}}{\rho_\infty c_p T_\infty \sqrt{g}}\right)^{2/5} \tag{32.32}$$

The larger the ratio H/D^*, the more important the plume becomes in the overall scenario. For empirical and zone models, it indicates whether or not the plume entrainment correlation is appropriate. For CFD, it indicates how "high" the plume actually is, in non-dimensional terms.

Quantifying Model Uncertainty

Having determined the appropriateness of the chosen experiments, it is now necessary to quantify the accuracy of the model in predicting the

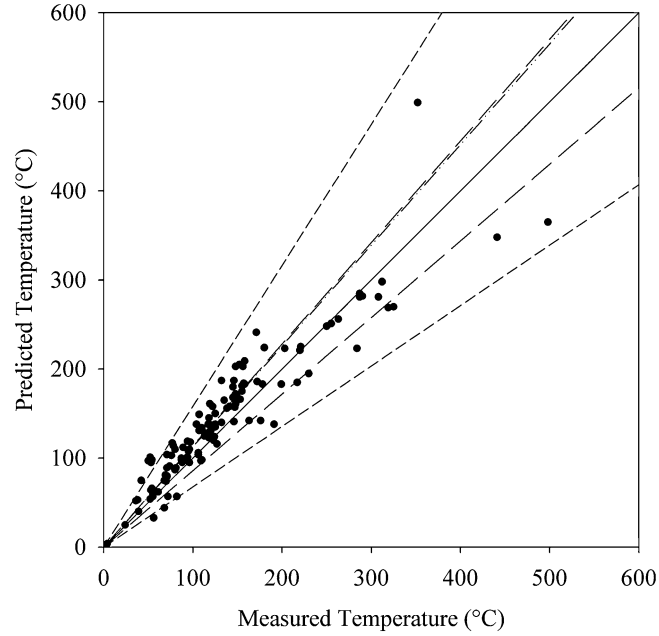

Fig. 32.2 A comparison of measured versus predicted wall temperature. The *off-diagonal lines* indicate the $2\widetilde{\sigma}$ bounds for the experiments (*long dash*) and the model (*short dash*)

outcome of these experiments. For each quantity of interest, a summary plot of the results should be constructed like the one shown in Fig. 32.2. The accuracy of the model can be expressed in terms of two statistical parameters. The first, δ, is the bias factor. It indicates the extent to which the model, on average, under or over-predicts the measurements. For example, the bias factor for the data shown in Fig. 32.2 is 1.13. This means that the model over-predicts wall temperatures by 13 %, on average, and this is shown graphically by the dash-dot line. The second statistic is the relative standard deviation of the model, $\widetilde{\sigma}_M$. This indicates the degree of scatter of the points. Referring again to Fig. 32.2, there are two sets of off-diagonal lines. The first set, shown as long-dashed black lines, indicate the estimated experimental uncertainty. The slopes of these lines are $1 \pm 2\widetilde{\sigma}_E$, i.e. the 95 % confidence interval for the measurements. In this case, $\widetilde{\sigma}_E = 0.07$. The second set of off-diagonal lines, shown as short-dashed lines, indicates the model uncertainty. The slopes of these lines are $\delta(1 \pm 2\widetilde{\sigma}_M)$. In this case, $\widetilde{\sigma}_M = 0.2$. If the model were as accurate as the measurements against which it is compared, the two sets of off-diagonal lines would merge and the dash-dot bias line would overlap the solid diagonal line. The extent to which the data scatters outside of the experimental bounds is an indication of the degree of model uncertainty.

The derivation of these uncertainty statistics is described in [37], and it is summarized here. First, a few assumptions are made:

1. The experimental measurements are assumed to be unbiased, and their uncertainty is assumed to be normally distributed with a constant relative standard deviation, $\widetilde{\sigma}_E$.
2. The model uncertainty is assumed to be normally distributed about the predicted value divided by a bias factor, δ. The relative standard deviation of the distribution is denoted as $\widetilde{\sigma}_M$.

Now, given a set of experimental measurements, E_i, and a corresponding set of model predictions, M_i, compute the following:

$$\overline{\ln(M/E)} = \frac{1}{n}\sum_{i=1}^{n} \ln(M_i/E_i) \qquad (32.33)$$

The relative standard deviation of the model, $\widetilde{\sigma}_M$, can be computed from the following equation:

$$\widetilde{\sigma}_M^2 + \widetilde{\sigma}_E^2 = \frac{1}{n-1}\sum_{i=1}^{n}\left[\ln(M_i/E_i) - \overline{\ln(M/E)}\right]^2 \tag{32.34}$$

The bias factor is:

$$\delta = \exp\left(\overline{\ln(M/E)} + \frac{\widetilde{\sigma}_M^2}{2} - \frac{\widetilde{\sigma}_E^2}{2}\right) \tag{32.35}$$

For a given model prediction, M, the "true" value of the quantity of interest is assumed to be a normally distributed random variable with a mean $\mu = M/\delta$ and a standard deviation of $\sigma = \widetilde{\sigma}_M(M/\delta)$. Using these values, the probability of exceeding a critical value, x_c, is:

$$P(x > x_c) = \frac{1}{2}\,\mathrm{erfc}\left(\frac{x_c - \mu}{\sigma\sqrt{2}}\right) \tag{32.36}$$

Note that the complimentary error function is defined as follows:

$$erfc(x) = \frac{2}{\sqrt{\pi}}\int_t^\infty e^{-t^2}dt \tag{32.37}$$

It is a standard function in most mathematical or spread sheet programs.

As an example of the procedure, suppose that the model whose results are plotted in Fig. 32.2 has predicted that the wall temperature within a compartment would peak at a value of 300 °C due to a given design fire. Suppose also that the failure criterion for the wall lining material is 325 °C. What is the probability that the wall temperature could reach 325 °C? First, it is best to work in terms of temperature rise. The ambient temperature is 20 °C; thus, the predicted temperature rise, ΔT_p, is 280 °C and the critical temperature rise, ΔT_c, is 305 °C. From Eq. 32.36, the probability that the temperature could exceed the critical value is:

$$\begin{aligned} P(\Delta T > \Delta T_c) &= \frac{1}{2}\,\mathrm{erfc}\left(\frac{\Delta T_c - (\Delta T_p/\delta)}{\widetilde{\sigma}_M\,(\Delta T_p/\delta)\sqrt{2}}\right) \\ &= \frac{1}{2}\,\mathrm{erfc}\left(\frac{305 - (280/1.13)}{0.2\,(280/1.13)\sqrt{2}}\right) \cong 0.12 \end{aligned} \tag{32.38}$$

It must be emphasized that this estimated probability of failure is based only on the model uncertainty. It does not account for parameter uncertainty; that is, the uncertainty in the input parameters.

Applications

This section presents examples of how CFD fire models are used in practice. These applications can be divided into three general categories—research, design, and forensic. For research, the models can help explain basic fire phenomena. For design, the models are used to predict the spread of smoke and heat from a hypothetical fire in a real or planned building. For forensics, the models aid in the reconstruction of an actual fire. For a design application, the fire is usually specified; that is, the ignition, growth, and eventual decay of the fire are not predicted by the model but rather specified by the design engineer and reviewed by the code enforcing authority. For a reconstruction, the model is usually used to explain how a small fire grew and spread to cause serious damage or injury. Rarely are fire models of the type described in this chapter used to show how a fire was actually ignited, as the physical mechanism of this event (electrical short, arcing fault, arson, etc.) is usually not included in the model.

Fundamental Fire Dynamics

CFD, in particular large eddy simulation, provides a convenient means to study basic fire behavior. The most obvious application is the study of fire plumes; for example, predicting the height of the visible flame, the centerline velocity and temperature, and the pulsation frequency. Heskestad's empirical flame height correlation (Eq. 32.30) is valid for values of $\dot{Q}^*$ between 0.1 and 10,000, characterizing intermittent grass fires all the way to oil well blowout fires. Figure 32.3 compares FDS predictions with Heskestad's correlation. Note that the

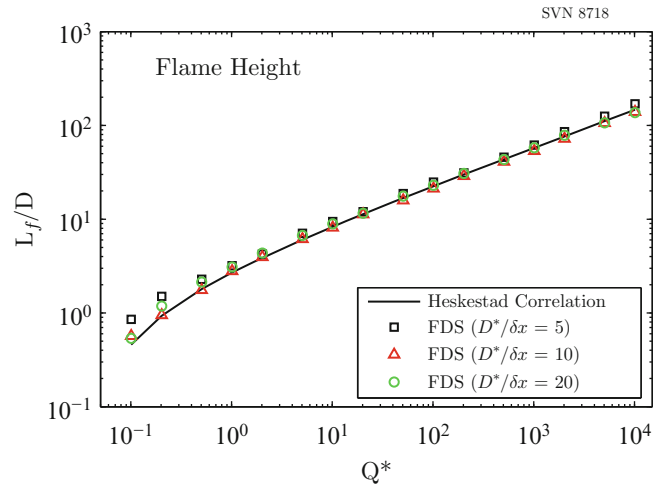

Fig. 32.3 Comparison of FDS predictions of flame height from a 1 m square pan fire for Q* values ranging from 0.1 to 10,000

simulations were run at three different grid resolutions. A useful way to characterize the grid resolution of a fire simulation is via the ratio $D^*/\delta x$, where D^* (Eq. 32.32) is a measure of the effective fire diameter, based on heat release rate, and δx is the size of a grid cell. In effect, $D^*/\delta x$ is the number of grid cells spanning the effective fire diameter.

The fundamental, or "puffing," frequency is a quantity that the fire model also ought to predict accurately. Figure 32.4 displays sequential flame images for a single puff from a simulation of a 1 m methane fire experiment conducted at Sandia National Laboratories [38]. The dominant puffing mode shows good agreement with the measured puffing frequency of 1.65 Hz. Higher frequency fluctuations from the simulation exhibit the classic $-5/3$ scaling of Kolmogorov turbulence [39].

Smoke Movement

A significant proportion of fire fatalities can be attributed to the inhalation of smoke particulates and toxic gases. Furthermore, the effects of reduced visibility, high temperature, radiative flux, and oxygen depletion may add to the hazard associated with the smoke generated by an enclosure fire. Means to control the movement of smoke include physical barriers, natural or mechanical smoke exhaust, and pressurization of protected spaces. In routine applications, the design of the smoke control measures may often be achieved by recourse to various guidance publications and empirical correlations [40, 41]. Network airflow and zone fire models are also available to assist in the design process. However, where the building space is large or complex in shape, or where a novel ventilation system is proposed, CFD can be a useful tool. Covered shopping malls, atria in hotels and office buildings, leisure complexes, airport terminals, and large warehouses are just some examples of where CFD is being increasingly employed.

Many of the earliest examples of the application of CFD to fire engineering were in smoke movement applications [42, 43]. Simulations were at that time restricted to a few tens of thousands of grid cells. Although this number has increased to hundreds of thousands or even millions of cells, many of the modeling issues remain the same and are discussed later [44].

Smoke Transport in a Mechanically Ventilated Library

In collaboration with Olof Granlund Oy, ANSYS Europe Ltd. conducted a CFD analysis of the movement of smoke generated by a fast-growing fire, with a peak heat release rate of 550 kW, inside a library for which the ventilation system was left running in its normal mode of operation.

Fig. 32.4 Snapshots of the flame envelope from a simulation of the Sandia 1 m diameter methane pool fire using 1.5 cm grid resolution. The images span a single "puff"

The building has a pitched, vented glass roof and diffusers at various elevations. ANSYS CFX is a general purpose, commercial CFD model that has a history in fire modeling dating back to the investigation of the 1987 Kings Cross fire in London [45]. Because it is designed to handle virtually any type of geometry, a model like this one can employ a numerical mesh that conforms to the unusual shape of the building. In this case, an unstructured mesh with 3.2 million mesh elements was used. Figure 32.5 shows a contour map of visibility distance after 3 min in a vertical slice through the building.

Smoke Transport in a Historic Landmark

CFD fire modeling is commonly used during the renovation of historic buildings. Often at issue is the inclusion or exclusion of a fire protection system (sprinklers, exhaust fans, etc.) that might require a variance from the local building code requirements. For example, as part of an overall effort in modernizing the Rhode Island Statehouse (the rotunda is the fourth largest self-supporting dome in the world), the LES model FDS was used to model a number of fire scenarios within the structure. The building supervisors wished to avoid having to disrupt the historical fabric of the rotunda while updating the building's fire protection systems. The model was used to examine a number of fire scenarios and how they might impact the ability of occupants to evacuate the building. Note in Fig. 32.6 the use of rectangular obstructions to approximate the very complicated geometry of the building—a simple alternative to the more CPU intensive body-fitted coordinate system.

Smoke Transport in a Multistory Residential Building

To assist means of escape and fire fighter access in high rise residential buildings it is common practice to provide some form of smoke control to the stairwells, which could take the form of a sophisticated pressurization scheme or a relatively simple natural ventilation provision. There may be cases where smoke protection is required also in the corridors and lobbies at each story, possibly as a compensatory measure for extended travel distances. Another approach, adopted in some parts of the world, is to provide

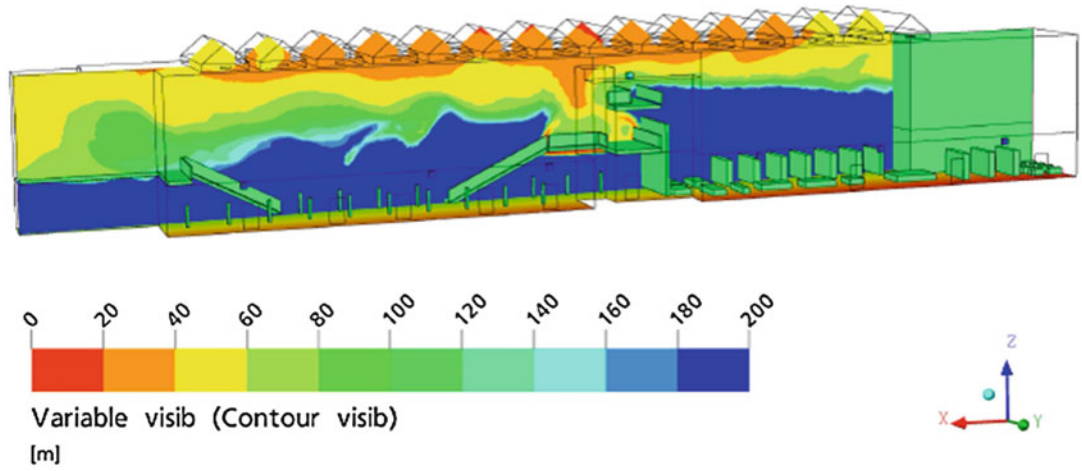

Fig. 32.5 Map of visibility in a vertical plane at time = 3 min for a fire in a library building (Figure courtesy: ANSYS Europe Ltd)

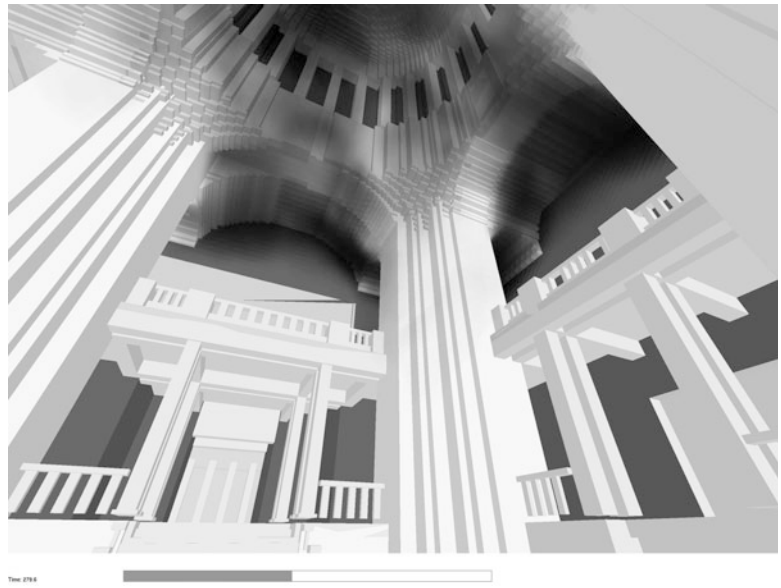

Fig. 32.6 Smoke filling analysis of the Rhode island State capitol (Figure courtesy: Hughes Associates)

mechanical ventilation in the corridor. In the event of a fire in an adjoining apartment smoke is purged from the corridor, while at the same time the ventilation system provides smoke protection to the stairwell by the combined action of pressure differentials and open-door airflows akin to a stair pressurization system. CFD modeling of the air and smoke transport in the corridor and stairwell is often required in support of the design, in particular where the corridors and lobbies have a more complicated layout or the ventilation inlets and outlets cannot be installed in ideal locations.

Tunnels

Historically, smoke control inside tunnels was often considered as an afterthought to design of ventilation for the provision of fresh air. Where natural ventilation was insufficient, mechanical ventilation was designed using network flow

theory aided in recent years by network models. As a two-layer description is generally not valid within a tunnel environment, fire zone models have been applied to tunnels in only a limited number of cases. CFD, however, is now finding increasing application to fire hazard analysis for road tunnels in particular. In recent years a number of major tunnel fire incidents such as the tragedy in the Mont Blanc tunnel in 1999, resulting in 39 deaths, have highlighted the need to understand better the mechanism of fire development and spread inside tunnels. In particular, heat transfer to the tunnel walls is important to account for correctly as this has a strong influence on the distribution of heat along the tunnel, the degree of stratification that can be expected, and the threat to the integrity of the structure.

One area where CFD has been applied successfully is in the analysis of the critical velocity required in a longitudinally ventilated tunnel to control the spread of heat and smoke so that it is forced in the downstream direction, providing safe conditions upstream [46]. Another area currently receiving much attention is the choice of design fire for tunnel fire safety design. In the light of the recent tunnel fire incidents and full-scale fire tests [47], the size of the fire load that can be generated from what were previously considered as nonhazardous cargoes has been revised. Heat release rates well in excess of 100 MW have been measured for heavy-goods vehicles carrying commercial merchandize.

CFD was used in the investigation into the Mont Blanc tunnel fire incident in 1999. One of the modeling studies involved the use of the JASMINE fire model to re-construct conditions inside the tunnel during the first 30 min, during which time most of the fatalities would have occurred. Using information available on the ventilation settings and the location of vehicles, the model predicted the transport of smoke and heat along the length of the tunnel. The data were then fed into a model for fractional effective dose to enable an assessment of when and how the fatalities occurred. Subsequent parametric simulations were performed to investigate whether alternative tunnel ventilation measures would have helped on the day of the incident [48].

Parking Garages

The application of CFD to the analysis and design of smoke control systems in basement car parks may share elements that apply also to road tunnels. Not only is the potential fire source similar, the ventilation strategies and performance criteria may well overlap. Two ventilation strategies that might be considered in a basement car park include dilution (purging by fresh air) and the directional control of smoke by the application of applied air flows.

While diluting smoke and vehicle emissions can in principle be achieved by ventilating at a specified air change rate, in many cases additional ventilation provisions will be required in order to ensure an even mixing of fresh air and the elimination of stagnant regions. This is commonly achieved by the strategic location of impulse (jet) fans on the underside of the ceiling, which assist the movement of air from the inlet points to the exhaust locations. CFD may be usefully employed to determine the number and location of these fans.

The directional control of smoke in the event of a fire, with the objective of providing a relatively smoke free access to the location of the fire for fire fighting personnel, presents a greater challenge than simply purging smoke from the car park. Here careful design of the ventilation system is required, with the impulse fans operating akin to the case of a longitudinally ventilated tunnel, directing the smoke and heat in a direction away from the approaching personnel.

Fire Investigation

CFD is increasingly used to reconstruct actual fires, providing fire service personnel and fire investigators with a better understanding of the events that led to injury, loss of life, or loss of the structure. In any reconstruction, the time line of events provided by the first responders and other eyewitnesses is as crucial as the model input, but it is also invaluable in assessing the results. Rendering the results of the simulation as realistically as possible facilitates the synthesis of

Fig. 32.7 Comparison of photographs of the Charleston furniture store fire with a numerical simulation. Figure courtesy of NIST

model simulation with photographic and visual evidence. Most people at the fire scene are certainly not experts in CFD, but they are very experienced with fire. Examples of how CFD has been used in actual fire reconstructions are available [49, 50, 51, 52, 53].

As an example, NIST researchers used the Fire Dynamics Simulator to analyze a fire that occurred on the evening of June 18, 2007, in a furniture store in Charleston, South Carolina [54]. Using evidence collected at the scene and eyewitness accounts, the investigators put together a plausible sequence of events that led to the deaths of nine fire fighters. Figure 32.7 presents a snapshot of the numerical simulation compared to a photograph of the actual fire.

Outdoor Applications and Wind

Buoyant windblown plumes have been studied since the early 1960s. A summary of the early work together with a useful bibliography is given by Turner [55]. Most of the models described in these works are integral models, where the profiles of physical quantities in cross-sectional planes perpendicular to the wind direction are assumed, together with simple laws relating entrainment into the plume to macroscopic features used to describe its evolution.

The potential shortcomings of these types of models are that they were designed for typical industrial sources, like smokestacks, that are much smaller in terms of energy output than a large fire. The plume from an oil or forest fire will rise higher into the atmosphere, and it is difficult to predict the rise based on empirical correlations. If the plume rise is not calculated correctly, substantial errors in downwind concentration can result. In the case of smoke-stack emissions, the plume does not rise appreciably high, reducing the uncertainty of the results. Most of the assumptions required by integral models can be removed by taking advantage of the advances in CFD over the past few decades. For example, as part of the process of evaluating the feasibility of using in situ burning as a remediation tool for large oil spills, NIST developed a numerical model, ALOFT (A Large Out-door Fire plume Trajectory), to predict the concentration of smoke and other combustion products downwind of a large fire [56]. The model is simply a variant of the large eddy simulation model FDS, with a simplified plume rise model coupled with a coarsely gridded wind calculation spanning tens of kilometers (Fig. 32.8). This combination of models is not unusual for outdoor application, as the range of length scales spans at least three orders of magnitude.

Virtual Experiments

Many codes and standards for fire protection are based upon simple room geometries. For example, the spacing for smoke detectors has historically been based upon smooth, level ceilings with some additional rules for beams, slope, and height. Under those rules a single story room with a 30 m by 30 m smooth ceiling could be protected by a grid of nine smoke detectors, but a ceiling of waffle concrete construction (Fig. 32.9) with structural deep beams 1 m on center, could, under a strict interpretation

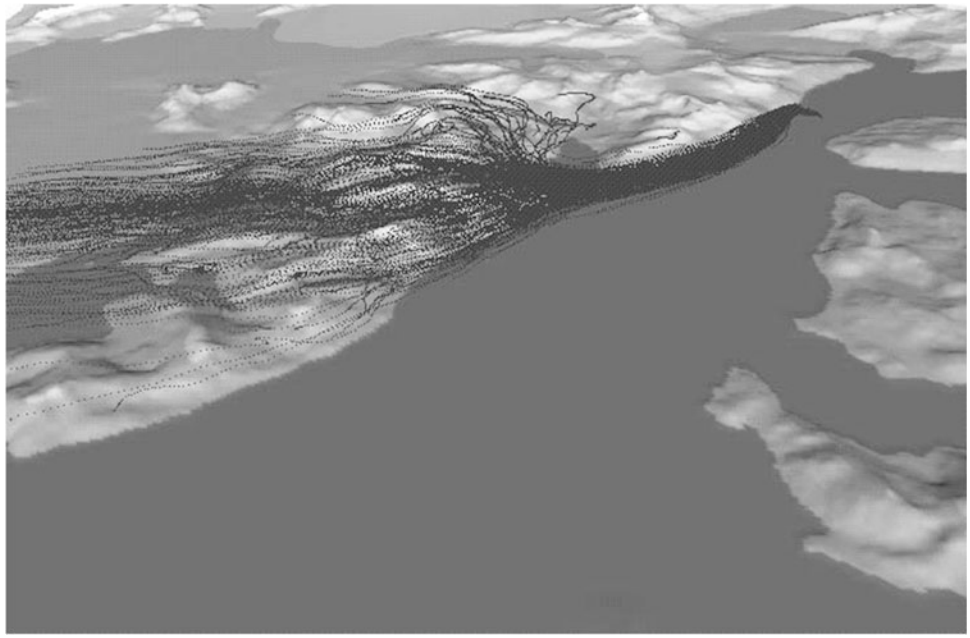

Fig. 32.8 Simulation of smoke from a large oil fire in the Valdez narrows, Alaska (Figure courtesy of NIST)

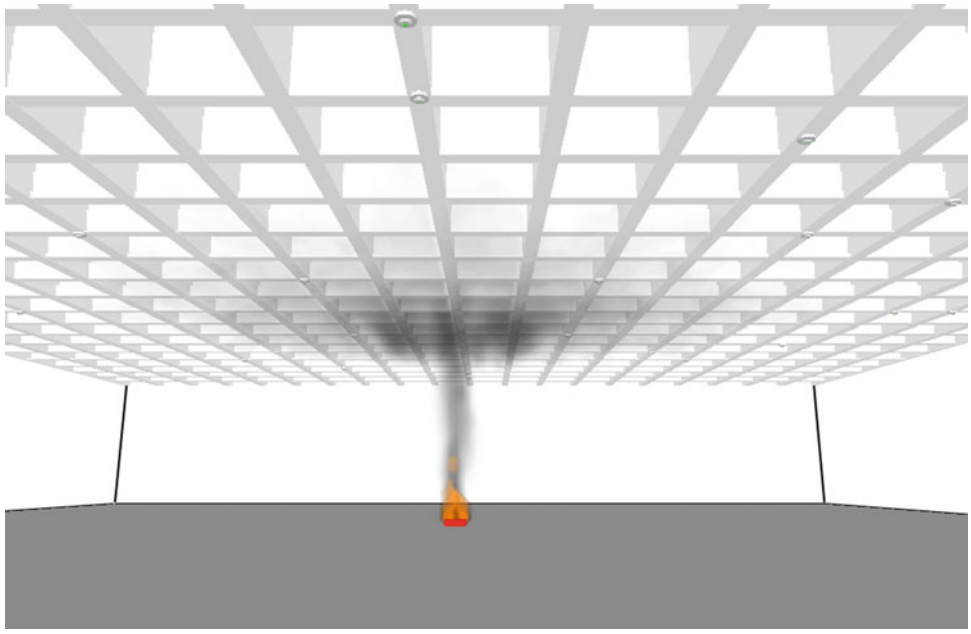

Fig. 32.9 Simulation of smoke filling under a coffered ceiling (Figure courtesy: Aon Fire Protection Engineering Corp.)

of the guidelines, require 900 detectors, one in each beam pocket. While this is obviously unreasonable, making a change to the building code requires evidence. In lieu of a large number of costly full-scale experiments, a small set of full-scale experiments was combined with a large set of "virtual" experiments done with CFD [57, 58]. The researchers evaluated the

appropriateness of the prescriptive provisions and identified ceiling structure parameters, which if altered, would cause significant differences in smoke detection performance as compared to a smooth level ceiling. It had been believed that such beam projections would significantly delay the activation time. The use of CFD modeling showed this expectation to be incorrect and a subsequent full-scale experimental study proved the general findings of the CFD analysis [59]. The final result of the study led to an exception, under some circumstances, to the code requirement of a smoke detector in every beam pocket.

The Role of CFD in the Design Process

As discussed elsewhere in this chapter, CFD has an ever increasing role to play in the development of fire safety science, and has an important contribution to make in better understanding the fundamentals such as flame spread and chemical species production where it is being used in parallel with physical experiments. However, it is as a fire engineering design tool that CFD is probably of most relevance to the majority of readers. Here a few words of caution are worth noting.

CFD modeling has a useful, and sometimes critical, role in developing safe and robust fire engineering solutions where the control of smoke and heat generated by fire forms part of the fire safety strategy. It allows architectural designs to be adopted that in previous eras would have been difficult to justify, for example in respect to smoke control in large and complicated building atria or where a reduced level of structural fire protection is desired. It should, however, be seen as a contributing component to the overall design process, and not as a "black box" that faithfully provides the correct answers regardless of the inputs and assumptions made. A great deal of care and experience is required in order to sensibly use CFD in support of fire engineering designs, and it should be employed alongside simpler calculation and design methods wherever possible to confirm that the CFD results are comparable to the empirical correlations that have traditionally been applied in fire protection engineering.

It is as a parametric design tool that CFD is often most gainfully employed, allowing the impact of varying the input and boundary conditions to be examined. For example, how sensitive is the smoke control solution to the design fire size, or how much influence does a change in wind direction have on a natural smoke ventilation strategy? The reader is encouraged to consult the guidance documents available on the best practice use of CFD in the various application areas and to consult the guidance documentation provided with the CFD model being employed. For example, the guidance document prepared by the US Nuclear Regulatory Commission and the Electrical Power Research Institute (EPRI) on fire modeling for nuclear power plants [60] includes useful information on the appropriate role and application of CFD in the fire safety design process, and is relevant also to fire scenarios outside the nuclear field.

Summary

Computational fluid dynamics modeling of fire has made tremendous progress over the past few decades as our understanding of fire improves and as computers get ever faster. However, although it appears to many that CFD is the cutting edge of fire protection engineering, many non-modelers are surprised to learn that our ability to reproduce fire phenomena via computer simulation lags our empirical understanding by about 10 years. Indeed, current-generation models address transport phenomena reasonably well, making them useful for many engineering applications. However, they have not yet reached the point of reliably predicting, for large-scale applications, such important phenomena as flame spread, extinction, suppression, and CO and smoke production, all of which demand more detailed chemistry and physics than are currently incorporated in the models.

Moving forward will require a new generation of engineers who have expertise in fire physics, mathematics, and computer science to build on

the knowledge possessed by the current generation of modelers. This chapter sets forth the basic elements to lay the foundation of further study for future modelers, and it also provides the current practitioner with a better understanding of the models being used.

Nomenclature

c_p	Specific heat
D_α	Material diffusivity of species α
$\mathbf{f}$	External body force
h	Sensible enthalpy
h_c	Convective heat transfer coefficient
I	Radiant intensity
k	Thermal conductivity; turbulent kinetic energy
$\dot{m}_\alpha'''$	Mass production (destruction) rate of species α per unit volume
p	Pressure
Pr	Prandtl number
$\mathbf{q}$	Heat flux vector
$\dot{q}''$	Heat release rate per unit area
$\dot{q}'''$	Heat release rate per unit volume
$\mathcal{R}$	Universal gas constant
$\mathbf{s}$	Direction vector
s	Stoichiometric air requirement of the fuel
S_{ij}	Strain tensor
Sc	Schmidt number
t	Time
T	Temperature
$\mathbf{u} = (u, v, w)$	Velocity vector
$\overline{W}$	Average molecular weight
$\mathbf{x} = (x, y, z)$	Position vector
Y_α	Mass fraction of species α

Greek Letters

ε	Rate of dissipation of turbulent kinetic energy
κ	Radiation absorption coefficient
λ	Generalized diffusion coefficient
μ	Dynamic viscosity
μ_t	Turbulent viscosity (in eddy viscosity turbulence model)
ρ	Density
σ	Stefan-Boltzmann constant
τ	Stress tensor

Appendix

Much of the difficulty in learning and applying computational fluid dynamics is the complexity of the governing equations. In this appendix, some of the common terms found in the mass, momentum, and energy equations are expanded. Many of the variables and operators can be represented as 3×3, 1×3, or 3×1 matrices, and the expansions can be carried out following the rules of linear algebra. For example, the divergence of the flow vector, $\nabla \cdot \mathbf{u}$, is a scalar formed by multiplying the 1×3 gradient operator ∇ and the 3×1 vector $\mathbf{u}$. On the other hand, the product of the velocity vectors, $\mathbf{u}\,\mathbf{u}$, is found by multiplying a 3×1 vector by a 1×3 vector:

$$\mathbf{uu} = \begin{pmatrix} u \\ v \\ w \end{pmatrix} (u, v, w) = \begin{pmatrix} u^2 & uv & uw \\ vu & v^2 & vw \\ wu & wv & w^2 \end{pmatrix} \tag{32.39}$$

Thus, the convection term in the momentum conservation equation can be expanded as follows:

$$\begin{aligned} \nabla \cdot (\rho \mathbf{uu}) &= \left(\frac{\partial}{\partial x} \frac{\partial}{\partial y} \frac{\partial}{\partial z} \right) \begin{pmatrix} \rho u^2 & \rho uv & \rho uw \\ \rho vu & \rho v^2 & \rho vw \\ \rho wu & \rho wv & \rho w^2 \end{pmatrix} \\ &= \begin{pmatrix} (\rho u^2)_x + (\rho vu)_y + (\rho wu)_z \\ (\rho uv)_x + (\rho v^2)_y + (\rho wv)_z \\ (\rho uw)_x + (\rho vw)_y + (\rho w^2)_z \end{pmatrix}^T \end{aligned} \tag{32.40}$$

The result is a vector whose components form the convective terms of the three component momentum equation. Note that here the subscripts x, y, and z denote partial derivatives with respect to that particular coordinate direction.

The term for the viscosity in the momentum equation, $\nabla\cdot\tau$, is deceptively simple. In reality, it is not, and because it constitutes the heart of the debate over turbulence models, some attention must be paid to it. Using customary tensor notation, the viscous stress tensor is defined as

$$\tau_{ij} = \mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3}\delta_{ij}\nabla\cdot\mathbf{u}\right);$$
$$\delta_{ij} = \begin{cases} 1 \text{ if } i = j \\ 0 \text{ if } i \neq j \end{cases} \tag{32.41}$$

These expressions assert that the viscous stresses are linearly related to the strains, the very definition of a Newtonian fluid. The proportionality constant, μ, is called the dynamic viscosity of the fluid. The viscous stress tensor can also be represented as a 3×3 matrix:

$$\tau = \mu\begin{pmatrix} 2u_x & u_y+v_x & u_z+w_x \\ v_x+u_y & 2 & v_yv_z+w_y \\ w_x+u_z & w_y+v_z & 2w_z \end{pmatrix} - \frac{2}{3}\begin{pmatrix} \nabla\cdot\mathbf{u} & 0 & 0 \\ 0 & \nabla\cdot\mathbf{u} & 0 \\ 0 & 0 & \nabla\cdot\mathbf{u} \end{pmatrix} \tag{32.42}$$

The dissipation function, ε, is a scalar formed by the dot product of two 3×3 matrices:

$$\varepsilon \equiv \tau\cdot\nabla\mathbf{u} = \mu\Big(2u_x^2 + 2v_y^2 + 2w_z^2 + (v_x+u_y)^2 + (w_y+v_z)^2 + (u_z+w_x)^2 - \frac{2}{3}(\nabla\cdot\mathbf{u})^2\Big) \tag{32.43}$$

Enclosure Smoke Filling and Fire-Generated Environmental Conditions

33

Frederick W. Mowrer

Introduction

Fires in buildings and other structures are distinguished from outdoor fires by the confinement effects associated with enclosure boundaries and by the ventilation effects associated with openings in these boundaries. The confinement of heat and smoke released by a fire in an enclosure gives rise to the evolution of fire-generated environmental conditions that can threaten life safety and cause thermal and nonthermal damage to the structure and its contents. For performance-based building fire safety analysis and design, it is important to be able to calculate the environmental conditions generated by fires in enclosures in order to evaluate the threat levels posed by anticipated fire scenarios. This chapter addresses the enclosure smoke-filling process and the fire-generated environmental conditions that develop within an enclosure during this process.

The concept of available safe egress time (ASET) has become a fundamental aspect of performance-based analysis of life safety from fire. In general, life safety from fire is achieved if the required safe egress time (RSET) is shorter than the available safe egress time (i.e., RSET $<$ ASET) for the range of expected fire scenarios. The time it takes to evacuate a space, the RSET, is addressed by Boyce and Gwynne (see Chap. 64) and Gwynne and Rosenbaum (Chap. 59). The available safe egress time is addressed in this chapter in terms of the time it takes for the smoke layer to descend and immerse people located within the fire enclosure and in terms of the hazards associated with fire-generated conditions within the smoke layer.

The control volume, or zone modeling, approach presented by Wade (Chap. 29) is used as the basis for the analyses presented here. A number of explicit equations for evaluating the smoke layer interface position and the average conditions within a smoke layer are presented in this chapter for certain idealized fire scenarios. These closed-form equations, sometimes called "hand calculations" because they can be solved without the aid of a computer, are useful for estimating smoke layer interface position and average smoke layer conditions for the range of applications for which these equations are valid.

For more detailed analyses and for scenarios where hand calculations are impractical or not valid, use of either a computer-based zone model or a computational fluid dynamics (CFD) model may be warranted to evaluate fire-generated conditions in an enclosure. Such computer-based models will generally be needed to evaluate multiroom fire scenarios and may be preferred to evaluate single room scenarios. The concepts presented here are relevant to the computer-based zone fire models, but the complexities associated with keeping track of multiroom fire scenarios are not addressed.

Computer-based zone models are addressed by Walton, Carpenter, and Wood (see Chap. 31), whereas computer-based CFD models are addressed by McGrattan and Miles (see Chap. 32).

Background

The first efforts to characterize the enclosure smoke-filling process and the environmental conditions generated by a fire in a closed room can be traced to the late 1970s and early 1980s. The seminal paper on this topic was published in 1978 by Zukoski [1], who applied thermodynamic control volume concepts to evaluate mass and energy balances within a closed room subjected to a fire. Shortly thereafter, Cooper applied Zukoski's concepts to develop the available safe egress time (ASET) model [2, 3], a computer-based fire model designed to calculate the evolution of the descending smoke layer interface position and the average temperature and smoke concentration conditions within the smoke layer in response to specified fires. During the early 1980s, Walton [4] converted the original ASET model from FORTRAN to BASIC and simplified the numerical methods used in the model to allow its convenient application on the desktop personal computers that were just then starting to be used in engineering practice; this version of the model was known as ASET-B. Since its original development, various versions of the ASET model have been incorporated into different fire modeling suites, such as FPETOOL [5]. Hurley [6] has compared ASET-B model predictions with large-scale experimental test data.

During the early 1990s, Mowrer [7] addressed the evolution of fire and smoke conditions in a closed room as part of the development of the FIVE Methodology [8] (see Chap. 89) for evaluating fire-induced vulnerabilities in commercial nuclear power plants. Subsequently, Milke and Mowrer [9] expanded this analysis for application to smoke management systems in atria and covered malls. This application has been incorporated into the NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria and Large Spaces* [10] and is discussed further by Milke (see Chap. 51). More recently, Mowrer [11] has revisited the enclosure smoke-filling process, recasting its formulation in terms of the volumetric flow rates generally used for ventilation system design. Mowrer [12] has also addressed the role of mechanical ventilation on smoke filling and management in terms of these volumetric flow rates. Matsuyama et al. [13] and Delichatsios [14] have developed closed-form solutions for enclosure smoke filling, whereas Delichatsios [15] has also addressed tenability conditions and filling times for fires in large spaces.

Stages of Enclosure Fires

Enclosure fires go through a series of stages that depend on the size and shape of the enclosure, the thermal properties of the boundary materials, the sizes and locations of ventilation pathways through the enclosure boundaries, and the development of the fire. Mowrer [11] has identified the four stages of enclosure fires as

- Fire plume/ceiling jet stage
- Enclosure smoke filling stage
- Preflashover vented stage
- Postflashover vented stage

Fire Plume/Ceiling Jet Stage

During the first stage of an enclosure fire, the fire plume/ceiling jet stage, air is entrained into the flame region, where it mixes with fuel being released from the fuel surface and burns, typically in a nonpremixed (diffusion) flame. The energy released by the combustion reaction causes the temperature of the combustion products to increase and their density to decrease. Because these combustion products are less dense than the surrounding air, they rise through the surrounding air in a buoyant coherent stream known as the fire plume, as shown in Fig. 33.1. As the buoyant gases rise in the fire plume, additional air is entrained into the fire

plume, causing the temperature and smoke concentration within the plume to decrease while causing the volume of smoke, which is defined to include the actual combustion products as well as the entrained air, to increase with increasing height above the fire source. Phenomena associated with fire plumes are addressed in more detail by Heskestad (see Chap. 13).

When the fire plume impinges on a smooth horizontal ceiling, the buoyant gases turn and spread out radially beneath the ceiling in a relatively thin layer known as the ceiling jet, as shown in Fig. 33.1. These gases continue to spread radially beneath the ceiling until they are confined by the enclosing walls of the fire room. The impingement of the plume at the ceiling and the confinement of flow beneath the ceiling constitute the first significant distinction between an enclosure fire and an outdoor fire. Ceiling jets are addressed in more detail by Alpert (see Chap. 14).

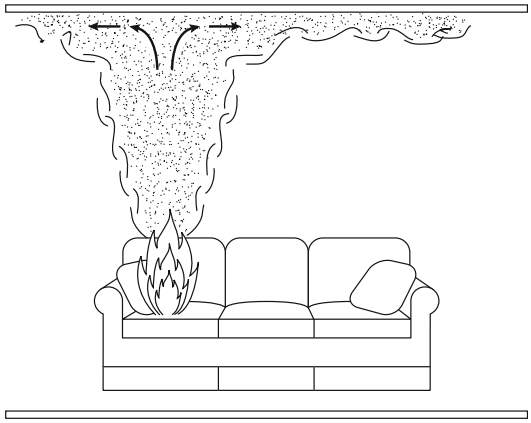

Fig. 33.1 The fire plume/ceiling jet stage of an enclosure fire

Enclosure Smoke-Filling Stage

Once the ceiling jet reaches the wall boundaries, the smoky gases in the ceiling jet turn downward and begin to accumulate beneath the ceiling, as shown in Fig. 33.2. This begins the second stage of enclosure fires, the smoke-filling stage. During the smoke-filling stage, smoke is injected via the fire plume into the developing smoke layer, where the buoyant smoke accumulates beneath the ceiling. The smoke layer interface descends within the enclosure as a result of continued smoke injection via the plume.

If no sizable vents are available in the enclosure boundaries, the smoke layer will continue

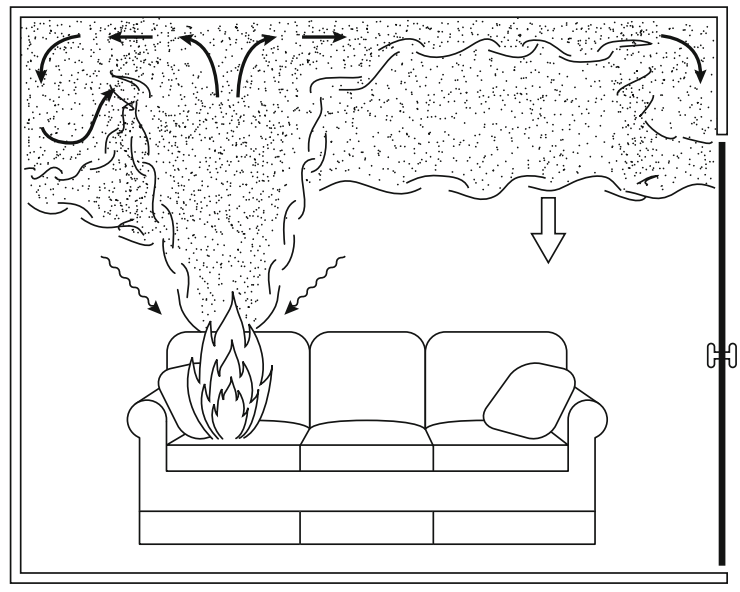

Fig. 33.2 The smoke-filling stage of an enclosure fire

to descend until it reaches either the elevation of the fire source or the floor. Enclosure boundaries in buildings are generally leaky enough to prevent significant pressure increases as a result of the gas expansion associated with enclosure fires. In a closed room, the smoke layer may descend to the level of the fire and act to suppress the fire due to oxygen depletion within the smoke layer, much as a candle flame will extinguish when placed beneath an inverted jar. On the other hand, if a vent is opened, such as a window that breaks from heat-induced stresses or a door that is opened by fire fighters, such a fire may rapidly redevelop due to the influx of fresh air. With an influx of fresh air, a backdraft explosion [16] may occur if sufficient unburned fuel vapors have accumulated within the room.

Preflashover Vented Stage

If one or more open wall vents are provided from the fire space, such as a window to the outside or a doorway to an adjacent space, then the smoke will flow from the enclosure into the adjacent space once the smoke layer descends to the level where a wall vent is available, as illustrated in Fig. 33.3. This begins the third stage of enclosure fires, the preflashover vented stage. During this stage, the smoke layer will descend to the elevation where the flow of air into the fire room is balanced by the flow of smoke out of the fire room. In many cases, both the inflow of air and the outflow of smoke will be through the same wall vent, as illustrated in Fig. 33.3. Vent flows are addressed in more detail by Tanaka (see Chap. 15).

Postflashover Vented Stage

The fourth stage of enclosure fires, the postflashover vented stage, occurs if the fire intensifies to the point where the smoke layer reaches a temperature sufficient to cause the radiant ignition of exposed combustible surfaces within the fire enclosure, as illustrated in Fig. 33.4. Either an average smoke layer temperature of approximately 600 C or an incident heat flux of approximately 20 kW/m [2] at floor level is often used as an indication of the onset of flashover. Methods for estimating the heat release rates necessary to cause flashover and for estimating smoke layer temperatures resulting from pre- and postflashover vented fires are addressed by Walton, Thomas and Ohmiya (see Chap. 30).

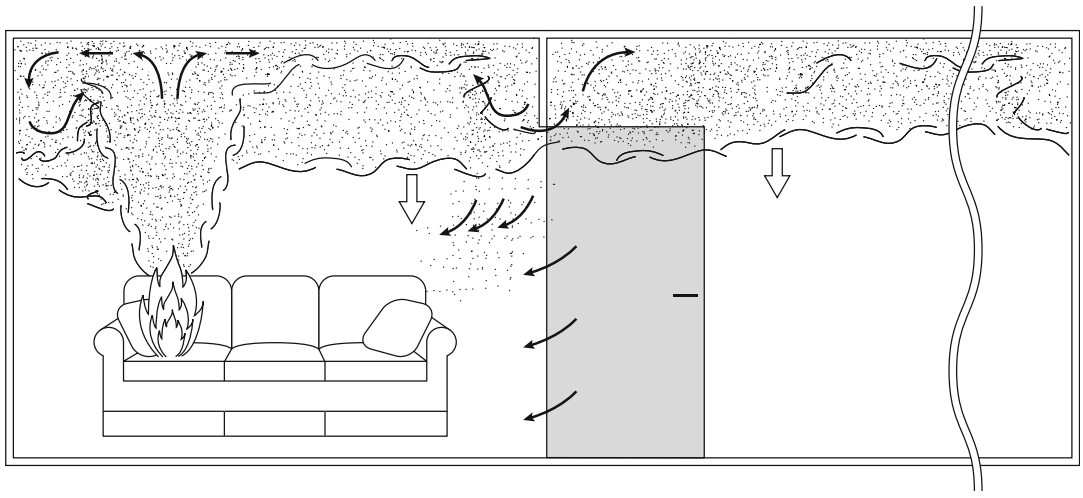

Fig. 33.3 The preflashover vented stage of an enclosure fire

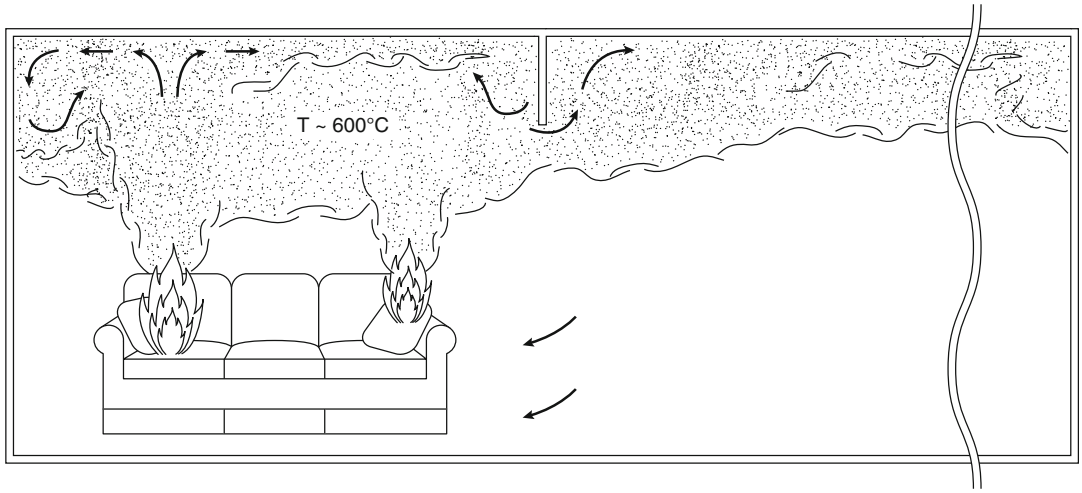

Fig. 33.4 The postflashover vented stage of an enclosure fire

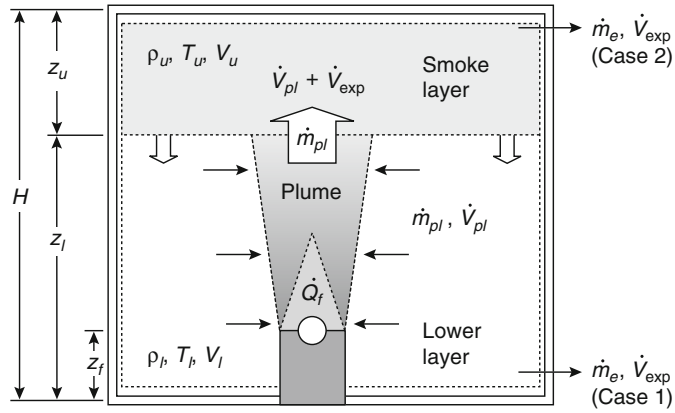

Fig. 33.5 Control volumes and phenomena associated with enclosure smoke filling

Phenomena Associated with Modeling of Enclosure Smoke Filling

Phenomena associated with the modeling of enclosure smoke filling are described in this section. The basic phenomena associated with this stage of enclosure fires are illustrated in idealized form in Fig. 33.5. A fire located at some arbitrary elevation, z_f, above the floor of a room is represented as a point source of heat addition, $\dot{Q}_f$, to the space. A fraction, χ_l, of the heat released by the fire is lost by heat transfer to the boundaries of the enclosure or to other surfaces within the enclosure, while the remaining fraction, $(1 - \chi_l)$, causes heating and expansion of gases within the enclosure. Of the heat released by the fire, a fraction, χ_r, is radiated away from the combustion zone, while the remaining fraction, $\chi_c = 1 - \chi_r$, is convected in the buoyant plume that rises from the fire source to the ceiling.

The plume entrains surrounding air as it rises through the atmosphere. Combustion products and entrained air are transported along with convected heat to the ceiling, where the plume turns to form a ceiling jet that spreads radially beneath the ceiling. When the ceiling jet reaches the wall boundaries of the enclosure, it is deflected downward. For purposes of modeling enclosure smoke filling, it is common to neglect the ceiling jet altogether and to assume that the

enclosure begins to fill uniformly with smoke from the ceiling down due to the injection of smoke into the smoke layer via the fire plume. This is the approach taken here.

The developing smoke layer is normally treated as a distinct control volume with uniform properties for zone modeling purposes. As a modeling idealization, the upper and lower layer control volumes are assumed to be separated by a distinct thermal discontinuity at the interface between the two layers. This interface is known as the smoke layer interface. The smoke layer descends within the enclosure due to the entrainment of fresh air from the lower layer into the fire plume and, depending on the location of leakage paths from the enclosure to surrounding spaces, the expansion of heated gases in the upper layer. Mechanical ventilation will also influence the development of the smoke layer and the conditions within the smoke layer; it is not included in this discussion of general phenomena, but the influence of mechanical ventilation on the development of the smoke layer and the conditions within the smoke layer is addressed in a subsequent section of this chapter.

The expansion of gases within the enclosure due to heat addition pressurizes the enclosure relative to adjacent spaces and forces the flow of gases from the enclosure through available leakage paths. Three different cases are addressed to consider these pressure effects for different leakage flow cases. First, a global analysis is presented where the entire enclosure is treated as a single, fixed control volume assumed to have uniform conditions throughout. The primary purpose of this global analysis is to address pressure effects, but this global analysis is also instructive with respect to temperature and smoke concentration effects, providing a basis for comparison of the more detailed smoke layer descent analyses. This global analysis is followed by two smoke layer descent analyses, designated as Cases 1 and 2, that address the descending smoke layer explicitly in terms of upper and lower layer control volumes. Leakage paths are assumed to be at floor level only in Case 1 and at ceiling level only in Case 2, as illustrated in Fig. 33.5. Case 1 is the scenario addressed by the ASET model [2]. As shown in the subsequent analysis of these two cases, the location of leakage paths does not have a large influence on smoke layer development or conditions.

Once the smoke layer descends to the elevation of the fire source, the fire source becomes immersed in the smoke layer, and further entrainment of fresh air from the lower layer is assumed to cease. After this time, the fire will entrain and recirculate smoke from within the smoke layer, as illustrated in Fig. 33.6, and the smoke layer will continue to descend due only to gas expansion. Because fresh air is no longer being entrained into the fire, the intensity of the fire will eventually diminish due to oxygen depletion within the smoke layer.

As a fire in a closed compartment diminishes due to oxygen depletion, the rate of heat losses to enclosure boundaries will become greater than

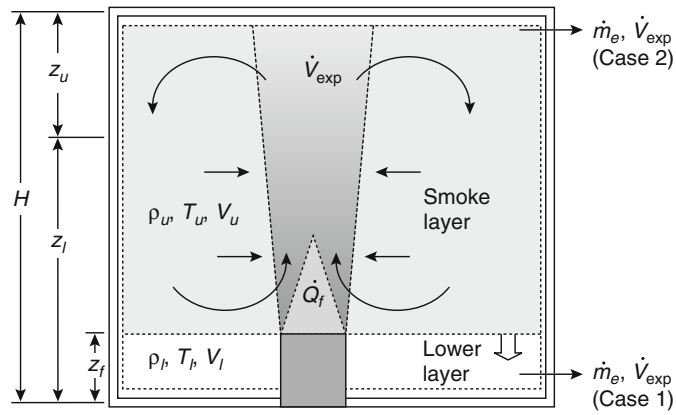

Fig. 33.6 Smoke recirculation associated with smoke layer descent to fuel surface

the rate of heat addition due to the fire. The smoke will cool and contract as a consequence, causing the fire enclosure to depressurize relative to adjacent spaces. This depressurization will draw air into the enclosure from surrounding spaces, which in turn may allow the fire to reintensify and repressurize the enclosure. This cycle of depressurization and repressurization, sometimes called *puffing* behavior, can repeat indefinitely and is one of the warning signs of an underventilated fire, which may result in a backdraft if a large ventilation opening is suddenly provided in an enclosure boundary.

Global (One-Zone) Analysis

In this section, the entire enclosure gas volume is treated as a fixed control volume, as shown in Fig. 33.7. Zukoski [1] addressed the pressure rise that would occur in both sealed and leaky enclosures by considering this global control volume. In both the sealed and leaky cases, a general energy balance for the enclosure control volume can be written as

$$\frac{dU}{dt} = \dot{Q}_{\text{net}} + \dot{m}_i h_i - \dot{m}_o h_o - P\frac{dV}{dt} \qquad (33.1)$$

where U is the total internal energy in the control volume and $\dot{Q}_{\text{net}}$ is the net rate of heat addition into the space; it is equal to the difference between the actual heat release rate of the fire, $\dot{Q}_f$, and the rate of heat loss, $\dot{Q}_l$, to boundaries and other solid surfaces, such as equipment located within the space.

Many fire models calculate boundary heat losses explicitly, usually in terms of one-dimensional heat transfer through a slab. For the present discussion, a constant heat loss fraction, χ_l, is used to represent boundary heat losses, such that

$$\dot{Q}_{\text{net}} = \dot{Q}_f - \dot{Q}_l = \dot{Q}_f(1 - \chi_l) \qquad (33.2)$$

This is the approach taken by Cooper [2, 3], who suggests values for χ_l in the range of 0.6–0.9 for most situations. Cooper suggests that values near the low end of this range are appropriate for spaces with smooth ceilings and large ceiling area to height (A/H^2) ratios. Values near the high end of the range would be appropriate for spaces with irregular ceiling shapes, with small ceiling area to height ratios, or where fires are located near walls. Mowrer [7] found that a value of 0.7 for the heat loss fraction provided good agreement with experimental temperature data for a series of fire tests [17] conducted in a room with a floor area of 223 m^2, a smooth ceiling, an aspect ratio (A/H^2) of 6, and a dimensionless heat release rate, Q^*, defined as

$$Q^* \equiv \dot{Q} / \left(\rho_a c_p T_a \sqrt{gH} H^2\right)$$

of approximately 1.7×10^{-4}.

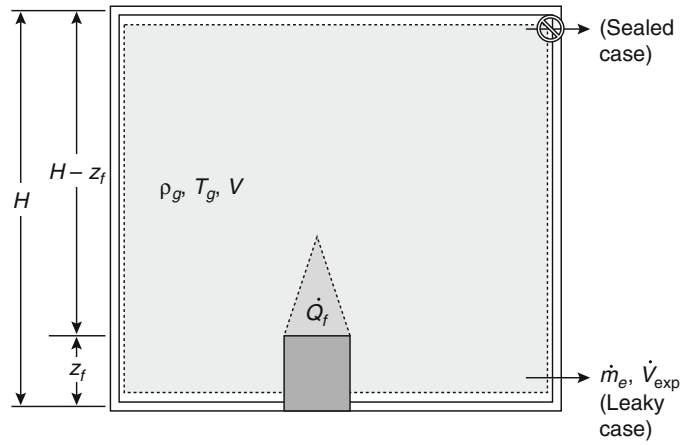

Fig. 33.7 Single control volume and leakage flows used for global analysis

It should be recognized that temperature predictions are sensitive to the selection of the heat loss fraction when using this approach. Because the heat retained in the gas volume is proportional to $(1-\chi_l)$, a seemingly small change in the heat loss fraction from 0.9 to 0.8 represents a twofold difference in the net heat addition term.

Sealed Compartment

Neglecting fuel vapor addition to the enclosure control volume associated with the fire, the mass flow rates into and out of the enclosure are assumed to be nil for the sealed compartment. The volume of the compartment does not change and the total mass within the compartment remains constant. Assuming ideal gas behavior and constant specific heat with properties of air, for the sealed compartment Equation 33.1 reduces to

$$\rho V\frac{du}{dt}=\rho c_v V\frac{dT}{dt}=\frac{c_v V}{R}\frac{dP}{dt}=\dot{Q}_{\text{net}} \tag{33.3}$$

Through manipulation of the ideal gas law, the normalized pressure and temperature rise in a sealed compartment subject to a net change of energy, but without a change in mass or molar quantity, can be expressed as

$$\frac{\Delta P}{P_o}=\frac{\Delta T}{T_o}=\frac{\int_o^t \dot{Q}_{\text{net}}dt}{\rho_o c_v T_o V}=\frac{Q_{\text{net}}}{Q_{o,v}} \tag{33.4}$$

where

$Q_{o,v}(\equiv \rho_o c_v T_o V)$ = Total internal energy of the control volume
P_o = Absolute ambient pressure
T_o = Absolute temperature of the control volume

The product of $\rho_o c_v T_o$ can be treated as a constant with a value of approximately 252 kJ/m^3, assuming air properties at standard temperature and pressure.

Application of Equation 33.4 to representative building fires demonstrates how quickly typical building boundaries would fail due to overpressurization if the boundaries were in fact hermetically sealed to prevent mass flow through enclosure boundaries. The following example illustrates this point. Pressure changes may be a significant issue for fires in airtight vessels, including submarines and space vehicles, but are not usually significant for typical building spaces, which are leaky by nature.

Example 1 Determine the pressure rise and average temperature increase associated with combustion of 1 L of gasoline within a sealed enclosure with dimensions of 10 m by 10 m by 3 m. Assume a heat loss fraction of 0.90. Assuming ordinary window glass can withstand a pressure differential of approximately 1013 Pa (0.01 atm) before failing [18], would this pressure rise be likely to cause window failure?

Solution First, estimate the enthalpy of reaction associated with the gasoline:

$$Q_f=m_f\Delta H_c=\rho_f V_f\Delta H_c=(760\,\text{kg/m}^3)\cdot\left(10^{-3}\text{m}^3\right)\cdot(44{,}000\,\text{kJ/kg})=33{,}440\,\text{kJ}$$

Then, calculate the net heat release associated with the burning of the gasoline:

$$Q_{\text{net}}=Q_f(1-\chi_l)=33{,}440\,\text{kJ}\cdot(1-0.9)=3344\,\text{kJ}$$

Next, calculate the ambient internal energy level associated with the enclosure gases:

$$Q_{o,v}=\rho_o c_v T_o V=\left(252\,\text{kJ/m}^3\right)\cdot\left(300\,\text{m}^3\right)=75{,}600\,\text{kJ}$$

Next, calculate the dimensionless pressure and temperature changes using Equation 33.4:

$$\frac{\Delta P}{P_o} = \frac{\Delta T}{T_o} = \frac{Q_{\text{net}}}{Q_{o,v}} = \frac{3344\ \text{kJ}}{75,600\ \text{kJ}} = 0.044$$

Finally, calculate the dimensional pressure and temperature changes:

$$\Delta P = 0.044 P_o = 0.044(101,325\ \text{Pa}) = 4482\text{Pa}$$

$$\Delta T = 0.044 T_o = 0.044(293\ \text{K}) = 13\ \text{K}$$

Thus, the calculated pressure increase is more than four times the specified pressure differential associated with window breakage, despite the following: the fuel source is only 1 L of gasoline, 90% of the heat release is assumed to be lost to the boundaries, the room volume is relatively large at 300 m^3, and the average temperature change is only 13 K. The fact that such small fires do not routinely cause overpressure failures of enclosure boundaries can be viewed as de facto evidence that real building enclosures are leaky by nature.

Leaky Compartment

For the global analysis of the leaky compartment, the entire enclosure volume is again considered as a fixed control volume, just as it was for the sealed compartment. In this case, the pressure rise in the compartment caused by the release of energy is assumed to force flow out of the enclosure through available leakage paths while at the same time preventing mass flow into the compartment through these same leakage paths. Consequently, for the leaky case, the energy balance expressed by Equation 33.1 reduces to

$$\frac{d(\rho u V)}{dt} = \dot{Q}_{\text{net}} - \dot{m}_o h_o \qquad (33.5)$$

As for the sealed compartment analysis, the left-hand side of Equation 33.5 can be expressed, for an ideal gas, as

$$\frac{d(\rho u V)}{dt} = \frac{c_v V}{R}\frac{dP}{dt} \qquad (33.6)$$

Substituting Equation 33.6 into Equation 33.5 permits the rate of pressure change to be calculated as

$$\frac{dP}{dt} = \frac{R}{c_v V}\left(\dot{Q}_{\text{net}} - \dot{m}_o h_o\right) = \frac{(k-1)}{V}\left(\dot{Q}_{\text{net}} - \dot{m}_o h_o\right) \qquad (33.7)$$

where $k \equiv c_p/c_v$ (≈ 1.4 for air).

Equation 33.7 generally requires numerical solution because the mass outflow term on the right-hand side is a function of the pressure differential between the fire enclosure and surrounding spaces, while the net heat release rate term can vary with time. Zukoski [1] examined the assumption that the rate of pressure change is negligible by comparing the time for the pressure to rise to 86% of its equilibrium value with the time for the smoke layer to descend to the floor. For most scenarios, he found the ratio of these times to be on the order of 10^{-2}; for relatively large fires or relatively small leakage areas, this ratio was on the order of 10^{-1}. Based on this analysis, Zukoski concluded that an assumption of quasi-steady pressure would be satisfactory for most fire scenarios. In all the cases considered by Zukoski, the pressure rise was so small that gas density and pressure were virtually unaffected. This quasi-steady pressure assumption is employed here.

From a practical standpoint, the overall pressure rise relative to atmospheric pressure, $\Delta P/P_o$, is generally very small for fires in leaky enclosures, typically on the order of 10^{-3} to 10^{-5}, depending on the heat addition rate and the area of leakage paths. Pressure differences of this magnitude are significant with respect to the flows they cause through leakage paths in the enclosure boundaries, but can be considered as negligible with respect to the energy equation. Consequently, for most enclosure fire scenarios, the pressure can be treated as quasi-steady (i.e., $dP/dt \to 0$ in Equation 33.7) and the quasi-steady global energy balance for the leaky compartment can then be expressed as

$$\dot{Q}_{\text{net}} = \dot{m}_o h_o = \rho_e c_p T_e \dot{V}_{\text{exp}} \qquad (33.8)$$

Equation 33.8 can be rearranged to solve for the volumetric flow rate of gases from a compartment due to expansion. Using air properties with the customary assumptions of constant specific heat, standard atmospheric pressure, and ideal

gas behavior, this volumetric flow rate caused by expansion can be expressed as

$$\dot{V}_{\exp}\left(\mathrm{m}^3/\mathrm{s}\right) = \frac{\dot{Q}_{\mathrm{net}}}{\rho_e c_p T_e} \cong \frac{\dot{Q}_{\mathrm{net}}(\mathrm{kW})}{353(\mathrm{kJ/m}^3)} \quad (33.9)$$

As illustrated in Figs. 33.5 and 33.6, Equation 33.9 also represents the volumetric expansion rate of the smoke layer.

The quasi-steady pressure rise associated with this volumetric expansion rate can be calculated using classical orifice flow theory as discussed by Tanaka (see Chap. 15):

$$\dot{V}_{\exp} = C_d A_{\mathrm{leak}} v_e = C_d A_{\mathrm{leak}} \sqrt{\frac{2\Delta P}{\rho_e}} \quad (33.10)$$

Equations 33.9 and 33.10 can be combined to solve for the quasi-steady pressure rise, ΔP, within the fire enclosure:

$$\Delta P = \frac{1}{2}\rho_e \left(\frac{\dot{Q}_{\mathrm{net}}}{\left(\rho_e c_p T_e\right) C_d A_{\mathrm{leak}}}\right)^2 \quad (33.11)$$

Equation 33.11 can be used to check the assumption that the pressure rise in a compartment fire is negligible relative to the ambient pressure level.

Example 2 Calculate the volumetric expansion rate and quasi-steady pressure rise that would be associated with a fire with a heat release rate of 500 kW, a heat loss fraction of 0.7, a discharge coefficient of 0.65, and a leakage area of 0.04 m^2. Assume air with a density of 1.20 $\mathrm{kg/m}^3$ is being expelled from the fire room.

Solution First, calculate the net heat release rate:

$$\dot{Q}_{\mathrm{net}} = \dot{Q}_f \cdot (1 - \chi_l) = (500\ \mathrm{kW}) \cdot (1 - 0.7) = 150\ \mathrm{kW}$$

Then, calculate the volumetric expansion rate associated with this net heat release rate:

$$\dot{V}_{\exp} = \frac{\dot{Q}_{\mathrm{net}}}{\rho_e c_p T_e} = \frac{(150\,\mathrm{kW})}{(353\,\mathrm{kJ/m}^3)} = 0.42\ \mathrm{m}^3/\mathrm{s}$$

Finally, calculate the quasi-steady pressure rise associated with this flow rate:

$$\Delta P = \frac{1}{2}\rho_e \left(\frac{\dot{V}_{\exp}}{C_d A_{\mathrm{leak}}}\right)^2 = \frac{(1.2\ \mathrm{kg/m}^3)}{2}\left(\frac{0.42\ \mathrm{m}^3/\mathrm{s}}{(0.65)\,(0.04\ \mathrm{m}^2)}\right)^2 = 157\mathrm{Pa}$$

Thus,

$$\frac{\Delta P}{P_o} = \frac{157\ \mathrm{Pa}}{101,325\ \mathrm{Pa}} \sim O\left(10^{-3}\right)$$

which supports the assumption of negligible effect on the energy equation. Based on measurements of pressure differentials during enclosure fire tests, this is a relatively high pressure differential, suggesting that real enclosures tend to be even more leaky than was assumed for this example.

Temperature Rise

The average temperature rise of the fixed control volume associated with a leaky compartment is considered in this subsection. First, the mass balance for the fixed control volume is introduced, recalling that the pressurization of the control volume caused by heat release from the fire is assumed to prevent mass inflow:

$$\dot{m}_o = -\frac{d(\rho V)}{dt} = -V\frac{d\rho}{dt} \quad (33.12)$$

Substituting Equation 33.12 into Equation 33.8 yields

$$\dot{Q}_{\mathrm{net}} = \dot{m}_o h_o = -c_p T V \frac{d\rho}{dt} \quad (33.13)$$

For an ideal gas at constant pressure, the density is related to the temperature as $\rho = \rho_o T_o / T$. Consequently, the rate of change of density can be related to the rate of temperature change as

$$\frac{d\rho}{dt} = -\frac{\rho_o T_o}{T^2}\frac{dT}{dt} \quad (33.14)$$

Substituting Equation 33.14 into Equation 33.13 yields

$$\dot{Q}_{\mathrm{net}} = \left(\rho_o c_p T_o V\right)\frac{dT}{T dt} = \frac{Q_{o,p}}{T}\frac{dT}{dt} \quad (33.15)$$

The term $Q_{o,p}$ ($\equiv \rho_o c_p T_o V$) is analogous to the $Q_{o,v}$ term for the sealed compartment case; this term represents the ambient enthalpy level for a fixed control volume at constant pressure. Assuming that gases within the control volume have the properties of air, the product of $\rho_o c_p T_o$ can be treated as a constant with a value of approximately 353 kJ/m^3 over the temperature range of interest for preflashover enclosure fires. Equation 33.15 can be rearranged and integrated as

$$\int_0^t \dot{Q}_{\text{net}} dt = Q_{o,p} \int_{T_o}^{T_g} \frac{dT}{T} \tag{33.16}$$

The solution to Equation 33.16 can be expressed in terms of the dimensionless average temperature rise in the fixed control volume:

$$\frac{\Delta T}{T_o} = \exp\left(\frac{Q_{\text{net}}}{Q_{o,p}}\right) - 1 \tag{33.17}$$

where

$Q_{\text{net}} = \int_0^t \dot{Q}_{\text{net}} dt$ = Net energy addition to the control volume as before

T_o = Absolute ambient temperature

The relationship expressed by Equation 33.17 is illustrated in Fig. 33.8.

Equation 33.17 permits calculation of an average temperature rise caused by a fire within an enclosure. Equation 33.17 is particularly useful for fire hazard screening purposes, because it allows thermal hazards to be estimated without the need to track conditions in the descending smoke layer by numerical integration. Global temperatures calculated with Equation 33.17 are compared with smoke layer temperatures for Case 1 and Case 2 descending layer scenarios in a subsequent section of this chapter.

Example 3 Determine the average global temperature rise in an enclosure with dimensions of 18.3 m by 12.2 m by 6.1 m in response to a fire that grows as a *t*-squared fire to a heat release rate of 500 kW in 240 s, then burns at a constant heat release rate of 500 kW for another 360 s. Estimate the average temperature rise within the enclosure at 240 s and at 600 s based on this heat release rate history, assuming a constant heat loss fraction of 0.70 and an ambient temperature of 20 °C (293 K).

Solution First, calculate the net heat release for the two selected times:

$$Q_{\text{net}} = \int_o^t \dot{Q}_{\text{net}} dt = \int_o^t \dot{Q}_f (1 - \chi_l) dt$$

During the period up to 240 s, the fire heat release rate follows the specified *t*-squared

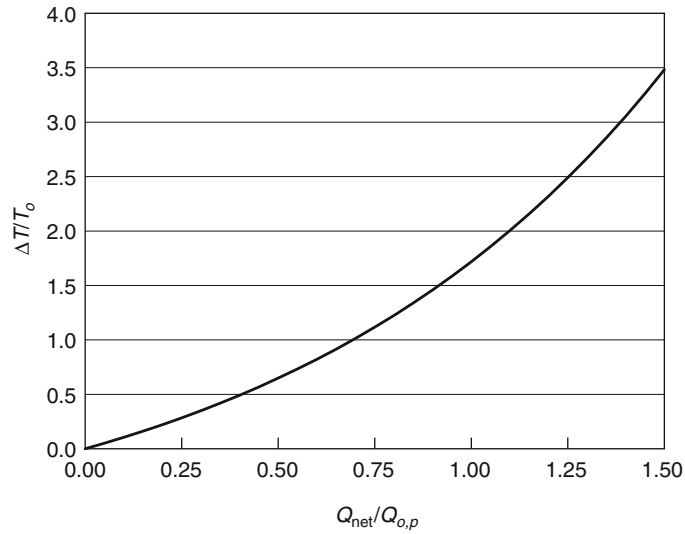

Fig. 33.8 Average dimensionless temperature rise in a closed room as a function of the dimensionless net energy addition

growth, and the net heat release during this period is calculated as

$$Q_{\text{net}}(@240\text{ s}) = \int_o^{240} \left(\frac{500}{(240)^2}\right)(1-0.7)t^2 dt$$
$$= \left(\frac{500}{(240)^2}\right)(0.3)\left(\frac{(240)^3}{3}\right)$$
$$= 12,000\text{ kJ}$$

The net heat release at 600 s is equal to this value plus the net heat release during the period from 240 s to 600 s, when the fire heat release rate is constant:

$$Q_{\text{net}}(@600\text{ s}) = Q_{\text{net}}(@240\text{ s}) + \int_{240}^{600} 500\,(1-0.7)dt$$
$$= 12,000\text{ kJ} + 54,000\text{ kJ}$$
$$= 66,000\text{ kJ}$$

Next, the ambient enthalpy level within the enclosure is calculated:

$$Q_{o,\,p} = \rho_o c_p T_o V = \left(353\text{ kJ/m}^3\right)\cdot\left(1362\text{ m}^3\right)$$
$$= 480,746\text{ kJ}$$

Then, the average dimensionless temperature rise at each time is calculated as

$$\frac{\Delta T}{T_o} = \exp\left(\frac{Q_{\text{net}}}{Q_{o,\,p}}\right) - 1 = \exp\left(\frac{12,000}{480,746}\right) - 1 = 0.025 \text{ at } 240\text{ s}$$

$$\frac{\Delta T}{T_o} = \exp\left(\frac{Q_{\text{net}}}{Q_{o,\,p}}\right) - 1 = \exp\left(\frac{66,000}{480,746}\right) - 1 = 0.147 \text{ at } 600\text{ s}$$

Finally, the dimensional temperature changes are calculated at each time as

$$\Delta T = 0.025 \cdot T_o = 0.025 \cdot 293\text{ K} = 7.3\text{ K at } 240\text{ s}$$

$$\Delta T = 0.147 \cdot T_o = 0.147 \cdot 293\text{ K} = 43.1\text{ K at } 600\text{ s}$$

Note that the ambient enthalpy level has been based on the entire volume of the enclosure, as illustrated in Fig. 33.7, not just on the volume above the fire source, as illustrated in Fig. 33.6. Rather than apply Equation 33.17 based on the entire enclosure volume, it makes sense to consider the fixed control volume defined as the volume between the base of the fire source and the ceiling, as illustrated in Fig. 33.6. Assuming that air entrainment occurs only laterally, this control volume will not have mass inflow across the lower control volume boundary. For this scenario, air entrained into the fire plume is simply recirculated from within the fixed control volume, with some gases forced out of this control volume through its lower face due to expansion. With the smaller control volume defined in this way, the temperature rise expressed by Equation 33.17 will increase more rapidly for elevated fires than if it is based on the entire enclosure volume, assuming the heat loss fraction does not change significantly for elevated fires. This will produce a more conservative estimate of temperature hazards based on application of Equation 33.17.

Example 4 For the previous example, estimate the average temperature rise within the upper layer at the same times (240 s and 600 s) assuming the fire source is located at an elevation of 3.0 m and assuming the same constant heat loss fraction of 0.70. How do these values compare with the results in the previous example?

Solution The only difference in this case compared with the previous example is that the size of the control volume has decreased by a factor of two. Therefore, the ambient enthalpy level within the control volume is calculated as

$$Q_{o,\,p} = \rho_o c_p T_o V = \left(353\text{ kJ/m}^3\right)\cdot\left(681\text{ m}^3\right)$$
$$= 240,373\text{ kJ}$$

For this case, the average dimensionless temperature rise at each time is calculated as

$$\frac{\Delta T}{T_o} = \exp\left(\frac{Q_{\text{net}}}{Q_{o,p}}\right) - 1 = \exp\left(\frac{12,000}{240,373}\right) - 1 = 0.051 \text{ at } 240 \text{ s}$$

$$\frac{\Delta T}{T_o} = \exp\left(\frac{Q_{\text{net}}}{Q_{o,p}}\right) - 1 = \exp\left(\frac{66,000}{240,373}\right) - 1 = 0.316 \text{ at } 600 \text{ s}$$

Finally, the dimensional temperature changes are calculated at each time as

$$\Delta T = 0.051 \cdot T_o = 0.51 \cdot 293 \text{ K} = 14.9 \text{ K at } 240 \text{ s}$$

$$\Delta T = 0.316 \cdot T_o = 0.316 \cdot 293 \text{ K} = 92.6 \text{ K at } 600 \text{ s}$$

Note that these values for the temperature rise are slightly more than twice the respective values in the previous example. The reason for this is that as the smoke layer heats up, more mass is expelled from the smoke layer, leaving less mass within the smoke layer to absorb additional heat input. That is why the temperature relationship expressed by Equation 33.17 increases exponentially with heat input rather than linearly as in the sealed enclosure case, where the mass within the control volume remains constant.

Concentrations of Smoke and Other Species

The conservation of different chemical species (e.g., O_2, N_2, CO_2, CO, H_2O, soot) within a control volume can be expressed generally as

$$\frac{d(mY_i)}{dt} = (\dot{m}_i Y_{i,in}) - (\dot{m}_o Y_i) + \dot{m}_{i,\text{gen}} \quad (33.18)$$

Y_i is the mass fraction of species i within the control volume. For the fixed control volume shown in Fig. 33.7, it is assumed that mass inflow is precluded by pressurization of the enclosure (i.e., this analysis does not address the "puffing" behavior noted previously), so the first term on the right-hand side of Equation 33.18 is negligible. Furthermore, the left-hand side of Equation 33.18 can be expanded to

$$\frac{d(mY_i)}{dt} = m\frac{dY_i}{dt} + Y_i\frac{dm}{dt} = m\frac{dY_i}{dt} - \dot{m}_o Y_i \quad (33.19)$$

The production of a particular species can generally be described in terms of the product of a species yield factor, f_i, by the fuel mass loss rate, $\dot{m}_f$, such that

$$\dot{m}_{i,\text{gen}} = f_i \dot{m}_f = \frac{\dot{Q}_f}{(\Delta H_c / f_i)} \quad (33.20)$$

Equations 33.18, 33.19, and 33.20 can then be combined and simplified to

$$\frac{dY_i}{dt} = \frac{\dot{m}_{i,\text{gen}}}{m_{cv}} = \frac{\dot{m}_{i,\text{gen}}}{(\rho V)_{cv}} = \frac{\dot{Q}_f}{(\rho V)_{cv}(\Delta H_c / f_i)} \quad (33.21)$$

Equation 33.21 applies under scenarios where the fire is fuel limited, such that the heat release rate of the fire can be expressed as $\dot{Q}_f = {}_i\dot{m}_f \Delta H_c$. The term $(\Delta H_c / f_i)$ in Equation 33.21 represents a "species heat of combustion;" it is the quantity of heat released per unit mass of species i produced (or consumed in the case of oxygen). The species heat of combustion can be estimated based on stoichiometry for products of complete combustion (i.e., CO_2 and H_2O) or based on experimental yield data for products of incomplete combustion (i.e., CO and soot). Extensive yield data for a range of fuels is provided by Tewarson

(see Chap. 36). Equation 33.21 can be integrated with appropriate limits to yield

$$(Y_i - Y_{i,o}) = \frac{\int_0^t \dot{Q}_f dt}{(\rho V)_{cv}(\Delta H_c/f_i)} = \frac{Q_f}{(\rho V)_{cv}(\Delta H_c/f_i)} \tag{33.22}$$

$Y_{i,o}$ is the initial mass fraction of species i in the control volume. For most products of combustion, the initial species mass fraction, $Y_{i,o}$, is nil. For this case, the species mass concentration can be expressed as

$$\rho Y_i = \frac{(Q_f/V)}{(\Delta H_c/f_i)} \tag{33.23}$$

where

ρY_i = Mass concentration of species i (kg_i/m^3)
(Q_f/V) = Fire heat release per unit volume of the control volume (kJ/m^3)
$(\Delta H_c/f_i)$ = Species heat of combustion (kJ/kg_i)

Example 5 Assume propylene (C_3H_6) is the fuel burned in the previous examples. Assume propylene has a heat of combustion of 46.4 MJ/kg of fuel and a soot yield of 0.095 g of soot per g of fuel. Estimate the average mass concentration of soot within the 18.3 m by 12.2 m by 6.1 m enclosure at 240 s and 600 s after ignition of a fire that grows as a t-squared fire to a heat release rate of 500 kW in 240 s, then burns at a constant heat release rate of 500 kW for another 360 s.

Solution First, calculate the fire heat released up to the 240 s and 600 s times, respectively:

$$\begin{aligned} Q_f(@240\text{ s}) &= \int_o^{240} \left(\frac{500}{(240)^2}\right) t^2 dt \\ &= \left(\frac{500}{(240)^2}\right)\left(\frac{(240)^3}{3}\right) \\ &= 40,000\text{ kJ} \end{aligned}$$

$$\begin{aligned} Q_f(@600\text{ s}) &= Q_f(@240\text{ s}) + \int_{240}^{600} 500\, dt \\ &= 40,000\text{ kJ} + 180,000\text{ kJ} \\ &= 220,000\text{ kJ} \end{aligned}$$

The volume of the space is calculated as 18.3 m × 12.2 m × 6.1 m = 1362 m^3. Therefore, the heat release per unit volume is calculated at each time as

$$Q_f/V(@240\text{ s}) = 40,000\text{ kJ}/1382\text{ m}^2 = 28.9\text{kJ/m}^3$$
$$Q_f/V(@600\text{ s}) = 220,000\text{ kJ}/1382\text{ m}^2 = 159.2\text{ kJ/m}^3$$

The species heat of combustion is calculated from the given data as

$$\Delta H_c/f_i = \frac{46.4\text{ MJ/kg}_f}{0.095\text{ kg}_{soot}/\text{kg}_f} = 488.42\text{ MJ/kg}_{soot}$$

Finally, the soot mass concentration at each time is calculated as

$$\begin{aligned} \rho Y_{soot}(@240\text{ s}) &= \frac{28.9\text{ kJ/m}^3}{488.42\times10^3\text{ kJ/kg}_{soot}} \\ &= 5.92\times10^{-5}\text{ kg}_{soot}/\text{m}^3 \\ \rho Y_{soot}(@600\text{ s}) &= \frac{159.2\text{ kJ/m}^3}{488.42\times10^3\text{ kJ/kg}_{soot}} \\ &= 3.26\times10^{-4}\text{ kg}_{soot}/\text{m}^3 \end{aligned}$$

As discussed in a subsequent subsection, the visibility through smoke can be related directly to the soot mass concentration.

For oxygen in air under standard conditions, the initial species mass fraction is $Y_{i,o} = 0.233$ and the species heat of combustion can be taken as the well-known "oxygen heat of combustion," for a wide range of representative fuels, with a value of approximately $\Delta H_c/f_{O_2} = -13,100\text{ kJ}/kg_{O_2}$, where the negative sign indicates that oxygen is consumed rather than produced in the combustion reaction. For these values, the oxygen mass fraction within the fixed control volume can be estimated as

$$\begin{aligned} Y_{O_2} &= Y_{O_2,o} + \frac{Q_f}{\rho V(\Delta H_c/f_{O_2})} \\ &= 0.233 - \frac{(Q_f/V)}{(13,100)\rho} \end{aligned} \tag{33.24}$$

Example 6 Assume propylene (C_3H_6) is the fuel burned in the previous examples. Assume propylene has a heat of combustion of 46.4 MJ/kg of

fuel and a soot yield of 0.095 g of soot per g of fuel. Estimate the average oxygen mass fraction within the 18.3 m by 12.2 m by 6.1 m enclosure at 240 s and 600 s after ignition of a fire that grows as a *t*-squared fire to a heat release rate of 500 kW in 240 s, then burns at a constant heat release rate of 500 kW for another 360 s.

Solution From the previous example, the fire heat released up to the 240 s and 600 s times is, respectively:

$$\begin{aligned} Q_f(@240\text{ s}) &= \int_o^{240} \left(\frac{500}{(240)^2}\right) t^2 dt \\ &= \left(\frac{500}{(240)^2}\right)\left(\frac{(240)^3}{3}\right) \\ &= 40,000\text{ kJ} \\ Q_f(@600\text{ s}) &= Q_f(@240\text{ s}) + \int_{240}^{600} 500\, dt \\ &= 40,000\text{ kJ} + 180,000\text{ kJ} \\ &= 220,000\text{ kJ} \end{aligned}$$

The volume of the space was calculated as 18.3 m × 12.2 m × 6.1 m = 1362 m^3 and the heat release per unit volume was calculated at each time as

$$Q_f/V(@240\text{ s}) = 40,000\text{ kJ}/1382\text{m}^3 = 28.9\text{ kJ/m}^3$$
$$Q_f/V(@600\text{ s}) = 220,000\text{ kJ}/1382\text{m}^3 = 159.2\text{ kJ/m}^3$$

The oxygen heat of combustion is assumed to be

$$\Delta H_c/f_i = -13,100\text{ kJ/kgO}_2$$

The average temperature in the enclosure was previously calculated at each time to be

$$T = T_o + \Delta T = 293\text{ K} + 14.9\text{ K} = 307.9\text{ K at 240 s}$$
$$(\text{so } \rho = \rho_o T_o/T = 353/307.9 = 1.15\text{kg/m}^3)$$
$$T = T_o + \Delta T = 293\text{ K} + 92.6\text{ K} = 385.6\text{ K at 600 s}$$
$$(\text{so } \rho = \rho_o T_o/T = 353/385.6 = 0.92\text{kg/m}^3)$$

Finally, the oxygen mass fraction at each time is calculated as

$$Y_{O_2}(@240\text{ s}) = 0.233 - \frac{(28.9)}{(13,100)\,(1.15)} = 0.231$$
$$Y_{O_2}(@240\text{ s}) = 0.233 - \frac{(159.9)}{(13,100)\,(0.92)} = 0.220$$

Thus, for these examples, the oxygen concentration is relatively close to the ambient concentration and consequently would not be expected to have a significant effect on the fire heat release rate. As discussed in the following subsection, however, this is not always the case.

Oxygen Limitations on Heat Release in a Closed Room Fire

There is a limit to how much heat can be released by combustion within a closed room because the release of heat is coupled with consumption of a finite amount of oxygen from the air in the enclosure. It is assumed that oxygen does not enter from outside due to pressurization of the compartment, so the fire must eventually die down due to oxygen depletion, much like the familiar candle flame trapped inside an inverted jar. Equation 33.17 will result in nonphysical and incredible temperatures if applied indefinitely because it does not account for the effect of oxygen depletion on limiting heat release within an enclosed space.

Mowrer [11] has addressed the issue of oxygen limitations on heat release in unventilated enclosure fires. The heat released by combustion in a room fire is related directly to the oxygen consumed. This relationship can be expressed as

$$Q_{f,\lim} = \frac{Q_{o,p}}{(1-x_l)} \ln\left[1 + \frac{\rho_o V}{Q_{o,p}} \frac{\Delta H_c}{r_{air}} \chi_{O_2,\lim}(1-\chi_l)\right] \tag{33.25}$$

Equation 33.25 can be inserted into Equation 33.17 to yield the limiting temperature rise associated with the oxygen-limited heat release in an enclosure:

$$\Delta T_{g,\lim} = \frac{\Delta H_c}{r_{air}} \frac{\chi_{O_2,\lim}(1-\chi_l)}{c_p} \tag{33.26}$$

where $\chi_{O_2,\lim}$ represents the fraction of oxygen that can be consumed before extinction; it is given in general as

$$\chi_{O_2,\lim} = \frac{\left(Y_{O_{2_o}} - Y_{O_2,\lim}\right)}{Y_{O_{2_o}}} = \frac{\left(X_{O_{2_o}} - X_{O_2,\lim}\right)}{X_{O_{2_o}}} \tag{33.27}$$

$\chi_{O_2,\lim}$ is normally evaluated at a limiting extinction value of X_{O_2} or Y_{O_2}. A representative value for X_{O_2} at extinction under normal ambient conditions is approximately 13% for a range of hydrocarbon fuels when the oxygen is diluted with nitrogen (see Chap. 17). For an ambient oxygen mole fraction $X_{O_{2,0}}$ of 21%, a representative value for $\chi_{O_2,\lim}$ would therefore be about 0.4.

Example 7 Determine the oxygen-limited average temperature rise in an enclosure fire for heat loss fractions of 0.6 and 0.9, respectively. Assume a value of $\chi_{O_2,\lim} = 0.4$.

Solution

$$\Delta T_{g,\lim} = \frac{3000(\text{kJ/kg})}{1.0(\text{kJ/kg}\cdot\text{K})}\cdot 0.4\cdot(1-0.6) = 480\ \text{K for}\ \chi_l = 0.6$$

$$\Delta T_{g,\lim} = \frac{3000(\text{kJ/kg})}{1.0(\text{kJ/kg}\cdot\text{K})}\cdot 0.4\cdot(1-0.9) = 120\ \text{K for}\ \chi_l = 0.9$$

Although these temperatures are potentially significant from a thermal injury or damage standpoint, they are below the temperature rise of approximately 580 K commonly associated with flashover conditions. This simple analysis suggests the difficulty of attaining flashover conditions in an unventilated, fully enclosed compartment fire. Lower heat loss fractions and higher oxygen consumption fractions would be needed to achieve temperature increases associated with flashover. On the other hand, these calculated global temperature increases might be sufficient to cause the fracture and collapse of ordinary plate glass windows [19–21] if present, providing new pathways for the introduction of oxygen to the enclosure and consequent escalation of the fire intensity.

Light Attenuation and Visibility Through Smoke

Light attenuation and visibility through smoke can be estimated based on the soot mass concentration within the smoke layer. The light extinction coefficient, K, is directly proportional to the soot mass concentration as

$$K = K_m \rho Y_{\text{soot}} \tag{33.28}$$

K_m is the specific light extinction coefficient. Seader and Einhorn [22] suggested a value of $K_m = 7600\ \text{m}^2/\text{kg}$ for flaming combustion and $K_m = 4400\ \text{m}^2/\text{kg}$ for smoke produced by pyrolysis. These values have been widely used for light attenuation and visibility calculations, but more recently Mulholland and Croarkin [23] have suggested a value of $K_m = 8700\ \text{m}^2/\text{kg}$ for flaming combustion of wood and plastic fuels.

Light attenuation within the smoke layer is calculated in accordance with Bougher's law for monochromatic light:

$$I/I_o = \text{e}^{-KL} \tag{33.29}$$

Visibility through smoke is expected to vary inversely with the light extinction coefficient, with this inverse relationship generally expressed as

$$\text{S} = \text{C}/K \tag{33.30}$$

where

S = Visibility distance (m)
C = Nondimensional constant associated with the object being viewed through the smoke

Mulholland [24] suggests a value of $C = 8$ for light-emitting signs and a value of $C = 3$ for light-reflecting signs based on the work of Jin (see Chap. 61). These values suggest that light-emitting signs can be observed when the light attenuation is $I/I_o = \text{e}^{-8} = 3.35 \times 10^{-4}$, that is, the transmitted light is much less than 1% of the unattenuated light intensity; whereas

light-reflecting signs can be observed when the light attenuation is $I/I_o = e^{-8} = 0.05$, that is, the transmitted light is reduced to 5% of the unattenuated light level.

Example 8 Estimate the visibility of a light-reflecting sign through the smoke layer based on the soot mass concentrations determined in a previous example.

Solution For this example, the soot mass concentration at each time was calculated to be

$$\rho Y_{soot}(@240\text{ s}) = \frac{28.9\text{ kJ/m}^3}{488.42 \times 10^3\text{ kJ/kg}_{soot}} = 5.92 \times 10^{-5}\text{ kg}_{soot}/\text{m}^3$$

$$\rho Y_{soot}(@600\text{ s}) = \frac{159.2\text{ kJ/m}^3}{488.42 \times 10^3\text{ kJ/kg}_{soot}} = 3.26 \times 10^{-4}\text{ kg}_{soot}/\text{m}^3$$

Using these values of soot mass concentration along with the specific light extinction coefficient of 8700 m^2/kg suggested by Mulholland and Croarkin, the extinction coefficient is determined to be

$$K(@240\text{ s}) = K_m \rho Y_{soot} = (8700\text{ m}^2/\text{kg}_{soot}) \times \left(5.92 \times 10^{-5}\text{kg}_{soot}/\text{m}^3\right) = 0.52\text{ m}^{-1}$$

$$K(@600\text{ s}) = K_m \rho Y_{soot} = (8700\text{ m}^2/\text{kg}_{soot}) \times \left(3.26 \times 10^{-4}\text{kg}_{soot}/\text{m}^3\right) = 2.83\text{ m}^{-1}$$

The visibility distance for a light-reflecting sign is then estimated at each time as

$$S\ (@240\text{ s}) = 3/0.52\text{ m}^{-1} = 5.8\text{ m (19.0 ft)}$$

$$S\ (@600\text{ s}) = 3/2.83\text{ m}^{-1} = 1.1\text{ m (3.6 ft)}$$

This concludes the global analysis of fire-induced conditions in a closed room. In the next section, methods to analyze fire-induced conditions within the descending smoke layer are addressed. These can then be compared with the global analysis results presented in this section.

Descending Smoke Layer Analysis

In this section, the descending smoke layer is treated as a distinct control volume, as illustrated in Fig. 33.5. Two limit cases are addressed based on the location of leakage paths in the enclosure boundaries, following the approach originally taken by Zukoski [1]:

- Case 1—Leakage paths near the floor (from the lower layer)
- Case 2—Leakage paths near the ceiling (from the upper layer)

In Case 1, the expansion of gases in the upper layer pushes fresh air at ambient temperature from the lower layer until the smoke layer descends to the floor. At that point, smoke at the upper layer temperature and composition would be expelled and the analysis would be the same as for Case 0, the global analysis presented in the previous section. The Case 1 scenario is the case addressed by Cooper [2, 3] in the development of the ASET model. In Case 2, the expansion of gases from the compartment is assumed to occur directly from the upper layer. Cooper does not address this scenario, but, as demonstrated by the following analysis, the differences between the two scenarios are minor.

Mass balances on the lower layer for the respective cases can be written as

$$\text{Case 1}: \quad \frac{d(\rho V)_l}{dt} = \rho_l \frac{dV_l}{dt} = -\left(\dot{m}_{pl} + \dot{m}_e\right) \tag{33.31}$$

$$\text{Case 2}: \quad \frac{d(\rho V)_l}{dt} = \rho_l \frac{dV_l}{dt} = -\left(\dot{m}_{pl}\right) \tag{33.32}$$

These mass balances for the lower layer can be converted to volumetric filling rates for the upper layer by noting that $dV_u = -dV_l$ and by dividing through by the lower layer density, ρ_l , assumed to remain constant at the ambient air density.

$$\text{Case 1}: \quad \frac{dV_u}{dt} = \frac{\left(\dot{m}_{pl} + \dot{m}_e\right)}{\rho_l} = \left(\dot{V}_{pl} + \dot{V}_{\exp}\right) \tag{33.33}$$

$$\text{Case 2}: \quad \frac{dV_u}{dt} = \frac{\left(\dot{m}_{pl}\right)}{\rho_l} = \dot{V}_{pl} \tag{33.34}$$

Equations 33.33 and 33.34 show that the volumetric growth rate of the smoke layer is due to both plume entrainment and gas expansion in Case 1 and due to entrainment only in Case 2. This difference occurs because the expanding gases are being expelled directly from the smoke layer rather than the lower layer in Case 2, and consequently gas expansion does not contribute to smoke layer development in Case 2.

The rate of smoke layer descent for the two cases derives directly from Equations 33.33 and 33.34 by noting that $dV_u = A_s dz_u$. For rooms with vertical walls and horizontal ceilings, the horizontal area of the space, A_s, remains constant with height, assuming no physical obstructions are located within the space. In general, Equation 33.33 must be integrated numerically to determine the smoke layer interface position as a function of time because analytical solutions do not exist for most realistic scenarios. Equation 33.34 does have an analytical solution for the case of a power law fire, where the fire heat release rate is assumed to vary with time as

$$\dot{Q}_f = \alpha_n t^n$$

and axisymmetric plume entrainment [25], where the plume volumetric flow rate varies as

$$\dot{V}_{pl} = k_v \dot{Q}_c^{1/3} z^{5/3}$$

For these conditions, Equation 33.34 can be rearranged and expressed as

$$\int_0^{z_u} \frac{dz_u}{(H - z_u)^{5/3}} = \frac{k_v}{A_s} \int_0^t (\alpha_n t^n)^{1/3} dt \tag{33.35}$$

The solution to Equation 33.35 can be expressed nondimensionally as

$$\frac{z_u}{H} = 1 - \left[1 + \frac{2t}{(n+3)\tau_V}\right]^{3/2} \tag{33.36}$$

where

$$\tau_V = \frac{V}{\dot{V}_{pl,H}} = \frac{A_s H}{k_v \dot{Q}_c^{1/3} H^{5/3}} = \frac{\left(A_s/H^2\right)}{\left(k_v (\alpha_n t^n)^{1/3}/H^{4/3}\right)} \tag{33.37}$$

τ_V is a characteristic smoke filling time constant, represented as the volume above the fire source divided by the volumetric entrainment rate evaluated at the ceiling height. Note that this *time constant* is actually only constant in the case of a steady fire ($n = 0$). The elevation of the smoke layer interface above the fire source derives directly from Equation 33.36:

$$\frac{z_L}{H} = 1 - \frac{z_u}{H} = \left[1 + \frac{2t}{(n+3)\tau_V}\right]^{-3/2} \tag{33.38}$$

The solution represented by Equation 33.38 is shown in Fig. 33.9 for the cases of a steady fire ($n = 0$) and a t-squared fire ($n = 2$). This solution is also approximately accurate for Case 1 scenarios where $\dot{V}_{pl} \gg \dot{V}_{\exp}$, such that $\dot{V}_{pl} + \dot{V}_{\exp} \approx \dot{V}_{pl}$.

Qualitatively, Fig. 33.9 illustrates the fact that smoke layer descent is initially very rapid, then slows down and asymptotically approaches the fuel surface. This is because the air entrainment rate for axisymmetric plumes varies with the 5/3 power of the elevation between the fuel surface and the smoke layer interface. As the smoke layer descends, the plume entrains less and less air, causing the descent rate to slow down as shown in Fig. 33.9.

The nondimensional representation of smoke layer descent given in Equation 33.38 and shown in Fig. 33.9 is useful to generalize the smoke layer descent analysis, but is not as useful for the computation of specific fire scenarios. This is particularly so for the case of growing t-squared fires because the characteristic time constant given in Equation 33.37 is a function of time for cases other than steady fires (i.e., other than when $n = 0$). For such computations it is more useful to represent the smoke layer descent in dimensional terms. To calculate the time for the

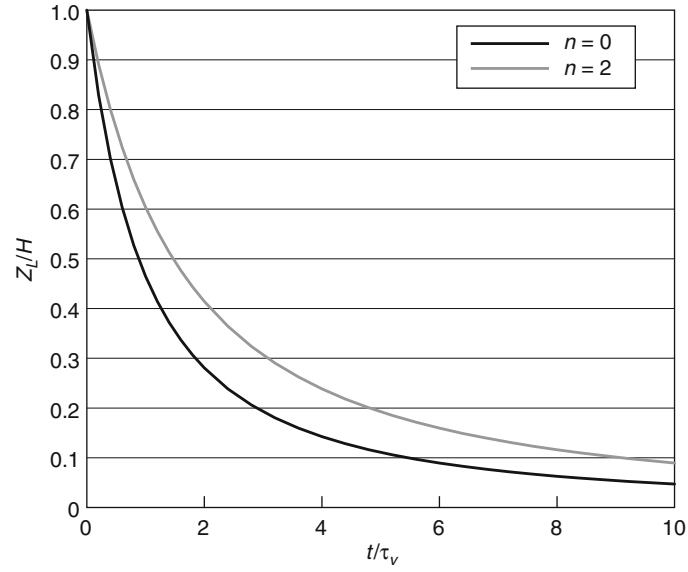

Fig. 33.9 Relative smoke layer interface position as a function of normalized time due to entrainment only in an axisymmetric fire plume

smoke layer to reach a particular elevation relative to the fuel to ceiling distance (z_L/H) for a t-squared fire, Equation 33.37 is substituted into Equation 33.38 and the resulting equation is solved for t. The result is

$$t = \left\{ \frac{(n+3)}{2} \frac{(A_s/H^2)H^{4/3}}{k_v \alpha_n^{1/3}} \left[\left(\frac{z_L}{H} \right)^{-2/3} - 1 \right] \right\}^{1/(1+n/3)} \tag{33.39}$$

Similarly, for a t-squared fire, the relative smoke layer elevation can be expressed explicitly as a function of time as

$$\frac{z_L}{H} = \left[1 + \frac{2k_v \alpha_n^{1/3} t^{(5/3)}}{5(A_s/H^2)H^{4/3}} \right]^{-3/2} \tag{33.40}$$

Example 9 For the previous enclosure fire example, determine how long it would take for the smoke layer interface to descend to elevations of 3.0 m and 1.5 m above the floor for the 6.0-m-high enclosure.

Solution For this example, the enclosure area is $A_s = 18.3\ \text{m} \times 12.2\ \text{m} = 223.3\ \text{m}^2$ and the enclosure height above the fire source is $H = 6.0$ m. The fire grows as a t-squared fire to reach a heat release rate of 500 kW in 240 s, then remains constant at 500 kW for an additional 360 s. Thus, during the growth stage,

$$\alpha_n = \frac{500\ \text{kW}}{(240\ \text{s})^2} = 8.68 \times 10^{-3} \text{kW/s}^2$$

and $n = 2$. Assuming an axisymmetric plume, the entrainment coefficient is taken to be

$$k_v = 0.064\ \text{m}^{4/3}/\text{kW}^{1/3} - s$$

For the smoke layer interface elevation of 3.0 m, the relative smoke layer interface elevation is

$$\frac{z_L}{H} = \frac{3.0\ \text{m}}{6.0\ \text{m}} = 0.5$$

Substituting these values into Equation 33.39 yields the time for the smoke layer to reach the 3.0 m elevation in the enclosure:

$$\text{t}(3.0\ \text{m}) = \left\{ \frac{2+3}{2} \frac{\left(223.3/6.0^2 \times 6.0^{4/3}\right)}{0.064 \times \left(8.68 \times 10^{-3}\right)^{1/3}} \left[\left(\frac{3.0}{6.0} \right)^{-2/3} - 1 \right] \right\}^{1/(1+2/3)}$$
$$= 212\ \text{s}$$

Because this time is less than the growth time of 240 s, the smoke layer will descend to the 3.0 m elevation during the growth period. From this analysis, it appears likely that the fire will stop growing before the smoke layer descends to the 1.5 m elevation. This can be confirmed by substituting this elevation of 1.5 m into Equation 33.39:

$$\begin{aligned} t(1.5\text{ m}) &= \left\{ \frac{(2+3)}{2} \frac{\left(223.3/6.0^2\right) \cdot 6.0^{4/3}}{0.064 \cdot \left(8.38 \times 10^{-3}\right)^{1/3}} \left[\left(\frac{1.5}{6.0} \right)^{-2/3} - 1 \right] \right\}^{1/(1+2/3)} \\ &= 375\text{ s} \end{aligned}$$

Because the fire stops growing at 240 s, it is necessary to apply Equation 33.40 to determine the smoke layer interface position at the end of the growth period, then use this elevation as the enclosure height H in Equation 33.39 to determine the additional time needed for the smoke layer interface to reach the 1.5 m elevation as a result of the steady 500 kW fire. Applying Equation 33.40 with a time of 240 s yields

$$\begin{aligned} \frac{z_L}{H}(@240\text{ s}) &= \left[1 + \frac{2(0.064)\left(8.68 \times 10^{-3}\right)^{1/3} 240^{(1+2/3)}}{(2+3)\left(223.3/6.0^2\right)6.0^{4/3}} \right]^{-3/2} \\ &= 0.44 \\ z_L(@240\text{ s}) &= 0.44 \cdot H = 0.44 \cdot 6.0 = 2.64\text{ m} \end{aligned}$$

This value then becomes the starting height (i.e., H) for the steady fire following 240 s:

$$\begin{aligned} t(1.5\text{ m}) &= 240 + \left\{ \frac{0+3}{2} \frac{\left(223.3/2.64^2 \times 2.64^{4/3}\right)}{0.064 \times (500)^{1/3}} \left[\left(\frac{1.5}{2.64} \right)^{-2/3} - 1 \right] \right\}^{1/(1+0/3)} \\ &= 240 + 159 = 399\text{ s} \end{aligned}$$

In other words, the smoke layer interface reaches the 2.64 m elevation at the end of the 240-s fire growth period, then takes another 159 s to reach the 1.5 m elevation during the ensuing steady fire period.

Conditions in the Descending Smoke Layer

The average temperature in the smoke layer is calculated by invoking the ideal gas law relationship for a constant pressure process, $\rho_o T_o = \rho_u T_u$,

and by noting that the average smoke layer density, ρ_u, is simply the mass of the upper layer divided by the volume of the upper layer. For the two cases, the average temperature of the upper layer is then evaluated as
Case 1:

$$T_u(t) = \frac{\rho_l T_l}{\rho_u} = \frac{\rho_l T_l V_u}{m_u} = \rho_l T_l \left(\frac{\int_o^t \frac{dV_u}{dt} dt}{\int_o^t \frac{dm_u}{dt} dt} \right) = T_l \frac{\int_o^t \left(\dot{V}_{pl} + \dot{V}_{\exp} \right) dt}{\int_o^t \dot{V}_{pl} dt} \tag{33.41}$$

Case 2:

$$T_u(t) = \frac{\rho_l T_l}{\rho_u} = \frac{\rho_l T_l V_u}{m_u} = \rho_l T_l \left(\frac{\int_o^t \frac{dV_u}{dt} dt}{\int_o^t \frac{dm_u}{dt} dt} \right) = \frac{\rho_l T_l \int_o^t \left(\dot{V}_{pl} \right) dt}{\int_o^t \left(\rho_l \dot{V}_{pl} - \rho_u \dot{V}_{\exp} \right) dt} \tag{33.42}$$

The mass fraction of oxygen in the smoke layer is calculated for the two cases as
Case 1:

$$Y_{O_2,u}(t) = \frac{m_{O_2,u}}{m_u} = \frac{\int_o^t \left[\left(\rho_l \dot{V}_{pl} Y_{O_2,o} \right) - \left(\frac{\dot{Q}_f}{\Delta H_c / r_{O_2}} \right) \right] dt}{m_u} \tag{33.43}$$

Case 2:

$$Y_{O_2,u}(t) = \frac{m_{O_2,u}}{m_u} = \frac{\int_0^t \left[\left(\rho_l \dot{V}_{pl} Y_{O_2,o} \right) - \left(\frac{\dot{Q}_f}{\Delta H_c / r_{O_2}} \right) - \left(\rho_u \dot{V}_{\exp} Y_{O_2,u} \right) \right] dt}{m_u} \tag{33.44}$$

The mass fractions of different products of combustion in the smoke layer are calculated for the two cases as
Case 1:

$$Y_{i,u}(t) = \frac{m_{i,u}}{m_u} = \frac{\int_0^t \left[\left(\rho_l \dot{V}_{pl} Y_{i,o} \right) + \left(\frac{\dot{Q}_f}{\Delta H_c / f_i} \right) \right] dt}{m_u} \tag{33.45}$$

Case 2:

$$Y_{i,u}(t) = \frac{m_{i,u}}{m_u} = \frac{\int_0^t \left[\left(\rho_l \dot{V}_{pl} Y_{i,0} \right) - \left(\frac{\dot{Q}_f}{\Delta H_c / f_i} \right) - \left(\rho_u \dot{V}_{\exp} Y_{i,u} \right) \right] dt}{m_u} \tag{33.46}$$

The denominators in Equations 33.43 through 33.46 are evaluated in the same way as in Equations 33.41 and 33.42, respectively. In general, Equations 33.41 through 33.46 do not have analytical solutions and therefore require numerical integration. Numerical methods are discussed in a subsequent section.

Influence of Mechanical Ventilation on Smoke Layer Conditions

The introduction of mechanical ventilation changes the analysis of enclosure smoke filling in a number of ways. As illustrated in Fig. 33.10, with mechanical ventilation, flow may be injected into or extracted from either the upper layer or the lower layer. This will depend on the type of mechanical ventilation system employed, the elevations of injection and extraction vents, and the elevation of the smoke layer interface at a particular time. Smoke layer descent may be either accelerated or retarded relative to the unventilated scenario as a result of mechanical ventilation. Conditions within the smoke layer will also be affected. A quasi-steady smoke layer interface position will develop if the flow rates balance properly. Indeed, the purpose of a dedicated mechanical smoke extraction system is normally to prevent the smoke layer interface position from descending past a certain elevation within a space, for example, to prevent smoke from reaching the highest elevation of human occupancy.

Global Effects of Mechanical Ventilation

Global conditions within a mechanically ventilated enclosure are first considered in terms of a one-zone analysis, as illustrated in Fig. 33.11. This global analysis assumes that conditions throughout the enclosure can be treated as uniform outside the fire-plume/ceiling-jet sublayer as a result of mixing caused by the mechanical ventilation and plume entrainment. One-zone approaches have been used previously to evaluate average fire conditions in mechanically ventilated spaces [7, 26–28].

Volumetric flow rates associated with a fire in a mechanically ventilated enclosure are illustrated in Figs. 33.10 and 33.11. Because the total volume of the enclosure remains essentially constant, the rate at which flow is forced through leakage paths in the boundaries of the enclosure can be expressed as

$$\dot{V}_{\text{net}} = \dot{V}_{\text{inj}} + \dot{V}_{\text{exp}} - \dot{V}_{\text{ext}} \tag{33.47}$$

$\dot{V}_{\text{net}}$ can be either positive or negative, depending on the values for the terms on the right-hand side (RHS) of Equation 33.47. As defined here, $\dot{V}_{\text{net}}$

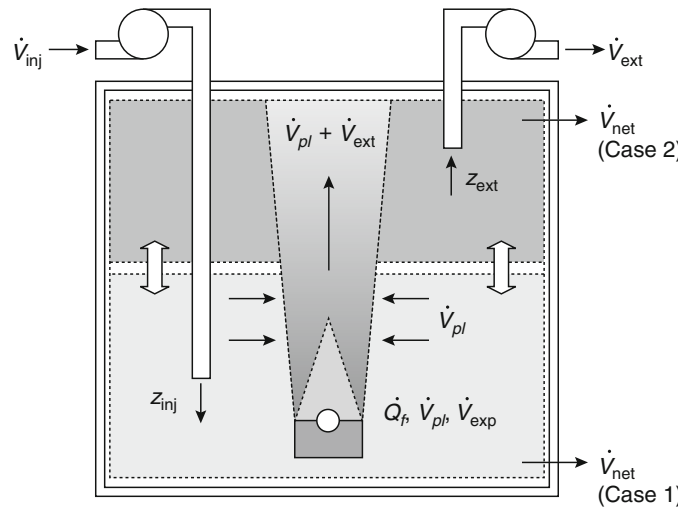

Fig. 33.10 Mechanical ventilation in a two-layer environment

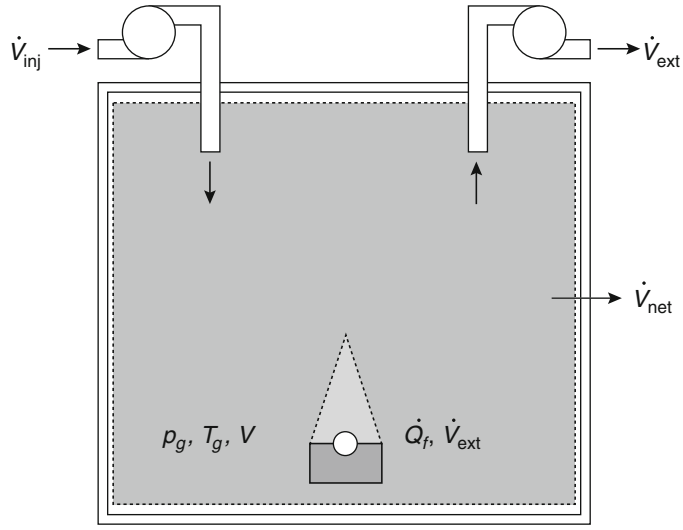

Fig. 33.11 Mechanical ventilation in a one-layer environment

will be positive if flow is forced from the enclosure to surrounding spaces and negative if flow is drawn from surrounding spaces into the enclosure.

The injection and extraction rates, $\dot{V}_{\text{in j}}$ and $\dot{V}_{\text{ext}}$, will depend on the design of the ventilation system. For present purposes, it is assumed that the user specifies the injection and extraction volumetric flow rates, although it should be recognized that these flow rates may be influenced by fan characteristics and space pressures. Under the quasi-steady pressure conditions assumed here, the volumetric expansion rate of gases can be related directly to the net rate of heat addition resulting from the fire, as shown in Equation 33.9.

A global mass balance for the enclosure can be expressed in terms of the volumetric flows across the enclosure boundaries. For situations where $\dot{V}_{\text{net}}$ is positive, flow is forced from the enclosure to adjacent spaces through available leakage paths. For this situation, the global mass balance can be expressed as

$$\begin{aligned}\frac{dm_{gl}}{dt} &= \rho_o \dot{V}_{\text{inj}} - \rho_{gl}\left(\dot{V}_{\text{net}} + \dot{V}_{\text{ext}}\right) \quad \dot{V}_{\text{net}} > 0 \\ &= \rho_o \dot{V}_{\text{inj}} - \rho_{gl}\left(\dot{V}_{\text{inj}} + \dot{V}_{\text{exp}}\right)\end{aligned} \tag{33.48a}$$

For situations where $\dot{V}_{\text{net}}$ is negative, air is drawn into the enclosure through leakage paths and the mass balance becomes

$$\begin{aligned}\frac{dm_{gl}}{dt} &= \rho_o\left(\dot{V}_{\text{inj}} - \dot{V}_{\text{net}}\right) - \rho_{gl}\dot{V}_{\text{ext}} \qquad \dot{V}_{\text{net}} < 0 \\ &= \rho_o\left(\dot{V}_{\text{ext}} + \dot{V}_{\text{exp}}\right) - \rho_{gl}\dot{V}_{\text{ext}}\end{aligned} \tag{33.48b}$$

For any individual species to be tracked, such as O_2, CO_2, CO, or soot, a global species balance also depends on the sign of $\dot{V}_{\text{net}}$. This global species balance can be expressed as

$$\begin{aligned}\frac{dm_i}{dt} &= \rho_o Y_{i,o}\dot{V}_{\text{inj}} - \rho_{gl}Y_i\left(\dot{V}_{\text{inj}} + \dot{V}_{\text{exp}}\right) \\ &\quad + \dot{m}_{i,\text{gen}} \quad \dot{V}_{\text{net}} > 0\end{aligned} \tag{33.49a}$$

$$\begin{aligned}\frac{dm_i}{dt} &= \rho_o Y_{i,o}\left(\dot{V}_{\text{ext}} - \dot{V}_{\text{exp}}\right) - \rho_{gl}Y_i\dot{V}_{\text{ext}} \\ &\quad + \dot{m}_{i,\text{gen}} \quad \dot{V}_{\text{net}} < 0\end{aligned} \tag{33.49b}$$

This global species balance can also be expressed in terms of the mass fraction for each chemical species of interest:

$$\frac{dY_i}{dt} = \frac{1}{m_{gl}}\left[\rho_o \dot{V}_{\text{inj}}(Y_{io} - Y_i) + \dot{m}_{i,\text{gen}}\right] \quad \dot{V}_{\text{net}} > 0 \tag{33.50a}$$

$$\begin{aligned}\frac{dY_i}{dt} &= \frac{1}{m_{gl}}\left[\rho_o\left(\dot{V}_{\text{ext}} - \dot{V}_{\text{ext}}\right)(Y_{io} - Y_i) + \dot{m}_{i,\text{gen}}\right] \\ &\quad \dot{V}_{\text{net}} < 0\end{aligned} \tag{33.50b}$$

The generation (or consumption) rate of a species, $\dot{m}_{i,\,\mathrm{gen}}$, can be expressed in terms of the fuel mass loss rate or the fire heat release rate, as shown in Equation 33.20.

The global temperature in the enclosure is calculated, assuming ideal gas behavior, constant pressure, and properties of air, as

$$T_{gl} = \frac{\rho_o T_o}{\rho_{gl}} = \frac{\rho_o T_o V}{m_{gl}} \tag{33.51}$$

Under quasi-steady conditions, the rate of change of mass in the enclosure goes to zero as the inflow and outflow equilibrate. For an injection-only mechanical system, $\dot{V}_{\mathrm{net}}$ will always be positive and the quasi-steady mass balance expressed by Equation 33.48a becomes

$$\rho_{gl}\left(\dot{V}_{\mathrm{inj}} + \dot{V}_{\mathrm{exp}}\right) = \rho_o \dot{V}_{\mathrm{inj}} \tag{33.52}$$

For this situation, the quasi-steady global temperature can be expressed in dimensionless form as

$$\frac{T_{gl}}{T_o} = \frac{\rho_o}{\rho_{gl}} = \frac{\left(V_{\mathrm{inj}} + \dot{V}_{\mathrm{exp}}\right)}{\dot{V}_{\mathrm{inj}}} = 1 + \frac{\dot{V}_{\mathrm{exp}}}{\dot{V}_{\mathrm{inj}}} \tag{33.53}$$

Alternatively, the quasi-steady global dimensionless temperature rise above ambient can be expressed simply as the ratio of the expansion flow rate to the injection flow rate:

$$\frac{\Delta T_{gl}}{T_o} = \frac{\dot{V}_{\mathrm{exp}}}{\dot{V}_{\mathrm{inj}}} \tag{33.54}$$

Example 10 Determine the quasi-steady average global temperature rise in a mechanically ventilated enclosure with dimensions of 18.3 m by 12.2 m by 6.1 m with an air injection rate of ten air changes per hour in response to a fire with a constant heat release rate of 500 kW. Assume a constant heat loss fraction of 0.70 and an ambient temperature of 20 °C (293 K).

Solution For this example, the volumetric expansion rate, $\dot{V}_{\mathrm{exp}}$, is calculated as in previous examples as

$$\dot{V}_{\mathrm{exp}} = \frac{\dot{Q}_{\mathrm{net}}}{\rho_e c_p T_e} = \frac{(500\ \mathrm{kW})\ (1 - 0.7)}{(353\ \mathrm{kJ/m^3})} = 0.42\ \ \mathrm{m^3/s}$$

The volumetric injection rate, $\dot{V}_{\mathrm{inj}}$, is calculated based on the compartment volume and the specified air exchange rate as

$$\dot{V}_{\mathrm{inj}} = \frac{10(18.3 \times 12.2 \times 6.1)\mathrm{m^3}}{3600\ \mathrm{s}} = 3.78\ \ \mathrm{m^3/s}$$

The quasi-steady global temperature rise is calculated by applying Equation 33.54:

$$\Delta T_{gl} = \left(\frac{\dot{V}_{\mathrm{exp}}}{\dot{V}_{\mathrm{inj}}}\right) T_o = \left(\frac{0.42}{3.78}\right) \cdot 293\ \ \mathrm{K} = 32.5\ \ \mathrm{K}$$

For an extraction only system, the analysis depends on the rate of extraction relative to the expansion rate. If the extraction rate is less than the expansion rate, then the extraction will serve simply to relieve a fraction of the expansion flow, with the remaining fraction forced through available leakage paths. This situation can be treated using the same global analysis as for an unventilated enclosure. There is not a quasi-steady solution for this situation.

For the situation where the extraction rate is greater than the expansion rate, $\dot{V}_{\mathrm{net}}$ will be negative, so air will be drawn into the enclosure through available leakage paths. From Equation 33.48b, the quasi-steady mass balance for this situation is

$$\rho_{gl}\dot{V}_{\mathrm{ext}} = \rho_o\left(\dot{V}_{\mathrm{ext}} - \dot{V}_{\mathrm{exp}}\right) \tag{33.55}$$

For this situation the temperature ratio is calculated to be

$$\frac{T_{gl}}{T_o} = \frac{\rho_o}{\rho_{gl}} = \frac{\dot{V}_{\mathrm{ext}}}{\left(\dot{V}_{\mathrm{ext}} - \dot{V}_{\mathrm{exp}}\right)} \tag{33.56}$$

The dimensionless temperature rise above ambient for this extraction scenario is

$$\frac{\Delta T_{gl}}{T_o} = \frac{\dot{V}_{\text{exp}}}{\left(\dot{V}_{\text{ext}} - \dot{V}_{\text{exp}}\right)} \tag{33.57}$$

Note the similarity between Equations 33.54 and 33.57. The extraction case is analogous to the injection scenario with an effective injection rate equal to the difference between the extraction and expansion rates. This difference is the rate at which air is being drawn into the enclosure when the extraction rate exceeds the expansion rate.

Example 11 Determine the quasi-steady average global temperature rise in a mechanically ventilated enclosure with dimensions of 18.3 m by 12.2 m by 6.1 m with an air extraction rate of ten air changes per hour in response to a fire with a constant heat release rate of 500 kW. Assume a constant heat loss fraction of 0.70 and an ambient temperature of 20°C (293 K).

Solution This example is the same as the previous example, except that the mechanical ventilation system is extracting smoke at ten changes per hour instead of injecting air at this rate. For this case, the volumetric extraction rate, $\dot{V}_{\text{ext}}$, is the same as the volumetric injection rate from the previous example:

$$\dot{V}_{\text{ext}} = \frac{10(18.3 \times 12.2 \times 6.1)\ \text{m}^3}{3600\ \text{s}} = 3.78\ \text{m}^3/\text{s}$$

The quasi-steady global temperature rise is calculated by applying Equation 33.57:

$$\Delta T_{gl} = \left[\frac{\dot{V}_{\text{exp}}}{\left(\dot{V}_{\text{ext}} - \dot{V}_{\text{exp}}\right)}\right] T_o = \left[\frac{0.42}{(3.78 - 0.42)}\right] \cdot 293\ \text{K} = 36.6\ \text{K}$$

The extraction scenario results in a slightly higher average temperature rise than the injection scenario because the airflow rate is lower for the extraction scenario. This assumes that the ventilation rates remain constant and the heat loss fractions remain the same for both scenarios.

Scenarios with both injection and extraction can be considered as variations on the injection only and extraction only analyses. If $\dot{V}_{\text{net}}$ is positive, which will occur if $\dot{V}_{\text{inj}} + \dot{V}_{\text{exp}}$ is greater than $\dot{V}_{\text{ext}}$, then the global temperature rise can be calculated with Equation 33.52. If $\dot{V}_{\text{net}}$ is negative, which will occur if $\dot{V}_{\text{ext}}$ is greater than $\dot{V}_{\text{inj}} + \dot{V}_{\text{exp}}$, then the global temperature rise can be calculated with Equation 33.57.

Neglecting the injection of fuel into the enclosure, the quasi-steady limits for different species can be evaluated by setting the left-hand side of Equation 33.50a to zero and solving for the mass fraction, Y_i:

$$Y_i = \frac{\rho_o Y_{i,o} \dot{V}_{\text{inj}} + \dot{m}_{i,\text{gen}}}{\rho_{gl}\left(\dot{V}_{\text{inj}} + \dot{V}_{\text{exp}}\right)} = Y_{i,o} + \frac{\dot{m}_{i,\text{gen}}}{\rho_o \dot{V}_{\text{inj}}} \tag{33.58}$$

Example 12 Assume propylene (C_3H_6) is the fuel burned in the previous mechanically ventilated examples. Assume propylene has a heat of combustion of 46.4 MJ/kg of fuel and a soot yield of 0.095 g of soot per g of fuel. Estimate the quasi-steady average mass concentration of soot within the 18.3 m by 12.2 m by 6.1 m enclosure for a fire that burns at a constant heat release rate of 500 kW, assuming the enclosure is mechanically ventilated with an injection system at ten air changes per hour. Based on this soot mass concentration, estimate the visibility distance for a light-reflecting sign.

Solution For this example, the ambient mass fraction of soot is assumed to be zero and the soot mass generation rate is calculated with Equation 33.20 as

$$\dot{m}_{i,\text{gen}} = f_i \dot{m}_f = \frac{\dot{Q}_f}{(\Delta H_c / f_i)} = \frac{500\ \text{kW}}{\left(46,400\ \text{kJ/kg}_f\right) / \left(0.095\ \text{kg}_{\text{soot}}/\text{kg}_f\right)} = 1.02 \times 10^{-3} \text{kg}_{\text{soot}}/\text{s}$$

Then the soot mass fraction is calculated with Equation 33.58 as

$$Y_{soot} = 0 + \frac{1.02 \times 10^{-3} kg_{soot}/s}{(1.20\ kg/m^3)\ (3.78\ m^3/s)}$$
$$= 2.26 \times 10^{-4} kg_{soot}/kg_{mix}$$

The average soot mass concentration is calculated based on the average temperature and density within the enclosure as

$$\rho Y_{soot} = \left(\frac{353}{(293 + 32.5)}\right) kg/m^3$$
$$\times \left(2.26 \times 10^{-4}\ kg_{soot}/kg\right.$$
$$= 2.45 \times 10^{-4}\ kg_{soot}/m^3$$

Using this value for the soot mass concentration, along with the specific light extinction coefficient of 8700 m^2/kg suggested by Mulholland and Croarkin, the extinction coefficient is determined to be

$$K = K_m \rho Y_{soot}$$
$$= (8700\ m^2/kg_{soot})\ \left(2.45 \times 10^{-4}\ kg_{soot}/m^3\right)$$
$$= 2.13\ \ m^{-1}$$

The visibility distance for a light-reflecting sign is then estimated as

$$S = 3/2.13\ m^{-1} = 1.4\ \ m\ (4.6\ ft)$$

As a final comment on the global analysis of mechanically ventilated enclosure fires, it is worth noting that $\dot{V}_{net}$ can switch during the course of a fire scenario from negative to positive, for example, for the case of a growing fire where $\dot{V}_{exp}$ increases with time; or from positive to negative, for example, for the case where an extraction system is started at some time after the fire starts. As a consequence, the appropriate equations used to calculate transient and quasi-steady conditions may change over the course of a fire scenario.

Smoke Layer Analysis with Mechanical Ventilation

In this section, conditions within the descending smoke layer are addressed in terms of the two limit cases illustrated in Fig. 33.10. These are

Case 1—Leakage paths near the floor (to and from the lower layer)

Case 2—Leakage paths near the ceiling (to and from the upper layer)

In Case 1, ambient air is expelled from, or drawn into, the enclosure through leakage paths near the floor until the smoke layer descends to the floor. At that point, smoke at the upper layer temperature and composition would be expelled if $\dot{V}_{net}$ were positive. In Case 2, smoke at the upper layer temperature and composition would be expelled from the upper layer through the leakage paths if $\dot{V}_{net}$ were positive, whereas ambient air would be drawn into the smoke layer through these leakage paths if $\dot{V}_{net}$ were negative.

The rate of smoke layer descent and conditions within the smoke layer will depend on the elevations of vents and the injection and extraction rates of the ventilation systems. For the present discussion, it is assumed that all injection vents are located at one elevation, z_{inj}, whereas all extraction vents are located at another unique elevation, z_{ext}. Multiple elevations for either injection or extraction vents are not addressed.

The elevation of the injection vents determines whether air is being injected into the upper layer $\left(\dot{V}_{inj,u}\right)$ or the lower layer $\left(\dot{V}_{inj,l}\right)$, depending on the current elevation of the smoke layer interface. If the elevation of the injection vents is below the smoke layer interface position, then air is injected into the lower layer; otherwise, it is injected into the upper layer. As the smoke layer interface position moves during a fire scenario, injection can shift between the upper and lower layers. Similarly, the elevation of the extraction vents determines whether smoke is being extracted from the upper layer $\left(\dot{V}_{ext,\ u}\right)$ or air is being extracted from the lower layer $\left(\dot{V}_{ext,\ l}\right)$. For the analysis presented here, it is assumed that no mixing occurs between the upper and lower layers.

Floor Leak (Case 1) Analysis

The rate of change of the upper layer volume can be expressed in terms of the volumetric flow rates into and out of the smoke layer. For Case 1, it is

assumed that there is no leakage from the upper layer until the smoke layer descends to floor level. The rate of change of the smoke layer volume or depth can be expressed as

$$\frac{dV_u}{dt} = A_s \frac{dz_u}{dt} = \dot{V}_{pl} + \dot{V}_{\exp} + \dot{V}_{\text{inj},u} - \dot{V}_{\text{ext},u} \tag{33.59}$$

The last two terms on the right-hand side of Equation 33.59 distinguish the mechanically ventilated Case 1 from the unventilated Case 1. If air is injected into the upper layer, then the rate of smoke layer descent will be faster than for the unventilated case. If smoke is extracted from the upper layer, then the rate of smoke layer descent will be slower than for the unventilated case. The injection or extraction of air from the lower layer does not influence the smoke layer descent rate for the Case 1 scenario. These flows simply affect the net flow rate through the leakage path in the lower layer boundary for this scenario.

Provided the upper layer extraction rate is at least large enough to offset the expansion and injection rates, the smoke layer interface will eventually equilibrate at the elevation where a balance is struck between the rates of flow into and out of the smoke layer:

$$\dot{V}_{\text{ext},u} = \dot{V}_{pl} + \dot{V}_{\exp} + \dot{V}_{\text{inj},u} \tag{33.60}$$

Equation 33.60 represents the typical situation for a smoke management system designed according to the *exhaust method*. For this situation, air is not typically injected into the upper layer because this would require higher extraction rates, so the last term on the right-hand side of Equation 33.60 would normally be zero. The upper layer extraction rate needed to maintain the smoke layer interface at a distance z_i above the floor can be determined from Equation 33.60 provided the relationship between plume entrainment, fire intensity, and elevation is known and the fire intensity can be estimated. For the case of an axisymmetric plume, this relationship is normally represented as

$$\dot{V}_{pl} = k_v \dot{Q}_c^{1/3} \left(z_i - z_f\right)^{5/3} \tag{33.61}$$

Based on the Zukoski [25] entrainment correlation, the value for k_v will be approximately 0.064 $\text{m}^{4/3}\ \text{s}^{-1}\ \text{kW}^{-1/3}$. For other plume geometries, such as window plumes, balcony spill plumes, or line plumes, other entrainment rate relationships exist [10]. Further information on plume entrainment is provided by Beyler [29], who prepared a comprehensive review of fire plume and ceiling jet correlations, and by Quintiere and Grove [30], who more recently reviewed the literature on different types of plumes and developed correlations for fire plumes of different geometries.

Once the extraction rate needed to maintain the smoke layer interface at an elevation z_i above the floor is determined, Equations 33.52 through 33.58 can be used to evaluate the global effects of this extraction rate. These effects will included the makeup air requirements $\left(-\dot{V}_{\text{net}}\right)$ to balance the design exhaust rate as well as the leakage opening area requirements to prevent excessive pressure drop and flow velocities across the enclosure boundaries. As indicated by Equation 33.47, mechanical injection of air into the lower layer can be used to reduce the makeup air requirements and consequently the pressure drop and flow velocities across openings in the enclosure boundaries.

At this point, conditions within the smoke layer are considered. For Case 1, mass conservation for the upper layer can be expressed in terms of the various volumetric flow rates into and out of the smoke layer:

$$\frac{dm_u}{dt} = \rho_l \left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right) - \rho_u \dot{V}_{\text{ext},u} \quad \text{if } V_1 > 0 \tag{33.62a}$$

$$\frac{dm_u}{dt} = \rho_l \left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right) - \rho_u \left(\dot{V}_{\text{ext},u} + \dot{V}_{\text{net}}\right) \quad \text{if } V_l = 0 \tag{33.62b}$$

The additional term in Equation 33.62b compared with Equation 33.62a accounts for the leakage flow from the upper layer that occurs once the upper layer completely fills the enclosure.

Similarly, different species can be tracked in terms of a species balance, which can be expressed for this case as

$$\frac{dm_{i,u}}{dt} = \rho_l Y_{i,o}\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right) - \rho_u Y_{i,u}\dot{V}_{\text{ext},u} + \dot{m}_{i,\text{gen}} \quad \text{if} \quad V_l = 0 \tag{33.63a}$$

$$\frac{dm_{i,u}}{dt} = \rho_l Y_{i,o}\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right) \quad \text{if} \quad V_l > 0 - \rho_u Y_{i,u}\left(\dot{V}_{\text{ext},u} + \dot{V}_{\text{net}}\right) + \dot{m}_{i,\text{gen}} \tag{33.63b}$$

Similar to the global analysis, the rate of change of the mass fraction of a species in the upper layer is calculated as

$$\frac{dY_{i,u}}{dt} = \frac{1}{m_u}\left[\rho_l\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right)\left(Y_{i,o} - Y_i\right) + \dot{m}_{i,\text{gen}}\right] \tag{33.64}$$

The generation, or consumption, rate of different species is expressed in terms of a yield factor, f_i, as given by Equation 33.20 for the global case. All products generated by the combustion reaction are assumed to enter the upper layer via the fire plume.

Finally, the temperature of the upper layer is calculated from the mass and volume of the upper layer as

$$T_u = \frac{\rho_o T_o}{\rho_u} = \frac{\rho_o T_o V_u}{m_u} \tag{33.65}$$

This assumes that the upper layer can be treated as an ideal gas at constant pressure with the properties of air. The mass, volume, and species mass fractions in the upper layer change with time in accordance with Equations 33.59, 33.62, and 33.64. Numerical integration is generally necessary to evaluate these differential equations. Once they are evaluated at a particular time, the upper layer temperature at that time can be calculated using Equation 33.65.

Ceiling Leak (Case 2) Analysis

All leakage is assumed to occur from the upper layer for Case 2. The rate of change of the smoke layer volume or depth can be expressed in terms of the upper layer flow terms shown in Fig. 33.10 as

$$\frac{dV_u}{dt} = A_s\frac{dz_u}{dt} = \dot{V}_{pl} + \dot{V}_{\text{exp}} + \dot{V}_{\text{inj},u} - \dot{V}_{\text{ext},u} - \dot{V}_{\text{net}} \tag{33.66}$$

Because $\dot{V}_{\text{net}} = \dot{V}_{\text{inj}} + \dot{V}_{\text{exp}} - \dot{V}_{\text{ext}}$, $\dot{V}_{\text{inj}} = \dot{V}_{\text{inj},u} + \dot{V}_{\text{inj},l}$, and $V_{\text{ext}} = V_{\text{ext},u} + V_{\text{ext},l}$, Equation 33.66 can be rewritten as

$$\frac{dV_u}{dt} = A_s\frac{dz_u}{dt} = \dot{V}_{pl} + \dot{V}_{\text{ext},l} - \dot{V}_{\text{inj},l} \tag{33.67}$$

The relationship expressed by Equation 33.67 may seem counterintuitive because it shows that, for Case 2, smoke layer descent is affected by injection and extraction in the lower layer but not in the upper layer. Noting that $dV_u = dV_l$, an analysis of flow terms can be conducted on the lower layer to reach the same result expressed by Equation 33.67. Alternatively, this result can be explained as follows. Because all leakage flow from the enclosure in Case 2 is assumed to occur via leakage paths from the upper layer, any injection of air into the upper layer will simply be forced through these paths rather than contribute to the descent of the upper layer. Similarly, all expansion is assumed to be forced through these leakage paths from the upper layer rather than contribute to the smoke layer descent, as in the unventilated Case 2 scenario. Finally, extraction from the upper layer will first act to relieve some of the expansion flow from the enclosure. If the extraction rate is less than the combination of the injection and expansion rates, then additional smoky gases will be forced through the leakage paths from the upper layer. On the other hand, if the extraction rate is greater than the combination of the injection and expansion rates, then

fresh air will be drawn through the leakage paths into the upper layer. Although these factors all influence the composition and temperature of the upper layer, they do not affect the smoke layer descent rate expressed by Equation 33.67.

With leakage occurring from the upper layer in Case 2, the injection of air into the lower layer will act to "push" smoke through leakage paths from the upper layer, reducing the rate of smoke layer descent in the process. In contrast, the extraction of air from the lower layer will act to draw the smoke layer down. If the extraction rate is greater than the combination of the injection and expansion rates, air will be drawn into the upper layer through the leakage paths, contributing to the smoke layer descent while at the same time diluting the smoke in the upper layer. For a scenario where there is no injection and the extraction rate is exactly equal to the expansion rate, then the net flow through leakage paths will be nil. In essence, this is the same scenario as the unventilated Case 1, with the expansion flow from the lower layer replaced by extraction from the lower layer at the same rate. In the unventilated Case 1 scenario, expansion contributes to the smoke layer descent just as an equivalent rate of extraction from the lower layer will in the ventilated scenario.

Equations 33.66 and 33.67 demonstrate that no amount of extraction from the upper layer will prevent the smoke layer from eventually descending to the elevation of the fire in Case 2 scenarios. Similarly, due to the location of the leakage paths in the upper layer, no amount of injection into the upper layer will affect the rate of smoke layer descent. Such injection or extraction will affect only the composition and temperature of the smoke layer.

For Case 2 scenarios, a quasi-steady smoke layer interface position can be achieved only by injecting more air into the lower layer than is extracted from it. The smoke layer will stop descending when the following flow balance is achieved:

$$\dot{V}_{\text{inj},l} = \dot{V}_{pl} + \dot{V}_{\text{ext},l} \tag{33.68}$$

The air injection rate needed to maintain the smoke layer interface at a distance z_i above the floor can be determined by Equation 33.68, provided the extraction rate is known and the relationship between plume entrainment and elevation is known. For the case of an axisymmetric plume, this relationship was given in Equation 33.61. For other plume geometries, other entrainment relationships are available in the literature [10, 29, 30].

The concept of injecting air low in an enclosure while providing ventilation openings high is the basis for the positive pressure ventilation (PPV) technique [31, 32] sometimes employed in fire-fighting operations. This technique is not used as often in building smoke management systems, in part because this technique places the fire enclosure at positive pressure relative to adjacent spaces. Although boundaries adjacent to the smoke layer are assumed to be perfectly tight for the limiting analyses presented here, in reality such boundaries will leak and smoke will be forced from the fire enclosure into adjacent spaces. In contrast, with the exhaust method described in the Case 1 analysis, the extraction of smoke causes the fire enclosure to be at a slightly negative pressure relative to adjacent spaces. Under these conditions, leakage tends to be from the adjacent spaces to the fire enclosure, thus reducing the likelihood and degree of smoke contamination in the adjacent spaces.

At this point, conditions within the smoke layer are addressed for the Case 2 scenario. Mass conservation for the upper layer can be expressed in terms of the various volumetric flow rates across the upper layer boundaries:

$$\frac{dm_u}{dt} = \rho_l\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right) - \rho_u\left(\dot{V}_{\text{ext},u} + \dot{V}_{\text{net}}\right) \quad \text{if } \dot{V}_{\text{net}} > 0 \tag{33.69a}$$

$$\frac{dm_u}{dt} = \rho_l\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u} - \dot{V}_{\text{net}}\right) - \rho_u\left(\dot{V}_{\text{ext},u}\right) \quad \text{if } \dot{V}_{\text{net}} < 0 \tag{33.69b}$$

Similarly, different species can be tracked in terms of a species balance, expressed as

$$\frac{dm_{i,u}}{dt} = \rho_l Y_{i,o}\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right) - \rho_u Y_{i,u}\left(\dot{V}_{\text{ext},u} + \dot{V}_{\text{net}}\right) + \dot{m}_{i,\text{gen}} \quad \text{if } \dot{V}_{\text{net}} > 0 \tag{33.70a}$$

$$\frac{dm_{i,u}}{dt} = \rho_l Y_{i,o}\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u} - \dot{V}_{\text{net}}\right) \quad \text{if } \dot{V}_{\text{net}} < 0$$
$$- \rho_u Y_{i,u} \dot{V}_{\text{ext},u} + \dot{m}_{i,\text{gen}} \tag{33.70b}$$

As for the other cases, these species balances can also be expressed in terms of mass fractions:

$$\frac{dY_{i,u}}{dt} = \frac{1}{m_u}\left[\rho_l\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u}\right)\ \left(Y_{i,o} - Y_i\right)\right.$$
$$\left. + \dot{m}_{i,\text{gen}}\right] \quad \text{if } \dot{V}_{\text{net}} < 0 \tag{33.71a}$$

$$\frac{dY_{i,u}}{dt} = \frac{1}{m_u}\left[\rho_l\left(\dot{V}_{pl} + \dot{V}_{\text{inj},u} - \dot{V}_{\text{net}}\right)\ \left(Y_{i,o} - Y_i\right)\right]$$
$$+ \dot{m}_{i,\text{gen}}\Big] \quad \text{if } \dot{V}_{\text{net}} < 0 \tag{33.71b}$$

Finally, the temperature of the upper layer is calculated from the mass and volume of the upper layer by Equation 33.65. For Case 2, the upper layer volume, mass, and species mass fractions change with time in accordance with Equations 33.67, 33.69a, 33.69b, and 33.71a, 33.71b. Numerical integration is generally necessary to evaluate these differential equations. Once they are evaluated at a particular time, the upper layer temperature at that time is calculated by Equation 33.65.

Numerical Methods for Solving Initial Value Problems

In the previous sections of this chapter, the enclosure smoke-filling process has been described in terms of a number of ordinary differential equations to describe the rate of change of volume, mass, and species within the smoke layer. The enclosure smoke filling process is in the class of problems known as initial value problems. This type of problem is also sometimes referred to as a *time marching* problem, because the objective is to determine the time history of the parameters of interest, given the initial values for these parameters along with equations describing how these parameters change with time as a result of specified boundary conditions.

As noted previously, the differential equations describing the smoke-filling process can be solved analytically for only a few idealized fire scenarios. For most realistic fire scenarios, these equations must be solved approximately using appropriate numerical methods. Computer models of the smoke-filling process, such as ASET and ASET-B, use a variety of similar numerical methods to develop approximate solutions for the enclosure smoke-filling process. Some of these methods are discussed briefly in this section. For a more comprehensive treatment of numerical methods, readers are referred to texts on this topic (e.g., Ferziger and Peric [33]).

Note that most of the equations presented in previous sections are expressed in the form

$$\frac{d\phi(t)}{dt} = f[t, \phi(t)] \tag{33.72}$$

where $\phi(t)$ represents the different parameters of interest, such as the smoke layer interface position and the smoke layer temperature and composition. In general, the objective is to predict values for the parameters of interest as a function of time based on the rate of change of the different parameters, $d\phi(t)/dt$, over each time interval, Δt, being evaluated. Mathematically, this is represented as

$$\phi(t_{n+1}) = \phi(t_n) + \int_{t_n}^{t_{n+1}} f[t, \phi(t)]dt$$
$$\cong \phi(t_n) + f[t, \phi(t)]\,\Delta t \tag{33.73}$$

The question is how to efficiently and accurately approximate the function, $f[t,\phi(t)]$ over a time increment, Δt.

The simplest approach to solving Equation 33.73 numerically, known as the explicit or forward Euler method, evaluates the derivative function at the current time, t_n, that is,

$$f[t, \phi(t)] \cong f[t_n, \phi(t_n)]$$

The forward Euler method is known as an explicit method because the value of the parameter at the future time, $\phi(t_{n+1})$, is evaluated based

on the values of parameters evaluated at the current time, t_n. For many applications, particularly those in which the function is changing rapidly with time, such an approximation may not be very accurate. This will depend to some extent on the time step selected and the nature of the function being evaluated.

The next level of complexity, as well as accuracy, is introduced by methods known as predictor-corrector methods. The simplest of these, known as the improved Euler method or as Heun's method, uses the explicit Euler method to predict the value of the derivative function; this predicted value is represented as $\phi^*(t_{n+1})$. This predicted value is then used to estimate the slope of the function at the endpoint. The average slope over the time step is then taken as the average of the slopes evaluated at the beginning and endpoints, that is, at times t_n and t_{n+1}. Heun's method can be expressed mathematically as

$$\phi^*(t_{n+1}) = \phi(t_n) + f[t_n, \phi(t_n)]\Delta t \tag{33.74a}$$

$$\phi(t_{n+1}) = \phi(t_n) + \frac{1}{2}\left\{f[t_n, \phi(t_n)] + f[t_{n+1}, \phi^*(t_{n+1})]\right\}\Delta t \tag{33.74b}$$

An iterative form of this predictor-corrector method was used in the development of the ASET-B model [4].

The explicit Euler method and Heun's method are single point methods because they use information at only the current time step to evaluate conditions at the future time step. Beyond these simple methods, multipoint methods have been developed that use information that has already been computed at previous time steps to fit a polynomial to a number of points. The Adams-Bashforth method is an explicit method that uses information at the current time step and the previous two time steps to evaluate the derivative function:

$$\phi(t_{n+1}) = \phi(t_n) + \frac{\Delta t}{2}\left\{23f[t_n, \phi(t_n)] - 16f[t_{n-1}, \phi(t_{n-1})] + 5f[t_{n-2}, \phi(t_{n-2})]\right\} \tag{33.75}$$

A disadvantage of multipoint methods is that they cannot be started using only data at the initial point because they require data from multiple points prior to the current one. Consequently, other methods must be used to start a calculation. Once started, the advantage of explicit multipoint methods is that they require only one evaluation of the derivative function per time step because the function has already been evaluated at previous time steps.

Runge-Kutta methods overcome the difficulties in starting multipoint methods by using additional points between times t_n and t_{n+1} rather than earlier points to evaluate the derivative function. The most popular Runge-Kutta method is the fourth-order method, which involves multiple evaluations over the time step:

$$\phi^*\left(t_{n-1/2}\right) = \phi(t_n) + f[t_n, \phi(t_n)]\Delta t/2 \tag{33.76a}$$

$$\phi^{**}\left(t_{n+1/2}\right) = \phi(t_n) + f\left[t_{n+1/2}, \phi\left(t_{n+1/2}\right)\right]\Delta t/2 \tag{33.76b}$$

$$\phi^*(t_{n+1}) = \phi(t_n) + f\left[t_{n+1/2}, \phi^{**}\left(t_{n+1/2}\right)\right]\Delta t \tag{33.76c}$$

$$\phi(t_{n+1}) = \phi(t_n) + \frac{\Delta t}{6}\left\{f[t_n, \phi(t_n)] + 2f\left[t_{n+1/2}, \phi^*\left(t_{n+1/2}\right)\right] + 2f\left[t_{n+1/2}, \phi^{**}\left(t_{n+1/2}\right)\right] + f[t_{n+1}, \phi^*(t_{n+1})]\right\} \tag{33.76d}$$

The fourth-order Runge-Kutta method was used in the development of the original ASET model [2].

Treatment of Enclosure Smoke Filling in Different Fire Models

A number of fire models have been developed over the past three decades to address the enclosure smoke-filling process. The best known of these include the ASET model developed by Cooper [2] during the early 1980s and the ASET-B adaptation of this model developed by Walton [4] during the mid-1980s.

Zone models, such as CFAST, address the enclosure smoke-filling process as a subset of the more general enclosure fire process. Through appropriate specification of vent sizes and locations, users can use these models to address enclosure smoke-filling scenarios. With such vent specifications, the smoke layer will descend within the enclosure until a balance occurs between inflows and outflows.

Similar to the more comprehensive zone models, computational fluid dynamics (CFD) models such as the Fire Dynamics Simulator (FDS) address the enclosure smoke-filling process as a subset of the more general enclosure fire process. As with the more comprehensive zone models, users can address enclosure smoke-filling scenarios by specifying appropriate vent sizes and locations along with appropriate fire parameters.

Comparisons with Experimental Data

The equations describing enclosure smoke filling and conditions presented in the previous sections of this chapter are amenable to solution with spreadsheet templates. A spreadsheet template has been developed [11, 12] based on the explicit Euler numerical method described in a previous section. This spreadsheet template includes calculations and graphs for the global case (Case 0), the floor leak case (Case 1), and the ceiling leak case (Case 2). The parameters calculated in the template include

$V_{ul}(t)$ Upper layer volume (m^3)
$z_{ul}(t)$ Smoke layer interface height above the floor (m)
$m_{ul}(t)$ Upper layer mass (kg)
$T_{ul}(t)$ Smoke layer average temperature (°C)
$Y_{O_2,ul(t)}$ Smoke layer oxygen mass fraction (kg O_2/kg total)

These parameters are calculated for both Case 1 and Case 2. The global temperature rise associated with Case 0 is calculated using Equation 33.17, with the net rate of energy addition, $\dot{Q}_{\text{net}}$, calculated using Equation 33.2. For comparison purposes, the smoke layer descent rate expressed by Equation 33.38 is identified as the global calculation of smoke layer position (Case 0) in the template. This represents the analytical solution for Case 2 for power law fires, permitting evaluation of the accuracy of the Case 2 numerical solution for smoke layer descent.

In the spreadsheet template, the fire is represented as a user-specified power law fire, $\dot{Q}_f = \alpha_n t^n$, which can be used to represent a wide range of fire growth scenarios, including the commonly used steady ($n = 0$) and t-squared ($n = 2$) fire growth rates. The maximum fire size is also specified. The fire grows according to the specified power law relationship until it reaches the maximum fire size and remains constant at the maximum size thereafter. Decay and burnout are not considered in the current implementation of the spreadsheet template.

The calculations performed by the spreadsheet template have been compared with experimental data. The first comparison is based on a fire test conducted by Hagglund et al. [34] in a 5.62 m by 5.62 m by 6.15 m high space with a reported steady fire size of 186 kW located 0.2 m above the floor. $Q^* = 1.6 \times 10^{-3}$ for this scenario, based on a heat release rate of 186 kW, a radiative fraction of 0.35, and a height $z = 5.4$ m. Karlsson and Quintiere [35] note that for this experiment there was a delay of up to 1 min for the fire to reach its steady value of 186 kW. To evaluate the effect of this delay, the fire was ramped up as a t-squared fire to reach a heat release rate of 186 kW at 60 s ($\alpha = 0.052$ kW/s^2), then maintained at a steady value 186 kW for the rest of the 300 s simulation. Results of this simulation are shown along with experimental data in Fig. 33.12.

Figure 33.12 shows that there is little difference between the two numerical cases (Cases 1 and 2) and the analytical solution (Equation 33.38) for the predicted smoke layer descent rates or among the three cases (Cases 0, 1, and 2) for the average smoke layer temperatures. At later times, the smoke layer descends slightly more rapidly for Case 1 than for the other two cases. This is due to the increasingly important role of expansion in Case 1 as the smoke layer

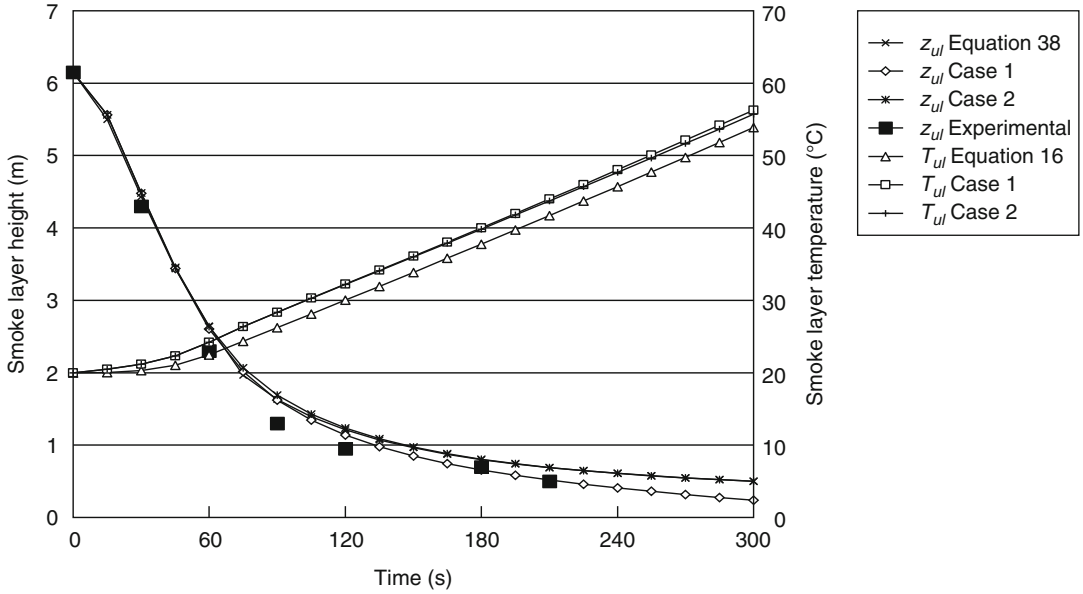

Fig. 33.12 Experimental and predicted results for smoke filling in a 6 m cube [34]

nears the fuel surface. Cooper [3] has previously noted the increasing importance of expansion as the smoke layer approaches the fuel surface. The smoke layer interface positions for Case 2 and the analytical solution are virtually identical at all times; this serves to verify the accuracy of the numerical solution. The smoke layer temperatures for Cases 1 and 2 are a few degrees Celsius higher than for the global case (Case 0), but for most hazard analysis purposes, these differences are not significant.

As a second comparison, an experiment conducted at the Building Research Institute (BRI) in Japan by Yamana and Tanaka [36] is considered. This experiment was conducted in an enclosure with a height of 26.3 m and a plan area of 720 m^2 ($A/H^2 = 1.0$). The enclosure was not mechanically ventilated for the experiment considered here. The fire source was a methanol pool with an area of 3.24 m^2, estimated to develop a steady heat release rate of approximately 1.3 MW after a 60 s period of initial growth assumed to follow a *t*-squared profile. $Q^* = 3.0 \times 10^{-3}$ for this fire, based on the maximum heat release rate of 1.3 MW, a radiative fraction of 0.10 for the methanol pool and a height of 26.3 m. For the calculations, the heat loss fraction was set to 0.50, a relatively low value. This value was selected on the basis that heat losses due to radiation from the flame would be lower than usual due to the relatively low luminosity of the methanol flame.

Results of the comparison with the BRI experiment are shown in Fig. 33.13. For the experimental temperature data, measurements made at an elevation of 16 m above the floor are shown. The experimental smoke layer interface position shown in Fig. 33.13 represents a composite of thermocouple and photometer measurements as well as visual observations reported for this experiment. Figure 33.13 shows generally good agreement between calculated results and measured data for this experiment.

Summary

Enclosure smoke filling and smoke layer conditions have been subjects of interest in the fire protection engineering community at least since Zukoski [1] first described the smoke-filling process in terms of thermodynamic control

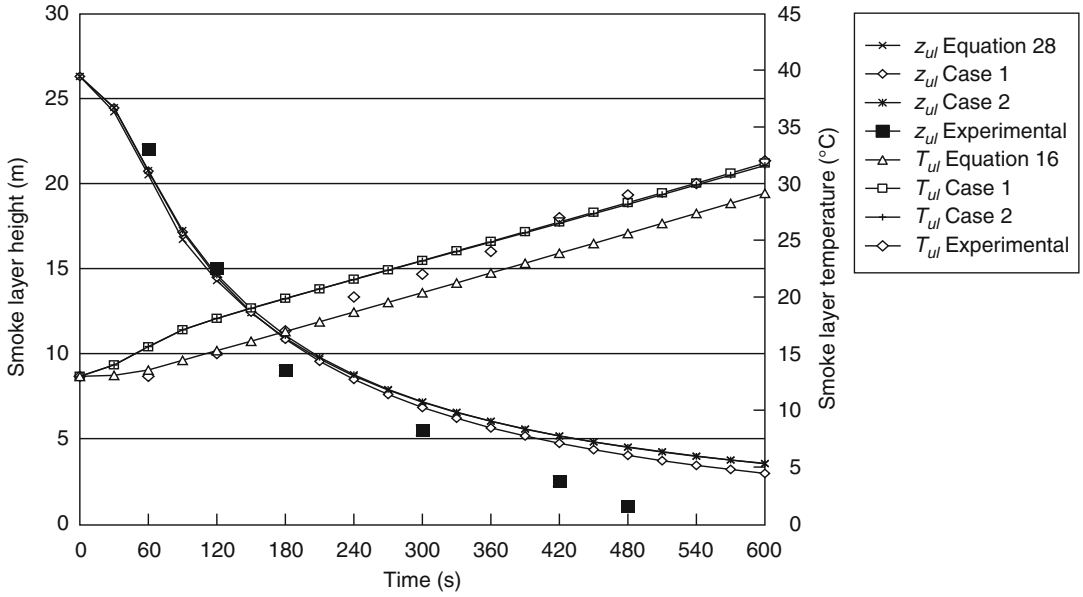

Fig. 33.13 Experimental and predicted smoke-filling results for BRI experiment [36]

volumes and plume flow rates more than 25 years ago. These concepts are now fundamental premises for performance-based consideration of available safe egress time (ASET) [2, 3] and smoke management in large spaces (e.g., NFPA 92B [10]).

This chapter reviewed the concepts of enclosure smoke filling first described by Zukoski [1] and addressed extensively by Cooper [2, 3]. It extended these concepts in a number of ways. First, the smoke-filling process was expressed in terms of volumetric flow rates, consistent with the normal practice of ventilation system design. This analysis also showed that the smoke-filling process can be described simply in terms of two distinct volumetric flow processes: plume entrainment and gas expansion. It further showed that the volumetric rate of gas expansion can be treated as a source term that is directly proportional to the net rate of heat addition to a space.

The relevant set of ordinary differential equations were shown for describing smoke layer descent, temperature, and composition for both unventilated and mechanically ventilated enclosure fire scenarios. In general, these equations must be solved numerically for realistic fire scenarios. Appropriate numerical methods were described briefly.

A number of example calculations were provided to demonstrate application of the enclosure smoke-filling equations. Such calculations are useful for performing preliminary analyses of enclosure smoke-filling fire scenarios. They can be supplemented by the use of computer-based zone and CFD models described in other chapters.

Nomenclature

A	area (m^2)
c_p	specific heat at constant pressure (kJ/kg · K)
c_v	specific heat at constant volume (kJ/kg · K)
C_d	orifice flow coefficient (–)
dm_{O_2}	mass of oxygen consumed by combustion (kg)
h	specific enthalpy (kJ/kg)
H	height of space from floor to ceiling (m)
k_v	volumetric entrainment coefficient ($m^3/s \cdot kW^{1/3} \cdot m^{5/3}$)

m	mass (kg)
$\dot{m}$	mass flow rate (kg/s)
P	pressure (Pa)
P_o	atmospheric pressure (101,325 Pa)
Q_f	heat released by combustion (kJ)
$\dot{Q}$	heat release rate (kW)
Q^*	dimensionless heat release rate—$\dot{Q}/\left(\rho_a c_p T_a \sqrt{gH}H^2\right)$
$r_{\mathbf{air}}$	air stoichiometric ratio (kg air/kg fuel)
r_{O_2}	oxygen stoichiometric ratio (kg oxygen/kg fuel)
R	ideal gas constant of air (287.0 J/kg · K)
t	time (s)
T	temperature (K or °C)
u	specific internal energy (kJ/kg)
U	total internal energy (kJ)
v	velocity (m/s)
V	volume (m^3)
$\dot{V}$	volumetric flow rate (m^3/s)
X_i	mole fraction of species i (n_i/n_{total}) ($moles_i/moles_{total}$)
Y_i	mass fraction of species i (m_i/m_{total}) (kg_i/kg_{total})
z	elevation variable (m)

Greek Letters

α_n	power law fire growth coefficient (kW/s^n)
χ_l	heat loss factor $\left(\dot{Q}_l/\dot{Q}_f\right)$ (–)
χ_{O_2}	oxygen consumption fraction (–)
ΔH_c	fuel heat of combustion (kJ/kg)
ΔT	temperature rise above ambient (K or °C)
ρ	density (kg/m^3)
τ	time constant (s)

Subscripts

atm	atmospheric
c	convective
e	exit
exp	expansion
ext	extraction
f	fire
g	global
i	in, interface
l	loss, lower layer
net	net
o	ambient, reference
$\mathbf{O_2}$	oxygen
p	constant pressure
pl	plume
r	radiative
s	space
tot	total
u, ul	upper layer
v	constant volume

Methods for Predicting Temperatures in Fire-Exposed Structures

34

Ulf Wickström

Introduction

The fire resistance of structural elements is traditionally determined by standard fire endurance tests. However, there is also a need to be able to predict the response of structures of various designs when exposed to alternative design fire conditions. Accurate and robust analytical methods are then needed. Such methods may also be used for predicting standard tests of, for example, structural elements that cannot be tested due to their size or for extending test results to modified structures.

It is necessary when using analytical methods, as well as when interpreting test results and their relations to real fires, to understand the fundamental physics governing the thermal behavior of fire-exposed structures. The focus in this chapter is to meet these needs. The content is based on textbooks on heat transfer theory (e.g., Holman [1] and others) and from various publications in the field of fire safety engineering.

Analytical methods for the design of fire resistance of structures have the following three main components:

1. Determining the duration and level of thermal fire exposure
2. Calculating the heat transfer and the internal temperature distribution
3. Estimating the structural response and the load-bearing capacity

U. Wickström (✉)

The first step is in general very complex and requires somewhat uncertain assumptions. Most often the fire exposure is assumed according to standardized time-temperature curves, as specified in ISO 834, ASTM E119, or EN 1363-1. Time-temperature developments determined by fire models or measured at ad hoc tests are seldom applied. The next step is very crucial as the deterioration of material strength depends on the temperature obtained. This chapter focuses on this second step. More information on the first and third steps of an analytical design procedure is outlined elsewhere in this section of the handbook.

The temperature calculation methods presented here disregard in general any mechanical failures that may occur that could alter the thermal conditions. Protection systems may, for example, fall off in case of fire exposure and completely change the thermal conditions. Such phenomena must be investigated by full-scale tests and, therefore, new types of structural systems must in general be tested in full scale in standard furnace tests as a basis for type approval and so on. Calculation methods can, however, be used for generalizations or extensions of test results to various dimensions and configurations.

Heat Transfer to Structures

Heat is transferred from hot fire gases to structures by convection and radiation. The

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,

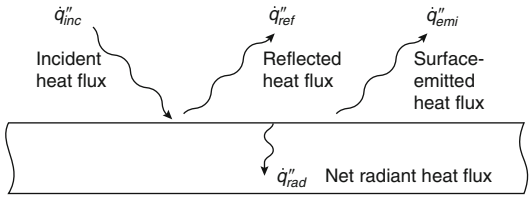

Fig. 34.1 Heat transfer by radiation to a surface, which depends on incident radiation, surface absolute temperature, and surface emissivity

contributions of these two modes of heat transfer are in principal independent and must be treated separately. The convective heat transfer depends on the temperature difference between the target surface and the surrounding gas and the velocity of the gas masses in the vicinity of the exposed surface, whereas the incident heat radiation on a surface originates from surrounding flames and gas masses as well as other surrounding surfaces.

Thus, the total heat flux $\dot{q}''_{\mathrm{tot}}$ to a surface is

$$\dot{q}''_{\mathrm{tot}} = \dot{q}''_{\mathrm{rad}} + \dot{q}''_{\mathrm{con}} \tag{34.1}$$

where $\dot{q}''_{\mathrm{rad}}$ is the net radiation heat flux and $\dot{q}''_{\mathrm{con}}$ is the heat transfer to the surface by convection. Details of these two contributions to follow.

Radiation

The net radiation heat flux $\dot{q}''_{\mathrm{rad}}$ depends on the incident radiation $\dot{q}''_{\mathrm{inc}}$, on the surface emissivity/absorptivity, and on the fourth power of the absolute temperature T_s of the targeted surface. The heat exchange at a surface is illustrated in Fig. 34.1.

Part of the incident radiation is absorbed and the rest $\dot{q}''_{\mathrm{ref}}$ is reflected. Then the surface emits heat by radiation $\dot{q}''_{\mathrm{emi}}$ depending on the emissivity and the surface absolute temperature to the fourth power. Thus, the net radiative heat can be written

$$\dot{q}''_{\mathrm{rad}} = \alpha_s \dot{q}''_{\mathrm{inc}} - \varepsilon_s \sigma T_s^4 \tag{34.2}$$

where α_s and ε_s are the target surface absorptivity and emissivity, respectively. In this presentation the surface emissivity and absorptivity are assumed equal according to the Kirchhoff's identity. Thus,

$$\dot{q}''_{\mathrm{rad}} = \varepsilon_s \left(\dot{q}''_{\mathrm{inc}} - \sigma T_s^4 \right) \tag{34.3}$$

The incident radiation to a surface is emitted by surrounding gas masses and in case of fire by flames and smoke layers and/or by other surfaces. It depends on the fourth power of the absolute temperature. The emissivity and absorptivity of gas masses and flames increase with depth and become, therefore, in general more important in large-scale fires than in, for example, small-scale experiments. In real fires surfaces are exposed to radiation from a large number of sources (surfaces, flames, gas masses, etc.) of different temperatures and emissivities. The heat fluxes are then in general very complicated to model. A simple summation of the main contributions yields in general a good estimate; that is,

$$\dot{q}''_{\mathrm{inc}} = \sum \varepsilon_i F_i \sigma T_i^4 \tag{34.4}$$

where ε_i is the emissivity of the ith source, F_i and T_i are the corresponding view factor (see Chap. 4, "Radiation Heat Transfer," of this handbook) and temperature, respectively. Equation 34.4 may then be inserted in Equation 34.3 to get

$$\dot{q}''_{\mathrm{rad}} = \varepsilon_s \sigma \left(\sum \varepsilon_i F_i T_i^4 - T_s^4 \right) \tag{34.5}$$

or

$$\dot{q}''_{\mathrm{rad}} = \varepsilon_s \sigma \left(T_r^4 - T_s^4 \right) \tag{34.6}$$

where T_r is here termed the black body radiation temperature or just the radiation temperature. T_r is a weighted average identified as

$$T_r^4 \equiv \sum \varepsilon_i F_i T_i^4 \tag{34.7}$$

The emissivities as used above are surface properties, in principle independent of the fire conditions.

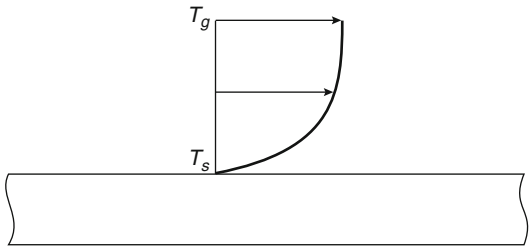

Fig. 34.2 Gas velocity profile, with the heat transfer by convection depending on the temperature difference between the adjacent gases and the target surface and on the gas velocity

Convection

The heat transferred by convection from adjacent gases to a surface varies a lot depending on adjacent gas velocities and geometries (Fig. 34.2).

In most cases it may be written as

$$\dot{q}''_{con} = h\left(T_g - T_s\right)^n \tag{34.8}$$

where h is the convective heat transfer coefficient and T_g is the gas temperature adjacent to the exposed surface. In cases of surfaces heated or cooled by natural or free convection a value of n greater than unity is motivated depending on flow conditions [1].

In fires the heat transfer conditions by convection may vary a lot and the parameters h and n are very hard to determine accurately. However, as radiation heat transfer dominates and the convective conditions are not decisive for the total heat transfer to fire exposed structures, the exponent n is assumed equal to unity for simplicity in most fire engineering cases. Thus,

$$\dot{q}''_{con} = h\left(T_g - T_s\right) \tag{34.9}$$

The convective heat transfer coefficient h depends mainly on flow conditions in the vicinity of the surface and not so much on the surface or the material properties.

Total Heat Transfer and Adiabatic Surface Temperature

The total heat transfer to a surface may now be obtained by adding the contributions by radiation and convection. Thus, by inserting Equations 34.6 and 34.9 into Equation 34.1, the total heat flux to a surface becomes

$$\dot{q}''_{\text{tot}} = \varepsilon_s\sigma\left(T_r^4 - T_s^4\right) + h\left(T_g - T_s\right) \tag{34.10}$$

In most fire engineering design cases the radiation temperature T_r and the gas temperature T_g are assumed equal to a fire temperature T_f. Then the total heat transfer may be calculated as

$$\dot{q}''_{\text{tot}} = \varepsilon_s\sigma\left(T_f^4 - T_s^4\right) + h\left(T_f - T_s\right) \tag{34.11}$$

or

$$\dot{q}''_{\text{tot}} = h_{\text{tot}}\left(T_f - T_s\right) \tag{34.12}$$

where the combined total heat transfer coefficient h_{tot} may be identified from Equations 34.11 and 34.12 as

$$H = \varepsilon_s\sigma\left(T_f^2 - T_s^2\right)\left(T_f + T_s\right) + h \tag{34.13}$$

Alternatively the two boundary temperatures in Equation 34.10, T_r and T_g, may be combined to one effective temperature T_{AST}, the adiabatic surface temperature. This temperature is defined as the temperature of a surface of an ideally perfectly insulating material, i.e. a surface which cannot absorb any heat [2]. Thus, T_{AST} is defined by the surface heat balance equation

$$\varepsilon_s\sigma\left(T_r^4 - T_{AST}^4\right) + h\left(T_g - T_{\text{AST}}\right) = 0 \tag{34.14}$$

The value of T_{AST} is always between T_r and T_g.

Then the total heat transfer may be written as

$$\dot{q}''_{\text{tot}} = \varepsilon_s\sigma\left(T_{AST}^4 - T_s^4\right) + h\left(T_{AST} - T_s\right) \tag{34.15}$$

The adiabatic surface temperature T_{AST} can in many cases be measured, and it may be used for calculating heat transfer to fire-exposed surfaces based on practical tests, as discussed later. It can also be obtained from numerical CFD modeling of fires using computer codes like FDS [2, 3].

Heat Transfer to Fire-Exposed Structures

Based on Equations 34.11 and 34.12 the heat transfer to a fire-exposed surface can be calculated for given fire and surface temperatures T_f and T_s. The emissivity ε_s is a surface property, which can be assumed to equal 0.8 for most building materials except for shiny steel where a lower value may be assumed. The convection coefficient h is not decisive for the temperature development near a fire-exposed surface of a structure as the radiative heat transfer dominates at high temperatures. In Eurocode 1 [4] a value of 25 W/m^2 K is recommended at fire-exposed surfaces. The temperature on the nonexposed side of a separating structure will, on the other hand, depend very much on the heat transfer conditions including the convection coefficient. In Eurocode 1 in this case a convective heat transfer coefficient value of 4 W/m^2 K is recommended.

In many cases, however, a fire-exposed surface will get temperatures very close to the fire temperature (i.e., $T_f \approx T_s$). This approximation applies for insulation materials with a low density and a low thermal conductivity. It may facilitate calculations considerably and is here applied on calculating temperature in insulated steel structures (as discussed later). Even a normal weight concrete surface will get a temperature of 90 % of the fire temperature after 30 min (as shown in Fig. 34.19, later in the chapter).

The heat transfer conditions may be very decisive for the temperature development in a fire-exposed bare steel structure (see discussion on unprotected steel structures later in the chapter). They are also very important for the temperature development on the back side of a fire-separating element. This is in particular the case for light weight structures where the thermal insulation properties are decisive rather than the thermal inertia.

Calculating Heat Transfer Using Plate Thermometer Temperatures

So-called *plate thermometers* are used to monitor the temperature in fire resistance furnaces according to the international standard ISO 834 and the European standard EN 1363-1. A plate thermometer (PT) consisting of an Inconel (trade name for a nickel-based superalloy) plate insulated on its back side is shown in Fig. 34.3. A thermocouple fixed to the plate registers its temperature. Figure 34.4 shows plate thermometers

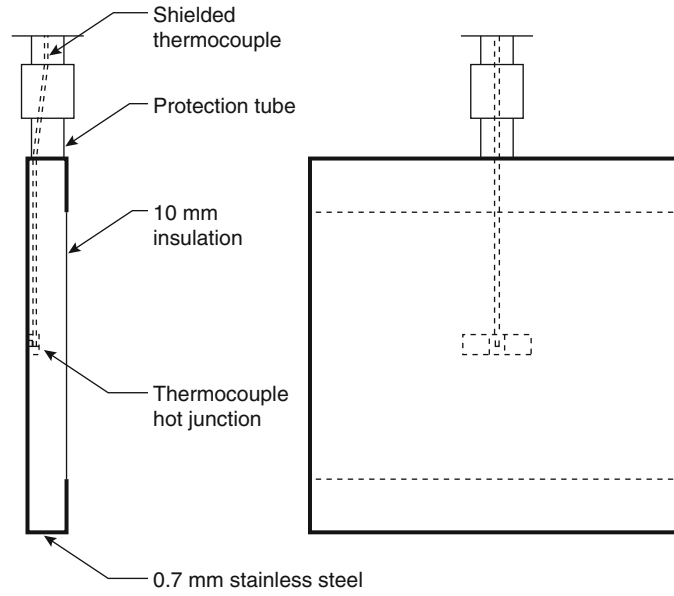

Fig. 34.3 The plate thermometer according to ISO 834 and EN 1363-1 is made of a shielded thermocouple welded to the center of a 0.7-mm-thick Inconel plate, which is insulated on its back side. The exposed front face is 100 mm by 100 mm

Fig. 34.4 Plate thermometers being mounted around a steel girder for measuring local thermal exposures. Note that the plate thermometers are mounted so that the front sides of the steel plates are exposed to roughly the same incident radiation as the girder and the back sides are insulated

being mounted at a steel girder with the insulated back side facing the specimen. The front side of the plate thermometer is exposed to approximately the same heating, including radiation conditions, as the specimen. The exposed surface of the plate thermometer is relatively large and, therefore, its sensitivity to convective heat transfer is about the same as that of the specimen surface. The steel plate is thin, only 0.7 mm, and thus responds quickly to temperature changes. As a matter of fact the plate thermometer in a standard fire resistance test measures approximately the temperature of an adiabatic surface (i.e., the temperature of an ideally perfect insulator exposed to the same heating conditions as the specimen surface, as discussed earlier).

The plate thermometer was introduced mainly to harmonize fire endurance tests (see Wickström and Hermodsson [5]), but the measured temperatures are also well suited as input for calculating heat transfer by radiation and convection to fire-exposed surfaces.

As any surface, the plate thermometer surface exchanges heat by radiation and convection. The sum of these equals the transient heat for raising the temperature of the Inconel plate and the backing insulation. Because the plate is thin and does not lose much heat on its back side, this sum is small and can be neglected except for the very first few minutes of a standard test. Thus, the heat balance of the plate can be written as

$$\varepsilon_{\mathrm{PT}}\left(\dot{q}''_{\mathrm{inc}} - \sigma T_{\mathrm{PT}}^4\right) + h_{\mathrm{PT}}\left(T_g - T_{\mathrm{PT}}\right) = 0 \tag{34.16}$$

or

$$\varepsilon_{\mathrm{PT}}\sigma\left(T_r^4 - T_{\mathrm{PT}}^4\right) + h_{\mathrm{PT}}\left(T_g - T_{\mathrm{PT}}\right) = 0 \tag{34.17}$$

The index PT refers to plate thermometer. This means the plate thermometer yields the adiabatic temperature of the specimen for a given surface emissivity and a given convective heat transfer coefficient.

An approximate alternative expression of the net heat transfer $\dot{q}''_{\text{tot}}$ to a specimen surface can now be obtained in terms of one effective temperature only by deducting Equation 34.17 from Equation 34.10:

$$\dot{q}''_{\text{tot}} = \varepsilon_s \sigma \left(T_{\text{PT}}^4 - T_{\text{s}}^4\right) + h(T_{\text{PT}} - T_{\text{s}}) \quad (34.18)$$

In other words the adiabatic surface temperature is approximated by the plate thermometer temperature. This rewriting of Equation 34.10 facilitates the calculations in many cases. The error $\Delta\dot{q}''$ introduced can be quantified by a simple algebraic analysis as

$$\begin{aligned}\Delta\dot{q}'' = {} & (\varepsilon_s - \varepsilon_{\text{PT}})\sigma\left(T_r^4 - T_{\text{PT}}^4\right) \\ & + (h_s - h_{\text{PT}})\left(T_g - T_{\text{PT}}\right)\end{aligned} \quad (34.19)$$

Thus, the error is small when the surface emissivity of the plate thermometer and the specimen are nearly the same and when the convective heat transfer coefficients are nearly the same. Therefore, the surfaces of the plate thermometers are blasted and heat-treated before being used to get an emissivity of about 0.8. It also has a relatively large surface, 100 mm by 100 mm, to obtain a convection heat transfer coefficient similar to a specimen. Because T_{PT} always has a value between T_r and T_g, the error vanishes when these two temperatures are close.

Modeling of Heat Conduction in Materials

Heat Conduction in Solid Materials

Heat or energy is conducted in solid materials due to temperature gradients. In one dimension in the x-direction the rate of heat transfer or heat flux is expressed according to Fourier's law as

$$\dot{q}''_x = -k\frac{\partial T}{\partial x} \quad (34.20)$$

where k is the thermal conductivity.

In fire problems the most usual objective is to determine the temperature distribution in a structure resulting from conditions imposed on its boundaries. Because these conditions vary with time, the temperature field will be transient or unsteady. It is then governed by the *heat diffusion equation*, which in one dimension is expressed as

$$\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) = \rho c\frac{\partial T}{\partial t} \quad (34.21)$$

where ρ is density, c is specific heat of the material.

If the conductivity k is constant, Equation 34.21 may be written as

$$\frac{\partial T^2}{\partial^2 x} = \frac{1}{\alpha}\frac{\partial T}{\partial t} \quad (34.22)$$

where α is the thermal diffusivity defined as $\alpha = k/\rho c$.

At the boundaries Fourier's law applies and may be expressed as

$$\dot{q}''_x(0) = -k\left.\frac{\partial T}{\partial x}\right|_{x=0} \quad (34.23)$$

Three types of boundary conditions may occur.

1. Given surface temperature: $T(0,t) = T_s$
2. Given surface heat flux: $-k\frac{\partial T}{\partial x}\big|_{x=0} = \dot{q}''_s$
3. Given convection and radiation conditions, for example: $-k\frac{\partial T}{\partial x}\big|_{x=0} = h\left(T_f - T_s\right) + \varepsilon\sigma\left(T_f^4 - T_s^4\right)$

All the specified boundary conditions, T_s, q_s, and T_f, may vary with time. A special type of heat flux boundary condition is the adiabatic or perfectly insulated surface where q_s is equal to zero.

The heat diffusion equation can be solved analytically only in some uncomplicated cases (see Chap. 2, "Conduction of Heat in Solids," of this book). Numerical methods are usually needed as boundary conditions in general are nonlinear and material properties vary with temperature. There are mainly two types of numerical methods, finite difference and finite element methods, depending on how the geometry is approximated and how the temperature field is

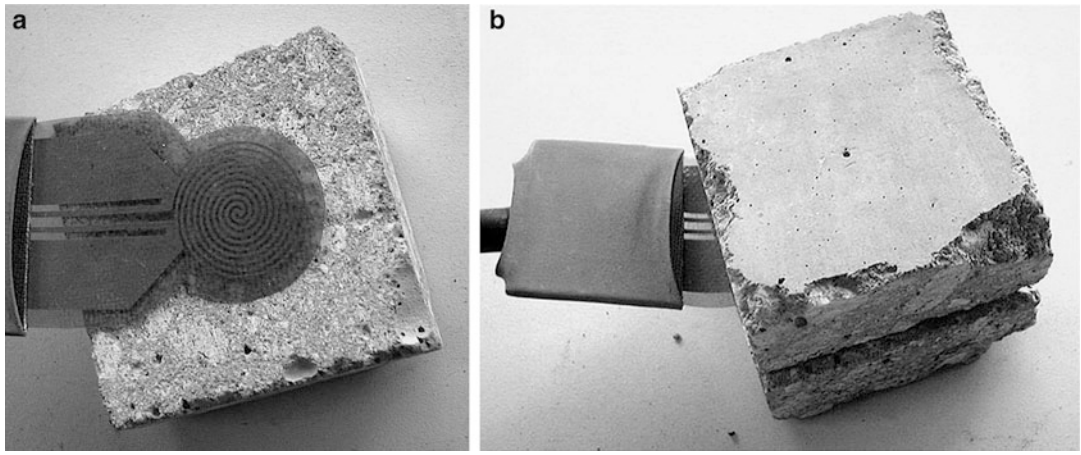

Fig. 34.5 The TPS sensor placed between two pieces of a concrete specimen

expressed by a limited number of discrete temperatures. The finite element method is described briefly later for the one-dimensional case.

Measurement of Thermal Properties

There are a number of techniques to measure thermal properties, each of them suitable for a limited range of materials, depending on thermal properties and temperature level (e.g., see Flynn [6]). However, only a few of the measuring techniques can be used at high temperature levels relevant for fire conditions. They can be divided into steady-state and transient techniques.

The steady-state techniques perform the measurements when the material is in complete equilibrium. Disadvantages of these techniques are that it generally takes a long time to reach the required equilibrium and that at low temperature the measurements are influenced by moisture migration. For moist materials like concrete, it is therefore often preferable to determine the apparent conductivity or thermal diffusivity with transient techniques. These techniques perform the measurements during a process of small temperature changes and can be made relatively quickly.

The guarded hot plate is the most common steady-state method for building materials with a relatively low thermal conductivity [7]. It is quite reliable at moderate temperatures up to about 400 °C.

Because transient thermal processes dominate in fire safety engineering, the thermal diffusivity, a measure of the speed at which temperature is propagating into a material, is the most interesting parameter. It is naturally best measured with transient methods. One of the most interesting techniques is the transient plane source method (TPS). In this method a membrane, TPS sensor, is located between two specimen halves and acts as a heater as well as a temperature detector (Fig. 34.5). By using this technique, thermal diffusivity, thermal conductivity, and volumetric specific heat can be obtained simultaneously for a variety of materials like metals, concrete, mineral wool, and even liquids and films [8].

Finite Element Calculations of Temperature in Fire-Exposed Structures

When calculating temperature in fire-exposed structures nonlinearities must in most cases be considered. The boundary conditions are nonlinear varying dramatically with temperature as shown above, and also the thermal properties of most materials vary significantly within the wide temperature span that must be considered in fire safety engineering problems. Therefore, numerical methods must be employed. The most general

and powerful codes today are based on the so-called finite element method (FEM).

Basic Equations Derived for One-Dimensional Case

The basic equations that follow are derived for a simple one-dimensional case as an illustration. The same type of equation may be derived for two and three dimensions.

Figure 34.6 shows a wall that has been divided into a number of one-dimensional elements. The temperature between the nodes is assumed to vary linearly along the length.

In any element, interior or at the surface, with length L, conductivity k, and a section area A (Fig. 34.7), the heat flow at the nodes can then be calculated as

$$q_1 = -kA/L^*(T_1 - T_2)$$

and

$$q_2 = -kA/L^*(-T_1 + T_2)$$

or in matrix format as

$$\overline{q}^e = \overline{k}^e \overline{T}^e \tag{34.24}$$

where $\overline{q}^e$ is the element node heat flow vector, $\overline{k}^e$ is the element heat conduction matrix, and $\overline{T}^e$ is the element node temperature vector. The element heat conduction matrix may then be identified as

$$\overline{k}^e = \begin{Bmatrix} k^e_{1,1} & k^e_{1,2} \\ k^e_{2,1} & k^e_{2,2} \end{Bmatrix} = (kA/L)\begin{Bmatrix} 1 & -1 \\ -1 & 1 \end{Bmatrix} \tag{34.25}$$

and the element nodal temperature and heat flow vectors as $\overline{T}^e = \begin{Bmatrix} T_1 \\ T_2 \end{Bmatrix}$ and $\overline{Q}^e = \begin{Bmatrix} Q_1 \\ Q_2 \end{Bmatrix}$ respectively.

In a similar way an element heat capacity matrix can be defined by lumping the heat capacity of the element in the nodes. Thus, an element heat capacity matrix may be obtained as

$$\overline{c}^e = \frac{ALcp}{2}\begin{Bmatrix} 1 & 0 \\ 0 & 1 \end{Bmatrix} \tag{34.26}$$

When several elements are combined, the global thermal conductivity matrix $\overline{K}$ can be assembled. In the very simple case of three one-dimensional elements the global heat conduction matrix becomes

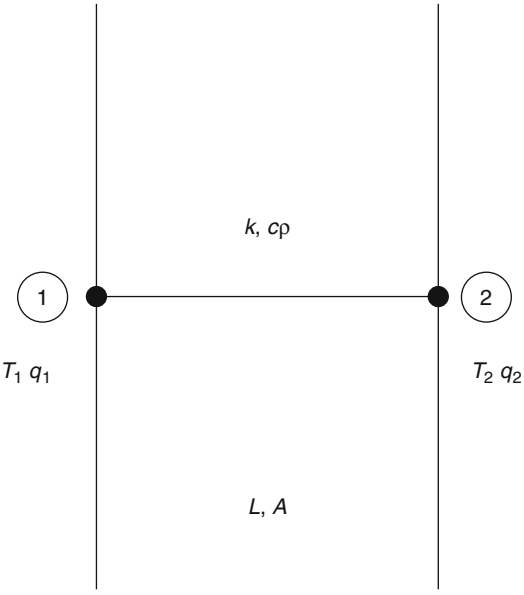

Fig. 34.7 A one-dimensional element with local element node numbers *1* and *2*, length L, and a section area A. The element is given a thermal conductivity k, a specific heat capacity c, and a density ρ

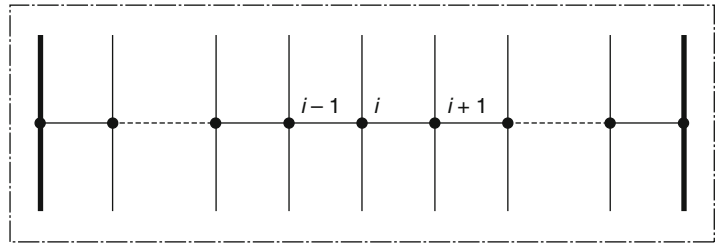

Fig. 34.6 A wall divided into one-dimensional elements

$$\overline{K} = \begin{Bmatrix} k^1_{1,1} & k^1_{1,2} & 0 & 0 \\ k^1_{2,1} & \left(k^1_{2,2} + k^2_{1,1}\right) & k^2_{1,2} & 0 \\ 0 & k^2_{2,1} & \left(k^2_{2,2} + k^3_{1,1}\right) & k^3_{1,2} \\ 0 & 0 & k^3_{2,1} & k^3_{2,2} \end{Bmatrix} \tag{34.27}$$

where the superscripts 1–3 denote element numbers. The global heat capacity matrix $\overline{C}$ may be assembled in a similar way as the global conductivity matrix. Notice that both the thermal conductivity and the heat capacity matrices are symmetric and dominated by their diagonal elements, and that the global heat capacity matrix assembled from element matrices according to Equation 34.26 will have nonzero elements only in the diagonal. This will have a decisive influence on how the global algebraic heat balance equation can be solved as shown below.

In global form the heat balance equation may now be written as

$$\overline{C}\,\dot{\overline{T}} + \overline{K}\,\overline{T} = \overline{Q} \tag{34.28}$$

where $\dot{\overline{T}}$ is the time derivative of the node temperatures. Each row in this equation system represents the heat balance of a node. For each equation or each node either the temperature or the heat flow given in the corresponding rows in the vectors $\overline{T}$ and $\overline{Q}$, respectively, is known. In principle three options are possible for each equation/row:

1. The node temperature T_i is prescribed.
2. The node heat flow Q_i is prescribed.
3. The node heat flow Q_i can be calculated as a function of a given gas temperature and the surface temperature.

In the first case the corresponding equation vanishes as the unknown quantity is prescribed. The most common case for internal nodes is the second case (i.e., the external flow is zero).

A typical boundary condition when calculating temperature in fire-exposed structures is according to the third option. Based on, for example, Equation 34.11, the external heat flow to the ith node becomes

$$Q_i = A_i\left\{\varepsilon\sigma\left(T_f^4 - T_i^4\right) + h\left(T_f - T_i\right)\right\} \tag{34.29}$$

where A_i is the section area of the ith node. The differential equation given in Equation 34.28 can be solved numerically by approximating the time derivative as

$$\dot{\overline{T}} = \frac{\left(\overline{T}^{j+1} - \overline{T}^{j}\right)}{\Delta t} \tag{34.30}$$

where $\overline{T}^{j}$ is the node temperature vector at time step j and Δt is a chosen time increment. Now the heat balance equation in matrix format (Equation 34.28) can be written as

$$\overline{C}\left(\overline{T}^{j+1} - \overline{T}^{j}\right)/\Delta t + \overline{K}\,\overline{T} = \overline{Q} \tag{34.31}$$

In this differential equation the temperature vector is known at time increment j. The new temperature vector at time $j + 1$ is obtained either explicitly based on the conditions at time step j as

$$\overline{T}^{j+1} = \overline{C}^{-1}\left(\overline{Q}^{j} - \overline{K}\,\overline{T}^{j}\right)\Delta t + \overline{T}^{j} \tag{34.32}$$

or implicitly as

$$\overline{T}^{j+1} = \left(\overline{C}/\Delta t + \overline{K}\right)^{-1}\left(\overline{Q}^{j} + \overline{C}\,\overline{T}^{j}/\Delta t\right) \tag{34.33}$$

Combinations of the solution schemes according to Equations 34.32 and 34.33 are also possible. All such schemes require the solution of an equation system containing as many unknowns as there are unknown node temperatures. Most finite element computer codes use such types of implicit solution schemes. They are numerically more stable than the explicit techniques (i.e., longer time increments may be used).

The explicit solution according to Equation 34.32 may be very simple when the heat capacity matrix $\overline{C}$ is diagonal (i.e., it contains only nonzero elements in the diagonal as shown for a one-dimensional element in Equation 34.26). The solution of the equation system

then becomes trivial because each nodal temperature can be obtained directly/explicitly one at a time. This solution scheme is numerically stable only when the time increment Δt is less than a critical value proportional to the heat capacity over the thermal conductivity of the material times the square of an element length dimension Δx (see Equation 34.34). This requirement applies to all the equations of the entire system. If violated in any of the equations (i.e., at any point of the finite element model), the incremental solution equation will turn unstable.

$$\Delta t_{cr} \approx \frac{c\,p}{k}(\Delta x)^2 \qquad (34.34)$$

A similar condition applies to boundaries of type 3 (e.g., according to Equation 34.29).

This means that short time increments are needed for materials with a low density and a high conductivity and when small elements are used. For information on critical time increments, see Sterner and Wickström [9].

In practice, when calculating temperature in fire-exposed structures, numerical stability is only a problem when modeling sections of thin metal sheets with high thermal conductivity. Then according to Equation 34.34, very short time increments are required. The problem may, however, be avoided by prescribing that nodes close to each other shall have the same temperature. This technique has been applied in the code TASEF [9]. In this code a technique is also developed in which the critical time increment is estimated and thereby acceptable time increments can be calculated automatically at each time step.

Available Computer Codes for Temperature Calculations

Several computer codes are commercially available for calculating temperature in fire-exposed structures. In general modern codes are based on the finite element method. Some are specifically developed and optimized for calculating temperature in fire-exposed structures whereas others are more general-purpose codes.

TASEF [10, 11] and SAFIR [12] are examples of programs that have been developed for fire safety problems. They both for temperature-dependent material properties and boundary conditions. TASEF employs a forward difference solving technique, which makes it particularly suitable for problems in which latent heat due to, for example, evaporation of water must be considered. It yields in most cases very short computing times, in particular for problems with a large number of nodes. Both TASEF and SAFIR have provisions for modeling heat transfer by convection and radiation in internal voids. TASEF can be obtained from TASEF Ltd., UK and SAFIR from the University of Liège, Belgium.

There are many very advanced general-purpose finite element computer codes commercially available such as ABAQUS [13], ANSYS [14], ADINA [15], HEATING [See www.oecd-nea.org/tools/abstract/detail/psr-0199/] and Comsol [16]. The main advantage of using such codes is that they can be used in combination with structural codes and that they come with advanced graphical user interfaces and postprocessors.

Accuracy of Finite Element Computer Codes

At the least the following three steps must be considered when estimating the accuracy of computer codes for numerical temperature calculations:

1. Validity of calculation model
2. Accuracy of material properties
3. Accuracy and reliability of the numerical algorithms of the computer code

The first point is, of course, important. For example, the effects of spalling or water migration cannot be accurately predicted with a code based on just heat transfer according to the Fourier heat transfer equation.

The second point is also crucial. Errors in material property input will be transmitted into output errors. Methods for measuring material properties at high temperature were briefly discussed earlier.

Finally, the numerical verification of the computer code itself is also important. By definition, *verification* is the process of determining that a model implementation accurately represents the developer's conceptual description of the model and the solution to the model [17]. If correctly used, most codes yield results with acceptable accuracy. A scheme to follow including a number of reference cases of various levels of complexity have recently been presented in an SFPE standard [Standard on calculation methods to predict the thermal performance of structural and fire resistive assemblies, please ask Chris Jelenewicz for advice on the status of the standard] partly based on cases earlier suggested by Wickström and Pålsson [18] and Wickström [19]. It is mainly developed for finite element codes but it may also be used for codes based on finite difference principles. The first reference example is a linear problem that can be solved analytically. When increasing the number of elements the results should converge to one correct value. Codes yielding results that converge smoothly when increasing the number of elements are generally deemed reliable for the type of problems considered. The scheme suggested employs problems that are relevant for fire safety engineering, including effects of conductivity varying with temperature, latent heat, radiant heat transfer boundary conditions, and combinations of materials, concrete, steel, and mineral wool. For the development of the SFPE standard the computer codes ABAQUS and TASEF were used to obtain solutions which were deemed reliable as these codes use different solutions algorithms.

Calculation of Temperature in Steel Structures

Metals in general conduct heat very well. The thermal conductivity of steel is on the order of 30 times higher than the corresponding value for concrete and 100–1000 times higher than that of insulation products. Therefore, the temperature field in a steel section may in many fire engineering cases be assumed uniform. In particular the temperature across the thickness of a steel sheet will be uniform, whereas the temperature in the plane of the sheet may vary considerably, depending on boundary conditions. The methods presented in Chap. 53, "Analytical Methods for Determining Fire Resistance of Steel Members," assume uniform steel section temperatures. Then zero- or one-dimensional calculation techniques may often be used. For more general two- and three-dimensional cases, numerical computer codes are needed.

Thermal Properties of Steel

The thermal conductivity of carbon steel as a function of steel temperature according to Eurocode 3 [20], is shown in Fig. 34.8. It can also be obtained from Table 34.1.

The specific heat capacity is in most cases more important than the conductivity. In many cases it is accurate enough and convenient to assume a constant specific heat capacity. However, for more accurate calculations the variations with temperature as shown in Fig. 34.9 [20] or given in Table 34.2 are recommended in Eurocode 3 [20]. This specific heat capacity varying with temperature yields in general lower calculated temperatures than when a constant value of 500 J/(kg K) is assumed.

Insulated Steel Structures

In particular in the case of *insulated steel sections* the steel temperature over a section may be assumed uniform. Then the surface heat transfer resistance $1/h_{tot}$ is in most cases negligible in comparison with the heat resistance (i.e., the thickness over the conductivity of the insulation d_i/k_i). h_{tot} is the combined heat transfer coefficient due to radiation and convection as given in Equation 34.13. The fire-exposed surface temperature is then approximately the same as the

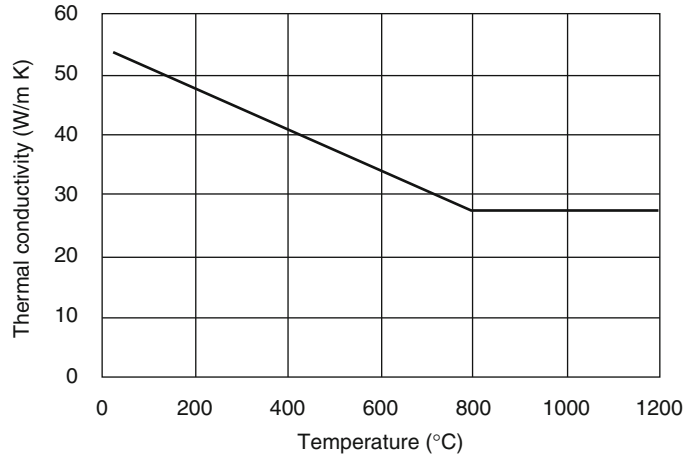

Fig. 34.8 Thermal conductivity of steel as a function of the temperature

Table 34.1 Thermal conductivity of carbon steel as a function of the temperature [20]

Temperature (°C)	Conductivity (W/m K)
$20 < T_{st} < 800$	$54 - 3.33 \times 10^{-2}\, T_{st}$
$800 < T_{st} < 1200$	27.3

fire temperature, and the heat transfer to the steel may under steady-state conditions be approximated as

$$q_{\text{tot}} = A_s(k_i/di)\left(T_f - T_s\right) \tag{34.35}$$

where A_s is the fire-exposed area, and T_f and T_s are the fire and steel temperatures, respectively. If the heat capacity of the insulation is negligible in comparison to that of the steel, transient steel temperature can be obtained from the heat balance equation

$$As(k_i/di)\left(T_f - T_s\right) = c_s\rho_s V_s(\partial T_s/\partial t) \tag{34.36}$$

where c_s and ρ_s are the specific heat capacity and density, respectively, of steel and V_s is the volume per unit length of the considered steel section. In case of heavy insulations when the heat capacity of the insulation cannot be neglected, see the following section on heavily insulated steel structures.

A very simple solution can be obtained if a constant fire temperature rise and constant material properties are assumed; that is,

$$(T_s - T_0) = \left(T_f - T_0\right)\left[1 - \mathrm{e}^{-(t/\tau)}\right] \tag{34.37}$$

where the characteristic response time or time constant τ of the section is identified as

$$\tau = c_s\rho_s V_s/A_s(k_i/d_i) = (d_i/k_i)(c_s\rho_s)/(A_s/V_s) \tag{34.38}$$

The relation A_s/V_s is denoted the section factor or the shape factor that has the dimension one over length. Instructions on how to obtain this factor for various configurations are given in Table 34.3.

For a fire temperature T_f arbitrarily varying with time or when the material properties vary with temperature, the steel temperature may be obtained (e.g., from the numerical scheme derived from Equation 34.36) as

$$\Delta T_s/\Delta t = \left(T_f^i - T_s^i\right)/\tau \tag{34.39}$$

where ΔT_s equals $\left(T_s^{i+1} - T_s^i\right)$ and Δt are the steel temperature rise and the time increment, respectively. The superscripts i and $i + 1$ denote the numerical order of the time increments. When the thermal properties vary with temperature, the time constant τ as defined by Equation 34.38 needs to be updated at each time increment. A forward difference solution scheme can be obtained as

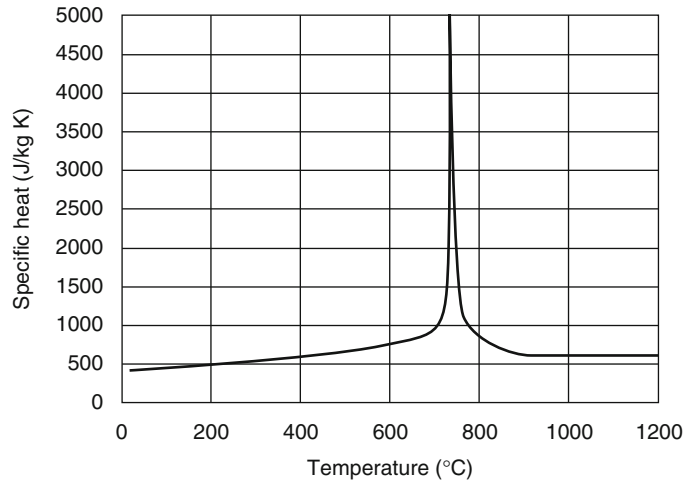

Fig. 34.9 Specific heat of steel as a function of the temperature [20]

Table 34.2 Specific heat capacity of carbon steel as a function of the temperature [21]

Temperature (°C)	Specific heat capacity (J/[kg K])
$20 < T_{st} < 600$	$425 + 7.73 \times 10^{-1}\, T_{st} - 1.69 \times 10^{-3}\, T_{st}^2 + 2.22 \times 10^{-6}\, T_{st}^3$
$600 < T_{st} < 735$	$666 + 13{,}002/(738 - T_{st})$
$735 < T_{st} < 900$	$545 + 17{,}820/(T_{st} - 731)$
$900 < T_{st} < 1200$	650

$$T_s^{i+1} = \Delta t/\tau \cdot T_f^i + (1 - \Delta t/\tau) \cdot T_s^i \qquad (34.40)$$

This forward difference scheme is, however, numerically stable only if

$$\Delta t \leq \tau = (d_i/k_i)(c_s\rho_s)/(A_s/V_s) \qquad (34.41)$$

This condition must be fulfilled at each time increment. In practice time increments Δt longer than 10 % of that critical value should not be used to ensure accurate results.

Heavily Insulated Steel Structures

The heat capacity of the insulation normally has an insignificant influence on the steel temperature rise rate. However, it will considerably reduce the steel temperature rise of sections protected with relatively heavy insulation. A simple approximative approach is then to lump a third of the heat capacity of the insulation to the steel [22–24]. Equation 34.39 may then be modified as

$$\Delta T_s/\Delta t = \left(T_f^i - T_s^i\right)/[\tau(1 + \mu/3)] + [exp(\mu/10) - 1]\Delta T_f/\Delta t \qquad (34.42)$$

where μ is the relation between the heat capacity of the insulation and the steel,

$$\mu = (A_i d_i \rho_i c_i)/(V_s \rho_s c_s) \qquad (34.43)$$

and where ρ_i and c_i are the density and the specific heat capacity of the insulation, respectively. When the material properties vary with temperature, they may be updated at each time increment. The latter term of Equation 34.42 represents a time delay due to the heat capacity of the insulation. ΔT_f is the fire temperature rise between two time increments. Notice that when the heat capacity of the insulation is much smaller than that of the steel, μ vanishes and Equation 34.42 becomes identical to Equation 34.39.

Table 34.3 Section factor A_s/V_s for steel members insulated by fire protection material [20]

Sketch	Description	Section factor (A_s/V_s)
	Contour encasement of uniform thickness	Steel perimeter / Steel cross-sectional area
	Hollow encasement of uniform thickness[a]	$2(b + h)$ / Steel cross-sectional area
	Contour encasement of uniform thickness, exposed to fire on three sides	Steel perimeter – b / Steel cross-sectional area
	Hollow encasement of uniform thickness, exposed to fire on three sides[a]	$2h + b$ / Steel cross-sectional area

[a]The clearance dimensions c_1 and c_2 should not normally exceed $h/4$

Equation 34.42 has been adopted by Eurocode 3 [20]. The steel temperature can then be obtained, for example, by a forward difference scheme derived from Equation 34.42 as

$$T_s^{i+1} = T_s^i + \Delta t\left(T_f^i - T_s^i\right)/[\tau(1+\mu/3)] - [exp(\mu/10) - 1]\Delta T_f \tag{34.44}$$

As an illustration of the importance of considering the heat capacity of the insulation, a simple example of a steel section is analyzed considering the relative heat capacity μ of the insulation and for comparison neglecting it (i.e., $\mu = 0$). A section factor $A_i/V_s \approx A_s/V_s = 500\ \mathrm{m}^{-1}$ and an insulation thickness $d_i = 0.05$ m, a conductivity $k_i = 0.2$ W/m K, and a specific heat capacity $c_i = 800$ Ws/kg are assumed. Calculated steel temperature developments applying Equation 34.44 considering and not considering the heat capacity of the insulation ($\mu = 0$) are shown in Fig. 34.10. For comparison, temperature rises obtained by accurate finite element calculations are shown as well. Notice how well the temperatures calculated by FEM match the temperatures obtained using the scheme according to Equation 34.44 considering the heat capacity of the insulation. On the other hand, the calculated temperature becomes much higher if the heat capacity of the insulation is not considered. In this case the predicted time to reach a steel temperature of 500 °C is on the

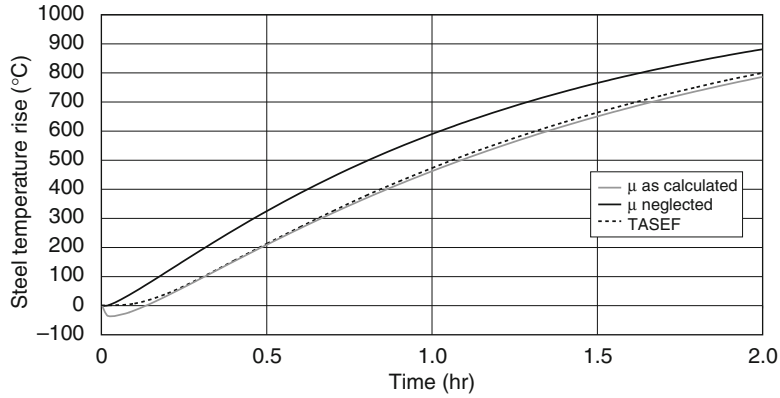

Fig. 34.10 Comparison of calculated steel temperature rise of an insulated steel section when exposed to a standard ISO 834 fire exposure, considering and neglecting the heat capacity of the insulation, respectively

order of a quarter of an hour shorter when the heat capacity is not considered. Notice also that Equation 34.44 predicts a negative temperature change for the first 5–10 min, which of course is a numerical error embedded in the equation.

Insulated Steel Structures Exposed to Parametric Fires

Eurocode 3 [20] (EN1991-2-1) has introduced the concept of parametric fires as a convenient way of expressing a set of postflashover design fires. The fire temperature T_f is then expressed as (see Eurocode 1 [4])

$$T_f = 20 + 1325\left(1 - 0.324e^{-0.2t^*} - 0.204\mathrm{e}^{-1.7t^*} - 0.472\mathrm{e}^{-19t^*}\right) \quad (34.45)$$

where the modified or scaled time is expressed as

$$t^* = \Gamma t \quad (34.46)$$

and where Γ is a function of the compartment properties (i.e., sizes of openings and thermal properties of enclosure surfaces). A Γ-value approximately equal to unity yields the ISO 834 standard fire, whereas Γ less than unity yields a more slowly growing fire and Γ greater than unity a faster growing fire. The fire duration depends on the fuel density in the fire compartment (see Eurocode 3 [20]). Below it is demonstrated how these types of design fires can facilitate the calculation and the presentation of temperature in fire-exposed insulated steel sections. The concept of parametric fires can also be used for concrete structures using the technique outlined later in this chapter.

Table 34.4 Constants in the analytical expression of the parametric fire curve

i	0	1	2	3
B_i (°C)	1325	−430	−270	−625
β_i (h^{-1})	0	−0.2	−1.7	−19

When using parametric design fires, the temperature of insulated steel sections can, of course, be obtained by numerical calculations according to Equation 34.40. Then nonlinear phenomena such as temperature-dependent material properties may be considered. However, if the thermal properties are assumed constant and the fire temperature is expressed by exponential terms as in Equation 34.45, then the steel temperature rise as a function of time can be obtained by integration as a closed-form analytic expression [25].

For convenience Equation 34.45 is first written in the form

$$T_s = 20 + \sum_{i=0}^{3} B_i \exp(-\beta_i t^*) \quad (34.47)$$

where the constants B_i and β_i are given in Table 34.4.

Then the steel temperature can be obtained as a function of the modified fire duration t^* and the modified time constant τ^* of the steel section as

$$T_s - 20 = \sum_{i=0}^{3} \frac{B_i}{1 - \beta_i \tau^*}\left[exp(-\beta_i t^*) - exp(-t^*/\tau^*)\right] \quad (34.48)$$

where

$$\tau^* = \Gamma\tau \tag{34.49}$$

The insulated steel section time constant τ is given in Equation 34.38. The relation between the temperature rise as a function of modified time as expressed in Equation 34.48 is also given in the diagram shown in Fig. 34.11 for various modified time constants τ^*. The diagram in Fig. 34.11 is particularly easy to use for ISO 834 standard fire exposures when Γ by definition is equal to unity.

As an example, consider a steel section with a section factor $A_{st}/V_{st} = 200\ \mathrm{m}^{-1}$ insulated with a 25-mm-thick protection board with a constant thermal conductivity of 0.1 W/(m K). The steel density and specific heat capacity are 7800 kg/m^3 and 500 J/(kg K), respectively. The section time constant may then be obtained from Equation 34.38 as $\tau = 4875$ s or 1.35 h. Then if the section is exposed to standard fire ($\Gamma = 1$), a temperature rise of 418 °C may be obtained from Equation 34.48 or from Fig. 34.11. If the same section is exposed to a more slowly growing fire with $\Gamma = 0.5$, then $\tau^* = \Gamma\tau = 0.68$ h and the temperature rise after 1 h may be found for a modified time of $t^* = \Gamma t = 0.5$ h to be 363 °C. On the other hand, if the section is exposed to a fast-growing fire with $\Gamma = 3.0$, then $\tau^* = (3.0) \cdot (1.35) = 4.05$ h and $t^* = (3.0) \cdot (1.0) = 3.0$ h, and the steel temperature rise can be obtained from Equation 34.47 or from Fig. 34.11 as 505 °C. Notice that the maximum steel temperature for a given fire exposure time increases considerably with an increasing Γ-factor. It must, however, also be kept in mind that the fire duration for a given fuel load is proportional to the inverse of the opening factor included in the Γ-factor. For more information see, for example, Eurocode 1 [4].

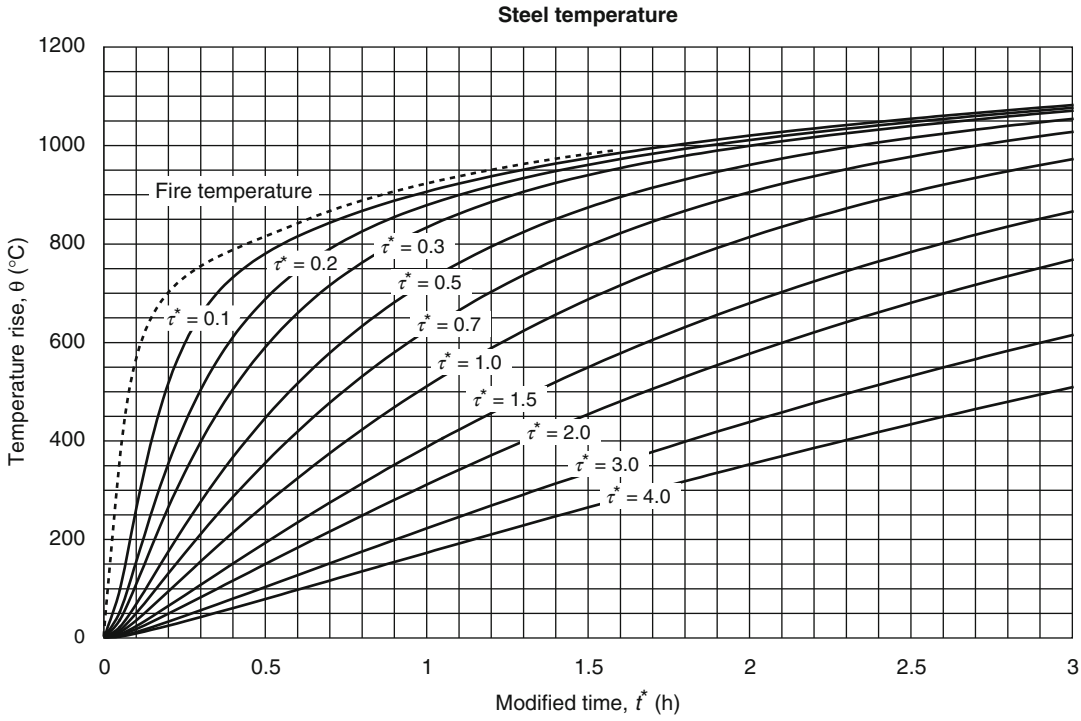

Fig. 34.11 Temperature of various insulated steel sections exposed to parametric fires in the heating phase as a function of modified time t^*. The thermal properties of the steel sections are expressed in modified time constants τ^* [25]

Unprotected Steel Structures

The temperature of unprotected steel structures is numerically more difficult to calculate as the highly nonlinear heat transfer is decisive for the temperature development of the steel. The total heat transfer q_{tot} may be obtained from Equation 34.11 or Equation 34.12. Then the steel temperature can be obtained from the differential heat balance equation in a similar way as for insulated steel sections (see also Equation 34.36).

$$h_{tot}\left(T_f - T_s\right) = c_s\rho_s(V_s/A_s)(\partial T_s/\partial t) \quad (34.50)$$

where the total heat transfer coefficient h_{tot} may be obtained from Equation 34.13. This equation can be solved numerically with a forward difference scheme in a similar way as for insulated sections as

$$T_s^{i+1} = (\Delta t/\tau)T_f^i + (1 - \Delta t/\tau)T_s^i \quad (34.51)$$

where the characteristic response time τ of the steel section in this case is defined as

$$\tau = c_s\rho_s V_s/A_s h_{tot} = (c_s\rho_s)/[h_{tot}(A_s/V_s)] \quad (34.52)$$

Notice that the thermal properties of the steel may vary with temperature, and in particular the total heat transfer coefficient h_{tot} will increase substantially with the temperature level. It would, therefore, be misleading to call τ a time constant in this case.

The stability criterion for the explicit numerical scheme according to Equation 34.51 may then be expressed as

$$\Delta t \leq \tau = (c_s\rho_s)/[h_{tot}(A_s/V_s)] \quad (34.53)$$

Thus, the critical time increment decreases considerably as h_{tot} increases with time and increasing temperature levels.

Principles for calculating the section factors for various types of configurations of unprotected steel can be found in Table 34.5 [20].

Shadow Effects

When an open section such as an I-section is exposed to fire, the heat transfer by radiation will be partly shadowed (Fig. 34.12). That means the section will only receive as much heat from the fire as if it had the same circumference as a boxed section. Therefore, it is appropriate to replace the area per unit length A_s with the so-called boxed area $A_\square$ in Equations 34.50 and 34.52 as the radiation heat transfer mode dominates at elevated temperature. The boxed area $A_\square$ is typically for an I-section 30 % less than the corresponding area A_s, which means a proportional increase of the section response time τ. Alternatively, a section with a 40 % higher section factor would yield the same temperature if the concept of shadow effects is applied. This means that by considering the shadow effects in the calculations many more open steel sections can be accepted without thermal protection.

The principal of shadow effects is particularly important for bare, unprotected steel sections, although the concept can be applied to other types of structures as well.

Example of Steel Temperatures Calculated Using Finite Element Codes

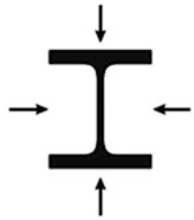
The preceding steel temperature calculations assume uniform steel temperatures in the section analyzed as a crude approximation. It leads indeed in general to solutions on the safe side (i.e., the temperatures are overestimated and often overdesigned, leading to unnecessary costs). For more precise analyses numerical calculations are needed employing, for example, finite element computer codes. An example is given below.

An encased I-section beam is carrying a concrete slab. It is exposed to standard fire conditions according ISO 834 (Fig. 34.13). Heat transfer conditions according to Equation 34.11 are assumed with $\varepsilon = 0.8$ and $h = 25$ W/m^2 K. The thermal properties of steel and concrete are

Table 34.5 Section factor A_s/V_s for unprotected steel members [20]

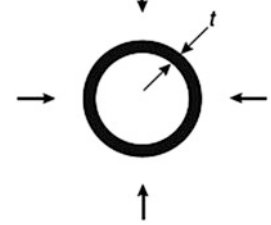
Open section exposed to fire on all sides:

$$\frac{A_s}{V_s} = \frac{\text{Perimeter}}{\text{Cross-sectional area}}$$



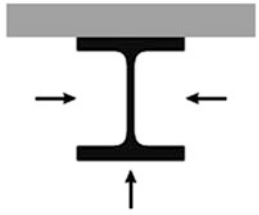
Tube exposed to fire on all sides:

$$A_s/V_s = 1/t$$



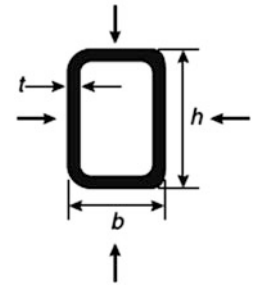
Open section exposed to fire on three sides:

$$\frac{A_s}{V_s} = \frac{\text{Surface exposed to fire}}{\text{Cross-sectional area}}$$



Hollow section (or welded box section of uniform thickness) exposed to fire on all sides:

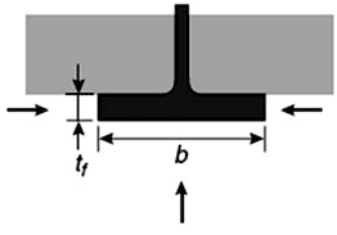
If $t \ll b$: $A_s/V_s \approx 1/t$



I-section flange exposed to fire on three sides:

$$A_m/V = (b + 2t_f)/(bt_f)$$

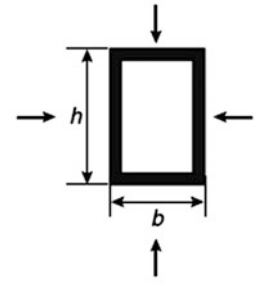
If $t \ll b$: $A_s/V_s \approx 1/t_f$



Welded box section exposed to fire on all sides:

$$\frac{A_s}{V_s} = \frac{2(b+h)}{\text{Cross-sectional area}}$$

If $t \ll b$: $A_m/V \approx 1/t$



(continued)

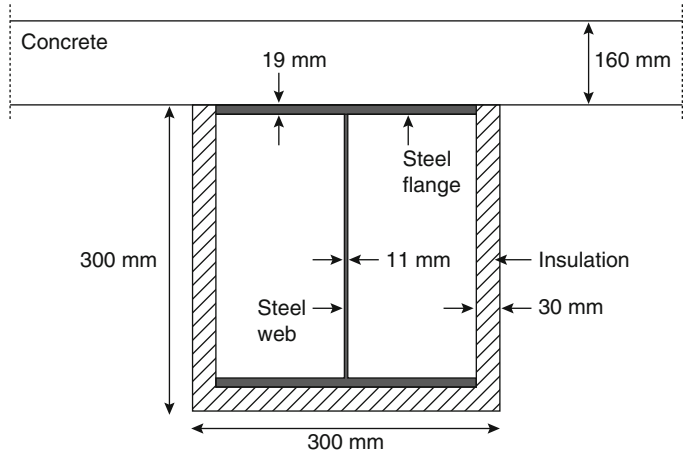

Fig. 34.13 Encased I-section steel (HE 300B) beam carrying a concrete slab. Slab thickness 160 mm, insulation thickness 30 mm, steel height and width 300 mm, flange thickness 19 mm, and web thickness 11 mm

as given in Eurocodes 2 and 3, respectively, shown above and below. The encasement boards are assumed to have a thermal conductivity (k) of 0.2 W/m K and a volumetric specific heat capacity ($c\rho$) of 40 kJ/m^3. The finite element discretization model is shown in Fig. 34.14. Heat transfer inside the void is assumed to be by radiation only with an internal surface emissivity of 0.8.

The calculated temperature histories in the steel flanges are shown in Fig. 34.15. For comparison the temperature calculated assuming uniform temperature is also included. Notice that the temperature difference between the minimum and maximum steel temperatures are on the order of 130 °C due to uneven heating and steel mass distribution and in particular due to the cooling of the top flange by the concrete slab. A simple approximate calculation can be obtained assuming a uniform steel section temperature, according to the discussion on insulated steel structures, with the section factor calculated as shown in Table 34.3. A time constant τ equal to 6460 s or 1.8 h can then be calculated (Equation 34.38) and a uniform steel temperature after 2 h of about 635 °C can be obtained from Fig. 34.10. Notice that this temperature is considerably higher than the average temperature obtained with the much more accurate finite element model.

Calculation of Temperature in Concrete Structures

Reinforced concrete structures are sensitive to fire exposure for mainly two reasons. They may spall due to combinations of internal water pressure and high thermal stresses, and they may gradually lose their load-bearing capacity when the reinforcement bars get hot, reaching temperature levels above 400 °C. Prestressed steel may even lose strength below that level. In addition the concrete loses both strength and stiffness at elevated temperature. When occurring, spalling usually starts within 30 min of severe fire exposure. Because the spalling phenomenon is very complex and cannot be predicted with simple mathematical temperature models, it will not be further discussed here. Thus, the procedures presented below presume that no spalling occurs that could considerably influence the temperature development.

In general, temperatures in fire-exposed structures may be obtained from tabulated values (see, e.g., Eurocode 2 [26]) or by more or less advanced calculations. Below some simple calculation methods are given. For more general situations, finite element calculations are needed.

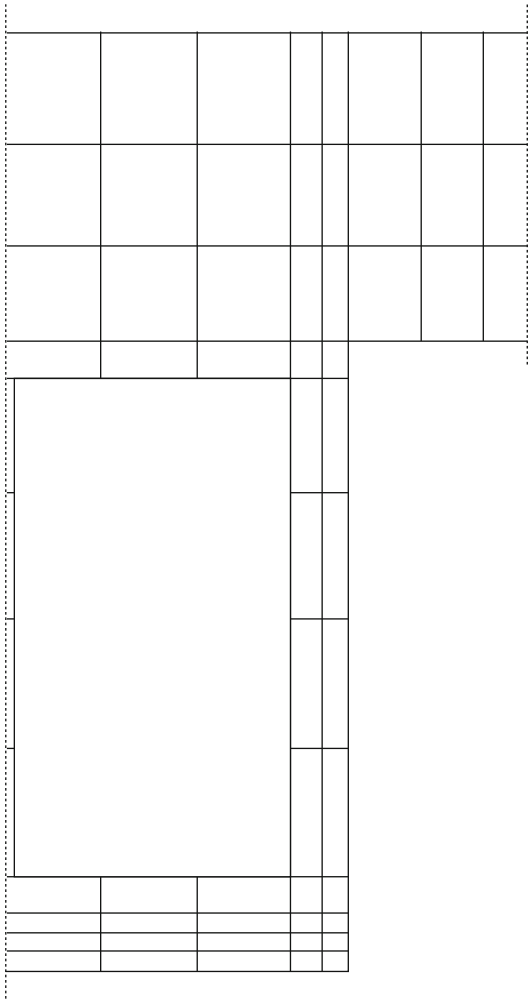

Fig. 34.14 Finite element discretization used to calculate the temperature development of the steel beam shown in Fig. 34.13 when exposed to a standard fire exposure according to ISO 834

Thermal Properties of Concrete

The thermal conductivity of concrete decreases in general with rising temperature. It depends on concrete quality and type of ballast. For design purposes curves as shown in Fig. 34.16 may be used according to Eurocode 2 [26]. For more accurate calculations with alternative concrete qualities more precise material data may be needed, as discussed earlier.

The specific heat of dry concrete does not vary much with temperature. However, in reality concrete structures always contain more or less physically bound water. This water will evaporate at temperatures above 100 °C and constitute a heat sink as the evaporation consumes a lot of heat. Thus, the specific heat capacity for normal weight concrete according to Eurocode 2 is as shown in Fig. 34.17.

The emissivity of concrete surfaces may be assumed to be 0.8 and the convective heat transfer coefficient may, when simulating fully developed fires, be assumed equal to 25 W/m^2 K. See, for example, Eurocode 1 [4]. In general the assumed values of these parameters have little influence on calculated temperatures inside concrete structures.

Penetration Depth in Semi-Infinite Structures

Concrete is a material with relatively high density and low conductivity. Therefore, it takes a

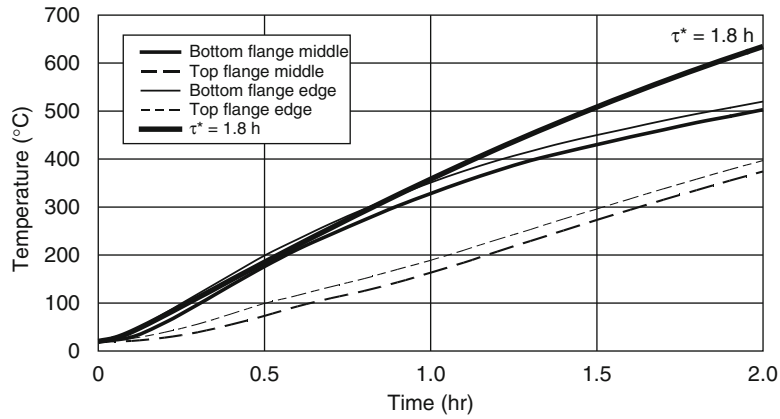

Fig. 34.15 Temperature history of bottom and top flanges, middle and corner points

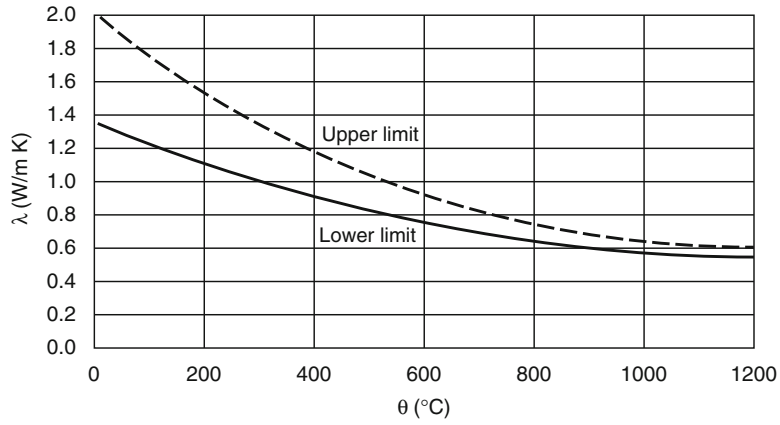

Fig. 34.16 Upper and lower limits of thermal conductivity as a function of temperature of normal weight concrete according to Eurocode 2 [26]

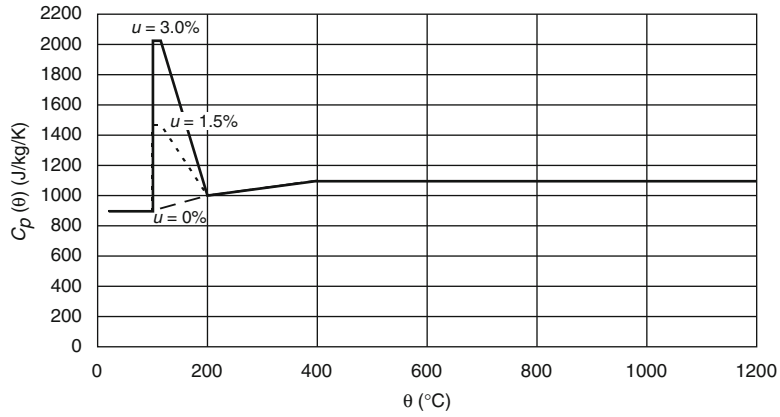

Fig. 34.17 Specific heat capacity of concrete as a function of temperature at three different moisture contents, 0 %, 1.5 %, and 3 %, for siliceous concrete according to Eurocode 2 [26]

long time for heat to penetrate into the structure and raise its temperature, or in other words it takes time before a temperature change at one point is noticeable at another point. Thus, in many cases a concrete structure may then be assumed semi-infinite.

For the idealized case of a semi-infinite body at a uniform initial temperature T_i where the surface temperature momentarily is changed to a constant level of T_s, the temperature rise $(T - T_i)$ inside the body at a depth x at a time t may be written as a function of the normalized group $\eta = x / \left[2\sqrt{(\alpha t)}\right]$ where α is an assumed constant thermal diffusivity as defined in Equation 34.22. The relative temperature rise may then be written as

$$\frac{(T - T_i)}{(T_s - T_i)} = erfc(\eta) = 1 - erf(\eta) \qquad (34.54)$$

The Gauss complementary error function *erfc* is shown in Fig. 34.18. Tabulated values of the Gauss error function may be found in textbooks such as Holman [1]. For values of η greater than a value of 1.4 the relative rise is less than 5 %. Thus, depending on accuracy, the temperature penetration depth δ at a given time may be estimated as

$$\delta = 2.8\sqrt{\alpha t} \qquad (34.55)$$

As an example, the temperature rise can be estimated to penetrate only about 0.11 m into a concrete structure after 1 h, assuming a

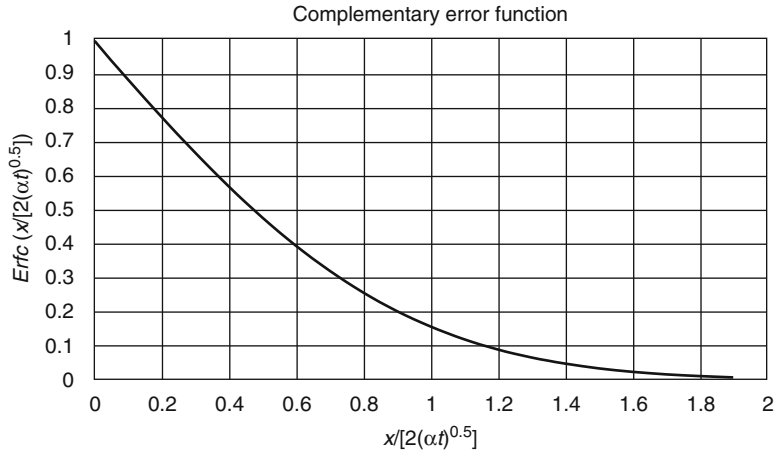

Fig. 34.18 Normalized temperature distribution in a semi-infinite body according to the Gauss complementary error function erfc as in Equation 34.54

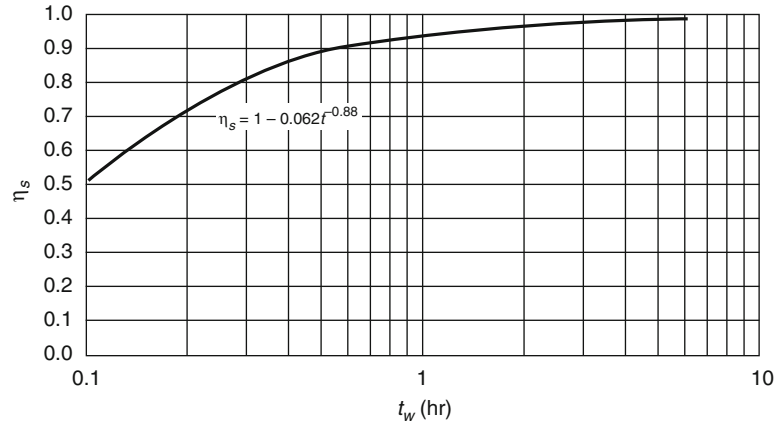

Fig. 34.19 Ratio η_s between concrete surface temperature T_s and the fire temperature T_f as a function of time for a normal weight concrete with thermal properties, according to Eurocode 2 [26], exposed to standard fire conditions, according to ISO 834

conductivity of a 1 W/m K, a density of 2300 kg/m^3, and a specific heat capacity of 1000 J/(kg K).

Penetration depth can actually be applied to steel as well. A temperature change at one point of a steel member will not be noticeable beyond a distance corresponding to the penetration depth.

Simple One-Dimensional Calculations

With the thermal properties of concrete as given in the earlier discussion on measurement of thermal properties, the temperature can be calculated in structures exposed to fires. In general, numerical procedures such as finite element methods need to be employed. Wickström [27–29] has, however, shown, based on numerous finite element calculations, that in one-dimensional cases the temperature inside concrete structures exposed to standard fire conditions according to ISO 834 may be obtained from the diagrams shown in Figs. 34.19 and 34.20. These diagrams apply to normal weight concrete with thermal properties, according to Eurocode 2 [26], as shown in the earlier section on measurement of thermal properties.

In Wickström [27–29] it is shown that the same type of diagrams can be used more generally considering both various parametric fires and various material properties. In these references techniques are also presented on how temperatures can be obtained in walls exposed from two sides and in simple two-dimensional cases by superpositioning based on the same

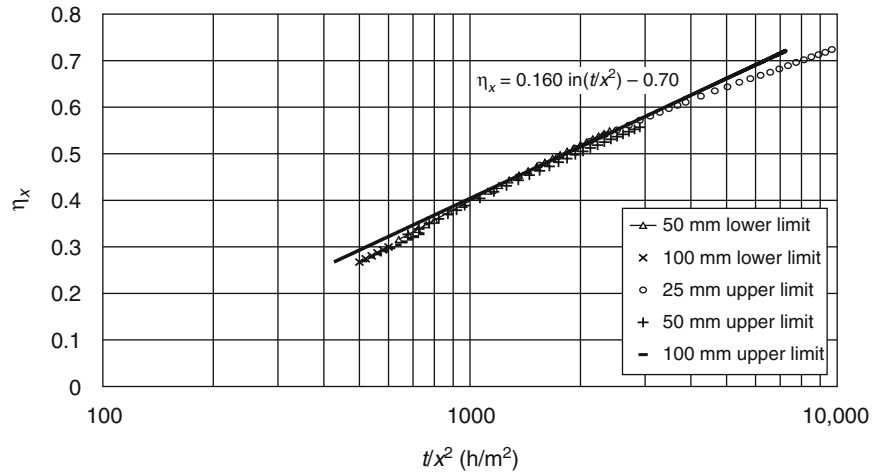

Fig. 34.20 Ratio η_x between internal concrete temperature T_x and the surface temperature T_s as a function of time divided by depth squared t/x^2 for normal weight concrete with thermal properties, according to Eurocode 2 [26], exposed to standard fire conditions, according to ISO 834. Calculations are made assuming the upper and lower limits of the conductivity as shown in Fig. 34.16

simple one-dimensional approximations as outlined below.

Thus, the diagram given in Fig. 34.19 shows the ratio η_s between the concrete surface temperature and the standard fire temperature, according to ISO 834, (see Equation 34.63) as a function of time.

$$\eta_s = \frac{T_s}{T_f} \tag{34.56}$$

The coefficient η_s is in general a function of the group time t over thermal inertia $\sqrt{(k\rho c)}$ of the concrete. In Fig. 34.19 normal weight concrete with thermal properties according to Eurocode 2 [26] is assumed.

Figure 34.20 shows in turn the ratio between the internal temperature T_x at a depth x and the surface temperature T_s. Thus,

$$\eta_x = \frac{T_x}{T_w} \tag{34.57}$$

The coefficient η_x is in principle a function of the Fourier number (i.e., the thermal diffusivity $k/(c\rho)$ of the concrete times the fire duration t over the depth x squared). Results from computer calculations are shown in Fig. 34.20. In these calculations thermal properties of concrete with a water content of 1.5 % are assumed according to Eurocode 2. Both upper and lower limit values of the conductivity (see Fig. 34.16) are included in the finite element calculations as well as depths of 25, 50, and 100 mm. A straight line is drawn in the logarithmic-linear diagram, which yields approximate temperatures slightly higher than would be obtained with more accurate finite element calculations.

The internal concrete temperature may now be written as

$$T_x = \eta_s \eta_x T_f \tag{34.58}$$

The graphs in Figs. 34.19 and 34.20 can be approximated by simple expressions. Thus,

$$\eta_s = \left(1 - 0.062 t^{-0.88}\right) \tag{34.59}$$

and

$$\eta_x = \left[0.16 ln\left(t/x^2\right) - 0.70\right] \tag{34.60}$$

respectively, where t is time in hours and x is distance in meters from the surface.

Then, in summary, for standard fire exposure according to ISO 834 and normal weight concrete according to Eurocode 2 [26] (see earlier section on thermal properties), a very simple closed-form solution may be obtained for the

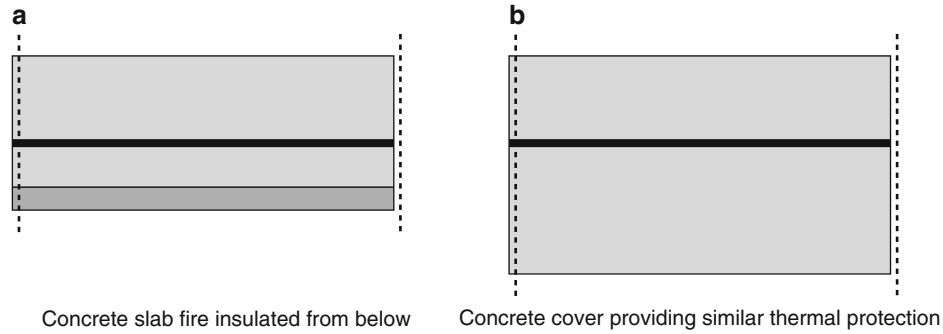

Fig. 34.21 Protection of a concrete structure layer with thickness d_i, which gives an equivalent thermal protection as a concrete layer with thickness d_c

temperature at arbitrary times and depths by inserting Equations 34.59 and 34.63 in hours 34.60 into Equation 34.58:

$$T_x = (1 - 0.062t^{-0.88})\left[0.16\,ln(t/x^2) - 0.70\right]345\log(480t + 1) \quad (34.61)$$

As an illustration, the temperature in a slab of normal weight concrete is calculated at a depth of 4 cm when exposed to an ISO 834 standard fire for 1 h. At first η_s is obtained from Fig. 34.19 to be 0.94 for $t = 1$ h. Then for $t/x^2 = 1.0/(0.04)^2 = 625$ h/m^2, Fig. 34.20 yields $\eta_x = 0.33$. As the standard time temperature rise after 1 h is 925 °C, the concrete surface temperature rise is obtained from Equation 34.56 as 0.94*925 = 870 °C and Equation 34.61 yields the temperature rise at a depth of 4 cm to be $T_x = 0.94*0.33*925$ °C = 287 °C. A corresponding accurate finite element calculation yields a temperature rise of $T_x = 277$ °C.

Fire-Insulated Concrete Structures

In some applications, it may be advantageous to insulate concrete structure surfaces to prevent them from fast temperature rises. This insulation may either be to avoid spalling or to give the concrete-embedded reinforcement bars additional thermal protection (Fig. 34.21). Behind the protection the temperature of the concrete surface will not rise as quickly as when directly exposed to fire. Some insulation materials undergo chemical transformations requiring a lot of heat (latent heat) to raise the temperature whereas others work just as passive thermal barriers. Only the latter type of insulation systems is further discussed here and the formula given below only applies to this type of inert material.

The thermal efficiency of a protection layer is sometimes expressed as the thickness of an additional concrete coverage that would yield the same protection. Wickström and Hadziselimovic [30] have shown that the same effect is approximately obtained when the thermal resistance of the insulation is the same as that for the concrete (i.e., $d_i/k_i = d_c/k_c$ where d is thickness and k conductivity, respectively, and the indices i and c stand for insulation and concrete, respectively). Thus, the equivalent concrete layer thickness can be calculated as

$$d_c = k_c d_i / k_i \quad (34.62)$$

which indicates that the influence of the specific heat capacity and density of the protecting material is negligible in the case of protecting concrete structures. The thermal inertia of the concrete is totally dominating over the inertia of the insulation.

As an example, a 10 mm board of vermiculite with a thermal conductivity of 0.2 W/m K corresponds to a concrete protection layer of 50 mm, assuming the concrete has a conductivity

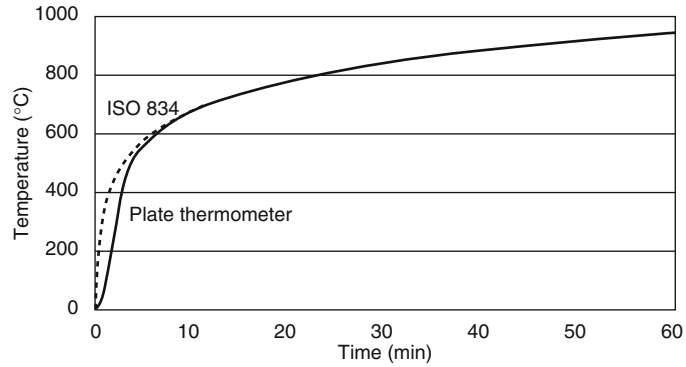

Fig. 34.22 Calculated response of a plate thermometer when exposed to standard fire test conditions, according to ISO 834, Equation 34.63

of 1.0 W/m K for the temperature interval considered. This could mean considerable savings in both weight and space for a concrete structure.

Calculation of Temperature in Timber Structures

Modeling the thermal behavior of wood is complicated by phenomena such as moisture evaporation and migration, and the formation of char has a decisive influence on the temperature development. Nevertheless, it has been shown that general finite element codes such as SAFIR, TASEF, and COMSOL can be used to predict temperature in fire-exposed cross sections of glued laminated beams [31] provided apparent thermal material properties and appropriate boundary conditions are used. Other specialized numerical codes for timber structures have been developed by Fung [32] and Gammon [33].

More commonly empirical rules are used to estimate the penetration of the charring layer and the loss of strength of timber structures (see, e.g., Eurocode 5 [34]).

Heat Transfer in Fire Resistance Furnaces

Nominal time-temperature relations are clearly defined in fire resistance test standards such as ISO 834, EN 1363-1, and ASTM E119. However, furnaces have various characteristics depending on the difference between the black body radiation temperature T_r (Equation 34.7) and the gas temperature T_g. In addition there is a time delay of the temperature recording due to the thermal inertia of the monitoring thermocouples. Therefore, when theoretically simulating fire resistance tests, it must be considered how the temperature has been measured in the various standards.

Furnaces Controlled According to ISO 834 and EN 1363-1

In ISO 834 and EN 1363-1 the nominal furnace temperature T_f is given as

$$T_f = 20 + 345\log_{10}(8t + 1) \qquad (34.63)$$

The furnace temperature shall be monitored with plate thermometers (see ISO 834-1 and EN 1363-1). The time delay or, in other words, the time constant of the plate thermometers in a furnace test is negligible, which is indicated in Fig. 34.22, where the calculated temperature response of a plate thermometer exposed to uniform furnace temperature according to ISO 834 is shown. The heat transfer is then calculated according to Equation 34.11 assuming the emissivity ε and the convection heat transfer coefficient h equal to 0.9 and 25 W/m^2 K, respectively.

Notice that the plate thermometer temperature follows the nominal curve very closely except for the first few minutes. Thus, the time delay of the plate thermometer temperature recordings due to inertia in a standard fire test may be neglected

and the heat transfer to a specimen surface can accurately be calculated according to Equation 34.18.

Sometimes it is of interest to know the *incident radiation* level under a furnace test. This level can be measured directly with heat flux meters, but in the section below it is shown how this radiation level may be obtained from plate thermometer measurements.

The incident radiation heat flux q_{inc} may be obtained from Equation 34.16, and plate thermometer temperature recordings given the gas temperature T_g, the emissivity ε_{PT}, and the convection heat transfer coefficient h_{PT} of the plate thermometer are known as

$$q_{inc} = \sigma T_{PT}^4 - h_{PT}\left(T_g - T_{PT}\right)/\varepsilon_{PT} \qquad (34.64)$$

The latter term in Equation 34.64 is relatively small and may be treated as an error term. For values of the emissivity ε_{PT} and the convection heat transfer coefficient h_{PT} equal to 0.8 and 25 W/m^2 K, respectively, a temperature level of 1000 K and a gas temperature T_g deviating from the plate thermometer temperature T_{PT} by as much as 50 K yields the latter term of Equation 34.64 to be less than 3 %. At higher temperature levels and at minor deviations between gas and radiation temperatures this error is much smaller and probably seldom greater than must be anticipated when measuring incident radiation directly with heat flux meters.

Furnaces Controlled According to ASTM E119

In the American test standard ASTM E119 the nominal furnace temperature is specified according to the time-temperature relation given in Table 34.6.

The standard thermocouple for monitoring the furnace temperature is, however, very thick and, therefore, very slow. According to ASTM E119, it shall have a time constant within the range of from 5.0 to 7.2 min. To eliminate the effects of the time delay the thermocouples may be analyzed as bare steel sections. Thus, by applying Equation 34.51, the effective fire temperature T_f can be derived from the corresponding thermocouple measurements T_{tc} as

Table 34.6 Standard Fire Time-Temperature Relation According to ASTM E119

Time (min)	Temperature rise (°C)	Time (min)	Temperature rise (°C)
0	0	90	986
5	556	120	1029
10	659	180	1090
15	718	240	1133
30	821	360	1193
60	925		

$$T_f^{i+1} = T_{tc}^{i+1} + \tau/\Delta t\left(T_{tc}^{i+1} - T_{tc}^{i}\right) \qquad (34.65)$$

The furnace thermocouple time constant, as referred to in the ASTM E119 standard, is rather imprecisely specified as the heat transfer by radiation that is nonlinear and increases by the temperature level raised to the fourth power. More realistic is to assume a time constant of 6 min (in the middle of the range from 5.0 to 7.2 min) at a furnace temperature level of perhaps 1000 K, and then obtain the heat transfer to the thermocouple by calculating the heat transfer according to Equation 34.11 assuming ε and h equal 0.9 and 50 W/m^2 K, respectively. Then match a surface-to-volume ratio obtained from Equations 34.52 and 34.13 to obtain the stipulated time constant. (As a comparison, the corresponding time constant for a plate thermometer at the same temperature level is on the order of 15 s.)

Figure 34.23 shows the actual furnace temperature rise in a furnace controlled ideally precisely according to ASTM E119. Notice that the real or effective furnace temperature is much higher than indicated by the slowly responding ASTM type of shielded thermocouples. It must, however, be noted that the above analysis assumes that the furnace radiation and gas temperatures are equal, which is seldom the case. The gas temperature may be higher than the radiation temperature and, therefore, the differences in practice between the ASTM thermocouple and the plate thermometer may be much less, as the

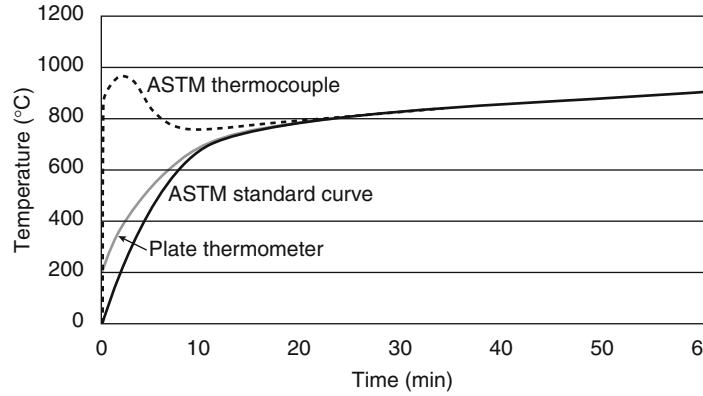

Fig. 34.23 Temperatures ASTM E119 and ISO 834 (plate thermometer), respectively, must follow to obtain the effective furnace temperature T_f according to ASTM E119 due to time delay

ASTM thermocouple is more sensitive to convective heat transfer than the plate thermometer. The general observation from this theoretical analysis agrees with the test results reported by Sultan [35]. The difference between the ASTM type of thermocouples and the plate thermometer is insignificant after 10 min.

Professor Ulf Wickström is teaching heat transfer in fire technology at Luleå University of Technology, Sweden. He is a former head of the Department of Fire research at SP Technical Research Institute of Sweden. Professor Wickström has a PhD from Lund University of Technology in fire technology and a master of science from the University of California, Berkeley. For his thesis research he developed the computer program TASEF for calculating temperature in fire-exposed concrete and steel structures. His focus of scientific interest is heat transfer analysis of structures exposed to fire, on which he has published several papers.

Fire Load Density

35

Mario Fontana, Jochen Kohler, Katharina Fischer, and Gianluca De Sanctis

Introduction

The fire load has a strong influence on the temperature development during a compartment fire. Therefore, the assessment of the fire load as an input to model the time-temperature relationship, is an important task in structural fire design.

In combination with the available oxygen and the combustion properties of the material, the fire load density determines the heat release rate *HRR* of a fire.

Figure 35.1 illustrates the qualitative behaviour of the heat release rate as a function of time during a fire. The fire growth phase (including potential flashover), the fully developed state and the decay phase are qualitatively shown for the two burning regimes of fuel (4) or ventilation (3) controlled fires. The area under both curves corresponds to the energy released by the available fire load in the room. The duration of a fire depends on the amount of fire load and the burning regime. For ventilation controlled fires the heat release rate is limited by the available oxygen. In a fuel controlled fire the maximal heat release rate in the room is achieved and the duration of the fire is usually shorter (1).

Definitions

The **fire load** [MJ] is defined as the quantity of energy which is released by the complete combustion of all combustible material in a fire compartment. The fire load is often subdivided into variable (movable or mobile) and permanent (fixed or immobile) fire load.

The **net heat of combustion** [MJ/kg] is defined as the potential combustion energy per kilogram contained in the material.

The **fire load density** is defined as the fire load per unit floor area [MJ/m^2] or per unit volume [MJ/m^3].

A **fire compartment** is defined as the enclosed space, which is separated from adjoining spaces by adequate fire barriers.

Representation of Fire Load

Basic Representation

The fire load in buildings consists of the energy content of combustible materials, generally comprising furniture, equipment and stored objects and goods (variable fire load) as well as combustible components of the structural elements (permanent fire load) which can burn during a fire. The variable fire load depends

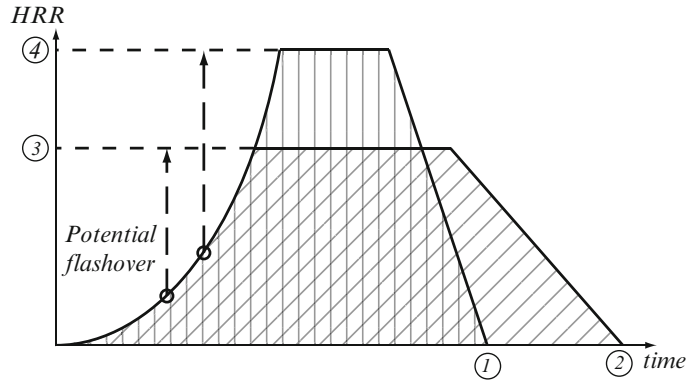

Fig. 35.1 Illustration of the heat release rate (HRR) development as a function of time during a compartment fire

mainly on the occupancy of the room or building, as e.g. residential buildings, hospitals, hotels, stores, storage buildings, industrial facilities, etc.

The fire load the also be represented by the fire load density or the distributed fire load by dividing the fire load by the room area. According to CIB W14 [1], the fire load density can be related to the total floor area of the fire compartment [MJ/m^2] including aisles and local empty spaces. In some literature [2], the area is related to the total interior area of the surfaces within the compartment including all openings [MJ/m^2]. For some building occupancies–especially for storage or industrial buildings–the relation to the volume [MJ/m^3] can be more efficient in order to address the effect of storage height on the fire load.

The fire load density of a fire compartment containing different combustible materials is defined as:

$$q = \frac{\sum_i m_i \cdot H_i}{A} \qquad (35.1)$$

m_i: the mass of a combustible material i [kg]
H_i: heat of combustion or specific energy released from combustion per mass unit of material i [MJ/kg]
A: area of fire compartment [m^2]

Stochastic Representation

The fire load density in a compartment varies in time and in space. In general, it is sufficient to represent the variation in time with a simple time independent random variable $\boldsymbol{q}(t,x,y) = \boldsymbol{q}(x,y)$.

The variation of the fire load density in space (x,y) can be represented in analogy to the approach proposed in CIB W81 [3] by a stochastic field $\boldsymbol{q}(x,y)$ as:

$$\boldsymbol{q}(x,y) = \exp(LN(\hat{q}) + \boldsymbol{V} + \boldsymbol{U}(x,y)) \qquad (35.2)$$

where $\hat{q}$ is the overall median fire load density (e.g. specified for a specific occupancy category), $\boldsymbol{V}$ is a zero mean normal distributed variable representing the variation between different structures and different points in time and $\boldsymbol{U}(x,y)$ is a zero mean random field representing the variation within the compartment. The quantities $\boldsymbol{V}$ and $\boldsymbol{U}$ are considered as stochastically independent.

Fire Load Density in Fire Safety Design

For localized fire models the spatial distribution of the fire load in space should be taken into account e.g. by the random field in Equation 35.2. Depending on the type and purpose of an analysis, the stochastic representation of the fire load can be simplified. For zone fire models the variability in space can usually be neglected. Then the random variable $\boldsymbol{q}$ can be represented as a simple lognormal distributed random variable with mean value μ_q and standard deviation σ_q.

In fire safety design the stochastic representation of the fire load is often simplified. Usually, characteristic values for the fire load are used. These characteristic values are chosen according to the safety format of the corresponding code format. In general, the characteristic values

Table 35.1 Calculation of characteristic values

Distribution type	Lognormal			Gumbel		
Fractile	80 %	90 %	95 %	80 %	90 %	95 %
k-value	0.84	1.28	1.64	0.72	1.30	1.87
Characteristic value	$q_k = \frac{\overline{q}}{\sqrt{v^2+1}} \cdot \exp\left(\sqrt{\ln(v^2+1)} \cdot k\right)$ with $v = {}^{\sigma_q}/_{\overline{q}}$			$q_k = \overline{q} + k \cdot \sigma_q$		

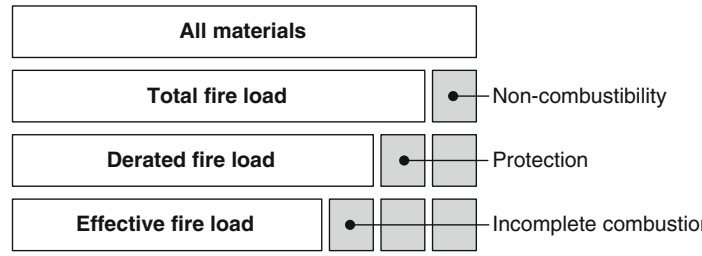

Fig. 35.2 Overview on the assessment of the fire load

correspond to a specific fractile value of the underlying distribution of $\boldsymbol{q}$. Fractile values are calculated depending on the distribution type and the mean $\overline{q}$ and standard deviation $\sigma_{\overline{q}}$ of the distributions according to Table 35.1.

It is suggested to represent the fire load density as a Lognormal distributed random variable. In some fire safety regulations the Gumbel distribution is prescribed. From a theoretical point of view the Gumbel distribution belongs to the family of extreme value distributions while the fire load is considered as a point in time realization of a random process. However, due to the usually large coefficient of variation of the fire load, it is acceptable to use a Gumbel distribution instead of a Lognormal distribution. Table 35.1 contains information for the use of both distributions.

Assessment of the Fire Load for Fire Safety Design

The fire load that is used for design purposes can be assessed as shown in Fig. 35.2: Among all materials only the combustible materials contribute to the potential energy that can be released by a fire. The fire load density of these materials can be assessed by Equation 35.1 using their mass and their heat of combustion and is denoted as of the total fire load (Fig. 35.2 second line). A part of total fire load is protected against direct participation in a fire through encapsulation (Fig. 35.2 third line). Derating factors can be used to account for those protected fire loads. The characteristic value that is used for design purposes is usually derived from the probability distribution of the derated fire load. Because the combustion under natural fire conditions is usually incomplete, the effective contribution of the fire load to the energy released during a fire is smaller than the derated fire load (Fig. 35.2 bottom line).

The design value of the fire load is related to the effective fire load and is usually calculated by multiplying the characteristic fire load with other factors like partial safety factors (e.g. taking account of the rate of fire occurrence, fire fighting measures etc.).

For the design of new buildings the design fire load is estimated based on statistical data of existing buildings with similar occupancies, size and regional tradition. The fire load in an existing compartment or building can be assessed by in situ surveys.

Estimation of Fire Loads Based on In Situ Surveys

The main task in an in situ survey is to identify and to assess the mass and the heat of combustion of all combustible materials and to determine the characteristic fire load for design purposes and can be conducted by different survey methods.

Survey Methods

In the literature (e.g. Zalok [4], Culver and Kushner [5]) several fire load survey methods can be identified:

- *weighing method*: direct measurement of weight of the combustible materials
- *inventory method*: indirect estimation of the weight by measuring the dimension and/or the density of the combustible items
- *questionnaire method*: distribution of questionnaires and estimation of the combustible material through photographic selection and inventory tables.

Common to all approaches is the attempt to assess the fire load density by the mass of the combustibles and their heat of combustion. The methods differ from each other e.g. in terms of the uncertainties associated with the survey method with the time needed for the survey, with the possibility to verify the results, and with privacy concerns and disruption of business.

Based on a study comparing the weighing and the inventory method, Culver and Kushner [5] estimated the relative error to approximately 10 % when using the inventory method instead of the weighing method. The uncertainty in the inventory method is caused mainly by the estimation of the dimensions by the surveyor. On the other hand, also the mass of combustible material estimated based on the weighing method has some inherent uncertainties, e.g. when assessing the individual weights of a composite material. Surveys conducted in the last years constitute that the combination of the inventory and the weighing method leads to results with smallest uncertainties and is therefore considered to be the most appropriate fire load survey method, see Zalok [4].

The advantage of the questionnaire method is that surveys can be carried out with relatively little effort and even without physically entering the building.

Assessment of Weight

The mass can be directly assessed by weighing the material. In some cases weighing of a material can be complicated because the item is too big for weighing or the item is composed of different materials. In the latter case, weighing of the item without destroying the item is often not possible. In those cases, the weight must be estimated indirectly by assessing the volume and the density of the individual components. As mentioned above the indirect estimation of the mass may lead to an error due to simplification made by the assessment of the volume, especially for irregularly shaped objects. In addition, the actual density of a material can deviate from tabulated or estimated values.

Heat of Combustion

The heat of combustion–also known as the calorific value or heating value–is the total amount of heat released when a quantity of a fuel is oxidized completely under standard temperature conditions and (atmospheric) pressure (see also Drysdale [6]). The heat of combustion is related to different units. The most commonly used unit in fire safety engineering is the SI unit [MJ/kg]. For some items values can be established with units like [MJ/m^2], [MJ/m^3], [MJ/l] or [MJ/piece]. For example the calorific value for a carpet can be defined per square meter [MJ/m^2] or for a wooden pallet per piece [MJ/piece]. This can simplify the assessment of the fire load and save time during a survey (see inventory method above). In some (older) surveys the fire load was converted to wood equivalent, e.g. the fire load in [MJ] was converted in kg of wood [kg of wood equivalent] by dividing the fire load by the heat

of combustion of wood. As the heat of combustion of wood is given by different values in different sources (see e.g. Appendix 3) this may lead to differences among different surveys.

The heat of combustion of the material depends on the aggregate state of the reactants and products after combustion. If the reactants and products are in their standard states, the heat of combustion is defined as the gross heat of combustion (or the gross calorific value). Rules how to determine the gross heat of combustion are given in standards e.g. ISO 1716 [7]. The net heat of combustion H_u (or net calorific value) refers to the case where especially water is in vapour state after the combustion. If solid materials are completely dry the gross heat of combustion corresponds to the net heat of combustion. The influence of the moisture content on the net heat of combustion of a material can be considered by accounting the latent heat of evaporation of water as follows [1]:

$$H_u = H_{u0}(1 - 0.01 \cdot u) - 0.025 \cdot u \qquad (35.3)$$

H_u: net heat of combustion [MJ/kg]
u: the moisture content expressed as mass percentage of dry weight
H_{u0}: the net calorific value of dry materials [MJ/kg]

The net heat of combustion of a mixed material $\overline{H}_u$ can be assessed by the mass and the net heat of combustion of the individual components:

$$\overline{H}_u = \frac{1}{M_{tot}} \sum_{i=1}^{n} M_i \cdot H_{u,i} \qquad (35.4)$$

M_i: mass of the material i [kg]
$H_{u,i}$: net heat of combustion of material i [MJ/kg]
M_{tot}: total mass of the mixed material [kg]

Values for the heat of combustion per kilogram can be found in the literature [1, 8–13] in the form of tabulated data for different materials and items. Data on the heat of combustion for some products and composites can be found in Appendix 3.

Total Fire Load

The total fire load is defined as the sum of the products of the mass and the heat of combustion of all combustible materials in the fire compartment (see Equation 35.1). In general, permanent (or fixed) and variable (or movable) fire load is distinguished. Combustible materials which are part of the structure or the confining elements (e.g. the walls, the floor or the ceiling) contribute to the permanent fire load. Combustible material that is moveable and typically varies in time (e.g. daily, weekly, monthly or during the service life of the building) contributes to the variable fire load. The energy released by the permanent and variable fire loads depends on their reaction to fire or combustibility. For this reason many national standards subdivide the combustibility of building materials (permanent fire load) in different reaction to fire classes. According to the Euroclass system EN 13501 [14], building materials are grouped into seven combustibility classes on the basis of their reaction-to-fire properties (see Table 35.2).

All combustible building material and building contents contributing energy to the fire should be accounted for in the fire load assessment.

Materials can be neglected if the energy required for pyrolysis is higher than the energy which is released from the material during the combustion. This means that those materials consume more energy than they release under fire exposure. According to Beilicke [8] this applies to materials with homogeneous or quasi-homogeneous properties that have a heat of combustion smaller than 8.5 MJ/kg. If favourable condition for the combustions apply, lower values are possible.

Materials (protected and unprotected) that are able to explode under fire exposure, e.g. combustible gases, should be considered separately and are not part of the fire load assessment.

Table 35.2 Euroclass system for classification of the combustibility of building materials, EN 13501 [14]

Class		Performance description	Possible test methods	Examples of products
Non combustible	**A1**	No contribution to fire	ISO 1182 [15] ISO 1716 [7]	Products of natural stone, concrete, bricks, ceramic, glass, steel, and many metallic products
	A2	No significant contribution to fire	ISO 1182 [15] ISO 1716 [7]	Products similar to those of class A1, including small amounts of organic compounds
Combustible	**B**	Very limited contribution to fire	ISO 11925-2 [16]	Gypsum boards with different (thin) surface linings Fire retardant wood products
	C	Limited contribution to fire	ISO 11925-2 [16]	Phenolic foam, gypsum boards with different surface linings (thicker than in class B)
	D	Contribution to fire	ISO 11925-2 [16]	Wood products with thickness $\geq$ about 10 mm and density $\geq$ about 400 kg/m^3 (depending on end use)
	E	Significant contribution to fire	ISO 11925-2 [16]	Low density fibreboard, plastic based insulation products
	F	Incapable of achieving Class E	—	Products not tested (no requirements)

Derated Fire Load

A building material will contribute to a fire depending on its combustibility and its reaction to fire. Non-combustible materials (class A1 and A2 according to EN 13501 [14]–e.g. gypsum boards) and materials with limited reaction to a fire (class B and C) are often used to protect combustible building materials (encapsulation of permanent fire load) and variable fire loads against ignition (e.g. steel containers with combustible content).

Whether protected material should be accounted for the fire load assessment should be related to the reliability of the protection under fire exposure. A failure of the protection leads to an ignition of the protected combustible material. Possible reasons include falling off of the protection, cracks or excessive heat transfer. If the combustible material is preheated at the time of ignition its combustibility may be increased. The failure of the protection is assessed considering the exposure of the protection during a fire. Because of the stochastic behaviour of a fire, the failure of the protection is an uncertain event. This uncertainty can be considered by assigning a failure probability to the protection.

CIB W14 [1] propose a semi-probabilistic approach to account for protected fire loads by introducing derating factors $\psi_{p,i}$. These factors represent the probability for a participation of the protected combustible material in the fire. The derated fire load density q may be written as:

$$q = q_{unprotected} + \sum_i \psi_{p,i} \cdot q_{i,protected} \quad (35.5)$$

$q_{unprotected}$ fire load density for the unprotected combustible materials [MJ/m^2]

$q_{i,protected}$ fire load density for the protected combustible material i [MJ/m^2]

$\psi_{p,i}$ derating factor for the protected combustible material i [-]

There is no generally agreed procedure for deriving the derating factor $\psi_{p,i}$. In an informative annex of the Eurocode 1991-1-2 [17] it is proposed that the protected fire load can be neglected (i.e. $\psi_{p,i} = 0$) when the largest protected fire load (minimum 10 % of the whole protected fire load) plus the unprotected fire load are not able to ignite the protected fire load. In other cases, the specific value of $\psi_{p,i}$ for a protected material should be assessed individually.

For a survey it is important to clarify whether derating factors were used or not. Both the underrated and the derated value of the fire load (especially with regard to the permanent fire load, e.g. encapsulated combustible insulation or structural elements) should be reported, to identify how much combustible material was considered as protected.

Effective Fire Load

The combustion behaviour of a material under real fire exposure depends on the material properties, the surface to volume ratio and the thermal action on the material. Material and geometrical properties, e.g. size, location, etc., will affect the heat release rate (HRR) during a fire and the combustion of the material itself. In most fires there will be no complete combustion of all materials in a room. To consider the incomplete combustion a combustion factor χ can be introduced. The combustion factor χ is defined as the ratio of the effective heat released q_{eff} and the theoretically maximal possible heat released q:

$$\chi = \frac{q_{eff}}{q} \tag{35.6}$$

This ratio describes the degree of combustion and has a value between 0 and 1. A combustion factor of 1 means that a complete combustion takes place, while a factor of 0 implies that no combustion of the material takes place.

The combustion efficiency depends on the quantity of the material burned and is mainly influenced by the fire exposure of the item (oxygen supply) and the ability of the material to protect itself against thermal actions (e.g. charring of wood). Another important factor which affects the combustion efficiency is the density of storage of the goods, e.g. wood-wool will burn fast and nearly completely, while a massive block of wood may self-extinguish and only burn partially on its surface.

Whether the combustion factor χ is considered in the fire load data of a survey should be stated clearly. However, the fire load under full combustion and under incomplete combustion should be reported to address the range of the maximal potential heat release during a fire. In the context of design this factor is typically used to estimate the design fire load.

A general assessment of the combustion factor does not exist yet. EN 1991-1-2 [17] proposes a combustion factor of 0.8 for materials which are mainly composed of cellulosic materials.

Defining Characteristic and Design Values from In Situ Surveys

It should be noted that the fire load assessed in an in situ survey represents only a momentary situation. Variation of the fire load over time should be considered (e.g. fire load before or after delivering products and daily, weekly, monthly, yearly variations). Fire loads that are supposed to remain unchanged during the service life time of the building should be accounted for their expected value. The fire loads that strongly vary in time should be considered depending on their frequency of occurrence. For design purposes, often a characteristic value of the fire load is used, e.g. an 80 % fractile value. Such a value denotes the fire load that is not exceeded during 80 % of the service time of the building.

For fire load surveys involving many buildings within the same occupancy class, the momentary fire load for each building can be assessed. Then, the variation of the fire load in time is characterized by the different momentary situation in the different buildings. The accuracy of predicting the fractile value for the characteristic fire load increases by increasing the number of rooms or buildings that are surveyed.

The design value for the fire load depends on the format of the fire safety design codes. It is usually defined as a function of the characteristic value of the fire load and the combustion efficiency. In the design fire load also additional factors can be considered e.g. the occurrence rate of a fire, the fire fighting measures and the required safety level for the structure (see EN 1991-1-2 [17]). It is therefore important to clearly state how design values of the fire load were established.

Fire Load Density for Different Occupancy Classes

If an in situ survey is not possible (e.g. during the design phase of a building) the mean and standard deviation of the fire load density can be

estimated based on data from fire load surveys in buildings within the same occupancy class. Such a statistical approach is especially valuable for common occupancy classes like residential buildings, offices, hotels, schools or hospitals. Choosing an upper fractile (characteristic) value of the statistical distribution, as required by many regulations, allows for future rearrangements as long as the occupancy class remains the same (e.g. different department stores in a shopping mall). In some occupancy classes, e.g. industrial buildings, the variability of the fire load density is very high. Nevertheless, even for industrial buildings information from fire load surveys in rooms of the same occupancy class can be helpful, e.g. for a preliminary analysis in the design phase or for comparison with the fire load estimate obtained by an in-situ survey. Due to the limited available statistical data and the high variability, the fire load density in industrial buildings will be discussed separately from the distributions for the more common situations.

Common Occupancy Classes

Due to socioeconomic and cultural characteristics specific to different countries or regions of the world, it is not possible to provide universal estimates for the distribution of the fire load density in different occupancies. For Europe, mean and fractile values have been defined for common occupancy classes in Annex E of EN 1991-1-2 [17]. The annex is informative only; allowing different values to be defined in the national annexes. Outside of Europe, guidance on fire load densities in common occupancy classes can be found in the International Fire Engineering Guidelines [18].

The mean values and standard deviations provided in Table 35.3 have been derived from EN 1991-1-2 [17]. Characteristic values (e.g. an 80 % fractile) can be estimated based on Table 35.1. The Eurocode assumes a Gumbel distributed fire load density, but Table 35.3 can also be applied assuming a Lognormal distribution. Another assumption is that the coefficient of variation of the fire load density is equal to 0.3 for all occupancy classes. No permanent fire load is included. The permanent fire load has to be estimated separately based on the methodology described in the in situ survey section above. Combustion factors still have to be applied if incomplete combustion is not treated elsewhere in the fire model.

Table 35.3 Mean and standard deviation of the variable fire load density for different occupancy classes according to the EN 1991-1-2 [17]

Variable fire load density [MJ/m^2]		
Occupancy	Mean	Standard
Dwelling	780	234
Hospital (room)	230	69
Hotel (room)	310	93
Library	1500	450
Office	420	126
Classroom of a school	285	85.5
Shopping centre	600	180
Theatre (cinema)	300	90
Transport (public space)	100	30

The information on the statistical distribution of the fire load density provided in Table 35.3 is valid for rooms of typical use for each occupancy class; special rooms have to be treated separately. At any rate, tabulated values should be used as a first estimate only.

An international overview on fire load surveys conducted before 1986 is given in CIB W14 [1]. However, when referring to older data sources one should bear in mind that today's furnishing materials and building contents are different to what was observed several decades ago. Therefore, older data may not be used unreflectingly and reference should be made to more recent studies. Since 1986, a number of fire load studies have been conducted in different parts of the world, including Canada [9, 12, 19, 20], India [21, 22], Japan [23, 24], Hong Kong [25, 26], Brazil [27] and Europe [28, 29].

Differences between data collected in different studies can be attributed to the fact that the studies were conducted in different geographical regions and within a time frame of several decades; also that the assumptions and methods

used for the different surveys can have large effects on the results. Based on the published reports, differences could be identified in the following areas:

- *Treatment of permanent fire loads*: The information published on the composition of the total (permanent and variable) fire loads is not always sufficient for comparison with studies focusing on variable fire loads only.
- *Fire load units*: The fire load is sometimes estimated in terms of "wood equivalent" [kg wood/m^2]. The conversion to the "fire load energy density" [MJ/m^2] or [Mcal/m^2] is ambiguous due to different assumptions for the net calorific value of wood.
- *Reference area*: In some older studies, the total internal surface area of the fire compartment is used as reference area for the fire load. The conversion to fire load per floor area requires assumptions on the geometrical properties of the fire compartment.
- *Derating factors and combustion efficiency*: Some studies use derating factors to account for protected fire loads and/or incomplete combustion while others estimate the full fire loads.
- *Sampling strategy*: The sample of buildings or rooms assessed during the individual studies may be more or less representative for the occupancy group mentioned in the report.
- *Survey method*: The uncertainty of the estimated values depends largely on the survey method (see discussion in the section on in situ surveys).
- *Simplifying assumptions*: The assumptions made e.g. for assessing the heat of combustion or the weight of the surveyed items can lead to a bias in the values provided by different studies.

Industrial Buildings

In occupancy classes with high variability (e.g. industrial buildings), the in situ survey method is preferred. Nevertheless, in this section some tentative values are proposed for several types of industrial buildings. This information may be used for a preliminary analysis or for comparison with the results of an in situ survey. Production and storage rooms are treated separately.

Even more than in other occupancy classes, the fire load densities in industrial buildings have to be expected to be changing in time. In 2005, a fire load survey in 95 Swiss industrial and commercial buildings was performed by ETH Zürich. Table 35.4 gives an overview on fire load densities surveyed in production rooms. Details of the survey methodology are described in Köhler et al. [30] (see also Thauvoye et al. [28]). Table 35.4 uses the same occupancy classification as proposed by Klein [31]. Only groups with five or more observations in at least

Table 35.4 Summary of fire load densities observed in Swiss industrial buildings (production rooms)

	Recorded fire load densities [MJ/m^2]				
Occupancy (production)	Sample size	Range	Mean	Standard deviation	Coefficient of variation
Wood processing	**17**	**80–4923**	**1488**	**1220**	**0.82**

Solvent storage	15	112–27,168	8686	7995	0.92
Packaging materials	8	372–6424	2229	1995	0.90

two different companies are included. Nevertheless, also for the remaining groups it should be kept in mind that with a coefficient of variation around 0.7, the statistical uncertainty becomes very high if the sample size is small.

The fire loads in storage rooms tend to be much higher than in production areas, see Table 35.5. Predicting the fire load density in one specific fire compartment based on data seems to be very difficult because of the high variability within each occupancy group.

The fire load density in storage rooms depends not only on the type of materials and goods stored, but also on the storage height and type (e.g. packing density). In the Swiss fire load study, both the gross storage volume (calculated from the total room area and the storage height) and the net storage volume (after subtraction of traffic areas etc.) were recorded. Herein, the fire load in a compartment is referred to the gross storage volume.

Based on this fire load survey, values for specific industrial occupancies (production and storage rooms) have been proposed by VKF [11] (available in German, French and Italian) as input data for a Swiss risk evaluation index method. In addition to a range of fire load "suggested values" are proposed derived on the detailed survey protocols of the fire load study summarized in Tables 35.4 and 35.6 and expert judgement. Due to the limited data sample and the large variability of the fire load density in industrial buildings, the estimates could not be defined mathematically, e.g. in terms of characteristic values. The values given in VKF [11] can thus only provide information on the order of magnitude of fire load densities in different industrial production and storage rooms. The older values given in SIA Dok 81 [32] should be interpreted in a similar way. Today these values should be used with care as the data was collected in the 1960s and cannot be assumed to represent well the present situation in buildings.

Besides the Swiss survey, fire load data for industrial buildings have also been reported in Germany by Schneider and Max [33] (see also CIB W14 [1]) and Halfkann and Wiese [34] (see also Schneider and Max [35]). Both studies recorded fire load densities that were quantified based on the 1978 (prestandard) version of the German DIN 18230 [36]. With a maximum of 20 observations per occupancy group, the sample size in the fire load study by Schneider and Max [33] is comparable to the Swiss study. A much larger sample of industrial buildings could be observed by Halfkann and Wiese [34]. However, their data is often related to specific fire design projects.

Table 35.6 Summary of fire load densities per gross storage volume (room area and storage height) observed in Swiss industrial buildings (storage rooms)

	Recorded fire load densities [MJ/m^3]

Mario Fontana is a professor at ETH Zurich in Switzerland at the Institute of Structural Engineering. His research activity have included structural fire safety, composite, steel and timber structures.

Jochen Kohler is a professor in NTNU in Norway in the Department of Structural Engineering. His research activities have included probabilistic design and analysis, of structures, risk analysis, probabilistic modelling, code calibration. Before becoming Prof. at NTNU Prof. Kohler was senior scientist at the Institute of Structural Engineering, ETH Zürich.

Katharina Fischer is a consulting engineer at Matrisk GmbH in Switzerland with expertise in risk analysis, probabilistic modelling and code calibration. Before her engagement at Matrisk, she made a PhD at ETH Zürich, focusing on fire risk assessment and societal decision-making.

Gianluca De Sanctis is a senior researcher at ETH Zurich in Switzerland. His research activities have included quantitative fire risk assessment for rational decision-making, assessment and probabilistic modelling of basic design parameters for fire safety and performance evaluation and optimization of fire safety design provisions.

Combustion Characteristics of Materials and Generation of Fire Products

Introduction

Hazards associated with fire are characterized by the generation of calorific energy and products, per unit of time, as a result of the chemical reactions of surfaces and material vapors with oxygen from air. Thermal hazards constitute those scenarios where the release of heat is of major concern. On the other hand, nonthermal hazards are characterized by fire products (smoke, toxic, corrosive, and odorous compounds.) Generation rates of heat and fire products (and their nature) are governed by

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_36, © Society of Fire Protection Engineers 2016

(1) fire initiation (ignition); (2) fire propagation rate beyond the ignition zone; (3) fire ventilation; (4) external heat sources; (5) presence or absence of fire suppression/extinguishing agents; and (6) materials: (a) their shapes, sizes, and arrangements; (b) their chemical natures; (c) types of additives mixed in; and (d) presence of other materials. In this handbook most of these areas have been discussed from fundamental as well as applied views. For example, the mechanisms of thermal decomposition of polymers, which govern the generation rates of material vapors, are discussed in Chap. 7, generation rate of heat (or heat release rate) from the viewpoint of thermochemistry is discussed in Chap. 5, Flaming ignition of the mixture of material vapors and air is discussed in Chap. 21, and surface flame spread in Chap. 23.

In this chapter emphasis is placed on small scale experiments and how such testing can be used to determine the generation per unit of time of (1) the calorific energy, defined as the heat release rate, and (2) fire products. From these tests, measurements of so-called "fire properties" are made that can be used in models to predict, under a variety of conditions, (1) heat release rate, to assess thermal hazards; and (2) generation rates of fire products, to assess nonthermal hazards. Fire properties are defined herein that help characterize the flammability of a given material and relationships are derived, based on empirical evidence, that elucidate the effect of environmental factors (such as external heat flux and ventilation) on the properties. Also important, and discussed in this chapter, is the connection of these properties to the behavior of large-scale fire phenomena under well ventilated as well as vitiated conditions (i.e., compartment fires.). Lastly, with the advent and quick development of computer modeling as applied to large scale fires, this chapter also discusses the value of small scale testing in determining material flammability parameters specific to such models.

Several other chapters in this handbook relate to the subjects discussed here and should be consulted for complete information and context. The chapters are as follows: Chaps. 27, 28, 16, and 24. Physical and combustion properties of selected fuels in air and heats of combustion and related properties of pure substances, plastics, and miscellaneous materials listed in Appendix 3 should be consulted for information that may not be included in this chapter. This chapter presents the applications of the principles discussed in several chapters in this handbook to determine the fire properties of materials. Simple calculations have been included in the chapter to show how the properties can be used for various applications.

Flammability Apparatuses and Measurement Capabilities

At the scales of relevance to this chapter, there are mainly three heat release rate apparatuses available: (1) The Ohio State University (OSU) Heat Release Rate Apparatus; (2) FM Global's Fire Propagation Apparatus (previously known as "Small-Scale Flammability Apparatus"); and (3) NIST's Cone Calorimeter. These apparatuses are briefly described below.

In 1972, gas temperature rise (GTR) calorimetry (details are given in section "Heat Release Rate" of this chapter) was used by the Ohio State University (OSU) to determine heat release rate [1, 2]. The apparatus used is now known as the OSU heat release rate apparatus; it is shown in Fig. 36.1. The OSU apparatus is an ASTM [3] and an FAA [4] standard test apparatus. In GTR calorimetry, it is assumed that almost all the thermal radiation from the flame is transferred to the flowing fire products-air mixture, as the flames are inside an enclosed space and heat loss by conductive heat transfer is negligibly small. Oxygen consumption (OC) calorimetry (details are given in section "Heat Release Rate" of this chapter) has now been adapted to the OSU apparatus [5].

Calorimetry methodologies based on carbon dioxide generation (CDG, details are given in section "Heat Release Rate" of this chapter), OC, and GTR calorimetries were used during the mid-1970s by FM Global Research

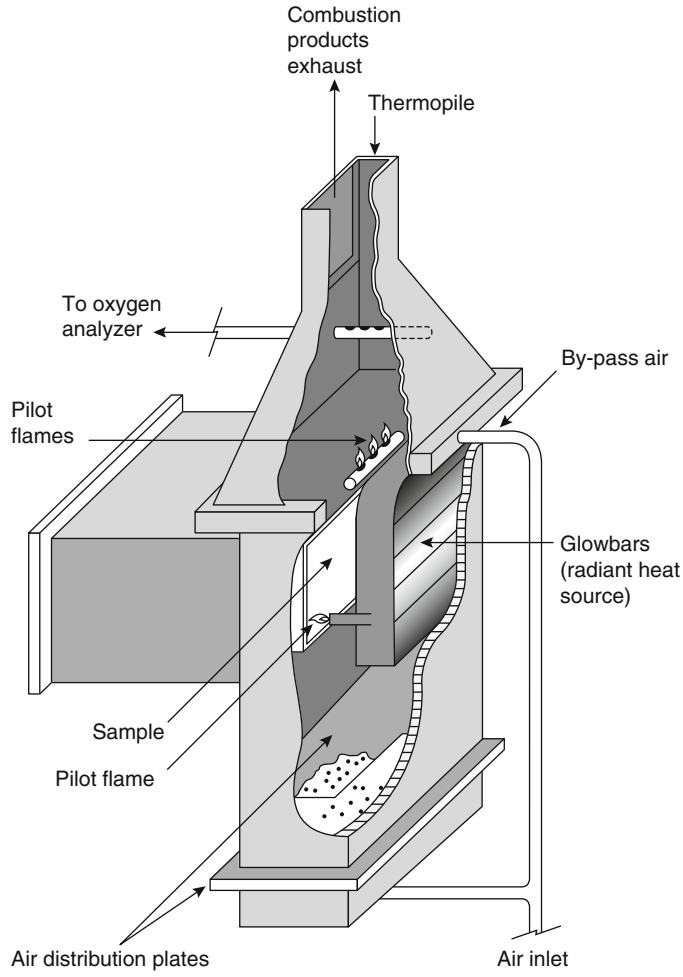

Fig. 36.1 Ohio State University's (OSU, ASTM E906) heat release rate apparatus [1–4]

(formerly, Factory Mutual Research Corporation—FMRC) to determine chemical, convective, and radiative heat release rates [6–9]. The apparatus used is now known as the Fire Propagation Apparatus (FPA) and is an ASTM [10] and ISO [11] standard; it is shown in Figs. 36.2 and 36.3. Heat release rate from CDG and OC calorimetries in the FPA was originally defined as the "actual heat release rate" until 1986 [9, 12–15]; thereafter, however, it was changed to "chemical heat release rate" to account for the effects of (1) the chemical structures of the materials and additives; (2) fire ventilation; (3) the two dominant modes of heat release, that is, convective and radiative; and (4) the effects of flame extinguishing and suppressing agents. The FPA is a standard test apparatus for electrical cables [16, 17], for wall and ceiling insulation materials, replacing the 7.6 m (25-ft) corner test (as described in section "Fire Propagation" of this chapter) [18], for clean room materials used in the semiconductor industry [19], and for conveyor belts [20].

In 1982 the National Institute of Standards and Technology (NIST) used OC calorimetry, following the methodology described by Hugget [21]. The apparatus developed to use this methodology, known as the cone calorimeter [22, 23], is shown in Fig. 36.4. The cone calorimeter became an ASTM standard [24] test apparatus in 1990. Details about the cone calorimeter are given in Chap. 28.

Sampling ducts have been designed for the FPA and the cone calorimeter to measure the mass generation rates of CO_2 and CO and mass consumption rate of oxygen for use in the

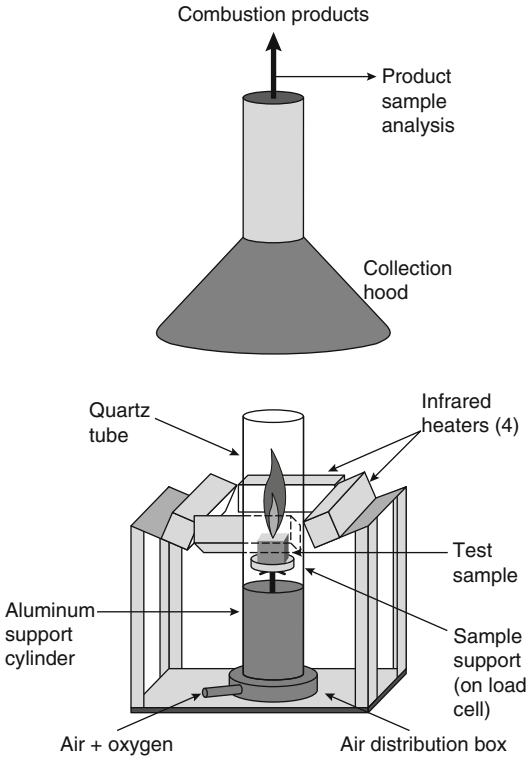

Fig. 36.2 Fire Propagation Apparatus (FPA) [10, 11] designed by FM Global Research. Sample configuration for ignition, pyrolysis, and combustion tests

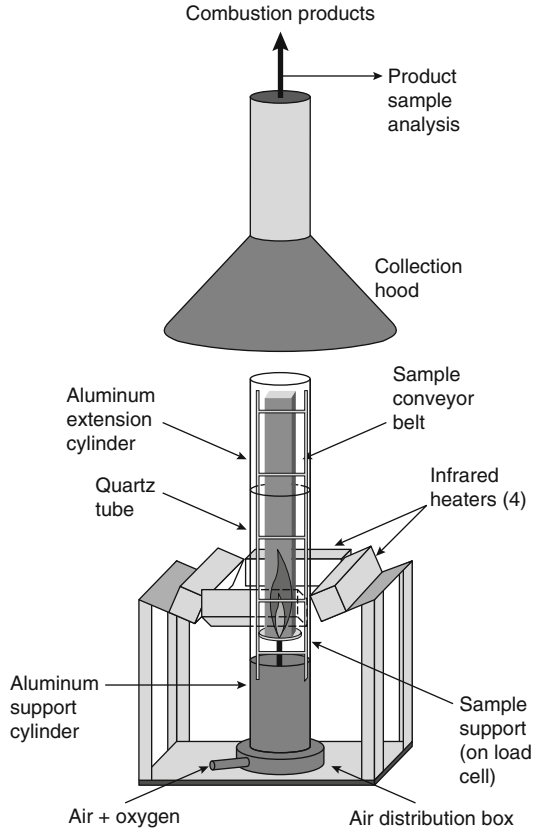

Fig. 36.3 Fire Propagation Apparatus (FPA) [10, 11] designed by FM Global Research. Sample configuration for fire propagation tests; a conveyor belt sample is shown

calorimetric equations (see section "Heat Release Rate" of this chapter). CDG and OC calorimetries are used in the FPA. In the OSU apparatus and the cone calorimeter, only the OC calorimetry is used. For application of GTR calorimetry, a thermopile located in the flue gas chimney is used in the OSU apparatus, and a thermocouple located in the sampling duct is used in the FPA, where heat losses by conduction are negligibly small. The cone calorimeter has not been designed to use GTR calorimetry. The FPA provides the advantage of determining the radiative heat release rate from the difference between the chemical (determined by CDG or OC) and convective (determined by GTR) heat release rates [25]. Details on sample preparation, sample holders, and measurement procedures are provided for each apparatus [3, 10, 11, 24]. The design features, test conditions, and types of measurements for the three apparatuses are listed in Table 36.1. As shown in the table, the Fire Propagation Apparatus measures flammability characteristics of materials under various air flow (ventilation) conditions, in enhanced or reduced oxygen environments, and also has the ability to determine flame extinction by extinguishing agents. Much of the data presented in this chapter takes advantage of all of these capabilities.

Figure 36.5 shows an example of typical heat release rate profiles measured in the FPA. These profiles correspond to the chemical heat release rate of polymethylmethacrylate, determined from CDG and OC calorimetries, as well as the convective heat release rate, determined by GTR. The polymethylmethacrylate (PMMA) sample was 100 mm in diameter and 9.53 mm in

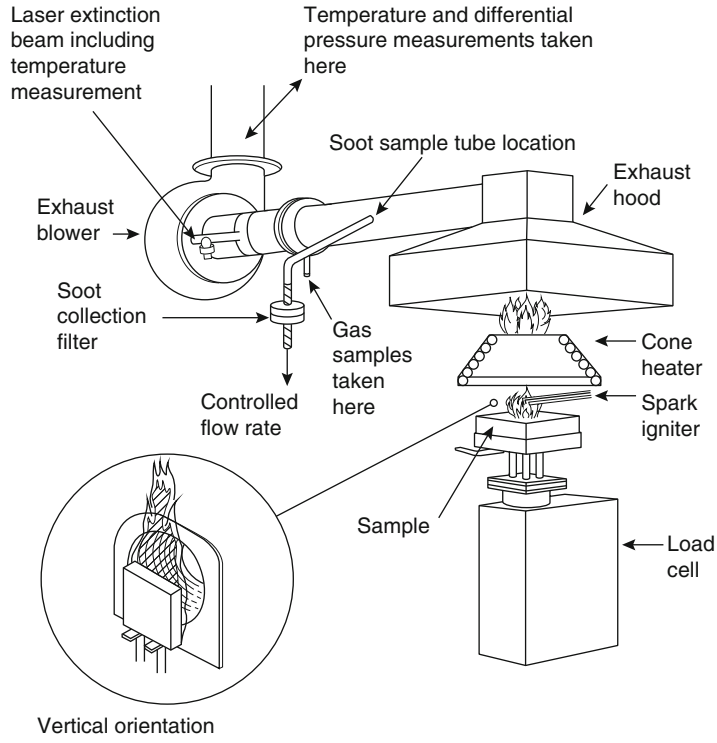

Fig. 36.4 The cone calorimeter [22–24] designed at the National Institute of Standards and Technology (NIST)

thickness. It was exposed to an external heat flux of 50 kW/m^2 under co-flowing normal air. The chemical heat release rate profiles from the CDG and OC calorimetries in the FPA are very similar, as expected.

Combustion Characteristics of Materials: Engineering and Modeling Applications

Ignition (Fire Initiation)

The fundamental ignition principles are described in detail in Chap. 21. These principles suggest that, for fire initiation, a material has to be heated above its critical heat flux (CHF, described below) for ignition. Generally speaking, ignition of a combustible solid, heated by an external source, starts with solid-phase thermal decomposition and evolution of combustible gases from the surface leading to gas-phase combustion, resulting in a sustained diffusion flame.

When a solid material is exposed to an external heat flux, it behaves either as thermally thin or thermally thick, depending on its material properties, dimensions and the magnitude of the incident heat flux. Materials typically behave as thermally thick at high heat fluxes (i.e., at high heating rates); and behave thermally thin at low heat fluxes (i.e., at low heating rates) near their critical heat flux for ignition. A thermally thick material is one having a physical thickness greater than the depth of thermal diffusion at the time of ignition, while the physical thickness of a thermally thin sample is less than the depth of thermal diffusion at ignition.

The equation for piloted ignition time of solids under thermally thick conditions may be expressed as [26, 27]:

$$t_{ig(thick)} = \frac{\frac{\pi}{4} k\rho c_p \left(T_{ig} - T_0\right)^2}{\left(\dot{q}''_e - \chi \dot{q}''_{cr}\right)^2} \qquad (36.1)$$

where, $t_{ig(thick)}$ is the time to piloted ignition (s); k, ρ and c_p are, respectively, thermal conductivity (kW/m/K), density (kg/m^3), and specific heat

Table 36.1 Design features, test conditions, and types of measurements for the OSU heat release rate apparatus, the Fire Propagation Apparatus, and the NIST Cone Calorimeter

Design and test conditions	OSU[a]	ASTM E2058 Fire Propagation Apparatus[b]	Cone[c]
Inlet gas flow	Co-flow	Co-flow/natural	Natural
Oxygen concentration (%)	21	0–40	21
Co-flow gas velocity (m/s)	0.49	0–0.146	NA
External heaters	Electrical resistance elements	Tungsten-quartz	Electrical coils
External heat flux (kW/m^2)	0–80	0–110	0–100
Exhaust product flow (m^3/s)	0.04	0.035–0.364	0.012–0.035
Horizontal sample dimensions (mm)	110 × 150	100 × 100	100 × 100
Vertical sample dimensions (mm)	150 × 150	100 × 600	100 × 100
Ignition source	Pilot flame	Pilot flame	Spark plug

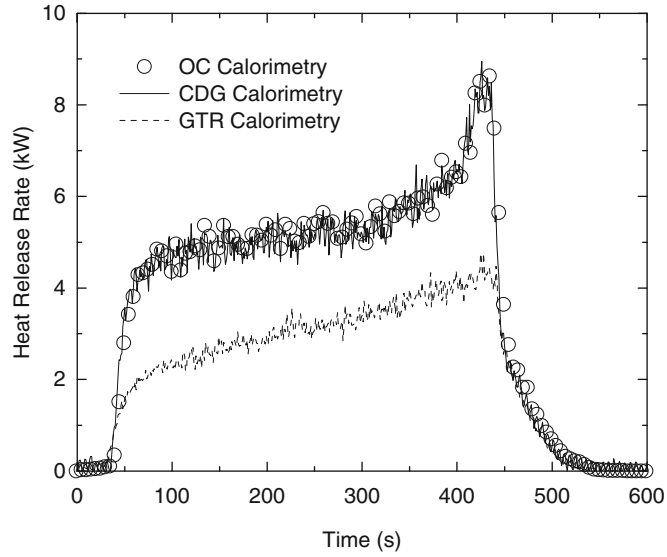

Fig. 36.5 Heat release rates determined employing the methodologies described in the text (CDG, OC, and GTR) for a 9.53-mm thick slab of polymethylmethacrylate (PMMA) exposed to an external heat flux of 50 kW/m^2 and 0.09 m/s co-flowing normal air in the Fire Propagation Apparatus

(kJ/kg/K) of the solid; their product represents the thermal inertia of the solid. T_{ig} and T_0 are the surface ignition temperature (K) and ambient temperature (K), respectively, $\dot{q}''_e$ and $\dot{q}''_{cr}$ are the incident heat flux (kW/m^2) and the critical heat flux for ignition (CHF) (kW/m^2), and χ is the average heat loss as a fraction of the critical heat flux and takes into account the fact that heat losses are initially zero and increase as the solid is heated to its ignition temperature. The square root of the term in the numerator of the right hand side of Equation 36.1 is sometimes referred to as the Thermal Response Parameter (TRP) [28]:

$$\mathrm{TRP} = \left(\frac{\pi}{4} k\rho c_p\right)^{1/2} \left(T_{ig} - T_0\right) \tag{36.2}$$

Under thermally thin conditions for solids of thickness d (m), the time to piloted ignition, $t_{ig(thin)}$, is based on the energy required to heat the material to its ignition temperature assuming a uniform temperature throughout the material:

$$t_{ig(thin)} = \frac{\rho c_p d \left(T_{ig} - T_0\right)}{\dot{q}''_e - \chi \dot{q}''_{cr}} \tag{36.3}$$

T_{ig} in Equations 36.1 and 36.3 is evaluated here assuming that reradiation heat losses dominate the ignition process so that $\dot{q}''_{cr} = \sigma\left(T_{ig}{}^4 - T_0{}^4\right)$ for a black surface, where σ is the Stephan-Boltzmann constant (kW/m^2/K^4).

The value of χ approximates the effect of heat losses during heat up of the solid. It was recommended [27] that $\chi = 0.64$ for thermally thick conditions assuming surface re-radiation losses close to $\dot{q}''_{cr}$ are dominant. After analyzing various materials, and considering both radiant and convective losses Khan et al. [29] proposed a single value of $\chi = 1.0$ for both thermally thin and thermally thick solids. A thermal diffusion time, τ_{th} (s), can be defined to demarcate the transition between thermally thick and thermally thin responses as [26, 29]:

$$\tau_{th} = \frac{4\rho c_p d^2}{\pi k} \tag{36.4}$$

Using Equations 36.1 and 36.4, the relationship between thermally thick and thin ignition behavior is given by [29]:

$$\begin{aligned} t_{ig(thin)} &= \left(\tau_{th} t_{ig(thick)}\right)^{1/2} \\ &= \frac{\left(\frac{\pi}{4} k\rho c_p\right)^{1/2} \left(T_{ig} - T_0\right)}{\dot{q}''_e - \chi \dot{q}''_{cr}} \left(\frac{4\rho c_p d^2}{\pi k}\right)^{1/2} \\ &= \frac{\rho c_p d \left(T_{ig} - T_0\right)}{\dot{q}''_e - \chi \dot{q}''_{cr}} \end{aligned} \tag{36.5}$$

A generalized form applicable to both regimes is [29]:

$$t_{ig(thick/thin)} = \left\{ \left[\frac{\dot{q}_e'' - \chi \dot{q}_{cr}''}{\left(\frac{\pi}{4} k\rho c_p\right)^{1/2} (T_{ig} - T_0)} \right]^4 \frac{1}{\tau_{th}{}^2} + \left[\frac{\dot{q}_e'' - \chi \dot{q}_{cr}''}{\left(\frac{\pi}{4} k\rho c_p\right)^{1/2} (T_{ig} - T_0)} \right]^8 \right\}^{-1/4} \tag{36.6}$$

The exponents ¼, 4, and 8 in Equation 36.6 provide a good fit to exact numerical solutions for transition between thermally thin and thick behavior [29]. In Equation 36.6, if t_{ig} is less than τ_{th} the response of the material becomes thermally thick; whereas, if t_{ig} is greater than τ_{th} the response becomes thermally thin. Thus τ_{th} provides the transition between thermally thin and thermally thick behaviors.

Critical Heat Flux (CHF)

The ignition and subsequent burning of a solid sample is sensitive to heat losses from the rear surface of the sample being tested. This heat loss depends on the sample holder and its surrounding environment. Theoretical studies of ignition and pyrolysis in flammability apparatuses show that the construction of the sample holder has a surprisingly large effect on measured parameters, especially for solids having thermally thin behavior near the critical heat flux [30]. This makes flammability measurements apparatus dependent. One naturally wishes to minimize any such heat losses, but to whatever extent such losses remain, they must be made reproducible and quantifiable so that one can correct for their presence. To minimize apparatus dependencies, de Ris and Khan have designed an insulated sample holder [30] that minimizes heat losses from the rear and sides of the sample being heated. The holder ensures that thermal processes remain one-dimensional so as to conform to most theoretical analyses used to interpret data.

The critical heat flux may provide a measure of the ignition temperature of a given material if, as stated above, one assumes that all heat losses near the CHF are dominated by radiation; this, again, reinforces the need for a well-insulated sample. Empirically, the CHF is obtained by collecting piloted ignition data in a flammability apparatus, such as the FPA, over a range of (low) heat fluxes. By plotting the inverse of time to ignition versus heat flux and using Equation 36.3, the intercept of a best-fit line on the heat flux axis corresponds to the CHF. Alternatively, ignition tests may be also performed in search of the heat flux for which no ignition occurs after a specified threshold (e.g., 15 min).

Thermal Response Parameter (TRP)

TRP is a very useful parameter for engineering calculations to assess resistance to ignition and fire propagation. For thermally thick materials, the inverse of the square root of time to ignition is expected to be a linear function of the external heat flux away from the CHF value (see Equation 36.1). The inverse of the slope of the line is the TRP (see Equations 36.1 and 36.2). Most commonly used materials behave in a thermally thick manner at practical fire conditions and, thus, satisfy Equation 36.1. This behavior is shown in Fig. 36.6 for polymethylmethacrylate (PMMA) [31]; in Fig. 36.7 for heavy corrugated paper sheets; and in Fig. 36.8 for cone calorimeter data [32].

The TRP value is determined, for example, in the Fire Propagation Apparatus, by (1) measuring the time to ignition for 100 mm × 100 mm square or 100-mm diameter and up to 25-mm-thick samples at different external heat flux values. The sample surfaces are blackened with a very thin layer of black paint or fine graphite powder to avoid errors due to differences in the radiation absorption characteristics of the materials, and (2) performing a linear regression analysis of the data away from the critical heat

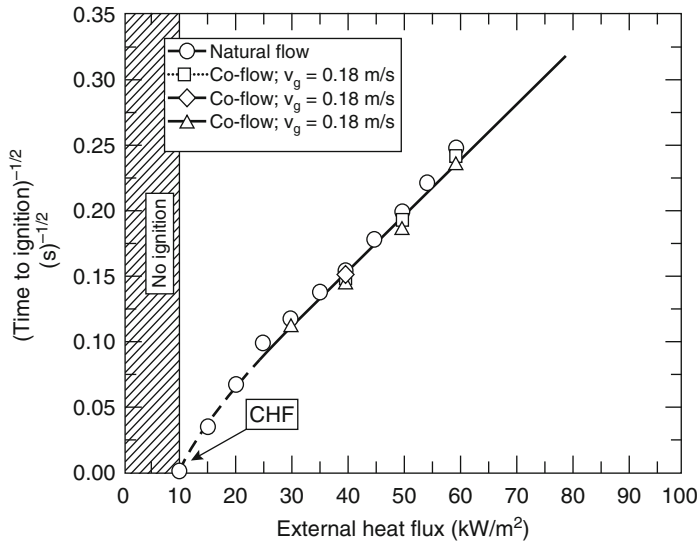

Fig. 36.6 Square root of the inverse of time to ignition versus external heat flux for 100-mm × 100-mm × 25-mm-thick polymethylmethacrylate (PMMA) slab with a blackened surface. Data measured in the Fire Propagation Apparatus [31]

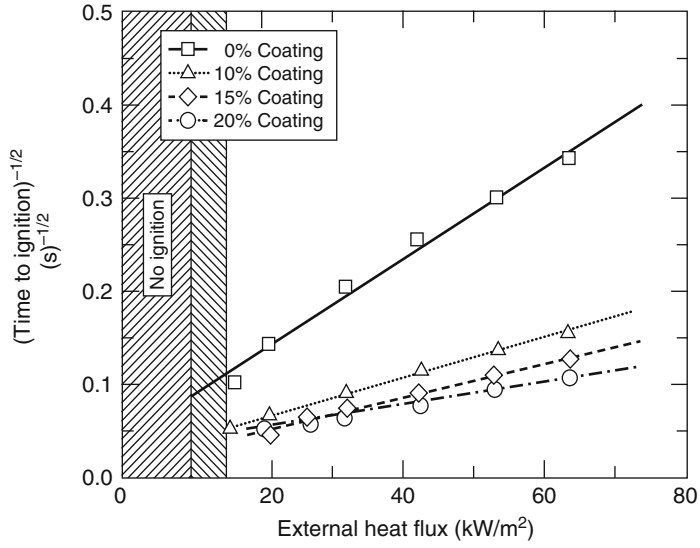

Fig. 36.7 Square root of the inverse of time to ignition versus external heat flux for two 100-mm × 100-mm × 11-mm-thick sheets of heavy corrugated paper with various levels of fire protection coating. Data measured in the Fire Propagation Apparatus. Lines are linear fits to the data; TRP values derived from the fits are given in Table A.35

flux condition, following Equation 36.1, and recording the inverse of the slope of the line.

The TRP for a surface may vary depending on whether or not it is blackened. For example, for nonblackened and blackened surfaces of polymethylmethacrylate (PMMA), TRP = 434 and 274 kW · s$^{1/2}$/m^2, respectively [31]. The TRP value for a blackened surface of PMMA is close to the value calculated from the known T_{ig}, k, ρ, and c_P values for PMMA [31]. These results highlight the importance of a well-defined boundary condition, provided by an appropriate high absorptivity surface coating, in ignition tests. Uncoated samples may be subject to other phenomena such as in-depth radiation [33] as well as the spectral characteristics of both sample surface and radiation source [34, 35]. It is for these reasons that standard FPA tests [10, 11] require that samples be coated with high emissivity paint to ensure surface absorption of imposed heat flux.

TRP depends on the chemical as well as the physical properties of materials, such as the

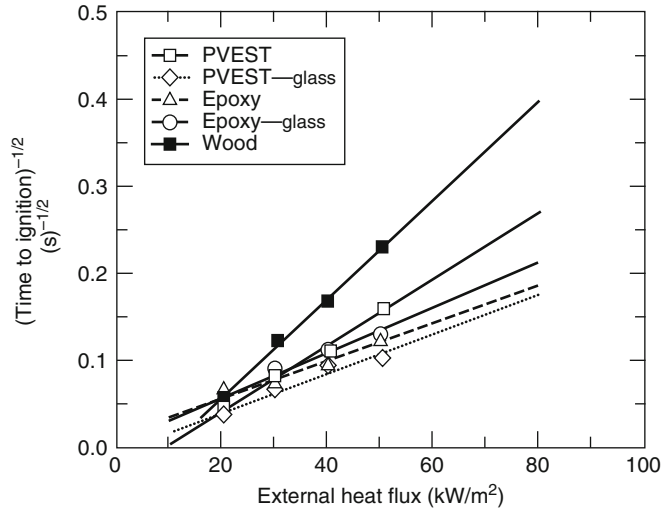

Fig. 36.8 Square root of the inverse of time to ignition versus external heat flux for 100-mm × 100-mm nonblackened surfaces of 10-mm × 11-mm-thick polyvinyl ester (PVEST), 11-mm-thick epoxy, and 6-mm-thick wood (hemlock). Data measured in the cone calorimeter [32]

chemical structure, fire retardants, etc. For example, Fig. 36.9 shows that TRP increases with sample thickness for a composite material (polyester/fiberglass) and increases in the amount of passive fire protection agent used, such as that provided by a surface coating to a heavy corrugated paper sheet (see Fig. 36.7). The TRP response versus thickness shown in Fig. 36.9 is counterintuitive given that TRP is strictly defined for thermally thick materials; this response is a result of the composite material considered and evidences the effect of physical structure and nonhomogeneity of the material.

CHF and TRP values for several materials derived from data for time to ignition versus external heat flux are listed in Table A.35. The ranges of CHF and TRP values in Table A.35 are due to differences in the compositions of materials having similar generic natures and differences in the test procedures, such as the use of an insulated sample holder, as described above.

Examples of calculated TRP values, using available T_{ig}, k, ρ, and c_p data and Equation 36.2, and those measured are listed in Tables A.36 and A.37. The calculated and measured TRP values (TRP_{cal} and TRP_{meas}, respectively) are plotted in Fig. 36.10. For ordinary polymers that do not contain halogen atoms and do not char significantly, the TRP_{cal} value is only about 17 % lower than the TRP_{meas} value, but for highly charring, high-temperature, engineered polymers and highly halogenated polymers, the TRP_{cal} values are significantly lower than the TRP_{meas} values. There is strong flame retardation by the fuel vapors of the highly halogenated polymers with a significant reduction in the fuel vapor concentration due to charring. Thus, for the ordinary polymers, thermal arguments to describe the ignition behavior (Equations 36.1 and 36.2) are sufficient, but not for the highly charring, high-temperature, engineered polymers and highly halogenated polymers.

The effects of the fuel vapors of the highly charring, high-temperature, engineered polymers and highly halogenated polymers on the ignition behavior can be compensated by performing the ignition experiments under enhanced oxygen concentration and, thus, thermal arguments again can be used to describe the ignition behavior. This is supported by the data reported by Khan and de Ris [36], which are listed in Table 36.2.

Example 1 In a fire, newspaper and polypropylene are exposed to a heat flux value of 50 kW/m^2. Estimate which material will ignite first, assuming physical conditions to be very similar for both the materials.

Solution From Table A.35, for newspaper and polypropylene, CHF = 10 and 15 kW/m^2, respectively, and TRP = 108 and 193 kW · s$^{1/2}$/m^2,

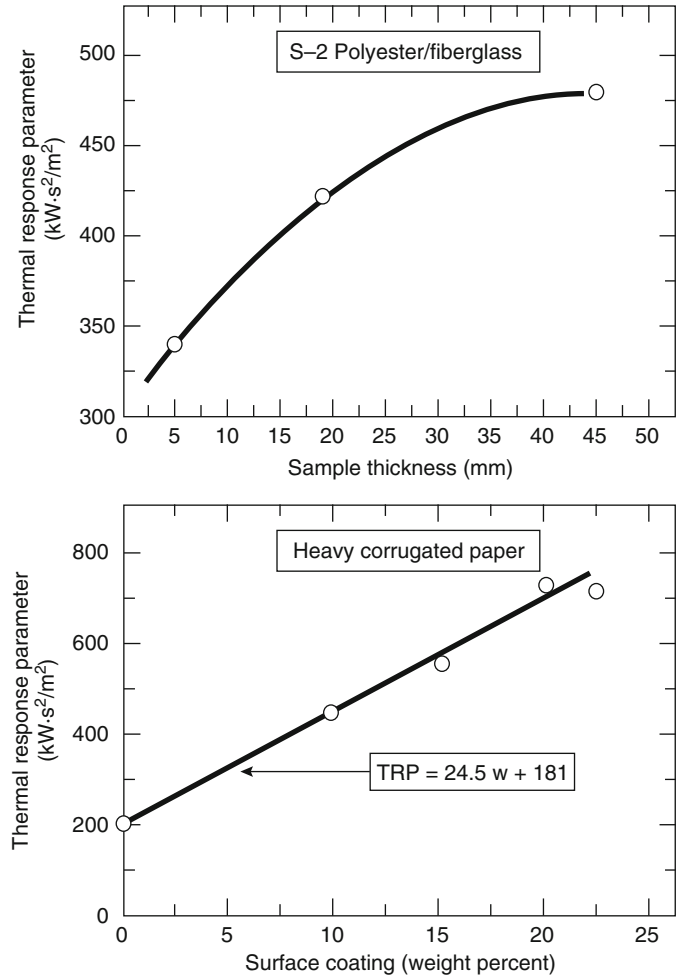

Fig. 36.9 Thermal response parameter versus thickness for S-2 polyester/fiberglass sample and weight percent of surface coating for the heavy corrugated paper (see Fig. 36.7). Data measured in the Fire Propagation Apparatus. *w* weight %

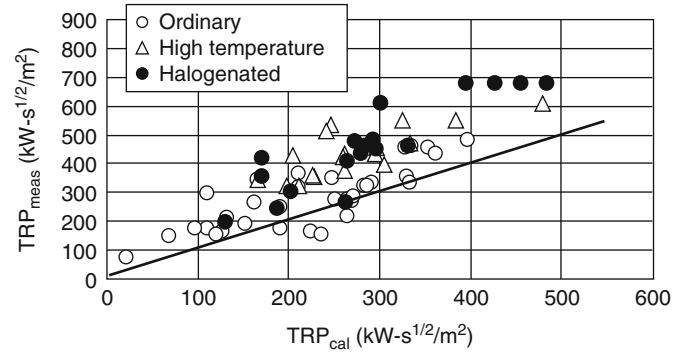

Fig. 36.10 Calculated versus measured values of the thermal response parameter

respectively. Substituting these values in Equation 36.1 with $\dot{q}_e'' = 50$ kW/m^2, the times to ignition are calculated to be 6 and 24 s for newspaper and polypropylene, respectively. Thus, newspaper will ignite first.

Example 2 Halogenated materials are obtained by replacing hydrogen atoms with halogen atoms in the chemical structures of the materials. For example, a unit in polyethylene (PE) consists of C_2H_4. If a hydrogen atom (H) is replaced by a

Table 36.2 Thermal response parameter values measured in normal air and 40 % oxygen concentration and calculated from physical properties [23, 37]

Polymer	TRP_{meas} (kW·s$^{1/2}$/m^2)		TRP_{cal} (kW·s$^{1/2}$/m^2)
	Normal air	40 % oxygen	
Ordinary polymers			
Polymethylmethacrylate (PMMA)	239	230	264
Polyoxymethylene (POM)	252	260	269
Polypropylene/fire retarded	276	301	242
Halogenated polymers			
Polyvinylchloride (PVC)—rigid	498	200	171
Chlorinated PVC (CPVC)—rigid	435[a]	230	280
Polyvinylchloride (PVDF)	447–508	324	301

[a]Data from Table A.35

chlorine atom (Cl) in a PE unit, it becomes a unit of rigid polyvinylchloride (PVC), that is, C_2H_3Cl. If two H atoms are replaced by two fluorine atoms (F) in a PE unit, it becomes a unit of Tefzel (ethylene tetrafluorethylene), that is, $C_2H_2F_2$. If all the hydrogen atoms are replaced by four F atoms in a PE unit, it becomes a unit of Teflon (polytetrafluoroethylene), that is, C_2F_4. Show how the replacement of hydrogen atoms by the halogen atoms affects the ignitability of the materials.

Solution From Table A.35, for PE (high density), PVC (rigid), Tefzel, and Teflon, the CHF values are 15, 15, 27, and 38 kW/m^2, respectively, and the TRP values are 321, 406, 356, and 682 kW · s$^{1/2}$/m^2, respectively. In the calculations, it is assumed that these materials are exposed to a uniform heat flux of 60 kW/m^2 in a fire under very similar physical conditions. From Equation 36.1, using $\dot{q}_e'' = 60$ kW/m^2, the times to ignition for PE (high density), PVC (rigid), Tefzel, and Teflon are calculated to be 40, 64, 91, and 755 s, respectively. Thus, resistance to ignition increases as the hydrogen atom is replaced by the halogen atom in the chemical structure of PE. The higher the number of hydrogen atoms replaced by the halogen atoms in the structure, the higher the resistance to ignition. When all the hydrogen atoms are replaced by the fluorine atoms, the material becomes highly resistant to ignition.

Fire Propagation

The fundamental surface flame spread principles are described in Chap. 23. According to these principles, the fire propagation process, as indicated by surface flame spread, can be explained as follows. As a material is exposed to heat flux from internal and/or external heat sources, a combustible mixture is formed that ignites, and a flame anchors itself on the surface in the ignition zone. As the vapors of the material burn in the flame, they release heat with a certain rate, defined as the chemical heat release rate. Part of the chemical heat release rate is transferred beyond the ignition zone as conductive heat flux through the solid and as convective and radiative heat fluxes from the flame. If the heat flux transferred beyond the ignition zone satisfies CHF, TRP, and gasification requirements of the material, the pyrolysis and flame fronts move beyond the ignition zone, increasing the burning surface area. Consequently, flame height, chemical heat release rate, and heat flux transferred ahead of the pyrolysis front all increase. The pyrolysis and flame fronts move again, and the process repeats itself further increasing the burning area. Fire propagation on the surface continues as long as the heat flux transferred ahead of the pyrolysis front (from the flame or external heat sources) satisfies CHF, TRP, and gasification requirements of the material.

The rate of movement of the pyrolysis front is generally used to define the fire propagation rate:

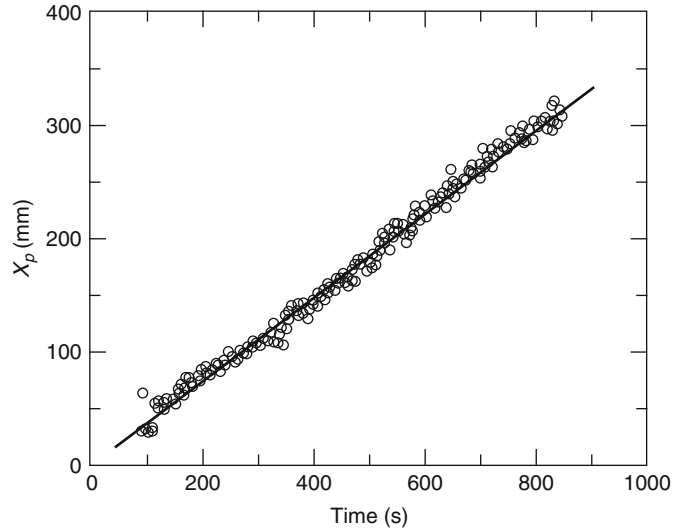

Fig. 36.11 Pyrolysis front versus time for downward fire propagation for a 300-mm-long, 100-mm-wide, and 25-mm-thick PMMA vertical slab under opposed airflow conditions in the Fire Propagation Apparatus. Airflow velocity = 0.09 m/s. Oxygen mass fraction = 0.334 (Figure is taken from Ref. [31])

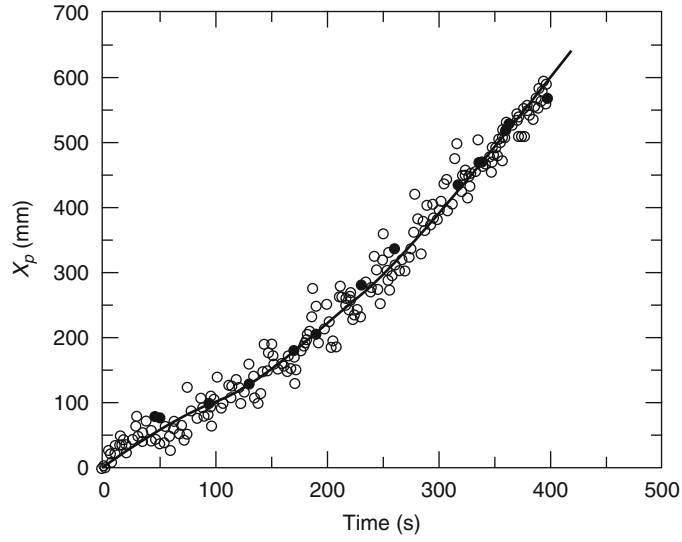

Fig. 36.12 Pyrolysis front versus time for upward fire propagation for a 600-mm-long, 100-mm-wide, and 25-mm-thick PMMA vertical slab under co-airflow conditions in the Fire Propagation Apparatus. Airflow velocity = 0.09 m/s. Oxygen mass fraction = 0.233 (Figure is taken from Ref. [31])

$$u = \frac{dX_p}{dt} \tag{36.7}$$

where u is the fire propagation rate (mm/s or m/s), and X_p is the pyrolysis front length (mm or m).

The fire propagation rate can be determined in one of several apparatuses: (1) the LIFT [37] described in Chap. 23; (2) the Fire Propagation Apparatus [10, 11] shown in Fig. 36.3. Examples of the type of data obtained from the FPA are shown in Figs. 36.11, 36.12, 36.13, and 36.14. In Fig. 36.14, heat release rates increase linearly with time during downward fire propagation, very similar to the pyrolysis front values for the downward fire propagation in Fig. 36.11.

The trends of the lines in Figs. 36.11, 36.12, 36.13, and 36.14 represent fire propagation rates. The upward fire propagation rate is much faster than the downward fire propagation rate. For downward fire propagation, linear increases in the pyrolysis front and heat release rates indicate decelerating fire propagation behavior. For upward fire propagation, nonlinear increases

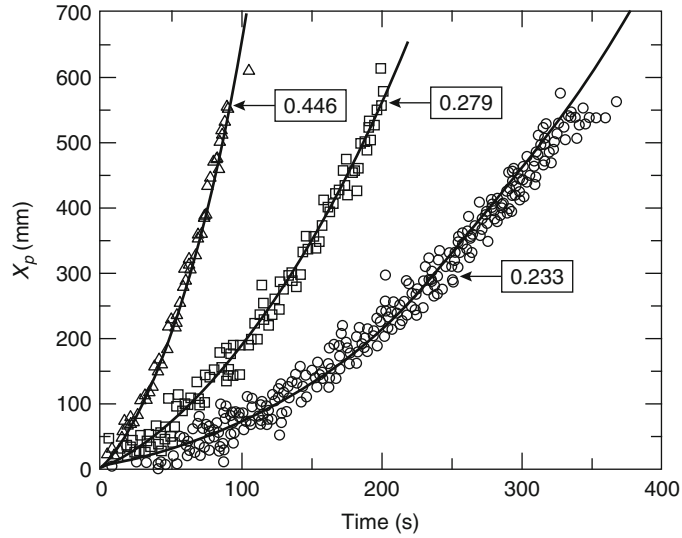

Fig. 36.13 Pyrolysis front height versus time for upward fire propagation for a 600-mm-long and 25-mm-thick diameter PMMA cylinder under co-airflow conditions in the Fire Propagation Apparatus. Airflow velocity = 0.09 m/s. *Numbers* inside the frames are the mass fractions of oxygen in air (Figure is taken from Ref. [31])

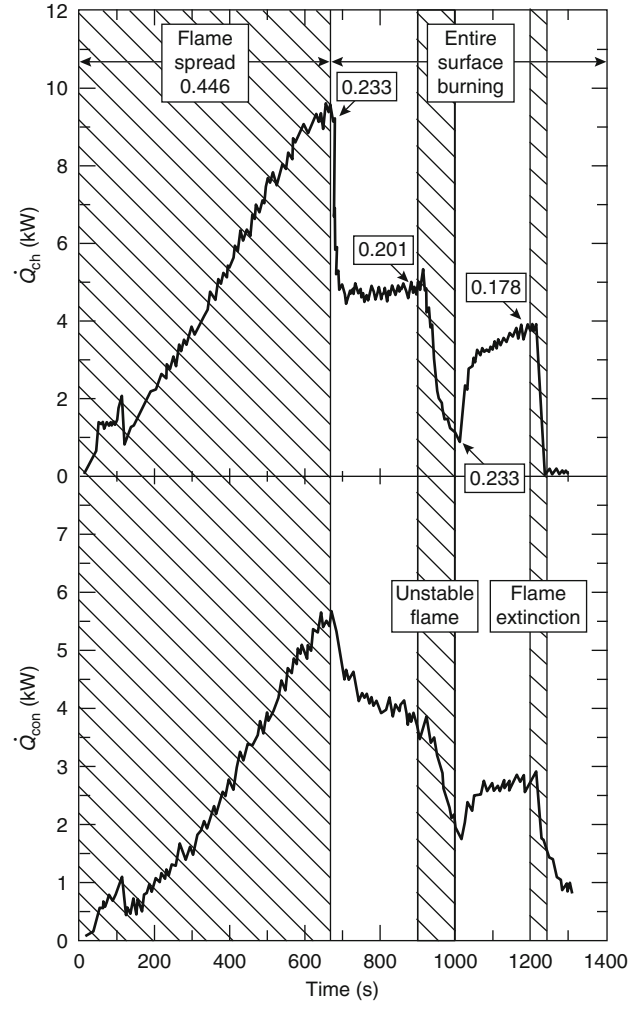

Fig. 36.14 Chemical (*top*) and convective (*bottom*) heat release rate versus time for downward fire propagation, combustion, and flame extinction for a 300-mm-long, 100-mm-wide, and 25-mm-thick PMMA vertical slab under opposed airflow conditions in the Fire Propagation Apparatus. Airflow velocity = 0.09 m/s. *Numbers* inside the frames are the mass fractions of oxygen in air (Figure is taken from Ref. [31])

in the pyrolysis front indicate accelerating fire propagation behavior.

Empirical Relationship Between Fire Propagation Rate, Flame Height, Pyrolysis Front, and Heat Release Rate

Numerous researchers have found the following relationship between the flame height and pyrolysis front (as discussed in Chap. 13, and reviewed in Refs. [31, 38]):

$$X_f = aX_p^n \tag{36.8}$$

where
X_f = Flame height (m)
$a = 5.35$
$n = 0.67–0.80$
for steady wall fires [31]. X_p is in m.

Fire propagation data for PMMA from the FPA and for electrical cables from several standard tests (ICEA [39], CSA FT-4 [40], and UL-1581 [41]) satisfy Equation 36.8, as shown in Fig. 36.15, with $a = 5.32$ and $n = 0.78$. The visual measurement of the pyrolysis front as damage length is used for the acceptance criterion in many of the standard tests for electrical cables. For example, for upward fire propagation in the CSA FT-4, a damage length of less than 60 % of the total length of the cable tray for a 20-min exposure is used as the acceptance criterion. For horizontal fire propagation in the UL-1581 test, a flame length of less than 40 % of the total length of the cable tray is used as the acceptance criterion.

The relationship between the flame height and the chemical heat release rate, expressed as the normalized chemical heat release rate (NCHRR), is defined as

$$\text{NCHRR} = \frac{\dot{Q}'_{\text{ch}}}{\rho c_p T_a g^{1/2} X_p^{3/2}} \tag{36.9}$$

where
$\dot{Q}'_{\text{ch}}$ = Chemical heat release rate per unit width (kW/m)
ρ = Density of air (g/m^3)
c_p = Specific heat of air (kJ/g · K)
T_a = Ambient temperature (K)
g = Acceleration due to gravity (m^2/s)
X_p is in m.

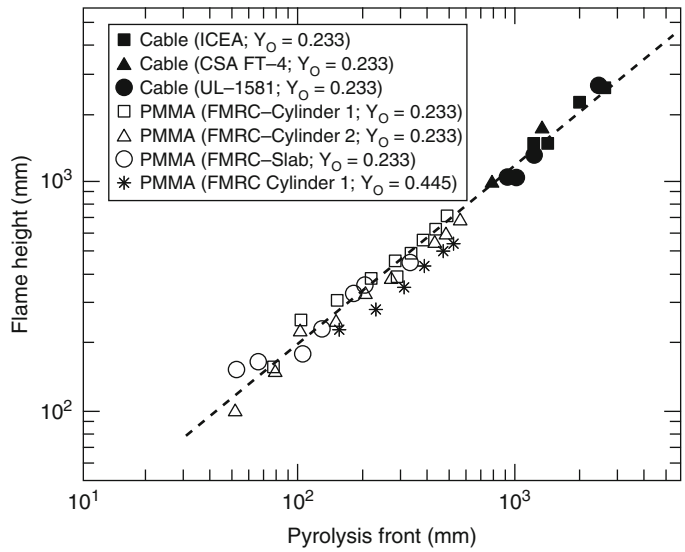

Fig. 36.15 Flame height versus pyrolysis front height for upward fire propagation in normal air. Data are for the vertical fire propagation for electrical cables contained in 2.44-m-long, 310-mm-wide, and 76-mm-deep trays in standard tests for electrical cables (ICEA, CSA FT-4, and UL-1581) and for 600-mm long PMMA slabs (100-mm-wide and 25-mm-thick) and cylinders (25-mm diameter) in the Fire Propagation Apparatus. Data for fire propagation in an oxygen mass fraction of 0.445 are also included (Figure is taken from Ref. [31])

Many researchers have shown that the height ratio of the flame to the pyrolysis front is a function of the heat release rate, such as the following relationship (as discussed in Chap. 13, and reviewed in Refs. [31, 38]):

$$\frac{X_f}{X_p} = a(\text{NCHRR})^n \tag{36.10}$$

where a and n are constants. This relationship reported in the literature (as reviewed in Ref. [31]) for methane, ethane, and propylene is shown in Fig. 36.16. The data for the upward fire propagation for PMMA [31] and for electrical cables from several standard tests (ICEA [39], CSA FT-4 [40], and UL-1581 [41]) also satisfy this relationship as indicated in Fig. 36.16.

In Fig. 36.16, data in the lower left-hand corner are for low-intensity polyvinylchloride (PVC) electrical cable fire propagation in standard tests for cables. These data show that for NCHRR < 0.2, $X_f/X_p < 1.5$ and $n = 1/10$. This is a characteristic property of materials for which there is either no fire propagation or limited fire propagation beyond the ignition zone. The data for higher-intensity fire propagation in Fig. 36.16 show that (1) for $0.2 <$ NCHRR < 5, $n = 2/3$ and $1.5 < X_f/X_p < 20$ (PMMA fire propagation and methane combustion); and (2) for NCHRR > 5, $n = 1/2$ and $X_f/X_p > 20$ (ethane and propylene combustion). Thus, the ratio of the flame height to pyrolysis front height is a good indicator of the fire propagation characteristics of the materials. Materials for which flame height is close to the pyrolysis front location during fire propagation can be useful indicators of decelerating fire propagation behavior.

Researchers have also developed many correlations between the flame heat flux transferred ahead of the pyrolysis front and heat release rate for downward, upward, and horizontal fire propagation (as discussed in Chap. 23, and reviewed in Refs. [31, 38]). For example, small- and large-scale fire propagation test data suggest that, for thermally thick materials with highly radiating flames, the following semiempirical relationship is satisfied [28]:

$$\dot{q}''_f \propto \left(\frac{\chi_{\text{rad}}}{\chi_{\text{ch}}}\dot{Q}'_{\text{ch}}\right)^{1/3} \tag{36.11}$$

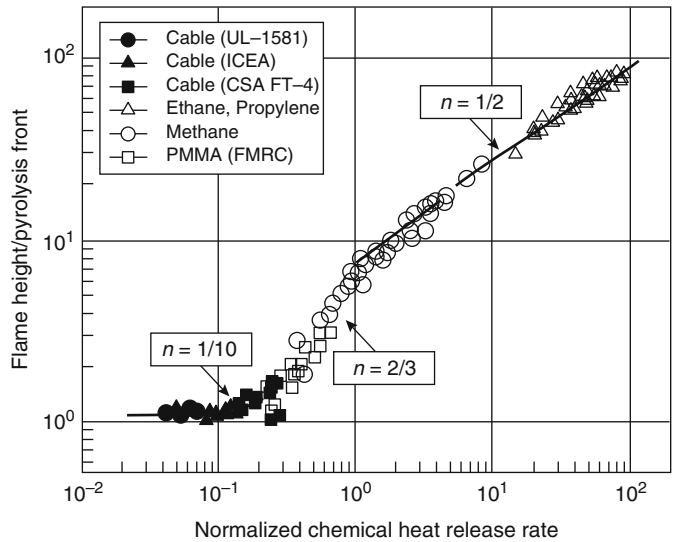

Fig. 36.16 Ratio of flame height to pyrolysis front height versus the normalized chemical heat release rate for upward fire propagation in normal air. Data for diffusion flames of methane, ethane, and propylene are from the literature. Data for cables are from standard tests for electrical cables (ICEA, CSA FT-4, and UL-1581). Data for PMMA are from the Fire Propagation Apparatus for 600-mm-long vertical PMMA slabs (100-mm-wide, 25-mm-thick) and cylinders (25-mm-diameter) [31]

where $\dot{q}''_f$ is the flame heat flux transferred ahead of the pyrolysis front (kW/m^2) and χ_{rad} is the radiative fraction of the combustion efficiency, χ_{ch}. The fire propagation rate is expressed as [28]

$$u^{1/2} \propto \frac{1}{TRP}\left(\frac{\chi_{rad}}{\chi_{ch}}\dot{Q}'_{ch}\right)^{1/3} \tag{36.12}$$

On the basis of the discussion above, an emprical parameter termed *fire propagation index* (FPI) [16, 17, 28, 42–46] has been defined:

$$FPI = 750\frac{\dot{Q}'^{1/3}_{ch}}{TRP} \tag{36.13}$$

FPI describes the fire propagation behavior of materials under flame-radiating conditions prevalent in large-scale fires. Small- and large-scale fire propagation test data of various materials along with understanding of fire propagation phenomena suggest that the FPI values can be used to classify materials as either propagating (fire propagates rapidly beyond ignition zone) and non-propagating (there is no fire propagation beyond the ignition zone) [28, 31, 43–46]. These FPI-based determinations have been validated by using intermediate-scale parallel panel tests (e.g., [19]) as shown in Figs. 36.17 and 36.18 and described below.

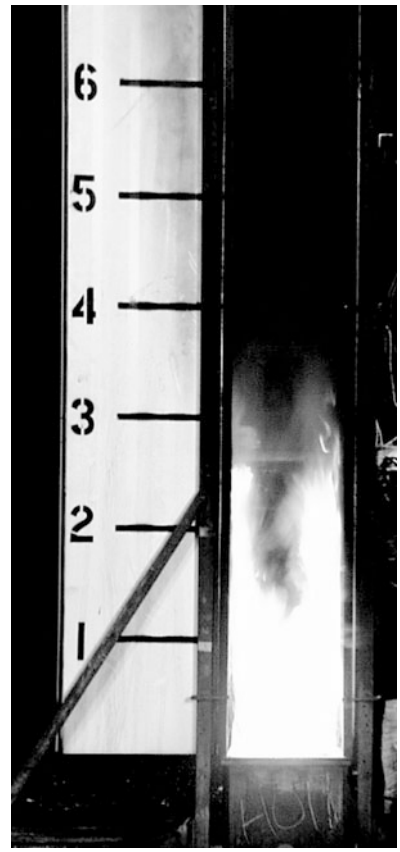

Fig. 36.17 Nonpropagating fire between two vertical parallel panels of a polymer (FPI < 6) for a test duration of 15 min [19]. The panels are about 0.61 m (2 ft) wide, 2.44 m (8 ft) high, and 25 mm (1 in) thick separated by 0.30 m (1 ft). The ignition source is a 60-kW, 0.30-m-wide, 0.61-m-long, and 0.30-m-high propane sand burner. The tip of the flame from the burner reaches a height of about 0.91 m (3 ft). Marks on the scale are in feet

Application of the Fire Propagation Index (FPI) to Classify Materials

The FPI values for the upward fire propagation, under flame-radiating conditions, have been determined for numerous materials at reduced scales in the Fire Propagation Apparatus. The highly radiating conditions, representative of large-scale fires, are created in the FPA by burning the materials in an enhanced oxygen environment (0.40 oxygen mass fraction). Two sets of tests are performed:

1. ***Thermal response parameter test:*** Ignition tests are performed in the FPA (materials are arranged as in Fig. 36.2), and the TRP value is determined from the time to ignition versus external heat flux as described in the subsection "Thermal Response Parameter (TRP)".
2. ***Upward fire propagation test:*** Fire propagation tests for vertical slabs, sheets, or cables are performed in the FPA (materials are arranged as in Fig. 36.3). About 300–600-mm-long, up to about 100-mm-wide, and up to about 100-mm-thick samples are used. The bottom 120–200 mm of the sample is in the ignition zone, where it is exposed to 50 kW/m^2 of external heat flux in the presence of a pilot flame. Beyond the ignition zone, the fire propagates by itself under co-airflow condition with an oxygen mass fraction of 0.40. During upward fire propagation, the chemical heat release rate is measured as a function of time.

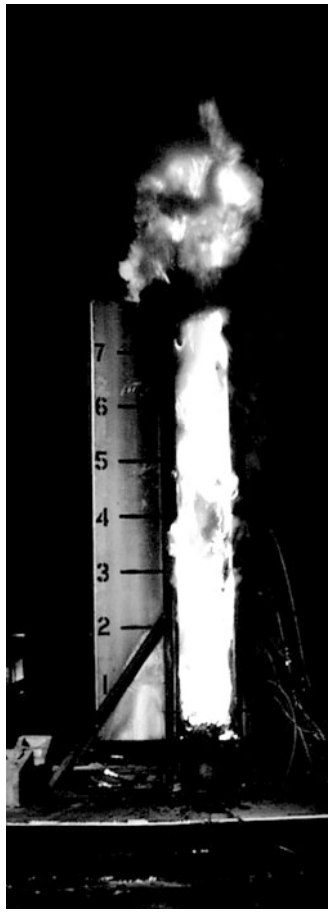

Fig. 36.18 Rapidly propagating fire between two vertical parallel panels of a polymer (FPI > 20) [19]. The panels are about 0.61 m (2 ft) wide, 2.44 m (8 ft) high, and 25 mm (1 in.) thick separated by 0.30 m (1 ft). The ignition source is a 60-kW, 0.30-m-wide, 0.61-m-long, and 0.30-m-high propane sand burner. The tip of the flame from the burner reaches a height of about 0.91 m (3 ft). Marks on the scale are in feet. The photograph was taken a few seconds before flames extended far beyond the top of the panels

The TRP value and the chemical heat release rate so determined are used in Equation 36.13 to calculate the FPI; the maximum (peak) measured chemical heat release rate value is used in the calculation.

Electrical Cables The FM Approval standard for cable fire propagation [17] is used to classify electrical cables, based on their upward fire propagation behavior, under highly flame-radiating conditions (0.40 oxygen mass fraction). A parallel panel intermediate scale test configuration was first introduced in 1988 [28] to verify the fire propagation behavior of electrical cables based on the fire propagation index (FPI), derived from bench-scale FPA measurements. It consists of two parallel panels of test material, each 0.61 m wide and 4.9 m long facing each other with a separation of about 0.31 m (keeping an aspect ratio of the panel width to the separation distance as 0.5). A 60 kW propane sand burner continuously provides an exposure fire at the base of the two panels. This intermediate scale test scenario contains the essential features of fire phenomena expected at larger scales, most notably enhanced radiant fluxes due to the radiation feedback between the panels. This test configuration provides sufficient size and confinement of flames to yield realistic flame heat transfer to the materials (see Figs. 36.17 and 36.18).

The nonpropagating fire condition is satisfied for FPI $\leq$ 10.0 for electrical cables (classified as Group 1) [17] that do not exhibit flame propagation beyond the vicinity of the ignition source in the parallel panel tests. In a recent study [46], plenum rated cables, having FPI values of $\leq$7.0, did not exhibit flame propagation in the parallel panel tests. Table 36.3 lists FPI values for selected electrical cables and conveyor belts.

Example 3 What type of fire behavior is represented by a 300-mm-wide, 8-m-high, and 25-mm-thick vertical cable array with a TRP value of 95 kW $\cdot$ $s^{1/2}/m^2$ if the peak chemical heat release during upward fire propagation is 50 kW?

Solution Fire propagation behavior is assessed by the FPI value. For the cable material, the chemical heat release rate per unit width, $\dot{Q}'_{ch} = 50/0.3 = 167$ kW/m. Substituting this value in Equation 36.13, with TRP = 95 kW $\cdot$ $s^{1/2}/m^2$, FPI = 43. The cable material will propagate fire.

Conveyor Belts A conveyor belt standard has been developed at FM Global [20]. In this

Table 36.3 Fire propagation index for cables and Conveyor belts, determined in the Fire Propagation Apparatus

	Diameter/ thickness (mm)	FPI

CR/SBR		8
PVC		4–10

[a]3–25 mm thick

standard, as with the cable standard [17], TRP and upward fire propagation tests are performed, and Equation 36.13 is used to calculate the FPI.

Conveyor belts are classified as propagating or non-propagating. For an approximately 600-mm-long and 100-mm-wide vertical conveyor belt, the data measured in the FPA under highly flame-radiating conditions show that the nonpropagating fire condition is satisfied for FPI $\leq$ 7.0 for belts that show limited fire propagation in the large-scale fire propagation tests [45, 47]. Table 36.3 lists FPI values for selected conveyor belts taken from Refs. [45, 47].

Example 4 Conveyor belts are made of solid woven or piles of elastomers, such as styrene-butadiene rubber (SBR), polychloroprene rubber (CR), polyvinylchloride (PVC), reinforced with fibers made of polymers, such as nylon. In large-scale fire propagation tests in a tunnel, fire on the surface of a CR-based conveyor belt was found to be nonpropagating, whereas for a CR/SBR-based conveyor belt fire was found to be propagating. Small-scale tests showed that the CR- and CR/SBR-based conveyor belts had the following fire properties, respectively: (1) CHF = 20 and 15 kW/m^2, (2) TRP = 760 and 400 $kW \cdot s^{1/2}/m^2$, and (3) peak $\dot{Q}'_{ch}$ = 114 and 73 kW/m under highly flame-radiating conditions (0.40 oxygen mass fraction). Show that small-scale test results are consistent with the large-scale fire propagation behaviors of the two conveyor belts, using the criterion that, for nonpropagating fire behavior, the FPI is equal to or less than 7.

Solution Substituting the TRP and $\dot{Q}'_{ch}$ values in Equation 36.13, the FPI values for the CR- and CR/SBR-based conveyor belts are 5 and 8, respectively. Thus, the CR-based conveyor belt is expected to have a nonpropagating fire behavior, whereas the CR/SBR-based conveyor belt is expected to have a propagating fire behavior. The small-scale test results, therefore, are consistent with the large-scale fire propagation behaviors of the two conveyor belts.

Polymeric Materials For Cleanrooms - Microchip devices are manufactured, in bulk, on wafers of semiconducting materials. Wafers are manufactured in several stages: material preparation, crystal growth and wafer preparation, wafer fabrication, and packaging. Wafers are fabricated in cleanrooms where cleanliness is highly controlled in order to limit the number of contaminants to which the wafer is exposed. The stringent requirements of the solid-state devices define levels of cleanliness that far exceed those of almost any other industry. Contamination in a cleanroom is defined as anything that interferes with the production of wafers and/or their performance. The overall cleanroom

design principle is to build a sealed room that is supplied with clean air, is built with polymeric materials that are noncontaminating, and includes systems to prevent accidental external contamination, interactions of the polymeric materials and wafer cleaning liquids, operator error, and accidental fires.

In 1997, FM Global Research introduced a new methodology, identified as the FM Approval Standard 4910 Test Protocol [19], for testing the fire propagation and smoke development behaviors of polymeric materials for use in cleanrooms for the semiconductor industry. For the acceptance of polymeric materials, two criteria need to be satisfied: (1) Fire Propagation Index FPI ≤ 6 $(m/s^{1/2})/(kW/m)^{2/3}$ and (2) Smoke Development Index SDI ≤ 0.4 (g/g) $(m/s^{1/2})/(kW/m)^{2/3}$.

In the 4910 Test Protocol [19], the Fire Propagation Index (FPI) is formulated from (1) the thermal response parameter (TRP), which relates the time to ignition to the net heat flux, and (2) the chemical heat release rate measured during the upward fire propagation in air having a 40 % oxygen concentration to simulate flame heat transfer at large scale, as described above. SDI is related to the smoke release rate and is obtained by multiplying the FPI value by the smoke yield as shown in Fig. 36.19. The smoke yield is defined as the ratio of the total mass of smoke released per unit mass of burned vapors from the polymeric material (see section "Generation of Fire Products and Smoke Yields" of this chapter). The FPI and SDI values for various polymeric materials (including composites) determined from FPA tests are listed in Table 36.4 [19, 43, 44, 48, 49].

It can be noted from Table 36.4 that specialty polymeric materials (highly halogenated thermoplastics and high temperature thermosets) have low FPI and SDI values and several of them satisfy the 4910 test protocol criteria (FPI ≤ 6 $(m/s^{1/2})/(kW/m)^{2/3}$ and SDI ≤ 0.4 $(g/g)(m/s^{1/2})/(kW/m)^{2/3}$) for acceptance as cleanroom materials [19]. These polymeric materials have high thermal stability with reduced release of carbon, hydrogen, and halogen atoms, as can be noted from their decomposition temperatures listed in Table 36.5 [50]. Ordinary thermoplastics (such as PE, PP, and PVC) can also be modified such that they behave similarly to the specialty polymeric materials and have low FPI and SDI values to satisfy the 4910 Test Protocol criteria for acceptance as cleanroom materials.

Composites and Fiberglass-Reinforced Materials Composites and fiberglass-reinforced materials are very attractive because of their low weight and high strength characteristics and have found practical applications in a large number of sectors such as in aircrafts, submarines, naval ships, military tanks, public transportation vehicles including automobiles, space vehicles, tote boxes, pallets, chutes, and so forth. Fire propagation, however, is one of the major concerns for

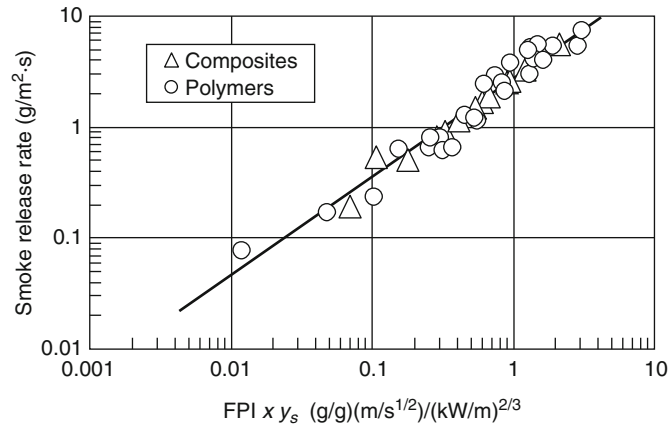

Fig. 36.19 Peak smoke release rate measured in combustion tests in normal air with imposed external heat flux of 50 kW/m^2 versus peak FPI values from the propagation tests in 40 % oxygen environments multiplied by the smoke yields from the combustion tests. Tests were performed in the Fire Propagation Apparatus

composites and fiberglass-reinforced materials; therefore, the FPI concept discussed above for electrical cables and conveyor belts can also be applied to these materials [43, 44]. In the case of composites and fiberglass-reinforced materials the nonpropagating fire condition is satisfied for FPI $\leq$ 6.0, for about 600-mm-long and 100-mm-wide vertical composites and fiberglass-reinforced materials, under highly flame-radiating conditions (0.4 oxygen mass fraction), very similar to the conveyor belts. Table 36.4 lists FPI values for selected composites and fiberglass-reinforced materials [43, 44].

Interior Finish Wall/Ceiling Materials Since 1971, FM Global Research has used the 25-ft (7.6 m) corner test as a standard test to evaluate the burning characteristics of interior finish wall and ceiling materials [18]. The 25-ft (7.6 m) corner test is performed in a 7.6-m (25-ft)-high, 15.2-m (50-ft)-long and 11.6-m (38-ft)-wide building corner configuration [51, 52]. The materials tested are typically panels with a metal skin over an insulation core material. The materials installed in the corner configuration are subjected to a growing exposure fire (peak heat release rate of about 3 MW) comprised of about 340 kg (750 lb) of 1.2-m (4-ft) $\times$ 1.2-m (4-ft) wood (oak) pallets stacked 1.5 m (5 ft) high at the base of the corner. The material is considered to have failed the test if within 15 min either (1) fire propagation on the wall or ceiling extends to the limits of the structure,

or (2) flame extends outside the limits of the structure through the ceiling smoke layer.

The fire environment within the 25-ft (7.6 m) corner test structure has been characterized through heat flux and temperature measurements [51, 52]. It has been shown that the fire propagation boundary (pyrolysis front) measured by visual damage is very close to the critical heat flux (CHF) boundary for the material, as shown in Fig. 36.20 [52]. This relationship is in agreement with the general understanding of the fire propagation process. Through small- and large-scale fire propagation tests for low-density, highly char-forming wall and ceiling insulation materials, a semi-empirical relationship has been developed for fire propagation rate for a 15-min test in the 25-ft (7.6 m) corner test [51, 52].

$$\frac{X_p}{X_t} = \frac{\dot{Q}''_{\text{con}}}{\text{TRP}} \tag{36.14}$$

where

X_p = Average fire propagation length along the eaves (Fig. 36.20) of the 25-ft (7.6 m) corner test (pyrolysis front) measured visually (m)

X_t = Total available length [11.6-m (38 ft)] in the 25-ft (7.6 m) corner test

$\dot{Q}''_{\text{con}}$ = Convective heat release rate (kW/m^2) measured in the small-scale test

The right-hand side of Equation 36.14 with the convective heat release rate measured (through GTR, see above) for a material exposed to 50 kW/m^2 of external heat flux in the Fire Propagation Apparatus is defined as the convective flame spread parameter (FSP$_c$) [51, 52]. Figure 36.21 shows a correlation between the convective flame spread parameter obtained from the FPA and the normalized fire propagation length in the FM Global 25-ft (7.6 m) corner test. Pass/fail regions, as determined from the 25-ft (7.6 m) corner test, are indicated in the figure. Materials for which FSP$_c \leq 0.39$ pass the 25-ft (7.6 m) corner test, and materials for which FSP$_c \geq 0.47$ are judged to be unacceptable (i.e., fail); the region where the FSP$_c$ values are greater than 0.39 but less than 0.47 is uncertain [18, 51, 52].

The correlation and pass/fail criterion shown in Fig. 36.21 have been adopted in the

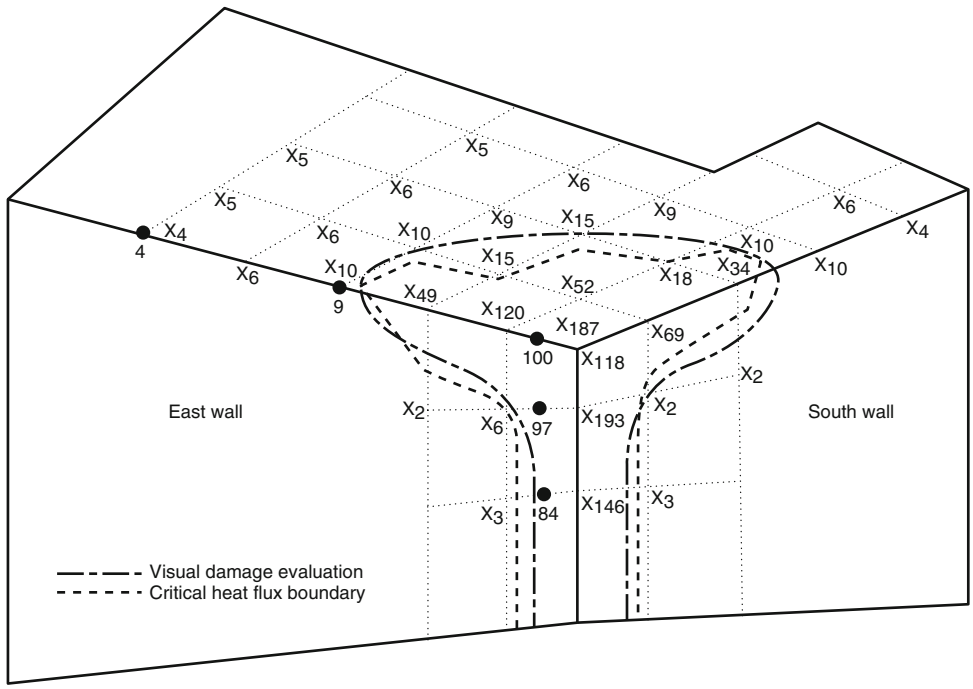

Fig. 36.20 Critical heat flux boundary and visual observations for the extent of fire propagation in the FM Global 25-ft corner test for a product that passes the tests [52]

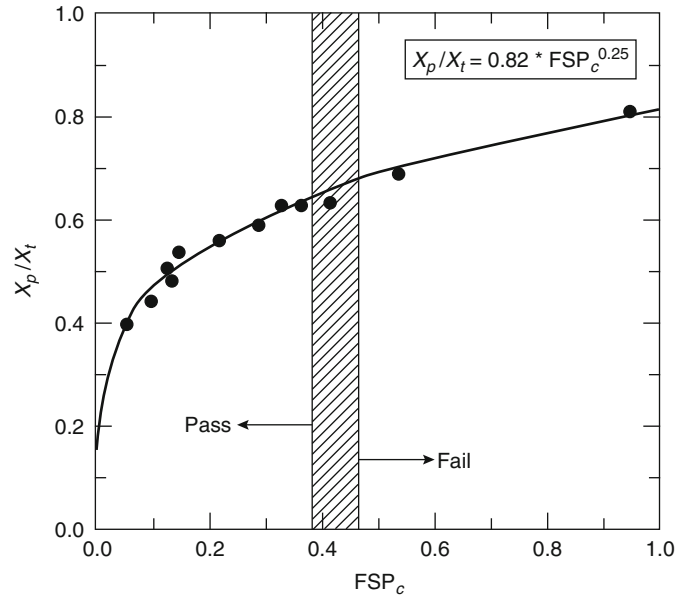

Fig. 36.21 Normalized fire propagation length measured in the 25-ft corner test versus the convective flame spread parameter obtained from the ASTM E2058 fire propagation apparatus (Figure is taken from Refs. [51, 52])

FM Approval Standard Class No. 4880 for insulated wall or wall and ceiling panels [18]. In this standard, the 25-ft (7.6 m) corner test has been replaced by the Fire Propagation Apparatus tests along with a new intermediate-scale parallel panel test [53], which are a cost-effective alternative and considerably simplify the test protocol. Two sets of tests are performed in the FPA [18, 51, 52]:

1. ***Thermal response parameter test:*** Ignition tests are performed using approximately 100-mm × 100-mm and up to 100-mm-thick samples. Times to ignition at various external heat flux values are measured to determine the TRP as described earlier.
2. ***Convective heat release rate test:*** Combustion tests are performed using about 100-mm × 100-mm and up to 100-mm-thick samples. Samples are burned in normal air under an external heat flux exposure of 50 kW/m^2. During the test, measurement is made for the convective heat release as a function of time.

Flaming and Nonflaming Phenomena

During fire propagation, the surface of the material regresses in a transient fashion with a rate slower than the fire propagation rate [31]. The surface regression becomes steady after fire propagates throughout the available surfaces. The surface regression continues until all the combustible components of the material are exhausted. During fire propagation and surface regression, the material generates vapors at a transient or steady rate. The generation rate of the material vapors is measured by the mass loss rate. In the presence of a flame and/or external heat flux, the mass loss rate, under steady state, is expressed as [14, 31, 44]:

$$\dot{m}'' = \frac{\dot{q}''_e + \dot{q}''_{fr} + \dot{q}''_{fc} - \dot{q}''_{rr}}{\Delta H_g} \tag{36.15}$$

where

$\dot{m}''$ = Mass loss rate (g/m^2 · s)

$\dot{q}''_{fr}$ = Flame radiative heat flux transferred to the surface (kW/m^2)

$\dot{q}''_{fc}$ = Flame convective heat flux transferred to the surface (kW/m^2)

$\dot{q}''_{rr}$ = Surface re-radiation loss (kW/m^2)

ΔH_g = Heat of gasification (kJ/g)

total flame heat flux to the surface $\dot{q}''_f = \dot{q}''_{fr} + \dot{q}''_{fc}$

According to Equation 36.15, the generation rate of material vapors is governed by the

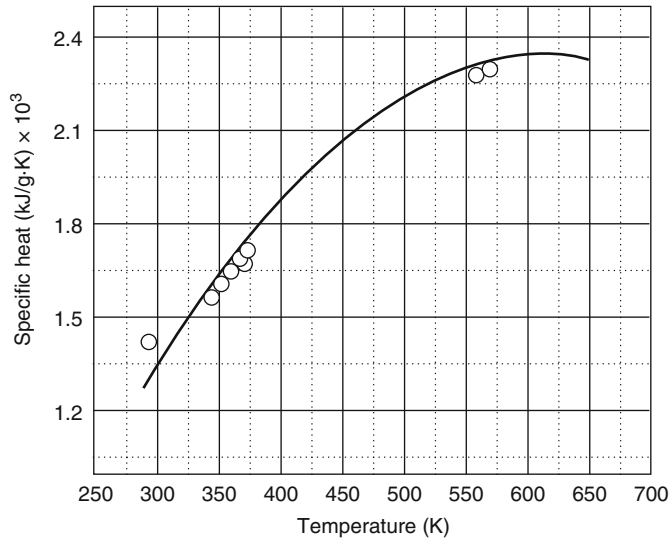

Fig. 36.22 Specific heat of polymethylmethacrylate versus temperature measured by a differential scanning calorimeter at the flammability laboratory of FM Global Research

external and flame heat flux, surface re-radiation loss, and the heat of gasification.

Heat of Gasification The heat of gasification for a melting material is expressed as [6]

$$\Delta H_g = \int_{T_a}^{T_m} c_{p,s} dT + \Delta H_m + \int_{T_m}^{T_v} c_{p,l} dT + \Delta H_v \tag{36.16}$$

where

ΔH_g = Heat of gasification (kJ/g)
$c_{p,s}$ = Specific heat of solid in kJ/g·K
$c_{p,l}$ = Specific heat of molten solid in kJ/g·K
ΔH_m = Heat of melting at melting temperature in kJ/g
ΔH_v = Heat of vaporization at vaporization temperature in kJ/g
T_a = Ambient temperature
T_m = Melting temperature
T_v = Vaporization temperature in K

For materials that do not melt, but sublime, decompose, or char, Equation 36.16 is modified accordingly. The heat of gasification can be determined from (1) the parameters on the right-hand side of Equation 36.16, which can be quantified by thermal analysis techniques or calculated from the properties listed in the literature; and (2) nonflaming tests using apparatuses, such as the OSU heat release rate apparatus, the FPA, or the cone calorimeter. The following are some examples of the techniques:

1. ***Heats of gasification of polymers from differential scanning calorimetry:*** *Values for* $c_{p,s}$, $c_{p,l}$, ΔH_m, and ΔH_v for polymers have been quantified in the FM Global Research Flammability Laboratory [6]. The techniques involve measurement of the specific heat as a function of temperature, such as shown in Fig. 36.22 for polymethylmethacrylate. Further measurements are also made of the heats of melting and vaporization. Some examples of the data measured at FM are listed in Table 36.6.
2. ***Heat of gasification from literature data for the heats of gasification for various molecular weight hydrocarbons (alkanes):*** The *CRC Handbook of Chemistry and Physics* [54] listing for the heats of gasification for liquid and solid hydrocarbons (alkanes) satisfies the following relationship in the molecular weight range of 30–250 g/mol:

$$\Delta H_g = 0.164 + 0.0042M - 3.72 \times 10^{-6} M^2 \tag{36.17}$$

where M is the molecular weight of the hydrocarbon (g/mol).

[a]From the Fire Propagation Apparatus under nonflaming conditions
[b]Calculated from the cone calorimeter data reported for the mass loss rate at various external heat flux values in flaming fires [13, 32]
[c]From the flammability laboratory using the differential scanning calorimetry
[d]Calculated from the data reported in the *CRC Handbook* [54]

The heats of gasification calculated from Equation 36.17 for various alkanes are listed in Table 36.6.

3. ***Heat of gasification from literature data for the specific heats and heats of vaporization:*** Water will be used as an example. The specific heat of liquid water, $c_{p,l}$, which is assumed constant, is 0.0042 kJ/g-K [55] and the heat of vaporization of water at 373 K is 2.26 kJ/g [54]. Assuming the ambient temperature to be 298 K and the vaporization temperature to be 373 K, the heat of gasification of water from Equation 36.16 is calculated as follows:

$$\Delta H_g = \int_{T_a}^{T_v} c_{p,l} dT + \Delta H_v$$
$$= c_{p,l}(T_v - T_a) + \Delta H_v$$
$$= 0.0042(373 - 298) + 2.26 = 2.58 \text{ kJ/g}$$

Using differential scanning calorimetry, the heat of gasification of water determined in the FM Global Research Flammability Laboratory is 2.59 kJ/g, which is in excellent agreement with the calculated value. These two values for the heat of gasification of water are listed in Table 36.6.

4. ***Heat of gasification from nonflaming tests using the Fire Propagation Apparatus:*** The measurement for the heat of gasification from the nonflaming tests in the ASTM E2058 [10] fire propagation apparatus was introduced in 1976 [6]. In the absence of flames, $\dot{q}''_f = 0$, and Equation 36.15 simplifies to:

$$\dot{m}'' = \frac{\dot{q}''_e - \dot{q}''_{rr}}{\Delta H_g} \tag{36.18}$$

where mass loss rate is now extrictly a linear function of the external heat flux. Therefore,

this equation provides a convenient method to determine the heat of gasification in nonflaming tests, where mass loss rate of the sample is measured at various external heat flux values. The heat of gasification is determined from linear regression analysis of the average steady-state mass loss rate as a function of external heat flux, using Equation 36.18. In the Fire Propagation Apparatus, samples can be exposed to radiant fluxes in 100 % nitrogen atmospheres, allowing the application of this methodology

Figure 36.23 shows a plot of the vaporization rate (i.e., mass loss rate), as a function of time, of water in a 0.0072 m^2 Pyrex glass dish exposed to 50 kW/m^2, measured in the Fire Propagation Apparatus. The figure also includes the predicted mass loss rate using Equation 36.18, where

$$\dot{q}''_{rr} = \varepsilon\sigma\left(T_v^4 - T_a^4\right) \tag{36.19}$$

where ε is the emissivity of water (0.95–0.963 in the temperature range 298–373 K), [56] and σ is the Stefan-Boltzmann constant (56.7×10^{-12} $kW/m^2\text{-}K^4$). For water, $T_v = 373$ K and $T_a = 298$ K, and thus $\dot{q}''_{rr} = 1$ kW/m^2. From Equation 36.18, using $\dot{q}''_e = 50$ kW/m^2, $\dot{q}''_{rr} = 1$ kW/m^2, and $\Delta H_g = 2.59$ kJ/g, $\dot{m}'' = 19.0$ $g/m^2{\cdot}s$. There is excellent agreement between the measured and predicted values at the steady state in Fig. 36.23.

Heats of gasification determined from mass loss rate as a function of external heat flux at nonflaming conditions in the FPA are listed in Table 36.6 for selected materials. Excellent agreement can be noted between the heats of gasification determined from the FPA data and those obtained from differential scanning calorimetry.

Heat of gasification can also be determined from flaming fires if high external heat flux values are used such that $\dot{q}''_e >> \dot{q}''_{fr} + \dot{q}''_{fc} - \dot{q}''_{rr}$ in Equation 36.15. This method has been used to calculate the heat of gasification from cone calorimeter data using mass loss rates measured in flaming fires reported in the literature [13, 32]. The values calculated from the cone calorimeter data are also listed in Table 36.6 and show a general agreement with the values from the FPA.

Example 5 Estimate the ignition temperature of a material with a CHF of 11 kW/m^2. Assume its surface emissivity to be unity, ambient temperature to be 20 °C, and vaporization temperature to be approximately equal to the ignition temperature.

Solution Following the assumption that at the CHF reradiation is the only mode of heat loss, from Equation 36.19,

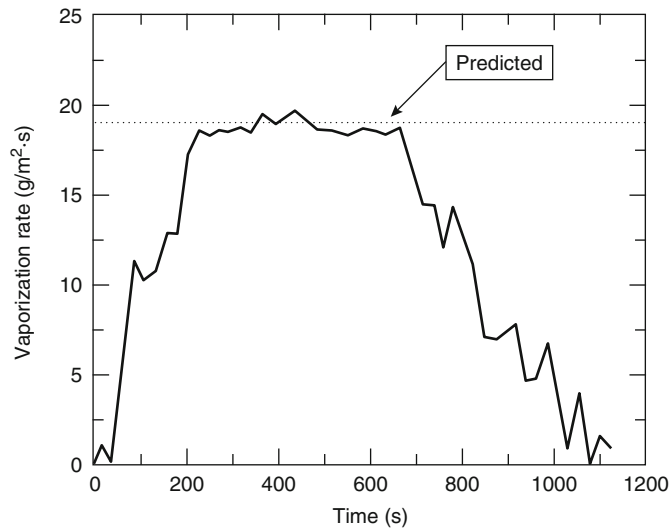

Fig. 36.23 Vaporization rate of water versus time measured in the Fire Propagation Apparatus using 99.69 g of water in a Pyrex dish with an area of 0.0072 m^2. Water was exposed to an external heat flux of 50 kW/m^2

$$\dot{q}''_{rr} = \text{CHF} = \varepsilon\sigma\left(T_v^4 - T_a^4\right)$$

$$T_v = T_{ig} = \left(\frac{\text{CHF}}{\varepsilon\sigma} + T_a^4\right)^{1/4}$$

$$T_{ig} = \left[\frac{11\frac{\text{kW}}{\text{m}^2}}{56.7 \times 10^{-12}\frac{\text{kW}}{\text{m}^2\text{K}^4}} + (298\text{K})^4\right]^{1/4}$$

$$T_{ig} = 670\text{K}$$

Example 6 A material with a surface re-radiation loss of 10 kW/m^2 and heat of gasification of 1.8 kJ/g was found to be involved in a fire with an exposed area of 2 m^2. The combined flame and external heat flux exposure to the material was estimated to be 70 kW/m^2. Estimate the peak mass loss rate at which the material may have been burning in the fire in terms of g/m^2 · s and g/s.

Solution From Equation 36.15,

$$\dot{m}'' = \frac{\dot{q}''_e + \dot{q}''_{fr} + \dot{q}''_{fc} - \dot{q}''_{rr}}{\Delta H_g}$$

$$\dot{q}''_e + \dot{q}''_{fr} + \dot{q}''_{fc} = 70\frac{\text{kW}}{\text{m}^2}$$

$$\dot{m}'' = \frac{(70-10)\frac{\text{kW}}{\text{m}^2}}{1.8\frac{\text{kJ}}{\text{g}}} = 33\frac{\text{g}}{\text{m}^2\text{s}}$$

The estimated peak mass loss rate of the burning material is 33 g/m^2/s, or 33 × 2 = 67 g/s.

Flame Heat Flux For flaming fires, in the absence of external heat flux, from Equation 36.15

$$\dot{m}'' = \frac{\dot{q}''_{fr} + \dot{q}''_{fc} - \dot{q}''_{rr}}{\Delta H_g} \tag{36.20}$$

The results from numerous small- and large-scale fire tests show that, as the surface area of the material increases, the flame radiative heat flux increases and reaches an asymptotic limit, whereas the flame convective heat flux decreases and becomes much smaller than the flame radiative heat flux at the asymptotic limit in large-scale fires [57]. It is also known that, in small-scale fires of fixed size with buoyant turbulent diffusion flames, as the oxygen mass fraction is increased, the flame radiative heat flux increases and reaches an asymptotic limit comparable to the asymptotic limit in large-scale fires, whereas the flame convective heat flux decreases and becomes much smaller than the flame radiative heat flux [13].

The effect of the mass fraction of oxygen on the flame radiative and convective heat fluxes in small-scale fires is shown in Fig. 36.24 for 100-mm × 100-mm square × 25-mm-thick slabs of polypropylene. The data were measured in the Fire Propagation Apparatus [13]. The increase in the flame radiative heat flux with increase in the mass fraction of oxygen is due to the increase in the flame temperature and soot formation and decrease in the residence time in the flame [13]. The oxygen mass fraction

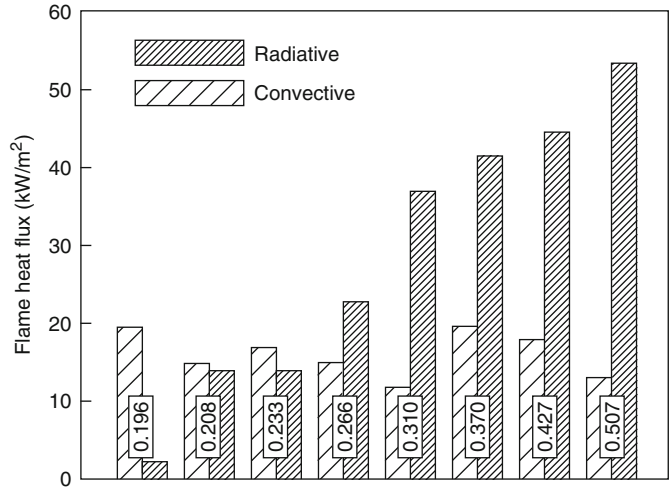

Fig. 36.24 Flame radiative and convective heat fluxes at various oxygen mass fractions for the steady-state combustion of 100-mm × 100-mm square × 25-mm-thick slabs of polypropylene in the FPA under co-airflow velocity of 0.09 m/s (Data taken from Ref. [13]). Mass fractions of oxygen are indicated by the numbers inside the frames

variation technique to simulate large-scale flame-radiative heat flux conditions in small-scale fires is defined as the *flame radiation scaling technique* [44]. This methodology forms the basis for the approaches described above regarding the flame propagating behavior of materials using the FPI concept.

In the flame radiation scaling technique, the flame radiative and convective heat fluxes are determined from (1) mass loss rate measurements at various oxygen mass fractions in the range of 0.12 (close to flame extinction) to about 0.60, under co-airflow conditions; (2) the convective heat transfer coefficient for the FPA, derived from the combustion of methanol; (3) the mass transfer number; and (4) Equation 36.20. In the Fire Propagation Apparatus, the asymptotic limit is reached for oxygen mass fractions in excess of 0.30. At the asymptotic limit, Equation 36.20 can be expressed as

$$\dot{m}''_{\text{asy}} = \frac{\dot{q}''_{f,\text{asy}} - \dot{q}''_{rr}}{\Delta H_g} \tag{36.21}$$

where subscript *asy* represents the asymptotic limit. The asymptotic values for mass loss rate and flame heat flux determined using the flame radiation scaling technique in the FPA are listed in Table 36.7. The measured asymptotic values for mass loss rate reported in the literature and flame heat flux in large-scale fires are also listed in Table 36.7. Flame heat flux values for the large-scale fires are derived from the asymptotic values of the mass loss rate and known values of surface re-radiation losses and heats of gasification.

The data in Table 36.7 show that asymptotic flame heat flux values, determined in the FPA using the flame radiation scaling technique, are in good agreement with the values measured in large-scale fires. The asymptotic flame heat flux values vary from 22 to 77 kW/m^2, depending primarily on the mode of decomposition and gasification rather than on the chemical structures of the materials. For example, for liquids, which vaporize primarily as monomers or as very low molecular weight oligomers, the asymptotic flame heat flux values are in the range of 22–44 kW/m^2, regardless of their chemical structures. For polymers, which vaporize as high molecular weight oligomers, the asymptotic flame heat flux values increase substantially to the range of 49–71 kW/m^2, regardless of their chemical structures. The independence of the asymptotic flame heat values from the chemical structures of materials is consistent with the dependence of flame radiation on optical thickness, soot concentration, and flame temperature in large-scale fires.

Example 7 Calculate the peak mass loss rate for polypropylene in large-scale fires, burning in the open, with no external heat sources in the surroundings.

Solution In the calculation Equation 36.21 will be used. From Table 36.6, $\dot{q}''_{rr} = 15$ kW/m^2 and $\Delta H_g = 2.0$ kJ/g, and from Table 36.7, $\dot{q}''_{f,\text{asy}} = 67$ kW/m^2. Using these values in Equation 36.21,

$$\dot{m}''_{\text{asy}} = \frac{\dot{q}''_{f,\text{asy}} - \dot{q}''_{rr}}{\Delta H_g}$$

$$\dot{m}''_{\text{asy}} = \frac{(67-15)\frac{\text{kW}}{\text{m}^2}}{2.0\frac{\text{kJ}}{\text{g}}} = 26\frac{\text{g}}{\text{m}^2\text{s}}$$

Example 8 Calculate the peak mass loss rate for polypropylene in large-scale fires burning in the open in the presence of a burning object, which provides 20 kW/m^2 of heat flux to the polypropylene surface, in addition to its own flame heat flux of 67 kW/m^2.

Solution In the calculation, Equation 36.15 will be used with $\dot{q}''_e = 20$ kW/m^2. From Table 36.6, $\dot{q}''_{rr} = 15$ kW/m^2 and $\Delta H_g = 2.0$ kJ/g and from Table 36.7, $\dot{q}''_{f,\text{asy}} = 67$ kW/m^2. Using these values in Equation 36.15,

$$\dot{m}'' = \frac{\dot{q}''_e + \dot{q}''_{fr} + \dot{q}''_{fc} - \dot{q}''_{rr}}{\Delta H_g}$$

$$\dot{q}''_e + \dot{q}''_{fr} + \dot{q}''_{fc} = (67+20)\frac{\text{kW}}{\text{m}^2}$$

$$\dot{m}'' = \frac{(87-15)\frac{\text{kW}}{\text{m}^2}}{2.0\frac{\text{kJ}}{\text{g}}} = 36\frac{\text{g}}{\text{m}^2\text{s}}$$

Pyrolysis and Determination of "Model-Specific" Material Properties

One of the most prevailing observations made with the bench-scale apparatuses discussed in section "Flammability Apparatuses and Measurement Capabilities" of this chapter is the rate of thermal degradation of condensed phase materials under a prescribed heating scenario. This behavior is captured in the tests through the measurement of a mass loss rate (MLR). In the context of this chapter such behavior is referred to as pyrolysis. Pyrolysis is a complex process that involves a number of coupled physical and chemical phenomena, which include, among many others, phase changes, char formation, water desorption/migration (e.g., in cellulosic fuels), gas diffusion, gas-solid heat exchange, oxidation, etc. (refer to Chaps. 21 and 23). These processes determine the formation of gradients (thermal, species, etc.) within a given material which control ignition, heat release, and flame propagation in fires.

There is strong and continued interest in the fire community in the development of predictive fire modeling capabilities for practical large-scale fires through the use of new-generation computational fluid dynamics (CFD) tools [58–60]. Such modeling can provide measures to interpret, interpolate, and extrapolate information obtained from limited experimental data as well as providing cost-effective alternatives by reducing the number of large-scale tests necessary to develop fire protection requirements or standards. To reach this objective, physical models for fluid mechanics, gas phase combustion, soot formation and oxidation, radiation, solid phase heat transfer and pyrolysis, and suppression need to be incorporated into an appropriate CFD solver to properly represent the multi-scale, multi-physics phenomena taking place in large-scale fires. Given the mathematical complexity of these CFD tools, it is important that such fire models be verified and validated against experimental data [59, 60].

Of relevance to the present chapter is how bench-scale experiments may contribute to the development of pyrolysis models to be used in the CFD tools described above. Models have become recently available [61–64] which represent the current state of the art of pyrolysis modeling; these are comprehensive models which share similar robust mathematical and numerical frameworks. These models, due to their complexity, require a potentially large number of adjustable input parameters, i.e., material properties. Many applications (e.g., large-scale industrial fires) involve fuels for which such properties are unknown. In certain cases (e.g., [65–67]) detailed property measurements may be performed (via thermogravimetric analyses, TGA, and differential scanning calorimetry, DSC, for example) and successfully used in the comprehensive models. However, experimental venues such as TGA and DSC, although extremely useful in providing fundamental material information, are often not representative of practical applications as they feature relatively slow heating rates and preclude the formation of mass and thermal gradients within the material. Furthermore, properties measured in this manner may not be directly used even in the most advanced models since they cannot reflect the true complexity and heterogeneity of the physical processes taking place during pyrolysis. To some degree models must always conceptualize and aggregate complex interactions by the use of only relatively simple mathematical equations. Therefore, in that sense, pyrolysis models cannot use "true" material properties if all the physics are not fully captured. Finally, in the context of large CFD simulations, use of comprehensive and complex models may be computationally prohibitive.

On the basis of the above discussion, then, one of the major challenges posed to the end user of CFD pyrolysis models is to make simplifications and approximations to keep the number of parameters manageable and the model computationally efficient while maintaining sufficient model generality and applicability to a given practical scenario. By following this approach the input parameters to the model can be considered "effective" or "model-specific" material properties which are sensitive to the physical processes included in the model. The methodology by which these model-specific properties are obtained is detailed in the following sections.

Optimization

The main requirement regarding the performance of CFD pyrolysis models is that they should properly reproduce aspects of the condensed-phase material behavior, such as pyrolysis gas (i.e., fuel) generation rates, surface temperatures, etc., which may be critical to the successful performance of the CFD fire simulation. These material response characteristics can in principle be measured via bench-scale tests such as those conducted in the Fire Propagation Apparatus. The model-specific material properties alluded to above are obtained by coupling a simplified pyrolysis model to optimization algorithms and the input parameters (i.e., the material properties) are adjusted in order to obtain the best possible agreement between model outputs and experimental bench-scale pyrolysis data. In the general framework of flammability properties this approach has been seldom used [68, 69]

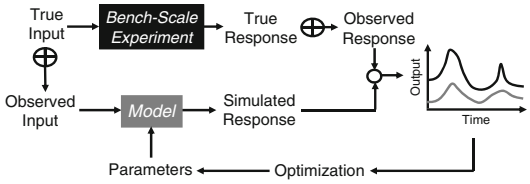

Fig. 36.25 Optimization approach

although it has recently received renewed attention [70–76]. Numerous similar efforts, though, exist in the literature mostly aimed at determining a limited set of thermal properties and for specific applications [77–82].

A schematic of the optimization approach is shown in Fig. 36.25. An experimental process is captured via a numerical model subject to a driving input (e.g., external radiation) and a set of parameters ("material properties"). In the figure, an important distinction is made between the true input to and true response of the experiment and what is actually observed, or measured, in order to represent experimental uncertainty. It is because of this uncertainty that parameters determined through optimization procedures such as the one discussed herein are sensitive to the accuracy of the experimental data used as optimization targets. As can be expected, the optimization problem is complex and highly non-linear. Therefore, local search methods such as direct search [83] and gradient search [84] algorithms are not applicable; however, such methods have been used widely for property estimation [68, 69, 77, 81, 82]. Global methods are needed which can tackle the major complications of high-dimensionality optimization such as local optima, multiple attraction basins, discontinuities, etc.

An optimization algorithm with high efficiency and robustness is needed if one is to perform multiobjective and multivariable optimization as little or no a priori knowledge is available of the structure of the model response surface. Furthermore, these qualities allow optimization algorithms to be easily generalized so as to provide consistent performance over a wide range of problems, even if optimization target data are limited. Here, the selected optimization algorithm is the Shuffled Complex Evolution (SCE) [85]. This is a method that has been mostly applied to hydrological problems [86] but, as will be shown below, it is general and robust enough to show considerably good performance in flammability applications. Chaos et al. [73–75] found SCE to be superior to other global optimization tools, such as genetic algorithms, a finding that has been confirmed by other researchers [87].

A schematic flowchart of the SCE algorithm is shown in Fig. 36.26. Similar to genetic algorithms, SCE is based on a process of natural evolution. A population of s points (i.e., vectors of "material properties" in the present context) is randomly sampled from the feasible parameter space (given the bounds for each parameter) and the value of the objective function to be optimized (e.g., minimization of the sum of squares between model outputs and experimental data) is computed. The points are ranked from smallest to highest objective function value and are then partitioned into p complexes each containing m points (note $s = p \times m$) so that the first complex contains every $(l-1)p + 1$ ranked point, the second every $(l-1)p + 2$ ranked point, etc. where $l = 1, 2, \ldots, m$. Each of these complexes is then allowed to evolve independently according to a competitive complex evolution (CCE) algorithm [85], described below. After the CCE process, all the points in each complex are combined back into a single population, ranked according to their objective function value, and re-partitioned following the procedure above; this effectively "shuffles" the complexes. This procedure is iteratively repeated until specified convergence criteria are met. SCE allows for more extensive (i.e., in different directions) and freer exploration of the feasible space due to the partition of complexes. Shuffling enhances survivability by sharing information about the space gained independently by each complex.

The key component of the SCE method is the CCE algorithm which is based on the Nelder-Mead simplex downhill search scheme [83]. In the CCE algorithm q points are randomly selected within each complex according to a

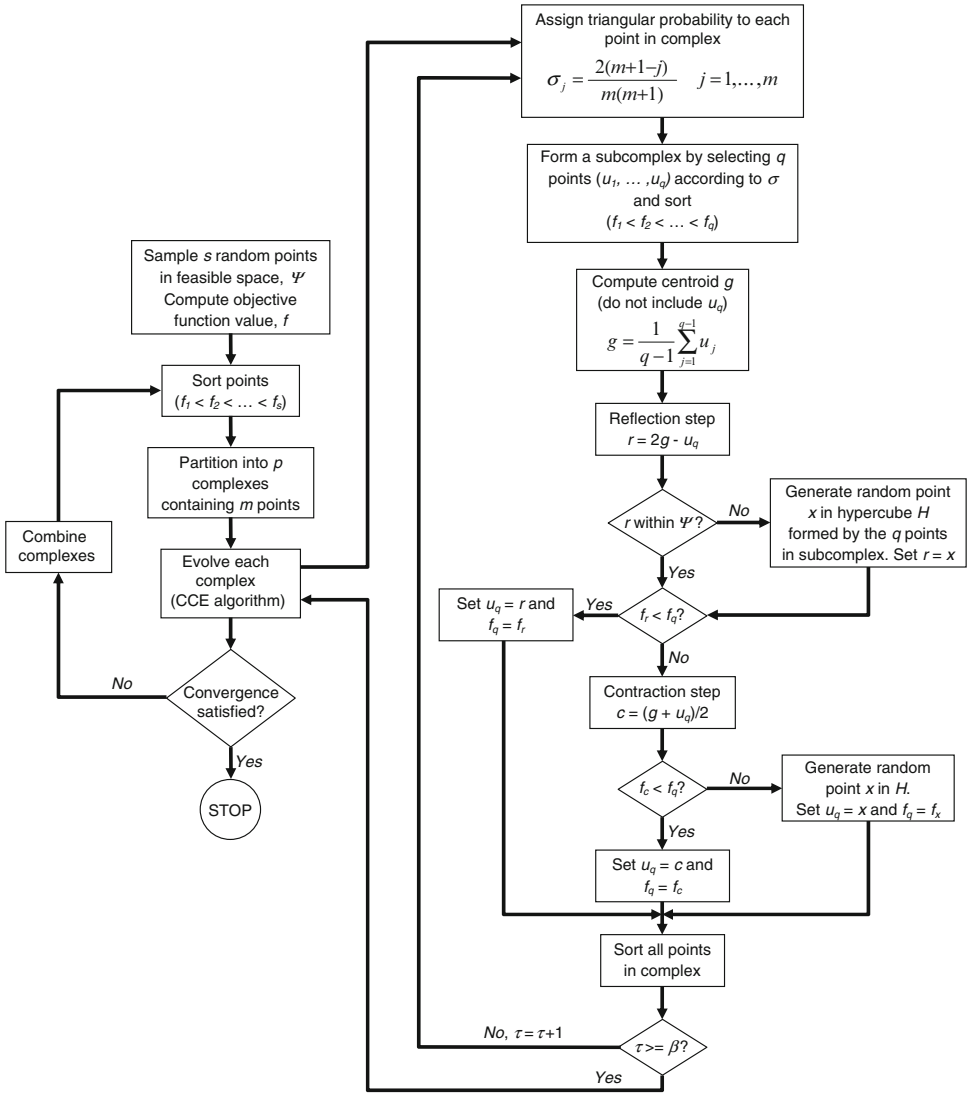

Fig. 36.26 The Shuffled Complex Evolution algorithm

trapezoidal probability distribution so that the best and worst points in the complex have the highest and lowest chance, respectively, of being chosen. The centroid of the subcomplex formed by the set of q points is calculated without considering the worst point in the subcomplex; then, this worst point is reflected through the centroid. If the new point so computed is better (i.e., its objective function value is improved) than the worst point, the worst point is replaced. Otherwise a point is computed halfway between the centroid and the worst point; if this point is better than the worst point, the worst point is replaced. In the case that the latter two steps do not generate a better point or if the reflection through the centroid yields a point outside the feasible space, a point is generated randomly which replaces the worst point. This procedure is repeated a specific number of times, β, before the complexes are shuffled as described above. In this manner, each complex evolves independently as a whole.

The SCE process is shown graphically in Fig. 36.27 by using a two-dimensional example. A test function was generated (left pane in

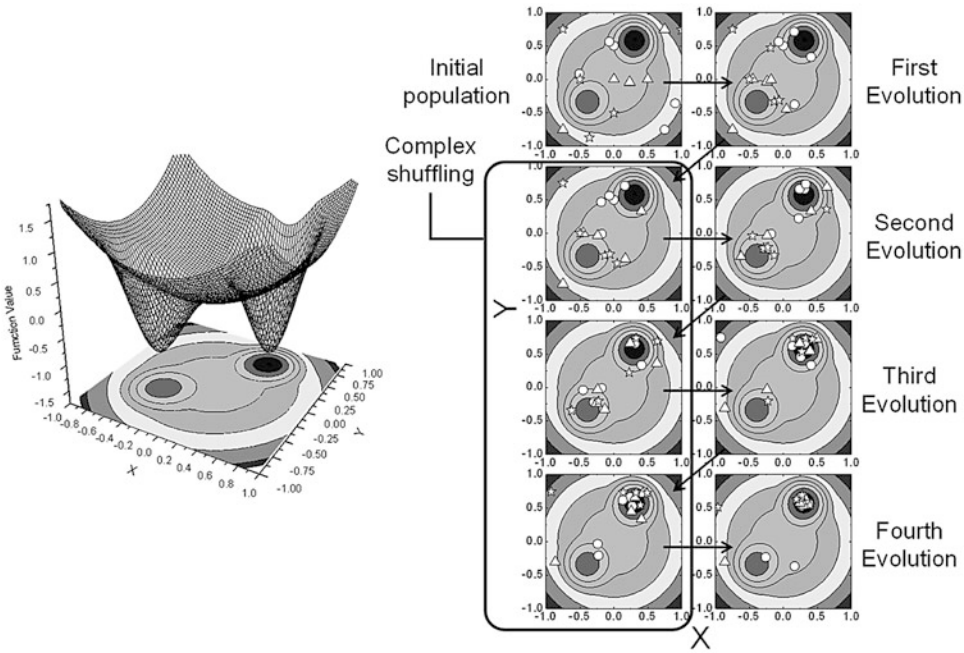

Fig. 36.27 SCE application to a two-dimensional problem

Fig. 36.27) by distorting selected regions of a convex quadratic function so as to introduce local minima with varying regions of attraction, following the methods of Gaviano and Lera [88]. A three-minima function was generated with one global minimum located at (X,Y) = (0.312,0.598). SCE was run with three complexes (denoted by stars, circles, and triangles in Fig. 36.27) consisting of 5 points each (i.e., $p = 3$, $m = 5$, $s = 15$). Note the effect of shuffling in Fig. 36.27. The overall distribution of points from the end of an evolution to the beginning of the next is unchanged; however, the distribution within each complex changes. Also note that some points converge towards the local minimum at (X,Y) = (-0.412,-0.351) in the first two evolutions but shuffling efficiently directs their convergence towards the global minimum.

Application

Synthetic Data and Target Selection

Foremost, it is important to illustrate the features and limitations of the SCE optimization algorithm when applied to problems of practical interest herein. In order to do this, a simplified one-dimensional pyrolysis model was used to generate synthetic experimental data for a supposed charring material. One-dimensionality is assumed as this is representative of tests conducted in the Fire Propagation Apparatus or cone calorimeter where the thickness of samples tested is small compared to their diameter and edge effects can be considered negligible. The specific details of the pyrolysis model used are beyond the scope of this chapter, and the reader is referred to [63, 64, 73–75] for further information; only the simplifications made to the model are described here for brevity. The model employs a control volume approach and the governing mass and energy conservation equations are solved numerically using a fully implicit scheme. Only three species are treated: virgin solid, char, and pyrolytic gas and it is assumed that the virgin solid decomposes to char and/or gas through a single heterogeneous nth-order Arrhenius-type reaction. Pyrolysis gas is assumed to be in thermal equilibrium with the solid and to immediately escape once formed. All material properties are assumed to be temperature-independent.

Table 36.8 Parameters used to generate synthetic data (Fig. 36.28) and parameters returned by optimization

			SCE optimization					
Property		Synthetic	LB	UB	Case 1	Case 2	Case 3	Case 4
Virgin	Thermal conductivity (W/m/K)	0.10	0.01	1.00	0.04	0.09	0.10	0.10

The synthetic dataset consists of mass loss rate and surface temperature data generated for a 5-mm thick material subjected to external radiation levels of 25, 50, and 100 kW/m^2. For simplicity, the back boundary of the material was assumed to be perfectly insulated (adiabatic) and a constant convective heat transfer coefficient of 15 W/m^2/K was assumed for the front surface. The material properties used in the model to generate the data are listed in Table 36.8. The model-generated curves were modified by adding Gaussian error with standard deviations representative of experimental uncertainty: 100 mg for mass loss and 15 K for temperature measurements [75, 89], In order to obtain mass loss rate, the modified mass loss curve was differentiated using Savitsky-Golay filters [37, 90, 91]. As opposed to previous applications of this methodology [36, 91] in which a fixed filter window size was recommended, the window size of the filter was kept between one and two times the full-width-half-magnitude size of the narrowest transient peak of interest [92] in order to avoid introducing unwanted bias in the derived MLR data. This approach ensured that the magnitude of these peaks was preserved after application of the filter. Figure 36.28 shows plots of the synthetic data prior to and after adding Gaussian error. Also in the figure, the effect of varying the smoothing filter size is shown for the 100 kW/m^2 case. Note that by increasing the filter window size by a factor of two the first mass loss rate peak, which is narrower, is "washed out" whereas the second peak is still properly captured.

Several optimization runs were preformed by selecting specific subsets of the data shown in Fig. 36.27. This was done in order to test the robustness of the SCE algorithm as it is often the case, especially with complex practical materials, that target experimental data may be limited and/or difficult to measure accurately. An algorithm that can reach the global optimum with the least amount of target data can be extremely useful as it can allow one to limit the target metrics to only those data that can presumably be measured more accurately without considering data with higher uncertainty. Four target data subsets were selected: Case 1—mass loss rate at 50 kW/m^2; Case 2—mass loss rate, cumulative mass loss, and surface temperature at 50 kW/m^2; Case 3—mass loss rate at 25, 50, and 100 kW/m^2; and Case 4—mass loss rate, cumulative mass loss, and surface temperature at 25, 50, and 100 kW/m^2. SCE was run subject to the property bounds shown in Table 36.8 and with algorithmic parameters (i.e., p, m, q, and β, see above) selected according to the guidelines of [86]; the population size was 150.

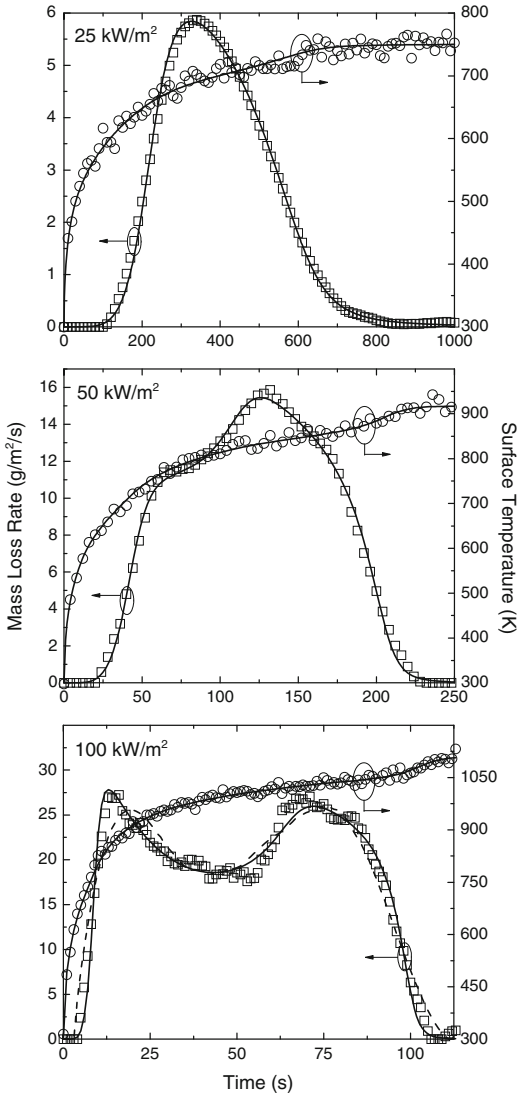

Fig. 36.28 Synthetic data. *Lines* show model outputs and symbols denote the model data after Gaussian error was added (see text). The *dashed line* for mass loss rate at 100 kW/m^2 shows the effect of varying the smoothing filter window size from 25 s to 50 s (see text)

The values for the optimized property parameters obtained for each of the four cases are listed in Table 36.8. For the sake of brevity and in lieu of showing plots it is noted that for all cases a near perfect match was obtained against each of the corresponding datasets used for optimization; the R-squared values for all cases were in excess of 0.99. However, regardless of the good agreement obtained, the original parameters are not recovered in most cases. A clear trend can be observed, nonetheless; the deviation from the original parameters is reduced when more target metrics are added (compare Case 1 to Case 2 and Case 3 to Case 4) and when more heat fluxes are considered for the same target metric (compare Case 1 to Case 3 and Case 2 to Case 4). This trend is an obvious manifestation of how the target data are able to constrain the model and, thus, the optimization algorithm. By considering mass loss rate alone (Case 1 and Case 3) parameters, most notably physical properties such as thermal conductivity and heat capacity, cannot be accurately determined. This is to be expected as these parameters are coupled through the thermal inertia and thermal diffusivity of the material. Introducing temperature as an optimization target improves agreement against these properties and the same can be said about considering additional heat flux levels. It is noted that, in a similar synthetic data exercise as that discussed here, SCE was found to recover the input parameters using datasets consisting of mass loss rate, front and back surface temperatures at two heat flux levels [87]; back surface temperature measurements may present a experimental challenge, however.

The discussion above should persuade the reader that the process of obtaining model-specific properties through optimization will be most successful when considering multiple experimental data (mass loss rate, temperature, etc.) over as wide a range of practical conditions as possible [60]. Furthermore, availability of properties that can be easily measured (e.g., virgin density) will further improve the results by reducing the dimensionality of the problem. Yet, there are cases in the literature (e.g., [76]) where optimization is performed against very limited datasets. As a last word of caution it is reiterated that the "material properties" obtained using the methodology described herein depend on the choice of pyrolysis model as well as the accuracy of the experimental data and are not universally applicable to other models or to scenarios that considerably depart from the experimental conditions used to derive the model-specific properties.

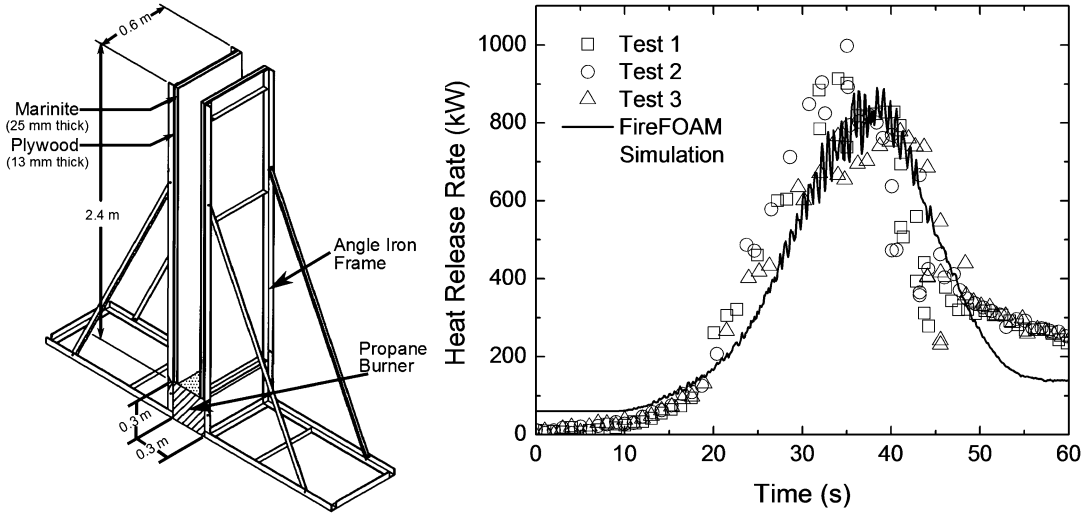

Fig. 36.29 Experimental (*symbols*) and computed (*lines*) parallel panel heat release rates for single-wall corrugated cardboard [96]. The experimental configuration is shown on the *left panel*

FPA Data and Intermediate-Scale Fire Growth Simulations

The approach outlined above has been extensively used and applied to the simulation of the vertical spread of fire between parallel panels at an intermediate scale [60, 93–97]. For this application, model-specific properties were determined using the pyrolysis model included in FireFOAM [98, 99], a Large Eddy Simulation (LES) solver. The target data used for optimization were collected in the Fire Propagation Apparatus in inert environments (i.e., 100 % nitrogen); this is a unique feature of the apparatus (see section "Flammability Apparatuses and Measurement Capabilities") which allows for the decoupling of flame heat flux from the pyrolysis process. Following the recommendations of the previous section, the data consisted of mass loss rates and surface temperatures over heat fluxes spanning the 20–110 kW/m^2 range. The model-specific material properties were shown to successfully predict, at least qualitatively, flame propagating and non-propagating behavior of several materials when used in the LES simulation [60].

Further experience with the application of the methodologies described herein has elucidated the importance of properly characterizing boundary conditions in the FPA experiments and the relative importance of oxidative pyrolysis in certain applications [35, 89, 97]. Considerable progress has been made in the predictive abilities of FireFOAM when compared against flame spread experiments in the parallel panel configuration [97]. An example is shown in Fig. 36.29 where the heat release rate of single-wall corrugated cardboard collected during three separate parallel panel tests (a schematic of the test is also shown in the figure, for more details refer to [93–97] as well as section "Fire Propagation") is compared against simulations. A considerably good agreement can be observed. This is an encouraging result which confirms that the approach described in this section for the characterization of material flammability is promising and may lead to cost-effective modeling alternatives to large-scale testing.

Heat Release Rate

The determination of heat release rate in fires has been influenced by the principles and techniques used for controlled combustion in the heating and power industries. Heat in the flowing combustion products (convective heat) and thermal radiation are used to generate steam, heat a furnace or space, produce mechanical power in internal

combustion engines or gas turbines, and so forth. Heat is generated by injecting fuel (gas, liquid, or solid) into a hot environment, where it undergoes evaporation, gasification, and thermal decomposition or pyrolysis.

Fuel vapors react chemically with oxygen and produce heat and products, such as carbon monoxide (CO), carbon dioxide (CO_2), hydrocarbons, water (H_2O), and soot and other particulates. The theoretical amount of air required for complete combustion is estimated from an empirical guide [100], which suggests that, for every 10.6 kJ of heat in the fuel burned, 3.4 g of air are required for complete combustion [101]. Equivalently, the heat of combustion per unit mass of molecular oxygen consumed (ΔH_0^*) is 13.4 kJ/g. Using $\Delta H_0^* \approx 13.4$ kJ/g to determine the heat release rate in fires from the mass consumption rate of oxygen is discussed in Refs. [14, 21]. This technique forms the basis of oxygen consumption (OC) calorimetry.

A combustion process is characterized by its *combustion efficiency*, χ_{ch}, defined as the fraction of heat of complete combustion released in the chemical reactions, which is the ratio of the chemical heat of combustion to the net heat of complete combustion. The calorific energy generated in chemical reactions leading to complete combustion per unit mass of fuel, with water produced being in the vapor state, is defined as the *net heat of complete combustion*. The calorific energy generated in chemical reactions leading to varying degrees of incomplete combustion per unit mass of fuel consumed is defined as the *chemical heat of combustion*. In the heating and power industries, combustion efficiency is determined routinely from the analysis of waste products (flue gas), especially for CO, CO_2, and O_2, and from the measurements of temperature in the combustion products-air mixture and thermal radiation. For higher combustion efficiency, *mass fuel-to-air ratio* relative to the *stoichiometric fuel-to-air mass ratio* or the *equivalence ratio* is controlled by maintaining the desired primary and secondary airflow.

The net heat of complete combustion can be measured in the oxygen bomb calorimeter [102] (see Chap. 27) and is calculated from the standard heats of formation of the materials, CO_2, and H_2O (the standard heat of formation of O_2 in its standard state being zero).

In fires, complete combustion is rarely achieved and products of incomplete combustion, such as CO and smoke, are quite common. An example of incomplete combustion is given in Table 36.9, where chemical heat of combustion and combustion efficiency decrease as CO, carbon, and ethylene are formed at the expense of CO_2 and H_2O with reduced O_2 consumption, a typical condition found in ventilation-controlled fires [103]. The upper limit of the combustion efficiency is 1.00, corresponding to complete combustion, and the lower limit is 0.46, corresponding to unstable combustion leading to flame extinction for combustion efficiency $\leq$0.40 [103, 104].

Table 36.9 Chemical heat of combustion and combustion efficiency of polymethylmethacrylate

Reaction stoichiometry	ΔH_{ch} (kJ/g)[a]	χ_{ch}
$C_5H_8O_2$ (g) + 6.0 O_2 (g) =		
5CO_2 (g) + 4H_2O (g)	24.9	1.00
$C_5H_8O_2$ (g) + 5.5 O_2 (g) =		
4CO_2 (g) + 4H_2O (g) + CO (g)	22.1	0.89
$C_5H_8O_2$ (g) + 4.5 O_2 (g) =		
3CO_2 (g) + 4H_2O (g) + CO (g) + C (s)	18.2	0.73
$C_5H_8O_2$ (g) + 3.0 O_2 (g) =		
2CO_2 (g) + 3H_2O (g) + CO (g)		
+ C (s) + 0.50 C_2H_4 (g)	11.5	0.46

[a]Standard heat of formation in kJ/mol: PMMA ($C_5H_8O_2$) (g) = −442.7; O_2 (g) = 0; CO_2(g) = 393.5; H_2O (g) = −241.8; CO (g) = −110.5; C (s) = 0; and C_2H_4 (g) = +26.2, where g and s stand for gaseous and solid states, respectively

Chemical Heat Release Rate

As described in section "Flammability Apparatuses and Measurement Capabilities" of this chapter, chemical heat release rate in bench scale apparatuses such as the Fire Propagation Apparatus and cone calorimeter can be determined from CDG and OC calorimetries.

CDG Calorimetry The chemical heat release rate is determined from the following relationships [14, 28, 31, 43, 44, 103, 105]:

$$\dot{Q}''_{ch} = \Delta H^*_{CO_2} \dot{G}''_{CO_2} + \Delta H^*_{CO} \dot{G}''_{CO} \tag{36.22}$$

$$\Delta H^*_{CO_2} = \frac{\Delta H_T}{\psi_{CO_2}} \tag{36.23}$$

$$\Delta H^*_{CO} = \frac{\Delta H_T - \Delta H_{CO} \psi_{CO}}{\psi_{CO_2}} \tag{36.24}$$

where

$\dot{Q}''_{ch}$ = Chemical heat release rate (kW/m^2)
$\Delta H^*_{CO_2}$ = Net heat of complete combustion per unit mass of CO_2 generated (kJ/g)
ΔH^*_{CO} = Net heat of complete combustion per unit mass of CO generated (kJ/g)
ΔH_T = Net heat of complete combustion per unit mass of fuel consumed (kJ/g)
ψ_{CO_2} = Stoichiometric yield for the maximum conversion of fuel to CO_2 (g/g)
ψ_{CO} = Stoichiometric yield for the maximum conversion of fuel to CO (g/g)
$\dot{G}''_{CO_2}$ = Generation rate of CO_2 (g/m^2/s)
$\dot{G}''_{CO}$ = Generation rate of CO (g/m^2/s)

The values for the net heats of complete combustion per unit mass of fuel consumed and CO_2 and CO generated are listed in Table A.38. The values depend on the chemical structures of the materials. With some exceptions, the values remain approximately constant within each generic group of fuels. The average values are also listed in the tables. From the average values, $\Delta H^*_{CO_2} = 13.3 \pm 1.5$ kJ/g and $\Delta H^*_{CO} = 11.1 \pm 2$ kJ/g. In CDG calorimetry, the CO correction (which accounts for the heat generated for incomplete combustion) for well-ventilated fires is very small because of the small amounts of CO generated. The variations of 11 % and 18 % in the $\Delta H^*_{CO_2}$ and ΔH^*_{CO} values, respectively, would reduce significantly if values for low molecular weight hydrocarbons with small amounts of O, N, and halogen were not used in averaging. For the determination of the chemical heat release rate, generation rates of CO_2 and CO are measured and either the actual values (if material composition is known) or the average values of the net heat of complete combustion per unit mass of CO_2 and CO generated are used. The measurements for the generation rates of CO_2 and CO are described in section "Generation of Fire Products and Smoke Yields" of this chapter.

Care must be taken in the application of CDG calorimetry depending on the scenario of interest. For example, in fires where incomplete combustion is ubiquitous and copious amounts of unburned hydrocarbons, soot, and other particulates are generated, the equations above will not yield an accurate measure of heat release rate as corrections for the formation of these species have to be included (much like is done above for CO). One more example is a scenario where a fire is suppressed by water (i.e., a sprinkler) and a large amount water vapor is present in the combustion-product-air mixture. Some correction procedures are available (e.g., [106]) to account for these effects.

OC Calorimetry The chemical heat release rate is determined from the following relationships [13, 21–24, 28, 31, 43, 44, 103, 105, 107]:

$$\dot{Q}''_{ch} = \Delta H^*_O \dot{C}''_O \tag{36.25}$$

$$\Delta H^*_O = \frac{\Delta H_T}{\psi_O} \tag{36.26}$$

where

ΔH^*_O = Net heat of complete combustion per unit mass of oxygen consumed (kJ/g)
$\dot{C}''_O$ = Mass consumption rate of oxygen (g/m^2/s)
ψ_O = Stoichiometric oxygen-to-fuel mass ratio (g/g)

The values for the net heats of complete combustion per unit mass of oxygen consumed are listed in Table A.38 along with the values for the

net heats of complete combustion per unit mass of fuel consumed and CO_2 and CO generated. The average values of the net heat of complete combustion per unit mass of oxygen consumed are also listed in the tables. The values depend on the chemical structures of the materials. With some exceptions, the values remain approximately constant within each generic group of fuels. From the average values, $\Delta H_O^* = 12.8 \pm 0.9$ kJ/g. The ΔH_O^* value of 12.8 kJ/g is in good agreement with the value 13.1 ± 0.7 kJ/g reported in Ref. [21]. The variation of ±0.9 kJ/g (7 %) would reduce significantly if values for low molecular weight hydrocarbons with small amounts of O, N, and halogen were used in averaging. For the determination of chemical heat release rate, mass consumption rate of oxygen is measured, and either the actual values or the average values of the net heats of complete combustion per unit mass of oxygen consumed are used. The measurement for the consumption rate of oxygen is described in section "Generation of Fire Products and Smoke Yields" of this chapter.

As discussed above for CDG calorimetry, in situations where incomplete combustion is prevalent, the equations above will have to be corrected for the formation of products such as soot and unburned hydrocarbons [108, 109]. Furthermore, for materials that have bound oxygen in their chemical structures, oxygen may be released as a product of combustion which will affect the OC methodology [110]. Thus, chemical structure plays an important role in the determination of heat release rate [111].

Convective Heat Release Rate

The convective heat release rate is determined from GTR calorimetry, where the following relationship is used [1–3, 13, 14, 28, 31, 44, 103]:

$$\dot{Q}''_{\text{con}} = \frac{\dot{W} c_p (T_g - T_a)}{A} \tag{36.27}$$

where

$\dot{Q}''_{\text{con}}$ = Convective heat release rate (kW/m^2)
c_P = Specific heat of the combustion product-air mixture at the gas temperature (kJ/g/K)
T_g = Gas temperature (K)
T_a = Ambient temperature (K)
$\dot{W}$ = Total mass flow rate of the fire product-air mixture (g/s)
A = Total exposed surface area of the material (m^2)

Radiative Heat Release Rate The chemical heat release rate consists of a convective and a radiative component [25]. Some fraction of the chemical heat release rate may be lost as conductive heat. In systems where such conductive heat losses are negligibly small, the radiative heat release rate can be obtained from the difference between the chemical and convective heat release rates [14, 25, 28, 31, 44, 103]:

$$\dot{Q}''_{\text{rad}} = \dot{Q}''_{\text{ch}} - \dot{Q}''_{\text{con}} \tag{36.28}$$

where $\dot{Q}''_{\text{rad}}$ is the radiative heat release rate (kW/m^2).

Energy Released in a Fire The total amount of heat generated as a result of chemical reactions in the combustion of a material is defined as chemical energy. The chemical energy has a convective and a radiative component:

$$E_{\text{ch}} = E_{\text{con}} - E_{\text{rad}} \tag{36.29}$$

where

E_{ch} = Chemical energy (kJ)
E_{con} = Convective energy (kJ)
E_{rad} = Radiative energy (kJ)

The chemical energy and its convective and radiative components are calculated by the time integration of the respective heat release rates, expressed here by a numerical summation:

$$E_i = A \sum_{n=t_{ig}}^{n=t_{ex}} \dot{Q}''_i(t_n) \Delta t_n \tag{36.30}$$

where

E_i = Chemical, convective, or radiative energy (kJ)
A = Total surface area of the material burning (m^2)
t_{ig} = Ignition time (s)
t_{ex} = Flame extinction time (s)

The total mass of the material lost during combustion can be measured directly from the initial and final mass or calculated by the time integration of the mass loss rate, expressed here by a numerical summation:

$$W_f = A\sum_{n=t_{ig}}^{n=t_{ex}} \dot{m}''(t_n)\Delta t_n \qquad (36.31)$$

where W_f is the total mass of the material lost (g) in the combustion process.

Heat release rate can also be expressed as the product of the mass loss rate and the heat of combustion of the material, if it is known a priori:

$$\dot{Q}_i'' = \Delta H_i \dot{m}'' \qquad (36.32)$$

where ΔH_i is the chemical, convective, or radiative heat of combustion (kJ/g). In turn, the average chemical, convective, or radiative heats of combustion can be calculated from the calorimetry relationships based on Equations 36.22 (or 36.25), 36.27, 36.28, and 36.30 so that:

$$\Delta\overline{H}_i = \frac{E_i}{W_f} \qquad (36.33)$$

where $\Delta\overline{H}_i$ is the average chemical, convective, or radiative heat of combustion (kJ/g). The average chemical heat of combustion determined in the cone calorimeter is defined as the effective heat of combustion [22–24].

Heat Release Parameter (HRP) From Equations 36.15 and 36.32 the amount of energy generated per unit amount of energy absorbed can be expressed as:

$$\dot{Q}_i'' = \left(\frac{\Delta H_i}{\Delta H_g}\right)\left(\dot{q}_e'' + \dot{q}_{fr}'' + \dot{q}_{fc}'' - \dot{q}_{rr}''\right) \qquad (36.34)$$

where the ratio $\Delta H_i/\Delta H_g$ is defined as the Heat Release Parameter (HRP) and, as the heat release rate itself, has chemical, convective, and radiative components (HRP_{ch}, HRP_{con}, and HRP_{rad}, respectively) [44]. The HRP values are characteristic fire properties of materials but depend on fire ventilation. The chemical HRP is independent of fire size.

Experimental data support Equation 36.34, as shown in Figs. 36.30, 36.31, and 36.32, where the average peak or steady-state chemical heat release rates are plotted against the net heat flux. A clear linear relationship between the chemical heat release rate and net heat flux can be discerned. For the condition $\dot{q}_e'' >> \dot{q}_{fr}'' + \dot{q}_{fc}'' - \dot{q}_{rr}''$, the average HRP value can be calculated from

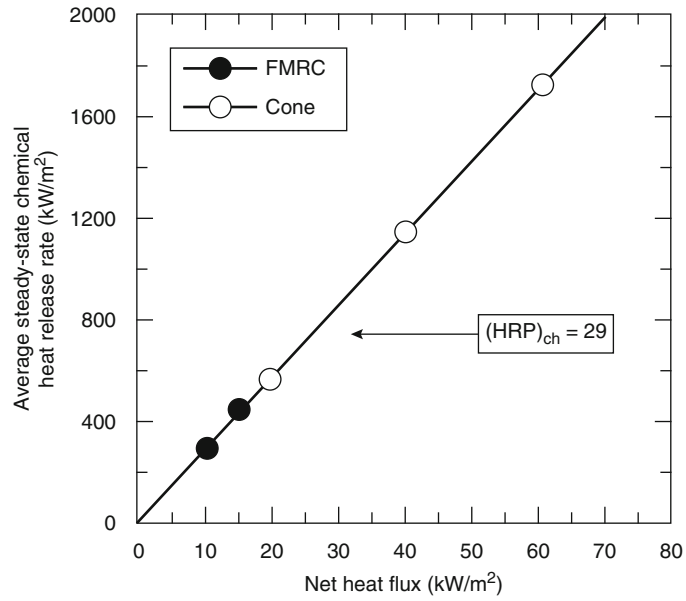

Fig. 36.30 Average steady-state chemical heat release rate versus net heat flux for a polystyrene sample. Net heat flux is the sum of the external and flame heat fluxes minus the surface re-radiation

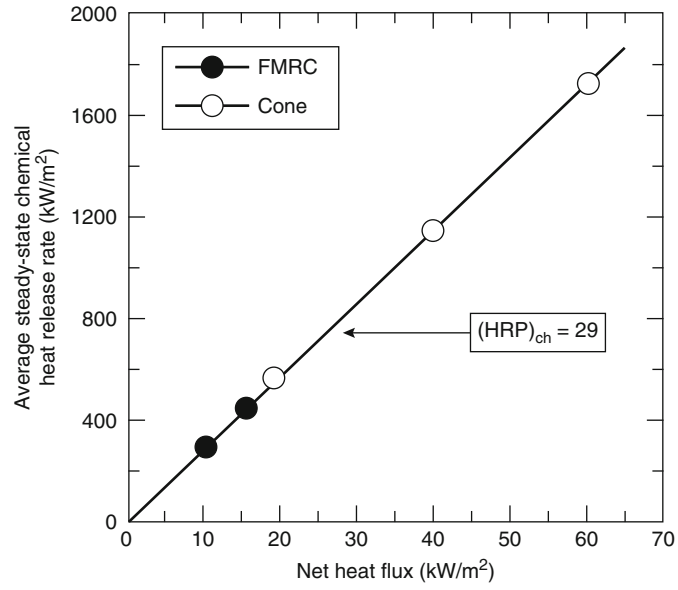

Fig. 36.31 Average steady-state chemical heat release rate versus the net heat flux for a high molecular weight hydrocarbon liquid burning in a 100-mm-diameter dish. The cone calorimeter data were measured at the research laboratory of the Dow-Corning Corporation, Midland, Michigan. Net heat flux is the sum of the external and flame heat fluxes minus the surface re-radiation

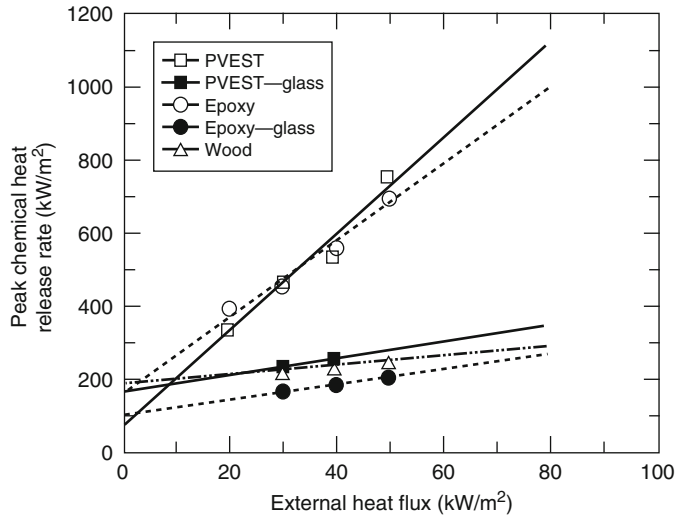

Fig. 36.32 Peak chemical heat release rate versus the external heat flux for a 100-mm × 100-mm × 3-mm to 11-mm-thick slab of polyvinyl ester (PVEST), PVEST/fiberglass, epoxy, epoxy/fiberglass, and wood (hemlock). Data measured in the cone calorimeter are shown [32]

the summation of the heat release rate and the external heat flux:

$$\overline{\mathrm{HRP}}_i = \frac{E_i}{A\int \dot{q}_e'' dt} = \frac{\sum_{n=t_{ig}}^{n=t_{ex}} \dot{Q}_i''(t_n)\Delta t_n}{\sum_{n=t_{ig}}^{n=t_{ex}} \dot{q}_e''(t_n)\Delta t_n} \qquad (36.35)$$

Incompleteness of Combustion In fires, combustion is never complete. Thus, the chemical heat release rate or the chemical heat of combustion are less than the heat release rate for complete combustion or the net heat of complete combustion, respectively. The ratio of the chemical heat release rate to the heat release rate for complete combustion or the ratio of the chemical heat of combustion to net heat of complete combustion is defined as combustion efficiency [13, 14, 28, 31, 44, 102]:

$$\chi_{\mathrm{ch}} = \frac{\dot{Q}_{\mathrm{ch}}''}{\dot{Q}_T''} = \frac{\dot{m}''\Delta H_{\mathrm{ch}}}{\dot{m}''\Delta H_T} = \frac{\Delta H_{\mathrm{ch}}}{\Delta H_T} \qquad (36.36)$$

where χ_{ch} is the combustion efficiency and $\dot{Q}_T''$ is the heat release rate for complete combustion (kW/m^2). The convective and radiative components of the combustion efficiency are defined in a similar fashion [13, 14, 28, 31, 44, 103]:

$$\chi_{con} = \frac{\dot{Q}_{con}''}{\dot{Q}_T''} = \frac{\dot{m}''\Delta H_{con}}{\dot{m}''\Delta H_T} = \frac{\Delta H_{con}}{\Delta H_T} \tag{36.37}$$

$$\chi_{rad} = \frac{\dot{Q}_{rad}''}{\dot{Q}_T''} = \frac{\dot{m}''\Delta H_{rad}}{\dot{m}''\Delta H_T} = \frac{\Delta H_{rad}}{\Delta H_T} \tag{36.38}$$

where χ_{con} is the convective component of the combustion efficiency and χ_{rad} is the radiative component of the combustion efficiency [25]. From the definitions,

$$\Delta H_{ch} = \Delta H_{con} + \Delta H_{rad} \tag{36.39}$$

$$\chi_{ch} = \chi_{con} + \chi_{rad} \tag{36.40}$$

The chemical, convective, and radiative heat release rates, heats of combustion, and combustion efficiencies depend on the chemical structures of the materials and fire ventilation. The distribution of the chemical heat into convective and radiative components changes with fire size. The larger the fire size, the larger the fraction of the chemical heat distributed into the radiative component.

Chemical, convective, and radiative heats of combustion and HRP values for several materials under well-ventilated fire conditions are listed in Tables A.38 and A.39, respectively. Comparisons between the limited data from the OSU apparatus, Fire Propagation Apparatus, and cone calorimeter are satisfactory. Data were taken from Refs. [32, 112–117].

Example 9 Heptane was burned in a 2-m-diameter pan, and measurements were made for the mass loss rate, mass generation rates of CO and CO_2, and mass consumption rate of O_2. The average values in g/m^2/s for the mass loss rate, mass generation rates of CO and CO_2, and mass consumption rate of O_2 were 66, 9, 181, and 216, respectively. For large-scale fires of heptane, the literature values are and $\chi_{ch} = 0.93$, $\chi_{con} = 0.59$, and $\chi_{rad} = 0.34$. The net heat of complete combustion for heptane reported in the literature is 44.6 kJ/g. Calculate the chemical heat release rate and show that it is consistent with the rate based on the literature value of the combustion efficiency. Also calculate the convective and radiative heat release rates.

Solution From Table A.38, for heptane, the net heat of complete combustion per unit mass of oxygen consumed is 12.7 kJ/g; the net heat of complete combustion per unit mass of CO_2 generated is 14.5 kJ/g; and the net heat of complete combustion per unit mass of CO generated is 12.8 kJ/g. From CDG calorimetry (Equation 36.22),

$$\dot{Q}_{ch}'' = \Delta H_{CO_2}^* \dot{G}_{CO_2}'' + \Delta H_{CO}^* \dot{G}_{CO}''$$

$$\dot{Q}_{ch}'' = \left(14.5\,\frac{kJ}{g}\right)\left(181\,\frac{g}{m^2 s}\right) + \left(12.8\,\frac{kJ}{g}\right)\left(9\,\frac{g}{m^2 s}\right)$$

$$\dot{Q}_{ch}'' = 2740\frac{kW}{m^2}$$

From OC calorimetry (Equation 36.25),

$$\dot{Q}_{ch}'' = \Delta H_O^* \dot{C}_O''$$

$$\dot{Q}_{ch}'' = \left(12.7\frac{kJ}{g}\right)\left(216\frac{g}{m^2 s}\right)$$

$$\dot{Q}_{ch}'' = 2743\frac{kW}{m^2}$$

The chemical heat release rate from the CDG and OC calorimetries are in excellent agreement, the average being 2742 kW/m^2.

The chemical heat of combustion can be obtained from Equation 36.36:

$$\chi_{ch} = \frac{\Delta H_{ch}}{\Delta H_T}$$

$$\Delta H_{ch} = \chi_{ch}\Delta H_T$$

$$\Delta H_{ch} = (0.93)\left(44.6\,\frac{kJ}{g}\right)$$

$$\Delta H_{ch} = 41.5\,\frac{kJ}{g}$$

The chemical heat release can now be obtained from the product of the mass loss rate

and chemical heat of combustion, as in Equation 36.32:

$$\dot{Q}''_{\text{ch}} = \Delta H_{\text{ch}} \dot{m}''$$
$$\dot{Q}''_{\text{ch}} = \left(41.5 \frac{\text{kJ}}{\text{g}}\right)\left(66 \frac{\text{g}}{\text{m}^2\text{s}}\right)$$
$$\dot{Q}''_{\text{ch}} = 2739 \frac{\text{kW}}{\text{m}^2}$$

Compare this result the averaged value 2742 kW/m^2 from the CDG and OC calorimetries. Thus, the chemical heat release determined from the measurements is consistent with the rate obtained from the literature values of the combustion efficiency.

Finally, the convective heat release rate can be computed much in the same manner as above. Here, for simplicity, Equations 36.32 and 36.36 are combined to yield the convective heat release rate:

$$\dot{Q}''_{\text{con}} = \chi_{\text{con}} \Delta H_T \dot{m}''$$
$$\dot{Q}''_{\text{con}} = (0.59)\left(44.6 \frac{\text{kJ}}{\text{g}}\right)\left(66 \frac{\text{g}}{\text{m}^2\text{s}}\right)$$
$$\dot{Q}''_{\text{con}} = 1737 \frac{\text{kW}}{\text{m}^2}$$

In a similar fashion, the radiative heat release rate is calculated to be 1001 kW/m^2.

Example 10 From the flame radiation scaling technique, the asymptotic mass loss rate values in g/m^2/s expected in large-scale fires, as listed in Table 36.7, for polyethylene, polystyrene, polyvinylchloride, and Teflon are 26, 36, 16, and 7, respectively. The chemical heats of combustion in kJ/g listed in Table A.38 for these materials are 38.4, 27.0, 5.7, and 4.1, respectively. Estimate the chemical heat release rates expected in large-scale fires of polyethylene, polystyrene, polyvinylchloride, and Teflon. (In this chapter Teflon refers mainly to FEP, except in cases where it is identified otherwise.)

Solution The chemical heat release rate is calculated from Equation 36.32. The chemical heat release rates estimated in the large-scale fires are (1) polyethylene: 26 × 38.4 = 998 kW/m^2; (2) polystyrene: 36 × 27.0 = 972 kW/m^2; (3) polyvinylchloride: 16 × 5.7 = 91 kW/m^2; and (4) Teflon: 7 × 4.1 = 28 kW/m^2.

Example 11 Heat release rate is the product of the HRP and the net heat flux absorbed by the material, as indicated in Equations 36.34 and 36.35. This concept is used in various models to predict fire propagation and heat release rates, whereas values for the HRP are taken from a handbook such as this handbook, and net heat flux is estimated through correlations. The lower the HRP value for a fixed value of net heat flux, the lower the heat release rate.

The values for the surface re-radiation, flame heat flux for large-scale fires, and chemical HRP are listed in Tables 36.6, 36.7, and 36.10, respectively. Calculate the chemical heat release rates expected in large-scale fires of heptane, kerosene, polyethylene, polypropylene, polystyrene, polymethylmethacrylate, polyvinylchloride, and Teflon.

Solution The chemical heat release rates are calculated from Equation 36.34:

$$\dot{Q}''_{\text{ch}} = \left(\frac{\Delta H_{\text{ch}}}{\Delta H_g}\right)\left(\dot{q}''_e + \dot{q}''_{fr} + \dot{q}''_{fc} - \dot{q}''_{rr}\right)$$

In this specific example, there is no external heat flux sources. Recognizing that $(\Delta H_{\text{ch}}/\Delta H_g) = \text{HRP}_{\text{ch}}$, and setting the asymptotic flame heat flux values from 7 to the relationship $\dot{q}''_{fr} + \dot{q}''_{fc}$ one obtains:

$$\dot{Q}''_{\text{ch}} = \text{HRP}_{\text{ch}}\left(\dot{q}''_{f,\text{asy}} - \dot{q}''_{rr}\right)$$

Therefore:

1. heptane: (75)(37 – 1) = 2700 kW/m^2
2. kerosene: (47)(29 – 1) = 1316 kW/m^2
3. polyethylene: (17)(61 – 15) = 782 kW/m^2
4. polypropylene: (19)(67 – 15) = 988 kW/m^2
5. polystyrene: (16)(75 – 13) = 992 kW/m^2
6. polymethylmethacrylate: (15)(57 – 11) = 690 kW/m^2
7. polyvinylchloride: (2)(50 – 15) = 70 kW/m^2
8. Teflon: (2)(52 – 38) = 28 kW/m^2

[a]Calculated from the data reported in Refs. [32, 113]
[b]Calculated from the data in Refs. [112, 114]
[c]From Ref. [115]

The example shows the importance of the chemical HRP, flame heat flux, and surface re-radiation.

Heat Release Rate and Fire Ventilation For the most part, fire hazards are due to fires occurring in enclosed spaces. In early stages, a building fire is well ventilated and is easy to control and extinguish. However, if the fire is allowed to grow, especially with limited enclosure ventilation and large material surface area, it becomes a ventilation-controlled fire and can lead to flashover, a very dangerous condition. In ventilation-controlled fires, the chemical reactions between oxygen from air and products of incomplete combustion from the decomposed and gasified material (e.g., smoke, CO, hydrocarbons, and other intermediate products) remain incomplete and heat release rate decreases [103].

In ventilation-controlled fires, heat release rate depends on the air supply rate and the mass loss rate, in addition to other factors. For ventilation-controlled fires, the effects of mass flow rate of air and fuel mass loss rate are characterized, most commonly, by the local equivalence ratio:

$$\Phi = \frac{S\dot{m}'' A}{\dot{m}_{\text{air}}} \tag{36.41}$$

where
Φ = Equivalence ratio
S = Stoichiometric air-to-fuel mass ratio (g/g)
$\dot{m}''$ = Mass loss rate ($g/m^2 \cdot s$)
A = Exposed area of the burning material (m^2)
$\dot{m}_{\text{air}}$ = Mass flow rate of air (g/s)

Generalized-state relationships between mass fractions of major species (O_2, fuel, CO_2, H_2O, CO, and H_2) and temperature as functions of local equivalence ratios for hydrocarbon-air diffusion flames are available [118]. The relationships suggest that the generation

efficiencies of CO, fuel vapors, water, CO_2, and H and the consumption efficiency of O_2 are in approximate thermodynamic equilibrium for well-ventilated combustion but deviate from equilibrium for ventilation-controlled combustion. This concept has been used for fires of polymeric materials [103]. In the tests, chemical and convective heat release rates, mass loss rate, and generation rates of fire products were measured for various equivalence ratios in the Fire Propagation Apparatus (Fig. 36.2) and in the Fire Research Institute's (FRI) 0.022 m^3 enclosure in Tokyo, Japan [103]. The combustion efficiency and its convective component were found to decrease as fires become fuel rich, due to an increase in the equivalence ratio. The ratio of the combustion efficiency and its convective component or chemical and convective heats of combustion for ventilation-controlled to well-ventilated combustion is expressed as [103]

$$\zeta_{\mathrm{ch}} = \frac{(\chi_{\mathrm{ch}})_{vc}}{(\chi_{\mathrm{ch}})_{wv}} = \frac{(\Delta H_{\mathrm{ch}}/\Delta H_T)_{vc}}{(\Delta H_{\mathrm{ch}}/\Delta H_T)_{wv}} = \frac{(\Delta H_{\mathrm{ch}})_{vc}}{(\Delta H_{\mathrm{ch}})_{wv}} \tag{36.42}$$

$$\zeta_{\mathrm{con}} = \frac{(\chi_{\mathrm{con}})_{vc}}{(\chi_{\mathrm{con}})_{wv}} = \frac{(\Delta H_{\mathrm{con}}/\Delta H_T)_{vc}}{(\Delta H_{\mathrm{con}}/\Delta H_T)_{wv}} = \frac{(\Delta H_{\mathrm{con}})_{vc}}{(\Delta H_{\mathrm{con}})_{wv}} \tag{36.43}$$

where ζ_{ch} is the ratio of the combustion efficiency for ventilation-controlled (vc) combustion to that for well-ventilated (wv) combustion; similarly, ζ_{con} is the ratio of the convective component of the combustion efficiency for ventilation-controlled combustion to that for well-ventilated combustion. These ratios can be represented by the ratio of the chemical or convective heats of combustion for ventilation-controlled to well-ventilated combustion.

The experimental data for the ratios of the chemical and convective heats of combustion for ventilation-controlled to well-ventilated fires at various equivalence ratios are shown in Figs. 36.33 and 36.34. The data and measurement details are described in Ref. [103]. The data for the polymers indicated in the figures satisfy the following general empirical correlations, regardless of their chemical structures:

$$\frac{(\Delta H_{\mathrm{ch}})_{vc}}{(\Delta H_{\mathrm{ch}})_{wv}} = 1 - \frac{0.97}{\exp\left[\left(\frac{\Phi}{2.15}\right)^{-1.2}\right]} \tag{36.44}$$

$$\frac{(\Delta H_{\mathrm{con}})_{vc}}{(\Delta H_{\mathrm{con}})_{wv}} = 1 - \frac{1.0}{\exp\left[\left(\frac{\Phi}{1.38}\right)^{-2.8}\right]} \tag{36.45}$$

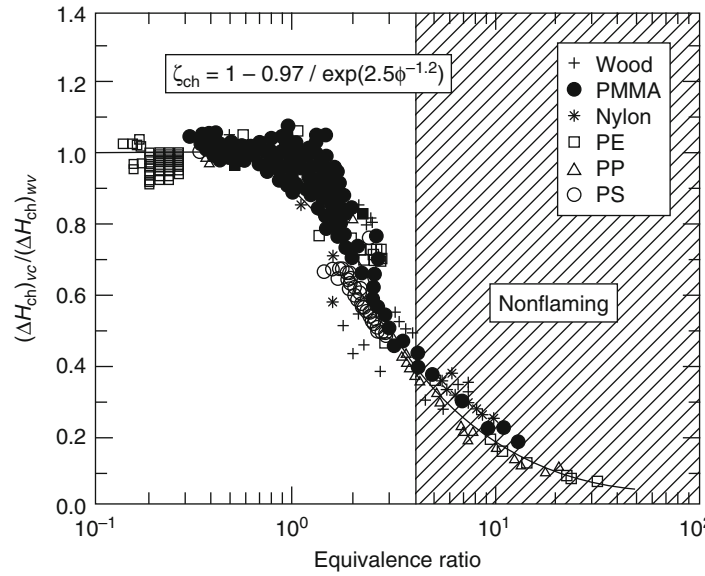

Fig. 36.33 Ratio of ventilation-controlled to well-ventilated chemical heat of combustion versus equivalence ratio (Data are taken from Ref. [103]). Subscript vc represents ventilation-controlled fires, and subscript wv represents well-ventilated fires

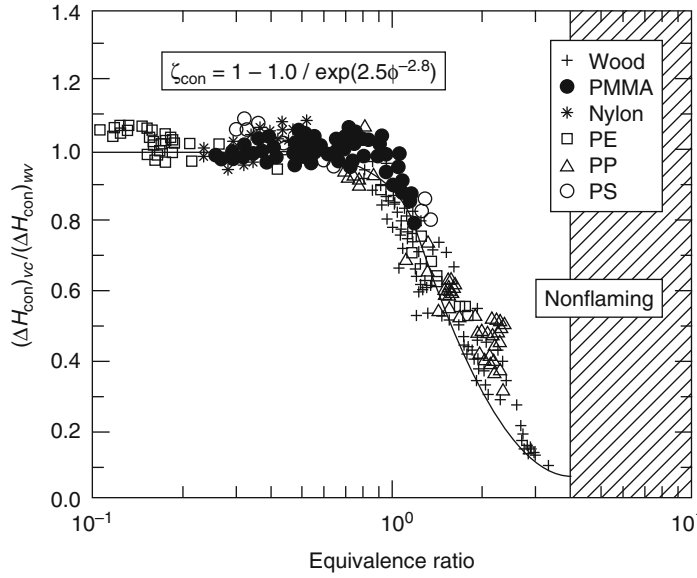

Fig. 36.34 Ratio of the ventilation-controlled to well-ventilated convective heat of combustion versus the equivalence ratio (Data are taken from Ref. [103]). Subscript *vc* represents ventilation-controlled fires, and subscript *wv* represents well-ventilated fires

The effects of ventilation on the chemical and convective heats of combustion are reflected by the magnitudes of the expressions within the parentheses on the right-hand sides of Equations 36.44 and 36.45. For a well-ventilated fire, $\Phi \ll 1.0$, $(\Delta H_{ch})_{vc} = (\Delta H_{ch})_{wv}$, and $(\Delta H_{con})_{vc} = (\Delta H_{con})_{wv}$.

As a fire changes from well ventilated to ventilation controlled, the equivalence ratio increases and the magnitudes of the expressions within the parentheses on the right-hand sides of Equations 36.44 and 36.45 increase. Thus, with increasing equivalence ratio, the chemical and convective heats of combustion decrease. The decrease in the convective heat of combustion is higher than that for the chemical heat of combustion because the coefficients for the equivalence ratios are different. The correlation suggests that a higher fraction of the chemical heat of combustion is expected to be converted to the radiative heat of combustion as fires change from well ventilated to ventilation controlled. This is in general agreement with observations for ventilation-controlled fires in buildings.

Equations 36.44 and 36.45 can be used in models for the assessment of the ventilation-controlled fire behavior of materials, using chemical and convective heats of combustion for well-ventilated fires such as from Table A.39.

Example 12 Calculate the chemical heats of combustion at equivalence ratios of 1, 2, and 3 for red oak, polyethylene, polystyrene, and nylon using Equation 36.44 and data from Table A.39 for well-ventilated fires.

Solution

	Chemical heats of combustion (kJ/g)			
Material	$\Phi \ll 1.0$	$\Phi = 1.0$	$\Phi = 2.0$	$\Phi = 3.0$
Red oak	12.4	11.4	8.3	6.2
Polyethylene	38.4	35.3	25.9	19.3
Polystyrene	27.0	24.9	18.2	13.6
Nylon	27.1	24.9	18.2	13.6

Generation of Fire Products and Smoke Yields

Chemical compounds (smoke, toxic, corrosive, and odorous compounds) are the main contributors to nonthermal hazards and, thus, the assessments of their chemical natures and generation rates are of critical importance for the protection of life and property.

In fires, compounds are generated as a result of gasification and decomposition of materials involved in the fire and burning of the species in the gas phase with air in the form of a diffusion flame. In general, generation of fire products and

consumption of oxygen in diffusion flames occur in two zones [103].

1. *Reduction zone*. In this zone, the material melts, decomposes, gasifies, and/or generates species that react to form smoke, CO, hydrocarbons, and other intermediate products. Very little oxygen is consumed in this region. The extent of conversion of the material to smoke, CO, hydrocarbons, and other products depends on the chemical nature of the material.
2. *Oxidation zone*. In this zone, the reduction zone products (smoke, CO, hydrocarbons, and other intermediates) react with varying degrees of efficiency with the oxygen from air and generate chemical heat and varying amounts of products of complete combustion, such as CO_2 and H_2O. The lower the reaction efficiency, the higher the amounts of reduction zone products emitted from a fire. The reaction efficiency of the reduction zone products with oxygen depends on the concentrations of the products relative to the oxygen concentration, temperature, and mixing of the products and air. For example, in laminar diffusion flames, smoke is emitted when the temperature of the oxidation zone falls below about 1300 K.

The hot ceiling layer in a building fire may be considered in terms of oxidation and reduction zone products. In building fires with plenty of ventilation, the concentrations of the reduction zone products are higher in the central region of the ceiling layer, whereas the concentrations of the oxidation zone products are higher closer to the room opening. As the air supply rate, or oxygen concentration available to the fire, decreases due to restrictions in the ventilation, the ceiling layer expands and starts occupying a greater room volume accompanied with an increase in the concentrations of reduction zone products. Under these conditions, large amounts of reduction zone products are released within the building increasing the nonthermal hazard.

The generation rate of a fire product is directly proportional to the mass loss rate, the proportionality constant being defined as the yield of the product (e.g., [9, 112]):

$$\dot{G}_j'' = y_j \dot{m}'' \tag{36.46}$$

where $\dot{G}_j''$ is the mass generation rate of product j (g/m^2/s), and y_j is the yield of product j (g/g). The total mass of the product generated is obtained by the summation of the generation rate:

$$W_j = A \sum_{n=t_0}^{n=t_f} \dot{G}_j''(t_n) \Delta t_n \tag{36.47}$$

where

W_j = Total mass of product j generated from the flaming and/or nonflaming processes involving the material (g)

t_0 = Time when the sample is exposed to heat(s)

t_f = Time when there is no more product formation

From Equations 36.31, 36.46, and 36.47, the average value of the yield of product j is

$$\overline{y}_j = \frac{W_j}{W_f} \tag{36.48}$$

Similarly, the mass consumption rate of oxygen is also directly proportional to the mass loss rate (e.g., [9, 112]):

$$\dot{C}_{\mathrm{O}}'' = c_{\mathrm{O}} \dot{m}'' \tag{36.49}$$

Where $\dot{C}_{\mathrm{O}}''$ is the mass consumption rate of oxygen (g/m^2/s), and c_{O} is the mass of oxygen consumed per unit mass of fuel (g/g).

In the bench-scale apparatuses described in this chapter, the mass generation rates of fire products and mass consumption rate of oxygen are determined by measuring the volume fractions of the products and oxygen and the total volumetric or mass flow rate of the fire products-air mixture (e.g., [10, 11, 28, 31]):

$$\dot{G}_j'' = \frac{f_j \dot{V} \rho_j}{A} = f_j \dot{W} \left(\frac{\rho_j}{\rho_g A} \right) \tag{36.50}$$

$$\dot{C}_{\mathrm{O}}'' = \frac{f_{\mathrm{O}} \dot{V} \rho_{\mathrm{O}}}{A} = f_{\mathrm{O}} \dot{W} \left(\frac{\rho_{\mathrm{O}}}{\rho_g A} \right) \tag{36.51}$$

where

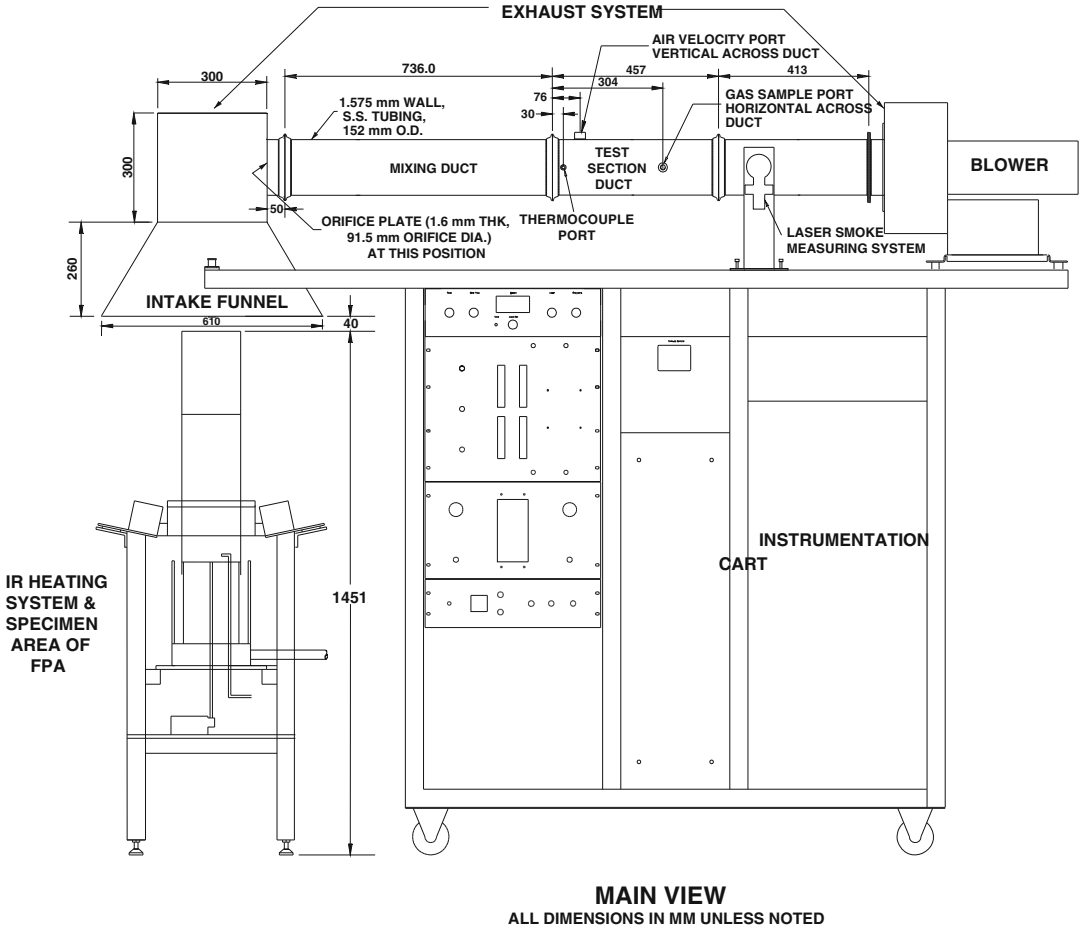

Fig. 36.35 Schematic of the commercial version [119] of the Fire Propagation Apparatus showing locations where measurements are made for product concentration, optical transmission, particulate concentration, and corrosion

f_j = Volume fraction of product j
f_O = Volume fraction of oxygen
$\dot{V}$ = Total volumetric flow rate of the fire product-air mixture (m^3/s)
$\dot{W}$ = Total mass flow rate of the fire product-air mixture (g/s)
ρ_j = Density of product j at the temperature of the fire product-air mixture (g/m^3)
ρ_g = Density of the hot fire product-air mixture (g/m^3)
ρ_O = Density of oxygen at the temperature of the fire product-air mixture (g/m^3)
A = Total area of the material burning (m^2)

For volume fraction measurements, sampling ducts are used where fire products and air are well mixed, such as in the Fire Propagation Apparatuses (Figs. 36.2, 36.3, and 36.35) and in the cone calorimeter (Fig. 36.4). Figure 36.35 shows the measurement locations in the sampling duct of a commercial version [119] of the Fire Propagation Apparatus. The volume fractions are measured by various types of instruments; for example, in the Fire Propagation Apparatus, they are measured continuously by (1) commercial non-dispersive infrared analyzers for CO and CO_2; (2) a high-sensitivity commercial paramagnetic analyzer for oxygen; (3) a commercial flame ionization analyzer for the mixture of low molecular weight gaseous hydrocarbons; and (4) by a laser (wavelength: 0.6328 μm) smoke measuring system.

The optical density at the measurement location in the sampling duct is determined from the following equation:

$$D = \frac{\ln(I_0/I)}{l} \tag{36.52}$$

where, D is the optical density (m^{-1}) at a laser wavelength of 0.6328 μm; I/I_0 is the fraction of monochromatic light transmitted through smoke; and l is the optical path length (m). The volume fraction of smoke f_s is obtained from the following expression [120]:

$$f_s = \frac{D\lambda \times 10^{-6}}{\Omega} \tag{36.53}$$

where, λ is the wavelength of the light source (μm) and Ω is the coefficient of smoke extinction taken as 7 [120]. The mass generation rate ($kg/m^2/s$) of smoke is given by:

$$\dot{G}_s'' = \frac{f_s \dot{V} \rho_s}{A} = \left(\frac{D\lambda \times 10^{-6}}{7}\right)\left(\frac{\rho_s \dot{V}}{A}\right) \tag{36.54}$$

Incorporating the value of smoke density, $\rho_s = 1.1 \times 10^6$ g/m^3, as determined in Ref. [120] and the laser wavelength of 0.6328 μm in Equation 36.54 then gives the following result:

$$\dot{G}_s'' = 9.944 \times 10^{-2}\left(\frac{D\dot{V}}{A}\right) \tag{36.55}$$

Equation 36.55 can then be used along with Equations 36.31, 36.47, and 36.48 to calculate the average smoke yield, $\overline{y}_s$, for a given material. The average value of smoke yield, can also be obtained from the average mass-specific extinction area [24, 121], $\overline{\tau}$ (m^2/g), at the same laser wavelength of 0.6328 μm:

$$\overline{\tau} = \frac{1}{W_f}\int \dot{V} D dt = \frac{1}{W_f}\sum_{n=t_0}^{n=t_f} \dot{V}(t_n) D(t_n) \Delta t_n \tag{36.56}$$

The average smoke yield is, in this case, calculated from the following expression:

$$\overline{y}_s = 9.944 \times 10^{-2}\overline{\tau} \tag{36.57}$$

The average data for the yields of CO, CO_2, mixture of gaseous hydrocarbons, and smoke for well-ventilated fires are listed in Table A.39.

Example 13 For a fiberglass-reinforced material, the following data were measured for combustion in normal air at an external heat flux value of 50 kW/m^2:

Total mass of the sample lost (g)	229
Total mass generated (g)	
CO	0.478
CO_2	290
Hydrocarbons	0.378
Smoke	6.31
Total energy generated (kJ)	3221

Calculate the average yields of CO, CO_2, hydrocarbons, and smoke and the average chemical heat of combustion.

Solution The average yields are calculated from Equation 36.48, and the average chemical heats of combustion are calculated from Equation 36.33.

Average yields (g/g)	
CO	0.0021
CO_2	1.27
Hydrocarbons	0.002
Smoke	0.028
Average chemical heats of combustion (kJ/g)	14.1

Example 14 A circular sample of polystyrene, about 0.007 m^2 in area and 25 mm in thickness, was burned in normal air in the presence of external heat flux. In the test, measurements were made for the mass loss rate and light obscuration by smoke in the sampling duct with an optical path length of 0.149 m. The total volumetric flow rate of the mixture of fire products and air through the sampling duct was 0.311 m^3/s, and the wavelength of light source used was 0.6328 μm. At the steady-state combustion of polystyrene, the measured mass loss rate was 33 $g/m^2/s$ with smoke obscuring 83.5 % of the light. Calculate the yield of smoke from the data using a value of 1.1×10^6 g/m^3 for the density of smoke.

Solution The optical density from Equation 36.52 is

$$D = \frac{\ln(I_0/I)}{l} = \frac{\ln(1/0.835)}{0.149} = 1.21 \ \text{m}^{-1}$$

The smoke generation rate from Equation 36.55 is

$$\dot{G}_s'' = 9.944 \times 10^{-2} \frac{\text{g}}{\text{m}^2} \left(\frac{D\dot{V}}{A}\right)$$

$$\dot{G}_s'' = 9.944 \times 10^{-2} \frac{\text{g}}{\text{m}^2} \left[\frac{\left(1.21 \frac{1}{\text{m}}\right)\left(0.311 \frac{\text{m}^3}{\text{s}}\right)}{0.007 \ \text{m}^2}\right]$$

$$\dot{G}_s'' = 5.35 \frac{\text{g}}{\text{m}^2\text{s}}$$

The smoke yield from Equation 36.46 is

$$\dot{G}_s'' = y_s \dot{m}''$$

$$y_s = \frac{\dot{G}_s''}{\dot{m}''} = \frac{5.35 \frac{\text{g}}{\text{m}^2\text{s}}}{33 \frac{\text{g}}{\text{m}^2\text{s}}}$$

$$y_s = 0.162$$

Efficiencies of Oxygen Mass Consumption and Mass Generation of Products

A chemical reaction between oxygen (air) and a fuel monomer of a material can be expressed as

$$F + \nu_O O_2 + \nu_N N_2 = \nu_N N_2 + \sum_i \nu_{j_i} J_i \tag{36.58}$$

where

F = Fuel monomer of a material

ν_O = Stoichiometric coefficient for oxygen

ν_N = Stoichiometric coefficient for nitrogen

ν_{j_i} = Stoichiometric coefficients for the maximum possible conversion of the fuel monomer to products J_i

The stoichiometric mass oxygen-to-fuel ratio for the maximum possible conversion of the fuel monomer is expressed as

$$\Psi_O = \frac{\nu_O M_O}{M_f} \tag{36.59}$$

where

Ψ_O = Stoichiometric oxygen-to-fuel mass ratio for the maximum possible conversion of the fuel monomer to products

M_O = Molecular weight of oxygen (32 g/mol)

M_f = Molecular weight of the fuel monomer of the material (g/mol)

M_f is calculated from its elemental composition which may be determined from microanalytical techniques.

The stoichiometric yield for the maximum possible conversion of the fuel monomer of the material to a product is expressed as

$$\Psi_j = \frac{\nu_j M_j}{M_f} \tag{36.60}$$

where Ψ_j is the stoichiometric yield for the maximum possible conversion of the fuel monomer of the material to product j, and M_j is the molecular weight of product (g/mol).

The stoichiometric yields for some selected materials, calculated from the elemental composition data from the flammability laboratory, are listed in Table 36.11 for fuel monomer conversion to CO, CO_2, hydrocarbons, smoke, HCl, and HF. The yields provide an insight into the nature of products and the amounts of products expected to be generated in flaming and nonflaming processes, when expressed as the stoichiometric oxygen mass consumption rate and stoichiometric mass generation rates of products:

$$\dot{C}_{\text{stoich,O}}'' = \Psi_O \dot{m}'' \tag{36.61}$$

$$\dot{G}_{\text{stoich},j}'' = \Psi_j \dot{m}'' \tag{36.62}$$

where $\dot{C}_{\text{stoich,O}}''$ and $\dot{G}_{\text{stoich},j}''$ are the stoichiometric oxygen mass consumption rate and stoichiometric mass generation rate of product j for the maximum possible conversion of the fuel monomer to the product, respectively (g/m^2/s).

In fires, due to incompleteness of combustion as discussed above, the actual oxygen mass consumption rate and the mass generation rates of products may be significantly less than the stoichiometric rates. The ratio of the actual oxygen mass consumption rate to stoichiometric rates is

Table 36.11 Stoichiometric yields of major products[a]

[a]Calculated from the data for the elemental compositions of the materials; subscript hc is total gaseous hydrocarbons; s is soot
[b]$\eta SiO_2 = 0.483$
[c]$\eta SiO_2 = 0.610$
[d]$\eta SiO_2 = 0.811$

thus defined as the efficiency of oxygen mass consumption or product mass generation (e.g., [103]):

$$\eta_O = \frac{\dot{C}''_{\text{actual,O}}}{\dot{C}''_{\text{stoich,O}}} = \frac{c_O \dot{m}''}{\Psi_O \dot{m}''} = \frac{c_O}{\Psi_O} \tag{36.63}$$

$$\eta_j = \frac{\dot{C}''_{\text{actual},j}}{\dot{C}''_{\text{stoich},j}} = \frac{y_j \dot{m}''}{\Psi_j \dot{m}''} = \frac{y_j}{\Psi_j} \tag{36.64}$$

Where η_O is the efficiency of oxygen mass consumption and η_j is the generation efficiency of product j.

Example 15 A material is made up of carbon, hydrogen, and oxygen. The weight of the material is distributed as follows: 54 % as carbon, 6 % as hydrogen, and 40 % as oxygen. Calculate the chemical formula of the fuel monomer of the material.

Solution From the atomic weights and the weight percent of the atoms, the numbers of atoms are as follows: carbon (C): 54/12 = 4.5; hydrogen (H): 6/1 = 6.0; and oxygen (O): 40/16 = 2.5. Thus, the chemical formula of the fuel monomer of the material is $C_{4.5}H_{6.0}O_{2.5}$ or, dividing by 4.5, $CH_{1.33}O_{0.56}$.

Example 16 For the material in Example 15, calculate the stoichiometric oxygen-to-fuel mass ratio, stoichiometric air-to-fuel mass ratio, and stoichiometric yields for maximum possible conversion of the fuel monomer of the material to CO, CO_2, hydrocarbons, water, and smoke. Assume smoke to be pure carbon, and hydrocarbons as having the same carbon-atom-to-hydrogen-atom ratio as the original fuel monomer.

Solution

1. For stoichiometric yields of CO_2 and water and the stoichiometric oxygen- and air-to-fuel mass ratio for the maximum possible conversion of the fuel monomer of the material to CO_2 and H_2O, the following expression is used:

$$CH_{1.33}O_{0.56} + 1.06\,O_2 = CO_2 + 0.67\,H_2O$$

The molecular weight of the fuel monomer of the material is $1 \times 12 + 1.33 \times 1 + 0.56 \times 16 = 22.3$ g/mol, the molecular weight of oxygen is 32 g/mol, the molecular weight of CO_2 is 44 g/mol, and the molecular weight of H_2O is 18 g/mol. Thus, from Equation 36.59:

$$\Psi_{CO_2} = \frac{44}{22.3} = 1.97$$

$$\Psi_{H_2O} = \frac{0.67 \times 18}{22.3} = 0.54$$

$$\Psi_O = \frac{1.06 \times 32}{22.3} = 1.52$$

The stoichiometric air-to-fuel mass ratio can be obtained by dividing Ψ_O by 0.233 (i.e., the

mass fraction of oxygen in air); that is, 1.52/0.233 = 6.52.

2. For stoichiometric yields of CO, hydrocarbons, and smoke for the maximum possible conversion of the fuel monomer of the material to these products, different chemical reactions have to be written, as follows:
For CO,

$$CH_{1.33}O_{0.56} + zO_2 = CO + x(HO)$$
$$\Psi_{CO} = 28/22.3 = 1.26$$

For hydrocarbons (same H/C ratio as fuel monomer),

$$CH_{1.33}O_{0.56} + zO_2 = CH_{1.33} + x(HO)$$
$$\Psi_{hc} = 13.3/22.3 = 0.60$$

For smoke (i.e., pure carbon),

$$CH_{1.33}O_{0.56} + zO_2 = C + x(HO)$$
$$\Psi_s = 12/22.3 = 0.54$$

Example 17 For the material in Examples 15 and 16, the generation efficiencies of CO_2, CO, hydrocarbons, and smoke are 0.90, 0.004, 0.002, and 0.036, respectively. The heat of gasification is 1.63 kJ/g, the surface re-radiation loss is 11 kW/m^2, and the predicted asymptotic flame heat flux value for large-scale fires is 60 kW/m^2. Calculate the yields and asymptotic values for the generation rates of CO_2, CO, hydrocarbons, and smoke expected in large-scale fires.

Solution

1. Yields from Equations 36.63 and 36.64 and data from Example 16:

$$y_{CO_2} = \eta_{CO_2}\Psi_{CO_2} = 0.90 \times 1.97 = 1.77 \ \text{g/g}$$
$$y_{CO} = \eta_{CO}\Psi_{CO} = 0.004 \times 1.26 = 0.005 \ \text{g/g}$$
$$y_{hc} = \eta_{hc}\Psi_{hc} = 0.002 \times 0.60 = 0.001 \ \text{g/g}$$
$$y_s = \eta_s\Psi_s = 0.036 \times 0.54 = 0.019 \ \text{g/g}$$

2. Asymptotic values for the mass loss rate from Equation 36.15:

$$\dot{m}'' = \frac{\dot{q}''_{f,asy} - \dot{q}''_{rr}}{\Delta H_g} = \frac{60 - 11}{1.63} = 30 \frac{\text{g}}{\text{m}^2\text{s}}$$

3. Asymptotic values for the mass generation rates of products from Equation 36.46 and the above data:

$$\dot{G}''_{CO_2} = y_{CO_2}\dot{m}'' = 1.77 \times 30 = 53 \ \text{g/m}^2\text{/s}$$
$$\dot{G}''_{CO} = y_{CO}\dot{m}'' = 0.005 \times 30 = 0.159 \ \text{g/m}^2\text{/s}$$
$$\dot{G}''_{hc} = y_{hc}\dot{m}'' = 0.001 \times 30 = 0.036 \ \text{g/m}^2\text{/s}$$
$$\dot{G}''_{hc} = y_{hc}\dot{m}'' = 0.019 \times 30 = 0.584 \ \text{g/m}^2\text{/s}$$

Generation Rates of Fire Products and Fire Ventilation Effects

As discussed previously, the effects of decreasing fire ventilation, as characterized by the increase in the local equivalence ratio, are reflected by an increase in the generation rates of the reduction zone products (smoke, CO, hydrocarbons, and others). For example, for flaming wood crib enclosure fires, as the equivalence ratio increases, the combustion efficiency decreases, flames become unstable, and the generation efficiency of CO reaches its peak for the equivalence ratio between about 2.5 and 4.0 [103].

Ventilation-controlled building fires are generally characterized by two layers: (1) a vitiated ceiling layer, identified as *upper layer,* and (2) an uncontaminated layer below, identified as *lower layer*. Incorporation of these two layers is the classical two-zone modeling of fires in enclosed spaces. Under many conditions, the depth of the upper layer occupies a significant fraction of the volume of the enclosed space. Eventually, the interface between the upper layer and the lower layer positions itself so that it is very close to the floor, very little oxygen is available for combustion, and most of the fuel is converted to the reduction zone products, that is, smoke, CO, hydrocarbons, and others.

Ventilation-controlled large- and small-enclosure and laboratory-scale fires and fires in the vitiated upper layer under experimental hoods have been studied in detail and reviewed [103, 122–125]. The results from these types of fires are very similar. Detailed studies [103] performed for the generation rates of fire products for various fire ventilation conditions

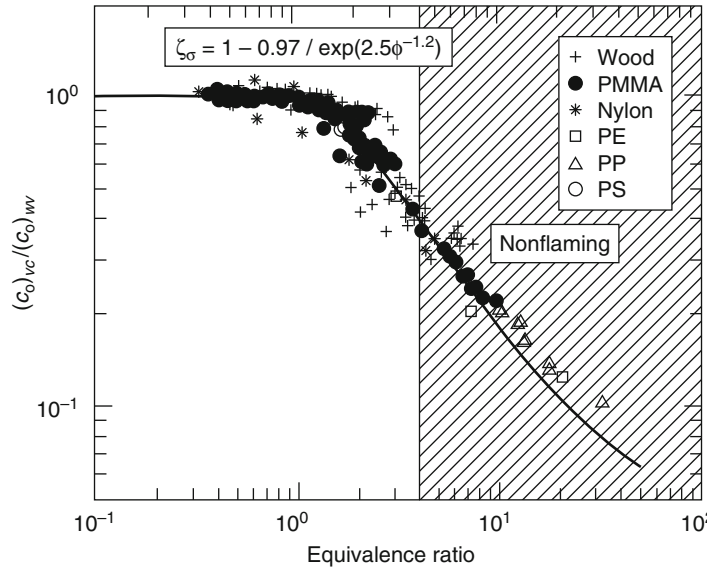

Fig. 36.36 Ratio of the mass of oxygen consumed per unit mass of the fuel for ventilation-controlled to well-ventilated fires (Data are taken from Ref. [103]). Subscript *vc* represents ventilation-controlled fires, and subscript *wv* represents well-ventilated fires

in the Fire Propagation Apparatus and in the Fire Research Institute's (FRI) enclosure, show that with an increase in the equivalence ratio (1) generation efficiencies of oxidation zone products, such as CO_2, and reactant consumption efficiency (i.e., oxygen) decrease, and (2) generation efficiencies of the reduction zone products, such as smoke, CO, and hydrocarbons increase.

Generalized correlations have been established between the generation efficiencies and the equivalence ratio for the oxidation and reduction zone products. The changes in the consumption or generation efficiencies of the products are expressed as ratios of the efficiencies for the ventilation-controlled (*vc*) to well-ventilated (*wv*) fires:

Reactants (oxygen)

$$\zeta_O = \frac{(\eta_O)_{vc}}{(\eta_O)_{wv}} = \frac{(c_O/\Psi_O)_{vc}}{(c_O/\Psi_O)_{wv}} = \frac{(c_O)_{vc}}{(c_O)_{wv}} \quad (36.65)$$

Oxidation zone products (carbon dioxide, water, etc.*)*

$$\zeta_{oxid} = \frac{(\eta_j)_{vc}}{(\eta_j)_{wv}} = \frac{\left(y_j/\Psi_j\right)_{vc}}{\left(y_j/\Psi_j\right)_{wv}} = \frac{\left(y_j\right)_{vc}}{\left(y_j\right)_{wv}} \quad (36.66)$$

where ζ_{oxid} is the oxidation zone product generation efficiency ratio.

Reduction zone products (smoke, carbon monoxide, hydrocarbons, etc.)

$$\zeta_{red} = \frac{(\eta_j)_{vc}}{(\eta_j)_{wv}} = \frac{\left(y_j/\Psi_j\right)_{vc}}{\left(y_j/\Psi_j\right)_{wv}} = \frac{\left(y_j\right)_{vc}}{\left(y_j\right)_{wv}} \quad (36.67)$$

where ζ_{red} is the reduction zone product generation efficiency ratio.

The relationships between the ratios of the mass of oxygen consumed per unit mass of fuel, the yields of the products for the ventilation-controlled to well-ventilated fires, and the equivalence ratio are shown in Figs. 36.36, 36.37, 36.38, 36.39, and 36.40. The ratios for oxygen and CO_2 (an oxidation zone product) do not depend on the chemical structures of the materials, whereas the ratios for the reduction zone products do depend on the chemical structures of the materials.

Oxygen and CO_2 The relationships for oxygen consumed and carbon dioxide generated are shown in Figs. 36.36 and 36.37, respectively. The relationships are very similar to the relationships for the chemical and convective

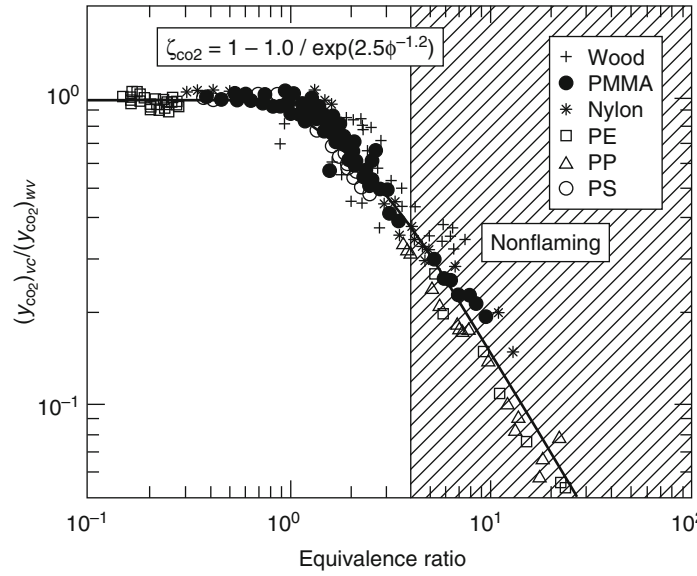

Fig. 36.37 Ratio of the mass of carbon dioxide generated per unit mass of the fuel for ventilation-controlled to well-ventilated fires (Data are taken from Ref. [103]). Subscript *vc* represents ventilation-controlled fires, and subscript *wv* represents well-ventilated fires

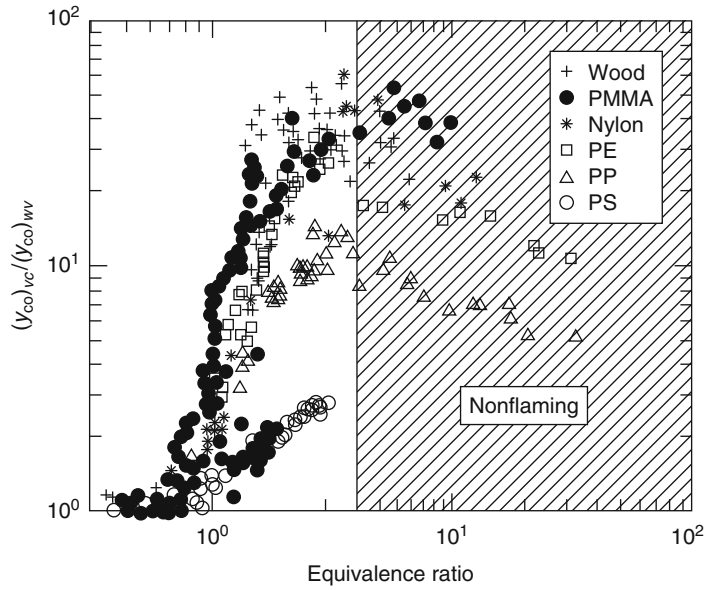

Fig. 36.38 Ratio of the mass of carbon monoxide generated per unit mass of the fuel for ventilation-controlled to well-ventilated fires (Data are taken from Ref. [103]). Subscript *vc* represents ventilation-controlled fires, and subscript *wv* represents well-ventilated fires

heats of combustion ratios (Equations 36.44 and 36.45), as expected:

$$\frac{(c_{\mathrm{O}})_{vc}}{(c_{\mathrm{O}})_{wv}} = 1 - \frac{0.97}{\exp\left[\left(\frac{\Phi}{2.14}\right)^{-1.2}\right]} \tag{36.68}$$

$$\frac{(y_{\mathrm{CO_2}})_{vc}}{(y_{\mathrm{CO_2}})_{wv}} = 1 - \frac{0.97}{\exp\left[\left(\frac{\Phi}{2.15}\right)^{-1.2}\right]} \tag{36.69}$$

Carbon Monoxide The relationship between the ratio of the CO yields for ventilation-controlled to well-ventilated fires and the equivalence ratio is shown in Fig. 36.38. The data suggest the following relationship [103]:

$$\frac{(y_{\mathrm{CO}})_{vc}}{(y_{\mathrm{CO}})_{wv}} = 1 + \frac{\alpha}{\exp\left(2.5\Phi^{-\xi}\right)} \tag{36.70}$$

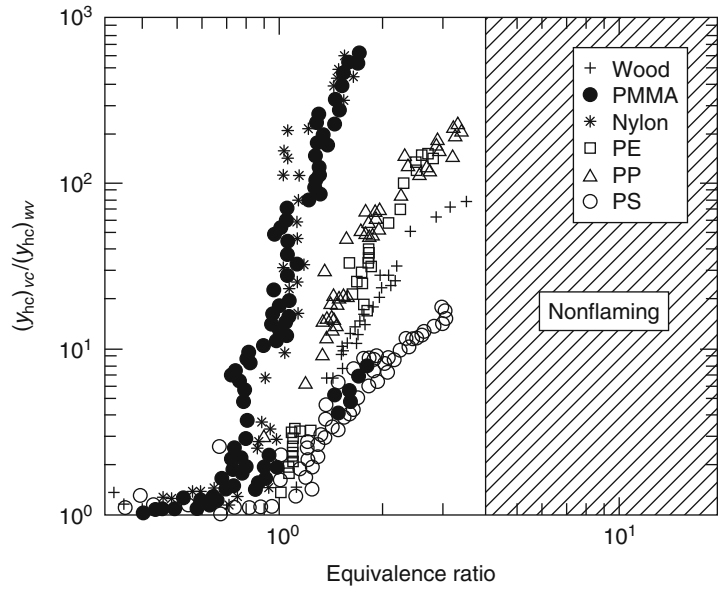

Fig. 36.39 Ratio of the mass of hydrocarbons generated per unit mass of the fuel for ventilation-controlled to well-ventilated fires (Data are taken from Ref. [103]). Subscript *vc* represents ventilation-controlled fires, and subscript *wv* represents well-ventilated fires

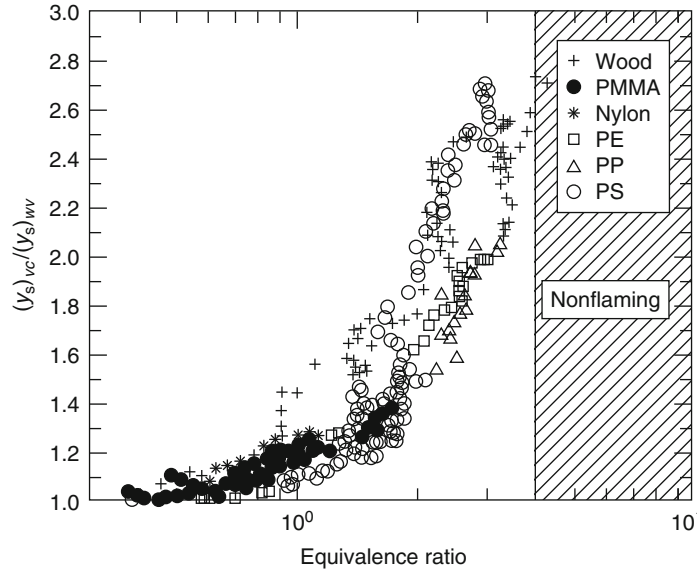

Fig. 36.40 Ratio of the mass of smoke generated per unit mass of the fuel for ventilation-controlled to well-ventilated fires (Data are taken from Ref. [103]). Subscript *vc* represents ventilation-controlled fires, and subscript *wv* represents well-ventilated fires

where α and ξ are the correlation coefficients, which depend on the chemical structures of the materials. The values for the correlation coefficients for CO are listed in Table 36.12.

The increase in the ratio of the carbon monoxide yields for the ventilation-controlled to well-ventilated fires with the equivalence ratio is due to the preferential conversion of the fuel carbon atoms to CO. The experimental data show the following order for the preferential conversion: wood (C-H-O aliphatic structure) > PMMA (C-H-O aliphatic structure) > nylon (C-H-O-N aliphatic structure) > PE (C-H aliphatic linear unsaturated structure) > PP (C-H aliphatic branched unsaturated structure) > PS (C-H aromatic structure). A similar trend is found for the liquid and gaseous fuels, such as shown in Table 36.13 [103]. The presence of O

and N atoms in the fuels with aliphatic C-H structure appears to enhance preferential fuel carbon atom conversion to CO.

Hydrocarbons The relationship between the ratio of the hydrocarbon yields for ventilation-controlled to well-ventilated fires and the equivalence ratio is shown in Fig. 36.39. The data suggest the following relationship [103]:

$$\frac{(y_{hc})_{vc}}{(y_{hc})_{wv}} = 1 + \frac{\alpha}{\exp\left(5.0\Phi^{-\xi}\right)} \tag{36.71}$$

The correlation coefficient values for hydrocarbons are listed in Table 36.12. The numerator in the second term on the right-hand side of Equation 36.71 is 10–40 times that of CO, whereas the denominator is twice that for CO. This relationship suggests that there is a significantly higher preferential fuel conversion to hydrocarbons than to CO, as the equivalence ratio increases. The order for the preferential fuel conversion to hydrocarbons is very similar to CO, except for wood; that is, PMMA > nylon > PE = PP > wood > PS. The exception for wood may be due to the char-forming tendency of the fuel, which lowers the C-to-H ratio in the gas phase.

Table 36.12 Correlation coefficients to account for the effects of ventilation on the generation rates of CO, hydrocarbons, and smoke

	CO			Hydrocarbons			Smoke		
Material	α	β	ξ	α	β	ξ	α	β	ξ
PS	2	1.44	2.5	25	2.45	1.8	2.8	2.02	1.3
PP	10	1.39	2.8	220	1.90	2.5	2.2	2.50	1.0
PE	26	1.39	2.8	220	1.90	2.5	2.2	2.50	1.0
Nylon	36	1.36	3.0	1200	1.65	3.2	1.7	3.14	0.8
PMMA	43	1.33	3.2	1800	1.58	3.5	1.6	4.61	0.6
Wood	44	1.30	3.5	200	2.33	1.9	2.5	2.15	1.2
PVC	7	0.42	8.0	25	0.42	1.8	0.38	2.02	8.0

Smoke The relationship between the ratio of the smoke yields for ventilation-controlled to well-ventilated fires and the equivalence ratio is shown in Fig. 36.40. The data suggest the following relationship: [103]

$$\frac{(y_s)_{vc}}{(y_s)_{wv}} = 1 + \frac{\alpha}{\exp\left(2.5\Phi^{-\xi}\right)} \tag{36.72}$$

The correlation coefficient values for smoke are listed in Table 36.12. The values of the correlation coefficients in the second term on the right-hand side of Equation 36.72 suggest that, with increasing equivalence ratio, the preferential fuel conversion to smoke is lower than it is to hydrocarbons and CO. Also, the order for the preferential conversion of the fuel carbon atom to smoke is opposite to the order for the conversion to CO and hydrocarbons, except for wood. The order is PS > wood > PE = PP > nylon > PMMA, suggesting that the order is probably due to a decrease in the preference for the reactions between OH and CO compared to the reactions between OH and soot.

Table 36.13 Carbon monoxide generation efficiency for ventilation-controlled and well-ventilated combustion[a]

		Ventilation-controlled (vc) $\Phi \approx 4.0$		
Fuel	Well-ventilated (wv)[b] $\Phi < 0.05$	Beyler [123]	Beyler [124]	$(y_{CO})_{vc}/(y_{CO})_{wv}$
Methane	0.001	0.10	–	100
Propane	0.001	–	0.12	120
Propylene	0.004	0.10	–	25
Hexane	0.002	0.10	0.52[c]	50 (260[c])
Methanol	0.001	0.27	1.00[c]	270 (1000[c])
Ethanol	0.001	0.18	0.66[c]	180 (660[c])
Isopropanol	0.002	0.21	–	105
Acetone	0.002	0.21	0.63[c]	105 (315[c])

[a]Table taken from Ref. [103]
[b]Data taken in the Fire Propagation Apparatus
[c]Nonflaming

Other Reduction Zone Products Since the sum of the generation efficiencies of all the products for a material cannot exceed unity, the generation efficiency of products other than CO, CO_2, hydrocarbons, and smoke is

$$\eta_{\text{other}} = 1 - \left(\eta_{\text{CO}} + \eta_{\text{CO}_2} + \eta_{\text{hc}} + \eta_{\text{s}}\right) \quad (36.73)$$

where η_{other} is the generation efficiency of products other than CO, CO_2, hydrocarbons, and smoke. The generation efficiency of other products can be calculated from Equations 36.68, 36.69, 36.70, 36.71 and 36.72 using correlation coefficients from Table 36.12. The generation efficiency values for other products calculated in this fashion for various equivalence ratios are shown in Fig. 36.41. The figure shows that, for equivalence ratios greater than 4, where fires are nonflaming, about 10–60% of fuel carbon is converted to products other than CO, CO_2, soot, and hydrocarbons.

The order for the preferential conversion of fuel carbon to other products in the nonflaming zone is PS (C-H aromatic structure) < PE & PP (C-H aliphatic structure) < wood (C-H-O aliphatic structure) < nylon (C-H-O-N aliphatic structure) < PMMA (C-H-O aliphatic structure). It thus appears that, in nonflaming environments, fuels with C-H structures are converted mainly to CO, smoke, and hydrocarbons, rather than to other products, whereas fuels with C-H-O and C-H-O-N structures are converted mainly to products other than CO, CO_2, smoke, and hydrocarbons. Some of the products include formaldehyde (HCHO) and hydrogen cyanide (HCN) [103].

Generation Efficiencies of Formaldehyde, Hydrogen Cyanide, and Nitrogen Dioxide The experimental data for the generation efficiencies of formaldehyde, hydrogen cyanide, and nitrogen dioxide versus the equivalence ratio are shown in Figs. 36.42 and 36.43.

Formaldehyde is generated in the pyrolysis of wood (C-H-O structure). It is attacked rapidly by oxygen (O) and hydroxyl (OH) radicals in the flame, if unlimited supply of oxygen is available. Thus, only traces of formaldehyde are found in well-ventilated fires. The generation efficiency of formaldehyde, however, increases with the equivalence ratio, indicating reduced concentrations of O and OH radicals and gas temperature due to lack of oxygen available for combustion.

In fires, hydrogen cyanide is formed in the reduction zone from materials with hydrogen

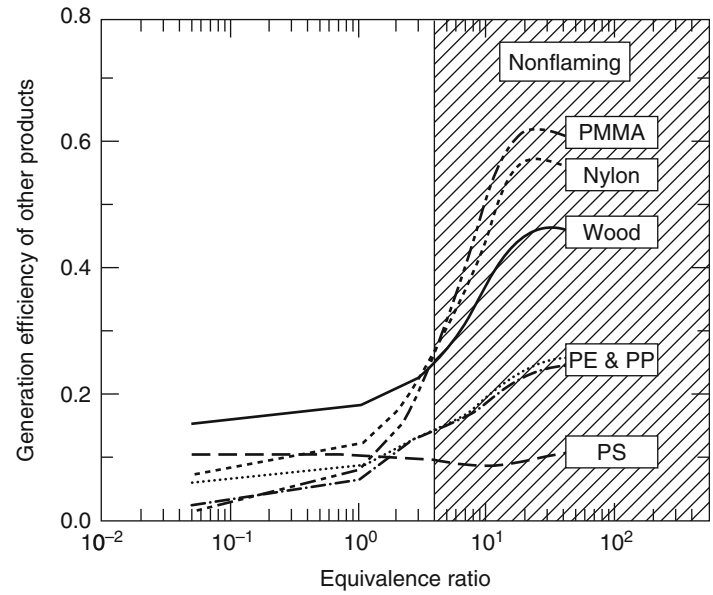

Fig. 36.41 Generation efficiency of products other than CO, CO_2, hydrocarbons, and smoke versus the equivalence ratio

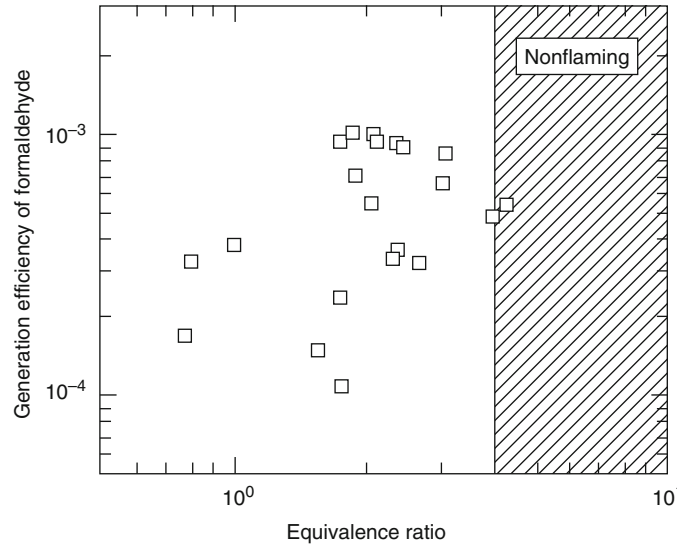

Fig. 36.42 Generation efficiency of formaldehyde generated from wood versus the equivalence ratio

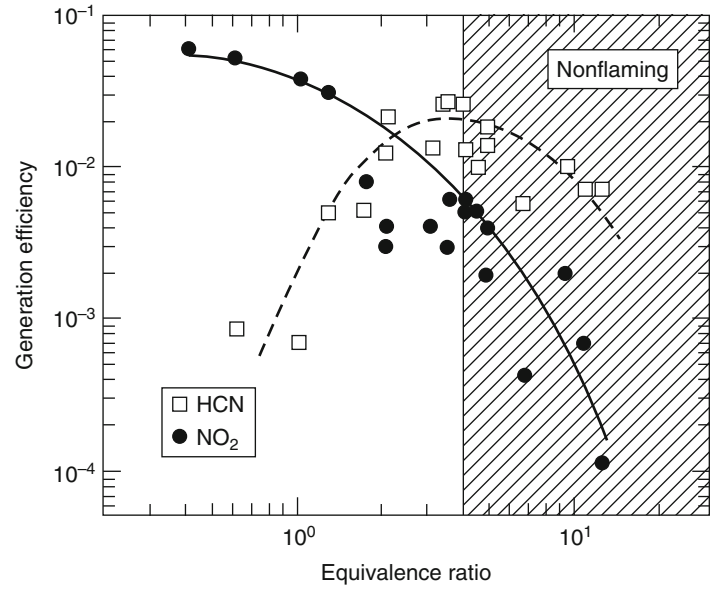

Fig. 36.43 Generation efficiencies of hydrogen cyanide and nitrogen dioxide generated from nylon versus the equivalence ratio

and nitrogen atoms in the structure, such as nylon (C-H-O-N structure). Nitrogen dioxide (NO_2), on the other hand, is formed in the oxidation zone, as a result of the oxidation of hydrogen cyanide. The data in Fig. 36.40 show that the generation efficiency of hydrogen cyanide increases and the generation efficiency of NO_2 decreases with the equivalence ratio. This observation supports that O and OH radical concentrations decrease with increase in the equivalence ratio. The decrease in the generation efficiency of hydrogen cyanide in nonflaming environments suggests a decrease in the fuel mass transfer rate.

Relationship Between the Generation Efficiencies of CO_2 and CO The relationship between the generation efficiencies of CO_2 and CO is shown in Fig. 36.44, where the data are taken from Ref. [103]. CO is generated in the reduction zone of the flame as a result of the

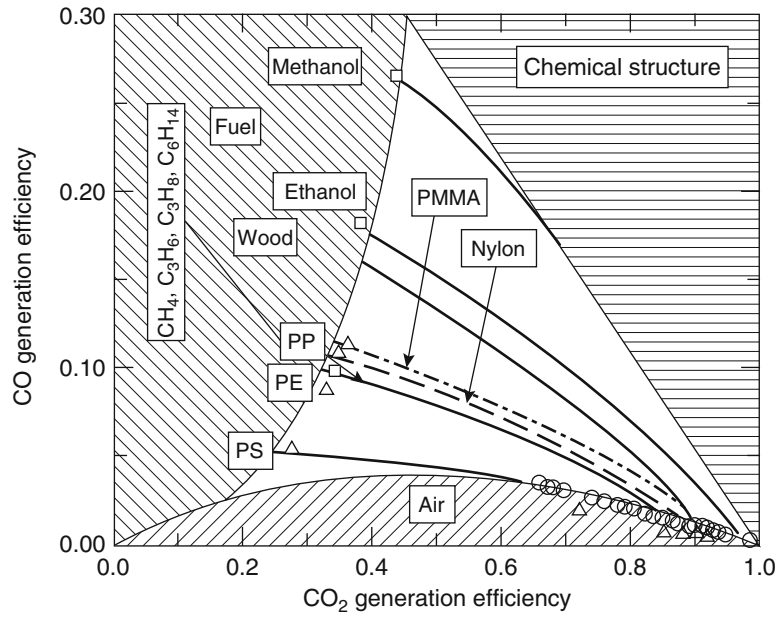

Fig. 36.44 Relationship between the generation efficiencies of CO_2 and CO (Data taken from Ref. [103])

oxidative pyrolysis of the fuel, and is oxidized to CO_2 in the oxidation zone of the flame. The generation efficiency of CO_2 is independent of the chemical structure of the fuel (Fig. 36.37), whereas the generation efficiency of CO depends on the chemical structure of the fuel (Fig. 36.38). In Fig. 36.44, the curves represent approximate predictions based on the correlation coefficients from Table 36.12 and Equations 36.69 and 36.70.

The relationship between the generation efficiencies of CO_2 and CO is quite complex. The boundary of the shaded region marked *air* in Fig. 36.44 is drawn using the data for the well-ventilated combustion for equivalence ratios less than 0.05. The boundary of the *air* region may be considered as equivalent to the lower flammability limit. No flaming combustion is expected to occur in this region, as the fuel-air mixture is below the lower flammability limit; however, nonflaming processes, generally identified as smoldering, may continue. The boundary of the shaded region marked *fuel* is drawn using the data for the ventilation-controlled combustion for equivalence ratio of 4.0, and may be considered as equivalent to the upper flammability limit. In the *fuel* region, no flaming combustion is expected to occur, as the fuel-air mixture is above the upper flammability limit; however, nonflaming processes may continue. The shaded region marked *chemical structure* and drawn to the right of the methanol curve is an imaginary region as it is not expected to exist, because there are no stable carbon-containing fuel structures below the formaldehyde with a structure of HCHO. For the stable fuels with C-H-O structures, formaldehyde (HCHO) and methanol (CH_3OH) have the lowest molecular weights (30 and 32, respectively). Thus, data for HCHO and CH_3OH probably would be comparable.

The curves in Fig. 36.44 show that, in flaming combustion, with increase in the equivalence ratio, the preference for fuel carbon atom conversion to CO, relative to the conversion to CO_2, follows this order: methanol (C-H-O structure) > ethanol (C-H-O structure) > wood (C-H-O structure) > PMMA (C-H-O structure) > nylon (C-H-O-N structure) > PP (C-H aliphatic unsaturated branched structure) ≥ (CH_4, C_3H_6, C_3H_8, C_6H_{14}) ≥ PE (C-H aliphatic unsaturated linear structure) > PS (C-H aromatic unsaturated structure). Thus, for fires in enclosed spaces, generation of higher amounts of CO relative to CO_2 at high local equivalence ratios is expected for fuels with C-H-O structures compared to the

fuels with C-H structures. The reason for higher amounts of CO relative to CO_2 for fuels with C-H-O structures is that CO is easily generated in fuel pyrolysis, but is oxidized only partially to CO_2 due to limited amounts of oxidant available.

Relationship Between the Generation Efficiencies of CO and Smoke The relationship between the generation efficiencies of CO and smoke is shown in Fig. 36.45, where data are taken from Ref. [103]. CO and smoke are both generated in the reduction zone of the flame as a result of the oxidative pyrolysis of the fuel, and their generation efficiencies depend on the chemical structure of the fuel (Figs. 36.38 and 36.40). In Fig. 36.45, the curves represent approximate predictions based on the correlation coefficients from Table 36.11 and Equations 36.70 and 36.72.

The relationship in Fig. 36.45 is quite complicated. The boundary of the shaded region marked *air* is drawn using the data for the well-ventilated combustion for equivalence ratios less than 0.05. The boundary of the shaded region marked *fuel* is drawn using the data for the ventilation-controlled combustion for equivalence ratio of 4.0. The boundary for the region marked *air* may be considered as equivalent to the lower flammability limit, and the boundary for the region marked *fuel* may be considered as equivalent to the upper flammability limit.

In Fig. 36.45, the order for the preference for fuel carbon atom conversion to smoke relative to conversion to CO is wood (C-H-O structure) < PMMA (C-H-O structure) < nylon (C-H-O-N structure) < PP (C-H aliphatic unsaturated branched structure) ≈ PE (C-H aliphatic unsaturated linear structure) < PS (C-H aromatic structure). The generation efficiency of smoke for PS, which is a polymer with aromatic C-H structure, is the highest. The generation efficiency of smoke for wood, which is a polymer with aliphatic C-H-O structure, is the lowest.

Generalized Relationships to Calculate Chemical, Convective, and Radiative Heats of Combustion and Yields of Products at Various Equivalence Ratios

Equations 36.44, 36.45, and 36.68, 36.69, 36.70, 36.71, and 36.72 can be generalized as follows:

$$fp = fp_{\infty}\left\{1 + \frac{\alpha}{\exp\left[\left(\frac{\Phi}{\beta}\right)^{-\xi}\right]}\right\} \qquad (36.74)$$

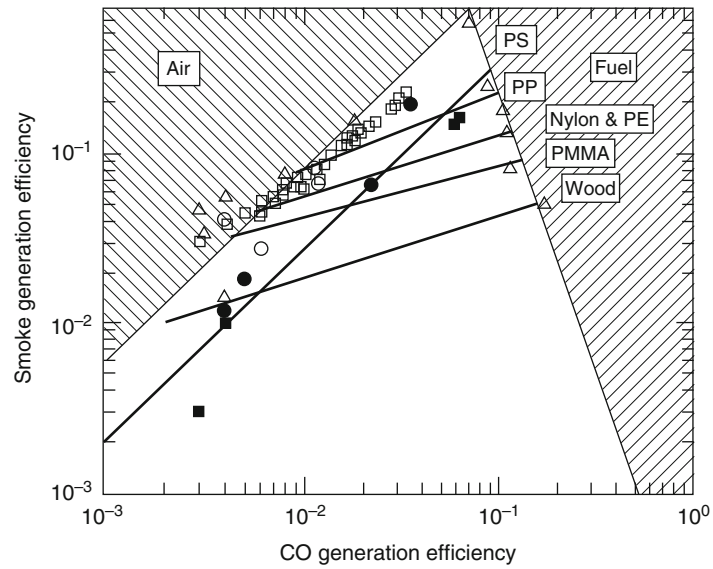

Fig. 36.45 Relationship between the generation efficiencies of CO and smoke (Data taken from Ref. [103])

where
fp = Fire property
α, β, and ξ = Correlation coefficients characteristic of the chemical structures of the polymers
subscript ∞ = Infinite amount of air (i.e., well ventilated conditions)

It is noted that this relationship is applicable under turbulent flame conditions where a given fire property remains constant (i.e., it is not a function of flow conditions). Fire properties to consider include heat of combustion (or combustion efficiency) and yields (or generation efficiencies) of products. Three conditions can be identified: (1) for $\Phi \gg \beta$, $fp = fp_\infty(1 + \alpha)$; (2) for $\Phi \ll \beta$, $fp = fp_\infty$; and (3) $\Phi \approx \beta$, $fp \approx fp_\infty(1 + \alpha/2.7)$. Thus, the parameter α is associated primarily with the magnitude of the fire properties in nonflaming processes (high Φ values). The parameter β is associated with the fire properties in the transition region between fires with an infinite amount of air and fires with a very restricted amount of air. The parameter ξ is associated with the range of Φ values for the transition region. A high value of α is indicative of a strong effect of ventilation on the fire and its properties and vice versa. High values of β and ξ are indicative of rapid change from flaming to nonflaming conditions by a small change in the equivalence ratio, such as for the highly fire-retarded or halogenated materials for which flaming combustion in normal air itself is unstable.

Chemical Heat of Combustion Versus Equivalence Ratio for Nonhalogenated Compounds From Equation 36.74,

$$\Delta H_{ch} = \Delta H_{ch,\infty}\left\{1 - \frac{0.97}{\exp\left[\left(\frac{\Phi}{2.15}\right)^{-1.2}\right]}\right\} \tag{36.75}$$

This equations stems from Equation 36.44. As stated above, this relationship is found to hold for a variety of compounds regardless of their chemical structure (Fig. 36.33). The values of $\Delta H_{ch,\infty}$ can be found in Table A.39.

Chemical Heat of Combustion Versus Equivalence Ratio for Halogenated Polymers (PVC) The effect of ventilation on the burning of halogenated materials is dramatically different from that shown in Equation 36.75,

$$\Delta H_{ch} = \Delta H_{ch,\infty}\left\{1 - \frac{0.30}{\exp\left[\left(\frac{\Phi}{0.53}\right)^{-11}\right]}\right\} \tag{36.76}$$

As can be noted from the terms inside the brackets in Equations 36.75 and 36.76, the effect of ventilation on the chemical heat of combustion is much stronger for PVC than it is for nonhalogenated materials. The effect for PVC occurs at $\Phi \geq 0.4$, which is significantly lower than $\Phi \geq 2.0$ found for nonhalogenated compounds [103, 126]. For PVC homopolymer, flaming combustion changes transitions to nonflaming for $\Phi \geq 0.70$, which is also significantly lower than $\Phi \geq 4.0$ found for nonhalogenated materials. This attribute is consistent with the highly halogenated nature of PVC and its mode of decomposition. The decomposition of PVC is characterized by the release of HCl, which is initiated at temperatures as low as about 100 °C. At temperatures of up to between 200 °C and 220 °C, HCl is the major effluent. The presence of oxygen in the air enhances HCl release. The generation of HCl from PVC leads to the formation of double bonds and release of various aromatic/unsaturated hydrocarbons (benzene, ethylene, propylene, butylene, etc.).

Convective Heats of Combustion Versus Equivalence Ratio for Nonhalogenated Compounds From Equation 36.74,

$$\Delta H_{con} = \Delta H_{con,\infty}\left\{1 - \frac{1.0}{\exp\left[\left(\frac{\Phi}{1.38}\right)^{-2,8}\right]}\right\} \tag{36.77}$$

Similar to the chemical heat of combustion this equation stems from Equation 36.45 and is applicable to a large number of materials, regardless of

their chemical structure (Fig. 36.34). Values for $\Delta H_{con,\infty}$ are listed in Table A.39.

Radiative Heats of Combustion Versus Equivalence Ratio Radiative heats of combustion are obtained from the difference between the chemical and the convective heats of combustion:

$$\Delta H_{rad} = \Delta H_{ch} - \Delta H_{con} \tag{36.78}$$

Consumption of Oxygen for Nonhalogenated Compounds As shown in Fig. 36.36 and similarly to the findings for chemical and convective heat release rates, ventilation effects on oxygen consumption are similar regardless of chemical structure. Therefore in generalized form. Equation 36.68 becomes:

$$c_O = c_{O,\infty}\left\{1 - \frac{0.97}{\exp\left[\left(\frac{\Phi}{2.14}\right)^{-1.2}\right]}\right\} \tag{36.79}$$

Yield of Carbon Dioxide for Nonhalogenated Compounds The generation of CO_2 follows similar trends with respect to equivalence ratio, as discussed above (see Fig. 36.37). Therefore, the generalized form of Equation 36.69 is:

$$y_{CO_2} = y_{CO_2,\infty}\left\{1 - \frac{1.0}{\exp\left[\left(\frac{\Phi}{2.15}\right)^{-1.2}\right]}\right\} \tag{36.80}$$

$y_{CO_2,\infty}$ values for well ventilated fires are listed in Table A.39.

Yield of Carbon Dioxide for Halogenated Polymers (PVC) Lastly, as indicated above for the chemical heat of combustion of PVC, ventilation effects are markedly different for halogenated materials compared to their nonhalogenated counterparts. In this case the generalized equation for CO_2 yield is:

$$y_{CO_2} = y_{CO_2,\infty}\left\{1 - \frac{0.30}{\exp\left[\left(\frac{\Phi}{0.53}\right)^{-11}\right]}\right\} \tag{36.81}$$

From the terms inside the brackets in Equations 36.80 and 36.81, a stronger effect of ventilation on the yield of CO_2 for PVC than for nonhalogenated compounds can be noted. $y_{CO_2,\infty}$ values are listed in Table A.39.

Yields of Carbon Monoxide, Hydrocarbons, and Smoke for Selected Nonhalogenated Materials As discussed above and shown in Figs. 36.38, 36.39, and 36.40, yields of CO, hydrocarbons, and smoke are affected by the chemical structure the given material involved in the fire. In this case the generalized correlation, Equation 36.74, will take different values for the parameters α, β, and ξ depending on the specific material considered, Parameters for polystyrene, polypropylene, polyethylene, nylon, PMMA, wood, and PVC are given in Table 36.12; these are to be used in Equation 36.74 along with the well ventilated values (i.e., fp_∞) for yields of CO, hydrocarbons, and soot listed in Table A.39 for the materials in Table 36.12.

For PVC, the relationships indicate that for $0.40 \geq \Phi \geq 1.0$, the maximum CO and smoke yields reach about 60 % of the stoichiometric yields, listed in Table 36.11. For the nonhalogenated materials, the maximum CO and smoke yields reach $\leq$30 % of the stoichiometric yields for $\Phi \geq 2.0$. Polystyrene is the only polymer, within the above group of polymers, for which the smoke yield exceeds that of PVC. These trends suggest that CO and smoke are generated much more readily from PVC than from the nonhalogenated materials, possibly due to the formation of double bonds, as HCl is eliminated at temperatures as low as 100 °C from the PVC structure, and formation of various compounds occurs with aromatic/unsaturated bonds.

For the nonhalogenated materials considered with $\Phi \geq 4.0$, the CO yield is lowest and the smoke yield is highest for polystyrene, an aromatic ring-containing polymer; whereas, for polymethylmethacrylate, an aliphatic carbon-hydrogen-oxygen-atom-containing polymer, the CO yield is highest and smoke yield is lowest. This result suggests that aromatic ring structure promotes smoke formation, whereas the strong C-O bond in the structure remains intact as ventilation is reduced.

Example 18 Following Example 12, calculate the yields of CO and smoke at equivalence ratios of 1, 2, and 3 for polystyrene, polyethylene, wood, and nylon using Equation 36.74 and the data in Tables A.39 and 36.12.

Solution

	Yield (g/g)							
	$\Phi \ll 1.0$ (Table A.39)		$\Phi = 1.0$		$\Phi = 2.0$		$\Phi = 3.0$	
Material	CO	Smoke	CO	Smoke	CO	Smoke	CO	Smoke
Polystyrene	0.060	0.164	0.070	0.202	0.137	0.331	0.162	0.417
Polyethylene	0.024	0.060	0.074	0.071	0.459	0.098	0.580	0.117
Wood	0.004	0.015	0.018	0.018	0.145	0.028	0.171	0.034
Nylon	0.038	0.075	0.149	0.086	1.040	0.105	1.280	0.120

Smoke Point

Smoke emission characteristics of fuels have been expressed for decades by smoke point, defined as a minimum laminar axisymmetric diffusion flame height (or fuel volumetric or mass flow rate) at which smoke just escapes from the flame tip [112, 114, 127–145]. More recently, the smoke point concept has been applied to develop subgrid soot formation, oxidation, and radiation models for CFD simulations [146, 147]. Smoke-point values have been measured for numerous gases, liquids, and solids [112, 114, 127–145].

Almost all the knowledge on smoke formation, oxidation, and emission from diffusion flames is based on the combustion of fuels containing carbon and hydrogen atoms (hydrocarbons) [128, 129, 134, 136, 141]. On the basis of the chemical structure, hydrocarbons are divided into two main classes: (1) aliphatic and (2) aromatic. Fuels containing both aliphatic and aromatic units are known as arenes. Aliphatic fuels have open-chain structure, and aromatic fuel structures consist of benzene rings. Aliphatic hydrocarbons are divided into three families: (1) alkanes (C_nH_{2n+2}) where n is an integer—the suffix *ane* indicates a single bond; (2) alkenes (C_nH_{2n})—the suffix *ene* indicates a double bond, and *diene*, two double bonds between carbon-carbon atoms; and (3) alkynes (C_nH_{2n-2})—the suffix *yne* indicates a triple bond. The integer n can vary from one in a gas, such as methane, to several thousands in solid polymers, such as polyethylene. In cyclic aliphatic fuels, carbon atoms are also arranged as rings. Dienes are classified as (1) conjugated—double bonds alternate with single bonds, (2) isolated—double bonds separated by more than one single bond, and (3) allenes—double bonds with no separation. Conjugated dienes are more stable than other dienes.

Solid carbonaceous particles present in smoke are defined as soot [129, 134]. Soot is generally formed in the fuel-rich regions of the flame and grows in size through gas-solid reactions, followed by oxidation (burnout) to produce gaseous products, such as CO and CO_2. Flame residence time available for soot formation is on the order of a few milliseconds. Soot particle inception occurs from the fuel molecule via oxidation and/or pyrolysis products, which typically include unsaturated hydrocarbons, especially acetylene, polyacetylenes, and polycyclic aromatic hydrocarbons (PAH). Acetylene, polyacetylenes, and PAH are relatively stable with respect to decomposition. Acetylene and PAH are often considered the most likely precursors for soot formation in flames. PAH have the same role in diffusion flames for both aliphatic and aromatic fuels. In all flames, regardless of the fuel, initial detection of soot particles takes place on the centerline when a temperature of approximately 1400 K [134] is encountered. Thus, even though the extent of conversion of a fuel into soot may significantly change from fuel to fuel, a common mechanism of soot formation is suggested.

Soot production in the flame depends on the chemical structure, concentration, and

temperature of the fuel and flame temperature, pressure, and oxygen concentration [128, 129, 134, 136, 141]. The diffusion-controlled flame ends when fuel and oxidant are in stoichiometric ratio on the flame axis. The flame is followed by a soot after-burning zone, which is partially chemically controlled. The soot oxidation zone increases from about 10–50 % of the visible flame length as the soot concentration increases. Flame luminosity and smoke emission in the plume depend on overall soot production and oxidation. Flames emit soot when soot temperature in the oxidation zone falls below 1300 K [134]. The soot temperature decreases downstream because of radiation losses and diffusion of fresh cold air, both of which quench soot oxidation. At high soot concentrations, flame emissivity approaches unity, and flame luminosity becomes independent of the amount of soot.

Smoke point, carbon-to-hydrogen ratio, aromaticity, and flame temperature have been suggested as useful parameters to assess relative smoke emission characteristics of fuels in laminar diffusion flames [112, 114, 127, 133–135, 140, 143]. The soot-forming tendency of fuels is inversely proportional to smoke point. General trends observed for smoke points for hydrocarbon fuels in laminar diffusion flames are aromatics < alkynes < alkenes < alkanes.

Smoke-point values have been correlated with flame radiation, combustion efficiency and its convective and radiative components, and generation efficiencies of products [112, 114, 127, 133–135, 140, 143]. Figures 36.46, 36.47, and 36.48 show the relationships between the smoke point and the combustion efficiency and its convective and radiative components, and generation efficiencies of CO and smoke. The data were measured in the Fire Propagation Apparatus (Fig. 36.2) and reported in Refs. [112, 114]. Smoke-point data measured for a number of polymers, as well as wood, are listed in Table 36.14. The following relationships can be discerned from the data [112, 114]:

$$\chi_{\mathrm{ch}} = 1.15 L_{sp}^{0.10} \tag{36.82}$$

where χ_{ch} is the combustion efficiency (−), and L_{sp} is the smoke point (m) as measured in the Fire Propagation Apparatus [112, 114].

$$\chi_{\mathrm{rad}} = 0.41 - 0.85 L_{sp} \tag{36.83}$$

where χ_{rad} is the radiative component of the combustion efficiency (−). This correlation is very similar to the one reported by Markstein [135]. The convective component of the combustion efficiency, χ_{con}, can now be obtained using Equation 36.40:

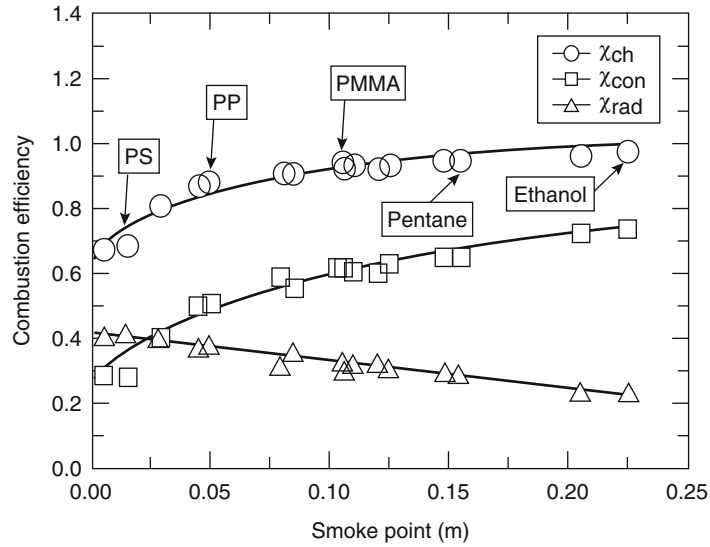

Fig. 36.46 Relationships between combustion efficiency, its convective and radiative components, and the smoke point (Data were measured in the Fire Propagation Apparatus and reported in Refs. [112, 114])

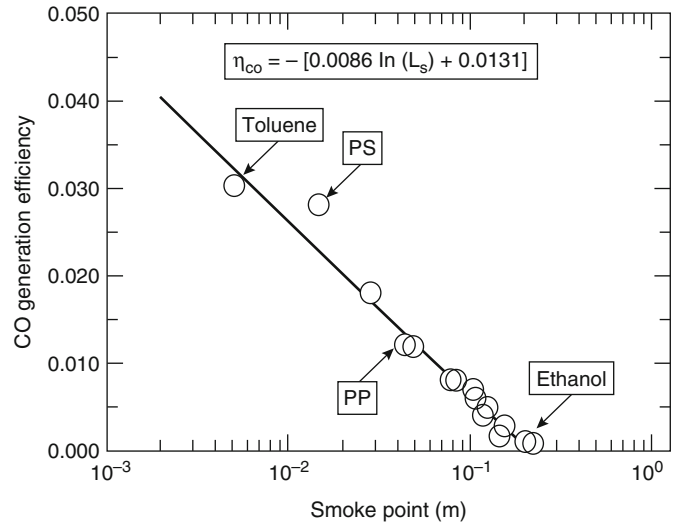

Fig. 36.47 Relationships between CO generation efficiency and smoke point (Data were measured in the Fire Propagation Apparatus and reported in Refs. [112, 114])

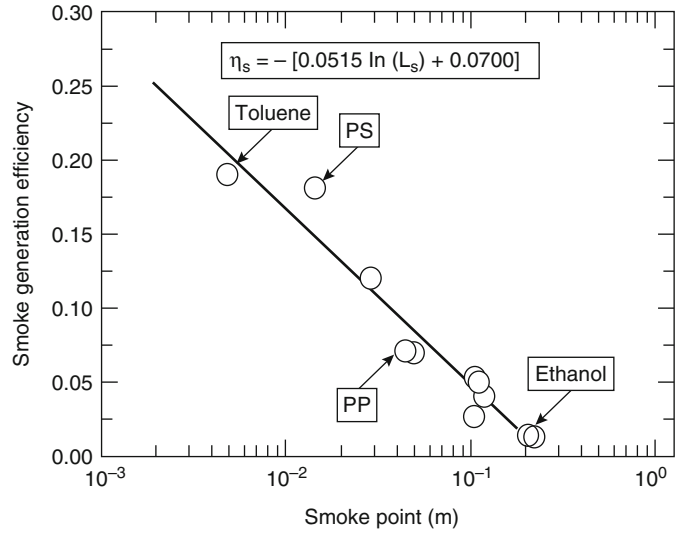

Fig. 36.48 Relationships between the smoke generation efficiency and the smoke point (Data were measured in the Fire Propagation Apparatus and reported in Refs. [112, 114])

$$\chi_{con} = \chi_{ch} - \chi_{rad}$$
$$\chi_{con} = 1.15 L_{sp}^{0.10} + 0.85 L_{sp} - 0.41 \quad (36.84)$$

For the generation efficiency of CO (η_{CO})

$$\eta_{CO} = 0.0086 \ln\left(\frac{0.218}{L_{sp}}\right) \quad (36.85)$$

For the generation efficiency of smoke (η_s)

$$\eta_s = 0.0515 \ln\left(\frac{0.257}{L_{sp}}\right) \quad (36.86)$$

Smoke points were estimated using Equations 36.82, 36.83, 36.84, 36.85 and 36.86 for the materials listed in Table 36.14 using properties (i.e., chemical combustion efficiency, smoke yield, etc.) measured in the Fire Propagation Apparatus and listed in Table A.39; in general, good agreement is observed. It is noted that the highest value of L_{sp} that has been measured is 0.24 m for ethane. Although methane and methanol would be expected to have smoke points higher than 0.24 m, they have not been measured experimentally. Since combustion efficiency cannot exceed unity and the generation efficiencies of CO and smoke cannot be negative, the relationships in Equations 36.82, 36.83, 36.84, 36.85 and 36.86 are valid for

[a]Data taken from Refs. [112, 114]
[b]Estimated from the polymer properties measured in the Fire Propagation Apparatus and their relationships with smoke point

$0 < L_{sp} \leq 0.24$ m. The correlations show that emissions of CO and smoke are very sensitive to changes in the smoke point values compared to combustion efficiency and its convective and radiative components. This condition is expected from the understanding of the relationship between the smoke point and chemical structures of fuels. For example, a decrease of 33 % in the smoke-point value from 0.15 to 0.10 m produces a decrease of 4 % and 12 % in the combustion efficiency and its convective component, respectively, and an increase of 14 % in the radiative component of the combustion efficiency; however, the generation efficiencies of CO and smoke increase by 89 % and 67 %, respectively.

Equations 36.82, 36.83, 36.84, 36.85 and 36.86 can be used to estimate the fire properties of gases, liquids, and solids from their smoke point values. The smoke point values, however, depend strongly on the apparatus used and cannot be used as reported. One of the approaches is to establish correlations between the smoke-point

values measured in different apparatuses and a single apparatus for which relationships such as those given in Equations 36.82, 36.83, 36.84, 36.85 and 36.86 are available. This type of approach has been described in Refs. [112, 114] for the Fire Propagation Apparatus, where smoke-point values for 165 fuels, reported in the literature, were scaled based on measurements performed in the FPA for 16 common fuels. Fire properties (chemical, convective, and radiative heats of combustion and yields of CO and smoke) were then estimated, using the scaled smoke-point-data, from Equations 36.82, 36.83, 36.84, 36.85 and 36.86, and are listed in Table A.40. In the table, molecular formula and weight, stoichiometric air-to-fuel mass ratio, and net heat of complete combustion have also been tabulated. The estimated data in the table have been validated by direct measurements in small- and large-scale fires using several fuels [112, 114].

Smoke point decreases with increasing molecular weight for a given molecular subgroup. The smoke point values for monomers and polymers, however, show different types of dependencies [112]: (1) the smoke-point values for ethylene and polyethylene are 0.106 and 0.045 m, respectively; (2) the smoke point values for propylene and polypropylene are 0.029 and 0.050 m, respectively; and (3) the smoke point values for styrene and polystyrene are 0.006 and 0.015 m, respectively. The smoke-point data for polymers support the accepted vaporization mechanisms of polymers [148]; that is, polyethylene, polypropylene, and polystyrene vaporize as higher molecular weight oligomers rather than as monomers, and thus, their smoke point values are different than the values for the monomers. The smoke point values suggest that polyethylene is expected to have higher smoke emission than ethylene, whereas polypropylene and polystyrene are expected to have lower smoke emissions than propylene and styrene.

The data in Table A.40 exhibit linear dependencies of the different fire properties on the molecular weight of the fuel monomer within each group [114]:

$$\Delta H_i = h_i + \frac{m_i}{M} \tag{36.87}$$

$$y_j = a_j + \frac{b_j}{M} \tag{36.88}$$

where

ΔH_i = Net heat of complete combustion or chemical, convective, or radiative heat of combustion (kJ/g)

y_j = Yield of product j (g/g)

M = Molecular weight of fuel monomer (g/mol)

h_i = Mass coefficient for the heat of combustion (kJ/g)

m_i = Molar coefficient for the heat of combustion (kJ/mol)

a_j = Mass coefficient for the product yield (g/g)

b_j = Molar coefficient for the product yield (g/mol)

The reader is referred to [114] for listings of h_i, m_i, a_j, and b_j for each fuel class. The coefficients depend on the chemical structures of the fuel; m_i and b_j become negative with the introduction of oxygen, nitrogen, and sulfur atoms into the chemical structure [114]. Relationships in Equations 36.87 and 36.88 support the suggestion [128] that generally smaller molecules offer greater resistance to smoke formation and emission. The relationships also indicate that for gases, liquids, and solids gasifying as high molecular weight fuels, $\Delta H_i \approx h_i$ and $y_j \approx a_j$. The variations of chemical, convective, and radiative heats of combustion as well as yields of CO and smoke with the chemical structures of the fuels are similar to the smoke point variations.

Example 19 The following smoke point values have been reported in Ref. [112]:

Polymer	PE	PP	PMMA	PS
Smoke point (m)	0.045	0.050	0.105	0.015

For well-ventilated conditions, estimate (1) the chemical, convective, and radiative heats of combustion using Equations 36.82, 36.83, and 36.84 and data for the net heat of complete combustion from Table A.39; and (2) yields of CO and smoke using Equations 36.64, 36.85, and 36.86 and stoichiometric yields from Table 36.10.

Solution

1. From Equations 36.82, 36.83, and 36.84 and ΔH_T from Table A.39,

Polymer	PE	PP	PMMA	PS
ΔH_T (kJ/g)	43.6	43.4	25.2	39.2
ΔH_{ch} (kJ/g)	36.8	37.0	23.1	29.6
ΔH_{con} (kJ/g)	20.6	21.1	15.0	14.0
ΔH_{rad} (kJ/g)	16.2	15.9	8.1	15.6

2. From Equations 36.64, 36.85, and 36.87 and Table 36.11,

Polymer	PE	PP	PMMA	PS
Ψ_{CO}	2.00	2.00	1.40	2.15
Ψ_s	0.857	0.857	0.600	0.923
y_{CO} (g/g)	0.027	0.025	0.009	0.050
y_s (g/g)	0.077	0.072	0.028	0.135

Ignition Resistance

Ignition resistance is provided by (1) modifying the chemical structures of the materials for high resistance to ignition and fire propagation, (2) incorporating fire retardants within the materials, (3) coating and wrapping the surfaces, (4) separating materials by inert fire barriers, (5) modifying configuration and arrangement of materials, and so forth. In the context of the concepts introduced and discussed in this chapter, ignition resistance may be interpreted as follows:

Increasing the Resistance to Ignition and Fire Propagation by Increasing the Critical Heat Flux (CHF) and Thermal Response Parameter (TRP) Values

As discussed in section "Ignition (Fire Initiation)" of this chapter, the critical heat flux (CHF) can be expressed as

$$\text{CHF} \approx \sigma\left(T_{ig}{}^4 - T_0{}^4\right) \tag{36.89}$$

where

σ = Stefan-Boltzmann constant (56.7×10^{-12} kW/m^2·K^4)
T_{ig} = Ignition temperature (K)
T_a = Ambient temperature (K)

In turn, the Thermal Response Parameter (TRP) is defined in Equation 36.2, and its relationship to fire propagation in Equations 36.12 and 36.13. The relationships between time to ignition, fire propagation rate, Fire Propagation Index (FPI), and TRP (Equations 36.2, 36.12, and 36.13) show that the time to ignition is directly proportional to the square of the TRP value and the fire propagation rate and FPI are inversely proportional to the TRP value to the power 2 and 1, respectively. Thus, the higher the TRP value, the longer the time to ignition, the slower the fire propagation rate, and the lower the FPI value. For high TRP values with relatively low FPI values, there is empirical evidence [28, 31, 43–46] that no fire propagation beyond the ignition zone will occur, defined as the nonfire-propagating behavior. Also, for materials with high CHF values, higher heat flux exposure is required to initiate a fire.

The CHF and TRP values can be increased by modifying the pertinent parameters, such as an increase in the chemical bond dissociation energy and a decrease in thermal diffusion (combination of the density, specific heat, and thermal conductivity). Figures 36.49 and 36.50 show the CHF and TRP values for a tri-wall corrugated paper sheet containing various amounts of a passive fire protection agent (identified as agent "A" here); the data were obtained from ignition experiments in the Fire Propagation Apparatus. Similarly, Fig. 36.51 shows the TRP value for a single-wall corrugated paper sheet containing various amounts of the passive fire protection agent A. The CHF and TRP values increase with increasing amount of agent; thus, the passive fire protection agent would complement active fire protection agents. Corrugated paper boxes treated with higher amounts of the passive fire protection agent are expected to require reduced amounts of active fire protection agents for fire control, suppression, or extinguishment compared to the amounts of active fire protection agents required for the untreated boxes [149]. The passive fire protection requirements for various materials can be assessed from the data for CHF and TRP listed in Table A.35.

Decreasing the Values of the Heat Release Parameter (HRP) and the Flame Heat Flux

Heat release rate is equal to the heat release parameter (HRP) times the net heat flux (Equation 36.34). HRP is the ratio of the heat of combustion to heat of gasification, and thus the HRP value can be decreased by decreasing the heat of combustion and/or increasing the heat of gasification by various chemical and physical means. An examination of data in Table A.39 for heats of combustion shows that introduction of oxygen, nitrogen, sulfur, halogen, and other atoms into the chemical structures of the materials reduces the heat of combustion. For example, the heat of combustion decreases when hydrogen atoms attached to carbon atoms in polyethylene are replaced by halogen atoms, such as by fluorine in Teflon. The chemical heat of combustion decreases from 38.4 kJ/g to 4.2 kJ/g (Table A. 39), and the chemical HRP value decreases from 17 to 2 (Table 36.10).

HRP values can also be reduced by increasing the heat of gasification and decreasing the heat of combustion by retaining the major fraction of the carbon atoms in the solid phase, a process defined as charring. Several passive fire protection agents are available commercially to enhance the charring characteristics of materials.

Figure 36.52 shows the reduction in the chemical heat release rate as a result of an increase in charring of a tri-wall corrugated paper sheet by the passive fire protection agent A; the data were obtained from combustion experiments in the Fire Propagation Apparatus. The amount of agent A increases from Treated 1 to 3 in Fig. 36.52. There is a very significant decrease in the chemical heat release rate of the tri-wall corrugated paper sheet by the passive fire protection agent A, which will complement active fire protection agents. Corrugated paper boxes treated with higher amounts of passive fire protection agent are expected to require reduced amounts of active fire protection agents for fire control, suppression, or extinguishment compared to the one required for the untreated boxes.

The effect on flame heat flux by passive fire protection is determined by using the radiation scaling technique ([44], described in section "Flaming and Nonflaming Phenomena" of this chapter), where combustion experiments are performed in environments with oxygen concentration levels higher than the ambient values. Very little is known about this subject. Table 36.7 lists some of the flame heat flux values derived from the radiation scaling technique, but no systematic study has been performed for the

effectiveness of passive fire protection. From the discussion in section "Flaming and Nonflaming Phenomena" of this chapter, materials that vaporize as species of low molecular weight tend to yield lower flame heat fluxes. Therefore, passive fire protection agents that can reduce the molecular weight of the vaporized materials would be effective in reducing the flame heat flux and complement the active fire protection agents.

Changing the Nature of Fire Products

Nonhalogenated passive fire protection agents or agents that reduce or eliminate the release of halogenated and highly aromatic products and enhance release of aliphatic products, rich in hydrogen and oxygen atoms but poor in carbon atoms, are effective in reducing the nonthermal damage due to smoke and corrosion. Some of the passive fire protection agents, available commercially, interact with the materials in the solid as well as in the gas phase during pyrolysis and combustion.

The critical parameter that needs to be examined in the presence and absence of the passive fire protection agents is the ratio of the generation rate of products (such as for smoke, CO, corrosive products [HCl], and others) to heat release rate. The effectiveness of the passive fire protection agent is reflected in the small values of the ratios at fire control, suppression, and/or extinguishment stages.

Flame Extinction

Flame extinction is achieved by applying agents to the flame and/or to the surface of the burning material. Fire control, suppression, and extinguishment have been described by the firepoint concept [150, 151]. According to the firepoint theory, the convective heat flux from the flame to the burning surface as the flame extinction condition is reached is expressed as [150, 151].

$$\dot{q}''_{fc} = \Phi \Delta H_T \dot{m}''_{\mathrm{cr}} \tag{36.90}$$

where

$\dot{q}''_{fc}$ = Convective flame heat flux from the flame to the surface as the extinction condition is reached (kW/m^2)

ϕ = Maximum fraction of combustion energy that the flame reactions may lose to the sample surface by convection without flame extinction and is defined as the kinetic parameter for flame extinction

ΔH_T = Net heat of complete combustion (kJ/g)

$\dot{m}''_{\mathrm{cr}}$ = Critical mass loss rate for flame extinction (g/m^2/s)

The kinetic parameter is defined as [150, 152]

$$\varphi = \frac{\Delta H_{g,\mathrm{con}}}{\Delta H_T} \tag{36.91}$$

where $\Delta H_{g,\mathrm{con}}$ is the flame convective energy transfer to the fuel per unit mass of fuel gasified (kJ/g). The kinetic parameter is expected to be higher for fast-burning material vapors and lower for slower-burning material vapors, such as materials containing halogens, sulfur, and nitrogen. It is suggested that, at flame extinction, combustion is controlled primarily by convective heat transfer, and thus the critical mass loss rate would follow Spalding's mass transfer number theory [152]:

$$\dot{m}''_{\mathrm{cr}} = \frac{h}{c_p} \ln(B_{\mathrm{cr}} + 1) \tag{36.92}$$

where

h = Convective heat transfer coefficient (kW/m^2/K)

c_P = Specific heat of air (kJ/g/K)

B_{cr} = Critical mass transfer number

The critical mass transfer number is defined as

$$B_{\mathrm{cr}} = \frac{Y_{\mathrm{O}} \Delta H^*_{\mathrm{O}} - c_p(T_s - T_a)}{\Delta H_{g,\mathrm{con}}} \tag{36.93}$$

where

Y_{O} = Oxygen mass fraction

ΔH^*_{O} = Net heat of complete combustion per unit mass of oxygen consumed (kJ/g), which is approximately constant

T_s = Surface temperature (K)

T_a = Ambient temperature (K)

[a]Ignition data measured in the Fire Propagation Apparatus
[b]Ignition data measured at the University of Edinburgh, U.K.

For ambient conditions, $Y_O \Delta H_T \gg c_p (T_s - T_a)$. From Equations 36.91, 36.92 and 36.93,

$$\Phi = \frac{Y_O \Delta H_O^*}{\Delta H_T \left[\exp\left(\frac{c_p}{h} \dot{m}''_{cr} \right) - 1 \right]} \tag{36.94}$$

Firepoint theory [150, 151] and experimental data show that the critical mass loss rate for flame extinction is similar to the critical mass loss rate for ignition [14, 122, 153–155] The data for the critical mass loss rate for ignition and flame extinction and the kinetic parameter for flame extinction are listed in Table 36.15. The values for the critical mass loss rate for ignition from the Fire Propagation Apparatus [14] were measured at the time period where the sustained flame is just being established and, thus, are higher than the values from Ref. [155] which were probably measured just before the establishment of a sustained flame. For polymethylmethacrylate,

the critical mass loss rate for ignition from Ref, [14] agrees with the critical mass loss rate for flame extinction from Ref. [154].

The data in Table 36.15 show that the values of the kinetic parameter are higher for the aliphatic materials than the values for the aromatic and chlorinated materials, which is opposite to the trend for the heat of combustion (Table A.39). The data suggest that the materials can be arranged in the following decreasing order of the kinetic parameter values (using data from Ref. [14]): polyoxymethylene ($\phi = 0.43$) > polymethylmethacrylate ($\phi = 0.28$) > polyethylene, polypropylene, and polyethylene foams ($\phi = 0.27$ to 0.25) > polystyrene ($\phi = 0.21$) > polyurethane, polystyrene, and polyisocyanurate foams and chlorinated polyethylenes ($\phi = 0.09$ to 0.19). As expected from the firepoint theory [150, 151], the reactivity of the vapors in the gas phase follows the kinetic parameter.

The combustion efficiency and product generation efficiencies follow the reactivity of the vapors in the gas phase, such as shown in Fig. 36.53 for the combustion efficiency. The lower the value of the kinetic parameter (Equation 36.94), the lower the reactivity of the material vapors, which is reflected in the (1) reduced values of the combustion efficiency (Equations 36.36, 36.37 and 36.38), (2) reduced values of the generation efficiencies (Equation 36.66) of the oxidation zone products (such as CO_2), and (3) increased values of the generation efficiencies (Equation 36.67) of the reduction zone products (such as smoke, CO, and hydrocarbons).

Flame extinction can also be expressed in terms of the critical heat release rate:

$$\dot{Q}''_{\mathrm{cr},i} = \Delta H_i \dot{m}''_{\mathrm{cr}} \tag{36.95}$$

where $\dot{Q}''_{\mathrm{cr},i}$ is the critical heat release rate (chemical, convective, or radiative in kW/m^2), and ΔH_I is the heat of combustion (chemical, convective, and radiative in kJ/g). Table 36.16 lists the critical chemical, convective, and radiative heat release rates for flame extinction, where critical mass loss rate values are taken from Table 36.15 and heats of combustion from Table A.39.

The data in Table 36.16 suggest that the critical heat release rate for flame extinction is weakly dependent on the chemical nature of the material, contrary to the critical mass loss rate. The critical heat release rates thus can be averaged, which are 100 ± 7, 53 ± 9, and 47 ± 10 kW/m^2 for the chemical, convective, and radiative heat release rates, respectively. For materials with highly reactive vapors, such as polyethylene, large amounts of extinguishing agent are needed to reduce the heat release rate to the critical value. For materials with highly

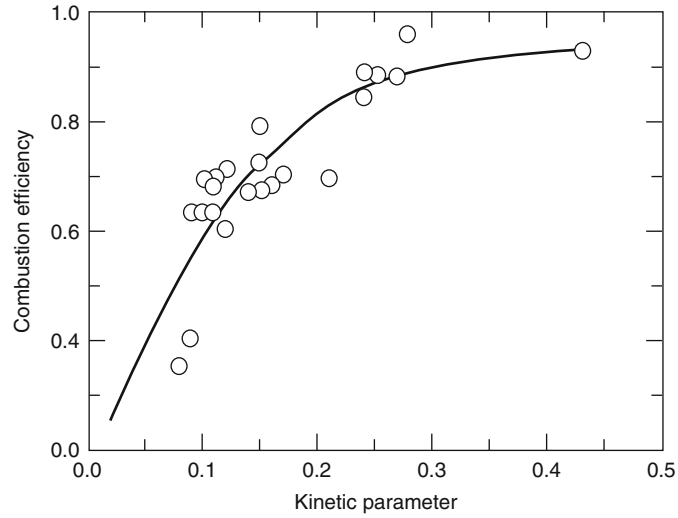

Fig. 36.53 Combustion efficiency versus kinetic parameter for flame extinction versus. Data were measured in the Fire Propagation Apparatus

Table 36.16 Critical chemical, convective, and radiative heat release rates for flame extinction

	Critical heat release rate (kW/m^2)

Note: Critical mass loss rates from Table 36.15, and heats of combustion from Table A.39

nonreactive vapors, such as Teflon, it is difficult to reach the critical heat release rate values unless high external heat flux is applied.

The energy balance at the surface as the flame extinction condition is reached can be represented by modifying Equations 36.15 and 36.34 [156]

$$\dot{m}'' = \frac{\Phi \Delta H_T \dot{m}''_{\text{cr}} + \dot{q}''_e - \dot{q}''_{rr} - \dot{q}''_{\text{agent}}}{\Delta H_g} \tag{36.96}$$

$$\dot{Q}''_i = \frac{\Delta H_i}{\Delta H_g}\left(\Phi \Delta H_T \dot{m}''_{\text{cr}} + \dot{q}''_e - \dot{q}''_{rr} - \dot{q}''_{\text{agent}}\right) \tag{36.97}$$

where

$\dot{q}''_e$ = External heat flux (kW/m^2)

$\dot{q}''_{rr}$ = Surface re-radiation loss (kW/m^2)

$\dot{q}''_{\text{agent}}$ = Heat flux removed from the surface or from the flame by the agent as the flame extinction condition is reached (kW/m^2)

ΔH_i = Chemical, convective, or radiative heat of combustion (kJ/g)

ΔH_g = Heat of gasification (kJ/g)

$\Delta H_i/\Delta H_g$ is defined as the heat release parameter (HRP) (see section "Heat Release Rate" of this chapter).

Flame Extinction by the Processes in the Gas Phase

The process of flame extinction by gaseous, powdered, and foaming agents and by an increase in the local equivalence ratio is predominantly a gas-phase process and, thus, is different from the process of flame extinction by water, which occurs predominantly in the solid phase at the surface of the material. The kinetic parameter for flame extinction defined in Equation 36.94, however, is still applicable [156]:

$$\Phi = \frac{\Phi_0 - \kappa Y_{j,\text{ex}}\left[\dfrac{1 + \Delta_{c_p}(T_{ad} - T_a) + \Delta H_D}{Y_{\text{O}} \Delta H^*_{\text{O}}}\right]}{1 - Y_{j,\text{ex}}} \tag{36.98}$$

where

ϕ = Kinetic parameter in the presence of the extinguishing agent

ϕ_0 = Kinetic parameter in the absence of the extinguishing agent

κ = Ratio between the kinetic parameters at the flame temperature and at the adiabatic flame temperature

$Y_{j,\text{ex}}$ = Mass fraction of the extinguishing agent

Δ_{cp} = Difference between the heat capacities of the extinguishing agent and the fire products (kJ/g/K)

T_{ad} = Adiabatic flame temperature at the stoichiometric limit (K)

T_a = Initial temperature of the reactants (K)

ΔH_D = Heat of dissociation (kJ/g)

Equation 36.98 shows that the addition of an extinguishing agent reduces the kinetic parameter from its normal value and includes the effects of four flame extinction mechanisms

[156]: (1) dilution, effects are included in the $\kappa Y_{j,\mathrm{ex}}$ term; (2) added thermal capacity, effects are included in Δ_{cp}; (3) chemical inhibition, effects are included through T_{ad}; and (4) kinetic chain breaking and endothermic dissociation through Δc_P and ΔH_D terms.

From Equation 36.96, in the presence of an extinguishing agent that works in the gas phase,

$$\dot{m}'' = \frac{\varphi \Delta H_T \dot{m}''_{\mathrm{cr}} + \dot{q}''_e - \dot{q}''_{rr}}{\Delta H_g} \tag{36.99}$$

For fixed values of external heat flux, the addition of an extinguishing agent reduces the normal value of the kinetic parameter by one or more of the four mechanisms expressed by Equation 36.98; the mass loss rate decreases and approaches the critical value at which the flame is extinguished. Increasing the external heat flux would increase the mass loss rate, and further addition of the extinguishing agent would be needed to reduce the mass loss to its critical value and to reestablish the flame extinction condition. Continued increases in the extinguishing agent for increasing external heat flux will result in the denominator of Equation 36.98 to approach zero, at which point it would represent a nonflaming condition.

For a fixed airflow rate, as is generally the case in enclosure fires where the extinguishing agent working in the gas phase is used, an increase in the mass loss rate due to increasing external heat flux results in an increase in the equivalence ratio, defined in Equation 36.41. As the equivalence ratio increases and approaches values of 4.0 and higher, the combustion efficiency approaches values less than or equal to 0.40 (see Fig. 36.33), flames are extinguished, and nonflaming conditions become important [103, 104]. Thus, the upper limit for the application of the extinguishing agent working in the gas phase is dictated by the equivalence ratio ≥ 4.0 and/or the combustion efficiency ≤ 0.40. Under nonflaming conditions, an increase in the external heat flux increases the generation rate of the fuel vapors and the reduction-zone products.

Flame Extinction by Reduced Mass Fraction of Oxygen

Flame extinction by reduced mass fraction of oxygen can be the result of (1) dilution and heat capacity effects due to the addition of inert gases, such as N_2 and CO_2; and (2) chemical effects due to the retardation of chemical reactions and reduction in the flame heat flux to the surface, especially the radiative component.

Theoretical and experimental analyses have been performed for flame extinction by reduced oxygen mass fractions. For example, for polymethylmethacrylate (PMMA), an oxygen mass fraction value of 0.180 is predicted for flame extinction [157] compared to the experimental values of 0.181 for a 70-mm-wide, 190-mm-high, and 19-mm-thick vertical PMMA slab [158] and 0.178 for a 100-mm-wide, 25-mm-thick, and 300- and 610-mm-high vertical slabs of PMMA, and 25-mm-diameter and 610-mm-high vertical cylinder of PMMA [31]. The critical values of the chemical, convective, and radiative heat release for PMMA are 106, 73, and 33 kW/m^2 [31], respectively, showing a trend similar to one reported in Table 36.16. At oxygen mass fractions equal to or less than 0.201, flames are unstable and faint blue in color [31].

The effect external heat flux on flame extinction due to reduced oxygen mass fraction has been examined for buoyant turbulent diffusion flames [159]. For example, for rectangular and circular horizontal PMMA slabs, 0.06–0.10 m^2 in area and 0.03–0.05 m in thickness, exposed to external heat flux values of 0, 40, 60, and 65 kW/m^2, flame extinction is found at oxygen mass fractions of 0.178, 0.145, 0.134, and 0.128, respectively [6]. The data support Equation 36.99 and show that, for buoyant turbulent diffusion flames, flaming can occur up to relatively low oxygen mass fraction values. The only condition is that, in the gas phase, the reactant-oxidizer mixture is within the flammability limit.

The effect of reduced oxygen mass fraction on flame extinction of materials in a three-dimensional arrangement, where flame heat flux is enhanced, has been examined. Figure 36.54 shows an example where chemical heat release

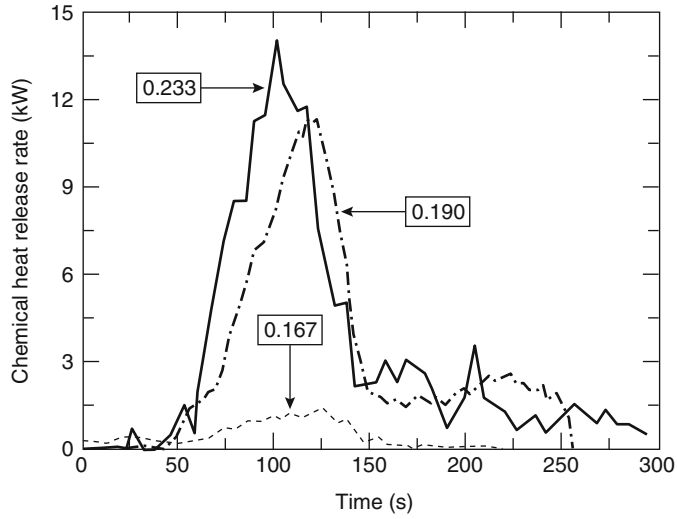

Fig. 36.54 Chemical heat release rate versus time for 50-mm empty corrugated paper boxes in a 2 × 2 × 2 arrangement (two boxes along the length × two boxes along the width × two layers, for a total of eight boxes separated by about 12 mm). Measurements were made in the Fire Propagation Apparatus with no external heat flux under co-flow conditions and at various oxygen mass fractions, which are indicated in the figure

rates at oxygen mass fractions of 0.233, 0.190, and 0.167 versus time are shown for the combustion of 50-mm cubes of empty corrugated paper boxes in a 2 × 2 × 2 arrangement. The weight of each box is about 13 g (839 g/m^2). The measurements were taken in the Fire Propagation Apparatus.

In Fig. 36.54, at an oxygen mass fraction of 0.167, the flame is close to the extinction condition, only 10.5 % of the initial weight of the boxes is consumed, which is equivalent to consumption of a single box with a surface area of about 0.0155 m^2. The peak chemical heat release rate close to flame extinction, in Fig. 36.54, is about 1.5 kW or 97 kW/m^2, using a surface area of 0.0155 m^2. This value is in excellent agreement with the average value in Table 36.16, derived from the critical mass loss rates for ignition. The data in Fig. 36.54 for the three-dimensional arrangement of the corrugated boxes thus support the firepoint theory [150, 151], independent of the critical heat release rate for flame extinction from the geometrical arrangement and surface areas of the materials, and Equations 36.98 and 36.99 as originally formulated in Ref. [156].

Definitions

Chemical heat of combustion	calorific energy generated in chemical reactions leading to varying degrees of incomplete combustion per unit fuel mass consumed
Convective heat of combustion	calorific energy carried away from the flame by the fire products-air mixture per unit fuel mass consumed
Heat of gasification	energy absorbed to vaporize a unit mass of fuel originally at ambient temperature
Heat release parameter	calorific energy generated per unit amount of calorific energy by the fuel
Kinetic parameter for flame extinction	maximum fraction of combustion energy that the flame reactions may lose to the sample surface by convection without flame extinction
Net heat of complete combustion	calorific energy generated in chemical complete reactions leading to combustion, with water as a gas, per unit fuel mass consumed

Radiative heat of combustion	calorific energy emitted as thermal radiation from the flame per unit fuel mass consumed

Nomenclature

A	total exposed surface area of the material (m^2)
a_j	mass coefficient for the product yield (g/g)
b_j	molar coefficient for the product yield (g/mol)
B_{cr}	critical mass transfer number
CHF	critical heat flux (kW/m^2)
$\dot{C}''_O$	mass consumption rate of oxygen ($g/m^2/s$)
$\dot{C}''_{stoich,O}$	stoichiometric mass consumption rate of oxygen ($g/m^2/s$)
c_O	mass of oxygen consumed per unit mass of fuel (g/g)
c_P	specific heat (kJ/g/K)
Δc_P	difference between the heat capacities of the extinguishing agent and the fire products (kJ/g/K)
D	optical density (1/m)
E_i	total amount of heat generated in the combustion of a material (kJ)
f_j	volume fraction of a product
fp	fire property
FPI	Fire Propagation Index
FSP_c	convective flame spread parameter
$\dot{G}''_j$	mass generation rate of product j ($g/m^2/s$)
$\dot{G}''_{stoich,j}$	stoichiometric mass generation rate of product j ($g/m^2/s$)
ΔH_i	heat of combustion per unit mass of fuel vaporized (kJ/g)
ΔH_D	heat of dissociation (kJ/g)
ΔH_g	heat of gasification at ambient temperature (kJ/g)
$\Delta H_{g,con}$	flame convective energy transfer to the fuel per unit mass of fuel gasified (kJ/g)
ΔH_m	heat of melting at the melting temperature (kJ/g)
ΔH_T	net heat of complete combustion per unit of fuel vaporized (kJ/g)
ΔH_v	heat of vaporization at the vaporization temperature (kJ/g)
ΔH^*_{CO}	net heat of complete combustion per unit mass of CO generated (kJ/g)
$\Delta H^*_{CO_2}$	net heat of complete combustion per unit mass of CO_2 generated (kJ/g)
ΔH^*_O	net heat of complete combustion per unit mass of oxygen consumed (kJ/g)
HRP	heat release parameter
h_i	mass coefficient for the heat of combustion (kJ/g)
I/I_0	fraction of light transmitted through smoke
j	fire product
k	thermal conductivity (kW/m/K)
L_{sp}	smoke point (m)
l	optical path length (m)
$\dot{m}''$	mass loss rate ($g/m^2/s$)
M	molecular weight (g/mol)
m_i	molar coefficient for the heat of combustion (kJ/mol)
$\dot{m}_{air}$	mass flow rate of air (g/s)
$\dot{q}''_e$	external heat flux (kW/m^2)
$\dot{q}''_f$	flame heat flux (kW/m^2)
$\dot{Q}''_i$	heat release rate per unit sample surface area (kW/m^2)
$\dot{Q}'_i$	heat release rate per unit sample width (kW/m)
S	stoichiometric mass air-to-fuel ratio (g/g)
t	time (s)
t_f	time at which there is no more vapor formation (s)
t_0	time at which the sample is exposed to heat (s)
T	temperature (K)
ΔT_{ig}	ignition temperature above ambient (K)
TRP	thermal response parameter ($kW \cdot s^{1/2}/m^2$)
u	fire propagation rate (mm/s or m/s)
$\dot{V}$	total volumetric flow rate of fire product-air mixture (m^3/s)
$\dot{W}$	total mass flow rate of the fire product-air mixture (g/s)

W_f	total mass of the material lost in the flaming and nonflaming process (g)
W_j	total mass of product j generated in the flaming and nonflaming process (g)
X_f	flame height (m or mm)
X_p	pyrolysis front (m or mm)
X_t	total length available for fire propagation (m or mm)
y_j	yield of product j
$Y_{j,\mathrm{ex}}$	mass fraction of extinguishing agent
Y_{O}	mass fraction of oxygen

Greek Letters

α	correlation coefficient (nonflaming fire)
β	correlation coefficient (transition region)
ϕ	kinetic parameter for flame extinction
ξ	correlation coefficient (transition region)
Φ	equivalence ratio
χ_{ch}	combustion efficiency
χ_{con}	convective component of the combustion efficiency
χ_{rad}	radiative component of the combustion efficiency
η_j	generation efficiency
κ	ratio between the kinetic parameters for the flame temperature and adiabatic flame temperature
λ	wavelength of light (μm)
σ	Stefan-Boltzmann constant (56.7×10^{-12} kW/m^2/K^4)
$\overline{\tau}$	average specific extinction area (m^2/g)
ρ	density (g/m^3)
ν_j	stoichiometric coefficient of product j
ν_{O}	stoichiometric coefficient of oxygen
Ψ_j	stoichiometric yield for the maximum conversion of fuel to product j
Ψ_{O}	stoichiometric mass oxygen-to-fuel ratio (g/g)
ζ	ratio of fire properties for ventilation-controlled to well-ventilated combustion
ζ_{oxid}	oxidation zone product generation efficiency ratio
ζ_{red}	reduction zone product generation efficiency ratio

Subscripts

a	air or ambient
ad	adiabatic
asy	asymptotic
ch	chemical
con	convective
cr	critical
e	external
ex	extinguishment
f	flame or fuel
fc	flame convective
fr	flame radiative
g	gas
g,con	flame convective energy for fuel gasification
i	chemical, convective, radiative
ig	ignition
j	fire product
n	net
0	initial
oxid	oxidation zone of a flame
rad	radiation
red	reduction zone of a flame
stoich	stoichiometric for the maximum possible conversion of fuel monomer to a product
rr	surface re-radiation
s	surface, smoke
vc	ventilation-controlled fire
wv	well-ventilated fire
∞	infinite amount of air

Superscripts

$\cdot$	per unit time (s^{-1})
$'$	per unit width (m^{-1})
$''$	per unit area (m^{-2})

Mohammed M. Khan is a Senior Lead Research Scientist (retired) (in place of Senior Research Specialist). He has more than 30 years of flammability research experience. He is recognized for his work on ignition, flame spread, and material flammability characterization.

Archibald Tewarson retired from FM Global. His major specialization is in chemical aspects of fires.

Marcos Chaos is a Senior Lead Research Scientist at the Research Division of FM Global. He has specialized in pyrolysis modeling and optimization algorithms as well as experimental aspects of flammability testing.

Performance-Based Design

37

Morgan J. Hurley and Eric R. Rosenbaum

Introduction

The *SFPE Engineering Guide to Performance-Based Fire Protection* [1] defines performance-based design as "an engineering approach to fire protection design based on (1) agreed upon fire safety goals and objectives, (2) deterministic and/or probabilistic analysis of fire scenarios, and (3) quantitative assessment of design alternatives against the fire safety goals and objectives using accepted engineering tools, methodologies, and performance criteria."

This definition identifies three key attributes of performance-based design. The first is a description of the desired level of fire safety in a building (or other structure) in the event of a fire. The second attribute includes definition of the "design basis" of the building. The "design basis" is an identification of the types of fires, occupant characteristics, and building characteristics for which the fire safety systems in the building are intended to provide protection. In the vernacular of performance-based design, these fires are referred to as "design fire scenarios." The third element involves an engineering analysis of proposed design strategies to determine whether or not they provide the intended level of safety in the event of the design fire scenarios.

M.J. Hurley (✉) • E.R. Rosenbaum

The purpose of this chapter is to provide an overview of performance-based design and to serve as insight into how other chapters in this handbook can be used as resources.

In most cases, utilizing performance-based design goes beyond code application to analysis of how a building and its occupants will be affected by fire. This generally requires consideration of the science of fire and human physiology and psychology. That is why performance-based design potentially utilizes many sections of the *SFPE Handbook of Fire Protection Engineering*.

Types of Performance

For performance-based design, Nelson [2] identifies the following four types of "performance" that may be evaluated.

Component Performance

Component performance identifies the intended performance in fire of individual building systems or components, such as doors, structural framing, or individual protection systems such as detection. In component performance analysis, individual components and systems are designed in isolation without considering how their performance may impact, or be impacted by, the performance of other systems or components. Any

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_37, © Society of Fire Protection Engineers 2016

system or component that meets the stated performance would be considered to be acceptable.

An example of a component-performance-based approach would be a structural element that is designed to achieve a 1-h fire resistance rating when exposed to the "standard" fire. In this case, the intended performance would involve maximum acceptable point and average temperatures, and the design fire scenario would be the standard time-temperature curve. Although building codes typically require this performance to be achieved through fire testing, calculation methods are available as well [3]. Any assembly that achieves the intended performance when exposed to the design fire scenario would be acceptable.

Another example would be an individual sprinkler used in a sprinkler system. Sprinkler design standards and component standards might require a maximum actuation temperature and thermal response characteristics. Any sprinkler that meets the performance identified would be acceptable.

It is noteworthy that the codes and standards that govern fire-resistant structural elements and sprinklers contain specific requirements that are not performance based, such as limitations on the types of materials that can be used in fire-resistant assemblies and sprinklers.

Environmental Performance

Environmental performance involves identification of the maximum permissible fire conditions within a building or portion thereof. The specification of environmental conditions could involve temperature, heat flux, or products of combustion. Environmental performance approaches identify conditions that are tolerable if a fire were to occur. It is not possible to include fire prevention strategies within an environmental performance approach.

An example of an environmental performance approach would be a requirement that the smoke layer within an atrium not descend below a given elevation above the highest occupied level. Any design that would achieve this criterion would be acceptable, and the performance requirement does not specify or limit how this can be achieved.

Threat Potential Performance

Threat potential performance involves identification of the maximum acceptable threat to life, property, business continuity, or the natural environment. Unlike environmental performance requirements, which involve statements of maximum acceptable conditions in the environment surrounding items that are desired to be protected from fire, threat potential performance involves a statement of the maximum tolerable conditions of the item or items being protected.

An example of a threat potential performance requirement would be a fractional effective incapacitation dose (see Chap. 63). Another example would be an identification of the maximum permissible temperature of an object. As with environmental performance requirements, threat potential performance requirements do not specify or limit how the conditions can be achieved.

Risk Potential Performance

In risk potential performance, the summation of the products of probabilities of occurrence of fire events and their consequences are specified. An example of a risk potential performance requirement would be that the average permissible property loss in a facility resulting from fire must not exceed an average of $10,000 in value per year. When applying this type of approach, a designer would evaluate all possible fire events and their potential consequences. This can be expressed mathematically as [1]:

$$\text{Risk} = \sum \text{Risk}_i = \sum (\text{Loss}_i \cdot P_i)$$

where

Risk_i = Risk associated with scenario i
Loss_i = Loss associated with scenario i
P_i = Frequency of scenario i occurring

Nelson [2] also identifies the typical "prescriptive" approach, which he defines as

"specification." "Specification" involves strict definition of dimensions, construction methods, and other features. An example of "specification" would be some of the requirements in NFPA *101®, Life Safety Code®,* [4] applicable to stairway construction. NFPA *101* identifies specific dimensional requirements for stairs and handrails.

History of Performance-Based Fire Protection Design

Early (pre-1900s) fire protection requirements largely fit into the category of "specification," with such requirements including the permissible materials from which building exteriors could be constructed or the minimum acceptable spacing between buildings. However, most modern building and fire code requirements have some element of performance associated with them.

Performance-based approaches for designing building fire protection can be traced to the early 1970s, when the goal-oriented approach to building fire safety was developed by the U.S. General Services Administration [5]. Other major developments in performance-based design include the following:

- Publication of the performance-based British Regulations in 1985
- Publication in 1988 of the first edition of the *SFPE Handbook of Fire Protection Engineering*
- Publication of the performance-based New Zealand building code in 1992 and the New Zealand *Fire Engineering Design Guide* in 1994
- Publication of the Performance Building Code of Australia and the Australian *Fire Engineering Guidelines* in 1995
- Publication of the *Performance Requirements for Fire Safety and Technical Guide for Verification by Calculation* by the Nordic Committee on Building Regulations in 1995
- Publication of the performance option in the NFPA *101, Life Safety Code,* in 2000
- Publication of the *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings* in 2000
- Publication of the Japanese performance-based Building Standard Law in 2000
- Publication of the *ICC Performance Code for Buildings and Facilities* in 2001
- Publication of the performance option in the *NFPA 5000®, Building Construction and Safety Code®,* in 2003

The foregoing documents represent only the formalization of performance-based design. Performance-based design has long been practiced through the use of "equivalency" or "alternate methods and materials" clauses found in most, if not all, prescriptive codes and standards. These clauses permit the use of approaches or materials not specifically recognized in the code provided that the approach or material can be demonstrated to provide at least an equivalent level of safety as that achieved by compliance with the code or standard.

However, "equivalency" or "alternate methods and materials" clauses typically do not provide any detail as to how an equivalent level of safety can be achieved. Therefore, the approaches used by individual designers or regulatory officials were frequently developed on an ad hoc basis, with approaches varying among designers and among regulatory officials. The effect of the documents identified in the preceding text was to standardize the practice of performance-based design.

The development of performance-based design has followed an evolution in the quantitative understanding of fire. Before fire science was well understood, proven technologies would be codified into regulations. Similarly, as major fires occurred, and the causes and contributing factors of those fires were identified, codes and standards were modified to prevent similar major fires from occurring in the future.

Specification codes have the following two disadvantages:

- They potentially only protect against events of a type that have occurred in the past. Major

fires are low-probability, high-consequence events. Because of their stochastic nature, some types of rare events have not yet occurred.
- They potentially stifle innovation. By specifying certain types of methods and materials, it can be difficult to introduce new methods and materials into the marketplace.

As the science of fire has become better understood, performance-based fire protection design has become possible. Other engineering disciplines have evolved in a similar manner—as the underlying science has become better understood, their design approaches have become more performance based.

Advantages and Disadvantages of Performance-Based Design

Performance-based design offers a number of advantages and disadvantages over specification-based prescriptive design. As the design approach used moves from specification based toward risk based, these advantages and disadvantages are magnified.

Advantages

One advantage of performance-based design is that it allows the designer to address the unique features and uses of a building. For example, the stores in a shopping mall might have an identical occupancy classification under prescriptive building and fire codes and, hence, require similar fire protection strategies. However, the stores could contain significantly different fire hazards. Some could contain flammable liquids, whereas others might contain few or no combustible items at all. A corollary to this advantage is increased cost-effectiveness of performance-based designs.

Another advantage is that performance-based design promotes a better understanding of how a building would perform in the event of a fire. Compliance with prescriptive codes and standards is intended to result in a building that is "safe" from fire. However, what constitutes "safe" is generally not defined. Similarly, the types of fires against which the building is intended to achieve fire safety are not identified. Although most common fire scenarios would likely result in acceptable performance, the low-frequency scenarios that are not envisioned may not.

Two fire scenarios can be used to illustrate this. Carelessly discarded smoking materials would likely be within the design basis for a code that is intended to apply to a high-rise residential building. However, a gasoline tank truck that accidentally crashes into the building's lobby likely is not. Within these two extremes is a large range of possible events. A corollary to this advantage is that increased thought and engineering rigor are brought to solving fire protection problems.

Disadvantages

A disadvantage of performance-based design is that it requires more expertise to apply and review than does prescriptive-based design. Generally, application of prescriptive codes only requires the selection of building features and systems that fit within the code's requirements. Verification of the acceptability of a prescriptive-based design is equally straightforward. Performance-based design can take more time to conduct and review than prescriptive-based design.

Another disadvantage of performance-based design is that it can be more sensitive to change than prescriptive-based design. Changes in use of a building or portion thereof can result in unacceptable performance in the event of a fire if the effect of the change on fire safety is not contemplated in the design. With prescriptive-based designs, changes in use may be acceptable if the portion modified stays within the original occupancy or hazard classification.

This is not to say that prescriptive designs are completely tolerant to changes; even if a modification remains with the original occupancy

classification, some types of changes could result in the modification not being compliant with prescriptive codes. For example, movement of walls during tenant renovations in an office building could result in the sprinkler system no longer being in compliance with governing codes and standards. If a building is designed according to a performance basis, then some changes in use may result in increased vulnerability in the event of a fire.

The process that is identified in the subsequent section provides methods of overcoming the limitations.

Process of Performance-Based Design [1]

The *SFPE Engineering Guide to Performance-Based Fire Protection* [1] provides a process, or framework, for performance-based design. This process is identified in the flowchart in Fig. 37.1. The process is intended to be flexible, so that it can be tailored to the individual requirements of individual performance-based design projects. This flowchart identifies the steps that are involved in performance-based design without specifying which methods or models should be used to perform specific calculations relating to the development or evaluation of an individual design.

Defining the Project Scope

The performance-based design process identified in the *SFPE Engineering Guide to Performance-Based Fire Protection* begins with developing the project scope. (Defining the project scope is Step 1 in the process section later in the chapter.)

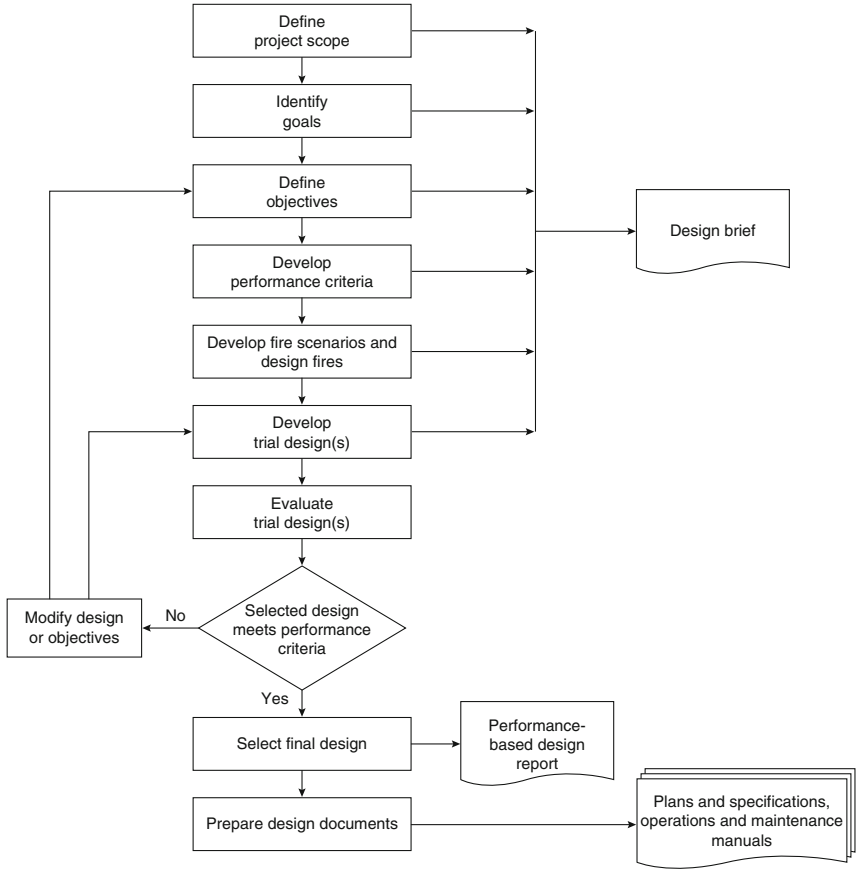

Fig. 37.1 Performance-based design process [1]

Project scopes for performance-based designs are frequently not highly different than project scopes for prescriptive-based designs, although unique features may be identified that might be difficult or impossible to achieve through compliance with prescriptive-based codes.

The project scope identifies the portions of a building or facility that will be considered by the design, the desired features of the design, the intended characteristics of the building, and the regulations that are applicable to the design. The scope also includes identification of the project stakeholders—those that have an interest in the success of the design. Stakeholders may include building owners or their representatives, regulatory authorities, insurance providers, building tenants, fire officials, or other parties. From the scope, a clear understanding can be gained of the needs of the project.

Identifying Goals

Once the scope is identified, the next steps involve the definition of goals and objectives for the design project. (Identifying goals is Step 2 in the process section later in the chapter.) The *SFPE Engineering Guide to Performance-Based Fire Protection* defines goals as the "desired overall fire safety outcome expressed in qualitative terms." Goals are intended to be stated in broad terms that can easily be understood by people who do not have engineering expertise. The purpose of identifying goals is to facilitate understanding and agreement on how the building is intended to perform in the event of a fire.

Laypeople would likely not be able to understand the significance of keeping the upper-layer temperature below a certain temperature, but they could understand what it means to provide for life safety in the event of a fire.

The *SFPE Engineering Guide to Performance-Based Fire Protection* identifies four fundamental goals for fire safety: life safety, property protection, mission continuity, and environmental protection. Although these types of statements are entirely qualitative in nature, they point the direction of the design process. For example, an unattended, fully automated warehouse may have property protection and mission continuity as its primary design goals. A hotel would likely have life safety as its primary fire safety goal.

Goals can come from a variety of sources. Some codes identify goals. For example, NFPA *101* specifies the following fire safety goal [5]:

4.1.1 Fire. A goal of this *Code* is to provide an environment for the occupants that is reasonably safe from fire by the following means:
(1) Protection of occupants not intimate with the initial fire development
(2) Improvement of the survivability of occupants intimate with the initial fire development

4.1.2 Comparable Emergencies. An additional goal is to provide life safety during emergencies that can be mitigated using methods comparable to those used in case of fire.

4.1.3 Crowd Movement. An additional goal is to provide for reasonably safe emergency crowd movement and, where required, reasonably safe nonemergency crowd movement.

NFPA 5000 [6] provides the following goals:

4.1.1 Goals. The primary goals of this *Code* are safety, health, building usability, and public welfare, including property protection as it relates to the primary goals.

NFPA 5000 specifies more goals than NFPA *101* does, which is due to the fact that *NFPA 5000* has a broader scope than NFPA *101*. NFPA *101* addresses only life safety, whereas *NFPA 5000* addresses many additional aspects of building safety. The *ICC Performance Code for Buildings and Facilities* [7] identifies goals that are similar to those contained in *NFPA 5000*.

Designs that comply with the prescriptive option of NFPA *101* or *NFPA 5000* are "deemed" to comply with the goals specified by those codes. Similarly, designs that comply with the ICC family of codes are deemed to comply with the goals of the *ICC Performance Code for Buildings and Facilities*. However, designers

who prepare performance-based designs would have to demonstrate that they achieve the goals of the applicable code.

In some cases, project stakeholders may specify their own goals. See the section on "Application of Performance-Based Design" later in this chapter.

As qualitative statements, goals are insufficient by which to judge the adequacy of a design. Therefore, they will have to be quantified as measurable values. The next two steps of the process outlined in the *SFPE Engineering Guide to Performance-Based Fire Protection* are intended to facilitate translating these broad statements into specific numerical criteria that can be predicted using engineering methods.

Defining Objectives

The next step in this process is the development of objectives. (Defining objectives is Step 3 in the process section later in the chapter.) The *SFPE Engineering Guide to Performance-Based Fire Protection* identifies two types of objectives: stakeholder objectives and design objectives. Stakeholder objectives provide greater detail of maximum allowable levels of damage than goals do.

Stakeholder objectives might be expressed in terms of maximum allowable levels of injury, damage to property, damage to critical equipment, or length of loss of operations. Stakeholder objectives facilitate agreement among the stakeholders of the maximum level of damage that would be tolerable if a fire were to occur.

After the stakeholder objectives have been developed, the *SFPE Engineering Guide to Performance-Based Fire Protection* recommends developing design objectives. Design objectives focus on the items that are intended to be protected from fire and describe the maximum or minimum acceptable fire conditions necessary to achieve the stakeholder objectives.

As with goals, stakeholder objectives could be specified by a performance-based code. For example, NFPA *101* [5] provides the following objectives:

4.2.1 Occupant Protection. A structure shall be designed, constructed, and maintained to protect occupants who are not intimate with the initial fire development for the time needed to evacuate, relocate, or defend in place.

4.2.2 Structural Integrity. Structural integrity shall be maintained for the time needed to evacuate, relocate, or defend in place occupants who are not intimate with the initial fire development.

4.2.3 Systems Effectiveness. Systems utilized to achieve the goals of Section 4.1 shall be effective in mitigating the hazard or condition for which they are being used, shall be reliable, shall be maintained to the level at which they were designed to operate, and shall remain operational.

NFPA 5000 provides additional objectives resulting from the additional goals of the code.

If they are not specified by a code, stakeholder objectives will need to be developed by the engineer in consultation with project stakeholders based on the goals. In most cases, design objectives would be developed by an engineer based on the goals and stakeholder objectives agreed to by the stakeholders.

Developing Performance Criteria

Performance criteria are threshold values that, if exceeded, indicate that unacceptable damage has occurred. (Developing performance criteria is Step 4 in the process section later in the chapter.) Although design objectives provide more detail than the goals or stakeholder objectives, they are not sufficiently detailed for the evaluation of trial designs.

Performance criteria might include temperatures of materials, gas temperatures, smoke concentration or obscuration levels, carboxyhemoglobin levels, or radiant heat flux levels. Performance criteria should be predictable with engineering tools such as fire models.

Table 37.1 Examples fire protection goals, stakeholder objectives, design objectives, and performance criteria [1]

Fire protection goal	Stakeholder objective	Design objective	Performance criteria
Minimize fire-related injuries and prevent undue loss of life	No loss of life outside of the room or compartment of fire origin	Prevent flashover in the room of fire origin	Upper-layer temperature not greater than 200 °C
Minimize fire-related damage to the building and its contents	No significant thermal damage outside of the room or compartment of fire origin	Minimize the likelihood of fire spread beyond the room of fire origin	Upper-layer temperature not greater than 200 °C
Minimize undue loss of operations and business-related revenue due to fire-related damage	No downtime exceeding 8 h	Limit the smoke exposure to less than would result in unacceptable damage to the target	HCl not greater than 5 ppm
			Particulate not greater than 0.5 g/m^3
Limit environmental impacts of fire and fire protection measures	No water contamination by fire suppression water runoff	Provide a suitable means for capturing fire protection water runoff	Impoundment capacity at least 1.20 times the design discharge

The *SFPE Engineering Guide to Performance-Based Fire Protection* divides the types of performance criteria that may need to be developed into two categories: life safety criteria and non–life safety criteria.

Life safety criteria address the survivability of people exposed to fire or fire products. The values selected as performance criteria might vary depending on the physical and mental conditions of building occupants and length of exposure. Performance criteria may need to be developed in the areas of thermal effects to people (e.g., exposure to high gas temperatures or thermal radiation), toxicity of fire products, or visibility through smoke.

Non–life safety criteria may need to be developed to assess the achievement of goals relative to property protection, mission continuity, or environmental protection. Performance criteria relative to these goals may relate to thermal effects, such as ignition, melting, or charring; fire spread, smoke damage, fire boundary damage, structural integrity, damage to exposed items, or damage to the environment.

Given that performance criteria can vary widely depending on the specific design situation, the *SFPE Engineering Guide to Performance-Based Fire Protection* does not provide specific performance criteria. Rather, the guide identifies a number of reference sources that can be used to assist with the development of design-specific performance criteria. Table 37.1 contains examples of goals, objectives, and performance criteria.

Some performance-based codes provide performance criteria. NFPA *101* [5] provides the following performance criterion:

5.2.2 Performance Criterion. Any occupant who is not intimate with ignition shall not be exposed to instantaneous or cumulative untenable conditions.

Since "instantaneous or cumulative untenable conditions" is not defined, this performance criterion is more akin to an objective. However, additional specificity can be found in the annex of NFPA *101*. The options outlined in the annex deal with prevention of incapacitation from smoke or prevention of exposure to smoke.

In many cases, the engineer will need to develop performance criteria from the goals and objectives. To develop performance criteria, the engineer will need to understand the mechanism of harm to the object being protected. Chapter 63 addresses the mechanisms of harm to people in detail.

Developing Fire Scenarios

A second input needed to evaluate whether a trial design is acceptable is the design fire scenario, which describes the conditions of exposure, such

as types of fires and building and occupant conditions for which a design is intended to provide protection. (Developing fire scenarios is Step 5 in the process section later in the chapter.)

The *SFPE Engineering Guide to Performance-Based Fire Protection* suggests a two-step process for identifying design fire scenarios. The first step is considering all possible fire scenarios that could occur in the building or portion of the building that is within the scope of the design. The second step is to reduce the population of possible fire scenarios to a manageable set of design fire scenarios.

Both fire scenarios and design fire scenarios comprise three sets of characteristics: building characteristics, occupant characteristics, and fire characteristics. Building characteristics describe the physical features, contents, and ambient environment within the building. They can affect the evacuation of occupants, growth and spread of fire, and the movement of combustion products. Occupant characteristics determine the ability of building occupants to respond and evacuate during a fire emergency and the potential impact a fire will have on the occupants. Fire characteristics describe the history of a fire scenario, including first item ignited, fire growth, flashover, full development, and decay and extinction.

The *SFPE Engineering Guide to Performance-Based Fire Protection* identifies a number of methods that can be used to identify possible scenarios, including the following:

- Failure modes and effects analysis, where the different types of failures that could occur are studied, and the effects of those failures are analyzed.
- Failure analysis, where potential causes of failures are identified and the expected system performance is investigated.
- "What if" analysis, where expert opinion is used to consider possible events and the consequences of those events.
- Historical data, manuals, and checklists, where past events in a building or a similar building are studied to consider whether similar events could occur in the building that is being designed or modified. Manuals and checklists can be studied to consider warnings, cautions, or operational sequences that could lead to a fire if not followed.
- Statistical data of fires across broad classifications of buildings.
- Other analysis methods such as hazards and operability studies, preliminary hazard analysis, fault tree analysis, event tree analysis, cause-consequence analysis, and reliability analysis.

Given the large number of possible fire scenarios for a given performance-based design project, it is usually necessary to reduce the possible fire scenario population to a manageable number of design fire scenarios for evaluating trial designs. If the design is being done on a deterministic basis, this can be accomplished in part by excluding scenarios that are highly unlikely to occur or that would result in an acceptable outcome regardless of the trial design strategy that is used. However, for a fire scenario to be excluded from further analysis because it is considered too unlikely, all stakeholders must recognize and accept that if the scenario were to occur, an unacceptable outcome may result.

Another method of reducing the number of fire scenarios is to select bounding scenarios, where if the performance criteria can be achieved in these scenarios, it can be safely assumed that they would be achieved in the scenarios that are not specifically considered.

For risk-based analyses, it would only be acceptable to exclude a fire scenario from further reconsideration if it could be established that no design could handle the scenario. Scenarios can be grouped into clusters of like scenarios according to common defining characteristics (e.g., all fires that start in a single room) [8].

When scenarios are clustered, the scenario cluster will be analyzed as a single, aggregate scenario. The probability that will be used for analysis will be the sum of the probabilities of all of the scenarios in the cluster. The consequence that will be used is an average of the consequences of the scenarios in the cluster.

Some performance-based codes provide fire scenarios. Even when such a code is applicable to a design, the fire protection engineer should work with project stakeholders to determine if there are other scenarios that should be considered. For example, NFPA *101* [5] and *NFPA 5000* [7] specify fire scenarios that must be addressed for performance-based designs. These fire scenarios include elements of fire characteristics, building characteristics, and occupant characteristics. However, these elements are not defined explicitly for all of the scenarios. The New Zealand building code [9] provides a verification method that includes fire scenarios in a similar manner as NFPA 101, but also provides information needed to quantify design fire scenarios. The Japanese building code also provides quantitative design fire scenarios. The *ICC Performance Code for Buildings and Facilities* [8] provides general classifications of fire events.

Developing Trial Designs

Trial designs are fire protection strategies that are intended to achieve the goals of the project. (Developing trial designs is Step 6 in the process section later in the chapter.) To be considered acceptable, trial designs much achieve each of the performance criteria when subjected to the design fire scenarios.

The *SFPE Engineering Guide to Performance-Based Fire Protection* groups the types of methods that might be used in trial designs into six subsystems. Attributes from one or more subsystems would be used in a trial design. The six subsystems identified in the guide are the following:

- Fire initiation and development, where methods are used to reduce the likelihood that ignition would occur or reduce the rate of fire development if a fire were to occur.
- Spread, control, and management of smoke, where smoke hazards are reduced by limiting smoke production, controlling smoke movement, or reducing the amount of smoke after it has been produced.
- Fire detection and notification, where the presence of a fire would be detected for purposes of notifying building occupants or first responders, or to activate a fire suppression system.
- Fire suppression, including automatic or manual systems.
- Occupant behavior and egress, where the travel to a place of safety prior to the onset of untenable conditions is facilitated.
- Passive fire protection, including limiting fire spread though construction or preventing premature collapse of all or part of a structure.

When developing trial designs, the engineer should refer back to the goals of the analysis and decide what types of strategies would best achieve those goals. NFPA 550, *Guide to the Fire Safety Concepts Tree* [10], can assist with the development of trial design strategies. The top branches of the tree may closely align with the objectives of the design. In these cases, the protection methods that are identified below the objectives that align with the design goals could be used as trial designs.

Trial design strategies involve the same types of building components and systems that would generally be included in a prescriptive design. In fact, compliant prescriptive system designs may be appropriate as part of a trial design strategy. However, in some cases, augmented performance may be needed beyond that which would be achieved by a prescriptive-compliant system.

Fire Protection Engineering Design Brief

The preceding steps constitute the qualitative portion of the design, and agreement of all stakeholders should be attained prior to proceeding to the quantitative analysis. A mechanism that is suggested by the *SFPE Engineering Guide to Performance-Based Fire Protection* for achieving this agreement is a fire protection engineering design brief.

Evaluating and formally documenting performance-based designs can require extensive effort, and if fundamental aspects of the design change after detailed evaluation, significant

rework may be required. For example, if a design is completed and evaluated based on achieving life safety goals, and after the design is evaluated property protection goals are identified, then effort previously expended may be wasted. Similarly, if project stakeholders insist on certain types of design strategies being used, then these should be identified before other types of design strategies are developed and evaluated. The purpose of the fire protection engineering design brief is to facilitate agreement on the qualitative portions of the design prior to conducting detailed engineering analysis.

The contents of the fire protection engineering design brief will typically include the project scope, goals, objectives and performance criteria, design fire scenarios, and trial design strategies proposed for consideration. The form of the fire protection engineering design brief is intended to be flexible, based on the needs of the project and the relationship of the engineer performing the design to other stakeholders. In some cases, a verbal agreement may be sufficient. In other cases, formal documentation, such as minutes of a meeting or a document that is submitted for formal review and approval, may be prudent.

Once the design team and stakeholders have agreed on the approach that is proposed for the performance-based design, the detailed analysis work begins. This includes quantification of the design fire scenarios, evaluation of trial designs, and development of project documentation.

Quantifying Design Fire Scenarios

After the design fire scenarios have been agreed upon by the stakeholders, they need to be quantified. (Quantifying design fire scenarios is Step 7 in the process section later in the chapter.) The building characteristics, occupant characteristics, and fire characteristics will need to be quantified as necessary to adequately evaluate the trial designs.

The *SFPE Engineering Guide to Performance-Based Fire Protection* identifies several types of characteristics. These characteristics are intended to include a listing of any item that might need to be quantified. However, for most design situations, it will not be necessary to quantify all of the characteristics.

Quantifying Building Characteristics Building characteristics describe the physical features, contents, and internal and external environments of the building. Building characteristics can affect the evacuation of occupants, the growth and spread of fire, and the movement of combustion products. The *SFPE Engineering Guide to Performance-Based Fire Protection* identifies the following building characteristics that may need to be quantified:

- Architectural features, such as compartment geometry, interior finish, construction materials, and openings
- Structural components, including any protection characteristics
- Fire load
- Egress components
- Fire protection systems
- Building services, such as ventilation equipment
- Building operational characteristics
- Fire-fighting response characteristics
- Environmental factors (interior and exterior temperatures, wind speeds, etc.)

Occupant Characteristics For any design in which life safety or occupant response is considered, it will be necessary to consider the occupant characteristics. The *SFPE Engineering Guide to Human Behavior in Fire* [11] identifies the following fundamental occupant characteristics that could influence the response of building occupants to a fire:

- Population (number and density)
- Alone or with others
- Familiarity with the building
- Distribution and activities
- Alertness
- Physical and cognitive ability
- Social affiliation
- Role and responsibility
- Location
- Commitment
- Focal point

- Occupant condition
- Gender
- Culture
- Age

Occupant characteristics provide information as to how people might respond when subjected to fire cues, where fire cues include seeing fire or smoke, smelling smoke, hearing a fire alarm audible signal, or other cues. This includes actions people may take as well as physical effects of fire products.

Design Fire Curves Fire characteristics will typically be quantified as design fire curves, which provide a history of the size of a fire as a function of time. Typically, the "size" of a fire is measured in terms of heat release rate. Figure 37.2 shows an example of a design fire curve.

The *SFPE Engineering Guide to Performance-Based Fire Protection* divides design fire curves into five stages. Depending on the scope of the design, it may not be necessary to quantify each stage of the design fire curve. For example, it may only be necessary to quantify the growth stage for evaluation of a detection system. Similarly, evaluation of structural integrity may only require quantification of the fully developed stage. The guide provides suggestions on how to quantify each stage of the design fire curve.

For most designs, ignition will be assumed to occur. Typically, the design team will consider different first items ignited. If information is known about an item and an energy source, it is possible to predict whether the item will ignite.

After an item ignites, the fire might grow in size. The rate at which a fire grows is a function of the first item ignited and the location of the item within a compartment. As the fire grows, additional items may be ignited and the fire may spread outside of an enclosure.

Flashover occurs when all combustible items within an enclosure ignite. Compartment geometry, compartment ventilation, fire heat release rate, and the thermal properties of the enclosure influence whether and when flashover occurs in a compartment.

If there is no intervention, a fire may reach a maximum size, which is a function of either the amount of fuel in the compartment or the amount of available ventilation. The fully developed stage of the fire is typically used to determine radiation through openings, failure of the structure, fire spread to other enclosures, or failure of compartmentation.

Fires will decay and eventually burn out. Decay can occur due to depletion of fuel, lack of ventilation, or suppression.

When developing design fire curves, it is important to realize that design fires need not be exact or should not be presented as precise predictions of what will happen in a fire. Design fires are meant to be a representation of anticipated fires. Current modeling technology and data make it unnecessary and impractical to create exact predictions of how a potential fire will burn.

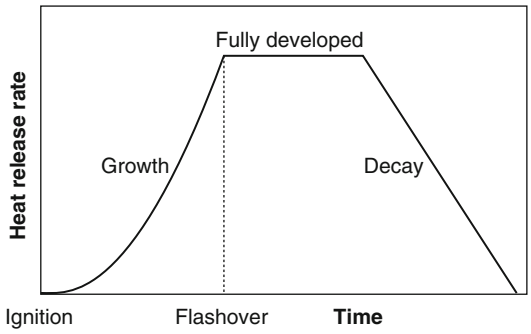

Fig. 37.2 Sample design fire curve

Evaluating Trial Designs

Evaluation is the process of determining if a trial design meets all of the performance criteria in each of the design fire scenarios. (Evaluating trial designs is Step 8 in the process section later in the chapter.) The *SFPE Engineering Guide to Performance-Based Fire Protection* states that the level, or detail, of an evaluation is a function of factors such as the complexity of geometry, level of subsystem interaction, and the margin between evaluation output and the performance

criteria. In some cases, a relatively simple evaluation may be appropriate, whereas in others, an in-depth evaluation would be required.

The levels of evaluation identified in the guide are (1) subsystem, (2) system, and (3) whole building.

Subsystem A subsystem performance evaluation typically consists of a simple comparative analysis in which the performance of a design that involves a single component or subsystem (e.g., egress, detection, suppression, fire resistance, etc.) is compared to the performance of a similar component or subsystem. This type of analysis is frequently employed when using the equivalency provision in a prescriptive code. For an alternate design strategy to be acceptable, it must provide equal or greater performance than that which is required by the code or standard.

System A system performance evaluation might consist of a comparison to prescriptive requirements or an analysis based on specific performance requirements. A system performance evaluation is used when more than one fire protection system or feature is involved. It is more complex than a subsystem evaluation because the analysis must account for the interaction between various subsystems.

Whole Building In a building performance analysis, all subsystems used in the protection strategy and their interactions are considered. A performance-based design that analyzes total building fire safety can provide more comprehensive solutions than subsystem or system performance analysis because the entire building-fire-target (where "targets" are the items being protected, such as people, property, etc.) interaction is evaluated.

The "levels of performance" describe the complexity of a design, whereas the types of performance identified by Nelson [2] in the Introduction describe approaches that a code or standard could use to state desired fire performance.

Typically, engineering tools such as fire models will be used to evaluate trial designs. The tools that are selected must provide information that can be used to determine whether or not the performance criteria have been achieved. Additionally, uncertainty is always present in any design or analysis.

Documenting the Design Process

Following completion of the evaluation and selection of the final design, thorough documentation of the design process should be prepared. This documentation serves three primary purposes: (1) to present the design and underlying analysis such that it can be reviewed and understood by project stakeholders, such as regulatory officials; (2) to communicate the design to the tradespeople who will implement it; and (3) to serve as a record of the design in the event that it is modified in the future or if forensic analysis is required following a fire.

The *SFPE Engineering Guide to Performance-Based Fire Protection* provides detailed descriptions of the types of documentation that should be prepared by the design team. This material includes the documentation associated with the fire protection engineering design brief (discussed previously), a performance-based design report, specifications and drawings, and operations and maintenance manuals.

The guide suggests that a detailed performance-based design report should be prepared that describes the quantitative portions of the design and evaluation. Every model or calculation method that was used should be identified, including the basis for selection of the model or calculation method. Similarly, any input data for the model or calculation method should be documented, including the source of the input data and the rationale of why the data are appropriate for the situation being modeled.

All fire protection analyses have some uncertainty associated with them. This uncertainty may come from limited ranges of applicability of a model or simplifications within models or calculation methods, applicability of data sources to the scenarios modeled, limitations of scientific understanding, or other sources. The design should include methods of compensating

for this uncertainty, and how this was accomplished should be documented.

As with prescriptive designs, performance-based designs use specifications and drawings to communicate to tradespeople how to implement the design. However, master specifications may not be applicable to performance-based designs without significant editing. Similarly, any features of a design that differ from typical prescriptive designs should be clearly identified on drawings.

One feature of documentation of performance-based designs that differs significantly from prescriptive-based designs is the operations and maintenance manual. The operations and maintenance manual communicates to facility managers the limitations that are placed on the design. These limitations stem from decisions made during the design process. For example, heat release rates used as input data place a limitation on the use of a space. Any furnishings placed within a space that could have higher heat release rates than the heat release rates used during fire modeling could result in greater consequences than the model predicted.

The operations and maintenance manual should be written in a format that can be easily understood by people who are not fire safety professionals, since most building owners and facility managers will not have this type of background.

Application of Performance-Based Design

Performance-based design can be applied in one of three situations: with prescriptive regulations, with performance-based regulations, and as a stand-alone design methodology [1]. It is noteworthy that many codes are not wholly performance based or prescriptive; many codes contain a mixture of performance-based and prescriptive requirements. For example, a performance-based code may contain a "deemed to satisfy" prescriptive option. Similarly, a prescriptive code may contain some performance-based requirements. As an example, the requirements for atrium smoke control systems in prescriptive codes are typically performance based.

Use with Prescriptive-Based Regulations

Prescriptive-based regulations provide requirements for broad classifications of buildings. These requirements are generally stated in terms of fixed values, such as maximum travel distances, minimum ratings of boundaries, and minimum features of required systems (e.g., detection, alarm, suppression, and ventilation).

In addition, most prescriptive-based regulations contain a clause that permits the use of alternative means to meet the intent of the prescribed provisions. This provides an opportunity for a performance-based design approach. Through performance-based design, it can be demonstrated whether or not a design is satisfactory and complies with the implicit or explicit intent of the applicable regulation.

When applying performance-based design in this manner, the scope of the design is equivalency with the prescriptive provision(s) for which equivalency is sought. The "intent," or performance achieved by compliance with the prescriptive code provision(s), is identified to provide the goals and objectives for the design.

Use with Performance-Based Regulations

Performance-based codes and standards provide goals, objectives, and performance criteria for buildings or other structures that fall within the scope of the code or standard. Performance-based codes generally either provide specific fire scenarios that must be addressed or information that is intended to identify the types of fire scenarios that must be addressed. Performance-based codes may also provide additional administrative provisions, such as review or documentation requirements.

Use as a Stand-Alone Methodology

In some cases, a building owner or insurer may have additional fire safety goals beyond the minimum requirements of applicable prescriptive codes and standards. In these cases, additional or complementary fire safety goals and objectives might be identified, thus requiring additional fire protection engineering analysis and design. For example, property protection and continuity of operations might be goals of a building owner or insurer, and these goals might not be fully addressed in applicable regulations. The performance-based design process can be used to identify and address these additional goals.

Hazard Versus Risk

In performance-based design, all scenarios must be considered in some manner. There are two ways that can be used to consider the universe of possible scenarios: risk based and deterministic.

Risk-Based and Deterministic Analyses

Risk-based analysis looks at the big picture of all of the possible scenarios—the consequences of each scenario are analyzed; however, these consequences are weighted by the probability of the event occurring. If the sum of the products of the probability of the scenarios occurring and the consequences of the scenarios (e.g., value of property lost, deaths or injuries, length of business interruption, etc.) are below some threshold value, then the design is considered acceptable.

In deterministic analysis, scenarios that are expected to occur with a frequency above a threshold value are analyzed to determine their consequences. If the consequences of those scenarios are within the design objectives, then the design is considered to be acceptable.

Although deterministic analyses are typically used in performance-based fire protection, it may be difficult to use deterministic analysis to judge the superiority of one type of system against another, particularly when the systems protect against fires differently. In deterministic analysis, any scenario that is expected to occur more frequently than a threshold frequency would be analyzed. If the probability of system failure is found to be below the established threshold, this scenario would not be addressed and it would be concluded the system being considered could be used without redundancy. Conversely, if the probability of system failure is found to be above the established threshold, then the scenario in which the system fails would be analyzed, and it would likely be concluded that both must be installed.

Deterministic analysis does not provide a complete evaluation of the fire safety in buildings. Although the probabilities of failure were considered, and the consequences determined by evaluation, probabilities and consequences were considered separately on a pass/fail basis.

Risk assessments differ from traditional, hazard-based assessments in that frequencies or probabilities of fires and the reliability of fire protection systems are explicitly addressed and used to weight the expected consequences. Hazard-based assessments evaluate the consequences given a set of conditions (e.g., a fire starts and sprinklers activate).

Event Trees

Event trees can be used to illustrate the possible courses of action of a fire following ignition. An event tree is a graphical means of identifying all possible outcomes following an initiating event [12]. Event trees are often used to analyze complex situations with several possible scenarios or where several fire or life safety systems are in place or are being considered [13].

Event trees are constructed by identifying an initiation event (the start of a fire) and branching out with the subsequent events that could occur. Possible successes and failures following an initiating event are identified on branches of an event tree. The branches follow a temporal sequence, based on which items would be expected to occur soonest following the fire start. For an event tree to be complete, all possible events should be identified. Figure 37.3 shows an example of an event tree for the possible course of action for a fire that starts in a room [14].

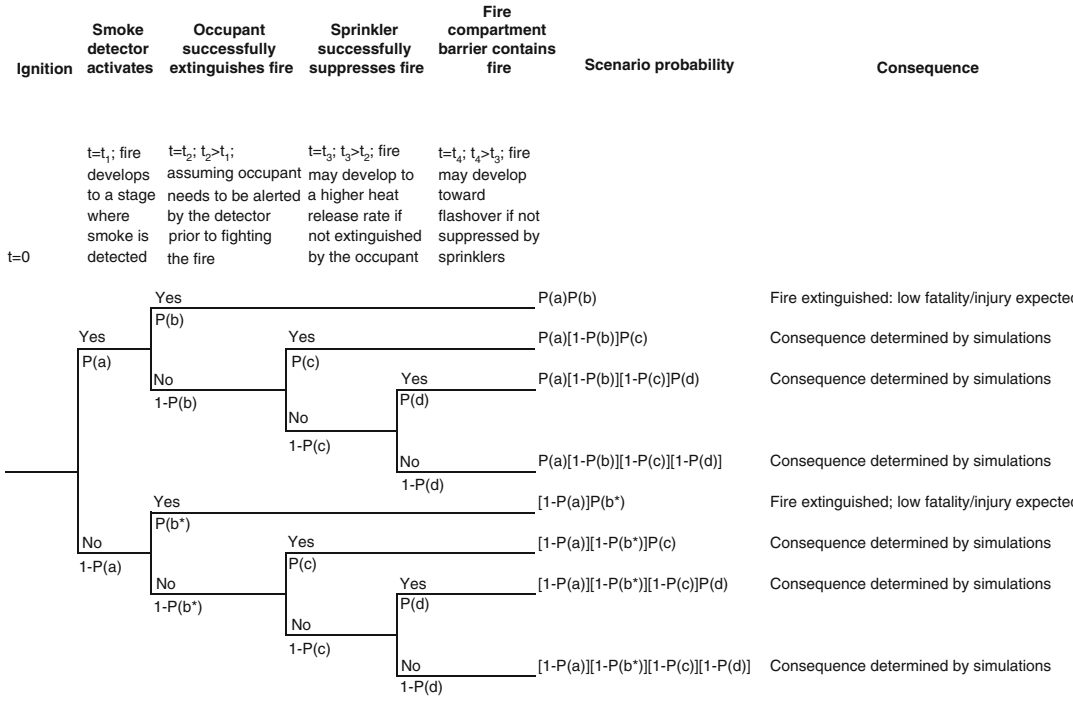

Fig. 37.3 Example of an event tree [14]

Following the ignition event in Fig. 37.3, the smoke detector that protects the room could either activate or not activate. Similarly, the room occupant could either successfully extinguish the fire or not. If the occupant does not extinguish the fire, the sprinkler that is installed in the room could either control the fire or not. Finally, if the sprinkler is not successful, the room compartmentation could either contain the fire or the fire could spread beyond the room of origin. Detector operation, occupant extinguishment, sprinkler activation, and barrier containment are all subsequent events that could occur (or not occur) following the initial fire initiation event.

From the single ignition event in the room, there are eight possible scenarios that could result. Each scenario occurs with a different probability that can be determined by multiplying the probabilities along each branch of the tree leading to an outcome. If the probabilities of the mitigation strategies being successful are high, then the overall probability that the fire will not be controlled or contained within the room of origin is low.

There would likely be a number of event trees that could be prepared for the room shown in Fig. 37.3. Figure 37.3 illustrates the possible scenarios that could occur following a specific ignition event, for example, a carelessly discarded cigarette. There are likely many other ignition events that could occur in this room, and each would have its own event tree associated with it. In some cases, the event tree for other ignition events might be identical or similar to Fig. 37.3. Identical would mean that the same possible subsequent events could occur with the same probabilities. Similar would mean that the same subsequent events could occur, but with different probabilities. However, for other ignition scenarios, the event trees might be much different.

If Fig. 37.3 illustrates the possible scenarios that could occur if smoking materials are carelessly discarded in a wastebasket, then other fire initiation events that start in the wastebasket might have similar or identical event trees. However, if the fire ignition event is a Christmas tree fire, then the event tree for this event would likely be much different—the occupant might

not be capable of extinguishing the fire, and the probability of success of the other mitigation methods would likely be different.

Additionally, the room in Fig. 37.3 would likely be located within a larger building, meaning that the event tree could be expanded to include other events that could occur if the fire is not contained within the room of origin.

Event trees might be prepared to evaluate different fire protection strategies. If so, one or more event trees could be developed for each strategy.

Each scenario that is a terminus on the right-hand side of an event tree represents a series of events that could occur. Each series of events occurs with a different probability, and the probabilities of some scenarios occurring are higher than others.

Model Use in Performance-Based Design

Fire models take a variety of forms. The simplest are algebraic models, which are mathematical equations used to estimate the value of one or more variables as a function of space and/or time. More complex are zone or lumped parameter models, which simplify the behavior of a system by making the approximation that a particular volume or region is homogeneous, uniform, or well-mixed. The most complex are computational fluid dynamics (CFD) models, which are also known as field models. CFD models provide a method for calculating the fluid flow through a volume using numerical solutions of the governing equations for conservation of total mass, chemical species, momentum and energy.

The use of fire models has flourished over the last few decades. Models are used to simulate fire phenomena to determine if a proposed design strategy is acceptable, to test hypotheses developed during fire investigations, or to simulate tests as part of fire research. Each of these applications has potential impacts on public health, safety or welfare, so it is incumbent on model users to make sure that they can have confidence in model results.

The American Society of Testing and Materials (ASTM) published a guide for evaluating fire models in 1990. The Guide is identified as ASTM E-1355. These guidelines provide an approach to evaluating models that consists of defining the model and the scenarios for the evaluation, verification of the appropriateness and the theoretical basis of the model, verifying the mathematical and numerical robustness of the model, and quantifying the uncertainty and accuracy of model results.

The ASTM guidelines are useful where someone wishes to evaluate a model for a broad range of applications. However, the methodology requires a level of effort that is prohibitive for specific, individual project applications. For example, the Society of Fire Protection Engineers evaluated DETACT-QS using the ASTM E-1355 methodology. DETACT-QS is one of the simplest fire models that have been published (it has under 200 lines of code); the evaluation required over a person-year of effort, and the report is 140 pages in length.

The standard of care that is applied to the use of model predictions is that the model should either be accepted by the relevant professional community or the user should demonstrate that the model is acceptable. Only a few models have been formally evaluated using the ASTM E-1355 process—including DETACT-QS and five models that were evaluated for application in nuclear power plants [15] (Fire Dynamics Tools, Fire Induced Vulnerability Evaluation, CFAST, MAGIC and FDS.)

In 2003, 168 fire models were identified [16], and several more have been published since then. Additionally, the published evaluations do not address every possible application of the models that were evaluated, so in most cases it will fall to the person who uses a model to show that the model is appropriate for the intended use.

In 2011, the Society of Fire Protection Engineers published the Guide to Substantiating a Fire Model for a Given Application to provide a framework for determining if a fire model is suitable for use for a specific fire protection application.

The Guide to Substantiating a Fire Model for a Given Application provides a five step process for determining the suitability of a fire model. These steps include defining the problem, selecting a candidate model, verifying and validating the model, determining the impact of uncertainty and user effects on the model results,

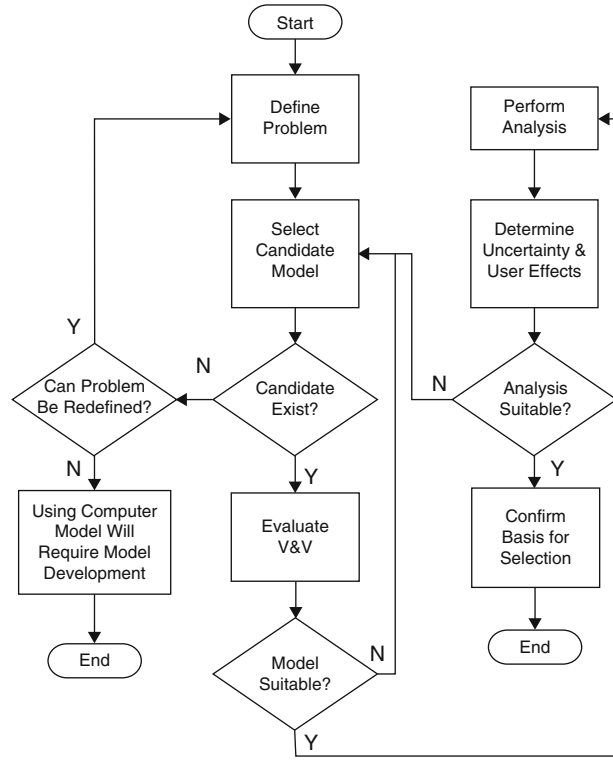

Fig. 37.4 Fire model selection flow chart

and finally, documenting of the model evaluation. This process is illustrated in Fig. 37.4.

Any of these steps may require repetition. If a candidate model is determined to be unsuitable, then another candidate may be selected for evaluation. If no suitable candidate models exist for a given application, then there are several options. These options include:

1. Reevaluate the application to determine if the problem being solved can be reposed to allow the use of another model.
2. Develop, verify, and validate either a new model or a modified version of an existing model.
3. Use an alternate method that does not use a fire model—such as fire testing.

Definition of the Problem of Interest

The first step described in the Guide to Substantiating a Fire Model for a Given Application is to define the problem of interest. The problem of interest should be clearly defined by identifying the relevant phenomena and key physics, collecting available information and determining the analysis objectives.

Commonly encountered key physics in fire modeling generally relate to thermodynamics, fluid dynamics, heat transfer, combustion, or material response. Identification of relevant phenomena and key physics requires knowledge of the details of the problem of interest as well as the underlying chemical and physical processes involved. The appropriate level of knowledge is required to prevent users from treating a fire model as a black-box tool, which can result in using a fire model beyond the scope of its capability.

Defining the problem of interest encompasses several elements. First, the geometry needs to be established. The geometry includes the spatial domain and the objects involved within the spatial domain. For a room or a facility such as a warehouse or office building, the spatial domain is often defined by the physical boundaries like walls, ceilings and floors. For open domain problems, e.g. outdoor pool fires of flammable liquids, a sufficiently large domain should be selected to avoid significant impact along the

boundaries. Detailed geometries should be provided for fuels, building structures, protection devices and other important objects in the spatial domain; however, some specific details may depend upon the type of model utilized.

Next, Guide to Substantiating a Fire Model for a Given Application recommends establishing a timeline. The timeline for the problem of interest includes the duration of the problem and the sequence of events. The problem of interest can be either transient, steady-state, or at a specific point along the timeline.

Events should be included in the information collection process unless they are deemed unimportant to the problem of interest. Examples of events are ignition, closing or opening of doors and windows, actuation of sprinklers or smoke exhaust fans, and collapse of furniture and building structures. Some events will occur at specific points on the timeline, while others will be modeled.

A list of materials relevant to the problem of interest should be generated and relevant material properties should be assigned to each material. The incorporation of specific material properties may depend upon the type of model used in the analysis. The most important properties for most fire problems are often whether the material is combustible and the products of combustion. Other relevant material properties may include, but are not limited to, viscosity, specific heat, heat of combustion, thermal conductivity, heat of gasification and heat of vaporization.

The initial and boundary conditions should be established. This type of information is often needed to start numerical simulations in time and space, respectively. Examples of initial conditions are room temperature and door and window status, while examples for boundary conditions are openings that allow free air passage or an air conditioner on the ceiling blowing at an established flow rate.

Lastly, the analysis objectives should be established. Analysis objectives define what the modeler hopes to achieve by using the fire model. The most important objective related to the use of a fire model is a list of quantities that should be determined to address the problem of interest.

Select a Candidate Model

The next step identified in the Guide to Substantiating a Fire Model for a Given Application is to select a candidate model. A wide variety of models are available for predicting a range of fire phenomena. A number of factors should be considered before selecting a particular model for a problem, including computational resources, time limitations, required level of accuracy, and most importantly, whether or not the governing equations and assumptions in the model are appropriate for the problem of interest.

The guide recommends three major considerations for selecting a candidate model: determining the available model inputs, identifying the desired model outputs, and determining the available resources.

Determining the available model inputs requires the model user to identify the inputs that are available for a given problem and to identify the inputs that are not available but must be acquired before proceeding with an analysis. To perform this analysis of available data, it is often helpful to list each relevant input, along with its value (or range of values) and an indication of any uncertainty that may be involved in the measurement of that input value. In addition to the known input variables, there may be unknown inputs that can be estimated through use of past research or engineering judgment; these inputs should also be listed, along with appropriate references or assumptions that were used to obtain a value.

In some cases, not all of the input data required by a model will be available. In such cases, the guide recommends three possible options:

- Perform preliminary calculations aimed at identifying the value of that specific variable.
- Make a reasonable assumption as to the range of values that the input could have and then perform a sensitivity analysis to determine the effect on the model results of changing that variable.
- Conduct experiments to obtain a value for the input.

After analyzing the available model inputs, but before proceeding with the selection of a fire model, it is important to define the accuracy that is required in the final model output. The acceptable level of resolution of the model output values will vary depending on the problem. It is up to the user of the fire model to determine how much detail is required to appropriately address a problem and to convey this decision to those who will review or make use of the results of the simulations.

When evaluating potential candidate fire models, some consideration should be given to the sensitivity of the desired output values to both the available input variables and to the type of model that is chosen. While this is not always a formal process, it is something that should be taken into account.

There is often more than one model available that may provide a sufficiently accurate solution to a problem. In such cases, model selection can be based upon the resources that are available to run the model. While a CFD model may provide benefits, such as the ability to more exactly represent the geometry of a space and better visualization tools than a zone model, it may not always provide a more accurate solution to a problem. If time constraints and lack of computer resources prohibit a thorough sensitivity analysis using CFD, then for some problems it might be more appropriate to use a zone model or algebraic model in order to more thoroughly address uncertainty.

The guide suggests developing a resourcing plan that follows the following steps before starting large fire modeling projects:

1. Determine the number of simulations needed to address any sources of uncertainty.
2. Determine the amount of time required to run a simulation on the available computational resources.
3. Determine whether or not several simulations can be run simultaneously.
4. Determine the available time before the project must be completed.

After following the steps noted above, the user should make a decision as to whether a candidate model is appropriate for the given problem. The modeler might select an algebraic model, a zone or lumped parameter model, or a computational fluid dynamics model.

Verification and Validation

Prior to using a model for a particular problem, the model user needs to determine if the model is capable of generating a useful result. The formal process by which this is demonstrated is verification and validation (V&V). Model verification serves two purposes. First, it ensures that the mathematical equations have been properly implemented. Second, it ensures that the model user understands the assumptions of the model. Verification ensures that the model is working as designed, i.e., that the equations are being properly solved. It essentially is a check of the mathematics.

The Guide to Substantiating a Fire Model for a Given Application suggests that, at a minimum, model users should read the model documentation that describes efforts made by the developers to verify the model. Then, the user should supplement the work performed by the developers to better address the specific application under consideration. The guide suggests a number of exercises that the model user can perform to supplement the verification efforts of the developers:

- *Verify the basic functionality of the model*—This typically involves creating simple test cases and comparing the model results to known analytical solutions.
- *Verify consistency of input parameters*—The user should address the appropriateness of input values, especially as they are used collectively.
- *Verify that the input parameters are appropriately used*—This generally involves studying the model documentation and diagnostic output.
- *Verify the range of validity for input parameter values*—Some values of the input parameters are only valid within a certain range. The model user should confirm that the input values are consistent with the underlying physical assumptions or experimental conditions.

- *Verify consistency of results*—In short, this involves demonstrating that the results make sense.

Verification ensures that the model is working as designed; that the equations are being properly solved. It essentially is a check of the mathematics. Validation is a check of the physics, i.e., whether the equations are an appropriate description of the fire scenario. Most often, validation takes the form of comparisons with experimental test data. Validation does not mean that a model makes perfect predictions, only that the predictions are good enough for its intended use. The meaning of "good enough" is up to the model user, and to say a model has been validated only means that an end user has decided that the model is sufficiently accurate for a particular application.

The Guide to Substantiating a Fire Model for a Given Application suggests the following procedure for validating a model for a given application:

Select Experiments

The guide provides the following considerations for selecting experiments that will be used as the basis for model validation:

- *Relevance to the application*. The organizations that perform model validation usually have a particular application in mind, which limits the scope, scale and measurements.
- *Comprehensive documentation*. The experimental results should be available and fully documented, or not needed, otherwise implies or interested modelers cannot replicate what was done in the validation study or attempt to do their own validation study.
- *Experimental uncertainty*. There are two major forms of experimental uncertainty to consider in a validation study. The most obvious is the measurement uncertainty. This is the uncertainty of the measurement of the quantity under consideration. The second form of uncertainty is the model uncertainty, which reflects the uncertainty in the model predictions that are due to the uncertainty of the physical parameters that are input into the model. The uncertainty in the input parameters needs to be propagated through the model to ascertain its impact on the final prediction.

Choose a Metric to Quantify Accuracy

Measurements can vary in space and time. Comparisons with model predictions can be based on extreme values, like peak temperatures, or spatial or temporal averages. The decision to use a particular metric is made by the organization doing the validation study based on the particular use of the model. Usually, it is convenient to express these comparative values in terms of a relative difference.

Report Results

The Guide to Substantiating a Fire Model for a Given Application recommends that the validation report provide sufficient detail about the experiments and the model inputs such that an interested reader could repeat the calculations. Specifically, the guide recommends providing the following information:

- Person or organization responsible for the validation study
- References to model documentation and reports of experimental measurements
- Description of the fire scenarios that the experiments were designed to address
- Quantification of the model accuracy
- Conclusion, including limitations of the model and its potential for extension for other fire scenarios

Typically, model validation involves a large amount of data—both in terms of model predictions and experimental measurements—and it can be difficult to succinctly display the results of the study. If all the experimental measurements can be quantified by the same total uncertainty, then a simple graph can be made to summarize the validation exercise. The graphs can indicate the experimental uncertainty in the experimental data. If the model predictions lie within the band defined by the experimental uncertainty, then it cannot be said that the model

predictions differ significantly from the measured data.

If the model predictions lie outside the uncertainty interval, this does not necessarily mean that the model is unsuitable. In such cases, the trend in the model's predictive ability needs to be evaluated in the context of the intended use.

User Effects

Once the verification and validation have been conducted, the next step identified in the Guide to Substantiating a Fire Model for a Given Application is to focus on the uncertainty that arises in model predictions due to the use of a predictive model. Possible sources of uncertainty include definition of the model space or computational domain, simplifying assumptions (in the application of the model), and the choice of input parameters. The result is a propagation of "error" or uncertainty through the model that should be understood, at minimum, at a qualitative level, but preferably, quantitatively.

Input Uncertainty

In addition to uncertainty that exists within the model, the input data can introduce uncertainty into the model calculation.

Predictive models require a description of the model space, often a simplified representation of the actual physical space. The choice of the model extents is a function of the model type and the available computational resources. Choice of the model domain and how boundary conditions—the physical conditions at the model boundaries—are defined can impact the analysis outcome.

The resolution of the model can also affect the analysis outcome. The analysis outcome should be independent of the definition of the domain or the grid resolution.

Input data, often based on assumed values or experimental data, is subject to many sources of uncertainty, including uncertainty in theory (for deriving the parameter) and measurement. Such uncertainty in input imposes a limit on the confidence in model output. It is important to understand the limitations of the input values and of the means by which they were derived in order to quantify or estimate the uncertainty or possible range of the property value. Variation in one or a combination of input parameters may substantially alter the model outcome. Treatment of uncertainty in the assumptions and input that define a problem is an important component of analysis that the modeler should address.

Implications for the Design Process

The Guide to Substantiating a Fire Model for a Given Application suggests several methods of dealing with uncertainty introduced through the use of models.

- Performance Criteria. Fire models are often used as part of a design process in which the results are evaluated against threshold performance criteria. The conclusions that may be drawn from an analysis are limited by the predictive accuracy of the model as well as the potential uncertainty in the input parameters. Performance criteria thresholds should account for limitations in the models and input.
- Safety Factors. Safety factors and margins of safety are used to provide a buffer to allow for uncertainty in the design process. A safety factor is a multiplier of a prediction for reference against a threshold or criterion. Safety margins are additive, not multiplicative.
- Sensitivity Analysis. A sensitivity analysis determines the relationships between the uncertainty in the input variables and the uncertainty in the resultant output. A sensitivity analysis provides information regarding how the uncertainty in the output of a model can be apportioned to different sources of variation in the input of a model. Sensitivity analysis allows the identification of those parameters that are most important to the outcome. It does not necessarily provide information regarding the value that should be used, but it can show the impact of using different values.

- Parametric Analysis. In a parametric analysis, a special form of a sensitivity analysis, detailed information of the effect of a certain input variable on model output is examined by systematically varying the input value of that variable, while holding others constant. A parametric analysis may be useful if detailed information regarding the potential variation of the input variable is unknown.
- Bounding. Bounding is a form of sensitivity study that evaluates the consequences of the extremes of possible values of an uncertain input quantity. If the outcome values at both extreme ends of the range of the uncertain input are acceptable relative to some criteria, further sensitivity analysis may be avoided. Bounding can be applied to not only input parameters but also selections for boundary conditions.
- Differential Analysis. For some models or systems, it is possible to solve directly for the partial derivative of the predicted values with respect to each of the input variables. The set of partial derivatives measures the sensitivity of the solution with respect to changes in the input parameters. A differential analysis has the advantages of being very quick and requiring very few resources to implement.
- Power Dependence. Less formal than differential analysis, power dependence assesses the proportionality or power-dependence of a model target output to an input parameter. By examining the relationship of model outcome to input, the user will be able to identify the relative importance of the input. As a result, the user may be able to focus on refining the estimate for a "more" important input variable, while accepting perhaps a higher variability in a "less" important variable.

Documentation

Finally, the results of the evaluation should be documented so that they can be understood by people who wish to understand how it was determined that the model is appropriate for its intended use.

SFPE Handbook Use in the Step-by-Step Process of Performance-Based Design

Publication of the first edition of the *SFPE Handbook of Fire Protection Engineering* in 1988 was one of the key events that supported the development of performance-based fire protection designs. Earlier in this chapter, the following steps in the performance-based design process as outlined in the *SFPE Engineering Guide to Performance-Based Fire Protection* were identified:

Step 1—Defining project scope
Step 2—Identifying goals
Step 3—Defining objectives
Step 4—Developing performance criteria
Step 5—Developing fire scenarios
Step 6—Developing trial designs
Step 7—Quantifying design fire curves
Step 8—Evaluating trial designs
Step 9—Documenting design process

Chapters within this edition of the *SFPE Handbook of Fire Protection Engineering* can be used to support design development and evaluation. This section identifies typical applications of the information contained in the *SFPE Handbook of Fire Protection Engineering* in the performance-based design process.

Step 1—Defining Project Scope

The project scope is generally defined as part of discussions between the engineer and the project stakeholders. One of the aspects that is determined to be part of the project scope is how the analysis will be conducted. Chapter 72 provides an overview of fire risk analysis that can be referenced when determining if the project will be done on a deterministic or a risk basis and, if the project will be done on a risk basis, the techniques that will be used.

Where risk assessments are to be used, Chap. 82 addresses fire risk index methods. Chapter 75 addresses the general subject of

building fire risk analysis. Specific applications of fire risk assessment can be found in the following chapters: Chaps. 83, 89, 90, and 85.

Step 2—Identifying Goals

The project goals are generally stated by or inferred from applicable codes and standards or through discussions between the engineer and other stakeholders.

Step 3—Defining Objectives

Since they represent a refinement of the amount of loss that is tolerable, objectives are typically developed by the engineer through discussions with the project stakeholders.

Step 4—Developing Performance Criteria

Performance criteria are quantitative values that are used to determine whether or not a trial design achieves the project goals and objectives. Developing performance criteria requires understanding the mechanism(s) of harm of the items that the design will protect from fire.

When people are to be protected from fire, performance criteria generally involve one or more of the following:

- Prevention of incapacitation by fire or smoke
- Prevention of thermal damage
- Providing sufficient visibility such that people can navigate means of egress

Chapter 63 provides information that can be used to set performance criteria associated with prevention of incapacitation by fire products. Additionally, Chap. 63, provides information that can be used to set performance criteria associated with thermal damage from heat exposure.

Several researchers have published suggested maximum values of limiting extinction coefficients or optical densities that could be used as performance criteria associated with maintaining visibility. For more information, see the following chapters: Chaps. 24, 61, and 63. However, these limiting values have embedded within them desired minimum visibility distances, and hence, these values should only be used when the geometry of interest correlates with the minimum visibility distances embedded within the limiting extinction coefficients or optical densities.

In some cases, avoidance of exposure to smoke altogether (either by keeping the smoke layer above a defined elevation or keeping smoke from entering a space) may be selected as a performance criterion.

When things other than people are protected, performance criteria may take one or more of the following forms:

- Prevention of ignition
- Prevention or minimization of flame spread
- Maintenance of fire barrier integrity or structural stability
- Avoidance of nonthermal damage due to exposure to smoke

Prevention of ignition of solid items is typically accomplished by keeping the incident radiant flux to a combustible object below a minimum value, typically the minimum heat flux for ignition ($\dot{q}''_{\min}$) or the critical heat flux for ignition ($\dot{q}''_{\text{crit}}$), depending on how it is measured. In some cases, values might be expressed as the minimum temperature at ignition. Values for a variety of fuels can be found in Appendix 3. The mechanism of ignition of solid fuels is described in Chap. 21.

For prevention of ignition of liquid fuels, performance criteria would typically involve keeping the liquid below its flashpoint. The flashpoint is not a fundamental material property and will vary depending on the test method used to measure it. More information and flashpoints for a variety of fuels can be found in Chap. 18.

For gases, performance criteria generally relate to keeping a gas/air mixture outside of its flammable range, which is discussed in more detail in Chap. 17. This chapter on flammability limits also contains flammability data for several gases.

Flame spread is a process of continuous ignition, as the flame front progresses from portions that are burning to unburned material. This is discussed in Chap. 23.

Performance criteria related to maintenance of barrier integrity is generally limited to specific

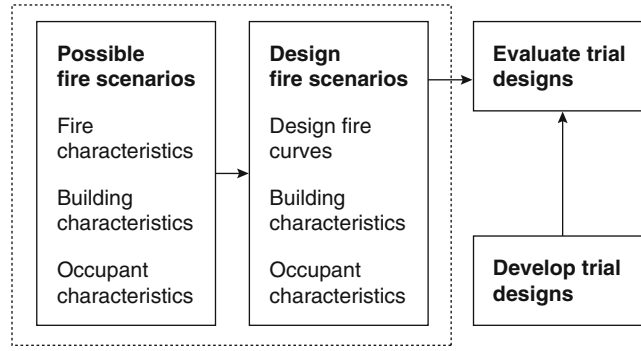

Fig. 37.5 Process for identifying design fire scenarios

assemblies. Chapter 55 provides information for gypsum board on wood studs. Chapter 54 discusses concrete assemblies. In many cases, the methodologies in the chapters referenced are limited to the standard time-temperature exposure.

Information related to structural integrity can also be found in Chap. 55, and Chap. 54, for wood and concrete structural materials, respectively. Steel assemblies are addressed in Chap. 53. Performance criteria associated with exposure of items to smoke can be developed using Chap. 36.

Step 5—Developing Fire Scenarios

A performance-based design requires the evaluation of fire safety based on various design fire scenarios. The *SFPE Engineering Guide to Performance-Based Fire Protection* provides a two-step process for identifying design fire scenarios. As depicted in Fig. 37.5, the first step is considering all possible fire scenarios that could occur in the building or portion of the building that is within the scope of the design. The second step is to reduce the population of possible fire scenarios into a manageable set of design fire scenarios. The design fire scenarios will be used to evaluate trial designs.

Fire scenarios are comprised of three elements: building characteristics, occupant characteristics and fire characteristics. Building characteristics are determined either by surveying an existing building, reviewing architectural design plans, or as part of a trial design strategy. Chapter 38 discusses fire scenarios. Fire load is frequently considered as part of a fire scenario, and this topic is addressed in Chap. 35. Chapter 57 provides information on occupant characteristics that can be used when developing fire scenarios.

Step 6—Developing Trial Designs

Several chapters in this *Handbook* relate to the design and evaluation of trial designs. When developing a trial design, an initial design is usually created. The initial design would be evaluated, and if it achieved the performance criteria when tested using the design fire scenarios, it would be considered acceptable. However, if the design did not achieve the performance criteria, it could either be eliminated or refined and revaluated. In this sense, the process of design development and evaluation can be iterative.

Several chapters can be used in both the development and evaluation of trial designs. These chapters generally do not articulate what must be done for strictly code-compliant designs but rather provide methods and engineering calculations that can be used to support system designs.

Chapter 39 provides a broad overview of the considerations involved with selecting a fire safety system as a trial design approach. System activation is addressed in Chap. 49.

Chapter 40 provides calculation methods for the design of heat detection systems, smoke detection systems, and radiant energy detection systems. That chapter also provides methodologies for designing fire alarm audibility. Approaches for developing occupant egress strategies are presented in Chap. 56.

For automatic sprinkler systems, Chap. 41, can be used to support the design of water supplies. Chapter 42 provides information relating to hydraulic calculations and also provides calculation methods relative to hanging and bracing and to sprinkler performance.

Water mist systems, which are water-based systems that utilize very small droplets, are covered in Chap. 46.

Foam systems are addressed in Chaps. 47 and 48. The former provides a basic description of foam agents and foam extinguishment. This chapter also discusses aviation fire protection considerations, foam water sprinkler systems, and environmental considerations associated with fire-fighting foams. Chapter 48, provides calculation methods associated with foam system design.

Clean agents are addressed in Chaps. 43 and 44. Chapter 43 would generally be used in the evaluation or modification of existing halon systems, since they are rarely used in new construction. Chapter 44 provides an overview of the halon replacements that are available and information that can be used in the design of halon replacement systems. Chapter 36 also provides information associated with fire control, suppression, and extinguishment. Chapter 45 addresses carbon dioxide system design.

Fundamental information relative to systems that employ fluids can be found in Chap. 1.

Several chapters provide information that is generally used in fire resistance design. Fire resistance design is comprised of three steps: determination of the thermal boundary conditions to the structure or portion thereof, determination of the heating of the structure that results from the thermal boundary conditions, and determination of the structural response of the structure at elevated temperature.

Chapter 53 provides an introduction to structural fire protection design. Chapter 30 provides methods for calculating the fire exposures that could be used in fire resistance design. These fire exposures form the thermal boundary conditions. Chapter 34 discusses heat transfer to the structure. Chapter 52 provides an overview of structural systems and frame effects. Chapters 53, 54, and 55 cover the design of fire resistance of steel members, concrete members, and timber members, respectively.

Chapters 54 and 55 address fire barrier design to a limited extent for concrete and timber-framed assemblies, respectively.

Smoke control is addressed in two chapters. Chapter 50 provides an overview, methodologies, and calculation methods for smoke control systems. Chapter 51 focuses on smoke management systems in covered malls, atria, and other similar large spaces.

Step 7—Quantifying Design Fire Curves

The design fire curve consists of many elements, including ignition, fire growth, fully developed burning, and decay. For information on ignition, consult the *SFPE Engineering Guide to Piloted Ignition of Solid Materials Under Radiant Exposure* [17], Chaps. 18 and 21.

There are a number of ways the fire curve can be produced, including testing (large and small scale) and correlations as well as analytical approaches. Information on flame spread and the effect on fire growth rates is provided in Chaps. 23 and 25. Chapter 65 provides information associated with liquid fuel fires. This chapter addresses determination of pool size, growth rate of pool fires, and fire size.

In many evaluations, one of the most critical tasks is estimating the size or heat release rate of a fire. The heat release rate that is estimated affects several other calculations that are used in the evaluation. Chapter 26 provides methodologies for estimating heat release rates and a tremendous amount of heat release rate data for a variety of commodities. In some cases, heat release rate data from small-scale test methods will be used in estimations of heat release rates. Chapters 27 and 28 provide overviews of bench-scale methods.

Compilations of fire data for many forms of fuel, including furniture and storage materials, can be found in Chaps. 26, 36, and 40. The information specifies material burning characteristics, fire growth curves, fire growth rates, and/or maximum heat release rates as well as other information that will assist in

estimates of design fires. Chapter 65, can also be used to calculate fully developed fire sizes for pool fires.

Fire is a dynamic phenomenon influenced by changes in air, fuel, and heat. Modification of any of these factors can increase or decrease the size of the fire. Chapter 16 discusses these effects.

Step 8—Evaluating Trial Designs

The evaluation of trial designs will usually involve performing fire dynamics calculations and hazard calculations. Several chapters address these types of calculations.

Calculations involving fire plumes (temperature, velocity, and mass entrainment), flame heights, and ceiling jets are included in Chaps. 13 and 14. These types of calculations are typically used in the analysis of detection systems and smoke control systems.

Chapter 15 addresses the flows through vents, where vents are any type of opening. These types of calculations are used in modeling the movement of smoke from or into enclosures, such as smoke flows through doorways.

Chapter 61 addresses visibility and human behavior in smoke. The calculation methods in this chapter would be used in any design in which people movement through smoke is contemplated. Equations and graphs are provided for estimating the effect of smoke on visibility and on the reduction on movement speed that could occur in smoky environments.

Chapter 58 provides an overview of behavioral response to fire and smoke. Chapters 64 and 59 provide methodologies and calculation methods for estimating evacuation times. Evacuation times consist of two components: the time for people to determine that there is a need to evacuate and the time necessary to move through building egress components. Evacuation models are addressed in Chap. 60.

In cases in which people may be exposed to smoke, it may be necessary to estimate the concentrations of combustion products. Chapter 16 identifies means of performing these analyses, and Chap. 24 provides additional information. The impact of the combustion products on people can be determined using the methodologies in Chap. 63. The information in Chap. 16, and in Chap. 24, is also useful in cases in which it is desired to consider the effect of constituents as part of a smoke detection analysis.

If an analysis involved determining whether or not an item will ignite, Chap. 17, 18, and 21, provide methods of determining if and when gases, liquids, and solids will ignite, respectively. Spontaneous combustion (self-heating that leads to combustion) is discussed in Chap. 20.

Chapter 19 covers smoldering combustion, including propagation of smolder through media and transition from smoldering combustion to flaming combustion. Chapter 23 addresses the spread of flaming combustion along the surface of solids and liquids.

The heat flux from local fires can be determined using Chap. 25. This type of analysis is typically performed in determinations of the heat flux from a local fire to part of a structure or to a fire barrier. This type of analysis could also be performed in calculations involving the ignition of items from exposure to a localized fire.

Chapter 66 presents methods of performing hazard calculations associated with large hydrocarbon pool fires.

Fire modeling is frequently used in the evaluation of trial designs. Chapter 36 and Appendix 3 provide a tremendous amount of data that can be used in fire modeling. Chapter 29 provides an overview of compartment fire modeling techniques. Chapter 30 provides closed-form equations that can be used for estimating compartment fire temperatures. Chapter 31 provides a discussion of zone modeling, and Chap. 32, addresses CFD, or field models. Smoke filling of enclosures is discussed in Chap. 33, these types of calculations are frequently employed in cases where it is desired to keep a smoke layer above a critical elevation. A broad overview of computer modeling can also be found in Chap. 80.

For designs in which protection from explosions is an objective (either prevention, suppression, or response), Chaps. 69 and 70, provide methods and data that can be used.

Once the engineering calculations have been completed, a decision must be made as to whether or not a design is acceptable. For most cases, acceptability will be judged by seeing if the results of the analyses do not exceed the performance criteria. Chapter 77 provides information where more complex decision analysis is needed.

Most fire protection strategies used will have a reliability that is less than 100 %, and the effects of imperfect reliability should be addressed. Chapter 74 addresses the subject of reliability.

Uncertainty will be introduced in many of the steps of the process. Chapter 76 provides several uncertainty analysis techniques.

Almost all analyses will require data of some sort as input into calculations or models. In some cases, the needed data will be readily available. However, in others, it will be difficult to find. Chapter 78 provides an overview of data types, sources, and issues associated with data.

In some cases, it will be desirable to measure all fire consequences using a single metric. Chapter 79 discusses measuring fire consequences in economic terms. Engineering economics, which are frequently considered in design decisions, are summarized in Chap. 81.

Step 9—Documenting Design Process

All aspects of the design are generally documented. Documentation is provided as a way for stakeholders, regulatory officials, and tradespeople to review, understand, and be able to implement the design. Documentation also serves as a record in case modification or analysis following a fire is required in the future.

Summary

Performance-based design, while drawing increased attention recently, has been evolving over the last several decades. The *SFPE Engineering Guide to Performance-Based Fire Protection* [1] provides a process for conducting performance-based designs. Information in the *SFPE Handbook of Fire Protection Engineering* can be used to support engineering designs and calculations associated with developing and evaluating performance-based designs.

Fire Scenarios

38

George V. Hadjisophocleous and Jim R. Mehaffey

Introduction

The engineering approach to fire safety design requires the selection and evaluation of fire scenarios that may occur in a building. Each fire scenario represents a unique combination of events and circumstances that influence the outcome of a fire in a building, including the impact of fire safety measures. The *SFPE Engineering Guide to Performance-Based Fire Protection* [1] refers to fire scenarios as "a set of conditions that defines the development of fire and the spread of combustion products throughout a building or part of a building."

It is obvious that the total number of fire scenarios that may occur in a building can be very large; hence it is not possible to analyze each scenario separately. To reduce the number of scenarios to a manageable number, it is necessary to follow a scenario identification and selection process in a systematic fashion to ensure that the outcome of the engineering analysis is credible and acceptable to all stakeholders. The scenario identification and selection process can be performed by considering both the expected frequency of occurrence of each scenario and its expected consequences. This must be done so that the selected fire scenarios yield a fire protection design that provides acceptable levels of safety for the building occupants and property.

The *SFPE Engineering Guide* [1], the *International Fire Engineering Guidelines* [2], and other publications that provide guidance on the design process clearly indicate that the task of identifying and selecting fire scenarios is an integral part of the design process. Figure 38.1 is a section of the performance-based design process described in the *SFPE Engineering Guide*. The figure shows that developing fire scenarios follows the tasks of defining the project scope, goals, and objectives, and developing performance criteria.

Project scope, goals, and objectives inform the scenario identification and selection process. The project scope identifies whether the design is for a new building or an existing building, specific building components for the whole or part of a building, or repairs to the whole or part of a building. The fundamental fire safety goals for a building can be to

- Provide life safety for building occupants and emergency responders
- Protect property
- Provide for continuity of operations
- Limit the environmental impact of the fire
- Protect the heritage and cultural value of the property.

Although the fire safety goals are expressed in general terms, the fire safety objectives delineate more specific ways of attaining these goals. Quantifiable performance criteria can then be chosen to provide the basis for assessing whether fire protection designs achieve these objectives.

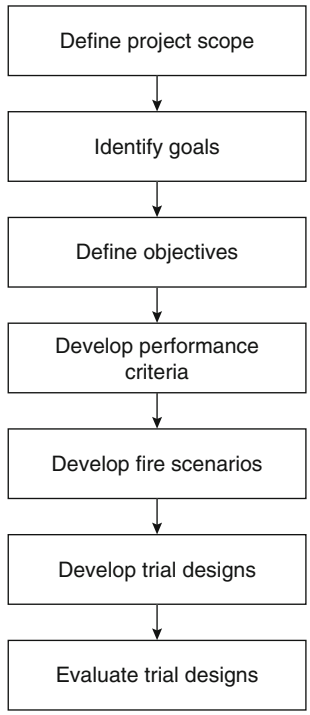

Fig. 38.1 Performance-based design process [1]

To ensure that the design will satisfy the above goals/objectives, the selected fire scenarios should be such that they challenge the proposed fire protection designs. Details on these steps can be found in the *SFPE Engineering Guide* [1].

A useful approach to the process of identifying and selecting fire scenarios has been developed by the International Organization for Standardization (ISO) [3], and it is summarized in Table 38.1.

Development of Fire Scenarios

Before one can identify potential fire scenarios, a significant amount of information about the project must be assembled. The types of information that may be required are described in this chapter.

Building Characteristics

Building characteristics need to be well documented, as they have a profound impact on potential fire scenarios. The physical layout of

Table 38.1 Steps used for identifying and selecting fire scenarios

Steps of ISO/TS 16733	Comments
1. Location of fire	Characterize the space in which fire begins as well as the specific location within the space
2. Type of fire	Characterize the ignition, initial intensity, and growth of potential fires
3. Potential fire hazards	Identify fire scenarios that could arise from fire hazards associated with the intended use of the property or the design
4. Systems impacting on fire	Identify the fire safety systems and features that are likely to have a significant impact on the course of the fire or development of untenable conditions. Characterize the initial status of each system or feature
5. Occupant response	Identify actions that people take that can have significant impact, favorable or otherwise, on the course of the fire or the movement of smoke
6. Event tree	Construct an event tree that represents alternative event sequences from fire ignition to outcome associated with fire scenarios
7. Consideration of probability	Estimate the probability of occurrence of each event using available data and/or engineering judgment
8. Consideration of consequence	Estimate the consequence of each scenario using available loss data and/or engineering judgment
9. Risk ranking	Rank the scenarios in order of relative risk. The relative risk can be evaluated by multiplying the consequence (step 8) by the probability of occurrence (step 7) of the scenario
10. Final selection and documentation	For each fire safety objective, select the highest ranked fire scenarios for quantitative analysis. Selected scenarios should represent the major portion of the cumulative risk (sum of the risk of all scenarios)

the building and the choice of building materials affect fire growth and severity within the compartment of fire origin. The building layout also plays major roles in fire and smoke spread through the building, occupant evacuation, and fire fighter access.

The detail required to describe building characteristics depends on the nature and complexity of the engineering analysis to be undertaken. Not all of the characteristics discussed below need to be quantified for every project.

The proposed layout and construction of compartments of interest, as well as interconnections among them, must be known. The information required could include

- Number of stories above and below grade
- Physical dimensions of compartments
- Construction materials and design of all building assemblies (walls, floors, etc.)
- Flammability and thermal properties of interior finish (density, thermal conductivity, specific heat, etc.)
- Location and dimensions of potential openings that could provide ventilation to the fire (doors, windows, areas of low fire resistance, etc.)
- Interconnections among compartments.

Other features of the construction of the building need to be considered as well, such as

- Location, dimensions, and properties of structural components (materials, thermal properties, mechanical properties, anticipated loads, etc.)
- Location and size of fire compartments (spaces enclosed by fire-resistant assemblies)
- Location and nature of concealed spaces
- Description of the proposed egress routes.

The nature and properties of proposed building services must be determined. This could include HVAC, electrical distribution, and plumbing systems as well as fire protection equipment related to automatic or manual fire suppression, smoke control, and fire detection. Plans for use of firestopping materials and dampers for such systems must also be considered.

Where the potential for fire spread to neighboring buildings is an issue, the location of the building on the site in relation to site boundaries must be determined. The properties of the exterior walls must also be known including their fire-resistant capabilities, the flammability of their claddings, and the size and nature of unprotected openings.

Fuel Loads

The combustible contents of a building can play a more significant role in fire development and severity than building products. It is therefore necessary to estimate the quantity of fuel in each compartment of interest as well as the types of fuel that may be present.

The quantity of fuel (combustible contents) is commonly expressed as a fuel load density; that is, fuel load per unit floor area in MJ/m^2. Statistical data derived from surveys are available for many occupancy types [4]. When a severe but credible representation of the quantity of fuel is desired, it is advisable to choose the 80th or even 95th percentile in the distribution of fuel load densities.

Although the fire load density concept implicitly assumes a uniform distribution of combustibles in compartments, it should be recognized that the actual distribution of combustibles may need to be addressed in some buildings.

Types of Combustibles

Different types of combustibles burn at different rates and exhibit different yields of various products of combustion as they burn. Characterizing the fuel in terms of the fuel load density, that is, in terms of its energy content, is often not sufficient. It can be important to know how much of the fuel is cellulosic, how much is plastic, how much is combustible liquid, and so forth. Some recent surveys provide such detailed data for selected occupancy types [5, 6].

Often the contents of a compartment come in the form of specific fuel packages. For example, an upholstered chair may be constructed of several combustible materials arranged in a unique configuration. It is challenging to model the burning of such a chair based on the flammability characteristics of each component. A simpler and reliable alternative is to rely on experimental data available in the literature [7–9].

Functions in Building

For many occupancy types, statistics are available to draw conclusions concerning likely sources of ignition and first items ignited. Statistics may also indicate which combinations of ignition sources and first item ignited lead to the most serious fire losses [10].

To supplement such statistics, an assessment of potential ignition sources and vulnerable combustibles can be undertaken for the proposed building layout and activities. This may be particularly important in an industrial building where several different manufacturing processes may be carried out, raw materials may be stored, finished products may be warehoused, and office space may be provided for staff. Although statistical data may not be available for the specific functions, the owner, operator, and perhaps even the insurance provider can be very helpful in identifying potential ignition sources and vulnerable combustibles.

Passive Fire Protection Systems

To inhibit fire spread through a building, it can be subdivided into fire compartments enclosed by fire-resistant assemblies. Commonly referred to as compartmentalization, this is a passive fire protection strategy. Although wall and floor/ceiling assemblies can be designed to be sufficiently fire resistant to meet the objectives of the design, the challenge is often to ensure connections between fire compartments are also sufficiently fire resistant.

Details and the statuses of closures intended to protect connections between fire compartments and to ensure the integrity of fire compartments in the event of fire must be determined. Doors can often be assumed to be closed and can be chosen to be sufficiently fire resistant; for example, doors between an apartment and a public corridor. In some occupancies or locations, fire-resistant doors may be held open for operational reasons and must be prompted to close in the event of fire. Detection systems can cut the current to electromagnetic "hold-open" devices and the doors will close. Thus the passive fire protection strategy is ensured by an automatic fire protection system. Similarly, ducts connecting fire compartments may need to be protected by dampers that operate by the use of fusible links or by other means.

Although most passive fire protection systems can be assumed to be very reliable, one must be confident that the design (resistance) of the system is adequate for the risk and that the system will not be compromised by modification (planned or accidental) through the years.

Detection and Suppression Systems

In the analysis of an existing building, the type (smoke detection, heat detection, UV/IR) of an automatic detection system must be documented. The location of detectors and their response time index (RTI) and activation temperatures (if appropriate) also must be noted [11]. The type of alarm notification, the location of alarm devices, and their acoustical performance should be noted. Of course, in the design of a new building the same information is required for the proposed (or trial) detection system(s).

Similarly, whether in an analysis of an existing building or in the design of a new building, the characteristics of automatic suppression systems must be documented. Information such as the types and locations of discharge devices is required. The activation characteristics (RTI and activation temperature) as well as the agent discharge density and distribution must be known [12].

Estimates of the reliability of detection and suppression should be made. Independently, one might also need to consider whether the anticipated fire development is such that these devices cannot be activated.

Occupant Load and Characteristics

Life safety is a common fire safety objective. Many of the variables affecting occupant behavior are either qualitative or difficult to quantify [13–15]. Nonetheless, whether the fire safety strategy involves evacuation or provision of safe areas of refuge, the following "occupant factors" must be considered:

- Occupant load (number and distribution of occupants)
- Familiarity with the building
- Alertness (sleeping or awake)
- Physical and mental ability.

Actions Taken by Occupants

The actions that occupants take can have significant impact, favorable or otherwise, on the course of the fire or the movement of smoke and should be considered. Depending on the nature of the building, trained staff or a well-equipped in-house fire brigade can have a profound influence on a fire in the early stages of development. In many facilities, fire wardens may play a significant role in assisting with evacuation. On the other hand, poorly trained staff or casual visitors could leave key doors open, allowing for rapid fire development and smoke transport. Any of these effects could introduce new potential fire scenarios.

Actions Taken by the Fire Department

A decision can be taken to ignore the beneficial actions taken by the fire department despite the fact that these actions can have a dramatic impact on fire spread within and between buildings. Whether fire department actions are explicitly modeled or not, the location, capability (types of equipment, training, etc.), and response time of the fire department need to be determined [16, 17]. The method of and hence inherent delay in alerting the fire department must be noted. The access of fire fighting appliances to the site and the access of fire fighters to the building must also be noted.

Identification of Potential Fire Scenarios

Having collected the data described in the preceding sections, it is now important to identify potential fire scenarios. One way to proceed is to follow the first five steps in the ISO methodology outlined in Table 38.1.

Step 1—Location of Fire The most likely locations for fire may often be determined by the review of statistics or from the assessment of potential ignition sources and vulnerable combustibles. Identification of the most adverse or challenging locations for fire normally entails the use of engineering judgment.

ISO/TS 16733 provides guidance on selecting challenging locations for fire [3]. Where life safety is the primary objective, Chap. 5 of NFPA *101*®, *Life Safety Code*®, identifies eight "required" design fire scenarios [18]. Most of these scenarios identify what are considered to be challenging locations.

As a minimum, the engineer should give consideration to modeling fires in the following locations:

- Fires in or its spread to "rooms" with a large number of occupants or vulnerable property
- Fires that render part(s) of the means of egress unusable
- Fires that commence within building assemblies and remain undetected while they grow in intensity (e.g., within concealed spaces, sandwich panels, etc.)
- Localized fires and/or postflashover fires that could challenge the structure and compartmentation in the building
- Fire locations that are challenging for proposed active measures (e.g., fires that are

shielded from sprinkler sprays, fires at floor level in the center of a space that generate large volumes of smoke that must be exhausted, etc.)

Step 2—Type of Fire At this point in the analysis, the type of fire refers to a qualitative description of the ignition, initial intensity, and growth of a fire. Much insight can often be gained from perusing statistics. For a given occupancy, one may be able to identify the most common ignition sources and the associated first item(s) ignited. One may also identify those combinations of ignition sources and associated first item(s) ignited that cause the largest percentage of deaths, the largest property losses, the largest percentage of fires that spread beyond the room (or compartment) of fire origin, and so forth [10].

Often Step 1 and Step 2 can be combined. Cooking fires take place on stoves in kitchens, and specific industrial fires take place at certain stages in the manufacturing process associated with specific equipment.

Step 3—Potential Fire Hazards Statistics give information of past and current fire problems but may not shed light on problems in the future as new designs, products, or hazards are introduced. It is therefore important to employ engineering judgment to identify potential fires that may not be identified by reviewing statistics.

For some occupancy types, for example, industrial buildings, the assessment of potential ignition sources and vulnerable combustibles undertaken in the section "Functions in Building" of this chapter may suggest types of fires that must be considered.

Step 4—Systems Affecting Fire The fire safety systems that are proposed for the building or facility, and that are likely to have a significant impact on fire development and the generation of untenable conditions, should be identified. For each system, consider the possibilities that it is operational and that it is not operational (due to routine maintenance, degradation over the years, etc.).

Passive systems that may play an important role are

- Fire separations such as walls and floors (ratings, penetrations, etc.)
- Closures in fire separations (fire doors, dampers, etc.)
- Structural members (rating, status of protection, etc.)
- Protection of means of egress.

Active systems that may play an important role are

- Suppression systems (sprinklers, CO_2, etc.)
- Smoke management systems (mechanical, natural venting, etc.)
- Fire detection systems (smoke, heat, etc.)
- Hold-open devices.

Step 5—Occupant Response Identify actions that people could take that can have significant impact, favorable or otherwise, on the course of the fire or the movement of smoke. Actions of occupants might also impact significantly on evacuation choices.

It may also be possible to consider the impact that in-house fire brigades or municipal fire fighters could have, particularly early in fire development while occupants are still evacuating. This may entail search and rescue efforts as well as suppression and smoke venting.

Selection of Design Fire Scenarios

In principle, all of the fire scenarios identified above should be used to evaluate trial fire protection designs. Such an approach is used by fire risk assessment models such as FiRECAM [19], which is applicable to typical apartment and office buildings. An example of the scenarios used by FiRECAM is described in Appendix 1 at the end of the chapter. In practice, it is not possible to evaluate all possible fire scenarios due to the large number for a given performance-based project. It is therefore necessary to filter possible fire scenarios to reduce their numbers to manageable levels. The selected scenarios are known as the design fire scenarios. The scenario

screening process is done using engineering judgment and a variety of deterministic and probabilistic tools such as event trees or qualitative analysis and risk ranking. Steps 6–10 of Table 38.1 can be followed to screen and select fire scenarios for quantitative analysis.

Event Trees

Step 6 of Table 38.1 deals with event trees, which are a useful tool for identifying and screening fire scenarios. An event tree can be constructed to explicitly display the possible states and alternative event sequences from ignition to burnout or extinguishment for each identified fire scenario. Some of the factors to be considered include the activation (or not) of detection and suppression systems, the presence of occupants in the fire area, the success of manual fire fighting, and fire department response and actions. In addition, factors such as the attainment of flashover, the status (open or closed) of fire doors in the compartment of fire origin, and the status (awake, asleep, infirm, etc.) of occupants of the building can also be considered.

An example of an event tree is shown in Fig. 38.2 for fire scenarios starting at a specified location. The frequency of fire of a specific type starting at this location, P_1, is an important factor that will influence the selection of design fire scenarios. Following ignition is the event "manual suppression," which has a conditional probability of success $P_{1,1}$ and of failure $P_{1,2}$ (equal to $1 - P_{1,1}$). The tree then considers the event "automatic suppression," with probability of success $P_{1,2,1}$ and of failure $P_{1,2,2}$ ($1 - P_{1,2,1}$). As can be seen from Fig. 38.2, the paths with successful events are not expanded for subsequent events, as these events will not have an impact on the final outcome of these paths. The tree considers two additional events, "venting effective" and "barriers effective," in a similar manner.

For each of the resulting paths, a path probability can be computed using the product of the probabilities of events found along that path.

$$P_{S11} = P_1 P_{1,1}$$

$$P_{S12} = P_1 P_{1,2} P_{1,2,1}$$

$$P_{S13} = P_1 P_{1,2} P_{1,2,2} P_{1,2,2,1}$$

$$P_{S14} = P_1 P_{1,2} P_{1,2,2} P_{1,2,2,2} P_{1,2,2,2,1}$$

$$P_{S15} = P_1 P_{1,2} P_{1,2,2} P_{1,2,2,2} P_{1,2,2,2,2}$$

For each path, the consequences in terms of life safety or property damage may be roughly estimated and placed in the last column of Fig. 38.2. Knowledge of the probabilities and

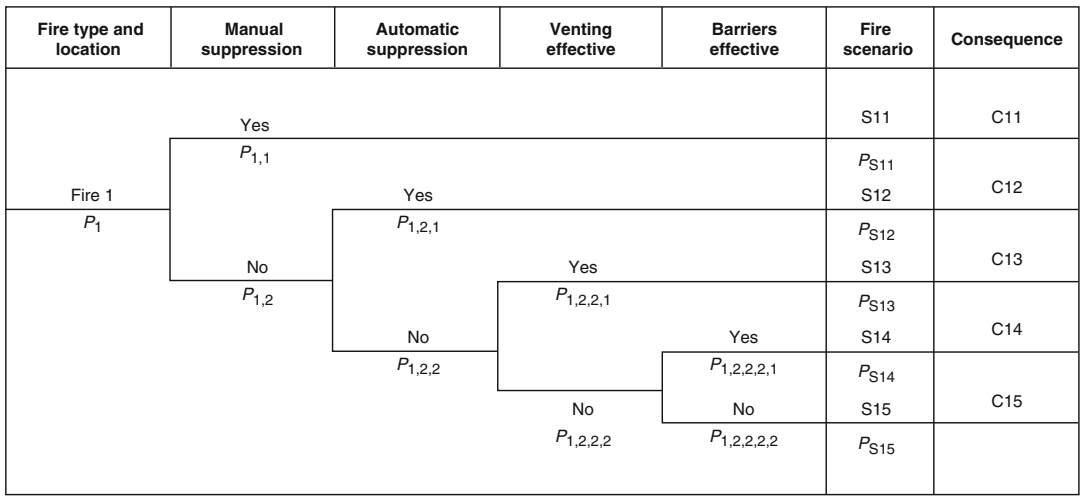

Fig. 38.2 Event tree for a given fire type occurring in a given location

consequence of each fire scenario (each path) can then be used to decide which scenarios should be considered as the design fire scenarios for more detailed analysis.

Frequency Calculation

Step 7 of Table 38.1 deals with the probability of occurrence of scenarios. Each fire scenario has a frequency of occurrence, which is the product of the frequency that this fire type occurs at a given location, P_1, and the probabilities of the occurrence of the different events associated with that scenario. In other words, it is the probability of the branch representing the fire scenario. Values required in determining fire scenario frequencies include the frequency that this fire type occurs at a given location; the reliability and effectiveness values of the active fire protection systems such as detection and alarm systems, suppression systems, and smoke control systems; as well the probability of failure of passive fire protection systems such as walls, floors, and rated doors. Data for estimating these values can be found from statistical databases, from expert judgment, and from mathematical models that may themselves include event and fault trees analysis.

Statistics and Historical Information

Statistical databases of past fire incidents contain data that could be analyzed to determine the most likely areas of ignition, item first ignited, and fuel source, as well as the probability of fire reaching various stages of severity and spreading to areas beyond the compartment of fire origin. Data can be found for various occupancies and can be used to determine frequency of ignition and the availability of active systems and their probability of activation and effectiveness [10].

Consideration of Consequence

In this step of the scenario selection process, Step 8 of Table 38.1, the expected consequences of each scenario or cluster of scenarios are estimated using available loss data and/or engineering judgment. This is a preliminary estimate of consequence for scenario screening purposes only using a risk-ranking matrix, as discussed below. A more detailed consequence analysis is done for each of the selected (design) fire scenarios as part of the quantitative engineering assessment.

Risk Ranking

Risk ranking, which is Step 9 in Table 38.1, is a useful method for screening scenarios because it allows comparison of scenarios based on both their frequencies and their consequences. Risk ranking can be used to perform either a quantitative or a qualitative analysis.

For a quantitative screening process, the probabilities and consequences of each potential scenario must be estimated and then the risk computed as the probability times the consequence. Design fire scenarios are chosen as those that represent the greatest risk. Two examples of how to select scenarios using this technique are provided in the annexes of ISO/TS 16733.

To perform a qualitative analysis, the identified scenarios can be grouped based on their expected consequences in order to implement a "risk binning" method. The *SFPE Engineering Guide* [1] suggests four consequence levels: negligible, low, moderate, and high. Consequences can reflect threat to life, property damage, downtime, environmental damage, and so on. Separate risk matrices can be developed for each type of consequence.

A description of the impact on occupants of the four consequence levels is as follows:

Negligible:	Negligible injuries
Low:	Minor injuries, no permanent disabilities
Moderate:	Serious injuries, permanent disabilities, hospitalization required
High:	Sudden fatalities, acute injuries, immediately life-threatening situations, permanent disabilities.

In terms of the impact on property and operations the four groups are described as follows:

Negligible: Minimum damage to building, minimal operational downtime

Low: Damage less than a specified dollar value $YY, reparable damage to building, significant operational downtime, no impact on surroundings

Moderate: Damage greater than $YY and less than a specified dollar value $XX million, major equipment destroyed, minor impact on surroundings

High: Damage greater than $XX million, building destroyed, surrounding property damaged.

Following the estimation of the consequences of the various scenarios, the risk binning method requires an estimate of the frequency level of each of the scenarios. In a similar fashion to the evaluation of the consequences, the frequencies can be determined using a qualitative or a quantitative approach. The *SFPE Engineering Guide* [1] suggests the following levels of frequencies:

- Anticipated, expected: incidents that might occur several times during the lifetime of the building $\left(f > 1 \times 10^{-2}/\text{yr}\right)$
- Unlikely: events that are not anticipated to occur during the lifetime of the facility $\left(1 \times 10^{-4}/\text{yr} < f \leq 1 \times 10^{-2}/\text{yr}\right)$
- Extremely unlikely: events that will probably not occur during the life cycle of the building $\left(1 \times 10^{-6}/\text{yr} < f \leq 1 \times 10^{-4}/\text{yr}\right)$
- Beyond extremely unlikely: all other incidents $\left(f \leq 1 \times 10^{-;6}/\text{yr}\right)$.

With these scales a risk-ranking matrix is constructed, as shown in Fig. 38.3. Once the risk matrix has been constructed, scenarios with high or moderate risk can be selected as the design fire scenarios for further analysis.

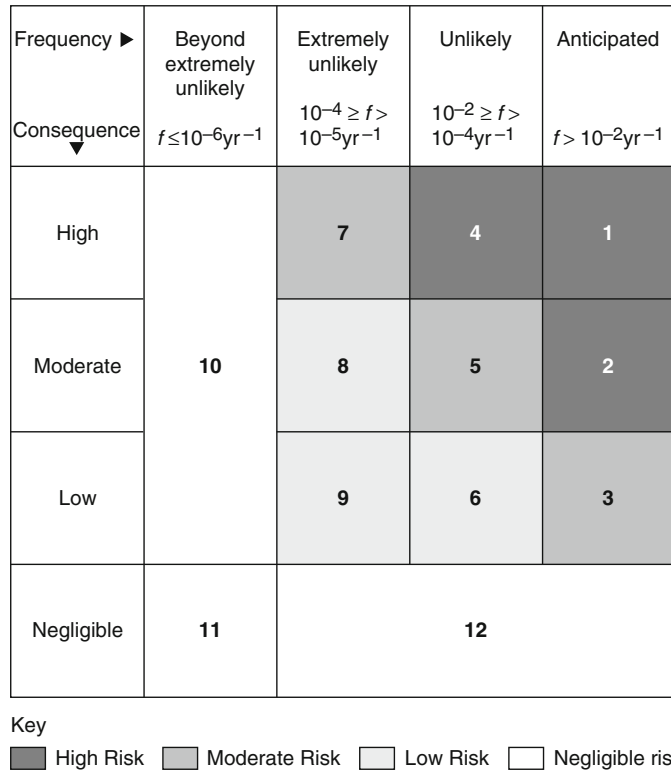

Fig. 38.3 Risk-ranking matrix (Adapted from SFPE Design Guide [1])

Scenario Selection

In Step 10 of Table 38.1, the selection of fire scenarios for quantitative analysis is done and documented. These are the highest ranked scenarios for each fire safety objective. Documentation should include a clear scenario description that includes the design fire associated with each selected scenario and the condition of the active and passive fire protection systems.

Quantifying Design Fire Scenarios

The process of quantifying the selected design fire scenarios is the essence of a fire protection engineering analysis. This process involves the quantification of the fire and smoke characteristics from ignition to outcome (referred to as the design fires) and their impact on property and building occupants (the consequences). In addition, it may involve the quantification of the frequencies of the various scenarios that can assist in selecting appropriate cost-effective designs. Although this process is very broad, it covers all aspects of fire safety engineering and utilizes computer models and other tools in the analysis. In the following sections, some guidelines are provided to assist fire protection engineers.

Design Fires

Following identification of the design fire scenarios, it is necessary to describe the assumed characteristics of the fire on which the scenario quantification will be based. These assumed fire characteristics are referred to as the "design fire." This section provides guidance on characterization of design fires in terms of time-dependent heat release rates.

In principle, a design fire may progress from an incipient phase to a growth phase to a fully developed phase and finally to a decay phase. Depending on the nature of the fire safety engineering assessment, one may not need to model every phase of the fire.

Modeling Preflashover Fire Growth The preflashover growth phase could consist of a smoldering and/or flaming stage. As smoldering produces heat at a slow rate, it is not considered here, but some models, such as FiRECAM [19], do address this phenomenon. For preflashover fires or fires that remain localized, the rate of heat release as discussed in this section, as well as the location of the fire, forms the fundamental description of the design fire.

Rate of Heat Release Modeling preflashover fire growth involves estimating the rate of heat release, $\dot{Q}$, of the fire as a function of time. Several methods are available for the purpose.

The first method is the *generic t^2 model*. When combustible items of varying composition are present, it is often not practical to attempt to model early fire growth by identifying the first item ignited and modeling fire spread from the first item to involve an increasing quantity of fuel. In such cases, it is more appropriate to use a generic fire growth curve that represents the general types of combustible material in the enclosure. Fires that do not involve flammable liquids or gases often grow relatively slowly at the outset. As the fire grows, the rate of growth accelerates. Such fires often grow proportionately to the square of the time.

$$\dot{Q} = (t/t_{1000})^2 \,(\text{kW}) \qquad (38.1)$$

where

t = time (s)

t_{1000} = time (s) to reach a heat release rate of 1000 kW (1 MW)

Analyses of the results of fire tests and real fires have provided a basis for estimating t_{1000}. Four fire growth rates, appropriate for design, are identified in Table 38.2. Each of these fire growth rates is characterized by a specific value of t_{1000} as depicted in the table. Table 38.2 also identifies examples of fuel configurations known to fit into each of the four fire growth categories.

Another method is the *experimental data method*. If it is possible to identify the first item likely to be ignited, the initial rate of fire growth can be determined from test data. Results from

calorimeter or large-scale tests may be used, provided the limitations are considered. Most information on burning rates for single items has been collected from items burning in a large enclosure. These data will be appropriate for the early stages of fire in large enclosures, but if the fire grows large or if it takes place in a small enclosure, the free-burning rate must be adjusted to account for

- Radiative feedback from the hot smoky layer or from enclosure surfaces
- Restriction of fire by an inadequate supply of oxygen.

Based on such large-scale tests, analytical models have been developed [20] to predict the rate of heat release when the burning item is a wooden crib, wooden pallets, or liquid (or thermoplastic) pool fires. Data are also available for a number of other products [7, 9, 20].

Another method is by *calculations from first principles*. In some circumstances, where the relative orientation and spacing of fuel packages are well known, it is possible to undertake calculations from first principles. Once the rate of heat release of the first item ignited has been determined from specific data or models, an analysis should be performed to ascertain whether the fire is likely to spread to neighboring items. This can be accomplished by considering the radiant heat transfer from flames to adjacent fuel items. The radiant flux incident on the adjacent packages should be compared with critical levels for the relevant materials to determine whether secondary ignition (fire spread) is likely. As the fire spreads from item to item, fire modeling can be used to estimate fire growth curves representative of the cumulative heat release rate due to the burning of multiple fuel packages. This should be considered an approximation since the nature and strength of the ignition source could differ from the ignition source used in the specific fire tests where the fire growth curves for the adjacent items were measured.

When modeling the preflashover growth phase as a t^2 fire (Equation 38.1), it should kept in mind that the fire may not be able to grow without limit. There may be a *maximum rate of heat release* that can be realized. If so, the heat release rate could be modeled employing Equation 38.1 until the maximum rate is reached and then assumed to level off at the maximum value. This is depicted in Fig. 38.4, where, in the growth phase, the fire grows as t^2, but levels off at a steady-burning rate. Several examples of this type of behavior follow.

At the point in time when sprinklers activate, if shielding of combustibles from the water spray can be expected, it might be advisable to assume that sprinklers prevent the fire from growing but do not suppress it. In such cases one could assume the heat release rate remains at the level

Table 38.2 Categories of t^2 fires

Growth rate	t_{1000} (s)	Typical real fires
Slow	600	Densely packed wood products
Medium	300	Solid wood furniture (desks) Individual furniture items with small amounts of plastic
Fast	150	High stacked wood pallets Cartons on pallets Some upholstered furniture
Ultrafast	75	Upholstered furniture High stacked plastic materials Thin wood furniture (wardrobes)

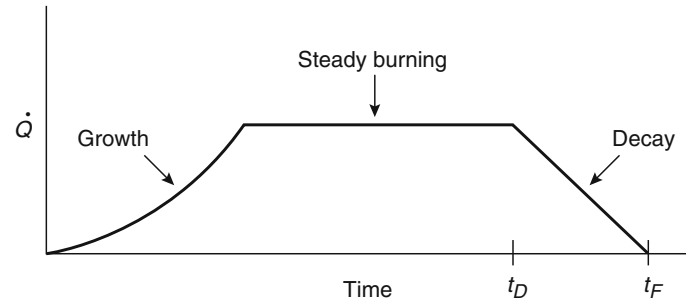

Fig. 38.4 Depiction of the three phases of fire: growth, steady burning, and decay

when sprinklers activated. For many scenarios, the activation of sprinklers will cause the heat release rate to drop; however, for some shielded fires, the heat release rate may continue to rise even after sprinklers activate.

In the absence of sprinkler activation, the amount, type, and configuration of burning items that can become involved in fire may also impose an upper limit on the rate of heat release. The maximum heat release rate then would be given by the maximum free-burning value.

The available ventilation can also impose an upper limit on the rate of heat release in the absence of sprinkler activation. If the available ventilation is restricted, the fire may not even reach flashover. Many computer models automatically account for the possibility of ventilation control. If hand calculations are to be undertaken and there is only one principal opening, the maximum rate of heat release can be predicted as

$$\dot{Q} = 1400A\sqrt{H}\,(\mathrm{kW}) \qquad (38.2)$$

Where A is the area of the opening in m^2 and H the height of the opening in m.

Modeling Postflashover Fires The discussion above does not account for the possibility of flashover. Flashover can be considered to occur when the

- Temperature of the hot gas layer under the ceiling reaches 500 °C
- Heat flux at the floor (or the level of combustibles) reaches 20 kW m^{-2}.

These criteria can be used along with two-zone fire models to predict whether or when flashover is expected to occur in an enclosure. Simple analytical models are also available to predict whether flashover is likely [21].

If flashover occurs, Fig. 38.4 would still apply, but the steady-burning rate would now be defined by the postflashover value predicted below.

Following flashover, the rate of heat release increases rapidly until it reaches the maximum value for the enclosure. The rate of consumption of fuel is approximately constant and is limited by the quantity and nature of the fuel or by the available ventilation. The rate of consumption for both fuel-bed-controlled and ventilation-controlled regimes should be calculated and the lesser value taken as representing the fully developed fire. To simplify design, the growth period between flashover and the maximum heat release rate is usually ignored, and it is assumed that the rate of heat release instantaneously increases to the steady-state level after flashover.

As with preflashover fires, the maximum rate of heat release for ventilation-controlled fires can, in general, be predicted employing Equation 38.2. With fuel-bed-controlled fire, the combustibles are able to burn freely. The rate of heat release is limited by the amount, type, and configuration of the burning items.

Modeling the Decay Phase of the Fire The decay phase of the fire commences at time t_D, which can be defined as the time when about 70–80% of the design fire load has been consumed. In the decay phase it can be assumed that the heat release rate exhibits a linear decrease with time.

Quantifying the Fire and Its Impacts

The process of quantifying the fire and its impacts on life safety and property for each fire scenario, also known as hazard analysis, involves calculations of all the subsystems of the fire safety system. Subsystems include fire initiation development and spread, smoke movement, activation of detection and suppression systems, impact on structure, occupant response and evacuation, and fire department intervention. These calculations may involve simple correlations such as plume calculations or the use of complex mathematical models such as computational fluid dynamics (CFD) models. The following sections consider each subsystem and discuss the various calculation approaches that may be used. The purpose is to provide guidance on the available calculation methods and refer the reader to the appropriate sources for more detailed analysis.

Smoke Movement Smoke movement from the compartment of fire origin to other areas in the building is the main cause of deaths and injuries in building fires. In addition to the life safety impacts of smoke due to toxic gases and high temperature, smoke spread may decrease visibility in the building causing disorientation, reducing traveling speeds, and rendering exits routes untenable, thereby preventing occupants from evacuating safely. The conditions in a building during a fire in terms of temperature, concentration of toxic gases, and visibility can be determined using a number of available computer models. In general, these models fall into three broad categories: network models, two-zone models, and computational fluid dynamics (CFD), or field, models. Network models, such as CONTAMW [22], can be used for large high-rise multicompartment buildings with hundreds or even thousands of compartments. Two-zone models, such as CFAST [23], can be used for buildings with a small number of compartments of typically small size in which the two-zone concept is valid. CFD models, such as the Fire Dynamics Simulator [24], are used for buildings with large compartments and complex geometries where a more detailed spatial resolution is required.

Criteria can be used to determine the impact of smoke conditions on occupants and can be related to the level of the hot layer in compartments or the dosage of toxic gases received by occupants. Details of how to determine impacts of smoke on life safety can be found in Purser [25].

Detection and Suppression Systems Detection and suppression systems may have a significant impact on the outcome of a fire. Detection systems may activate smoke management systems, initiate the activation of suppression systems, and trigger alarm systems. Early warning to building occupants of the fire may lead to its extinguishment if the fire it is still in the early stages of development and will initiate building evacuation. Activation of suppression systems will affect fire development leading to its control or extinguishment. In fire scenarios that consider the impact of detection or suppression systems, it is necessary to predict the activation time of these systems.

The prediction of the activation time depends on the type of system, the rate of growth of the fire, and the location of the fire in relation to the detector. In the case where computer models such as CFAST or FDS are used to predict fire development, the activation time can be predicted by these models. Simple calculations can also be done to predict detection times by following the procedures outlined in Schifiliti et al. [26] or by using simple computer models such as DETACT [27].

The effect of the activation of suppression systems such as sprinklers on the fire depends on the fire size at the time of activation, whether the fire is shielded so that the suppression agents do not reach it, and the spray density of the agent. If the system has no effect, then we can assume that the fire will continue to grow as if the system were not present. In the case when the suppression system controls the fire, we can assume that the fire will continue to burn at the same intensity as at the time of activation. In the case of fire extinguishment by the suppression system, the equation derived by Madrzykowski and Vittori [28] can be used to predict the heat release rate after activation time.

$$Q(t) = Q_{\text{act}} \mathrm{e}^{-0.023\Delta t}$$

where
$Q(t)$ = Heat release rate at time t (kW)
Q_{act} = Heat release rate at activation time (kW)
Δt = Time after sprinkler activation (s)
t = Time (s)

Impact on Structure The fire impact on structures can be used not only to estimate consequences based on structural damage but also to determine fire spread from the compartment of fire to other compartments in the building as a result of failure of compartment barriers to contain the fire. Typically fire attack on structures for most buildings begins after flashover has occurred. The duration of the attack depends on fire duration, which is a function of the total fire

load in the compartment and the postflashover heat release rate. In certain instances, the structure may be subjected to direct flame impingement; hence it would be necessary to include this in the calculations. Direct flame impingement may cause greater damages to the structure due to the fact that flame temperatures are higher than hot layer temperatures.

Occupant Response and Evacuation Occupant response to a fire depends on the warnings received by the occupants during fire development. These in turn depend on the relative location of the occupants to the fire and the availability and operation of fire detection and alarm systems. The earliest occupants can respond to a fire is by receiving fire cues at their location such as seeing the fire, smelling smoke, and hearing fire noises. As not all occupants receive and respond to the various warnings at the same time, an event tree can be constructed, as shown in Fig. 38.5, that considers the types of warnings and response to such warnings. The three different warnings occur at different times as shown in the figure. The response of occupants to the fire cues is denoted as "Occupant response I" in Fig. 38.5 and occurs at time t(I). If a fire detection and alarm system is available, it will detect the fire and warn occupants at a later time. The response to the alarm signals is denoted as "Occupant response II" in the figure and occurs at t(II). Occupants that responded to the various warnings would notify other occupants in the buildings. The response to these warnings is denoted as "Occupant response III" and occurs at t(III). The probability associated with each response type depends on the probability of receiving the warning and the probability that occupants will respond to that warning.

$$P(\mathrm{I}) = P(\mathrm{cues}) \times P(\mathrm{resp})$$

where

P(I) = Probability of response at time t(I)

P(cues, I) = Probability of cues at time t(I)

P(resp, I) = Probability of response to cues

For example, if the probability of smoke detector activation given a fire is 0.7 and the

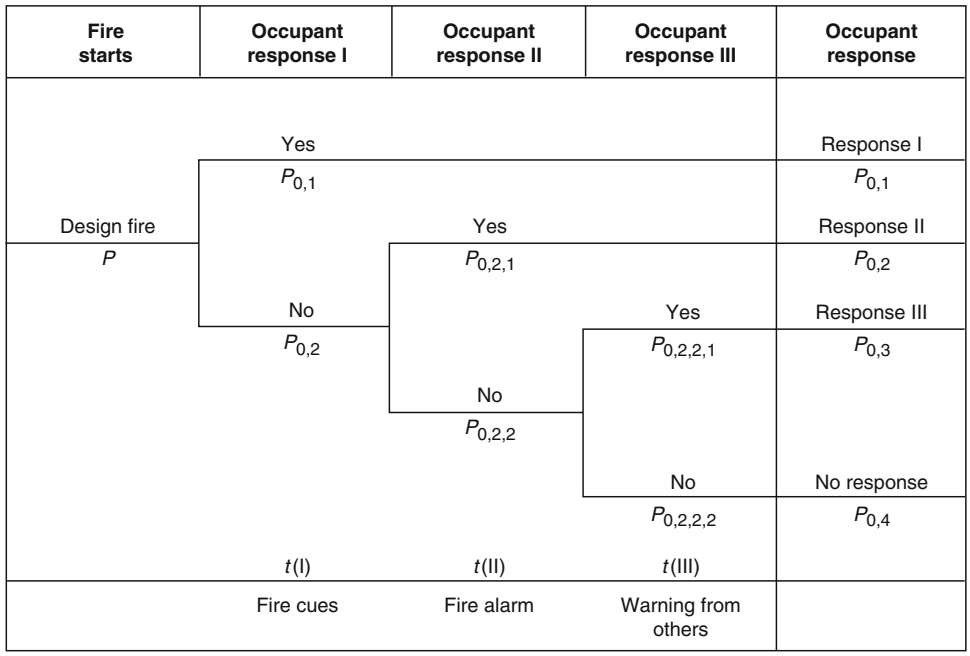

Fig. 38.5 Event tree for occupant response

probability that occupants will respond to the alarm issued by the smoke detector is 0.8, the probability of responding to this warning is $0.7 \times 0.8 = 0.56$. As these probabilities may be different for occupants in the compartment of fire and for occupants in remote compartments, event trees may be constructed for different groups of occupants.

Occupants who respond to the various warnings will commence evacuation. The time required for evacuation depends on the location of occupants in the building, the number of occupants, and the number of available egress routes. The total time required for evacuation can be computed using

$$t_e = t_w + t_r + t_d + t_m$$

where
t_e = Evacuation time (s)
t_w = Time of receiving warning (s)
t_r = Time to respond to warning (s)
t_d = Delay time, preparing to evacuate (s)
t_m = Movement time (s)

Fire Department Intervention Fire department intervention will have a significant impact on the outcome of the fire and the response and evacuation of occupants. This impact, however, is considered as a additional safety feature, and it is usually not explicitly considered in the design calculations.

Consequence Analysis

The consequence of a particular design fire scenario can be determined from information on the fire, its heat and smoke production rates, and fire spread and smoke movement from the location of the fire to other locations. The outcome of the consequence analysis includes injuries and fatalities and property damages to both the building and its contents, as well as damages to the environment and losses resulting from business interruption.

Injuries and Fatalities Injuries and fatalities are caused by the inhalation of toxic products of combustion, exposure to thermal radiation, or direct contact with flames. The impact of a fire scenario on life safety can be determined by tenability analysis. This analysis involves not only calculations of fire development and spread and smoke movement but also an occupant response and evacuation analysis that determines the location of occupants at different times during the fire scenario and the effect of the exposure on occupants. Criteria for determining the effect of the exposure can be found in Purser [25].

Damages to Building and Contents Property damage is a result of exposure to thermal loads, exposure to soot, and corrosive gases. In addition, water damage should be considered as water is the most common fire-extinguishing agent. Thermal loads that include both radiation heat fluxes and convective heat fluxes can be computed from the available information on fire development and spread. Similarly, damage from smoke can be estimated using information on smoke movement and concentration of toxic gases in the building. The level of damage to contents depends to a great extent on the sensitivity of contents to heat, smoke, and water. Information on thermal damages for many materials obtained from results of standard tests can be used to determine threshold damage levels.

Business Interruption Losses from business interruption refer to loss of income as a result of the fire. These losses can be estimated based on expected downtimes caused by the fire. An exact estimate of this may not be easily determined, however, good estimates can be determined. For example, total damage to process equipment may require its replacement. Knowledge of the time for the manufacture, delivery, and installation of this equipment is necessary in estimating downtimes.

Environmental Damage Damage to the environment can be a result of the release of toxic products of combustion or contaminated runoff water. The potential for damage is great especially when dealing with chemical process plants that store significant amounts of chemicals,

the release of which into surface or groundwater reservoirs may have a great impact on aquatic life and the health of people using these resources. Deposition of toxic products of combustion on vegetables and other vulnerable plants and animals may also cause large damages.

Example An example that demonstrates the use of the described methodology for identifying and selecting fire scenarios for a multi-use building is included in Appendix 2 at the end of the chapter.

Summary

The development of fire scenarios is an integral part of the performance-based fire protection design process. The process of identifying and quantifying fire scenarios is described in this chapter. This process requires knowledge of building characteristics, fuel loads and types of combustibles, functions of building, passive and active fire protection systems, and occupant load characteristics. Based on this information all potential fire scenarios can be identified, the number of which may be too large for further analysis. To reduce the number of the identified fire scenarios to those that merit further analysis a selection process is described that involves the use of event trees and other tools to estimate the frequency and consequence of the identified scenarios. Information on the frequency and consequence of the identified scenarios can then be put into a risk-ranking matrix that facilitates the selection of scenarios. The selected fire scenarios can then be quantified using engineering analysis to determine fire severity and impact on occupants and property, as well downtime and impact on environment.

Appendix 1: Fire Scenarios in Risk Model FiRECAM

FiRECAM™ is a fire risk and cost assessment model developed by the National Research Council of Canada [19, 29]. As a result of simplifying assumptions made, the model is applicable to apartment and office buildings. FiRECAM calculates the expected risk to life and fire cost expectation based on a hazard analysis of a number of scenarios. These scenarios and their probability of occurrence are hard coded in the model.

The approach employed in FiRECAM is to consider only three generic fire types that represent the three distinct types of fires that may occur. They are (1) smoldering fires where only smoke is generated, (2) nonflashover flaming fires where a small amount of heat and smoke is generated, and (3) flashover fires where a significant amount of heat and smoke is generated with a potential for fire spread to other parts of the building. The design fires can occur on each floor of the building, and each fire could happen with the apartment door open or closed. In addition, scenarios are considered with occupants being awake or asleep, and suppression systems being effective in extinguishing the fire or not. Within each fire scenario analysis, the times of occupant response and evacuation are based on analysis of the impact of fire detection systems, alarm systems, and other possible perceptions that occupants may receive during the fire.

The probabilities of these three fire types, for both apartment and office buildings, were obtained for Australia, the United States, and Canada [30]. They were obtained based on independent analyses of fire statistics in these three countries. The definition of fire type is based on the severity of the fire when it was observed and recorded by the fire fighters on their arrival. Obviously, small fires can develop into fully developed, postflashover fires if they are given enough time and the right conditions. For risk assessment purposes, however, the fire conditions at the time of fire department arrival are the appropriate ones to use. They represent the fire conditions that the occupants are exposed to prior to fire department extinguishment and rescue operations. In the event of no fire department response, then the eventual conditions of the fire at extinguishment, either by itself or by occupant intervention, are the ones to be used.

Table 38.3 Probabilities of fire types for apartment buildings

Type of fire	Australia (%)	United States (%)	Canada (%)
Smoldering fire	24.5	18.7	19.1
Nonflashover fire	60.0	63.0	62.6
Flashover fire	15.5	18.3	18.3

The reason why fires can develop into different types with different probabilities is because they are governed by a number of random parameters that cannot be predicted, such as the type of ignition source, the point of ignition, and the arrangement of the combustibles. Table 38.3 shows the probabilities of the three fire types, after ignition, for apartment buildings. It is interesting to note that the probabilities are quite similar among the three countries, even though there is no reason that these numbers should be the same due to climatic and cultural differences. Table 38.3 also clearly demonstrates the importance of considering all fire types. For example, flashover fires, which can pose significant hazards to the occupants, have a relatively low probability of occurrence; whereas nonflashover and smoldering fires, which pose lower hazards to the occupants, have a higher probability of occurrence.

Design Fires

In addition to the random parameters, described in the previous section, that govern the type of fire that can develop, the condition of the door to the compartment of fire origin is another random parameter that also affects the fire growth. The fire type and the door condition can be combined to create six design fires that allow all the random parameters that govern fire growth to be easily considered. These six design fires are (1) smoldering fire with the fire compartment entrance door open, (2) smoldering fire with the fire compartment entrance door closed, (3) flaming nonflashover fire with the fire compartment entrance door open, (4) flaming nonflashover fire with the fire compartment entrance door closed, (5) flashover fire with the fire compartment entrance door open, and (6) flashover fire with the fire compartment entrance door closed. The probability of each of these design fires is the product of the probability of the fire type (Table 38.3) and the probability of the door to the compartment of fire origin being open or closed. The probability of the door being open or closed can be estimated based on experience. For example, the entrance door to an apartment unit can be assumed to be mostly closed (for security and privacy reasons), whereas the entrance door to an office room can be assumed to be mostly open (to allow work interaction).

The scenarios used in FiRECAM are shown in Fig. 38.6, which demonstrates the various parameters used that may impact fire development and smoke movement as well as occupant response. The model does not attempt to decrease the number of scenarios, although it is evident from the results that some scenarios such as the smoldering scenarios and flaming nonflashover scenarios contribute less to the overall risk to life. Important scenarios, as identified by the model, are the flashover scenarios with door open and sprinklers nonfunctioning.

Appendix 2: Example Demonstrating Selection of Fire Scenarios

Example The fire protection team is in the process of performing a performance-based design for a complex building with multiple occupancies, including a parking garage on the four floors below grade and shopping areas on the first four floors, which are interconnected through an atrium and a 20 story hotel tower. The complex is fully sprinklered with a central alarm and voice communication, and the atrium has a smoke exhaust system.

Solution The ten steps identified in Table 38.1 are followed for the solution of this example.

Step 1—Location of Fire

A brainstorming session has identified the following fire locations to be considered in the analysis:

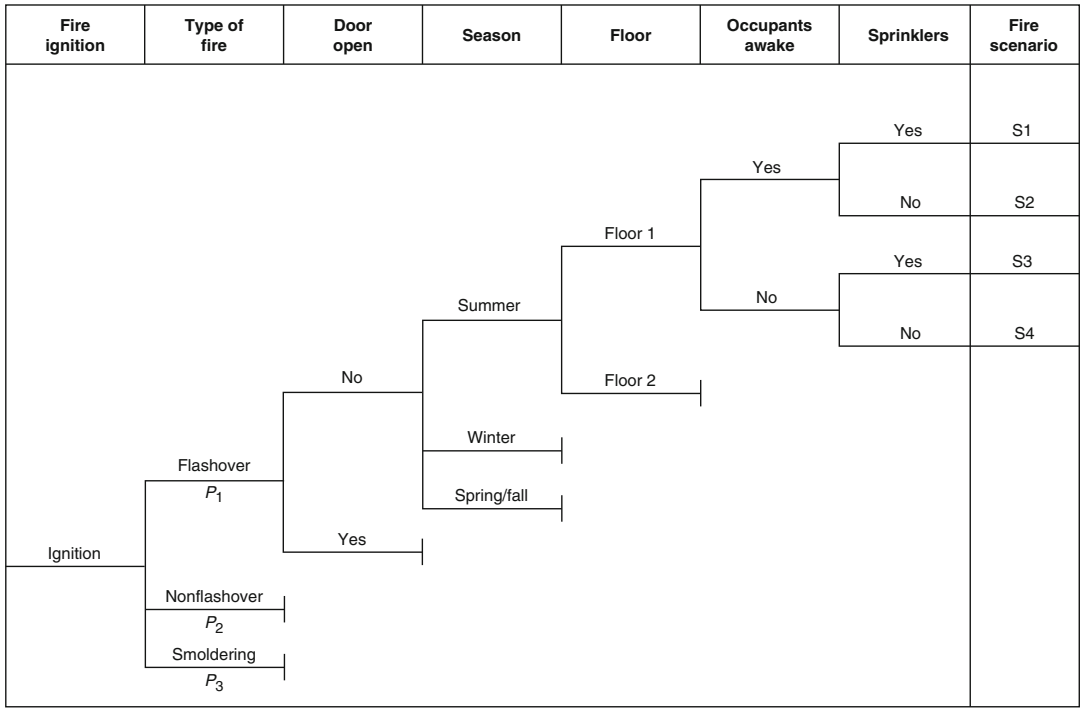

Fig. 38.6 Event tree showing fire scenarios in FiRECAM

- Fire in a hotel room
- Fire in the underground parking garage
- Fire in the atrium
- Fire in the restaurant of the hotel adjacent to the hotel lobby
- Fires in stores of the commercial area

Step 2—Type of Fire

The type of fire that may start at each location depends on the type of combustibles, fuel load, and ignition sources.

Hotel Room One type of fire that may be expected in a hotel room are those that start with a cigarette thrown into a garbage container that ignites curtains and then spreads to a couch and bed. Another type of fire may start in a garbage can but then ignites the wood cabinet with a TV and clothing items in the drawers. Fire development for these two fires may be different, although after flashover both fires may have similar characteristics.

Underground Parking Garage The type of fire expected in an underground garage is one that involves a car and then spreads to adjacent cars.

Atrium In the atrium area, the expected fire could be a fire of a Christmas tree that is placed there during the holidays or a fire involving couches and tables located there.

Restaurant In the case of restaurants, the fire may start in the kitchen area or it may start in the sitting area. These two types of fire are different.

Commercial Area Fire in this area could potentially start in any store. This may result in different types of fires depending on the combustible materials and fire loads in each store as well the size and ventilation characteristics. Examples of different fires in stores are fires in clothing stores, bookstores, and shoe stores. A survey of commercial stores done in 2004 has identified a number of different types of fires that should be considered for commercial areas [5, 6].

Due to space limitations and to avoid repetition, only the fires in the hotel room, the parking

garage, and the atrium are considered in the remainder of the example.

Step 3—Potential Fire Hazards

For this type of occupancy, no special hazards are anticipated. However, the authorities having jurisdiction may request consideration of arson or hazards as a result of functions or events that may be held in the atrium space. This could include exhibitions and displays of goods and merchandise.

Step 4—Systems Affecting Fire

The building is fully sprinklered with central alarm with voice communication. In addition, the atrium and the parking garage have smoke management systems. The effects of these systems should be considered.

Step 5—Occupant Response

Consideration is given here to the response of the occupants to the various warnings and their likelihood to extinguish the fire. For this example, a probability of response and effectiveness in extinguishing the fire is assigned as 0.3 for all fire scenarios.

Step 6—Event Tree

For each fire location, an event tree is constructed so that the different fire scenarios can be identified. Figure 38.7 shows the event tree for fire starting in a hotel room. As the figure shows, four scenarios are associated with this fire type. The probability of occurrence of this fire type could be obtained from statistics. For this example, however, it is assumed that the probability of fire starting at the three locations is the same. Probabilities for each of the events shown in the tree can also be obtained from statistical data; however, because this is a qualitative analysis, expert judgment can be used.

Figure 38.8 shows the event tree for the fire starting in the parking garage. This tree considers the events of manual suppression, sprinkler activation and effective control of the fire, effective smoke ventilation, and barriers that are effective in containing the fire. The fire in this location results in six fire scenarios.

Figure 38.9 shows the event tree for the atrium fire. It considers the same events as the parking garage fire, so it results in six scenarios. (Although it is possible that sprinklers operate but venting does not, for brevity, this potential scenario is not considered here.)
