For a risk avoider whose increasing utility function is concave, the risk premium RP given by Equation 79.3, for any situation in which the outcome is uncertain, is positive (EMV is greater than CE). For a risk taker whose increasing utility function is convex, RP is negative. For a risk neutral person whose utility function is linear, RP is always zero (EMV = CE).

The CE is defined mathematically as

$$U(CE) = E[U(x)] = \overline{U} \tag{79.4}$$

where the right-hand side is the expected value of the utility over the range of values taken by x. If $x_1, x_2, \ldots, x_n$ are the values (consequences) with probabilities $p_1, p_2, \ldots, p_n$

$$\overline{U} = E[U(x)] = \sum_{i=1}^{n} p_i U(x_1) \tag{79.5}$$

If x is a continuous variable with probability density function $h(x)$, the expected utility is given by

$$\overline{U} = \int_x U(x)h(x)dx \tag{79.6}$$

The CE or CME of a risky venture, V, is an amount, $\hat{x}$, such that the decision maker is indifferent between the risky venture, V, and the certain amount, $\hat{x}$. Put another way, $\hat{x}$ is the value for which $U(\hat{x})$, the utility function on $\hat{x}$, is equal to the expected value of the utility function on the full range of possible outcomes.

The expected value of a random variable, x, is given by

$$\overline{x} = E(x_i) = \sum_{i=1}^{n} p_i x_i \tag{79.7}$$

or by

$$\overline{x} = \int_x xh(x)dx \tag{79.8}$$

in the continuous case.

To illustrate the procedure for calculating a CE or CME, consider, as an example, the specific utility function

$$U(x) = -\mathrm{e}^{-cx} \tag{79.9}$$

Suppose the decision maker is faced with a venture with two possible outcomes: x_1 with probability ½ and x_2 with probability ½. The expected value of the venture is

$$\overline{x} = \frac{x_1 + x_2}{2}$$

The certainty equivalent (CE) is therefore the solution to this equation:

$$\begin{aligned} U(\hat{x}) &= \mathrm{e}^{-c\hat{x}} \\ &= -\frac{\mathrm{e}^{-cx_1} + \mathrm{e}^{-cx_2}}{2} \end{aligned}$$

It may be verified that for $c = 1$, $x_1 = 10$, and $x_2 = 20$, the certainty equivalent is

$$\hat{x} = 10.69$$

The expected value is

$$\frac{(10 + 20)}{2} = 15$$

Consider a second example in which the risky venture has a continuous range of outcomes, ranging from 0 to 20, with an exponential probability density function

$$f(x) = \mathrm{e}^{-x}$$

The expected value is

$$\overline{x} = \int_0^{20} x e^{-x} dx = 1$$

Suppose we further assume a utility function as

$$U(x) = -\mathrm{e}^{-2x}$$

The certainty equivalent is given by $\hat{x}$ such that

$$-\mathrm{e}^{-2\hat{x}} = -\int_0^{20} \mathrm{e}^{-2x}\mathrm{e}^{-x} dx$$
$$= -\int_0^{20} \mathrm{e}^{-3x} dx = -\frac{1}{3} \quad \hat{x} - 0.55$$

Specific Probability Distributions for Utility Analysis of Fire Safety Choices

Based on the formulations just discussed, a utility analysis requires a probability distribution function for the outcomes of a risky choice and a utility function on those same outcomes. For a risky choice where fire loss is the source of risk, the key variable in differentiating the outcomes is the size of the fire loss (in monetary terms). Let that be defined as x.

Consider a property owner with an asset value of W. If a loss of x is incurred in a fire, the asset value would be reduced to

$$X = W - x \tag{79.10}$$

The property owner's utility function will be defined in terms of the reduced asset value, rather than the fire loss, because the reduced asset value reflects the owner's wealth and ability to absorb a loss. An appropriate utility function in terms of positive X would be

$$U(X) = -\mathrm{e}^{-\theta X}, \quad \theta > 0 \tag{79.11}$$

which is an increasing risk averse utility function [36].

Although the extent of risk aversion quantified by θ is constant for all X, this exponential utility function is widely used in view of its computational simplicity.

Next, in order to match the form of the utility function to the form of a distribution on probabilities of fire loss size, Equation 79.11 should be rewritten as

$$U(x) = -\mathrm{W}'\mathrm{e}^{\theta x} \tag{79.12}$$

where $W' = e^{-\theta W}$ and is a constant. As discussed earlier, the certainty equivalent $\hat{x}$ is given by solving the following equation for $\hat{x}$:

$$-W'\,\mathrm{e}^{\theta x} = -W' \int_x \mathrm{e}^{\theta x} v(x) dx \tag{79.13}$$

where $v(x)$ is the probability density function of fire loss, x.

As x increases from zero, $U(x)$ decreases from a value of $-W'$ A larger loss means a lower adjusted asset value and hence lower utility.

According to statistical studies carried out by Ramachandran [37–39], Shpilberg [40], and other authors, loss in a fire has a skewed (nonnormal) probability distribution. Ramachandran has concluded that a good fit is obtained from an exponential-type distribution applied to the logarithm, z, of fire loss size, x (i.e., $z = \log x$ follows an exponential distribution). Among distributions of this type, a normal distribution for z or a log-normal distribution for x is commonly used. An exponential distribution for z or a Pareto distribution for x has also been considered by some actuaries.

If the probability distribution function for fire loss is expressed in terms of z (= log x) instead of x, it will be computationally necessary to have a utility function expressed in terms of z as well. Ramachandran [41] has argued that z (= log x) may be used in Equation 79.12 instead of x so that the utility function is

$$U(z) = -\mathrm{e}^{\theta z} \tag{79.14}$$

which is equivalent to

$$U(x) = -x^{\theta} \tag{79.15}$$

The utility function in Equation 79.15 is a decreasing function with $\theta = 1$ representing risk neutrality. The value of θ should be greater than unity to express a risk averse attitude. The degree of risk aversion increases with θ.

Consider a property worth total financial value V belonging to a risk category with fire loss x having a log-normal distribution. If μ and σ are the mean and standard deviation of z ($= \log x$), following the method described by Ramachandran [1], the certainty equivalent for the range $(0, V)$ is given by

$$\hat{x}^{\theta} = \frac{1}{G(k)} \frac{1}{\sqrt{2\Pi}\sigma} \int_{-\infty}^{\log V} \exp\left[-\frac{1}{2}\left(\frac{z-\mu}{\sigma}\right)^2\right] e^{\theta z} = \frac{G(k-\sigma\theta)}{G(k)} \exp\left(\mu\theta + \frac{\sigma^2\theta^2}{2}\right) \tag{79.16}$$

where

$$k = (\log_e V - \mu)/\sigma$$

$$G(k) = \frac{1}{\sqrt{2\pi}} \int_{\infty}^{k} \exp\left(-\frac{t^2}{2}\right)$$

$$G(k-\sigma\theta) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{k-\sigma\theta} \exp\left(-\frac{t^2}{2}\right)$$

and $G(t)$ is the standard normal distribution. The expected monetary value of the loss is given by $\theta = 1$ in Equation 79.16, because risk neutrality means utility is linearly related to loss. For a decreasing utility function (or increasing disutility function) such as Equation 79.15, the certainty equivalent, CE, is greater than the EMV.

For a property with a given level of fire protection, the CE corresponding to a given degree (θ) of risk averse attitude of the owner is the maximum insurance premium the owner will be willing to pay to meet the uncertain consequences of a fire. The CE will increase with θ; an owner more risk averse than another will be prepared to spend more money on insurance.

Both EMV and CE will decrease with increasing levels of fire protection. Hence, by adopting efficient fire protection measures, a property owner with a given degree of risk aversion can reduce the cost of the insurance premium. He or she can also obtain a further reduction in the premium by taking self-insurance for small losses.

G. Ramachandran retired in November 1988 as head of the Operations Research Section at the Fire Research Station of the United Kingdom. Since then he has been practicing as a consultant in risk evaluation and insurance. He is a visiting professor at the universities of Manchester and Leeds. His research has focused on statistical and economic problems in fire protection and actuarial techniques in fire insurance.

John R. Hall Jr. is retired from the division director for fire analysis and research of the National Fire Protection Association. He has been involved in studies of fire experience patterns and trends, models of fire risk, and studies of fire department management experiences since 1974 at NFPA, the National Bureau of Standards, the U.S. Fire Administration, and the Urban Institute.

Computer Simulation for Fire Risk Analysis

80

William G.B. Phillips and Rita F. Fahy
Revised by Douglas K. Beller

Introduction

Fire protection engineers are required to deal with complex fire scenarios that include human reactions and behavior, in addition to the physical and chemical fire processes. Operations research (OR) pioneered the application of the scientific method to the management of organized systems in which human behavior is a key element. Fire protection engineering could be defined as the application of operations research to the fire system.

Systems involving human beings are difficult to study because realistic experiments may be impossible and neither past experience nor the available data provide sufficient insight to any given fire situation. Operations research overcomes these difficulties by the use of simulation models. Simulation models are widely used in science, engineering, and mathematics to study problems that involve ordinary and partial differential equations (either overtly or implicitly). In fire science, for example, simulation models have been used to handle phenomena such as smoke movement and absorption of toxic substances. Both computational fluid dynamics (CFD) models and zone models are solved by similar techniques. These matters are dealt with elsewhere in this handbook. This chapter concentrates on the variety of procedural simulation models that may be applied to interdisciplinary systems, specifically those involving human agents and objectives.

Simulation models describe the system under study in terms of individual events of the individual components of the system [1]. In a gross sense, the simulation model of interest to fire protection practitioners can be divided into human (i.e., evacuation or egress) and physics (i.e., fire effects) components. The simulation model then combines these parts in their natural order and allows the computer to present the effect of their interaction on each other [1]. After the model is constructed, it is provided with data and run to simulate the actual operation of the system. Advances in computer software and hardware have greatly reduced the cost and simplified the use of simulation models. Recent developments in virtual reality are expected to facilitate more realistic interaction between the model and its user.

Uncertainty can be handled by introducing stochastic elements into the model. Estimates of risk can be derived from simulation models by the use of Monte Carlo techniques. Regression analysis can be applied to obtain compact expressions that can be used to measure the sensitivity of the output variables to variations in the inputs.

Types of Models

A model can represent a system as a unified and precisely definable whole, all of whose aspects are simultaneously and unambiguously accessible

for assessment. Models include pictures, diagrams, and "scale models," as well as mathematical structures.

Models can be classified as descriptive, physical, and symbolic [2]. The *descriptive model* is expressed in ordinary language and is the most common tool for decision making in science, engineering, and everyday life. Descriptive models function like metaphors. For example, the flow of smoke through a vent might be compared to the flow of water in a channel, implying that buoyancy and gravity play a similar role, albeit with a reversal of sign.

Physical models include scale models, and examples can range from basic hydraulic models of harbors and estuaries to transparent plastic models to demonstrate the flow of smoke in buildings. They make it possible to try out alternative arrangements in the search for an optimum design or strategy. Analogue models are a special type of physical model that exploits the isomorphisms that exist between different physical processes. The behavior of voltages, currents, resistance, capacitance, and inductance in an electrical circuit has many analogies with processes in heat and fluid flow and acoustic, electromagnetic, and mechanical systems.

Science and engineering depend heavily on *symbolic models* in which algebraic symbols represent the values of variables and the relationships between them. Once a model has been cast in symbolic form, the whole mathematical apparatus can be deployed to deduce additional relationships and solve equations to find optimal solutions. Symbolic models may be static or dynamic; in the latter case they specifically include a variable representing time. A very important type of dynamic model is formulated in terms of ordinary or partial differential equations. Many problems in fire science lead to models that can be expressed in the form of one or more simultaneous differential equations. Some of these have simple analytic solutions, but many interesting cases do not; for example, the partial differential equations that arise in fluid dynamics (Navier-Stokes equations). Such equations are normally solved on computers by standard numerical methods.

A *simulation model* treats the dynamic relationships that are assumed to exist in the real situation as a series of elementary operations on the appropriate variables. A simulation model is made to predict outcomes by actually executing the procedural steps with appropriate initial data and parameters. All of the components comprising a simulation model need not be contained in a single piece of software. Furthermore, as long as each procedural step is represented in the model, the model need not be entirely computer-based. This is to say that, the procedural steps associated with some components of the model may be determined using simple hand calculations. The model user then ensures that the components are constructed in the proper manner to provide the intended output. Running the model creates the prediction. The variables in a simulation may change continuously in value or take on only certain discrete values. These changes may take place at any time or only at certain times, or both. For example, a simulation of a fire incident might handle the flow of hot gases by a differential equation expressed in continuous terms, while the people would be treated as discrete individuals moving at prescribed moments in time. However, because such a model would almost certainly be implemented on a computer, the differential equations would be approximated by a difference equation for the purposes of numerical integration (a computer cannot handle "real" numbers). Therefore, the distinction between continuous simulation models and the dynamic symbolic models discussed in the previous paragraph tends to blur.

Simulation Models

A procedural simulation model is a representation of a dynamic system in which the processes or interactions bear a close resemblance or relationship to those of the specific system being simulated or studied. These models are concrete rather than abstract and may contain approximations and subjective elements. They are amenable to manipulations that would be

impossible, too expensive, or impractical to perform on the entity portrayed. The operation of the model can be studied, and properties concerning the behavior of the actual system or its subsystems can be inferred. Manipulation of a procedural model requires the acceptance of inputs and the generation of outputs that are similar or analogous to those of the system represented.

Procedural simulation is essentially a technique that involves setting up a model of a real situation and then performing experiments on the model. The idea that a computer model might partly replace experimentation is both dangerous and attractive. It is, therefore, appropriate to remember a warning given by Ackoff and Beer: [3]

> Often when an operations researcher does not understand a phenomenon which he can nevertheless describe well, he can simulate it on a computer and thus conduct experiments. These are experiments on the model on which the simulation is based, not on the system involved. The fact that a simulation may reproduce history with some accuracy does not by itself establish a correspondence of structure between the model and reality. This is true for the same reason that a straight line may have been generated by a sine function, not one that is linear.

Procedural simulation modeling has been widely applied; examples are Link (aircraft pilot) trainers, military war games, business management games, space exploration, physical models of river basins and estuaries, econometric models, electrical analogue devices, and wind-tunnel tests for aircraft. It has proved particularly useful in situations involving human intervention of one kind or another. There are great opportunities for improving the interface between the model and operator, making use of virtual reality techniques. In this way, "realistic experience" of rare events can be acquired without danger and at low cost.

Types of Simulation Models

Simulation models can be classified as either discrete or continuous. In the real world there is no such distinction, yet it is possible to model some real-world systems either discretely or continuously. In both types of simulation what is of concern are the changes in the state of the model. Continuous simulations are analogous to a stream of fluid passing through a pipe. The volume may increase or decrease, but the flow is continuous. Using the pipe analogy for discrete event simulation, the pipe could either be empty or have something traveling through it. Whether anything came out of the pipe would depend on some event occurring at the other end.

Both types of simulation can be applied to fire. As time progresses the state of a building changes continuously as the once small fire becomes larger, overwhelms the building, and eventually dies out as it runs out of fuel. The chemical processes in the fire and the physical processes that mediate the flow of heat and hot gases naturally lend themselves to the continuous type of model. On the other hand, discrete simulations are more appropriate to the strategies used to fight the fire and evacuate the building. For example, the fire is ignited and detected, fire fighters and equipment arrive, hoses are deployed, water is applied, more equipment may be called in, and so on. Similarly the occupants respond to the alarm, collect their belongings, locate their household members, and go toward the exits in a sequence of clear-cut stages.

In continuous models, changes in the variables are directly based on changes in time. The values of the variables reflect the state of the model at any particular time, and simulated time advances from one step to the next, usually in equal increments. In discrete event models, events occur as items move through the simulation. The state of the model changes only when those events occur. Simulated time advances from one event to the next (generally in unequal increments) and the mere passing of time has no direct effect.

Discrete Event Simulation Models

Discrete event simulation models are built up from several different elements. These are given

different names in different programming languages. A terminology based on *blocks, items,* and *events* will be used in this discussion. *Items* are characterized by *attributes, priorities,* and *values.*

A *block* is used to represent an action, operation, resource, or process. It is like a block in a block diagram. These blocks are connected in an activity or data flow diagram that represents the system. Information comes into the block and is processed by the program that is in the block. The block then transmits information out of the block to the next block in the simulation. Some blocks may simply represent a source of information that is passed on to other blocks. Other blocks may modify information as it passes through them. Output blocks take information from the simulation and present it to the user in graphic form.

The basic unit passed between the blocks is called an *item.* An item is a data set that carries information about the item's attributes, priorities, and values. In a manufacturing model, an item might be a part on an assembly line; in a network model, an item would be a packet of information; in an evacuation model, an item would be an occupant. Items are generated by special blocks, either according to a fixed schedule or a random distribution.

The model moves items from block to block only when an *event* occurs. Events occur only when specific blocks specify that they should. For example:

1. Blocks that depend on time cause events to happen at an appropriate time. For example, a block representing an activity, say the journey from the fire station to the fire location, might introduce a delay of t min into the system representing the duration of the journey. If the alarm was received by the fire station at T min, the block would post an event in the event queue at $T + t$ min.
2. Blocks that have an accumulated demand for inputs cause an event immediately after they receive items. For example, a block representing a parent searching for a child, following a fire alarm, would cause an event when the child is located.
3. Blocks that do not generate events allow the blocks after them to pull items during a single event. Thus, an item can pass through many blocks after a single event if those blocks do not stop it.

Note that every event has the potential to cause every block in a model to move items. Thus, one event may cause many unrelated items to progress in the simulation.

In order to provide true discrete event simulation, the time clock that controls the simulation must move to the exact time of each event. The most common way of doing this is to have an event queue. Each block places the time of its next event in a slot in the event queue. In each cycle the event queue is checked to find the next closest time point; the current time is set to that value, and a "simulate" message is sent to every block. Most blocks ignore these messages unless the message occurs at the event time that was previously posted by the block, or there are items waiting in the block's inputs that can be pulled in. For example, a block representing a queue should pull in an available item whenever it gets a "simulate" message, no matter which block posted the event.

Attributes are an important aspect of discrete event simulation. Attributes are characteristic properties of an item that stay with it as it moves through the simulation. For example, an occupant making an escape from a building might have attributes representing mobility and the amount of carbon monoxide absorbed. *Priorities* specify the relative importance of an item. *Values* allow the model to deal with items that represent groups of identical entities.

Continuous Simulation Models

There is a close similarity between continuous simulation models and the solution of ordinary differential equations by numerical methods. Almost any phenomenon that can be represented by differential equations may be modeled by continuous simulation. This classification includes virtually the whole of classical physics,

and the method can easily be extended to chemistry and biology, and more speculatively to economics, ecology, and human behavior. The fundamental principle is that the rate of change of certain variables can be expressed as a function of a set of variables (the state variables) that describe the state of the system at a given time. Therefore,

$$\frac{dx_i}{dt} = f(x_1 \ldots x_i \ldots x_n), i = 1 \ldots n$$

The solution to this set of equations is found by integration and yields a function that depends on time, which characterizes the dynamic behavior of the system. For example, suppose the rate at which a chemical reagent is consumed is proportional to the concentration of the reagent. This relationship could be expressed in the form of a differential equation, with the following solution:

$$\frac{dx}{dt} = -kx$$

and, therefore,

$$x = Ae^{-kt}$$

This result can be interpreted to mean that the concentration declines exponentially and tends toward zero as the reaction proceeds. Note that the result is a function of time and not concentration. This example leads to a first-order linear differential equation that has an analytic solution. Many systems of interest, however, give rise to higher order nonlinear differential equations, which, in general, do not have analytic solutions or have solutions only if drastic simplifications are imposed. Their solution is normally carried out on computers using one of the standard numerical methods (e.g., Euler, Runge-Kutta). Higher order differential equations can lead to very complex dynamic behavior, for example, various types of oscillation. (It is useful to note that differential equations of an order above the first can always be replaced by one or more first-order simultaneous differential equations).

For a computer to handle a differential equation expressed in continuous terms, the equation has to be replaced by an equivalent difference equation. Consider the following differential equation that shows that the rate of change in volume is equal to flow.

$$\frac{d(\text{volume})}{dt} = \text{flow}$$

This equation has an analytic solution that can be found by integration; that is,

$$\text{volume} = \int_{t=\text{start}}^{t=\text{stop}} \text{flow} \cdot dt$$

The original differential equation can be written as a difference equation:

$$\frac{\text{volume}_t - \text{volume}_{t-\Delta t}}{\Delta t} = \text{flow}$$

which can be rearranged to show that

$$\text{volume}_t = \text{volume}_{t-\Delta} + \Delta t \cdot \text{flow}$$

This equation implies that the value of volume at time t is simply the sum of the value of volume at time $t - \Delta t$ plus the time interval Δt multiplied by flow. This solution (which amounts to Euler's method) can be implemented directly on a computer. Note that the analytic integral solution and the finite difference method will give the same result only if flow is constant. If flow is changing rapidly, the finite difference method will require a large number of iterations (i.e., $\Delta t \to 0$) to converge to the analytic integral solution.

Continuous simulation models are particularly suited to the analysis of dynamic processes. Frequently, the system under examination will display a particular behavior pattern that may be interesting in itself or may be causing a problem. The objective of the model designer is then to construct a model based on differential equations that will reproduce this reference pattern. Decisions need to be made as to which state variables and rates of change are significant. If the model is being used to address some well-understood phenomena, it may be possible to use established relationships that have been tested by experiment. Otherwise, it may be necessary to introduce parameters into the model that lack theoretical backing but enable the model to exhibit the reference behavior either qualitatively or quantitatively.

The overall behavior of the model often depends not as much on the precise value of the parameters and the detailed algebra as on the structure of the model itself. Systems of simultaneous differential equations can usually be shown to be linked together in longer or shorter loops that can be of either positive or negative sign. Positive feedback loops tend to reinforce change and often give rise to exponential growth. Negative feedback loops tend to negate change and are usually associated with goal-seeking activity.

Model building can be thought of as passing through a sequence of iterations in which the model becomes more and more realistic. At each iteration the model designer makes observations, forms hypotheses, carries out tests, modifies the model, and tests the model again. The advantage of working within this framework is that simulation models can be objective and explicit rather than subjective and implicit. These characteristics make them particularly valuable for (1) communicating results and (2) acting as a workbench on which alternative solutions to problems can be tested.

Monte Carlo Procedures

Monte Carlo analysis is a simulation technique applicable to problems having a stochastic or probabilistic basis. Two different types of problems give rise to the use of this technique. Firstly, there are those problems that involve some kind of stochastic process. The rate of flame spread and fire growth and the response of individuals to fire alarms are examples of variables that may be considered to be stochastic in nature. In this case, the stochastic element may be introduced at any point in the model run so that the value of a variable at any time depends in some way on its previous value and a random component. Second, there are problems in which the process is treated as deterministic, but the starting conditions and model parameters are randomly selected from probability distributions.

The model may be used simply to estimate the value of the endogenous variables at a given location and time. The estimate will, of course, depend on the values of the parameters supplied to the model. However, the exact value of a parameter may not be known, but it might be possible to estimate its mean and variance and the form of its distribution. This information can be encoded as a probability density. A sequence of runs of the model can then be carried out using samples drawn from this distribution. Methods have been developed for generating values from most of the well-known probability distributions as well as any empirical distribution (For details see Appendix A of this chapter.). It is then possible to estimate probability densities representing, for example, the fire conditions or the number of casualties from the model output. If sensitivity analysis shows that the uncertainty in the input has little effect on the uncertainty in the output, it would not be necessary to go to great expense to refine the value of the input parameter.

Everything said so far about Monte Carlo methods has been on the assumption that there is only one input variable and one output variable. This assumption can now be relaxed so that all the uncertain input parameters can be treated as random samples from probability densities. The probability density of the output variables is now generated by the probability densities of all the input variables. This function is important because it allows analysis of synergistic effects in which certain combinations of symmetrically distributed input variables can give rise to strongly skewed distributions of the output variables. Distributions of this type are typical of multiplicative stochastic processes. Probability distributions of fire damage are frequently skewed and can often be described by a density of the log-normal variety with a pronounced right-hand tail [4]. This result may be due to the simultaneous occurrence of several adverse factors which tend to reinforce each other due to nonlinearities in the system.

The input parameters can be interpreted as exogenous variables and the model outputs as endogenous variables. This approach suggests that it would be possible to regress the outputs on the inputs using a standard multiple linear regression routine. This method is equivalent to

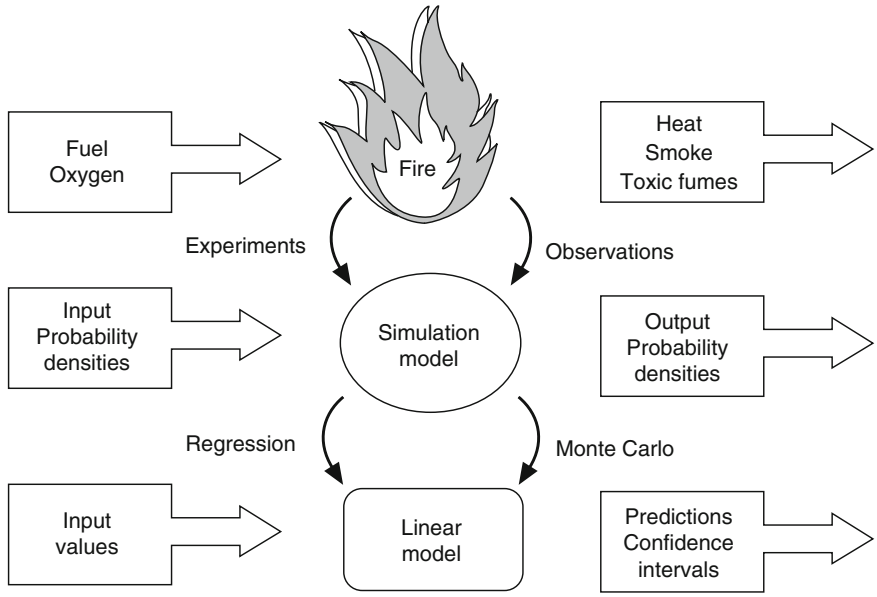

Fig. 80.1 Relationships between observations and models [5]

creating a linear model of the nonlinear simulation model. The relationships between the actual fire, the simulation model, and the linear approximation to the simulation model are shown in Fig. 80.1 [5].

It can be shown [6] that the resulting regression coefficients correspond to the partial differential coefficients (i.e., the rate of change of an endogenous variable, y, with respect to each of the exogenous variables, x).

Sensitivity Analysis

Sensitivity analysis can be used to draw useful conclusions to guide decisions on fire safety design and priorities for research. In its simplest form, sensitivity analysis is carried out by varying one of the input parameters in steps over a prescribed range and observing the effect on chosen output parameters, either at the end of the model run or at a set time after the run commences. (Advanced methods of sensitivity analysis are available that allow more than one variable to be varied at a time.) The results of this exercise can then be presented as a table or, more usefully, the output parameter can be regressed against the input parameters to give a simple linear or nonlinear expression that summarizes the results and permits interpolation and extrapolation.

The rate of change of the output parameter, with respect to the input parameter, is defined as the *sensitivity*. In fire safety terms, sensitivity might indicate how much the risk is reduced as fire protection measures are improved. If the cost of improved protection is also known, it is possible to estimate the cost of saving a life.

Figure 80.2 shows five runs of an evacuation model in which the delay in giving the fire alarm has been increased in steps of 1 min, from 6 to 10 min. The number of people trapped in a building at, for example, 18 min is represented by the distances between the curves and the horizontal axis. If the number of casualties is regressed against the delay, the results shown in Fig. 80.3 are obtained. The number of casualties that would occur if the alarm were delayed by t minutes can be calculated directly from the formula. Conversely, the formula can be used to predict the number of lives that might be saved if the delay were reduced by, for example, an improved alarm system. Note that in this case,

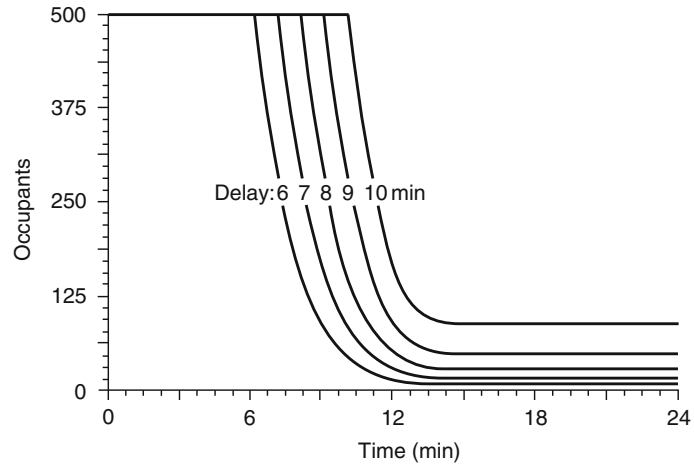

Fig. 80.2 Occupants remaining in a place of assembly if the alarm is delayed for the periods shown

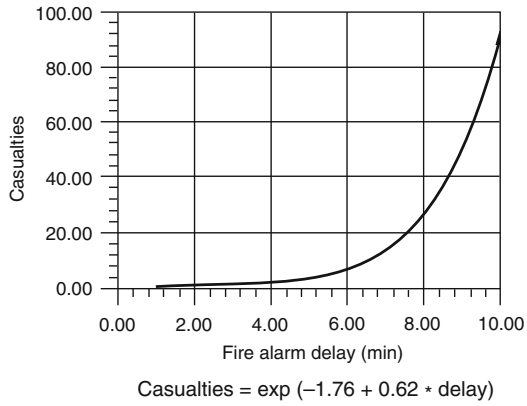

Fig. 80.3 The number of casualties rises exponentially as the delay in giving the signal to evacuate is increased

the sensitivity is not a constant, but an exponential function of time.

A similar exercise can be undertaken for fire effects models. Ideally, every input parameter that is based on an assumption should be the subject of a sensitivity analysis. After establishing a base case, the user should vary the "assumed" input parameter values by ± 10 % and observe what effect this change has on the output variable of interest. If the predicted output value varies by less than ± 10 %, then the output variable is insensitive to that input variable. Conversely, if the predicted output value varies by more than ± 10 %, then the output variable is sensitive to the input variable in question. The more sensitive input parameters may require further investigation depending on their degree of sensitivity.

The significance of calculations like these is that they enable designers to select those areas where expenditure on fire protection measures would earn the greatest return in terms of lives saved. It also makes it possible to identify those areas where additional expenditure might have little or no effect. This approach is also helpful for making decisions on research priorities. If preliminary calculations indicate that the fire risk can be substantially reduced by a small change in a parameter, it would make sense to put research effort into investigations designed to refine the measurement of that parameter and reduce the level of uncertainty associated with it.

Sensitivity analysis makes it possible to place the tools of fire protection engineering in the hands of designers and other users who might not have the time or the inclination to work directly with a simulation model. The results of the analysis could be published as tables or graphs in manuals for the guidance of draftspersons who would not need to know in detail how the figures were derived. It is vital to ensure that figures are not applied outside their range of application. This criterion implies that the work must be verified by a fully qualified professional who would check that the guidance was appropriate to the circumstances. Similar

problems of professional self-regulation have been successfully resolved in other disciplines.

Applications

There are not many fully developed applications of procedural simulation models to fire protection engineering. For example, CRISP II would certainly qualify, while FIRE STATION is not a complete system model because it ignores the interactions between the fire and the occupants. FIRE STATION might be better described as an OR simulation model. Suites or collections of applications are also available.

CRISP II (Computation of Risk Indices by Simulation Procedures) [7]

Simulation models can be used to compensate for lack of information about "real" fires and to work out the fire risk implications of new materials, building designs, and protection systems. A fire risk assessment model called CRISP II was developed at the Fire Research Station of the United Kingdom to decide priorities for remedial action and to test the validity of new guidelines for building control officers. CRISP II is a Monte Carlo simulation of an entire fire scenario. The model consists essentially of a two-zone model of smoke flow for multiple rooms and a detailed model of human behavior and movement, supervised by a Monte Carlo controller. Its component submodels, which include rooms, doors, windows, detectors and alarms, items of furniture, hot smoke layers, and people, run simultaneously so they can continually interact with each other. The model is capable of generating a rich variety of fully interactive behavior patterns. It calculates the fractional effective dose (FED) for occupants as they move through the building and are exposed to smoke. When an occupant's FED reaches 100 %, that person is considered dead. CRISP II expresses the fire risk of a building design in terms of the number of deaths predicted over a large number of simulations.

FIRE STATION [8], Optimum Fire Station Location for Minimum Loss of Life and Property

The FIRE STATION model determines the optimum location, among five alternate sites, for an urban fire station in a community of 25 wards. Optimization is the minimization of lives lost, building damage, and capital outlay. The model generates a sample population from an observed distribution by ward, structure value, and relative population density. The travel time from the station to the fire is also chosen from an observed distribution. The amount of damage and the number of lives lost is then calculated with reference to the delay in reaching the fire, which depends on the travel time.

Suites or Collections of Fire Protection Computer-Simulated Procedures

Computer models can also be packaged in an integrated set or suite of models that are linked but do not interact as directly as do the modules of CRISP II. Independent models can also be used sequentially, as will be described below. Two examples of integrated suites of computer models are HAZARD I [9] and FiRECAM [10].

HAZARD I is a fire hazard assessment method that is comprised of four distinct computer models: (1) FAST [11], a multicompartment energy and mass transport model; (2) DETACT [12], a detector/sprinkler activation model; (3) EXITT [13], a human decision/behavior evacuation model; and (4) TENAB [9], a tenability model that considers incapacitation and lethality from temperature and toxicity. Figure 80.4 illustrates how these, and other, software modules are organized. Figure 80.4 follows the progress of a hypothetical scenario entitled "CASE" and shows why HAZARD I is a semiautomatic simulation model.

HAZARD I can model up to 15 compartments on multiple floors of a building. Like all zone models, HAZARD I is applicable to spaces with the dimensions of normal-size rooms with conventional contents. The egress component,

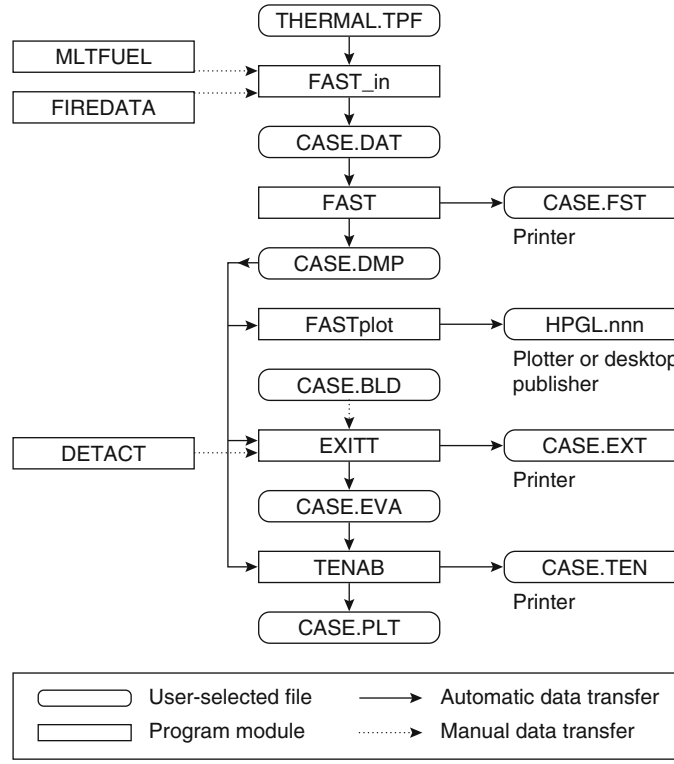

Fig. 80.4 HAZARD I software

however, is based on data from fires in one- and two-family dwellings, and the dynamics of family groups.

The method guides the user to identify the fire problems of concern and then to specify representative fire scenarios. The user then employs a computer software package to predict the outcome of each of the identified scenarios in considerable detail. The software predicts over time the temperature, smoke, and fire-gas concentrations in each room of the building; the behavior and movement of the building occupants as they interact with the fire, the building, and each other; and the impact of exposure of each occupant to the fire-generated environment. The occupant exposures are presented as a prediction of successful escape, physical incapacitation, or death along with time, location, and cause. By accounting for the interactions of a large array of factors on the result of a given fire scenario, the method enables the user to analyze the impact of changes in the fire performance of products, building design and arrangement, or of the inherent capabilities of occupants in the likely outcome of fires. With such information it should be possible to provide better, more cost-effective strategies for reducing fire losses. An overview of the process used by HAZARD I is shown in Fig. 80.5.

FiRECAM (Fire Risk Evaluation and Cost Assessment Model) consists of submodels that are run in sequence to assess the fire safety performance of a building design in terms of expected risk to life and expected cost of fire. These submodels include a building and risk evaluation model, a fire department response model, a boundary element failure model, an economic model, a design fire model, a fire growth model, a smoke movement model, an occupant response model, a fire department effectiveness model, an evacuation model, a smoke hazard model, a fire spread model, a life loss probability model, a property loss model, an expected number of deaths model, an expected risk to life model, and a fire cost expectation model. FiRECAM has been used to assess

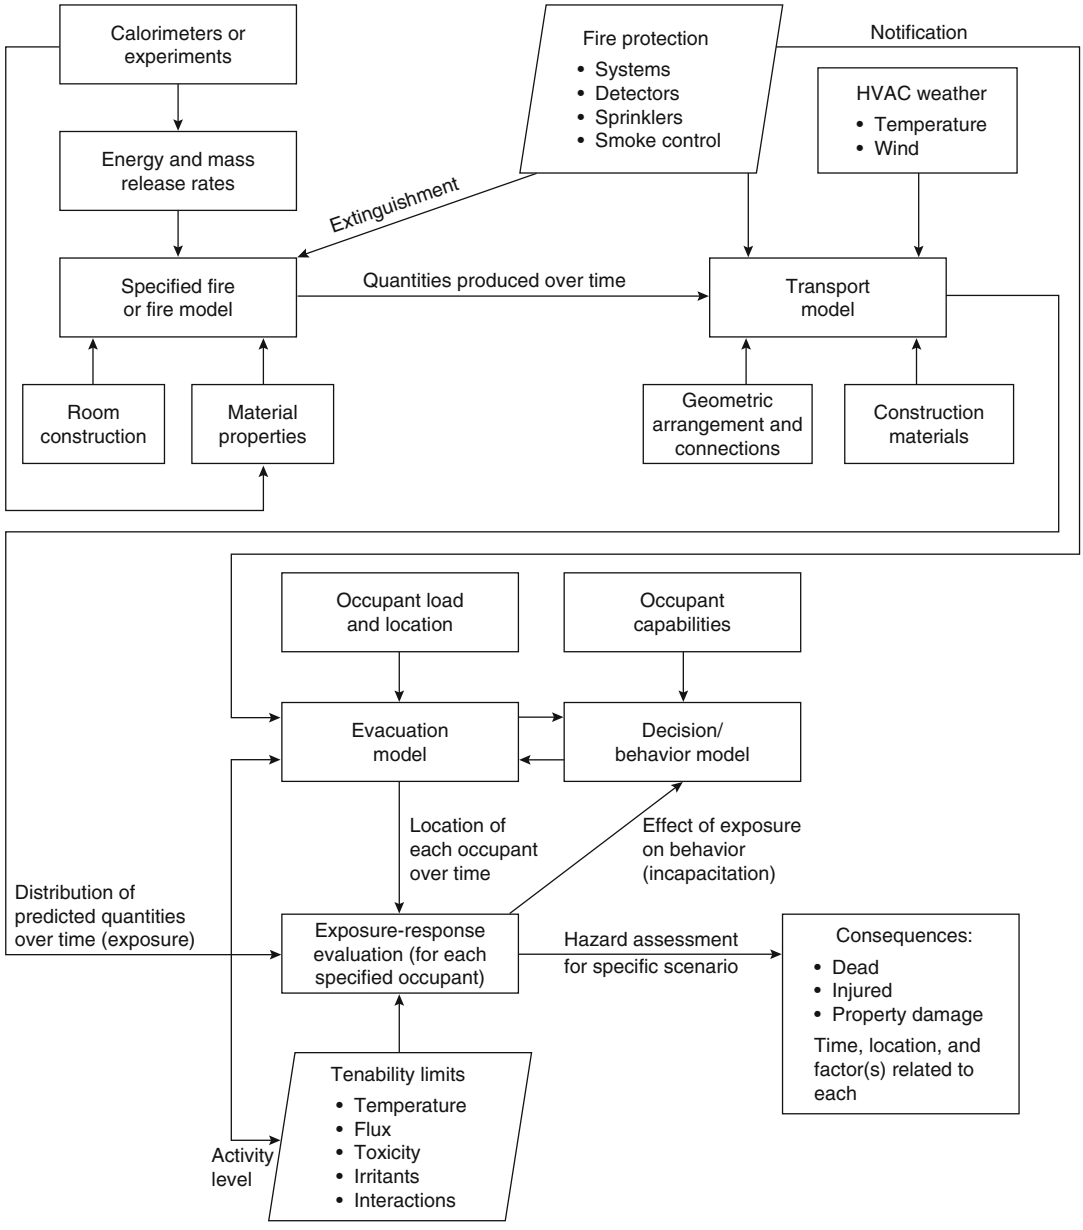

Fig. 80.5 Interrelationships of major components of a fire hazard model

whether a proposed design meets the requirements of a performance-based code and can determine whether the design is cost effective.

HAZARD I and FiRECAM are examples of methods that link a variety of computer models in such a way that the output from one model can be used directly as the input for the next. It is also possible for the fire protection engineer to use independent models in sequence. There are available collections of programs that cover different aspects of fire technology and science that are components of fire protection simulation models. For example, these collections contain individual programs that predict gas temperatures, heat fluxes on objects, activation of devices, and some aspects of human behavior or evacuation.

These collections do not tend to be comprehensive in nature in that the individual programs are independent of other programs in the collection. Therefore, these programs must be run sequentially and data manually transferred between programs. Although less sophisticated and more cumbersome than the integrated simulation models, these models have their uses and may be adequate in some cases. Two advantages of these collections of programs are that they offer the user a significant amount of control over the input to any given component, and they lend themselves to being run many times. This latter point is important when the user wishes to characterize a single component. By running the component program many times the user can adequately define the probabilistic nature of the component in question. Examples of these collections include FPEtool [14] and FireCalc [15].

The fire protection engineer can also evaluate a design by combining more specialized standalone models of the individual components of interest, for example, a human behavior or egress model with a fire effects model. This approach to simulation modeling, while more cumbersome (because it requires more user intervention), may also be more effective because it allows the user greater control over the process as well as the use of more sophisticated models.

In this approach, the fire effects model would be run independently of the human behavior or egress model. This approach would facilitate analyzing a number of fire scenarios and choosing the ones that most closely reflect the expected conditions. The human behavior or egress model could also be run for a number of conditions and assumptions. The user would then go through the exercise of comparing the predicted output from the two component models and arriving at the final answer.

A number of human behavior or egress models and fire effects models are available that can be used in tandem to perform fire protection simulation modeling. (Space does not permit an attempt to list all models known to the authors, but compendia have been developed [16, 17] and are updated regularly to reflect the state of the art. See http://www.firemodelsurvey.com). Given the predicted fire effects obtained from a fire model and the predicted locations of occupants from an evacuation model, the designer or engineer could then use a toxicity model, either a computer model or one of the available calculation methods, to predict the cumulative exposure of the occupants as they move through the modeled fire environment.

Model Validation

Simulation models can never be validated over the whole range of their behavior. However, confidence in the reliability of a model is enhanced if the relationships built into it are based on accepted scientific theory supported by experimental evidence. The model must also stand up to tests designed to show it behaves reasonably in response to exogenous disturbance. The calibrated model should also be able to simulate time-series data from instrumented experimental fires. Finally, the model should be able to mimic the sequence of events recorded by observers at real fires.

Like other models, the validity of simulation models depends on goodness of fit and predictive power. In the fire situation, deterministic predictions are not feasible except in very simple cases. In a typical case, a simulation model would be calibrated to produce an output distribution whose mean and variance were in agreement with an observed distribution. Changes in fire protection strategy would be reflected in the model, which would then be used to generate a new output distribution with a different mean and variance. Comparisons between the output distributions before and after implementing the strategy can be used to calculate confidence intervals for statements such as "if strategy B is preferred to A, casualties will be reduced in x percent of cases." Statistical predictions of this kind are quite sufficient for the purposes of fire protection engineering.

Models undergo limited validation; that is, they are applicable to the experimental results they are based on and/or the limited set of

scenarios to which the model developers compared the model's output. The Society of Fire Protection Engineers formed a task group to independently evaluate computer models. They have completed and published an evaluation of DETACT-QS. Guides exist for the validation and verification of computer models [18]. Until more models can be independently evaluated, the model user must rely on the available documentation and previous experience for guidance regarding the appropriate use of a given model. By choosing a specific model, the user is tacitly assuming that the model is valid for the scenario under consideration.

Summary

Overall, progress in fire protection engineering is handicapped by data limitations and the difficulty of conducting realistic experiments on complete fire systems involving human behavior; although efforts in the collection of the data on human behavior have intensified over the past several years, particularly in the areas of occupant characteristics and premovement delay times [19–30]. These problems may be overcome by applying a variety of procedural simulation models originally developed in operations research. These models make efficient use of the available data and can be used to test fire protection strategies. They can be complemented by Monte Carlo methods to take account of uncertainty in the data, measure the sensitivity of the casualty rate to fire protection measures, and estimate fire risk.

Appendix A: Handling Uncertainty

Generating Random Numbers

In order to introduce a stochastic element into simulation modeling, a source of random numbers is required. Virtually every computer is equipped with a subroutine that can generate a pseudo-random number in the interval [0, 1] on demand. These are not truly random numbers because they are generated by a deterministic algorithm that will repeat itself cyclically after an interval. The algorithm is designed to make this interval as long as possible given the capacity of the computer. A variety of methods, most of which are based on congruence relationships, are discussed by Naylor et al. [31]

Generating Probability Distributions for Monte Carlo Studies

The generation of simulated statistics is entirely of a numerical nature and is carried out by supplying pseudo-random numbers into the process or system under study and obtaining probability distributions from it as the result. As a rule, statistical simulation involves replacing an actual sample population by some assumed theoretical distribution and then sampling from this theoretical population by means of some type of random number generator. In some cases it may not be possible to find a standard theoretical distribution that describes a particular stochastic process. In these cases the process can be simulated by sampling from an empirical distribution rather than a theoretical one. Naylor et al. [31] provide specific techniques for generating variates from several of the widely used probability distributions as well as general methods for generating variates from empirical distributions.

Inverse Transformation Method This method depends on the relationship between the probability density function (pdf) and the cumulative distribution function (cdf). The pdf gives the probability that the variate x lies between x and $x + dx$. The cdf gives the probability that $x \leq x$. The cdf $F(x)$ is obtained from the pdf $f(x)$ by integrating $f(x)dx$ over the interval from—∞ to x.

To generate variates x_i from some particular statistical population whose pdf is given by $f(x)$, one must first obtain the cdf $F(x)$. Since $F(x)$ is defined over the range [0, 1], one can generate uniformly distributed random numbers and set $F(x) = r$. It is clear that x is uniquely determined by $r + F(x)$. It follows that for any particular value of r, say r_0, that is generated, it is possible

to find the value of x, in this case x_0 corresponding to r_0 by the inverse function, if it is known. That is,

$$x_0 = F^{-1}(r_0)$$

where $F^{-1}(r)$ is the inverse transformation or mapping of r on the unit interval into the domain of x.

Example 1 Generate variates x with pdf $f(x) + 2x$, $0 \leq x \leq 1$.

Solution

$$\begin{aligned} r = F(x) &= \int_{-\infty}^{x} f(t)dt \\ &= \int_{0}^{x} 2tdt \quad 0 \leq x \leq 1 \\ &= x^z \end{aligned}$$

Then taking the inverse transformation, $F^{-1}(r)$, that is, solving this equation for x, one obtains

$$x = F^{-1}(r) = \sqrt{r} \quad 0 \leq r \leq 1$$

Therefore, values of x with pdf $f(x) = 2x$ can be generated by taking the square root of random numbers r.

Example 2 Generate a variate x with density function

$$\begin{aligned} f(x) &= \frac{1}{4} \quad 0 \leq x < 1 \\ &= \frac{3}{4} \quad 1 \leq x < 2 \end{aligned}$$

Solution The pdf and cdf are illustrated graphically in Fig. 80.6. Using the previous results

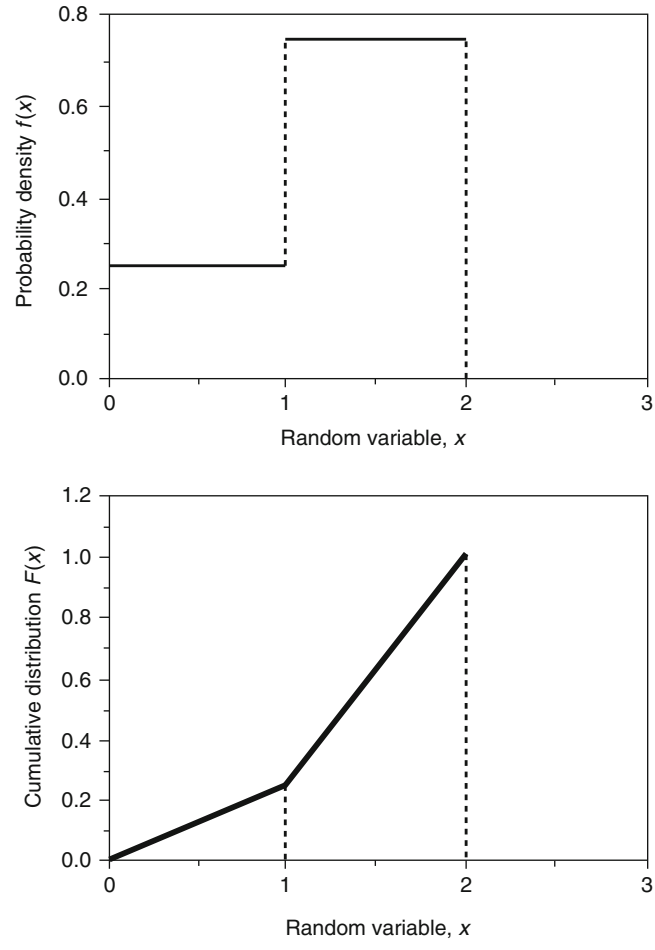

Fig. 80.6 Probability density function (*top*) and cumulative distribution (*bottom*) for empirical data

$$r = F(x) = \int_0^x \frac{1}{4}dt \quad 0 \le x < 1 = \frac{x}{4}$$

$$r = F(x) = \frac{1}{4} + \int_1^x \frac{3}{4}dt \quad 0 \le x \le 2$$

$$= \frac{3}{4}x - \frac{1}{2}$$

Taking the inverse transformation, that is, solving the above equations for x, one obtains

$$x = 4r \qquad 0 \le r < \frac{1}{4}$$

$$x = \frac{4}{3}r + \frac{2}{3} \quad \frac{1}{4} \le r \le 1$$

The Rejection Method In many cases it is either impossible or very difficult to express x in terms of the inverse transformation of the probability distribution, $F^{-1}(r)$. In these cases it is necessary to obtain a numerical approximation to the inverse function, F^{-1}, or make use of the rejection method. The application of the rejection method requires the following steps:

1. Normalize the range of f by a scale factor, c, such that

$$cf(x) \le 1 \quad a \le x \le b$$

2. Define x as a linear function of r

$$x = a + (b - a)r$$

3. Generate pairs of random numbers (r_1, r_2)
4. Whenever one encounters a pair of random numbers that satisfy the relationship

$$r_2 \le cf[a + (b - a)r_1]$$

then "accept" the pair and use $x + a + (b - a)r_1$ as the variate generated.

The theory behind this method is based on the realization that the probability of r being less than or equal to cf(x) is

$$P[\mathrm{r} \le cf(x)] = cf(x)$$

Consequently if x is chosen at random from the range $[a, b]$ according to Step 2 above and then rejected if $r >$ cf(x), the probability density function of accepted x will be exactly $f(x)$. It can be shown [32] that the expected number of trials before a successful pair is found is equal to $1/c$. This result implies that the method may be quite inefficient for certain probability density functions. The rejection method can also be used as a Monte Carlo technique to evaluate definite integrals. This application may be particularly useful for the evaluation of multivariate functions.

Example 3 Use the rejection method to generate variates x with density function $f(x) = 6(x - x^2)$, where $0 \le x \le 1$.

Solution Since x was defined over the unit interval, $x = r$. But $f(r) = 6(r - r^2)$ is defined over the interval $0 \le f(r) \le 1.5$. Scaling will transform $f(r)$ to the unit interval if $g(r) = 2/3f(r)$, in which case $g(r) = 4(r - r^2)$. The rejection method then consists of the following four steps:

1. Generate r_1 and calculate $g(r_1)$.
2. Generate r_2 and compare with $g(r_1)$.
3. If $r_2 \le g(r_1)$, accept r_1 as x from $f(x)$. If $r_2 > g(r_1)$, then reject r_1 and repeat Step 1.
4. Repeat this procedure until n values of x have been generated.

A comparison between the theoretical distribution and the distribution obtained by using the rejection method is shown in Fig. 80.7.

Example 4 Generate a variate with a normal distribution.

Solution If a random variable x has a pdf $f(x)$ given as

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2}, \quad -\infty < x < \infty$$

it is said to have a normal or Gaussian distribution with parameters μ and σ.The graph of this function is the familiar bell-shaped curve. The cdf $F(x)$ does not exist in explicit form and, therefore, the inverse transformation method cannot be applied. There are several ways to avoid this difficulty, which are fully described in the literature. However, it is useful to include here a method for generating variates from a normal distribution, because data with this type of distribution is so widely encountered in practice.

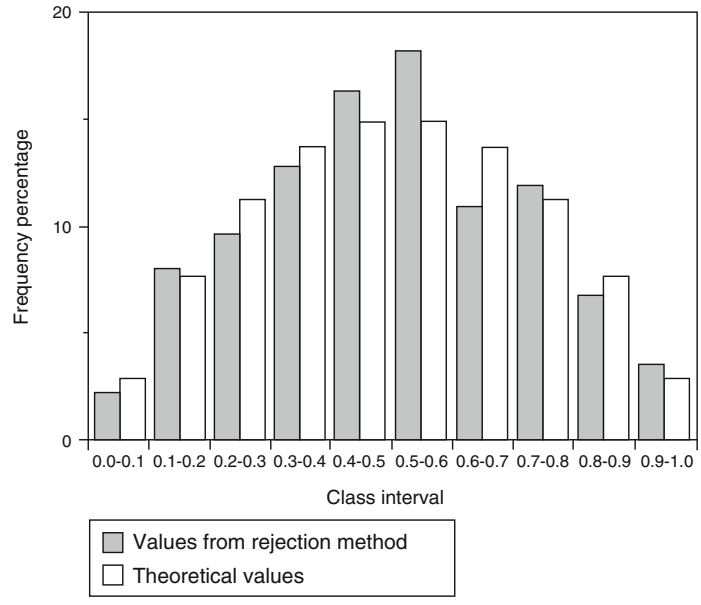

Fig. 80.7 Generating a sample from a quadratic pdf using the rejection method

Let r_1 and r_2 be two uniformly distributed random variables defined on the interval [0, 1]. Then

$$x_1 = (-2\log_e r_1)^{1/2} \cos 2\pi r_2$$

$$x_2 = (-2\log_e r_1)^{1/2} \sin 2\pi r_2$$

are two variates from a standard normal distribution. This method produces exact results and is quite fast, subject to the efficiency of the special function subroutines [33].

Appendix B: Analysis of Model Output

Local Linearization

Suppose that at a given time, *t,* the output variables are dependent on the input variables of the model, according to a set of functions:

$$y_i = f_i(x_1, x_2, \ldots, x_n); \quad \mathrm{i} = 1, \ \ldots, n$$

Then, in the neighborhood of x_1, x_2, . . ., x_n, one can make a local linear approximation to y_i by expanding $f_i(x_1 + \Delta x_1, x_2 + \Delta x_2, \ldots, x_n + \Delta x_n)$ as a Taylor series about $f_i(x_1, x_2, \ldots, x_n)$ and then truncating all terms after the second. The Taylor series expansion of the *i*th variable is

$$y_i = f_i(x_1 + \Delta x_1, x_2 + \Delta x_2, \ \ldots, \ x_n + \Delta x_n)$$

$$\therefore y_i = f_i(x_1, x_2, \ldots, x_n) + \sum_j \Delta x_j \frac{\partial y_i}{\partial x_j}$$

$$+ \frac{1}{2!}\left(\sum_j \Delta x_j^2 \frac{\partial^2 y_i}{\partial x_j^2} + 2 \sum_{j \neq k} \sum_k \Delta x_j \Delta x_k \frac{\partial^2 y_i}{\partial x_j \partial x_k} \right)$$

$$+ \ldots . \therefore \Delta y i \cong \sum_j \Delta x_j \frac{\partial y_i}{\partial x_j}; \quad i = 1, \ldots, n$$

provided that Δx_j is small. It is more convenient to express this in matrix notation:

$$\Delta y = A \Delta x$$

where A is the Jacobian for the *y*s, that is,

$$a_{ij} = \frac{\partial y_i}{\partial x_j}$$

Note that, if S is the variance-covariance matrix for the *x*s, then V is the variance-covariance matrix for the *y*s and is given by

$$\mathrm{V} = \mathrm{A}'\mathrm{SA}$$

Additivity of Variances

It can often be shown that a model is stable, with respect to variations in any one of its input variables taken one at a time. However, it is

possible that, if more than one variable were allowed to change simultaneously, the variance of the sum would be greater than the sum of the variances. This result would imply that the interaction or covariance term could not be ignored. However, if the regression procedure establishes that the linear hypothesis is valid, then the variance of the output is equal to the sum of the variances of the inputs weighted by the squares of the coefficients. Note, however, that the linear hypothesis will probably hold only over a limited range, and can be estimated by examining a plot of the residuals.

If it is established that the linear hypothesis holds over a certain range, that is,

$$y = a_0 + a_1x_1 + a_2x_2 + \cdots + a_nx_n$$

and if $x_1, \ldots, x_n$ are random variables, then

$$\operatorname{var}(a_0 + a_1x_1 + a_2x_2 + \cdots + a_nx_n) = \sum_i a_i^2 \operatorname{var}(x_i) + \sum_i \sum_j a_i a_j \operatorname{cov}(x_i, x_j)$$

The variables $x_1, \ldots, x_n$ have been generated so as to be independent, which implies that the covariance term vanishes, and, therefore,

$$\operatorname{var}(y) = \sum_i a_i^2 \operatorname{var}(x_i)$$

The regression model can, therefore, be used to predict the variance of a dependent variable on any assumptions that are chosen about the variances of the independent variables.

If it turned out that the contribution of one variable to the total variance were large, it would be desirable to undertake further studies to establish more exact values for this parameter. A smaller variance could then be assigned to this variable, and one could immediately deduce how much effect this would have on the uncertainty in the dependent variable, without having to carry out any further Monte Carlo runs. Within limits there is no need to be too particular about the variances ascribed to the independent variables in the preliminary studies, since these can be revised at a later date. It is necessary to make a distinction between (1) parameters that have a large variance due to measurement uncertainties (which can be improved), and (2) parameters drawn from populations having a large variance (where further measurement may reduce the uncertainty of the variance but not the variance itself).

Appendix C: Monte Carlo Simulation Example

Introduction

Because of the nature of a Monte Carlo simulation providing a real world, step by step example is prohibitive. Instead, an outline of the procedure is provided below. This procedure is meant to be universal and can be used with computer fire models other than the ones discussed in this example.

Monte Carlo simulation consists of the following steps:

1. Define a domain of possible inputs.
2. Generate inputs randomly from a probability distribution over the domain.
3. Perform a deterministic computation on the inputs.
4. Aggregate the results.

The first step identifies the random variables of interest in the given problem. The second step involves drawing a random sample from each of the previously identified random variables. The third step is where all of the calculations are performed and the results stored. Steps 2 and 3 are repeated a "large" number of times (i.e., n), typically anywhere from 1000 up to 10,000 times. In step 4, the results are analyzed using various tools: histograms, summary statistics, confidence intervals, etc.

The life safety of occupants is of paramount importance in fire scenarios. Typically, this "fire problem" can be viewed as a race between the time when the toxic effects of a fire may be experienced by a given occupant and the time required for that occupant to reach a point of safety; specifically, the available safe egress time (ASET) and the required safe egress time (RSET). Both of these variables have the units of time and are functions of other variables as

detailed in other sections of this handbook. ASET has three input variables whose values are not fixed by room geometry (heat loss fraction, fire radiation fraction, height of base of flames) and RSET has six input variables which may be considered randomly distributed (travel speed on level routes, vertical travel speed on stairs, flow rate through doors, flow rate on stairway, population, speed of slowest evacuee).

In this fire problem, the goal of a Monte Carlo simulation would be to determine the probability that occupants will safely evacuate a fire scenario, i.e., p(ASET $>$ RSET).

Setup

There are at least two possible ways to accomplish step 1 of a Monte Carlo simulation for determining whether occupants may safely evacuate a fire scenario. The domain of possible inputs could be either the values of variables that comprise ASET and RSET or the domain could be values of ASET and RSET. When considering the first possibility, each of the variables for ASET and RSET discussed above are assumed to be described by some kind of distribution. Using ASET as an example:

1. ASET may be simulated using the high, low, and most likely values of each variable; or,
2. A simulation could be generated by assuming each input variable has a uniform distribution.

Instead of defining or assuming a distribution for individual variables that constitute ASET, one may assume, a priori, that ASET has a known distribution, e.g., log-normal, based on available data or other calculations. One way of doing this calculation is to use "best guess" values of the input variables for ASET. The resulting value of ASET is then assumed to be the mean of a log normal distribution. A value for the standard deviation is then assumed.

The domain of possible RSET inputs would then be determined as described above; either define distributions for the RSET input variables or a distribution for RSET itself.

Analysis

If the input variables of ASET and RSET are defined as distributions, then these distributions are randomly sampled n times as indicated above. These input values are then used to deterministically compute n values for ASET (and RSET), which are stored for later analysis. The probability of safely evacuating from the fire of interest is found by adding the number of times ASET $>$ RSET and dividing this sum by n.

If distributions of ASET and RSET are assumed, a priori, or calculated as described above, then these distributions are sampled n times and the values stored for later analysis. This sampling is greatly facilitated by the use of a spreadsheet, e.g., EXCEL. EXCEL's = RAND() function will generate uniformly distributed random numbers between zero and one. These random values and EXCEL's = LOGINV() function can then be used to generate the n ASET and RSET values required for further analysis. Once again, the probability of safely evacuating from the fire of interest is found by adding the number of times ASET $>$ RSET and dividing this sum by n. When this method is used, a sensitivity analysis should also be performed on the standard deviations assumed for the log normal distributions of ASET and RSET.

Engineering Economics

81

John M. Watts Jr. and Robert E. Chapman

Introduction

Engineering economics is the application of economic techniques to the evaluation of design and engineering alternatives [1]. The role of engineering economics is to assess the appropriateness of a given project, estimate its value, and justify it from an engineering standpoint.

This chapter discusses the time value of money and other cash-flow concepts, such as compound and continuous interest. It continues with economic practices and techniques used to evaluate and optimize decisions on selection of fire safety strategies. The principles of benefit-cost analysis are then introduced. The chapter concludes with a discussion of standards for evaluating economic performance and software tools for implementing those standards.

An in-depth treatment of the practices and techniques covered in this chapter is available in the ASTM compilation of standards on building economics [2]. The ASTM compilation also includes case illustrations showing how to apply the practices and techniques to investment decisions.

A broader perspective on the application of engineering economics to fire protection engineering can be found in *The Economics of Fire Protection* by Ramachandran [3]. This work is intended as a textbook for fire protection engineers and includes material and references that expand on several other chapters in the SFPE handbook.

Cash-Flow Concepts

Cash flow is the stream of monetary (dollar) values—costs (inputs) and benefits (outputs)—resulting from a project investment.

Time Value of Money

The following are reasons why $1000 today is "worth" more than $1000 1 year from today:

1. Inflation
2. Risk
3. Cost of money

Of these, the cost of money is the most predictable, and, hence, it is the essential component of economic analysis. Cost of money is represented by (1) money paid for the use of borrowed money, or (2) return on investment. Cost of money is determined by an interest rate.

Time value of money is defined as the time-dependent value of money stemming both from changes in the purchasing power of money (inflation or deflation) and from the real earning potential of alternative investments over time.

Cash-Flow Diagrams

It is difficult to solve a problem if you cannot see it. The easiest way to approach problems in economic analysis is to draw a picture. The picture should show three things:

1. A time interval divided into an appropriate number of equal periods
2. All cash outflows (deposits, expenditures, etc.) in each period
3. All cash inflows (withdrawals, income, etc.) for each period

Unless otherwise indicated, all such cash flows are considered to occur at the end of their respective periods.

Figure 81.1 is a cash-flow diagram showing an outflow or disbursement of $1000 at the beginning of year 1 and an inflow or return of $2000 at the end of year 5.

Notation

To simplify the subject of economic analysis, symbols are introduced to represent types of cash flows and interest factors. The symbols used in this chapter conform to ANSI Z94 [4]; however, not all practitioners follow this standard convention, and care must be taken to avoid confusion when reading the literature. The following symbols will be used here:

P = Present sum of money ($)
F = Future sum of money ($)
N = Number of interest periods
i = Interest rate per period (%)

A complete list of the ANSI Z94 symbols is given in Appendix 1 of this chapter.

Interest Calculations

Interest is the money paid for the use of borrowed money or the return on invested capital. The economic cost of construction, installation, ownership, or operation can be estimated correctly only by including a factor for the economic cost of money.

Simple Interest To illustrate the basic concepts of interest, an additional notation will be used:

$$F(N) = \text{Future sum of money after } N \text{ periods}$$

Then, for simple interest,

$$F(1) = P + (P)(i) = P(1 + i)$$

and

$$F(N) = P + (N)(P)(i) = P(1 + Ni)$$

For example: $100 at 10 % per year for 5 years yields

$$\begin{aligned} F(5) &= 100[1 + (5)(0.1)] \\ &= 100(1.5) \\ &= \$150 \end{aligned}$$

However, interest is almost universally compounded to include interest on the interest.

Compound interest:

$$F(1) = P + (P)(i) = P(1 + i)$$

is the same as simple interest,

$$F(2) = (F)(1) + F(1)(i)$$

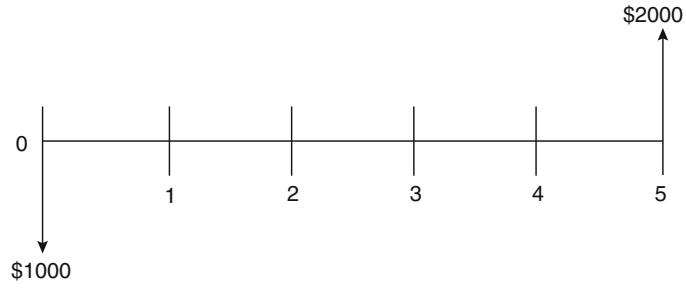

Fig. 81.1 Cash-flow diagram

Interest is applied to the new sum:

$$\begin{aligned} &= F(1)(1+i) = P(1+i)^2 \\ F(3) &= F(2)(1+i) = P(1+i)^3 \end{aligned}$$

and by mathematical induction,

$$F(N) = P(1+i)^N$$

Example \$100 at 10 % per year for 5 years yields

$$\begin{aligned} F(5) &= 100(1+0.1)^5 \\ &= 100(1.1)^5 \\ &= 100(1.61051) \\ &= \$161.05 \end{aligned}$$

which is over 7 % greater than with simple interest.

Example In 1626 Willem Verhulst bought Manhattan Island from the Canarsie Indians for 60 florins (\$24) worth of merchandise (a price of about 0.5 cents per hectare [0.2 cents per acre]). At an average interest rate of 6 %, what is the present value (2006) of the Canarsies' \$24?

$$\begin{aligned} F &= P(1+i)^N \\ &= \$24(1+0.06)^{380} \\ &= \$9.9 \times 10^{10} \end{aligned}$$

Ninety-nine billion dollars is a reasonable approximation of the present land value of the island of Manhattan.

Interest Factors

Interest factors are multiplicative numbers calculated from interest formulas for given interest rates and periods. They are used to convert cash flows occurring at different times to a common time. The functional formats used to represent these factors are taken from ANSI Z94 [4], and they are summarized in Appendix 2 of this chapter.

Compound Amount Factor

In the formula for finding the future value of a sum of money with compound interest, the mathematical expression $(1 + i)^N$ is referred to as the *compound amount factor*, represented by the functional format $(F/P, i, N)$. Thus,

$$F = P(F/P, i, N)$$

Interest tables: Values of the compound amount, present worth, and other factors that will be discussed shortly, are tabulated for a variety of interest rates and number of periods in most texts on engineering economy. Example tables are presented in Appendix 3 of this chapter. Although calculators and software tools have greatly reduced the need for such tables, they are often still useful for interpolations.

Present Worth

Present worth is the value found by discounting future cash flows to the present or base time.

Discounting The inverse of compounding is determining a present amount that will yield a specified future sum. This process is referred to as discounting. The equation for discounting is found readily by using the compounding equation to solve for P in terms of F:

$$P = F(1+i)^{-N}$$

Example What present sum will yield \$1000 in 5 years at 10 %?

$$\begin{aligned} P &= 1000(1.1)^{-5} \\ &= 1000(0.62092) \\ &= \$620.92 \end{aligned}$$

This result means that \$620.92 "deposited" today at 10 % compounded annually will yield \$1000 in 5 years.

Present Worth Factor In the discounting equation, the expression $(1 + i)^{-N}$ (is called the *present worth factor* and is represented by the symbol $(P/F, i, N)$. Thus, for the present worth of a future sum at i percent interest for N periods,

$$P = F(P/F, i, N)$$

Note that the present worth factor is the reciprocal of the compound amount factor. Also note that

$$(P/F, i, N) = \frac{1}{(F/P, i, N)}$$

Example What interest rate is required to triple \$1000 in 10 years?

$$P = \frac{F}{3} = (P/F, i, 10)$$

therefore,

$$(P/F, i, 10) = \frac{1}{3}$$

From Appendix 3,

$$(P/F, 10\ \%,\ 10) = 0.3855$$

and

$$(P/F,\ \ 12\ \%,\ \ 10) = 0.3220$$

By linear interpolation,

$$i = 11.6\ \%$$

Interest Periods

Normally, but not always, the interest period is taken as 1 year. There may be subperiods of quarters, months, weeks, and so forth.

Nominal versus effective interest: It is generally assumed that interest is compounded annually. However, interest may be compounded more frequently. When this occurs, there is a *nominal interest* or annual percentage rate and an *effective interest*, which is the figure used in calculations. For example, a savings bank may offer 5 % interest compounded quarterly, which is not the same as 5 % per year. A nominal rate of 5 % compounded quarterly is the same as 1.25 % every 3 months or an effective rate of 5.1 % per year. If

$$r = \text{Nominal interest rate}$$

and

$$M = \text{Number of subperiods per year}$$

then the effective interest rate is

$$i = \left(1 + \frac{r}{M}\right)^{M} - 1$$

Example Credit cards usually charge interest at a rate of 1.5 % per month. This amount is a nominal rate of 18 %. What is the effective rate?

$$\begin{aligned} i &= (1 + 0.015)^{12} - 1 \\ &= 1.1956 - 1 \\ &= 19.56\ \% \end{aligned}$$

Continuous Interest A special case of effective interest occurs when the number of periods per year is infinite. This represents a situation of *continuous interest*, also referred to as continuous compounding. Formulas for continuous interest can be derived by examining limits as M approaches infinity. Formulas for interest factors using continuous compounding are included in Appendix 2. Continuous interest is compared to monthly interest in Table 81.1.

Example Compare the future amounts obtained under various compounding periods at a nominal interest rate of 12 % for 5 years, if $P = \$10{,}000$ (Table 81.2).

Table 81.1 Continuous interest (%)

	Effective	
Nominal %	Monthly	Continuous
5	5.1	5.1
10	10.5	10.5
15	16.1	16.2
20	21.9	22.1

Table 81.2 Example of continuous interest $N = 5$ years, $r = 12\ \%$

Compounding	M	i	NM	F/P	F
Annual	1	12.000	5	1.76234	17,623.40
Semiannual	2	12.360	10	1.79085	17,908.50
Quarterly	4	12.551	20	1.80611	18,061.10
Monthly	12	12.683	60	1.81670	18,167.00
Weekly	52	12.734	260	1.820860	18,208.60
Daily	365	12.747	1,825	1.821938	18,219.38
Hourly	8,760	12.749	43,800	1.822061	18,220.61
Instantaneously	∞	12.750	∞	1.822119[a]	18,221.19

[a]F/P (instantaneous) $= e^{Ni} = e^{5(0.12)} = e^{0.6}$

Series Payments

Life would be simpler if all financial transactions were in single lump-sum payments, now or at some time in the future. However, most situations involve a series of regular payments, for example, car loans and mortgages.

Series Compound Amount Factor Given a series of regular payments, what will they be worth at some future time?

Let

$$A = \text{the amount of a regular end} - \text{of} - \text{period payment}$$

Then, note that each payment, A, is compounded for a different period of time. The first payment will be compounded for $N-1$ periods (yr):

$$F = A(1+i)^{N-1}$$

and the second payment for $N-2$ periods:

$$F = A(1+i)^{N-2}$$

and so forth. Thus, the total future value is

$$F = A(1+i)^{N-1} + A(1+i)^{N-2} + \cdots + A(1+i) + A$$

or

$$F = \frac{A\left[(1+i)^N - 1\right]}{i}$$

The interest expression in this equation is known as the *series compound amount factor*, $(F/A, i, N)$—thus

$$F = A(F/A, i, N)$$

Sinking fund factor: The process corresponding to the inverse of series compounding is referred to as a *sinking fund*; that is, what size regular series payments is necessary to acquire a given future amount?

Solving the series compound amount equation for A,

$$A = F\left\{\frac{i}{\left[(1+i)^N - 1\right]}\right\}$$

Or, using the symbol $(A/F, i, N)$ for the *sinking fund factor*

$$A = F(A/F, i, N)$$

Here, note that the sinking fund factor is the reciprocal of the series compound amount factor, that is, $(A/F, i, N) = 1/(F/A, i, N)$.

Capital recovery factor: It is also important to be able to relate regular periodic payments to their present worth; for example, what monthly installments will pay for a \$10,000 car in 3 years at 15 %?

Substituting the compounding equation $F = P(F/P, i, N)$ in the sinking fund equation, $A = F(A/F, i, N)$, yields

$$A = P(F/P, i, N)(A/F, i, N)$$

And, substituting the corresponding interest factors gives

$$A = P\frac{\left[i(1+i)^N\right]}{\left[(1+i)^N - 1\right]}$$

In this equation, the interest expression is known as the *capital recovery factor*, since the equation defines a regular income necessary to recover a capital investment. The symbolic equation is

$$A = P(A/P, i, N)$$

Series present worth factor: As with the other factors, there is a corresponding inverse to the capital recovery factor. The *series present worth* factor is found by solving the capital recovery equation for P.

$$P = A\frac{\left[(1+i)^N - 1\right]}{\left[i(1+i)^N\right]}$$

or, symbolically

$$P = A(P/A, i, N)$$

Other Interest Calculation Concepts

Additional concepts involved in interest calculations include continuous cash flow, capitalized costs, beginning of period payments, and gradients.

Continuous cash flow: Perhaps the most useful function of continuous interest is its application to situations where the flow of money is of a continuous nature. *Continuous cash flow* is representative of

1. A series of regular payments for which the interval between payments is very short
2. A disbursement at some unknown time (which is then considered to be spread out over the economic period)

Factors for calculating present or future worth of a series of annual amounts, representing the total of a continuous cash flow throughout the year, may be derived by integrating corresponding continuous interest factors over the number of years the flow is maintained.

Continuous cash flow is an appropriate way to handle economic evaluations of risk, for example, the present value of an annual expected loss.

Formulas for interest factors representing continuous, uniform cash flows are included in Appendix 2.

Capitalized Costs Certain undertakings such as some public works projects are considered to last indefinitely and thereby provide perpetual service. For example, how much should a community be willing to invest in a reservoir that will reduce fire insurance costs by some annual amount, A? Taking the limit of the series present worth factor as the number of periods goes to infinity gives the reciprocal of the interest rate. Thus, *capitalized costs* are just the annual amount divided by the interest rate. When expressed as an amount required to produce a fixed yield in perpetuity, it is sometimes referred to as an *annuity*.

Beginning-of-Period Payments Most returns on investment (cash inflows) occur at the end of the period during which they accrued. For example, a bank computes and pays interest at the end of the interest period. Accordingly, interest tables, such as those in Appendix 3, are computed for end-of-year payments. For example, the values of the capital recovery factor assume that the regular payments, A, occur at the end of each period.

On the other hand, most disbursements (cash outflows) occur at the beginning of the period (e.g., insurance premiums). When dealing with beginning-of-period payments, it is necessary to make adjustments. One method of adjustment for beginning-of-period payments is to calculate a separate set of factors. Another way is to logically interpret the effect of beginning-of-period payments for a particular problem, for example, treating the first payment as a present value. The important thing is to recognize that such variations can affect economic analysis.

Gradients It occasionally becomes necessary to treat the case of a cash flow that regularly increases or decreases at each period. Such patterned changes in cash flow are called *gradients*. They may be a constant amount (linear or arithmetic progression), or they may be a constant percentage (exponential or geometric progression). Various equations for dealing with gradient series may be found in Appendix 2.

Software Tools for Interest Calculations

Modern computer spreadsheet software typically includes a significant array of economic functions. Within these are the 18 standard factors for computation of compound interest found in Appendix 2. However, not all software follows the terminology or notation of ANSI Z94. For example, sometimes "present worth" is referred to as "present value." Thus, care must be taken in selecting spreadsheet functions for economic analysis.

Comparison of Alternatives

Most decisions are based on economic criteria. Investments are unattractive unless it seems likely they will be recovered with interest. Economic decisions can be divided into two classes:

1. Income expansion—that is, the objective of capitalism
2. Cost reduction—the basis of profitability

Fire protection engineering economic analysis is primarily concerned with cost-reduction decisions, finding the least expensive way to fulfill certain requirements, or minimizing the sum of expected fire losses plus investment in fire protection.

There are four common methods of comparing alternative investments: (1) present worth, (2) annual cost, (3) rate of return, and (4) benefit-cost analysis. Each of these is dependent on a selected interest rate or discount rate to adjust cash flows at different points in time.

Discount Rate

The term *discount rate* is often used for the interest rate when comparing alternative projects or strategies.

Selection of Discount Rate If costs and benefits accrue equally over the life of a project or strategy, the selection of discount rate will have little impact on the estimated benefit-cost ratios. However, most benefits and costs occur at different times over the project life cycle. Thus, costs of constructing a fire-resistive building will be incurred early in contrast to benefits, which will accrue over the life of the building. The discount rate then has a significant impact on measures such as benefit-cost ratios, since the higher the discount rate, the lower the present value of future benefits.

In view of the uncertainty concerning appropriate discount rate, analysts frequently use a range of discount rates. This procedure indicates the sensitivity of the analysis to variations in the discount rate. In some instances, project rankings based on present values may be affected by the discount rate as shown in Fig. 81.2. Project A is preferred to project B for discount rates below 15 %, whereas the converse is true for discount rates greater than 15 %. In this instance, the decision to adopt project A in preference to project B will reflect the belief that the appropriate discount rate is less than or equal to 15 %.

A comparison of benefits and costs may also be used to determine the payback period for a particular project or strategy. However, it is important to discount future costs or benefits in such analyses. For example, an analysis of the Beverly Hills Supper Club fire compared annual savings from a reduction in insurance premiums to the costs of sprinkler installation. Annual savings were estimated at $11,000, whereas costs of sprinkler installation ranged from $42,000 to $68,000. It was concluded that the installation would have been paid back in 4–7 years (depending on the cost of the sprinklers). However, this analysis did not discount future benefits, so that $11,000 received at the end of 4 years was deemed equivalent to $11,000 received in the first year. Once future benefits were discounted, the payback period ranged from 5 to 11 years with a discount rate of 10 %.

Inflation and the Discount Rate Provision for inflation may be made in two ways: (1) estimate all future costs and benefits in constant prices, and use a discount rate that represents the opportunity cost of capital in the absence of inflation;

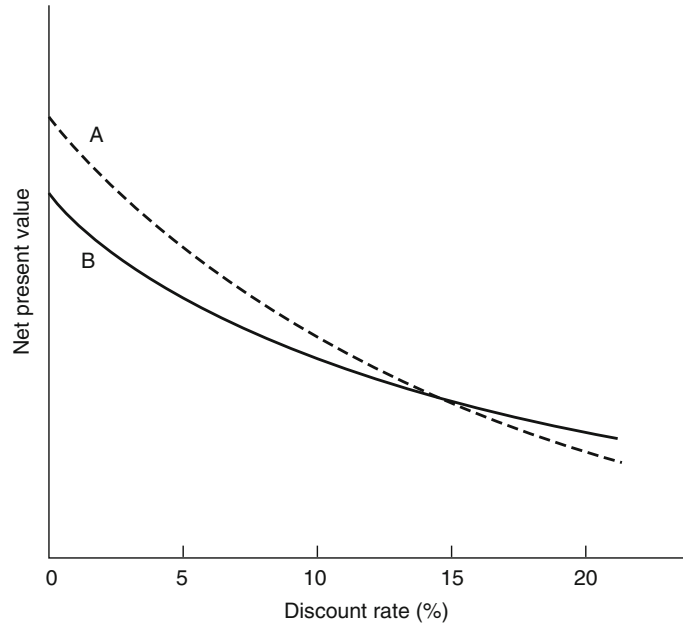

Fig. 81.2 Impact of discount rate on project selection

Table 81.3 Estimated cost data for two alternate plans for increasing water transmission capacity

	Plan A pipeline	Plan B pumping station
Construction cost	$1,000,000	$200,000
Life	40 years	40 years (structure)
		20 years (equipment)
Cost of replacing equipment at the end of 20 year	0	$75,000
	$1,000/year	$50,000/year
Operating costs		

or (2) estimate all future benefits and costs in current or inflated prices, and use a discount rate that includes an allowance for inflation. The discount rate in the first instance may be considered the real discount rate, whereas the discount rate in the second instance is the nominal discount rate. The use of current or inflated prices with the real discount rate, or constant prices with the nominal discount rate, will result in serious distortions in economic analysis.

Present Worth

In a *present worth* comparison of alternatives, the costs associated with each alternative investment are all converted to a present sum of money, and the least of these values represents the best alternative. Annual costs, future payments, and gradients must be brought to the present. Converting all cash flows to present worth is often referred to as *discounting*.

Example Two alternate plans are available for increasing the capacity of existing water transmission lines between an unlimited source and a reservoir. The unlimited source is at a higher elevation than the reservoir. Plan A calls for the construction of a parallel pipeline and for flow by gravity. Plan B specifies construction of a booster pumping station. Estimated cost data for the two plans are as shown in Table 81.3.

If money is worth 12 %, which plan is more economical? (Assume annual compounding, zero salvage value, and all other costs equal for both plans.)

$$\begin{aligned}\text{Present worth (Plan A)} &= P + A(P/A,\ 12\ \%,\ 40)\\ &= \$1,000,000 + \$1000(8.24378)\\ &= \$1,008,244\end{aligned}$$

$$\begin{aligned}\text{Present worth (Plan B)} &= P + A(P/A,\ 12\ \%,\ 40)\\ &\quad + F(P/F,\ 12\ \%,\ 20)\\ &= \$200,000 + \$50,000(8.24378)\\ &\quad + \$75,000(0.10367)\\ &= \$619,964\end{aligned}$$

Thus, plan B is the least-cost alternative.

A significant limitation of present worth analysis is that it cannot be used to compare alternatives with unequal economic lives. That is, a 10-year plan and a 20-year plan should not be compared by discounting their costs to a present worth. A better method of comparison is annual cost.

Annual Cost

To compare alternatives by annual cost, all cash flows are changed to a series of uniform payments. Current expenditures, future costs or receipts, and gradients must be converted to annual costs. If a lump-sum cash flow occurs at some time other than the beginning or end of the economic life, it must be converted in a two-step process: first moving it to the present and then spreading it uniformly over the life of the project.

Alternatives with unequal economic lives may be compared by assuming replacement in kind at the end of the shorter life, thus maintaining the same level of uniform payment (Table 81.4).

Example Compare the value of a partial or full sprinkler system purchased at 10 % interest.

$$\begin{aligned}\text{Annual cost (partial system)} &= A + P(A/P,\ 10\ \%,\ 15)\\ &= \$1000 + \$8000(0.13147)\\ &= \$2051.75\end{aligned}$$

$$\begin{aligned}\text{Annual cost (full system)} &= A + P(A/P,\ 10\ \%,\ 20)\\ &= \$250 + \$15,000(0.11746)\\ &= \$2011.90\end{aligned}$$

The full system is slightly more economically desirable. When costs are this comparable, it is especially important to consider other relevant decision criteria such as uninsured losses.

Rate of Return

Rate of return is, by definition, the interest rate at which the present worth of the net cash flow is zero. Computationally, this method is the most

Table 81.4 Comparison of alternatives by annual cost

	System cost	Insurance premium	Life (in years)
Partial system	$8000	$1000	15
Full system	$15,000	$250	20

complex method of comparison. If more than one interest factor is involved, the solution is by trial and error. Microcomputer programs are most useful with this method.

The calculated interest rate may be compared to a discount rate identified as the "minimum attractive rate of return" or to the interest rate yielded by alternatives. Rate-of-return analysis is useful when the selection of a number of projects is to be undertaken within a fixed or limited capital budget.

Example An industrial fire-fighting truck costs \$100,000. Savings in insurance premiums and uninsured losses from the acquisition and operation of this equipment are estimated at \$60,000 per year. Salvage value of the apparatus after 5 years is expected to be \$20,000. A part-time driver during operating hours will accrue an added cost of \$10,000 per year.

What would the rate of return be on this investment at 40 % present worth? At 50 % present worth?

By linear interpolation, the rate of return is 43 %.

$$\begin{aligned} 40\ \%\ \text{Present worth} &= P + F(P/F, 40\ \%, 5) + A(P/A, 40\ \%, 5) \\ &= -\$100,000 + \$20,000(0.18593) + (\$60,000 - \$10,000)(2.0352) \\ &= \$5,478.60 \end{aligned}$$

$$\begin{aligned} 50\ \%\ \text{Present worth} &= P + F(P/F,\ 50\ \%,\ 5) + A(P/A,\ 50\ \%,\ 5) \\ &= -\$100,000 + \$20,000(0.13169) + (\$60,000 - \$10,000)(1.7366) \\ &= -\$10,536.40 \end{aligned}$$

Benefit-Cost Analysis

Benefit-cost analysis, also referred to as cost-benefit analysis, is a method of comparison in which the consequences of an investment are evaluated in monetary terms and divided into the separate categories of benefits and costs. The amounts are then converted to annual equivalents or present worths for comparison.

The important steps of a benefit-cost analysis are

1. Identification of relevant benefits and costs
2. Measurement of these benefits and costs
3. Selection of best alternative
4. Treatment of uncertainty

Identification of Relevant Benefits and Costs

The identification of benefits and costs depends on the particular project under consideration. In the case of fire prevention or control activities, the benefits are based on prior fire losses, classified either as direct or indirect. Direct economic losses are property and content losses. Indirect losses include such things as the costs of injuries and deaths, costs incurred by business or industry due to business interruption, losses to the community from interruption of services, loss of payroll or taxes, loss of market share, and loss of reputation. Direct costs of fire protection activities include constructing fire-resistive buildings, installation of fire protection systems, and operating fire departments. Indirect costs are more difficult to measure. They include items such as the constraints on choice due to fire protection requirements by state and local agencies. In the measurement of benefits, it is appropriate to adjust for utility or disutility that may be associated with a fire loss.

A major factor in the identification of relevant benefits and costs pertains to the decision unit involved. Thus, if the decision maker is a property owner, relevant benefits from fire protection are likely to be reduced fire insurance premiums and less fire damage or business interruption losses not covered by insurance. For a

municipality, relevant benefits are the protection of members of the community, avoidance of tax and payroll losses, and reductions in costs associated with assisting fire victims. Potential benefits, in these instances, are considerably greater than those faced by a property owner. However, the community may ignore some external effects of fires. For example, the 1954 automobile transmission plant fire in Livonia, Michigan, affected the automobile industry in Detroit and various automobile dealers throughout the United States. However, there was little incentive for the community to consider potential losses to persons outside the community in their evaluation of fire strategies. It might be concluded, therefore, that the more comprehensive the decision unit, the more likely the inclusion of all relevant costs and benefits, in particular, social costs and benefits.

Measurement of Benefits and Costs

Direct losses are measured or estimated statistically or by a priori judgment. Actuarial fire loss data collected nationally or for a particular industry may be used, providing the information is adequately specific and the collection mechanism is reliable. More often, an experienced judgment of potential losses is made, sometimes referred to as the *maximum probable loss* (MPL).

Indirect losses, if considered, are much more difficult to appraise. A percentage or multiple of direct losses is sometimes used. However, when indirect loss is an important decision parameter, a great deal of research into monetary evaluation may be necessary. Procedures for valuing a human life and other indirect losses are discussed in Ramachandran [3].

Costs may be divided into two major categories: (1) costs of private fire protection services, and (2) costs of public fire protection services. In either case, cost estimates will reflect the opportunity cost of providing the service. For example, the cost of building a fire-resistive structure is the production that is foregone due to the diversion of labor and resources to make such a structure. Similarly, the cost of a fire department is the loss of other community services that might have been provided with the resources allocated to the fire department.

Selection of Best Alternative

Two considerations pertain to determining benefit-cost criteria: project acceptability and project selection.

Project acceptability may be based on benefit-cost difference using subtraction or benefit-cost ratio, in which the monetary equivalent benefits are divided by the monetary equivalent costs. The first criterion requires that the value of benefits less costs be greater than zero, whereas the second criterion requires a benefit-cost ratio greater than one.

The issue is more complicated in the case of project selection, since several alternatives are involved. It is no longer a question of determining the acceptability of a single project, but rather selecting from among alternative projects. Consideration should be given to changes in costs and benefits as various strategies are considered. Project selection decisions are illustrated in Fig. 81.3. The degree of fire protection is given on the horizontal axis; the marginal costs and benefits associated with various levels of fire safety are given on the vertical axis. As the diagram indicates, marginal costs are low initially and then increase. Less information is available concerning the marginal benefit curve, and it may, in fact, be horizontal. The economically optimum level of fire protection is given by the intersection of the marginal cost and marginal benefit curves. Beyond this point, benefits from increasing fire protection are exceeded by the costs of providing the additional safety.

The numerical example shown in Table 81.5 presents five possible strategies or programs. Strategy A represents the initial situation, with the remaining four strategies representing various fire loss reduction activities, each with various costs, arranged in ascending order of costs. Fire losses under each of the five strategies are given in the second row. The sum of fire losses and fire reduction costs for each strategy given in

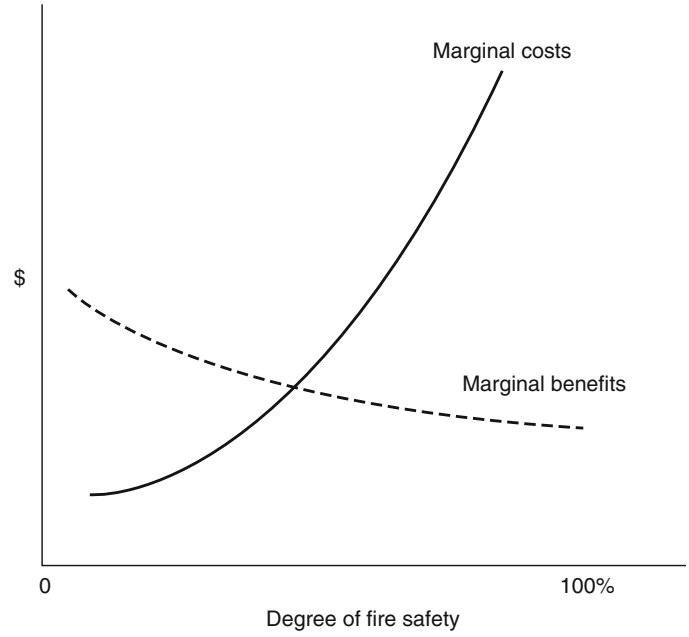

Fig. 81.3 Project selection

Table 81.5 Use of benefit-cost analyses in strategy selection

	Strategy				
Category	A	B	C	D	E
Fire reduction costs	0	10	25	45	70
Fire losses	100	70	50	40	35
Sum of fire reduction costs and fire losses	100	80	75	85	105
Marginal benefits	0	30	20	10	5
Marginal costs	0	10	15	20	25
Marginal benefits minus marginal cost	0	20	5	–10	–20
Marginal benefit-cost ratio	–	3.0	1.33	0.5	0.2

the third row is equivalent to the life-cycle cost of that strategy. Life-cycle cost analysis is an alternative to benefit-cost analysis when the goal of the investment decision is cost savings rather than benefits. Additional information on life-cycle cost analysis is found in Fuller and Petersen [5].

Data in the first two rows may then be used to determine the marginal costs or marginal benefits of replacing one strategy with another. Thus, strategy B has a fire loss of $70 compared to $100 for strategy A, so the marginal benefit is $30. Similarly, the marginal benefit from strategy C is the reduction in fire losses from B to C of $20. The associated marginal cost of strategy C is $15. Declining marginal benefits and rising marginal costs result in the selection of strategy C as the optimum strategy. At this point, the difference between marginal benefits and marginal costs is still positive.

Marginal benefit-cost ratios are given in the last row. It is worth noting that, while the highest marginal benefit-cost ratio is reached at activity level B (as is the highest marginal benefit-cost difference), project C is still optimum, since it yields an additional net benefit of $5. This finding is reinforced by examining changes in the sum of fire reduction costs and fire losses (i.e., life-cycle costs). Total cost plus loss first declines, reaching a minimum at point C, and

then increases. This pattern is not surprising, since as long as marginal benefits exceed marginal costs, total losses should decrease. Thus, the two criteria—equating marginal costs and benefits and minimizing the sum of fire losses and fire reduction costs—yield identical outcomes.

Treatment of Uncertainty

A final issue concerns the treatment of uncertainty. One method for explicitly introducing risk considerations is to treat benefits and costs as random variables that may be described by probability distributions. For example, an estimate of fire losses might consider the following events: no fire, minor fire, intermediate fire, and major fire. Each event has a probability of occurrence and an associated damage loss. The total expected loss (EL) is given by

$$\mathrm{EL} = \sum_{i=0}^{3} p_i D_i$$

where
p_0 = Probability of no fire
p_1 = Probability of a minor fire
p_2 = Probability of an intermediate fire
p_3 = Probability of a major fire
D_n = Associated damage loss, $n = 0, 1, 2, 3$

Expected losses may be computed for different fire protection strategies. Thus, a fire protection strategy that costs, C_3 and reduces damage losses of a major fire from D_3 to $D_3^{'}$ will result in an expected loss

$$\mathrm{EL} = p_0 D_0 + p_1 D_1 + p_2 D_2 + p_3 D_3^{'} + C_3$$

Similarly, a fire control strategy that costs C_3 and reduces the probability of an intermediate fire from p_2 to $p_2^{'}$ as an expected loss

$$\mathrm{EL} = p_0 D_0 + p_1 D_1 + p_2^{'} D_2 + p_3 D_3 + C_2$$

Comparing expected losses from alternative strategies may then be used to determine the optimal strategy. Use of expected value has the limitation of considering only the average value of the probability distribution. Discussion of other procedures for evaluating uncertain outcomes is given by Anderson and Settle [6].

Dealing with Extreme Events

Protecting buildings from extreme events—fires, floods, earthquakes, and other natural and man-made hazards—is a constant challenge for building owners and managers. Choosing among alternative protection strategies is complicated by the fact that such strategies frequently have significant up-front investment costs, result in operations and maintenance costs that are spread over many years, and impact key stakeholders in different ways. A methodology is needed to ensure that all relevant costs are captured and analyzed via well-defined metrics.

To address this need, the National Institute of Standards and Technology (NIST) is developing economic tools to aid building owners and managers in the selection of cost-effective strategies for responding to extreme events. Economic tools include evaluation methods for measuring economic performance, standards that support and guide the use of those methods, and software for implementing the evaluation methods.

An economic analysis integrates the economic tools and facilitates the identification and selection of cost-effective building protection strategies. Since an economic analysis is only as good as the data and assumptions on which it is based, NIST developed a three-step protocol that establishes a methodology for dealing with extreme events, documented in NISTIR 7073 [7].

Three-Step Protocol

The three-step protocol helps decision makers assess the risk to their facility of damages from extreme events; identify engineering, management, and financial strategies for abating damage risk; and use standardized economic evaluation methods to select the most cost-effective combination of risk mitigation strategies to protect their facility.

Step 1 is to assess the risk of uncertain and costly hazards, whether man-made or natural. Because limited resources do not allow full protection of all facilities against every possible hazard, economic efficiency dictates that investments for protection be a function of the likelihood of a disaster occurring, the expected value of damages, and the cost of protection. By assessing the risks facing a facility and the damages that might result from various disasters, decision makers can determine if a facility merits some degree of protection over and above that required by building codes and standards.

Step 2 is to identify engineering, management, and financial strategies to abate the risk of damages. Some strategies will lower the probability of a disaster occurring; others will lower the damages incurred once the disaster happens. Engineering strategies include structural upgrades, HVAC upgrades, and strengthening or tightening the building envelope. Management strategies include access controls, background checks, and emergency training and drills. Financial strategies include insurance, tax incentives, and cost-sharing arrangements. NISTIR 7073 stresses the need to employ a combination of risk mitigation strategies rather than focusing only on engineering-based approaches. Although engineering approaches are essential to protecting capital assets, management practices and financial mechanisms have the potential to both harden a particular asset and offer flexibility in responding to new challenges. Once engineering, management, and financial mitigation strategies have been identified, it is necessary to create a candidate set of alternatives, each of which combines mitigation strategies that address some or all of the hazards identified in the risk assessment. Each alternative has a set of costs based on the unique combination of mitigation strategies employed, varying according to both their timing and magnitude. In most cases, higher up-front costs result in lower future costs.

Step 3 uses economic analysis to select the most cost-effective alternative. The life-cycle cost method is the core component of the economic evaluation. It measures the sum of all relevant costs associated with owning or operating a constructed facility over a specified time period. Other standardized methods, such as present value net savings and the savings-to-investment ratio, can be derived directly from life-cycle cost calculations, so decision makers have multiple measures of economic performance on which to base their choice. By using these economic evaluation methods, building owners and managers can reduce the life-cycle costs associated with extreme events.

Developing a risk mitigation plan requires both guidance and data—guidance to help owners and managers assess the risks facing their facility and data about the frequency and consequences of natural and man-made hazards to measure the risks facing a particular facility. Cost estimates of protection are needed to ensure that the operational budget for safeguarding personnel and physical assets is kept in balance. Guidance on the use of economic evaluation methods helps ensure that the correct economic method, or combination of methods, is used. Despite the large amount of high-quality information available on risk assessment and management, natural and man-made hazards, and economic tools, there are few central sources of data and tools to which owners and managers of constructed facilities and other key decision makers can turn for help in developing a cost-effective risk mitigation plan. NISTIR 7390 [8] serves as such a central source.

Standards Development

A suite of standards and materials for a training course on how to apply the standards to produce a cost-effective risk mitigation plan has been developed by ASTM. The suite consists of three standards: (1) a revised and expanded version of the life-cycle cost standard practice, E917 [9]; (2) a revised and expanded version of the standard guide for summarizing economic impacts, E2204 [10]; and (3) a new standard guide on how to use the three-step protocol to produce a cost-effective risk mitigation plan, E2506 [11].

The life-cycle cost standard practice, E917, is the core standard of ASTM Subcommittee

E06.81 on Building Economics. The life-cycle cost standard occupies a unique position, since three other E06.81 standards can be derived from it and nine others reference it. Consequently, the focus was on a major rewrite of E917 to incorporate the treatment of extreme events into not only the life-cycle cost standard but also into the present value net savings (E1074) [12], the savings-to-investment ratio (E964) [13], and the adjusted internal rate of return (E1057) [14] standards as well.

The impact summary guide, E2204, provides a generic format for summarizing the economic impacts of building-related projects. The guide provides technical persons, analysts, and researchers a means for communicating project impacts in a condensed format to management and nontechnical persons. Effective communication of project impacts to senior management and other decision makers is a critical part of the economic analysis (Step 3 in the three-step protocol). Communicating the pros and cons of the alternative identified as the most cost-effective risk mitigation plan requires both concise statements and adequate back-up documentation. Consequently, the impact summary guide was substantially rewritten and a case study illustrating the treatment of extreme events was incorporated as an appendix.

Cost-Effectiveness Tool

The Cost-Effectiveness Tool for Capital Asset Protection is a user-friendly decision support system for choosing among alternative building protection strategies. It includes multiple evaluation methods, event-modeling features, a cost accounting framework, and a multitiered analysis strategy. All evaluation methods employed within the Cost-Effectiveness Tool are consistent with ASTM standard measures of economic merit. The event-modeling features are the means for assessing and managing the risks associated with natural and man-made hazards. The cost accounting framework classifies costs by who bears them, which budget category they fall into, and how they are distributed across building systems and across mitigation strategies. These different dimensions of cost provide important perspectives to the decision problem.

A key component informing the decision maker is the analysis strategy, which uses multiple levels of analysis to promote an increased understanding of the decision problem. The Cost-Effectiveness Tool addresses uncertainty and financial risk—the probability of investing in a project whose economic outcome is different from that desired or expected—in a structured, three-part manner.

First, best-guess estimates are used to establish a baseline analysis, which uses fixed parameter values to calculate economic measures of performance. The results of the baseline analysis allow the alternative combinations of risk mitigation strategies to be ranked according to their economic measures of performance. The ranking and the calculated measures of performance provide a frame of reference for the treatment of uncertainty and financial risk.

Second, a sensitivity analysis is performed in which selected inputs are varied about their baseline values. Despite being helpful in identifying shifts in the rank ordering of alternatives and addressing uncertainty in input values, the sensitivity analysis produces only a crude measure of financial risk.

Third, a Monte Carlo simulation is performed to obtain an explicit measure of financial risk associated with the competing alternatives. Monte Carlo simulation is especially useful in identifying shifts in the rank ordering of alternatives and documenting the factors and circumstances associated with those shifts.

Example The results of an economic analysis (Step 3 in the three-step protocol) for a case study building are presented in Fig. 81.4. The case study covers a renovation project for the data center of a major financial institution. The case study findings presented in Fig. 81.4 use the generic format specified in ASTM Standard Guide E2204. The generic format calls for a description of the significance of the project, the analysis strategy, a listing of data and

1.a Significance of the Project:

The data center undergoing renovation is a single-story structure located in a suburban community.The floor area of the data center is 3716 m^2 (40,000 ft^2). The replacement value of the data center is $20 million for the structure plus its contents. The data center contains financial records that are in constant use by the firm and its customers. Thus, any interruption of service will result in both lost revenues to the firm and potential financial hardship for the firm's customers.

The building owners employ two different renovation strategies. The first, referred to as the Base Case, employs upgrades that meet the minimum building performance and security requirements. The second, referred to as the Proposed Alternative, results in enhanced security as well as selected improvements in building performance. Both alternatives recognize that in the post-9/11 environment the data center faces heightened risks in two areas. These risks are associated with the vulnerability of information technology resources and the potential for damage to the facility and its contents from chemical, biological, radiological, and explosive (CBRE) hazards. Two scenarios—the potential for a cyber attack and the potential for a CBRE attack—are used to capture these risks.

1.b Key points:

1. The objective of the renovation project is to provide cost-effective operations and security protection for the data center.
2. The renovation is to upgrade the data center's HVAC, telecommunications and data processing systems, and several security-related functions.
3. Two upgrade alternatives are proposed:
   - Base Case (Basic Renovation) and
   - Proposed Alternative (Enhanced Renovation), which augments the Base Case by strengthening portions of the exterior envelope; limiting vehicle access to the data center site, significantly improving the building's HVAC, data processing, and telecommunications systems; and providing better linkage of security personnel to the telecommunications network.

2. Analysis Strategy: How Key Measures Are Estimated

The following economic measures are calculated as present-value (PV) amounts:

1. **Life-Cycle Costs** (LCC) for the Base Case (Basic Renovation) and for the Proposed Alternative (Enhanced Renovation), including all costs of acquiring and operating the data center over the length of the study period. The selection criterion is lowest LCC.
2. **Present Value Net Savings** (PVNS) that will result from selecting the lowest-LCC alternative, PVNS greater than zero indicates an economically worthwhile project.

Additional measures:

1. **Savings-to-Investment Ratio** (SIR), the ratio of savings from the lowest LCC to the extra investment required to implement it. A ration of SIR greater than one indicates an economically worthwhile project.
2. **Adjusted Internal Rate of Return** (AIRR), the annual return on investment over the study period. An AIRR greater than the discount or hurdle rate indicates an economically worthwhile project.

Data and Assumptions:

- The Base Date is 2006.
- The alternative with the lower first cost (Basic Renovation) is designated the Base Case.
- The study period is 25 years and ends in 2030.
- The discount or hurdle rate is 7.0 percent real.
- The minimum acceptabel rate or return is 7.0 percent real.
- Annual probabilities for the outcomes for each attack scenario are given along with outcome cost.
- Annual probabilities and outcome costs differ by renovation strategy.

(continued)

Fig. 81.4 Summary of data center case study

assumptions, and a presentation of key economic measures of project impact.

The building owners wish to employ the most cost-effective risk mitigation plan (i.e., the plan that results in the lowest life-cycle cost) that will meet their objectives. Two alternative combinations of mitigation strategies—Base Case and Proposed Alternative—are available to the building owners (see Section 1.b of Fig. 81.4). The case study covers a 25-year period beginning in 2006. Life-cycle costs are calculated using a 7 % real rate for the baseline analysis. A sensitivity analysis was used to identify five key cost drivers. These five input variables were analyzed in-depth via a Monte Carlo simulation, which produced 1000 observed values for each of the economic measures of performance.

The results of the baseline analysis and the Monte Carlo simulation indicate that the Proposed Alternative is the most cost-effective risk mitigation plan. These results are summarized in Sections 3.a and 3.b of Fig. 81.4. Reference to the

3.a Calculation of Savings, Costs, and Additional Measures

Savings and Cost in Thousands of Dollars ($K)

PV of Investment Costs	**Base Case**	**Proposed Alt.**
Capital Investment	$1150K	$1765K

PV of Increased Investment Costs for Proposed Alternative $615K

PV of Noninvestment Costs	**Base Case**	**Proposed Alt.**
O&M Costs	3000K	2369K
Other Costs	493K	224K
	$3493K	$2593K

PV of Noninvestment Savings for Proposed Alternative $900K

LCC	**Base Case**	**Proposed Alt.**
PV of Investment Costs	1150K	1765K
PV of Noninvestment Costs	393K	2593K
	$4643K	$4358K

PVNS from Proposed Alternative $285K

Savings-to-Investment Ratio (SIR)

PV of Noninvestment Savings $900K
Divided by PV of Incr. Investment $615K
SIR = 1.46

Adjusted Internal Rate of Return (AIRR)

$(1 + 0.07)\ 1.46^{1/25} - 1 = 0.086$
AIRR = 8.6 percent
which exceeds the minimum acceptable rate of return of 7.0 percent

3.b Key Results:

- **LCC**
  Base Case $4643K
  Proposed Alt. $4358K
- **PVNS from Alt.** $285K
- **SIR** 1.46
- **AIRR** 8.6%

3.c Traceability:

Life-cycle costs and supplementary measures were calculated according to ASTM standards E917, E964, E1057, and E1074.

Treatment of uncertainty and measures of project risk were calculated according to ASTM standard E1369.*

Results of Monte Cario Simulation

Fig. 81.4 (continued)

table showing the results of the Monte Carlo simulation at the bottom of Section 3.a reveals that the minimum values for present value net savings (PVNS), savings-to-investment ratio (SIR), and adjusted internal rate of return (AIRR) indicate improved marginal performance of the Proposed Alternative vis-à-vis the Base Case (i.e., a rank reversal has occurred). An examination of the raw data, however, reveals that marginal performance is associated with a single observation. Readers wishing an in-depth discussion of the Data Center Case Study are referred to NISTIR 7349.

How to Obtain the Cost-Effectiveness Tool Released in September 2006, Version 2.0 of the Cost-Effectiveness Tool produces the types of analysis results that provide decision makers with the means for choosing among alternative combinations of the three risk mitigation strategies. NISTIR 7349 [15] serves as a users' manual for Version 2.0; it is available as a printed copy or in electronic format as part of the software's online "Help" feature. The Cost-Effectiveness Tool is available free of charge to users through NIST at http://www2.bfrl.nist.gov/software/CET.

Appendix 1: Symbols and Definitions of Economic Parameters

Symbol	Definition of parameter
A_j	Cash flow at end of period j
A	End-of-period cash flows (or equivalent end-of-period values) in a uniform series continuing for a specified number of periods
$\bar{A}$	Amount of money (or equivalent value) flowing continuously and uniformly during each period, continuing for a specified number of periods
F	Future sum of money—the letter F implies future (or equivalent future value)
G	Uniform period-by-period increase or decrease in cash flows (or equivalent values); the arithmetic gradient
M	Number of compounding periods per interest period[a]
N	Number of compounding periods
P	Present sum of money—the letter "P" implies present (or equivalent present value). Sometimes used to indicate initial capital investment
S	Salvage (residual) value of capital investment
f	Rate of price level increase or decrease per period; an "inflation" of "escalation" rate
g	Uniform *rate* of cash flow increase or decrease from period to period; the geometric gradient
i	Effective interest rate per interest period[a] (discount rate), expressed as a percent or decimal fraction
r	Nominal interest rate per interest period,[a] expressed as a percent or decimal fraction

[a]Normally, but not always, the interest period is taken as 1 year
Subperiods, then, would be quarters, months, weeks, and so forth

Appendix 2: Functional Forms of Compound Interest Factors[1]

Name of factor	Algebraic formulation	Functional format
Group A. All cash flows discrete: end-of-period compounding		
Compound amount (single payment)	$(1+i)^N$	$(F/P, i, N)$
Present worth (single payment)	$(1+i)^{-N}$	$(P/F, i, N)$
Sinking fund	$\frac{i}{(1+i)^N-1}$	$(A/F, i, N)$
Capital recovery	$\frac{i(1+i)^N}{(1+i)^N-1}$	$(A/P, i, N)$
Compound amount (uniform series)	$\frac{(1+i)^N-1}{i}$	$(F/A, i, N)$
Present worth (uniform series)	$\frac{(1+i)^N-1}{i(1+i)^N}$	$(P/A, i, N)$
Arithmetic gradient to uniform series	$\frac{(1+i)^N-iN-1}{i(1+i)^N-i}$	$(A/G, i, N)$
Arithmetic gradient to present worth	$\frac{(1+i)^N-iN-1}{i^2(1+i)^N}$	$(P/G, i, N)$
Group B. All cash flows discrete: continuous compounding at nominal rate r per period		
Continuous compounding compound amount (single payment)	e^{rN}	$(F/P, r, N)$
Continuous compounding present worth (single payment)	e^{-rN}	$(P/F, r, N)$
Continuous compounding present worth (single payment)	$\frac{e^{rN}-1}{e^{rN}(e^r-1)}$	$(P/A, r, N)$
Continuous compounding sinking fund	$\frac{e^r-1}{e^{rN}-1}$	$(A/F, r, N)$
Continuous compounding capital recovery	$\frac{e^{rN}(e^r-1)}{e^{rN}-1}$	$(A/P, r, N)$
Continuous compounding compound amount (uniform series)	$\frac{e^{rN}-1}{e^r-1}$	$(F/A, r, N)$
Group C. Continuous, uniform cash flows: continuous compounding		
Continuous compounding sinking fund (continuous, uniform payments)	$\frac{r}{e^{rN}-1}$	$\bar{A}/F, r, N$
Continuous compounding capital recovery (continuous, uniform payments)	$\frac{re^{rN}}{e^{rN}-1}$	$\bar{A}/P, r, N$
Continuous compounding compound amount (continuous, uniform payments)	$\frac{e^{rN}-1}{r}$	$(F/\bar{A}, r, N)$
Continuous compounding present worth (continuous, uniform payments)	$\frac{e^{rN}-1}{re^{rN}}$	$(P/\bar{A}, r, N)$

[1] See Appendix 1 for definitions of symbols used in this table.

Dr. John M. Watts Jr. holds degrees in fire protection engineering, industrial engineering, and operations research. He is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. Dr. Watts also serves as editor of NFPA's *Fire Technology.*

Robert E. Chapman is chief of the Office of Applied Economics, Building and Fire Research Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland.

Fire Risk Indexing

82

John M. Watts Jr.

Introduction

Fire risk indexing is a link between fire science and fire safety. As we learn more about the behavior of fire, it is important that we implement new knowledge to meet fire safety goals and objectives. One of the barriers to implementing new technology is the lack of structured fire safety decision making. Fire risk indexing is evolving as a method of evaluating fire safety that is valuable in assimilating research results. Fire safety decisions often have to be made under conditions where the data are sparse and uncertain. The technical attributes of fire risk are very complex and normally involve a network of interacting components. These interactions are generally nonlinear and multidimensional. However, complexity and sparseness of data do not preclude useful and valid approaches. Such circumstances are not unusual in decision making in business or other risk venues. (The space program illustrates how success can be achieved when there are few relevant data). However, detailed risk assessment can be an expensive and labor-intensive process, and there is considerable room for improving the presentation of results. Indexing can provide a cost-effective means of risk evaluation that is both useful and valid.

J.M. Watts Jr. (✉)

Fire risk indexing systems are heuristic models of fire safety. They constitute various processes of analyzing and scoring hazard and other system attributes to produce a rapid and simple estimate of relative fire risk. They are also known as rating schedules, point schemes, ranking, numerical grading, and scoring. Using professional judgment and past experience, fire risk indexing assigns values to selected variables representing both positive and negative fire safety features. The selected variables and assigned values are then operated on by some combination of arithmetic functions to arrive at a single value, which is then compared to other similar assessments or to a standard.

There are numerous approaches to fire safety evaluation that can be construed as risk indexing. A more general description of this area is presented in "Index Approach to Quantifying Risk," [1] whereas greater detail on the more rigorous application is given in "Fire Risk Assessment Using Multiattribute Evaluation" [2].

Fire Risk Indexing

Quantitative fire risk assessment originated with the insurance rating schedule. The approach has broadened to include a wide variety of applications [3, 4]. In general, fire risk rating schedules assign values to selected variables based on professional judgment and past experience. The selected variables represent both positive and negative fire safety features, and

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_82, © Society of Fire Protection Engineers 2016

the assigned values are then operated on by some combination of arithmetic functions to arrive at a single value. This single value can be compared to other similar assessments or to a standard to rank the fire risk.

A risk index is defined as a single number measure of the risk associated with a facility [5]. Thus, insurance rates are fire risk indexes, as are the outputs of other similar schedules or scoring methods. Fire risk indexing, then, is the process of modeling and scoring hazard and exposure attributes to produce a rapid and simple estimate of relative risk. The concept has gained widespread acceptance as a cost-effective prioritization and screening tool for fire risk assessment programs. It is a useful and powerful approach that can provide valuable information on the risks associated with fire.

Figure 82.1 [6] provides a graphic view of the relative power and limitations of three broad levels of risk quantification. Curves A, B, and C do not represent actual data points but are demonstrative of a continuum of fire risk analysis possibilities.

Curve A is representative of a rigorous probabilistic risk analysis where hazard and exposure are analyzed through full quantitative analysis of the hazard and the statistics of exposure. It is clear that this analysis is the most accurate approach to defining risks, especially where the risk is low. However, it is also clear that a large resource investment is necessary to accomplish this task.

Curve C is a simple fire risk indexing that provides the ability to screen for high-risk catastrophic-type situations where the analysis can be consequence oriented. However, for small differences in risk, the ability of the more simplistic screening system to differentiate between two more subtle risks diminishes.

A more complex and accurate assessment model will provide greater differentiation between lesser risks and an improved overall accuracy. The trade-off for this approach is increased time and resources expended for model development, implementation, and data collection.

Applications

Choosing the depth of the risk analysis is a critical decision that depends on such factors as time, resource commitment, and the intended use of the results. Each approach may have certain advantages or trade-offs for specific tasks. A fire risk indexing approach may be appropriate in several situations:

1. Where greater sophistication is not required
2. Where risk screening will be cost effective
3. Where there is a need for risk communication

The level of accuracy demanded for a fire risk analysis is not typically the same as for other

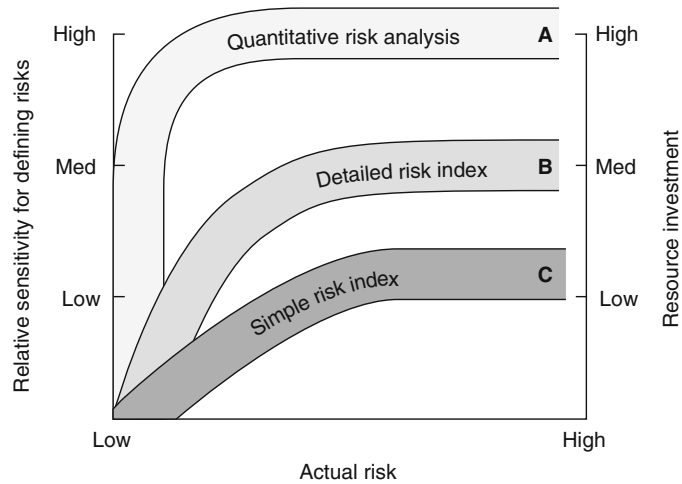

Fig. 82.1 Risk index systems and relative sensitivity for defining actual risk [6]

engineering purposes. Often, establishing an order of magnitude will suffice. Time and resource expenditure will increase as the depth of analysis is increased. Where resources are scarce and efficiency is prized, maximizing the utility of the fire risk indexing is clearly desirable.

The principles of fire risk indexing have been applied to a variety of hazard and risk assessment projects to set priorities and help manage resources. Risk assessment can be an expensive and labor-intensive process. Much time and money can be wasted if the products or facilities with the greatest potential for risk and associated liability are not identified and assessed first. Without a prioritization plan, it will not be known whether a risk was worth assessing until after the time and money have been spent.

Fire risk indexing also has appeal to staff charged with risk management decision-making responsibilities and those who may be unfamiliar with the details and mechanics of the risk assessment process. Because fire risk indexing simplifies basic fire risk assessment principles, it can be an effective way to acquire a global grasp of the issues.

Significance

The importance of fire risk indexing has been widely recognized. A working group of educators and researchers addressed the issue of fire risk indexing at the National Academy of Sciences 1987 "Workshop on Analytical Methods for Designing Buildings for Fire Safety" [7]. They concluded there is a need for a three-part system of fire safety comprised of (1) codes; (2) the methods of fire risk indexing, referred to as numerical grading systems; and (3) the means of supplying inputs to that system derived, as far as feasible, from basic principles of decision science. The working group went on to state the rationale for its conclusion:

> The advantage of keeping numerical grading systems in the trio is that they provide a coherent structure that still allows some qualitative analysis of fire safety. These systems also readily accept change associated with aspects of operations research, management science, risk analysis, and quantitative analytical solutions or models to the fire safety problem or parts of it [7].

The importance of scientific rigor in the development of fire risk indexing methods cannot be overemphasized and will be addressed in more detail in a later section of this chapter.

Examples of Approaches to Fire Risk Indexing

It is difficult to describe a typical fire risk indexing method. The practical necessity of trying to assess dozens or hundreds of risks with limited resources has led to the creation of an array of fire risk indexing systems. Approaches to fire risk indexing are virtually limitless in their possible variations. Representative examples of fire risk indexing were selected from the literature and are summarized in the following sections. They provide some idea of the types of variations involved with modeling and quantifying fire risk. Publicly available computer applications of these and other fire risk indexing methods are described in the final section of this chapter.

Insurance Rating

The purpose of risk analysis is to facilitate the process of risk management. One of the most fundamental tools of risk management is the transference of risk by insurance. To be acceptable to an insurer, the risk is rated by actuarial means, applying principles of mathematics to the particular pricing problems of the insurance industry.

Fire insurance rates are promulgated as *class* rates and *specific* rates. Class rates apply to all properties that fall within a given category or classification. The most common example of class rating is for dwellings or residences. When class rates do not apply, specific rates are determined by the application of a schedule or formula designed to measure the relative

quantity of fire hazard present. This process, known as *schedule rating*, is typically used for institutions, manufacturing properties, and business establishments.

The two most widely used schedules in the United States are known as the *mercantile schedule* and the *analytic system* [8]. At present, the analytic system is predominantly used throughout the country. It is more generally referred to as the Dean Schedule, named for A. F. Dean, author of the plan [9]. The schedules differ basically in their fundamental analysis of the factors affecting insurance rates, but they are alike in that they establish an arbitrary point from which to build up the rate, based on various physical hazards. A schedule of additions and reductions is computed, and the difference is applied to the arbitrary point of departure.

Schedule rating, then, is a plan by which fire hazards to any particular property are measured. A schedule has been defined as "an empirical standard for the measurement of relative quantity of fire hazard" [10]. Schedule rating takes into consideration the various factors contributing to the peril of fire, such as construction and occupancy, and helps determine which features either enhance or minimize the probability of loss. Credits and charges representing departures from standard conditions are incorporated in the schedules. Thus, the schedule rate is typically the sum of all charges less the sum of its credits and constitutes a standard for the measurement of the fire risk.

Specific Commercial Property Evaluation Schedule

The most commonly used insurance rating schedule in the United States is the Insurance Services Office's Specific Commercial Property Evaluation Schedule [11]. For each building, a percentage occupancy charge is determined from tabulated charges for classes of occupancy modified by factors such as the specific hazards of a particular occupancy. The basic building grade is a function of the resistance to fire of structural walls and floor and roof assemblies. The building fire insurance rate is the product of occupancy charges and building grade modified by factors such as the exposure to fire in nearby buildings and protection provided by portable extinguishers, fire alarm systems, and so forth.

An important concept of insurance rating is the use of loss experience. In general, tabulated values and conversion factors are based on actuarial analysis of fire losses paid by insurers and reported to the insurance industry.

Gretener Method

In 1960, Max Gretener of the Swiss Fire Protection Association began to study the possibility of an arithmetical evaluation of fire risk in buildings. His premise was that determining fire risk by statistical methods based on loss experience was no longer adequate for the following reasons [12]:

1. Lack of exchange of loss experience
2. Inadequate analysis with respect to causes and factors determining the size of loss, resulting in distortion of statistical data
3. Rapid technological change altering the credibility of previous experience
4. Different criteria, according to country and company, for data collection and evaluation

As a result of this new approach to schedule rating, the Gretener method has developed into a widely used fire risk index in Switzerland [13] and other European countries [14, 15]. The basic idea of the process consists of expressing, in relative, empirically derived numerical values, factors for fire initiation and spread and factors for fire protection. The product of the hazard factors is a value for potential hazard, whereas the product of the fire protection factors expresses a value for protective measures. The ratio of these products is taken as the measure of expected fire severity.

Of immediate appeal is that the approach begins with the explicit concept of risk as the expectation of loss given by the product of hazard probability and hazard severity:

$$R = A \times B$$

where

R = Fire risk
A = Probability that a fire will start
B = Fire hazard, degree of danger, or probable severity

Thus, the Gretener method is based on these two probabilities and combines them in accordance with probability theory.

A further departure from U.S. schedule rating is the calculation of fire hazard as a ratio rather than a sum:

$$\text{Fire hazard} = \frac{\text{Potential hazard}}{\text{Protective measures}}$$

that is,

$$B = \frac{\mathrm{P}}{N \times S \times F}$$

where
B = Fire hazard
P = Potential hazard
N = Standard fire safety measures
S = Special measures
F = Fire resistance of the building

Potential hazard, P, is the product of hazard elements whose magnitudes are influenced on the one hand by the building contents, that is, materials and merchandise present, and on the other hand by the building itself.

As with most other schedule approaches, the values for these individual factors are not based on statistics but are empirical figures resulting from a comparison of analyses of fire risks for which fire protection measures are either common or required by law.

Dow's Fire and Explosion Index

A need for systematic identification of areas with significant loss potential motivated Dow Chemical Company to develop the Fire and Explosion Index and risk guide [16]. The original edition issued in 1964 was a modified version of the Chemical Occupancy Classification rating system developed by Factory Mutual prior to 1957. It has been subsequently improved, enhanced, and simplified, and is now in its seventh edition [17].

Today there are many risk assessment methods available that can examine a chemical plant in great detail. The Fire and Explosion Index (FEI) remains a valuable screening tool that serves to quantify the expected damage from potential fire, explosion, and reactivity incidents and to identify equipment that could likely contribute to the creation or escalation of an incident [18]. Risks associated with operations where a flammable, combustible, or reactive material is stored, handled, or processed can be evaluated with this system. The guide is intended to provide a direct and logical approach for determining the probable "risk exposure" of a process plant and to suggest approaches to fire protection and loss prevention design. An important application of the FEI is to help decide when a more detailed quantitative risk analysis is warranted, as well as the appropriate depth of such a study [19]. This section will provide an overview of the method. The source document [17] should be consulted for specific application.

The concept of the Fire and Explosion Index (FEI) is to divide a process plant into separate operations or units and consider each of these individually. The key aspect of the method is the identification and assessment of thermodynamic properties of the dominant combustible material in the unit being studied. This basic material factor is then built up with a series of individual features concerning operation of the unit. These potential hazards are based on experience and information from incident records. They are intended to cover the majority of likely abnormal situations leading to fires, explosions, and material releases. Features considered are those on which all hazard and reliability analyses are based. However, the FEI does not purport to be as comprehensive as a detailed hazard and reliability study. The approach identifies most of the potentially hazardous features of a unit. Quantitative measurements used in the analysis are based on historic loss data, the energy potential of the key material, and the extent to which loss prevention practices are applied.

Index Calculation

The basic procedure for calculation of the Fire and Explosion Index is shown in Fig. 82.2. The first step is to identify those process units considered pertinent to the process and having the greatest potential impact in the event of loss by fire or explosion. A *unit* is considered to be a part of the plant that can be readily and logically characterized as a separate entity. Generally a unit consists of a segment of the process, such as reactors, blenders, furnaces, storage tanks, and so forth. In some instances, units may be portions of a plant separated from the remainder by distance, fire walls, or other barriers. In other cases, the unit may be an area where a particular hazard exists.

The next step is the determination of the material factor for the dominant combustible component of the process unit. The *material factor* is a measure of intensity of energy release from a chemical compound, mixture of compounds, or substance. It is determined by considering the flammability and reactivity of a material as described in NFPA 704, *Standard System for the Identification of the Fire Hazards of Materials*, 1990 edition [20]; NFPA 49, *Hazardous Chemicals Data*, 1991 edition [21]; and NFPA 325, *Guide to Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids*, 1991 edition [22]. Based on these values the material factor is denoted by a number from 1 to 40. This arrangement is an arbitrary ordinal ranking.

Subsequent to selecting the appropriate material factor, penalties for contributing hazards are assessed as indicated by the schedule shown in Fig. 82.3. Items listed in the schedule are considered contributing factors to an incident that may result in fire or explosion. Not every hazard is applicable to a given process unit; however, all applicable items should be evaluated and an appropriate penalty applied. The list is divided into two parts, "General Process Hazards" and "Special Process Hazards." General process hazards relate to a type of process and represent conditions that may increase the magnitude or severity of an incident. Special process hazards are items that increase the probability of a fire or explosion.

Penalties are summed separately for each class of process hazard. These sums are then multiplied (severity × probability) to yield a process unit hazards factor. This factor has

a numerical range from 1 to 8 and is considered a measure of the probable relative damage exposure magnitude. The Fire and Explosion Index (FEI) is the product of the material factor and the process unit hazards factor.

Risk Analysis

The process unit hazards factor and the material factor are also used to derive a damage factor. The damage factor represents the overall effect of fire, plus blast damage resulting from a fire or reactive energy release, caused by the various contributing factors associated with the process unit. It is estimated graphically. A radius of exposure in feet is estimated as 84 % of the FEI. The dollar value exposed is the estimated value of all equipment within the circle prescribed by the exposure radius. That is, the defined circular area of exposure indicates those assets that may be exposed to a fire or explosion generated by the process unit being evaluated. The replacement value of equipment in this area multiplied by the damage factor provides the base maximum probable property damage (MPPD), that is, the value at risk times the relative damage potential.

Three categories of loss control features have been assigned credits that can potentially reduce the base MPPD to an actual MPPD: (1) process control, (2) material isolation, and (3) fire protection. Twenty-two potential credit factors are shown in Table 82.1. The base MPPD reduced by the loss control credit factor gives the actual MPPD. This value represents the probable resulting loss from an incident of a reasonable magnitude given the proper functioning of protective equipment. Failure of the protective equipment could revert the probable loss to the base MPPD. Final steps include determination of the maximum probable days outage and the business interruption cost. The risk analysis procedure is summarized in Fig. 82.4.

The most important goal of the FEI analysis is to make the engineer aware of the loss potential of each process area and to help identify ways to lessen the severity and resultant loss of potential incidents. The Dow Chemical Company requires an FEI analysis for existing plants [18]. The requirement for use of the FEI has been adopted into law in the Netherlands [23]. The FEI has been found to be a valuable screening tool that can be used in conjunction with other analyses to help determine the relative risk of process units and to provide valuable guidance to both engineering and management staffs.

Mond Fire, Explosion, and Toxicity Index

The Mond division of Imperial Chemical Industries (ICI), Ltd., identified that the Dow Fire and Explosion Index method had considerable scope for the evaluation of plant hazard potential at the earliest design stages. Following trials with the published Dow method, it was clear that there was a need to extend the method in a number of directions to develop its potential for new project design. The resulting Mond Fire, Explosion, and Toxicity Index [24, 25] was developed and has been applied to a range of new projects within ICI.

The main contribution of the Mond method is the inclusion of *offsetting features*, which allow the effect of good design concepts, good management attitudes, and other preventative measures to reduce the overall hazard. An important outcome of using the technique is to raise questions concerning hazard potential at an early enough stage in planning to allow for adequate investigations to be made before the process is in operation. Achieving some measure of hazard early in the planning process provides information that can be used to select appropriate protection features as the planning proceeds. Early assessment of hazards has value in dealing with possible problems in obtaining approval for proposals and in predicting possible delays and problems that are likely to be encountered.

Fire Safety Evaluation System

The Fire Safety Evaluation System (FSES) [26, 27] is a risk indexing approach to determining equivalencies to the NFPA *101®*, *Life Safety Code®*, 2000 edition [28], for certain institutional occupancies. The technique was developed at the Center for Fire Research, National Bureau of Standards in cooperation with the U.S. Department of Health and Human Services (formerly Health, Education, and Welfare) in the late 1970s. It was adapted to new editions of the *Life Safety Code* and is presently published in NFPA 101A, *Guide on Alternative Approaches to Life Safety*, 2001 edition [29]. (The tables in this section are taken from the worksheets for health care occupancies in Chapter 4 of NFPA 101A.)

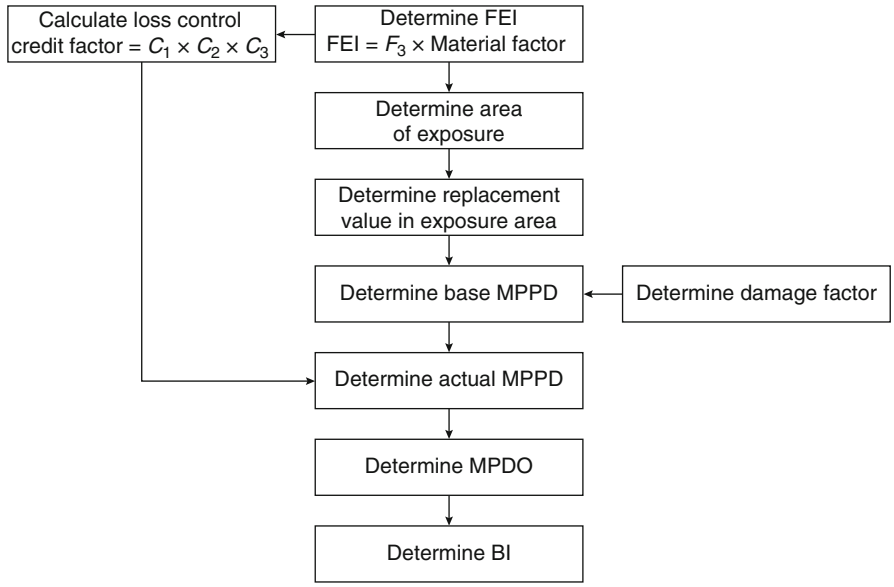

Fig. 82.4 Dow procedure for calculating other risk analysis information

Equivalency Concept

In an effort to promote economical upgrading of fire safety, U.S. codes include an equivalency option. This provision allows alternative designs to satisfy regulations if they provide a level of fire safety equivalent to that called for by the regulations. The difficult decision as to what constitutes equivalency has been left to local jurisdictions. Local interpretations lead to a lack of uniformity across the country in terms of what may be waived and what constitutes an adequate alternative to provide the required level of safety. The FSES was developed to provide a uniform method of evaluating health care facilities to determine what fire safety measures would provide a level of fire safety equivalent to that provided by the *Life Safety Code*. The objective was to compile an evaluation system that would be easily workable, presenting useful information for the amount of effort expended.

Fire Zone Concept

Unlike the Life *Safety Code*, the FSES subdivides a building into fire zones for evaluation. A fire zone is defined as a space separated from other parts of the building by floors, fire barriers, or smoke barriers. When fire or smoke barriers do not partition a floor, the entire floor is the fire zone. In application, every zone in the facility should be evaluated. Repetitive arrangements may be evaluated by selection of a typical zone.

Risk

Also unlike the *Life Safety Code*, the FSES begins with a determination of relative risk deriving from characteristics of a health care occupancy. Five occupancy risk parameters are used: (1) patient mobility, (2) patient density, (3) fire zone location, (4) ratio of patients to attendants, and (5) average patient age. Variations of these parameters have been assigned relative weights, as indicated in Table 82.2. These values were determined from the experienced judgment of a group of fire safety professionals and represent the opinions of that panel of experts. There is no documented process for validating or revising these values.

Occupancy risk factor for a zone is calculated as the product of the assigned values for the five risk parameters. Multiplication implicitly

Table 82.2 FSES occupancy risk parameter factors

Risk parameters	Risk factor values					
1. Patient mobility (M)	Mobility status	Mobile	Limited mobility	Not mobile	Not movable	
	Risk factor	1.0	1.6	3.2	4.5	
2. Patient density (D)	No. patients	1–5	6–10	11–30	>30	
	Risk factor	1.0	1.2	1.5	2.0	
3. Zone location (L)	Floor	1st	2nd or 3rd	4th to 6th	7th and above	Basements
	Risk factor	1.1	1.2	1.4	1.6	1.6
4. Ratio of patients to attendants (T)	Patients / Attendant	1 – 2 / 1	3 – 5 / 1	6 – 10 / 1	> 10 / 1	One or more[a] / None
	Risk factor	1.0	1.1	1.2	1.5	4.0
5. Patient average age (A)	Age	Under 65 years and over 1 year		65 years and over, 1 year and younger		
	Risk factor	1.0		1.2		

[a]Risk factor of 4.0 is charged to any zone that houses patients without any staff in immediate attendance

suggests these factors are interdependent. A hardship adjustment for existing buildings is applied to the occupancy risk factor. This adjustment modifies the risk in existing buildings to 60 % of that for an equivalent new building.

Fire Safety Parameters

Safety features must offset the calculated occupancy risk. Thirteen fire safety parameters were selected. These parameters and their respective ranges of values (shown in Table 82.2) were also developed by the same panel of experts. Table 82.2 is designed to be used as a survey instrument whereby appropriate values for each safety parameter can be selected by inspection of the fire zone. There is no attempt made to directly correlate these fire safety parameters to the previously defined risk parameters.

Fire Safety Redundancies

An important concept of the FSES is redundancy through simultaneous use of alternative safety strategies. The purpose is to ensure that failure of a single protection device or system will not result in a major fire loss. Three fire safety strategies are identified: (1) containment, (2) extinguishment, and (3) people movement. Table 82.3 indicates the expert panel's opinion of which fire safety parameters apply to each fire safety strategy. Values from Table 82.2 are entered in the appropriate places on Table 82.3 and summed for each column. The implication of addition is that there is no interaction among the fire safety parameters. The limited value of automatic sprinklers for people movement safety is adjusted for by using one-half of the parameter value in this column. The resulting sums are considered to be the available level of each fire safety strategy.

Equivalency Evaluations

The FSES determines whether the fire zone in question possesses a level of fire safety equivalent to that of the *Life Safety Code*. This conclusion is made by comparing the calculated level for each fire safety strategy to stated minimum values. These values for existing buildings range from 100 % down to 12 % of those for new buildings. For the column of Table 82.4 labeled "General Safety," the sum of all available safety parameter values is compared to the occupancy risk factor calculated from the parameters in Table 82.3.

Supplemental Requirements

Because the 13 selected fire safety parameters were found not to cover all requirements of the

Table 82.3 FSES safety parameter values

Life Safety Code, an addendum to the FSES was created. The addendum consists of 12 additional parameters that may be required by the *Life Safety Code*. It should not be implied that these parameters are extraneous to the risk and safety factors of Tables 82.2 and 82.3 or to the identified fire safety strategies.

Optimization

A distinct advantage of index approaches to fire risk assessment is that they lend themselves to optimization techniques. This characteristic has been exploited for the FSES through incorporation of a linear programming

optimization algorithm [30–35]. Linear programming refers to a mathematical model for allocating limited resources among competing activities subject to a set of constraints. The procedure finds the distribution of values that optimizes an objective function.

For a fire risk index, the objective is to minimize cost of fire protection that will meet a prescribed acceptable level. In the FSES, the acceptable levels are given and the variables are the safety parameters that can take on the values indicated in Table 82.2. By assigning a cost to each value in Table 82.2, an economic optimum can be calculated. A personal computer version of this model is described in the last section of this chapter.

Derivative Applications

NFPA 101A now includes FSESs for health care occupancies, correctional facilities, board and care homes, and business occupancies. One of the most widely used of these is Chap. 8. NFPA 101A classifies the transaction of business other than mercantile, the keeping of accounts and records, and similar purposes as a business occupancy. Typical examples are professional, financial, and governmental offices. The FSES for business occupancies was derived from a project to appraise the relative level of life safety from fire in existing office buildings and combination office-laboratory buildings of a U.S. government agency [36]. It was based on the approach developed for health care occupancies and was subsequently incorporated into NFPA 101A. An analysis of the FSES for business occupancies, using the attribute value spread as a measure of importance to rank the fire safety attributes, found a difference between criteria for new and existing buildings of 6–10 % [37]. A PC-based computer program, Enhanced Fire Safety Evaluation System for Business Occupancies (EFSES), is described later in this chapter.

Also derived from the original FSES is Section 3408, "Compliance Alternatives," of the BOCA *National Building Code*® [38], an indexing system for fire safety in existing buildings. As stated in paragraph 3408.1, the purpose of this section is to maintain or increase safety in existing buildings without full compliance of other chapters of the code. This system allows for older designs to be judged on their performance capabilities rather than forcing the buildings to comply with modern standards for new construction. Originally adopted in the 1985 code, significant changes were effected between the 1993 and 1996 editions. Section 3408 is applicable to all occupancy use groups. For each use group there are separate point values for each safety attribute and separate mandatory values to be considered as criteria for equivalency. This procedure for compliance alternatives has also been adopted as an appendix to Chapter 34 in the *International Building Code* [39]. A detailed comparison of both qualitative and quantitative aspects of Section 3408 of the BOCA *National Building Code* and Chapter 8 of NFPA 101A shows some significant differences [40].

Chapter ILHR 70 of the *Wisconsin Administrative Code* is a building code for historic structures [41]. Its purpose is to provide alternative building standards for preserving or restoring buildings or structures designated as historic. Subchapter IV of the code is a risk indexing system, called the Building Evaluation Method. It assesses life safety for a qualified historic building by comparing 17 building safety attributes with the requirements of the prevailing code. If a historic building has less of a safety attribute than is required by the prevailing code, a negative number is assigned. If a historic building has more of a safety attribute than is required by the prevailing code, a positive number is assigned. Thus, evaluation is directly related to the prevailing code. If the sum of all the attributes is greater than or equal to zero, the building is compliant. The same trade-offs previously would have been allowed under the variance petition process but are now codified. This system adds a degree of certainty of approval that did not previously exist, often impeding development of historic buildings. Unlike the FSES and BOCA Chapter 34, the Building Evaluation Method has no mandatory scores. If the total

safety score is equal to or greater than zero, the building is considered code compliant. Also unlike the FSES and BOCA, Wisconsin Subchapter IV does not vary by occupancy. A table for each attribute gives a set of numerical values, one of which is selected for each evaluation. Criteria for these values refer directly to the prevailing code. The same set of values applies for all nonexcluded building uses and occupancies. This code can be accessed through the State of Wisconsin, Department of Commerce website (http://www.commerce.state.wi.us).

Hierarchical Approach

Development of a hierarchical approach to fire risk ranking was initially undertaken at the University of Edinburgh, sponsored by the U.K. Department of Health and Social Services [42–44]. The objective of this study was to improve the evaluation of fire safety in U.K. hospitals through a systematic method of appraisal. This approach was further developed at the University of Ulster for application to dwelling occupancies [45, 46]. It has been refined and implemented for the assessment of fire risk in telecommunications facilities [47, 48].

Defining fire safety is difficult and often results in a listing of factors that together comprise the intent. These factors tend to be of different sorts. For example, fire safety may be defined in terms of goals and aims, such as fire prevention, fire control, occupant protection, and so forth. These broad concepts are usually found in the introductory section of building codes and other fire safety legislation. Or, fire safety may be defined in terms of more specific hardware items, such as combustibility of materials, heat sources, detectors, sprinklers, and so forth. These topics are more akin to items listed in the table of contents of building codes. A meaningful exercise is to construct a matrix of fire safety goals versus more specific fire safety features. This matrix helps to identify the roles of these two concepts in theory and in practice.

Decision-Making Levels

As a logical extension of a single fire safety matrix, consider that there are more than two categories of fire safety factors. This idea suggests a hierarchy of decision-making levels, or lists denoting things that comprise fire safety. A hierarchy of fire safety decision-making levels is presented in Table 82.5.

These represent common levels of fire safety decision making, but there may be more or fewer in a particular application. For example, an even lower level dealing with individual physical items could be added or intermediate levels could be used to better define certain relationships.

This hierarchy of levels of detail of fire safety suggests that a series of matrices is appropriate to model the relationships among various fire safety factors; that is, a matrix of policy versus objectives would define a fire safety policy by identifying the specific objectives that are held most desirable. In turn, a matrix of objectives versus strategies would identify the relationship of these factors, and a matrix of strategies versus attributes would suggest where to use what. Thus, a matrix may be constructed to examine the association of any two adjacent levels in a hierarchy of fire safety factors.

An even more appealing aspect of this approach is that two or more matrices may be

Table 82.5 Hierarchy of fire safety decision-making levels

Level	Name	Description
1	Policy	Course or general plan of action adopted by an organization to achieve security against fire and its effects
2	Objectives	Specific fire safety goals to be achieved
3	Strategies	Independent fire safety alternatives, each of which contributes wholly or partly to the fulfillment of fire safety objectives
4	Attributes	Components of fire risk that are determinable by direct or indirect measure or estimate
5	Survey	Measurable feature that serves as items a constituent part of a fire safety attribute

combined (multiplied) to produce information on the importance of specific detail of building elements to an overall fire safety policy—information not previously available. This approach is the only such grading of fire safety with an explicitly defined relationship to fire safety goals and objectives.

Generalized Procedure

A generalized procedure for ranking fire safety attributes to determine their relative importance is summarized in the following five steps:

1. Identify hierarchical levels of fire safety specification.
2. Specify items comprising each level.
3. Construct and assign values to matrices of each sequential pair of levels.
4. Combine (multiply) matrices to yield importance ranking of items.
5. Verify the results.

Table 82.4 represents an example of Step 1. Step 2 requires that lists of objectives, strategies, attributes, and survey items be developed. A list of fire safety objectives might include statements about life safety, property protection, continuity of operations, environmental protection, and heritage preservation.

No significant work has been done to identify just what it is that fire safety is trying to achieve (i.e., allocation of resources for fire safety is not generally directly associated with a specific corporate objective), so these objectives are a very subjective list. (One benefit of the hierarchical approach is facilitating the incorporation of fire safety into more global organizational objectives).

In most applications a Delphi process is used to define fire safety policy in terms of the specified list of objectives. That is, a group of experts is asked to rank fire safety objectives with respect to their importance to policy. Each member of the Delphi group receives feedback in the form of response averages, and the process repeats until an acceptable level of consensus is reached. The Delphi exercise yields a vector representing the relative importance of each objective to organizational policy. In some work the more formal analytic hierarchy process (AHP) is used [49, 50]. However, this process is unstable when there are more than six or seven factors to be ranked [2].

The next decision-making level involves fire safety strategies. A list of strategies can be derived by taking a cutset of the NFPA Fire Safety Concepts Tree [51]. Example fire safety strategies are ignition prevention, limitation of combustibles, compartmentation, fire detection and alarm, fire suppression, and protection of exposed people or things.

Now, a matrix of objectives versus strategies can be constructed. Values of the cells are again supplied by Delphi or some other subjective decision-making process. In this case the question to be answered is, how important is each strategy to the achievement of each objective?

In order to facilitate mathematical manipulation, the values of the matrices can be normalized. Then, multiplying the objectives/strategies matrix by the policy vector yields a new vector that shows the relative contribution of each strategy to overall fire safety policy. Although this vector is not essential to the fire safety evaluation, it illustrates the matrix manipulation process that is the essence of the hierarchical approach.

Continuing this procedure, the next level of fire safety attributes is considered. The following is a typical list of these attributes:

Construction	Equipment	Fixed suppression
Height	Special hazards	Fire department
Compartmentation	Detection	Egress system
Building services	Alarm	Personnel
Furnishings	Smoke control	Management

A matrix of strategies versus fire safety attributes is then constructed and evaluated. Multiplying this matrix by the previously derived vector yields a new vector that weighs each fire safety attribute according to its relative contribution to organizational fire safety policy. The significance of this vector is that it is the only such weighing of fire safety factors that has an explicit link to fire safety goals and objectives. The matrix manipulation process is summarized in Fig. 82.5.

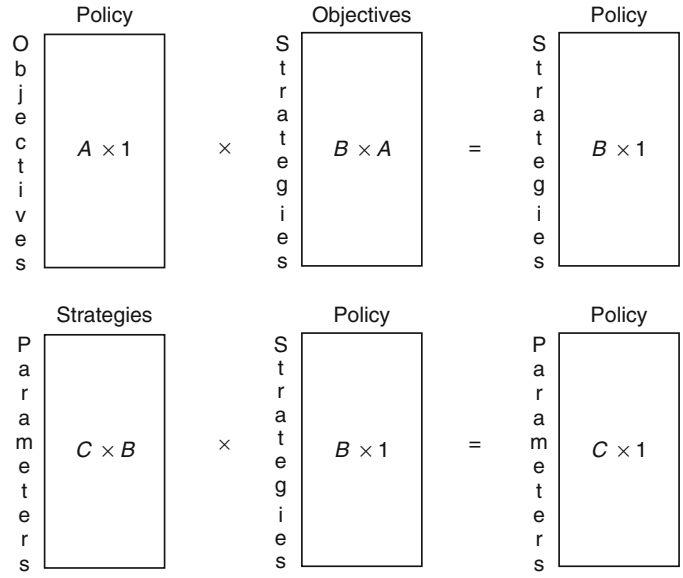

Fig. 82.5 Schematic summary of hierarchical approach

Attribute Weighting

Not all fire safety attributes are equally important. The role of weight serves to express the importance of each attribute compared with the others. Hence the assignment of weights is a key component of fire risk indexing. Formal methods of analysis generally require information regarding the relative importance of each attribute, which is usually supplied by a cardinal scale. Weights can be directly supplied or developed by specific methods. In some simple cases the weights default to equality as in a checklist. There are many weight assessment techniques used in multiattribute evaluation that are reviewed in the literature [52, 53].

Generally, hierarchical methods have been found effective in fire safety evaluation. For example, importance weighting of fire safety attributes can be developed using pairwise comparisons and the analytic hierarchy process (AHP). AHP has been widely reviewed and applied in the literature and its use is supported by several commercially available user-friendly software packages. The best known and most supported by commercial software is the eigenvalue prioritization method [54, 55]. However, there are limitations to the use of AHP in a fire risk index. The analytic hierarchy process is not as intuitive or transparent as simpler approaches, and it significantly restricts the number of attributes that can be considered. Also, under certain unusual circumstances AHP can be subject to distortion and rank reversal.

Evaluating Attributes

In order to use the resulting vector of attribute weights to develop a fire risk ranking of a building or facility space, the extent to which each attribute is present must be evaluated. That is, a level of functional value of each fire safety attribute must be assessed. These attribute grades may be directly observable or, more often, they are derived from various functions of a lower level of features that includes specific hardware components, for example, fire safety survey items.

Attributes are defined as components of fire risk that are quantitatively determinable by direct or indirect measurement or estimation. They are intended to represent factors that account for an acceptably large portion of the total fire risk. In most cases they are not directly measurable. This case is especially true for existing buildings for which only limited information is readily available.

Each attribute has a specific relative importance that is universal for all facilities within the scope of the assessment method. Individual buildings will vary in the degree to which attributes exist or occur in a space. Attribute grades are a measure of the intensity level or degree of danger or security afforded by the attribute. Partitioning them into measurable constituent parts facilitates grading of attributes. Usually these parts are directly assessable survey items, the next lower level in the decision hierarchy. The determination of attribute grades is dependent on those features of a space identified as survey items.

A survey item is a measurable feature of a space that serves as a constituent part of one or more attributes. In developing means to grade attributes in a given building, each attribute is associated with one or more survey items. These specific features evolve from analysis of the attributes. Items are chosen for contributing significantly to the effectiveness of the irrespective attributes and for being directly measurable. It is, therefore, necessary that survey items be defined in sufficient detail to support these traits. Detailed descriptions of the survey items are required to frame questions that provide input into the decision logic that produces the attribute grades.

In one application, grades were established for each fire risk attribute by associating readily measurable survey items, using logic described by decision tables [56]. Input to these tables included fire test results, fire hazard modeling, field experience from previous fire events, logic diagrams, and professional judgment. The scalar product of the resulting attribute weights and grades yields a relative measure of fire risk. The result may be used to rank facilities, or it can be compared to a standard value.

Areas of Application

As indicated in the beginning of this section, the hierarchical approach has evolved from applications in the areas of health care facilities, dwellings, and telecommunications central office facilities. Recent applications of this approach to fire risk indexing have developed in many forms and for many uses. In the United States, a Historic Fire Risk Index has been developed that includes an assessment of the cultural significance as a parameter of fire risk [57, 58]. In Hong Kong, aspects of fuzzy systems theory have been incorporated into a fire risk indexing technique to evaluate existing high-rise buildings [59]. Also in Hong Kong, a derived fire risk index has been tested on 122 existing high-rise buildings [60].

Whereas most fire risk indexing methods focus on life safety issues, FireSEPC (fire safety evaluation procedure for the property of parish churches) is insurance motivated and deals with building worth [61]. Using the hierarchical framework, the procedure rates the contribution of 18 fire safety components and compares the score to a "collated norm" developed from guidance documents.

In Sweden there is a significant program for the development and verification of a fire risk index method for timber-frame, multistory apartment buildings [62, 63]. This work is of particular importance due to its comprehensive documentation and validation procedures.

Criteria for Development and Evaluation of Fire Risk Ranking

The fire protection engineering community appears to be largely unconcerned with the proliferation of fire risk ranking and how it is being used. The available literature deals only with development and application of a specific method or general descriptions of several selected approaches. Like any analytical technique, risk-ranking methods have their limitations and should not be used uncritically.

The purpose of fire risk ranking is to provide a useful aid to decision making. It must be easy to apply but sophisticated enough to provide a minimum of technical validity. Credibility can also be improved through consistency and transparency. The approach should be systematic, and it should be clear to all interested parties that the

relevant technical issues have been appropriately covered. Based on the review of numerous fire risk ranking systems, ten criteria have been proposed to aid in the development and evaluation of other such systems [64].

Criterion 1 *Development and implementation of the method should be thoroughly documented according to standard procedures*. One of the hallmarks of professionalism is that, as a study proceeds, a record is made of assumptions, data, attribute estimates and why they were chosen, model structure and details, steps in the analysis, relevant constraints, results, sensitivity tests, validation, and so on. Little of this information is available for most fire risk ranking methods.

In addition to facilitating review, there are three other practical reasons not to slight the documentation: (1) if external validation is to be conducted, adequate documentation will be a prerequisite; (2) during the life cycle of a fire risk ranking system the inescapable changes and adjustments will require appropriate documentation; and (3) clear and complete documentation enhances confidence in the method, whereas its absence inevitably carries with it the opposite effect.

The value of the documentation will be improved if it follows established guidelines. Standard formats for documentation are primarily directed at large-scale computer models [65, 66] but can be readily adapted in principle to more general applications.

Criterion 2 *Partition the universe rather than select from it*. One of the least well-established procedures in fire risk ranking is the choice of attributes. In following a systemic approach it is best to be comprehensive. Using an exhaustive model of fire safety, such as the NFPA Fire Safety Concepts Tree [51], is helpful in being inclusive. This logic tree branches out from the holistic concept of fire safety objectives. A cut set on the tree will then identify a group of attributes that encompasses all possible fire safety features.

Criterion 3 *Attributes should represent the most frequent fire scenarios*. In determining the level of detail of the attributes, it is necessary to look at those factors that are most significant, statistically or by experienced judgment. This criterion may also be used as an alternative to Criterion 2, providing the need for systemic comprehensiveness is satisfied.

Criterion 4 *Provide operational definitions of attributes*. If the methodology is to be used by more than a single individual, it is necessary to ensure precise communication of the intent of key terms. Many fire risk attributes are ambiguous concepts that have a wide variety of interpretation even within the fire community.

Criterion 5 *Elicit subjective values systematically*. Most fire risk ranking methods rely heavily on experienced judgment. The use of formalized, documented procedures, such as the multiattribute utility theory, analytic hierarchy process, and Delphi process, significantly increases credibility of the system. Similarly, use of recognizable scaling techniques will enhance credibility.

Criterion 6 *Attribute values should be maintainable*. One variable that is not explicitly included in fire risk ranking, but which is very important, is time. It influences the fire risk both internally (e.g., deterioration) and externally (e.g., technological developments). In order for a method to have a reasonable, useful lifetime, it must be amenable to updating. This requirement implies that the procedure for generating attribute values must be repeatable. Changes over time and new information dictate that the system facilitate revisions.

Criterion 7 *Treat attribute interaction consistently*. In the majority of cases, treating attribute interaction consistently will consist of an explicitly stated assumption of no interaction among attributes. Where interactions are considered, it is important that they be dealt with systematically to avoid bias.

Criterion 8 *State the linearity assumption*. Although the linearity assumption is universal

in fire risk ranking, it is also well known that fire risk variables do not necessarily behave in a linear fashion. It is important to the acceptance of ranking methods and their limitations that such assumptions are understood.

Criterion 9 *Describe fire risk by a single indicator*. The objective of most fire risk ranking methods is to sacrifice details and individual features for the sake of making the assessment easier. Information should be reduced to a single score, even in the most complex applications. The results should be presented in a manner that makes their significance clear in a simple and unambiguous way. Unless all those involved can understand and discuss the meaning of the ranking, there will not be general confidence in its adequacy.

Criterion 10 *Evaluate predictive capability*. Some attempt should be made to verify that the method does in fact differentiate between lesser and greater fire risks with sufficient precision. It is not feasible to validate a model per se, but some testing should be documented. The American Society for Testing and Materials [67] gives some guidance on this subject. The level of accuracy demanded here is not the same as for other engineering purposes, and establishing an order of magnitude will generally suffice.

Computer Models for Fire Risk Indexing

In most cases, a fire risk index can be readily implemented on a typical computer spreadsheet. However, several software packages or programs have been developed to facilitate optimization, file management, and extensions of fire risk indexing methods. The following programs are presented as illustrative examples and do not constitute an exhaustive list.

ALARM 1.0 (Alternative Life Safety Analysis for Retrofit Cost Minimization) is a PC software tool that helps decision makers in health care facilities to achieve cost-effective compliance with the *Life Safety Code* [68, 69]. The program is based on earlier work by Chapman and Hall [30–35]. It uses a mathematical optimization algorithm called linear programming to quickly evaluate all possible code compliance solutions and identify the least-cost means of achieving compliance. ALARM 1.0 generates a set of options from which the most appropriate code compliance strategy based on cost and design considerations can be selected. Also listed—for both individual zones and the entire building—are up to 20 alternative, low-cost compliance plans and the prescriptive solution for benchmarking purposes. The software includes the integrated code compliance optimizer, full-screen data editor, and file manager.

ALARM 2.0 is a follow-up to ALARM 1.0 that is specific to life safety analysis of detention and correctional occupancies corresponding to Chapter 5 of NFPA 101A [70]. It allows users to enter data about the physical dimensions of a prison facility through an interface that mirrors the main worksheet of NFPA 101A. The program then applies its cost algorithms and unit cost data to estimate the cost of each safety improvement to be considered. The cost estimates automatically vary by facility location using the built-in geographic area cost factors of the nearest major city. Finally, the software quickly finds the most cost-effective construction plan for achieving compliance with the *Life Safety Code*.

COFRA (Central Office Fire Risk Assessment) is a proprietary computer program that assesses risk in telephone central office facilities [71]. Two incidents in the last decade have shown the potential severity of a fire that causes interruption of a telecommunications network. Conformance with fire safety code requirements does not adequately address the susceptibility of critical equipment or service continuity. Initial evaluation of this issue revealed that significant conflicts existed among demands for technical accuracy, ease of use, and implementation cost. This evaluation led to the development of a fire risk indexing method for the assessment of telecommunications network integrity. The approach uses a multiattribute evaluation model to determine the potential contributions to fire risk from individual fire safety attributes of a

facility space [47, 48]. Weights for the identified attributes were developed systematically from fire safety policy, objectives, and strategies. Methods were constructed to grade the attributes from onsite survey information. Principles of the Delphi process, decision tables, analytic hierarchy process (AHP), and other techniques of decision analysis were used in the development of attribute weights and grading methods. The scalar product of the attribute weights and grades produces a relative measure of the fire risk to integrity of a communications network. This program is presently an unsupported product of Telcordia Technologies.

EFSES (Enhanced Fire Safety Evaluation System for Business Occupancies) [72, 73] is a PC-based computer implementation of Chapter 8 in NFPA 101A and has been adopted as Chapter 9 of NFPA 101A. The PC-based software automates the calculation process and forms generation. Also, it provides the user with guidance and online help in making the decisions involved in completing the FSES. The help screens provide background information and reference material to assist the user in choosing attribute values. Another enhancement allows the user to interpolate between attribute values in the worksheet table. The program also allows "refinement calculations" that consider attributes in more depth. For example, the construction refinement calculation uses Law's fire severity calculation to estimate the fire duration in the worst-case space in the building. If this result is less than the fire resistance of the building's structural elements, then the attribute value can be increased. The program is distributed through NFPA and can be downloaded and installed from ftp://209.21.183.33/efsesinstall.exe, where the EFSES user manual is online in PDF format.

FREM (Fire Risk Evaluation Model) is Windows-based software that calculates a simplified assessment of fire risk associated with a given building [74, 75]. FREM follows the general approach of the Gretener method [13]. Developed by National Risk Control Services in Australia, the program was sold to Gallagher Basset Services, Inc., in Itasca, Illinois, in 1996.

RiskPro is another model based on the Gretener method [13] that was also developed in Australia [76]. It incorporates a database of input values for more than 400 typical occupancies.

The software tool Dow Indices [77] uses the Dow Fire and Explosion Index [17] in an interactive, computer-based environment to identify hazards associated with the storage and use of flammable and explosive materials in a chemical plant. The program includes a library of chemicals, online help, and a variety of visual tools to determine the dominant contributors to the overall hazard. The Dow Indices tool can be linked to existing chemical process simulators through the Visual Basic programming platform. In addition, the software can be coupled with economic evaluators, such as a cash flow analysis, using the maximum probable property damage and business interruptions loss predicted by the index. The American Institute of Chemical Engineers (AIChE) is currently reviewing the program for marketing opportunities.

Summary

Fire risk indexing systems have become common because of their high utility and relative ease of application. Fire safety evaluation involves a large number of ill-defined factors that are hard to assess in a uniform and consistent way. Analysis of such a complex system is difficult but not impossible, as evidenced by activities in the fields of nuclear safety and environmental protection. More detailed risk assessment can be an expensive and labor-intensive process that is sometimes not transparent. A fire risk index can provide a cost-effective means of fire safety evaluation that is sufficient in both utility and validity. Additional information can be found in Chapter 13 of Rasbash et al. [78].

Risk-Informed Industrial Fire Protection Engineering

83

Thomas F. Barry

Introduction

Risk-informed fire protection evaluation is a risk-based decision support tool that evaluates fire and explosion consequence likelihood and includes an analysis of fire protection system (s) performance reliability [1].

The type of risk-based evaluation and level of detail should be dependent on the complexity of the risk and the needs of the decision maker. Table 83.1 lists three general levels of decisions to help decision makers choose an appropriate basis for their decisions [2, 3].

Based on the decision class, risk management goals, and risk-informed project objectives, the most efficient risk assessment and risk communication methods should be applied. The results must provide the information needed to make informed fire protection decisions based on risk tolerance and cost-effectiveness.

The risk-informed evaluation framework, presented in Fig. 83.1, includes the following:

- Hazard evaluation
- Consequence analysis
- Fire risk evaluation method selection
- Risk-reduction decision making
- Risk monitoring

The purpose of this chapter is to provide an overview of fire risk-informed evaluation methods. References are included to allow the reader to pursue further detail. Emphasis is given to the fire risk evaluation method called fire protection system–layer of protection analysis (FPS-LOPA), which is becoming a popular approach for evaluating industrial process fire and explosion risks. An example FPS-LOPA is included in the chapter.

Hazard Evaluation

All fire risk-informed methods start with hazard evaluation and consequence analysis. Risk-informed approaches supplement these evaluations but do not replace them.

The purpose of a hazard evaluation is to identify and analyze the hazards, identify initiating events and scenarios, and provide appropriate documentation. A hazard evaluation can be conducted in any stage of design, operation, or decommissioning. In industrial applications, there are generally the following three types of hazard evaluations:

1. Process hazard analysis (PHA) using techniques such as the following:
   - Hazard and operability analysis (HAZOP)
   - What-if analysis
   - What-if checklists [2]
2. Fire hazard analysis (FHA)
3. Special analysis
   - Failure modes and effects analysis (FMEA)
   - Human reliability analysis (HRA)

Table 83.1 Decision class and fire risk assessment approach

Decision class	Decision context	Fire risk assessment approach	Remarks
Class A	Nothing new or unusual	Codes and standards	Easiest to apply, generally uses qualitative risk analysis
	Well-understood risk	Good practice	
	Established risk	Engineering judgment	
Class B	Life cycle implications	Fire protection system–layer of protection analysis (FPS-LOPA), which provides order-of-magnitude risk estimates based on specific cause-consequence scenarios	Simplified quantitative risk-informed evaluation methods are gaining popularity in the industry
	Some risk trade-offs		
	Some uncertainty or deviation from standard or best practice		
	Economic implications		
Class C	Very novel or challenging	Quantitative risk assessment (QRA), which provides additional detail regarding event, contributing factors, risk reduction options, and cost-benefit analysis	Most demanding on resources and skill sets but delivers most detailed understanding and best decision basis if major expenditures are involved
	Significant risk trade-offs		
	Large uncertainties		
	Strong stakeholder views or perceptions		

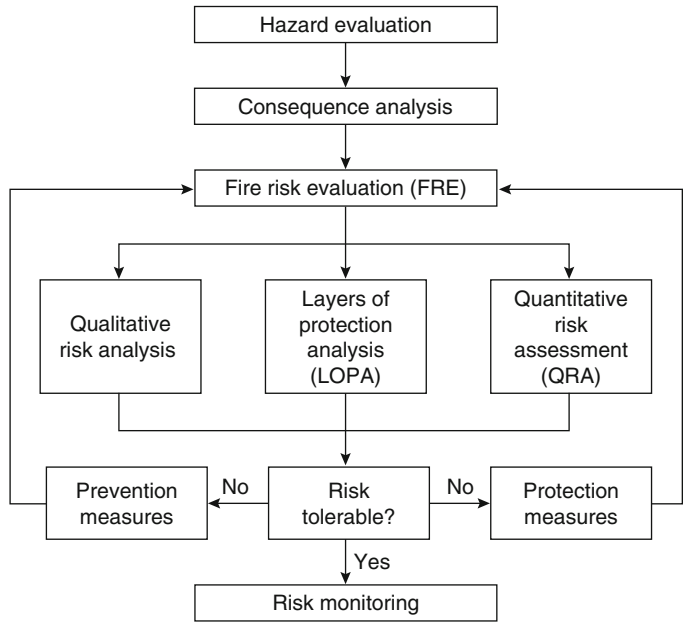

Fig. 83.1 Risk-informed evaluation framework

The most common hazard analysis and documentation techniques employed for industrial processes are what-if analysis and HAZOP. What-if analysis provides an adequate evaluation method for processes that are not highly complex and for processes that require a fair degree of operator monitoring and intervention. In general, for more complex processes, hazard and operability analysis (HAZOP) is typically used. For specific equipment failure mode analysis, failure mode and effect analysis (FMEA) is often used in combination with HAZOP or what-if analysis. Human reliability analysis is applied when operator actions are a critical component in the hazard evaluation. These methods are described in detail in *Guidelines for the Hazard Evaluation Procedures with Examples*, [4] Lees, [5] and Sutton [6].

Fire hazard analysis (FHA) specifically focuses on fire and explosion hazards, protection

features, scenarios, life safety, and property exposures, with fire protection recommendations. Numerous chapters in the *SFPE Fire Protection Engineering Handbook* and NFPA *Fire Protection Handbook*®, [7] Schroll, [8] and Zalosh [9] provide further information on industrial fire and explosion hazards.

Consequence Analysis

Consequence analysis is the process of determining the impact of initiating event scenarios to a defined target or targets independent of frequency and probability. Consequence analysis approaches range from the use of loss experience and historical data (e.g., plant or companywide loss experience, industry incident data, applicable generic accident data) to the application of deterministic fire and explosion models. Depending on consequence analysis complexity, models can range from the use of spreadsheet fire dynamics equations to zone models to computational fluid dynamics (CFD) models. In many cases consequence analysis involves a hybrid approach using available historical incident data, modeling tools, and engineering judgment to derive a consequence category.

Fire and explosion consequence analysis generally involves the evaluation of the following two segments:

- The rate of development of a hazardous environment (intensity, distance, time) within the boundaries of the predicted hazardous event, sometimes called the hazard footprint, hazard or consequence envelope, or consequence boundary. This is generally known as a physical effects severity measure. Physical effects can include thermal, combustion products, and/or overpressure effects.
- The susceptibility or vulnerability of people to harm; physical damage to equipment, stock, or structures; production downtime or business interruption; environmental damage; or other indirect losses such as loss of customers, regulator penalties or fines, or an overall financial impact estimate. This is generally known as a vulnerability measure. Overall vulnerability may be affected by variables such as the potential number of people present, evacuation capabilities, contingency plans to minimize business interruption, and so on.

When estimating consequence vulnerabilities levels for understanding by management decision makers, simplicity and consistency are key aspects. Whether it is a qualitative consequence analysis provided by a fire protection engineer or explosion expert or a deterministic first- or second-order modeling effort, the use of consequence categories provides a consistent approach and is a good risk management communication tool.

Life safety exposure and consequence levels can be broken down into categories related to injury or fatality potential to operators, employees, on-site contractors, and off-site exposure to the public. Table 83.2 presents a general example of establishing life safety exposure and consequence levels [1].

Property damage impact levels can also be broken down into categories as shown in Table 83.3 [1].

Consequence categories can also be set up for production downtime, environmental damage potential, and other various direct and indirect financial impacts, regulatory penalties or fines, media reaction, and/or loss of customers, financial (economic) impact, and so on [1].

Target threshold damage limits are generally used to provide the link between physical effects (thermal effects, products of combustion,

Table 83.2 Example life safety exposure categories

Life safety exposure	General definition	Remarks
1—Low	First aid (minor injury associated with fighting fires or evacuation)	
2—Moderate	Single-person injury requiring hospital treatment	
3—Heavy	Multiple-person injuries requiring hospital treatment	
4—High	Life-threatening injury or death on-site	
5—Major	Life-threatening injury or death off-site	

Table 83.3 Example property damage impact categories

Property damage levels	Damage factor range (%)	General definition	Remarks
1—Slight	0–1	Limited localized minor damage, not requiring repair	
2—Light	1–10	Significant localized damage of some components, generally not requiring major repair	
3—Moderate	10–25	Significant localized damage of many components warranting repair	
4—Heavy	25–60	Extensive process equipment damage requiring major repairs	
5—Major	60–100	Major widespread damage including major structural damage	

explosion overpressure, domino effects such as chemical or radiological releases, etc.), which are usually derived from fire and explosion modeling and potential end consequences (life safety injuries or fatalities, property damage, production downtime, environmental impacts, etc.). Fire and explosion modeling techniques are discussed in many chapters of the *SFPE Fire Protection Engineering Handbook*, as well as elsewhere [1, 5, 10–12].

Fire Risk Evaluation Method Selection

Risk is the product of the expected frequency (events/year) and consequences (effects/event) of a single accident or group of accidents. The equation is generally shown as

$$\text{Risk}_{\text{accident scenario}} = \text{Event frequency} \times \text{Expected consequences}(s)$$

For a group of accident scenarios, which could affect a defined target area, the equation can be expressed as

$$\text{Risk} = \sum_{\text{scenarios}} \text{Event frequency} \times \text{Expected consequences(s)}$$

In fire risk-informed evaluations we are concerned with how the performance of fire protection systems mitigates an existing risk level. Mitigated risk requires the evaluation of the following three components:

- Frequency or likelihood of the initiating event
- Probability of the failure of fire protection system performance
- Expected consequence(s)

The risk associated with the potential realization of an undesirable consequence level, taking the performance of fire protection systems into account, can be shown as

$$\text{Risk}_{\text{accident scenario}} = \text{Initiating event frequency} \times \text{Probability of FPS performance failure} \times \text{Expected consequence(s)}$$

The three primary risk methods or risk assessment techniques that are addressed in this chapter include the following:

- Qualitative risk analysis (for Class A decisions)
- Fire protection system–layer of protection analysis (for Class B decisions)
- Quantitative risk assessment (for Class C decisions)

Class A Decisions: Qualitative Risk Analysis

Qualitative risk analysis is an extension of the hazard evaluation and consequence analysis, and is primarily conducted for risk screening, risk ranking, and recommendation prioritization activities. Basis can be unmitigated risk,

Table 83.4 Example event likelihood categories

Likelihood	General definition
1—Very low	Very remote possibility of occurrence (e.g., 1/300 to 1/1000 years)
2—Low	Possibility of occurrence once over two to three times the useful life of the process (e.g., 1/100 years)
3—Moderate	Possibility of occurrence once over the lifetime of the process (e.g., 1/30 years)
4—High	Possibility of occurrence once per average process life cycle (e.g., 1/15 years)
5—Very high	Occasional possibility of occurrence (e.g., 1/5 years)

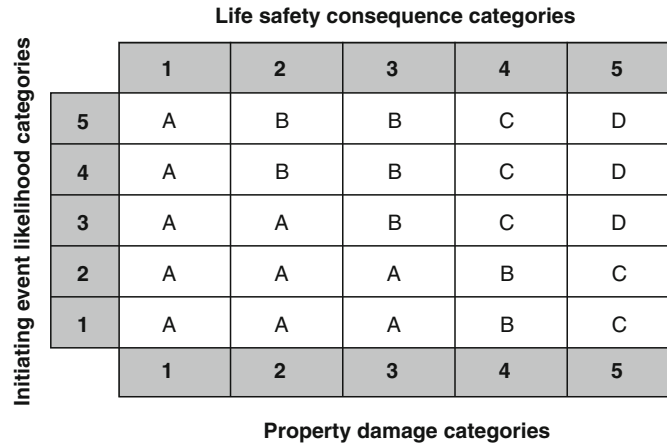

Fig. 83.2 Risk classification screening matrix

Table 83.5 Risk classification actions

Risk class	General description	Actions
A	Low-risk events	Require no further risk reduction actions
B	Low- to moderate-risk events	Require minor risk reduction improvements; generally addressed by codes, standards, industry practices, and engineering judgment
C	Moderate- to high-risk events	Require further analysis to determine an optimal risk reduction strategy or analysis of the performance and reliability of risk controls
D	High-risk events	Require immediate risk reduction analysis

mitigated risk, or both to show the relative change in risk with mitigation measures.

This method normally employs the following:

- Consequence category tables (refer to example Tables 83.2 and 83.3)
- Event likelihood category tables (refer to example Table 83.4)
- Risk classification matrix (refer to Fig. 83.2)
- Associated risk class action matrix (refer to Table 83.5)

Table 83.4 provides an example of likelihood categories [1].

Figure 83.2 presents an example of a risk classification table. In this particular example, life safety consequences and property damage categories are labeled on the same matrix for illustration purposes.

Table 83.5 presents an example of a risk class action table. This table lists action items associated with the risk classifications presented in Fig. 83.2.

Qualitative risk methods usually employ consequence categories, event likelihood ranges with qualitative descriptors, and simplified risk matrix–action item tables.

Team members' experience with similar events will have a major impact on their judgment. It is sometimes difficult to visualize and judge the risk of events that have not occurred at the plant. Uncertainty in risk judgments seems to

increase for more complex scenarios and moderate to high consequences in terms of how much credit should be given to risk mitigation measures (i.e., fire protection systems). Because of this uncertainty, many scenarios fall into a risk classification action (such as Risk Class C in Table 83.5), which recommends further detailed risk analysis (i.e., may lead to a resource-intensive QRA). Therefore, it was clear to the chemical process industry that an intermediate risk analysis method was needed, one that provided additional information on the performance of independent risk reduction measures as related to specific scenarios. This spurred the development of layer of protection analysis (LOPA), which is discussed next.

Class B Decisions: FPS-LOPA

FPS-LOPA Basics

Fire protection system–layer of protection analysis (FPS-LOPA) goes beyond the typical use of a qualitative risk matrix but is less detailed than quantitative risk analysis (QRA). FPS-LOPA provides an order-of-magnitude risk analysis tool. It addresses the fire risk mitigation equation by separating the question of "how likely is it?" into the following two components [13]:

- Likelihood (frequency) of the initiating fire event
- Probability of failure on demand (P_{fod}) of independent fire protection layers (IFPLs)

This method has proven to be an effective tool to determine whether there are enough protection layers and sufficient risk reduction to meet the risk tolerance criteria for scenarios developed from process hazard analysis (PHA) and fire hazard analysis (FHA) information. The method uses event tree logic in a table or spreadsheet format to assess moderate to high fire or explosion consequences in terms of the likelihood of occurrence. The initiating event likelihood and the probability of success of fire protection systems are evaluated quantitatively and compared to risk tolerance criteria to determine if additional fire protection layers are needed.

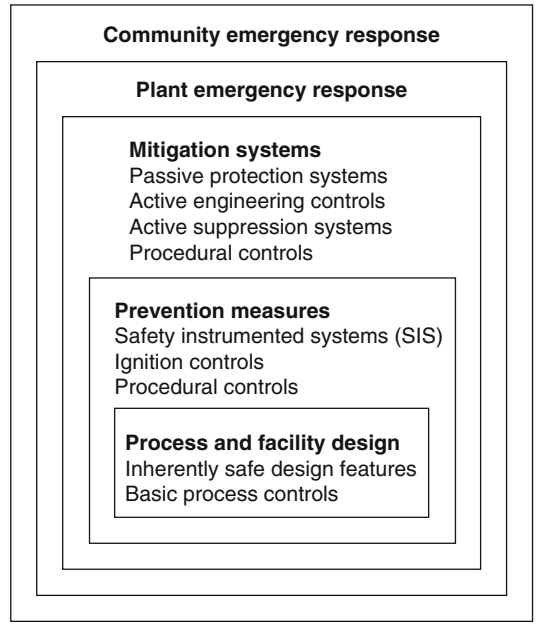

Fig. 83.3 Typical risk reduction layers at industrial facilities

Figure 83.3 illustrates typical risk reduction layers at industrial facilities.

Prevention measures can be defined as the act of causing an event not to happen and can include elimination of hazards, ignition source controls, and procedural methods such as combustible control measures.

Mitigation systems are related to measures that cause a consequence to be less severe and generally include passive protection systems, detection systems and active engineering controls, active suppression systems, and procedural systems.

- *Passive protection systems*. Systems that reduce consequences without the active functioning of any device, such as dikes, blast walls, fire barrier walls, and so on
- *Detection systems and active engineering controls*. Detection and alarms, controls, safety interlocks, and emergency shutdown systems designed to detect potentially hazardous process deviations, conditions, or equipment malfunctions and to take corrective action, including pressure relief devices; gas, smoke, and fire detection and alarm systems;

emergency shutdown systems; smoke exhaust/control systems, and so on
- *Active suppression systems*. Active suppression systems may include both automatic and manual systems: automatic systems may include sprinkler and water spray deluge systems, foam systems, gas extinguishing systems, and so on; manual suppression may include responses from operators, plant fire brigade, and public fire department
- *Procedural systems*. Operating procedures, administrative checks, plant site emergency responses, and other management approaches to minimize the severity of an incident

Discussions regarding the amount or layers of fire protection needed can result in heated debates when approached on a purely qualitative basis. Underprotection (too few layers) can potentially lead to loss of life, excessive property damage, and unexpected business interruption. Overprotection (too many layers) can lead to increased and unwarranted costs. Industrial plant risk management decision makers have to live within the constraints of available time, money, and resources. A common question is whether the company's money should be invested in prevention, mitigation, or emergency response. For example, if a system is designed to prevent a fire and provide passive mitigation features, then why are active mitigation features or additional plant fire brigade improvements necessary? Or if there is an active mitigation system, such as a sprinkler system, why are any additional fire protection features needed?

From a fire or explosion risk analyst's viewpoint, the degree of reason (need for mitigation layering) is based on the potential consequence levels, likelihood of realizing the consequences (risk level), confidence in the performance of fire protection measures (effectiveness, reliability), degree of human element involved in the scenario, and degree of risk tolerance. Inherently safe design and prevention measures should receive first attention and should be evaluated and documented through the process hazard analysis and fire hazard analysis to verify that the design features minimize the potential occurrence of a fire or explosion event.

Mitigation systems usually receive attention next and are evaluated in terms of independent fire protection layers (IFPLs): how much passive protection, how many active engineering controls, what type and how many active suppression systems, and how much procedural action will be needed. Emergency response from internally funded plant fire brigades generally receives next consideration along with public fire department response.

Several reasons not to rely on one type of fire protection, especially when dealing with uncertain fire or explosion risks, include the following:

1. No one independent fire protection system is perfect, meaning that 100 % performance, 100 % of the time is not possible.
2. Fire protection systems are subject to human error (e.g., fire door blocked open, etc.).
3. Arson or security breaches can compromise a fire protection system.
4. Inspection, maintenance, and testing deficiencies can reduce the performance reliability of a fire protection system.
5. Explosion overpressures can render a fire protection system inoperative.

These items should especially be kept in mind when developing a performance-based fire protection system design for moderate-high fire or explosion risks. This not only applies to industrial facilities but also should apply to high-rise buildings, health care facilities, airports, large assembly areas, and so on where the life safety consequences of a fire are high.

LOPA Definition and Steps

Layer of protection analysis (LOPA) defines risk as the likelihood of a specific consequence resulting from a postulated hazardous incident scenario. LOPA involves identifying initiating events, assessing existing or proposed layers of safety-related controls, and establishing tolerable frequency targets for people, property, or business interruption exposure. *Layers of Protection Analysis* [14] and Dowell [15] provide information on LOPA methods.

LOPA is a useful tool for prioritizing hazard scenarios and supporting risk-based decisions regarding the most cost-effective measures to meet risk tolerance criteria. LOPA is becoming a popular and widely used tool in the chemical, oil, gas, nuclear, and various high-tech industries. In the nuclear fuels processing industry a similar approach called risk indexing is required by the Nuclear Regulatory Agency as part of integrated safety assessments.

The Center for Chemical Process Safety (CCPS) book, *Layer of Protection Analysis, Simplified Process Risk Assessment*, states "The techniques of LOPA can be extended to most any type of risk reduction decision" [14]. LOPA methodology, whose most common application has been in the evaluation of the release of hazardous chemicals, is being applied more and more to postignition fire scenarios, pre- and postexplosion scenarios, and evaluation of emergency action plans following fire or explosion incidents. LOPA methods are also being applied to the evaluation of security failure scenarios, which could lead to terrorist-caused toxic material, fire, or explosion exposures. This type of evaluation is known as rings of protection analysis, the security equivalent of LOPA [16].

Fire protection system–layer of protection analysis (FPS-LOPA) is used in this chapter to focus on the evaluation of fire protection systems. FPS-LOPA provides a rational, objective, and simplified risk-based approach for decision making on the fire protection layers needed for specific scenarios to meet established risk tolerance criteria.

The steps involved in conducting an FPS-LOPA evaluation include the following:

1. Develop accident scenarios
2. Determine initiating fire event likelihood (events/year)
3. Quantify the performance of independent fire protection layers (IFPLs)
4. Evaluate target vulnerability
5. Estimate scenario risk
6. Conduct risk tolerance comparison
7. Make decisions on risk reduction
8. Monitor the risk

Step 1: Develop Accident Scenarios

Once a scenario has been identified and screened as a candidate for fire or explosion risk evaluation, it must be further developed and documented to a level where an understanding of the initiating events, enabling events, and independent fire protection layers (IFPLs) is achieved.

The primary components of FPS-LOPA scenario development are the following:

- Initiating event
- Enabling event(s)
- Independent fire protection system layer(s) (IFPLs)

FPS-LOPA follows an event tree calculation approach toward quantifying the likelihood of a specific cause-consequence scenario with a primary focus on the performance reliability (or probability of performance failure) of independent fire protection layers. Figure 83.4

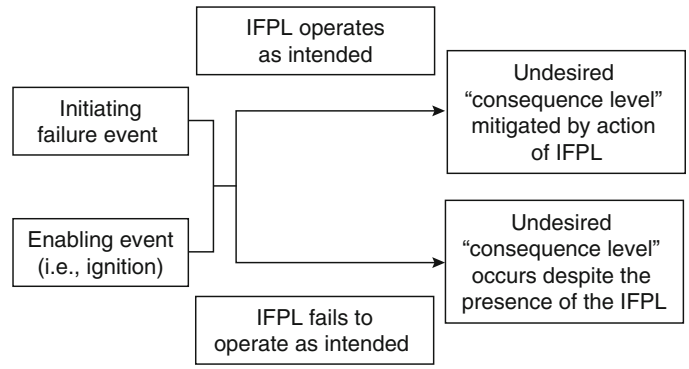

Fig. 83.4 Effect of IFPL failing to operate as intended

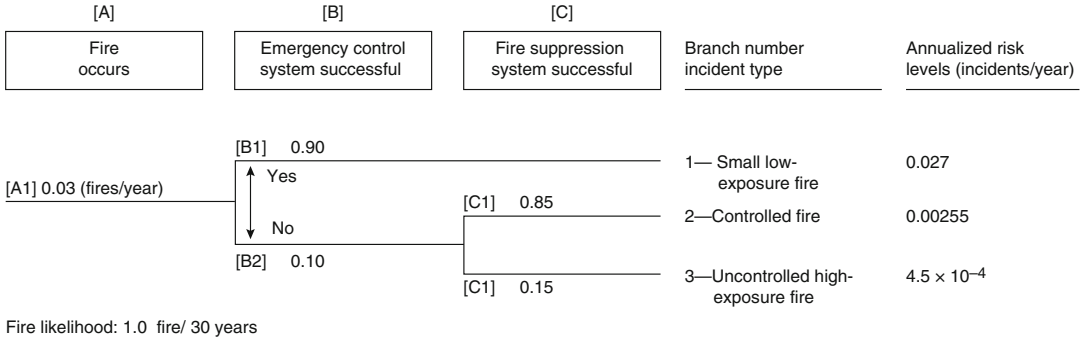

Fig. 83.5 Example of a simple fire event tree

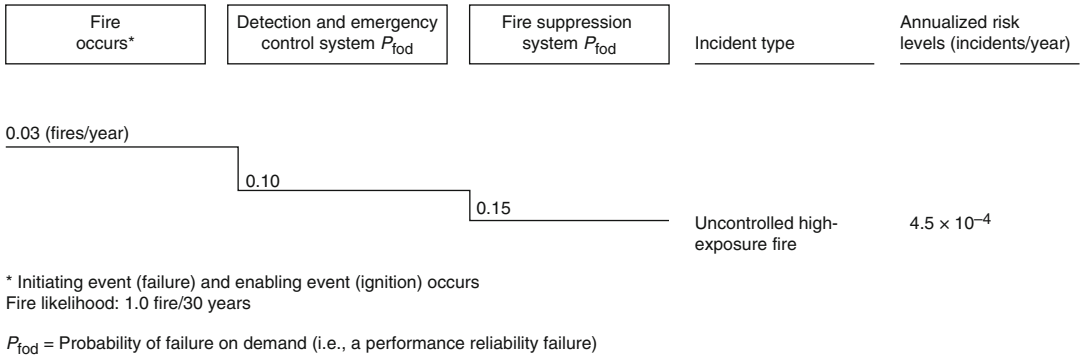

Fig. 83.6 Example of the correlation between a simple fire event tree and FPS-LOPA

illustrates an event tree showing the effect of IFPL success or failure.

As indicated, FPS-LOPA estimates the likelihood of an undesirable consequence occurring by applying a similar approach and calculation methods used in typical fire event tree analysis. As shown in Fig. 83.5, branch 3 logic indicates occurrence of an undesirable consequence in terms of an uncontrolled high-exposure fire. For this example, the likelihood of this event scenario occurring is predicated on failure of two independent protection layers: failure of (B) emergency control system, and failure of (C) fire suppression system.

The math in Fig. 83.5 for the uncontrolled high-exposure fire is as follows:

$$\begin{aligned}\text{Likelihood}_{\text{uncontrolled high-exposure fire}} &= (\text{A1}) \times (\text{B2}) \times (\text{C2}) = 0.03\,\text{fires/yr} \\ &\times 0.10 \times 0.15 = 4.5 \times 10^{-4}\,\text{events/yr}\end{aligned}$$

FPS-LOPA specifically focuses on the cause-consequence scenario pathway that leads to the high-exposure or high-consequence event, as shown in Fig. 83.6. In most cases it evaluates the likelihood of reaching that upper-bound credible or worst-case credible consequence.

Information extracted from hazard evaluations, including what-if analysis, HAZOP, fire hazard analysis, or insurance probable maximum loss reports, can form the basis for the FPS-LOPA cause-consequence scenario selection and development [1, 17].

Step 2: Determine Initiating Fire Event Likelihood

$$\begin{aligned}\text{Fire}_{\text{likelihood}} = {} & \text{Initiating event failure frequency} \\ & (\text{i.e., component failure, human error}) \times \\ & \text{Ignition probability (i.e., enabling event)}\end{aligned}$$

In most cases, when evaluating industrial processes, the primary component failure is viewed as the initiating event and ignition is the enabling event leading to a fire scenario. They are usually evaluated separately in terms of initiating event frequency and enabling event probability. In rare cases, applicable confident fire statistics may be available and can be input directly into the FPS-LOPA evaluation as the initiating fire event frequency.

For industrial FPS-LOPA evaluations, initiating events of concern are generally related to equipment component failures or human errors that cause the release or availability of flammable or highly combustible materials, which could lead to major fire or explosion incidents. These incidents usually present bounding-type scenarios in terms of people and property damage exposure.

Equipment component failure rates and human error data are extracted from plant-specific records, industry failure data, and/or generic failure databases. Table 83.6 presents an example of some equipment component failure rate ranges [14].

It is preferable to extract equipment component failure rate data from plant-specific data sources. The best sources of data are obtainable from operational and maintenance logs, other records, and interviews conducted with experienced plant personnel. Engineering judgments concerning the use and adjustment of these data can be based on plant surveys, available data, interviews, and experience. Some published failure rate data are provided in Barry, [1] *Guidelines for Process Equipment Reliability Data*, [18] *Guide to the Collection and Presentation of Electrical*, *Electronic*, *Sensing Component*, [19] and *Offshore Reliability Data Handbook* [20].

Human Error Human error probabilities are generally estimated from actual operating experience, task simulation, or expert opinion. Data derived from actual operating experience are best, but sufficient data may not be available. Expert opinion is acceptable and useful if a consistent methodology is applied within a team consensus framework. Based on review of numerous human error and human reliability references, Fig. 83.7 presents an example of human failure probability ranges for the following three cases [1]:

1. Unplanned emergencies (i.e., postfire or explosion)
2. Routine oversight (normal operations)
3. Error in operator judgment

Within each case (i.e., probability range) there is a midpoint range and upper and lower bounds that relate knowledge, experience, and training factors. How often an operation is performed, stress factors, and other relevant performance-shaping factors should also be considered. The important part in human error probability estimation is to recognize the contributing factors and to apply a credible and consistent evaluation method.

Enabling Event: Probability of Ignition Characterizing the probability of ignition following an equipment failure or human error scenario starts with the identification and understanding

Table 83.6 Example of some initiating event frequency ranges

Initiating event	Frequency range from literature (events/year)
Piping leak (10 % section)—100 m	10^{-3}–10^{-4}
Atmospheric tank failure	10^{-3}–0^{-5}
Gasket/packing blowout	10^{-2}–10^{-6}
Turbine/diesel engine overspeed with casing breach	10^{-3}–10^{-4}
Safety valve opening spuriously	10^{-2}–10^{-4}
Pump seal failure	10^{-1}–10^{-2}
Unloading/loading hose failure	1–10^{-2}
Basic process control system (BPCS) instrument loop failure	1–10^{-2}
Regulator failure	1–10^{-1}

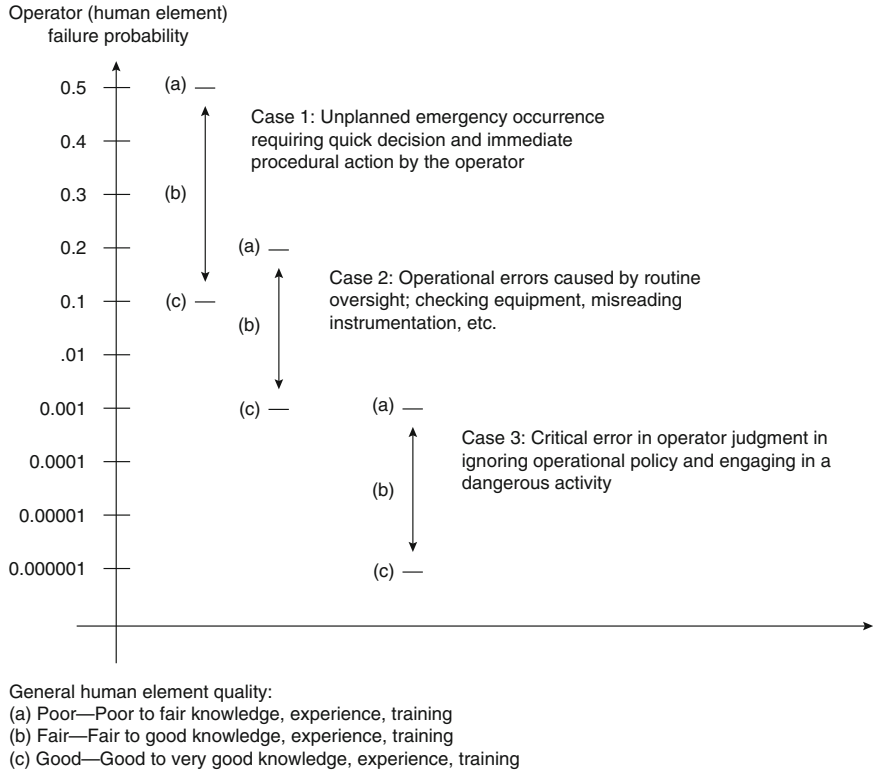

Fig. 83.7 Example of human failure probability ranges

of relevant ignition sources within the FPS-LOPA evaluation boundaries. This approach includes the following:

- Identifying ignition sources (fixed, mobile, variable) within defined exposure boundaries
- Evaluating ignition source strength (temperature, energy) in relation to the fuel's ignition sensitivity
- Estimating the frequency of time the ignition source is present

In addition to reviewing available historical fire incident data that may describe ignition factors for similar scenarios, a plant survey of the area under FPS-LOPA evaluation should be conducted to identify and evaluate specific ignition source potentials. Based on engineering review and evaluation, identified ignition sources can then be categorized in terms of availability, source strength, and ignition probability. Table 83.7 provides an example of ranking ignition source strengths in categories and relating ignition probability ranges [1].

Table 83.7 Example ignition source strength vs. ignition probability range

Ignition source strength ranking	Ignition probability ranges
Strong (S)	0.25–1.0
Medium (M)	0.05–0.24
Weak (W)	0.01–0.049

Support sources for ignition identification and availability (i.e., frequency that ignition source is present) include the following:

- Identification of plant specific ignition sources
  Plant survey
  Plant records
  Plant interviews
- Review of available industry or generic historical incident ignition data sources similar to the hazard/ignition potentials being evaluated
  Identification of major ignition contributing factors
  Ignition flame spread propagation potentials

Various sections in the *SFPE Fire Protection Engineering Handbook*, Lees, [5] and the NFPA *Fire Protection Handbook*, [7] provide information on ignition sources. *Ignition Handbook* [21] provides a comprehensive examination of ignition dynamics. Barry [1] provides information on characterizing potential ignition likelihood.

Step 3: Quantify the Performance of Independent Fire Protection Layers (IFPLs)

An independent fire protection layer (IFPL) is a device, system, or action that is capable of preventing a scenario from proceeding to the undesired consequence level regardless of the initiating event frequency or the action of any other fire protection layer associated with the scenario. In addition, the effectiveness and independence of an IFPL must be auditable. The audit process confirms that the IFPL design, installation, and functional testing and maintenance systems are in place to achieve the specified performance reliability for the IFPL [14].

In a standard LOPA evaluation, usually conducted for chemical process hazards, the focus is on measures to prevent a consequence, such as a toxic chemical release or explosion, via instrumentation, emergency isolation valves, pressure relief valves, and so on. A major assumption is that the protection safeguard is designed to perform its intended function in an effective manner and, therefore, only the operational reliability parameter is estimated [22].

Operational reliability is a measure of the probability that a protection system will operate as intended when needed. Performance reliability is a measure of the adequacy of the system to successfully perform its intended function under specific fire scenario conditions. Performance reliability, or the probability of success of a fire protection system to perform its functional performance objectives, includes both operational reliability and design effectiveness parameters.

The probability of failure of a fire protection system (P_{fod}) is the failure of the protection measure to perform its designed functional performance requirement to mitigate a scenario consequence. Fire protection systems are usually evaluated in terms of their probability of performance success (i.e., they performed their functional performance requirement as intended). The correlation here is

$$\text{Probability of success} = 1.0 - \text{Probability of failure}$$

For example, if the probability of failure due to design ineffectiveness, response time, unavailability, or operational reliability is estimated at 0.10, meaning that it may fail to perform its full functional requirements 1 out of 10 times, then the probability of success is estimated at 0.90, meaning that 9 out of 10 times it should perform successfully in meeting its functional performance requirements.

As fire protection systems (FPS) are mitigation systems, they must be viewed in terms of a performance-based reliability, which incorporates design effectiveness and operational reliability. In FPS-LOPA we are interested in the probability of success of an FPS meeting its functional performance objectives and are thus concerned with estimating the performance reliability. This is generally approached in the following ways:

1. Using historical operational reliability data (statistical data from plant records, industry data, generic databases, published equipment or component failure rate data tables) along with an analysis of the design effectiveness to meet the functional performance objectives for the specific FPS-LOPA scenario
2. Using an engineering assessment model to evaluate a performance integrity level (PIL) that is used to select performance reliability from within a range of failure probability categories, which are established from Item 1 type sources and engineering judgment
3. Using qualitative fault tree analysis (FTA) to identify contributing factors to the success or failure of the IFPL, and then using Item 1 and Item 2 sources and methods toward quantitative estimation

Operational Reliability Data and Engineering Design Assessment Statistical data on the performance of fire protection systems under exact or comparable scenario conditions are generally hard to find. Bukowski et al. [23] and British Standard 7974 [24] are often cited when first-order estimates are applied in fire risk assessments. Both references are based on compilation of available statistics from worldwide sources and expert opinion surveys. Both references use many of the same sources and, therefore, the data are fairly comparable. Bukowski et al. [23] provides a definition and distinction between operational reliability (operates as intended) and performance reliability (meets a performance requirement) and indicates data are based on operational reliability statistics. Table 83.8 provides a range of operational reliability data from published estimates [23].

It should be noted that the majority of data were compiled from residential, commercial, and institutional occupancies. The data do, however, provide an insight into an operational reliability range or bandwidth for the selected fire protection systems.

When using such data in an FPS-LOPA evaluation, selection of either an upper or lower bound for the operational reliability is generally done by conducting a survey of the installation quality and evaluating the inspection, testing, and maintenance (IMT) program. The design effectiveness is based on an engineering design evaluation and may incorporate deterministic modeling to evaluate the protection system response to the specific scenario. Uncertainty in the design effectiveness may be expressed probabilistically based on engineering evaluation and judgment. The combination of the design effectiveness (P_{de}) and operational reliability (P_{or}) probabilities can be expressed as

$$\text{Fire protection system (FPS) performance reliability} = P_{de} \times P_{or}$$

For example, if the FPS design effectiveness was evaluated by an engineer who graded the P_{de} at 0.99 and selected P_{or} at 0.95 for the specific scenario, the FPS performance reliability would be estimated as

$$\begin{aligned}\text{FPS performance reliability} &= 0.99 \times 0.95 \\ &= 0.94\end{aligned}$$

This result would indicate that the FPS should meet the functional performance objectives for the specific scenario 94 out of 100 times.

Developing an Engineering Assessment Model to Evaluate a Performance Integrity Level An engineering assessment approach that incorporates a performance-integrity basis can be applied in an FPS-LOPA evaluation. To develop a relationship between performance integrity levels (PILs) and performance reliability, the following actions are recommended:

- Conduct a code and practices compliance review
- Evaluate performance integrity measures (PIMs), based on a site-specific survey
- Assess the quality of the inspection, maintenance, and testing (IMT) program

Current codes such as mechanical, plumbing, or electrical codes, along with specific National Fire Protection Association (NFPA) standards, provide various levels of FPS design criteria. In addition, some industry associations and property insurance companies provide interpretive guides to certain NFPA standards and "good

Table 83.8 Some operational reliability ranges

Fire protection system	Operational reliability probability of success (%)	General criteria
Automatic sprinkler systems	95–97	Sprinklers operate
Masonry construction	70–95	Limit flame spread, maintain structural integrity
Gypsum partitions	69–95	Limit flame spread, compartmentation
Heat detection systems	89–95	Notify occupants and fire service
Smoke detection systems	70–90	Notify occupants and fire service

practice" design supplements based on lessons learned from fire and explosion losses.

In general, design criteria developed by these sources focus on equipment, components and materials of construction, installation requirements, and acceptance testing. Normally, very little information is provided on FPS performance factors such as the following:

- System response time design guidance and quantification methods
- Online availability issues such as design factors, which could minimize downtime
- Failure rate data references for systems, equipment, components
- Common cause failure effects (i.e., corrosion, freezing, etc.)
- Relationship of system reliability versus various design enhancement options
- Effect of inspection, maintenance, and testing on FPS reliability

What FPS design codes and standards do provide, however, is design guidance based on past failure experience; therefore, in a qualitative sense, they provide a level of reliability. In addition, FPS equipment and components must be listed or approved by nationally recognized testing laboratories.

Some primary performance integrity measures (PIMs) for FPS evaluation might also include the following:

- Design suitability, capacity, and duration for the specific hazard being evaluated
- Installation: certified installers, quality control, full acceptance test
- Response time: meets functional response time objectives
- Management of change (MOC) program: a written procedure in place for hazard review versus FPS performance
- Online availability: not subject to excessive IMT downtime, false-trip downtime, physical damage unscheduled downtime, external common cause exposure downtime, such as freezing weather, and so on
- Life cycle: age of components, repair-replacement program
- Operating environment: subject to abnormal temperatures, dust, corrosion, vibration, and so on
- Continuous online diagnostics (i.e., continuous electronic fault detection, supervision)
- Redundancy features (redundant components, secondary power supply, etc.)

Operational reliability is impacted by the frequency of proof testing as well as by the failure rate of FPS components. For fire protection systems, documenting the required test interval and test procedure associated with a required reliability and performance level is critical. The test procedure must prove the correct functioning of all parts of the FPS (i.e., input devices, control unit, and output functions). Proof testing is particularly important for detecting hidden failures that may not be revealed during normal operations.

An Engineering-Based Performance Reliability Model Barry [1] discusses the use of engineering evaluation scoring models, using grading and importance weighting measures to relate PIM quality scores for adjusting and selecting FPS failure rates (or performance success probability) from a range of generic data or statistical data bandwidths.

Using an engineering evaluation model, based on site-specific assessment, to select an FPS performance success probability may in many cases be a better choice at an industrial facility than trying to rely on some generic operational reliability statistics.

Table 83.9 presents a generic example of relating performance measures to a performance success probability range (This table is shown solely for example purposes.). The last column provides performance reliability ranges in terms of performance success probability. Again, performance reliability is based on meeting functional performance objectives or requirements based on a specific scenario.

Fault Tree Analysis Qualitative fault tree analysis (FTA) is a good tool for breaking down the contributing component failures that could lead to failure of a fire protection system. FTA can assist in the understanding of the components and factors that affect performance reliability parameters such as design effectiveness, online availability, and operational reliability. This

Table 83.9 Relating performance measures to performance success probability (solely for example purposes)

Performance measures	Performance integrity level (PIL) rating	Performance failure on demand (P_{fod}) range	Performance success probability range
Design standards, minor to major deviations	PIL-1	>0.20	<0.80
Low–medium PIM quality score			
Below average IMT program			
Design standards, no major deviations, only minor	PIL-2	0.10–0.20	0.80–0.89
Medium PIM quality score			
Average IMT program			
Design standards, compliance met	PIL-3	0.10–0.05	0.90–0.95
High PIM quality score			
Above average IMT program			
Design standards, exceed compliance requirements	PIL-4	0.05–0.01	0.96–0.99
Very high PIM quality score			
Excellent quality IMT program			

analysis provides supplemental information for assessing FPS operational reliability. FTA quantification is not usually done in an FPS-LOPA but can be used to supplement an evaluation of a complex FPS if warranted.

Use of Engineering Judgment and Subjective Probabilities In most cases a hybrid approach must be taken to estimate FPS performance reliability. A hybrid approach generally uses available frequency or probability data, engineering-based assessments and models, and engineering judgment to estimate FPS performance reliability as related to a specific scenario. Subjective engineering judgment, when used in a structured and consistent manner, has great value in understanding FPS performance under specified scenario conditions and for documenting the reliability selection rationale. In cases of industrial facilities with unique design features, unique process hazards, or new technology, supplementing the evaluation with subjective probabilities by engineers and knowledge experts may be the best approach for judging performance reliability. Vick [25] provides detailed discussion on the use of subjective engineering judgment.

Step 4: Evaluate Target Vulnerability

FPS-LOPA can be used to evaluate multiple targets including people, property, and production downtime (business interruption). The primary target in most FPS-LOPA evaluations is the potential exposure vulnerability to people in terms of the probability of serious injury or fatality from the postulated FPS-LOPA scenario. This evaluation mainly relates to emergency response actions. For example, for a given fire scenario that presents a life safety risk, the probability of occupant vulnerability is based on the population affected (i.e., people present at the time of the potential incident), evacuation or life safety egress capability beyond the fire scenario exposure boundaries, egress response time, sheltering capabilities, and so on.

Vulnerability assessment requires an understanding of the manner in which the physically described quantities and types of fire effects (e.g., thermal exposure, combustion products, and overpressure) combine with characteristics of the target (e.g., exposed people, exposed property) to produce a particular level of impact. Unusual vulnerabilities of occupants (e.g., operators must shut down equipment before

exiting), high number or density of occupants, unusual vulnerability of property (e.g., clean rooms), vulnerability to escalation (e.g., chemical releases, radiological release, collapse of structure, etc.) must also be considered [17].

The probability of fatal injury to a person, within the boundaries of the exposure zone, is evaluated as an enabling event within the cause-consequence scenario. The base equation is the product of the frequency (F) of people present and the probability (P) that the people are vulnerable (i.e., susceptible to the effects of the fire or explosion). The vulnerability component may have multiple subfactors such as the notification system reliability, effectiveness of evacuation routes, sheltering facilities, time-related human response reliability, and so on.

$$\text{Likelihood}_{\text{fatal injury}} = F_{\text{people present}} \times P_{\text{vulnerability}}$$

The presence of humans in the exposure zone raises the level of risk. If people are present 100 % of the time, then the risk will be much higher than if people are present in the area 1 % of the time. The frequency of people present can "normally" be derived from plant records and interviews with operations and maintenance managers. However, many incidents occur under nonnormal situations such as when maintenance workers or contractors are working in an area performing nonroutine maintenance, testing, or emergency repairs.

The objective of planned evasive action is to reduce the potential consequences to people from fire or explosion incidents and, thus, is a mitigation factor. Evasive actions can include sheltering-in-place, blast-resistant control rooms, escape to a designated safe shelter, or evacuation from a building, a process area, or the plant area. For assessing evacuation time effectiveness from a building, there are numerous factors to consider, such as the nature of the incident and its intensity level, the type of building, building construction, ventilation systems, fire or blast resistance integrity, type of occupants, populations, efficiency of egress routes, and frequency and quality of occupant training. For an existing facility, based on specific initiating event scenarios, these factors can be evaluated and evacuation drills can be conducted and timed. For proposed facility design for new construction or renovation projects, evacuation time effectiveness may have to be modeled. Building evacuation models are commonly termed *egress models* and are based on studies of peoples' movement within buildings.

Human performance reliability or actions in fires versus emergency response and evacuation time can be a complex evaluation. Other chapters in this handbook and *Guidelines for Evaluating Process Plant Buildings* [26] and *Engineering Guide* [27] provide further information on this subject area.

Step 5: Estimate Scenario Risk

The likelihood of realizing a specific cause-consequence scenario is calculated using the general equation format

$$\begin{aligned}\text{Likelihood}_{\text{cosequence}} = {} & \text{Frequency (initiating failure event)} \\ & \times \text{Probability of Ignition (enabling event)} \\ & \times \Pi\ \text{IFPL}\ P_{\text{fod}}\ \text{(probability of failure on demand of IFPLs)} \\ & \times \text{Probability of target vulnerability (enabling event)}\end{aligned}$$

Each of these items has been addressed in previous sections of this chapter. The enabling events in this general equation include ignition and target vulnerability. Additional enabling events may be needed to realize the consequences associated with a specifically defined scenario.

Having a consistent format in which to perform FPS-LOPA risk calculations and providing

the appropriate level of documentation are very important parts of the evaluation. The general process is illustrated in the FPS-LOPA example included in this chapter.

Step 6: Conduct Risk Tolerance Comparison

In this step, the calculated risk is compared to the risk tolerance criteria established by the plant and/or company. For FPS-LOPA evaluations at industrial facilities, the term *risk tolerance criteria* is normally used instead of acceptable risk limits. *Risk tolerance* infers an internal guideline that establishes risk threshold guidelines on fire and explosion incidents in terms of affecting life safety, company stability, and profitability. Risk criteria establish the types of risks and risk levels a company will tolerate for existing, new, or proposed processes, facilities, and plant operations.

Sources used to assist in the development of risk tolerance criteria include both human-caused and natural hazard accident statistics. The elements of acceptable risk, risk tolerance, risk perception, and so on are beyond the scope of this chapter. Barry [1] and Barry and Johnson [28] provide additional information on this subject.

For a project that involved the processing of combustible liquids, company management authorized a risk-based evaluation and established life safety and property risk tolerance criteria. Examples of the established fire risk tolerance criteria are presented in Tables 83.10 and 83.11 (for example purposes only). Table 83.10 presents an example of risk tolerance limits for life safety exposure levels. Table 83.11 presents an example of risk tolerance limits for property damage impacts from fire.

Step 7: Make Decisions on Risk Reduction

FPS-LOPA can provide the following information for a scenario on a consistent basis [13]:

- Worst-case unmitigated risk (assuming all fire protection layers fail)
- As-is mitigated risk (with existing or proposed fire protection layers in place)
- Fire protection layer improvements necessary to reach a tolerable risk threshold

Table 83.10 Life safety exposure categories for ABC complex

Life safety exposure	General definition	Likelihood tolerance limits (events/year)
1—Low	First aid (minor injury associated with firefighting or evacuation)	0.100
2—Moderate	Single-person injury requiring hospital treatment	0.010
3—Heavy	Multiple-person injuries requiring hospital treatment	0.001
4—High	Life-threatening injury or death on-site	1×10^{-5}
5—Major	Life-threatening injury/rad exposure or death off-site	1×10^{-6}

Table 83.11 Property damage impact categories for ABC complex

Property damage levels	Damage factor range (%)	General definition	Likelihood tolerance limits (events/year)
1—Slight	0–1	Limited localized minor damage not requiring repair	0.1
2—Light	1–10	Significant localized damage of some components generally not requiring major repair	1×10^{-3}
3—Moderate	10–25	Significant localized damage of many components warranting repair	1×10^{-4}
4—Heavy	25–60	Extensive process equipment damage requiring major repairs	1×10^{-5}
5—Major	60–100	Major widespread damage that may result in major structural damage	1×10^{-6}

If risk tolerance criteria are not met, the following can be further evaluated:

1. Existing (or proposed) IFPLs need improvement (e.g., increased performance reliability)
2. More independent fire protection layers are needed
3. A combination of both may be needed

The foregoing three items are usually evaluated by the risk assessment team by listing fire protection system options and examining each alternative in terms of independence, effectiveness (to meet risk tolerance criteria), initial and annual costs, and the ability to audit the measure. The FPS-LOPA example included in this chapter illustrates the general process.

Step 8: Monitor the Risk

The effectiveness and independence of an IFPL must be auditable. The audit process confirms that the IFPL design, installation, and functional testing and maintenance systems are in place to achieve the specified performance reliability for the IFPL [14].

The plant must adopt a zero tolerance toward IFPL inspection, maintenance, and testing (IMT) deviations and enforcement of administrative IFPLs. Any deviation without prior approval should be considered a serious deficiency on internal audits, as it can significantly modify the risk.

A management of change (MOC) program must also be implemented to address changes in occupancy, process operations, facility modifications, and so on, as these changes may substantially affect the performance reliability of IFPLs and, thus, affect the risk level. An impairment program must be in place to address the level of contingency (temporary protection equivalent to the IFPL being taken out of service) needed for an impaired IFPL. If an IFPL is taken out of service for a planned or emergency impairment, the risk level will be affected. A continuous, high-quality, risk monitoring program is crucial for performance-based and risk-based fire protection design approaches.

Simple Example to Illustrate FPS-LOPA Steps

For the purpose of illustrating the steps involved in FPS-LOPA, a simple example related to a chemical process facility will be used. Plant X, utility area ABC, contains chemical pipe racks, cable trays, solvent pumps, and steam and cooling water lines for supplying process facilities A, B, and C. A fire in this area could expose operators and maintenance staff to fire and toxic chemicals and could potentially shut down production in all three process areas.

As discussed at the beginning of this chapter, the type of risk-informed evaluation and level of detail should depend on the complexity of the risk and the needs of the decision maker. Plant management realizes the importance of the utility area in the operation of process areas A, B, and C and the potential exposure it could present to workers.

Due to the uncertainty involving the potential likelihood of a major fire event, concerns about the performance reliability of the existing fire protection in this area, and various past opinions regarding fire protection improvements, plant management has identified this as a Class B decision (see Table 83.1) and has requested an FPS-LOPA evaluation. The following summarizes the steps conducted by the FPS-LOPA team, which consists of representatives from engineering, operations, maintenance, safety, environmental, and fire protection.

Step 1: Develop Accident Scenarios

Table 83.12 provides a summary of FPS-LOPA components related to the specific scenario involving a combustible solvent pool fire, exposing overhead chemical lines and operations and maintenance personnel. It was assumed that, based on hazard evaluation, consequence analysis, and risk screening, this scenario provides an upper-bound credible scenario in terms of people exposure. In addition, it provides a primary

Table 83.12 Example of FPS-LOPA scenario components

Fire hazard	Initating event(s)[a]	Enabling event(s)[b]	Expected consequence(s)[c]	Prevention controls[d]	Mitigation measures[d]
Combustible solvent	Mechanical failure—pump seal failure releases solvent into utility area	1. Ignition of the solvent creates a pool fire	Potential for major fire, which exposes chemical lines and could expose operators or maintenance staff in the area to fire and toxic chemicals	Pump design—double mechanical seals	Dike around pump
		2. Operators and maintenance staff are present in the area for instrumentation checks, sampling, safety checks, equipment maintenance, and testing		Pump mechanical integrity program	Ceiling-level sprinkler system
				Combustible control program to keep combustibles away from equipment	Trained plant fire brigade

Table 83.13 Continuing example, FPS-LOPA initiating fire event likelihood

Scenario number	Initiating event	Enabling event—ignition	Initiating failure event frequency	Enabling event—ignition event probability[a]	Initiating fire likelihood (fires/year)
SN-01	Mechanical failure—pump seal failure releases solvent into utility area ABC	Ignition of solvent creates a pool fire scenario	0.03 failures/year	0.60	0.018 fires/year
			Note: There are three solvent pumps	Engineering judgment[a]	
			Reference Table 83.6 for pump seal failure, lists a lower-bound failure frequency of 0.01 failures/pump-year		

[a]Enabling event—ignition event probability; engineering judgment based on hazard evaluation, site-specific inspection, interviews with plant operators and maintenance staff. Ignition sources in area identified in terms of availability, ignition source locations mapped, and ignition source strengths evaluated in relationship to the initiating event scenario(s)

design-basis scenario for evaluating the performance reliability of existing fire protection systems in this area.

Step 2: Determine Initiating Fire Event Likelihood

Table 83.13 provides a summary of FPS-LOPA initiating fire event likelihood. The lower-bound failure rate for pump seal failures from Table 83.6, "Example of Some Initiating Event Frequency Ranges," was used in this example based on the engineering evaluation of the prevention features.

Information on prevention controls is generally used in an FPS-LOPA analysis to choose between an upper or lower bound for initiating event failure frequency. In this example pump design includes a double mechanical seal making it less prone to leakage. The pump is used in a relatively low-pressure, low-flow-rate application. The pump is part of the plant's mechanical integrity program so it receives scheduled IMT (inspection, maintenance, and testing). The plant has a combustible control program, which

involves monthly self-inspections and quarterly audits, and includes limiting and maintaining transient combustibles in the utility area so a transient combustible fire will not cause failure in utility area equipment such as the solvent pump system.

The solvent pool fire bounds an electrical fire, transient combustible fire, electric forklift fire in terms of the risk of exposure to the chemical pipe rack and to people in the area at the time of a potential incident. Therefore, it represents a credible design-basis fire scenario in which to evaluate the performance reliability of fire protection mitigation measures in meeting the established risk tolerance criteria.

Step 3: Assess Performance Reliability of Independent Fire Protection Layers (IFPLs)

Fire protection evaluation boundaries are the utility area, which is cut off from the adjacent process areas A, B, and C by 2.0-h fire-rated walls and 1.5-h fire-rated doors. Since the fire scenario being evaluated is exposure within the utility area to operators, maintenance staff, and chemical pipes, the performance of the fire walls is not directly evaluated within this example FPS-LOPA. However, because of the fire barrier importance in confining the fire to the utility area, it could be further reviewed in a supplemental fire wall performance reliability analysis to validate the selection of the fire evaluation boundaries.

The following provides a brief description of the fire protection mitigation measures listed in Table 83.12 in terms of their functional performance expectations or requirements.

Dike Around Solvent Pump The existing dike is 4.0 in. (10.16 cm) high and was initially designed to contain small solvent spills. At the existing solvent flow rate, a seal failure or failure at a flanged inlet or outlet connection to the pump could result in a solvent release rate that could overflow the existing solvent dike within 2–3 min. The dike has not been credited as an IFPL.

Ceiling-Level Sprinkler System This system is an automatic active mitigation measure. The original design intent was to provide for fire control and suppression of fires in the utility area. This design allowed the pipe rack, which contains a variety of process chemicals (some of which are highly corrosive and highly toxic), to be protected from excessive temperatures that could cause pipe failure and release of these materials. The existing system is designed for 0.40 gpm per ft^2 (16.3 L/min·m^2) over the most remote 2500 ft^2 (232 m^2).

Operation of the sprinkler system sounds an outside water motor gong alarm and transmits a water flow signal to a constantly attended control room, from which the plant's fire brigade is notified. There are obstructions to water spray distribution over the solvent pump equipment due to sprinklers being obstructed by overhead pipe runs and ventilation ducts. Some sprinkler heads are corroded; some IMT records are missing information and are not consistent.

For this example, we will assume the use of an engineering evaluation model approach (see Table 83.9) to assess the potential performance success of the existing sprinkler system. Based on identified minor design compliance deficiencies, medium PIM (performance integrity measure) score, and average IMT (inspection, maintenance, testing), a PIL-2 (performance integrity level) lower bound was selected, which is equivalent to a 0.20 P_{fod} (probability of failure on demand).

Plant Fire Brigade Response The plant fire brigade response performance can provide a minimum of five responders to this fire area in full turnout gear within 10–12 min. Based on evaluation of alarm notification time, resource availability analysis, and timed response drills, this capability can be provided 80 % of the time. The public fire department response time is approximately 20–25 min.

Based on fire modeling, an uncontrolled solvent pool fire could initiate failure of chemical pipe lines and a severe people exposure within 5–10 min. Based on the response time constraints for this specific scenario neither the plant fire

Table 83.14 Example FPS-LOPA—IPL probability of failure on demand

Independent fire protection layers—IFPLs	Engineering-based performance integrity level (PIL)	Probability of FPS performance success based on functional Requirements	P_{fod} of IFPL (probability of failure on demand)	Remarks
Dike around solvent pump				Not being credited as an IFPL
Ceiling-level sprinkler system	PIL-2 Lower bound	0.80	0.20	Can be credited as an automatic IFPL; refer to Table 83.9
Plant fire brigade response				Not being credited as an IFPL
Fire barrier wall between utility area and process areas A, B, and C				Not directly relevant to the solvent pool fire scenario affecting chemical lines in the utility area or operators/maintenance staff present in the utility area

brigade nor the public fire department is credited as an IFPL.

Table 83.14 provides a summary of FPS-LOPA independent fire protection layers (IFPLs). Based on the specific solvent pool fire scenario and the time frame for target vulnerability, the only existing credible IFPL is ceiling-level automatic sprinkler protection.

Step 4: Evaluate Target Vulnerability

Vulnerability evaluation involves solvent fire exposure to overhead chemical pipes, which contain corrosive and toxic chemicals, and exposure to operators and maintenance staff from fire and released toxic chemicals.

Based on fire modeling, an uncontrolled solvent pool fire could initiate failure of chemical pipe lines and a severe people exposure within 5–10 min. The factor that enables the life safety exposure likelihood is the probability of having operators or maintenance staff present in the utility area at the time of a potential solvent pool fire incident and the probability of severe or fatal injury vulnerability.

$$\text{Likelihood}_{\text{fatal injury}} = \text{Probability}_{\text{people present}} \times \text{Probability}_{\text{life safety vulnerability}}$$

The probability of having people in this area can generally be estimated from interviews with department supervisors. The probability of severe or fatal injury requires evaluation of the expected fire growth profile, smoke generation, and the domino effect from heated toxic chemicals being released into the area versus the time the fire is detected by the people in the area (either by sensing the situation or by alarm notification) and the time to exit the area.

Table 83.15 provides a summary of the life safety exposure likelihood evaluation for the solvent pool fire scenario.

Step 5: Estimate Scenario Risk

The general FPS-LOPA equation for estimating the likelihood for a specific cause-consequence scenario, such as the solvent pool fire scenario in this example, can be shown as

Table 83.15 Example FPS-LOPA—life safety exposure likelihood

Scenario	Consequences	Frequency of people in area	Probability of fatal injury	Life safety exposure likelihood
SN-01	Major fire that exposes chemical lines and could expose operators or maintenance staff in area to fire and toxic chemicals	Operators and maintenance staff are in the utility area approximately 4100 h per year	This is the probability of fatal injury if a person is in area at the time of an uncontrolled solvent fire incident	People availability (frequency) × Probability of fatal injury = 0.57 people present/year × 0.60 fatal injury potential = 0.34
		4100 h/8760 h-year = 0.47 1–3 people are in the utility area approximately 47 % of the time. To be conservative, estimate people availability at 57 % of time	Based on deterministic modeling and engineering judgment of the rate of fire growth and toxic gas development versus evaluation of the time for personnel sensing of the fire or alarm notification and time to exit the area, a probability of 0.60 has been assigned	To be conservative, round up to 0.40 as life safety exposure likelihood

$$\begin{aligned}\text{Likelihood}_{\text{consequence}} = {} & \text{Frequency (initiating failure event)} \\ & \times \text{Probability of ignition (enabling event)} \\ & \times \Pi \text{ IFPL } P_{\text{fod}} (\text{probability of failure on demand of IFPLs}) \\ & \times \text{Probability of target vulnerability (enabling event)}\end{aligned}$$

Substituting the results from the example (from Tables 83.12, 83.13, 83.14, and 83.15)

$$\begin{aligned}\text{Likelihood}_{\text{consequence}} = {} & 0.03 \text{ pump seal failures/year} \\ & \times 0.60 \text{ ignition} \times 0.020 \ P_{\text{fod}} \text{ sprinkler system} \\ & \times 0.40 \text{ life safety exposure} \\ = {} & 1.44 \times 10^{-3} \text{events/year}\end{aligned}$$

Normally a form or spreadsheet is used to document an FPS-LOPA scenario evaluation. Table 83.16 provides an example of a documentation format.

Step 6: Conduct Risk Tolerance Comparison

Based on Step 5, the existing risk is estimated at 1.44×10^{-3} events/year. The plant's risk tolerance criterion is 1.0×10^{-5} events/year (assumes a risk tolerance based on Table 83.10, "Example Life Safety Exposure Categories," for life-threatening injury or death on-site, established at 1.0×10^{-5} events/year). For this example, the estimated existing risk level exceeds the established risk tolerance level; therefore, additional IFPLs are needed (i.e., to reduce the existing risk level approximately two orders of magnitude).

Step 7: Make Decisions on Risk Reduction

The general approach for this step involves conducting an FPS-LOPA team brainstorming

Table 83.16 Example FPS-LOPA—documentation table

FPS-LoPA no: **Sn-01**		**Date**:	
Plant X: **ABC utility area**		**Evaluation by**:	
Location: **Bldg. 601- utility corridor**		**Review by**:	
Process: utility area ABC contains chemical pipe racks, cable trays, solvent pump, steam and cooling water lines for supplying process facilities A, B, C. A fire in this area would expose operators and maintenance staff to fire and toxic chemicals and could shut down production in all three process areas		**Area/process** ⊠ Existing Design ❍ New Design ❍ Proposed Design Modifications	
Scenario source: process hazard analysis (PHA) Item ABC-01; pump seal failure resulting in a solvent pool fire		**P&ID nos. or equipment IDs**: 601-A, 602-B, 603-C **risk tolerance**:	
Scenario: mechanical failure of pump seal failure releases combustible solvent into utility area; ignition of the solvent creates a pool fire		**Maximum target Likelihood**: 1.0×10^{-5} events/year	
Operators and maintenance staff are in area approximately 4100 h per year, generally 1–3 people. Major fire would fail chemical lines and could expose operators or maintenance staff in area to fire and toxic chemicals		**Reference**: plant risk assessment guideline RA02	
Item	Description	Probability	Frequency
Initiating event likelihood: solvent pump seal failure	Pump seal failure releases solvent into the utility area		0.03 events/year
	Note: there are three solvent pumps. Reference Table 83.6 for pump seal failure, lists a lower-bound failure frequency of 0.01 failures/pump-year		
Enabling event likelihood: ignition occurs	Ignition event probability; engineering judgment based on hazard evaluation, site-specific inspection, and interviews with plant operators and maintenance staff. Ignition sources in area were identified in terms of availability and ignition source strengths in relationship to the initiating event scenario	0.6	
Likelihood of an initiating fire		P_{fod}	0.018 fires/year
IFPL fire protection layers	Ceiling-level sprinkler system activates, suppresses fire, and prevents failure of chemical lines with corrosive and toxic chemicals	0.20	
P_{fod}—probability of performance failure on demand	Based on engineering evaluation used a PIL-2 (performance integrity level) lower bound from Table 83.9		
Other safeguards not directly credited as independent protection layers	Dike around solvent pump		
	Plant fire brigade (response time to this scenario not adequate)		
Likelihood of an unmitigated fire (uncontrolled fire)			3.6×10^{-3} uncontrolled fire events/year
Target vulnerability: life safety exposure to operators/ maintenance people	Enabling event: life safety exposure likelihood to operators/maintenance people	0.40	
	Probability of fatal injury (see Table 83.15)		
Likelihood of consequence being realized			1.44×10^{-3} events/year
Fire risk tolerance established by plant	**1×10^{-5} events per year**; **maximum tolerable risk of a** major fire that could cause extensive equipment damage; maximum tolerable risk of a fatal injury		Comment: fire risk tolerance criteria are not met with existing IFPLs

session, where various fire protection options and alternatives are discussed in terms of the risk reduction potential, feasibility, initial and annual costs, installation issues, process downtime during installation, and so on. For this example, it is assumed that relocating solvent pumps outside, rerouting chemical pipes, and constructing a fire-rated compartment around the solvent pumps are not feasible alternatives. It is further assumed that based on review of several different alternatives, the following fire protection measures are selected for further FPS-LOPA evaluation.

Install Heat Detection System and Interlocks to Minimize the Size of a Solvent Release Install a localized heat (fire) detection system for the three solvent pumps. Operation of the heat detection system would be interlocked to automatically close a safety shutoff valve on the solvent line outside the building and send an alarm to the control room. This detection and mitigation measure would reduce the potential size, intensity, and burning duration of a solvent fire and reduce the likelihood of overhead chemical line failure. This system would be designed for a minimum 0.95 performance reliability.

Make Improvements to the Existing Automatic Sprinkler System Install radiant heat flame shields at the underside of the chemical pipe rack. Install sprinkler protection under flame shields and under the ventilation air-supply duct, which is over 4.0 ft (1.22 m) in width. This will provide improved water spray coverage in this area, especially over the solvent pump equipment. Interlock the activation of the sprinkler systems to automatically close isolation valves on the bulk chemical tanks and the solvent safety shutoff valve and activate local alarms. Replace the corroded sprinkler heads and inspect the rest. Improve the sprinkler system inspection, maintenance, and testing program.

For this example, we will again assume the use of an engineering evaluation model approach (see Table 83.9) to assess the potential performance success of the proposed sprinkler system improvements. Based on engineering evaluation and judgment, improvements would increase the PIL (performance integrity level) to an upper bound PIL-3 level, which is equivalent to a 0.05 P_{fod} (probability of failure on demand) or a 0.95 performance reliability.

Reduce Life Safety Vulnerability by Early-Response Fire Alarm Notification Install two beam-type smoke detectors at the ceiling level. Operation of any one detector activates local alarms in the utility area, including strobe lights, as this area has moderate noise levels. Manual fire alarm pull boxes will be installed at both exterior exit doors and will be interlocked to automatically close isolation valves on the bulk chemical tanks and the solvent safety shut off valve. Operation of one detector, a manual fire alarm pull box, or sprinkler system will transmit a signal to a constantly attended control room and the plant fire brigade will be immediately dispatched.

Plant management realizes the importance of the utility area in the operation of process areas A, B, and C. The installation of beam smoke detectors also provides the capability for detection of potential electrical cable fires and faster response of the plant's fire brigade. The provision of automatic interlocks reduces the potential for a large solvent or toxic chemical release inside the utility area.

Table 83.17 illustrates spreadsheet-type documentation of the proposed risk reduction strategy. The proposed risk reduction measures reduce the solvent pool fire life safety exposure likelihood to 9.0×10^{-6} events/year, which meets the plant's established risk tolerance criteria.

Step 8: Monitor the Risk

As previously stated, the effectiveness and independence of an IFPL must be auditable. The audit process must confirm that the risk reduction system IFPL design, installation, and functional testing and maintenance systems are in place to achieve the specified performance reliability for the IFPL based on the FPS-LOPA risk reduction decision analysis.

Table 83.17 Example FPS-LOPA risk reduction evaluation spreadsheet

Design Phase	*A* Initiating failure event	*B* Enabling event 1: ignition	*C* FPS-IPL 1 P_{fod}	*D* FPS-IPL-2 P_{fod}	*E* Enabling event 2: target vulnerability	Likelihood Fire scenario incident likelihood
Existing design	0.03	0.60	0.20		0.40	1.44×10^{-3} events/year
	Pump seal failure	Ignition of solvent release	Ceiling-level sprinkler protection		Life safety exposure 1–3 people	
Proposed risk reduction design strategy	0.03	0.60	0.05	0.05	0.20	9.0×10^{-6} events/year
	Pump seal failure	Ignition of solvent release	Install an independent heat detection system interlocked to shut down bulk chemical isolation valves and solvent safety shut off valve	Make improvements to the sprinkler system	Life safety exposure reduced 50 % based on installation of beam smoke detectors and local alarms	
			Design for a minimum 0.95 performance reliability	Design for a minimum 0.95 performance reliability	Engineering evaluation and judgment	

Auditing, management of change (MOC), and impairment procedures will be established for the independent solvent heat detection system and interlocks, the ceiling-level automatic sprinkler protection system protecting the utility area, and the beam early-warning smoke detection system and alarms for improved independent people notification and evacuation time response (i.e., independent from the sprinkler system water flow local alarm). It is critical that these risk-monitoring measures are implemented to continuously maintain the risk tolerance criteria established by plant management.

Class C Decisions: Quantitative Risk Assessment (QRA)

FPS-LOPA goes beyond the typical use of a qualitative risk matrix but is less detailed than quantitative risk analysis (e.g., QRA used for Class C decisions).

FPS-QRA methods provide a higher degree of detail and accuracy than FPS-LOPA. For example, in FPS-QRA, fault tree analysis is normally applied to assess the primary contributing factors associated with initiating fire events and fire protection system performance. Having a detailed breakdown of contributing risk factors and quantification of these factors allows more insight into options and alternatives to reduce the risk to a tolerable level in a cost-effective manner. Event tree analysis of multiple scenarios, use of input sensitivity analysis, use of probability distribution, and use of uncertainty analysis methods provide additional information on which more intelligent risk-based decisions can be made [1, 12].

Figure 83.8 [1] presents an example of the steps to take in an FPS-QRA risk-informed, performance-based fire protection evaluation, which can be used to address Class C decisions when additional levels of analysis and detail are warranted. Risk-informed, performance-based assessments involve the quantification of initiating fire event likelihoods, development of exposure and consequence profiles (life safety, property, business interruption) using fire and explosion modeling and event tree analysis, evaluation of the performance success probability (i.e., performance reliability) of existing or proposed fire protection systems, comparison of risk results with risk tolerance criteria, and cost-benefit analysis of risk reduction alternatives if risk tolerance limits are exceeded.

Table 83.18 provides a brief comparison between FPS-LOPA and FPS-QRA methods.

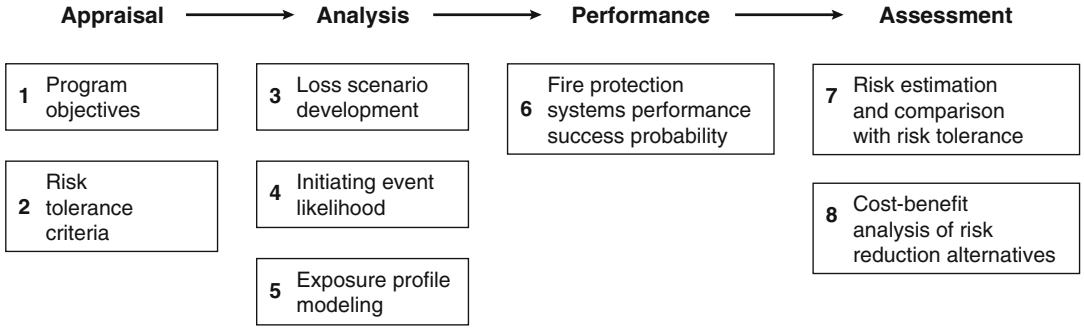

Fig. 83.8 Risk-informed performance-based fire protection steps [1]

Table 83.18 Brief comparison between FPS-LOPA and FPS-QRA methods

Item	FPS-LOPA	FPS-QRA
Decision level (note: refer to Table 83.1)	Class B decisions	Class C decisions
Accident scenario development	Evaluates a defined (normally bounding) cause-consequence pairing (typically identified during a qualitative hazard evaluation)	Can accommodate multiple cause-consequence scenarios using event tree analysis (ETA)
Initiating event frequency	Generally evaluates single component failure or single human error with a probability estimate for ignition	Can assess multiple failures and contributing factors leading to a fire or explosion event, using fault tree analysis (FTA)
	Single point frequency estimate	Probability distributions can be applied within the ETA
Performance of independent fire protection system layers (IFPLs)	Generally applies an engineering judgment-based performance reliability estimate	Usually applies a performance success tree, which allows a more detailed evaluation of performance reliability in terms of
Probability of performance failure		• Design effectiveness
		• Availability
		• Operational reliability
Scenario risk estimation	Proves an order-of-magnitude estimate of the likelihood of realizing a specific cause-consequence scenario	Provides higher-accuracy risk estimates through application of FTA and ETA
		Can accommodate sensitivity and uncertainty analysis to improve confidence
Risk reduction analysis and decision analysis	FPS-LOPA takes a specific cause-consequence scenario, determines how many protection layers are provided by existing and/or recommended independent fire protection layers (IFPLS), and evaluates whether the number and performance reliability of IFPLs provide adequate risk mitigation to meet risk tolerance criteria	Goes beyond FPS-LOPA in terms of evaluating contributing risk factors through FTA and ETA, thus allowing better decisions to be made regarding risk reduction strategies
		Provides necessary information to conduct a credible cost-benefit economic analysis

Summary

The use of an integrated or layered fire safety design approach (fire prevention, detection, passive and active protection levels, and emergency response) within a risk-informed framework provides both a balanced and quantitative method for addressing complex fire and explosion issues. It delivers supplemental decision-support information and alternatives, which allow engineers, risk managers, and regulators

the capability to make cost-effective decisions based on the unique risk factors associated with a specific building, facility, or process.

The authority having jurisdiction (AHJ) is responsible for ensuring that the layers of independent fire protection needed are relative to the risk level and imposed risk tolerance criteria. However, it may be difficult to do without risk-based information that supports the level of fire safety achieved with the fire protection design strategy under review.

The use of risk-based computations, including quantification of the performance reliability of independent fire protection layers for scenarios with uncertainty factors or potentially moderate to high consequence levels, needs to be incorporated into performance-based fire protection design submittals if this supplemental information is requested by the AHJ.

The risk-informed evaluation approaches discussed in this chapter have been performed for numerous types of industrial processes, facilities, and operations. The techniques present many crossover application capabilities to examine design-based fire scenarios and risk levels at commercial buildings, high-rise buildings, hospitals and health care facilities, large assembly areas, and so on.

A robust performance-based fire safety design code cannot be achieved without practical guidelines for delivering supplemental risk-informed information either as a supplement to performance-based design submittals on a voluntary basis or as requested by the building code official or regulator.

Nomenclature

AHJ	Authority having jurisdiction
ETA	Event tree analysis
F	Frequency
FHA	Fire hazard analysis
FMEA	Failure modes and effects analysis
FPS	Fire protection system
FPS-LOPA	Fire protection system-layer of protection analysis
FPS-QRA	Fire protection system-quantitative risk assessment
FRE	Fire risk evaluation
FTA	Fault tree analysis
HAZOP	Hazard and operability analysis
HRA	Human reliability analysis
IFPL	Independent fire protection layer
IMT	Inspection, maintenance, testing
IPL	Independent protection layer
LOPA	Layer of protection analysis
MOC	Management of change
NFPA	National fire protection analysis
P	Probability
P_{de}	Probability of design effectiveness
P_{fod}	Probability of failure on demand
PHA	Process hazard analysis
PIL	Performance integrity level
PIMs	Performance integrity measures
PML	Probable maximum loss
P_{or}	Probability of operational reliability

Barry is principal engineer and director of Risk and Reliability Services for HSB Global Standards and director of http://FireRiskForum.com, an independent website that provides fire and explosion risk-based educational and training materials. Thomas, who is a member of NFPA, SFPE, and AIChE, has over 28 years of experience as an industrial fire protection engineer and fire and explosion risk analyst in the chemical, oil, gas, power, and nuclear industries. He has written many articles on fire and explosion risk assessment; has conducted seminars on fire dynamics, fire modeling, and fire risk assessment; and is the author of the book *Risk-Informed, Performance-Based Industrial Fire Protection*.

Product Fire Risk Analysis

84

John R. Hall Jr.

Introduction

Since the late 1990s, there has been an explosion of fire risk assessment guidance documents, both in the United States and around the world. Some address the whole subject of fire risk assessment, whereas others are focused on major component tasks, such as the selection of scenarios. But nearly all of these documents are intended for assessments at the level of whole buildings or similar-sized construction projects. Almost none are intended to support design and purchase decisions at the level of products.

Most risk applications conducted by fire protection engineers will be of the whole-building type. Even for product decisions, most applications will probably be in the context of a larger design for a new building.

This chapter discusses fire risk assessment as applied to product choices. These techniques may be of use to fire protection engineers responsible for changing over the contents and furnishings of an existing building or, better still, a collection of buildings of similar type and design. However, these techniques are more likely to be used by manufacturers and industry groups—and fire protection engineers working for such employers—as part of design decisions for products to be offered to all buildings of a certain type. Someone deciding on the design of the next generation of chairs for a general office environment or carpeting for use in the lodging industry will have enough money riding on the decision to justify the nontrivial cost of analysis. Those deciding on which currently available chairs to buy for an office renovation or which carpeting to buy for use in a hotel remodeling probably will not be able to justify the cost of analysis by the value of the information to their decision. Another application of product fire risk assessment would be in the evaluation of candidate new regulations—will the risk reduction benefits exceed the costs?—and in manufacturers' product design decisions aimed at providing performance-based equivalent proof of satisfying existing regulations.

In the big picture of fire safety, there are only two ways to make changes—change things or change behavior. Every *thing* you can change could be seen as a product, in that it is a physical object that people buy, for example, from the raw materials that are used to make furniture to the finished furniture, from the components of fire detection and suppression systems to the complete systems, from wood and steel and concrete to whole buildings. That definition of product is too broad for one chapter.

For purposes of this chapter, a product will be a finished product, not raw materials or components in an assembly, but objects in an end-use form. And a product will be something that starts or feeds a fire as either a heat source or

J.R. Hall Jr. (✉)

M.J. Hurley (ed.), *SFPE Handbook of Fire Protection Engineering*,
DOI 10.1007/978-1-4939-2565-0_84, © Society of Fire Protection Engineers 2016

a fuel source. Computationally, fuel-source products involve much more elaborate calculations and effects, because the risk of heat-source products is measured solely in terms of whether or not ignition occurs. The treatment in this chapter will reflect that.

The fire risk of a product captures the range of severities of fires associated with the product and the probabilities that fires will occur having those severities. Fire risk is usually measured as expected loss, that is, the sum over all fires of probability times severity, or as the probability of having a fire more severe than a stated threshold. Either way, fire risk analysis relies heavily on fire scenarios, which are used to set up calculations of both probabilities and severities. This is *not* the same as choosing a handful of specific fires and calculating their severities and probabilities. A valid calculation must demonstrate that each specific fire analyzed is representative of a larger class of fires, that probabilities are calculated for the larger classes of fires rather than the specific fires, and that collectively the larger classes include every type of fire there can be.

For additional guidance, examine the sections on fire risk analysis in the two Society of Fire Protection Engineers references on performance-based design [1, 2] and the SFPE guide on fire risk assessment [3].

Steps in a Product Fire Risk Analysis

Of the many fire protection engineering guides and standards now available on fire risk assessment, only the guide from the American Society for Testing and Materials (ASTM) is designed for application to products rather than whole buildings. ASTM E1776 [4] is actually written as a guide to writing more product-specific fire risk assessment standards within ASTM rather than as a full guide to conducting product fire risk assessments, and ASTM E1776 relies for much of its content on ASTM E1546 [5], a counterpart document on fire hazard assessments. Therefore, the steps and substeps briefly described in this chapter reflect not only the ASTM E1776 structure but also the other documents that elaborate on fire risk assessment for application to buildings.

Here is a brief overview of the steps in a product fire hazard assessment:

1. *Define the scope of products*. In nearly all cases, one will calculate the risk reduction benefit associated with a product as a percentage reduction in the baseline risk associated with the product group or class that best fits the product of interest. A new design for upholstered furniture will be assessed against the baseline of risk in fires due to the involvement of upholstered furniture. A new design for carpeting will be assessed against the baseline of risk in fires due to the involvement of floor coverings. The product group or class contains all and only the products for which the new product of interest is a suitable substitute.
2. *Specify the class of properties in which the product will be used*. The class of properties will help to specify not only the context or environment in which the product will be used but may also specify ranges of product characteristics.
3. *Specify goals*, *objectives*, *and measures*. Are you interested in risks of death, injury, property damage, or environmental impact? Do you intend to measure those risks in those terms or are you going to use functional statements to define proxy measures in engineering terms?
4. *Set assumptions*. The assumptions referred to here are all those characteristics that will influence the ignition or development of the fire and the achievement of the goals and objectives but that are not addressed in the product or building design. For example, what are the burnable items that will make it easy or difficult for a fire begun on the product to grow to a larger fire? Or, for buildings, what are the contents and furnishings brought in by occupants but not specified in the building design that will make it easy or difficult for a fire to begin and grow rapidly?
5. *Identify and specify scenarios and scenario clusters*. For a heat-source product, this involves dividing up all the fires started by

such a product into scenario clusters based primarily on the types of burnable items the product ignites. For a burnable product, this involves dividing up the fires where the product is the first item ignited by different types of heat sources and also addressing the fires where the product is the primary fuel package though not the first fuel package.

6. *Identify test methods*, *models*, *and other data sources and calculation procedures*. The centerpiece of the necessary elements for risk calculation will be a suitably assembled and structured database on baseline fire experience.

Here are the six steps with more detail on what the steps involve. Later sections expand on techniques to be used in executing these steps.

1. *Define the scope of products to be analyzed*, *including context of use*.
   (a) Define the product or, more typically, the product class to be evaluated. Assuming you wish to match the product class specifications to a fire incident data base, the product class will likely be defined first by the product's function (e.g., for heat-source products, heating vs. cooking vs. lighting vs. power distribution; for burnable items, floor covering vs. upholstered furniture vs. cooking material). For burnable items, the product class may also be defined by the material composition of the product (e.g., fabric vs. wood vs. metal vs. plastic).
   (b) Specify where and how the product is used. For example, the product class of floor coverings would not include all uses of carpeting, because carpeting is sometimes used as a wall covering. The specification of application will not only limit the range of product characteristics, but also specify or limit the input parameters used to identify fire scenarios in which the product may play a role.
2. *Specify the class of properties in which the product will be used*. Part of identifying the scope is categorizing and specifying the property in which the product is used. The end-use or principal activity in a property defines it as an *occupancy*, which will imply a variety of characteristics and conditions in the environment of the product. For example, a risk analysis of upholstered furniture in homes will be different from a risk analysis of upholstered furniture in offices, and both will be different from a risk analysis of upholstered furniture in hotels. The types of pieces used are different, the applicable standards are different, the mix of fires they could be exposed to are different, and the mix of people likely to be present (and their capabilities) are different.
3. *Specify goals*, *objectives*, *and measures*.
   (a) Specify goals in terms of acceptable target outcomes, usually in terms of types of harm to be prevented, minimized, or otherwise reduced. Life safety, defined in terms of fatal injury or other health effects, is usually the principal goal. Property protection, avoidance of indirect loss, and protection of heritage and the environment are other typical goals.
   (b) Specify objectives, which are more specific means to the end, that is, the goals. If objectives are restated in terms of the systems and features that engineers design, they may be called *functional statements*, but for calculation purposes, they are used in the same way as objectives, as a source of quantitative performance criteria defining a threshold of acceptable fire safety or at least a scale dividing better from worse. Alternatively, objectives may be stated in terms of events (e.g., flashover) or other physical conditions of fire.
   (c) Specify or quantify goals and objectives in the form of performance criteria or other measures of loss or harm. Some measures, called *end* measures, are meaningful in and of themselves but are very difficult to predict in models or measure in tests (e.g., monetary damages, injuries). Some measures are easily predicted in models or measured in tests, but are not meaningful in

themselves (e.g., temperature or toxic gas concentrations or obscuration for particular areas or volumes). Typically, models must be used to convert readily measurable quantities to end measures of loss.

4. *Set assumptions*. Set assumptions covering all aspects of the building, occupant, system, feature, fuel load, modeling, or other elements affecting the outcomes that are not defined either by the product specifications (for the product being assessed) or by the scenarios, which address factors that vary. Set assumptions in terms of *average* conditions (or, if necessary, *typical* conditions), in order to predict overall risk-severity weighted by probability.
5. *Identify and specify the relevant scenarios and scenario clusters*. A scenario is a description of fire conditions from ignition to extinguishment. For calculation purposes, a scenario is usually defined by a set of initial conditions that can be used as input conditions to a test method or fire model. A scenario cluster is a set of scenarios, suitable for calculation of probability or likelihood. (a) To describe the baseline, it is necessary to sort and group all the fires in the baseline into non-overlapping scenario clusters that collectively include all fires. For risk analysis of a heat-source product, the clusters can most usefully be defined by groups of items that will react to the heat of the product in similar ways, for example, by smoldering or by transitioning immediately from pyrolysis to flaming. For risk analysis of a burnable-item product, the clusters can most usefully be defined by groups of heat sources that will ignite the product in similar ways, such as (i) ignitions by a smoldering heat source, typically a cigarette, (ii) ignitions by close exposure to an open flame heat source, (iii) ignition by radiative and/or convective heat at a distance or by other heat transfer from a hot object in contact with the burnable item, and (iv) ignition as a secondary item ignited by an existing unwanted fire. (b) To capture fires where the product is the main fuel package but not the initial fuel package, one begins by identifying the baseline fires where items from the product's product class played that role of main fuel package. Then those fires will need to be divided into clusters based on type of item first ignited, the size of initial fire that will tend to be produced by such items, and the proximity of such items to the product. Each cluster describes a fire challenge to the product, typically described by a heat flux at a defined range of distances. If the product is made more resistant to such ignitions or the product is changed to produce slower fire growth or lower peak intensities, then this can be modeled as a change from the baseline consequences associated with that group of fires. The baseline may provide information on the presence and performance of fire protection systems and on other nearby combustibles that may become more important to fire growth if the product is made less susceptible to ignition or rapid fire growth. In that case, test methods and engineering models can be used to provide a better estimate of the expected fire consequences if baseline fires were to begin in the same way but grow without the baseline product characteristics to feed or spread the fire.
6. *Identify test methods*, *models*, *and other data sources and calculation procedures*. The models needed will depend, in part, on the scenarios to be addressed. Each model has implications for data needs, including fire tests and statistical databases.

These are commonly available models that may be useful when estimating the likely change in consequences in a type of baseline fire that became large and consequential because of the baseline product's role as a secondary item ignited:

(a) Fire growth model
    (i) Model of rate of growth in terms of heat release rate, for example, as a function of fuel load and distances between items
    (ii) Horizontal flame spread model
    (iii) Barrier failure (e.g., door, ceiling, window)

(iv) Exterior vertical flame spread model
(v) Flame spread model in concealed spaces
(vi) Building-to-building flame spread

(b) Smoke spread model
(i) Model of room filling
(ii) Model of spread between rooms
(iii) Flashover models, including timing of flashover and postflashover smoke spread
(iv) Model of spread via heating, ventilation, or air conditioning system

(c) Occupant behavior model
(i) Model of automatic detection equipment performance
(ii) Model of how fire is discovered in the absence of automatic detection
(iii) Model of decision-making activities leading to decisions to egress or attempt rescue
(iv) Model of egress and rescue activities

(d) Intervention models
(i) Automatic suppression models, including timing of activation and effects on fire growth
(ii) Model of other suppression or extinguishment efforts and their effects (e.g., whether fire extinguishers will be used and to what effect)
(iii) Fire fighter response models

These are models that may be useful to convert outputs of calculation from engineering terms, such as physical measures of fire size, into outcomes valued for themselves, such as deaths or property damage.

(a) Fire effects or outcome models
(i) Predicted deaths and injuries due to fire effects in affected areas as a function of time
(ii) Structural damage or failure models
(iii) Predicted extent or monetary value of property damage

These are models that may be useful in estimating from test results the expected reduction in likelihood of fires based on product changes designed to prevent ignitions:

(a) Ignition probability models
(i) Fault tree, success tree, or event tree
(ii) Bayesian analysis of test results, historic fire probabilities, and other data

Defining the Scope of Products to Be Analyzed

The scope definition should define a class of interchangeable items having a common function or application in a specified occupancy and with a range of allowable choices for composition. Specification of the product should be done in a way that facilitates use of existing data, from fire incident data to product test data.

For heat-source products and fuel-source products, this means that initial specification of the product by function and construction should begin with the categories used in the National Fire Incident Reporting System (NFIRS) (see Chap. 78).

Further specification of the product by function may be needed (e.g., selecting bookcases from the cabinetry group). In such cases, the nationally representative fire incident databases will not be sufficient to estimate probabilities. Other, special fire incident databases and expert judgment will be needed.

When calculating probabilities, be sure to include appropriate shares of fires involving products that were partially or wholly undefined (e.g., upholstered furniture fires should include shares of fires involving unknown-type furniture or unknown-type form of material first ignited, and might include shares of fires involving unclassified furniture or unclassified form of material first ignited).

The range of items defined as examples of the product—which may be referred to as members of the product class—must, for analysis purposes, be reduced to a manageable number of subgroups. Each subgroup will be *defined* by a range of characteristics (e.g., all cellulosic versions of the product) but will be *represented* by one specific set of product fire characteristics.

Ordinarily, these product fire characteristics will be identified from review of results of actual fire tests on one or more representatives of the product class.

Specifying the Class of Properties

For reasons similar to those already cited for product scope definitions, property classes (i.e., occupancies) should have their primary definitions stated in terms of the categories used in NFIRS. Whenever occupancy scenarios can be defined using nationally representative, valid fire incident data, the analyst will have the strongest possible basis for estimating probabilities. The principal weakness of this data source involves the level of detail of readily available fire incident data, which often falls well short of the detail needed to run the fire hazard analysis portion of the method.

Specifying Goals, Objectives, and Measures

Overall goals for fire safety tend to fall into one of the following categories:

- Prevent adverse health effects, particularly fatal injury, to people exposed to fire. Emergency responders are normally addressed separately and may be excluded from consideration.
- Prevent monetary losses due to direct property damage.
- Prevent indirect losses due to fire, such as business interruption, missed work, and temporary housing. The types of indirect losses will differ for residential versus nonresidential occupancies, as will the relative importance of direct damage versus indirect loss.
- Prevent environmental damage. This may be damage due to fire, damage incidental to firefighting or other suppression activities, or damage associated with fire prevention or protection strategies. The negative impact of some fire retardants on recyclability of plastics could be addressed under the latter type of goal.
- Prevent harm to cultural heritage. This refers to historic buildings and similar structures for which fire damage may be more expensive or impossible to repair if historical authenticity is an objective.

A fire risk assessment of products can be conducted using the overall goals and objectives. It is also possible to use the overall goals and objectives to set functional statements for the product class.

For fire risk assessment, both severity and likelihood are important measures. Two common summary measures are expected loss (i.e., a sum over all scenarios of scenario probability times predicted scenario hazard) and probability of loss exceeding a certain threshold. Both measures can be calculated for a baseline directly from nationally representative fire incident databases, provided that the product class and property use specifications match the categories used in those databases. For example, a fire risk analysis comparison of the major types of home heating equipment is possible, because each can be identified within the fire incident databases. However, a comparison of different designs for, say, portable electric heaters could not be done using national statistics alone, because different designs are not distinguished in the national database.

Even if the national data suffices to set the baseline, a product fire risk analysis will usually require test methods and models to develop likelihood estimates and possibly revised consequence estimates for the new product. In such cases, estimation of consequence can often be simplified by focusing on flashover, and specifically on whether flashover occurs, and if so, how quickly:

1. Likelihood of flashover and/or of flame spread beyond the room of origin
2. Likelihood that time to flashover exceeds x minutes (where x could be chosen to reflect

the expected arrival of suppression and rescue forces or the time required for occupants to safely exit the building)

One approach that should usually be avoided is to try to measure loss in terms of the product's share of responsibility for overall fire severity. Such measures tend to be far too subjective and require answers to inherently unanswerable questions. For example, suppose a small trash can fire leads to a large couch fire. If *either* factor in the initial trash ignition or the burning properties of the couch is changed, no large fire would have resulted. How much loss should be assigned to the couch? There is no good answer to that question.

Instead, fire risk analysis should proceed through calculations of differences, that is, fire risk with the product of interest versus fire risk with something else substituted for the product of interest.

From this perspective, one can see how fire risk analyses can be constructed as extensions of past successful applications of fire modeling. For example, one of the earliest practical applications of the Harvard code was to the reconstruction of the 1980 MGM Grand Hotel fire. As suggested above, flashover was used as a well-defined event to focus the analysis, after it was shown that most of the fatal fire victims would have survived if flashover had been prevented. Professor Howard Emmons then used the model to rerun the fire with changes, considered individually, in the room of origin's ceiling covering; its benches and chairs; and the area's heating, ventilating, and air-conditioning (HVAC) arrangements.

If one wished to do a fire risk analysis on, say, benches and chairs for dining areas of hotels, one could define a range of possible fire scenarios, do a similar fire development analysis of each, weight the consequences by the scenario likelihoods, and thereby calculate an overall likelihood of flashover with two different choices of benches and chairs. The difference between the two likelihoods would be a valid product fire risk measure.

Setting Assumptions

Fire risk assessment requires the analyst to make assumptions. Some of the assumptions are embedded in elements of the analysis, such as a zone model's assumption that fire conditions in a room can be reasonably approximated by dividing the room into an upper and a lower layer. Some assumptions set boundaries to the analysis, such as an assumption that an effective local public fire department will respond within 5 min, which permits the designer to track fire development and effects for a limited period of time.

Many assumptions address the building, occupant, fuel load, or system characteristics that do not vary from one scenario to another. These assumptions may be treated as scenario characteristics in one assessment and as assumptions in the next assessment. Therefore, the more detailed discussion of elements of scenarios, in the next section, also applies to most of the candidate assumptions.

There is a critical difference in the handling of assumptions in fire risk assessment versus fire hazard assessment. In fire risk assessment, the purpose of the calculation is to predict what *will* happen. Challenging, high-severity scenarios must be addressed but given only as much or as little weight as the probabilities of those scenarios would justify. In fire hazard assessment, the purpose of the calculation is to predict what *might* happen for which the designer is responsible. This is where concepts like *probable worst-case scenario* become relevant. Fire hazard assessment needs to address only challenging, high-severity scenarios, and does not discount the scenarios it addresses by their probabilities. But some high-severity scenarios will be declared too challenging for a fire hazard assessment. Thus, fire hazard assessment takes an all-or-nothing approach to scenarios.

Fire risk assessment, for these reasons, will assign more variables to scenarios and fewer to assumptions than will hazard assessment. Fire risk assessment needs to address all possible scenarios. But fire risk assessment will tend to

set assumptions in terms of reproducing conditions that are typical or average *for the particular scenario or scenario cluster*.

Put another way, fire hazard assessment—a typical engineering analysis—addresses the potential for high-challenge, very severe fires by deciding which of those fires need to be addressed to satisfy the acceptable safety thresholds and constructing and conducting the analysis accordingly. Fire risk assessment addresses the potential for high-challenge, very severe fires by creating scenarios clusters of such fires so that they will receive the appropriate weight in terms of their likelihood and their severe consequences will not be lost amid a much larger number of less severe fires in the same scenario cluster.

Specifying Fire Scenarios: Using Fire Size to Shape Calculation of Change in Consequences

The baseline fires should be marked not only as to loss but also as to fire size. The fire size scale used in NFIRS has the following categories: A critical element in this approach is data on final extent of flame damage, which are captured in the major fire incident databases, as follows:

- Confined to certain specific objects—cooking vessel, chimney, flue, boiler, fuel burner, compactor, incinerator, or trash
- Confined to object of origin
- Confined to room of origin
- Confined to floor of origin
- Confined to building of origin
- Extended beyond building of origin

It may be easier to estimate how a product change will alter the mix of fire sizes, then use estimates of loss per fire as a function of fire size, than to develop a more sophisticated and precise estimation of fire size and then cope with the absence of comparably detailed data tying detailed fire size to estimated loss per fire. Also this scale directly identifies two key events in fire development—spread beyond the first fuel package and spread beyond the room of origin (which is the best proxy for flashover available in the national fire incident database).

One can assume that a fire confined to object of origin involved only the first item ignited and that a fire extending beyond the room of origin reached flashover in the room of origin.

When fire spread beyond the first item ignited and especially when fire spread beyond the room of origin, it is possible to isolate the fires for which the product class provided the item contributing most to fire spread or flame spread and to limit that group to fires in which the same product class did not provide the item first ignited. With this calculation available for calibration purposes, the risk analyst can construct and weight representative scenarios—specifying burnable items near the first item ignited and near the product, as well as room dimensions and linings—so that the models used to estimate consequences will reproduce the baseline statistics, showing the baseline's historic likelihoods of fire spread beyond the room of origin and of product involvement as the item contributing most to fire spread.

Specifying Fire Scenarios: Characterizing the Environment the Fire Is Growing Into

The previous section indicated the need to specify scenarios and then calibrate that the specifications and weights will reproduce the baseline characteristics of historic fire experience as closely as possible.

This section provides an overview of the characteristics of the environment around the product and the initial fire that will likely need to be included in those specifications.

1. *Nearby combustibles*. Characteristics of the fuel load of the room of origin whose burning properties and proximity to the initial fire and the product may play a significant role in fire development.
2. *Room linings*. Thermal properties of rooms that may bear on burning at and after flashover.

3. *Building dimensions and geometry*. Dimensions of rooms and other areas in which fire may grow or smoke may spread.
4. *Openings*. Dimensions of openings between rooms and areas relating to paths of flame or smoke spread and sources of air to feed the fire.

Nearby Combustibles One can use surveys of typical fuel loads, room configurations, and the like. Then, one can run a fire growth model with these specifications. Such survey data are very scarce, but when they exist, they may not be in the form needed. What you would like ideally would be a large database on the probability distribution of distances between possible first ignited items and the product, and a second large database on the heat flux profile for burning objects from each of the categories of possible first ignited items. The latter may be available, but the former generally is not. The surveys that are available may provide detail on too many specific combustibles, most of which will not be major contributors to the fire, or too little detail, specifying only mass per square meter normalized to some heat of combustion figure. There are few if any published examples of developing scenarios in this way, which means the risk analyst will need to experiment until he or she finds an approach that provides credible, useable results.

As in so many other areas, the temptation will be to reshape the analysis to bypass elements that cannot now be modeled with confidence. However, the analysis must somehow provide a valid basis for combining different product burning properties, and the phenomenon of secondary ignition is central to any evaluation of the product's relative ignitability. Each of the questions needs to be answered through a crosswalk between the physical parameters measured in tests and used in models and the parameters recorded in fire incident databases, because the latter is always needed to calibrate probability estimation.

Room Linings Linings of rooms and other areas need to be addressed in terms of the thermal properties required for calculations of time to flashover, speed of vertical flame spread, and the like.

Room and area linings for most occupancies are tightly regulated by codes. However, some of the most important occupancies (e.g., dwellings) are not so covered, and even for those that are, one must allow for a significant probability that the codes will not have been in force when fire occurs. Unfortunately, there is little or no data on the probabilities of different combinations of fuels in particular occupancies; and there is only very limited, dated information on typical or average fuel loads and only for some occupancies.

Building Dimensions and Geometry The overall building size and geometry can be structured into a series of questions on which data must be sought and decisions made. The first is the range of variation in the number of floors. After determining this point, the user must specify a number of floors for each occupancy scenario and assign a probability to each.

The second is a room layout for each floor. Room heights and the sizes of openings connecting rooms tend to be standardized by common industry practices, so there may be no need to consider variations. For other factors, (e.g., the number and sizes of rooms) there usually is too much variation in practice and too little data on the relative likelihood of these variations to do much more than (1) estimate one or two values for the number of rooms or the total square feet per floor, and (2) use expert panels to develop detailed layouts for the purposes of modeling and analysis of the rooms or spaces specified in (1).

However, panels of people who are experts on buildings of a certain type are likely to think in terms of the characteristics of the particular buildings they know best. They may therefore give estimates biased toward characteristics of new construction or characteristics of the buildings they live in or frequent. Fires are more likely to occur in smaller, less prestigious units in any property class. The expert panel needs to be continually reminded to adjust their perspective to think in terms of those kinds of buildings.

Openings There usually will be some information on the sizes of doors and windows, because construction practices are highly standardized even beyond code requirements. However, in a fire, the openings will depend critically on whether and how much key doors and windows are open. There are little or no data on this point for any occupancy. It may be possible to ignore windows, because there are studies indicating that windows affect most fires only after the point in time where fire severity has been determined. (However, the few exceptions will tend to be very large fires, so the reasonableness of an assumption excluding windows will need to be rechecked for any analysis.) How does one set the assumptions for doors, short of large-scale property surveys or special fire data collection projects?

For most fire protection engineering studies, the answer would be to make conservative assumptions, that is, those that present the greatest fire challenge. It is important to understand that this is usually not the right answer for fire risk analysis. If conservative assumptions lead to an overestimate of fire risk, then they may also lead to a gross overestimate or underestimate of the fire risk consequences of particular product choices. There is no substitute for a best estimate, without conservatism, in fire risk analysis.

However, an assumption that might be made in fire hazard analysis because it is conservative may also turn out to be a reasonable best estimate for fire risk analysis, if it reflects a pattern in actual fire experience. If a certain arrangement *could* produce more serious fires, it qualifies as a conservative assumption for fire hazard analysis. If that same arrangement *is producing* more serious fires, then it is more likely that that arrangement is present when a reported fire occurs than that it is present in buildings in general, and one could be justified in assuming that that arrangement is likely, in a fire risk analysis.

However, this line of reasoning has limits. Suppose that open doors is the conservative assumption, but that we know that doors tend to be open only 5 % of the time. In that case, the fire risk analysis could reasonably assume that doors are open 10–20 % of the time, reflecting the likelihood that open doors will be more likely in reported fires than in buildings, in general. But the typical situation would still be closed doors.

The analysis would need to have scenarios with open doors and scenarios with closed doors, because neither condition is dominant enough to justify omitting the other condition for a variable (i.e., whether doors are open) that is so influential on final fire size. Or, it might be possible to use one condition, consisting of doors open slightly, trying to seek a single physical condition that will reproduce the appropriate average between fully open and fully closed. Either way, considerable judgment would be needed.

Remember that, if an *average* value is used, the analyst is implicitly assuming that the fire severity associated with that average value is equal to the average of the fire severities associated with all the individual values that occur. In mathematics, this is sometimes called assuming that the average of the function equals the function of the average, and it is not usually the case. The analyst has to make the case that the assumption is reasonable in the situation being analyzed.

Specifying Fire Scenarios: Exposure of People or Property

The baseline will provide the analyst with the basics of loss per fire—life, health or damage—for different groups of fires. However, if the calculation indicates changes in fire development for particular groups of fires, then it will be necessary to match modeled predictions of changes in fire effects as a function of time and location with modeled predictions of target presence and vulnerability, also as a function of time and location. One must address (1) the locations of people or property as a function of time; and (2) the damage or loss consequences to people or property of the different possible physical characteristics of fire, for example, temperature,

quantities of toxic gases by type, corrosive properties, and quantities of smoke. The methods for doing this are not extensively developed, except for deaths. Therefore, this section will focus on that outcome.

Occupant exposure depends on (1) initial locations of the occupants relative to the fire, and (2) their escape behavior. A complete specification of the number of occupants with their initial locations and other characteristics is called an *occupant set*. The user must first define a group of occupant sets that can validly represent all possible combinations of people and their characteristics and locations, and then must estimate probabilities for each. These must then be joined to a model of occupant behavior. (See Custer and Meacham [2] for a list of evacuation models.)

Occupant behavior models consist of a set of rules for calculating the locations of occupants at a time, *t*, as a function of their locations, other occupant characteristics, and fire characteristics at the time stage just prior to *t*. Some such models track occupants individually; others give only the number of people at each location. Some, but not all, models include interactions among occupants, such as congestion or queuing effects or behavioral rules based on relationships between occupants (e.g., parents who seek to rescue babies). The more comprehensive the model may be in capturing potentially important phenomena, the more computationally demanding it will be and the more data it will demand, possibly including data that are not readily available. As in all other aspects of fire risk analysis, tradeoffs must be made in the modeling.

A brief summary of the steps required is as follows:

- Develop a probability distribution for the number of people present in the building.
- Expand the basic distribution to address relevant characteristics, including ages and relationships of occupants, time of day, and occupant conditions.
- Develop probability distributions for occupant activity as a function of time of day and of occupant characteristics, specified in the previous step.
- Develop probability distributions for occupant location given occupant activity and other occupant characteristics. (If every activity implies a unique location, this will reduce to a crosswalk.)
- Combine all probability distributions to produce a probability distribution for all occupant sets. Merge very similar occupant sets, if needed, for computational simplicity.

Specifying Fire Scenarios: Fire Protection Systems and Features

Here again, this modeling is only necessary if the analyst has shifted into the use of physical models to estimate changes in consequences. The baseline will usually indicate whether fire protection systems were present and whether they were operational, and so the calculations here will need to focus on performance under different fire conditions. Here again, there are few if any published examples of fire risk analysis using these approaches—most product fire risk assessments limit their scope to prevention—but there is increasing interest in product fire performance during the fire's growth phase.

It will be necessary to specify rules for how the system or feature will affect the fire development, the evacuation, or other conditions being tracked. Often, this will be fairly simple. One could assume that a fully operational sprinkler system will activate once a specified set of fire conditions are reached and, once activated, will totally and immediately stop the fire, except for certain specified fire scenarios (e.g., fire origin in concealed spaces), when its effect will be only to block fire entry into sprinklered areas. One could assume that a full-coverage automatic detection system will activate once a specified set of smoke or heat conditions is reached and, once activated, will alert everyone in the building to the fire, leading anyone not already in motion in the occupant evacuation model to begin evacuating. In fact, both these examples are oversimplified and possibly dangerously so. A sprinkler's full effect on fire and a detection/alarm system's full effect on occupant behavior will not be

instantaneous. The delay may be critical to outcomes and needs to be addressed in the analysis, if only to make explicit what simplifying assumptions have been made.

Identifying Test Methods and Models

Analyzing Ignition Probability While historic fire data may suffice to estimate ignition probabilities for the mix of existing products, they may not suffice to estimate ignition probabilities for specific existing products, and they will not suffice for new products. The basic approach involves converting laboratory test results to ignition probabilities.

Probabilities of ignition must be estimated from frequencies of ignition in laboratory tests of existing and new products. In essence, it is assumed that, if the new product produces more or fewer ignitions in laboratory tests than the existing products did, then the new product will have a higher or lower probability of ignition, increased or decreased by the same proportion as the ratio of the laboratory ignition frequencies. This key assumption is rarely literally true, because the test conditions are rarely weighted so as to provide a valid representation of the variety of real fire initiating conditions. Sensitivity analysis is especially important.

For fuel-source products, this estimation should be done separately for each of the major classes of heat sources (e.g., flaming versus smoldering), because product ignitability may vary across different heat sources. For heat-source products, it should be done for suitably chosen classes of initial fuel sources.

To prepare a set of laboratory test data for use in these calculations on a fuel-source product, organize the data according to the following terminology:

- Distinguish different versions of the product ($i = 1, 2, \ldots$).
- Distinguish different heat sources ($j = 1, 2, \ldots$).
- Estimate the share of all the product now in use that is version i; call this q, where $\Sigma_i\ q_i = 1$.
- Let N_{ij} be the number of times that version i of the product has been tested in the laboratory against heat source j; let n_n be the number of times that ignition occurred; and let $f_{ij} = n_{ij}/N_{ij}$.
- Let p_j be the probability of ignition of the mix of existing product by heat source j, calculated from fire experience data on the occupancy being studied.

Then assume that p_j (the product's overall probability of ignition) is proportional to $\Sigma_i\ q_i f_{ij}$ (the weighted frequency of laboratory ignitions). For a more sophisticated approach, one may wish to use Bayesian analysis, which requires estimating prior probability distributions to which one can apply the lab tests.

- Let f_{Ij} be corresponding values summarizing laboratory tests on new product I against heat source j. Note that every heat source must have its own body of test results.
- Let p_{Ij} refer to the quantities to be estimated, which are the probabilities of ignition of product I by each heat source j. Estimate as follows:

$$P_{Ij} = P_j \left[\frac{f_{ij}}{\left(\sum_i q_i f_{ij} \right)} \right]$$

In general, the p values will be much smaller than the f values, which is assumed to reflect the fact that the p values incorporate all the probabilities involved in bringing the heat source and the product in contact with one another. This estimation procedure is not so reliable if the f values are equal to, or very near, 0 or 1. Bayesian analysis is definitely required in such cases.

Calibration, Sensitivity, and Uncertainty Analysis Any fire risk analysis will involve complex calculations, with many unavoidable assumptions. While you should not use a more complex method than necessary, you also should not use a less complex method than is valid. A fire risk analysis model without a long list of stated assumptions is bound to be a model with many hidden assumptions, which are almost certain to be less well-founded, if examined, than a list of shaky but explicit assumptions.

For these reasons, running the calculations in a product fire risk analysis is easier to do well than the blend of science and art required to set up the analysis correctly (e.g., appropriate models, reasonable assumptions, best data) and to interpret the results, which includes calibration and sensitivity analysis.

Every step, starting with framing the problem and choosing the models, tests, and data, is subject to error and uncertainty, and that uncertainty must be examined in any interpretation or evaluation of the analytical conclusions. A design analyzed as having an acceptably low risk may also have enough uncertainty in the analysis to create a significant probability of unacceptably high risk.

The principal rule to remember is that the model is calibrated by assessing how well it reproduces recent fire experience from data on recent product use patterns and other practices. If the model captures the principal aspects of fire risk, then it will predict rates of loss that are very close to those actually experienced in the properties being analyzed. Results should be close not only from an overall perspective, but also for major groups of scenarios. Use the specifics of the scenarios that need better calibration as guides to which assumptions need to be modified. For example, if predictions are poor for fires with long smoldering periods, but good for all other fires, then one might want to adjust the assumptions on length of smoldering period or on fire profiles (e.g., rate of heat release curve) during smoldering periods.

Some options involve changes not just to the parameter values, but to the model structure. Examples include changes that would further multiply scenarios by allowing for multiple values (and associated probabilities) of walking speeds, evacuation decision rules, rules for waking people without detectors, and so forth.

Another approach to calibration is to use the model not to directly predict losses, but to predict percentage changes in losses due to product choices, by major scenario group. The advantage of this approach is that it allows the analyst to use the fire experience statistics to do a great deal of automatic recalibration. The disadvantage is that it does not directly address, or correct, the flawed assumptions and estimates that are preventing the model from producing accurate results without such recalibration.

Most analysts will need to both (1) adjust the structure of the analysis, and (2) use fire statistics to recalibrate.

Identify Data Sources

Product and Property Survey Data There are many good sources of national data on the characteristics of occupancies or products in general. For occupancies, this kind of data may be obtained from ongoing federal government data collection activities (typified by publications of the U.S. Census Bureau; the General Services Administration, e.g., fuel load per room, by type of room; and the U.S. Departments of Defense and Energy), from major one-time studies, or from industry association surveys (e.g., Building Owners and Managers Association, American Hotel and Motel Association, and American Restaurant Association).

For products, there may exist market surveys on patterns of composition or use. The U.S. Census Bureau and, for certain types of products, the U.S. Departments of Commerce, Energy, Housing and Urban Development, and Health and Human Services are all likely sources of information. Much of the data gathered by the U.S. government can be found in summary form in the *Statistical Abstract of the United States* or in the primary sources cited by the *Statistical Abstract*, now that the *Statistical Abstract* as a publication has been discontinued by the U.S. government. Another source of information is the U.S. Consumer Product Safety Commission, which carries out some field surveys of product performance and usage.

Chapter 78, gives specific references for these data sources if they are readily accessible. Industry association data are available through the association's periodicals or by special request to the association.

For products, however, often the only source of such information is trade associations of

manufacturers and sellers of the product. It is important to recall, however, that some products have a lifetime longer than that of a trade association, which means the association's knowledge of current industry practice, however accurate, may not describe use patterns as a whole. Upholstered furniture, for example, is typically cushioned today with synthetics, with previously used natural materials, such as cotton batting and horsehair, now a rarity. Nevertheless, the lifetime of a piece of furniture can be 30 years or more, during which time it may be re-covered several times and pass through several owners, often of continually diminishing economic station. Therefore, it is reasonable to expect that a substantial fraction of the current furniture inventory retains the burning characteristics of products of a bygone era.

In general, people knowledgeable of today's product will tend to have statistics on, and think in terms of, what is currently being *sold*, not what is currently being *used*. Translating sales data into usage statistics is far from straightforward. Moreover, one might suspect that such products would be found disproportionately where fires are likely to be more common, that is, among people and places at the lower end of the economic spectrum.

For the method to operate, all of these qualitative observations must take a quantitative form, and it is the analyst who must decide how this is to be accomplished.

Always remember that, although data on national practices are more representative of the nation than fire incident data, they are less desirable for that very reason for fire risk analysis, because they do not provide probabilities implicitly weighted by the likelihood of having a fire. For example, if you walked into a randomly selected U.S. home in 1989, the chances were better than 85 % that you would find a smoke detector present; but if you focused on homes that had fires, the chances would drop below 50 %. It is the latter probability that is more relevant in determining how risk will develop in home fires. Therefore, when data on national practices are used, it is necessary to review the data for any adjustments that may be needed to better estimate probabilities relevant to fires.

Code Requirements Many relevant building characteristics are covered by provisions of building and fire codes. Some product fire characteristics also are covered by regulations. In the absence of direct data from the field, one may assume that all buildings and products have the characteristics implied by compliance with these codes and regulations. This assumption bypasses the need for probability estimation and usually provides enough detail to permit calculation of the input needs of the fire hazard analysis method.

When this approach is followed, the analyst needs to check a number of points that may undercut the central assumption of the approach, namely, that all buildings and products are as the codes and regulations would have them. In practice, many code provisions are of fairly recent vintage so that they were not in place when many or even most of the buildings and products now in use were put into place. Some jurisdictions do not follow national consensus codes, and many more lack the enforcement apparatus to ensure a high rate of compliance. Buildings and products can be altered or may deteriorate after being built, manufactured, or sold. And some building and product features may be better than code requirements because of marketplace demands.

Putting all this together, it is important that the user verify, through the expertise of people with broad familiarity with the state of old and new buildings and products around the country, that the particular characteristics of interest are ones where the code provisions are good indicators of actual practice in nearly all buildings and products in recent use.

Expert Judgment When all else fails and numbers are needed, there is no alternative but to make the best estimates possible. In some cases, it will be a judgment made by the user alone, but especially in areas where the user is least experienced, one or more true experts should be sought. For example, if the user is a maker or seller of the product, it would be wise to make use of fire scientists for assistance in assigning values to the product's fire properties.

One of the persistent potential pitfalls in the method is the danger that the typical product in use is not the typical product involved in fires. There is no foolproof way to avoid this situation, but one way to address it is to include fire service personnel in drawing up the profile of product characteristics. Firefighters and fire marshals see the products involved in fires, whether or not they make up a substantial fraction of the statistical profile of the product.

Another pitfall is that, no matter what the expert's area of expertise, he or she may tend to underestimate the (typically) enormous variation in every characteristic of interest. Manufacturers may focus on a few best-selling versions of the product; surveys may focus on a few most widely used versions; and fire officials may focus on a few of the worst, most obsolete versions, seen in the worst (but not necessarily the most) fires. This illustrates the value of (1) a panel of experts, where biases can be balanced; and (2) a facilitator sensitive to the variation in practice, who can steer the group away from premature or overly narrow consensus.

It also suggests that, even when data are available, expert judgment is needed to interpret the data and apply them correctly. Knowledge of common versus uncommon practices, relevant codes and standards, and the length of time they have been in place, are among the kinds of information essential to spot areas of likely bias or critical uncertainty.

For all these reasons, the user can expect to make extensive use of expert judgment and should make sure that the expertise available to the project is both broad and deep.

Health Care Application of Quantitative Fire Risk Analysis

85

Håkan Frantzich

Introduction

Quantitative risk analysis (QRA) is a very powerful tool with which the fire protection engineer systematically can analyze fire safety problems. Risk analysis methods have during the last decades become more common for analyzing fire safety problems. This is partly because of the development of fire simulation tools enabling a quantitative estimation of the consequences. The increased use of risk analysis methods can also be traced back to the development of performance-based regulations and standards [1–4]. In such regulations and standards the requirement is to verify that the proposed design solution meets the fire safety objectives but they do not necessarily state how this shall be performed. The engineer, therefore, needs some tools by which he or she can structure the relevant problems and transform them to engineering problems that can be solved. Risk analysis is such a structured method.

Other chapters in this handbook provide the overall framework for performing a fire risk analysis. As evident the term *risk analysis* has no clear definition. It is, therefore, important to give a clear description of the meaning of risk analysis for every single case. It is important to state if the analysis is deterministic or probabilistic (i.e., implicitly how uncertainties are handled). This chapter deals with a quantitative and probabilistic approach to a fire safety problem.

To illustrate the methodology a sample case will be analyzed. The risk analysis covers patient safety on a fictive hospital ward. Although many of the assumptions can be traced back to Swedish building traditions, the methodology is universal. It must be noted that the calculations made are purely for the demonstration of the methodology and some of the assumptions may not be so well-founded. The sample calculations are complemented with discussions, many of which represent the personal opinion of the author. It is assumed that the reader is familiar with quantitative risk analysis procedures.

The risk measures will be derived using a standard procedure for a QRA. An extended procedure of a QRA will also be presented at the end of the chapter. The extended risk analysis can be used if one, for example, will answer the question: *How certain are we on the calculated risk measure*?

In the analysis the endpoints define when escape no longer is possible. This state will be derived using the kind of untenable conditions that are not considered lethal as is customary in fire safety engineering. It should, however, be pointed out that in using QRA for other engineering disciplines, lethal levels of untenable conditions are frequently used. There is no problem in using different definitions of untenable conditions as long as the tolerable risk levels are defined in the same manner. In performing

comparative analyses, the choice of untenable levels becomes even less important. The level chosen to define untenable conditions is given by conditions commonly used for design purposes in Sweden.

For the extended QRA procedure at the end of the chapter, however, some slightly more severe conditions are used in the calculations. The reason for changing endpoint conditions is to observe the effect of the change.

Hospital Ward System Limits

General Assumptions and Limitations

The first step in this sample risk analysis is to define the engineering problem. This step is the most important as decisions made here affect the rest of the analysis. The problem is structured according to the event tree methodology. To limit the size of the event tree some limitations are introduced. First, the analysis is restricted to only one ward in the hospital. Second, only one fire source is used for the illustration. Third, the only targets specified in this analysis are the patients on the ward. A more complete analysis, not shown here, should cover all possible fire locations, sources, and targets including the staff members.

More fire sources and fire locations may not necessarily increase the reliability of the risk measures. The chosen fire source and location are assumed representative of all sources and locations on the ward. Separation of the chosen fire location into more locations could be performed within the analysis (Fig. 85.1).

When further subdivisions in the event tree are made, the result will only affect the resolution of the societal risk profile. It is then assumed that the initial part of the event tree is unaffected.

The current analysis, using only one representative fire source, will result only in a slightly less detailed risk profile.

Multiple fire sources are implicitly considered in the extended QRA as the development of the fire is subject to uncertainty. In this standard QRA procedure, a representative value is used for all fires chosen according to principles for this type of analysis.

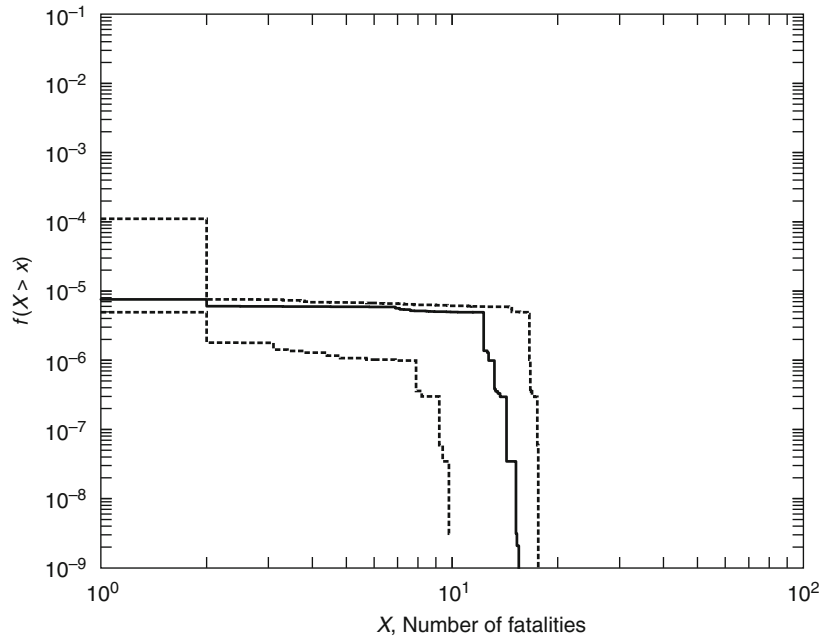

Fig. 85.1 Multiple fire scenario analysis

The magnitude of the societal risk is dependent only on the risk analysis perspective (i.e., whether the analysis covers one ward or the whole hospital). Therefore, the physical boundaries of the analysis must be made appropriately.

The risk analysis could be extended to consider, for example, the whole hospital. If a larger part of the hospital is considered in the analysis, the fire frequency will also be higher because of the higher number of possible fire locations. If this more global analysis is chosen, the event tree and initial frequency must be chosen accordingly, which can be illustrated as shown in Fig. 85.2.

The probability of the fire starting in any of the wards in the hospital will not differ due to the more global analysis perspective, but the total frequency of fire occurring will be higher for the whole hospital. This result displaces the risk profile higher up in the diagram, indicating a higher risk than when only considering a single ward.

If identical situations are assumed for the four wards in Fig. 85.2 and the likelihood of fire occurrence is the same for all the wards, the societal risk profile for the whole hospital is increased by a factor of four compared with the single-ward risk profile. The consequences are not changed, if the fires are independent events and fire spread between wards is neglected, but the probabilities are increased. In the real situation it might not be appropriate to assume similar likelihood of fire in the wards. Different activities on the wards and differences in types of installations may affect the likelihood of fire breaking out.

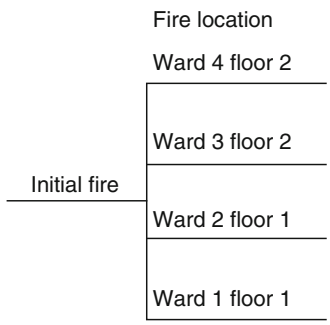

Fig. 85.2 Example of initial part of a complete event tree for risk analysis of a smaller hospital

The true risk level for the hospital is, of course, dependent on the actual situation on each floor, but the fire probability at a specific location is not changed by changes in the analysis perspective. Therefore, the risk measures will depend on the limitations set out for the analysis. If tolerable risk measures are available, it might be possible to determine the maximum allowed size of, for example, a building, as the risk increases with building size.

It is also necessary to be aware of how "the society" is defined. From a societal point of view it may be different, with respect to fire hazards, whether we have one hospital with four wards or four hospitals with one ward each. The risk to society is the same but the societal risk for each facility is different. This is based on the assumption that the fire does not spread from one ward to another in the four-ward hospital.

The purpose of this example is merely to demonstrate the methodology. It is assumed that the quantitative risk analysis has been preceded by qualitative screening methods to determine the quantitative scenario. The members of staff are excluded from the risk measure and are only considered as an aid to patient evacuation.

Hospital Ward Conditions

The calculations are performed on a hospital ward with fixed dimensions. It is always assumed that the fire is located in a room close to one exit preventing it from being used. Figure 85.3 shows the assumed ward with 11 patient rooms, a TV room, and a staff room. The exit to the right leads to a protected lobby, which, in the other direction, is connected to a second ward. The patients and the staff are considered to be safe when they have reached the protected lobby.

All rooms in the ward are $5 \times 6 \times 3.2\ m^3$ and the corridor is $35 \times 3 \times 3\ m^3$. All patient rooms are equipped with one window to the outside and a door leading to the corridor. The window is $0.9 \times 0.9\ m^2$ and the windowsill is located 1.2 m

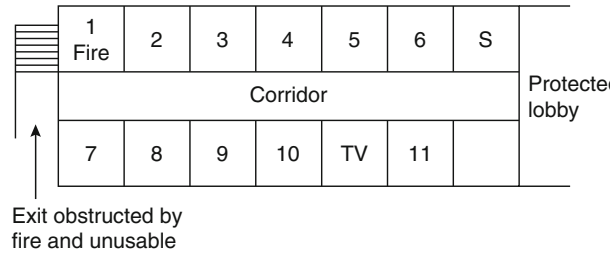

Fig. 85.3 Ward layout, with *TV* indicating a TV room and *S* indicating the staff room

above floor level. It is assumed that the window is initially closed in the fire room and breaks when the fire in the room reaches a certain temperature. The door between the patient room and the corridor is 1.2×2.1 m^2. It may be open or closed according to the scenario definition.

The door between the corridor and the protected lobby is open only during evacuation. Otherwise it is closed, as it is equipped with a closing device. The door has a height of 2.1 m. The patient rooms are not separate fire compartments, but it is assumed that no smoke can leak directly from one patient room to another. The walls between the patient rooms and the corridor prevent smoke from leaking into the corridor.

The ceiling and walls are covered with gypsum plasterboard and the floor is concrete. These conditions are common for the whole ward.

The ward is equipped with a sprinkler system designed to extinguish a fire. The sprinkler system is designed according to the current regulation. The sprinkler heads activate at a temperature of 68 °C and are of quick-response type (*RTI* value $35\sqrt{m \cdot s}$). The coverage area of each sprinkler head is 20 m^2, which means two sprinkler heads per patient room.

The likelihood that a sprinkler system will work and be able to extinguish a fire is assumed to correspond to a probability of operation of 0.96. This value is chosen based on judgement combined with information in Bukowski [5]. This value will be used without any uncertainty.

An automatic fire alarm system is installed in the building. The alarm system is equipped with smoke detectors in every patient room and in common areas. The alarm system does not only indicate the presence of a fire but also gives an alarm to the staff and patients in the ward. The sounding of the alarm informs the staff that there is a fire in the ward.

Table 85.1 Proportions of patients in various groups according to need for help in evacuation

Need for help	Day Sleeping	Day Awake	Night Sleeping	Night Awake
Much help needed	0.70	0.10	0.75	0.10
Little help needed	0.20	0.20	0.15	0.15
No help needed	0.10	0.70	0.10	0.75
Total	1.00	1.00	1.00	1.00

The likelihood that the automatic fire detection system will work and be able to detect a fire is assumed to correspond to a probability of operation of 0.94. This value is chosen based on judgment combined with information in Bukowski [5]. The reliability of this system is considered less well defined than that of the sprinkler system. It has, therefore, been subjected to uncertainty in some of the extended QRA calculations. The probability of operation will then follow a uniform distribution (0.9, 0.98). The mean probability value will be the same with and without the uncertainty consideration.

Patients and Members of Staff

There are 22 patients on the ward, two in each patient room. The physical conditions of the patients may vary according to the scenario. Three different physical conditions are used to determine their need for help and their mobility. The number of patients in each of the three categories depends on whether day or night is considered (Table 85.1). These proportions, used as branch probabilities in the event

Table 85.2 Duration of t_{care} and t_{patM} for the standard QRA

Awake or asleep	Need for help	t_{care}	t_{patM}
Awake	None	10	25
Awake	Little	15	40
Awake	Much	20	50
Asleep	None	13	25
Asleep	Little	25	50
Asleep	Much	40	60

Note: Values are in seconds

Table 85.3 Duration of t_{care} and t_{patM} for the extended QRA

Awake or asleep	Need for help	t_{care}	t_{patM}
Awake	None	(5, 5)	(20, 5)
Awake	Little	(10, 5)	(30, 30)
Awake	Much	(15, 5)	(40, 40)
Asleep	None	(10, 3)	(20, 5)
Asleep	Little	(20, 5)	(40, 30)
Asleep	Much	(30, 10)	(50, 30)

Note: Values are the mean and standard deviation in seconds

tree, are arbitrarily chosen and may vary between wards.

Help is needed to make the patient aware of the situation and to prepare the patient for evacuation. Different patient categories require different amounts of time. The time period, t_{care}, is defined as the time spent by the staff in preparing a patient for movement and the physical movement time to the corridor. The values of t_{care} for the six different patient categories are given in Tables 85.2 and 85.3.

Rather low values have been chosen for t_{care}. This implies that patients requiring a great deal of help in preparation and movement have been excluded from this investigation. The movement time along the corridor to the safe lobby is determined by t_{patM} and includes the time required by the staff to reach the next patient. In the extended QRA, both t_{care} and t_{patM} are normally distributed.

The number of staff members on the ward depends on whether it is daytime or nighttime. During the day, four nurses are on the ward and during the night two nurses are on duty.

After the fire has been detected by either the automatic fire alarm or manually, the staff spend some time reacting and interpreting the situation. As they are trained to respond to various kinds of signals, the response time, $t_{\text{resp}}^{\text{staff}}$, is rather short. The staff response time is assumed to be normally distributed (10, 3) seconds in the extended QRA. In the standard QRA, the value is assumed to be 10 s.

Table 85.4 Untenable conditions

Type	Tolerable	Severe
Radiation at floor level	2.5 kW/m^2	2.5 kW/m^2
Smoke layer height (z)	1.5 m if $T_g > 80$ °C	1.0 m if $T_g > 100$ °C
Temperature in layer (T_g)	80 °C if $z < 1.5$ m	100 °C if $z < 1.0$ m
Toxicity	FED = 0.5	FED = 1.0

If a fire occurs, the staff members will most likely be able to put it out. Therefore, situations in which the ward must be evacuated have the following characteristics: the staff members are not able to extinguish the fire and it does not self-extinguish. This event is very infrequent and its probability has been estimated on the basis of statistics and discussions with other fire professionals. The probability of successful extinguishment by the staff or self-extinguishment has been set to 0.95.

If the staff members do not tackle the fire, they will move toward the patients. This movement time, t_{staffM}, is assumed to follow a normal distribution (15, 5) seconds. In the standard QRA the value used is 20 s.

The evacuation of the ward must be completed before untenable conditions arise. The limits used to define untenable conditions are given in Table 85.4. The tolerable conditions are used in the standard QRA calculations. In the extended QRA the severe conditions are, however, used for illustration purposes.

Toxicity is measured in terms of the fractional effective dose (FED), which considers the effect of a number of toxic gases [6].

Fire Frequency

In defining the risk to which patients in a hospital ward are exposed, it is necessary to know the fire

occurrence rate (i.e., the frequency that a fire will start). The statistics in this area are, unfortunately, rather limited. It is usually possible to predict the number of fires occurring in a town or country each year. Some information is given in Rutstein [7] that relates the frequency of fires occurring to the floor area of the building. According to this reference, the frequency of having a fire in a hospital ward per year can be calculated as

$$f_{\text{fire}} = 0.0007 \cdot A^{0.75} \qquad (85.1)$$

This relationship has been derived from reports from fire departments in the United Kingdom. The expression gives an average value of the fire frequency and the deviation can be large. As the number of fires in hospitals is low, the reliability of the expression can be questioned. The value of the exponent has been arbitrarily assumed to be 0.75 due to low incident rate. It is, however, generally assumed that the frequency increases with increasing building area.

Using this expression for the hospital ward studied in this research gives a frequency of a fire event of 0.077 fires per year. The floor area used for this calculation was 35×15 m^2.

Some preliminary Swedish data concerning fire occurrence rates are available from fire departments in the country. The data have been collected from the rescue reports following an emergency operation handled by the fire departments (Table 85.5). Almost all Swedish health care facilities (including hospitals) are equipped with smoke detectors that are connected to the local fire department, which means that if a fire occurs in a hospital, it is very likely that the fire department will be notified. The fire department rescue reports are, therefore, a good estimate of the number of actual fires in a hospital. The total number of fires reported was 59 per year.

Table 85.5 Fire frequencies in hospital wards per year in three towns in Sweden [8]

Town	Fire frequency per year
Town 1	0.038
Town 2	0.078
Town 3	0.068

The fire frequency, f_{fire}, has been set at 0.07 fires per year. The value for the wards in town 1 is half that of the others but still of the same order of magnitude. This difference will be examined in the extended QRA, where f_{fire} is treated as a random variable. The variable f_{fire} will then be assumed to follow a uniform distribution (0.04, 0.1) fires per year. On the basis of the statistics from the fire departments, it is assumed that the frequency of a fire occurring at night is 0.33 and, during the day, the frequency is 0.67.

The condition leading to evacuation of the ward is that a fire is initiated and will continue to grow, which means that a smoldering fire will not lead to evacuation unless it develops into a flaming fire. It is assumed that a smoldering fire is harmless, at least on the time scale considered here. Calculations of the conditions in a room in which there is a smoldering fire have been performed using input parameters from Quintiere et al. [9].

Fire Growth

The energy release rate from the fire is simply assumed to follow an $\alpha_f t^2$ relationship. It is assumed that the fire always arises in a patient room and does not spread to a neighboring room or corridor during the time of interest. The time available for escape depends on how fast the fire grows (i.e., the growth rate of the fire, α_f).

It is reasonable to assume a low value for the growth rate. Tests on the fire behavior of hospital beds indicate a growth rate of approximately 0.01 kW/s^2 [10]. The bed used for that test was a standard bed used in hospitals until a couple of years ago. Newer beds are especially designed to be difficult to ignite and fires in such beds are reported to have a substantially slower growth rate in initial fire development.

After the fire in the Hillhaven Nursing Home in Norfolk, Virginia, in 1989, it was determined that the fire in the bed ignited and had a growth

rate of approximately 0.01 kW/s^2 [11]. In simulations of patient room fires growth rates in the region of 0.0001–0.00025 kW/s^2 have been used, which are very low [12].

After examining similar fires, it was decided to use a fire growth rate following a log-normal distribution (0.01, 0.005) kW/s^2. This will result in untenable conditions in the fire room within a few minutes, which is in good agreement with experiments and postfire investigations. The value used for the standard QRA was chosen to be 0.007 kW/s^2 to include the very slow growing fires reported.

The Event Tree

The event tree for the sample calculation is defined by the scenarios illustrated in Figs. 85.4 and 85.5. Figure 85.4 shows the initial part of the event tree leading to the two final parts, A and B. Part A defines scenarios 1–48 and is shown in Fig. 85.5. Part B, defining scenarios 49–96, has the same general appearance but differs in terms of when the fire starts. In the initial part of the event tree, four scenarios are identified, which do not result in any unwanted consequences. In these scenarios, the fire may have been suppressed by the staff or will not grow. If these scenarios occur, no evacuation will be necessary.

Each scenario is defined by an individual expression that, considering the variables, reflects the current condition. How the consequences for the scenarios are calculated will be shown in the following paragraph.

Model Description

Available Escape Time

The unwanted consequences are derived by comparing the available time and the escape time. For situations where the difference (i.e., the escape time margin) is negative, some people will not be able to evacuate in time. The unwanted consequences are expressed in the number of patients not being able to escape safely. The safety factor is expressed by the time expression for each location of interest. In this case, two locations will be studied: the fire room and the corridor. The choice of the fire room is obvious, but the choice of the corridor may need some explanation. As all patients are moved out from their rooms, they all must pass along the corridor. The conditions in the corridor will then determine the time available for evacuation of the ward. Untenable conditions will only occur in the corridor if the door to the fire room is left open. Otherwise, untenable conditions will not arise at that location.

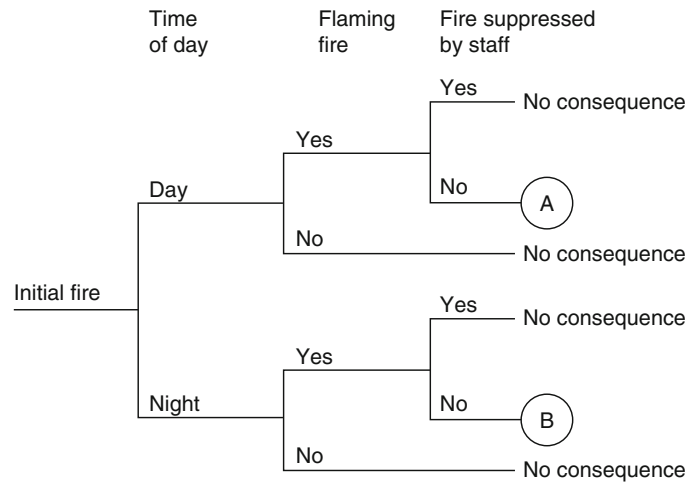

Fig. 85.4 Initial part of the event tree for fire on the hospital ward

Fig. 85.5 Continuation of the event tree for daytime conditions

The program CFAST [13] has been used to derive a response surface, an equation describing the time taken to reach untenable conditions as a function of the growth rate of the fire, α_f. The purpose of using the response surface methodology is mainly for the extended QRA. Using only a standard QRA technique one can more efficiently use the CFAST results directly

(if CFAST is the chosen software). But as the response surface equations are available in this sample analysis they are also used in the standard QRA. All response surface equations in this sample risk analysis will have the same general appearance as follows

$$t_u = \exp(\lambda + \delta \ln \alpha_f) \qquad (85.2)$$

where λ and δ are the regression coefficients (Tables 85.6, 85.7, and 85.8). A more detailed model like a CFD model can be used instead of the simple zone model CFAST. But as many scenarios are to be analyzed, a fast model is preferred.

The event tree results in a number of different fire situations, each with a new response surface equation describing the time available for evacuation. New expressions must be derived describing whether the door to the patients' room is open or closed after passage and whether the sprinkler system operates or not.

Door Open/Closed After patients have been removed, the door between the corridor and the patients' room can either be left open or it can be closed. If the door is closed after passage of both patients, the conditions in the corridor will never reach untenable levels. If the door is left open after the patients have been removed, untenable conditions will eventually arise in the corridor. Untenable conditions will always occur in the patient room in which the fire started, independent of whether the door is open or closed. For the CFAST calculations it is assumed that the door is opened after 90 s to let the patients escape. If it is closed after passage, it is assumed that the door will be completely closed after 150 s; otherwise, it will be kept open.

Equations have been derived for scenarios both with and without the sprinkler system. The sprinkler activation times in the patient room are, for all scenarios, much longer than the time taken to reach untenable conditions. The sprinkler operation will, therefore, not affect the time available for escape from the fire room. The sprinklers will, however, affect the conditions in the corridor if the door to the patient room is left open, thus increasing the overall safety. When sprinklers activate, they will for many situations result in an infinite available escape time (i.e., the conditions will never reach untenable levels).

The available escape time in the corridor is also dependent on when or whether the window breaks in the patient room. There are few data for window breakage and how much glass falls out. It is assumed here that the windows are 60 % open when the fire gas temperature in the room reaches 250 °C.

Table 85.6 Regression coefficients for time taken to reach tolerable conditions, mean and standard deviation

Condition	λ	δ	R^2
Fire room Open door	(2.77, 0.03)	(−0.42, 0.01)	1.00
Fire room Closed door	(2.71, 0.06)	(−0.43, 0.01)	0.99
Corridor Sprinklers work	(4.60, 0.10)	(−0.13, 0.04)	0.90[a]
Corridor Sprinklers fail	(4.10, 0.11)	(−0.35, 0.02)	0.96

[a]Untenable conditions only for fire growth rate $\alpha_f > 0.05$ kW/s^2

[a]The severe conditions did not arise in corridor

Table 85.8 Regression coefficients for smoke detector detection time

Condition	λ	δ	R^2
All conditions	(3.02, 0.04)	(−0.31, 0.01)	0.99

Detection Time

The model Detact-t2 is used to calculate detection times for smoke detectors for different fire growth rates [14]. The Detact-t2 model calculates the activation time for a given fire and detector configuration. The smoke detectors are assumed to behave like heat detectors but with a much faster response. The detectors have the following characteristics: $RTI = 0.5\sqrt{m \cdot s}$, activation temperature = 25 °C (i.e., 5 °C above ambient temperature). A response surface equation is created for the detection time. The equation has the same format as Equation 85.2 but using t_{det} instead of t_u. The parameters are presented in Table 85.8.

If the smoke detectors fail to operate, someone on the ward must observe the fire and alert the staff. The manual detection time, t_{det}, is assumed to be a random variable, normally distributed with the parameters (90, 45) seconds for daytime and (120, 60) seconds for nighttime. These two distributions are chosen purely based on judgment. The nighttime distribution results in longer detection times as there are fewer staff members present than during the day. In the standard QRA, the mean values plus one standard deviation were chosen to represent the conditions.

Model Uncertainty

There is no computer model that predicts reality without any error. Limitations and simplifications in the models inevitably result in deviations between the predicted values and those measured in a test or a real fire. A correction factor must be used to compensate for some of the differences between experimental results and predictions.

Two computer models are used in this study. CFAST is used for the prediction of the time available for evacuation or the time taken to reach untenable conditions. Detact-t2 is used to calculate the activation times for detectors and sprinkler heads. Based on the results of a few experiments, the difference in available escape time may be treated as a random variable, M_S, normally distributed (1.35, 0.1) [15]. The model CFAST underestimates the time available for evacuation by a factor of 1.35 on average.

The uncertainty in the Detact-t2 model is assumed to be unknown. The activation time in reality is highly dependent on the ceiling configuration and other obstructions in the upper part of the room. The variation in detection time may be significant.

Movement Time

Movement will take place from two locations: from the patient room to the corridor and from the corridor to a safe place outside the ward. First, after the staff members have responded to the alarm, they move toward the patients during the time period t_{staffM}. Then they start to prepare the patients for movement. The time required to move the patients from their room to the corridor can be derived using the following equation:

$$t_{\text{move}}^{\text{room}} = t_{\text{care}} \cdot (PatInRm/StaffInRm) \qquad (85.3)$$

The variables *PatInRm* and *StaffInRm* indicate the number of patients and staff members in the patient room during evacuation (i.e., two patients and two nurses).

After the patients have been evacuated from the room in which the fire started, the rest of the patients may also need to be evacuated. This will be the situation if the door between the corridor and the patient room is left open. If it is closed, there is no acute need to evacuate the other patients.

The expression for the evacuation time for the whole corridor is

$$t_{\text{move}}^{\text{corr}} = \left(t_{\text{care}} + t_{\text{patM}}\right) \cdot (NoPat/NoStaff) \qquad (85.4)$$

The time required to evacuate each patient is now the sum of the preparation time, t_{care}, and the movement time to the safe place, t_{patM}. *NoPat* and *NoStaff* are equal to the total number of patients and staff members on the ward.

Calculation of the Consequences

The problem can now be formulated in terms of the number of people who might not be able to be evacuated before untenable conditions arise. The governing equation is based on the escape time margin, which expresses the time difference between the available time and the required escape time. The appearance of the equation depends on whether the door to the patient room where the fire starts is open or not. The closed door scenario means that only the patient room containing the fire must be evacuated. Differences in variable values will result in different consequence values, defined by the variable c_i indicating the consequences for scenario i.

The maximum number of patients who may be trapped in the scenarios in which the door is being closed is two, as this is the maximum number of patients in a room. If the door is left open, the number is increased to 22 as the other patients also have to be evacuated and might be subjected to the hazard. The two governing equations can be formulated as escape time margins for the fire room and the corridor as

$$\text{Room margin} = t_u^{\text{room}} M_S - t_{\text{det}} - t_{\text{resp}}^{\text{staff}} - t_{\text{staffM}} - t_{\text{move}}^{\text{room}} \quad (85.5)$$

$$\text{Corridor margin} = t_u^{\text{corr}} M_S - t_{\text{det}} - t_{\text{resp}}^{\text{staff}} - t_{\text{staffM}} - t_{\text{move}}^{\text{corr}} \quad (85.6)$$

These can be expressed, for each scenario i, in terms of the number of patients as follows:

- When the door is closed
  $RoomCons = 2$, if Room margin <0
  $c_i = RoomCons$
- When the door is left open
  $CorrCons = (Corridor\ margin\ t_{\text{move}}^{\text{corr}})\ NoPat$ if Corridor margin <0
  $c_i = RoomCons + CorrCons$

If the escape time margin is positive, all patients have been evacuated before untenable conditions occur. A short summary of the values used in the risk analysis is presented in Tables 85.9 and 85.10.

Table 85.9 Values of variable used in the risk analysis

Variable	Standard QRA	Extended QRA
α_f	0.007 kW/s^2	LN(0.01, 0.005) kW/s^2
M_S	1.35	N(1.35, 0.1)
t_{det} (day)	135 s	N(90, 45) s
t_{det} (night)	180 s	N(120, 60) s
$t_{\text{resp}}^{\text{staff}}$	10 s	N(10,3) s
t_{staffM}	20 s	N(15,5) s
t_{care}	See Table 85.2	See Table 85.3
t_{patM}	See Table 85.2	See Table 85.3
PatInRm	2	2
StaffInRm	2	2
NoPat	22	22
NoStaff (day)	4	4
NoStaff (night)	2	2

Table 85.10 Variables used in the risk analysis

Variable	Standard QRA	Extended QRA
f_{fire}	0.07	Unif(0.04, 0.1)
p_{day}	0.67	0.67
p_{flaming}	0.50	0.50
$p_{\text{suppressed}}$	0.95	0.95
$p_{\text{sprinkler}}$	0.96	0.96
$p_{\text{detection}}$	0.94	Unif(0.9, 0.98)
p_{door}	0.90	0.90
p_{sleeping} (day)	0.05	0.05
p_{sleeping} (night)	0.95	0.95
p_{help}	See Table 85.1	See Table 85.1

Presenting the Risk

Societal Risk

Based on the preceding information, the risk to the hospital ward can be analyzed. The QRA results in 100 scenarios. The first 96 scenarios represent the final outcomes of the event tree; 48 for daytime conditions and 48 for nighttime conditions. The last four scenarios can be found in the initial part of the event tree (Fig. 85.4) but do not result in any unwanted consequences as the fire is either extinguished or will not continue to grow.

The scenario frequency (f_i) and consequences (c_i) are derived and collected in two vectors.

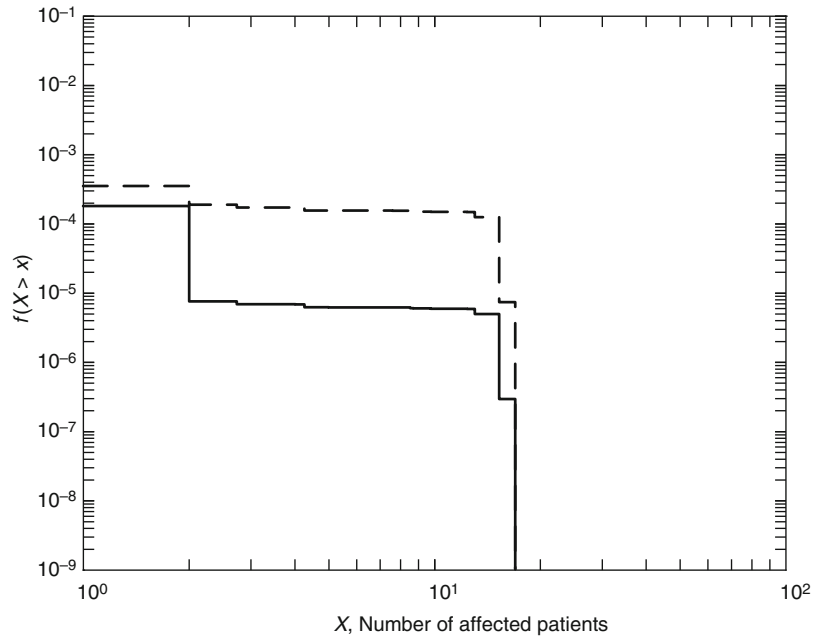

Fig. 85.6 Risk profile for the standard quantitative risk analysis using critical untenable conditions. *Dashed line* represents risk profile for design alternative without sprinkler system

The consequences are expressed in terms of the number of patients not being able to escape within the available time. The vectors are sorted by increasing consequences and the resulting cumulative risk profile (see Chap. 83 in this handbook) is shown in Fig. 85.6 as the solid line.

An alternative design strategy, with no sprinkler system on the ward, was also examined using this method. The dashed line shows this design risk profile. This risk profile indicates a higher risk, which is rational and understandable as sprinkler systems are assumed to decrease the hazard of fires.

The profiles in Fig. 85.6 were derived using the critical conditions for untenable environment.

Based on the results, the average societal risk can also be obtained. The products of the frequency and the consequences for each scenario are summed to give the average societal risk. For this scenario the average risk using tolerable conditions is $4.4 \cdot 10^{-4}$ persons per year per ward.

The alternative design solution without the sprinkler system has also been analyzed in terms of the average societal risk. The corresponding values for the average societal risk are $2.7 \cdot 10^{-3}$ patients per year per ward. There is, thus, an approximate difference in risk of six times between the scenarios with and without sprinklers.

This comparison between a ward with and without sprinklers was presented to illustrate the capability of the method. Similar results can be obtained by comparing situations with and without an automatic fire detection device, and so on. The risk profiles and average risk measures will be different, but it is possible to illustrate the benefit of devices that increase safety in a quantitative manner.

The question is whether the ward without the sprinkler system is acceptable or not. The sprinkler-equipped ward may result in an "oversafe" and too expensive situation. On the other hand, with a sprinkler system, a higher number of patients could be housed on the ward with the same risk level as the ward without the sprinkler system.

Individual Risk

The individual risk has also been derived for the two levels of untenable conditions. The individual risk is defined here as the frequency per year of the escape routes being blocked by the fire.

In the sprinklered case, the individual risk was equal to $1.8 \cdot 10^{-4}$ per year using the endpoint criteria corresponding to tolerable levels. If the more severe conditions are applied, the individual risk measure is $1.0 \cdot 10^{-4}$ per year. The measure of risk is the sum of the scenario outcome frequencies leading to the unwanted event (i.e., that the escape routes are blocked).

Extended Quantitative Risk Analysis Procedure

The standard QRA is performed without explicitly considering the uncertainty that is inevitably present in each variable. Instead, the variables are assigned values that, for example, are the most likely values.

The results from such an analysis are usually presented as a single risk profile as in Fig. 85.6, but such profiles do not contain any information on the uncertainty of the profiles themselves. If one wishes to know how certain the calculated risk profiles are the uncertainties in the variables involved must also be considered. To obtain this information, risk analysis, according to the standard QRA method, should be combined with uncertainty analysis. Formalizing this methodology results in the extended QRA.

Basically, the procedure for performing an extended QRA is similar to that for the standard QRA. As the variables not are constant but are expressed in terms of frequency distributions, the propagation of uncertainty must be modeled for all scenarios simultaneously. Simply, the process can be seen as a standard QRA that is repeated a large number of times. For each new iteration, the variables are assigned new values according to the frequency distribution. Figure 85.7 shows the process schematically.

This analysis results in a new risk profile for each iteration, providing a family of risk profiles (Fig. 85.8). The family of risk profiles can be used to describe the uncertainty inherent in the resulting risk measure. The figure shows the uncertainty in the risk profiles for the sample calculation on the hospital ward using data presented for the extended QRA in the previous paragraph, which means that the variables are represented in terms of a distribution instead of a single value.

It is clear that the information is very extensive. Therefore, alternative presentation methods may have to be used in order to be able to interpret the information, which is why it is better to present the societal risk profiles in terms of the median or mean risk profile and to complement these with relevant confidence bounds. The confidence interval can, for example, be the 80 % interval. The extended QRA can be used to express the degree of credibility in the resulting median risk profile by complementing the profile with confidence bounds (Fig. 85.9).

The technique can be used to see when the standard QRA analysis and the extended analysis coincide. Which percentile in the extended QRA is represented by the standard analysis? To answer this question the results of the standard QRA and the percentiles obtained from the extended QRA using severe conditions can be plotted in the same diagram. It is then possible to get information on how safe a design solution using conservative estimates of the variables actually is.

The method can also, as for the standard QRA, be used to evaluate the benefits of different design strategies in efforts to obtain an optimal solution. As the variation in risk profiles originates from the uncertainty in the actual scenario if it occurs, it can be used to determine if additional safety measures afford any measurable increase in safety. If the new design risk profile falls between the accepted confidence limits, there is no statistically significant change in safety, on the specified confidence level, due to the additional safety measures. The risk profile resulting from a new design might not be different from the inherent uncertainty of the scenario.

In the same manner as for the standard QRA, the average risk can be calculated. But as the variables are subject to uncertainty, the average risk will also be subject to uncertainty and will consequently be presented as an empirical distribution. Each iteration will generate one sample of the average risk. These average risk values will form the distribution of the average risk.

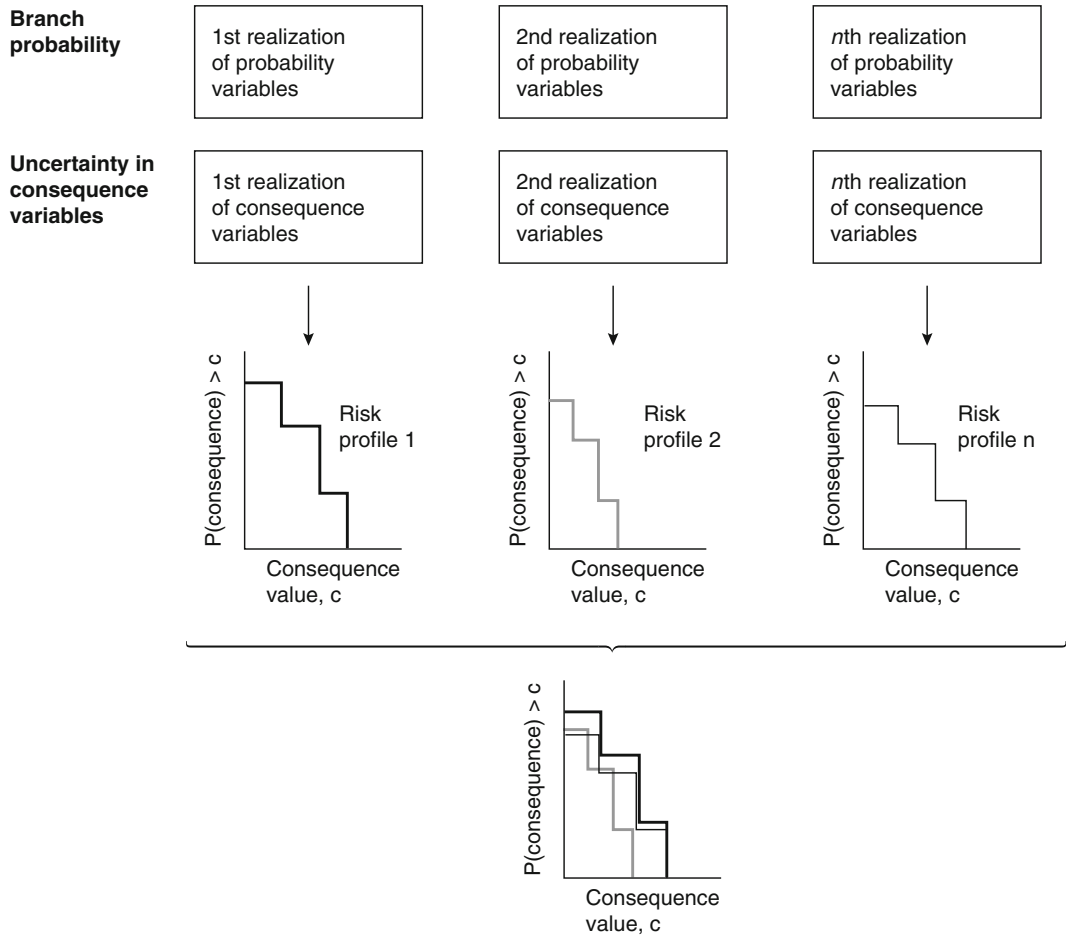

Fig. 85.7 Uncertainty analysis of a QRA

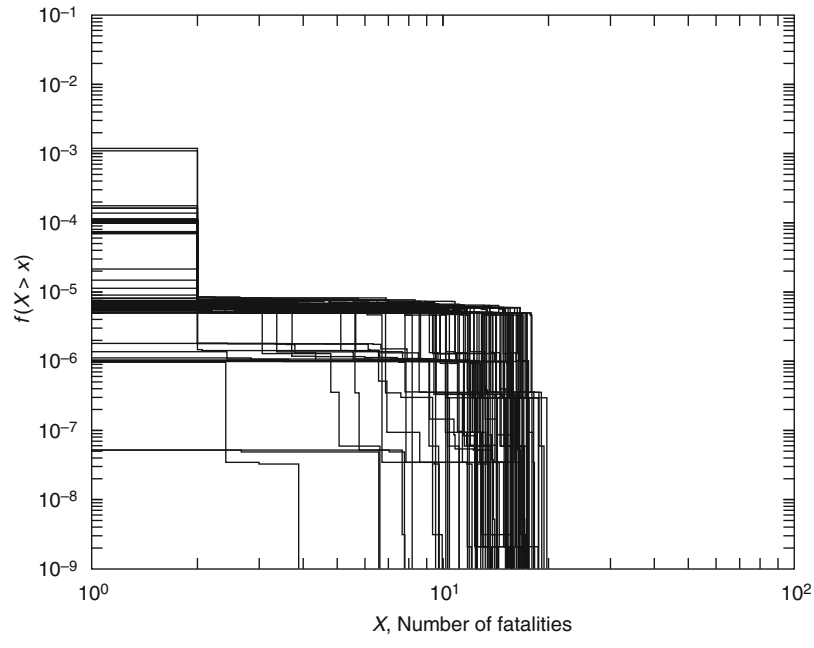

Fig. 85.8 Family of risk profiles for the extended quantitative risk analysis using severe untenable conditions

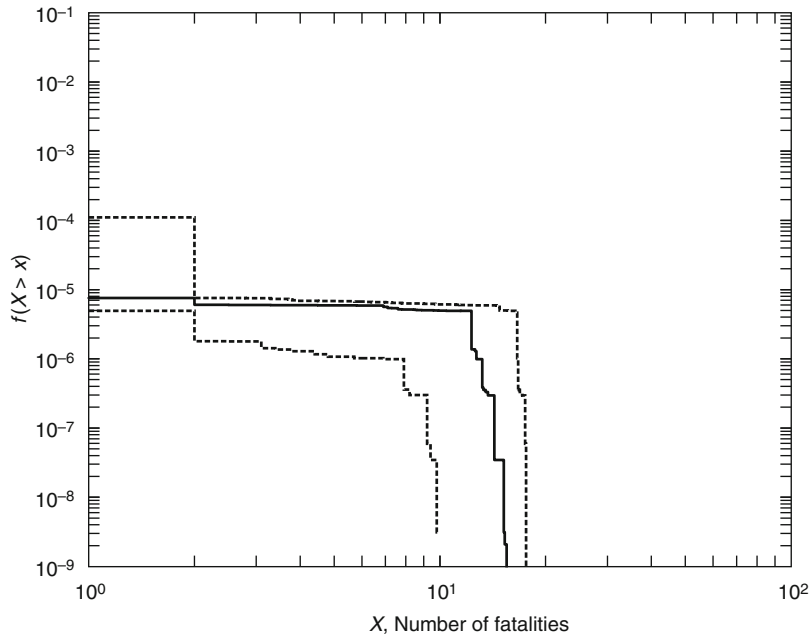

Fig. 85.9 Percentiles from the extended quantitative risk analysis using the severe untenable conditions in which *lines* represent the 10th, 90th, and 50th (or median) percentiles

Also the individual risk measure can be derived from the extended QRA. Some combinations of the variables used to derive the consequence in a scenario will lead to conditions resulting in fatalities or blocked escape routes. Similarly, due to randomness, some scenarios will not always contribute to the individual risk measure. Therefore, there will be a degree of uncertainty in the individual risk originating from variable uncertainty.

The extended QRA is performed as a numerical procedure that involves Monte Carlo sampling techniques. Today, no commercial software exists that can handle both scenario variable uncertainty and branch probabilities. The calculated data can, however, be treated with Matlab or similar software.

Summary

The chapter has used a methodology for performing a quantitative fire risk analysis and various ways to consider parameter uncertainty. Using these methods, it is possible to derive risk measures both with and without explicitly considering the inherent uncertainty in the system. These risk measures can be used either to compare different design solutions or to compare a solution with tolerable risk levels. The former use is the most likely as tolerable risk levels have not been fully defined for most architectural work. Only in very special cases have tolerable risk levels been used in the design process (e.g., in large infrastructures). The risk analysis methods can be used for comparison with traditionally accepted design solutions.

The Building Envelope: Fire Spread, Construction Features and Loss Examples

86

Daniel J. O'Connor

General Mechanisms of Exterior Fire Spread

Exterior building fire spread occurs in three basic ways. One scenario considers fire spread from one building to an adjoining building separated by a wall or barrier. In this case, the fire spread occurs when fire exposure to the wall or barrier and any protected openings has sufficient duration and intensity to negate the integrity of the fire wall/barrier or any protected openings. Additionally, flame extension (often exacerbated by wind) above the roof or around the edges the fire barrier/wall can cause the fire to spread to the adjoining building by radiation, direct flame contact or possibly burning brands.

Fire Spread Between Buildings Separated by Distance

A second scenario considers fire spread from one building to another building located some distance away. Here, the risk of fire spreading from a burning building to an adjacent structure is related to the intensity of heat radiation transferred to combustible materials on the exterior of the distant building or radiation through windows to combustible contents within the structure. Additionally, if flying brands alight on surfaces heated by radiation, the potential for ignition is increased. Various guides and procedures have been developed to evaluate the separation distances between adjacent buildings or properties and the potential effects of the radiation emitted from a burning building. A generalized engineering approach for assessing separation distances between adjacent properties/buildings has been outlined [1] and restated in an edited form in Table 86.1. This approach relies on the basic principles of radiation transfer from a flame front (radiator) across some distance to an exposed building as generalized in Figs. 86.1 and 86.2.

For complex scenarios (e.g., varied windows, angled exposure, varying fuel loads) NFPA 80A, *Recommended Practice for Protection of Buildings From Exterior Fire Exposures* and the BRE Fire Research Station's document titled *External Fire Spread*: *Building Separation and Fire Distances* (BR 187) [2] provide discussions on methods for assessing potential radiation transfer and associated considerations and assumptions important to addressing fire spread between adjacent properties. One key assumption in both guides is that the fire service will respond in the 10–20 min range. During this period, maximum radiation levels are not expected to be obtained (NFPA 80A and BR 187) and it is anticipated ignition time requires roughly 10 min of preheating before ignition occurs (BR 187.)

NFPA 80A and BR 187 consider that radiation can cause fire spread when there is direct line-of-sight from the radiating building to an

Table 86.1 Zalosh's nine step approach for assessing safe separation distances (as edited)

Step order	Engineering procedure
1	Postulate a credible worst-case exposure fire scenario in terms of the extent of the materials or structures that are burning
2	Determine the heat release rate and the effective flame ration temperature and emissivity
3	Calculate the flame emissive power for relevant fuel
4	Calculate the flame height
5	Determine the flame-target configuration factor
6	Calculate the radiant heat flux impinging on the target
7	Compare the calculated impinging heat flux to the critical heat flux for ignition or structural damage of the exposed structure property
8	Repeat the calculations accounting for wind effects on flame height, configuration factor for a wind tilted flame and a downwind target
9	If the calculated radiant heat flux is > the ignition/damage threshold and the distance cannot be increased, then evaluate the feasibility of the exposed structure with a more fire resistant material or using outside sprinkler/water spray protection

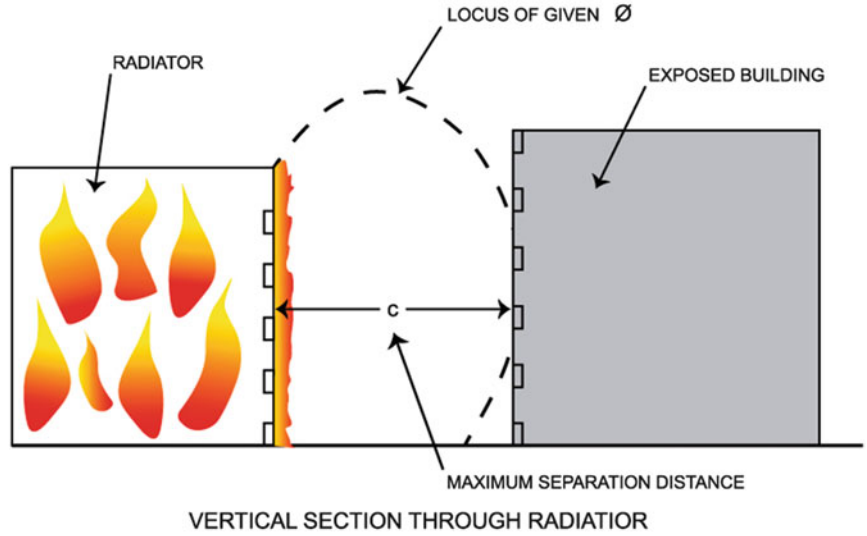

Fig. 86.1 Generalized concept of radiation transfer between buildings (vertical section)

exposed building. For buildings with combustible wall surfaces, the entire wall can act as the radiator. When windows are located in a wall of noncombustible construction (e.g. brick), then the windows and emitted flames only act as the source of radiant heat. The collective area of the windows (those that are radiating) and the distance from adjacent buildings directly impact the risk of fire spread since the size and distance determine the configuration factor, which influences the level of incident radiation on the exposed building. The configuration factor effectively is a measure of how much an exposed building sees the radiation from the burning building. The configuration, or view factor is used to determine the heat flux to the exposed building based on the following general relationship for incident radiation, I_R (kW/m^2).

$$I_R = K_1\, \theta\, \varepsilon\sigma(273 + T_e)^4$$

θ—*configuration factor*
ε—*emissivity of the emitter (generally assumed ~ 1)*

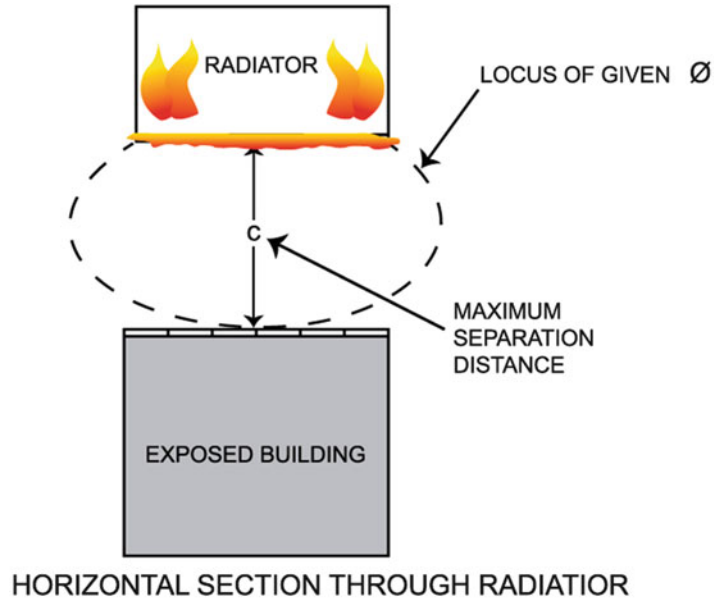

Fig. 86.2 Generalized concept of radiation transfer between buildings (plan view)

σ —*Stefan-Boltzmann constant*, 56.7×10^{-12} (kW/m^2K^4)

T_e—*temperature of the emitting surface*, °C

K_1—*radiation reduction factor for glazing of exposed building when wall cladding is noncombustible*

The irradiance levels needed to cause ignition of a distant exposed building were originally related to that needed to ignite wood materials. For spontaneous ignition the value is 33.5 kW/m^2 and for piloted ignition, as may occur with an exposure to burning brands, is 12.5 kW/m^2. The two guides noted above err on the side of conservatism recommending the use of the pilot ignition irradiance threshold for wood or cellulosic materials in their described methodologies. NFPA 80A notes, however, that newer building materials available today may have greater or lesser ability to resist ignition. Therefore, materials with greater propensity to ignite need greater separation distances and those with higher ignition resistance could be separated by smaller distances.

Example 1 A simple example that illustrates the application of the configuration factor and radiation calculations considers the case of two wood clad buildings with one the wall (red oak) of one building fully in flames [1]. In this situation the two wood frame buildings face each other with a separation of 6.1 m. A 3.7 m high by 7.6 m wide wall facing the adjacent building, is ignited and the flaming façade exposes the adjacent building as illustrated in Fig. 86.3. The question of concern, "Is the 6.1 m separation adequate to prevent flame propagation to the adjacent building?"

The heat release rate for a 3.7 m high wood wall fire is about 1040 kw/m per 0.3 m of width. The corresponding flame height calculated using Delichatsios correlation for rectangular wall flames [3] is 5.1 m. The emissive power is the radiant heat release rate per unit flame surface, which for a radiant heat release fraction (red oak) of 0.26 is,

$$0.26(1040)/5.1 = 53 \text{ kW/m}^2$$

This value is significantly lower than would be calculated using know flame temperatures and an emissivity of unity. The lowest expected flame temperature of 1100 K would produce an emissive power as follows

$$\sigma(273 + T_e)^4 = 56.7 \times 10^{-12} \left(kW/m^2K^4\right) 1100^4 \left(K^4\right) = 83 \text{ kW/m}^2$$

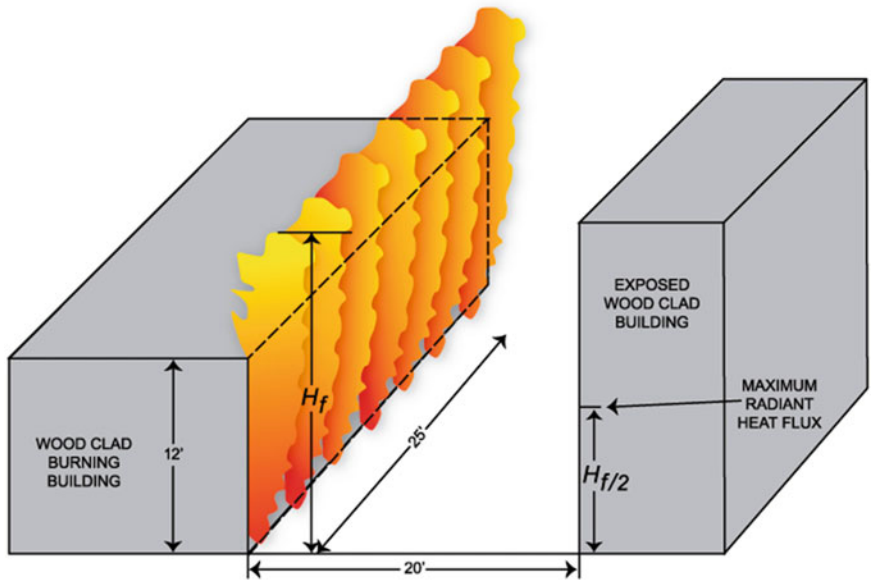

Fig. 86.3 Fire involved building with 17 ft high flame front radiative exposure

Since this radiative heat flux is higher than the 53 kW/m^2 calculated using the heat release rate, it will be used in the interest of estimating a conservative safe separation distance. The configuration factor needed to complete the analysis can be found from Fig. 86.4, which provides the view or configuration factors for a parallel rectangular radiator. It is about 0.6 for a target at mid-flame height and the given combination of flame height, wall width, and separation distance.

Assuming an atmospheric transmissivity of unity, the incident radiation is therefore,

$$I_R = (0.6)(83) = 49.8\ \text{kW/m}^2$$

This value is higher than the threshold for pilot ignition of many woods (12 kW/m^2), and more importantly exceeds the critical threshold for spontaneous ignition of 33.5 kW/m^2. Flame spread would be expected even without exposure to burning brands. Zalosh notes wind effects would not be expected to affect this conclusion given that the wind would be expected to produce some flame leaning above the wall and slightly increase the already high heat flux on the exposed building [1].

Vertical Building Fire Spread

A third scenario considers the fire spread from floor-to-floor in a single structure rather than fire spread between buildings separated by some distance. From a fire dynamics perspective, flames emitting from an exterior window can extend higher than 5 m above the top of the window [5]. One test of Yokoi's was a test room with plywood walls/ceilings and a fire load of 40 kg/m^2, which is characteristic of residential occupancies and at the lower end of the fire load scale. The hot gases from the fire room window measured 400–600 °C at 1.750 m above the top edge of the fire room window. The glass broke out under this exposure.

Analysis of 400 fire compartment experiments [6] helped to more fully explain the physical phenomena of ventilation controlled fires. Ventilation-controlled fires represent the scenario where a fire burning in a building breaks the window glazing, permitting hot gases to flow out the top portion of the opening. A portion of the hot gases are unable to burn inside the room due to limited air (ventilation

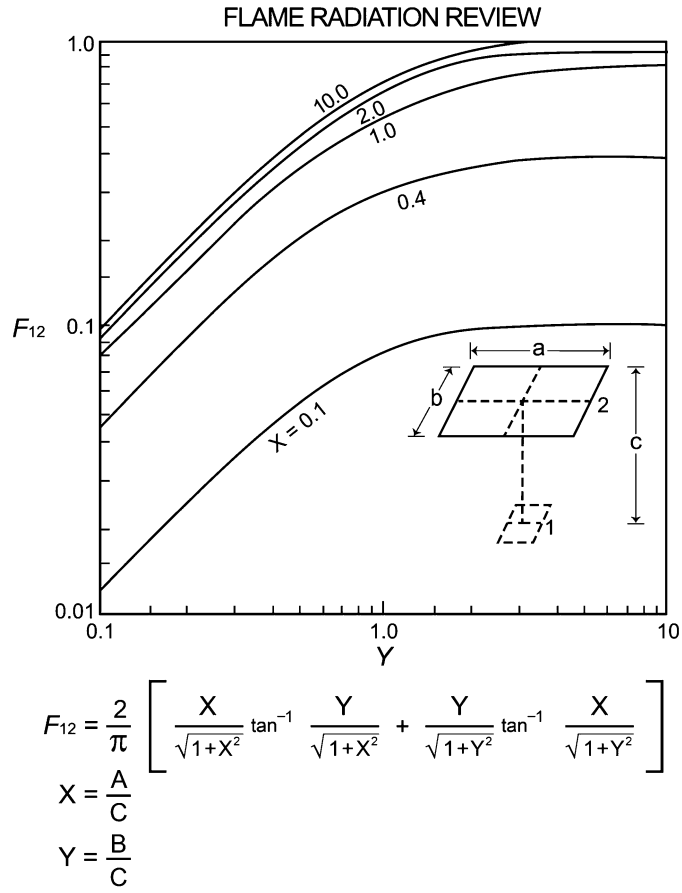

Fig. 86.4 View or configuration factors for a parallel rectangular radiator (Based on Blackshear [4])

controlled) but, upon movement to the exterior, encounter sufficient air entrainment, allowing the hot fuel gases to burn outside the building. The result is a flame projecting out and upward from the window. From a visual perspective, flame extension is estimated at the point that flame temperature drops below 540 °C, which corresponds to the flame no longer appearing luminous.

Taking the data of various researchers, Ove Arup and Partners developed a number of correlations to estimate flame projections and flame temperatures under natural or forced draft conditions [7]. This work showed that the fire flame projection and temperature profile will be a factor of window area and height, room geometry, fuel contents and burning rate, and wind velocity.

Figure 86.5 illustrates several of the common conditions and notational flame structure that is used to predict flame position and extension. All these factors have been combined in into a guide for evaluating the temperatures from exposed exterior structural steel members when subjected to flames emitting from the windows or vents of exterior walls. However, this methodology can be useful in evaluating the temperature and heat flux exposure to other elements on the exterior side of the wall such as widow glazing or wall cladding. This methodology can be found in the American Iron and Steel Institute's *Fire Safe Structural Steel*: *Design guide* [8].

Figure 86.6 illustrates the potential temperature and heat flux characteristics of a fully developed, unsprinklered compartment fire.

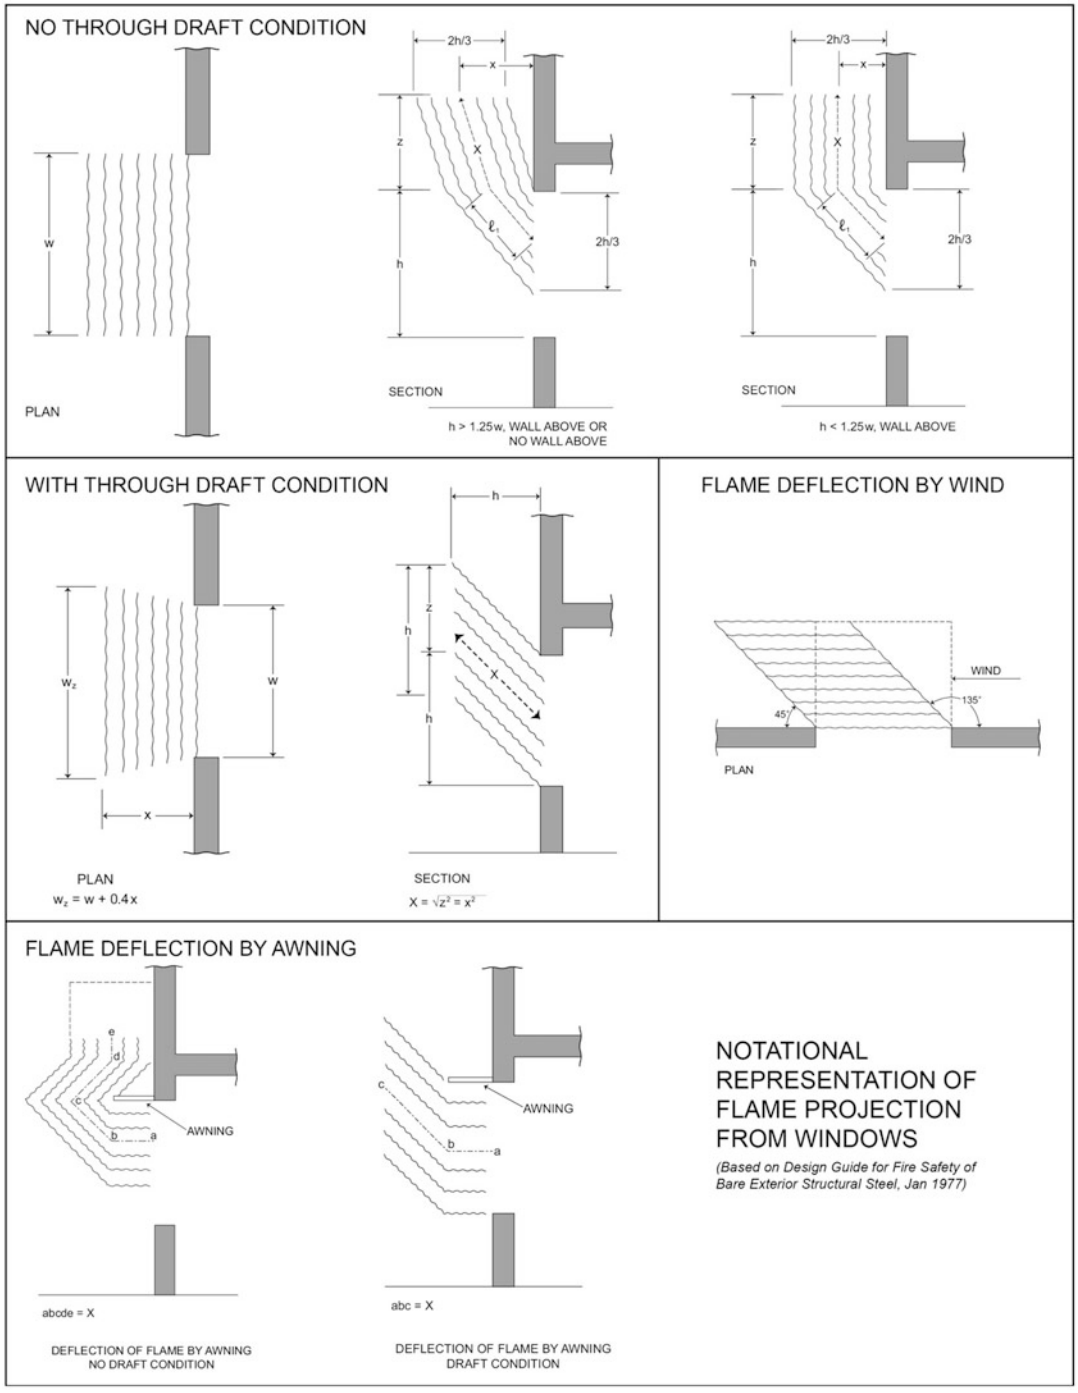

Fig. 86.5 Notational representation of flame projection from windows

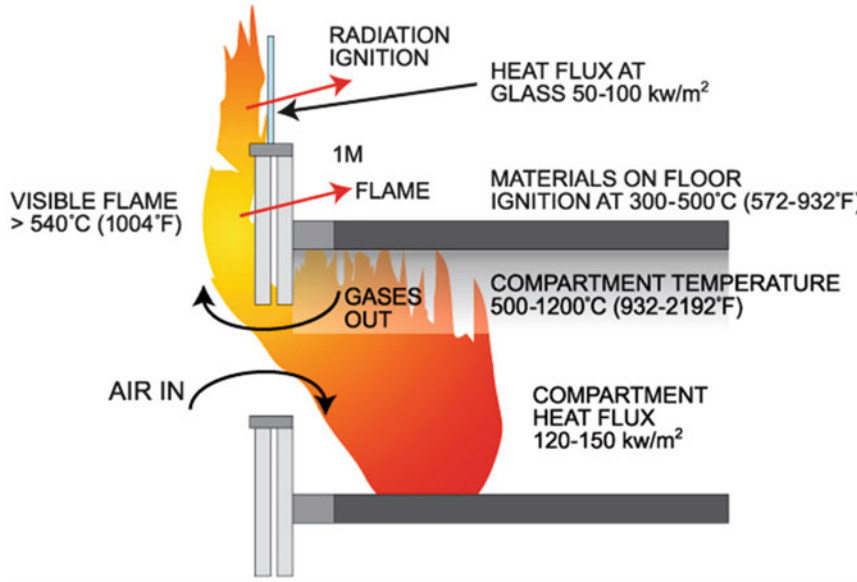

Fig. 86.6 Exterior wall and floor fire exposure mechanisms [9] (Courtesy of CTBUH)

The three principal floor-to-floor flame spread mechanisms at work in Fig. 86.6 are as follows:

- Inside—Flames and fire gases in the building attack the interior surfaces and details of the wall assembly and associated perimeter fire barrier materials.
- Outside—Flames and hot gases projecting from fire-broken glazing or other openings directly impinge on the wall exterior face (convection). Wall designs using exterior combustible cover or claddings (e.g. insulated metal panels, metal composite material panels) may be subject to further fire development posed by the combustible components of the exterior cover/cladding.
- Outside—Flames projecting from broken glazing or other openings radiate heat to and through glazed surfaces or through other openings to building contents and furnishings.

Building Exterior Wall and Enclosure Systems

Exterior wall types commonly associated with above-grade, modern building design can generally be classified as follows: as a cavity wall, a barrier wall, or a mass wall, or cladding systems which include curtain walls. In addition to these four basic wall types, there is a mixed or hybrid type of enclosure system known as "double skin façades" which are described later in this Chapter.

There are numerous sources for descriptions and detailed explanations regarding the construction of exterior walls. Several documents [10–12], address building envelop wall system design and curtain wall design concepts. These sources are relied upon for their descriptive information which is included in the following narrative that summarizes key characteristics of the basic four building enclosure methods. Additional specific details related to construction of walls can be found in *Construction—Principles, Materials, and Methods* [13].

Cavity Wall

Cavity walls are also referred to as "screen" or "drained" wall systems and in Europe as "cold façades". These cavity walls or cold façades are identifiable by the presence of a cavity, ventilated internally, between the outer layer

which offers weather protection and an internal insulation layer. This allows the insulating layer to dry if water penetrates in to the façade.

Often this is a preferred method of construction in climatic and rainfall zones. The term "cavity wall" is most often used to describe clay brick and/or concrete masonry wall systems installed over a largely open, unobstructed air space or drainage cavity. This term is now generally used to define any wall system or assembly that relies upon a partially or fully concealed air space and drainage plane to resist bulk rainwater penetration and which is also used to improve the thermal performance at the building enclosure. Drained cavity walls typically include the following characteristics [11] as depicted in Fig. 86.7:

- An exterior cladding element that is intended to either shed or absorb the majority of bulk rainwater penetration before it enters the concealed spaces of the wall assembly.
- A drainage cavity or air space, that is intended to collect and control rainwater that passes through the exterior cladding element and re-direct that water to the building exterior. The cavity may be ventilated for pressure equalization, either mechanically or passively, to facilitate this process by preventing negative pressure that may draw rainwater across the cavity into the "dry" sections of the wall assembly via anchors, wall ties, and similar penetrations).
- An internal drainage plane that is intended to function as the primary line of defense against uncontrolled rainwater penetration. This layer serves functionally as the dividing line between the "wet" and "dry" sections, or "zones," of the exterior wall assembly.

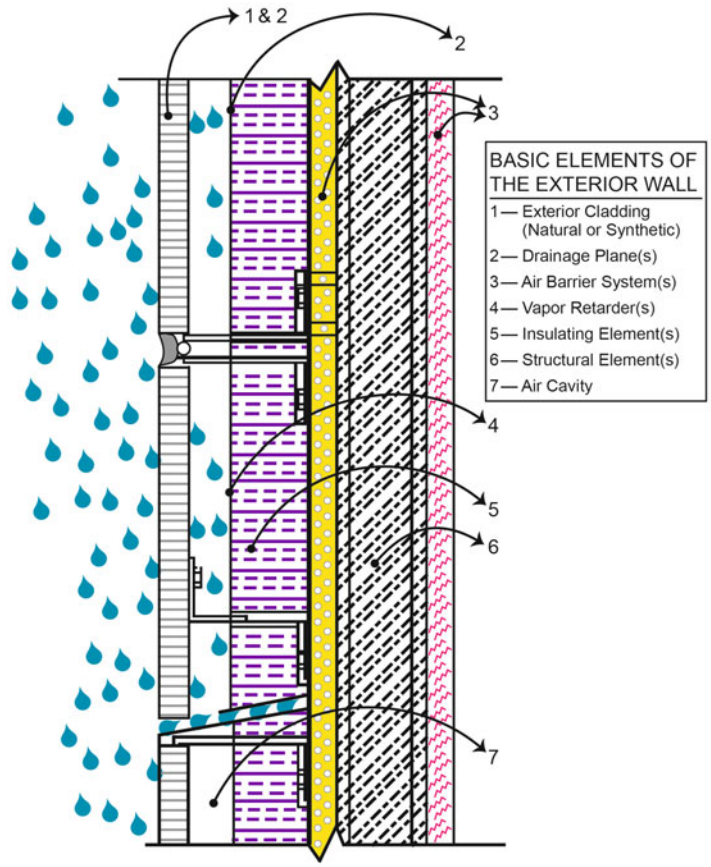

Fig. 86.7 Cavity wall diagram showing rainwater penetration into air cavity bounded by insulation layer (Based on Lemieux and Totten [11])

This layer can be created using a variety of both dry sheet-goods or wet, trowel-applied products depending upon the climate in which the building is to be located and the desired level of vapor permeability necessary to prevent condensation and potential mold growth on the dry side of the exterior wall assembly.

- An insulating layer, which can be located either inboard or outboard of the internal drainage plane depending upon the geographic region and climate in which the building or structure is to be located. In colder climates, the insulation is also placed outboard of the innermost (primary) drainage plane in this type of wall assembly, inside the wet zone (drainage cavity) of the wall. The combination of a combustible insulation layer adjoining the air cavity poses a risk of fire spread via the cavity if fire breaches into this zone.

Barrier Wall

A barrier wall or "warm façade" (European nomenclature) is commonly used to describe any exterior wall system of assembly that relies principally upon the weather-tight integrity of the outermost exterior wall surfaces and construction joints to resist bulk rainwater penetration and/or moisture penetration as shown in Fig. 86.8. Barrier walls have a thermal insulation layer applied directly to the surface of the building. If the insulation is on the exterior side, it must be water resistant to maintain the insulating properties. If the insulating layer is on the inside, the ability of the solid wall to store heat and contribute to the interior environment will be negated. This type of wall system is commonly associated with precast concrete spandrel panels, certain types of composite and solid metal plate exterior cladding systems, and exterior insulation and finish systems (EIFS). Although a cost-effective solution, barrier walls are cause for concern since they are difficult to implement correctly and can require substantial maintenance.

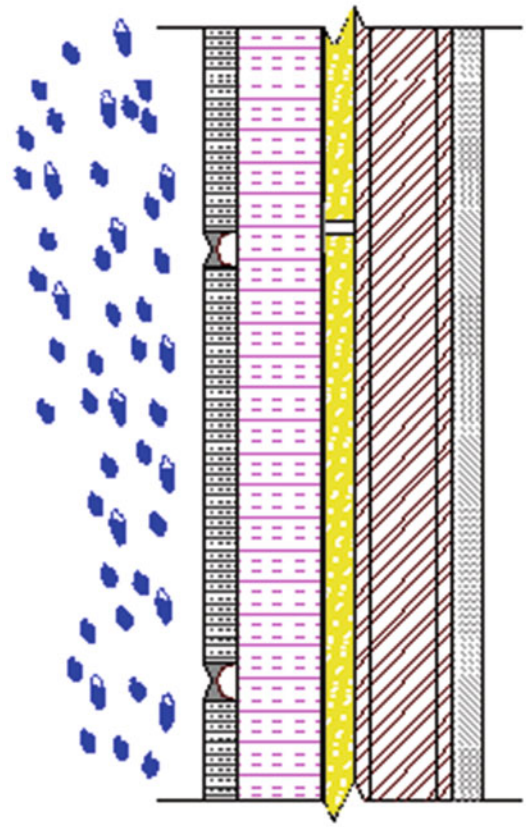

Fig. 86.8 Barrier wall section showing outermost layer resisting water penetration (Lemieux and Totten [11])

Mass Wall or Solid Wall

Unlike a cavity wall system, where the wall is constructed with a wall cavity and through-wall flashing to collect and redirect bulk rainwater to the building exterior, mass or solid walls rely principally upon a combination of wall thickness, moisture storage capacity, and (in masonry construction) bonding between masonry units and mortar to effectively resist bulk rainwater penetration (See Fig. 86.9).

For economic reasons, mass walls are less common in design and construction today. However, when constructing an addition, or incorporating a portion of an existing building into a new building or structure, the design and behavior of mass walls relative to storage

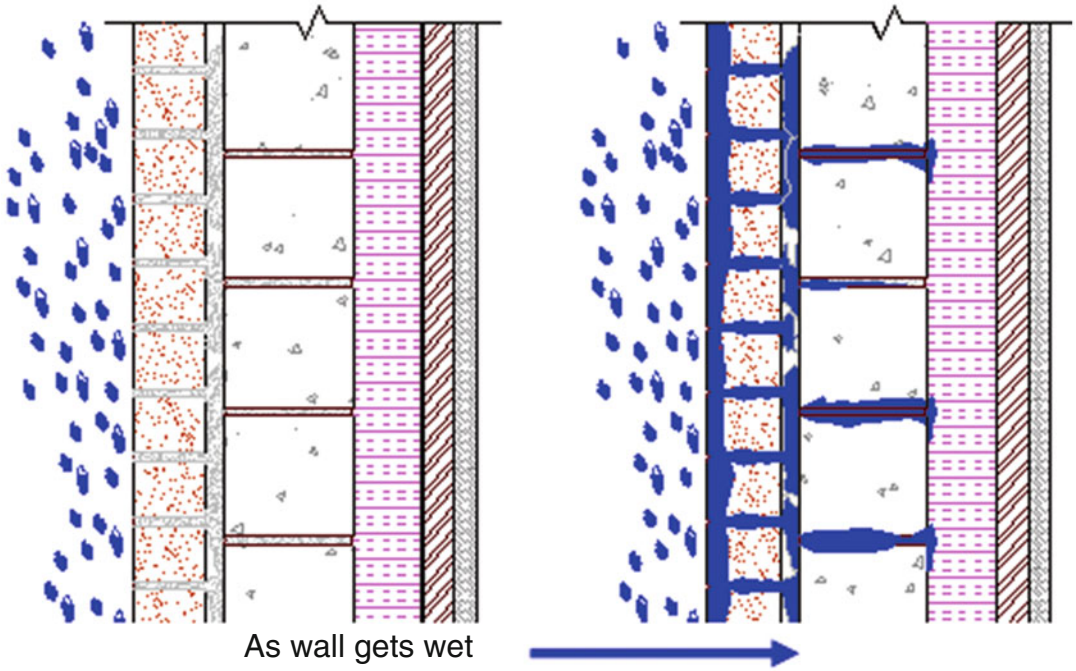

Fig. 86.9 Mass wall section showing reliance on masonry and mortar to resist rainwater penetration (Lemieux and Totten [11])

capacity and both heat and moisture transfer must be considered by the designer.

In addition to bulk rainwater penetration and moisture ingress that is often difficult to track (and therefore effectively isolate and repair) in this type of wall construction, the potentially negative effects of drying must also be considered when designing around or otherwise restoring this type of wall system. Evaporative drying across this type of wall assembly, either to the interior or exterior, can contribute to efflorescence (soluble salts deposited at or near the wall surface, with visible discoloration, sometimes spalling), deterioration of interior cement plaster finishes (common finish in early twentieth century), and organic/microbial growth on either the interior or exterior exposed wall surfaces.

Curtain Wall Construction

A curtain wall is relatively thin, lightweight type of wall assembly used to provide a weather resistant building envelope. A curtain wall is usually an aluminum-framed wall, containing in-fills of glass, metal panels, or thin stone. Curtain wall framing components are attached to the building structure and are not designed to carry any structural floor loading or roof loads of the building. Imposed wind loads and gravity loads of the curtain wall components are transferred to the building structure, typically supported at the floor line. The loads are primarily positive and negative wind loads but might also include a snow load applied to large horizontal areas, seismic loads, maintenance loads and others.

Curtain walls can be classified by their method of fabrication and installation as stick systems and unitized/modular systems. With stick systems (See Fig. 86.10), the curtain wall frame (mullions) and glass or opaque panels are installed and connected together piece by piece, such that all installation and glazing is typically performed at the construction site.

In the building of unitized or modular type system, the curtain wall is composed of large units that are assembled and glazed in the

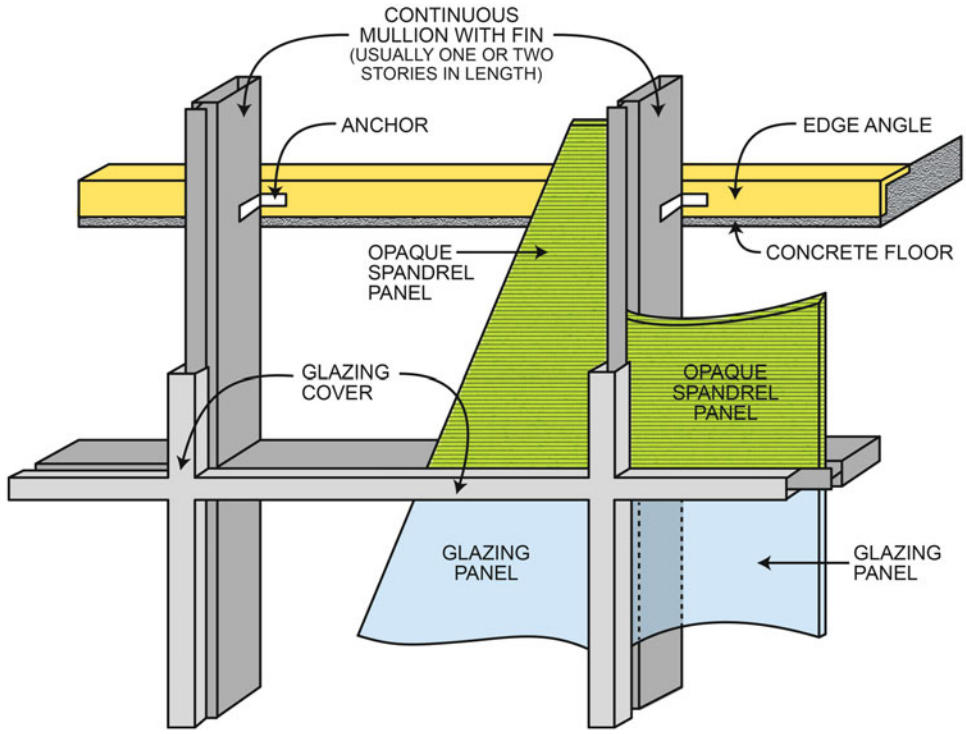

Fig. 86.10 Basic details of a stick type curtain wall

factory, shipped to the site and hung on the building to form the building enclosure. Vertical and horizontal mullions of the modules fit together with the adjoining modules. Modules are generally constructed one story tall and one module wide (typically 1.5–2 m) but may incorporate multiple modules. There are variations on these themes of stick systems and unitized/modular systems as shown in Fig. 86.11 [14].

There are several components that make up a curtain wall assembly. Typical opaque panels include spandrel glass, metal panels, thin stone, and other materials, such as terra cotta or FRP (fiber-reinforced plastic). Vision glass is predominantly insulating glass and may have one or both lites laminated, usually fixed, but sometimes glazed into operable window frames that are incorporated into the curtain wall framing. Spandrel glass can be monolithic, laminated, or insulating glass. The spandrel glass can be made opaque through the use of film/paint or ceramic frit treatment applied on an unexposed surface or through "shadow box" detailing.

Shadow box construction creates a perception of depth behind the spandrel glass by providing an enclosed space behind clear spandrel glass. Metal panels can take various forms, including aluminum plate, stainless steel or other non-corrosive metal, thin composite panels consisting of two thin aluminum sheets sandwiching a thin plastic interlayer, or panels consisting of metal sheets bonded to rigid insulation, with or without an inner metal sheet to create a sandwich panel. Thin stone panels are typically 75–100 mm thick and of granite, marble, travertine or limestone. White marble is not recommended due to its susceptibility to deformation. In cases where the weight of the stone is to be reduced, such stone may be attached to an aluminum honeycomb backing, which also increases the strength of the panel.

Back pans are metal sheets, usually aluminum or galvanized steel that are attached and sealed to the curtain wall framing around the perimeter behind opaque areas of a curtain wall. In cold climates insulation is typically installed between

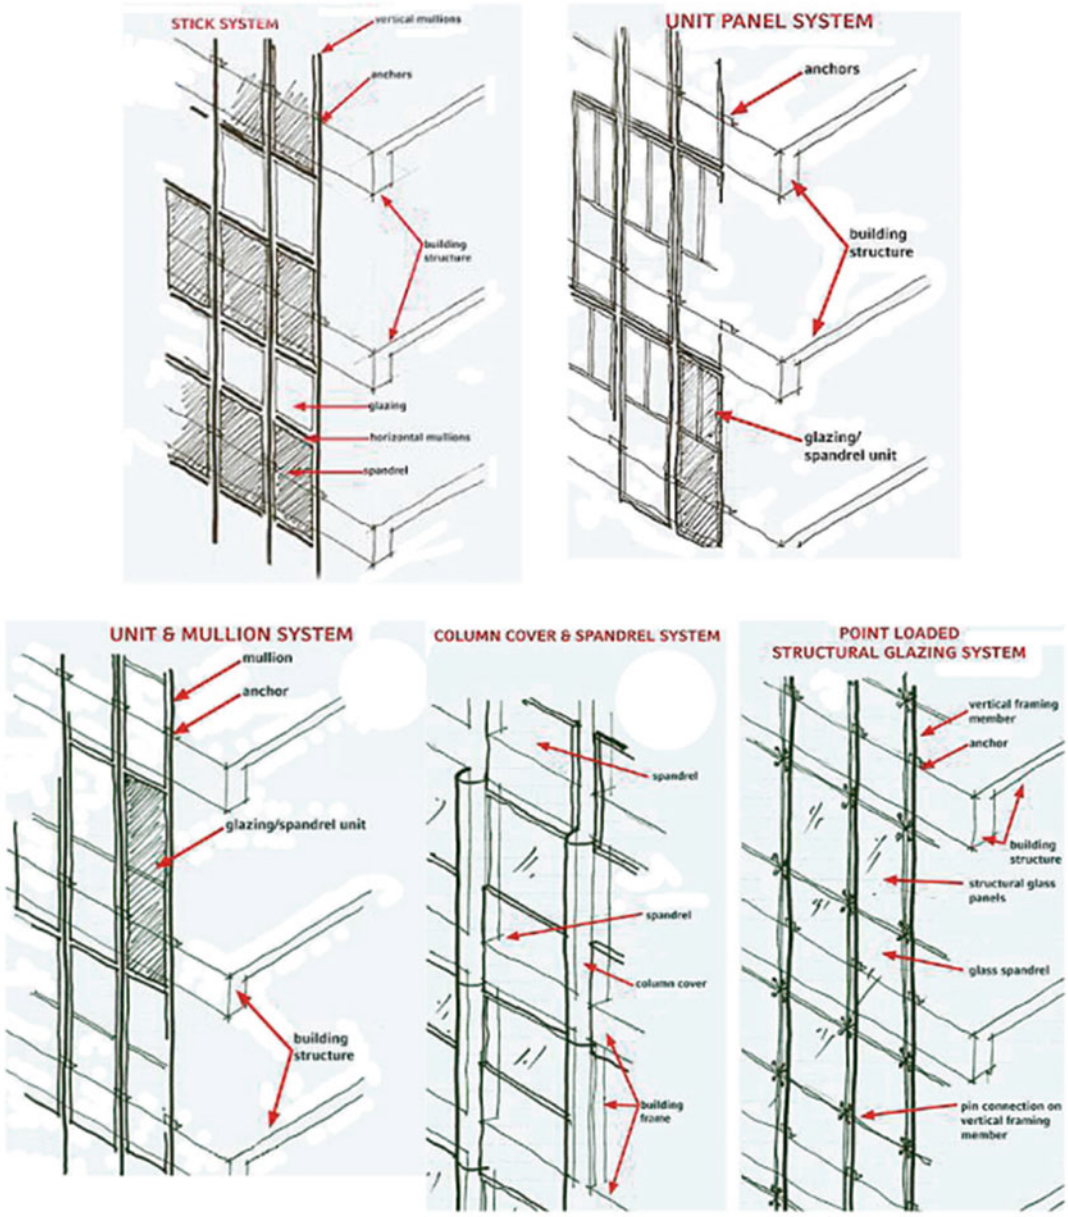

Fig. 86.11 Variations of curtain wall systems [14]

the back pan and the exterior cladding in order to maintain the dew point outboard of the back pan so that the back pan acts as an air and vapor barrier. Back pans provide a second line of defense against water infiltration for areas of the curtain wall that are not visible from the interior and are difficult to access.

Because the aluminum framing components of a curtain wall have a high thermal conductivity, it is common practice to incorporate thermal breaks of low conductivity materials and reduce the temperature transmission via the aluminum components. PVC, Neoprene rubber, polyurethane and polyester-reinforced nylon are

materials used to create the thermal break for improved thermal performance.

In 1986, South West Research Institute performed full scale fire tests of aluminum curtain walls. This testing identified problems of fire spread through voids that appear between the aluminum curtain wall and the edge of the floor slab. The voids were created when tested panels became distorted or when sufficient distortion occurred that allowed fire stopping to fall out of place [15].

The ability of curtain wall systems to remain intact for only short periods of time under fire exposure, uncontrolled by sprinklers, was shown in tests sponsored by the Loss Prevention Council (UK) using an aluminum stick curtain wall assembly. In those tests, failure of the glazed window and spandrel panel units occurred after 13 min, failure of the aluminum façade frames after 24 min and failure of aluminum attachment brackets after 28 min [16]. The Loss Prevention Council tests show the relative short duration of integrity afforded by a stick panel curtain wall, however, there are available passive design techniques where the integrity of the curtain wall components can be designed to provide longer duration resistance (based on specific test criteria) to fire exposure [16, 17].

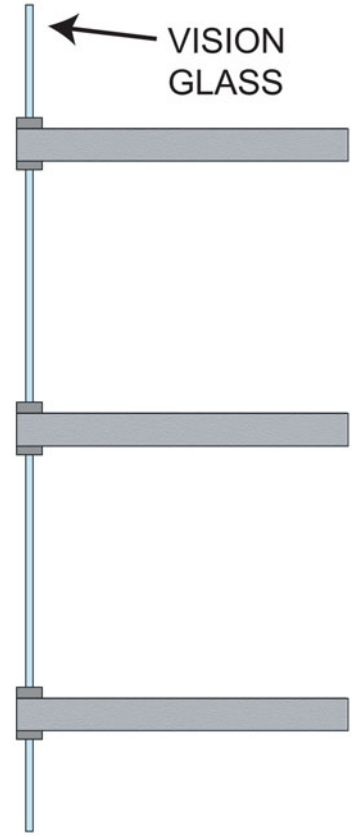

Fig. 86.12 Curtain wall supported on slab edge [9]

Curtain Walls and the Building Edge Condition

Today's codes, such as the *International Building Code* [18] and the National Fire Protection Association's *Building Construction and Safety Code* (NFPA 5000), recognize that with a properly designed and operational sprinkler system, the threat of fire spread along the exterior of the curtain wall is effectively mitigated. This is a critical assumption that deserves further consideration in the context of super high-rise buildings and is discussed in detail later.

From a fire containment perspective, there are two basic ways to provide a code complying curtain wall design in fully sprinklered buildings. The most basic approach is for the curtain wall to be supported directly on the structural floor slab edge, which precludes any gap or joint condition, given that the floor slab is continuous to or extends past the building envelope. This type of installation would permit floor-to-floor glazed curtain wall assemblies in fully sprinklered buildings as shown in Fig. 86.12. This approach is sometimes observed in high-rise building design, but it is not the most common approach for the installation and support of curtain walls. The second approach is applicable when the curtain wall assembly is positioned just outside the edge of a fire rated floor system, such that a void space results between the floor system and the curtain wall assembly as shown in Fig. 86.13.

The noted codes require that the void space at the slab edge in Fig. 86.13 be sealed with an approved material or system to prevent the interior spread of fire (IBC, NFPA 5000). This

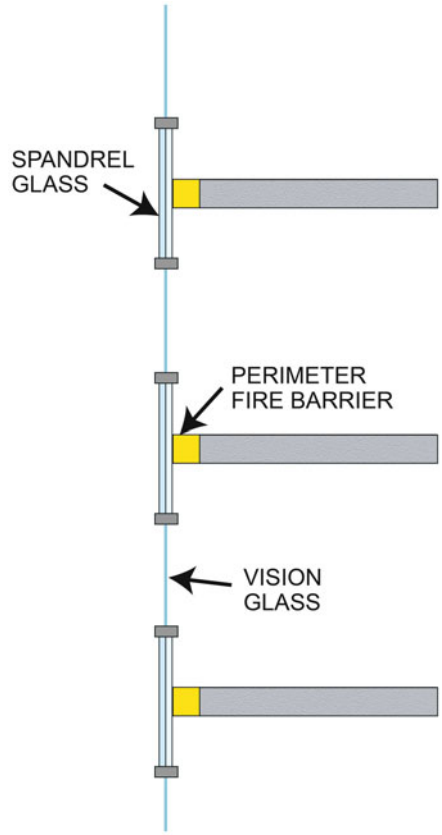

Fig. 86.13 Curtain wall hung-off Slab edge [9]

requires some form of a joint system or what are called "perimeter fire barrier systems." The basic performance criterion for these perimeter fire barrier systems is either one of the following:

1. Such material or systems shall be securely installed and capable of preventing the passage of flame and hot gases sufficient to ignite cotton waste, where subject to ASTM E119 time-temp fire conditions for a time period equal to the fire resistance of the floor assembly, or
2. Such material or systems are to be tested in accordance with ASTM E2307, "*Standard Test Method for Determining Fire Resistance of Perimeter Fire Barrier Systems Using Intermediate-Scale Multi-Story Test Apparatus*".

The methodology for compliance with either the criteria of item 1 above or item 2 is essentially the same, the former being the original performance intent statement which evolved into the more recent and formally defined ASTM Standard. Although a defined ASTM Standard does exist, there is confusion in the building industry resulting from differences in the rating criteria imposed by various testing laboratories. Underwriters Laboratories (UL) certifies perimeter fire barrier systems under the product category "Perimeter Fire Barrier Containment Systems" [17]. The systems certified by UL use the same two-story large scale fire test apparatus as are described in the ASTM E2307 Standard. However, the systems certified by UL are measured in four aspects—an F-Rating, a T-Rating, an Integrity Rating and an Insulation Rating. The ASTM E2307 Standard requires the reporting of an F-Rating and a T-Rating. This is in contrast to the F-rating which is the only requirement stipulated by the IBC and NFPA 5000. It is important to understand these ratings and the purpose behind each rating.

F-Rating An F-rating evaluates the most fundamental function of a perimeter fire barrier system. The F-rating is given if the vertical passage of flame and hot gases sufficient to ignite a cotton pad is prevented by the perimeter fire barrier system. This tests the ability of the perimeter fire barrier system to maintain fire resistance in the void space between the interior surface of the curtain wall assembly and the floor slab edge. The F-rating is expressed in hours (e.g. 2 h) for comparison to the fire resistance rating of an associated floor assembly.

T-Rating A T-rating evaluates the extent of temperature increase on the non-fire side of the perimeter fire barrier system. The temperature measurements are taken at a point 25.4 mm (or less above the fill materials perimeter fire barrier system. A T-rating is expressed in hours for perimeter fire barrier systems that do not show a temperature rise of 181 °C for any individual thermocouple, or a temperature rise of 139 °C for averaged thermocouple points (required for wide voids). T-ratings are typically on the order of 0, 0.25 and 0.50 h.

Insulation Rating This rating provided under the UL certification process is similar to the T-Rating per the ASTM E2307 procedure; however, UL additionally evaluates the temperature rise on the unexposed interior surface of the curtain wall assembly above the fill materials. This is intended to determine if fire can spread to a floor above through the curtain wall construction and not just the fill material of the perimeter fire barrier system. Insulation ratings are typically on the order of 0, 0.25 and 0.50 h.

Integrity Rating This rating provided under the UL certification process is similar to the F-Rating per the ASTM E2307 procedure; however, UL additionally evaluates if there is any flame passage or surface flaming on the interior surface of the curtain wall assembly above the fill materials. In addition, the glazing above the fire exposed floor is monitored to determine when the glazing breaks. The intent of monitoring the glazing integrity is to identify how long in hours the curtain wall glazing will survive, resisting the fire leapfrog that has been observed to occur in multi-story buildings.

The F-Rating and Integrity Rating are sometimes interrelated in that a perimeter fire barrier system will not be capable of achieving an F-Rating if the curtain wall does not maintain integrity and allows the perimeter fire barrier system to become dislocated or displaced during the fire test. This is generally the case for fully glazed curtain wall systems that incorporate glazed insulated spandrel panels. The failure mode for such assemblies occurs if the spandrel glazing and framing members are not sufficiently insulated. Under these conditions, the perimeter fire barrier system fill materials will fall out of place when the glazing panel and associated insulation fail to maintain a compression fit with the fill materials of the perimeter fire barrier system.

Given that the IBC and NFPA 5000 codes only require the void at the intersection of the curtain wall and the floor assembly be protected with fire barrier fill materials, there is often confusion. There are no formally published tested perimeter fire barrier systems that allow for floor-to-floor height vision glazing. This is mostly an artifact of the nature of compression-fit type fire barrier methods and their integration with fully glazed curtain walls. If a tested perimeter fire barrier system could be shown to stay in-place in the void after the glazing failed, then code compliance would be achieved. However, the extent of the failed glazing may raise concerns for flames readily entering adjacent spaces above. This lack of such capable perimeter fire barrier systems poses a challenge to curtain wall designers/architects who wish to create façades using expansive vision glass panels.

The issue of performance expectations of non-fire rated curtain walls and the associated perimeter fire barrier assembly has been a significant item of discussion in the United States. As a result of recent code changes, it is reported [19] that the code intent is to recognize that if the curtain wall assembly does not have the same fire resistive capability of the floor slab, then the system protecting the void space need not perform after curtain wall integrity is lost.

Curtain Wall Components: Performance Factors

Curtain walls are a relatively complex combination of components that include aluminum frames; vision glass; spandrel panels of glass, metal or stone; metal back pans; insulation; gaskets; sealants; and anchors or connectors of steel or aluminum. Given a fully-developed fire exposure in a room or space (i.e. sprinkler system out of service or failure scenario) bordered by a building's curtain wall system, it can be expected that vision glass failure will occur within minutes. Once the failure occurs and flames extend to the exterior, the various curtain wall components and any perimeter fire barrier system are then subject to thermal forces and degradation that can result in fire spread to the floor above.

The possible complexity of a curtain wall is illustrated in Fig. 86.14. In this hypothetical case, a number of components are used to build,

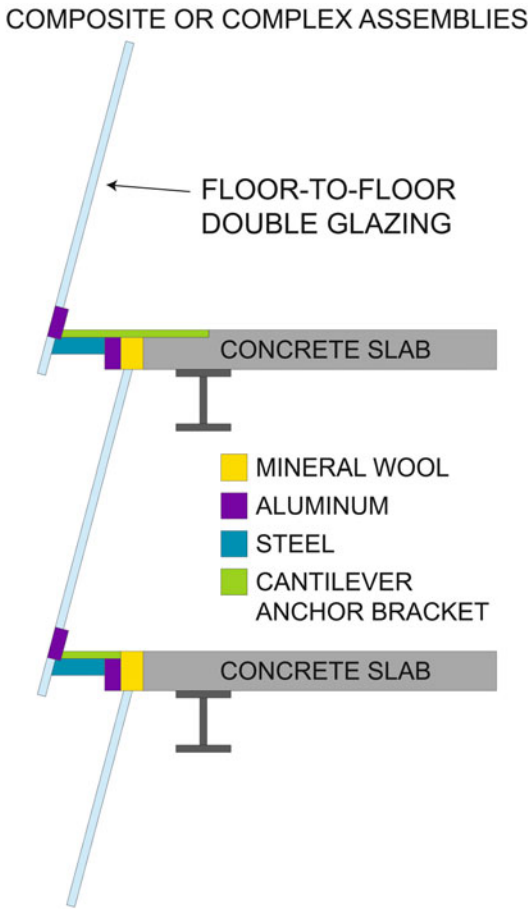

Fig. 86.14 Hypothetical illustration of a complex constructed curtain wall assembly using an inclined glazing surface with slight bottom extension of the glazing to create a shingle effect [9]

support and anchor the curtain wall system to the structure. Additional materials such as mineral wool are used to provide perimeter fire barrier protection. Although it can be straightforward to design and size the components to readily fit together and form an appropriate weather enclosure, it is difficult to know how the components and attachment methods will survive a high temperature fire exposure and the resulting thermal expansion, particularly, when unlike materials are interconnected. Aluminum loses roughly 50 % of its strength at 200 °C and will melt in the range of 550–600 °C. The steel component is not expected to melt, but will expand, inducing stress in other elements of the composite assembly. In Fig. 86.14, potential flame exposure to the curtain wall components is likely exacerbated by the geometry of the inclined overlapping shingle design.

The nature of the curtain wall design will dictate the relative capability to resist floor-to-floor fire spread. Key factors that impact the curtain wall's resistance to vertical fire spread are as follows:

- Full height or partial height (e.g. spandrel panel design) vision glass systems
- Nature of the glass used to construct glazing system
- Nature of the curtain wall components (e.g. framing, spandrel panels)
- Height of spandrel panels
- Vertical or horizontal projections on exterior that may deflect or enhance flame behavior
- Building geometry at curtain wall—twister, staggered, sloped, etc.
- Operable windows/openings—size, vertical or horizontal orientation
- Ability of perimeter fire barrier system to remain in void during fire exposure

When full height vision glass systems are used, flame extension and heat fluxes to the window areas above can be expected to be greater than that expected for curtain walls using a spandrel panel design. A spandrel panel design will limit the flame extension and reduce heat flux to the areas above by providing an opaque surface to block the heat transfer. To prevent the leapfrog effect using a spandrel design requires a vertical spandrel dimension of approximately 4 and 5 ft in order to match the performance, respectively, of 1 and 2 h fire rated floors [20]. The construction of the spandrel can be an important factor to the performance of the perimeter fire barrier system. Typical aluminum framed curtain walls using spandrel glass require that the glass be appropriately insulated using mineral wool rather than fiberglass-based insulations that will melt. Additionally, the aluminum mullions require insulation protection; otherwise the aluminum frame will melt and no longer support the wall system. These measures will help keep the glass spandrel panel and any associated fire barrier

system intact. Precast panels offer the advantage of high resistance to heat exposure and offer a solid rigid surface for securely positioning or compression fitting a perimeter fire barrier system into the void between the precast panel and the floor slab edge. Metal curtain wall panels or metal back pans that, when subjected to the fire heat, may warp or distort allowing gaps to develop at the perimeter fire barrier system, and specific measures may be needed to stiffen the metal pans.

Glass used in curtain wall assemblies may be one of several types—float glass which may be heat strengthened or tempered glass, and laminated or wired glass. Vision glass can be single, double or triple glazed, and are typically assembled into an insulating glass unit (IGU). Vision glass may also be tinted to provide a heat absorbing quality, or coated to provide a heat reflective capability. All of these features can impact the performance of glass under fire exposure, however, very little is currently known about the fire performance of the wide variety of IGUs that are possible. What we do know about glass performance is limited to standard single glazed assemblies and, recently, some information on double glazed units has been presented (see glass discussion in later sections of this Chapter). More testing to determine the performance of large IGUs is needed to better understand these fire-related performance metrics. It may be that actual IGUs may show fire performance benefits not yet understood, however, full installations with framing elements, sealants and gaskets may play a key role—positive or negative. Such full scale installations are not known to have been tested to any degree that allows for reasonable conclusions about installed performance.

Building geometry and exterior projections of the curtain wall or building structural elements can have a beneficial or negative effect on flame length extension and heat flux exposure to curtain wall elements above the fire compartment. This can be particularly important if operable windows or ventilation openings are used. Of course, any such opening can allow the unrestricted passage of flames and hot gases from a fire on a floor below into the floor above. The position of the window or ventilation opening relative to the expected flame extension is a factor in assessment of the risk of upward flame spread.

Today many unique wall designs veer from the more traditional continuous vertical façade surfaces of the past, often using curved surfaces and rotated floor plates that complicate the façade connections and hidden details of fire barrier assemblies. Such new designs can result in an orientation that allows for either more direct flame exposure (Fig. 86.15) or diminishes the threat of direct flame contact (Fig. 86.16). It is important to note that regardless of the façade

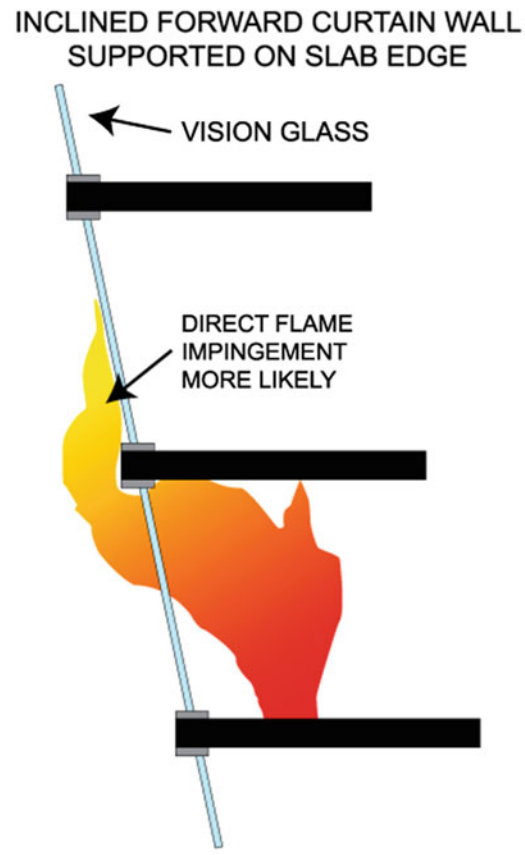

Fig. 86.15 An inclined forward curtain wall condition can allow for more direct flame impingement and higher exposure temperatures on curtain wall components [9]

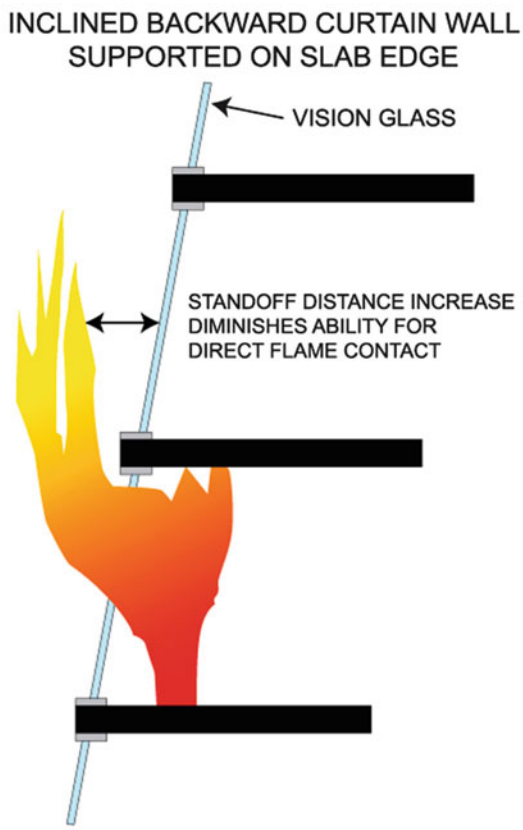

Fig. 86.16 An inclined backward curtain wall condition can diminish the ability of flames to contact the curtain wall components [9]

orientation that wind conditions are a significant factor which may reduce or exacerbate the flame and temperature exposure.

Double Skin Façades

The idea of double skin façades dates back to 1849 with first implementation noted to be in 1903 at the Steiff Factory in Gienge/Brenz, Germany [21]. In recent years, the green building/sustainability movement has resulted in the deployment of new concepts in façade or curtain wall design that intended to enhance the energy efficiency of building façades.

Double-skin façades are a key development in this area that offers solutions to heating, cooling, sound control and lighting efficiency for buildings. The basic components of a double skin façade system often involve the use of an outer glazed curtain wall, usually with ventilation openings, a cavity (usually ventilated) with dimensions of centimeters to meters in depth, and a second inner curtain wall with insulated glazed units.

There are wide variations possible for the design of these double skin façades. Design variables include the ventilation scheme (passive or active), use of louvers, motor operated openings or fans, shading devices, horizontal or vertical partitions within the cavity and operable windows on the inner skin of the double façade. Depending on local climate, the double façade concept may be used in different ways.

For example, in winter climates, the air cavity is closed and the system is used as a triple glazed system with the air in the cavity acting as a transparent insulator. The temperature of the internal glazing is effectively raised, reducing heating costs and increasing occupant comfort at vicinities close to the glazing. In hot climates, air inlets and outlets may be opened to develop a stack effect (hot air rises) allowing hot air to be released at the top of the cavity and replaced by fresh air from the lower regions of the cavity. Within the air cavity, sun shades can be used to absorb and reflect solar heat energy which can promote an even higher temperature differential for the stack effect to take place within the cavity. As a result, cooling costs for inhabited areas are reduced and occupant comfort increased.

Building enclosure designs using ventilated double skin façades should not be confused with windows made of sealed, double or multiple glazed assemblies. A concise but comprehensive definition/explanation (edited) of double skin façades is provided by the Belgian Building Research Institute (BBRI) [22] as follows:

> A ventilated double façade can be defined as a traditional single façade doubled inside or outside by a second, essentially glazed façade. Each of these façades is commonly called a skin. A ventilated cavity—having a width which can range from several centimeters at the narrowest to several meters for the widest accessible cavities—is located between these two skins.

There exist façade concepts where the ventilation of the cavity is controllable, by fans and/or openings, and other façade concepts where this ventilation is not controllable. The indoor and outdoor skins are not necessarily airtight (e.g. louver type façades). Automated equipment, such as shading devices, motorized openings or fans, are most often integrated into the design.

Ventilated double skin façades offer advantages in terms of reducing peak wind pressure on building elements, noise control and improving the overall energy efficiency of buildings. Such energy benefits can accrue from one or a combination of the following mechanisms.

- Natural ventilation enhancement (using stack effect principles)
- Solar heat gain reduction (summer season)
- Thermal heat loss reduction (winter season)
- Passive solar heat gain (winter season)

The BBRI offers a classification system for double skin façades [22]. The classification method considers (1) the type of ventilation scheme, (2) how the façade is partitioned to create vertical and horizontal cavities or spaces for airflows (one example is shown in Fig. 86.17), and (3) the modes of ventilation (see Fig. 86.18). Table 86.2 summarizes the variety of basic features that may be found in the design of double skin façades.

There are a number of issues for the fire engineer to consider when a double skin façade is used. The double-skin façade concept poses conditions that impact fire spread that are not encountered with single skin or more common curtain wall designs. The risk of fire spread through such double-skinned façades introduces concerns arising from the fact that should flame break through the inner façade it would then be confined within a long tall shaft-like space as shown in Fig. 86.19.

The dynamics of the flame and radiant heat exposure for this case are potentially more severe than a flame freely flowing to the open atmosphere. Other types of double-skinned façades may reduce the risk of fire spread, particularly those using a partitioning scheme within the cavity of the double-skinned façade. The cavity can act as shaft for fire and smoke spread, but depending on the cavity design and ventilation scheme, the result may be either an increase or decrease in flame extension and risk of fire spread.

In addition, a naturally ventilated building can challenge the operational aspects of mechanical smoke control systems and pressurized stair systems that generally rely on tightly closed façades in order to develop the pressure differentials and appropriate air flow patterns necessary to manage or resist the movement of smoke and fire with in a tall building. Although no credible research exists on the subject, it is plausible that the presence of a ventilated double skin façade could be used to the advantage of fire department or fire brigade for smoke management during a fire emergency.

There are many sources of case studies and design considerations for double skin façades [21–23]. One well described case study [23] that illustrates the implementation of

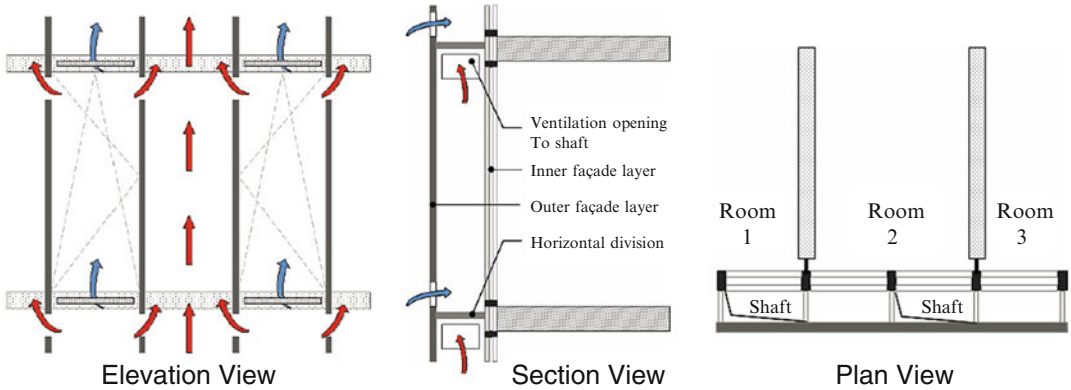

Fig. 86.17 Elevation, section and plan view of "shaft-box" VDF (Ventilated Doubles Façades—classification and illustration of façade concepts, Belgian Building Research Institute (BBRI))

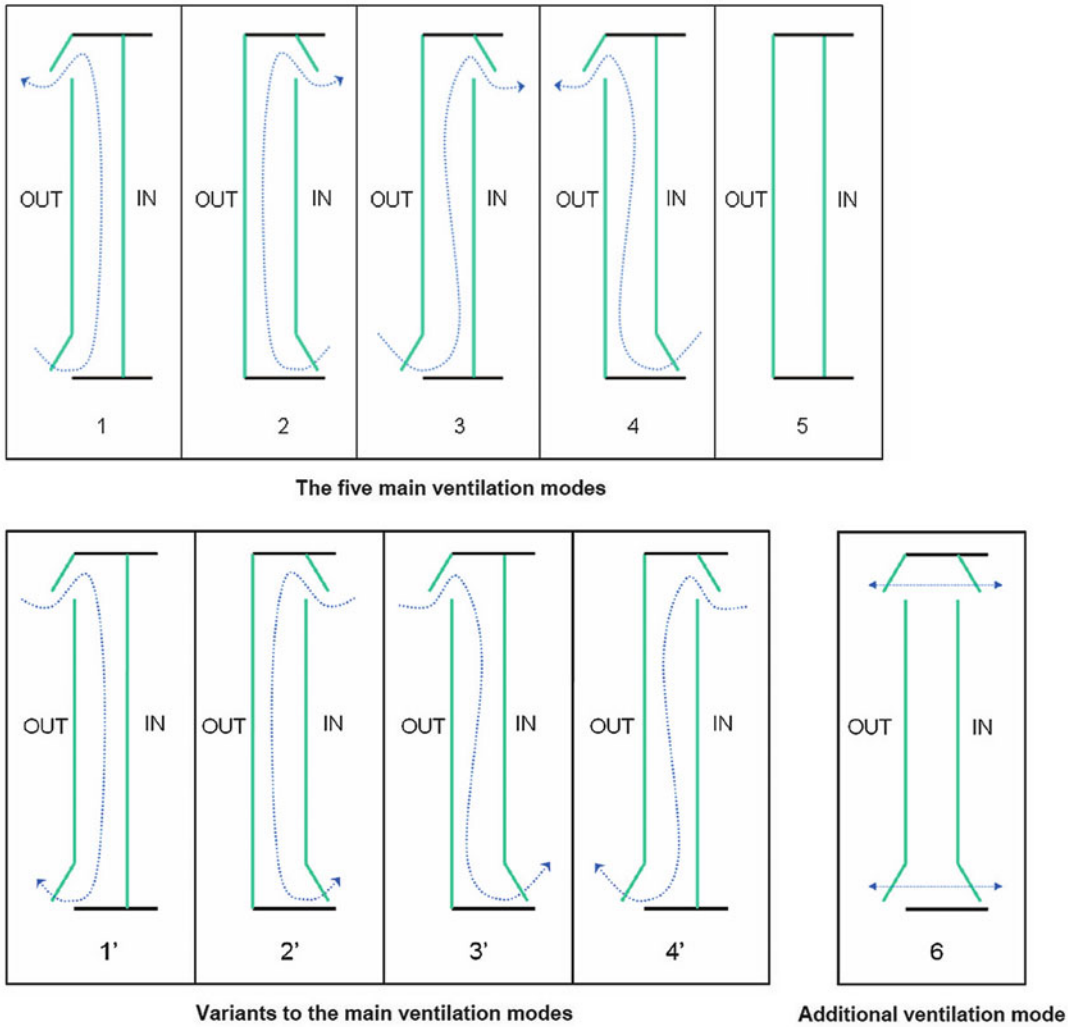

Fig. 86.18 Basic and variant ventilation modes for VDFs (ventilated doubles façades—classification and illustration of façade concepts, Belgian Building Research Institute (BBRI))

ventilation schemes throughout a building including the use of atrium spaces in support of the ventilation scheme is the Commerzbank in Frankfurt, Germany. The BBRI definition recognizes that atrium spaces can be regarded as a ventilated double façade with a very large cavity [22].

The Commerzbank, built in 1997, uses a double skin façade with a cavity of 200 mm. the exterior cladding modules measure 1.5 m horizontally and 2.4 m vertically. The building uses a hybrid scheme and the natural ventilation mode relies on both cross ventilation and stack effect air movement.

Perimeter offices use a outdoor air curtain ventilation mode and offices facing atrium spaces are ventilated by air moving from windward sky gardens across central atrium spaces to leeward sky gardens. Figure 86.20 [23] illustrates the natural ventilation flow patterns in plan and section views of the building, which is utilized approximately 80 % of the year, resulting in a 63 % annual energy savings compared to measurements of a fully air conditioned office buildings in Germany.

With regard to fire protection, the case study reviewers offer a few fire-related observations of the Commerzbank design [23].

Table 86.2 Features of ventilated double façades (Based on [22])

Ventilation type
• Natural ventilation (passive)—ventilation that relies on the differences in pressure created by stack effect and wind
• Mechanical ventilation (active)—ventilation aided by powered air moving components (e.g. fans)
• Hybrid ventilation—both natural and mechanical modes used, with mechanical systems triggering when natural ventilation is inadequate to assure performance
Partitioning of the cavity
• Ventilated double window (box window)—characterized by a window doubled inside or outside by a single glazing or by a second window. From the partitioning perspective, it is thus a window which functions as a filling element in a wall
• Ventilated double façade partitioned by story—the façade module has a height limited to one story. The cavity dimensions are generally consistent with the horizontal and vertical dimensions of the modules
• Corridor-type ventilated double façade partitioned by story—characterized by a large cavity in which it is generally possible to walk. While the cavity is physically partitioned at the level of each story (the cavities of each story are independent of one another), it is not limited vertically, and generally extends across several structural bays or even an entire floor
• 'Shaft-box' ventilated double façade—composed of an alternation of juxtaposed façade modules partitioned by story and vertical ventilation ducts set up in the cavity which extends over several floors. Each façade module is connected to one of these vertical ducts, which encourages the stack effect, thus supplying air via the façade modules. This air is naturally drawn into the ventilation duct and evacuated via the outlet located several floors above which represents a schematic view of the partitioning of this type of façade
• Multi-story ventilated double façade—characterized by a cavity which is not partitioned either horizontally or vertically, the space between the two glazed façades therefore forming one large volume. The cavity is wide enough to permit access and floors which can be walked on are installed at the level of each story in order to make it possible to access the cavity, primarily for reasons of cleaning and maintenance
• Multi-story louver naturally ventilated double façade—cavity is not partitioned either horizontally or vertically and therefore forms one large volume. The outdoor façade is composed exclusively of pivoting louvers rather than a traditional monolithic façade equipped (or not) with openings. The outside façade is not airtight, even when the louvers have all been put in closed position
Ventilation/non-ventilation modes
• Outdoor air curtain—in this ventilation mode, the air introduced into the cavity comes from the outside and is immediately rejected towards the outside. The ventilation of the cavity therefore forms an air curtain enveloping the outside façade
• Indoor air curtain—the air comes from the inside of the room and is returned to the inside of the room or via the ventilation system. The ventilation of the cavity therefore forms an air curtain enveloping the indoor façade
• Air supply—the ventilation of the façade is created with outdoor air. This air is then brought to the inside of the room or into the ventilation system. The ventilation of the façade thus makes it possible to supply the building with air
• Air exhaust—the air comes from the inside of the room and is evacuated towards the outside. The ventilation of the façade thus makes it possible to evacuate the air from the building
• Buffer zone—this ventilation mode is distinctive inasmuch as each of the skins of the double façade is made airtight. The cavity thus forms a buffer zone between the inside and the outside, with no ventilation of the cavity being possible

- The vertical segmentation of the atrium into 12 story-high segments through the use of glass and steel diaphragms prevents the development of extreme stack flows and drafts due to large pressure differentials between the top and bottom of the atrium.
- The segmentation of the atrium also provides fire separation and ventilation zones.
- Though the atrium is compartmentalized into 12-story sections for smoke spread, there is still the potential for significant smoke/fire spread within the villages due to the amount of open atrium space.

The Commerzbank is illustrative of the degree to which double skin façades can influence the air movement in a building. Other building designs have similarly relied on using the stack effect to move air through atriums, or multi-story escalator wells as in the example of the 23-story Liberty Tower of Meiji University in Tokyo, shown in Fig. 86.21.

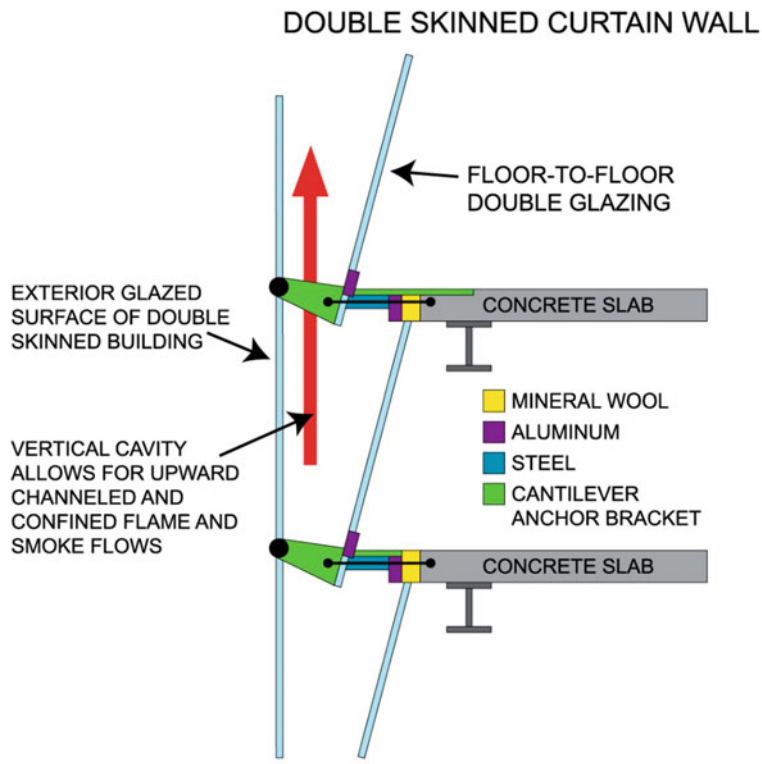

Fig. 86.19 Vertical cavity and potential fire spread route

In this case the fire protection concern is the intentional movement of smoke through the multi-story escalator well. Fire/smoke shutters are arranged to be lowered at the 18th floor atrium openings, presumably to suspend the stack effect created by the "wind floor" concept.

Another concern may be the window ventilation opening detail that poses a risk for exterior floor-to-floor fire spread. If a sufficiently developed fire breaks the exterior glazing, then there may be flame exposure upward and through the vent. Of course, a fire resistive damper may exist in the vent design; however, the case study [23] does not indicate such a protective device being installed in the vent opening.

Exterior Cladding Materials for Wall Construction

There are a variety of materials that may be used to create the outer most, directly weather-exposed surface of a building enclosure wall commonly known as the "cladding". Exterior wall claddings may be noncombustible or combustible materials. Primary categories are as follows:

- Noncombustible Cladding materials
  - Brick
  - Masonry
  - Stone
  - Terracotta
  - Concrete
  - Stucco (Cementitious)
  - Fiber Cement boards/panels
  - Metal siding
  - Glass/metal/concrete curtain wall panels
- Combustible Cladding Materials
  - Wood
  - Vinyl siding
  - Aluminum siding
  - Exterior Insulation and Finish Systems (EIFS)
  - Metal/Aluminum composite Materials (ACM, MCM)
  - Fiberglass Reinforced Plastics (FRP)
  - High Pressure Laminates (HPL)

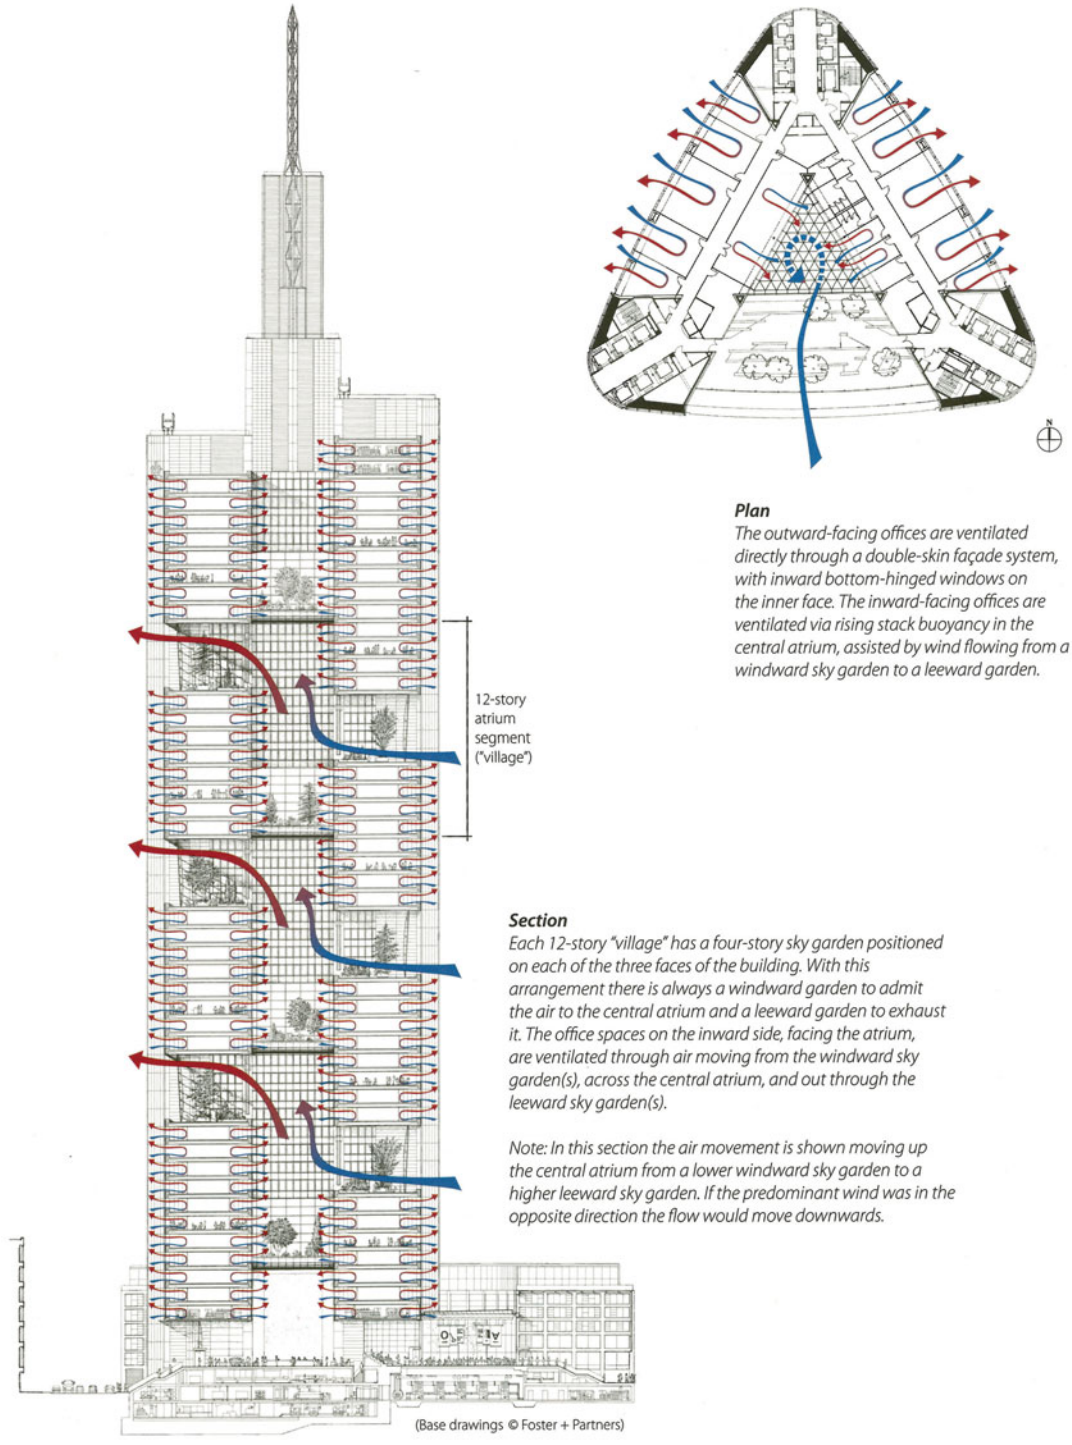

Fig. 86.20 Ventilated façade concept at Commerzbank [23] (Courtesy of CTBUH)

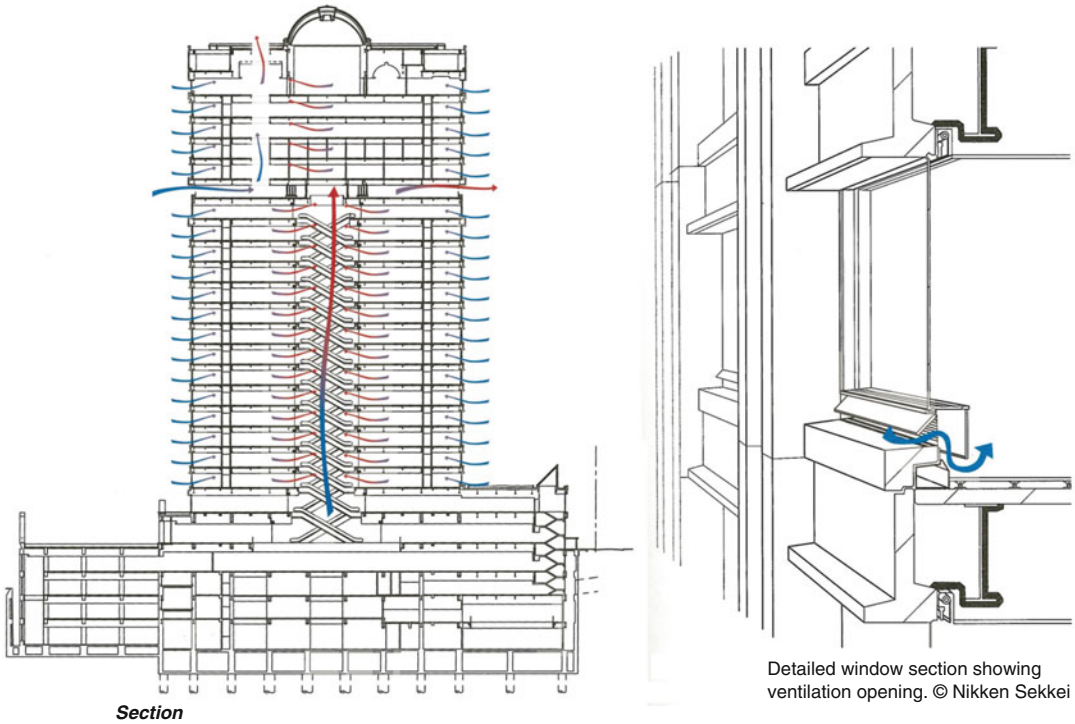

Section

The stack effect in the central escalator void (the "Wind Core") pulls air from the classrooms at each floor. Fresh air enters the classrooms through openings at the base of each window. The eighteenth floor, "Wind Floor" has openings on four sides. As wind passes through the Wind Floor it creates suction, pulling warm air from the escalator void. A similar effect is achieved through an atrium in the upper section of the building, between floors 19–23.

– Insulated foam core sandwich panels

Model building codes in the United States traditionally have required exterior walls to be constructed of noncombustible materials in buildings of Type I, II, III or IV construction. This requirement is intended to serve multiple objectives, including:

- Resistance to ignition from external exposure fires
- Resistance to ignition from interior fires propagating through wall openings
- Prevention of vertical fire spread on building façades
- Prevention of building-to-building fire spread by means of exterior wall ignition
- Assurance of fire resistive capability of the wall (when structural fire resistance required)

From the 1980s forward, the requirements for noncombustible exterior walls have been revised to allow for the use of combustible materials in exterior walls, including metal composite materials (MCM), exterior insulation and finish systems (EIFS, See Fig. 86.22) and foam plastic insulation (FPI), and most recently high-pressure decorative exterior grade compact laminates (HPL). Generally, assemblies incorporating these materials can be used provided that such assemblies constructed with combustible materials can demonstrate through large-scale fire testing that they can meet these objectives.

A number of well-publicized fires involving foam plastic insulation or MCM assemblies in high-rise buildings have demonstrated potential fire safety issues associated with these products,

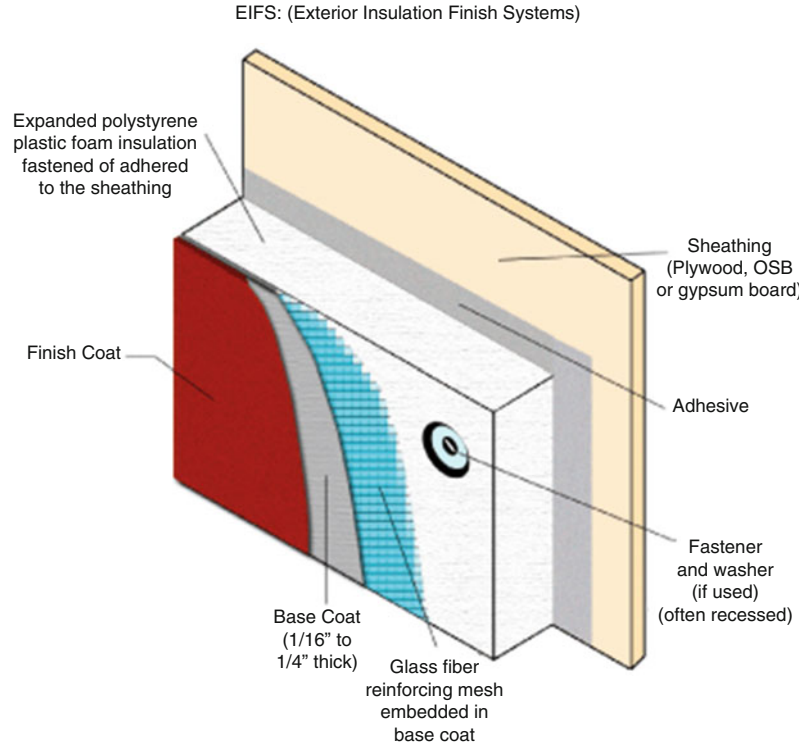

Fig. 86.22 Cutaway view showing typical EIFS assembly components (Courtesy of Pro Stucco http://pro-stucco.com/images/efis-instalation.gif.png)

as well as difficulties associated with fighting fires involving these products in high-rise buildings. These fires include the Borgata Water Club fire in Atlantic City [24] and the Monte Carlo Hotel fire in Las Vegas [25].

In 2007 the Atlantic City Fire Department responded to a fire at the 41 story Water Club Tower finding MCM panels composed of 3 mm aluminum sheets bonded to a 6 mm polyethylene core in flames. The back sides of the panels were covered with 18 mm polystyrene insulation.

The panels were used as a decorative finish on a structural frame set approximately 2 m distant from a concrete sheer wall that prevented major fire extension into the building. This fire resulted in large pieces of aluminum flying off of the MCM support structure and upward flame spread from the third to 38th floor (Fig. 86.23). Fire department personnel indicated that the fire was of relatively short duration having subsided 10–15 min after fire service crews began their engagement at the building [24].

This installation of the MCM panels was not a standard installation where the panels would be mounted closely against an exterior wall assembly. In this case, the panels were simply attached to a structural frame open on all sides to the exterior environment. The Water Club Tower fire is an example of building designers using MCM panels and polystyrene insulation in a creative, but nonstandard way that did not fully consider the fire risk implications.

In the case of the 32-story Monte Carlo Hotel & Casino in Las Vegas, Nevada, exterior wall cladding features were the fuel source for a fire reportedly started by work activities on the roof. The exterior cladding consisted of an EIFS used to clad flat areas of the building from the 29th to 32nd floor.

EIFS assemblies generally consist of a layer of 50–100 mm thickness of expanded polystyrene (EPS) foam insulation adhered to or mechanically fastened over a substrate such as gypsum sheeting. A multi-layer covering or lamina is then provided over the EPS consisting of a polymer/cement adhesive, fiberglass mesh and a final outer coating of a colorized weather-resistant, polymer/cement mixture.

Fig. 86.23 Fire at the water club tower (Courtesy of J. Foley, Atlantic City Fire Department)

Non-EIFS material was also installed to add decorative cornices between the 28th and 29th levels and at the top of the 32nd floor. Although EIFS was involved in the fire, the investigation report [25] cites the decorative elements consisting of expanded polystyrene (EPS) with a polyurethane resin as the primary reason for fire progression. Also, although the EIFS was found to have a non-compliant thickness of lamina, it was observed to burn only in the area of fire exposure [25]. In summary, the decorative EPS features lacked an EIFS covering and were formed into components of relatively large thickness (200–900 mm) which provided the primary fuel for this fire incident, while the EIFS contribution to this incident was limited.

The Water Club Tower and the Monte Carlo Hotel & Casino are two U.S. examples that illustrate the negative consequences of using combustible materials as part of the exterior wall cladding or decorative exterior features. Others [26, 27] cite other international incidents of fires and fire spread where EIFS, insulated sandwich panels, FRP and MCM panels have been involved.

Combustible Components in the Wall Cavity

From a fire perspective, there are a wide variety of combustible components that contribute to the thermal insulating performance and weather resistive performance of exterior walls and enclosure systems. Insulation in walls may be noncombustible material such as fiberglass or mineral wool, but often combustible foam plastic materials with high insulating capabilities; such as extruded polystyrene, expanded polystyrene, spray foam polyurethane insulation and polyisocyanurate insulation; are common insulation choices.

Also, to control air, water and vapor penetration from the exterior to interior spaces, various types of thin membrane or sheet materials of combustible nature are used. Air barriers are used to resist airflow, water-resistive barriers (WRBs) provide resistance to bulk-water penetration and vapor barriers serve to retard or resist moisture vapor diffusion.

Modern day energy codes are driving the design and multi-layered configuration of

exterior wall systems with significant emphasis on achieving a layer of continuous insulation and WRBs. The relative location of these insulating and weather barrier materials in three example steel framed wall configurations is shown in Fig. 86.24. This Figure shows the main types of steel framed wall construction (similar design options and compliance criteria apply to wood stud construction) and their compliance with prescriptive U.S. energy code requirements [28]. Spinu explains the three designs as follows:

Traditional Wall Design (with insulation inside the stud cavity) will no longer meet the prescriptive energy code criteria in most or all climate zones because of continuous insulation requirements.

Hybrid Wall Design (or split insulation design, with insulation within the stud cavity and exterior continuous insulation) is becoming the most common design for framed wall construction which meets energy code requirements.

Exterior Insulated Wall Design (or EXULTATION) with entire insulation placed outside the framed structure, is unlikely to meet the prescriptive code requirements with current insulation materials, especially in cold climates.

As the demand for improved energy performance of building envelopes has increased, new technologies such as continuous insulation shown in Fig. 86.24 have been developed to meet this demand. But it is important that improvements in energy efficiency are achieved without undue compromise of fire safety.

It has been common for architects and building constructors to select individual components of insulation, WRBs, air barriers, brick, masonry, panels and combine then to create an insulated and water resistant wall system. The combination of these materials in to a wall system may not have considered the fire performance of the composite assembly.

One prominent example of was the fire at the 44-story Mandarin Oriental Hotel in 2009. This fire was the result of an illegal fireworks display that ignited building materials at the top of the structure, which then spread downward through the air cavity between the exterior metal cladding and the building insulation and weather resistant barrier layers.

This fire was remarkable in that it demonstrated on a large scale the potential for a downward conflagration along the skin of a high-rise building. Such rapid downward fire spread has not been noted on such a scale in recent

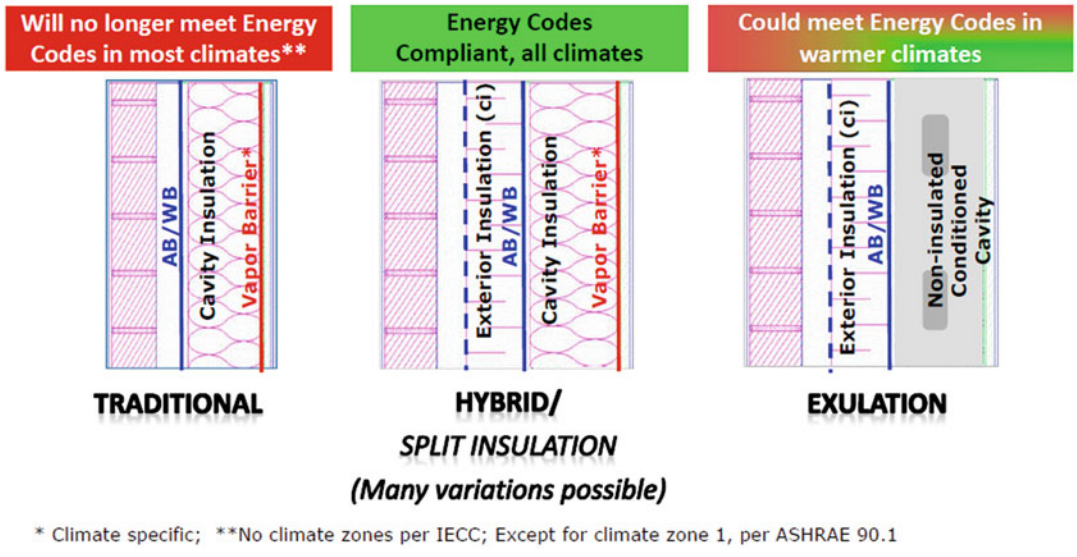

Fig. 86.24 Wall sections showing locations of insulating layers and weather resistant membranes [28]

times. Most all large scale high rise fire spread incidents have occurred in the upward direction (Figs. 86.25 and 86.26).

Fire Performance Tests for Exterior Cladding

The need to quantify the performance of combustible claddings and exterior walls using combustible components (insulation, WRBs, etc.) has been recognized for decades. Various full scale and intermediate scale tests have been developed. Reviews and summaries of these various test methods listed in below can be found in the literature [26, 27, 29]:

- NRC Canadian Full Scale Façade Test (CAN/ULC 5-134)
- Modified ASTM E108 Test Method
- UBC 26-9 or NFPA 285—Intermediate-Scale Multi-story Apparatus
- British Standard Cladding System Test
- ISO/DIS Intermediate Scale Façade Tests (ISO 13785-1)
- ISO/DIS Full Scale Façade Tests (ISO 13785-2)
- ISO/DIS Intermediate Scale Sandwich Panel Tests (ISO 13784-1)
- ISO/DIS Full Scale Sandwich Panel Tests (ISO 13784-2)
- Factory Mutual 25-ft and 50-ft Corner Tests
- Loss Prevention Council Test Method (LPS 1181)
- Swedish Full Scale Façade Test (SP105)
- Vertical Channel Test Apparatus

An important aspect of these tests is the variation in heat flux exposure scenarios. Figure 86.27 [29] shows a comparison of total heat flux profiles for seven test methods. The variation among the test methods is significant.

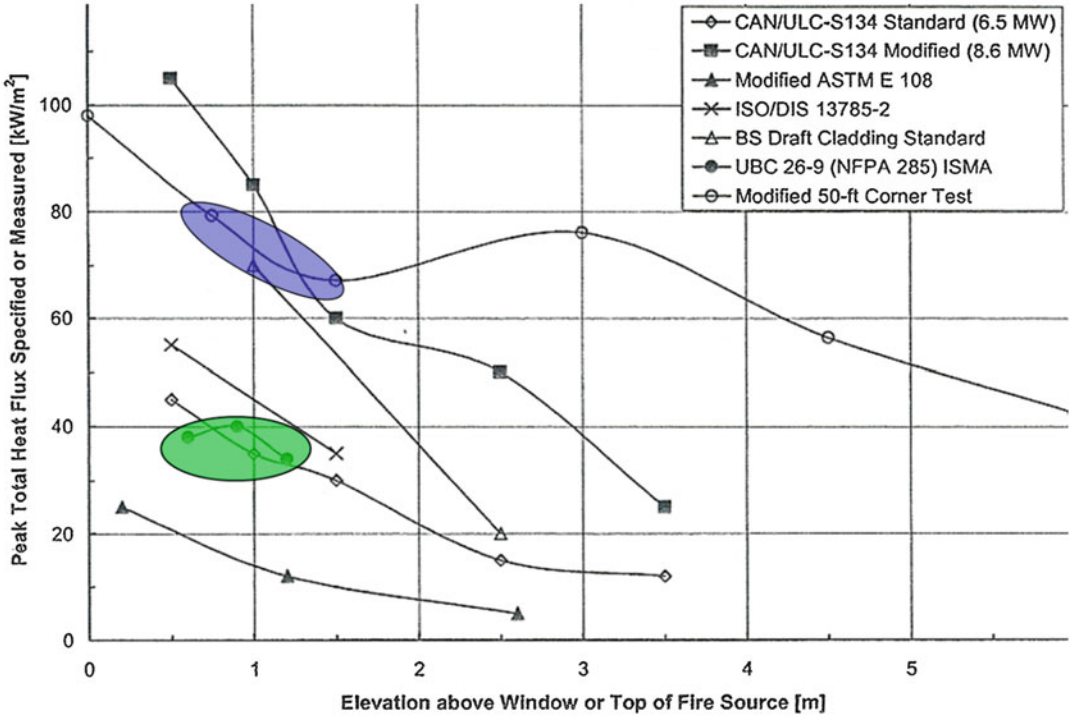

Fig. 86.27 Comparison of heat flux exposures. Colored/shaded areas compare UBC 26-9/NFPA 285 versus the modified 50-ft corner test [29]

The reasons for variation are attributable to the nature of the type of exposure used in the tests, the performance metrics being judged by each test method and the heat flux imposed by the assumed fire source. For example, the modified 50-ft (15 m) Corner Test protocol (Fig. 86.27) may be most relevant for combustible cladding materials subject to an exterior fire source juxtaposed to two walls forming a 90° angle. However, for exposure flames from interior fires onto a flat wall cladding, the UBC 26-9/NFPA 285 test may be appropriate. UBC 26-9/NFPA 285 assumes flames project out a window from an interior post-flashover fire, while the modified 50-ft Corner Test addresses an exterior combustible fuel package set near (0.15 m) a 90° corner façade geometry and the associated re-radiation effects. These two scenarios pose significantly different heat flux exposures on the exterior cladding or exterior walls having combustible components.

Glass and Glass Performance

Glass in a window or curtain wall system can present a route for flames to spread should the glass break and fall from its containment or framing system. Today's windows and curtain wall systems use a wide variety of glass types and framing methods (vinyl, wood, aluminum). Glass can be of a variety of colors, opacity, area, varying sheet thickness and with or without multilayer construction (e.g. single, double, or triple glazed). Glass panels may be annealed or float glass, heat strengthened, tempered/toughened, reflective, laminated, or wired as further described in Table 86.3. The complexity of glass installations from building to building can vary significantly and the current state-of-the art available to predict glass breakage is limited with high degrees of uncertainty given the possible

Table 86.3 Basic glass types and characteristics [30]

Annealed/float glass	Manufacturing process: glass is cooled gradually from a high temperature to minimize residual stress
	Characteristics: can be cut by scoring and snapping. Weakest type of glass; when forced to break tends to form sharp edged pointed shards. Differential Temperatures of 33 °C in the sheet of glass will cause thermal shock stresses and cracking
Tempered/toughened glass	Manufacturing process: glass is heat treated to a uniform temperature of approximately 650 °C and rapidly cooled to induce compressive stresses on the surfaces and edges
	Characteristics: extremely strong glass, but if subject to deep scratch or impact the glass will break into small relatively blunt glass fragments. Used in safety glazing applications
Heat strengthened glass	Manufacturing process: a type of tempered glass strengthened thermally by inducing surface compression that is twice that of annealed glass through only half that of fully tempered glass
	Characteristics: retains the normal properties of annealed glass but provides resistance to thermal stress associated with high performance glazing (tinted, reflective glass). Suitable for spandrel and vision panels and for laminated glass panels for safety
Reflective glass	Manufacturing process: metallic coating is applied to one side of the glass to increase significantly the amount of reflection by both visible and infra-red (heat and light) radiation
	Characteristics: mirror like appearance, reduces heat gain and glare from exterior yet allows optimum visible light transmission
Laminated glass	Manufacturing process: uses normal or tempered glass in two or more layers with one or more layers of a transparent/pigmented specially treated plastic Polyvinyl Butyral (PVB) sandwiched between the glass layers
	Characteristics: if glass is broken, it does not shatter like normal glass, but rather absorbs impact, resisting penetration with broken fragments tending to adhere to the PVB interlayer

configurations and variations in window and curtain wall construction.

Additionally, the age of the installation and associated seals/edge supports as well as environmental stress factors such as temperature and wind loads can impact the performance at the time of a fire exposure. Several reviews of glass breakage research due to fires and heat exposure [31, 32] provide data that is largely limited to single-glazed assemblies. Table 86.4 presents the data of several studies reviewed by Heron et al.; however, the authors' summary comment regarding glass breakage data is that "A number of studies have been conducted on the breakage of glazing under heat stress but no conclusive results have been recorded".

Table 86.4 Summary of glass breakage studies [32]

Glass type	Temperature/ heat flux	Condition
Toughened	43 kW/m^2	Falls out
3 mm float	4–5 kW/m^2	Cracks
3 mm float	16 kW/m^2	Doesn't fall out
Normal float	150–200 °C	Cracks
6 mm toughened	300 °C	Falls out
Plain	150–175 °C	Breaks
6 mm plain	110 °C or 3 kW/m^2	Cracks
6 mm plain	35 kW/m^2	Falls out
3 mm plain	9 kW/m^2	8–24 % falls out
6 mm plate	23 kW/m^2	Breaks and falls out

Small scale tests have shown that plain float glass exposed to radiation at 10 kW/m^2 and 40 kW/m^2 in glass broke at temperatures of 150–175 °C within 8 min and 1 min respectively. In these same tests, heat strengthened and tempered glass survived 43 kW/m^2 for 20 min without breaking while reaching temperatures of 350 °C. Additional small scale tests [33] showed that single glazed windows failed in the range of 40–50 kW/m^2, noting that 33 kW/m^2 appeared to be a level below which failure did not occur.

Of course, fire spread via windows or glass curtain walls is dependent on the potential for the ignition of materials on the unexposed side of a glazed surface. It is known that glass is effectively opaque in the infra-red wavelengths associated with natural fires, and as a result

the heat flux transmission is typically reduced by approximately 50 % for single glazed systems.

For double glazed windows, the radiation transmitted through the first pane is transmitted only in a spectrum where the second pane shows no heat absorption [31]. It is important to know what quantity of radiation will be transmitted through a glass layer to combustible materials on the unexposed side, given that 10–40 kW/m^2 can ignite materials in the range of lightweight fabric materials to common cellulosics [34]. Again, the results of small scale tests have shown that a double glazed assembly will absorb approximately 90 % of the thermal flux and is capable of reducing heat flux from 100 to 8 kW/m^2 (unsprinklered conditions.) This is significant only if the glass does not break and maintains its integrity as a solid barrier. Another study [57] indicated that double glazed systems exposed to heat fluxes as high as 25–170 kW/m^2 provided better integrity than single glazed systems. Tests using fire resistant glass products [35], known as SAFTI Superlite II XL and Superlite I, showed that single pane glass would fall from the frame at temperatures of 400–500 °C with nearby heat fluxes measured at 50–70 kW/m^2.

Fire Behavior at Exterior Wall Openings

Exterior building detailing or articulations incorporated as elements of the façade or, which perhaps, are due to the structural floor plate changes, can impact the flame projection and associated heat exposure to the façade. Work done at the National Research Council of Canada [36, 37] showed the extent to which a horizontal projection located above flames issuing from a window can be effective at reducing the flame exposure. This work also showed that vertical exterior elements could have a negative impact by increasing the vertical projection of flames along a façade. Figure 86.28 illustrates the change in fire flame position and extension due to a horizontal projection above a window and vertical panels located at each side of a window.

In terms of hazard reduction or increase, Fig. 86.29 illustrates how the deflection of the flame by a horizontal projection reduces the heat transferred to the wall above the burning compartment. Conversely, the vertical projections increase the heat transfer to the wall. The increase in heat flux with vertical projections installed is due to the restriction of lateral air entrainment, which forces a lengthening of the gas plume as it seeks to entrain more air for combustion.

Oleszkiewicz conducted propane fueled experiments in a three-story high facility using a window of 2.6 m width and 1.37 m high and fires on the order of 6 MW. Horizontal projections of 0.3, 0.6 and 1.0 m were compared to the case of flames issued from the window along a vertical wall with no projections. Heat flux (connective + radiative) measurements taken at 1, 2, and 3 m above the top of the window showed a significant decrease in heat flux with horizontal flame deflectors in place.

For example, at the 1 m height above the window opening, heat flux ranged from approximately 50 to 100 kW/m^2. However, as indicated in Fig. 86.30, at the 1 m height, total heat flux was reduced by approximately 55 %, 60 % and 85 % respectively for projections of 0.3, 0.6 and 1.0 m. These reductions show the relative effectiveness of a horizontal projection. By comparison, Oleszkiewicz noted that a vertical spandrel wall was not found to be a practical means of protection against flames issuing from an opening. Achieving a 50 % decrease in heat flux exposure via a vertical spandrel panel in this same test would require a 2.5 m high spandrel. It is noted that the same performance in heat flux reduction was achieved with the 0.3 m horizontal projection at 1 m above the opening.

Based on Oleszkiewicz's data, Bong has observed trends and variations of total heat flux density in relation to compartment heat release rates and window parameters [26]. Bong notes the variation of heat flux with height above the window for a 2.6 m wide by 2 m high window at

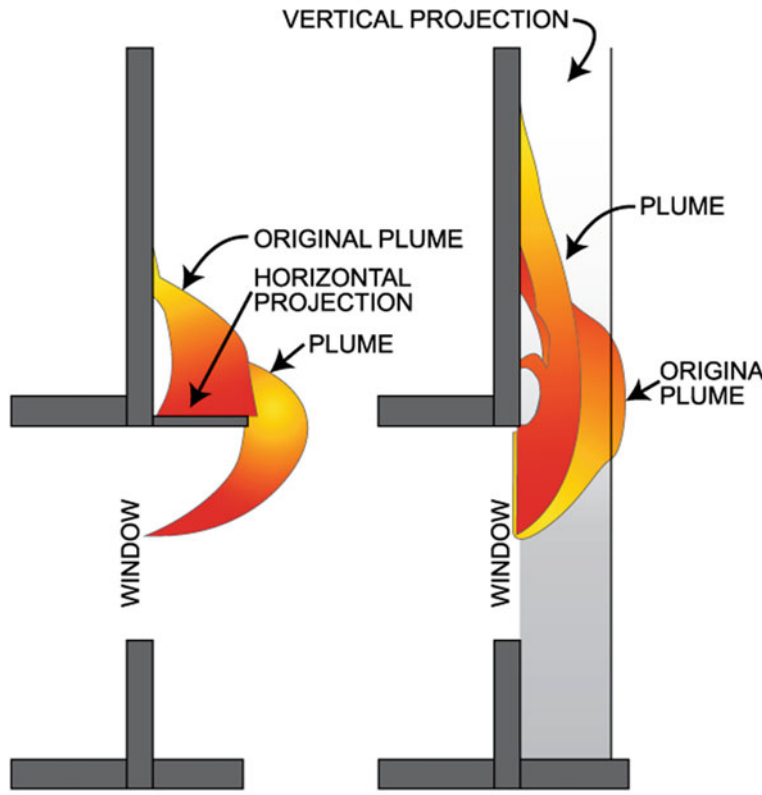

Fig. 86.28 Impact of horizontal and vertical projections on window plume (Based on Oleszkiewicz [36])

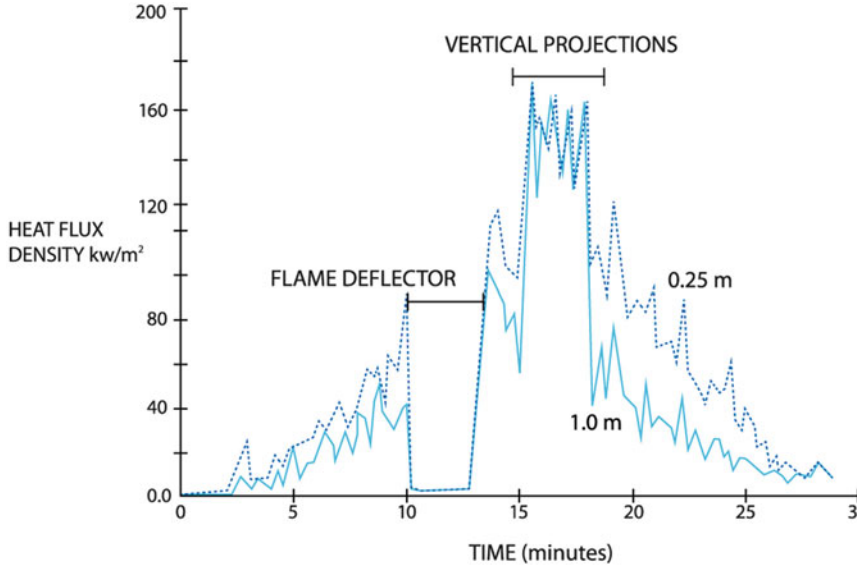

Fig. 86.29 Decrease and increase of heat transfer for horizontal and vertical projections on window plume [9] (Based on Oleszkiewicz [36])

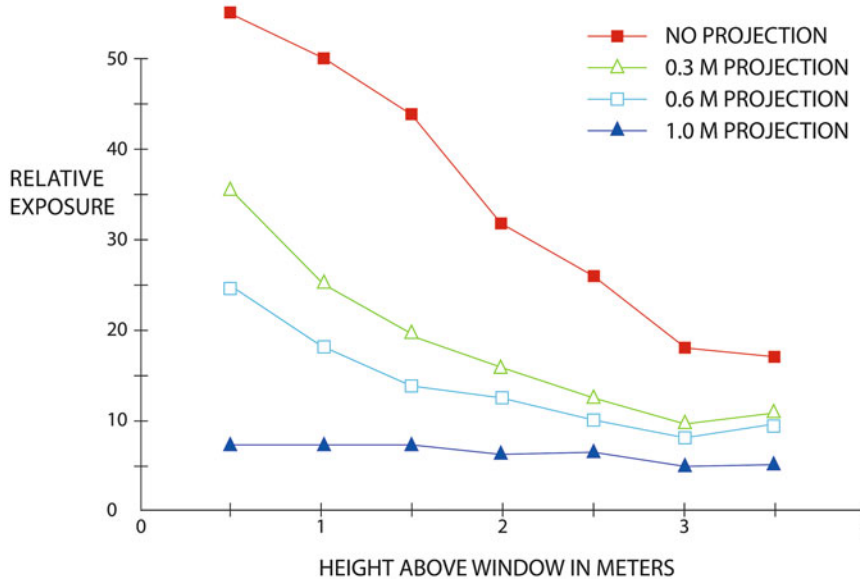

Fig. 86.30 Heat transfer comparison of exposures for 0.3, 0.6 and 1.0 m horizontal flame deflectors. The data is normalized to readings taken at 1 m above the opening with no horizontal deflector (Based on Oleszkiewicz [37])

various compartment heat release rates achieved with a propane gas burner. The total heat flux density (radiation + convection) received from the windows varies with the heat release rate and the position along the height of the wall above the window as indicated by Fig. 86.31. The heat flux measurement increases with increasing compartment heat release rates, yet decreases as the height above the window increases.

With respect to window dimensions, the relationship of heat release rate verses heat flux measured at 0.5 m above the top of the window is indicated in Fig. 86.32. The heat flux increases with increasing compartment heat release rate and decreasing window size. The smallest window (Window 1) has shown a higher heat flux on the exterior wall compared to most other windows (Window 3 is the exception). Total heat flux drops from 43.9 to 6.5 kW/m^2 at 0.5 m above the window with an window area increase from 1.88 m^2 (Window 1) to 7.02 m^2 (Window 5).

The imposed heat flux is shown to increase more rapidly with decreasing window area than increasing compartment heat release rate. This is attributed to the increasing portion of fuel burning outside the fire compartment when the compartment burning regime is ventilation controlled.

Building Codes have often recognized the benefit of providing a horizontal projection or a fire resistive spandrel panel to limit floor-to-floor fire spread, particularly in the case of nonsprinklered buildings [38]. However, such requirements in buildings codes do not preclude the potential for floor-to-floor fire spread along the exterior wall.

The findings of various researchers [27] as found in Table 86.5 point to the limited benefits of horizontal projections and spandrels. In several cases, researchers note the impossibility of preventing floor to floor fire spread (from fully developed fires) via the exterior except by omitting all windows or vents through which flames could project. To impose such restrictions for the purpose of preventing exterior flame spread via windows and openings would radically change the character of buildings and be contrary to current sustainability objectives (e.g. ventilation, natural lighting) in building design.

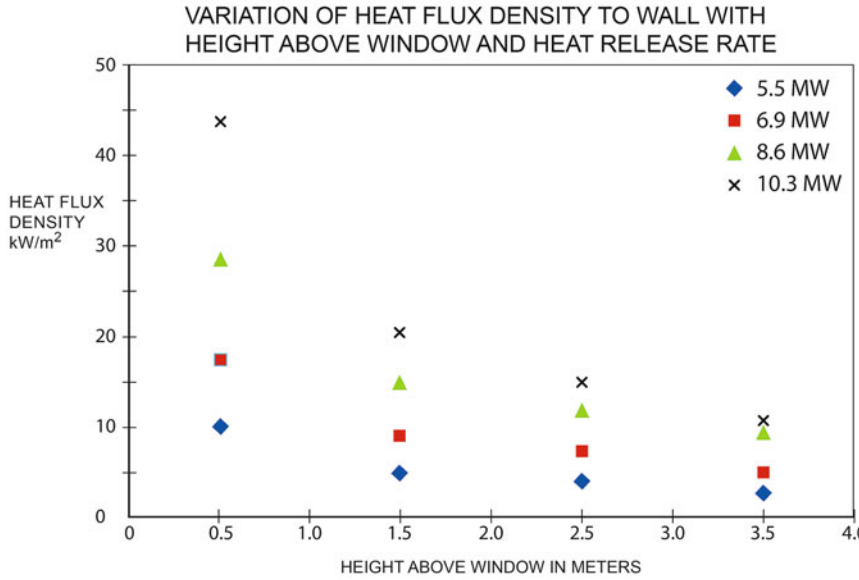

Fig. 86.31 For a Window of 2.6 m width and 2 m height the graph shows total heat flux density varying with compartment HRR and height above the window (Based on Bong [26])

Fig. 86.32 For windows of varying size the graph shows total heat flux density measured 0.5 m above the windows varying with compartment HRR (Based on Bong [26])

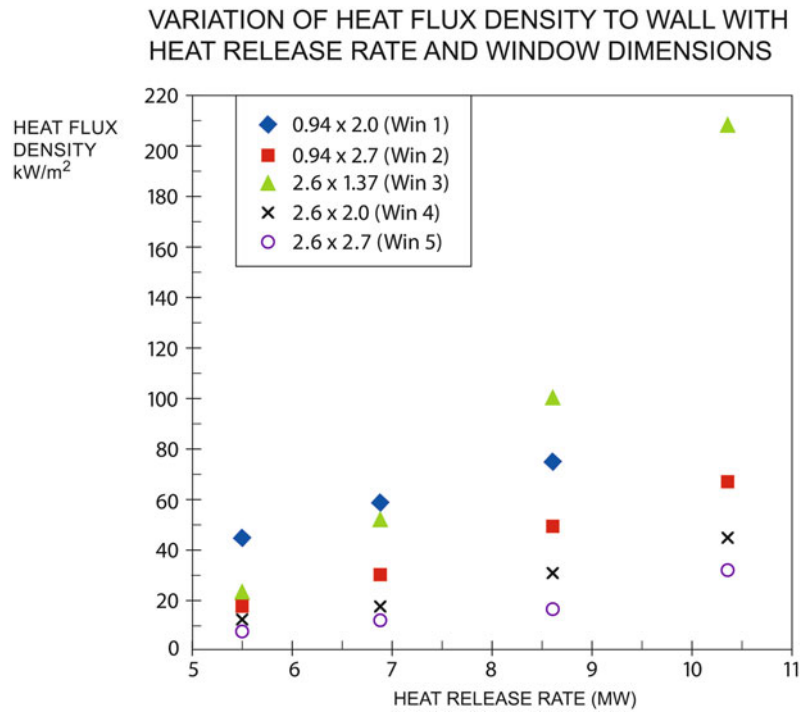

Table 86.5 Summary of research/viewpoints regarding apron (horizontal projection) and spandrels as method to prevent vertical fire spread [27]

Yokoi [5] Full scale experimental fires	0.74 m deep horizontal projection protected panes of ordinary glass from breaking despite the fact that the panes were install only 0.3 m above the top of the opening
[39] Large scale experiments of fire spread using a 4-story building	Vertical separation of 900 mm or a horizontal separation of 600 mm was inadequate to prevent entry of external flame from a fire in a lower story; the research did not determine what separation would be needed
Langdon-Thomas and Law [40]	To provide adequate protection, it would be necessary virtually to omit all windows from the story immediately above the one with window openings in it
NRCC [41]	A spandrel wall was found not be to a practical means of protection against flames issuing from an opening. In order to achieve a 50 % decrease in exposure to the wall above the opening, a 2.5 m high spandrel would be required
Moulen [42] Used one-tenth scale models to investigate various combinations of vertical and horizontal separating construction between story	Concluded that spandrel wall construction above and below the floor slab could not necessarily be considered to have equal effect. He also found that a horizontal projection of 650 mm would allow flames to curl back onto the face of the building when there was no vertical wall construction directly below the floor slab. However, a 900 mm vertical separation below the floor slab in combination with a 650 mm horizontal projection was sufficient to cause flames to be projected away from the façade
National Research Council of Canada [36, 43]	Significant drop in heat transfer from a window fire plume to a building façade above it when a horizontal panel was deployed immediately above the window opening
Oleszkiewicz [37] Using a three-story high burn facility with a window opening of 2.6 m wide by 1.37 m high and with compartment fire sizes of 5.75 MW and 6.9 MW, showed horizontal projections installed above the window offered substantial protection as follows.	A 300 mm horizontal projection reduced the exposure (at 1 m distance above the opening) by approximately 50 % A 600 mm horizontal projection reduced the exposure (at 1 m distance above the opening) by approximately 60 % A 1000 mm horizontal projection reduced the exposure (at 1 m distance above the opening) by approximately 85 %

Loss History: Vertical Fire Spread at the Exterior Façade

The threat of floor-to-floor fire spread at the exterior façade of any building is confirmed via actual unsprinklered high-rise building fires. A number of incidents have been identified in the literature [20, 44–50]). The extent of fire spread in ten well known incidents has been reviewed in order to report some key observations of past incidents which are graphically represented in Fig. 86.33.

John Hancock Center, Chicago, Illinois, USA, 100 Stories [47] In 1972, this fire started on the 96th story in an unsprinklered two-level cocktail lounge, and caused damage to the 95th through 97th stories. The fire burned for about an hour and 20 min. The floors throughout were of poured concrete; outer skin was of glass set in aluminum mullions with a 6 mm-thick aluminum skin over the steel beams and columns on the exterior of the building.

Plate glass windows that were 12 mm thick in aluminum mullions extended from the floor to the ceiling. At the firefighters' arrival, the fire had broken windows on the 96th floor, and burning fire gases were pushing out of the openings. Because the sides of the building tapered toward the top and because there was very little wind

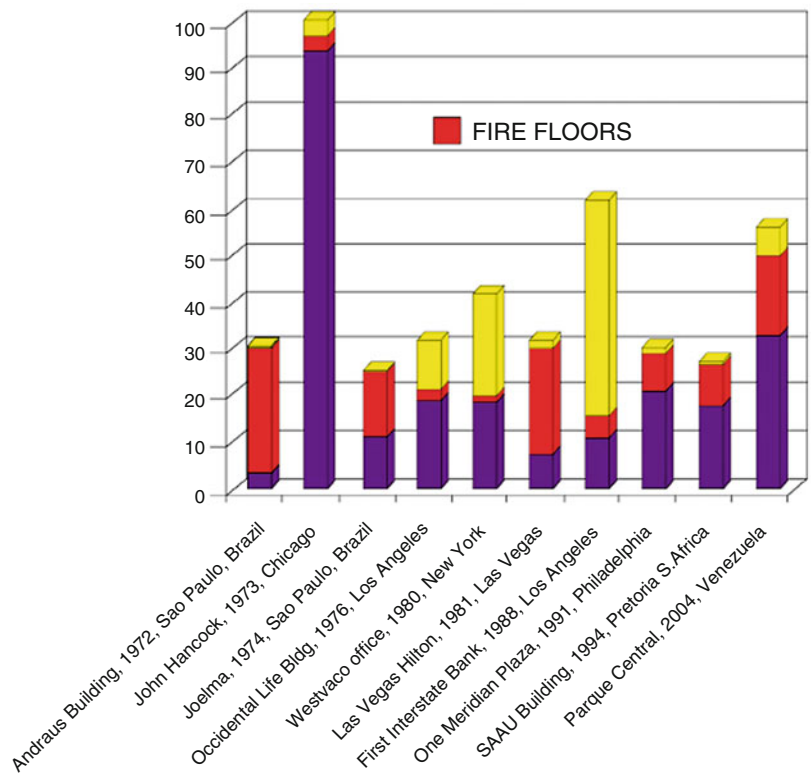

Fig. 86.33 Fire involved floors of ten past high-rise fire incidents (O'Connor [9])

that morning, breaking glass slid down the side of the building instead of falling freely. Windows along approximately 60 ft of the 96th story were cracked or broken, some exterior aluminum skin near them melted, as did some of the mullions.

Fire entered the 97th story through the window, but was confined to some combustibles on a test bench. Very little combustible material in the 97th story was a major reason the damage from this fire was not much greater. Investigators noted that had there been a different occupancy on the 97th floor, with more combustible materials near the windows, a serious fire probably would have developed.

Andraus Building, Sao Paulo, Brazil, 31 Stories [51] This building was a department store occupying the basement and seven stories above grade. The 8th–31st floors were office use. In 1972 this fire occurred on the fourth floor of the department store. The fire developed on the 4 floors of the department store and then spread externally up the side of the building, involving another 24 floors.

The fire gutted most areas of the building. A total of 16 fatalities resulted. The building façade had extensive floor-to-ceiling areas of 6 mm plate glass set in steel frames supported on a 360 mm high concrete spandrel that was integral with the concrete floor slab. Every other section of windows was operable.

From the fourth and fifth floors, the fire spread up the open stairs to involve the sixth and seventh floors. As heat broke window glass, flames broke out the north side on all four floors, forming a flame front that exposed three or four floors above the department store. The heat from exposing flames ignited combustible ceiling tiles and wood partitions on each floor.

The estimated time for full involvement of the façade after flame had emerged from the department store floors was 15 min. Approximately 300 people fled to the roof top heliport and

were eventually rescued by helicopters. Fire department response involved 28 pumpers, numerous tank trucks, and 4 aerial ladders.

Occidental Center Tower, Los Angeles, CA, USA, 32 Stories [46] In 1976 this fire was of incendiary origin on the 20th floor of a non-sprinklered building. A flammable liquid was used, and the fire was large from the very beginning.

The exterior curtain wall consisted of glazed terrazzo tile extending 1.3 m below the floor line, and 0.83 m above it. The window openings were approximately 1.8 m high. The windows were of tempered glass. Both horizontal and vertical aluminum sun screens were attached to the exterior of the building.

Fire damaged approximately 60 % of the floor of fire origin, and then spread externally to the 21st floor, destroying approximately 10 % of that floor. Broken glass falling from the building was reported to have hit the ground at distances up to 20 m from the building. The fire was knocked down approximately 1 h and 30 min after the initial alarm. A total firefighting force of approximately 300 men were utilized in suppressing the fire.

The Las Vegas Hilton, Las Vegas, NV, USA, 30 Stories [45] In 1981, this fire occurred on the eighth floor in the vicinity of the east tower elevator lobby. Fire spread from the 8th floor to the 30th floor vertically. The fire caused 8 fatalities and approximately 350 injuries.

On the exterior wall of the elevator lobbies, three 0.9 m-by 1.8 m windows of double-strength plate glass created a large glass area 1.8 m by 2.7 m set on the concrete slab. The glass was recessed 450 mm and was separated vertically by a 1 m spandrel. The spandrel was prefabricated assembly of masonry, plaster, and gypsum wallboard on steel studs, with no apparent evidence of combustible material.

The fire progressed vertically up the exterior of the building, floor by floor. After the eighth floor become involved, it is estimated that the vertical exterior spread took 20–25 min to reach the top of the 30-story building. Occupants evacuated the building by way of the stairway, were trapped in their rooms by the fire, or waited out the fire in their rooms. Many people encountered smoke in the stairway, especially in the east tower east interior stairway. Some people in the stairway were able to get to the roof and were rescued by helicopters. A total of 23 engines, 6 ladders, 2 snorkels, 9 rescue units, 2 air cascade units, and 12 helicopters were utilized during the firefighting and rescue operations.

First Interstate Bank Building, Los Angeles, CA, USA, 62-Story Office Building [52] In 1988, this fire started on an office floor, and by the time the fire department arrived, a significant portion of the floor was involved. Fire extended to four floors before being contained after 3–0.5 h.

The building was being retrofitted with sprinklers, but the system was not operational at the time of the fire. A 76 mm void between the floor slab and the exterior aluminum and glass curtain wall was filled with thermal insulating material extending approximately 450 mm above and below the floor slab. Gypsum board enclosed the safing material above the floor slab. The insulation below the floor deck was open to a ceiling return air plenum.

About 40 persons were in the building at the time of the fire. The fire department rescued two from the 37th floor and one from the 50th. The fire department with 64 fire companies and 383 fire fighters made a stand on the not-yet-involved 16th floor and was able to stop further spread.

One Meridian Plaza, Philadelphia, PA, USA, 30 Stories [53] In 1991, this fire started on the 22nd floor in a vacant office in a pile of linseed-soaked rags. It burned for more than 19 h, completely consuming eight floors. There were 3 firefighter fatalities, and 24 were injured.

The exterior of the building was covered by granite curtain wall panels with glass windows attached to the perimeter floor girders and spandrels. Exterior vertical fire spread occurred as a result of exterior window breakage, and this was the primary means of fire spread. There were no sprinklers in the building up to the 30th floor,

where ten sprinklers supplied by fire department pumpers stopped fire spread. Only building staff were in the building at the time of the fire. Fire attack was hampered by heavy smoke, complete failure of the building's electrical system, and inadequate water pressure. Firefighting was abandoned after 11 h due to risk of structural collapse.

Parque Central, East Tower, Caracas, Venezuela, 56-Story Office Building In 2004, this fire started on the 34th floor and eventually extended to the top of the 56-story building. There were no functioning sprinkler systems. Pumps and standpipe systems were not in service.

Photographs show evidence of fire spread along the exterior façade. The building was unoccupied, but 3 employees and up to about 25 firefighters were injured. Firefighters backed by helicopters and troops battled the blaze for 12 h before abandoning the effort due to fear of structural collapse.

Several observations are apparent upon review of the ten reviewed incidents, which point to fire risk assessment considerations.

1. Large fire department personnel and apparatus response was observed in eight of the ten incidents. In two cases, One Merdian Plaza and Parque Central, the fire departments abandoned their efforts due to fears of structural collapse.
2. In several incidents, occupants fled to the roof of the building to be rescued by helicopters. In contrast, many of today's super high-rise buildings will not have an accessible roof to facilitate occupant rescue operations. The fact that many tall buildings may not have an accessible roof should not be cause for requiring such. Roof top operations pose significant challenges and hazards.
3. Fire spread was attributable to broken windows and flame extension along the exterior façades. The number of floors involved was as few as two stories in a 32 story building, but ranged up to as many as 23 stories in three of the ten incidents reviewed.
4. The value of sprinklers was observed in the One Meridian Plaza incident where ten sprinklers supplied by fire department pumpers stopped fire spread. It is reported [53] that the sprinklers activated as a result of heat transmission via broken windows and through the void space that existed between the floor slab and exterior granite façade, as well as heat conduction through the floor slab. As combustibles ignited at multiple locations, the sprinklers operated and extinguished the fires.

Risk Assessment Factors

Several factors to consider in a risk assessment of upward fire spread at the building façade include, but may not be limited to, the following:

- Automatic sprinkler systems' reliability
- Fire department/brigade response capabilities
- Building height
- Building occupancy considerations—e.g., office, residential, hospitals, mercantile
- Building compartmentation features
- Building evacuation strategies
- Fire hazard—fuel loads, continuity of combustibles, compartment sizes
- Security threat assessment scenarios

Sprinklered high-rise buildings have a very successful record of life safety and property protection performance. For this reason, the IBC and NFPA 5000 do not require fire resistance rated spandrels or flame deflectors at the building façade in fully sprinklered buildings. Significant reliance on sprinkler systems becomes exceedingly more critical for super high-rises. As the height of buildings increase, so does the complexity of sprinkler systems with an integrated network of piping zones, valves, pumps, power supplies, and water supply tanks. Many components are required to be operational and operated properly for the sprinkler system's success.

Sprinkler system maintenance can be a major maintenance activity for today's super high-rise buildings and is key to successful performance. A recent analysis [54] of data from the National Fire Incident Reporting System (U.S. data) indicates that for all building types, sprinklers failed to operate in 7 % of structure fires. The identified reasons for these failures were 65 % of the systems

were shut off, 16 % were defeated by manual intervention, 11 % were due to lack of maintenance, 5 % of the systems were the wrong type, and 3 % were due to damaged system components. These failure rates may or may not be applicable to new super high-rise buildings, but it is important to note that human error is the primary factor. Consequently, it is important for buildings with complex sprinkler system design to have features and redundancies that can overt issues of human error and maximize sprinkler system reliability.

Sprinkler system designs can be enhanced to improve their reliability. Gravity feed systems that do not rely solely on electric pumps and emergency power supplies can assure that pressure is available to supply sprinklers. Also, piping schemes that use riser cross connections or feeds from alternate floors can provide additional assurances that a single closed valve does not negate sprinkler water flow. Electrical supervision of valves and other sprinkler components has long been recognized to be a most important feature to monitor sprinkler operational status. The value of sprinklers was observed in the One Meridian Plaza incident where ten sprinklers supplied by fire department pumpers are reported to have stopped fire spread after burning for 19 h. If buildings' sprinkler systems can be designed so that successive floors cannot be turned off with a single valve, then a significant level of redundancy to protect against vertical exterior fire spread can be maintained.

Fire department response capabilities should be factored into the vertical exterior fire spread analysis for super high-rise buildings. Prior incidents in unsprinklered buildings demonstrate the difficulty that large, capable fire departments may have for buildings 60 stories or less in height. Many of the new class of high-rise buildings will double or triple this height. An important question in this regard is, "Does the local fire department have the response capabilities and response plan to handle an unsprinklered fire in a super high-rise building?" If the answer is "no," then, again, great reliance is shifted to the automatic sprinkler system.

Several basic building features and occupancy considerations that may impact the assessment of vertical exterior fire spread risk are:

- Assembly occupancies—have large and potentially dense populations of occupants. Often these occupancies are found at the very top levels of super high-rise buildings.
- High-rise residential—have sleeping occupants in buildings that generally have a high degree of fire resistive construction and floor-to-floor compartmentation (except for the façade). The defend-in-place concept has been used in apartment buildings of fire-resistive construction, where it can be safer to remain in the apartment than to attempt evacuation. If the defend-in-place concept is to be viable for the wide variety of possible fire scenarios, then the vertical exterior fire spread issue needs to be addressed. Human behavior has been, on several occasions, cited as playing a major role in the fatalities and injuries in high-rise residential buildings [55, 56]. Both authors' works have seriously questioned the appropriateness of evacuation of high-rise residential buildings, including hotels. Frequently, occupants who stayed in their apartments or hotel rooms were safe and uninjured, while those who evacuated became casualties. In an unsprinklered super high-rise fire scenario, maintaining safe floor areas (safe from vertical exterior fire spread) for residential occupancies could be a critical need.
- Hospital facilities—these are facilities in which occupants can be expected to require assistance from staff and are physically not capable of relocating down stairs or to the building exterior. This may be the most critical situation that deserves consideration of the vertical exterior fire spread risk. Horizontal exits, where a floor is subdivided into two fire areas, are often used in hospital facilities and can be a mitigating factor in the risk assessment for hospitals or other occupancy groups.
- Super tall buildings—buildings with large occupant loads and long total evacuation times (e.g., >1 h). In an unsprinklered, super high-rise fire scenario, fire spread by vertical means, whether exterior or interior, may unnecessarily subject large numbers occupants to adverse conditions from a single fire event.

The relative fire hazard of various occupancies can present varying levels of concern in assessment of vertical exterior fire spread risk. Residential occupancies are generally well compartmented units. In the event of a sprinkler failure and fire spread to a residential unit on the floor above, it should be recognized that the fire would not propagate readily due to the fire-resistive enclosure walls of apartment units. This generally assumes vertical stacking of units. Conversely, in retail or office occupancy, there is far less subdivision to provide passive fire containment, increasing the risk of fire spread.

Security threat assessment scenarios should consider the impact of any damage scenarios on the performance of the buildings fire protection features and, specifically, the sprinkler systems. The survivability of sprinkler system features and water supplies may be critical to prevent a major fire spread event that results from a security threat scenario.

Wildland Fires

87

Albert Simeoni

Introduction

Wildland fires have a big impact on the environment, human life, and property and have posed significant economic losses as demonstrated by devastating wildfires that occurred over the last few years. In August 2012, the total of 1470 km^2 (3.64 million acres) burned by wildfires in the United States ranked as the highest for any August since 2000. Moreover, nearly half the entire acreage burned since January 2012 occurred within the single month of August and brought the total acreage burned in a year to the highest on record, exceeding 3100 km^2 (7.72 million acres) [1]. The ignition and corresponding spread of these fires were predominantly influenced by extreme drought and high winds. At the global scale, the impact of wildfires is expected to increase dramatically in the future because of the combined effects of the spreading of the Wildland Urban Interface (WUI) and climate changes [2, 3].

The WUI problem is particularly relevant to fire protection engineering because it impacts people's safety and activities, as well as property and structures. In the future, this problem will shape the way of life of a large part of the population as the WUI is growing faster than any other populated areas [4]. The main differences between building fires and WUI fires are the scale of the phenomenon—with a large number of structures being impacted at the same time (an example is the Waldo Canyon fire in Colorado in June 2012 [5])—and the fact that the structures have to be protected from a fire coming from the outside.

Several issues linked to WUI fires can benefit from further developing fire protection engineering solutions, such as improving structure design to make them more fire resistant, creating new protection systems for houses and other structures, improving evacuation schemes, or supporting communities to develop their wildfire protection plans [6]. The scientific community has developed many tools through research in wildland fire spread, prevention, and suppression that are helpful to mitigate wildland and WUI fire problems. However, fire behavior is still a young and immature topic, particularly compared to other fields of science relevant to wildland fires, such as forestry, ecology and geoscience. It would benefit greatly from the application of approaches developed in fire science as some of the already developed tools could be adapted and applied to wildland and WUI fires.

This chapter presents some basic knowledge about fire behavior and the basic tools that are available in literature to help dealing with wildland and WUI fire problems. The next section presents the wildland fire context both in terms of the general problem and the related scientific

issues. Then, the fundamental mechanisms that drive fire behavior are detailed in the following section and different kinds of extreme fire behavior are reviewed as they become more common every day. Two additional sections present the different kinds of models that allow predicting fire spread and the fire danger estimation systems that are available and currently used around the world. Finally, the last section presents some ways to estimate fire impact on people and structures.

The Wildland Fire Context

Beyond the fact that they already represent a global problem, wildland fires are emerging as an increasing threat on humans and ecosystems. The dire consequences of these fires include loss of life and injuries, health impact through smoke exposure, property and infrastructure loss, business interruption, ecosystem degradation, and soil erosion, all of this despite huge firefighting costs. In addition to the 2012 fires cited in the previous section, the fires in Southern California in October 2007 and the Black Saturday fires in Australia in February 2009 are perfect examples of the increasing impact that wildland fires have on people, property and the environment. These fires had a large impact on the WUI. The state of emergency was declared in California in 2007 and over 1600 houses were burnt for losses estimated over $1.8 billion [7].

Wildland fires are likely to occur more frequently and to be more intense because of global warming. For instance, the number of uncontrolled fires is expected by USDA to increase by around 50 % in the region of San Francisco and by more than 100 % in Northern California [8]. Their impact will also increase because the Wildland Urban Interface (WUI) is spreading quickly. As an example, during the 1990s, WUI area in the three States of the U.S. West Coast increased by 11 % to nearly 53,000 km^2 and the number of housing units at the WUI was around 6.9 million units in 2000, increasing by more than 15 % every 10 years [2]. This combination of factors is not specific to the US and is relevant to many other regions of the world [9, 10].

The occurrence of massive fires at a growing WUI overwhelms fire fighting and induces huge losses. This growing problem is fully described in the final report of the 2009 Victorian Bushfires Royal Commission [11], which documents Australia's highest loss of life ever induced by bushfires. Among the 173 fatalities, 113 people died inside their houses. The cost of the disaster is estimated to be more than $4 billion. Similar events could potentially happen in other locations, such as California or the South of Europe [11]. The report is very extensive and includes a lot of recommendations about safety policy, emergency management, fire fighting, fuel management and research among others, which are based on the statement that these kind of fires are likely to occur more frequently.

In this context, it is of primary importance to develop the auto-resistance of structures at the WUI and to make them more defendable. It would reduce the economic loss and provide shelter to the population. All protagonists are concerned with this global threat, from private owners, who have to clean vegetation around their houses to central governments, which create regulations and national policies. Some of the players lack the technical skills required to understand fire behavior and evaluate its impact and they would benefit greatly from the development of fire protection engineering solutions.

The fires in developed countries are given extensive media coverage because their impact on human lives, human activities and infrastructures is huge. However, greater surfaces are burned in Asia and South-America for agricultural reasons. Every year, Amazonian and South-Asian forests burn because of the development of cropping, grazing and plantations [12] or because of extreme weather events, of which the intense fires caused by El Niño in 1997 in Kalimantan and Borneo, Indonesia are examples [13]. These fires have dramatic effects on the ecosystem and produce emissions that have a global impact. In addition to these regions, Africa is named the 'Fire Continent' and experiences large savannah

fires on a yearly basis. It is also subjected to changing fire regimes in damp forests and excessive logging.

Wildland fire can be mitigated through fire fighting and prevention. In many countries, fire fighting absorbs the great majority of the financial and human resources devoted to wildfires [14]. In the US, the total (federal, state and local) government firefighting cost grew from $1.3 billon/year in the 1990s to $3.3 billion/year in the 2000s [15]. Despite the huge resources used in firefighting, there is always a threshold when firefighting is overwhelmed by the size and intensity of the fire. Then, the fighting means can only be devoted to protect infrastructure and people at the WUI or to prepare future actions to fight the fire under more favorable conditions. In the US, 97 % of all fires are contained to 40,000 m^2 (10 acres) or less, and the remaining 3 % of large fires have a strong impact on the WUI [15]. It is estimated that the majority of the suppression costs are devoted to protect private homes [16].

On the other hand, prevention is necessary to decrease fire intensity over the long term and make fire fighting more efficient. This objective becomes of primary importance in the frame of global climate and socioeconomic changes (such as urban sprawling), leading to the emergence of new and more intense fire regimes. The most developed prevention approach is fuel treatment (or fuel reduction) in forests or at the WUI to increase the auto-resistance of vegetation.

In the US, congress devoted $500 M/year in the 2000s to support this activity [17]. Fuel treatment is done by cleaning the understory and/or thinning trees in order to avoid crowning and fires that consume the whole vegetation layer. Mechanical or chemical fuel reduction techniques can be used, but prescribed burning remains the main tool because it allows covering large areas with low resources and it can be applied in difficult topographies. Prescribed burning consists in conducting low to medium intensity fires out of the peak fire season to "clean" vegetation, mainly the fuel laying on the ground and the shrub layer but also sometimes the tree branches. The aim is to remove the dry and live fuel that may sustain fire.

The technique used in the specific location will depend on the local context and none is better than the others. At the WUI, cleaning around infrastructures can be drastic in order to break the fire dynamics and decrease infrastructure exposure. Several best practice programs exist to support fuel treatment around infrastructures, such as FireWise (USA), FireSmart (Canada) and FireSafe (California). Fire resistant structures can also be developed, and several standards exist as displayed in Table 87.1, which includes the standards applicable to the WUI.

These programs, codes and standards provide some guidance to develop fire protection solutions at the WUI (NFPA), to provide guidance for building construction at the WUI (ICC) or to develop test methods for materials exposed to fires at the WUI (ASTM). While they represent very valuable tools to help protecting the WUI, a lot remains to be done. For instance, the exposure techniques used in the different codes and standards need to be better linked to the actual exposure conditions happening during WUI fires. Recent field studies show the tendency of firebrands to ignite many houses during WUI fires, even the ones protected by fuel treatment, and the ability of a burning house to create a large amount of firebrands that may propagate a fire in a community, even when the wildland fire no longer impacts it [18]. These topics are the object of research [19].

Over the last 60 years, the scientific community has become more involved in the modeling of forest fires, and a number of physical approaches have emerged. The understanding of the physical mechanisms that control wildfire ignition and spreading constitutes the keystone of the development of fire protection engineering tools useful to management and fire fighting. Wildfire is a complex phenomenon in which the levels of description cover a huge range, from the details of the kinetics of gaseous combustion and thermal degradation of fuels, up to the chemical and physical characterization of the flame and the vegetation cover as a fuel. Figure 87.1 represents an overview of the different space and time scales involved in wildfires and the related difficulties for modeling.

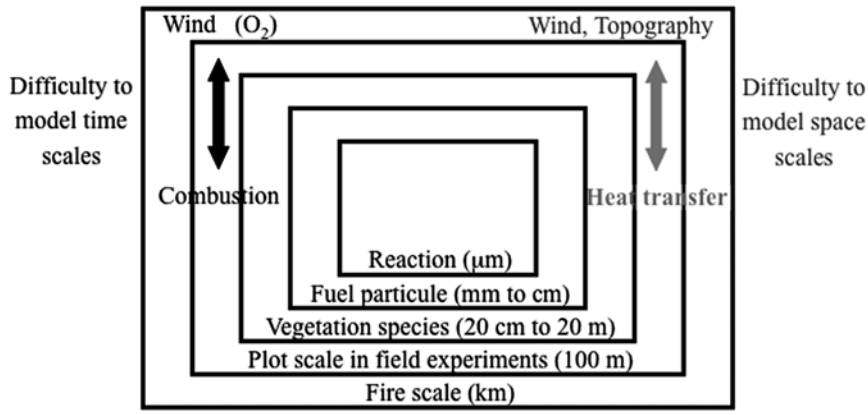

Fig. 87.1 Different space and time scales involved in wildfires

Even if the physical laws are known and GIS and weather models can provide the environmental data, modeling fire spread is really challenging. The difficulties rely in the high variability of the environmental parameters, in the large range of scales, and also in the huge number of phenomena involved in the process, such as drying and degradation of vegetation, flaming and smoldering combustion, flow inside and above the fuel bed, turbulence, and radiative transfer. These phenomena are all coupled and their respective importance in driving fire spread is difficult to assess and varies with the fuel and external condition. The next section describes the basics of wildfire spread in general terms, as well as different kinds of extreme fire behavior.

Fire Behavior

Mechanisms of Fire Spread

Basic Mechanisms

An unburned piece of vegetation (Fig. 87.2a) can be approximated as being a fuel particle. This particle is submitted to a heat insult when the fire front is getting closer.

The heat transfer influence on fire spread is essentially through two modes: radiation and

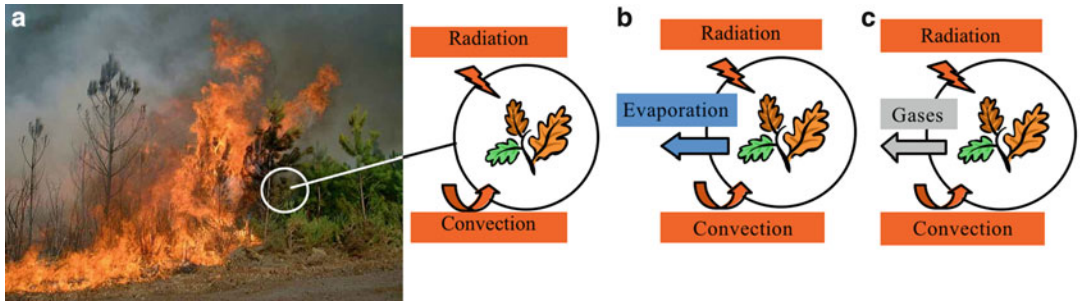

Fig. 87.2 Fire spread mechanisms—(**a**) fuel particle and thermal transfer, (**b**) drying, (**c**) pyrolysis

convection. Radiative heat transfer acts at a larger range than convective heat transfer ahead of the fire front. Radiant sources are the flame front and the smoldering vegetation. Heating by convective heat transfer needs some flow to come from the burning area and to be in contact with unburned vegetation (otherwise, vegetation is only cooling by convection).

When a vegetation particle is submitted to thermal transfer from the fire front, it heats. When its temperature is high enough (usually around 100 °C), it starts to dehydrate (see Fig. 87.2b). The water content in vegetation, called fuel moisture content (FMC), plays an important role in fire spread because it acts as a heat sink, which can delay or even prevent fuel ignition.

Once the vegetation particle has dried, it starts to pyrolyze. The proximity of flames makes the flammable mixture ignite and the fire spread. First, combustion occurs in the gas phase. Then, embers appear when the particle has finished emitting gases and is fully converted into char. The combustion appears at the surface of the char and the particle glows. The embers emit a large amount of radiation and burn slowly. When the embers are fully consumed, the particle turns into ash.

A fire spreads in the presence of three simultaneous factors: flammable gases, oxygen (in air) and a heat source strong enough to ignite the flammable mixture.

Parameters

The most obvious parameters driving fire behavior are the properties of vegetation, wind and topography. They are diverse kinds of vegetation properties: particle and bulk properties, fuel moisture content (FMC), and the spatial distribution of vegetation [20]:

- The particle properties represent vegetation as a fuel. They include the physical and chemical properties. The physical properties are the thermal properties—such as the heat capacity, heat conductivity, absorptivity and emissivity of radiation—the density, and the surface-to-volume ratio. The surface-to-volume ratio is an important parameter regarding heat transfer that will condition radiative and convective transfer between vegetation and the flame. The chemical properties are the chemical composition of vegetation (cellulose, hemicellulose, lignin, extractives, and minerals) that conditions the nature and quantity of the degradation gases, the latent heats of drying and pyrolysis, the heats of combustion of the pyrolysis gases and of the char. Some vegetal species are more flammable than others, such as sapwood compared to hardwood.
- The bulk properties represent vegetation as a fuel layer. They include bulk density, permeability (or drag forces) and attenuation of radiation [21]. All of these bulk quantities are a mix of particle properties and porosity. For instance, permeability depends on many fuel properties, including the surface-to-volume ratio, the roughness of the particle's surface and the fuel bed porosity. Wildland fuels are different from the usual fuels encountered in the built environment. Among all fuels present in a vegetation layer, it is commonly

accepted that only the thinner particles (diameter lower than 6 mm) are involved in fire spread [20], i.e. the leaves or needles, burn faster than branches or trunks and are the main contributors to fire spread. However, larger particles can burn later and participate in a structure's or soil's life exposure to heat. They can also create hot spots that have the potential of igniting new fires after the initial fire has gone. Vegetation is porous, with porosities ranging from 0.05 for pine needle litters to 0.002 for tree canopies [22, 23]. The bulk density represents the quantity of fuel mass (usually only considering thin particles) per unit volume. The permeability represent the interaction between vegetation and flow, either meteorological wind or wind induced by the fire itself. The attenuation of radiation represents how radiation coming from the fire front is absorbed by unburned vegetation. Many other properties can be represented as bulk properties. For instance, convective and conductive transfer will be conditioned by porosity and empirical laws including porosity can be derived [24]. Combustion in the fuel layer will depend on the availability of oxygen and hence be a function of porosity and drag forces.

- FMC is one of the most critical parameters. It is the main energy sink that can slow down ignition and decrease the fire heat release rate. Its value will condition the ability of a fire to spread and its rate of spread. The factors influencing FMC are as diverse as the air humidity, the air temperature, the sunlight exposure, the soil moisture, and plant physiological factors [25]. FMC varies in time and space, depending on local conditions and can create heterogeneous burn patterns [26]. The dynamics of FMC variations is very different for dead and dry fuels. Dry fuels are very sensitive to short term variations of weather conditions whereas moist fuels are more sensitive to long term variations. Dry fuels are mainly located on—or close to—the ground (litter/grass) and live fuel can be located at the surface (grass, shrubs) or at the top of higher vegetation (chaparral and tree canopies). The dry fuel is classified as 1 h, 10 h, 100 h, and 1000 h fuel, depending on the time it takes to adjust to changes in the external conditions. The time-lag classification is directly related to the size of the particles, 1 h fuels being particles no greater than 6 mm in diameter and 1000 h fuels being larger than 7.5 cm in diameter [20]. Fine dead FMC determines the rate of fire spread in surface fires. Live fuels are less sensitive to weather conditions in the short term but exhibit seasonal FMC variations due to plant physiology. This pattern is important to estimate the risk of crown fires. The worst-case scenario is the combination of drought and low seasonal FMC that can lower canopy FMC and even add dead fuel from otherwise live plants. In some ecosystems, this combination happens in winter or spring.
- The spatial distribution of the fuel can influence fire spread. There are two types of spatial distributions: vertical and horizontal. Vertical distribution is related to fuel layers. Fuel layers are usually defined as ground layer (duff or peat), surface layer (litter, herbaceous vegetation, and low shrubs), and crown layer (large shrubs and tree canopy). If these layers get very close to each other or overlap, a 'fuel ladder' exists that may create intense fires involving all vegetation at once. Horizontal distribution represents the fuel layer density, as for instance open or close canopies, as well as larger heterogeneities such as non-flammable areas (for instance rocks, rivers, and roads). The horizontal heterogeneities have a strong influence on fire spread. They also condition the occurrence of crown fires and can create heterogeneous fire patterns [26].

Wind has the effect of tilting flames. It also brings fresh air and thus fresh oxygen to enhance combustion and make flames longer. The flames being longer and tilted, the thermal transfer towards the unburned fuel will be increased greatly (see Fig. 87.3a and compare to Fig. 87.2a): the radiative source is larger and

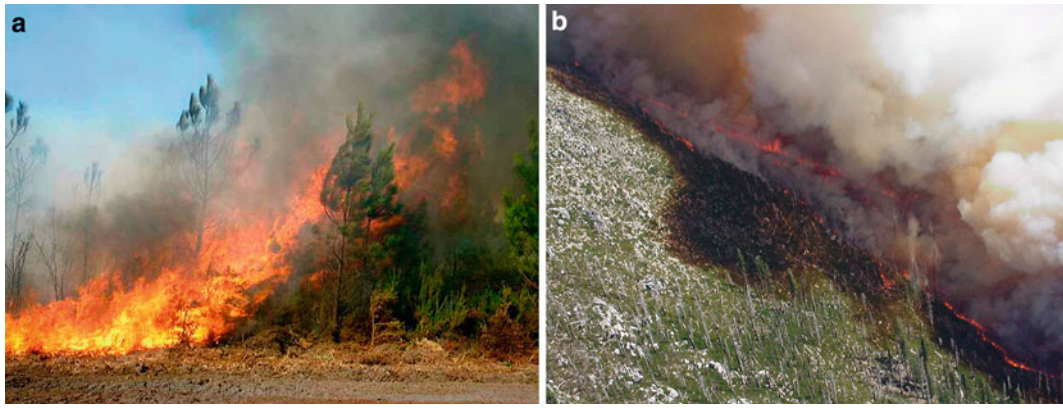

Fig. 87.3 External parameters for fire spread—(**a**) wind effects, (**b**) slope effects

closer and sometimes flames will engulf unburned vegetation and increase convective transfer. This change in behavior can induce steep accelerations of the fire front. Another wind effect is to make the fire front deeper by increasing the fire rate of spread. More vegetation is ignited ahead of the fire while vegetation is still burning at the back of the fire. Such fires are usually intense and difficult to fight. However, the impact on the ecosystem can sometimes be less dramatic because wind also cools the fuel after the fire, and the heat insult on vegetation and on the soil can be shorter.

The last effect is the effect of topography and more specifically of slope. The flame front is closer to vegetation in the slope direction, so a particle located ahead of the fire in the direction of slope will be heated more by radiation than another particle located on the flanks of the fire (because of the radiative view factor between the fire font and the particles). The fire head will then spread faster than the flanks and it will accelerate. This effect creates the specific pointed heads that are encountered for upslope fire spread as seen in Fig. 87.3b. For fires spreading under windy conditions, the flames are tilted in the wind direction and this effect of pointed head does not appear.

Except for the pointed head, the effects of wind and slope are similar for low winds and low slopes. For instance, when a fire spreads upslope, the vegetation facing the slope will be closer to the flames and the radiative transfer will be enhanced. Air is entrained more into the fire front from downslope than upslope. In confined conditions, such as canyons, this effect can increase the fire rate of spread as described in the next section for eruptive fires.

Obviously, this representation of the basics of fire spread is simplified, and all the phenomena are coupled, making predictions difficult. The coupling between the fire and the atmosphere will be mentioned later.

Extreme Fire Behavior

The previous section described the basics of fire behavior, but under specific conditions, fire can shift to extreme behavior that, when unexpected, can have catastrophic consequences. Several types of extreme fire behavior exist. Fire eruptions or blowups, crown fires, spot fires, fire whirls, and peat fires will be presented in this section.

Eruptive Fires

Eruptive fires imply a sharp acceleration of the fire in confined topography. Under specific slope, wind, and vegetation conditions, a fire that spreads in a usual way can ‘erupt’ and multiply its rate of spread by 5–10 [27]. This induces the creation of a large area simultaneously on fire.

An example of such a fire can be seen in Fig. 87.4a for a fire that happened in Corsica, France in 2000 [29]. The picture is extracted from a movie taken by a tourist and is the only

Fig. 87.4 (**a**) Video capture of a fire eruption [28]. (**b**) Eruption laboratory experiment at ADAI laboratory, Portugal

known video recording of such an event. The area simultaneously on fire was estimated to be around 6 ha and the fire rate of spread during the eruption was estimated to be around 20 km/h. When firefighters are caught in such a phenomenon, they usually die or are severely injured, even when sheltering in their vehicles. Europe has a long record of death by such events, numbering more than 200 fatalities over a 30 years period [29].

The factors leading to eruptions are only partially understood. Several physical and chemical phenomena could cause them: wind, topography, vegetation distillation, and smoke accumulation are found as potential explanations in literature. Experimental studies conducted in Portugal [28] allowed reproducing eruptions at the laboratory scale and demonstrate a strong coupling effect between a canyon—in the case of the experiments, a bi-panel tilted bench (see Fig. 87.4b)—and the fire that increases heat transfer at the fire head. This explanation is similar to the trench effect demonstrated for the King's Cross station fire in London [30]. However, laboratory studies and feedback studies from past accidents do not allow separating all the potential causes of fire eruptions, and a general theory is still to be developed. More research is necessary to understand the phenomena involved in fire eruptions and the mechanisms that trigger them. This research will have the potential to improve fire fighter safety, particularly in canyon configurations.

This behavior in canyons is called 'blowup' in the US, and the difficulty of conducting feedback studies for such complex and extremely rapid phenomena led to the definition of an alignment of factors. The difficulty lays in identifying which of these factors really triggers blowups. However, the specific meteorological phenomenon of 'Cold front' seems to be one of them and was apparently involved in several accidents [31].

Crown Fires

Crown fires can produce intense wildfires and are overwhelming for anyone who observes them. Van Wagner [32] defined three classes of crown fires:

- Passive crown fire: When the crown cannot sustain fire spread and needs the energy from the surface fire to get a flame in the crown layer. In this case, the rate of spread of the surface fire controls the crown fire.
- Active crown fire: When the crown cannot sustain fire spread but can develop a substantial flame that creates a heat feedback to the surface fire. Then, the crown fire and the surface fire spread together at a rate that is greater than the rate of spread of the surface fire, would it be alone.
- Independent crown fire: When the crown can sustain fire spread and does not need to receive additional heat from the surface fire. Then, the crown fire will spread on its own, faster than the surface fire.

The latter class is the most dangerous with the highest rates of spread and heat release rates and is most likely to occur under strong winds. However, the optimal conditions to get independent spread are so difficult to reach that long-lasting independent crown fires are rare events.

Another way to classify crown fires is between wind-driven and plume-dominated fires [33]. For wind-driven fires, the plume is tilted in the direction of wind, and for plume-dominated fires the plume is vertical. Under wind conditions, the power of wind and the power of the buoyancy-induced fire plume compete to create one or the other kind of plume, depending on the size and intensity of the fire. The wind-driven fires are more likely to lead to independent crown fires and to send a large quantity of firebrands in front of the fire. However, the turbulence created by the plume-dominated fires can create a recirculation of hot gases in front of the fire and induce sudden and unexpected accelerations of the fire front [20].

Spot Fires

Spot fires are created by firebrands that land on unburned vegetation. Firebrand generation is the process through which fuels such as shrubs and trees are heated and broken into smaller burning pieces during a fire [34]. Subsequently, they may be transported far away from the fire through the plume [35]. If firebrands are still burning when landing and if the recipient vegetation on the ground is dry and dense enough, they may create spot fires.

Firebrand effects can be split in long-range and short-range effects. Long-range firebrands are lifted by the fire plume at high altitude and are transported horizontally by wind over a long distance. If these firebrands start a new fire, it will be independent from the source fire, at least during its growth. The very short-range firebrands don't really influence fire spread because the fires they may start are absorbed by the main fire front before having time to develop. However, they can sometimes allow a fire to cross small natural or man-made obstacles. Short-range firebrands that land at a longer distance from the fire front can accelerate the fire spread by creating a spot fire that had enough time to develop and that is drawn into to the main front when getting closer to it, hence accelerating the fire spread. This phenomenon is dangerous for firefighters if they get caught in the middle, before they realized that a fire has ignited behind them [20].

The analysis of spot fires is complex because they are made of several distinct stages that are still poorly described [35]:

- Firebrand production that depends on the fuel type, the fire plume intensity, and the local burning dynamics of vegetation.
- Travel distance that is a function of the size and shape of firebrands, the plume intensity, and the wind velocity.
- Landing conditions that depend on the burning state of the firebrand (smoldering or flaming), the fuel type at the landing spot, the FMC and even the type of contact to transfer enough heat to ignite the ground fuel.

For more than 40 years, studies have focused on understanding how far firebrands can fly [36, 37], whereas more recent studies evaluated the production and ignition processes [19, 38].

Fire Whirls

Fire whirls are due to the combination of the strong buoyancy created by the fire front and any phenomenon that creates air rotation. They can pose an issue for prescribed burning or for fire fighting safety [20]. In wildland fires, this rotation usually happens on flat ground, at the leeside of obstructions, or at mountain ridges [20]. The combustion rate is multiplied inside the fire whirl, increasing the heat release rate and the fuel consumption [20]. Some fire whirls can propagate the fire front by moving towards unburned vegetation or by producing a large amount of firebrands that land close to the fire. The resulting firebrands can be larger than usual because of the strength of the vertical winds inside the fire whirl that can lift large burning particles. The created spot fires can suddenly enlarge the fire front and make it much more intense than the supporting fire [20].

Fire tornadoes can be created when large pyro-cumulonmibi develop over massive fires.

Fire tornadoes occurred during the 2003 Camberra fires that were estimated to be at least of F2 intensity on the Fujita scale [39].

Fire whirl mechanisms are not different from those encountered in other fires in the open like urban conflagrations and they can be described in the same way [40].

Peat Fires

Peat fires are not labeled as extreme because of their rate of spread or their intensity but because of their magnitude and the fact that they happen during extreme weather conditions, such as the fires that circled Moscow in June 2010.

Peat fires are smoldering flameless fires that spread slowly in the soil layer [41]. They occur relatively frequently in Northern boreal ecosystems and can also happen in humid tropical forests like during the Indonesia fires of 1997 [13]. Usually, peat fires are ignited by surface wildfires that migrate into the peat layer, which thickness ranges from 0.5 to 12 m. The fires can be totally underground because of the low intensity of smoldering combustion that does not require much oxygen. Once ignited, they are particularly difficult to extinguish despite extensive rains or fire-fighting attempts and can linger for long periods of time (weeks and up to years) [13] and spread over very extensive areas of forest and deep into the soil. The oxygen is supplied through cracks in the ground, and the heat loss is low in the insulating soil layer, which can sustain fire for months. Very often, they allow flaming combustion to re-establish during wildfires at unexpected locations (e.g. across a fire break) and at unexpected times (e.g. long after burnout of the flame front). This feature is also shared with duff fires, and to a lesser extent, with hummus fires. The usual way to fight these fires is to create trenches by digging to the mineral soil and creating a fuel break or trying to soak them with water. These techniques are challenging to use when the underground fire is not accurately located and the area to cover is large [41].

Peat fires can cover wide areas and consume large quantities of carbon. It has been reported that smoldering of surface fuels can consume around 50 % or more of the total burned biomass in temperate and boreal fires, as well as in Amazonian tropical-woodland fires [42]. Smoldering of forest fuels is also responsible for a significant fraction of the total pollutants emitted into the atmosphere during a wildfire [13]. Peat fires play a major role in the global emission to the atmosphere, the destruction of carbon storage in the soil and the damage to the natural environment. In addition, large peat fires can create health issues for the exposed population and economic losses, such as those induced by airport closure or the loss of activity for industries sensitive to smoke pollution.

Small-scale laboratory experiments have studied the ignition and spread of peat fires [43]. The governing factors are heat transfer, oxygen availability and FMC [44].

Models and Simulators

Several reviews have been published about fire-spread modeling [45–49]. Based on the classification proposed by Weber [45], three types of models can be identified. The first type includes statistical models that do not consider any physical information at all. The second type of models incorporates semi-empirical models. They are based on the principle of energy conservation without distinction between the different mechanisms of heat transfer. Finally, physical models describe the various mechanisms of heat transfer and production. Among those, the detailed approach takes the finest physical and chemical mechanisms into account and is the most detailed modeling that has been developed so far [24]. Contrarily, simplified physical models only consider the main mechanisms involved in fire spread [47].

Empirical Models

Empirical models are based on simple equations that do not include any physical information but that relate the fire head rate of spread to a set of statistically significant parameters. The data is

collected in experimental fires or in well documented prescribed or wildland fires. Some of these models are part of simulators that are efficient for places with homogeneous vegetation and external parameters, such as Australian grasslands or Canadian boreal forest.

The Australian fire behavior meters provide the rate of spread of the fire head as a function of environmental parameters, FMC, and fuel availability for fire spread in grasslands [50] or Eucalyptus forests [51]. Fire predictions are given by fire danger meters, which are disks for which the alignment of the parameter values will give the fire head rate of spread. These meters are used on a day-to-day basis by foresters and firefighters in the field. Noble et al. [52] have expressed the meters as equations. For instance, the MK4 meter for grasslands predictions provides the rate of spread as [53]:

$$F = 2\exp\left(-23.6 + 5.01\,C_d + 0.0281\,T_a - 0.226\,H_r^{1/2} + 0.663\,U_{10}^{1/2}\right) \tag{87.1}$$

where C_d is the degree of curing, T_a is the ambient temperature in Celsius, H_r is the air humidity in percentage and U_{10} is he wind velocity at 10 m in m/s. F is the fire index and the rate of spread is given by:

$$V = 0.036\,F \tag{87.2}$$

The Canadian Fire Behavior Prediction System is not directly used as a prediction system for the fire rate of spread by itself, but it is integrated in the fire weather index (FWI) that provides a daily estimation of the fire risk in Canada [54]. The following equation provides the fire rate of spread:

$$RSI = a\,[1 - \exp(-b\,ISI)]^c \tag{87.3}$$

where ISI is the Initial Spread Index and a, b, and c are fuel-dependent factors that are divided in eight classes representative of Canadian ecosystems [54]. ISI is expressed as:

$$ISI = 0.208\exp(0.0504\,U_{10})\,91.9\exp(-0.138\,FMC)\left(1 + \frac{FMC^{5.31}}{4.93}10^7\right) \tag{87.4}$$

These models are statistically derived to provide the rates of spread for a given range of fuel and weather conditions, and they must be used with care when the conditions differ from the ones used to derive the model. The Canadian FWI has been extended and adapted with success to other regions of the world for the local ecosystems [55].

Semi-empirical Models

Semi-empirical models are based on the principle of energy conservation but do not discriminate the different types of heat transfer and the different combustion processes. The energy conservation principle means that the energy produced by the fire is either transferred to the unburned fuel to maintain the fire, or lost to the ambient. The formulation of the energy balance takes the following general form:

$$Q = \rho\,h_i\,R \tag{87.5}$$

where Q is the net energy going through the ignition surface per unit of surface area, ρ is the fuel density, h_i is the enthalpy per unit mass that is required to ignite the fuel and R is the rate of fire spread. These models are steady-state—in the sense that one set of conditions gives one rate of spread—and one-dimensional.

Q is expressed by using heat transfer laws but its different components are estimated

empirically by conducting a large number of laboratory fire spread experiments under varied experimental conditions.

The most famous of these models that is still extensively used is Rothermel's model [56], which is based on Frandsen's model of fire spread [57]. The equation for the rate of spread of the fire head is expressed as:

$$R = \frac{(I_p)_0 (1 + \varphi_W + \varphi_S)}{\rho_b \varepsilon Q_{ig}} \tag{87.6}$$

where R is the rate of spread (m/s), $(I_p)_0$ is the heat flux from the fire front that reaches the unburned fuel ahead of it for a fire spreading on a flat surface and without wind (kW/m^2), ρ_b is the fuel bulk density (kg/m^3), ε is an effective number that defines the amount of fuel which is available to sustain fire spread (-), Q_{ig} is the heat which is necessary to bring the fuel to ignition (kJ/kg), and φ_w and φ_s are correction factors for wind and slope, respectively (-).

The different parameters are either obtained from the physic-chemical properties of the fuel or empirically derived. The huge number of experiments conducted along time in the most diverse configurations allows the model to provide a good estimation of the fire rate of spread for a large range of conditions. As for the Canadian system [54], several fuel classes have been developed that are characteristic of American ecosystems [58, 59]. The model—and in general terms, the semi-empirical approach—is more general than the empirical approach and provides acceptable results in diverse configurations. However, the parameters still remain in a relatively narrow range, and the model is challenged when applied to areas with a large variability of parameters, like the Mediterranean basin.

The main simulation tools currently used by foresters and firefighters in the field are based on Rothermel's model [56]. For instance, Behave Plus [60] provides a quick estimation of the fire head rate of spread through nomograms and Farsite [61] is a whole GIS-based simulation suite that extends Rothermel's model to two-dimensions along the ground by applying Huggens' ellipse principle. Farsite also includes other models as detailed later. Even if they are widely used, these tools are more of strategic value, as they give an indication of the long term tendencies of a fire, than of tactical value to base any immediate decision on their short term predictions. These predictions can be biased because of the simplified nature of the models.

Physical Models

Simplified Physical Models

These models are conceptually more general than empirical and semi-empirical models. They can provide the fire shape and rate of spread, as well as an estimation of heat transfer and energy release with simulation times that can be close or even under real time, if some optimization techniques are used for computation. However, they have not been used extensively until now due to the fact that it is difficult to ensure that the chosen simplifications are relevant to diverse sets of conditions. Contrarily, empirical and semi-empirical models have the benefit of being statistically relevant to given conditions.

Simplified models do not calculate the flow as it is too computationally expensive but usually provide the fire rate of spread and the fire shape on the ground. The general formulation is around a single thermal balance with the addition of sub-models to take into account phenomena such as combustion or wind [62, 63]. The fuel is assumed as being a medium equivalent to the gas and the solid phases that coexist inside the fuel layer, and thermal equilibrium is assumed between phases. The flame has to be modeled as it cannot be computed in the absence of flow. It is often described as a radiant panel with a given height and emissivity.

As an example, the following thermal balance can be written, taking into account heat transfer mechanisms (radiation and convection) and heat production [64]:

$$\frac{\partial T}{\partial t} + k\vec{V}_g \cdot \vec{\nabla} T = -h(T - T_a) + K\Delta T + R - q\frac{\partial \sigma}{\partial t} \tag{87.7}$$

where k is the advection coefficient, K is the diffusion coefficient, h represents the loss to the ambient, q is the heat of combustion of the fuel and σ is the fuel load (mass per unit area). The model is closed by using sub-models: a simplified flow model to obtain the horizontal flow velocity in the fuel layer $\vec{V}_g$, a radiant panel approximation to describe the radiative transfer from the flame R, and a simplified mass loss law to describe the variation of σ due to the combustion reaction.

Several other variations exist that complicate more or less the formulation to describe better some aspects of the fire [65, 66].

A recent simplified model has been tested with a large set of available experimental data at laboratory scale for fire spread under diverse conditions [67]. The model has demonstrated good predictive capabilities that demonstrate the potential of simplified physical models to provide a general frame for improved predictions compared to the existing tool based on semi-empirical models. The predictive ability of the model at field scale has been improved by coupling it with an atmospheric model [68].

Detailed Physical Models

The multiphase approach is described as an example of detailed physical models as it is the most detailed available formulation. The full details of the model presented below can be found in [69]. This approach represents the fire spread medium as being multiphase, reactive and radiative [24]. The medium is defined by the fluid phase and N solid phases. Each solid phase consists of a set of particles that possess the same geometry and thermochemical properties (see Fig. 87.5). An elementary multiphase volume is defined that allows describing the fire phenomena at the relevant scale. A volume averaging procedure is applied to the volume to obtain averaged properties for both the gaseous and solid phases.

The system of averaged equations includes balances of mass, species, momentum and energy for each species, as well as a radiative transfer equation. The strong coupling between the solid and gas phases is represented by interface relationships. For clarity, no volume averaging symbol is added and only the mass equations are presented:

$$\text{Gas phase}: \quad \frac{\partial}{\partial t}\left(\alpha_g \rho_g\right) + \vec{\nabla}\left(\alpha_g \rho_g \vec{V}_g\right) = \sum_{k=1}^{N} \left[\dot{M}\right]_{gk} \tag{87.8}$$

$$\text{Solid phase } (N \text{ equations}): \frac{\partial}{\partial t}\left(\alpha_k \rho_k\right) = -\left[\dot{M}\right]_k^{surf} - \left[\dot{M}\right]_k^{pyr} \tag{87.9}$$

$$\text{Interface equations}(N \text{ equations}): \left[\dot{M}\right]_{gk} = \left[\dot{M}\right]_k^{surf} + \left[\dot{M}\right]_k^{pyr} \tag{87.10}$$

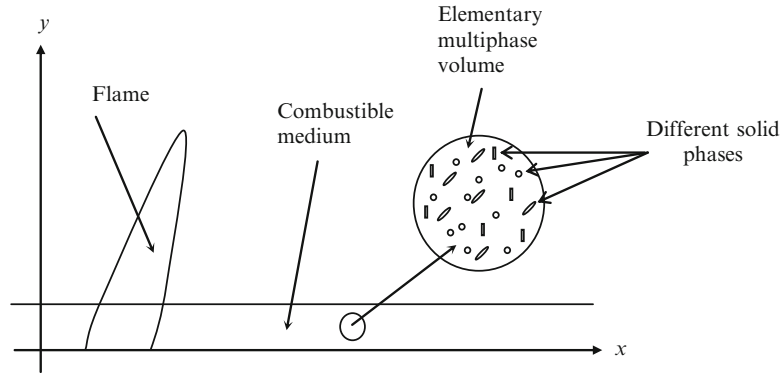

Fig. 87.5 Schematic representation of the problem for the multiphase approach

where α is the volume fraction of the considered phase (percentage of the volume occupied by the phase), ρ is the density and $[\dot{M}]$ is the mass flux. The subscripts g, k and gk denote the gas phase, the k^{th} solid phase and the flux from the k^{th} solid phase into the gas phase, respectively. The superscript *surf* denotes the surface reaction of oxidation (smoldering) and *pyr* denotes the gasification of the solid phase (pyrolysis gases fuelling the flames).

From this method, different terms appear on the right side of the balance equations that need to be determined via sub-models. For the mass equations, they consist mainly in Arrhenius type laws for drying, pyrolysis and charring of vegetation. One of the key issues of applying the model is to design proper experiments to evaluate the sub-models under actual fire conditions, which can be very difficult, if not impossible to achieve for some of the sub-models.

The model—as other CFD models—provides fields for all variables, such as temperature and velocity, but also species mass fractions and turbulent kinetic energy. However, it is difficult to design experiments to validate its results. Usually, the rate of spread and the flame geometry are compared to experiments [70], but it does not represent a proper validation as these experimental parameters are not directly related to the variables of the model.

Simulators

Table 87.2 presents the main simulators that are available to describe fire spread and provide at least the fire rate of spread and the fire shape. Other tools exist that provide nomograms, statistical fire behavior or spatial analysis, such as Behave plus [60], Nexus [70], and FlamMap [73].

Farsite [61] provides the fire shape and rate of spread as a function of vegetation and external parameters. Several other outputs are available, such as the fire-line intensity [74] (defined as the mean heat release rate per meter of fire front), crown fire initiation [32] and spread [33], as well as the basic effects of fire-fighting on fire spread. The predictions for crown fire spread underestimate actual fire spread because the crown fire models have been developed based on a very limited set of experiments and have not been fully validated [75]. Additionally, the surface and crown fire models are of different nature, making their coupling very difficult to achieve [75]. This statement extends to the other simulation tools based on empirical and semi-empirical surface fire models that are not described in this section. Simple wind modeling that represents the variability of wind with topography can be coupled to Farsite and allows substantially improving its predictions [76].

NCAR [25] is dedicated to the understanding and description of the direct atmosphere/fire interaction, as well as fire emissions. As it uses Rothermel's model [56], the description of the fire is submitted to the same limitations described for the semi-empirical approach. However, the atmospheric aspect allows describing the large scale effects that happen due to the fire/atmosphere coupling and that can influence fire spread, particularly for massive fires.

WFDS [71] is a full simulation suite that is based on the multiphase approach detailed above. It is dedicated to describe Wildand urban interface fires. It resolves flow, heat transfer and combustion at the scale of vegetation.

Table 87.2 Simulation tools available in literature

Simulator	Type of fire model	Fire/atmosphere interaction
Farsite [61]	Semi-empirical	Constant or topographical wind effect on fire
NCAR [25]	Semi-empirical	Atmospheric coupling (MM5)
WFDS [71]	Detailed physical	Detailed physic-based (no atmospheric coupling)
Firetec [72]	Detailed physical	Atmospheric coupling (HighGrad)
Forefire [68]	Simplified physical	Atmospheric coupling (Meso-Nh)

The simplifications in the model based on the Fire Dynamics Simulator [77] allow the model to describe the fire at the fire front scale with the use of heavy parallel computational power.

Firetec [72] couples fire spread modeling in a simpler way than the multiphase approach to atmospheric modeling. It is very efficient to describe fire spread in relation with the local flow around the fire. However, the computational needs imply the use of supercomputing capacities to be able to simulate the scale of a small wildland fire.

Forefire [68] couples simplified physical fire-spread modeling to atmospheric modeling to study fire spread and emissions. The fire plume and the fire/atmosphere interaction are described at a scale much larger than the fire.

WFDS [71] and Firetec [72] are still research tools but they represent the future of fire-spread simulation that will allow going beyond the current limitations of available simulators. They will not be used as operational simulation tools for a long time, and their applicability is not even assured because of their complexity and the large number of parameters and inputs they require. However, they will allow developing simpler models that will include the relevant phenomena that actually drive fire behavior. This is something that the semi-empirical models are not able to achieve. Forefire [68] is already a step in this direction.

Another approach, which could improve the predictive capability of fire spread models, is data assimilation. This approach was initially developed in meteorology. It consists in informing the fire spread model with real-time measurements from the fire it aims to predict. The data is used to correct the model's predictions through a reevaluation of its parameters [78], hence avoiding the increasing gap between model predictions and actual fire behavior that systematically happen along time. This divergence is due to many factors, such as the variation of conditions, the inaccuracy of parameters, or the approximate nature of the fire spread model. The application to Rothermel's model showed that this approach has the potential to improve predictions [79].

Fire Danger

Operational fire danger rating systems have mainly been developed in Australia [80] Canada [54] and the US [58]. The Canadian system has particularly been adopted by several countries and adapted to local conditions [55]. The main variables taken into account in the systems are live and dead fuel FMC, as well as meteorological variables, such as wind, air temperature and air humidity [81].

The most empirical approach is used in Australia because of the fairly constant external conditions that exist in many parts of the country and the large amount of empirical data that was collected allow obtaining good results with the empirical models for fire spread in grassland [50] and eucalyptus forests [51]. The meteorological parameters are wind velocity and ambient air conditions, as well as rain history. For grasslands, the percentage of dead material (curing) is an important parameter because it drives fire behavior for such very fine fuels constituting a single vegetation layer.

The Canadian Forest Fire Danger Rating System [59] is more detailed than the Australian one and aggregates different types of fuel ecosystems from grassland to forest through its fuel models. It combines the effect of weather conditions and FMC on fire behavior. The moisture of the soil fuel layer is finely described as it represents the potential of a fire to ignite. The danger is expressed as the expected fire-line intensity [74], which is a combination of the initial rate of spread (given in the previous section) and the fuel load:

$$I = HWR \tag{87.11}$$

where H is the heat of combustion of the fuel (kJ/kg), W is the fuel mass consumed per unit area (kg/m^2), and R is the rate of fire spread (m/s).

The National Fire Danger Rating System is used in the US [82] and is similar in nature to the Canadian system. The main difference is that it includes semi-empirical modeling that is more detailed than the modeling used in the Canadian

System. For instance, the fire rate of spread is determined with Rothermel's model [56] and the soil moisture is determined by a semi-empirical approach that balances precipitation and evapotranspiration [82].

All these models have proven to be efficient and are used routinely for the daily assessment of fire danger all around the world. However, they have shown their limitation in the context of the occurrence of extreme conditions when the values of the parameters are well out of range and the empirical and semi-empirical models cannot provide good predictions anymore. Despite this, there is no physical approach available yet and the models are extrapolated to try to anticipate higher levels of risk that become more and more common due to socio-economic and climate changes.

Fire Impact

Fire impact under the fire safety viewpoint refers mainly to the impact on people and structures. The main mechanism that supports the impact on people is heat transfer, i.e. radiative and convective transfer from the fire front. The main factor that influence structural ignition at the WUI is also heat transfer from approaching flames but firebrands deposit has to be added. Firebrands can ignite a structure by two ways: they can accumulate on the outer surface of a structure and ignite it, or they can find a way through the structure to reach easy-to-ignite fuels.

Other forms of impact, such as ecological impact or health impact are not developed here.

Heat Transfer

Heat transfer can impact people or structures. The impact on structures is mainly related to the WUI problem. It is difficult to ignite wood panels or vinyl siding only by radiation, and flame contact is often necessary [83]. Fuel treatment programs, such are FireWise are based on this observation and recommend fuel removal up to a certain distance around houses.

The people who are close enough to be impacted by fire and can sustain exposure to relatively high heat fluxes are fire-fighters wearing personal protective equipment. Thus, the main concern for people exposure is fire-fighters safety, and a better evaluation of safety distances would improve it greatly. The safety distance is related to three aspects: the intensity of the fire, the mode of heat transfer, and the resistance of the target to the heat insult. The exposure time is also an important parameter. In this context, the knowledge of fire behavior and the good representation of the heat transfer are of primary importance.

The current models used to evaluate safety distances are only based on radiative transfer. They use the solid flame assumption (flame equivalent to a radiant panel) with constant values of flame height and flame temperature [84, 85] and express the fire radiative impact as a function of the flame height. A latter model [86] takes into account finite fire front width, which is more realistic, and express the safety distance as a function of the fire front width/flame height ratio. The problem of these models is that they assume that the flames have constant properties, whereas flame radiation is defined by the turbulent nature of flames with changing geometry and distribution temperature. Furthermore, radiation has a relatively short range effect [87] and at a short distance, convective transfer is likely to have a strong role [88]. The models will need to take this transfer into account to provide better estimations of the safety distance. The solid flame models do not describe the flow, and adding convection could be difficult. CFD models could potentially yield much better results, but they are not mature enough to be used in this context. They are also very sensitive to radiation as a slight variation in flame properties (emissivity, temperature distribution, and volume) can have a large effect on radiative transfer.

Firebrands

If the research has focused for quite a long time on radiative and convective impact on structures, recent field studies have highlighted that structural ignition from embers is a main cause of structure loss at the WUI [18, 89].

The structure ignition can come from a single ember that found its way to the weak points in a structure, like going through vents or depositing under the roof. However, the main impact happens during exposure to the short-range firebrand shower that induces exposure to a large quantity of burning (smoldering and flaming) firebrands, creating accumulations in wedges, corners, and cracks [18, 90]. In this case, several parts of a structure are likely to ignite, such as roofs, decks, siding, and even surrounding elements, such as fences and any pile of combustible materials (as wood stored for winter) that would spread a fire to the structure when ignited.

NIST has a research program to characterize ember production, as well as vegetation and structure ignition when submitted to an ember shower [19]. In the case of a firebrand landing on vegetation, it is more likely that vegetation will ignite when the firebrand is still flaming [91]. In the case of an accumulation of firebrands, the structures are very weak and ignite quickly by the roof, sides and decks [90].

For fires spreading at the WUI, it is common to experience structural loss even at locations inside communities that were not touched by the fire front, highlighting the issue of structural ignition by firebrands [89]. When a structure is ignited, the fire can spread from structure to structure by two mechanisms: heat transfer from the burning structure to the next one if the structures are close enough. This is similar to the issue of building-to-building spread in urban settings [92]. The second mechanism is again by firebrands generated by the burning structure that have the potential to ignite neighboring structures, at distances greater than the zone of influence of the flames. It has been found that firebrands generated from structures are larger and broader than those generated by burning vegetation [93].

Summary

Societies face great challenges due to wildland and WUI fires, and they will benefit greatly from a more systematic approach of fire safety engineering.

Wildland fires represent an intricate problem that adds the complexity of vegetation, large scale effects and open boundaries to usual fire problems, rendering any quantitative estimation of fire spread and fire impact difficult.

If it is already difficult to predict fire behavior under usual conditions, extreme fires pose additional challenges and more research is needed to understand them and predict their occurrence.

Wildland fire science is still a young science that was able to deliver some operational tools at the empirical and semi-empirical levels. The physical approach is promising and may produce the tools of the future, but it will necessitate a long investment in the fundamentals and in validation.

Fires in Vehicle Tunnels

88

Ricky Carvel and Haukur Ingason

Introduction

The scenario of a large vehicle fire remains one of the most troublesome issues for designers of tunnels and underground facilities. Two of the main questions which continue to be raised and debated at tunnel safety symposia are:

- What should be used as 'design fires' for road, rail and subway tunnel design?
- What fire protection and prevention measures are effective against fires in tunnels?

Most of the major experimental research projects investigating vehicle fires in tunnels carried out in the past two decades, including the EUREKA EU499 project [1], the Runehamar fire tests [2, 3] and the METRO project [4, 5], have shown that real vehicle fires in tunnels may be more severe than the scenarios which have historically been used as 'design fires' for vehicle tunnels, subway stations, etc. The reason is twofold;

- The knowledge on fire development and sizes is limited due to limited number of tests leading to "expert views" on reasonable worst case fire sizes. These views tend to lower the values used in design as they usually are a product of a consensus between the experts.
- The tests performed sometimes may exaggerate the real conditions. For example in the Runehamar tests, the fuel load was fully exposed to the wind conditions whereas in reality the load may be blocked by the truck or the front wall of the trailer resulting in a lower fire growth rate.

This chapter provides a review of the published data produced as part of these studies and identifies the characteristics common to most of these fire experiments. If design fires used for vehicle tunnels are to be in any way realistic, these characteristics must be taken into account. The chapter then looks at the question of fire protection for vehicle tunnels and discusses the current state-of-the-art.

Full Scale Fire Experiments in Tunnels

This section considers only very large vehicle (and solid fuel) fire tests carried out in full-scale tunnels, it is not intended to be a comprehensive review of all tunnel fire tests. In particular, the Memorial Tunnel Fire Ventilation Test Program (MTFVTP) results are not considered here as these tests involved fuel pools, not vehicles or realistic vehicle cargoes [6]. Similarly, smaller fire tests carried out as part of other test series will not be discussed. For a reasonably comprehensive summary of fire experiments at full and reduced scale, see Carvel and Marlair [7] or chap. 3 in Ingason et al [8]. As most design fires are specified in terms of the heat release rate (HRR) of the fire, and as this is a good

measure of the severity of such fires, this review will focus on HRR data from the experiments considered. A summary with focus on HRR data from each vehicle type is given in Ingason and Lönnermark [9].

The EUREKA EU499 Fire Tests (1992)

The EUREKA EU499 'Fires in Transport Tunnels' project involved researchers from nine European countries and the main data were gathered from a series of 21 fire tests which were carried out in a disused tunnel in Repparfjord in the north of Norway, near Hammerfest [1]. The tunnel has a rough-rock, irregular surface and varies between 4.8 and 6.0 m high and 5.3–7.0 m wide; the average cross-sectional area is about 34 m^2; the tunnel is 2.3 km long and has a 1 % uphill gradient towards the 'downstream' end of the tunnel, which terminates in a shaft, open to the air. The large vehicles fire tested in this series (for which HRR data were estimated) were a subway carriage, two full railway carriages, one 'joined' railway carriage, one bus, and a heavy goods vehicle (HGV); a large 'mixed load' was also tested, which may be considered analogous to a vehicle cargo. In each case, the fire load was positioned approximately 295 m from the 'upstream' (downhill) end of the tunnel.

The bus fire test (B11) involved a single decker, Volvo school bus built in the early 1960s [10]. It was 12 m long and had 40 seats. During the fire test the luggage compartment door and the front door of the bus were both open, and the partition between the luggage compartment and the passenger compartment had been removed. 310 pine sticks, 800 × 40 × 40 mm, were distributed throughout the bus to represent luggage. The bus fire test was carried out without forced longitudinal ventilation. During the test, smoke from the fire travelled in the 'upstream' direction with a velocity of about 0.3 ms^{-1}, while the smoke velocity in the 'downstream' direction was not recorded. Estimates of the HRR were made using oxygen and CO/CO_2 concentration measurements taken on both sides of the fire location [11]. The fire reached a peak HRR of 29 MW within 8 min of ignition. By 18 min after ignition, the HRR had diminished to less than 13 MW, after which the fire gradually burned out over a period of more than an hour. Figure 88.1 shows a simplified representation of the measured HRR data [11].

The mixed fire load test (LF1) involved a load of 2850 kg, three-fourth of which was wood, one-eight of which was tyres, and one-eight of which was other plastic materials. This was distributed in a stack approximately 2.4 m long, 2.2 m high and 2.4 m wide. No forced ventilation was used during the test and the smoke travelled

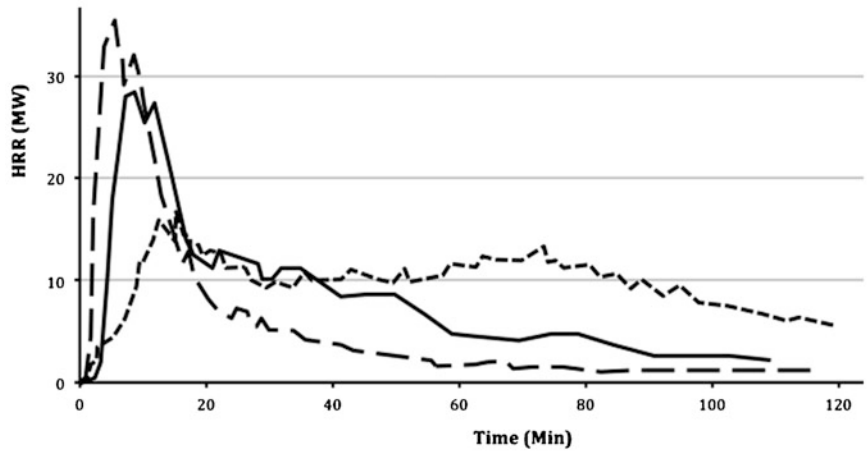

Fig. 88.1 Approximate HRR data from EUREKA EU499 bus fire test B11 (*solid line*), mixed load test LF1 (*short dash*) and subway carriage fire test F42 (*long dash*) (Adapted from [10])

in the 'upstream' direction until it reached about 115 m upstream of the fire, where the smoke front stopped. The smoke transport in the downstream direction was not recorded. The fire grew rapidly to a peak HRR of about 17 MW in about 15 min; the HRR data [11] are shown in Fig. 88.1.

The HGV fire test (HF1) is described in several places in the literature including [12, 13]. The fuel load in this instance consisted of a tractor unit (built by Leyland DAF in 1988) and a double axle trailer unit loaded with about 2 tonnes of wooden framed furniture. The trailer was 12.5 m long, 2.4 m wide and 2.5 m high. During the test, the HGV was positioned with the tractor unit facing upstream. A blockage of two shipping containers was positioned in the tunnel 29 m upstream of the HGV. The ventilation in the tunnel was forced longitudinally and was varied during the test. In the initial stages of the test the ventilation flow was about 6 ms^{-1}, after the fire spread from the cab to the trailer the fan was switched off for 2 min, then restated at 2.9 ms^{-1} (the velocity corresponding to the intended emergency ventilation flow rate in the Channel Tunnel, which the test was designed to partially replicate). All smoke from the fire was blown downstream of the fire, except during the period that the fan was switched off. The ventilation system was switched off after about 15 min into the test while the fire was still growing, so it is not known how large the fire would have grown with a flow of 6 ms^{-1}. Once the fans were established again at 2.9 ms^{-1} (after about 2 min), the fire reached a peak of 128 MW. The most reliable HRR data from this test were obtained by Grant and Drysdale and are shown in adapted form in Fig. 88.2 [12].

A fire test was carried out using two joined half railway carriages as a fuel load. The half-carriage designated F2Al was an aluminium bodied carriage, while the half designated F7 was steel bodied. The carriages were joined by a corrugated bellows, similar to those common on railway carriages. The tunnel was initially longitudinally ventilated at about 6–8 ms^{-1}. The first and second ignitions of the fuel load were rapidly

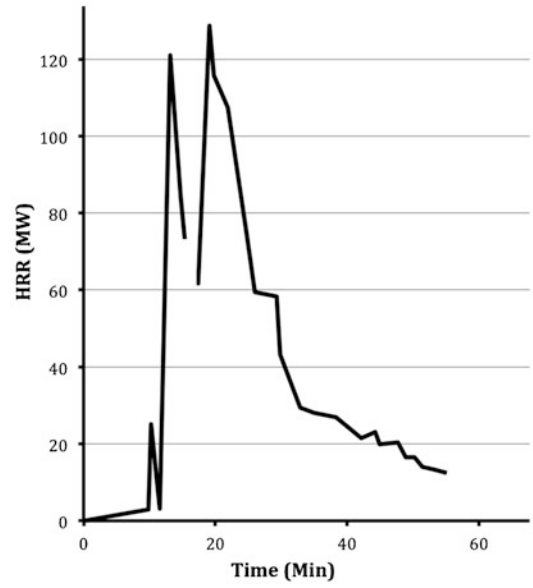

Fig. 88.2 Approximate representation of HRR data from Hammerfest HGV fire test HF1 (Adapted from [11]). The HRR during the period when the fan was shut down could not be estimated, so is not presented

extinguished following instrument failures. The third ignition of the fuel was carried out after adding about 360 wooden sticks to the carriages. The fire was ignited in the upstream aluminium carriage. After 32 min, the ventilation was stopped and restarted at a lower flow rate 4 min later. At approximately 48 min after ignition, the fire appears to have spread to the steel half carriage, and 'the whole car seems to ignite immediately' [1]. Shortly after this, the HRR peaked at about 43 MW, as shown in Fig. 88.3. The atypical fire behaviour during this test was due to the unusual test setup, ignition location and ventilation changes during the test.

Two fire tests were carried out with full railway carriages. The first test, designated FS1, involved an old steel bodied railway carriage which was refurbished with a 'modern' interior, similar to that used on a German 'Inter City Express' train. Tunnel ventilation was set on 'low' with the longitudinal airflow before the test being less than 0.4 ms^{-1}. The first ignition of this fuel load burned out without growing

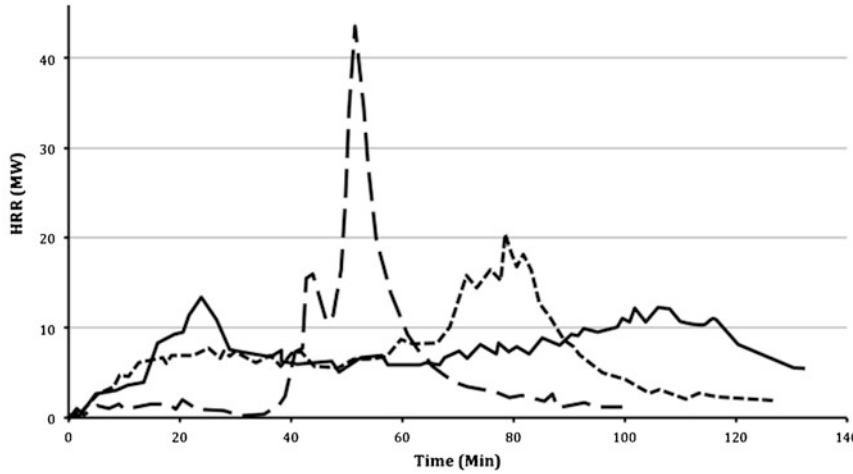

Fig. 88.3 Approximate HRR data from Hammerfest IC train test F11 (*solid line*) [10], ICE train carriage test FS2 (*short dash*) and joined half-carriage test FA3 (*long dash*) (Adapted from [13])

significantly after 18 min. Following this, 170 wood sticks were added to the carriage, in the vicinity of the ignition location, and some of the windows were opened. The fire was reignited, designated Test FS2. The fire grew and consumed all combustibles in the vehicle, reaching a peak HRR of 19 MW after 80 min, as shown in Fig. 88.3.

The second rail carriage test also featured a steel bodied inter-city vehicle, but with an older style interior to that tested in FS2. This test was designated F11. Once again, the ventilation was set to 'low'. The fire reached a peak of about 13 MW after about 25 min, which quickly diminished by about 50 % and then grew again to a second peak of about 12 MW after 90 min. A simplified representation of the HRR data from this test is given in Fig. 88.3.

The subway carriage tested was aluminium bodied and the seats in it were replaced with seats corresponding to the contemporary standards at the time of testing. Two ventilation panels and one of the carriage doors were left open for the test. Ventilation was set to 'low' as with other tests. The first ignition of the load (Test F41) used 0.7 kg of isopropanol in two fuel pans as an initial fuel, but this burned out before spreading to involve the rest of the carriage. The second ignition (Test F42) involved 6.2 kg of isopropanol in two larger fuel pans. This resulted in a very rapid fire growth and witnesses report the entire carriage was involved in the fire within 2 min. The peak HRR was about 35 MW after about 5 min, as shown in Fig. 88.1.

Large Fire Test in the 2nd Benelux Tunnel (2001)

A number of fire tests were carried out in the 2nd Benelux Tunnel, Rotterdam, the Netherlands, shortly before the tunnel was opened to the public [15]. The tunnel is rectangular in section and is approximately 5.1 m high by 9.8 m wide. While several of these fire tests involved vehicles and vehicle mock-ups, only one of the tests (Test 14) had a very large fire load using 72 wood pallets using a longitudinal velocity of 1–2 ms^{-1}. In three tests, designated tests 8–10, half this fuel load was used (36 pallets) but the velocity was varied from test to test.

In Test 14, eight stacks, each containing nine wooden 'Euro pallets', were arranged in a 2 × 4 configuration to represent a HGV cargo. Six car tyres were added to the load and two small bowls of petrol were ignited at the centre of the load to start the fire. The ventilation used was longitudinal at about 1–2 ms^{-1}. The primary aim of Test 14 was to investigate the capabilities of a sprinkler system in protecting a fuel tanker, which was

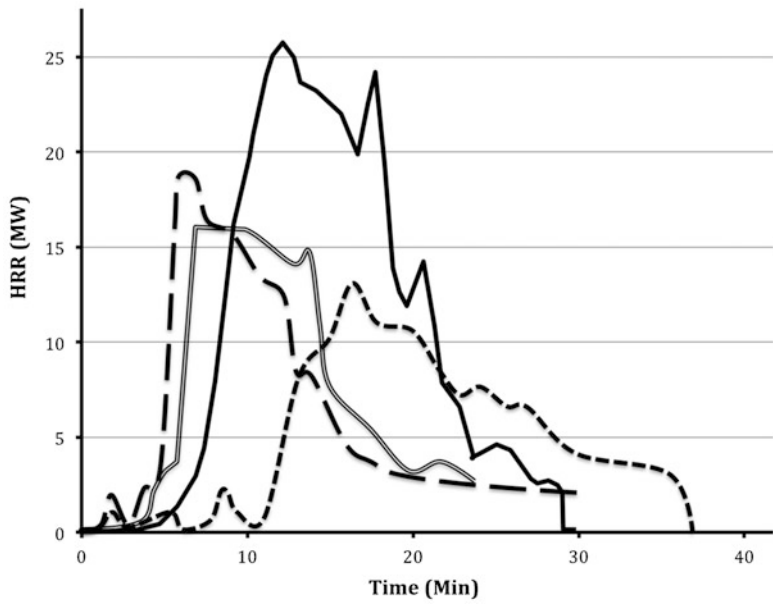

Fig. 88.4 Approximate representation of HRR data from [15]. Test 14 (*solid line*, 72 pallets, 1–2 m/s), Test 8 (*short dash*, 36 pallets, natural ventilation), Test 9 (*double line*, 36 pallets, 4–6 m/s) and Test 10 (*long dash*, 36 pallets, 6 m/s) of the Benelux tunnel fire tests

positioned downstream of the fire. The sprinklers above the tanker were activated after 21 min into the test. The sprinklers cooled the tanker, but were not directed toward the fire source until after 31 min into the tests when they were manually activated, meaning it burned freely most of the test time. In Tests 8–10, the fuel load consisted of four stacks with nine pallets in each without any interaction of the sprinkler system or any cover. In Fig. 88.4 the adapted data from Lemair and Kenyon [16] is given.

When observing Fig. 88.4 two important observations can be made. The maximum heat release rate is affected by both the ventilation rate and the number of wood pallets (tilt the flames), (i.e. the amount of fuel). Higher ventilation rates tend to spread the flames faster inside the pallets, and thereby increase the fire growth rate considerably (the growth rate of the fires varies considerably depending on ventilation rate). Consequently the maximum heat release rate is increased as the tilted flames spread faster through the entire fuel surface.

The Runehamar Tunnel Fire Tests (2003)

A series of four fire tests was carried out in a disused two-lane road tunnel in Norway in September 2003 [2, 3]. The tunnel is 1.6 km long and has a rough rock cross-sectional area of about 47–50 m^2. At the location of the fire experiments (approximately 1 km into the tunnel), a 75 m length of the tunnel was lined with fire-protective panels, and this reduced the cross-sectional area of the tunnel to 32 m^2 in the vicinity of the fire.

Each of the tests comprised a fire load of equivalent size and shape to a standard HGV trailer (10.45 m long, 2.9 m wide, 4.5 m high). In test 1, the fire load consisted of 11.0 tonnes of wooden pallets and mattresses. There was no plastic material except the tarpaulin, but that was the case in all the tests and a 'target' object positioned 15 m downstream of the fire. In test 2, the fire load consisted of 6.9 tonnes of wooden pallets and mattresses. In test 3, the fire load consisted of 7.8 tonnes of furniture on wooden pallets, and ten tyres (800 kg) were positioned around the frame at the locations where they would be on a real HGV trailer. In test 4, the fire load consisted of 2.85 tonnes of plastic cups in cardboard boxes on wooden pallets. In each test the amount of plastic materials was estimated to be about 18–19 % (by weight). Similar tarpaulin coverings were used in all four tests. In each test, two mobile fans positioned near the tunnel portal were used to generate a longitudinal

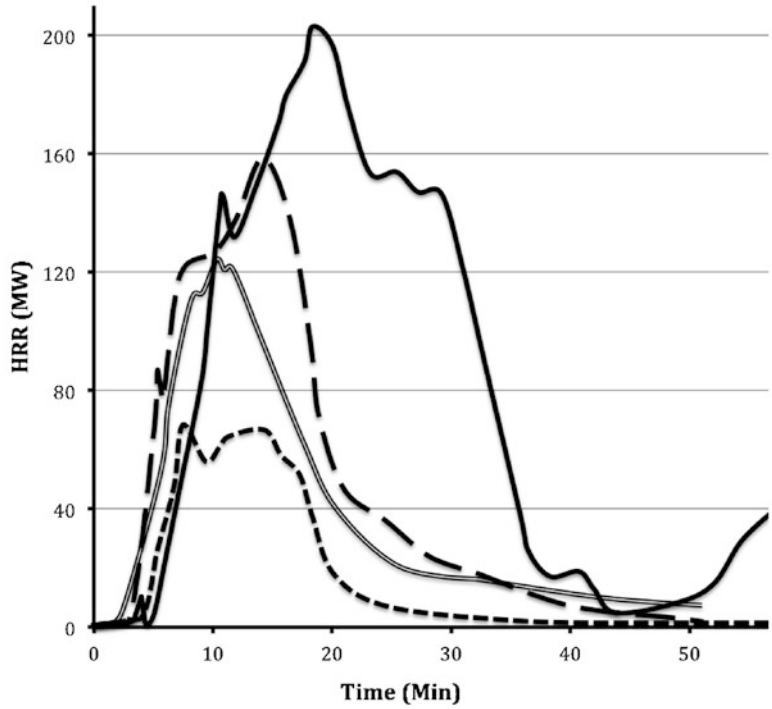

Fig. 88.5 HRR data from the Runehamar fire tests [2, 3] with Test 1 (*solid line*), Test 2 (*long dash*), Test 3 (*double line*) and Test 4 (*short dash*)

airflow, this was about 3 ms^{-1} at the start of each test, but reduced to about 2–2.5 ms^{-1} once the fires became fully active. The peak heat-release rates of the fires in tests one to four were 202, 157, 119 and 67 MW, respectively. The HRR data are shown in Fig. 88.5.

Fire Tests at Carleton University (2011)

Two full scale fire tests were carried out in a 10 m wide, 5.5 m high by 37.5 m long 'tunnel' facility at Carleton University in Canada [17]. The facility is open to the outside through a reduced height opening at the 'upstream' end and is blocked at the 'downstream' end, with an opening in the ceiling leading to smoke/air extraction ducts. The ventilation in the facility is generated by extraction fans, with a maximum capacity of 132 m^3/s. One of the tests involved an intercity style railway carriage, 23 m long, 3 m wide and 3.7 m high, while the other test involved a subway car which was 19.7 m long, 3.15 m wide and 3.45 m high. The estimated fire load of the railway car was 50 GJ and the estimated fire load of the subway car was about half of that. In both tests the extraction system was initially set to 50 % capacity, but was increased to maximum capacity after 3 min into the subway car test and 6 min into the intercity car test. The longitudinal flow during the experiments is not reported in the paper, but is assumed to decrease as the fires grew, due to greater volumes of smoke generated, yet a constant extraction rate. The HRR data, estimated by oxygen consumption, are shown in Fig. 88.6.

Subway Car Tests During Project METRO (2011)

Two fire tests involving fires inside subway cars were carried out as part of the METRO project in Sweden in 2011 [4, 5]. The fire tests were carried out in the 276 m long abandoned 'Old Brunsberg Tunnel' in Western Sweden. The tunnel is an irregular horseshoe in shape and varies from 6.7 to 7.3 m high and from 5.9 to 6.8 m wide. One

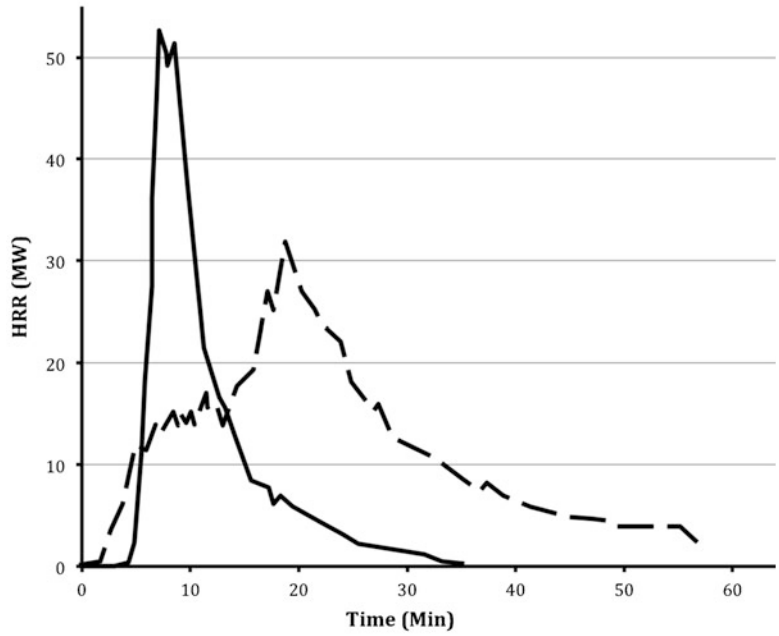

Fig. 88.6 Approximate representation of HRR data from the Carleton University fire tests. The rail car is indicated by the *broken line* and the subway car by the *continuous line* (Adapted from [16])

subway carriage was used as supplied, with older style seats and furnishings, the other was refurbished inside to resemble a modern 'C20' train carriage. This was obtained by cover the combustible wall and ceiling linings with 1.5 mm thick aluminium sheets. A realistic selection of luggage types were placed in the subway carriages as fire load. Longitudinal flow in the tunnel was generated by a mobile fan, positioned upstream of the fire location. This generated a flow of between 2 and 2.5 ms^{-1}, before the fire was ignited. At peak burning, the fires both resisted the airflow, effectively reducing the flow velocity (see the discussion of the 'throttling effect' in section "Using Ventilation Systems for Fire Safety in Tunnels," below). The fire tests were intended to simulate an arson fire on a subway carriage, so both fire tests were initiated with a small quantity of gasoline/petrol on one of the seats. In the test involving the old style carriage, the fire rapidly took hold and grew to flashover-like conditions within the carriage in a few minutes. In the test involving the refurbished carriage, the fire remained small and localised for over 100 min. However, this test also eventually reached flashover-like conditions and from there rapidly transitioned to a fully involved fire, much like the earlier fire test had done at about 12 min after ignition. This was due to the 'melted' aluminium sheets. Following this rapid fire growth, both tests exhibited very similar fire behaviour, as shown in Fig. 88.7, both reached a peak of about 77 MW, both burned at this level of intensity for about 12 min, before rapidly decreasing in intensity to below 20 MW, then slowly burning out over the next 30 min.

Observed Tunnel Fire Characteristics

In the design of fire safety systems in tunnels there is often a need for a "design fire". This fire may be obtained from tabulated data or it may be based on engineering methods calculating the actual fire growth and maximum HRR. The tabulated data is often based on consensus of technical committees such as NFPA or PIARC. A round table discussion using the latest test results such as those presented above informs proposals about the highest value for different vehicle types. This gives guidance to engineers that need the information for design of ventilation systems, the tunnel structure or evacuation

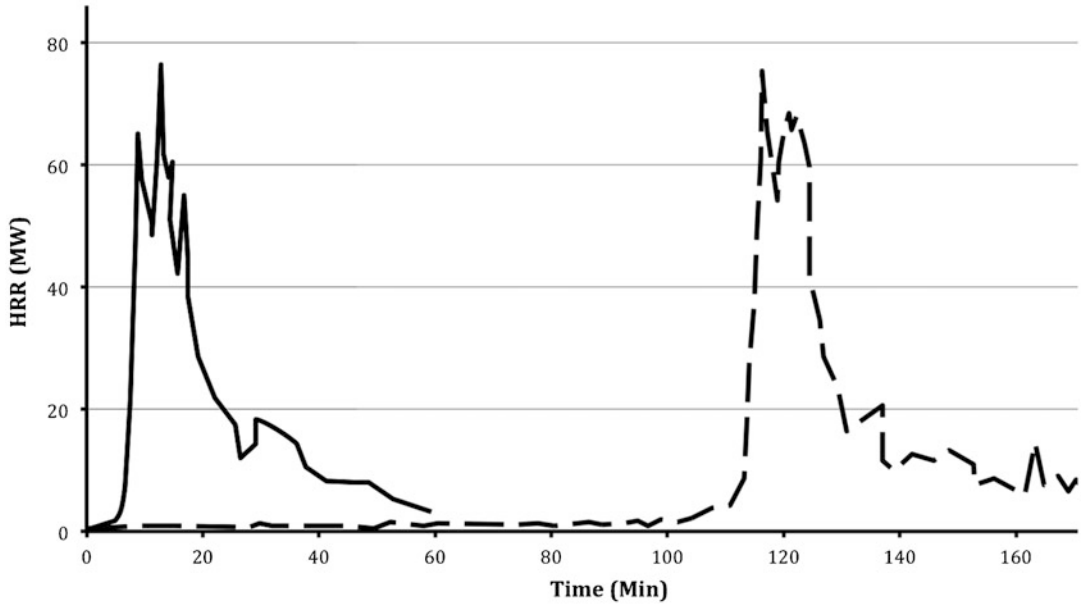

Fig. 88.7 Approximate representation of HRR data from the METRO project fire tests [4, 5]. Test 2 is indicated by a *solid line* and Test 3 with a *double line*

procedures. Traditionally it has been the design of the ventilation capacity that has been the primary focus of designers, although structural considerations have become more important in recent years. As advanced calculation models have been created and developed, the need for realistic design fires has increased.

Most fire protection engineers are familiar with the general picture of a compartment fire which grows in a 't^2' manner from ignition to flashover, burns at a more or less constant, ventilation controlled, peak heat release rate for a significant period of time, before beginning to burn out and entering a decay phase. Because of this familiarity, fire protection engineers have frequently tried to apply the same concepts and assumptions to tunnel fires. However, the above survey through the published tunnel fire heat release rate data should be sufficient to demonstrate that vehicle fires in tunnels do not conform to this common assumption.

It is clear from the above presented data that tunnel fires, particularly when influenced by longitudinal ventilation, do not grow in anything like a t^2 manner. Instead the growth of a tunnel fire may more readily be characterised by a two step linear growth model [18]. The first step in this process, which is generally characterised by slow fire growth is variously described in the literature as the 'incipient', 'incubation' or 'delay' phase, may last for a very long time, as demonstrated by the METRO results (see Fig. 88.7), but may be as short as a few minutes. It is currently unclear exactly what factors govern how long the incipient phase lasts, although it has been suggested that variations in ventilation velocity may reduce or extend the duration of this phase [18]. The second step in this process is a very rapid growth phase which, in tunnels with significant ventilation flow, generally appears to reach peak fire size in just a few minutes. As is clear from Fig. 88.4, above, the rate of growth in this phase varies with longitudinal ventilation velocity [18]. Other models of fire growth are available, including the exponential model presented by Ingason [19] which has the benefit that the entire fire growth, peak and decay process can be described with a single mathematical expression.

Another way in which vehicle fires in tunnels differ from the common compartment fire model is in the duration of peak burning. By peak burning we mean the period where most of the fuel is fully involved in an intensive burning. In the majority of cases described above, the period of peak burning was relatively short, mostly less than 10 min and almost always shorter than 20 min, and was generally followed by a decay which was almost as fast as the rapid growth phase.

Another interesting aspect of vehicle fires is the observation that the HRR per square meter of exposed fuel is generally found to be in a very narrow range. This was first observed through analysis of the several tunnel fire tests [20] and it has been shown that the recent large scale tests in the METRO project confirm this trend. For most vehicles the maximum HRR per square meter of exposed burning fuel surface between 0.27 MW/m^2 and 0.4 MW/m^2, even for fully involved 'post flashover' railway carriages. The METRO tests were equivalent to 0.31 MW/m^2 at maximum HRR. This information can be used to estimate the potential maximum HRR for different types of vehicles. In HGV cargo this value may vary from 0.1 to 0.5 MW/m^2, where the cellulosic materials will tend to have values at the lower end of the range, whereas plastics will tend to have higher values.

It is proposed that these features, common to all large fire experiments in longitudinally ventilated tunnels, be considered when defining 'design fires' for tunnels. This will be discussed in more detail below.

Multiple-Vehicle Fires and Fire Spread

All tunnel fire incidents which have been characterised under the heading of 'catastrophic tunnel fires' have involved fire spread from the initial vehicles involved in the incident, to other vehicles in the vicinity. Table 88.1 lists some of the most significant multiple vehicle fires of recent years. For a more comprehensive list, with details of these and many other incidents, see Carvel and Marlair [21].

In order to understand the fire spread in many large tunnel fires with multiple vehicles involved it is necessary to recognise how these fires progress and spread. Fires in road tunnels may start in one vehicle or in two vehicles due to a collision and then spread to the adjacent vehicles largely by radiation from the flames and the hot smoky gases. In rail vehicles at least one carriage needs to become fully involved in order to obtain fire spread between different carriages. It is not only the nature of the vehicles themselves that is required for a fire spread, but also the geometry of the tunnel, especially the tunnel height, and the ventilation conditions. The main mechanism of fire spread is through heat transfer by convection, radiation and conduction from the volume

Table 88.1 Significant recent multiple vehicle fires [20]

Tunnel	Initial cause	Vehicles involved	Country	Year
Eiksund tunnel	Collision	Lorry and van	Norway	2009
Channel Tunnel	Possible electrical fire	25 HGV and 2 vans, train locomotive and carriages	UK/France	2008
Newhall pass tunnel	Collision	33 HGV	USA	2007
Burnley tunnel	Collision	3 HGV and 4 cars	Australia	2007
Viamala tunnel	Collision	Bus and 2 cars	Switzerland	2006
Fréjus tunnel	Overheating	4 HGV	France/Italy	2005
Baregg tunnel	Collision	3 HGV and car	Switzerland	2004
Daegu subway	Arson	2 subway trains	South Korea	2003
St Gotthard tunnel	Collision	23 vehicles, mostly HGV	Switzerland	2001
Tauern tunnel	Collision	16 HGV and 24 cars	Austria	1999
Mont Blanc tunnel	Overheating	34 vehicles, mostly HGV	France/Italy	1999
Channel tunnel	Possible overheating	10 HGV, train locomotive and carriages	UK/France	1996

of flames and hot gases. The difference in the temperatures between the cooler solids and the hot gases drives this heat transfer.

Among the more spectacular fires that have occurred in tunnels are the large fires in the Channel Tunnel with HGVs on open train wagons in 1996 and 2008 [22]. Rew and Deaves [23] postulated five mechanisms for fire spread in tunnels in their analysis of the 1996 incident. These mechanisms are discussed in detail by Carvel [24] or chapter 11 in Ingason et al. [8]. The first mechanism of fire spread in large fires is **flame impingement**. In low ventilation conditions, the flames are deflected by the presence of the ceiling, mainly in the direction of the ventilation flow. The flames appear to 'crawl' along the ceiling above the vehicles, see Fig. 88.8. Rew and Deaves [23] presented a flame length model for tunnels, which included the heat release rate of the initial fire and the longitudinal flow velocity but not the tunnel width or height. Much of their work is based on the investigation of the Channel Tunnel fire in 1996, with test data from the HGV-EUREKA 499 fire test [1] and the Memorial Tests [6]. They defined the horizontal flame length, L_f, as the distance of the 600 °C contour from the centre of the HGV or the pool, or from the rear of the HGV, see Fig. 88.8.

The other mechanisms of fire spread in tunnels are **surface spread**, that is to say flame spread across the surface of the fire load, **remote ignition** (or spontaneous ignition); the conditions at vehicles that are not very close to the initial fire are raised to the point of spontaneous ignition due to the high temperatures produced by the fire. Another is **fuel transfer**, since burning flammable liquids can spread from fuel tanks in the downhill direction, or flaming debris may blow downwind of the fire. The last mechanism postulated was **explosion** i.e. explosion of fuel tanks may spread burning fuel to adjacent vehicles. None of these other postulated mechanisms fully explain the fire spread between multiple vehicles which has occurred in large tunnel fires. The first mechanism postulated, i.e. **flame impingement**, in combination with spontaneous ignition when the flames virtually crawl over the target vehicle, as shown in Fig. 88.8, is generally the most plausible option. This has been confirmed through numerous full scale and model scale tests performed by SP, the Technical Research Institute of Sweden (SP) [3, 25–28]. Other works on fire spread in tunnels can be found in the work by Beard et al. [29–32].

The possibility of ignition of the target vehicle can be obtained by investigating whether or not the exposed surfaces of the vehicle would attain a critical ignition temperature, T_{cr}. There are two types of ignition, piloted ignition or spontaneous ignition. The possibility of ignition of the target vehicle can be obtained by evaluation of whether or not the exposed surface would attain a critical ignition temperature. The critical temperature, T_{cr}, varies with the nature of the target material, but is generally estimated as follows: 600 °C for radiant exposure or 500 °C for pure convective exposure in the case of spontaneous ignition; or, 300–410 °C for radiant exposure or 450 °C for pure convective exposure in the case of piloted ignition. Note that these values are mostly deduced from experiments on small vertical specimens [33]. Newman and Tewarson [34] argued that, at ignition, $T_{cr} \approx T_{avg}$ (the average gas temperature over the cross-section at a

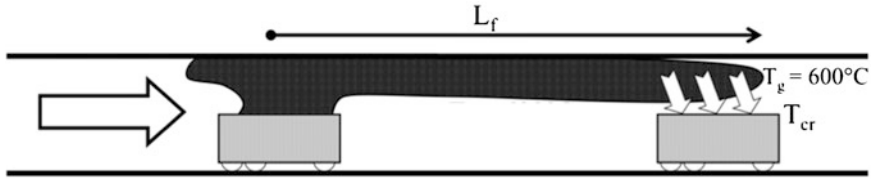

Fig. 88.8 The flame impingement mechanism in tunnels with longitudinal flow. The target vehicle is about to ignite and L_f is the flame length [24]

certain position) for a duct flow, i.e. when the T_{avg} has obtained a critical ignition temperature, the material at that location will ignite. This would comply with the flame impingement mode discussed earlier and complies well with the experimental observations obtained by SP.

There is a strong correlation between the ignition and the ceiling gas temperature in a ventilated tunnel fire [3]. The critical ceiling gas temperature, i.e. the minimum ceiling gas temperature required to ignite the material, has been analyzed for full and model scale tests. In the vicinity of the flame volume, radiation dominates the heat transfer. Since the tunnel ceiling is enclosed by the flame and hot gases, the view factor can be regarded as being unity. Thus the incident heat flux at the ceiling can be simply expressed as [3]:

$$\dot{q}''_{inc} = \varepsilon_g \sigma \left(T_g^4 - T_s^4 \right) \qquad (88.1)$$

where ε_g is the gas emissivity, σ Stefan-Boltzmann constant (kW/m^2·K^4), T_g is the gas temperature in degrees Kelvin and T_s is the solid surface temperature, also expressed in Kelvin. According to Ingason and Li [35], a gas temperature of 600 °C should be obtained for wood before its spontaneous ignition in model tunnels, see Fig. 88.9.

In a recent work by Ingason et al. [3] analyzing the Runehamar fire test data, it was concluded that the critical ceiling gas temperature is about 700 °C for fire spread to a wooden object *at the floor level* and about 600 °C for fire spread to a wooden object with *surface close to the ceiling* in a tunnel fire. The location of vehicle target surface relative to the smoke layer height plays therefore an important role in fire spread. Therefore, the authors argue that fire spread to subsequent vehicles is very difficult to occur if the vehicle height is small compared to the tunnel height, perhaps below about half the tunnel height [3].

When the fire starts to spread to the second vehicle the fire development is difficult to stop if there are more vehicles in the vicinity of the first two vehicles. Figure 88.10 gives a schematic description of a large tunnel fire with relatively high forced longitudinal ventilation rate and multiple vehicles. The burning process can be viewed as stationary and the fire-spread progress can be divided into different key zones [25, 36]:

Provided there are sufficient vehicles in the vicinity of the initial fire, these different zones move forward in a dynamic manner. The 'burnt out zone' involves vehicles that have been completely consumed in the fire and where the fire gases are now cool. The 'glowing ember

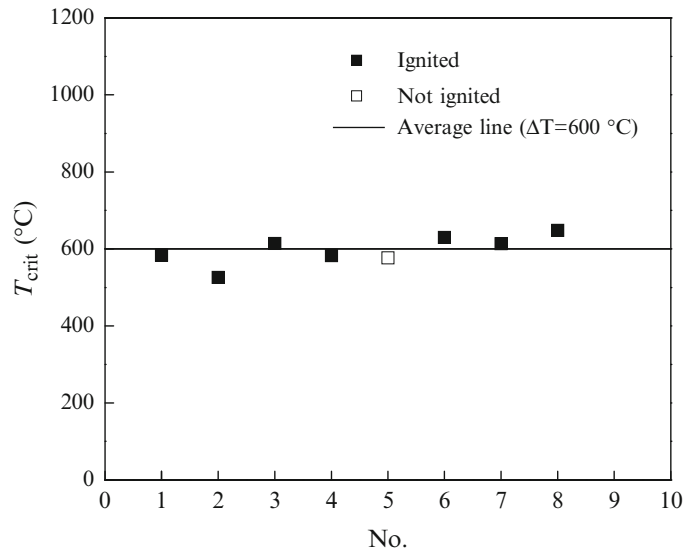

Fig. 88.9 The critical gas temperature beneath ceiling when a second wood crib ignites [26]. The number on the *horizontal axis* refers to test number in the test series

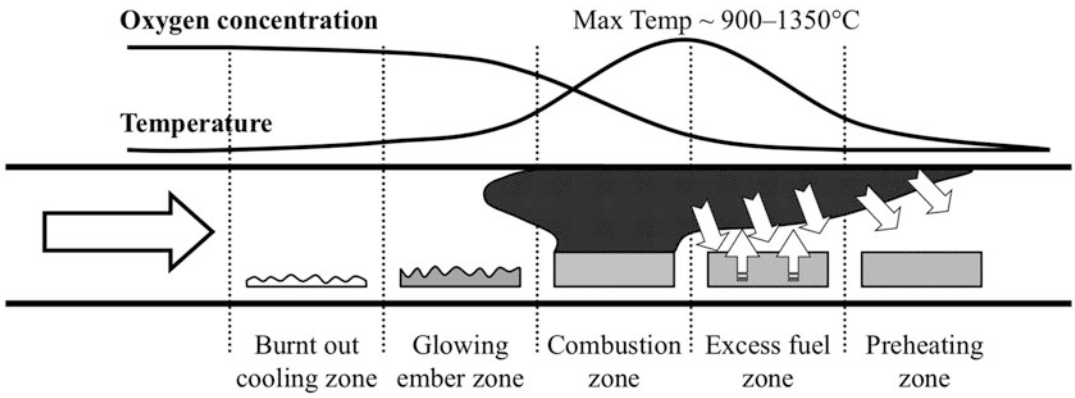

Fig. 88.10 Schematic presentation of a flame impingement fire spread process in a tunnel with multiple vehicles/coaches [24, 35]. Note: there may be multiple vehicles in each designated zone, and the zones are only shown as having the same length as each other for convenience

zone' contains vehicles at a very late stage of the decay phase (predominantly a pile of glowing embers). The 'combustion zone', contains the violently burning vehicles (fully developed fire) where sufficient fuel is vaporising to support gas phase combustion. Flaming combustion is observed throughout this zone. The gas phase temperature in this zone increases rapidly. Simultaneously the oxygen is rapidly depleted and the temperature reaches a maximum just beyond the 'combustion zone'. This gas temperature can vary between 900 and 1365 °C.

If all the oxygen is consumed within the combustion zone, an 'excess fuel zone' starts behind this. In the case where all the oxygen has been depleted we have a **ventilation-controlled** fire. In the case where useful oxygen is still available (due to flammability limits, oxygen concentrations below about 8–10 % may not be 'useful' unless the gas phase temperature is high enough to sustain combustion) we have a **fuel-controlled** fire and no excess fuel (no more vehicles in place to sustain the progress). In the case of ventilation-controlled fire, the fuel continues to vaporise from the vehicles throughout this zone up to a point along the tunnel where the gas stream has cooled to the fuel vaporisation (pyrolysis) temperature ($T_{vap} \geq 300$ °C for the majority of solid materials). Beyond this point, no vaporisation of the vehicle materials occur but the gas flows into a 'preheating zone' and loses its heat to the tunnel walls and preheats the vehicle material within this zone.

de Ris [36] showed that the combustion and excess fuel zone lengths are proportional to the forced ventilation rate when the fire becomes ventilation-controlled and Comitis et al. that the fire will propagate at a constant speed [37] (when ventilation-controlled) provided that there is enough combustible material available. Delichatsios [38] concluded that active burning in a fibreglass-reinforced plastic duct will take place up to a maximum length corresponding to $L_c/D_h = 10$ where D_h is the hydraulic diameter of the duct (m) and L_c is the combustion length (m). Assuming that this number is reasonable for tunnels the combustion zone, for a ventilation-controlled fire with forced ventilation, would not exceed 50–100 m for most common road and rail tunnels (assuming high vehicle density) where D_h is ranging between 5 and 10 m.

Considerations for Design Fires for Vehicle Tunnels

Tunnel designers, ventilation engineers, suppression system manufacturers and others commonly need to define the characteristics of the fire which they are designing their facilities or systems to be able to manage. Thus, specification of *realistic*

design fires is of great importance, if tunnel facilities and systems are to be made robustly.

A design fire need not be the most severe fire imaginable for a given situation, but should be at the upper bound of fire scenarios deemed credible, or likely to happen within a specified timescale. In other words, it need not be necessary to design a system to be able to manage a 'once in 10,000 years' incredible event, but consideration should be given to the more likely, though still improbable, 'once in 1000 years' type event.

Design fires should also be tailored to the system being designed. For example, a design fire for structural protection or structural resistance calculations should be radically different to the design fire used for the detection and alarm system.

There are a number of guidance documents which discuss design fires for tunnels, which go into the subject in far greater detail than can be devoted here, including [39–41]. These brief comments are intended to enable the designer to consider realistic fire features in design fires.

Design fires for tunnel structures, fire protection system design and smoke management should be based on the realistic maximum peak fire size. Such design fires need not consider the incipient stage of the fire, and assuming the growth phase to be of only a few minutes in duration, this can be neglected too. The design fire here should therefore be characterised by a maximum HRR plateau, from the outset, the duration of which should be prescribed on the basis of the maximum number of vehicles deemed likely to be involved in a fire. The duration of peak burning is limited by the availability of fuel and the availability of oxygen, and therefore this period of peak burning can be extended if additional fuel becomes available by means of the fire spreading to an adjacent vehicle or vehicles.

For property protection purposes it is also important to consider the cooling/decay phase of the fire, as it is well known that some structures which have endured throughout a fire or a furnace test at high temperature have failed as they cool, however this is rarely commented upon in the literature.

In situations like the experiments described above, where the fire load was large, relative to the tunnel, the peak HRR may be defined and limited by the available oxygen in the airflow. The maximum theoretical (ventilation-controlled) HRR may be estimated using the well known correlation between HRR and the mass of oxygen consumed in a longitudinal ventilation flow:

$$\dot{Q} = \left(0.21 - \eta_{O_2}\right) V \rho \Delta H_{c,ox} \qquad (88.2)$$

where η_{o2} is the depleted oxygen level on the downstream side, V is the volumetric airflow, ρ is density of the inflowing airflow (approx. 1.2 kg/m^3) and $\Delta H_{c,ox}$ is the heat of combustion for oxygen, generally taken to be 13 kJg^{-1} [42].

Thus, for example, in a tunnel with a 40 m^2 cross section and a 2 ms^{-1} longitudinal flow, we might expect the theoretical maximum ventilation controlled HRR to be about:

$$\dot{Q} = (0.21 - 0.0) \times 2 \times 40 \times 1.2 \times 13.02 = 262\ MW$$

It should be noted that in most circumstances with one or two collided vehicles involved in a fire, it is not likely that all the oxygen in the airflow will be usable by the fire as much of it may bypass the combustion zone. In the case when another vehicle is standing downstream a fire, the environment may not be combustible due to flammability limits (relation between the oxygen concentration and gas phase temperature).

It is important to note here that, provided sufficient fuel is available (for example, in multiple vehicle fire scenarios), it is the tunnel airflow which defines the theoretical peak fire size, and hence should define the design fire for structural purposes. A similar design fire should be used also for dimensioning the ventilation system. If fuel is limited, for example by considering only a single vehicle fire, then the fire may remain fuel controlled and the peak size may be estimated based on the fuel area, as described above [20].

However, this idea goes against the notion, so prevalent in the tunnel fire and design literature, that a ventilation system designer should first

identify a 'design fire' size and then dimension the ventilation system in order to generate adequate smoke control. In the case of a multiple vehicle fire, the fire size does not define the required airflow, rather the airflow entirely defines the maximum possible fire size.

This relationship, where the theoretical maximum fire size is defined entirely on the basis of ventilation flow, will hold in general terms in situations like most of those described above, where the vehicle on fire is large, relative to the cross-section of the tunnel; that is to say, in single lane tunnels, which are generally subway and railway tunnels. The relationship is not likely to be as simple as this in two or more lane tunnels, such as are common for road transport. In larger tunnels, it is expected that a greater proportion of the longitudinal airflow will bypass, not directly feed the fire, so the resulting HRR could be significantly lower.

For single lane tunnels where multiple vehicle fires are possible, however, it is proposed that the peak HRR of a 'design fire' for structural and ventilation considerations, should be based entirely on the anticipated longitudinal airflow in the tunnel.

As noted above, the factors governing the duration of the incipient phase are not well understood at the present time, therefore, without further tests to demonstrate the performance of a particular system, it should be assumed—for design purposes of all tunnel systems—that the incipient stage will remain short, perhaps only of the order of a few minutes. Assuming an extended incipient phase as part of a design fire cannot be justified from the above data.

Design fires for detection systems and water spray systems need to consider the growth phase of the fire. Such systems are intended to detect the fire while it is as small as possible, and to suppress or control the fire, that is to say, prevent the fire from reaching its unsuppressed potential. The important characteristics of a fire for design of a water spray system are therefore those relating to fire growth [18]. Important parameters to consider here are the ventilation rate in m/s and the ceiling height. These parameters govern, together with the HRR at each time interval, the gas temperature at the tunnel ceiling. The location of the maximum gas temperature varies along the ceiling depending on these parameters. For further information see Li and Ingason [43].

Using Ventilation Systems for Fire Safety in Tunnels

The systems which we commonly consider to be safety systems for tunnels were not, in most instances, initially installed in tunnels as safety devices. The most common safety system in tunnels is the ventilation system, yet it must be recalled that the original and primary function of ventilation systems is not smoke management in the event of a rare event like a fire, but rather is pollution and environmental control in everyday usage.

The first ventilation system installed in a railway tunnel was in Liverpool's Edge Hill tunnel in the UK, in 1870, although mechanical ventilation had been commonplace in mine tunnel networks for at least three centuries before this [44]. This was an exhaust fan for the removal of smoke from steam engines. In 1927, the Holland Tunnel in the USA became the first road tunnel equipped with a (fully) transverse ventilation system, that is, a system of ducts and openings provided fresh air into the tunnel at periodic locations along its length, while a second system of openings and ducts extracted polluted air from the tunnel at periodic locations. The first tunnel to have longitudinal ventilation with jet fans was the Bargagli-Ferriere tunnel in Italy in 1971. While all these systems were originally conceived as means of replacing polluted air with fresh air, these systems began to be understood as a means of controlling smoke in the event of a fire in a tunnel. The addition of jet fans to transversely ventilated tunnels in the 1980s (for example, the Dartford tunnel in the UK) reflects this change in mindset. In 1994, the Channel Tunnel opened with the world's first ventilation system intended 'from the drawing board' as a smoke control system as well as a pollution control system [45].

Because almost all tunnels of significant length have ventilation systems, it is easy to understand why these systems became adapted to be emergency response devices. For the past two decades, perhaps longer, the tunnel safety industry appears to have been fixated on questions associated with using ventilation for smoke control in the event of a tunnel fire. The question of appropriate design for ventilation systems has therefore been generally reduced to the question of extract capacity, for transversely ventilated tunnels, or of identifying the 'critical ventilation velocity' (CVV) for tunnels with longitudinal ventilation.

The CVV is generally defined as the minimum longitudinal ventilation velocity required to blow all the smoke produced by a fire in a tunnel to one side of the fire location, that is, to prevent any smoke propagating upstream of the fire location, against the prevailing airflow. CVV varies with tunnel geometry and with fire size, up to a certain limit. A number of studies, including that of Oka and Atkinson [46], have identified that there is generally a 'super critical ventilation velocity' which is sufficient to control the smoke from all sizes of fire, for a given tunnel geometry. A review of tunnel CVV studies is presented by Ingason [47] and need not be repeated here.

The critical flow conditions are generally expressed in the literature in terms of a single ventilation velocity, which is commonly taken to be the average flow across the tunnel cross-sectional area, however, it may be better in some instances to speak in terms of a critical volumetric flow rather than a velocity. The focus on ventilation velocity also masks the throttling effect of tunnel fires, identified in the 1970s by Lee et al. [48]. In a given tunnel it may well be the case that, say, a 3 ms^{-1} airflow may be sufficient to control smoke in the event of either a 50 MW fire or a 100 MW fire, but expressing the situation in these terms hides the fact that more ventilation devices will be required in the case of a 100 MW fire to generate the 3 ms^{-1} airflow than would be required to generate the same magnitude flow in the case of a 50 MW fire. A computational example of this, derived from Vaitkevicius et al. [49], expanding on the work of Colella et al. [50], is shown in Fig. 88.11. Here, there is no increase in CVV beyond 31 MW, yet the number of fans required to generate the CVV continues to increase with fire size.

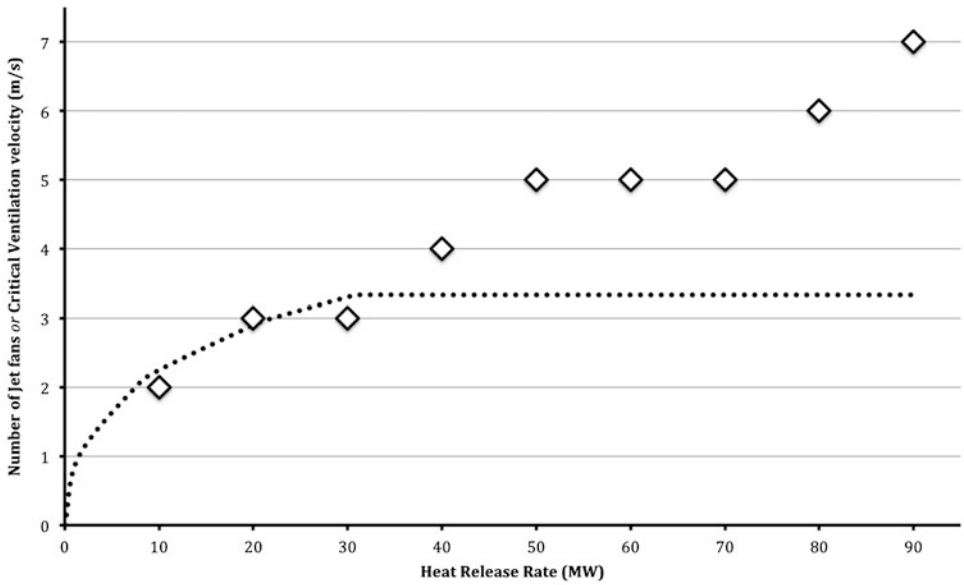

Fig. 88.11 Critical Ventilation Velocity (CVV; *dotted line*) and the number of jet fans required to generate CVV (*diamonds*) vs. fire heat release rate, for a modelled rectangular tunnel (Adapted from Vaitkevicius et al. [49, 50])

While our understanding of longitudinal ventilation for smoke control is reasonably advanced [51], our understanding of the influence of ventilation on fire behavior is considerably less mature. Various studies in the past decade have shown that peak fire size is influenced by longitudinal ventilation velocity [52] and by the geometry of the tunnel [53], other studies have shown that longitudinal ventilation also has a significant influence on fire growth rates [18, 27]. Each of these factors must be considered when designing ventilation systems for use in emergency situations.

As observed above, in tunnel fire experiments the fire tends to grow in two reasonably distinct stages. For the first few minutes after ignition there is an incipient phase, followed by a period of much more rapid fire growth. From observation of the experimental tunnel fire data, there appears to be a weak relationship between the length of the incubation phase and the longitudinal ventilation velocity [18]. Such limited data as are available suggest that the incipient phase is generally shorter at longitudinal velocities of about 2–3 ms^{-1} than it is at lower (0–1 ms^{-1}) and higher (circa 6 m/s) velocities. This suggests that ventilation flows of about 2–3 ms^{-1} should be avoided in the initial stages of a fire. Unfortunately, 3 ms^{-1} is close to the CVV for design fires in many tunnels, so has commonly been used as an emergency ventilation flow. However, it should be noted that many different (and apparently contradictory) emergency ventilation strategies are used in tunnels worldwide, some opting to increase the flow greatly when a fire is detected, in order to dilute the smoke, while others opt to reduce the flow below about 1.5 ms^{-1}, in order to maintain smoke stratification.

There are also issues associated with reversing ventilation direction [54]. It appears, from an analysis of the Channel Tunnel fire incidents, that changes in the direction of the airflow, after a fire is fully developed, can lead to very rapid fire spread between vehicles and very fast fire growth rates, but further work is required to confirm these observations.

Passive Fire Protection: Tunnel Lining Systems

As with ventilation systems, the original intent of the tunnel lining system was not as a fire protection system, and many older tunnel lining systems which are still in use today serve only a cosmetic function and provide no fire protection. Tunnel lining systems were primarily installed to act as drip shields, to provide a visual aesthetic and, in some instances, for acoustic reasons.

Today, while the above reasons remain valid, the main design consideration for tunnel lining systems is how much thermal protection they can provide for the primary tunnel structure. Modern tunnels are generally made of concrete, although many older tunnels constructed out of cast iron segments or masonry are still in use. Concrete has excellent structural properties at ambient temperatures, but may fail when subjected to high temperatures and rapid heating, under fire conditions.

According to the guidance of NFPA 502 [55], the primary concrete structure in tunnels with cast in situ concrete provided with structural fire protection material temperatures shall not exceed 380 °C at the concrete surface and 250 °C at any of the rebar, when subjected to a time-temperature curve deemed equivalent to a tunnel fire. These requirements are mirrored in other standards [56]. Temperatures up to these limits will not significantly reduce the load carrying capacity of concrete.

One major concern with concrete structures is the still inadequately understood phenomenon of spalling [57]. Spalling is an explosive failure which commonly occurs when concrete is rapidly heated and steep temperature gradients are formed in the bulk material, leading to thermal stresses and high pore pressures in the material. Spalling has also been observed during rapid cooling, such as during fire-fighting activities [58]. Spalling has even been observed to occur at relatively low temperatures [59], so the function of a fire protection system is not merely to protect the structure from exposure to high

temperatures, but also to protect the structure from rapid heating. As well as having excellent thermal barrier properties, it is vitally important that passive fire protection systems not be prone to spalling themselves.

Passive protection systems for tunnels are generally either a bolted on panel system or a sprayed on mortar system. Other options, such as intumescent coatings which are common in the building industry, do not seem to have been considered for tunnel applications. Research is on-going into the performance in fire of concrete containing various forms of fibres, some of which have been demonstrated to resist spalling and, thus, improve the fire resisting properties of concrete [60]. However, neither a spalling proof concrete mixture, nor a method for accurately predicting spalling behaviour has yet been developed. If suitable concrete mixes can be developed, this may have a considerable impact on the way that future concrete tunnel structures are made.

Finally, there is an increasing tendency in the tunnel protection industry to consider fire suppression systems as structural protection systems, and a number of recent papers have discussed 'trade-offs', that is, reducing or removing the requirement for a passive thermal barrier system if a suppression system is being installed [61, 62]. This will be discussed further in the next section.

Water Spray Systems

It is the opinion of one of the authors that the terminology used to describe water based fire protection systems these days is somewhat misleading [63]. The way the word 'suppression' is used by fire protection engineers strays considerably from the dictionary definitions of the word 'suppression' used by the rest of the world. Describing water spray systems as 'suppression' systems implies that these technologies have the ability to halt the growth of, or reduce the size of fires in tunnels. According to the definition given by NFPA 502, "Fire suppression systems are designed to arrest the rate of fire growth and significantly reduce the energy output of the fire shortly after operation". In order to do that the system has to be able to deliver certain amount of water onto the burning fuel surface and actively cool it. Simultaneously it has to have the ability to hinder fire spread to adjacent fuel surfaces. As will be discussed below, neither of these abilities is guaranteed or even commonly observed with many 'suppression' systems promoted for use in tunnels. Such systems do not fulfill the basic requirements implied in the word 'suppression'.

Similarly, the terminology which seems to be in vogue at present, 'fixed fire fighting systems' (FFFS), implies that the systems so described are actually able to 'fight' fires. Once again, this is not always guaranteed. There is a need for clear definitions that should be accepted by all involved partners. The term "deluge system" relates to systems with open nozzles operated on zone-to-zone basis creating water droplets in order of 1 mm, whereas "water mist system (WMS)" is a high-pressure deluge system creating very small droplets, in order of 50–250 μm. The blanket term FFFS is used to include all these system, together with foam based systems (high expansion, CAFS), which we do not consider in the short discussion here. The terms 'suppression' and 'fire fighting' both imply performance criteria which not all systems described as such can achieve. Thus, the term water spray system will be use here to include both deluge systems (even with foam additives) and water mist systems.

Although the benefits of fire sprinkler systems in buildings have been recognized widely for many years, the use of water spray systems in tunnels has generally been discouraged until comparatively recently. However, this generalisation is not universal. Deluge systems have been routinely used in Japanese tunnels since the 1960s, and in Australian tunnels since the early 1990s. There were hardly any European or North American tunnels with water spray systems until the last decade. In 1999, the World Road Association, PIARC reported that no road tunnels in Belgium, Denmark, France, Italy, the Netherlands, the UK or the USA were equipped with water spray systems, while Sweden had only one and Norway had two [64].

Deluge systems have been routinely installed in Japanese tunnels since 1963, when the first system was installed in the Tennozan Tunnel. Eighteen experimental test series were carried out in Japan between 1960 and 1985, the majority of these being carried out using fuel pans, although fire tests using cars, a small van, trucks and a bus were also carried out [65]. In general, these tests demonstrated the effectiveness of the deluge system in reducing temperatures in the tunnel and hindering fire spread. However it was observed that "the fire tends to expand less in vertical and more in horizontal direction" and that while fires of "wood or other open load" could be extinguished, fires inside or underneath vehicles "could not be extinguished at all".

In practice, the Japanese experience is also good. Between 1963 and 1990 there were 90 fire incidents in tunnels operated by the Japan Highway Public Corporation. The vast majority of these fires (80 %) did not require the application of the (manually operated) water spray systems. In the 16 instances when the deluge system was used, the results were found to be "fairly satisfactory" [65]. No incident escalated to disastrous proportions. Australia has a shorter length of experience of deluge systems—the first system was installed in the Sydney Harbour Tunnel in 1992—but their experience is also positive [66]. The deluge systems have proven to be effective in vehicle fire exercises and during fire incidents, the highest profile of which was the fire in the Burnley Tunnel in March 2007 [67]. In general, testing and experience has demonstrated that water spray systems are reasonably able to contain vehicle fires and prevent fire spread in tunnels, allowing safe evacuation of people, effective fire fighting by the fire brigade and a rapid return to normal operation of the tunnel.

However, elsewhere in the world, the negative attitude to water spray systems in tunnels extends back to the 1960s and 1970s, but was enshrined in international recommendations up until the late 1990s and early 2000s, as exemplified by this quote from the 1999 PIARC report "Fire and Smoke Control in Road Tunnels" [64]:

> *. . .the use of sprinklers raises a number of problems which are summarised in the following points*:
> - *water can cause explosion in petrol and other chemical substances if not combined with appropriate additives*,
> - *there is a risk that the fire is extinguished but flammable gases are still produced and may cause an explosion*,
> - *vaporised steam can hurt people*,
> - *the efficiency is low for fires inside vehicles*,
> - *the smoke layer is cooled and de-stratified, so that it will cover the whole tunnel*,
> - *maintenance can be costly*,
> - *sprinklers are difficult to handle manually*,
> - *visibility is reduced.*
>
> *As a consequence, sprinklers must not be started before all people have evacuated.*
>
> *Based on these facts, sprinklers cannot be considered as an equipment useful to save lives. They can only be used to protect the tunnel once evacuation is completed. Taking into account this exclusively economic aim (protection of property and not life safety) sprinklers are generally not considered as cost-effective and are not recommended in usual road tunnels.*

The spate of catastrophic tunnel fires in road tunnels which occurred almost immediately following the publication of this report forced the transport tunnel industry to reconsider the importance of property protection and continuity of business, particularly on the trans-European road network, and the industry very quickly realised that water spray systems were a viable and economic option for improving life safety levels and ensuring business continuity.

A number of large, government funded, research projects were carried out in the 2000s to address the issues of tunnel safety, security and sustainability, including the UPTUN project [68], the SAFE-T project and the SOLIT project [69]. Integral to each of these projects was a fresh consideration of suppression technologies for tunnel applications, and as the focus of much of the research was on 'novel' technologies, deluge systems were generally overlooked in favour of water mist systems (WMS).

Detailed reviews of the findings of these projects are published and summarised elsewhere [e.g. 70] and do not need repeated here. To date, no WMS has been deployed during a

real fire incident in a tunnel, so there is no information on their capabilities in practice.

Some testing of WMS for tunnels has been presented in the public literature. Almost all of these tests have involved either open pans of liquid fuel or stacks of wooden (occasionally plastic) pallets. In general, it is claimed that water mist systems have been demonstrated to: reduce the temperature in the vicinity of the fire, reduce visibility in the locality of the fire, improve visibility at locations distant from the fire, slow or halt the fire growth rate, reduce the 'peak' fire size, prevent fire spread and protect the tunnel structure.

However, in some instances (in the public literature, presumably also in some of the many unpublished tests), the WMS have not performed as expected [71]. For example, in one of the fire tests carried out in the Hagerbach tunnel complex in Switzerland for the Paris A86 project [72] the fire (initially involving three cars in a 'collision' configuration) spread to two adjacent cars while the WMS was operational. From the presented data, WMS seem unable to halt fire growth on solid cargo loads, but fire growth rate is, in general, observed to slow or, at least to be interrupted for a period of time upon WMS activation. Under certain circumstances (cargoes covered by tarpaulin, mixed load of wood and plastics) fires have been observed to grow considerably, over a period of minutes, during WMS operation. In one instance the WMS was switched on when the (covered, mixed load) fire was only about 10 MW in size, and the fire continued to grow to over 60 MW [73]. In another similar instance, the WMS was switched on when the (covered, wooden cribs) fire was about 10 MW in size and the fire grew to about 55 MW during system operation [74].

Thus, it appears that for all but the simplest, uncovered, fire loads, fire control cannot be guaranteed using a water mist system. However, such systems do appear to perform very well in terms of temperature control (hence structural protection) and, to some extent, for smoke control.

WMS (and other water spray systems) effectively cool the hot smoke layer in tunnel fire scenarios. This tends to destroy stratification, but also to reduce the momentum of the smoke. Thus, if water spray systems are operated in tunnels, considerably smaller ventilation velocities should be required to control smoke. This has yet to be studied in any detail. There may also be an optimum ventilation airflow for promoting the suppressing effects of water spray systems. This also has yet to be studied in any detail.

It should be stressed that the emphasis of this discussion is on the influence of the various systems on the fire itself. Even though the behavior of the fire itself may not be greatly impacted by the activation of certain types of FFFS, in some situations, such systems may have a large effect by mitigating the consequences of the fire on the structure and on persons and objects distant from the fire. Water sprays have excellent thermal radiation blocking properties, which serve to protect the structure, to allow the fire brigade to approach the fire to fight it and also to prevent fire spread to other vehicles, in conditions where there is no direct flame impingement [63].

At a workshop presenting the results of the SOLIT^2 project in Gijon, Spain, in 2011 [75], one of the delegates, having heard the project results and having witnessed a very large fire (comprised of wooden pallets, approximately 20–25 MW at peak HRR) in a tunnel with an active water mist system, commented that the action of the WMS effectively made the magnitude of the fire (expressed as a heat release rate) an irrelevant concept for specifying the design fire for structural design of tunnels. While the WMS may not be able to suppress or reduce the absolute HRR of a vehicle fire in a tunnel, it has been demonstrated able to considerably mitigate the effects of such a fire, such that the thermal attack on the structure due to, say, a 25 MW fire in water mist may be less than that due to a 4 or 5 MW fire without water mist.

Observations such as these suggest that fixed water spray systems in tunnels should really be considered as 'protection' systems rather than 'suppression' systems. The ability to suppress a fire is not guaranteed, the ability to protect a

structure, on the other hand, has been more than adequately demonstrated [76].

Of course, if we were to re-classify water spray systems as protection systems, then the question of 'trade-offs' mentioned above becomes less controversial. It is no longer a question of reducing passive structural protection if a suppression system is installed, the question resolves to which system is better in the instance considered—a passive thermal barrier, or an active water spray thermal management system? There is no 'one size fits all' solution for all tunnel environments, but in every instance it is a matter of engineering judgment and calculation.

Concluding Comments

Tunnel fire safety is a complex problem with no clear solution at this moment in time. Even in tunnels with cross passages to another tube or a safety gallery, egress distances can be several hundreds of metres. Vehicles carrying 'non-hazardous' cargoes can result in rapidly growing fires with peak heat release rates of over a hundred megawatts. Yet systems exist which can mitigate the effects of large fires in tunnels and provide adequate protection for escaping tunnel users and thermal protection for the tunnel structure. Few countries have prescriptive standards for tunnel fire safety, so defining how such systems are to be installed and used in the event of a fire inevitably involves a 'performance based' analysis of each tunnel on a case by case basis. The data and discussions presented here are provided in order that such analyses are based on realistic 'design fires' and realistic assessments of the performance of protection systems under consideration. In many rural and urban parts of the world, tunnels provide essential, efficient and sustainable transportation links. We can make them safer.

Nomenclature

CAFS	Compressed Air Foam System
CVV	Critical Ventilation Velocity
FFFS	Fixed Fire Fighting System
HGV	Heavy Goods Vehicle
HRR	Heat Release Rate
MTFVTP	Memorial Tunnel Fire Ventilation Test Program
NFPA	National Fire Protection Association
UPTUN	Upgrading of Existing Tunnels Project
PIARC	World Road Association
SAFE-T	Safe Tunnels Project
SOLIT	Safety Of Life In Tunnels Project
WMS	Water Mist System
D_h	Hydraulic diameter of the tunnel (m)
$\Delta H_{c,ox}$	Heat of combustion for oxygen (13.02 kJ/g)
L_c	Combustion zone length (m)
L_f	Flame length (m)
Q	Heat release rate (kW or MW)
q_{inc}	Incident heat flux (kW/m^2)
T_{avg}	Average gas temperature across a tunnel cross-section (K or °C)
T_{cr}	Critical ignition temperature (K or °C)
T_g	Gas temperature (K or °C)
T_s	Solid (surface) temperature (K or °C)
T_{vap}	Vaporization/ pyrolysis temperature (K or °C)
V	Volumetric airflow (m^3/s)
ε_g	Gas emissivity (between 0 and 1)
η_{O2}	Depleted oxygen level (less than 0.21)
ρ	Density of air (1.2 kg/m^3)
σ	Stefan-Boltzmann constant (5.67×10^{-8} W/m^2·K^4)

Dr Ricky Carvel is Lecturer in Combustion & Fire Dynamics in the BRE Centre for Fire Safety Engineering at the University of Edinburgh, Scotland. Originally from Edinburgh he studied Chemistry and Physics as an undergraduate at The University of St Andrews, and stayed there to do a Masters degree in Chemistry. Since then he has worked for the University of Wales, Aberystwyth, Heriot-Watt University, International Fire Investigators and Consultants and the University of Edinburgh. In 2004 he was awarded a PhD from Heriot-Watt University (Edinburgh, Scotland) for his thesis "Fire Size in Tunnels".

Dr Haukur Ingason is a senior research scientist at SP Fire Research since 1988 and adjunct professor since 2007. At the present he is adjunct professor at the Department of Fire Safety Engineering at Lund University where he is supervising and giving classes for students on fire dynamics in tunnels, foam systems and rack storage fires. He has nearly twenty five years of international experience in fire safety research and engineering and published nearly 50 peer review journal papers.

Fire Risk Analysis for Nuclear Power Plants

89

Nathan O. Siu, Nicholas Melly, Steven P. Nowlen, and Mardy Kazarians

Introduction

Fire risk analysis for nuclear power plants, as currently performed in the U.S. and abroad, is focused on assessing the likelihood of a particular industrial accident: the loss of cooling to the reactor core and subsequent core damage.[1] This is one main area nuclear power plant fire protection differs from many industrial facilities. The main focus on nuclear fire protection is to mitigate reactor core damage events which can be caused by fires within the plant. Nuclear power plants have numerous safety systems intended to prevent or mitigate such accidents, thus the fire risk analysis concentrates on assessing the potential effects of fires on these systems' equipment (components and cables). The effects of fire on building occupants (the plant operators in this case) or the building itself, are factors in the analysis, but are addressed only to the extent that these effects can contribute to the accident.

The nuclear power industry uses a general risk analysis method, known as Probabilistic Risk Assessment (PRA), to estimate the risk associated with all recognized threats to the plant. These threats include equipment failures, human errors, extreme weather conditions, seismic events, and fires within the plant. This chapter addresses fire PRA, i.e., PRA conducted specifically for internal fires.

As discussed by Kaplan and Garrick [1] and in Chap. 72 risk analysis is the process of:

1. Identifying potentially important accident scenarios ("what can go wrong"),
2. Determining their consequences ("what can happen when something goes wrong"), and

[1] From a public health and risk standpoint, the integrity of the nuclear fuel is the main safety concern at nuclear power plants. Absent sufficient cooling, the heat generated from radionuclide decay can lead to fuel melting and the potential release of radioactivity into the environment. Past studies have shown that accidents involving the loss of cooling to the reactor core (see Figs. 89.1 and 89.2) are the dominant contributors to risk, and these accidents continue to be the focus of current risk studies. Recent analytical studies, as well as the March 11, 2011 accident at the Fukushima nuclear power plant in Japan, have indicated that accidents involving used ("spent") nuclear fuel outside of the core may be more risk significant than previously thought. Studies to re-assess the potential importance of these accidents are ongoing.

This paper was prepared, in part, by employees of the United States Nuclear Regulatory Commission. It presents information that does not represent an official staff position. The NRC has neither approved nor disapproved its technical content. The views and conclusions in this chapter are those of the authors and should not be interpreted as necessarily representing the views or official policies, either expressly or implied, of the U.S. Nuclear Regulatory Commission.

3. Assessing their likelihood ("how likely is it that something will go wrong")

PRA is a form of risk analysis in which both the consequences and likelihood are expressed in quantitative terms. In particular, the likelihood is expressed in terms of mathematically defined probabilities.

PRA has been used in all U.S. plants and most international plants to evaluate the risk associated with electric power generation from nuclear power plants since the landmark "Reactor Safety Study" (*WASH-1400*) published in 1975 [2]. PRA, sometimes called "probabilistic safety assessment" (PSA) in international reports,

provides a systematic, multidisciplinary approach for using a wide range of information sources including model predictions, experimental results, and plant operational experience, including reported event data, to assess plant behavior under a variety of conditions, sensitivities, and areas of uncertainty and importance.

Numerous fire PRA studies have shown that fire can be a significant or even dominant contributor to the overall risk for a given nuclear power plant. Past estimates for fire-induced Core Damage Frequency (CDF) range from 4E-8 to 2E-4 per reactor year, with the majority of estimates lying between 1E-6 and 1E-4 per reactor year. Fire events are not formally designated as design basis accidents for the nuclear industry, yet their contribution to risk can equal or exceed contributions from other causes (including equipment failures). Lessons learned from a number of serious events, including Browns Ferry (United States, 1975), [3] Armenia (Armenia, 1982), [4] Vandellos (Spain, 1989), [5] and Narora (India, 1993), [6] further emphasize fire's potential importance. NUREG/CR-6738, "Risk Methods Insights Gained from Fire Incidents," provides a useful, PRA-oriented review of these and other notable nuclear power plant fires [7].[2]

Whether fire is an important risk contributor at a particular plant is determined by, not only the reactor design, but also such plant-specific differences as locations for redundant, diverse safety equipment, routing of key electrical cables (e.g., the separation and orientation of the respective cable trays and conduit), fire protection schemes for particular rooms, and the procedures employed by plant operators in response to a fire. Fire PRA evaluates these details and shows how they relate to risk. It provides a systematic framework for examining the complex phenomenology underlying a fire using a wide variety of information sources (e.g., experimental results, model predictions and reported event data), and furnishes a useful context for discussions of areas with significant controversies and uncertainties.

Fire PRA (and PRA in general) is performed to support decision making. The decision problems can be faced by the plant owner (e.g., how to rationally allocate safety resources) or by the regulator (e.g., whether to accept a proposed plant change). The increasing, more direct use of fire PRA in regulatory applications, which is consistent with the NRC's PRA Policy Statement, [8][3] implies a need for a high level of fidelity. It is important that the fire PRA be sufficiently realistic to appropriately address the decision problem at hand. Both excessive optimism and excessive conservatism need to be avoided, as biased analyses could lead to suboptimal or even inappropriate decisions. The problems associated with an overly optimistic analysis are clear. On the other hand, conservatism has traditionally been viewed as, in effect, the price paid for imperfect knowledge. Common engineering practice is to apply realistic assumptions wherever possible, but when in doubt, conservative assumptions generally prevail. However, excessive or uneven levels of conservatism might lead to inappropriate conclusions. For example, an excess of conservatism in the analysis of one particular set of fire sources may cause the fire risk for those sources to be sharply over-estimated. This might, in turn, mask the importance of another risk contributor where more realism and less conservatism have been applied.

Numerous papers and reports have been written on fire PRA. The objective of this chapter is to provide a general review of the subject as it applies to nuclear power plants. The chapter presents some key characteristics of fire PRA, discusses the fire PRA methodology employed by most current domestic studies, summarizes results of a number of analyses, and then briefly outlines current activities and anticipated future developments. Detailed guidance needed to perform a fire PRA can be found in cited references,

[2] The U.S. Nuclear Regulatory Commission (NRC) designates its staff-prepared reports using the nomenclature "NUREG." NUREG/CR contractor reports are reports prepared by NRC contractors.

[3] Among other things, this statement indicates that the NRC intends to increase its use of PRA technology "in all regulatory matters to the extent supported by the state-of-the-art in PRA methods and data. . .".

notably NUREG/CR-6850/EPRI TR-1011989, [9][4] a fire PRA methodology report jointly developed by the Electric Power Research Institute (EPRI) and the U.S. Nuclear Regulatory Commission (NRC) Office of Nuclear Regulatory Research (RES). Recognizing that fire PRA is a multidisciplinary enterprise, this chapter touches on all elements of the fire PRA but the emphasis is placed on topics of direct interest to fire protection engineers. Details on those aspects of fire PRA requiring input from other disciplines, including electrical engineering, human factors, and nuclear power plant systems analysis can be found in NUREG/CR-6850 and other guidance documents cited in this chapter.

Nuclear Power Plant PRA and Fire PRA

Before discussing some of the details of fire PRA, it is useful to note some of its key characteristics and history.

First, in most applications of interest, the risks of eventual concern involve the health of the general public. Thus, the focus of the analysis is on accidents that can have significant health effects offsite. Fire PRA methods can be applied to plant worker safety and economic issues, but have not been to date.

Second, rather than directly estimating the likelihood of offsite health effects, fire PRA studies typically are aimed at assessing a surrogate measure of risk, the plant "core damage frequency" (CDF). This measure characterizes the likelihood that the plant will suffer an accident that damages nuclear fuel contained in the reactor core.[5] As discussed previously, the attention on core damage is due to the results of past studies (e.g., WASH-1400) that have shown that core damage accidents are the dominant contributors to overall plant risk. It is important to recognize that nuclear power plant fires, by themselves, will not lead to core damage; that is, plant fires do not directly threaten core integrity. In order to cause core damage, a fire-initiated scenario must involve a plant upset condition (i.e., an accident scenario "initiating event") and the compromise of plant safety systems. Damage to plant systems may occur either directly (e.g., fire-induced damage to a pump) or indirectly (e.g., fire-induced damage to supporting equipment such as electrical cables or power distribution busses).

Third, fire PRAs usually focus on accident scenarios involving fire-induced failure of critical electrical cables and cabinets. The notion of "critical" arises from the degree of redundancy and defense-in-depth built into nuclear power plant designs. In practice, a risk significant fire must actually damage most or all of the safety systems provided to handle the initiating event. Multiple, independent safety system failures due to random causes (i.e., non-fire causes), while possible, tend to be far less likely and therefore less important to overall risk. Risk significant fires typically involve multiple system failures caused by fire-induced damage to collocated electrical cables (including instrument and control cables) that support these systems. In fact, one of the most predominant fire safety strategies in nuclear power plant applications is ensuring physical separation (or passive fire protection) for important electrical cables.

Fourth, fire PRA is normally performed following, or in concert with, the performance of a PRA addressing accident scenarios initiated by hardware failures or operator errors. Such a PRA, which is called an "internal events" PRA for historical reasons, includes detailed event tree and fault tree models that identify potential responses of the nuclear power plant and operators to postulated initiating events (Figs. 89.3 and 89.4 provide abbreviated examples.) In the fire PRA, these internal event models are modified to address those events and conditions introduced by potential fires. It is important to recognize that the set of modified models, called the "plant response model" later in this chapter, needs to include the effects of both fire- and non-fire caused equipment failures and human errors.

Fifth, those fire PRA studies that quantitatively treat uncertainties do so within the methodological framework employed by the overall plant PRAs. Consistent with Chap. 76 and as

[4] NUREG/CR-6850/EPRI TR-1011989 will be referred to as NUREG-6850 for simplicity.

[5] Technically, the CDF is the expected (in a statistical sense) number of core damage events per unit time.

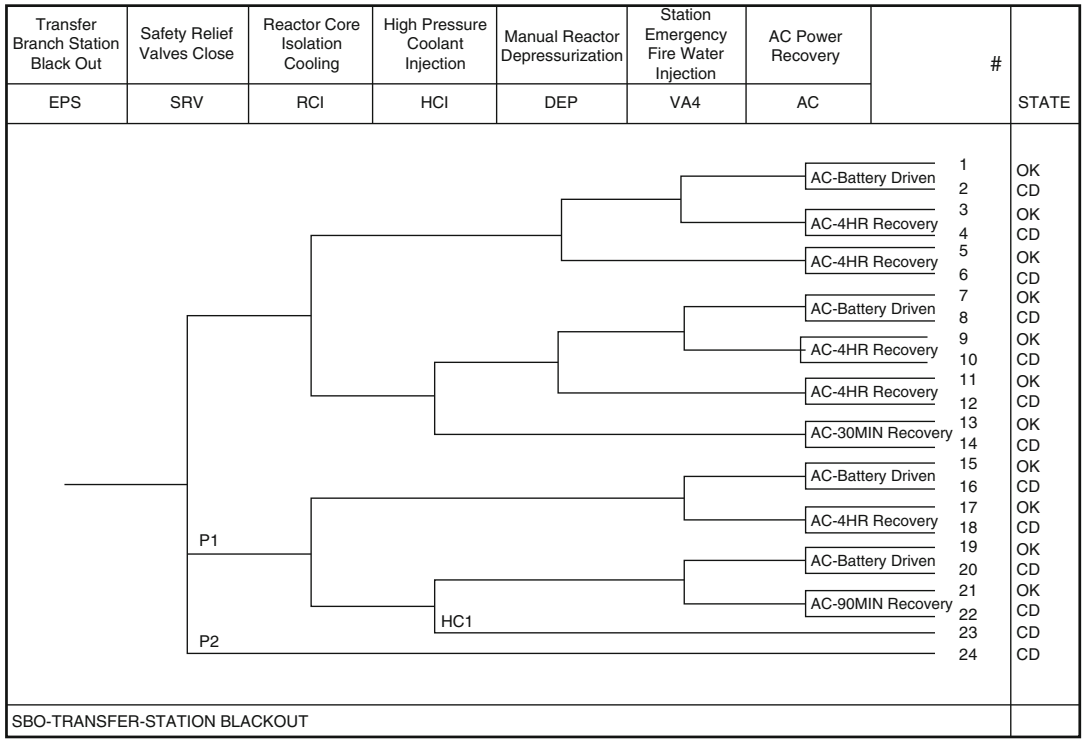

Fig. 89.3 Example event tree for internal events analysis

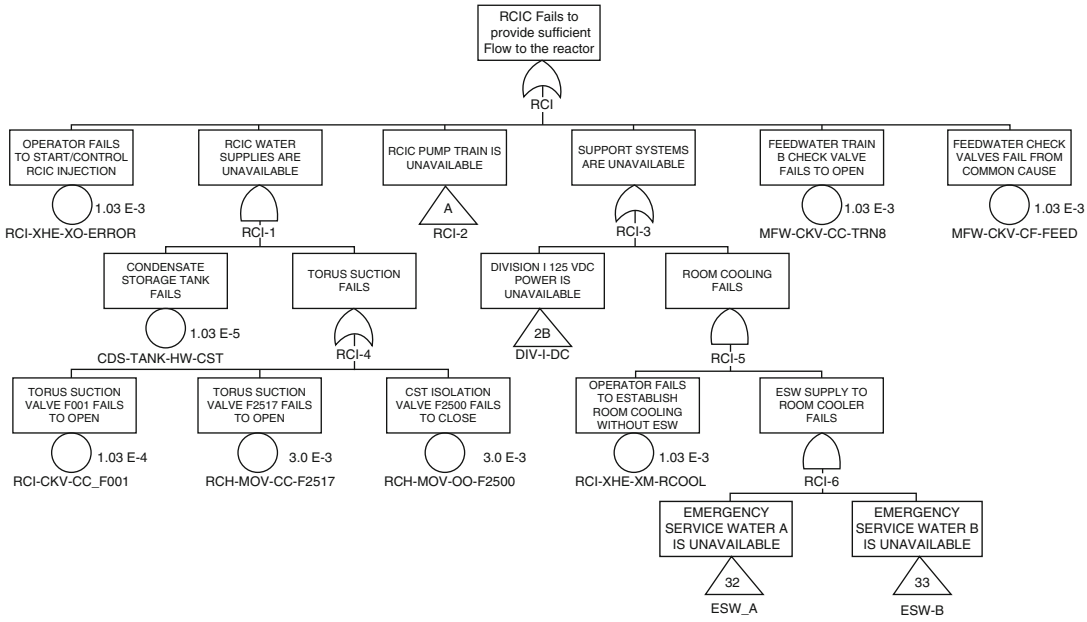

Fig. 89.4 Example portion of a fault tree for internal events analysis (model used depicts a Boiling Water Reactor BWR)

discussed later in this chapter, this framework distinguishes between aleatory (also called random or stochastic) uncertainties and epistemic (also called state of knowledge) uncertainties [10]. The distinction between aleatory and epistemic uncertainties is useful for decision making because it helps identify appropriate risk management options. For example, aleatory uncertainty in the occurrence of core damage events can be reduced by making design changes to reduce CDF, whereas epistemic uncertainty can be reduced through research on key phenomenology (e.g., electrical circuit behavior when cable bundles are exposed to fires). NUREG-1855 [11] describes the treatment of uncertainty in a decision support context.

Sixth, because fire PRAs often need to consider the risk contributions of an enormous number of scenarios, these analyses are almost always performed in an iterative fashion. Starting with a fairly coarse analysis using conservative modeling assumptions, the analysis team develops an understanding as to what scenarios are likely to be important contributors to overall risk. Focusing attention on important scenarios, the team progressively adds detail and more realistic modeling approaches until the analysis is sufficiently accurate to support the decision problem being addressed by the fire PRA. This approach does not guarantee an accurate assessment of absolute CDF (or risk). A conservative assessment that is adequate for one decision problem (e.g., whether additional regulatory action is needed to address fire vulnerabilities in the nuclear fleet) may be overly conservative with respect to a different decision problem (e.g., selecting between different plant-specific risk management solutions).

We note that certain situations that have received little or no coverage from general PRA studies also receive little or no coverage in the fire PRA. These situations include the scenarios associated with acts of sabotage and scenarios when the plant is not operating at steady-state, full power conditions. Sabotage is usually excluded from the scope of general PRA studies. Regarding scenarios during low power or plant shutdown operating conditions, fire PRAs have been performed [12, 13], but such assessments are not yet routine. Draft NUREG/CR-7114 [14] provides a framework for performing fire PRA for these conditions.

History of Fire PRA

The earliest fire risk assessment for a nuclear power plant was performed in 1975 as a supplement to WASH-1400 (the Reactor Safety Study) [2]. The assessment was aimed at providing a quick estimate of the risk implications of the Browns Ferry cable fire in 1975. The analysis indicated that the CDF associated with that fire was around 10^{-5} per year, or about 20 % of the total plant CDF associated with the accidents addressed in the main body of the study. It also noted the usefulness of developing a more detailed fire PRA methodology (including improved models and data). Another early fire PRA was performed in 1979 as part of a PRA for a proposed high-temperature gas-cooled reactor design. The analysis focused on the risk contribution of cable spreading room fires, and it concluded that the core heat-up frequency due to such fires was also around 10^{-5} per year, or about 25 % of the total core heat-up frequency due to all causes.

The first comprehensive, detailed fire PRAs for commercial nuclear power plants were performed in 1981 and 1982 as part of the commercially-sponsored Zion [15] and Indian Point [16] PRA studies, respectively. A key question addressed by both PRA efforts was if additional accident mitigation systems (e.g., filtered, vented containments) were needed for the two plants. The study results indicated that the fire risk for Zion Units 1 and 2 was relatively small (the mean CDF was about 5×10^{-6} per year for each unit, about 10 % of the total mean CDF) and that the fire risk at the Indian Point plants was relatively large (the mean fire-induced CDF for Unit 2 was about 2×10^{-4} per year, about 40 % of the total mean CDF). Because the Zion and Indian Point fire PRA studies were performed by the same analysis team using the same analysis methodology and tools, these studies demonstrated how plant-specific features could greatly affect fire risk. More important, the studies also identified

plant design changes for reducing risk (e.g., fire barriers, a self-contained charging pump, provisions for an alternate power source in the event of damaging fires) that were assessed to be more cost-effective than the proposed accident mitigation systems prompting the studies.

In the years following the Zion and Indian Point studies, a number of additional fire PRA studies were performed. The results of these analyses confirmed that fire could be a significant and even dominant contributor to the overall risk for a given plant. Many of these studies resulted in estimates of mean fire-induced CDFs of 10^{-4} per year or greater, predicted contributions to total CDF of 20 % or greater, or both. In the late 1980s through very early 1990s, the NRC sponsored a Risk Methods Integration and Evaluation Program (RMIEP) [17] addressing the LaSalle Unit 2 nuclear power plant and the NUREG-1150 [18, 19] PRA studies, each of which included assessments of fire risk. The RMIEP study involved an analysis of the LaSalle nuclear power plant and the goal of the study was to extend and demonstrate state of the art analysis methods for PRA in general. The NUREG-1150 studies focused on the application of existing methods, rather than the development of new methods, to a set of five reactors representing a range of U.S. designs. From the standpoint of fire PRA, both studies used similar frameworks and (for the most part) methods. Insights from both of these programs paralleled other PRA studies of the era and again found that fires were potentially significant contributors to overall plant risk. Both studies also confirmed that plant-specific details can substantially impact both the magnitude and source of fire risk.

In 1991, recognizing the value of systematic assessments of fire (and other so-called "external events"), the NRC requested that licensees perform Individual Plant Examination of External Events (IPEEE) studies for their plants [20]. The primary goal of the fire risk portion of the IPEEE program was for plant licensees to identify plant-specific vulnerabilities to fire-induced severe accidents that could be fixed with low-cost improvements. Four supporting objectives with respect to external events were for licensees to (1) develop an appreciation of severe accident behavior, (2) understand the most likely severe accident sequences that could occur under full-power conditions, (3) gain a qualitative understanding of the overall likelihood of core damage and fission product releases, and (4) reduce, if necessary, the overall likelihood of core damage and radioactive material releases by appropriately modifying hardware and procedures to prevent or mitigate severe accidents. Guidance on the performance of an IPEEE analysis was provided by Chen et al. [21].

The results of the NRC's review of the IPEEE submittals are presented in NUREG-1742 [22]. The review showed that fire was a significant contributor to overall risk at a number of plants. In addition, it also showed that over half of the IPEEE submittals identified cost-effective improvements. Finally, as discussed earlier in the section on fire modeling, the review process also identified a number of technical issues associated with then-current guidance.

In the early 2000s, as the IPEEE review process was coming to a close, EPRI and the NRC's Office of Nuclear Regulatory Research initiated a joint effort to update available fire PRA methods and guidance. This effort was intended to consolidate lessons learned from the IPEEEs and from ongoing fire PRA research and development activities, and was aimed at supporting anticipated regulatory applications of fire PRA (discussed in the following section). This joint effort resulted in the guidance document NUREG/CR-6850, cited extensively in this chapter.

Currently, a number of U.S. plants are using NUREG/CR-6850 and more recent guidance [23] to update their fire PRAs. These efforts have resulted in a number of lessons learned, including the following.

- As in previous fire PRAs, the fire risk profile is often dominated by the contribution from a relatively small number (on the order of ten) scenarios. These scenarios often involve situations identified in past studies (e.g., electrical cabinets, control rooms, locations with large concentrations of cables) with major consideration given to targets vulnerable to fire-induced spurious operations. These targets can have a pronounced impact on the fire scenarios selected.

- Overall, current estimates of fire CDF (with mean values on the order of 10^{-5} to 10^{-4} per year) are consistent with the results of past studies. Note that some of these estimates reflect the assumption that planned modifications are in place and operational [24].
- NUREG/CR-6850 provides guidance on performing screening-level (intentionally conservative) analysis as well as guidance for detailed (realistic) analysis. Fire PRAs that do not employ the latter guidance can produce unrealistically conservative fire CDF estimates.
- Although the fire CDF tends to be dominated by the contribution from a few scenarios, the total fire CDF is also a function of the contributions from other scenarios. A realistic fire PRA can require the quantitative analysis of large number (on the order of a few thousand) scenarios. Such a study requires considerable resources to trace cables as well as perform analyses [24].
- Fire PRA is a useful tool for identifying plant modifications that will improve plant safety with respect to non-fire as well as fire-initiated accidents.

The recent updating efforts have also identified areas where additional improvements are needed to increase the realism of results and to reduce the effort needed to perform a realistic fire PRA. These areas are the subject of current fire PRA research and development activities. The results of these activities are aimed at supporting the continued use of fire PRA in ensuring and, as needed, improving the fire safety of U.S. nuclear power plants.

Although this chapter is centered on U.S. plants and practices, we note that fire PRA is also widespread internationally. In particular, the Organization for Economic Cooperation and Development's (OECD) Nuclear Energy Agency (NEA) has published the results of a member country survey on their PRA activities. This report and its more recent update indicate that fire PRAs have been performed for a large number of nuclear power plants abroad [13, 26]. The OECD/NEA has also published a state-of-the-art report [25] and supports a number of activities aimed facilitating the exchange of fire-PRA relevant information among member countries. Guidance on the performance of fire PRA is also available from the International Atomic Energy Agency [27]. In general, current international guidance and practices are generally consistent with those in the U.S., and the results of international studies are also qualitatively consistent regarding the relative importance of fire (as compared with other hazards) and the plant areas that are important contributors to risk.

Fire PRA Guidance and Standards

Fire protection for the U.S. commercial nuclear power industry is governed by several NRC-issued documents. The primary regulations are published in Title 10, Section 50.48 of the Code of Federal Regulations (10CFR50.48) [28]. These primary regulations are supported by a number of subsidiary regulatory guidance documents. Of particular interest to fire PRA are Regulatory Guides (RG) 1.205, "Risk-Informed, Performance-Based Fire Protection for Existing Light-Water Nuclear Power Plants" [29] and 1.200, "An Approach For Determining The Technical Adequacy Of Probabilistic Risk Assessment Results For Risk-Informed Activities" [30]. These documents, respectively, provide one acceptable method to develop and maintain risk-informed, performance-based fire protection programs; and on quality expectations for the use of general PRA (including fire PRA) in regulatory decision making. Also of interest are RGs 1.174, "An Approach for Using Probabilistic Risk Assessment in Risk-Informed Decisions on Plant-Specific Changes to the Licensing Basis," [31] and 1.189, "Fire Protection for Nuclear Power Plants" [32]. The former provides a framework for the application of PRA information in the regulatory context, and the latter addresses specific fire protection issues. Links to current fire protection regulation, guidance, and other regulatory documents

can be found on the NRC's fire protection website.[6]

The current guidance for performing a fire PRA is provided in NUREG/CR-6850 and a series of companion documents covering various methods refinements, clarifications, and expansions developed since that publication was released [23].[7] NUREG/CR-6850 is built on lessons learned from the performance and review of past fire PRAs, including the NRC sponsored NUREG-1150 studies [18] and the industry methods and corresponding studies performed as part of the NRC's Individual Plant Examinations of External Events (IPEEE) program [21, 22, 33, 34]. The document also reflects the results of research and development activities (e.g., regarding the treatment of fire-induced failure of cables and circuits) that led to improvements in the treatment of specific fire PRA issues, as well as lessons learned from the application of a draft form of the document in a number of field tests. Similarly, fire PRA guidance developed after NUREG/CR-6850 have benefitted from industry applications of that report. Fire PRA will continue to evolve, and it is often through applications that refinement needs are identified. Research is also ongoing. As research results are developed, these are factored into the fire PRA methods and guidance as appropriate. Methods development and related research activities are discussed later in this chapter.

A joint American Society of Mechanical Engineers (ASME)/American Nuclear Society (ANS) consensus standard providing requirements for nuclear power plant PRAs quality and scope, including fire PRAs, is also available [35]. This standard delineates the requirements (i.e., the "whats") for a quality fire PRA, but does not prescribe particular methods (i.e., the "hows") for achieving these requirements. The discussion of methods is left to guidance documents, such as those discussed above. A second national consensus standard, National Fire Protection Association (NFPA) 805, "Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants," provides requirements for developing and maintaining a risk-informed, performance-based fire protection program [36]. The 2001 edition of NFPA 805 has been endorsed by the NRC (10 CFR 50.48(c)) as an optional alternative to the deterministic regulatory requirements in place since 1980.

As noted above, PRAs have historically focused on at-power plant conditions (i.e., with the plant up and running at full power). This is reflected in the cited methodology documents and implementation standards. For example, NFPA 805 focuses on the use of fire PRA as a tool supporting fire protection decision making under at-power plant conditions. This standard does require consideration of low-power and shutdown (LPSD) risk, but current decision making relies mainly on qualitative, defense-in-depth methods. Defense in depth is an approach to designing and operating nuclear facilities that prevents and mitigates accidents that release radiation or hazardous materials. The key is creating multiple independent and redundant layers of defense to compensate for potential human and mechanical failures so that no single layer, no matter how robust, is exclusively relied upon. Defense-in-depth includes the use of access controls, physical barriers, redundant and diverse key safety functions, and emergency response measures. It is envisioned that LPSD applications may evolve to be more quantitative. Standard approaches for performing LPSD PRAs are in the developmental stage. NUREG/CR-7114 [14] presents a PRA method framework for quantitatively analyzing fire risk in commercial nuclear power plants during LPSD conditions.

[6] http://www.nrc.gov/reactors/operating/ops-experience/fire-protection.html

[7] Guidance documents on a number of specific fire PRA issues can be found on the NRC public web site. Agency documents are maintained on its Agencywide Documents Access and Management System (ADAMS) at http://www.nrc.gov/reading-rm/adams.html#web-based-adams. A number of fire PRA methodology enhancements and clarifications have been developed as a part of industry and NRC efforts to implement risk-informed performance-based fire protection based on the NFPA-805 standard. These can be found using the search term "NFPA 805 FAQ".

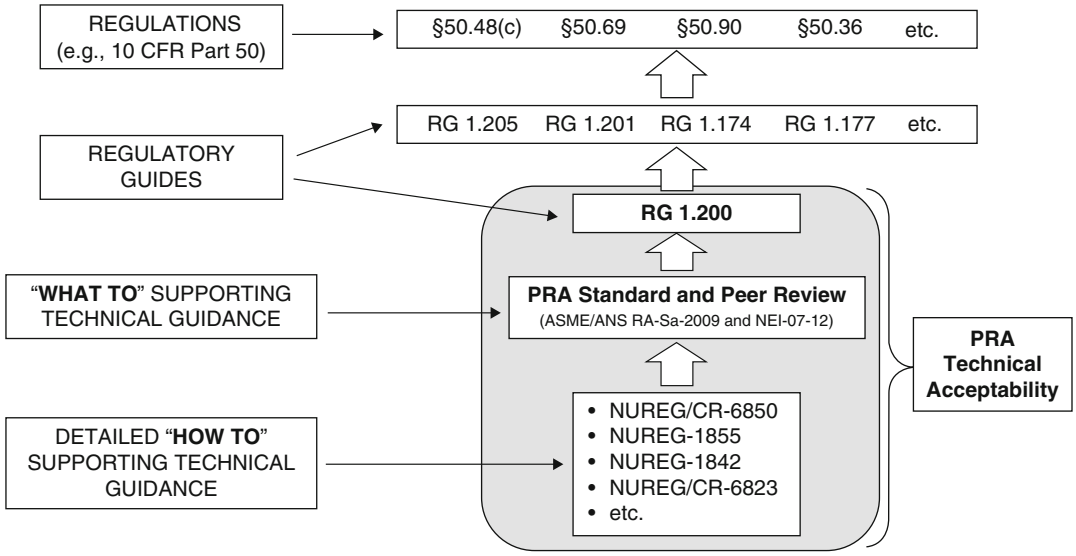

Fig. 89.5 Document hierarchy associated with nuclear power plant fire risk regulatory applications

Figure 89.5 illustrates the relationship between various classes of documents and specific documents that govern the application of risk information to nuclear power plant applications. The top tier represents the actual regulations that govern plant operations as published in the U.S. Code of Federal Regulations (CFR). For example, NRC's endorsement of the NFPA 805 standard is found in 10CFR50.48(c). The second tier represents various regulatory guides (RG) which are documents prepared by the NRC staff that generally describe one acceptable method (non-exclusive) for meeting the regulatory requirements. (Four relevant RGs were cited above.) Also represented in the fourth tier is a Nuclear Energy Institute (NEI) guidance document (NEI 07-12 [37]) which provides specific guidance on implementing the ASME/ANS standard. Finally, the fifth tier represents specific methodology guidance documents that express how to perform various aspects of a risk study and includes NUREG/CR-6850 which is heavily cited in this chapter. Tiers 3-5 are all associated with PRA quality expectations: that is, these tiers together define quality expectations for analyses that are to be used in the regulatory decision making process.

Fire PRA Overview

The fundamental structure of current fire PRAs is little changed from that used in the Zion [15] and Indian Point [16] PRA studies of the early 1980s and described by Apostolakis et al. [38, 39] a structure that is also called out in the 1983 PRA Procedures Guide [40]. In this structure, the CDF arising due to fire-initiated accidents is the sum of the CDF contributions from individual fire-initiated scenarios contributing to this total CDF. The CDF contribution due to a single fire scenario (where, in this discussion, a fire scenario is defined by the location and burning characteristics of the initiating fire), in turn, can be divided into three principal components:

1. Frequency of the fire scenario
2. Conditional probability of fire-induced damage to critical equipment given the fire
3. Conditional probability of core damage given the specified equipment damage

Mathematically,

$$CDF_i = \lambda_i \times p_{ed,\,j|i} \times p_{CD,k|i,j} \qquad (89.1)$$

Where:

λ_i = Frequency of fire scenario i

$p_{ed,j|i}$ = Conditional probability of damage to critical equipment set ("target set")[8] *j* given the occurrence of fire scenario *i*

$p_{CD,k|i,j}$ = Conditional probability of core damage due to plant response scenario *k* given fire scenario i *and* damage to target set *j*

The first term accounts for the likelihood that a fire of specified characteristics will occur in a given location within the plant. The second term addresses the likelihood that the fire will not be suppressed prior to component damage (this term may include a measure for the severity of the fire). Analysis of this term requires treatment of the issues of fire growth, detection, suppression, and component damageability. The third term, often referred to as the Conditional Probability of Core Damage (CCDP), addresses the ability of the plant to achieve safe shutdown given the loss of equipment damaged by the fire. Analysis of this term also requires treatment of the unavailability or random failure of equipment unaffected by the fire and the treatment of potential errors by plant operators.

The total fire CDF is obtained by summing Equation 89.1 over all possible fire scenarios (index i), target sets (index j), and plant responses (index k):

$$CDF = \sum_{i} \lambda_i \left[\sum_{j} p_{ed,\,j|i} \left(\sum_{k} p_{CD,k|i,\,j} \right) \right] \tag{89.2}$$

The three-term breakdown used in these equations provides a useful discussion framework because it aligns with the objectives of fire protection defense-in-depth for nuclear power plants, as discussed in RG 1.189. Three objectives of defense in depth are: first to prevent fires from starting; if that fails, then to detect rapidly, control, and extinguish those fires that do occur; and if that fails to provide protection for structures, systems, and components important to safety so that a fire not promptly extinguished by fire suppression activities will not prevent safe shutdown of the plant. Further, the breakdown aligns with the modeling approaches used in different parts of a fire PRA. In particular, the fire frequencies are generally estimated using simple statistical models for fire occurrences, the likelihood of fire damage is estimated using combinations of deterministic and probabilistic models for the physical processes involved, and the likelihood of core damage is estimated using PRA event tree and fault tree models (modified appropriately to address the needs of fire PRA). The current approach for addressing each of these technical elements is more fully discussed later in this chapter.

Fire PRA Process

Figure 89.6 provides a schematic of the overall process for performing a fire PRA. This figure is based on the technical elements set forth in Section 4 of the ASME/ANS PRA Standard, which closely parallels the process defined in NUREG/CR-6850.[9]

As discussed in greater detail in the remainder of this section, the fire PRA process identifies and characterizes, for each plant area, potentially important fire scenarios, installed fire protection systems and features, physical and geometric characteristics required to support fire modeling, and potentially important equipment, components and cables (i.e., nuclear-safety relevant items potentially susceptible to fire damage). The Plant Familiarization elements shown in Fig. 89.6 establish the boundaries of the analysis and define the key characteristics of the plant in both physical and systems modeling contexts. Qualitative screening is then done to identify locations and

[8] "Targets" in this context are PRA components and cables near the fire location and "target sets" are simply collections of individual targets that may be threatened by a given fire.

[9] As one minor difference, NUREG/CR-6850 defines two stages of physical fire analysis; namely, a preliminary fire source screening task called "scoping fire modeling" and a follow-up task called "detailed fire modeling". In the ASME/ANS standard, these two tasks have been incorporated into one technical element called "fire scenario selection and analysis".

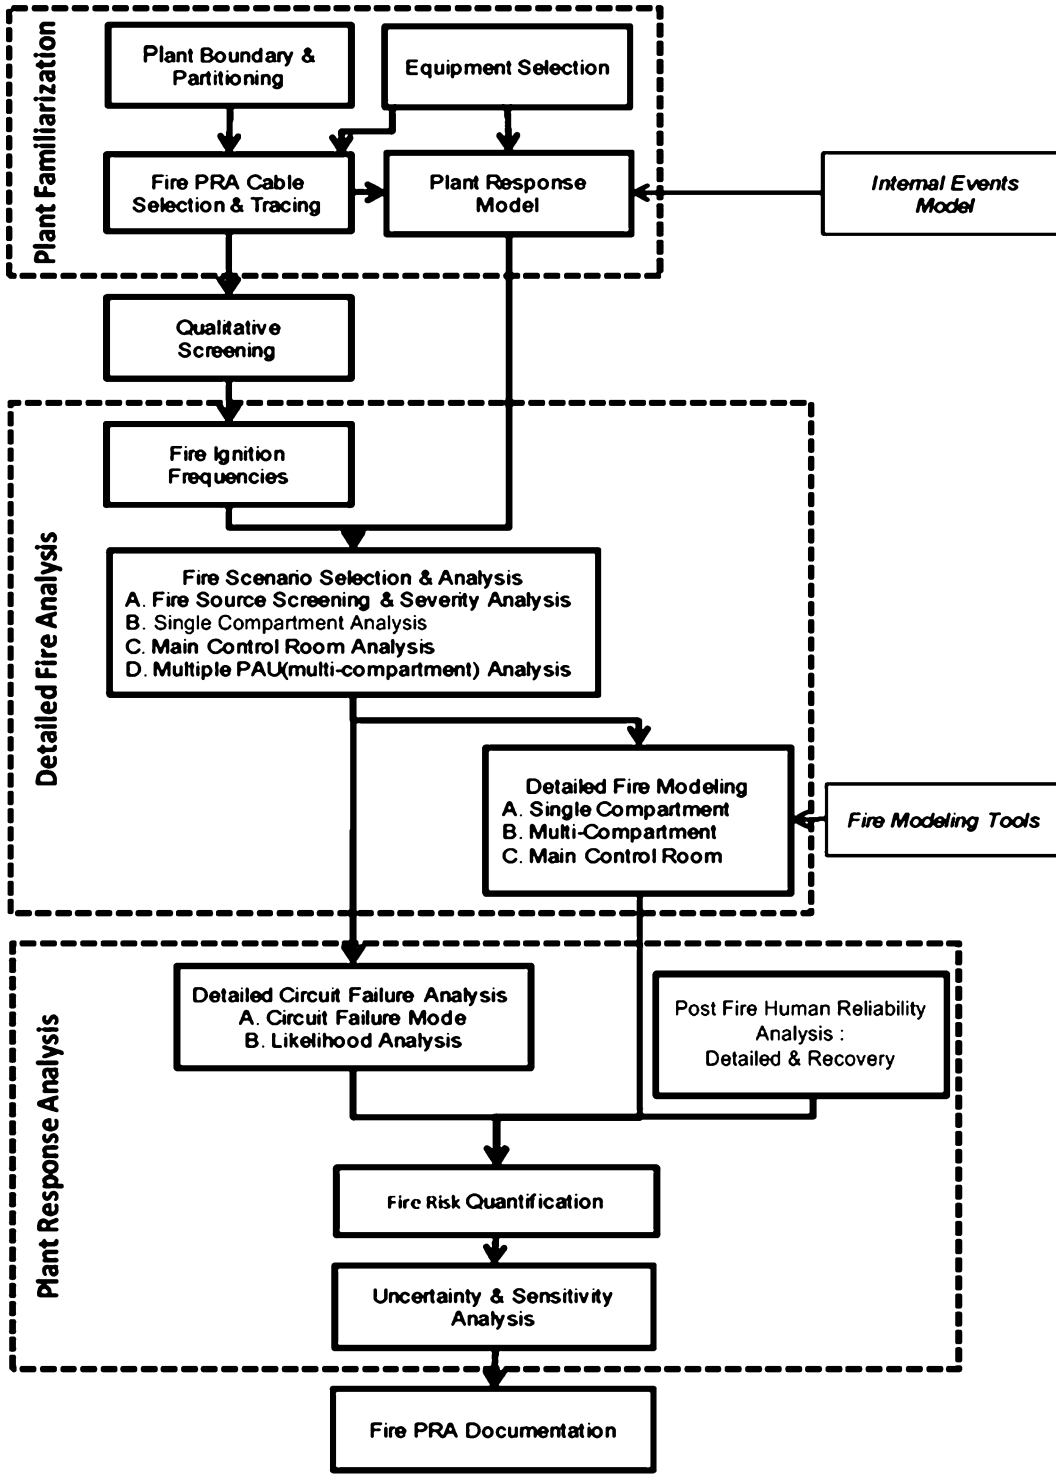

Fig. 89.6 Fire PRA elements

scenarios that need not be quantitatively analyzed because they are not expected to contribute to the fire CDF. This first screening step typically eliminates plant areas that meet the following criteria: (1) the area houses no potentially important equipment, components, or cables and (2) a fire in the area would not be able to initiate a plant upset condition (i.e., an accident scenario "initiating event").

Following qualitative screening, the fire PRA continues with Detailed Fire Analysis and Plant Response Analysis elements. These elements involve a series of progressively more detailed quantitative assessments for unscreened plant areas. Conservative quantitative analyses are usually performed in initial evaluations of CDF to identify additional plant areas and scenarios that can be screened from detailed analysis (based on their contribution to total fire CDF). Progressively more accurate models are then employed for unscreened locations. The objective of this iterative approach is to focus analysis resources on those locations that contribute most to CDF. For example, in many screening analyses, suppression efforts are initially assumed to fail to prevent fire-induced component damage. This conservative assumption is relaxed only for those locations where a detailed analysis is needed.

When documenting the fire PRA, the results of the analysis are typically presented on a location by location basis, and the key or dominant fire scenarios associated with each plant area are typically described in some detail. This detail usually includes some discussion of plant-specific characteristics driving those scenarios, often including relevant design and operational practices, in addition to key fire protection features credited in the analysis. The importance of providing qualitative as well as quantitative results cannot be overstated. Such information ("what can go wrong") is part of the triplet definition of "risk" provided at the beginning of this chapter and is needed when efficiently managing fire risk.

For the purpose of clarity, Fig. 89.6 provides a simplified, once-through picture of the process. In actual practice, the analysis can involve multiple iterations. (In some situations, even early elements might need to be revisited should the results of detailed analysis indicate that additional information is needed.) Note also that that the figure does not emphasize the location-by-location nature of a fire PRA; many of the elements are exercised for each plant area.

Fire PRA Elements

In this section, we discuss each of the technical elements identified in Fig. 89.6.[10] The discussion provides an overview of current analysis approaches, addresses important sources of uncertainty and ongoing development, and identifies references for further reading.

Plant Definition and Partitioning

The purpose of the plant definition and partitioning element is to: (a) prescribe the analysis boundaries separating what's included in the analysis (i.e., that portion of the plant addressed in the fire PRA) from what's not included in the analysis, and (b) define how the analyzed plant is to be separated into smaller, non-overlapping spatial units of analysis (spatial partitions). In the language of the ASME/ANS Standard, the first step is referred to as defining the "global analysis boundary" and the second step is referred to as "plant partitioning." The term used in this chapter to identify fire PRA spatial

[10] The ASME/ANS Standard includes a requirement to address Seismic-Fire Interactions that is not shown in Fig. 89.6. Current methods for analyzing these interactions are mainly qualitative and have no direct impact on the fire PRA process or results. Furthermore, since a seismic event is the actual initiating cause, the consequential fire scenarios should, following typical PRA conventions, be included in the seismic portion of the PRA rather than the fire portion. (Of course, care should be taken to ensure the issue does not fall through any gaps.) With recent events in Japan, including seismically-induced fires at the Kashiwazaki and Onagawa plants in Japan, the NRC and the nuclear power industry are considering developments to address the risk of such events quantitatively.

partitions is "plant areas".[11] Regardless of terminology, the key point is that the fire PRA is typically managed and organized based on where a postulated fire occurs. The intent of the plant partitioning element is to define a set of plant areas, each with specific boundaries (physical or not), that collectively account for all locations within the plant while also ensuring that no location is encompassed within more than one plant area.

Plant areas are ideally bounded by non-combustible barriers, such as fire-rated, or non-fire-rated, barriers. However, plant areas may also be defined on other bases including active features, such as water curtains, and in some cases spatial separation (i.e., extended distances between fire sources or concentrations of in-situ fuels). These distinct plant areas are where heat and products of combustion from a fire will be substantially confined. For example, in typical practice, the main control room will generally be treated as a single distinct plant area whereas areas within the auxiliary building may be segregated into many different plant areas. Note that the potential failure of a credited partitioning feature is addressed in the multi-compartment fire scenario analysis element described later in this section.

The analysis team has considerable flexibility in defining plant areas. For example, it can group several rooms together and treat them as a single plant area, as long as this grouping does not substantially affect the realism of the analysis results. Such grouping can reduce the amount of analysis required for risk-insignificant scenarios. In general, the fire PRA process is designed to minimize the level of effort spent on low-risk scenarios and focus analysis attention on risk-significant scenarios. Since the analysis results are not known beforehand, analyst judgment and some iteration are necessary.

From the above discussion, it can be seen that plant partitioning relies heavily upon fire protection engineering expertise, as this is needed to determine the extent to which provided fire protection features will substantially confine heat and products of combustion from potential fires associated with the fire hazards in a given area. Plant partitioning also requires substantial input from other disciplines, as it requires knowledge of the general location and PRA-model relevance of plant systems and equipment (including cables). For example, returning to the above discussion on grouping plant areas, if detailed information for the routing of key cables is unavailable, then a detailed partitioning of a plant area containing those cables may provide little benefit to the analysis.

It is important to recognize that, as in other parts of the fire PRA, plant definition and partitioning is not just a paper exercise. Confirmatory walkdowns are essential to confirm the existence and integrity of the fire protection features and elements credited in defining each plant area.

Equipment Selection

The equipment selection element defines those pieces of plant equipment and components (other than electrical cables) that will be included in the "plant response model"; that is, the PRA systems model used to perform the plant response analysis. (The development of the plant response model will be discussed later in this chapter.) The selected equipment and components are often referred to as *PRA* or *fire PRA components*.

[11] The terminology surrounding the naming of fire PRA spatial partitions has a somewhat checkered history. Various terms used in fire protection engineering have definitions that were not developed for fire PRA. For example, in fire protection engineering "fire zone" is often defined in the context of coverage areas for a fire detection or suppression system. Similarly, "fire area" has a very specific meaning in the context of the NRC fire protection regulations (see Regulatory Guide 1.189 for related discussions). NUREG/CR-6850 avoids the use of these and other preexisting terms and instead refers the spatial units as "fire compartments," although the fire PRA spatial partitions may or may not be enclosed spaces. The more accurate, albeit fairly technical phrase used in the ASME/ANS Standard is "physical analysis units" or PAUs. Fire PRA spatial units may correspond to a fire zone, a fire area, a compartment, a subset of any of these, or indeed a superset of smaller compartments. For the sake of simplicity, this chapter uses the very generic term "plant area."

This element does not start from a blank sheet of paper; rather, the selection of plant equipment for the fire PRA usually begins with the equipment already included in the internal events PRA plant response model. It is common that most, if not all, of the equipment credited for safe shutdown in the internal events PRA is also credited in the fire PRA. The ultimate goal of the fire PRA equipment selection element is to refine the list of credited equipment. The analyst adds new equipment with unique fire induced failure modes such as spurious operation,[12] not considered in the internal events PRA.

The equipment selection element is performed in close coordination with the development of the fire PRA plant response model. Indeed, it is often the case that choices made in development of the plant response model are what ultimately drive equipment selection decisions. In some cases, these two elements are performed as, in effect, one larger element encompassing the goals of both as described here.

The analysis team performing this element should have collective knowledge of plant systems operation, potential component failure modes, and potential operator responses to different component and instrumentation behaviors. Fire protection engineering inputs include the above-mentioned fire response procedures and the supporting technical basis for those procedures (including the plant's safe shutdown analysis, developed to ensure compliance with fire protection regulations).

The output of the Equipment Selection Element is a list of equipment (with associated characteristics) to be considered when developing the plant response model, and to be used in identifying key electrical cables, as discussed in the next section.

[12] Spurious operations are defined as a circuit-fault mode wherein an operational mode of the circuit is initiated (in full or in part) due to failure(s) in one or more components (including the cables) of the circuit; examples are a pump spuriously starting, or the spurious repositioning of a valve.

Cable Selection and Tracing

The purpose of the cable selection and tracing element is to identify the power, control, and instrumentation cables associated with the components identified in the equipment selection task, plus any other cables whose failure might adversely affect the plant response. Once identified, it is also necessary to determine their physical routing through the plant. This element is usually performed by electrical engineers with extensive plant personnel support.

For reasons previously discussed, risk-significant fire scenarios typically involve damage to electrical cables. The ability of a fire to damage cables decreases rapidly with distance; hence, the more detailed the cable routing information the more realistic the results will be. However, the development of detailed information can be an extremely resource intensive activity depending on the extent and quality of pre-existing information. Clearly, plants that have up-to-date cable routing databases are much better placed to support detailed analyses. Ideally, cables are traced not just to plant areas, but down to the tray/conduit level. This effort has proven to be one of the most costly elements of a fire PRA.

The output of the Cable Selection and Tracing element is not simply a list of cables. This element also establishes, for each cable, a link to the associated plant response model components, to specific component failure modes (e.g., loss of function and/or spurious operation), and to the cable's routing and location. These relationships provide the basis for identifying potential component functional failures at a plant area or raceway level. Inaccurate selection of cables will ripple through the entire PRA and can result in erroneous CDF estimates. It should be noted that many analysts perform this task in conjunction with a detailed circuit analysis (discussed later) in order to avoid unnecessary effort. For example, plant records may "associate" cables with a component whose failure would not, in fact, impact component function (so-called "off-scheme" cables). Identifying such cables early may avoid time consuming cable tracing efforts.

Qualitative Screening

The qualitative screening element is the first pass made at identifying plant areas that are of such low risk importance that quantitative analysis is not needed. It is not intended to develop CDF estimates for particular plant areas at this stage. It is intended, however, to identify those plant areas where, according to pre-determined criteria (already described above), the fire risk is expected to be very low or nonexistent both compared to other plant areas and in absolute terms. This step can be performed by both system engineers and fire protection engineers once the plant partitioning, equipment selection and cable tracing tasks are completed.

As PRA is an iterative process, if the analyst chooses to modify the list of credited equipment or the cable list at a later stage of analysis, the qualitative screening analysis should also be reviewed to ensure that plant areas initially screened out still satisfy the screening criteria. Plant areas qualitatively screened in this element will be reexamined in a later step for fires that may cause potentially risk-significant damage to equipment located in adjacent plant areas (see the later discussion on multi-compartment fire scenarios).

Plant Response Model

The plant response model characterizes how combinations of equipment failures and operator errors can lead to core damage. Equipment failure can occur either from causes internal to the component itself (also known as random failures) or from sources external to the component (e.g., fire, earthquake and flooding). As noted above, the plant response model is typically developed by modifying an existing internal events model. This internal events model is typically expressed using event trees and fault trees, as discussed in the PRA Procedures Guide [40].

As in the case of the internal events model, the fire PRA plant response model supports the analysis of initiating events and ensuing chains of events. Initiating events are conditions that may occur randomly or, in the case of the fire PRA, due to fire-induced component and cable damage. These conditions perturb the balance of plant operation requiring response from automatically or manually activated systems to prevent unsafe conditions. Two examples of initiating events are a loss of offsite power (LOOP) and loss of coolant accident (LOCA). The chains of events ensuing from each initiating event can be represented at different levels of detail. At a high level, as typically represented using event trees (see Fig. 89.3), the events often represent system or functional failures. At a more detailed level, as typically represented using fault trees (see Fig. 89.4), the events can represent failures of specific equipment or operator actions that can contribute to the higher level system or functional failures. These are generally defined in terms of equipment status (failed positions) and erroneous operator actions.

Event trees and fault trees help the analyst to break down potential event progressions into their elemental parts and also to identify a wide range of event sequences. The plant response model specifies many of the important conditions affecting the probability of equipment failures and operator errors, and also provides a mathematical mechanism to estimate CDF based on the equipment failure and operator error probabilities. The event tree and fault tree models can be very complicated, containing thousands of scenarios and a total number of event sequences that easily number in the millions. Dedicated computer programs (e.g., SAPHIRE [41] and CAFTA [42]) have been developed to support the development, execution, review, and documentation of these models.

Since the fire PRA typically starts with an internal events model, the primary concern of the fire PRA analyst is to ensure that the internal events PRA plant response model is appropriately modified to address the special conditions imposed by the fire scenarios analyzed. These conditions include: (1) the failure of plant equipment directly caused by the fire; (2) spurious actuation of equipment due to control circuit failures; (3) new accident sequences that may have been dismissed in the internal events

model as very unlikely to occur given only random failures; (4) new accident sequences due to implementation of plant procedures specific to fire conditions (e.g., alternate shutdown in the event of a main control room fire); (5) instrumentation failures not included in the internal events model; and (6) new or modified plant operator performance related events. (These topics are discussed in some detail later in this chapter.) The information management demands arising during the development and execution of the plant response model can be considerable. Specialized computer programs (e.g., FRANX [43]) have been developed to aid the analysts.

Fire Frequency Analysis

The fire frequency analysis involves two primary goals. The first is to define representative fire scenarios for the area of interest; that is, to define those fire ignition sources that might lead to risk-relevant fire scenarios. The second is to estimate the frequency of fires (typically events per year) involving each identified ignition source. Depending on the particular objectives of the fire PRA and the potential risk significance of the plant area, the scenarios can be defined in a broad or detailed manner. For example, for plant areas where a conservative analysis is sufficient to demonstrate low risk, the representative fire scenario can be defined as a fire anywhere in the area. For plant areas where a more detailed analysis is needed, multiple fire scenarios defined in terms of the precise location and initial magnitude may need to be specified. The estimation process generally involves the statistical analysis of historical data and the application of engineering judgment.

In many past PRAs, the statistical analysis has been done on an area/location basis [38, 40]. However, under current guidance, the analysis is typically done on an ignition source basis. The first approach involves estimating fire frequencies for common plant area types (e.g., main control room, cable spreading room, switchgear room, auxiliary building, turbine building, etc.). The second approach involves estimating fire frequencies for common component types (e.g., pumps, electrical panels, transformers) and objects of particular interest to fire analysis (e.g., collections of transient combustibles). Currently, the component-based approach is preferred because it enables the analyst to account for plant-specific differences in the location of ignition sources. NUREG/CR-6850 identifies roughly 40 unique fire ignition source groupings (bins) that reflect both component and source types and, in some cases, the specific fire type to be postulated for a given component type. (For example, pumps may be involved in either oil fires or electrical motor fires, and higher energy electrical switching equipment may be involved in either slower developing "thermal" fires or rapid high energy arcing fault fires).

The fire frequency for a specified component group (or plant area type) is estimated using conventional statistical modeling methods[13] [44, 45]. (See also Chap. 74.) These methods include direct approaches that assume that all of the industry data for a particular fire type come from the same population and can be pooled, and more sophisticated approaches that assume that there is plant-to-plant variability in fire occurrence rates even for a specified fire type. In the first class of approaches, generic industry

[13] Consistent with typical PRA modeling practices for many hazards it is generally assumed that fire frequencies are constant over time. One uncertainty regarding fire frequencies is whether or not this is a good assumption. The U.S. nuclear industry has documented fire event data going back to 1965, but the appropriateness of using of older events in a current analysis has been questioned. Prior analyses of fire frequency trends have reached divergent conclusions. One review of fire event data published in 2001 [44] showed that the frequencies of reported fires in key U.S. nuclear power plant compartments had not changed dramatically when comparing the periods 1965–1985 and 1986–1994, and thereby supported the use of the Poisson model for U.S. nuclear power plant fire occurrences. However, a more recent analysis demonstrated an apparent shift towards lower fire occurrence rates around 1990. The fire PRA community has not reached consensus on the subject, and as discussed in the "Current Activities and Future Directions" section below, an ongoing effort to gather additional fire event data is being performed, in part, to resolve the question.

frequencies are generated using observations of the form n occurrences (events) in time t, grouped by the component types defined in the fire PRA. In a Bayesian approach, the generic industry data are used to develop a prior distribution for the fire frequency. This prior distribution is then updated using plant-specific data. Regarding the second class of approaches, a two-stage Bayes method, described by Kazarians and Apostolakis [46], has been used in developing the frequencies provided in NUREG/CR-6850.

Regarding the data used in the statistical estimation process, reports of fire events at U.S. nuclear power plants beyond those that require reporting to the NRC are provided to Nuclear Electric Insurance Limited (NEIL) by the plant licensees on a voluntary basis. For fire PRA, the event reports are screened to exclude construction fires and other plant fires not relevant to fire CDF (e.g., office building or warehouse fires). The remaining reports were used by EPRI to establish a proprietary fire event database used to develop the fire frequencies reported in NUREG/CR-6850. Limited fire event information from the EPRI database, modified to ensure plant anonymity, is provided in NUREG/CR-6850. The proprietary database has many shortcomings, one of which being its completeness (since the reporting of many fire events is voluntary). A plant-to-plant variability analysis has been performed to address the impact of apparent differences in reporting. The result was a moderate increase in fire frequencies for all fire ignition sources, but the question of potential underreporting remains an area of uncertainty relative to fire event frequencies. As discussed further below, efforts are currently underway to gather a more complete, comprehensive and consistent set of event data from the entire U.S. commercial nuclear fleet. This work is being performed as a collaborative activity between the NRC and EPRI.

Despite the large uncertainties typically resulting from any of these approaches (due to the small amount of data available for each fire type), it is common practice to use simple point estimates of fire frequencies. The mean values of the uncertainty distributions provided in NUREG/CR-6850 are generally used for this purpose. In recent fire PRAs, these uncertainty distributions are propagated through the risk model only for dominant contributors to estimate the uncertainties in the total fire CDF.

The above discussion focuses on estimating the occurrence rate of fires (regardless of fire magnitude). We note that the severity of a fire event is also an important element of fire PRA. In many early studies, "severity fractions" or "severity factors" were used to address the relative likelihood of "challenging fires," fires that have the potential to cause significant damage in a relatively short amount of time, as a fraction of all the fires included in the fire frequency calculation. One complication of this approach was that, in general, the applied severity factors implicitly took some credit for early fire suppression activities and fire suppression that was then independently credited later in the analysis. Care must be taken when analyzing fire detection and suppression (as discussed in the following section) to avoid double-counting their effectiveness. Under current approaches, the event data are pre-screened to eliminate fire events that would not have led to risk-relevant challenges under any foreseeable circumstances. While severity factors remain a part of the current analysis methods, their role in the analysis has changed. Severity factors are now used to reflect aleatory uncertainty regarding the severity of fires that do occur; that is, even for a given fire ignition source, no two fires will develop exactly the same and this is reflected using a severity factor approach. This topic is discussed in the following section.

The component-based frequency approach has not yet reached full maturation. Current practice begins with the generic plant-wide frequency values and then partitions those values within the plant based on the locally calculated population of specific fire ignition source types (e.g., pumps, motors, electrical cabinets, etc.). Hence, it represents something of a hybrid between the earlier location-based approaches (where in this case the location is in effect the entire plant) and a true component-based frequency where a given pump would have a specific frequency value and

the plant-wide pump fire frequency would then be based on the number of pumps present at the plant. There are challenges to implementing such an approach and a true component based frequency approach remains a challenge for the future. This is discussed further in the Current Activities and Future Directions section.

Fire Scenario Selection and Analysis

General Approach The goal of the fire scenario selection and analysis element is to perform a detailed analysis of the fire growth, propagation and possibility of fire suppression before damage to a specific target set for each applicable fire scenario per plant area. Plant areas that have been previously screened out because the plant area of fire origin does not contain important equipment are reexamined for the potential that fire damage might spread to adjacent, important plant areas. The analysis is based on the evaluation of fire scenarios which are defined based on the general characteristics of the fire being postulated, the potential extent of fire-induced damage, and fire mitigation measures that will be credited for preventing damage.

As discussed by Apostolakis et al. [38, 39], the assessment models the occurrence of fire damage as the outcome of a "race" between two parallel processes: (1) fire growth and damage, and (2) fire detection and suppression. To determine the outcome for a particular fire scenario, the analyst needs to address two key questions: "how quickly (if at all) will this fire cause damage if it is allowed to burn without intervention?" and "how quickly will the fire be suppressed?" Since the fire growth and suppression processes are both subject to random variability, this race is a probabilistic process and the probability of equipment damage, the $p_{ed,j|i}$ term in Equation 89.1, can be conceptually represented by the following equation:

$$p_{ed,\,j|i} = P\left(t_{ed,\,j|i} < t_{s|i}\right) \tag{89.3}$$

where:

$t_{ed,j|i}$ = the damage time for target set *j* given fire scenario *i*; *and*

$t_{s|i}$ = the suppression time for fire scenario *i*.

In practice, the probability of equipment damage is decomposed into two parts as given by:

$$p_{ed,\,j|i} = SF_i \times P_{ns,\,j|i} \tag{89.4}$$

Where

SF_i = severity factor for fire source i; and

$P_{ns,j|i}$ = probability of non-suppression prior to damage to target set j given ignition source i.

The severity factor reflects the fraction of fires involving the fire source that are potentially damaging and the non-suppression factor reflects the probabilistic outcome of the fire damage versus fire suppression race given a potentially damaging fire. Both of these terms are discussed further below.

From a process standpoint, the assessment generally requires:

1. The identification of specific combinations of fire sources and target sets,
2. An analysis of the fire-induced environmental conditions,
3. An assessment of the response of each target set to these conditions, and
4. An assessment of the effectiveness and timeliness of fire mitigation features including detection, suppression and fire barriers.

The fire barrier assessment needs to address barrier effectiveness in preventing fire propagation to adjacent plant areas, as well as in preventing fire damage to protected equipment in the room of fire origin.

In practice, the fire PRA must, at some level, consider any fire that might occur anywhere within the plant. Hence, the analysis may initially consider several hundred to a few thousand potential fire scenarios. The fire scenario selection and analysis element is structured to allow progressive scenario screening to optimize analysis resources by identifying and focusing on those fire scenarios that are the most important CDF contributors. Less important scenarios are analyzed in limited detail and then set aside (screened out) once the conclusion of low CDF importance has been reached. Other fire

scenarios are carried forward through the analysis and ultimately quantified[14] as substantive contributors to fire CDF. The decision as to which scenarios to screen out and which to carry forward is typically based on a quantitative screening criteria designed to ensure that the vast majority of the fire-induced CDF is captured by detailed analysis. This process follows the same iterative approach that is commonplace in most fire PRAs. In the end, a typical fire PRA may quantify well over 100 fire scenarios in considerable detail. The next four subsections provide an overview of this analysis process.

Preliminary Fire Source Screening and Severity Factor Analysis Fire Source Screening is the first task in the Fire PRA framework where fire modeling tools are used to identify and analyze ignition sources that may impact the fire-induced CDF. Screening some of the ignition sources in a plant area may, in effect, reduce the compartment fire frequency previously calculated. This task also introduces the previously discussed severity factor (SF_i). The two main objectives of this task are to screen out fixed ignition sources that do not pose a threat, and to assign severity factors to unscreened fixed ignition sources. This task is performed by fire protection engineers using various fire modeling tools (discussed later) in coordination with methods described in this section with the following material readily available;

- List of components in plant areas,
- Equipment layout drawings, and
- Elevation drawings of rooms and equipment.

The fire protection engineer will also have to establish the characteristics of a credible fire associated with a specific ignition source. The exact nature of the information will depend on the characteristics of the ignition source. The following are examples of such information:

- Quantity of the oil maintained inside rotating machinery,
- Power and voltage of a motor,
- Power of electrical cabinets, and
- Quantity and nature of combustible and flammable materials maintained in an enclosure.

This task is commonly based on plant walkdowns and zone of influence (ZOI) considerations. Regarding the latter, the fire protection engineer specifies a ZOI for the ignition sources in a specific plant area. Each ZOI reflects the potential for an ignition source to cause some level of damage beyond the ignition source itself. Those sources that cannot, by themselves, damage target sets of interest or cause the spread of fire to secondary combustibles are screened out from further analysis.

The analysis should consider the following potential targets:

- The closest component (including cabinets and cables) to the fixed ignition source if no specific knowledge about PRA target locations in the area is currently available;
- Known fire PRA components (targets of interest to the analysis) in the area, if the specific target locations are known; or
- Another intervening combustible material.

These targets can be affected through the following exposure situations:

1. Engulfed in flames,
2. Within fire plume,
3. Within the ceiling jet,
4. Within the smoke layer, or
5. Within the flame irradiation zone.

The type of exposure will depend on the location of the target with respect to the fire. The fire ZOI is defined using fire models to determine the regions where fire conditions will cause target damage or ignition. Conservative fire modeling calculations are then performed to predict the fire conditions near a target to assess if target damage or ignition is possible. The analyst can then be confident that an ignition source can be screened out if no relevant targets receive thermal damage or are ignited. Ignition sources that are part of the fire PRA component list cannot be screened because the loss of the ignition source itself represents loss of at least one PRA target.

[14] In the context of a PRA study, scenarios are "quantified" by estimating their frequencies of occurrence. Ideally, the estimates are expressed in terms of probability distributions for these frequencies.

However, it is rare for scenarios limited to loss of the ignition source to be found risk-significant. Exceptions typically involve electrical cabinets and, in some cases, cable raceways. (It should also be recognized that the internal events PRA model includes the independent component failures, regardless of the failure cause.) For ignition sources that do not screen out, the severity level of the fire needed to cause damage can be established and the corresponding severity factor is estimated.

Fire source burning behavior is commonly characterized by a distribution on peak heat release rate (HRR) reflecting the aleatory uncertainty associated with fire development. Once the peak HRR distribution is developed, higher percentiles of the distribution can be used to estimate the severity factor. For example, if the minimum HRR needed to cause target damage (or ignition, in the case of intervening combustibles) corresponds to the 98th percentile of the distribution, the severity factor for that case is 0.02. This is illustrated in Fig. 89.7, which involves the case of a target within the range of damaging flame radiation. After determining the probability distribution for the peak HRR, the lowest HRR required for damage, $\dot{Q}_{dam}$, is computed. The percentile corresponding to $\dot{Q}_{dam}$ is determined from the probability distribution. The complement of this percentile is the fraction of fires whose peak HRR exceeds the minimum required for damage.

At this point, the analyst should have a list of unscreened ignition sources with the respective distance to the nearest target and fire condition affecting it (ignition or damage) as well as the corresponding severity factor.

Analysis of Fires Impacting Single Plant Areas The next step in the Fire Scenario Selection and Analysis element is to perform a more complete analysis of unscreened plant areas as individual contributors to fire CDF. This task, which is performed by fire protection engineers, involves a detailed analysis of fire scenarios involving unscreened ignition sources in each unscreened plant area that damage target sets located within the same plant area. The majority of fire scenarios analyzed in the fire PRA generally fall into this category.

In early stages of the iterative fire PRA process, the analysis is based on conservative assumptions regarding fire growth and damage. In particular, the fire ignition frequency, plant response (as characterized by the CCDP), and all other relevant parameters are based on the simplifying assumption that any fire in an area would damage all important target sets in that area. In this step, the focus is shifted towards specific damaging fire scenarios impacting a single plant area, and the objective is to estimate their frequencies of occurrence; that is, the frequency of fires leading to the loss of specific target sets within a plant area.

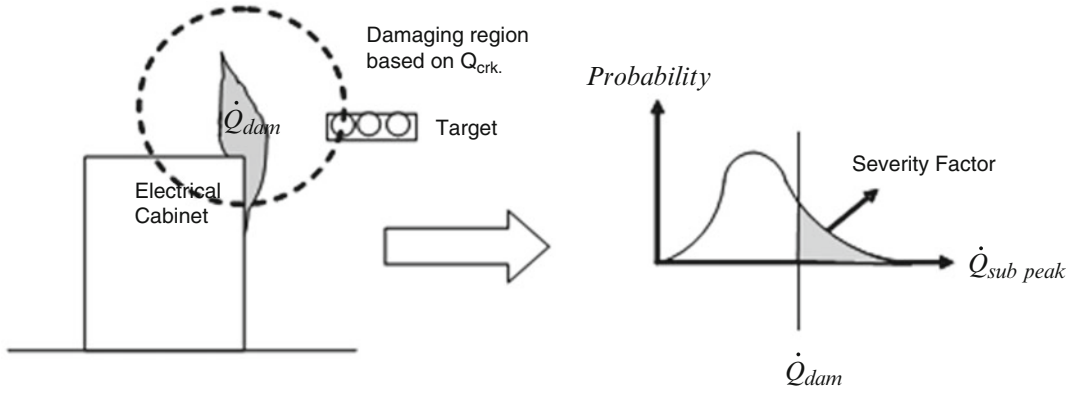

Fig. 89.7 Determination of severity factor using fire models

The analysis includes both fixed ignition sources (e.g., fixed plant equipment) and transients. Transients, in turn, include both transient fuel packages such as trash or temporary storage items, and transient activity related ignition sources such as welding and cutting operations.

The initial steps performed in this analysis characterize the plant area and, in practice, are often performed during execution of the Plant Partitioning element. These steps involve:

- Identifying and characterizing the plant area,
- Identifying and characterizing fire detection and suppression features and systems,
- Characterizing fire ignition sources,
- Identifying secondary combustibles, and
- Identifying and characterizing target sets.

Most of this information will be identified during plant walkdowns as well as various equipment selection and cable tracing tasks.

The next steps in this process will largely dictate the resources and time needed to complete the fire PRA. These are:

- Defining the fire scenarios to be analyzed,
- Conducting fire growth and propagation analysis, and
- Conducting fire detection and suppression analysis

In order to define a scenario, the analyst starts with an ignition source, postulates potential growth and propagation to other combustibles, and identifies the target set (or target sets) that may be exposed to the specific fire. The process commonly includes the consideration of an expanding ZOI over time for a single fire ignition source. That is, the ZOI is expanded over time until all relevant targets are included. Another ignition source is then selected and the process repeated until all target set and ignition source combinations are considered. This process should yield all potential fire scenarios that may damage the various target sets identified in the preceding steps. Note that this process represents a "one-to-many" mapping of ignition sources to potential risk scenarios because each target set that is defined has unique implications relative to plant safe shutdown. That is, each unique target set implies that a unique CCDP value ($p_{CD,klj,i}$) will be calculated using the plant response model.

The typical analysis approach for detection and suppression is relatively simple. Fixed fire protection systems are credited provided they actuate in time to prevent target damage (based on fire modeling) and are deemed effective against the postulated fire source (based on engineering judgment). Manual fire suppression is typically credited based on historical event data. These topics are discussed in greater detail in the section entitled "Fire Detection and Suppression Analysis".

Depending on the characteristics of the plant area, the analysis may need to treat the potential for dynamic fire growth. Such growth can, over time, cause damage to more and more equipment. This implies more serious plant response challenges and higher CCDP values. On the other hand, the equipment is often spatially separated, and more distance implies longer damage times. Longer damage times, in turn, imply a greater chance that the fire will be put out prior to damage (i.e., a lower non-suppression probability; $P_{ns,jli}$—value). A multi-stage approach to assess damage allows for a proper balancing of these two competing effects.

A typical example is illustrated in Fig. 89.8 which shows a stack of cable trays above the fire with fire PRA targets in the first and fourth trays (T1 and T2). A third target tray (T3) is also present but will only be damaged given formation of a damaging hot gas layer.

The conservative approach to this case is to assume all targets are damaged at the same time but this approach requires that damage be assumed for *all* targets as soon as the *first* target fails (in order to avoid an optimistic result). In this case, all trays would be assumed to fail when the first tray fails. The more complex but also more realistic multi-stage alternative is to represent the scenario as a progression of discrete steps accounting for the success or failure of fire suppression efforts within each relevant time frame. Figure 89.8 illustrates the multi-stage damage state model as applied to the 3-tray example.

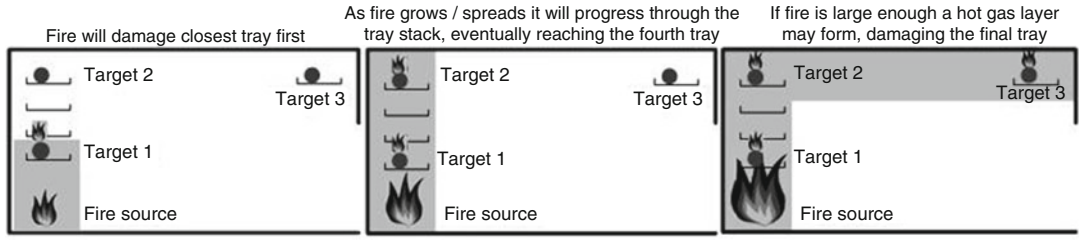

Fig. 89.8 Example case with three PRA targets present that have some degree of spatial separation

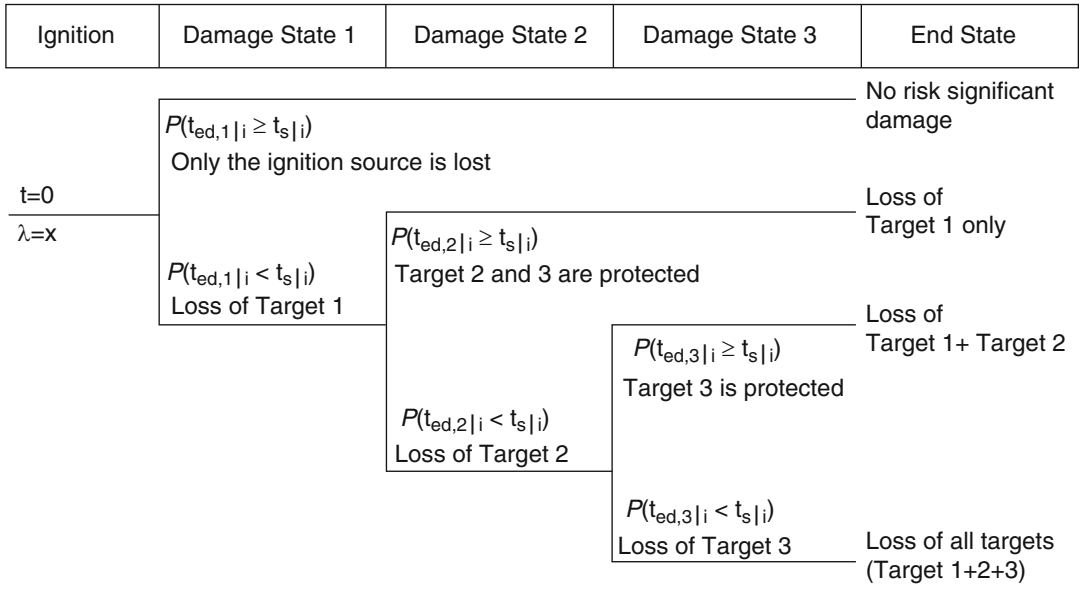

Fig. 89.9 Conceptual event tree representing a scenario progression

It is important that the various damage states be properly balanced in terms of scenario frequency because all arise from the same fire source. One common approach to modeling this type of scenario is through the use of a fire event tree as illustrated in Fig. 89.9. The events in the tree begin with ignition of a damaging fire, and progress through a series of three suppression success/failure events ultimately leading to one of four possible outcomes: namely; no damage to PRA targets; loss of Tray 1 only; loss of Trays 1 and 2; and loss of all PRA targets (Trays 1, 2 and 3). The branch point conditional probability values based on factors that include, as appropriate, the reliability of automatic detection and suppression systems, timing of each fire damage state, and the performance of manual firefighting. Inherent in the event structure is the condition that the success of an event implies a timely response; that is, the fire must be mitigated before a given damage state is reached. Chapter 38 provides additional discussion regarding event trees as used in fire protection engineering applications.

A wide range of tools is available for the analyst to conduct fire growth and spread analysis and most of those tools have been described in other Chapters of this Handbook. The tools range from simple empirical equations to computerized, numerical, three-dimensional models. Later in this Chapter, we discuss some of the more common tools used in fire PRA applications.

Analysis of Fires Impacting the Main Control Room The Main Control Room (MCR) has a unique role in nuclear power plant operations and fire risk, and is typically treated separately from other general plant areas due to its unique fire risk aspects. In MCRs the control and instrumentation circuits of all redundant trains for almost all plant safety systems are present. Furthermore, redundant train controls may be installed within a short distance of one another (e.g., on the main control boards). Therefore, even small fires within control panels may be risk-significant. Additional scrutiny is placed on the MCR also because plant safety depends on the performance of control room operators. A fire adversely affecting the operators' ability to perform needed functions may have severe safety implications. In extreme situations, fire-generated conditions (loss of control functions, high temperature and heat flux, toxic gases, and reduced visibility) could force control room abandonment. All U.S. plants have an alternate shutdown capability, that is, a critical set of independent controls and instrumentation outside the MCR, to deal with control room abandonment scenarios. Part of the MCR analysis is to analyze the reliability of this capability. On the risk-reducing side, another unique feature of the MCR is that it is continuously occupied with trained operators. This increases the probability that a fire will be promptly detected and addressed.

The MCR analysis task covers all fires that occur within the MCR. This task also covers scenarios involving fires in plant areas other than the MCR that may force MCR abandonment, for example, due to fire-induced loss of a critical set of plant controls and instrumentation. Within the MCR, the target sets consist, for the most part, of control- and instrumentation-related components and wiring within one, adjacent, or nearby electrical control panels and cabinets. As opposed to other plant areas, where targets are usually cables throughout the area, control room targets are cabinets controlling safe shutdown related functions. Cabinets in some MCRs are equipped with smoke detectors, which can reduce the fire detection time and indicate which specific cabinet is on fire. Although MCRs are equipped with smoke detector systems, due to potential risk of spurious activation no fixed suppression is available. Manual suppression is typically the extinguishing method used. Each of these characteristics will impact the risk analysis by influencing the non-suppression or abandonment probabilities.

As compared with the analysis of other plant areas, the unique aspects of the MCR analysis include the consideration of much smaller fire damage footprints (due to the expectation of prompt detection and suppression). For example, a typical scenario in the MCR will assume that damage is limited to a small portion of the main control board rather than assuming loss of an entire electrical cabinet plus external targets. The MCR analysis also considers the impact of fire on operators whereas the analysis of most plant areas considers only equipment and cables. The MCR analysis also involves unique human performance considerations including the decision-making process associated with abandonment. Another unique aspect of the analysis is that, unlike other plant areas, most MCRs are equipped with some form of a smoke purge system. Such systems provide the ability to ramp-up exhaust flow and switch to full fresh-air makeup at a minimum. A well-designed smoke purge capability can delay, or even prevent, forced abandonment. The analysis of such systems calls for more sophisticated models than are typically needed for fire scenarios in general plant areas.

Analysis of Fires Impacting More Than One Plant Area The analysis of multi-compartment fire scenarios covers all fire scenarios involving fire spread from one plant area to another and, therefore, damage in multiple plant areas. Adjacent plant areas are considered systematically and generally in pairs only. That is, based on the occupancy of most nuclear power plant fire areas and the existence of robust fire protection measures, fire spread beyond to a third plant area is generally not considered likely.

Commercial nuclear power plants have numerous interconnected compartments that may be aligned horizontally or vertically. Connections between plant areas include fire doors, stairways, sealed cable and piping penetrations, openings, and gratings. Depending on how plant areas were defined during plant partitioning, plant area interfaces may also include open space (free of combustibles), active fire protection features (such as water curtains or a normally open fire door) and non-rated fire barrier elements. Considering the numerous interconnected compartments and the amount of analysis needed to evaluate fire-generated conditions in multi-compartment scenarios, a detailed multi-compartment analysis can be resource intensive. Practical analysis, therefore, emphasizes screening multi-compartment combinations before identifying fire scenarios that need to undergo detailed fire modeling.

The analysis often involves combining plant areas of interest into a single area and assessing the potential for fires leading to formation of a damaging hot gas layer in the combined area. This analysis uses standard fire modeling tools, described elsewhere in this Handbook. The analysis also considers paths for direct spread of fire across a barrier element, including the potential that a fire barrier element (e.g., a penetration seal) may randomly fail (e.g., it may have a hole through it due to improperly completed maintenance activities at the time of the fire). The analysis also considers that multi-compartment scenarios will only have a unique risk contribution if new target sets are threatened given fire spread to a second plant area (i.e., as compared to those already threatened in the area of fire origin and encompassed by the single compartment scenarios).

The methods of analysis for multi-compartment scenarios remain relatively unsophisticated, and some areas of uncertainty remain. For example, the random failure probability for a rated fire barrier element is not well characterized. Current practice is to define the plant areas during the plant partitioning task such that risk-significant multi-compartment fire scenarios are unlikely. In theory, regardless of how partitioning decisions are made, the analysis should reach the same conclusions.

Circuit Analysis

Circuit Failure Mode Analysis

Circuit analysis has become an increasingly complex and important aspect of fire PRAs in recent years. All past fire PRA studies have addressed fire-induced circuit failures that lead to a loss of function and many have included the possibility of fire-induced spurious operation of plant equipment (although the treatment was limited by current standards). The latter failure mode has become an increasingly important analysis topic over time based on the results of tests and analysis indicating the likelihood of spurious operations, and especially multiple spurious operations, is higher than previously thought [47–50]. Spurious operations can be caused by hot shorts (i.e., electrical faults between cable conductors without a loss of circuit power). Depending on the specifics of the circuit, they can also be caused by other fire-induced cable faults (e.g., single ground shorts or a ground equivalent hot short on an ungrounded power source like station batteries) [47, 49]. The likelihood of fire-induced spurious operations and the associated contribution to fire CDF appears to be influenced by a number of plant-specific factors. Although the precise values are uncertain, under any circumstances a modern analysis of these failures is a resource-intensive effort.

Circuit failure mode analysis is performed by electrical engineers. The analysis involves the deterministic failure analysis of important circuits. The purpose of the analysis is to identify those circuits and cables that can adversely affect the credited functionality of essential equipment/components, and to document the equipment responses to the possible cable failure modes induced by fire damage. As noted above, this element is often conducted in close coordination with the Cable Selection and Tracing element, which is aimed at identifying cables. This

element determines the functional impact of potential failures of these cables.

Although this element is performed by electrical engineers, it is useful for fire protection engineers to recognize: (a) the importance of this element to the overall fire PRA results, (b) the potential need to model scenarios involving damage to multiple cables (since multiple cable faults may be needed to induce a spurious operation, and also since multiple spurious operation scenarios might be important to fire CDF), and (c) the particular fire-induced cable faults (shorts to conductors within a single cable, shorts to conductors in another cable, shorts to ground) that may need to be modeled in the analysis.

Circuit Failure Mode Likelihood Analysis

The circuit failure mode likelihood analysis is the probabilistic complement to the deterministic circuit failure mode analysis. That is, this step assigns conditional probability values to specific component failure modes given fire-induced cable failures. Should a fire damage a target cable or set of cables, the likelihood of the above-mentioned cable faults and the durations of these faults are complex functions of many factors, including raceway fill, thermal exposure conditions, fuse size, circuit type, cable construction, and raceway routing. Experiments have been performed to evaluate cable electrical performance for a number of different configurations [51]. The results of these experiments have directly supported deterministically-oriented analyses of fire-induced circuit damage phenomena. In addition, although the tests were not designed to generate a representative random sample, their results provide valuable input to expert elicitation panels tasked with developing estimates for the conditional probability of spurious operations (given fire-induced cable damage) and the duration of these spurious operations. The panels include fire protection engineers (to bring in knowledge regarding both the test conditions and fire modeling approaches for nuclear power plant scenarios), as well as electrical engineers and PRA experts.

The results of an expert panel elicitation for estimating the likelihood of fire-induced spurious operations involving alternating current circuits (AC) are provided in EPRI TR-1006961 [52]. An analogous effort aimed at addressing direct current (DC) circuits is ongoing. This latter effort, building on lessons learned from past elicitations, is using guidance on conducting structured expert elicitations originally developed for seismic PRA applications but applicable to other areas as well [53, 54].

Human Reliability Analysis

In the context of nuclear power plant PRA, Human Reliability Analysis (HRA) is the process used to identify, characterize, and estimate the likelihood of potentially important human errors. These errors can occur prior to the occurrence of an accident (e.g., failure to properly re-align equipment after maintenance), trigger an accident (e.g., inadvertently initiate a reactor shutdown), or during the course of the accident (e.g., fail to appropriately execute a step in plant procedures). HRA has both qualitative and quantitative analysis elements. A general overview is provided in Chap. 74.

In the context of fire PRA, the focus of the HRA element is on errors that may occur as plant operators (including but not limited to the crew of operators in the MCR) respond to fire-initiated scenarios. Human errors causing fires (e.g., inadequately controlled hot work) are built into the fire event data used to estimate fire frequencies, as described earlier in this chapter. Human errors in detecting and suppressing fires are addressed as part of the detailed fire analysis effort. (Such errors affect the time to suppress a fire, denoted by t_{sli} in Equation 89.3. Additional discussion on analyzing this term is provided later in this Chapter).

The specific errors of interest in the HRA element involve operator manual actions taken, in accordance with the operators' procedures and training, to perform needed safety functions (e.g., initiate emergency cooling). These manual actions are typically represented in the plant

response model as human failure events (HFEs). HFEs can be provided in event trees (as illustrated by "Manual Reactor Depressurization" branch in Fig. 89.3) or in fault trees (as illustrated by the basic event "Operator Fails to Start/Control RCIC Injection" in Fig. 89.4). They can be errors that are already included in the internal events model (albeit with potentially different probabilities) or they can be introduced into the plant response model due to unique conditions created by the fire scenario (e.g., an inability to complete a desired action due to the fire's location). These conditions are extremely important to the estimation of the HFE probabilities (commonly referred to as Human Error Probabilities or "HEPs"), since human error probabilities depend strongly on the context for the actions being taken. In the case of fire PRA, the analysis team needs to consider such factors as the potential effects of the fire on needed equipment (including such plant support systems as lighting) as well as such physical hazards as heat and toxic gases.

NUREG-1921/EPRI 1023001 [55] provides detailed guidance for performing fire HRA. As indicated in this guidance, fire HRA is a multidisciplinary effort. The analysis requires input regarding a wide range of information, including plant procedures,[15] associated operator training, potential fire-induced environmental effects, fundamental psychological and social mechanisms leading to human error, and the "Performance Shaping Factors" (PSFs) affecting these mechanisms. The general steps involve:

1. HFE identification and definition,
2. Qualitative analysis of each HFE and,
3. Quantitative analysis of each HFE.

The first step identifies those operator actions and associated instrumentation necessary for the successful mitigation of fire scenarios and defines associated HFEs at a level of detail appropriate to support qualitative analysis and quantification.

In the second step, the HRA team develops an understanding as to how each HFE interacts with the overall plant PRA. This understanding should reflect the "as-built, as-operated" response of the operators and plant. Key characteristics include:

- Potential fire-induced initiating events,
- Potential accident sequences (particularly functional failures and successes, including preceding operator errors and successes),
- Event timing information,
- Accident-specific procedural guidance,
- Availability of cues and other associated indications that may be needed to identify necessary actions, as well as those that might subsequently enable the operators to detect the need for a correct action that has been omitted or performed incorrectly,
- Preceding operator errors or successes in sequence,
- Criteria defining operator action success, and
- Physical environment information.

The team translates this information into a form useful for the estimation of HEPs. A sound qualitative analysis also allows the HRA to provide feedback to the plant on the factors contributing to the success of an operator action and those contributing to the failure of an operator action.

In the third step, the HRA team develops estimates for the HEPs. This quantification process can be carried out at varying levels of detail, depending on the significance of the HFE. Screening-level analyses using conservative HEP estimates are commonly used for unimportant HFEs, thereby enabling the team to focus attention on those HFEs important to the overall fire CDF.

As with the rest of fire PRA, fire HRA is typically performed in an iterative fashion. Initially simple, conservative analyses are upgraded with more detailed analyses as the team gains a more accurate understanding of the fire CDF and its principal contributors.

Fire Risk Quantification

Risk quantification is where the results of the various elements of fire PRA are assembled to produce the desired risk estimates. This chapter

[15] These procedures include Emergency Operating Procedures (EOPs), Annunciator/Alarm Response Procedures (ARPs), and Abnormal Operating Procedures (AOPs), as well as specific fire response procedures.

has focused on the fire CDF. Estimates of another risk metric of interest, the large early release frequency (LERF), is developed in a similar fashion to CDF. As its name implies, the LERF metric represents the likelihood of a large, relatively quick release of radionuclides into the environment after a core damage event. A LERF analysis builds on a CDF analysis, but adds models to address the possibility of a breach in the containment structure (see Figs. 89.1 and 89.2) following a core damage accident.

Conceptually, risk quantification is performed by summing the contributions of individual fire scenarios, as shown in Equation 89.2. In practice, the large number of fire scenarios considered in a typical fire PRA, compounded by the multiplicity of potential plant responses to each fire scenario, calls for the use of specialized PRA software tools to ensure correct treatment of model complexities (e.g., dependencies between different parts of the model) and avoidance of inappropriate conservatism or non-conservatism in the final results. The previously mentioned SAPHIRE [41], CAFTA [42] and FRANX [43] are examples of software packages used in current studies. These programs support the construction and documentation of models, the development of results, and the analysis of results. The last activity includes the identification of key scenarios, the use of diagnostic ("importance") measures to better understand the contributors to these scenarios, and the performance of sensitivity studies to better understand the impact of different modeling assumptions.

Uncertainty Analysis

Uncertainty analysis is that element where the key state-of-knowledge uncertainties (often called "epistemic uncertainties") associated with the fire PRA are identified and treated.[16] Various approaches to uncertainty analysis can be used, depending on the needs of the decision problem addressed by the fire PRA as well as the technical nature of the uncertainties themselves.

In general, the epistemic uncertainties in fire PRA model parameters (e.g., fire frequencies, fire model parameters such as the heat release rate for a specified fire) and in the fire PRA models themselves (e.g., physical models for fire-induced component damage, event tree models for plant safety impacts of fire) are handled as described in this Chap. 76. Assuming the decision problem (including potential future decision problems) and the role of the fire PRA in addressing this decision problem have already been defined, the uncertainty analysis involves:

- Identifying the sources of uncertainty in all aspects of the fire PRA model (including such non-fire protection engineering aspects as the plant response model);
- Characterizing the uncertainty in the fire PRA model (both inputs and model structure);
- Characterizing the uncertainty in the fire PRA model output; and
- Interpreting the results of the uncertainty analysis and presenting this information in a form suitable for use by decision maker(s)

The notion of "characterizing" (as opposed to "quantifying") uncertainties is used to include situations for which a rigorous analysis may not be needed. From a decision support perspective,

[16] As with nuclear power plant PRA in general, fire PRA addresses two types of uncertainty: aleatory and epistemic uncertainty [10]. Aleatory uncertainty, also called "random uncertainty" or "stochastic uncertainty," is that associated with inherent, potentially observable variability in the events and behaviors being modeled. Epistemic uncertainty is associated with limitations in the PRA analyst's state of knowledge, and can involve such things as uncertainties in the true value of an input parameter for a fire model or in the appropriateness of the model itself. Unlike aleatory uncertainty, epistemic uncertainty can be reduced through the collection of additional information (e.g., via experiments).

The fundamental structure of fire PRA is aimed at assessing aleatory uncertainty, as the fire-induced CDF is a measure of aleatory uncertainty (it addresses the likelihood of a random event—the occurrence of a core damage accident due to fire). The uncertainty analysis element discussed in this section deals with the epistemic uncertainty in the fire PRA inputs, models, results, and insights.

the key point is not whether the uncertainty analysis results in a mathematically-derived probability distribution for a fire PRA output metric (e.g., the fire-induced CDF), but whether the output uncertainty and its drivers are sufficiently understood to enable selection of the best decision option.

NUREG/CR-6850 provides a number of different possible strategies for treating uncertainties. These strategies, some of which can be used in combination, include:

- Explicitly quantifying epistemic uncertainties in model parameters using probability distributions, and propagating these probability distributions through the fire PRA model using such techniques as Monte Carlo sampling or Latin hypercube sampling;
- Developing multiple models for an issue (e.g., the rate of fire growth for a particular fire), assigning a probability that each model best represents the situation based on engineering judgment, and propagating these probabilities through the fire PRA model;
- Identifying a base case as the best estimate model with best estimate data values, performing sensitivity analyses where the models or parameters of interest are varied within a reasonably expected range, and documenting the quantitative effect on the overall results;
- Identifying sources of uncertainty that can be (or should be) treated in a single group;
- Addressing the uncertainty in only qualitative terms (e.g., describing which scenarios would be affected and providing a qualitative judgment as to the effects); and
- Using a quality review process to ensure sufficient accuracy and a reasonable level of completeness (such as a review of the identified cables in a plant area to be sure none have been missed in the PRA model).

The choice of which strategy (or set of strategies) to use may include consideration of the perceived importance of the uncertainty on the overall results of the Fire PRA; the possible effects on future applications or other decision-making activities; and the resources needed and available, including schedule constraints, to execute the strategy.

NUREG/CR-6850 also points out that, given finite analysis resources, not all sources of uncertainties can be treated. The analysis team therefore needs to:

- Identify those uncertainties that will not be addressed because they are expected to be unimportant (e.g., they are associated with screened out scenarios) or they cannot be addressed (with reasons noted); and
- Identify the strategy (or strategies) to be used to address remaining uncertainties (including which issues that will be treated using sensitivity analysis).

Fire PRA Documentation

As with any engineering analysis, it is important to document the fire PRA to a level sufficient to enable review of the study by external parties and its use in decision support applications. Specific documentation requirements are provided in the ASME/ANS PRA Standard. These requirements cover such things as the need to document, as appropriate, the methods, data, key factors, modeling assumptions, and results of each of the fire PRA elements discussed earlier in this section.

Somewhat unique to PRA (and therefore fire PRA), it is important to recall that the triplet definition of risk mentioned at the beginning of this chapter includes qualitative as well as quantitative elements. Thus, in general, the results of a PRA need to include descriptions of the scenarios contributing significantly to the overall risk, as well as estimates of the total quantitative risk. These descriptions can be organized along many themes, including the general hazard triggering the scenarios (e.g., fires, floods, hardware failures), the particular initiating event demanding a response from plant safety systems (e.g., unplanned reactor trip, loss of electrical power, loss of coolant), the types of safety functions or systems involved (e.g., low pressure versus high pressure coolant injection systems), or even specific contributing elements (e.g., operator errors).

In the case of fire PRA, a common approach is to present aggregated results for specific plant areas (e.g., the estimated CDF associated with fires in a particular switchgear room, and the uncertainties in the estimated CDF). Depending on the needs of the decision problem addressed by the fire PRA, these area-level results can be further broken down into results for specific scenarios within an area or for specific target sets (e.g., if strategies to protect cable trays from fire damage are being considered).

Another useful presentation of results involves the CCDP for all analyzed plant areas. A given plant area may have many scenarios each with a corresponding CCDP value. However, one value typically generated is the CCDP given loss of all PRA targets in the area. This term, which quantifies the likelihood of core damage assuming that a severe damaging fire occurs, provides a sense of how serious a damaging fire could be. Recognizing that the independent failure probability of typical safety systems can be on the order of 10^{-2} to 10^{-3}, a CCDP in that range indicates that, in addition to the fire damage, an independent failure of an additional safety system would be needed before core damage could occur. This would be an indication that redundancy in safety functions remains even given loss of the entire area. Conversely, a CCDP closer to 1.0 would indicate that a severely damaging fire would be likely to cause core damage by itself. An area with a high CCDP value but a low CDF contribution is also of interest because this indicates that some factor, or factors, have been given substantial risk-reduction credit. Credited factors might typically include assumed fire characteristics, physical separation of PRA targets from fire sources, or fire protections systems and features. Understanding the importance of such factors can be important to decision making.

Armed with these results, decision makers have the information to understand not only the "bottom line" results, but also the reason for the bottom line. This detailed information has proven useful in the development and assessment of potentially effective risk management alternatives.

The Use of Fire Modeling Tools in Fire PRA

The preceding section has discussed all of the elements of fire PRA. Most of these elements require at least some input from the fire protection engineer. The two elements requiring the most substantial fire protection engineering involvement lie at the middle of Fig. 89.6: "Fire Scenario Selection and Analysis" and "Detailed Fire Modeling." Both of these elements require the use of fire modeling tools. These tools are further discussed in this section.

Fire Environment Analysis

Predicting the time to fire-induced failure of PRA targets requires two types of calculations. The first estimates the time-dependent environmental conditions created by the postulated fire in the proximity of the equipment and cables of interest (i.e., the targets). The second addresses the response of the damage target to that environment. This section discusses modeling of the exposure environment; target response modeling is discussed in the following section.

The environmental conditions that a fire model is asked to predict correspond to the target's damage mechanisms. Most commonly, the assessment focuses on temperature and/or heat flux leading to thermal damage. However, other environmental conditions such as heavy smoke may also be of interest, depending on the vulnerability of the target to these conditions. The estimation of environmental conditions requires the treatment of a variety of phenomena as the fire grows in size and severity, including: the spread of fire over (or within) the initiating component (or fuel), the characteristics of the fire plume and ceiling jet, the spread of the fire to noncontiguous components, the development of a hot gas layer, and the propagation of the hot gas layer or fire to adjacent compartments.

The modeling tools used to analyze nuclear power plant fire scenarios are much the same as those described elsewhere in this handbook.

Common empirical correlations are employed for the aforementioned phenomena, including initial estimates of hot gas layer development. The commonly available compartment fire models including both zone models and computational fluid dynamics (CFD) models are also used.

Nuclear plant fire scenarios have a number of characteristics that may not be directly addressed by fire models not explicitly designed to model these scenarios. These characteristics include: a variety of source fire types unique to industrial facilities such as cable trays, electrical cabinets, and pressurized gases; the possibility of propagation through complex fuel arrays such as cable tray stacks; the lack of openings to the external environment; generally complex and often highly congested geometries; the elevated location of many important fire sources and fuels (note that many plume correlations have been based on experiments where the fire is at ground level); local obstructions such as ventilation ducts, piping, and structural members; and a range of localized fire barriers including raceway fire wraps. By and large, the ability to model such features in detail is limited and often either a conservative approach or an empirical approach are employed in lieu of detailed fire modeling.

Another special aspect of fire risk assessment for nuclear power plants is that fire PRA studies often require that fire modeling be done for many fire scenarios. Within a given plant area, many fire scenarios can be defined depending on the number of fixed and transient combustible sources, the number of unique target sets, the success or failure of fire barriers, and the variety of ventilation conditions, including possible changes (e.g., the opening of a fire door to allow fire-fighting access or the shutdown of a forced ventilation system due to closing of fire dampers). Even a single fire source may be modeled using different assumptions regarding, in particular, peak fire intensity. Given that multiple plant areas may need to be analyzed, and given the potential need to perform calculations to support a quantitative uncertainty analysis, the number of scenarios to be modeled can be quite large.

A variety of fire-modeling tools, or tool packages, have been developed to address these needs. In U.S. fire PRA studies, including Individual Plant Examinations of External Events (IPEEEs) [21, 22, 33, 34], the most commonly used tools were the package of closed-form empirical correlations drawn from handbooks and provided by the FIVE methodology [33], the compartment fire zone model COMPBRN IIIe [56], and the methods described in the FPRAIG [34]. More recent tools include the Fire Dynamics Tools (FDTs) [57], another collection of handbook correlations provided in spreadsheet form and developed to support NRC's risk-informed fire protection-related inspection activities, and the zone models MAGIC and CFAST [58, 59]. Other general purpose fire models that have been used in fire PRAs include the field model Fire Dynamics Simulator (FDS) [60].

Empirical correlations such as those assembled in FIVE and FDTs are generally used in quick scoping analyses and during ignition source screening analyses. As such, it is preferable that such tools provide conservative estimates but in particular, optimistic results are to be avoided. The zone and field models are typically used to support more detailed analyses where more realistic values are desired.

Information relevant to fire modeling for fire PRA, including data on cable properties (e.g., ignition thresholds, mass burning rates, heat release rates), is contained in several reports [61–66]. Other required parameters (e.g., for cable thermal conductivity, specific heat, density) are typically estimated using data for generic materials. Most zone models follow one of two approaches to modeling the fire source. One approach is to translate all fire sources into an equivalent liquid fuel pool fire (e.g., based on pool size, fuel properties, and fuel quantity). The second approach is to directly specify the fire in terms of a predefined heat release rate versus time. Discussions on appropriate heat release rates for a range of fire sources (e.g., for electrical cabinet fires, based on experimental data reported by Chavez [67] and Chavez and Nowlen [68]) are provided in NUREG/CR-6850 and in a

more recent "Nuclear Power Plant Fire Modeling Application Guide" [69]. This later report consolidates previously available information and details modeling approaches as they apply to nuclear power plant fire PRA needs.

As discussed earlier in this chapter and Chap. 76 it is important to treat uncertainties. The predictions of fire models are, of course, subject to significant uncertainties. Applications of fire models that neglect these uncertainties (e.g., applications that neglect the possibility of damage to critical cables because they are a few centimeters above the damage height predicted by a given model, or, conversely, those that neglect the possibility of cable survival when the predicted damage height is just above the cable location) can lead to unrealistic assessments of fire risk. The treatment of uncertainty is needed not only to indicate the degree of confidence in analysis predictions, but can also indicate whether improvements in fire modeling sophistication are likely to change the risk insights for a given scenario. Uncertainty is also an important factor in the assessment of safety margin as called for in the NFPA-805 Standard.

The uncertainties in the predictions of the fire models arise from: (a) "model uncertainties," those uncertainties arising from inherent limitations of current understanding of governing phenomena as well as from model simplifications arising when applying fire models to a specific situation, and (b) from a lack of knowledge concerning the actual values of key model parameters.

Regarding uncertainties in fire models, many of the same issues discussed elsewhere in this handbook apply to the analysis of fires in nuclear power plants. For the purposes of this chapter, it is useful to observe that, as discussed earlier in this section, fire PRAs can involve unique concerns and associated complexities (e.g., the spread of a fire over complex fuel beds such as partially filled cable trays, the propagation of fire to secondary combustibles separated from the initial fire source, and the behavior of fires initiated by explosive electrical faults). Available empirical data, for example, those from the 20 ft (6.1 m) separation tests documented by Cline et al. [70] the German Heissdampfreaktor (HDR) tests (see Nicolette and Yang) [71] the Baseline Validation Tests (see Nowlen [72]), and the recent tests performed as part of the International Collaborative Fire Modeling Project [73], address only some of these complexities, and do so in a limited fashion. Thus, it is not surprising that there can be considerable uncertainties in the predictions of fire models (including state-of-the-art fire models) when applied in fire PRAs.

Model simplifications, such as assumptions made by software code developers or the code user, are not necessarily from lack of knowledge but rather are routinely made to enable assessments within time and resource constraints. These simplifications can introduce both conservative and non-conservative biases. As examples of conservative simplifications, analyses often ignore (1) the effect of intervening obstacles when calculating heat transfer to a specified target, (2) the heat sink effect of room equipment and the impact of local oxygen starvation on heat release rates, (3) the limiting effect of forced ventilation, and (4) the time required for the fire to reach the "initial" size used to start the fire model simulation. Examples of non-conservative simplifications include the neglect of radiation feedback to the burning fuel in some models and the common assumption that fires in closed metal cabinets will stay confined within these cabinets.

Engineering methods for quantifying fire model uncertainty using integral test data have been developed and applied in a small number of studies [74, 75]. A systematic framework for treating model uncertainties, including applications to fire modeling, is provided by Droguett and Mosleh [76]. However, as mentioned in this Handbook's discussions on model uncertainty and in NUREG-1855 [11], a quantitative treatment of model uncertainty may not be needed. For example, appropriate efforts to characterize model uncertainty (e.g., through the performance of sensitivity studies to assess the effect of different modeling assumptions) may be sufficient to meet the needs of the fire PRA.

The uncertainty in model parameter values is due to the sparseness of experimental data for some of the parameters (e.g., piloted and non-piloted ignition temperatures for cables) and the uncertainty as to the applicability of the existing data to the situation in the field (i.e., the particular fire scenario being analyzed). Distributions for a number of parameters have been developed (e.g., see Brandyberry and Apostolakis) [77] and used in a number of fire PRA studies. The propagation of these uncertainties through the fire model can be done using readily available tools and methods (e.g., Monte-Carlo or Latin hypercube sampling), as discussed in Chap. 76.

Equipment Response Analysis

Given a predicted fire environment for a PRA target, the fire PRA needs to assess the target's response to that environment and determine the timing of equipment failure. Grouped electrical cables present a common cause failure mechanism for multiple plant systems; hence, a key fire PRA concern is the response of electrical cables. However, the responses of other potentially vulnerable equipment (e.g., electromechanical and electronic components in electrical cabinets) are also of interest. Information relevant to the estimation of thermal fragilities of key equipment is provided in a number of reports [62–64, 78–80]. Information on the effects of smoke on sensitive equipment is more limited [81, 82]. Smoke effects on sensitive equipment are not yet explicitly addressed in detailed fire PRA analyses. (The effects of smoke and fire suppressants on sensitive equipment are implicitly addressed in those screening analyses that assume that any fire within a plant area will damage all equipment within that area).

Current fire PRA treatments of equipment failure due to heat typically involve very simple thermal models. In the early stages of analysis, it is generally assumed that damage will occur if a representative temperature (e.g., the air temperature surrounding a cable) exceeds a threshold value. Similarly, component damage may also be assumed if the incident heat flux exceeds a critical value. These both represent conservative approaches and a relaxation of this conservatism typically involves the use of simple heat transfer models such as lumped capacitance models or one-dimensional transient heat conduction models. One model recently developed specifically for the analysis of cables is called THIEF [83]. This model is a relatively simple one-dimensional heat transfer model than can take a predicted environmental temperature and estimate the thermal response of cables either in open air or in a conduit. THIEF was calibrated based on an extensive series of small-scale cable exposure tests and validated based on large-scale cable fires. This model incorporates some conservatism because it does not account for the thermal mass effects of grouped cables which will tend to slow down cable heat-up. Instead, the model treats cable bundles as a single target cable. However, the use of even simple thermal response models such as THIEF can substantially reduce analysis conservatism because they account for damage time delays associated with target heating. The longer the predicted time to damage, the more credit can be taken for fire suppression prior to damage.

Fire Detection and Suppression Analysis

Equation 89.3 shows that within the context of a fire PRA, the objective of a detection and suppression analysis is to determine the likelihood that a fire will be detected and suppressed before the fire can damage critical equipment. This objective requires an assessment of both the performance of automatic systems and the effectiveness of manual fire-fighting efforts.

Most fire PRA studies performed to date have used a simple detection/suppression model in which automatic systems, if they actuate, are assumed to be immediately effective so long as the fire suppression system is appropriately designed and installed to be effective against the postulated fire. The effectiveness assessment is commonly based on expert judgment and on traditional fire protection design and installations

practices (see the guidance provided in the EPRI FPRAIG) [34]. The results of calculations for equipment damage times are sometimes compared with the results of simple fire modeling calculations for fire detector and sprinkler actuation times to determine if automatic systems can be credited. Random failure of the system is also considered. If automatic suppression is unsuccessful (i.e., automatic suppression is not available or, if available, it either fails or is not timely), the likelihood that manual suppression efforts will be effective before equipment damage is then determined. The event data clearly indicate the importance of manual fire fighting because the vast majority of reported fires are suppressed manually rather than by fixed suppression systems.

A weakness with many fire PRA studies that model both automatic and manual suppression is the failure to treat a number of potentially important dependencies between automatic and manual suppression activities. Although the fire water supply system is generally designed such that a single failure of a valve, pump, or piping should not compromise both the primary and backup suppression systems, common cause failure (e.g., due to fire water pumps) cannot be excluded. Most current fire PRA studies do not include a systematic search for such common cause failures. As a second example, if an automatic suppression system were to fail on demand, some delay in manual fire-fighting efforts might occur while personnel attempt to recover the failed automatic system. This dependency has been acknowledged in various methods [9, 34] but the actual means for treating this dependency is not well defined and left to the discretion of the analyst. These deficiencies can lead to non-conservative results. Another weakness is that analyses typically neglect delays in fire suppression following fixed-system actuation. However, because the fire growth models used in fire PRA studies do not account for the retarding effects of suppression activities, the risk impact of this neglect is not clear.

Ultimately, manual fire fighting is the final line of defense relative to fire suppression. All U.S. nuclear power plants maintain a fire brigade or fire department. The most common approach to incorporate the fire brigade response in the fire PRA is based on non-suppression curves that are derived from event data. These curves express the probability that a fire will remain unsuppressed as a function of time. An example of such a curve, taken from NUREG/CR-6850, is shown in Fig. 89.10. This particular curve is based on data from all fire events in the EPRI fire events database [44]. NUREG/CR-6850 also provides curves for various specific fire types (e.g., electrical fires, oil fires, etc.) and for certain unique plant areas (e.g., the MCR).

The following process is followed to use the non-suppression curves in deriving a probability of non-suppression due to manual means.

1. Using fire models, predict both the time to fire damage and the time to fire detection.
2. Compute the time available for manual fire suppression as the difference between the time to damage and the time to detection.

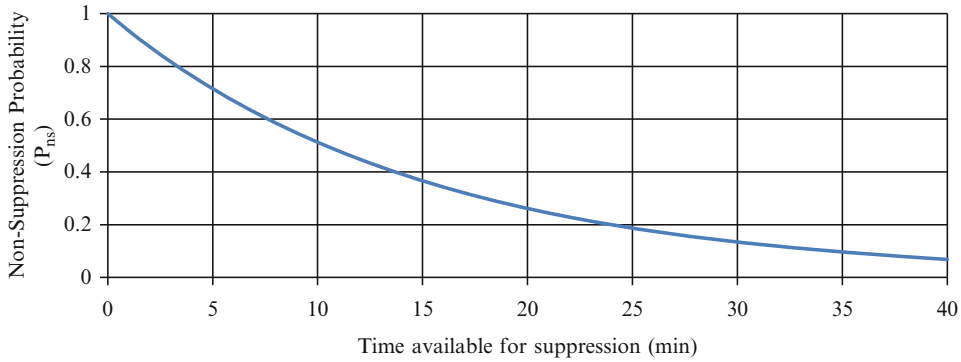

Fig. 89.10 Non-suppression probability curve

3. If the computed damage time is less than the computed detection time, set the probability of non-suppression to 1.0 (no suppression credit).
4. Otherwise, use the computed time available on the x-axis of the non-suppression curve to determine the appropriate point on the non-suppression curve and read the corresponding probability of non-suppression from the y-axis.

Note that this simple approach includes an assumption that manual suppression activities begin once the fire has been detected.

This simple approach to modeling manual suppression has some weaknesses. In particular, the non-suppression curves provided in NUREG/CR-6850 neglect scenario and location-specific effects on initial brigade response time. Different plant locations imply different response times for fire fighters to arrive on scene. However, the NUREG/CR-6850 curves are based on generic, industry-wide statistics partly because, for most events, it is not possible to discern the response times. Also, the currently available event records do not provide sufficient information to address plant- and scenario-specific factors such as fire brigade staffing, training, procedures, and equipment available. As a result, the impact of plant-to-plant differences on the fire suppression response cannot currently be reflected in the analysis.

Siu and Apostolakis [84] describe a state-transition methodology that provides a more detailed probabilistic treatment of the detection and suppression process intended to address weaknesses in current practice. This methodology identifies multiple detection/suppression scenarios involving different possible pathways to eventual fire suppression, based on available fire protection equipment for the area of interest. The methodology identifies and treats possible sources of dependencies between elements in these scenarios. Model parameters characterizing key event times (e.g., the time to suppression) are quantified in a Bayesian framework [10] using generic fire protection system reliability estimates and detection/suppression time data obtained from nuclear power plant fire events. The Bayesian framework provides a direct means for updating model parameters to reflect plant-specific information. (A condensed and somewhat simplified version of this methodology employing data from operational experience has also been developed [85].) The methodology has been used in a few fire PRA studies (e.g., see Musicki et al. [12]). An alternate methodology was used in a study of the LaSalle plant, [17] but that method (1) does not explicitly identify different detection and suppression scenarios, (2) uses physical models included in FPETOOL [86] to estimate detector and sprinkler actuation times, and (3) uses expert judgment to estimate other characteristic delay times in the fire detection/suppression process.

In NUREG/CR-6850, the state-transition model of Siu and Apostolakis has been restructured in the form of an event tree model, and fire event data have been used to support quantification of the model. As the availability of fire event data has expanded, the data available to support statistical assessments of fire brigade response and suppression times has also expanded. For example, NUREG/CR-6850 provides fire brigade non-suppression curves appropriate for various categories of fires. However, the analysis weaknesses cited above remain. Related activities are described in the "Current Activities and Future Directions" section.

Fire Barrier Analysis

As part of determining the immediate environment of equipment potentially affected by a fire, the fire PRA needs to consider the effectiveness of fire barriers. Two general types of fire barriers appear in the analysis. First there are the primary physical structures and features (walls, floors, ceiling and associated penetration seals, doors, hatchways, etc.). Second there are also localized fire barrier systems used to protect plant equipment and cables. The most common localized systems are Electrical Raceway Fire Barrier

Systems (ERFBS) including, for example, thermal insulating wraps used to protect cable trays, conduits, or groups of raceways.

The primary fire barriers come into the PRA through the multi-compartment analysis described earlier in this chapter. In the U.S., the most extensive investigation of multi-compartment fires and the effect of inter-compartment barriers was performed by the Risk Methods Integration and Evaluation Program (RMIEP) study [17]. In that study, which was intended to extend the PRA state-of-the-art in a number of areas, the possibility of fire propagation across rated fire barriers between up to three fire areas was treated explicitly. Screening analyses using barrier failure probabilities and assuming the loss of all equipment in all affected fire areas were employed to eliminate unimportant combinations of fire areas. More refined analyses, which distinguished between active barriers (e.g., doors, dampers) and passive barriers (e.g., penetration seals) and employed less conservative barrier failure probabilities (but still assumed the failure of all equipment in all affected areas), were then performed for the remaining combinations of fire areas. The study determined that no combinations passed its CDF screening criterion of 10^{-8} per year, and so multi-area fires were determined to be insignificant contributors to fire risk at the LaSalle plant. One factor in that conclusion is that the plant partitioning analysis was based on physical barriers rather than spatial separation. Hence, in all cases, the inter-compartment barriers were all substantial physical barriers. If an analyst chooses to credit less robust boundaries (e.g., spatial separation) in defining the PRA plant areas, then multi-area scenarios may prove to be more important.

Regarding the treatment of local fire barriers, these barriers are usually either assumed to be completely reliable for up to their rated fire endurance or are conservatively neglected. It is common, for example, to neglect features such as radiant energy shield and partial height walls. Even when physical models for barrier performance are employed (e.g., COMPBRN IIIe provides a one-dimensional steady-state heat conduction model) [56], these models do not address such behaviors as gross distortion and mechanical failure of the barrier system. Fire tests have shown that such behaviors are strongly affected by installation practices (e.g., the method of sealing joints) [87]. Furthermore, the physical properties of the barriers needed to address such complex issues are not readily available.

In typical practice, a fire barrier that is monitored as a part of the plant maintenance program, and that has been demonstrated by testing to provide a specific fire endurance, is credited for providing equipment protection consistent with the fire endurance rating. Again, the most common form of such barriers is raceway wraps. Such wraps can sharply impact the estimated risk. For example, the presence of a 1-hour rated raceway barrier systems reduces the likelihood of fire-induced damage to the protected cables substantially. In a typical fire scenario such a barrier can reduce risk estimate by approximately two orders of magnitude (based on manual fire suppression credit given for a fire lasting greater than 1 h).

Current Activities and Future Directions

Fire PRA currently supports a wide range of activities in the nuclear industry. The most visible activities involve licensee actions to risk-inform their fire protection programs. However, fire PRA support of other activities, both licensee- and regulator-driven, are also important. This section provides a brief overview of both sets of activities, as well as of current research activities aimed at improving the technical basis and performance of fire PRA.

It is important to note that the fire PRA study results (and, more generally, PRA study results) are typically not used as the sole basis for decision making. Other sources of information, including other engineering analyses, are also used to support the decision. In other words, the decision making process is risk informed, rather than risk based. Under this risk-informed approach, the decision maker can make use of

information from imperfect or even flawed PRA models, as long as the use of the PRA results and insights improves the decision-making approach for the problem of interest. Siu and Cunningham [88] provide a discussion of challenges of using risk information in fire protection applications and identify a number of lessons from NRC's experience that may be useful to the general fire protection community.

Risk-Informing Plant Fire Protection Programs

In 2004, the NRC amended Section 48 to Part 50 of Title 10 of the Code of Federal Regulations (10 CFR 50.48) [28], which governs fire protection programs for operating U.S. nuclear power plants. The amendment added a risk-informed, performance-based option to what had been a completely deterministic rule. In particular, the amended rule allows (with some exceptions specified in the rule) licensees to maintain a fire protection program that complies with NFPA 805 2001 Edition, the National Fire Protection Association standard for a risk-informed, performance-based fire protection program mentioned earlier in this chapter. The purpose of this amendment, as discussed in NRC staff paper SECY-00-0009, "Rulemaking Plan, Reactor Fire Protection Risk-Informed, Performance-Based Rulemaking," [89] was to, among other things, establish a more reactor-safety-oriented fire protection rule, add appropriate flexibility in some aspects of a licensee's fire protection program, and facilitate the use of alternate approaches that may reduce the need for NRC-approved exemptions from deterministic requirements. The implementation of this rule relies on the licensee's use of a plant-specific fire PRA.

As of mid-2012, as discussed by Harrison et al. [90], two licensees have received NRC approval for their requests to transition their previously deterministic fire protection programs to the risk-informed, performance-based approach allowed by the amended rule. As part of the approval process, the licensees, the broader regulated industry, and the NRC have learned a number of important lessons, some of which apply to the methods, models, and tools of fire PRA. A number of these fire PRA technology issues were addressed during the approval process and documented in a supplement [23] to NUREG/CR-6850 and other publicly available documents (e.g., the NRC's response to a "frequently asked question" on changes to fire frequencies over time [91]). Other issues are being addressed by EPRI and the NRC's Office of Nuclear Regulatory Research. It is expected that the results of this work will support future updates of NUREG/CR-6850, and thereby the development, review, and approval of the three dozen license amendment requests received or anticipated in the next few years.

Other Uses of Fire PRA

Fire PRA methods, tools, data, results, and insights have become integral to the treatment of many fire protection and fire-related issues. For example, the results of work on fire-induced cable failures and circuit faults has been used to rank (by risk significance) potentially important factors governing the likelihood of spurious actuations [90]. This risk ranking has allowed the categorization of these factors into sets governing how they will be treated during fire protection inspections or future research. As another example, NRC is using fire PRA results to focus plant fire inspections on the most important fire protection systems and uses a fire PRA—based tool in its Reactor Oversight Program (ROP) to assess the significance of findings from inspections. Using the results of the Significance Determination Process (SDP), the NRC can employ a number of regulatory responses (e.g., fines, heightened levels of regulatory oversight) [93].

More generally, because the risk from fires is a component of total risk, fire PRA can also play an important role in broader risk-informed activities, even those that are not focused on fire. For example, fire PRA is being used in support of analyses supporting the management

of changing plant configuration (e.g., to inform decisions as to how long a plant may continue to operate when certain equipment is taken out of service for maintenance). As another example, the NRC's guidance on the use of risk information in proposing plant changes indicates under what conditions a small increase in total CDF could be allowed [31]. If fire is an important contributor to either the baseline (pre-change) total CDF or to the change in total CDF, fire PRA can provide important input to decisions regarding the acceptability of the proposed plant change.

Uncertainty in Fire PRA and Current Research

As mentioned earlier, the NRC's 1995 PRA policy statement [8] states that:

> The use of PRA technology should be increased in all regulatory matters to the extent supported by the state-of-the-art in PRA methods and data . . .

The statement's concern with the limitations of PRA remains important in the case of fire PRA, where research is ongoing to address the still-significant uncertainties in results. (Variations in key analytical assumptions can lead to orders of magnitude variations in estimates of fire-induced CDF and qualitatively different risk insights).

The uncertainties in fire PRA results are not due to the general analytical approach described at the beginning of this chapter. All current nuclear power plant fire PRAs use this approach or some slight variant on it. Rather, a good deal of the uncertainty is due to weaknesses and gaps in the current treatment of a number of application details and to the assumptions used by analysts when addressing these weaknesses and gaps. Significant uncertainties can arise in the estimation of the likelihood of important fire scenarios (e.g., when addressing the frequency of large, transient-fueled fires or of self-ignited cable fires), identifying initial conditions leading to fire growth (e.g. size of an oil pool fire upon pump system failure), the modeling of fire growth and suppression (challenges include fire propagation through a stack of cable trays and the incorporation of plant-specific factors as fire brigade training and staffing in the treatment of manual fire fighting), the prediction of fire-induced loss of systems (e.g., when quantifying the likelihood of spurious actuations, when addressing the effect of smoke on equipment), and the analysis of plant and operator responses to the fire (e.g., when modeling operator actions during a severe control room fire). Uncertainties also extend to the mode of operation, as no standard approach has been developed to address fire risk at low power and shutdown operations. Research to reduce (or at least better understand) uncertainties in a number of these areas is continuing. Much of this research is being performed as a collaboration between EPRI and the NRC's Office of Nuclear Regulatory Research. The research activities include:

- The development of a comprehensive U.S. fire events database (FEDB)
- The collection of statistics characterizing potential fire sources in U.S. nuclear power plants
- The performance of experimental studies to examine fire effects and behaviors relevant to fire PRA
- The verification and validation (V&V) of currently available fire models
- The development of improved fire PRA models

Regarding the FEDB, current fire PRAs rely heavily on an EPRI database based largely on voluntary reports [44]. Concerns with the completeness of the reported data have been a limiting factor in the application of event data to fire PRA. The current activity to develop a new, comprehensive FEDB has been planned jointly by EPRI and RES with the actual data gathering activities being led by EPRI. The goal of the effort is to compile a complete list of all fire events at every operating U.S. reactor site occurring between 2000 and 2009. The effort is based on a direct search of plant records. To date, hundreds of thousands of reports have been searched and filtered to identify a few hundred

potentially risk-relevant fire events. This effort is nearing completion as of the fall of 2012 with somewhat more than 80 % of all reactor sites expected to be represented in the initial database release.

Once the new FEDB is complete, EPRI and the NRC are planning to use the data to support new estimates of fire event frequencies and of the manual fire suppression curves. The updated fire frequencies are expected to generally follow the fire frequency bins defined in NUREG/CR-6850, although some refinements may be pursued as feasible (e.g., electrical cabinets may be segregated into voltage or functional classes). The effort is also expected to re-examine the question as to whether fire frequencies are changing over time and to address the treatment of historical events in the fire frequency estimation process.

The update of the manual fire suppression curves will be performed to ensure consistency with the fire frequency analysis. If, for example, the fire frequency estimates include many fires of very short duration, then the suppression curves, which are conditioned on the occurrence of a fire, will be quite aggressive (indicating a high likelihood of successful suppression in a short amount of time). If instead very short duration fires are uniformly screened from the fire frequency analysis, then the estimated fire frequencies will be lower but the matching suppression curves would reflect a higher likelihood of longer duration fires.

Regarding plant fire source population statistics, the estimation of component-based fire frequencies requires data characterizing the potential sites for fires (e.g., electrical cabinets, pumps), as well as data for actual fire event occurrences. Many U.S. plants are currently performing fire PRAs and are counting their ignition source populations. EPRI is working with these plants to compile this information.[17]

Regarding experimental studies, work is continuing on a number of projects. These include the Cable Heat Release, Ignition, and Spread in Tray Installations During Fire (CHRISTIFIRE) project [92], whose data is intended to support the development of improved cable tray fire growth models; the Direct Current Electrical Shorting in Response to Exposure Fire (DESIREE-Fire) project [50], whose data will be used in an expert-elicitation based effort to estimate the likelihood and duration of fire-induced spurious operations in direct current circuits; and an international collaboration with OECD member countries addressing the behavior of high energy arc fault (HEAF) fires associated with electrical switchgear faults. The NRC is also sponsoring research investigating the effectiveness of fire retardant cable coatings to delay fire spread and fire-induced damage, and is planning further research on the behavior of electrical cabinet fires.

Regarding fire model V&V, EPRI and the NRC have jointly addressed a set of fire modeling tools used in current fire PRAs: FIVE-Rev 1 [94], the Fire Dynamics Tools (FDTs) [57], MAGIC [58], CFAST [59], and FDS [52]. The V&V effort, which was performed according to ASTM E1355 ("Evaluating the Predictive Capability of Deterministic Fire Models"), selected appropriate fire scenarios for testing the models, established the theoretical basis and assumptions for the models and their implementation, and validated the models over the range of conditions covered by available fire tests. NUREG-1824/EPRI 1911999 [95] and NUREG-1934/EPRI TR-1023259 [69] provide qualitative and quantitative comparisons of the model predictions versus measurements. Currently the NRC, in conjunction with the National Institute of Standards and Technology (NIST), is in the process of updating the V&V effort to include additional data. This effort is intended to expand the validation ranges of the models for

[17] In addition to data collection, the development of a component-based fire frequency approach that goes beyond that provided in NUREG/CR-6850 will require further analysis. This analysis is needed to characterize the relationship between the number of ignition sources and fire frequency, since this relationship may not be linear. (For example, a plant with 50 pumps may not have twice as many pump fires as a plant with just 25 pumps.)

some application and to refine current understanding of biases. The results of these efforts are documented during routine updates of the FDS technical reference guide [96].

Finally, regarding fire PRA models, a range of analytical methods development activities are underway by NRC and various industry groups. These activities are addressing a variety of topics, including manual fire suppression modeling, fixed fire suppression system reliability, multi-compartment analysis, fire barrier analysis, multiple spurious operation likelihood analysis, and the characterization and analysis of transient fires. NRC and industry are working on suitable processes to develop, review, endorse, and promulgate new or revised analysis methods. The vetting process continues to evolve but has already yielded a number of methods improvements and clarifications.

Additional summary-level information can be found in NUREG-1925 [97], which provides an overview of NRC's research efforts in a wide variety of areas (including but not limited to fire safety).

Summary

Fire probabilistic risk assessment (PRA) is a systematic quantitative tool for dealing with the complex issues that arise when assessing fire safety at a nuclear power plant. Nuclear power plant fire PRA development efforts date back to the late 1970s. While the supporting methods, tools and data used in the analysis process have been refined substantially, the fundamental analysis framework remains essentially unchanged. The most significant change that has occurred over this time is the manner in which fire risk information is being used. In particular, the NRC's development of a risk-informed option to its previously deterministic fire protection regulations, as part of NRC's broader push to increase its use of PRA and risk in all of its regulatory activities, has increased the attention of industry and regulators on fire PRA.

The increased use of fire PRA in regulatory applications implies a need for higher levels of completeness, realism, accuracy, consistency across the analysis and overall quality. Consistency and realism across the multiple analysis elements are goals that continue to challenge fire PRA methods development activities. A particularly important current challenge involves the treatment of fire-induced spurious equipment operation. This analysis, which involves substantial effort to identify key electrical circuits and analyze the potential effects of fire, holds the potential to significantly alter the insights and quantitative results of a fire PRA. A range of efforts are being undertaken by both the NRC and industry to support the evolutionary process of fire PRA maturation in this and other areas. Development needs and priorities are currently being driven in large part by the desire to increase realism. The overarching goal is to increase analysis fidelity and thereby increase decision makers' confidence in the risk insights gained.

Nathan O. Siu is a senior technical adviser for PRA analysis in the Office of Nuclear Regulatory Research of the U.S. Nuclear Regulatory Commission. His major activities involve the development of improved methods for probabilistic risk assessment, including fire risk assessment.

Nicholas Melly is a fire protection engineer in the Office of Nuclear Regulatory Research. His major activities involve development of improved methods for fire risk assessment.

Steven P. Nowlen is now retired, but was distinguished member of the technical staff at Sandia National Laboratories. His major activities involve fire protection research for nuclear power plants including experimental investigations and the development and application of fire PRA methods, tools, and data.

Mardy Kazarians is a consultant who has conducted several fire PRAs in the U.S. and abroad. He was a major contributor in the development of the fire PRA methods used in early fire PRAs and still in use today.

Fire Risk in Mass Transportation

90

Armin Wolski and Jarrod Alston

Introduction

For many, the concept of fire risk elicits thoughts of the built environment. Yet occupants in the built environment are also passengers on airplanes, in trains, and on ships. According to the U.S. Department of Transportation, the number of passengers boarding scheduled commercial airlines exceeded 700 million in 2014. Rail rapid transit systems throughout the United States (U.S.) carry almost two billion passengers annually. APTA reports that ferryboats account for more than 400 million passenger miles per year nationally [1]. In 2010, motor coaches (or buses) topped 76.1 billion passenger miles in the U.S. and Canada [2]. Every mode of transportation carries with it unique risks; the risks are dependent on a myriad of factors, including design, construction, maintenance, and operation. Understanding or comparing the risks associated with and between the various methods of transport is not always direct. It is complicated by various metrics that can be used for example, risk per distance, risk per trip, risk per passenger exposure hour. For example per mile traveled, the fatality risk in air transport is less than that for bus transport, however, per trip, the risk in air transport is on the order of 100 times greater than that of bus transport [3].

The fire risk problem in most passenger transportation systems is unlike the fire risk problem in the built environment. In comparison to small fires in buildings, the small fires in many modes of transportation could have a significant impact on life and business continuity. From the regulatory perspective, the fire risk problem in transportation systems is undoubtedly affected by risk perceptions. Passengers may perceive risk, including fire risk, in airplanes different from fire risk in buildings. And from an engineering perspective, standard fire risk management solutions for buildings may not be appropriate for transportation systems. For example, options such as compartmentation or automatic fire sprinkler systems may not be available to some transportation systems.

This chapter discusses some of the unique fire risks posed by transportation systems, the current regulatory framework for various systems, and how risk assessment can be or has been used by regulators, operators, or owners to their benefit. Since the three transit systems share common risk factors, decision makers and risk managers face similar risk problems and might be served well by similar risk assessment methods. The methods can be applied either at the regulatory level in order to optimize safety regulations or at the project level, where decision analysis is a means to choose between design options.

Fire Risk in Transportation Systems

Distinguishing characteristics in transportation systems amplify the risk factors compared to building fire safety. A (small) 40 kW fire in the middle of a five story atrium poses little threat to the building or its occupants, whereas the same fire in a subway carriage is a major and possibly imminent life safety threat with additional and significant financial impacts. Or, compared to building occupants, passengers 25,000 ft (7620 m) above ground, or 25 ft (7.62 m) underground, or 25 mi (40.2 km) out to sea may not have the option of "leaving" the scene of the fire at their discretion. Furthermore, in contrast to buildings, egress from a train or a vessel may be impaired, due to an accident-induced fire. In extreme cases, a train may be overturned [4] or a boat may be listing, affecting egress.

Solving the risk problem in transportation systems is further complicated by the sensitivity to operational issues. Vessel, vehicle, or aircraft operation is highly dependent on human factors. Improper operation of a vessel or vehicle has higher consequences, many relating to fire safety. As dynamic systems, fire safety systems in transportation systems rely more on proper operations and maintenance than do static structures.

Aviation Fire Safety

Over the course of 100 years, air transport has developed into an international and transcontinental business. For some, it is the only option for long-range travel, and for many, it is a mode of mass transit. A complicated set of international agreements is required to ensure safe design and operation of aircraft between countries. Most countries have their own airworthiness codes and regulations to some degree. However, many countries accept sections of other countries' codes, particularly Federal Aviation Regulations of the United States, British Civil Airworthiness Requirements (BCARs) of the United Kingdom, [5] and Joint Airworthiness Regulations (JARs) from the Joint Aviation Authorities of Europe.

The overall general risk to aircraft and air passengers has been reduced over the decades with improvements in warning systems (both ground proximity and transponders), de-icing operations, runway overrun design, aircraft controls, and improvements in material/structural testing. Still, aircraft risk, including aircraft fire risk, remains a high-risk problem characterized by low-frequency, high-consequence potential. The overall accident rate of aircraft on a per-mile basis is roughly 1000 times safer than that of rail or ferry; however, the likelihood of fatality is significantly higher per occurrence [6].

Efforts have been ongoing to address the aviation fire risk problem among passenger aircraft. Key improvements include the following:

1. *Electrical systems*. The aging of electrical systems and improper maintenance of damaged or worn systems are areas of vulnerability. Advancements in wiring insulation technology and maintenance operation are reported to have reduced the number of accidents attributed to electrical systems.
2. *Combustible furnishings*. Combustible furnishings in the main cabin present a significant fire load. Ongoing research and development is expected to improve the performance of furnishings and finishes, particularly composite materials.
3. *Lavatories*. As a result of numerous in-flight fires, the Federal Aviation Administration (FAA) amended regulations to require a smoke detector in each lavatory and an automatic fire extinguisher in each lavatory trash receptacle [7]. Small fires in lavatories have been responsible for several fatal accidents [1].

More recent areas of concern include the following [8]:

1. *Cargo holds*. Cargo holds can harbor dangerous goods that pose either a significant ignition threat or fuel load. Cargo hold fires have been one of the most significant sources of fires in major fire incidences in modern passenger jet transportation [9]. Further research and development has been intent on improving test methods, suppression system effectiveness, and fire resistive integrity [7].
2. *Fuel tanks*. Fuel tanks present an explosion and rupture hazard. Developments in gaseous

inerting systems are expected to decrease the incidences of fuel tank fires in the future. In addition, efforts are under way in reducing the fire impact due to fuel tank rupture.

3. *Hidden materials fires*. Insulation within the hull cavity is under investigation for possible improvements [10].
4. *Postcrash survivability*. When the crash involves high-impact forces, passenger and crew survivability is unlikely; however, risk reduction has focused on what is referred to as "impact survivable, postcrash fire" scenario. Under this scenario, increased attention has been placed on improving egress [11].

Improvements in these areas are making in-flight fires on new commercial airplanes extremely rare and the trend of fire fatalities has been falling [12, 13] (Figs. 90.1, 90.2, and 90.3).

Simply the scale and geometry of an aircraft creates a fire environment wherein the occupants are much vulnerable to fires. A small fire, which would ordinarily pose little or no threat in a

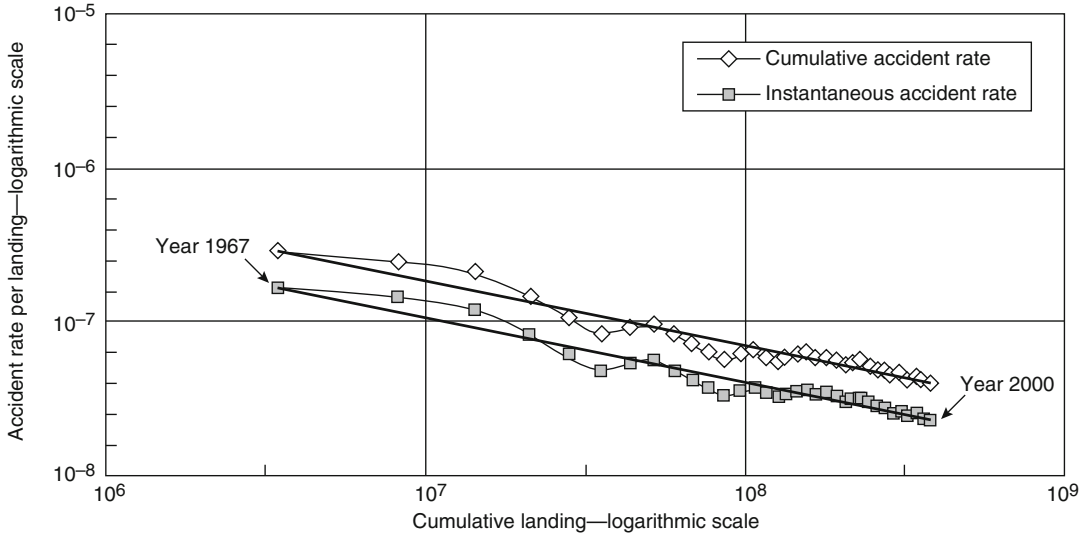

Fig. 90.1 Rate of fire-caused accidents

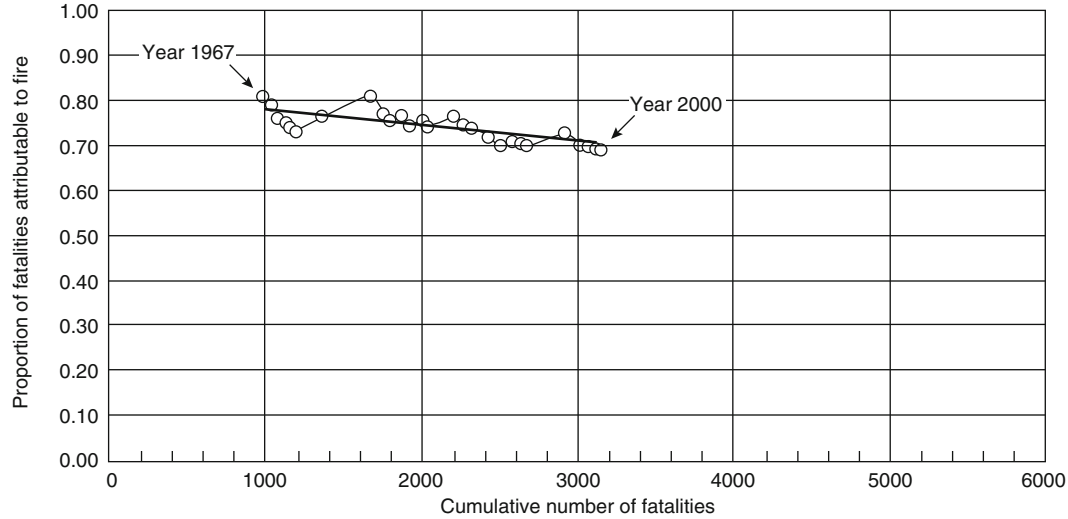

Fig. 90.2 Proportion of fatalities attributed to fire

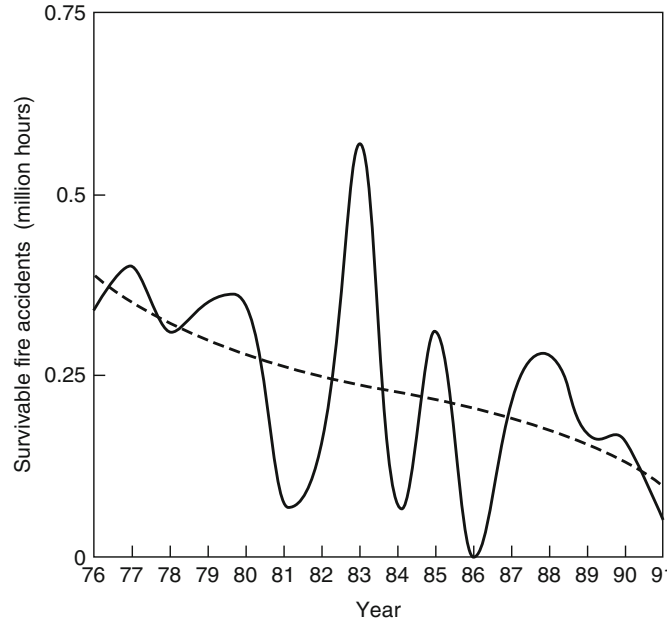

Fig. 90.3 Survivable fire incidents per million flight hours (larger jet/turboprop)

building, could be catastrophic in an aircraft. The cabin space of even the largest airplanes could rapidly fill with smoke endangering the lives of passengers.

Unlike occupants of a building, passengers do not have the option of escape during an in-flight fire occurrence. Obviously, passengers and crew must await landing the plane before any reasonable egress can begin. In the 1980s research conducted by the FAA on commercial aircraft exposed to an external fuel fire indicated that the time available for passenger egress before flashover occurred in the cabin was approximately 90 s. This 90-s emergency evacuation performance, through half the number of exits, is demonstrated in every commercial aircraft in order for an aircraft to be certified. The demonstration is based on a configuration with a full load of passengers having a distribution of gender and age approximating that of the flying public. Evacuation modeling has been shown to be a useful tool in initial assessments [14].

Rail Fire Safety

Similar to the aircraft risk problem, a small fire in a rail carriage, which would ordinarily pose no threat in a building, could pose a serious emergency issue in a rail vehicle. Like an aircraft cabin, a rail carriage could rapidly fill with smoke endangering the lives of passengers, have immediate impact on sensitive and expensive equipment, and affect schedules and operations for hours. And, although rail passengers may, like in aircraft, be more vulnerable to smaller fires, rail passengers often have better means and more options to remove themselves from the imminent hazard by escaping to other rail compartments, into a station, or into a tunnel.

One source of U.S. rail accident statistics is the Federal Railroad Administration (FRA). Taking the time period from 2002 to 2006 as an example, the FRA reports that most fires are electrical in origin. For the reported time period, fire caused more than $20 million in damage [15]. Another source of fires is collisions with vehicles at grade crossings or with other trains, which lead the list of all accidents. Similar to an aircraft liquid fuel fire, a fuel fire spilled from the collided vehicle or a (diesel-electric) train is a common fire exposure. An example of such an accident occurred near Bourbonnais, Illinois, in 1999 [16] when a train struck a truck at a grade crossing. Leaking fuel from one of the locomotives ignited and engulfed a sleeping car

where 11 deaths occurred. Interior fires in moving rail vehicles are uncommon with most such incidents involving small quantities of smoke from malfunctioning or overheating equipment. A fatality involving an Amtrak bilevel sleeping car (cigarette on a mattress) occurred in 1982 in Gibson, California [17].

Vandalism is another source of fires in subways and commuter rail systems. Scenarios may involve newspapers and small amounts of flammable liquids used to ignite seats that may be slashed to expose interior padding. Flammable liquids were the ignition source in a catastrophic fire in the 2003 Daegu subway fire in Korea, which resulted in 193 fatalities and 146 injuries. The fire started while the car was still in the station. Many of the fatalities were passengers who arrived in a later incoming train on adjacent tracks. The passengers on the second train, delayed in evacuation, were exposed to heavy smoke as they moved through the station to their nearest exits. Operational errors are alleged to have led to the delays and significant life losses [18].

Tunnels and bridges represent further complications for rail fire safety. Fires in tunnels pose an additional threat because the fire effluent is contained around the train where it can expose passengers both inside and outside the carriages. Although emergency procedures usually require trains to continue to travel to a point outside a tunnel, fires can be coincident with breakdowns and accidents in these sensitive areas. Exiting is then often difficult and often severely restricted. Furthermore, a fire may affect the tunnel's structural integrity necessitating the interruption in service for an indeterminate period for inspection and repair. Bridges or other elevated track sections also restrict the ability of people to move to a safe location away from the train.

The 1996 English Channel tunnel fire involved a fire originating in a carrier wagon at the rear of the train [19]. Normally, the standard emergency procedure under such conditions was to continue travel to the end of the tunnel; however, a warning light on the train's control panel indicated an abnormality that necessitated stopping the train. When the chef de train (conductor) investigated the fire, heavy smoke entered the occupied club car affecting more than 30 passengers. The passengers needed to be evacuated into the tunnel through a cross passage and onto a train in the adjacent tunnel. The fire burned for more than 8 h and resulted in significant spalling of the tunnel's concrete liner. These issues need to be addressed where trains operate in long tunnels or have extended elevated sections.

In the United States, although all serious passenger rail accidents are investigated by the National Transportation Safety Board (NTSB), public pressure for safety regulation of rail transportation has not always been strong [20]. However, following the 1996 Silver Spring accident where a Marc commuter train collided with an Amtrak passenger train, resulting in 11 deaths, there was increased interest by the Federal Railroad Administration (FRA) to replace 1984 Federal Transit Administration safety guidelines with regulations. These regulations, updated with information from National Institute of Standards and Technology (NIST) research, were promulgated in 1999 [21] and the associated performance criteria can be found in NFPA 130 [22]. The focus is on providing a high level of fire performance for combustible materials found in vehicles. Like aircraft materials, many are designed to be difficult to ignite, and generate less smoke.

There are other fire databases that can be examined, such as the National Fire Incident Reporting System (NFIRS). A recent search of NFIRS for passenger rail fire incidents for the 10 year period from 1988 to 1997 identified 71 fires resulting in 2 civilian deaths and 4 injuries. Federal regulations (49CFR, Part 225) require that incidents that result in a fatality or injury or result in damage to property exceeding a threshold ($6700 for 2004) be reported. A recent search of this database identified 156 fire incidents of interest in United States for the 14 year period from 1985 to 1998.

Fire Safety in Motor Coaches and Buses

According to the Federal Transit Administration, bus fires are considered a serious problem: they cause safety, financial, and service problems for transit agencies [23]. Not unlike a fire in a rail vehicle, a small fire in a bus could pose a serious emergency issue. Should a fire occur within the passenger compartment of a bus, the compartment can rapidly fill with smoke and generate a dangerous environment for passengers. Similarly, if a fire originates in the engine compartment or the wheel housing and is able to develop and penetrate into the passenger compartment, a dangerous environment can rapidly develop. The majority of fires originate in the engine compartment, often due to damaged wiring near fuel and oil lines, mechanical problems, and electrical deficiencies [24]. Some fires are caused by humans, discarded smoking materials and/or arson. However, buses typically operate as surface vehicles in open environments which would allow the operator to rapidly bring the vehicle to a stop upon detection of the fire and initiate evacuation. Additionally, the passengers would be evacuating to a relatively safe environment unless operating in a shared or dedicated tunnel.

The United States Federal Transit Administration collects statistics of transit accidents, casualties, and crimes under the National Transit Database (NTD) reporting system. The statistics are collected for multiple modes of transportation including heavy rail, light rail, busses, and vanpools, among others. The data (available online at http://transit-safety.volpe.dot.gov/Data/SAMIS.aspx) are compiled into *Transit Safety & Security Statistics & Analysis Annual Report* [25, 26]. Data from 1997 to 2007 relating to busses are provided in Table 90.1.

The focus of the statistics is the occurrence of incidents that result in property losses, injury, or fatalities. The data also include operating statistics useful in risk analyses such as numbers of vehicles in operation, vehicle miles travelled, numbers of passengers, and numbers of passenger miles travelled. Information regarding the fire area of origin cause is not available in the NTD. Focusing on the period after 2002, as this is the point at which the NTD's thresholds for reporting were changed, an average of 207 bus fires occurred annually in which medical treatment was necessary or resulted in damage in excess of $7500. In that period, an average of 23 injuries were reported and no fatalities.

In 2006, in response to a September 2005 Texas motorcoach fire that results in 23 fatalities, the National Fire Protection Association published *Vehicle Fires Involving Buses and School Buses* [27]. The data in the report was drawn from the National Fire Incident Reporting System (NFIRS) and is indicative of the number of incidents to which fire departments in the United States responded. As such, it was not subject to the NTD threshold levels and is more extensive than the NTD database as it extends beyond those agencies or operators that are required by law to submit to the NTD. The statistics were later updated in *U.S. Vehicle Fire Trends and Patterns* [28] and indicated that on average of 2350 bus or school bus fires were reported annually or more than six (6) per day, during the 5-year period of 2003–2007. From these 2350 fires were annual averages of seven (7) civilian deaths, 27 civilian injuries, and $26 million in direct property damage which equate to 1 % of vehicle fires, 2 % of vehicle fire deaths, 2 % of vehicle fire injuries, and 2 % of vehicle fire property damage. Further examination of the statistics reveals an increased risk of bus fires in relation to other highway vehicles. The rate of bus vehicle fires on a miles travelled basis is almost four (4) times that of all other highway vehicles. The increase in risk is further exaggerated when considering the rate of fatalities (7×) or injuries (9×) from bus fires relative to that from all other highway vehicles.

With respect to the vehicle fire causes, the majority (59 %) of bus and school bus fires were attributed to a mechanical failure or malfunction. An additional 25 % were the result of electrical failures or malfunctions. Collisions or overturns only accounted for 10 (<1 %) bus or school bus fires per year. Exposure fires were attributed as the cause of up to 90 (1 %) fires

Table 90.1 Bus incidents from 1997 to 2007 resulting in losses and/or casualties broken down by incident type (Source: National Transit Database [25])

	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007

Vehicle miles (× 1,000,000)	1719	1779	1835	1868	1911	1919	1876	1891	1853	1849	1872
Passengers (× 1,000,000)	4554	4712	4926	4959	5065	5078	4810	4732	4815	4822	4804
Passenger miles (× 1,000,000)	16,696	17,113	17,743	17,763	18,369	18,120	17,241	16,855	17,207	17,655	17,635

The drop in the incidents, injuries, collisions, and not otherwise classifieds (personal casualties) starting in 2002 is due to the change of the incident thresholds. The injury definition was changed in 2002 to only incidents involving immediate medical treatment away from the scene; previously, any reported incident/injury was reported. The property damage reportable threshold was also changed in 2002 to total property damage exceeding $7500; previously, the threshold for property damage incidents was $1000 in transit property damage only

Table 90.2 U.S. bus and school bus fires by cause, 1999–2003 averages (Source: Vehicle Fires Involving Buses and School Buses [27])

Cause	Fires		Civilian deaths		Civilian injuries		Direct property damage (in millions)	
Failure of equipment or heat source	1320	(60 %)	1	(39 %)	22	(74 %)	$14.0	(58 %)
Unintentional	660	(30 %)	1	(34 %)	6	(19 %)	$7.8	(32 %)
Unclassified cause	130	(6 %)	1	(27 %)	0	(0 %)	$1.3	(5 %)
Intentional	100	(4 %)	0	(0 %)	0	(0 %)	$1.1	(5 %)
Act of nature	10	(0 %)	0	(0 %)	2	(7 %)	$0.0	(0 %)
Total	2210	(100 %)	3	(100 %)	30	(100 %)	$24.2	(100 %)

per year. Roughly 4 % of bus and school bus fires were designated as intentional in nature. Based on the previous statistics, it would be expected that the majority (69 %) of fires originate in the bus "engineering" areas (engine area, running gear, wheel area) [27, 28] (Table 90.2).

Outside of the U.S., the problem of bus fires has garnered special attention. The SP Technical Research Institute of Sweden undertook a project on bus fire safety with the objective of decreasing the number and consequence of bus fires [29]. Of particular focus in the project was the adequacy or inadequacy of current test methods in screening materials used in bus construction. A key part of the SP project, was a statistical survey of fires in Norway and Sweden focusing on fire causes and consequences. The survey results showed that an annual average of 49 and 122 bus fires were reported in Norway and Sweden, respectively [30]. The number of incidents implies that roughly 1.0–1.4 % of buses in service in Norway and Sweden are involved in a fire incident each year. The study identified several principle causes of fires in buses: arson, heat, vibration, material fatigue/malfunction, and inadequate maintenance. Measures to reduce the impact of a fire event on a bus include good engineering, detection systems, manual and automatic suppression/extinguishment systems, and inherently ignition resistant interior finish materials.

Fire Safety at Sea

The regulation of commercial vessels that operate internationally, including ferries and cruise ships, is primarily conducted under international law. The International Maritime Organization (IMO), headquartered in London, is an agency of the United Nations and is the repository of all treaties dealing with commercial vessel safety. The IMO promulgates regulations established by the International Convention for the Safety of Life at Sea (SOLAS) treaty. SOLAS includes both design requirements and test methods for fire resistance and flame spread on interior materials. The U.S. Coast Guard (USCG) enforces these and some other safety and sanitation requirements for foreign flag vessels that operate in U.S. waters. Fire protection of marine vessels in the United States (operated as U.S. flag vessels) is regulated by a collection of Code of Federal Regulations promulgated by the USCG. Vessels and their associated levels of regulations are divided into classes depending on their size and capacity.

Table 90.3 Passenger casualty rates, 1963–1997

Mode	Fatalities	Fatalities or seriously injured
Air	0.13	0.20
Rail	0.73	3.19
Water	6.69	44.28

In order to frame the maritime risk problem, comparative passenger accident and casualty rates are illustrative. Passenger casualty rates for different modes of transport for the 15 year period from 1963 to 1997 are given on a per billion passenger kilometers as shown in Table 90.3 [31].

Peachey [31] asserts that the casualty rates for water transport are dominated by two large-scale accident events, the *Herald of Free Enterprise* in

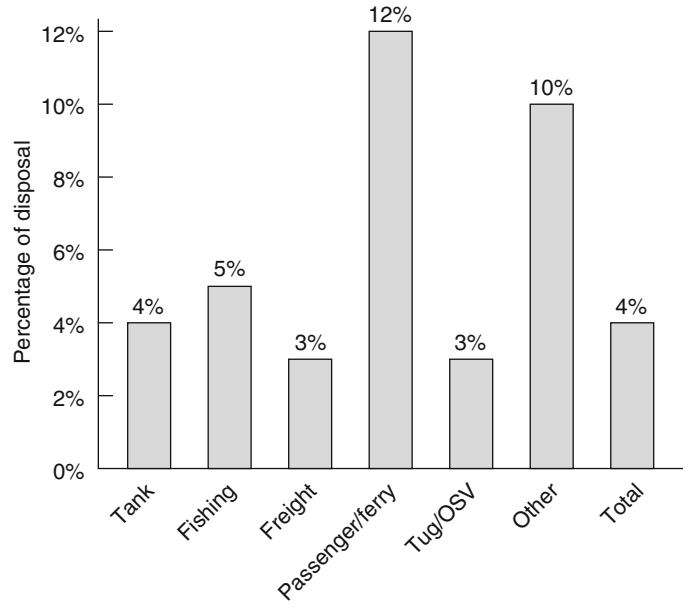

Fig. 90.4 Percentage of world fleet's vessel disposals caused by fire or explosion, from Lloyd's database by vessel type in 1997

1987 and the *Marchioness* in 1989, which, if excluded, would result in an underlying fatality rate of about 0.5 per billion passenger kilometers.

Providing further context, the major risks in cruise ships for the same period are collisions and fires. Between 1963 and 1997, fatalities were roughly divided between the two with 436 collisions and 411 fires, whereas grounding only led to one fatality [32].

The statistical distribution of fire risk based on vessel type can be found in Lloyds Casualty System database and the Marine Safety Information System [33]. Notably, the number of "disposals," or vessels "written off," in sample year 1997 found passenger ships to be of the highest percentage type of vessel in the fleet (Fig. 90.4).

In Washington State the rate of ferry accidents in the state ferry system was estimated at 1.8 per million miles (1.1 per million kilometers) whereas the rate of fire was 0.59 per million miles (0.37 per million kilometers). The accident rate for ferry passengers is roughly half that of aircraft [6].

Cruise ships are often larger than most buildings. Cruise ships in particular, once built as floating hotels, are now built as floating resorts. In some cases, cruise ships carry great population loads, and can have more passengers than some cities have residents. There are, in addition, unique aspects to such large passenger vessels that make the fire safety risk problem in ships a greater fire safety design challenge than in buildings. Unique fire safety design factors of passenger vessels include geometry, construction materials and design, and fire-extinguishing systems [34].

The basic geometry of a passenger ship creates challenges not often found in building fire safety. Multistory passenger ships are commonplace; however, unlike most multistory buildings, which have similar footprints on each floor, passenger ships' floor-by-floor geometry can vary both in size and in use. The typical rectilinear floorplate arrangements found in buildings simplify fire safety design challenges such as fire barrier locations and egress strategies. With some exceptions, as in convention centers, factories, and casinos, most buildings have grown vertically versus horizontally. In order to maintain fire compartmentation, additional subdivisions are necessary, and atypical floorplates creates greater challenges.

Similar to air and rail systems, exiting is more complex in a ship than in a building. Although it may be "easier" to evacuate a ship than an

airplane, it is more difficult than evacuating a train. Take, for example, the geometry of a cruise ship: the larger size, the variation in decks, the need to (counterintuitively) ascend stairs in order to evacuate, and the fact that passengers may be asleep further complicates evacuation. Furthermore, exiting in a ship entails the movement to a safe place of assembly in order to await further instruction. Only if the ship is in peril does exiting lead to shipboard evacuation into survival craft.

The installation and use of combustible materials in ship design is a significant concern. Although significant advances have been made in the areas of composites and use of aluminum in shipbuilding, particularly for high-speed craft, most modern ships (as opposed to boats) are constructed of steel and other noncombustible materials. Although this construction provides a certain increased reliability in ship integrity under fire conditions, it does not solve the fire risk problem associated with combustible interior finish and furnishings. Because of these hazards, SOLAS requires areawide sprinkler protection and smoke detector coverage of all accommodation areas.

Not unexpected, vehicle holds and engine rooms are common sources of fire origins. In fact, engine spaces account for more than half of the reported fire incidents [35]. For this reason they are given additional attention. Some suggested protection measures for such spaces include the following [36]:

- Fire separations of engine rooms and redundant machinery spaces
- Mist or gaseous suppression systems
- Fire/flame detection and video monitoring
- Rigorous training in emergency procedures

A number of accidents in the 1980s provided evidence that fires were a serious and growing concern. In 1991 the IMO adopted amendments to SOLAS, which became effective in January 1994 [37]. These included additional requirements for exiting, sprinkler systems, and smoke control. After a 1993 special report on passenger vessels by the National Transportation Safety Board, the U.S. Coast Guard obtained international agreement to require various fire safety improvements on all passenger ships, including existing ships. The focus of the improvements—automatic sprinklers, fire detection and alarm systems, and emergency lighting—are compulsory on all ships able to carry 36 or more passengers that were delivered after October 1994 [1].

As a result of U.S. regulatory reform, the USCG initiated and chaired an NFPA technical committee to develop consensus standards as an alternative to the current fire regulations. Various NFPA 301, *Code for Safety to Life from Fire on Merchant Vessels*, requirements are described for vessels carrying more than 12 passengers [38]. Material requirements are similar to the USCG regulations with some exceptions. The passenger capacity, type of service (day or overnight), and whether or not the space is protected with automatic sprinklers determine flame spread limits. NFPA 301 means-of-egress provisions are adapted maritime equivalents of NFPA *101*®, *Life Safety Code*®, [39] egress provisions. Among the requirements, many depend on the number of passengers and whether or not overnight accommodations are provided.

Fire Risk-Informed Decision Making in Air, Rail, and Sea Transportation

Risk-Based Decision Making Defined

In risk-based decision making, an orderly structure is applied to a situation in which one or more options are available and one or more unwanted outcomes, or losses, in varying severity may result. These losses can include such things as harmful effects on occupants or passengers, property, or business continuity. The risks for an engineered system or activity are determined by the types of possible losses, the frequency at which they are expected to occur, and the effects they might have. Risk-based decision making is not only hazard assessment, although it may be included. One difference between hazard assessment and risk-based decision making is that hazard assessments might include likelihood and frequency or the recognition of relative risk,

whereas risk-based decision making explicitly considers issues of likelihood and frequency or relative risk.

Risk-based fire safety analysis and decision making is a concept gaining momentum in the fire safety community. Publications including the *SFPE Engineering Guide to Fire Risk Assessment*, the *National Fire Protection Research Foundation Guidance Document for Incorporating Risk Concepts into NFPA Codes and Standards*, and NFPA 551, *Guide for Evaluation of Fire Risk Assessments*, are resources for decision makers, regulators, analysts, and designers. The concepts can be used for the development of air, rail, or maritime regulations or for the benefit of the vehicle or vessel designers and operators. The key to applying the concepts is to identify the appropriate assessment tool or tools, completing each step in the most simple, practical way to provide the information the decision maker needs, and recognition of its limitations as a tool for the decision maker. There are many issues that might seem overwhelmingly complex; however, they can often be investigated with simpler risk assessment tools.

Although many of the fire risk characteristics of the three transit systems are similar, such as the confined spaces, the lack of readily available exits, and the potential for catastrophic consequences, the approaches to manage those risks and their solutions can vary. Solutions that may be acceptable to one mass transit system may not be acceptable to another transit system. In some cases, this may be obvious, like the installation of a fire sprinkler system, which may be acceptable for ships, yet unacceptable for airplanes.

The primary objective of safety regulations for transportation is to minimize loss of life and injuries in accidents. Preserving property or avoiding business interruption is a secondary regulatory effect; however, it might be of significant interest to transit operators. Thus, regulations that focus on design, material selection, and emergency procedures may prove to be an adequate approach to managing the passenger safety risk problem, but may not be far-reaching enough for an owner or operator.

Fire Safety Objectives

The following fire safety objectives, suggested for rail, [40] have been adapted here to show the wide application they could have in the three transit options:

1. Preservation of the personal safety of passengers and staff capable of reacting readily to a fire situation
2. Preservation of the personal safety of passengers and staff who through illness, age, or disability cannot respond readily to a hazard situation
3. Preservation of the structure of vehicle/vessel involved in the fire
4. Preservation of the operating function of the vehicle/vessel
5. Reasonable preservation of the contents of the vehicle/vessel
6. Protection of the traveling and non-traveling community from the effects of fire

The risk managers intent on improving fire safety in the air, on rails, in buses, or at sea face a decision problem as they consider managing their fire risk problem. In the aviation industry, safeguarding the public might have priority to maintaining a viable business; however, cost-benefit analyses play a major role in determining viable risk management approaches. The direct cost of just one significant commercial aviation fire can total hundreds of millions of dollars. Small fires, such as those that are fuel limited or those that are extinguished by staff, can have great business consequences. Larger uncontrolled fires can have disastrous effects. Investment in risk reduction can save on overall costs. Because of inherent characteristics associated with the physics of air travel, the aviation industry has limitations when resolving the fire risk problem.

In the rail industry, a transit agency might accept the risk of a small fuel-controlled fire, as such fires are unlikely to cause injury or significant business interruption. However, because it is land based, during the risk management process, the rail industry may have a larger palette of safety options from which to decide. Automatic fire sprinklers, on-board alternative suppression

systems, smoke and flame detection systems, and materials (fuel) restrictions are all reasonable options for trains and/or stations.

Marine transit risk management has a combination of issues. Similar to air travel, normal exiting is not readily available or is at least significantly delayed. However, size and weight issues are less of a concern, and water-based fire suppression including sprinklers is a viable option. One unique aspect of some marine transit vessels is size. Significantly more passengers can be put at risk in the event of a large fire. Another is fire fighting; external fire-fighting efforts from a fireboat or from dock side must be enacted with caution. If too much water is applied, the ship can be in jeopardy of sinking.

Risk-Based Decision-Making Methods

As we have noted, fire risk in mass transit, whether in the United States, Europe, or on the seas, is addressed by various regulatory organizations. Historically the approach has been either one of bootstrapping, addressing specific concerns as they arise with new prescriptive regulations, or the ALARP method (i.e., "as low as reasonably practical"). Data gathering and statistical evidence for aircraft accidents, rail accidents, and marine accidents are part of the regulatory structure.

Many systematic risk assessment methods used to assist the decision-making process can be broken down into two generalized families, as suggested by Modarres: [41] the economic method and the noneconomic method. Examples of economic methods include cost-benefit, cost-effectiveness, and risk-effectiveness methods. Examples of noneconomic methods include exceedence analysis, value analysis, decision trees, and the analytical hierarchy process (AHP). Hazard assessments, including what-if and hazard and operability (HAZOP) analyses, although not necessarily strict risk analyses, may include frequency or likelihood assessments and, therefore, can also be considered examples of noneconomic methods.

Depending on the transport mode, the mass transit risk manager may need to consider applying a combination of two or more of the economic and noneconomic methods. The following sections describe various risk assessment methodologies or risk issues in light of the fire risk problem in the three systems.

Fire Risk Decision Making in Air Transportation

FAA System Safety Process

From a regulatory process, the FAA is a leading authority in developing safety systems for the flying public. Over its history, the concept of risk, reliability, redundancies, and analysis of statistics for the improvement of safety has been recognized and implemented. Fire risk is a large part of the risk problem in aircraft. It is estimated that one-fifth of passengers who die in air crashes are killed by fire. Recently, the FAA has published a forward-looking approach to risk management, known as the System Safety Process [42]. Although the experience of the past has great value in addressing risk issues today, the System Safety Process is intended to be a forward-looking document, a proactive means to incorporate risk assessment. Figure 90.5 describes the method.

Through the systematic review and risk assessment process, the *System Safety Process Handbook* is intended to achieve numerous objectives. Among the most important are the following:

1. Implementation of cost-effective, timely safety measures
2. Identification of hazards throughout a system
3. Recognition of residual risk
4. Support of best engineering and management practices
5. Use of statistical and historical data
6. Recognition of risk reduction through best available technology
7. Appropriate and timely retrofit actions
8. Consideration of the life cycle
9. Development of a lessons learned data bank

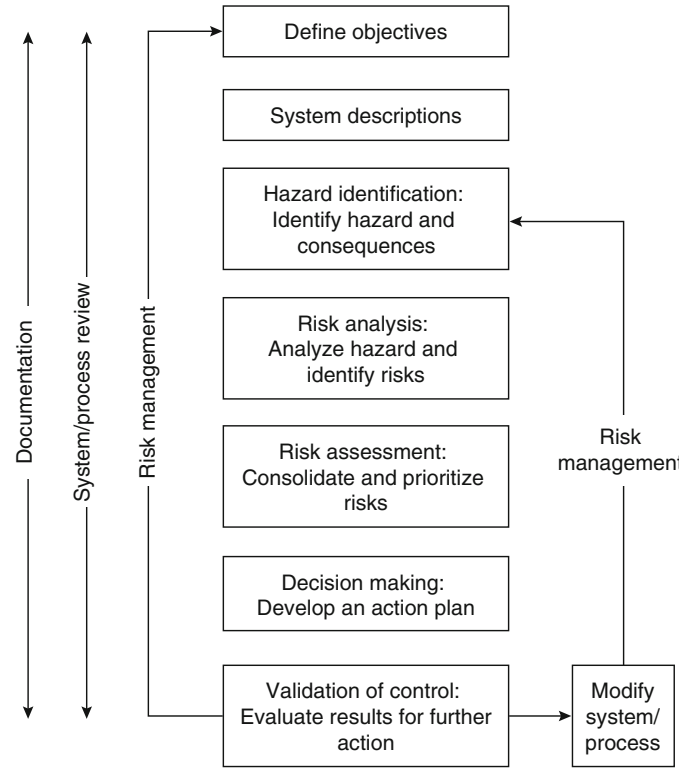

Fig. 90.5 FAA system safety process

Many of the preceding points can be addressed by formal risk assessment methods, including but not limited to cost-benefit analyses, ALARP analyses, and risk effectiveness.

Cost-Benefit Analyses

Optimizing the cost-benefit relationship is a particularly significant part of the fire risk management challenge in aircraft. In building fire safety, the installation of an automatic suppression system throughout most new buildings comes at a small cost relative to the cost of the building. In aviation fire safety, the introduction of a fire suppression system comes at a relatively significant cost due to the weight of the suppression agent, as increased weight has a relatively great impact on the airplane's fuel consumption and operating costs. In fact, any automatic active fire safety system, including fire detection and suppression systems, can have cost impacts not normally associated with buildings. Besides the issue of weight, a false alarm by cargo area smoke detection in aircraft can be costly if it means that the aircraft is required to enact emergency landing procedures in the event of detector activation.

In contrast to buildings, aircraft fire safety design and regulatory structure have the luxury of tightly controlling the fire hazard of aircraft interior furnishings. As part of the risk and decision-making process, a great deal of focus has been placed on this issue recently. In 2006, in a relatively minor "crash" incident, an Airbus A340 could not stop on landing and headed into a ravine with an ensuing fire, but everyone was able to escape. The successful evacuation was in large part attributed to the use of fire-retardant materials [43].

It has been estimated that a 73 % risk reduction results in approximately $620 million annual savings to the industry [44]. Nevertheless, cost-benefit analyses can be deceptive and difficult to quantify. Both benefits and the costs of implementing a strategy can have direct and

indirect components that should be considered. Whereas *direct* benefits and costs may seem clear, *indirect* benefits and costs may be difficult to quantify. A direct benefit of implementing a cabin mist suppression system may be uninterrupted business operations, whereas an indirect benefit may be a higher marketable safety reputation. And whereas direct costs may be attributed to the potential loss of the aircraft, indirect costs may be related to the fees associated with litigation and increased insurance costs.

The cost-benefit ratio (R_{b-c}) is defined as

$$R_{b-c} = B/C$$

where B represents the benefit and C represents costs, typically in monetary units.

Cost-benefit analysis in aviation fire safety has been performed for [45]:

1. Nitrogen inerting of aircraft fuel tanks
2. Cabin water spray systems and enhanced fuselage burn-through protection
3. Analysis for enhanced protection from fires in hidden areas on transport aircraft
4. Installation of automatic hatches

At the current time, cabin-based suppression systems, although shown to provide potential benefits, have been disputed to be too costly to install and maintain, in part due to the additional fuel costs related to weight. The systems are estimated to cost $20 to 30 million per life saved [46] in comparison to $0.4 million per life saved for aircraft seat cushion flammability standards [47]. Furthermore, a cabin suppression system may not be effective for all fire scenarios, particularly the postcrash survivable scenario in which the system may be damaged. Still, the debate is not without merit. As aircraft become more fuel efficient, as the fire safety issues change, such as with two-story commercial passenger aircraft, as suppression technology changes, or as risk tolerances decrease, new analyses may be warranted.

In general, cost-benefit analyses need to be considered with some level of caution. Some argue [48] that there may be situations in which the benefits of a new safety system may not exceed the costs. And there is always the difficulty of applying the value of human lives to the analysis. Even in the comparison of two options, holding the value of human life constant in the analysis could lead to different outcomes, particularly if one option would result in more life safety protection while the other results in more property protection.

Without compelling cost-benefit data for active cabin fire suppression equipment, fire risk management in aviation fire safety has historically focused on passive systems: fuselage integrity, seat cushion materials, lighting, and evacuation effectiveness. In the past decade a shift has occurred to address hidden in-flight fires and fuel tank explosions.

ALARP Analyses

Another risk-based decision-making tool, which may be complementary to the cost-benefit analyses, is the "**a**s **l**ow **a**s **r**easonably **p**ractical" (ALARP) principle. With ALARP, risk reductions are implemented into a system until risks are as low as reasonably practical, or as low as reasonably cost-effective. Often this is combined with and compared to the concept of best available technology. Figure 90.6 conceptually represents the idea of an ALARP curve for passenger aircraft cabin fire safety, using in-cabin automatic fire suppression as an example of a currently considered cost-prohibitive, but possibly very effective, fire risk management solution for managing passenger fire risk.

Risk Effectiveness

Risk effectiveness is a measure of the cost of a risk reduction or control per unit of risk reduction. The solution is an excellent comparative method for introduction of a discrete technology, regulation, or operation [41].

$$RE = \frac{S}{\sum_{i=1}^{n} F_i C_i - \sum_{i=1}^{n} F_i' C_i'}$$

where S is the annualized cost of the risk reduction, F is the frequency of scenario I without

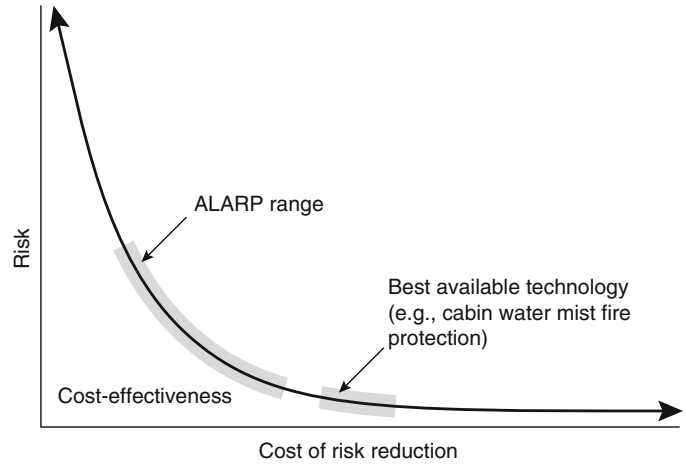

Fig. 90.6 ALARP curve for accidental passenger aircraft cabin fire safety (Source: Adapted from Modarres [41])

implementation of the risk reduction, C is the consequence of scenario I, and F' and C' are the frequency and consequence after implementation of the risk solution.

As part of a risk assessment, some level of deterministic modeling can be anticipated, particularly when there is a need to evaluate the benefits associated with lives saved. Several models have been developed for building fire safety and a limited few have been developed for aircraft [14, 49]. The challenge with such predictive accident analysis tools is in dealing with the quantity diversity and detailed amount of information both available and unavailable.

Fire Risk Decision Making in Rail Transportation

Rail transport fire risk managers face a variation of the aircraft fire risk problem. Business interruption issues due to fire are not as acute. The loss of a carriage is not typically as significant as the loss of an aircraft. Fire safety options are broader and, due in part to risk perceptions, a higher level of risk is tolerated.

Regulation of Combustible Materials

The primary method to manage fire risk in rail transport involves the regulation of combustible materials. Combustible materials may be used on seats, seat shrouds, interior liners, insulation, floors, and ceilings. In contrast to commercial passenger aircraft, many rail operators are less inclined, from a business perspective, to provide comfortable, cushioned seating. Operators have the option of limiting or restricting the amount of combustible, cushioned materials used for seating or insulation, thereby reducing the fire risk significantly. However, other rail operators may seek the benefits (increased ridership) provided by more comfortable carriages while acknowledging some increased potential risks associated with padded (combustible) seating or increased costs associated with new fire-resistant cushions. Another option, particularly for those rail systems that are more luxurious, is the consideration of on-board fire suppression systems. Compared to aircraft cabins, on-board fire suppression or carriage mist systems are significantly less expensive in trains as they minimally affect running costs.

Decision Tree as Decision-Making Tool

With more options, the risk management tools may need to consider more than just cost-benefit analyses. As options increase, decision trees can help form a balanced picture of risks and benefits associated with each course of action. As a simple example, consider two types of subway carriages. Subway transit operators are considering two types of new carriages and are very

concerned about fire safety in their system. They have experienced many fires and estimate that there is a 5 % probability of fire in a given carriage per year. The first option of carriages is the Spartan option. It is outfitted with basic furnishings resulting in minimal combustible loading, but equipped with surveillance cameras with the intent of reducing probability of vandalism related fires (to 1 %) and assist in early detection. The second type of subway carriage is the luxury option. It is outfitted with cushioned seating and well-insulated, acoustically treated walls that may be lined with fire retardant but with combustible seats and panels. The second type is equipped with on-board mist systems but no surveillance cameras. Although the first type of carriage may be much more economical to build and maintain, the second may produce more revenue as it attracts more riders.

For the purposes of this example, we assume that the annualized costs of the two types of carriages are $100,000 and $200,000 respectively. Based on expert opinion, and the expected ignition source used, the probability of fire causing a flashover in carriage option 1 is estimated at 60 %. The probability of the mist system working effectively to prevent flashover in carriage option 2 is estimated at 95 %. If flashover occurs, the carriages are considered complete losses; if flashover does not occur, the carriages are expected to suffer some damage.

All other things being equal, a simple decision tree can be drawn as shown in Fig. 90.7.

Rolling back the tree, the decision analyst calculates the expected annual cost for carriage option 1 as

$$[(0.40 \times \$20{,}000) + (0.60 \times \$100{,}000)] \times 0.01 = \$680$$

The analyst calculates the expected annual cost for carriage option 2 as

$$[(0.95 \times \$10{,}000) + (0.05 \times \$200{,}000)] \times 0.05 = \$975$$

For this example, the decision maker may wish to consider carriage option 1, the more Spartan carriage of the two. However, as discussed previously, these values are only meant for assisting the decision maker in an overall cost-benefit decision-making process. There may be indirect benefits or costs associated with choosing the more Spartan carriage. A Spartan carriage may attract fewer riders, leading to less revenue; however, a Luxury carriage may carry higher maintenance costs. These indirect costs need to be considered carefully through a full risk characterization and sensitivity analysis.

NFPA 130, Standard for Fixed Guideway Transit and Passenger Rail Systems

NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems*, is an internationally recognized standard on fire life safety throughout

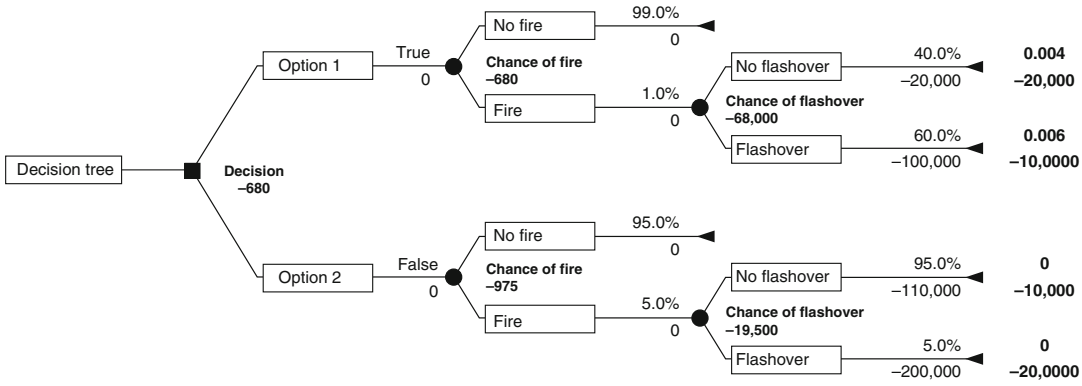

Fig. 90.7 Simple decision tree

passenger rail systems including carriages, tunnels, and stations [22]. The purpose of the standard is to establish minimum requirements that will provide a reasonable degree of safety from fire for passengers throughout such systems. The standard is used throughout the United States and as a reference in many countries, including Hong Kong, Australia, and the United Kingdom.

NFPA 130, primarily a prescriptive set of regulations for rail systems, permits the use of an engineering hazard analysis or performance-based approach for the design of carriages and station egress systems. The required fire hazard analysis is outlined in Annex E of NFPA 130. For performance-based egress design, Annex E refers to the *SFPE Guide to Performance-Based Fire Protection Engineering* and NFPA *101*®, *Life Safety Code*®. In turn, Annex E gives directions for performing a fire hazard analysis for vehicles. It suggests the following four-step evaluation process:

1. Define vehicle performance objectives and design.
2. Calculate vehicle fire performance.
3. Evaluate specific vehicle fire scenario.
4. Evaluate vehicle car design suitability.

The two concepts, performance-based engineering analysis of egress systems and the hazard analyses of carriages, are intertwined and dependent on issues of risk. To some extent, the prescriptive structure of NFPA 130 addresses some issues of risk such as the likelihood that an escalator will be nonfunctioning, the likelihood of one missed headway (resulting in more people at risk), and specifies safety electrical and mechanical equipment of a reliability that is higher than in standard building applications. However, in the event that a true performance-based approach for rail safety is pursued, the designer and risk manager should consider further risk issues such as the following:

1. *Passenger loads*. What is the likelihood of passenger loads on platforms and trains exceeding the code prescribed loads? What is the resulting impact?
2. *Reliability of station or tunnel safety systems*. What is the likelihood of equipment failure?
3. *Ignition source*. What is the ignition source and would it have an effect on the peak heat release rate? Is it acceptable to utilize an accidental ignition source or does arson need to be evaluated? In the evaluation of vehicle fire performance through material testing, has the testing been performed assuming the appropriate ignition source strength?
4. *Fire scenario*. The fire may have a different impact depending on when it starts along the rail line. For example, what is the likelihood/impact of a fire when the train is in the middle of a long tunnel or in the middle of a long elevated track?
5. *Coincident problems*. What is the likelihood of a fire while a train is disabled in a tunnel or on a bridge?
6. *Fire location*. Given a fire on a train, what is the likelihood that the fire will be at the front, the middle, or the end carriage? Can this lead to different consequences on the train passengers or in the station?

Each of the preceding risk issues is representative of a short list of questions that should be either implicitly or explicitly considered or discussed during the course of an engineered performance-based hazard assessment in rail fire safety design. How the issues are resolved is, in part, a value decision that should be considered by the transit agency. Not surprisingly, resolution of these issues can be assisted by a decision analysis framework in the determination of appropriate policy.

Fire Risk Decision Making in Motor Coaches or Buses

A fundamental goal of transit systems is to provide passengers and employees the highest level of safety that is practical and consistent with the mission of the system. To do so, a transit agency or bus operator needs to develop a safety program that addresses the hazards and risks associated with the operation of the system in order to: (1) prevent the occurrence of accidents, (2) respond to and recover from accidents, and (3) learn from accidents that have occurred [24].

While the occurrence of a bus fire is a relatively rare event in terms of vehicle miles or passenger miles, the risk of fire is present and attention must be paid to fire hazards and mitigating measures put in place to identify them, reduce their probability, and limit their consequence.

Bus Characteristics

The term bus covers a wide category of vehicles that vary significantly along a number of characteristics. The choice and selection of bus type are often dictated by their intended operational use. However, each type poses varying hazards based on their characteristics, some of which include:

- Chassis (rigid, articulated);
- Levels (single-decker, double-decker, open-air double-decker);
- Size/capacity (large, medium, midi, mini-buses);
- Propulsion type/fuel (gasoline, diesel, CNG, LPG, hybrid, electric);
- Engine location (front, rear);
- Floor height (high-floor, low-floor, kneeling);
- Use (long-distance, transit, student transport, tourism, private charter);
- Ownership (public, private);
- Service life (light-, medium-, heavy-duty).
- Operating environment (guided, fixed/dedicated lanes, shared roads/tunnels, dedicated tunnels).

Each bus, depending on its characteristics, will be subject to certain hazards. For example, electric buses will have different ignition hazards owing to the necessary electric equipment than those associated with a diesel engine. Buses intended for long-distance travel will likely have cushioned upholstered seating for comfort, which might increase the interior combustible load. Alternatively, mass transit buses, meant for intra urban travel, would more likely have seating made of hard surfaces which are easy-to-clean. A bus fire risk assessment would begin with characterization of the hazards, from the combustible materials, notably the interior finish and furnishings, to the operating systems, the propulsion, air conditioning and the braking system.

Regulation of Combustible Materials

Materials used in bus construction can possibly increase the severity of a fire incident depending on their susceptibility to ignition or propensity to support flame spread. Different materials can be expected to produce varying level of toxic combustion products. The impact of accidents involving fire and smoke development may be minimized through the selection of proper vehicle materials. For automobiles and school buses, passenger compartment materials (exposed to the air) must meet the flame spread test in FMVSS (Federal Motor Vehicle Safety Standard) 302, as regulated by the National Highway Traffic Safety Administration (NHTSA) [50]. In addition to FMVSS 302, many commercial bus operators use a set of voluntary guidelines based primarily on a flame spread test (ASTM E162 [51]) and a smoke test (ASTM E662 [52]).

FMVSS 302 (ISO 3795) [53] specifies burn resistance requirements for materials used in the occupant compartments of motor vehicles. Its purpose is to reduce deaths and injuries to motor vehicle occupants caused by vehicle fires, especially those originating in the interior of the vehicle from sources such as matches or cigarettes. The test exposes a sample of material in a horizontal orientation to a Bunsen burner flame at one end; the horizontal flame spread rate away from the burner is measured and compared to a limiting acceptable rate of 102 mm/min (4 in./min) [54, 55]. However, recent studies have highlighted limitations of the test protocol as the sole regulatory tool as is (1) applies only to passenger compartment materials, (2) does not consider the potential for fires originating outside of and penetrating the passenger compartment [29, 30, 56, 57]. Further, the horizontal orientation of the test does not correlate well to the potential burning in the vertical configuration. The aforementioned SP study reviewed the fire performance of a number of materials typically used in bus interiors. All materials were tested in accordance with FMVSS 302 and several alternative fire test methods used for other applications such as trains, ships and buildings. The study demonstrated that FMVSS 302 does not provide a sufficiently high level of fire safety

insomuch that products fulfilling the horizontal test for buses would not even meet the lowest performance requirements for buildings [30].

Other Risk Reduction Measures

In gasoline- or diesel-powered buses, additional safety considerations are given to the engine compartment. Fires occur when flammable materials come in contact with an ignition source in the presence of oxygen. Within an engine compartment fires can occur when fuel or hydraulic fluid leaks and comes in contact with a hot surface (ignition source) such as the engine manifold. Fuel and hydraulic lines should be routed and placed such that leaking fluids are not likely to come in contact with a hot surface [24]. Additional safety measures often incorporated in buses that can reduce the potential and/or magnitude of fire events include: master shut-off switch to cut all current from the battery, engine-shut-down switch, fuel tank protection, engine compartment overheat detection, and engine compartment fire suppression [24].

Bus Fire Hazard Analysis

Transit systems and bus operator often must utilize scarce funds for costs associated with liability claims; property and equipment damage; the replacement of service, equipment and employees; and insurance premiums. Risk analysis and risk management is essential in identifying fire hazards and means for limiting and controlling those hazards as part of a comprehensive system safety program. The objectives of such a program is the reduction of accidents, specifically fires, in order to costs associated with claims, vehicle, repair, and insurance while also reducing employee and passenger injuries [24].

The FTA Office of Safety and Security has published guidelines for the hazard analyses of all transit projects including buses and bus systems [58]. The proposed approach is general in nature encompassing all systems and sub-systems and all associated hazards, not just fire.

The FTA process involves three separate analyses: a Preliminary Hazard Analysis (PHA) to provide an early assessment of hazards; a Failure Modes and Effects Analysis (FMEA) to determine the effects of system and sub-system failures; and an Operating Hazard Analysis (OHA) to identify and analyze hazards during operations, maintenance, and emergencies. The objective of each analysis is to identify risks and hazards early and to provide preventive or corrective measures to eliminate the hazard or to minimize the risk.

Hazards in bus systems will likely include one or more of the following types of hazards [24]:

- Design Deficiencies (inadequate or inappropriate wiring, fuel lines vulnerable to damage or heat, etc.)
- Inherent Hazards (mechanical wear/failure, presence of flammable liquids/fuel)
- Malfunctions (mechanical and/or electrical failures)
- Maintenance Hazards (improper connections, damage)
- Environmental Hazards (extreme weather, lightning)
- Human Factors (errors, improper connections, intentional acts)

While a number of hazards are inherent in the operation of a bus transit system, for which there may be no means of preventing or controlling (such as acts of nature). There are, however, a number of control methods that may be employed upon identification of a hazard. These may include [24]:

- Improved or changed design (fail-safe design, increased margins, redundancy, fire-resistant materials)
- Safety devices (interlocks, temperature sensors, pressure release valves)
- Warning devices (visible and audible)
- Procedures and training (use of safe procedures, emergency procedures, training, protective equipment)
- Preventive maintenance (scheduled maintenance, upgrades and replacement).

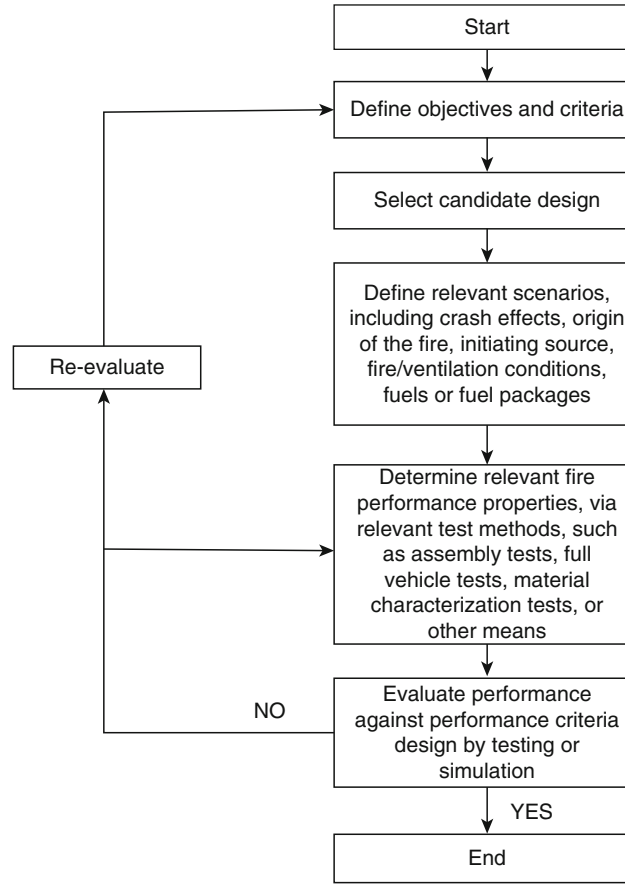

Fig. 90.8 Flow chart for the performance-based approach recommended by NFPA 556 for evaluation of vehicle designs

Additional guidance on fire risk assessments that can be applied to bus systems can be found in the *Guide on Fire Safety Risk Assessment: Transport Premises and Facilities* [59].

Fire Hazard in Passenger Road Vehicles

The development of NFPA 556, Guide on Methods for Evaluating Fire Hazard to Occupants of Passenger Road Vehicles [60] was prompted by vehicle fire statistics documented by the National Highway Traffic Safety Administration and the understood limitations of FMVSS 302. The guide identifies major fire safety concerns associated with passenger road vehicles, particularly material selections, and provides guidance on (1) alternative testing and evaluation methods, (2) tools for decreasing fire hazard or fire risk in passenger road vehicles, and (3) a hazard-based assessment for fires involving passenger road vehicles.

The guide proposes a performance-based approach to analyzing candidate vehicle designs with the objectives of reducing expected loss of life and the likelihood of injuries due to fires in passenger vehicles [61]. The process, illustrated in Fig. 90.9, allows for the objectives to be satisfied in a number of ways whether by increasing resistance to ignition, reducing flame spread and/or heat release rate, or reducing the rate of production of smoke and other combustion products.

NFPA 556 addresses issues associated with the development of hazardous conditions from fire involving passenger road vehicles and the time available for safe egress or rescue. The guide identifies fire scenarios for consideration

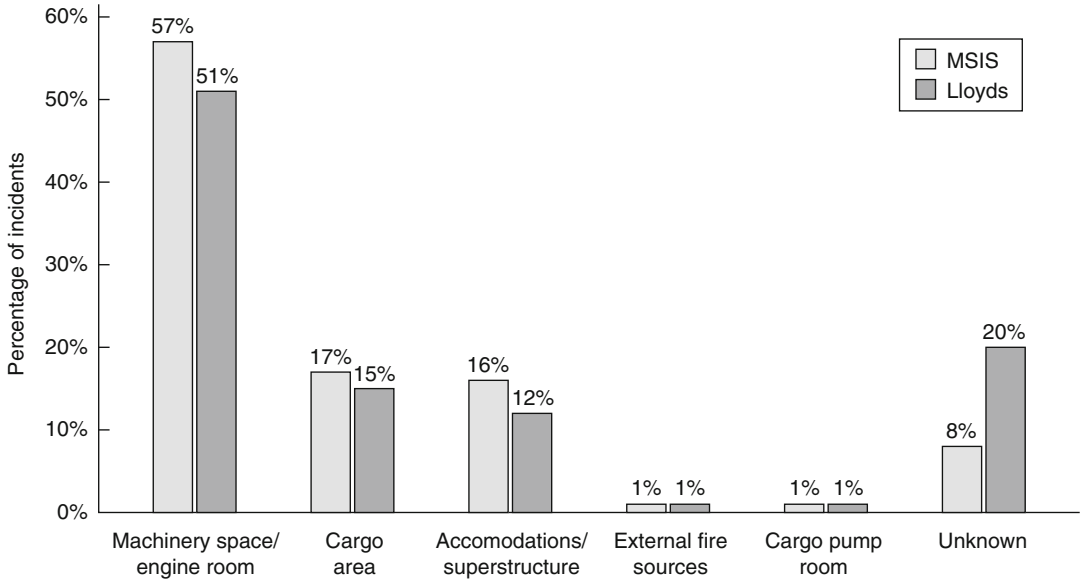

Fig. 90.9 1993–1998 cumulative percentages for MSIS and Lloyds databases by location of origin

that start: (1) inside the passenger compartment, (2) in the engine compartment, (3) in the trunk or load carrying area, (4) from pool fires resulting from fuel tank failure and burning under the vehicle, and (5) from other external heat sources. The key issue in each case, as it pertains to fire risk, is the impact of a fire in the passenger compartment.

Factors to be considered in the analysis are:

- Fuel type (lining materials, upholstery, insulation, flammable liquids),
- Status of vehicle including motion (engine on or off, collision. overturn),
- Ignition sources (mechanical sparks, electrical arcing, hot surfaces (manifold), pool fire),
- Area of fire origin (passenger compartment, engine compartment, exterior), and
- Means for penetrating the passenger compartment (ductwork, bulkheads, windshield).

While allowing for multiple approaches to mitigate the consequences of a vehicle (bus) fire, such as vehicle/engine compartment fire separation, the underlying premise of the guide is the reduction of risk and hazard through appropriate, engineering informed material selection to reduce the potential heat release rate and minimize the hazard presented by the products of combustion.

Fire Risk Decision Making at Sea

U.S. Coast Guard Safety Alert

The 2006 fire on the *Star Princess*, which started on a balcony of a sprinkler-protected cruise ship, led to 1 fatality and 13 hospitalizations, spread to 5 decks with a loss of 79 cabins, and resulted in a safety alert published by the United States Coast Guard (USCG). The alert included recommendations to institute risk assessments for shipboard fire safety [62]. The recommendations outlined the following steps:

1. Identify apparent fire hazards.
2. Assess severity of potential fires that could occur involving the hazards.
3. Identify safeguards for reducing risks associated with the hazards.
4. Identify actions to reduce the risk such that, should a fire occur, it will not spread and will be readily extinguished.

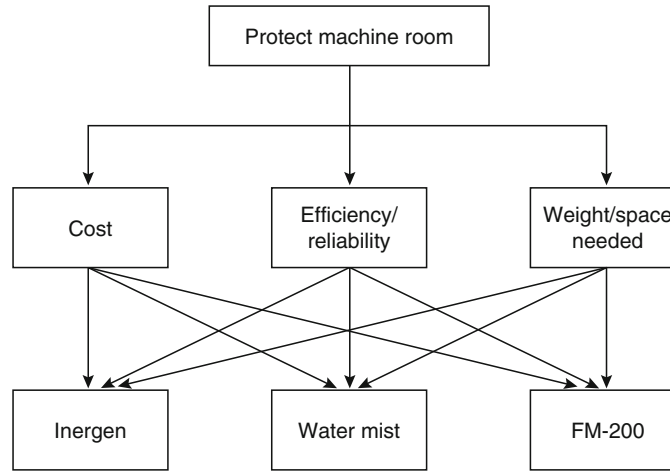

Fig. 90.10 Example of analytical hierarchy process setup

Although these steps may appear more like a hazard assessment rather than a risk assessment, each of the steps involves consideration of a separate risk subproblem in the overall hazard assessment context. In turn, this assists the decision maker in understanding the most appropriate action.

In determining the most appropriate fire safety solutions for any industry or system, one needs to analyze the risk problem in order to understand where the risks lie. Bayesian analysis and the use of conditional probability have also been used in analyzing both ferry safety issues as well as the overall fire safety problem [63]. Hanson reduced World Fleet data regarding ship fires of all types on a ship-type basis, location, and ignition source for the period of 1993–1998 [33]. Data were analyzed from Lloyds and Coast Guard Marine Safety Information System (MSIS) and an AHP analysis was performed. Figure 90.10 and Tables 90.4, 90.5, and 90.6 highlight key fire statistics.

Hanson used the MSIS data to develop probabilities of a fire occurring on a given vessel type, location, and ignition source. Due to the lack of total vessel population data, the probabilities are based on the condition that a fire occurs in the population of vessels. Nevertheless, the results are noteworthy, as shown in Table 90.2.

Almost 15 % of all fires reported occurred on passenger ships. Table 90.6 shows a breakdown of the ignition sources/origin points.

Table 90.4 Conditional probabilities by vessel type

Vessel type	Total incidents	Average number of incidents/year	Conditional probability
Fishing	420	70.0	0.3336
Tug	274	45.7	0.219
Tanker	87	14.5	0.070
Passenger	182	30.3	0.146
Other	71	11.8	0.057
Freight	118	19.7	0.95
Recreational	98	16.3	0.078
Totals	1250	208.3	1.00

Table 90.5 Conditional probabilities for locations of origin

Fire location	Number of incidents	Conditional probability
Machinery spaces	715	0.5720
Cargo areas	217	0.1736
Accommodations	201	0.1608
External fire sources	12	0.0096
Cargo pump rooms	8	0.0064
Unknown	97	0.0776
Totals	1250	1.0000

Understanding the statistical data and their limitations is the first step in risk management. Once the risk is understood, appropriate risk management tools are applied in order to assist in implementing the appropriate solution. Risk tools for maritime fire safety decision analysis

Table 90.6 Conditional probabilities of ignition sources in machinery spaces

Fire location	Number of incidents	Conditional probability
Heat/hot surfaces	324	0.4538
Electrical	198	0.2773
Internal to machinery	28	0.0392
Welding/hotwork	17	0.0238
Unknown	147	0.2059
Totals	714	1.0000

have included the ship fire safety engineering method and computer program SAFE used by the U.S. Coast Guard [64]. Other risk and decision analysis tools can also be employed. For example, when faced with options with multiple objectives, multicriteria decision-making approaches such as SMART [65], or the analytical hierarchy processes (AHP) [33] can also be applied to analyze appropriate risk reduction options.

Analytical Hierarchy Processes (AHP)

For example, an AHP process could be used discretely for a ship design to assist in the decision of the desired fire protection system for a ship or it could be used to assist the decision making for policy makers. AHP is a decision-making tool that is based on weighting and expert subjective assessment [41]. For example, assume that the risk manager has performed a risk assessment of a fleet of cruise ships to analyze where the most significant fire risks lie and has found that the ship's engine room presents the greatest fire risk. In the next stage the risk manager may wish to explore various options to protect an engine room. Several extinguishing options may be considered, including Inergen, water mist, and FM-200. The attributes to be explored could be cost, effectiveness, and space requirements. The AHP would be set up as shown in Fig. 90.11.

In this case, only one set of three attributes is established: cost, efficiency/reliability, and weight/space needed. The merits of each attribute are subjectively assessed against each other and assigned a value between 1 and 9. Typically, the values assigned are simply either 1, 3, 5, 7, or 9. The three fire protection system choices are assessed on a 9 point scale in terms of each attribute as well. A 3×3 matrix is established for each choice attribute combination. The normalized principal eigenvector of each matrix is calculated and is called the priority vector. The three priority vectors associated with the three choices are weighted by the priority vector associated with the attributes to provide a solution. As this process can be relatively tedious, Expert Choice™ software is one tool that can be used to solve such problems. A benefit to using the AHP versus other multicriteria approaches is that it can check for consistency in the expert judgment.

Hanson [33] listed a set of alternative maritime safety and regulatory priorities to be examined through the AHP process, as analyzed by experts. Eighteen fire safety alternatives with 19 associated attributes were analyzed by eight fire maritime safety experts. Examples of the alternatives included smoke control, hazard review of regulations, investigation into use of alternates to welding, egress of passengers and crews, international fire protection system standards, fire-fighting doctrine review, review of electrical fire safety standards, and so on. The process resulted in top two alternatives: egress of passengers and crew and hazard analysis review of regulations.

Notably, hazard analysis review of regulations was an alternative that was described as a systematic review of the fire safety regulations from a holistic performance-based perspective. Such systems approach reviews often benefit from an understanding of the underlying risks.

NFPA 301, Code for Safety to Life from Fire on Merchant Vessels

NFPA 301 includes an appendix intended to allow the vessel designer and operator to comply with the code while accommodating new or unique vessel uses or incorporating new or transfer technology. The appendix provides a standardized hazard analysis and risk assessment

methodology to use in demonstrating equivalent safety. The methodology includes a description of several analysis techniques including systems hazard, fault tree, event tree analysis, HAZOP, what-if, and criticality analysis. As part of these analyses, deterministic assessments may be necessary [66].

The U.S. Coast Guard has developed guidelines in risk-based decision making for both assessment of risks of its fleet and systems and of its regulations that affect U.S. flagged maritime vehicles over certain minimum sizes. The guidelines include detailed explanations and examples of various methods. A number of risk assessment studies have been undertaken by the Coast Guard in recent years from what-if scenarios to checklists to event trees [67]. Comprehensive risk assessment studies have also been carried out and published by others for passenger ferries in various locations including Washington State and the San Francisco Bay Area [68, 69].

Summary

The fire safety challenge in modern air, rail, and maritime transit systems differs from building fire safety risk challenges. The environments are more sensitive, populations are more vulnerable, and the business impact is potentially greater. Although there has been a significant improvement, which has resulted in an excellent record in all of the systems, as stakeholders in the transit systems look to improve matters, they are faced with a more complicated risk problem. Transit systems change—bigger planes, bigger ships, and faster trains are creating new challenges. The traditional prescriptive approach to fire safety is shifting as these industries are recognizing that they have a problem of risk management with a need for proactive risk-informed solutions. At a minimum, the FAA, the IMO, the Coast Guard, the FRA, and the NFPA have either acknowledged or recognized the use of risk and hazard assessments in order to improve safety.

It is important to recognize that most risk assessment and decision-making tools are universal and can be applied across many industries at many different levels. Independent of their perspectives, the stakeholders—regulators, owners, and operators—who may have different reasons and perspectives on the fire risk challenges, can benefit from their application. This chapter includes only a sampling of the challenges faced across these industries as well as basic examples of how and where the tools could be applied. Further insight and more detailed instruction can be found in either the references or in other chapters of this handbook.

Armin Wolski, P.E. holds a B.Sc. in civil engineering from U.C. Berkeley and a M.Sc. in fire protection engineering from Worcester Polytechnic Institute. He is two-time Fulbright Specialist Grantee having taught in Spain and South Korea. He has published extensively on the subject of acceptable risk in fire safety regulation. Armin is based in the San Francisco Bay Area.

Jarrod Alston, P.E. holds a B.Sc. from Worcester Polytechnic Institue. He is the secretary of the NFPA 130 Technical Committee on Fixed Guideway Tranist and Passenger Rail Systems and is a member of the NFPA 502 Technical Committee on Road Tunnels, Bridges and Limited Access Highways. Jarrod is Associate Principal in Arup, currently based in Australia.

Appendix

Appendix 1: Conversion Factors

The names of multiples and submultiples of SI units can be formed by application of the prefixes in Table A.3. The International Organization for Standardization (ISO) recommends the following rules for the use of SI prefixes:

1. Prefix symbols are printed in roman (upright) type without spacing between the prefix symbol and the unit symbol.
2. An exponent affixed to a symbol containing a prefix indicates that the multiple or submultiple of the unit is raised to the power expressed by the exponent.
   Example: $1\ \mathrm{cm}^3 = 10^{-6}\ \mathrm{m}^3$
   $1\ \mathrm{cm}^{-1} = 10^2\ \mathrm{m}^{-1}$
3. Compound prefixes, formed by the juxtaposition of two or more SI prefixes, are not to be used.
   Example: 1 nm *but not:* 1 mmm

ISO has issued additional recommendations with the aim of securing uniformity in the use of units. According to these recommendations,

1. The product of two or more units is preferably indicated by a dot. The dot may be dispensed with when there is no risk of confusion with another unit symbol.
   Example: $\mathrm{N \cdot m}$ or Nm *but not:* mN
2. A solidus (oblique stroke, /), a horizontal line, or negative powers may be used to express a derived unit formed from two others by division.
   Example: m/s, $\frac{\mathrm{m}}{\mathrm{s}}$, or $\mathrm{m \cdot s^{-1}}$
3. The solidus must not be repeated on the same line unless ambiguity is avoided by parentheses. In complicated cases negative powers or parentheses should be used.
   Example: $\mathrm{m/s^2}$ or $\mathrm{m \cdot s^{-2}}$ *but not:* m/s/s
   $\mathrm{m \cdot kg/(s^3 \cdot A)}$ or $\mathrm{m \cdot kg \cdot s^{-3} \cdot A^{-1}}$
   but not: $\mathrm{m \cdot kg/s^3/A}$

Table A.4 lists physical constants from the work of B. N. Taylor, W. H. Parker, and D. N. Langenberg [2]. Their least-squares adjustment of values of the constants depends strongly on a highly accurate (2.4 ppm) determination of *e/h* from the ac Josephson effect in superconductors and is believed to be more accurate than the 1963 adjustment, which appears to suffer from the use of an incorrect value of the fine structure constant as an input datum. See also *NBS Special Publication 344,* issued March 1971.

The following tables express the definitions of miscellaneous units of measure as exact numerical multiples of coherent SI units, and provide multiplying factors for converting numbers and miscellaneous units to corresponding new numbers and SI units.

The first two digits of each numerical entry represents a power of 10. An asterisk following a number expresses an exact definition. For example, the entry −02 2.54* expresses the fact that 1 in. $= 2.54 \times 10^{-2}$ m, exactly, by definition. Most of the definitions are extracted from National Bureau of Standards (NBS) documents. Numbers not followed by an asterisk are only approximate representations of definitions, or are the results of physical measurements.

The conversion factors are listed alphabetically in Table A.5 and by physical quantity in

Table A.1 Names and symbols of SI units [1]

Quantity	Name of unit	Symbol	
SI base units			
Length	Meter	m	
Mass	Kilogram	kg	
Time	Second	s	
Electric current	Ampere	A	
Thermodynamic temperature	Kelvin	K	
Luminous intensity	Candela	cd	
Amount of substance	Mole	mol	
SI-derived units			
Area	Square meter	m^2	
Volume	Cubic meter	m^3	
Frequency	Hertz	Hz	s^{-1}
Mass density (density)	Kilogram per cubic meter	kg/m^3	
Speed, velocity	Meter per second	m/s	
Angular velocity	Radian per second	rad/s	
Acceleration	Meter per second squared	m/s^2	
Angular acceleration	Radian per second squared	rad/s^2	
Force	Newton	N	$kg \cdot m/s^2$
Pressure (mechanical stress)	Pascal	Pa	N/m^2
Kinematic viscosity	Square meter per second	m^2/s	
Dynamic viscosity	Newton-second per square meter	$N \cdot s/m^2$	
Work, energy, quantity of heat	Joule	J	$N \cdot m$
Power	Watt	W	J/s
Quantity of electricity	Coulomb	C	$A \cdot s$
Potential difference, electromotive force	Volt	V	W/A
Electric field strength	Volt per meter	V/m	
Electric resistance	Ohm	Ω	V/A
Capacitance	Farad	F	$A \cdot s/V$
Magnetic flux	Weber	Wb	$V \cdot s$
Inductance	Henry	H	$V \cdot s/A$
Magnetic flux density	Tesla	T	Wb/m^2
Magnetic field strength	Ampere per meter	A/m	
Magnetomotive force	Ampere	A	
Luminous flux	Lumen	lm	$cd \cdot sr$
Luminance	Candela per square meter	cd/m^2	
Illuminance	Lux	lx	lm/m^2
Wave number	1 per meter	m^{-1}	
Entropy	Joule per kelvin	J/K	
Specific heat capacity	Joule per kilogram kelvin	$J/(kg \cdot K)$	
Thermal conductivity	Watt per meter kelvin	$W/(m \cdot K)$	
Radiant intensity	Watt per steradian	W/sr	
Activity (of a radioactive source)	1 per second	s^{-1}	
SI supplementary units			
Plane angle	radian	rad	
Solid angle	Steradian	sr	

Table A.2 Definitions of SI units [1]

Meter (m)	The *meter* is the length equal to 1 650 763.73 wavelengths in vacuum of the radiation corresponding to the transition between the levels 2 p_{10} and 5 d_s of the krypton-86 atom	Volt (V)	The *volt* is the difference of electric potential between two points of a conducting wire carrying a constant current of 1 ampere, when the power dissipated between these points is equal to 1 watt
Kilogram (kg)	The *kilogram* is the unit of mass; it is equal to the mass of the international prototype of the kilogram. (The international prototype of the kilogram is a particular cylinder of platinum-iridium alloy that is preserved in a vault at Sèvres, France, by the International Bureau of Weights and Measures)	Ohm (Ω)	The *ohm* is the electric resistance between two points of a conductor when a constant difference of potential of 1 volt, applied between these two points, produces in this conductor a current of 1 ampere, this conductor not being the source of any electromotive force
Second (s)	The *second* is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom	Coulomb (C)	The *coulomb* is the quantity of electricity transported in 1 second by a current of 1 ampere
Ampere (A)	The *ampere* is that constant current, which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in a vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length	Farad (F)	The *farad* is the capacitance of a capacitor between the plates of which there appears a difference of potential of 1 volt when it is charged by a quantity of electricity equal to 1 coulomb
Kelvin (K)	The *kelvin*, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water	Henry (H)	The *henry* is the inductance of a closed circuit in which an electromotive force of 1 volt is produced when the electric current in the circuit varies uniformly at a rate of 1 ampere per second
Candela (cd)	The *candela* is the luminous intensity, in the perpendicular direction, of a surface of 1/600 000 square meter of a blackbody at the temperature of freezing platinum under a pressure of 101 325 newtons per square meter	Weber (Wb)	The *weber* is the magnetic flux that, linking a circuit of one turn, produces in it an electromotive force of 1 volt as it is reduced to zero at a uniform rate in 1 second
Mole (mol)	The *mole* is the amount of substance of a system that contains as many elementary entities as there are carbon atoms in 0.012 kg of carbon 12. The elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles	Lumen (lm)	The *lumen* is the luminous flux emitted in a solid angle of 1 steradian by a uniform point source having an intensity of 1 candela
Newton (N)	The *newton* is that force that gives to a mass of 1 kilogram an acceleration of 1 meter per second per second	Radian (rad)	The *radian* is the plane angle between two radii of a circle that cut off on the circumference an arc equal in length to the radius
Joule (J)	The *joule* is the work done when the point of application of 1 newton is displaced a distance of 1 meter in the direction of the force	Steradian (sr)	The *steradian* is the solid angle that, having its vertex in the center of a sphere, cuts off an area of the surface of the sphere equal to that of a square with sides of length equal to the radius of the sphere
Watt (W)	The *watt* is the power that gives rise to the production of energy at the rate of 1 joule per second		

Table A.3 SI prefixes [1]

Factor by which unit is multiplied	Prefix	Symbol
10^{12}	Tera	T
10^{9}	Giga	G
10^{6}	Mega	M
10^{3}	Kilo	k
10^{2}	Hecto	h
10	Deka	da
10^{-1}	Deci	d
10^{-2}	Centi	c
10^{-3}	Milli	m
10^{-6}	Micro	μ
10^{-9}	Nano	n
10^{-12}	Pico	p
10^{-15}	Femto	f
10^{-18}	Atto	a

Table A.6. The listing by physical quantity (Table A.6) includes only relationships that are frequently encountered, and deliberately omits the great multiplicity of combinations of units that are used for more specialized purposes. Conversion factors for combinations of units are easily generated from numbers given in the alphabetical listing (Table A.5) by the technique of direct substitution or by other well-known rules for manipulating units. These rules are adequately discussed in many science and engineering textbooks and are not repeated here.

Table A.4 Physical constants [2]

Quantity	Symbol	Value	Error (ppm)	Prefix	Unit
Speed of light in vacuum	c	2. 997 925 0	0.33	$\times 10^{8}$	$m \cdot s^{-1}$
Gravitational constant	G	6. 673 2	460	10^{-11}	$N \cdot m^{2} \cdot kg^{-2}$
Avogadro constant	N_A	6. 022 169	6.6	10^{26}	$kmol^{-1}$
Boltzmann constant	k	1. 380 622	43	10^{-23}	$J \cdot K^{-1}$
Gas constant	R	8. 314 34	42	10^{3}	$J \cdot kmol^{-1} \cdot K^{-1}$
Volume of ideal gas, standard conditions	V_0	2. 241 36	–	10^{1}	$m^{3} \cdot kmol^{-1}$
Faraday constant	F	9. 648 670	5.5	10^{7}	$C \cdot kmol^{-1}$
Unified atomic mass unit	u	1. 660 531	6.6	10^{-27}	kg
Planck constant	h	6. 626 196	7.6	10^{-34}	$J \cdot s$
	h/2π	1. 054 591 9	7.6	10^{-34}	$J \cdot s$
Electron charge	e	1. 602 191 7	4.4	10^{-19}	C
Electron rest mass	m_e	9. 109 558	6.0	10^{-31}	kg
		5. 485 930	6.2	10^{-4}	u
Proton rest mass	m_p	1. 672 614	6.6	10^{-27}	kg
		1. 007 276 61	0.08	–	u
Neutron rest mass	m_n	1. 674 920	6.6	10^{-27}	kg
		1. 008 665 20	0.10	–	u
Electron charge to mass ratio	e/m_e	1. 758 802 8	3.1	10^{11}	$C \cdot kg^{-1}$
Stefan-Boltzmann constant	σ	5. 669 61	170	10^{-8}	$W \cdot m^{-2} \cdot K^{-4}$
First radiation constant	$2\pi hc^2$	3. 741 844	7.6	10^{-16}	$W \cdot m^{2}$
Second radiation constant	hc/k	1. 438 833	43	10^{-2}	$m \cdot K$
Rydberg constant	R_∞	1. 097 373 12	0.10	10^{7}	m^{-1}
Fine structure constant	α	7. 297 351	1.5	10^{-3}	
	α^{-1}	1. 370 360 2	1.5	10^{2}	
Bohr radius	α_0	5. 291 771 5	1.5	10^{-11}	m
Classical electron radius	r_e	2. 817 939	4.6	10^{-15}	m
Compton wavelength of electron	λ_C	2. 426 309 6	3.1	10^{-12}	m
	$\lambda_C/2\pi$	3. 861 592	3.1	10^{-13}	m
Compton wavelength of proton	$\lambda_{C,p}$	1. 321 440 9	6.8	10^{-15}	m
	$\lambda_{C,p}/2\pi$	2. 103 139	6.8	10^{-16}	m

(continued)

Table A.4 (continued)

Quantity	Symbol	Value	Error (ppm)	Prefix	Unit
Compton wavelength of neutron	$\lambda_{C,n}$	1. 319 621 7	6.8	10^{-15}	m
	$\lambda_{C,n}/2\pi$	2. 100 243	6.8	10^{-16}	m
Electron magnetic moment	μ_e	9. 284 851	7.0	10^{-24}	$J \cdot T^{-1}$
Proton magnetic moment	μ_p	1. 410 620 3	7.0	10^{-26}	$J \cdot T^{-1}$
Bohr magneton	μ_B	9. 274 096	7.0	10^{-24}	$J \cdot T^{-1}$
Nuclear magneton	μ_n	5. 050 951	10	10^{-27}	$J \cdot T^{-1}$
Gyromagnetic ratio of protons in H_2O	γ'_p	2. 675 127 0	3.1	10^{8}	$rad \cdot s^{-1}\ T^{-1}$
	$\gamma'_p/2\pi$	4. 257 597	3.1	10^{7}	$Hz \cdot T^{-1}$
Gyromagnetic ratio of protons in H_2O	γ'_p	2. 675 196 5	3.1	10^{8}	$rad \cdot s^{-1}\ T^{-1}$
Corrected for diamagnetism of H_2O	$\gamma'_p/2\pi$	4. 257 707	3.1	10^{7}	$Hz \cdot T^{-1}$
Magnetic flux quantum	Φ_0	2. 067 853 8	3.3	10^{-15}	Wb
Quantum of circulation	$h/2m_e$	3. 636 947	3.1	10^{-4}	$J \cdot s \cdot kg^{-1}$

[a]Definition: One atmosphere (standard) = 76 cm of mercury at 0°C

[b]To convert height h of a column of mercury at t degrees centigrade to the equivalent height h_0 at 0°C, use $h_0 = h[1 - (m - l)t/(1 + mt)]$ where $m = 0.0001818$ and $I = 18.4 \times 10^{-6}$ if the scale is engraved on brass; $I = 8.5 \times 10^{-6}$ if on glass. This assumes the scale is correct at 0°C; for other cases (any liquid) see *International Critical Tables*, Vol. 1 (1968)

[c]$1\ g/cm^2 = 10\ kg/m^2$

Table A.17 Energy, work, and heat (ML^2T^{-2}) or (FL)

Multiply number of → by → to obtain ↓	British thermal units[a]	Centimeter grams	Ergs or centimeter dynes	Foot pounds	Horsepower hours	Joules[b] or watt seconds	Kilogram calories[a]	Kilowatt hours	Meter kilograms	Watt hours
British thermal units[a]	1	9.297×10^{-8}	9.480×10^{-11}	1.285×10^{-3}	2,545	9.480×10^{-4}	3.969	3,413	9.297×10^{-3}	3.413

Watt hours	0.2930	2.724×10^{-8}	2.778×10^{-11}	3.766×10^{-4}	745.7	2.778×10^{-4}	1.163	1,000	2.724×10^{-3}	1

Note: The *horsepower* used in Tables A.17 and A.18 is equal to 550 foot pounds per second by definition. Other definitions are one horsepower equals 746 watts (U.S. and Great Britain) and one horsepower equals 736 watts (continental Europe). Neither of these latter definitions is equivalent to the first; the *horsepowers* defined in these latter definitions are widely used in the rating of electrical machinery

[a]Mean calorie and Btu used throughout. One gram-calorie = 0.001 kilogram-calorie; one Ostwald calorie = 0.1 kilogram-calorie. The IT cal, 1,000 international steam table calories, has been defined as the 1/860th part of the international kilowatt-hour (see *Mechanical Engineering*, Nov., 1935, p. 710). Its value is very nearly equal to the mean kilogram-calorie, 1 IT cal-1.00037 kilogram-calories (mean). 1 Btu = 251.996 IT cal

[b]Absolute joule, defined as 10^7 ergs. The international joule, based on the international ohm and ampere, equals 1.0003 absolute joules

Table A.18 Power or rate of doing work (ML^2T^{-3}) or (FLT^{-1})

Table A.20 Specific heat ($L^2T^{-2}\,t^{-1}$, t = temperature) (To change specific heat in gram calories per gram per degree centigrade to the units given in any line of the following table, multiply by the factor in the last column)

Unit of heat or energy	Unit of mass	Temperature scale (exact)	Factor
Gram calories	Gram	Centigrade	1
Kilogram calories	Kilogram	Centigrade	1
British thermal units	Pound	Centigrade	1.800
British thermal units	Pound	Fahrenheit	1.000
Joules	Gram	Centigrade	4.186
Joules	Pound	Fahrenheit	1,055
Joules	Kilogram	Kelvin	4.187×10^{3}
Kilowatt hours	Kilogram	Centigrade	1.163×10^{-3}
Kilowatt hours	Pound	Fahrenheit	2.930×10^{-4}

(exact)Temperature conversion formulae:
t_C = temperature in centigrade degrees
t_f = temperature in Fahrenheit degrees
t_K = temperature in kelvin degrees
$1^\circ\text{F} = \frac{5^\circ}{9}\text{C}$
1 K = 1°C
$t_C = \frac{5}{9}(t_f - 32)$
$t_f = \frac{9}{5}t_C + 32$
$t_K = t_C + 273$

Table A.21 Thermal conductivity ($LMT^{-3}\,t^{-1}$)

From → multiply by → to obtain ↓	Btu · ft per h · ft^2 · °F	Btu · in. per h · ft^2 · °F	Btu · in. per s · ft^2 · °F	Joules per m · s · °C	Kcal per m · h · °C	Erg per cm · s · °C	Kcal per m · s · °C	Cal per cm · s · °C	W per ft · °C	W per m · K
Btu · ft per h · ft^{2}·°F	1	8.333×10^{-2}	3.0×10^{2}	5.778×10^{-1}	6.720×10^{-1}	5.778×10^{-6}	2.419×10^{3}	2.419×10^{2}	1.895	5.778×10^{-1}
Btu · in. per h · ft^{2}·°F	12	1	3.6×10^{3}	6.933	8.064	6.933×10^{-5}	2.903×10^{4}	2.903×10^{3}	2.275×10^{1}	6.933
Btu · in. per s · ft^{2}·°F	3.333×10^{-3}	2.778×10^{-4}	1	1.926×10^{-3}	2.240×10^{-3}	1.926×10^{-8}	8.064	8.064×10^{-1}	6.319×10^{-3}	1.926×10^{-3}
Joules per m · s · °C	1.731	1.442×10^{-1}	5.192×10^{2}	1	1.163	1.000×10^{-5}	4.187×10^{3}	4.187×10^{2}	3.281	1.0

Note: Dashes = either not measured or are less than 0.001

[a]Data measured in the ASTM E2058 fire propagation apparatus. Data measured in the cone calorimeter are identified by superscripts [b] and [c]. Some of the data are corrected to reflect well-ventilated fire conditions. All the data are reported for turbulent fires, that is, materials exposed to higher external heat flux values

[b]Calculated from the data measured in the cone calorimeter as reported in [16,17]

[c]Calculated from the data measured in the cone calorimeter as reported in [18]

[d]100-mm × 100-mm × 100-mm corrugated paper boxes with and without the 99-mm × 99-mm × 99-mm polymer boxes or pieces on corrugated paper compartments. The boxes are arranged in one and two layers, about 12 mm apart, with one to four boxes in each layer, separated by about 12 mm. All the boxes are placed on a very light metal frame made of rods with screen base. Measurements made in the ASTM E2058 fire propagation apparatus; numbers in parentheses are the weight percents

[e]Data from [19] measured in high-pressure liquid spray combustion in the fire products collector (5,000-kW scale apparatus)

Fig. A.2 View factor for parallel, rectangular radiator [21]

$$F_{12} = \frac{2}{\pi}\left[\frac{X}{\sqrt{1+X^2}}\tan^{-1}\frac{Y}{\sqrt{1+X^2}} + \frac{Y}{\sqrt{1+Y^2}}\tan^{-1}\frac{X}{\sqrt{1+Y^2}}\right]$$

$$X = \frac{a}{2c}$$

$$Y = \frac{b}{2c}$$

$$F_{1-2} = \frac{1}{2\pi}\left\{\begin{array}{l}\tan^{-1}\dfrac{1}{L} + V(N\cos\phi - L)\tan^{-1}V \\ + \dfrac{\cos\phi}{W}\left[\tan^{-1}\left(\dfrac{N - L\cos\phi}{W}\right) + \tan^{-1}\left(\dfrac{L\cos\phi}{W}\right)\right]\end{array}\right\}$$

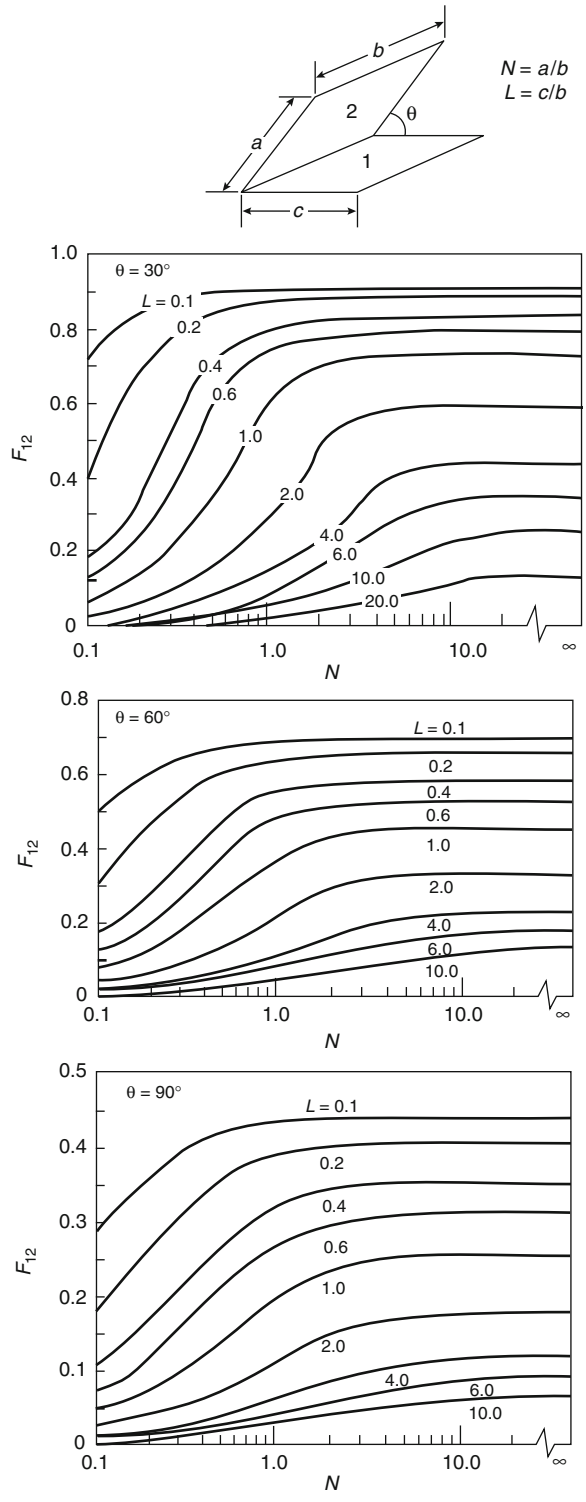

Fig. A.3 View factor for rectangular plates at various angles [21]

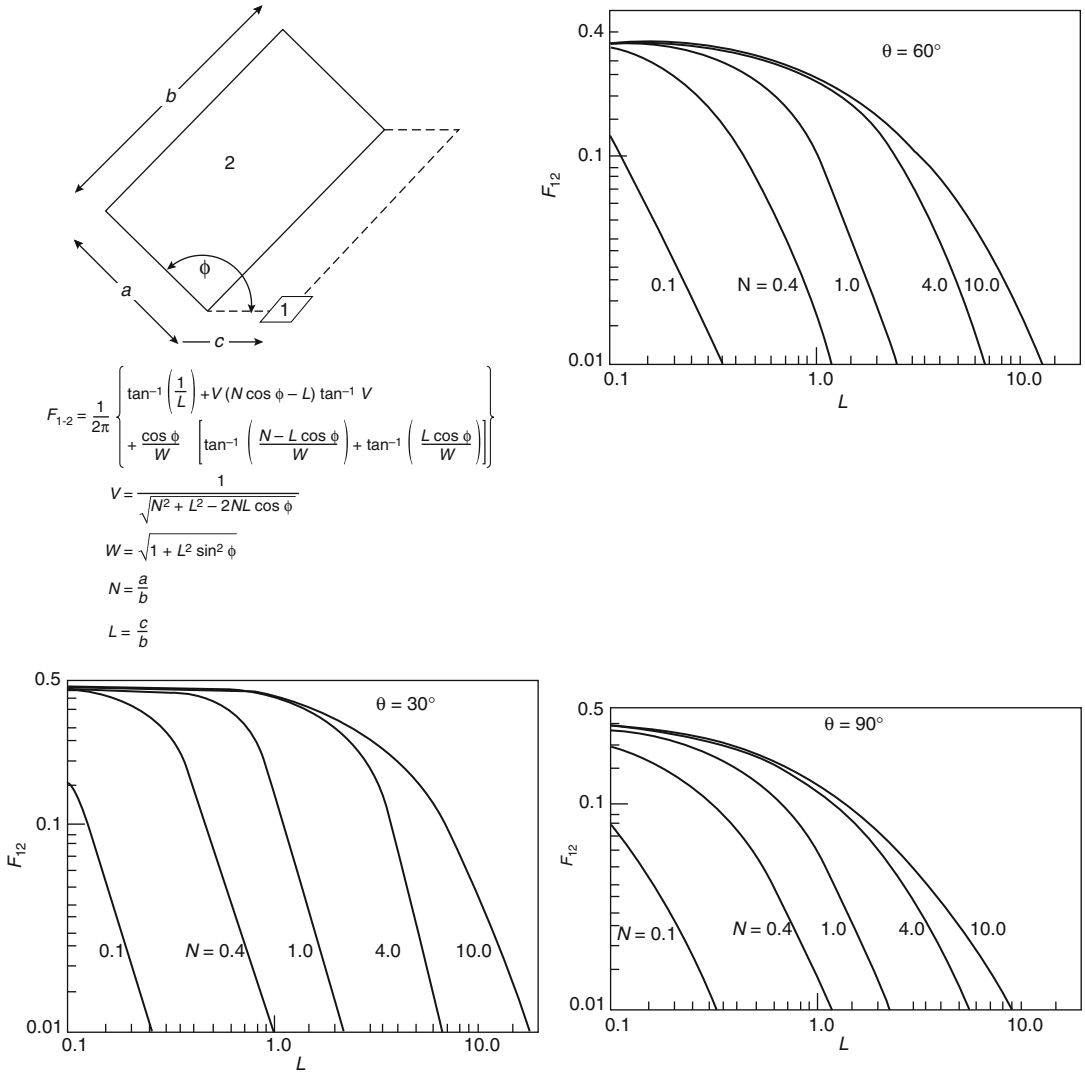


$$F_{1\text{-}2} = \frac{1}{2\pi}\left\{\begin{array}{l}\tan^{-1}\left(\frac{1}{L}\right) + V\,(N\cos\phi - L)\tan^{-1} V \\ + \frac{\cos\phi}{W}\left[\tan^{-1}\left(\frac{N - L\cos\phi}{W}\right) + \tan^{-1}\left(\frac{L\cos\phi}{W}\right)\right]\end{array}\right\}$$

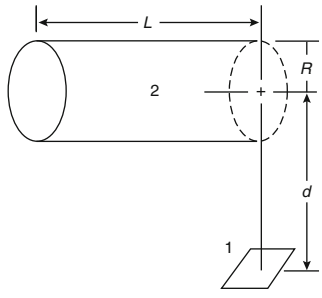
$$V = \frac{1}{\sqrt{N^2 + L^2 - 2NL\cos\phi}}$$

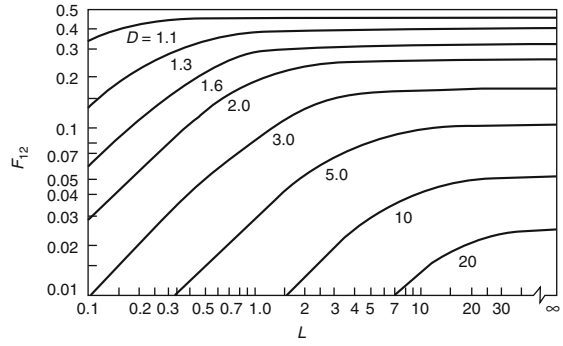
$$W = \sqrt{1 + L^2\sin^2\phi}$$

$$N = \frac{a}{b}$$

$$L = \frac{c}{b}$$

Fig. A.4 View factor for rectangular radiator to differential area at various angles [21]



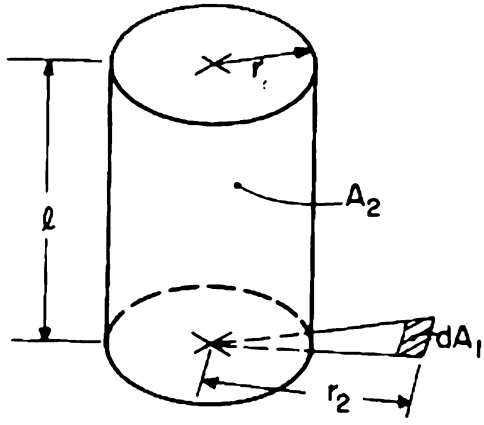


$$F_{12} = \frac{1}{\pi D}\tan^{-1}\left(\frac{L}{\sqrt{D^2-1}}\right) + \frac{L}{\pi}\left[\frac{A-2D}{D\sqrt{AB}}\tan^{-1}\sqrt{\frac{A(D-1)}{B(D+1)}} - \frac{1}{D}\tan^{-1}\sqrt{\frac{D-1}{D+1}}\right]$$

$$D = \frac{d}{R} \qquad L = \frac{L}{R}$$

$$A = (D+1)^2 + L^2 \qquad B = (D-1)^2 + L^2$$

Fig. A.5 Cylindrical radiator to parallel receiver [21]

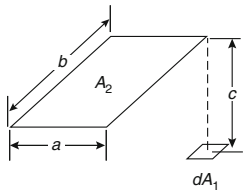


$$R = \frac{r_1}{r_2}$$

$$L = \frac{h}{r_2}$$

$$X = \sqrt{\left(1 + L^2 + R^2\right)^2 4R^2}$$

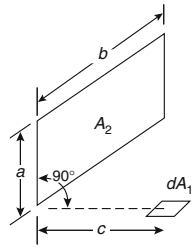
$$F_{d1-2} = \frac{1}{2\pi}\cos^{-1}R + \frac{1}{\pi}\left\{\tan^{-1}\left[\frac{R}{\left(1-R^2\right)^{1/2}}\right] - \frac{\left(1+L^2-R^2\right)}{X}\tan^{-1}\left[\frac{X\tan\left(0.5\cos^{-1}R\right)}{1+L^2+R^2-2R}\right]\right\}$$



Plane element dA_1 to plane parallel rectangle; normal to element passes through corner of rectangle

$$X = \frac{a}{c} \qquad Y = \frac{b}{c}$$

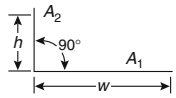
$$F_{d1-2} = \frac{1}{2\pi}\left(\frac{X}{\sqrt{1+X^2}}\tan^{-1}\frac{Y}{\sqrt{1+X^2}} + \frac{X}{\sqrt{1+Y^2}}\tan^{-1}\frac{X}{\sqrt{1+Y^2}}\right)$$

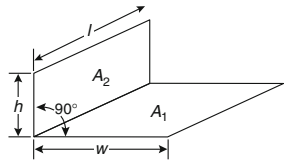


Plane element dA_1 to rectangle in plane 90° to plane of element

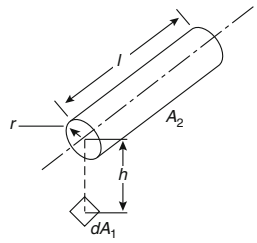
$$X = \frac{a}{b} \qquad Y = \frac{c}{b}$$

$$F_{d1-2} = \frac{1}{2\pi}\left(\tan^{-1}\frac{1}{Y} - \frac{Y}{\sqrt{X^2+Y^2}}\tan^{-1}\frac{1}{\sqrt{X^2+Y^2}}\right)$$





$$F_{1-2} = \frac{1}{\pi W}\left(\begin{array}{l} W\tan^{-1}\frac{1}{W} + H\tan^{-1}\frac{1}{H} - \sqrt{H^2+W^2}\tan^{-1}\frac{1}{\sqrt{H^2+W^2}} \\ + \frac{1}{4}\ln\left\{\frac{(1+W^2)(1+H^2)}{1-W^2+H^2}\left[\frac{W^2(1+W^2+H^2)}{(1+W^2)(W^2+H^2)}\right]^{W^2}\left[\frac{H^2(1+H^2+W^2)}{(1+H^2)(H^2+W^2)}\right]^{H^2}\right\} \end{array}\right)$$



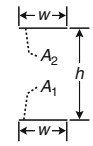
Plane element dA_1 to right circular cylinder of finite length l and radius r; normal to element passes through one end of cylinder and is perpendicular to cylinder axis

$$L = \frac{l}{r} \qquad H = \frac{h}{r}$$

$$X = (1+H)^2 + L^2$$
$$Y = (1-H)^2 + L^2$$

$$F_{d1-2} = \frac{1}{\pi H}\tan^{-1}\frac{L}{\sqrt{H^2-1}} + \frac{L}{\pi}$$

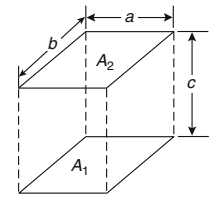
$$\left[\frac{X-2H}{H\sqrt{XY}}\tan^{-1}\sqrt{\frac{X(H-1)}{Y(H+1)}} - \frac{1}{H}\tan^{-1}\sqrt{\frac{(H-1)}{(H+1)}}\right]$$



Two infinitely long, directly opposed parallel plates of the same finite width

$$H = \frac{h}{w}$$

$$F_{1-2} = F_{2-1} = \sqrt{1+H^2} - H$$



Identical, parallel, directly opposed rectangles

$$X = \frac{a}{c} \qquad Y = \frac{b}{c}$$

$$F_{1-2} = \frac{2}{\pi XY}\left\{\begin{array}{l} \ln\left[\frac{(1+X^2)(1+Y^2)}{1+X^2+Y^2}\right]^{1/2} + X\sqrt{1+Y^2}\tan^{-1}\frac{X}{\sqrt{1+Y^2}} \\ + Y\sqrt{1+X^2}\tan^{-1}\frac{Y}{\sqrt{1+X^2}} - X\tan^{-1}X - Y\tan^{-1}Y \end{array}\right\}$$

Two infinitely long plates of unequal widths h and w, having one common edge and having an angle of 90° to each other

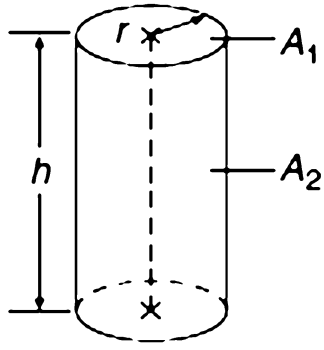
$$H = \frac{h}{w}$$

$$F_{1-2} = \frac{1}{2}\left(1 + H - \sqrt{1+H^2}\right)$$

Two finite rectangles of same length, having one common edge and having an angle of 90° to each other

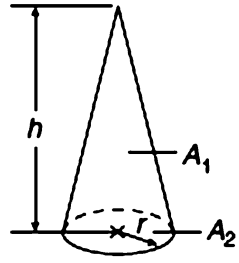
$$H = \frac{h}{l} \qquad H = \frac{w}{l}$$

Fig. A.6 View factor equations for various geometries [22]



$H = h/2r$

$F_{1-2} = 2H\left[\left(1 + H^2\right)^{1/2} - H\right]$



$H = h/2r$

$F_{1-2} = \frac{1}{\left(1+H^2\right)^{1/2}}$
